When arsenic is used as the emitter diffusant in a n-p-n silicon transistor, it is well known that the emitter dip effect is not observed. However, it was found that the diffusion of boron underneath the arsenic emitter was accelerated during heat-treatment at 500°-800°C. This phenomenon is related to abnormal behavior of arsenic in silicon. The diffusion of arsenic is enhanced by such treatment. The anomalous diffusion of arsenic depends on treatment time, and is remarkable in the beginning of the treatment. The diffusivity is extremely large in comparison with the normal one extrapolated from high temperature data. It is considered that this anomaly is caused by the generation of excess vacancies during such treatment. The emitter dip effect is also caused by these excess vacancies during heat-treatment at relatively low temperature.

Arsenic is generally used as the emitter diffusant for a microwave n-p-n silicon transistor. The arsenic emitter avoids the emitter dip effect, and the carrier profile is suitable in comparison with phosphorus. The covalent radius of arsenic is nearly equal to that of silicon. Therefore, the lattice strain is considerably reduced as compared to phosphorus.

However, the authors (1) reported that the diffusion of arsenic was accelerated by low temperature heat-treatment and that this caused the emitter dip effect. Such a phenomenon may be due to the excess vacancies formed during these treatments. Large decreases in the conductivity of arsenic-doped silicon during 500°-970°C heat-treatments were reported by Schwenker *et al.* (2). They suggested that the effect was due to the formation of As-As clusters. Miyamoto *et al* (3) also reported using the x-ray double crystal diffraction technique that the lattice constant of the arsenic-doped silicon was increased after heat-treatment at low temperature. They explained that this lattice expansion and the increase of resistivity were due to arsenic atom precipitation and SiAs formation. Osvenskii *et al.* (4) made an electron microscopic investigation of the structure of silicon single crystals doped with arsenic to a concentration of 5×10^{20} cm^{-3} and observed the formation of prismatic dislocation loops during annealing at 800°C. They concluded that the observed dislocation loops were formed by the decrease of a solid solution of arsenic in silicon. Furthermore, Haskell *et al.* (5) investigated the channeling measurements in arsenic-doped silicon using a He^+ ion backscattering technique, and both silicon- and arsenic-aligned yields increased in the arsenic-diffused samples during low temperature annealing. They suggested the model of the formation of the complex on substitutional lattice sites.

Arsenic, which is a relatively normal diffusant in silicon at high temperature, shows the complicated behavior described above by low temperature annealing.

In this paper, the emitter dip effect in a n-p-n transistor using arsenic for the emitter impurity by low temperature heat-treatments is reported. The previous paper (1) suggested that such emitter dip effect was due to the anomalous diffusion of arsenic. First, the anomalous diffusion of arsenic is investigated in detail and the relation between the anomalous diffusion of arsenic and the emitter dip effect is studied. Finally, the influence of such treatments on the electrical characteristic of the silicon devices is examined with the junction field effect transistor (JFET). From these experimental results, the mechanism of this emitter dip effect is discussed.

Key words: emitter dip effect, enhanced diffusion, arsenic diffusion.

Experimental

In the case of singly diffused structures, arsenic was diffused in silicon from an arsenosilicate glass. The glasses were deposited onto p-type 1-2 ohm-cm (111) oriented epitaxial silicon wafers by the reaction of silane, arsine, and oxygen at 450°C. The thickness of the glass was about 1000Å. The diffusion was carried out at 1000°C in an atmosphere of N_2 and O_2 mixture. The arsenic surface concentration was varied by changing the arsenic content in the glasses.

In doubly diffused structures, boron was first diffused into n-type 0.4-0.6 ohm-cm (111) oriented epitaxial silicon wafers with a boron nitride source at 900°C for 30 min and oxidized in wet O_2 at 950°C for 60 min. The silicon dioxide grown during the oxidation was removed by hydrofluoric acid. Then, arsenic was diffused into the boron-diffused layer by the same way described above. The glass was removed by hydrofluoric acid before low temperature heat-treatment. The low temperature heat-treatments were carried out at 500°-800°C in N_2.

The carrier concentration profiles were determined using the anodic oxidation-resistivity technique and Irvin's data (6). Junction depths were confirmed by the thermal probe method.

The diffusion coefficient of the boron base underneath the arsenic emitter during low temperature heat-treatment was calculated by the following procedure. It is assumed that the diffusivity of the boron-base impurity is not affected by an internal electric field (7, 8) or other interaction between impurity and carrier (9). The base impurity profile is approximated by complementary error function during the heat-treatment. The base-collector junction depth (x_j) is given by

$$x_j^2 = 4(D_1t_1 + D_2t_2 + D_3t)\{\text{erfc}^{-1}(C_b/C_s)\}^2 \quad [1]$$

where D_1, D_2, and D_3 are the diffusion coefficient of boron during the base diffusion, the emitter diffusion, and the subsequent low temperature heat-treatment, respectively; t_1 and t_2 are the diffusion times of initial base and emitter; t is the heat-treatment time, and C_b and C_s are the bulk concentration and the surface concentration of the base. The velocity of increase in the junction depth is given by

$$dx_j/dt = 2\{\text{erfc}^{-1}(C_b/C_s)\}^2 x_j^{-1} D_3 \quad [2]$$

When the increase in the junction depth (Δx_j) during the heat-treatment for ΔT is sufficiently smaller than the x_j, Δx_j is given by

$$\Delta x_j = 2\{\text{erfc}^{-1}(C_b/C_s)\}^2 x_j^{-1} D_3 \Delta T \quad [3]$$

The similar assumption is used in determining the diffusion coefficient of the amount of dip in the phosphorus-boron system by Nakamura *et al.* (10). The diffusion coefficient can be determined from Eq. [3].

In order to examine the influence of arsenic during low temperature heat-treatment on silicon devices, JFET's were fabricated; gate length and width were 20 and 70 μm, respectively. The current between source and drain in a JFET is restricted to the region beneath the depletion layer boundary. The saturation current at pinch-off on the drain side was measured before and after heat-treatment.

Results

The anomaly of arsenic during low temperature heat-treatment.—The typical change in carrier profiles in the arsenic-diffused layers by low temperature heat-treatment is shown in Fig. 1. The following phenomena have already been reported in a previous paper (1). The carrier concentration of arsenic decreased during heat-treatment at 700°C, and this decrease occurred at first from the surface. Furthermore, the junction depth increased, and its increase was remarkable in the beginning of the treatment.

In Fig. 1, junction depths are increased considerably even at 500°C. The carrier concentration near the surface decreases, and tails in the low concentration region. The decrease in carrier concentration is not due to the out-diffusion because the recovery of carrier concentration was observed when the sample was heated once more at the initial diffusion temperature after low temperature heat-treatment as shown in Fig. 2.

The change in the sheet resistivity is shown in Fig. 3(a) as a function of heat-treatment time and temperature. The sheet resistivity increases rapidly in the

Fig. 1. beginning of the heat-treatment and approaches the equilibrium value at long times. As the heat-treatment temperature increases, its equilibrium value decreases. The increase in the sheet resistivity at 600°C is not rapid, and its equilibrium value is not attained in the range of the treatment time in this experiment. This agrees with the result of Schwenker *et al.* (2). On the other hand, the junction depths were increased greatly during such treatment. The increase in the junction depth (Δx_j) is shown in Fig. 3(b). In the same figure, the calculated values of Δx_j, using the diffusion coefficient of arsenic extrapolated from high temperature data (11) and considering the effect of internal electric field and variation of equilibrium vacancy concentration (12, 13), are also shown. The experimental results are considerably larger than the calculated values. Δx_j increases rapidly in the beginning of the heat-treatment, and increases hardly at all over long times. These changes have the same tendency as that of the sheet resistivity.

In the above experiments, the carrier concentration in the arsenic-diffused layer before low temperature heat-treatment was 2.4×10^{20} cm^{-3}. This anomalous diffusion depends on the arsenic concentration. Samples with a varying surface concentration with junction depths 1000-1500Å were treated at 600°C for 45 hr. In Fig. 4, the increase in the junction depth (Δx_j) is shown as a function of the arsenic surface concentration. The dependence on arsenic concentration is remarkable, and this enhanced diffusion could not be observed for the arsenic surface concentration below 1×10^{20} cm^{-3}.

The emitter dip effect during low temperature heat-treatment.—In the case of the n-p-n transistor, a study was made to determine whether the abnormal behavior of arsenic mentioned above affected the boron base layer underneath the arsenic emitter. The surface concentration of boron for base impurity before the arsenic diffusion is 8×10^{18} cm^{-3}. Typical carrier profiles before and after low temperature heat-treatment are shown in Fig. 5. The emitter-base and base-collector junction depths before heat-treatment were

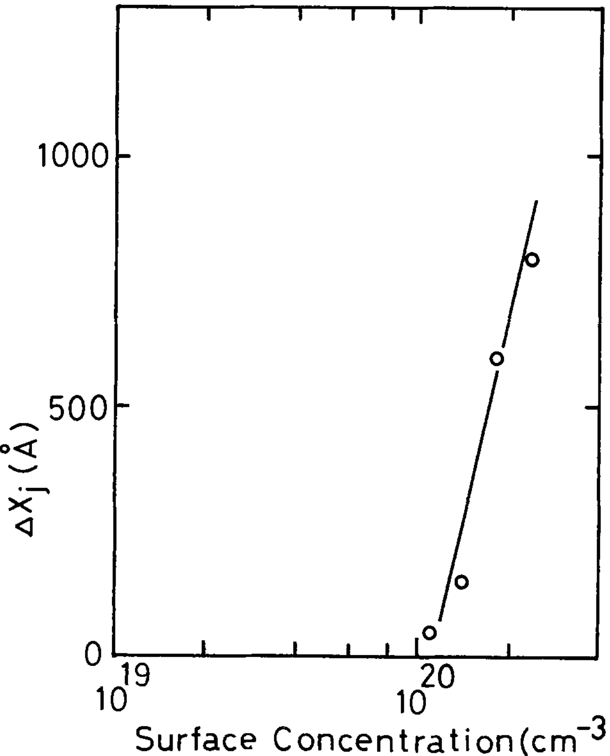

Fig. 4. Dependence on surface concentration of increase in the junction depth. Low temperature heat-treatment is carried out at 600°C for 45 hr.

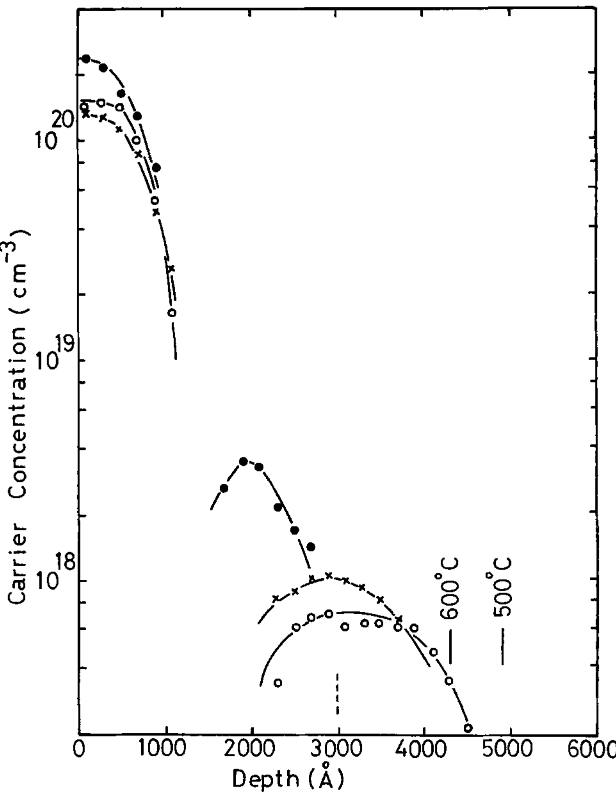

Fig. 5. Effect of heat-treatment at low temperature on carrier profiles of n$^+$-p-n structure. Impurities in the n$^+$- and p-diffused layer are arsenic and boron: ● before heat-treatment; × heat-treated at 600°C for 45 hr; ○ heat-treated at 500°C for 336 hr. The points marked 500°C and 600°C are the junction depths, which are determined by the thermal probe method.

1000 and 3000Å, respectively. When the boron-diffused layer without the arsenic emitter was treated at such conditions, its carrier profile was not changed. On the other hand, the diffusion of boron underneath the arsenic emitter is extremely enhanced at relatively low temperature. The base-collector junction depth was increased from 3000 to 4900Å by heat-treatment at 500°C for 336 hr. The diffusion of arsenic is enhanced in the low concentration region, as shown in Fig. 1. Therefore, in this structure, the increases in the emitter-base junction depths could be hardly observed because of the compensation with the base impurity.

When the heat-treatments are carried out for 24 hr, the effective diffusion coefficient of boron underneath the arsenic emitter is plotted in Fig. 6 as a function of temperature. The diffusivity of boron during the heat-treatment depends on the time, and therefore, the diffusion coefficient is a function of time. However, D_{eff} shown in Fig. 6 was calculated on the assumption that the diffusion coefficient was constant during the heat-treatment for 24 hr. This D_{eff}, which is the "average" effective diffusion coefficient, is larger in the beginning of the heat-treatment. In Fig. 6, these values are not changed much by temperature, and are maximum at about 600°C. They are much larger than the normal value extrapolated from the high temperature data (14). This emitter dip effect may be due to the abnormal behavior of arsenic during low temperature heat-treatment. In Fig. 3, the increases in the junction depths of arsenic during the heat-treatment are much larger than the values which are considered the effect of an internal field and equilibrium vacancy concentration (12, 13). Furthermore, their increases occur in the low concentration region, as shown in Fig. 1. Assuming that the arsenic profile is a complementary error function, the "average" effective diffusion coefficients of arsenic in the singly diffused samples were determined from the same procedure as for boron. This

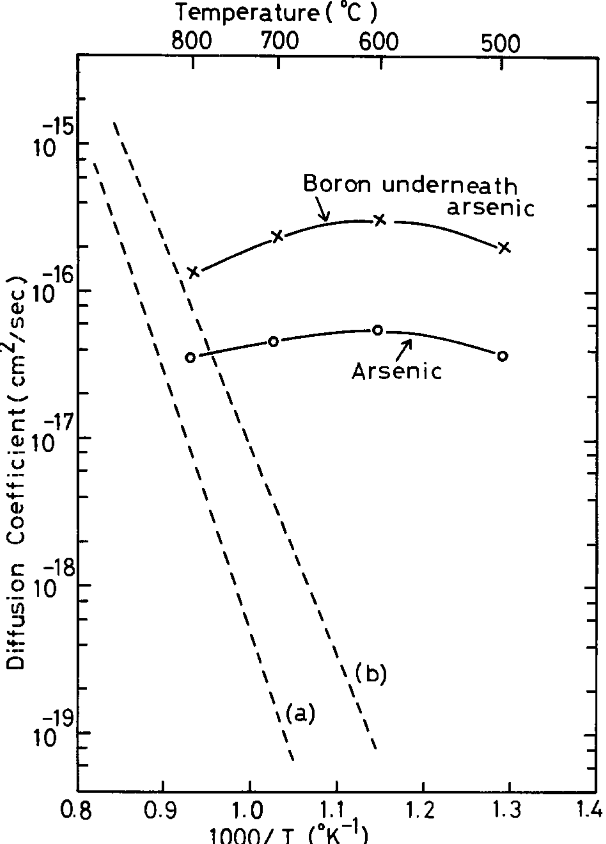

Fig. 6. Effective diffusion coefficient of arsenic and boron underneath the arsenic-diffused layer as a function of temperature. Heat-treatment is carried out for 24 hr in N_2. Dashed lines are diffusion coefficients extrapolated from high temperature data. (a) and (b) are the diffusion coefficients of arsenic and boron, respectively.

result is also plotted in Fig. 6. The value extrapolated from Fuller's data (15) which were determined by complementary error function is also shown in Fig. 6. The diffusivity of boron underneath the arsenic emitter has the same tendency as that of arsenic.

The influence of low temperature heat-treatment on the JFET.—It was clear in the above experiments that the boron diffusion underneath the arsenic-diffused layer was enhanced during low temperature heat-treatment. The influence of this abnormal diffusion on silicon devices was investigated using the JFET shown in Fig. 7. In this JFET, the arsenic- and boron-diffused layers act as the gate and the channel, respectively. Arsenic was diffused into the boron-diffused layer, of which the surface concentration and the junction depth are 7×10^{18} cm^{-3} and 1200Å; the values of the arsenic-diffused layer are 2.4×10^{20} cm^{-3} and 800Å. The equation for current between source and drain in the JFET which had a nonuniform carrier profile in the channel was solved by Bockemuehl (16). The saturation current is a function of the carrier profile, channel height, and device dimensions. In this sample, the saturation current before heat-treatment is 140-170 μA.

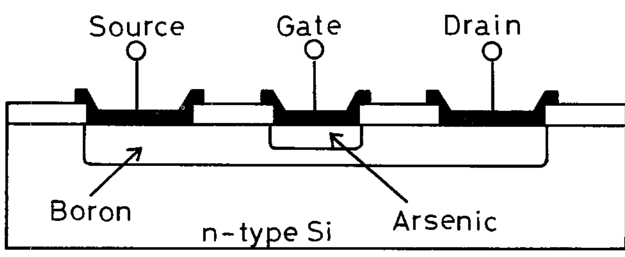

Fig. 7. Schematic cross section of JFET

Heat-treatments were carried out at 500°-800°C for 24 hr. The results are shown in Fig. 8. The changes in saturation current are very large, and remarkable at 600°C. This result agrees with the diffusion coefficient in Fig. 6.

The heat-treatment over a long time was not carried out in the ordinary device processing. Therefore, the change in saturation current by heat-treatment for 30 min was measured. The result is shown in Fig. 9 as a function of temperature. The influence of low temperature heat-treatment on saturation current is considerable, and the saturation current is minimum at 700°C.

The electrical characteristics of the device are considerably changed by heat-treatment even for a short time. As a matter of course, the temperature at which the saturation current is minimum depends on treatment time.

Discussion

In a n-p-n transistor using phosphorus for the emitter, the boron base layer underneath the emitter is pushed out during the emitter diffusion. In the arsenic-boron system, a retardation of the boron base layer is generally observed. It is considered that this effect is caused by the internal electric field (7, 8), vacancy clustering, or divacancy formation (17) and ion pairing (18), for example. Recently, Fair (19, 20) suggested that the retardation effect was due to the formation of the vacancy- arsenic complex, ($V_{Si}As_2$), which acted as a vacancy "sink." In the present study, the emitter dip effect was observed in the arsenic-boron system by low temperature heat-treatment. This phenomenon may be due to the abnormal behavior of arsenic during the heat-treatment.

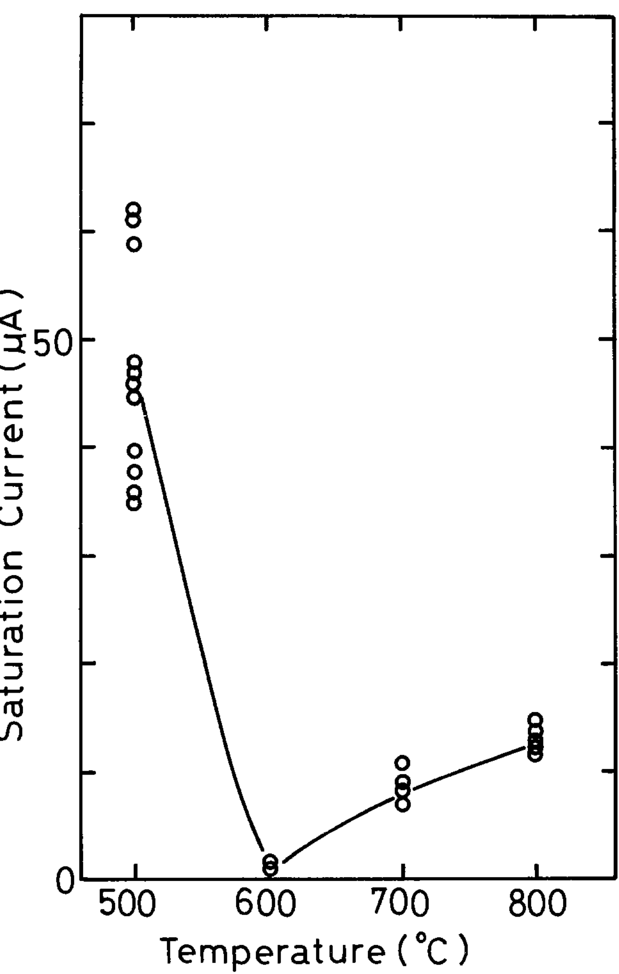

Fig. 8. Changes in saturation current of the JFET by low temperature heat-treatment. Initial saturation current is 140-150 μA. Low temperature heat-treatment is carried out at 500°-800°C for 24 hr in N_2.

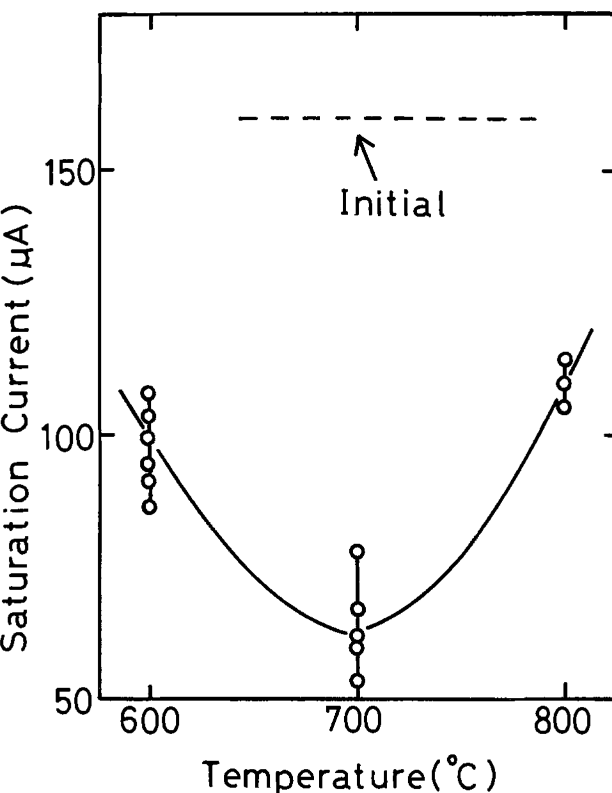

Fig. 9. Changes in saturation current during low temperature heat-treatment. Initial values are 150-170 μA. Heat-treatment time is 30 min.

Various phenomena were observed by low temperature heat-treatment of heavily doped silicon with arsenic. The decreases of conductivity by the heat-treatment were observed, and were explained by a model of substitutional arsenic atoms becoming non-ionized upon clustering together, with one or more vacancies (2). An increase in both silicon- and arsenic-aligned yields during the heat-treatment was investigated by the channeling measurement using He^+ ion, and this increase in aligned yields was due to the formation of the complex involving substitutional arsenic atoms, as predicted by Schwenker *et al.* (5). In the study using the x-ray double crystal diffraction technique, the lattice expansion due to the arsenic atom precipitation and SiAs formation was observed by the heat-treatment, and could not be observed in the arsenic concentration lower than 1×10^{20} cm^{-3} (3). This result agrees with our diffusion data in Fig. 4. The transmission electron microscopic investigation was made on arsenic-doped silicon crystal, and the formation of prismatic dislocation loops during annealing at 800°C after quenching, which had an interstitial character, was observed (4). Similarly, Dash and Joshi (21, 22) also observed the arsenic precipitation and the interstitial dislocation loop in the arsenic-diffused silicon crystal.

In the present study, the diffusivity of arsenic is enhanced anomalously during low temperature heat-treatment. This effect depends on the treatment time and is extremely large in the beginning of the heat-treatment. This diffusivity is maximum at a particular temperature. As shown in Fig. 8 and 9, this temperature decreases as the heat-treatment time. Supposing the predominant mode of the arsenic diffusion in silicon is via vacancies, it is necessary to generate a large amount of excess vacancies in the beginning of the treatment and to increase excess vacancies with decreasing temperature.

The arsenic concentration in silicon probably exceeds the solid solubility limit during low temperature heat-treatment. The arsenic precipitation or the formation of the complex which involves arsenic is naturally expected. In this process, excess vacancies may be generated. It is also considered that the excess vacancies are generated when interstitial dislocation loops observed by the transmission electron microscope climb. These excess vacancies enhance the diffusion of arsenic and of boron underneath the arsenic-diffused layer.

The similarly enhanced diffusion of phosphorus during low temperature heat-treatment was observed (23, 24). In the case of phosphorus, the kink in the impurity profile in silicon depends remarkably on the temperature, but this kink is obscure in the case of arsenic. Compared with arsenic, the enhanced diffusion of phosphorus continues well after the decrease of the carrier concentration in the high concentration region stops. These phenomena are different from that of arsenic. Therefore, the mechanism may be a little different from that of arsenic.

Conclusions

In this work, it was found that the diffusion of arsenic was extremely enhanced during low temperature heat-treatment. This anomalous diffusion is a function of the treatment temperature and time. Under a certain condition, the diffusivity of arsenic increases with decreasing temperature. Such anomaly depends on the arsenic concentration. The enhanced diffusion is hardly observed below 1×10^{20} cm^{-3} in the surface concentration.

The abnormal behavior of arsenic by low temperature heat-treatment affects the diffusion of boron underneath the arsenic-diffused layer, and causes the emitter dip effect.

It is considered that this anomaly is caused by the generation of excess vacancies during such treatment. However, this mechanism is difficult to ascertain at this time. and further work is needed.

These phenomena have a bad influence on electrical characteristics such as the microwave transistor which are required to control the base width and concentration precisely.

Burning and Extinction of a Laser-Ignited Carbon Particle in Quiescent Mixtures of Oxygen and Nitrogen

Shivadev K. Ubhayakar[1] and Forman A. Williams

Department of Applied Mechanics and Engineering Sciences, University of California, San Diego, La Jolla, California 92093

ABSTRACT

Experimental data on the burning mode and lifetime, on the surface temperature, and on the spontaneous extinction of a laser-ignited particle of electrode carbon (50-200μ) in quiescent mixtures of oxygen and nitrogen at room temperature are presented. The test variables were the oxygen mass fraction (0.5-1) and the pressure (0.5-3 atm) of the mixture. High speed cinemicrography of the burning particle showed that the visible combustion zone was restricted to the surface. Two theoretical models, one neglecting the dissociation of oxygen and the other including it approximately, are developed in order to explain the extinction phenomenon. Comparison of the extinction results computed from these models with the data indicates that the model neglecting dissociation is the preferred one. Based on this model it is shown that the kinetics of oxidation of electrode carbon in the temperature range 2000°-3500°K can be represented by an effective Arrhenius surface oxidation reaction producing CO and having an activation energy of 18 kcal/mole and an order in the range 0.5-1.

The oxidation of carbon has been one of the most widely studied topics in the field of combustion, and yet there remains a paucity of data on the burning of submillimeter particles in quiescent oxidizing atmospheres. About two decades ago Spalding (1, 2) proposed two models for the burning of spherical carbon particles, one of which assumed a CO-O_2 gas-phase reaction producing CO_2 which in turn oxidizes carbon heterogeneously at its surface, while the other assumed a heterogeneous surface reaction of O_2 with carbon producing CO and/or CO_2. To date, there exist no experimental data to confirm the validity of either of these two models for small carbon particles. Furthermore, there has been much discussion of the fact that large carbon spheres often burn by a mechanism that involves diffusion and reaction within the pores (3, 4). Therefore, an initial objective of the present study was to ascertain whether a gas phase burning mechanism or a surface burning mechanism, possibly accompanied by pore diffusion, occurs for submillimeter particles. An additional objective was to obtain burning duration data of improved accuracy.

High speed cinemicrography soon demonstrated that the burning zone is restricted to the surface and/or interior of the particle. In addition, disagreement of burning duration data with the theory of diffusion-controlled droplet burning led eventually to the discovery of an extinction phenomenon in which the combustion ceases abruptly after the particle burns to a critical size, which depends on the oxygen mass fraction and the total pressure of the ambient mixture. Since the existence of extinction raised hope of extracting fundamental kinetic data, extinction sizes and burning durations were measured for different ambient conditions.

Attempts to develop theoretical explanations for the extinction data presented here consistently led to predictions of particle temperatures in excess of 2000°K, well above the temperature ranges in which voluminous data (4-11) on the oxidation of various forms of carbon exist. The previous data exhibited activation energies that for the most part tended to decrease with increasing temperature, becoming very near or even less than zero (7, 8, 12) at the highest temperatures. This shed doubt on the particle temperatures inferred theoretically, since the phenomenon of sudden extinction disappears at zero or negative activation energies.

In order to check temperature estimates it was deemed desirable to develop an independent experimental method for measuring the surface temperature of the burning particle. A technique of two-color optical pyrometry was devised and applied to establish that temperatures were in the range 2000°-3500°K, thereby supporting the theoretical estimates. These results along with the extinction data confirmed our original inference (13) of a nonzero positive activation energy of about 21.5 kcal/mole at temperatures exceeding 2000°K. In this respect, it is interesting that the activation energy of soot oxidation recently measured by Park and Appleton (14) at oxygen partial pressures around 0.1-0.5 atm in the temperature range 2200°-4000°K appears to be about 16 kcal/mole, a value near our result on electrode carbon.

The foregoing experimental techniques, data, and theoretical ideas are described in detail in the following sections.

Experiment

The carbon particles for the tests were obtained by grinding in a mortar a rod of electrode carbon manufactured by National Carbon Company and sieving the powder into different sizes in the range 50-200μ. The density of the particles was measured as follows. A rod of electrode carbon was weighed, dunked in water to obtain the displaced volume, immediately removed from the water, wiped clean, and reweighed. The initial and final weights differed by less than 3%, the increment resulting from the absorbed water. The weight to displaced volume ratio was 1.5 g/cm^3. It was assumed that the ground particles have the same density as the rod. This assumption was supported qualitatively by visual observation of the surface of the original carbon rod and one of the ground particles under a microscope; there was no observable structural difference. Since the density of graphite is 2.25 g/cm^3, the particles were about 33% porous. The composition of the particles was measured with an Ortec Delphi x-ray energy spectrometer. The analysis yielded the following sulfur 0.5%, traces (ppm) of calcium and iron, the rest carbon. Figure 1a shows scanning electron micrographs of a typical particle. Only those particles which were nearly spherical in shape were selected from the size-graded powder. After mounting a particle in the apparatus, its three major dimensions were measured under a stereomicroscope. The cube root of their product was taken to be the diameter of an equivalent sphere.

The experimental apparatus to study the combustion of submillimeter particles has been described by Wilson and Williams (15). Here we briefly point out its essential features. A carbon particle is mounted at the bottom tip of a vertically hanging glass fiber, about 25μ in diameter with the aid of a speck of grease (less than 5% of the volume of the particle) as an adhesive. The particle and the fiber are enclosed in a metal bell jar about 18 cm in diameter, 25 cm high, with 4 quartz windows on the circumference at right angles. The atmosphere within the jar is at room temperature, and its pressure and oxygen mass fraction are preset to desired values. For the tests reported here, industrial grade mixtures of oxygen and nitrogen having less than 30% relative humidity were used. Light from a pulsed ruby laser, with maximum rated energy output of 35 joules, is focused onto the particle through one of the windows. A concave mirror refocuses the laser energy emerging from the opposite window such that the particle receives approximately equal radiant flux on both sides. The laser pulse ignites the particle, and the particle detaches from the glass fiber and falls downwards, because of gravity, as it burns. It is reasonable to assume that the speck of grease used for mounting the particle ignites and is dispersed before the particle starts burning. The ignition and the burning sequences were observed visually through a green filter having a 0.01 μm bandwidth which cut off all harmful light of the laser frequency and were recorded by a high speed "Hycam" 16 mm movie camera. The burning duration is measured with reference to timing marks recorded synchronously on the film edge. Laser-based techniques of this general type were developed independently by a number of investigators, notably Marshall, Nelson, Prentice, and Wilson, all beginning at about the same time (1965); see, for example, Ref. (16-18).

Preliminary tests in air at atmospheric pressure showed that a particle with equivalent sphere diameter in the range 50-200μ could not sustain combustion and extinguished a few milliseconds after the ignition pulse. This was verified by collecting the extinguished

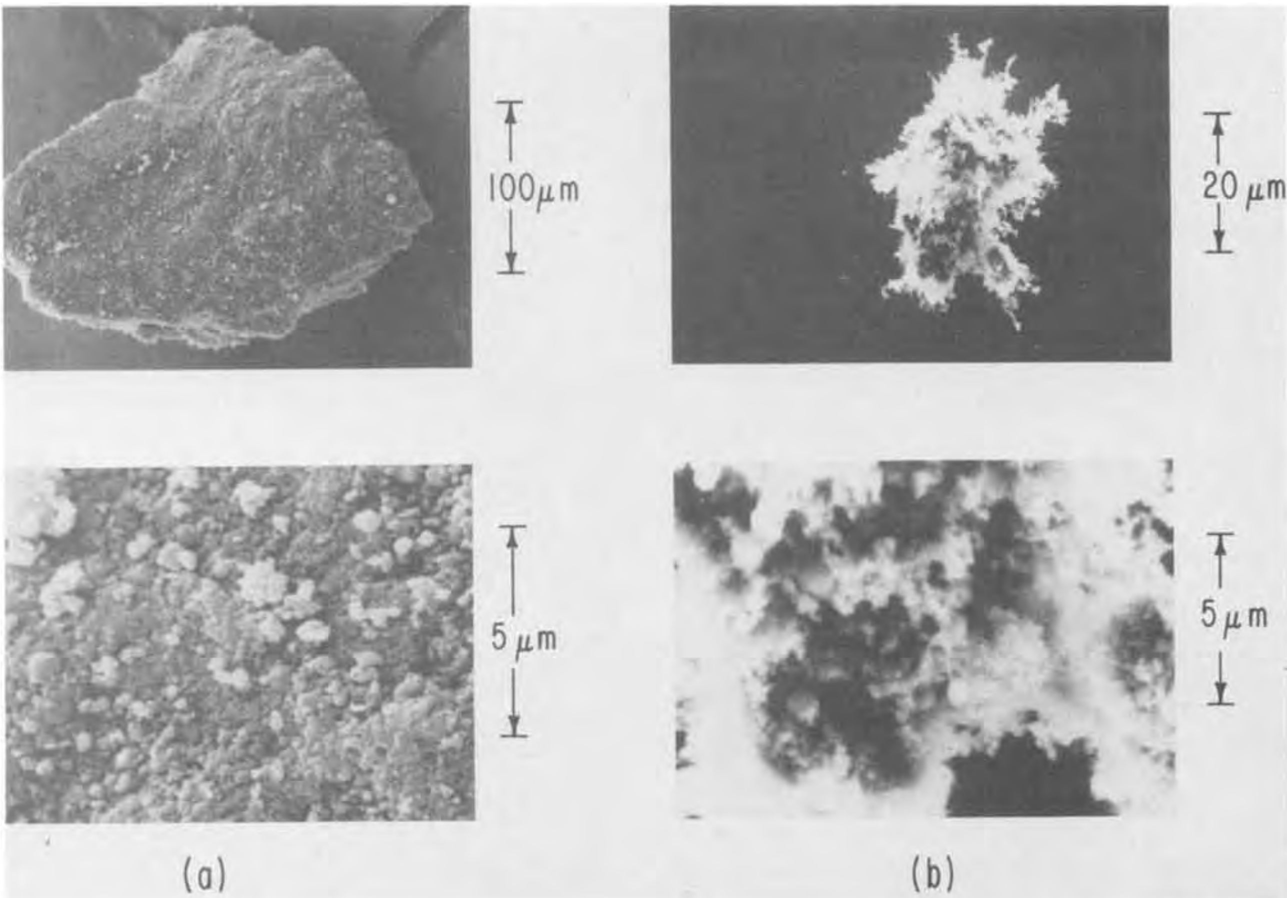

Fig. 1. Scanning electron micrographs of (a) an unburnt particle of electrode carbon and (b) a particle after it extinguished spontaneously while burning in pure oxygen at 0.75 atm.

particle on a large, clean, white sheet of cardboard placed a few inches under the particle. The laser energy could be set high enough to raise the particle temperature to nearly 4500°K, its vaporizing temperature. Despite such high ignition pulses, the particle extinguished without any significant burning. However, tests in oxygen-enriched atmospheres of oxygen mass fraction greater than 0.6 at a pressure of 1 atm displayed sustained combustion as the particle fell downwards. Visual observation of the burning showed that the particle burned intensely, without any noticeable change in the intensity of light emission, until it suddenly disappeared from view. Initially it was thought that the particle burned completely, but careful examination of the cardboard placed under the particle, far below its point of disappearance, revealed a tiny speck about 20μ in diameter. Evidently the disappearance of the particle signifies extinction rather than complete consumption.

Further tests showed that the extinction diameter d^* increased with decreasing oxygen mass fraction Y_{O^∞} and decreasing pressure p; for any particular Y_{O^∞} and p, d^* was the same, within a certain scatter band, regardless of the initial size of the particle. Scanning electron micrographs of a typical extinguishd residue are shown in Fig. 1b, where a highly porous, flakelike structure is evident. The circles in Fig. 2 show the measured extinction data; here the data are shown repeatedly in three sets in order to avoid clutter of the comparative theoretical results which are derived later. In this figure we note that at 1 atm the extinction diameters increase rapidly with decreasing Y_{O^∞} for Y_{O^∞} less than 0.6. This indicates that air at a pressure of 1 atm is beyond the extinction limit for particles of this size. In pure oxygen at $p \geq 1$ atm, the extinguished particles could not be detected either because they were too small to be caught or because they burnt completely.

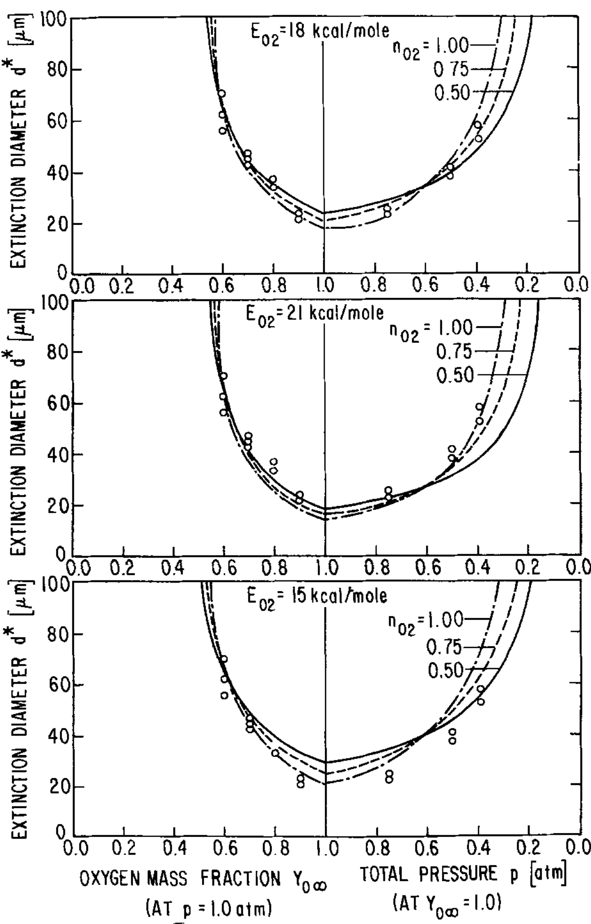

Fig. 2. Extinction diameters shown by the circles. The lines represent extinction diameters computed from Eq. [15], model 1, assuming the activation energies and orders as shown. The values of the preexponential factors (with orders in parentheses) computed to give $d^* = 65$ μm at $Y_{O^\infty} = 0.6$ and $p = 1$ atm are the following. Top: E_{O2} = 18 kcal/mole, k_{O2} (0.5) = 799 $g^{0.5}/cm^{0.5}$-sec, k_{O2} (0.75) = 1.08×10^4 $(g\text{-}cm)^{0.25}$/sec, k_{O2} (1) = 1.38×10^5 cm/sec. Middle: E_{O2} = 21 kcal/mole, k_{O2} (0.5) = 1561 $g^{0.5}/cm^{0.5}$-sec, k_{O2} (0.75) = 2.2×10^4 $(g\text{-}cm)^{0.25}$/sec, k_{O2} (1) = 2.91×10^5 cm/sec. Bottom: E_{O2} = 15 kcal/mole, k_{O2} (0.5) = 400 $g^{0.5}/cm^{0.5}$-sec, k_{O2} (0.75) = 5.12×10^3 $(g\text{-}cm)^{0.25}$/sec, k_{O2} (1) = 6.18×10^4 cm/sec.

Motion pictures of the burning sequences were taken for various values of Y_{O^∞} and p. Figure 3 shows an eight-frame sequence of a typical film strip. The time interval between the bright lines on the left margin is 1 msec. The intense flash in the first frame is due to the laser; the top of the hot probe is visible in the second frame. From such films the velocity of fall of each particle was measured to be in the range 5-50 cm/sec. While burning, the particle appears as a bright spot on the film, retaining its original shape, and no gas-phase flame is seen on the film. Gas-phase flames were not registered on the film for any of the various values of Y_{O^∞} and p. This suggests that the burning zone is restricted to the surface and that a gas-phase reaction between CO and O_2 does not occur outside the particle.

The surface temperature history of the burning particle was measured by two-color optical pyrometry. The technique is well known (19), including its application in situations requiring short time resolution (20-22), the principal potential difficulty being influences of band radiation (19). Based on Wien's approximation for Planck's radiation equation for a thermally radiating surface, the temperature of the surface is uniquely determined by the ratio of intensities at any two wavelengths

$$\frac{J_1}{J_2} = \frac{\epsilon_1}{\epsilon_2}\left(\frac{\lambda_2}{\lambda_1}\right)^5 \exp\left[\frac{C}{T_s}\left(\frac{1}{\lambda_2} - \frac{1}{\lambda_1}\right)\right] \quad [1]$$

where $\lambda_{1,2}$ are the two wavelengths, $\epsilon_{1,2}$ are the spectral emissivities of the surface at $\lambda_{1,2}$, T_s is the surface temperature, C is Planck's second radiation constant equal to 14,388 (μm°K), and $J_{1,2}$ are the intensities at $\lambda_{1,2}$. If the emitting surface is gray then $\epsilon_1/\epsilon_2 = 1$; this is a good approximation when the two wavelengths $\lambda_{1,2}$ are chosen close to each other. With known values of $\lambda_{1,2}$ and the measured ratio J_1/J_2, the surface temperature T_s can be evaluated from Eq. [1]. This method is accurate if only the thermal radiations from the particle surface are metered.

The experimental arrangement using this technique to measure the temperature history of a burning carbon particle is shown schematically in Fig. 4. The particle is located at the center of the chamber. The light emanating from the burning particle is partially focused by a convex lens and split into two beams by a thin glass sheet. These two beams pass through narrow band filters of wavelengths λ_1 and λ_2 as shown. Each beam of filtered light falls on the active surface of a phototube. By partially focusing the beams, the effect of movement of the burning particle is eliminated since the surface area of the filter is uniformly illuminated irrespective of the position of the particle. One of the phototubes has a variable gain control for calibration purposes. The outputs from the two phototubes are fed to a dual-beam storage oscilloscope set for a single sweep. The laser console switch triggers the ignition pulse as well as the oscilloscope simultaneously. From the stored traces of intensities registered on the oscilloscope the ratio J_1/J_2 is obtained as a function of time. This ratio history is reevaluated in terms of the surface temperature history by using Eq. [1].

The foregoing technique is prone to errors because the intensities measured by the phototubes may in-

Fig. 3. Initial segment of a typical film strip of a carbon particle burning in pure oxygen at 1 atm pressure. Initial size of the particle was about 100 × 130 × 130 μm. Magnification on the 1.6 cm wide film is 2.32. Time runs top to bottom. Initial bright region represents the laser pulse. Timing marks on the left edge are spaced 1 msec apart.

clude, in addition to the thermal contribution, the band emissions from any of the gases in the combustion zone. Since the nature of these gases at the surface of the burning carbon particle is not known, an effective way of checking the validity of this technique is to choose two or more pairs of wavelengths. If the temperatures measured for these pairs under the same experimental conditions are the same within the experimental scatterband, then the results can be accepted. Therefore, all the tests were conducted using two pairs of wavelengths: $\lambda_{1,2}$ = 0.4393, 0.5203 μm and 0.5203, 0.6000 μm, each centered within a bandwidth of 0.01 μm.

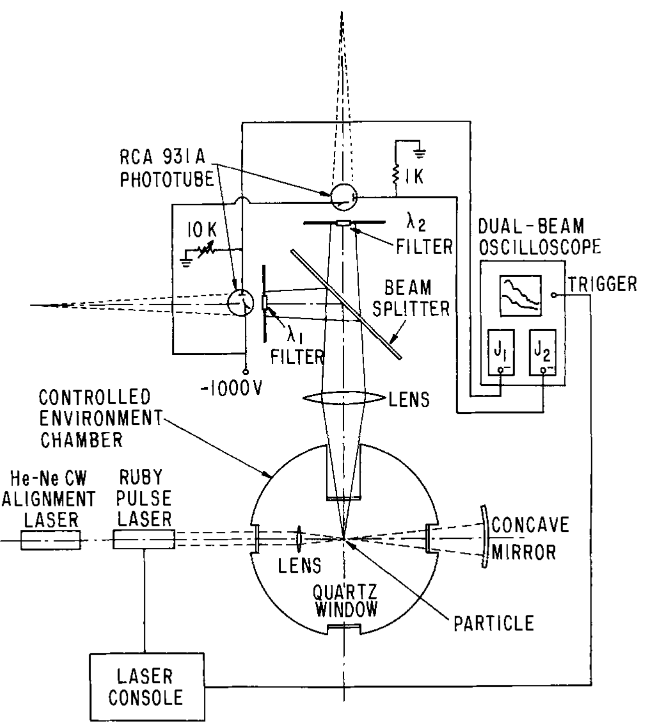

Fig. 4. Schematic diagram for the test arrangement for surface temperature measurement.

A General Electric tungsten ribbon lamp was used for calibration of the test setup. The ribbon was positioned at the same location as the particle, and its intensity was adjusted to any desired level by an autotransformer input. The brightness temperature of the ribbon was measured by a Leeds and Northrup disappearing filament optical pyrometer. Using the conversion chart given in the report by Rutgers and DeVos (23), the true surface temperature of the ribbon was obtained, and the ratio J_1/J_2 was evaluated from Eq. [1]. Then the gain of the phototube 1 was adjusted such that the ratio of the two intensities registered on the oscilloscope was equal to the evaluated ratio. With the same gain adjustment the temperatures at other ribbon intensities were then checked from the measured intensity ratios. The agreement was within 6% of the temperature measured by the optical pyrometer. The temperature range of calibration was 1800°-2700°K.

The spectral emissivity data on carbon given by Touloukian and DeWitt (24) was used to calculate ϵ_1/ϵ_2. This ratio was about 1.04 for the two pairs of wavelengths chosen, thereby justifying the gray surface approximation.

A typical oscilloscope trace is shown in Fig. 5. Here the oscillations in the intensities are caused by the oscillations in the projected area of the randomly rotating nonspherical particle as "seen" by the focusing lens. Were the particle perfectly spherical, there would not have been oscillations. The ratio of the intensities at any instant determines the surface temperature T_s. It was observed that the temperatures measured by the chosen two pairs of wavelengths were within the experimental scatterband. We therefore infer that the errors in the temperature measurements caused by any band emissions from the gases at the surface of the burning particle were probably negligible. Figure 6 shows the measured surface temperature T_s as a func-

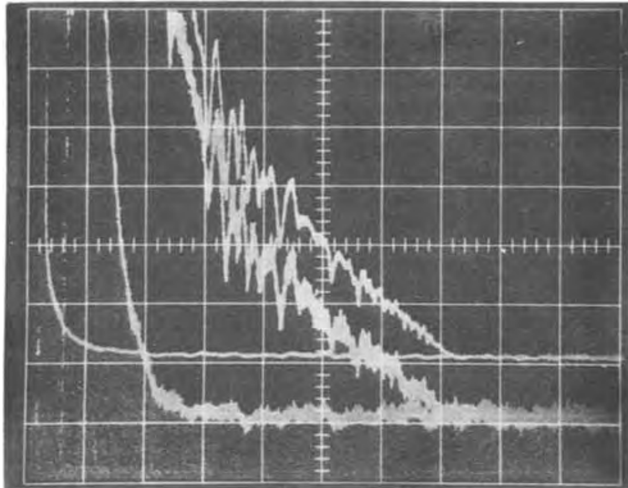

Fig. 5. Oscilloscope traces of the outputs of the two phototubes. The two leftmost curves ending horizontally are the traces of the laser pulse; the horizontal regions serve as base lines for intensity measurements. Horizontal scale is 10 msec per division. Initial size of the particle was 100 × 120 × 120 μm. Bottom trace is J_1 and the top trace is J_2. Actual J_1/J_2 = 0.375 × (measured J_1/J_2) where 0.375 is the calibration factor. $\lambda_{1,2}$ = 0.4393, 0.5203 μm.

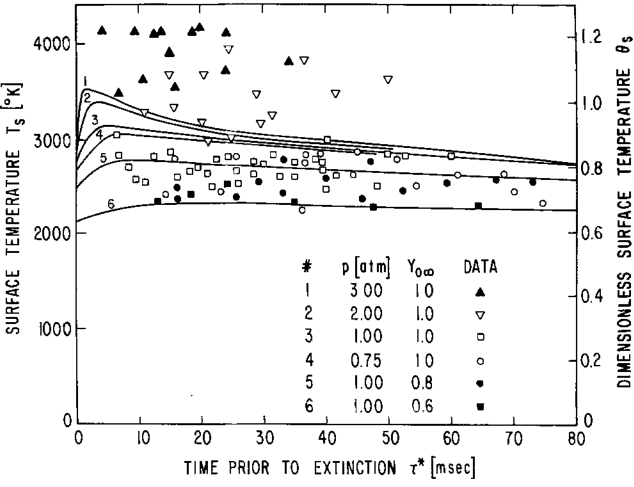

Fig. 6. Surface temperature histories. Full lines computed from Eq. [13]-[15], model 1, for n_{O2} = 0.5, E_{O2} = 18 kcal/mole, k_{O2} = 799 $g^{0.5}/cm^{0.5}$-sec, using other data from Table I.

tion of time τ^* prior to extinction. Here despite the scatter we note that in pure oxygen, higher pressure corresponds to higher temperature. Also, all measured temperatures are above 2000°K.

In Fig. 5 the average intensity is seen to decrease linearly with time. Since the intensity is proportional to the projected area ($\propto d^2$) of the particle, we infer that the square of the diameter decreases approximately linearly with time; this inference is accurate only if the surface temperature does not change with time. Indeed it is seen that this is true within the scatterband shown in Fig. 6 for each test condition.

Figure 7 shows the burning duration τ^* as a function of the initial diameter d^o of the particle. These data were obtained from the movie film strips by measuring the time interval between the ignition pulse (which lasted about 0.5 msec) and the last frame in which the particle is registered. The oscilloscope traces also yielded the burning durations. In this figure the data points suggest again that the square of the diameter decreases approximately linearly with time. If we compare the data points for Y_{O^∞} = 0.6 and p = 1 atm with those for Y_{O^∞} = 1 and p = 1 atm, we observe that the burning duration in pure oxygen is longer than that in lower Y_{O_∞} atmospheres for a fixed initial diameter. This apparent anomaly can be explained by the fact that an earlier extinction at a larger diameter for a lower Y_{O^∞} atmosphere makes the burning duration for the same initial diameter shorter.

The nearly linear decrement of the square of the diameter with time prior to extinguishment suggests a diffusion-controlled burning, whereas the phenomenon of spontaneous extinction must be caused by a slower reaction at the surface. Furthermore, extinction conditions are approached as the size of the particle decreases. Therefore, during the lifetime of a particle the burning mechanism initially is diffusion controlled, but as the size decreases the reaction rate becomes smaller than the diffusion rate, thereby ultimately forcing an extinction.

Theory

In a recent paper Ubhayakar (25) has analyzed the burning and extinction characteristics of a spherical particle gasified at its surface by oxidant diffusing from the surrounding quiescent gas mixture. Assuming an Arrhenius first-order reaction at the surface with respect to oxygen, he derived theoretically the burning and extinction characteristics. This theory is a segment of a more detailed analysis on carbon particles by Ubhayakar and Williams (13) which includes the dissociation of oxygen as its approaches the hot surface. We present here this analysis and point out the effects of dissociation of oxygen and of the order and activation energy of the surface reaction on the burning and extinction characteristics. The symbols appearing in this section, their definitions and dimensions, are listed

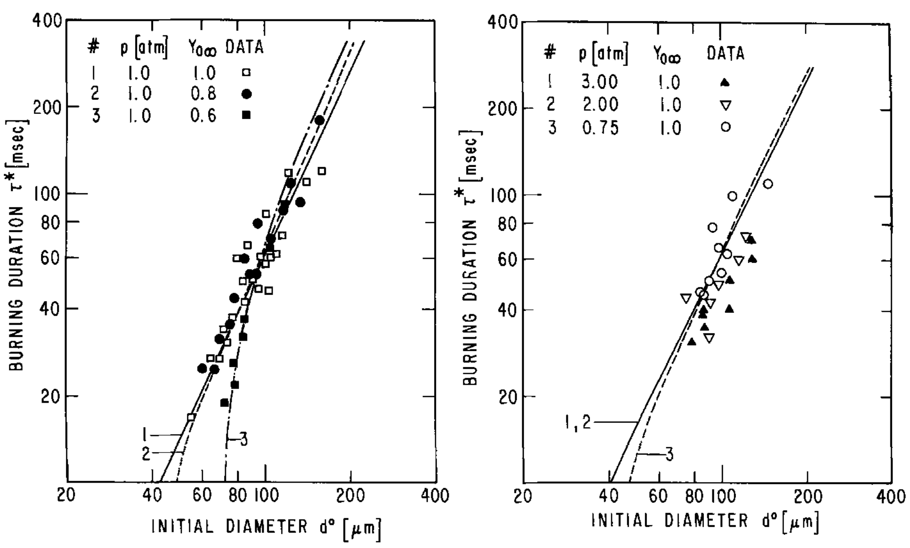

Fig. 7. Burning duration as a function of the initial diameter. Lines computed from Eq. [13]-[15], model 1, for n_{O2} = 0.5, E_{O2} = 18 kcal/mole, k_{O2} = 799 $g^{0.5}/cm^{0.5}$-sec, using other data from Table I.

at the end of the paper. While developing the results a number of simplifying assumptions or approximations are made. These are numbered in order to highlight their significance.

(*i*) The particle is spherical and its velocity of fall (5-50 cm/sec) has little influence on the diffusion flow fields; spherical symmetry is assumed. (*ii*) For any fixed diameter all flow and reaction conditions are steady, that is, the particle is assumed to burn quasi-steadily. (*iii*) The particle is isothermal at its surface temperature T_s. (*iv*) The ambient mixture of oxygen and nitrogen is at constant temperature T_∞, constant oxygen mass fraction Y_O^∞, and constant pressure p. (*v*) The dissociation of nitrogen is negligible since it is significant only at temperatures exceeding 5000°K (26). (*vi*) Part of the oxygen diffusing inward may dissociate, in which case the molecular and atomic oxygen equilibrate instantly at any temperature. (*vii*) The properties ρD, λ, and c for each species are the same and constant. (*viii*) The gas mixture and its components behave as ideal gases. (*ix*) The total emissivity of the particle surface and of the surroundings have an equal and constant value of ϵ, and the gases surrounding the particle are radiatively non-participating. (*x*) The atomic and molecular oxygen arrive stoichiometrically at the surface and react to form CO at a rate per unit area equal to

$$k_O(\rho_s Y_{Os})^{n_O} \exp(-E_O/RT_s) + k_{O2}(\rho_s Y_{O2s})^{n_{O2}} \exp(-E_{O2}/RT_s)$$

(*xi*) These Arrhenius rates are the effective rates in the surface temperature range of the burning particle and include effects of the surface area per unit projected area of the particle (Fig. 1b) as well as any influence of reaction during diffusion within the porous subsurface; nevertheless the effective kinetic parameters k_O, E_O, n_O, k_{O2}, E_{O2}, and n_{O2} are taken to be constant. (*xii*) CO_2 production is neglected because it is known (4, 5) that at the measured high temperatures in excess of 2000°K the product of carbon oxidation is primarily CO; the CO produced is assumed to diffuse outwards without further reaction.

Including Fickian diffusion and Stefan flux from the surface, the mass flow rate for each species is

$$m_i = mY_i - 4\pi r^2 \rho D(dY_i/dr) \quad [2]$$

where i ≡ O, O_2, CO, or N_2. The conservation equation for energy is (13, 25)

$$\sum_i m_i[c(T - T_s) - q_i] - 4\pi r^2 \lambda(dT/dr) = -\pi d^2 \epsilon\sigma(T_s^4 - T_\infty^4) \quad [3]$$

The rates of consumption of oxygen atoms and molecules at the surface are equal to their respective rates of arrival at the surface

$$-(m_O + m_{O2}) = \pi d^2[k_O(\rho_s Y_{Os})^{n_O} \exp(-E_O/RT_s) + k_{O2}(\rho_s Y_{O2s})^{n_{O2}} \exp(-E_{O2}/RT_s)] \quad [4]$$

It is more convenient to write the preceding equations in terms of total oxygen ($\bar{O}$). We therefore define a dissociation fraction $Z = Y_O/(Y_O + Y_{O2}) = Y_O/Y_{\bar{O}}$. Then $Y_O = ZY_{\bar{O}}$, $Y_{O2} = (1 - Z)Y_{\bar{O}}$, and $Y_{\bar{O}} + Y_{CO} + Y_{N2} = 1$. Owing to stoichiometry we have $m_{\bar{O}} = m_O + m_{O2} = -(\nu - 1)m$, $m_{CO} = \nu m$, and $m_{N2} = 0$. Also, by definition heats of formation are $q_{O2} = q_{N2} = 0$. Using the preceding relations we write Eq. [2]-[4] in the following dimensionless forms

$$\nu M = MY_{CO} - \eta^2(dY_{CO}/d\eta) \quad [5]$$

$$-(\nu - 1)M = MY_{\bar{O}} - \eta^2(dY_{\bar{O}}/d\eta) \quad [6]$$

$$M(\theta - \theta_s) - \nu M + Q_O[(\nu - 1)ZM + \eta^2 Y_{\bar{O}}(dZ/d\eta)] - \eta^2 \,\mathrm{Le}(d\theta/d\eta) = G\,\mathrm{Le}(\theta_s^4 - \theta_\infty^4) \quad [7]$$

$$(\nu - 1)M = K_O(\alpha ZY_{\bar{O}}/\theta)_s^{n_O} \exp(-\beta_O/\theta_s) + K_{O2}(\alpha(1 - Z)Y_{\bar{O}}/\theta)_s^{n_{O2}} \exp(-\beta_{O2}/\theta_s) \quad [8]$$

where the equation of state $p = R\rho T(Y_O/W_O + Y_{O2}/W_{O2} + Y_{CO}/W_{CO} + Y_{N2}/W_{N2}) = R\rho T/(\alpha W_{O2})$ has been used in Eq. [4], with $\alpha = [(W_{O2}/W_O - 1)ZY_{\bar{O}} + (W_{O2}/W_{CO} - 1)Y_{CO} + W_{O2}/W_{N2}]^{-1}$ and $(dZ/d\eta) = (\partial Z/\partial\theta)(d\theta/d\eta) + (\partial Z/\partial Y_{\bar{O}})(dY_{\bar{O}}/d\eta) + (\partial Z/\partial Y_{CO})(dY_{CO}/d\eta)$. Here Z, $(\partial Z/\partial\theta)$, $(\partial Z/\partial Y_{\bar{O}})$, and $(\partial Z/\partial Y_{CO})$ are known functions of θ, $Y_{\bar{O}}$, and Y_{CO}, and are derived in the Appendix.

The known boundary conditions at $\eta \to \infty$ are $Y_{CO}(\infty) = 0$, $Y_{\bar{O}}(\infty) = Y_O^\infty$, and $\theta(\infty) = \theta_\infty$. Equations [5] and [6] with the first two boundary conditions are readily integrable, whereas Eq. [7] is not because of the nonlinear terms. The solutions $Y_{\bar{O}}(\eta)$ and $Y_{CO}(\eta)$ may be substituted into Eq. [7] to obtain a nonlinear first-order differential equation in θ which, in principle, can be solved. However, since M and θ_s are the unknown eigenvalues of the problem, and since they have to be determined from the boundary conditions at infinity and at the surface given by Eq. [8], the problem is too complicated to solve exactly analytically. We shall therefore consider two limiting models to extract useful information from these equations by introducing additional simplifying approximations and assumptions. A reasonable further approximation is (*xiii*) $W_{O2} = 2W_O \simeq W_{CO} = W_{N2}$, which produces $\alpha = (ZY_{\bar{O}} + 1)^{-1}$.

Model 1

In this model the effects of dissociation are neglected. This may be reasonable if the surface temperatures are less than about 4000°K (at which $Z \sim 0.5$, cf., Appendix) and the reaction of molecular oxygen with carbon is dominant. Then Z and all its derivatives will be zero, $\alpha = 1$, and consequently Eq. [7] becomes integrable. Equations [5]-[7] are solved subject to the boundary conditions at infinity to produce the following relations at surface conditions

$$M = -\ln(1 - Y_{COs}/\nu) \quad [9]$$

$$M = -\ln[(\nu - 1 + Y_{\bar{O}s})/(\nu - 1 + Y_O^\infty)] \quad [10]$$

$$M = \mathrm{Le}\ln[1 + \{M(\theta_s - \theta_\infty)/(M\nu - G\,\mathrm{Le}(\theta_s^4 - \theta_\infty^4))\}] \quad [11]$$

Equation [8] simplifies to

$$M = [K_{O2}/(\nu - 1)][Y_{\bar{O}s}/\theta_s]^{n_{O2}} \exp(-\beta_{O2}/\theta_s) \quad [12]$$

The eigenvalues M, Y_{COs}, $Y_{\bar{O}s}$, and θ_s may now be obtained from Eq. [9]-[12] since the following are presumed to be known: Le (physical property of the gases), θ_∞, Y_O^∞ (ambient), ν, K_{O2}, β_{O2}, and n_{O2} (reaction) and G (radiation). Here the reaction number $K_{O2} \propto p^{n_{O2}}d$ and the radiation number $G \propto d$. The solutions therefore depend on the particle size which decreases as the particle burns. The phenomenon of spontaneous extinction brought about by decreasing diameter d for an order $n_{O2} = 1$ has been described by Ubhayakar (25). We shall study here the effect of the order n_{O2} on the extinction characteristics. First, Eq. [10] and [11] are written in the linearized forms

$$M = C_Y(Y_O^\infty - Y_{\bar{O}s})/(\nu - 1) \quad [13]$$

$$M = C_\theta\,\mathrm{Le}\,M(\theta_s - \theta_\infty)/[M\nu - G\,\mathrm{Le}(\theta_s^4 - \theta_\infty^4)] = (\mathrm{Le}/\nu)[C_\theta(\theta_s - \theta_\infty) + G(\theta_s^4 - \theta_\infty^4)] \quad [14]$$

where C_Y and C_θ are correction factors. Then M and $Y_{\bar{O}s}$ are eliminated between Eq. [12]-[14] to obtain the single equation

$$f(\theta_s) = g(\theta_s) \quad [15]$$

where

$$f(\theta_s) = [\mathrm{Le}(\nu - 1)/\nu][C_\theta(\theta_s - \theta_\infty) + G(\theta_s^4 - \theta_\infty^4)]$$

and

$$g(\theta_s) = C_Y Y_{O^\infty} \left[1 + C_Y \theta_s \left\{ \frac{f(\theta_s)^{1-n_{O2}}}{K_{O2} \exp(-\beta_{O2}/\theta_s)} \right\}^{1/n_{O2}} \right]^{-1}$$

The characteristics of the solutions to this equation have been delineated by Ubhayakar and Williams (13, 25). We summarize the results briefly: (a) $f(\theta_s)$ represents the heat loss rate while $g(\theta_s)$ represents the reaction heat release rate; their relative values (which depend on d through the reaction number K_{O2} and the radiation number G) determine whether or not there exists a solution θ_s significantly greater than θ_∞. Extinction occurs when $f(\theta_s)$ becomes tangent to $g(\theta_s)$, as illustrated in Fig. 8. (b) Such a tangency is possible only if the activation energy E_{O2} is greater than a certain positive nonzero value. (c) For a zero-order reaction the extinction diameters are independent of the pressure p.

We adopt the following procedure to compare the theoretical extinction results with the data in Fig. 2. Using the constants in Table I and a chosen value of $d^* = 65\ \mu$m (at $Y_{O^\infty} = 0.6$ and $p = 1$ atm), we compute G^*. Then with $C_Y = C_\theta = 1$, Eq. [15] is solved numerically for the tangency condition to get the value of K_{O2}^* for certain prechosen values of E_{O2} and n_{O2}. The numerical solution involved use of a computer for calculating and plotting the functions $f(\theta_s)$ and $g(\theta_s)$ for various values of K_{O2}. Next C_Y and C_θ are evaluated from Eq. [13] and [14] by use of values of M and $Y_{\bar{O}s}$ obtained through Eq. [10] and [11], and K_{O2}^* is recomputed with these new correction factors. This iterative procedure is continued until the value of K_{O2}^* converges. Then the preexponential factor k_{O2} is evaluated from the definition of K_{O2}^*. Using this value of k_{O2} and the chosen values of E_{O2} and n_{O2} along with the constants in Table I, the extinction diameters d^* are computed in a similar iterative procedure for the tangency condition for other values of Y_{O^∞} and p. The results are shown in Fig. 2 for three asumed values of the activation energy E_{O2} and three assumed values of the order n_{O2}. We notice here that the best agreement of the theory with the data is for $E_{O2} = 18$ kcal/mole and $n_{O2} = 0.75$, although the agreement for n_{O2} in the range 0.5-1 is favorable, considering the scatter in the data.

Model 2

In this model we assume that because of the high reactivity of oxygen atoms, the dissociation fraction Z is negligible in Eq. [7] but nonnegligible with regard to the surface rate in Eq. [8]. Then Eq. [5]-[7] yield Eq. [9]-[11], as before. Since Z is assumed small, we put $\alpha = 1$ and $Z_s = (a^2/pY_{\bar{O}s})^{0.5} \exp(-\Gamma/\theta_s)$, as derived in the Appendix. For further simplification of Eq. [8] we assume $n_{O2} = n_O$, an approximation expected to have a small effect because of the relative unimportance of n_{O2} in model 2. Then Eq. [8] can be written as

$$M = \frac{K_O}{(\nu - 1)\theta_s^{n_O}} [(a^2 Y_{\bar{O}s}/p)^{n_O/2} \exp\{-(\Gamma n_O + \beta_O)/\theta_s\} + \chi Y_{\bar{O}s}^{n_O} \exp(-\beta_{O2}/\theta_s)] \quad [16]$$

where $\chi = K_{O2}/K_O = k_{O2}/k_O$.

Experimental results of Rosner and Allendorf (12) and Strickland-Constable and co-workers (7, 8) have proven that at temperatures greater than 2000°K there exists a temperature region in which the activation energy of the reaction between pyrolytic graphite and molecular or atomic oxygen is zero or somewhat negative. To investigate whether this can also be true for our experiments with electrode carbon, we set $\beta_{O2} = \beta_O = 0$ in Eq. [16]. Since the reaction of carbon with molecular oxygen is slow compared to that with atomic oxygen (12), the value of χ is small. If $\chi = 0$, then comparison of Eq. [16] with Eq. [12] reveals that by including the dissociation of oxygen we have effectively introduced a pseudo-activation energy (γn_O) and a pseudo-order ($n_O/2$).

The solutions to Eq. [13], [14], and [16] at the extinction tangency condition were computed in a manner similar to that explained in model 1, and the computed extinction diameters d^* are shown in Fig. 9 for $\chi = 0$ and $\chi = 0.01$ for three assumed values of n_O. The computations also indicated that for higher values of χ the extinction tangency condition could not be satisfied. The interesting feature of this model is that it shows that extinction can occur even if the activation energies of the reactions between carbon and molecular and atomic oxygen are zero provided that the pseudo-activation energy (γn_O) arising from the dissociation heat of molecular oxygen is included. How-

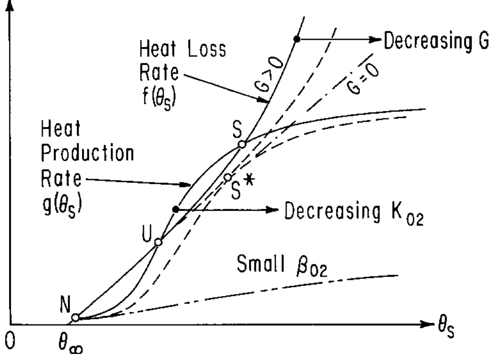

Fig. 8. Schematic diagram of energy balance defined by Eq. [15], illustrating attainment of extinction condition. Solid lines are typical curves having nonburning N, unstable U, and stable burning S solutions. Dashed lines represent extinction conditions with S* the tangency point. Also shown are the linear dependence of f on θ_s when $G = 0$ and the absence of sufficient curvature in $g(\theta_s)$ to produce multiple intersections when β_{O2} is small.

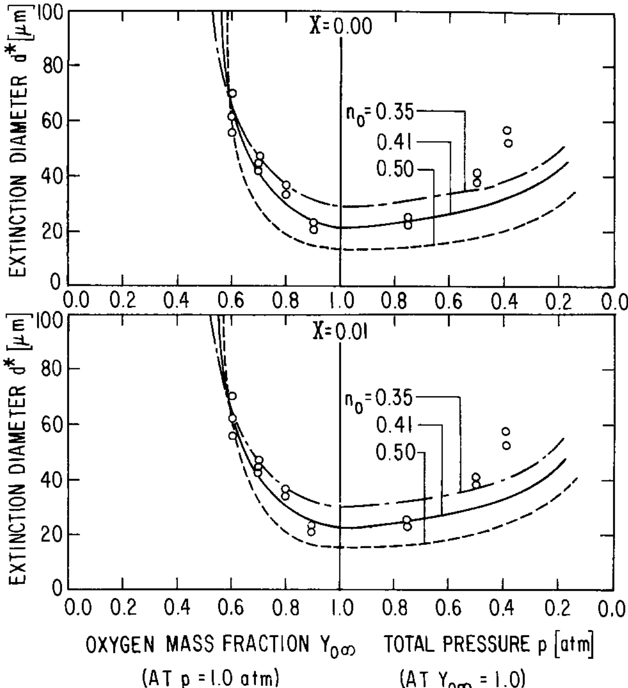

Fig. 9. Extinction diameters computed from Eq. [13], [14], and [16], model 2, using other data from Table I. The circles are the same data shown in Fig. 2. The values of the preexponential factors (with orders in parentheses) computed to give $d^* = 65\ \mu$m at $Y_{O^\infty} = 0.6$ and $p = 1$ atm are the following. Top: $\chi = 0$, k_O (0.35) = 16.69 $g^{0.65}/cm^{0.95}$-sec, k_O (0.41) = 41.48 $g^{0.59}/cm^{0.77}$-sec, k_O (0.5) = 167.4 $g^{0.5}/cm^{0.5}$-sec. Bottom: $\chi = 0.01$, k_O (0.35) = 16.26 $g^{0.65}/cm^{0.95}$-sec, k_O (0.41) = 39.89 $g^{0.59}/cm^{0.77}$-sec, k_O (0.5) = 152.72 $g^{0.5}/cm^{0.5}$-sec.

ever, the agreement between the theory and data is good only for $n_O = 0.41$ on the constant-p side and is not good on the constant-Y_{O^∞} side in Fig. 9. A value of n_O as low as 0.41 is difficult to justify theoretically. This model therefore does not appear to be as favorable as model 1. We therefore conclude that model 1 is the preferred model between the two.

Discussion

The kinetics of oxidation of carbon are known (11) to be distinctly non-Arrhenius in the temperature range 300°-4000°K, and to be dependent on the type of carbon, its impurities, structure, etc. For example, the kinetics of oxidation of pyrolytic graphite measured by Strickland-Constable and co-workers (7, 8) are different from those of electrode carbon measured by Golovina and Khaustovich (9) and Okada and Ikegawa (10). Above 2000°K these differences may arise because of fundamentally different kinetics or because of diffusion-controlled rate limitation. Strickland-Constable and co-workers (7, 8) devised their tests specifically to eliminate the diffusional effects and still found that the reaction rate reaches a maximum and then decreases as the temperature increases. Extrapolation of their rate formula to higher temperatures predicts a minimum rate beyond which the rate begins to rise again. Also, according to their rate formula the rate maximum and minimum disappear at high partial pressures of oxygen. They have explained this behavior by assuming the surface to consist of two types of active sites which are thermally interconvertible. In contrast, Ong (27) has deduced similar results based on fundamental statistical thermodynamics and on only one type of active site. Both schemes appear plausible and yet disagree with each other (11). One of the reasons for this may be the different structures of the carbon studied. According to our preferred model 1, the effective activation energy of the oxidation of electrode carbon in the temperature range 2000°-3500°K has a positive nonzero value of about 18 kcal/mole which is (a) in disagreement with the data of Rosner and Allendorf (12) on pyrolytic graphite at very low p_{O2}, (b) in partial agreement with the results of Strickland-Constable and co-workers (7, 8) on pyrolytic graphite at $p_{O2} \sim 0.21$ atm (partial because beyond the temperature of minimum rate, their formula predicts an activation energy of 15.2 kcal/mole), and (c) in good agreement with the data of Park and Appleton (14) on soot at $p_{O2} \sim 0.1$-0.5 atm. The values of p_{O2s} at extinction, calculated from Eq. [12]-[14], are of the order of 0.2 atm, which is in the range of this data of Park and Appleton.

The measured kinetics of oxidation are also known (3, 4) to be affected by diffusion and reaction within the porous subsurface. Although the present data are insufficient to differentiate between these effects and the fundamental kinetic details indicated in the last paragraph, the highly porous structure in Fig. 1b suggests that as extinction is approached, the diffusional resistance within pores may become negligible. If this occurs, then the rate constants listed in the caption of Fig. 2 are related to absolute surface rate constants through a roughness factor f, defined as the ratio of the actual surface area at which reaction occurs to the surface area of the sphere of diameter d^*. If the previously mentioned surface reaction rates of Park and Appleton (14) are assumed to be correct for the present experiments, and if the aforementioned value of p_{O2s} is employed along with our measured surface temperatures and rate constants, then values of f at extinction ranging from 50 to 100 are calculated. Although these values seem to be qualitatively consistent with Fig. 1b, the result cannot be termed definitive. Since the sizes of the soot particles were on the order of 100Å, less than 10^{-3} times the diameter of the present extinguished particles, the rough agreement appears encouraging.

Owing to the scatter in the extinction data shown in Fig. 2, it is not possible to ascertain the exact order of the reaction. The theoretical curves for n_{O2} in the range 0.5-1 fit the data favorably, although $n_{O2} = 0.75$ appears to give the best fit. A convincing fundamental justification for the latter value has not been obtained.

Ong's (27) scheme for carbon oxidation predicts an order of 0.5 at temperatures greater than 2000°K. We shall therefore choose $n_{O2} = 0.5$ and the corresponding k_{O2} from Fig. 2, and compute the burning durations and temperature histories, the data for which are shown in Fig. 6 and 7. Once n_{O2}, E_{O2}, and k_{O2} are known, Eq. [13]-[15] are solvable for M, θ_s, and $Y_{\bar{O}s}$ for any diameter d. Since $m = -(d/dt)(\pi \rho_C d^3/6) = (2\pi\rho D d)M$, the burning duration is

$$\tau^* = \int_{t^o}^{t^*} dt = \frac{\rho_C}{4\rho D} \int_{d^*}^{d^o} \left(\frac{d}{M} \right) dd$$

which can be computed for any given initial diameter d^o. Figures 6 and 7 show the computed curves using the constants given in Table I.

In Fig. 6 we note that the theory agrees with the data favorably for all conditions except those in pure oxygen at $p > 1$ atm. In the diffusion-controlled regime the theory gives the same surface temperature for any fixed diameter and Y_{O^∞} for all pressures; this result depends on the fact that we have assumed the mass diffusivity ρD to be independent of pressure and temperature. Since it is known (28) that $\rho D \propto T^{b-1}$ where $1.5 \leq b \leq 2$, the tests at higher pressure, which are seen according to the theory to have higher temperatures as a consequence of the finite-rate chemistry, also correspond to higher ρD. This diffusivity effect tends to shift the theoretical high-pressure curves to somewhat higher temperatures. However, the effect does not appear to be sufficiently large, and the greater scatter in the high-pressure tests suggests the possibility of nonnegligible experimental errors brought about by band emissions from the diatomic gases in the combustion zone. Therefore it is unclear whether the discrepancies of temperature at oxygen pressures above atmospheric are attributable primarily to errors in theory or experiment.

In Fig. 7 we observe that the computed lines conform to the "square law" or diffusion-controlled burning for large diameters and that as the diameter decreases toward the extinction value finite-rate chemistry influences the burning duration. Within the accuracy of the data, the agreement between theory and experiment is good in Fig. 7.

Conclusions

A comparison of the two theoretical models with the extinction data has shown that model 1 is preferred. Based on this model, the kinetics of oxidation of electrode carbon in the temperature range 2000°-3500°K can be effectively represented by an Arrhenius surface reaction having an activation energy of 18 kcal/mole and an order in the range 0.5-1. The burning durations and temperatures computed from this model also agree with experiment, within the accuracy of the data. It

APPENDIX

Because of assumption (*vi*) we have $p_O = K_p p_{O2}^{1/2}$, where $K_p = 2a \exp(-\gamma/RT) = 2a \exp(-\Gamma/\theta)$ is the equilibrium constant for the dissociation reaction $\frac{1}{2} O_2 \rightleftarrows O$ at temperature T. Here $a = 1600$ atm$^{0.5}$ and $\gamma = 60.5$ kcal/mole O (26). Since all component gases as well as the mixture are assumed to behave ideally, we have $Y_O = ZY_{\bar{O}} = (p_O W_O)/R\rho T$, $Y_{O2} = (1 - Z) Y_{\bar{O}} = (p_{O2} W_{O2})/(R\rho T)$. Elimination of p_{O2} and $(R\rho T)$ between these equations produces

$$p_O = K_p^2 (W_O/W_{O2})[(1 - Z)/Z] \quad \text{[A-1]}$$

The ideal gas law for the mixture is

$$p = \frac{R\rho T}{W_O}\left[\left\{Z + \frac{W_O}{W_{O2}}(1 - Z) - \frac{W_O}{W_{O2}}\right\} Y_{\bar{O}} + \left(\frac{W_O}{W_{CO}} - \frac{W_O}{W_{N2}}\right) Y_{CO} + \frac{W_O}{W_{N2}}\right] \quad \text{[A-2]}$$

since $Y_{N2} = 1 - Y_{CO} - Y_{\bar{O}}$. Eliminating $(R\rho T)$ between Eq. [A-2] and the relation $Y_O = (p_O W_O)/(R\rho T)$, we get an equation for p_O which may be equated to Eq. [A-1] to obtain a quadratic in Z

$$AZ^2 + BZ + C = 0 \quad \text{[A-3]}$$

where

$$A = pY_{\bar{O}}\left(\frac{1}{K_p^2}\right)\left(\frac{W_{O2}}{W_O}\right) - \left(1 - \frac{W_O}{W_{O2}}\right) Y_{\bar{O}}$$

$$B = \left(\frac{2W_O}{W_{O2}} - 1 - \frac{W_O}{W_{N2}}\right) Y_{\bar{O}} + \left(\frac{W_O}{W_{CO}} - \frac{W_O}{W_{N2}}\right) Y_{CO} + \frac{W_O}{W_{N2}}$$

and

$$-C = \left(\frac{W_O}{W_{O2}} - \frac{W_O}{W_{N2}}\right) Y_{\bar{O}} + \left(\frac{W_O}{W_{CO}} - \frac{W_O}{W_{N2}}\right) Y_{CO} + \frac{W_O}{W_{N2}}$$

From this equation it is easy to obtain the following

$$Z = [-B + (B^2 - 4AC)^{1/2}]/(2A) \quad \text{[A-4]}$$

$$(2ZA + B)\frac{\partial Z}{\partial \theta} = Z^2 p Y_{\bar{O}}\left(\frac{W_{O2}}{W_O}\right)\left(\frac{1}{K_p^2}\right)\left(\frac{2\Gamma}{\theta}\right) \quad \text{[A-5]}$$

$$(2ZA + B)\frac{\partial Z}{\partial Y_{\bar{O}}} = \frac{W_O}{W_{O2}} - \frac{W_O}{W_{N2}} - Z^2\left\{\frac{W_{O2}}{W_O}\frac{p}{K_p^2} + 1 - \frac{W_O}{W_{O2}}\right\} - Z\left(\frac{2W_O}{W_{O2}} - 1 - \frac{W_O}{W_{N2}}\right) \quad \text{[A-6]}$$

$$(2ZA + B)\frac{\partial Z}{\partial Y_{CO}} = (1 - Z)\left(\frac{W_O}{W_{CO}} - \frac{W_O}{W_{N2}}\right) \quad \text{[A-7]}$$

From Eq. [A-4] we find that $Z = 0.5$ when $p = 3$ atm, $Y_{\bar{O}} = 1$ and $T = 4140$°K and when $p = 0.5$ atm, $Y_{\bar{O}} = 1$ and $T = 3660$°K. Therefore, in the temperature range of the tests Z is less than 0.5. It is a good approximation to consider Z small.

Assumption (*xiii*) simplifies Eq. [A-4] to

$$Z = \frac{[1 - Y_{\bar{O}}]}{2Y_{\bar{O}}\left(\frac{4p}{K_p^2} + 1\right)}\left[\left(1 + \frac{4Y_{\bar{O}}}{[1 - Y_{\bar{O}}]^2}\left(\frac{4p}{K_p^2} + 1\right)\right)^{1/2} - 1\right] \quad \text{[A-8]}$$

Since Z is small when K_p is small, or when $T < 4140$°K, the 1's in the parentheses in Eq. [A-8] can be neglected in comparison with the other terms, giving for small Z

$$Z \simeq [a/(pY_{\bar{O}})^{1/2}] \exp(-\Gamma/\theta) \quad \text{[A-9]}$$

Flash Desorption as a Surface Ion Spectroscopy for Solid Electrolytes

M. L. Knotek

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

An application of flash desorption techniques to solid electrolyte materials which yields a "surface ion spectroscopy" is described. The desorption spectra as a function of surface coverage for Na^+ and K^+ on Na-β-alumina are presented as an illustration and show that there are marked differences in their behavior. The kinetics of the desorption process and its dependence on surface coverage are seen to yield abundant detail on the ion-surface interaction.

There are presently available a number of techniques for the study of such surface properties of solids as their elemental makeup, electronic structure, and crystal structure. In addition, various desorption techniques have been used to study the energetics of the adsorption of molecular species on surfaces. The main use of these techniques has been the study of metals and to a lesser extent semiconductors and insulators.

There has emerged in the past few years a particularly intriguing group of materials, the so-called superionic conductors or solid electrolytes (1). These materials are characterized by open cagelike or tunnellike structures with a number of negatively charged sites per unit cell on which cations sit (typically more than one site per cation). The cagelike structures are generally covalent and quite stable and serve as a framework through which the cations can move quite freely owing to the high site density and open structure. This feature gives rise to unique properties. These materials exhibit high cationic conductivities ($\sim$ 1 ohm-cm at 300°K) and show promise of being technologically important as solid ion transport media for various electrochemical applications. At least two of these materials, β-alumina and the zeolites, also have catalytic properties in which (for the case of zeolites) the cations in the structure have recently been shown to play a major role (2-5). In addition, these materials have unique physical properties which are fundamentally important from the solid-state physics standpoint. A knowledge of the details of the cations interaction with these structures and with each other is needed for a better understanding of their fundamental properties. The surfaces of these materials seem particularly interesting to study since the surface properties should be as complex as the bulk properties, and surfaces can be technologically important. One purpose of this work is to look at the surfaces of these materials with such elemental, electronic, and structural characterization tools as Auger spectroscopy, characteristic loss spectroscopy, depth profiling using ion sputter etching, LEED, and secondary ion mass spectroscopy.

In addition it is important to study the details of the energetics of the ion interaction with the surface, the ionic properties of these materials being their unique feature. We present here the first use of the technique of flash desorption to study ion energetics on these surfaces. The results shown here (which are a representative sample) are interesting from two standpoints. First of all, they provide fundamentally new information on these materials (in essence a "surface ion spectroscopy") which no other technique offers. The results enumerate the spectrum of binding energies of a particular ion on the "surface," and provide data with which to correlate results using other surface characterization techniques. Second, the particular use of the

Key words: β-alumina, surfaces, interfaces, sodium, potassium.

flash desorption technique reported here contains several unique features, and the data show behavior quite unlike that seen in the desorption of neutral species from (say) metals. From both of these viewpoints it would appear that this is an interesting new area for study.

Experimental Details

The data shown here were taken in an all-metal baked ultra high vacuum system which had the capabilities for Auger spectroscopy, characteristic loss spectroscopy, and quadrupole mass analysis. An array of ion sources, based on the appropriately ion exchanged zeolite such as described by Weber and Cordes (6), and Cuderman (7), was used to deposit ions of Li, Na, K, Cs, Ag, or Cu onto the surface being studied. The type of results reported here have been observed on both single crystal Na-β-alumina (both the a-c and a-b planes) and on the Na-zeolite. We report here the results for Na^+ and K^+ on the a-c plane (nominally) of single crystal β-alumina which was the most extensively studied. The a-c plane is perpendicular to the high conductivity plane. The sample surface was prepared by heat cleaning in vacuum at $\approx$ 1000°C.

The experiment consisted of depositing controlled amounts of ions onto the surface being studied (incident energy of the ions was < 8 eV to avoid lattice damage) followed by positioning of the sample near a negatively biased collector probe where the sample was heated at a controlled rate. Monitoring of the ion current emitted from the sample surface and collected by the biased probe as a function of time or sample temperature (interrelated) resulted in a spectrum of desorbing ions. Two points should be made about this particular technique as opposed to the classical flash desorption. First, since ions are deposited and ions are desorbed there is no need for an ionizer in the collector assembly and since a biased probe is used, virtually 100% of the desorbed ions are collected. This results in enormously enhanced sensitivity over the standard flash desorption technique (< 10^{-5} monolayer on an area $\approx$ 0.03 cm^2 can easily be detected during desorption as opposed to the limit of $\approx$ 0.1 monolayer for gases on metals). Second, since the ion collection is line of sight this corresponds to the ideal infinite pumping speed case of flash desorption yielding the highest possible resolution.

Results

Shown in Fig. 1 and 2 are the results for Na^+ and K^+ on the a-c plane of Na-β-alumina as a function of the ion dose in microcoulombs (μC) to the surface. The data have a large amount of detail both as a function of temperature and coverage indicating a complicated interaction. We briefly discuss the behavior as a function of coverage to point out the major features and to contrast Na and K.

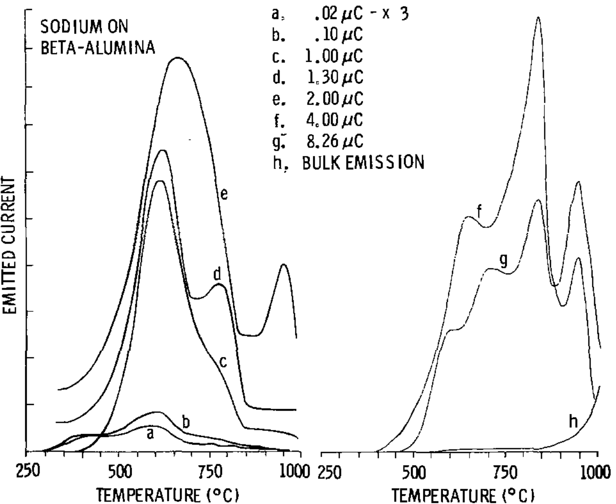

Fig. 1. Emitted sodium ion current vs. sample temperature for a heating rate of $\approx$ 100°C/sec, as a function of ion dose in microcoulombs. Each peak corresponds to a well-defined surface desorption energy. Peak temperatures are not a function of coverage, but the population shifts to higher temperature at higher dose. Current due to bulk Na^+ emission is also shown (curve h).

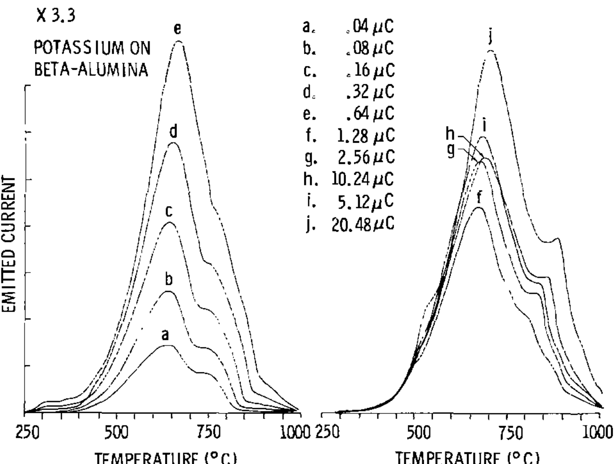

Fig. 2. Emitted potassium ion current vs. sample temperature for a heating rate of $\approx$ 100°C/sec, as a function of ion dose in microcoulombs. Peak temperatures shift with ion dose.

The data are plotted as emitted current *vs.* sample temperature (°C). For the sample configuration used in taking this data one monolayer corresponds to ~20 μC. The heating rate was approximately linear at ~100°C/sec. Using the results of Redhead (8) for first-order processes with a linear heating curve we can approximately relate the temperature of the peak maxima $T_p(K)$ to the desorption energy E by $E = 2.5 \times 10^{-3}\ T_p$(eV) assuming an attempt frequency $\nu_1 = 10^{13}$ sec^{-1}.

At the lowest dose levels ($\leq$0.16 μC) Na has three peaks located at ~425°, 620°, and 760°C (E = 1.74, 2.23, and 2.58 eV) while K has two peaks at 630° and 750°C (E = 2.25 and 2.56 eV). In this range both show roughly linear growth of all features with increasing dose. Mass balance, *i.e.*, ions collected during desorption/ions deposited, is close to unity in this range of dosage. We note that this low dose region is the only range of dosages for which K desorbs by what appears to be a first-order process. The assignment of energies using the above discussion is only good under these circumstances.

In the next range of dosage (0.2 μC $\leq d \leq$ 1.5 μC) the Na spectra show a loss of the 425°C peak with initial major growth in the 620°C peak followed by growth of the 760°C peak as dose increases. There is no shift in peak temperatures with coverage, indicating a first-order process. K in this range shows a roughly equal growth of the major features and a continuous shift of the peaks to higher temperatures with increasing coverage, indicating a higher order process. Minor features at 275° and 525°C also appear in this range. A shifting of the K desorption peaks to higher temperatures with increased coverage is quite unlike the usual behavior seen in (say) metals, as illustrated by hydrogen on tungsten (9). Na shows no shifts, but is also unusual in that the least stable states fill first, which is the converse of metals. Thus, both ions tend to be more tightly bound as coverage increases although the details are quite dissimilar. One conclusion is that the ions are immobile on the surface, which is surprising. Another conclusion which seems more likely is that lateral interactions account for the behavior as a function of coverage.

In the remaining range of dosages Na maintains the same type of trend, with major growth at 760°C and the appearance of another peak at 950°C (3.06 eV) which eventually becomes the major feature. The 620°C peak is seen to split into one at $\approx$ 600° and

700°C at the highest dose. K shows a continued growth and shift to higher T_P of the two major features and gradual growth of the shoulder at 525°C. Mass balance for both ions is drastically reduced at the highest dose levels.

In all cases studied only the first flash heating of the surface after a deposition was found to yield desorption peaks with subsequent scans (without an intervening deposition) showing no desorption peaks. From this behavior we conclude that the ions coming off are the ones that were deposited and no ion exchange is occurring at the surface. In the case of high dose runs with low mass balance, Auger analysis of the surface after the scan showed that appreciable levels of the species deposited remained on the surface. A more detailed Auger study should determine whether significant diffusion into the bulk is occurring or the deposited species are localized to the surface. It was also found that atoms remaining on the surface significantly affected subsequent runs by altering their spectral shape. Removal of the surface atoms by high temperature anneals returned the spectra to their original shape. This may indicate that some details in the spectra are due to ions interacting with neutrals or clusters of neutrals of the deposited species on the surface (lateral interactions).

Finally, curve h in Fig. 1 is a current due to a continuous bulk emission of Na (no ions were deposited before this scan). This current can be varied over many decades and when plotted on a log I *vs.* $1/T$ plot displays an activation energy of ≈ 2.9 eV.

One striking point is the large amount of charge that we are able to deposit on these surfaces. An ideal insulating surface of this size (≈ 0.03 cm^2) with microcoulombs of charge deposited on it would be charged to potentials $\gtrsim 1$ kV, yet we see no large surface charging. This suggests an enormous surface capacitance such as a Helmholtz layer which is a direct consequence of the high ionic conductivity of this material. The point is receiving further study. The possibility of electrons tunneling through such a layer to cause ion neutralization on the surface, leading to the reduced mass balance seen at high dose, would be another consequence of such an interaction.

Discussion and Conclusions

The results show that there are major differences between the interaction of Na^+ and K^+ with the β-alumina structure. In addition, the general features of ion interactions with these surfaces show major and fundamental differences with that seen for (say) molecules on metals. Both Na and K show a tendency for tighter binding with higher coverage, with the Na desorption appearing first order and that of K of more complex order in that there is a continual change in desorption peak temperatures with coverage. It should be noted that Li^+ and Ag^+ tend to behave like Na^+, while Cs^+ behaves more like K^+. K spectra maintain two major features throughout, while those of Na have five features in total throughout the range of coverage. The finding that the ions are immobile on the surface is puzzling, although lateral interactions seem a plausible explanation of the spectral dependence on coverage.

More important than the specific results for Na and K on this particular material is the fact that a method exists to study in detail the energetics of ion interactions with the "surfaces" of this type of material. When the term surface is used here it must be understood that this must include a considerable amount of what could be referred to as "internal surface." This is particularly true of the zeolite materials, which are extremely open structures with large channels. On the nominal a-c plane of β-alumina we expect a considerable density of steps which expose the basal plane, due to the tendency of these materials to cleave along the a-b plane. The relationship of the interactions with the surface studied here to those in the bulk is an important question, since no method exists to derive the bulk energetics. Walstedt and Remeika (10) also noted distinct differences in the bulk properties of Na^+ and K^+ in β-alumina as did Rees (11) in interdiffusion studies on Na/K zeolite. The bulk as well as the surface energetics are important when studying catalytic reactions involving the cations or the reactions that occur on the surfaces of these materials when they are part of an interface in an electrochemical cell.

While the preliminary results are promising, we feel that due to the complexity of the data the matter of interpretation should be approached cautiously. In the regime of very low dosages to the surface all features behave like classical first-order desorption and thus the simple interpretation given here would seem to suffice. In the region of higher dosages considerable complexity is introduced and more data is needed before the nature of the interaction can be unambiguously determined. The use of Auger spectroscopy and characteristic loss spectroscopy for precise determination of elemental as well as electronic make up of the surface, LEED for determination of surface structure and adsorbate registry, as well as quadrupole mass analysis of both ionic and neutral desorbed species are now being carried out to obtain a more well-defined picture of this complicated process.

In conclusion we have shown that flash desorption provides a "surface ion spectroscopy" for solid electrolyte materials. We expect that the information gained using this and other surface techniques will be of major importance in understanding the electrochemical and catalytic properties of these materials.

Acknowledgments

I gratefully acknowledge the support of R. J. Baughman who provided the single crystal Na-β-alumina used in this study. I also wish to acknowledge many helpful discussions with R. R. Rye and the help of R. A. Jaramillo with the experimental phase of this study. This work was supported by the U. S. Energy Research and Development Administration.

In Situ Thickness Monitoring of Silicon Epitaxial Layer

Katsuro Sugawara,* Takeo Yoshimi, Yukiyoshi Nakazawa, and Katsuhiko Itoh

Hitachi, Limited, Semiconductor and Integrated Circuits Division, Kodaira, Tokyo, Japan

For silicon devices with high performance and large scale integration, precise control of silicon epitaxial layers has been required. One of the control methods is an *in situ* monitoring. The development of in process film thickness monitoring is reviewed in Table I, together with mutual interconnections. In a previous paper (7), the thickness monitoring of thick polycrystalline silicon film was reported wherein an improved infrared radiation method was employed. However, uncertainties remained regarding precise control of the thickness of silicon epitaxial layers. A lack of reproducibility was observed in determining the difference between the deposition rate of polycrystalline films and epitaxial single crystal layers. To solve this problem a novel technique was devised. A silicon substrate, in which a thin "buried" insulating film was formed by ion implantation was used as a test sample and included in a deposition run with other substrates which had not been ion implanted. The thickness of the single crystal deposit on the ion implanted test sample was measured during growth using an optical interference method. Ion implantation of the test sample provides the difference in refractive index between the substrate and the deposit which is required for monitoring the thickness by the optical method. In this note, results using this technique are reported.

The experiment was carried out in the same horizontal epitaxial reactor that was used in a previous investigation (7). The growth temperature was 1220°C [corrected for emissivity according to Allen's data (9)]. The reactant gas ratio was $SiCl_4/H_2 = 0.005$ for this $SiCl_4$-H_2 system. The substrate was Czochralski grown, (111) oriented, and phosphorus doped with a resistivity of 5-10 ohm-cm. Nitrogen implantation of the substrate was performed with fluences of 1×10^{18} ion/cm^2 and by 170 keV energy at room temperature. Calculation of the nitrogen profile based on LSS theory (10) predicts a Gaussian distribution with a projected range $R_p = 0.46$ μm, and a range spread $\Delta R_p = 0.1$ μm. The peak of the nitrogen concentration was 4×10^{22}/cm^3. A Si_3N_4 film in the silicon substrate was formed after annealing 30 min at 1200°C in dry nitrogen. The epitaxial layer was grown on the "buried" nitride layer in the substrate (11) by the $SiCl_4$-H_2 reaction as shown in Fig. 1. During the epitaxial growth, infrared radiation emitted from the substrate was received by a PbS cell. All but the 2.0 μm wavelength radiation was excluded with a filter (12). The signal was amplified and recorded as interference waves on the recorder. Since the period of radiation can be related to the thickness of the epitaxial layer, the interference pattern can be used to monitor the thickness during the epitaxial growth.

Figure 2 is the result of monitoring when the epitaxial layer was deposited on the nitrogen-implanted silicon substrate. The abscissa reveals both reaction time and film thickness measured by the Talystep. One cycle of the interference wave was equivalent to approximately 0.28 μm in film thickness when the glancing angle of the photocell was 40°. In this figure, the solid line is an observed value and the broken line represents a calculated one using the following equation

$$T = 1 - \rho \quad [1]$$

where T is transmissivity and ρ is reflectivity. The reflectivity equation for the reflection in unpolarized light is

$$\rho = (|R_p|^2 + |R_s|^2)/2 \quad [2]$$

where R_p and R_s are reflective coefficients parallel and perpendicular to the plane of incidence in polarized light, respectively. The formula for three layers is (13)

$$R = \frac{r_{32} + r_{21}e^{-2i\delta_2} + r_{10}e^{-2i(\delta_1+\delta_2)} + r_{32}r_{21}r_{10}e^{-2i\delta_1}}{1 + r_{21}r_{10}e^{-2i\delta_1} + r_{32}r_{21}e^{-2i\delta_2} + r_{32}r_{10}e^{-2i(\delta_1+\delta_2)}} \quad [3]$$

where r_{ij} is the Fresnel reflection coefficient of the interface

$$\delta_1 = \frac{2\pi}{\lambda} n_1^* d_1 \cos\theta_1 \quad [4]$$

$$\delta_2 = \frac{2\pi}{\lambda} n_2^* d_2 \cos\theta_2 \quad [5]$$

$$n_1^* = n_1 - ik \quad [6]$$

$$k = \alpha\lambda/4\pi \quad [7]$$

where δ_i = phase retardation in wavelength λ on crossing the layer, n = refractive index, d_i = film thickness, θ_i = refractive angle in each layer, k = extinction coefficient, and α = absorption coefficient at 2.0 μm wavelength. The refractive index of silicon and the extinction coefficient were taken as 3.62 and 0.13, respectively. This refractive index of silicon was obtained from extrapolation to the growth temperature, 1200°C, using the value of n = 3.45 in 2.0 μm wavelength at room temperature (14) and the temperature dependence on the refractive index between 80° and 400°K (15). Improvement was observed in the maximum monitoring thickness, d_{max}, compared with the result of the polycrystalline silicon film (7). In the epitaxial case, d_{max} increased to approximately 3.9 μm. However, the effective d_{max} of the epitaxial layer was (3.9 − 0.3) μm = 3.6 μm because of the thin layer (0.3 μm thickness) of silicon on the Si_3N_4 layer implanted into silicon substrate. The calculated pattern approximately coincided with the experimental pattern. The crystallinity of the epitaxial layer was not as good as that of the layer grown onto the usual silicon substrate; stacking fault densities were $10^4 \sim 10^5/cm^2$ after a Sirtl etch. However, there was no problem in thickness monitoring because the implanted substrate was used only for the test sample.

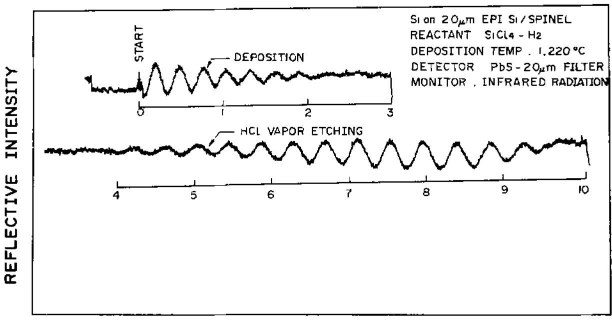

Fig. 3. Interference patterns when the silicon epitaxial layer and then HCl vapor etching were successively formed on the silicon-on-spinel substrate.

The above result was confirmed by the next experiment as shown in Fig. 3. The epitaxial growth and HCl vapor etching process were successively carried out on a silicon-on-spinel substrate; the spinel was (111) oriented and the epitaxial layer on the spinel was 2.0 μm in thickness. The maximum monitoring thickness, d_{max}, 3.9 μm (total thickness of the spinel-epitaxial and this epitaxial layers) proved to be the same for the layer grown on the spinel and the nitrogen-implanted silicon substrate. In this case, the effective d_{max} was (3.9 − 2.0) μm = 1.9 μm. Autodoping from the spinel substrate caused contamination of the silicon epitaxial layer near the spinel test sample (16). Therefore, the wholly or partially nitrogen-implanted substrate was better in realizing contamination-free epitaxial layers of good quality.

Results of the d_{max} are tabulated in Table II. With increase of the growth temperature, the d_{max} showed a tendency of increasing to a maximum and then decreasing for the polycrystalline silicon film (7). The same tendency might be expected for the epitaxial layer. Competition between increasing radiation intensity and increasing absorption coefficient of silicon (the latter becoming dominant at higher temperature) may bring about the tendency of increase-maximum-decrease with increase of the deposition temperature. The absorption coefficient at 1200°C may be estimated as 8×10^5 cm^{-1} from the observed interference pattern, while that at room temperature is 5×10^{-2} cm^{-1} (17).

Table II. Maximum monitoring thickness, d_{max}, when the single or polycrystalline silicon film was grown on the various substrates

Grown film		Silicon single crystal		Polycrystalline silicon	
Substrate		Nitrogen-implanted Si substrate	Epitaxial layer on spinel	Si_3N_4 film on Si substrate	Thermally grown SiO_2 film on Si substrate
Growth condition	Reactants	$SiCl_4$-H_2	$SiCl_4$-H_2	$SiCl_4$-H_2	$SiCl_4$-H_2
	Growth temp	1220°C	1220°C	1220°C	1220°C
Maximum monitoring thickness, d_{max}		Sub. (3.6 + 0.33) μm = 3.9 μm	Sub. (1.9 + 2.0 μm = 3.9 μm	2.9 μm* (3.0 μm)**	3.1 μm* (3.3 μm)**
Control accuracy		±0.03 μm	±0.03 μm	±0.03 μm?	±0.03 μm?
Remark		Crystallinity—no problem for monitoring	Autodoping → contamination	Difference from thickness of single crystal layer	

* Maximum monitoring thickness for the single crystal silicon film, calibrated by the correlation between thickness of the polycrystalline silicon film and that of the silicon epitaxial lay

** Maximum monitoring thickness for the polycrystalline silicon film.

By further developing the monitoring of the CVD film thickness, in process thickness monitoring of the silicon epitaxial layer was investigated in order to control the thickness precisely. Using the nitrogen-implanted silicon substrate as the test sample, thickness monitoring of the single crystal layer during epitaxial growth was carried out by the improved method. The silicon epitaxial layer, grown at 1220°C by the $SiCl_4$-H_2 reaction, was controlled within ± 0.03 μm up to 3.9 μm in thickness, when the filter of 2.0 μm was adapted to detect the infrared radiation emitted from the substrate. The maximum monitoring thickness may be limited by the large absorption coefficient in silicon material, which has a large temperature dependence. The competition between the radiation intensity and the absorption coefficient may bring about the d_{max} tendency of increase-maximum-decrease with increase of the growth temperature. The smaller absorption coefficient, approximately ½ in the single crystal layer compared with that in the polycrystalline silicon film, caused enhancement of the maximum monitoring thickness for the single crystal layer, approximately 30% larger than that for the polycrystalline silicon film.

Acknowledgments

The authors express their sincere gratitude to Mr. S. Nishida, Mr. M. Ono, and Dr. Y. Sugita for their valuable discussions and encouragement, to Dr. T. Tsuchimoto for helpful discussion of the ion implantation, and to Mr. Y. Sasaki for his help in the calculation.

Reaction of Anodized GaAs Surfaces in Hydrogen Atmospheres and Their Applications

R. M. Malbon*

Hughes Aircraft Company, Torrance Research Center, Torrance, California 90509

and J. M. Whelan*

Materials Science Department, University of Southern California, Los Angeles, California 90007

The growth of anodic oxides with well-controlled thicknesses from aqueous and nonaqueous solutions has been described (1-5). These oxides with thicknesses between ~200 and ~2500Å are soluble in dilute solutions of nonoxidizing mineral acids. Sequential anodization and oxide dissolution have been used to thin GaAs epitaxial films in a controlled manner (3). Composition of the anodic oxide has been reported to be an amorphous equimolar mixture of Ga_2O_3 and As_2O_3 with a variation in the mole ratio near the outside surface opposite to the GaAs-oxide interface (6). This paper is concerned with the consequences of heating anodized GaAs in hydrogen under various conditions and their application to ion implantation and epitaxial growth.

* Electrochemical Society Active Member.

Key words: oxide reduction, oxides of gallium, epitaxial growth.

Experimental

The GaAs used in this study was either low resistivity n^+ type Te-doped boat-grown substrate slices or epitaxial films grown on those substrates. Etch pit densities varied from 1000 to 3000 cm^{-2}. Orientation of the epitaxial film and substrate surfaces were 3° off the <100> toward the <111>. The substrate slices were chemically polished to remove ~75 μm after mechanical lapping so as to produce a mirrorlike damage-free surface. As-grown surfaces were used for those samples with epitaxial films. The anodizing solution consisted of deionized water acidified to a pH of 2.4 by adding a sufficient amount of a H_3AsO_4 solution. The anodic oxides were grown at room temperature to various thicknesses by adjusting the final voltages using a current-limited supply. Platinum foil served as

the cathode. The GaAs anodes were supported by titanium tweezers which had been previously anodized except for a small area about the tips. Care was taken to immerse the GaAs and its supporting tweezer tips in the anodizing solution before applying a bias. After immersion the bias was adjusted to give the desired anodic oxide film thickness as judged by color comparison with a previously prepared group of oxidized GaAs samples. The oxide thickness of these samples had been verified by etching a section of the oxide in aqueous HCl and measuring the oxide step height with a commercial stylus step-height analyzer. It is to be noted that the anodization procedure described above clearly delineated doping inhomogenities and local surface damage if present.

The anodized samples were annealed under a H_2 atmosphere using a quartz envelope/furnace assembly shown schematically in Fig. 1. The intended purpose was to provide a simple gas-flow pattern with a minimum linear gas velocity of 10 cm sec^{-1} at the annealing temperatures.

Inlet H_2 from a liquid H_2 source was preheated by passage through one leg of the horizontal U tube and passed over a small quartz boat containing solid GaAs and a liquid Ga solution saturated with As at the annealing temperature. This source was intended to provide a fraction of the As_4 pressure necessary for equilibrium. Samples to be annealed were mounted on a quartz support assembly attached to a fine quartz rod for easy positioning. The over-all assembly was intended to have a low heat capacity so that it would warm and cool quickly as a resistance furnace on rollers was positioned either for annealing or cooling/loading. Samples cooled typically from the annealing temperatures to 100°C in ~5 min. After loading, the chamber was flushed for a minimum of 1 hr so that the air+H_2O concentrations were under ~3 ppm. Based on prior experience, the H_2O concentration rises to ~10 ppm at the annealing temperatures due to outgassing of the quartz (7). Results of annealing are given below. For a typical sample, chemically polished and anodized to create 1400Å of oxide, the result of annealing for 15 min at 740°C in H_2 is the formation of a high density of small Ga droplets as indicated by Fig. 2. The droplets dissolved preferentially in aqueous HCl or in hot H_2 gas which would be expected for Ga. The resultant GaAs surfaces exposed and under the Ga droplets had height irregularities due to pitting of less than 1000Å. Densities of the droplets varied from a value of 3×10^8 cm^{-2} in the central 70-80% of the wafer area to near zero at the extreme somewhat rounded edges of the wafer. A feature to be noted is the relatively small spread in the droplet sizes. As indicated in Fig. 2, the average diameter at the interface is approximately 0.4 μm. Based on the estimated volume of an average droplet and their number per cm^2 of substrate surface, the volume of Ga in the droplets agrees within 20% of the volume expected if the only source of Ga were that resulting from the reduction of the oxide. This agreement is coincidental as is described below.

The sequence of changes upon annealing anodized GaAs surfaces in the H_2 atmospheres is as follows. Provided the temperature is high enough for the reduction of the oxide to yield Ga droplets, the droplets form quickly at densities possibly as high as 10^9-10^{10} cm^{-2}. The larger droplets initially grow at the expense of the smaller ones. With larger annealing times, the droplet density decreases eventually to zero. Rates for these changes increase with temperature. Figure 3 shows the results of annealing a GaAs surface with a 1000Å anodic oxide for 10 min in H_2 at 800°C. The droplet density is smaller, $\sim 7 \times 10^7$ cm^{-2}, but the spread in size is somewhat larger than for that shown in Fig. 2. Longer annealing causes the droplet density to decrease, in part, because of droplet migration and coalescence. Evidence for this is shown in Fig. 4. This sample is identical to that represented by Fig. 3 except that the annealing time at 800°C was 20 min. The smoothed droplet traces or rivulets have moved from left to right. Further evidence for the rivulets was apparent in optical photomicrographs at 700X. The tracks are roughly parallel but do not follow straight-line courses. The consequence of annealing a very thin GaAs anodic film ~200Å for 20 min in H_2 is shown in Fig. 5. The average interfacial droplet diameter is ~0.2 μm and the density is $\sim 3 \times 10^8$ cm^{-2}. Gallium in the droplets is approximately half that in the original oxide. Both the exposed and GaAs droplet-covered surfaces were smoother than that shown in Fig. 4 which was treated identically except that the original oxide was five times thicker.

Control samples of GaAs with chemically polished surfaces did not show the characteristic droplet forma-

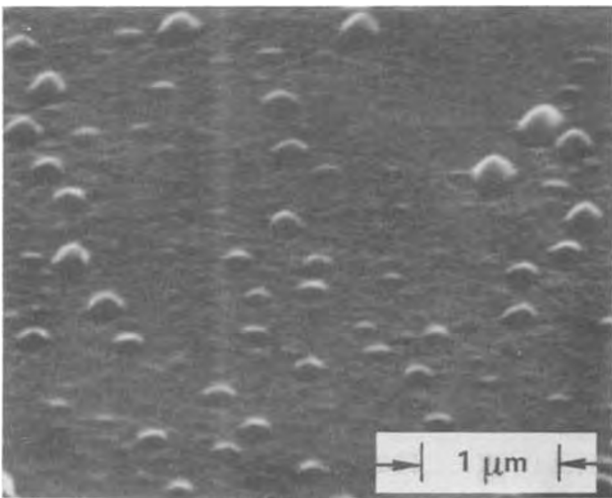

Fig. 5. SEM photograph of an anodized GaAs surface after a 20 min anneal in H_2 at 800°C. The anodic oxide thickness was 200Å. Original magnification 18,000X.

tion upon annealing as did those with anodic oxides. The resultant surfaces were, by comparison, featureless except in areas of strain at the edges or near an incompletely removed scratch. As an example, large Ga droplets formed along the original sawed edges of the wafers. This also illustrates the point that arsenic is lost much more rapidly from a saturated Ga solution than from a strain-free GaAs surface.

These results and supporting ones may be summarized as follows. The droplet size resulting from short anneals increases with the thicknesses of the original anodic oxides. Surface textures of the GaAs surfaces indicate that the densities of droplets may reach values substantially in excess of the highest noted, 5×10^8 cm^{-2}. The initial source of these is the reduction of the Ga species in the oxide which at the reduction temperature must have a gallium-to-arsenic ratio substantially greater than unity. Subsequent to this, the GaAs contributes as an additional source of Ga. As the annealing period is increased, the droplets show signs of migration and eventually they disappear. The latter point requires an eventual loss of Ga to the vapor phase at a greater rate than that for As. Times required for these characteristic changes decrease with increasing annealing temperatures. These features are discussed in the following section in terms of the preliminary loss of As from the anodic oxide, the reduction of the residue to Ga, its dissolution of GaAs, and eventual removal by reaction with H_2O which is present as an impurity in the H_2.

Discussion

The observations described in the previous section are in accord with the conclusions of Feldman *et al.* (6) regarding the basic composition of the anodic oxide, namely, equimolar amounts of As_2O_3 and Ga_2O_3. Arsenic oxide is more volatile than Ga_2O_3 and is less stable with respect to reduction by a hydrogen atmosphere buffered with a given amount of water. It is reasonable to assume the selective loss of arsenic from the anodic oxide by these means upon heating in hydrogen at 700°-800°C and as summarized by the following reactions

$$As_2O_3\ (\text{anodic oxide}) \rightarrow As_2O_3(g) \qquad [1]$$

$$2As_2O_3\ (\text{anodic oxide}) + 6H_2(g) \rightarrow As_4(g) + 6H_2O(g) \qquad [2]$$

The involvement of Eq. [1] has been previously postulated by Feldman *et al.* upon heating anodic films in oxidizing atmospheres up to 650°C. Evidence has been summarized to the extensive but incomplete loss of As_2O_3 from the anodic films upon heating in oxidizing atmospheres to >700°C and for the formation of β-$Ga_2O_3(s)$ and $GaAsO_4(s)$ on the GaAs surface (6). This contrasts with heating in a hydrogen atmosphere. Upon heating a GaAs anodic oxide film in a hydrogen stream, a temperature is reached at which the hydrogen is sufficiently reducing to reduce Ga_2O_3 in the residue of the original film. Possible reactions are represented by Eq. [3] and [4]

$$Ga_2O_3\ (\text{anodic film}) + 3H_2(g) \rightarrow 2Ga(l) + 3H_2O(g) \qquad [3]$$

$$Ga_2O_3\ (\text{anodic film}) + 2H_2(g) \rightarrow Ga_2O(g) + 2H_2O(g) \qquad [4]$$

From a thermodynamic point of view one would expect [3] to prevail as the temperature rises towards 700°C (8-10). The existence of Ga droplets after short heating times indeed suggests that [3] dominates. This liquid droplet formation triggers another concurrent set of reactions. These are represented by Eq. [5], the dissolution of GaAs in the Ga to form a saturated solution and Eq. [6], the evaporation of arsenic from the saturated solution

$$GaAs(s) = Ga(l) + As(l) \qquad [5]$$

$$GaAs(s) = Ga(l) + \tfrac{1}{4}As_4(g) \qquad [6]$$

The effect of Eq. [5] and [6] is to increase the amount of Ga in the saturated liquid phase as the arsenic evaporates. The rate of As evaporation is much faster from the liquid solution than from a solid GaAs surface. Since the vapor pressure of arsenic over the saturated solution and thus the evaporation rate both decrease as the drop size increases, it is to be expected that the drop size distribution will tend to cluster about a given value depending on temperature, flow rate, and the purity of the hydrogen. The mean droplet diameter will also be influenced by the anodic oxide thickness since the drops are initially formed by the reduction of the Ga_2O_3. For short heating times in very high purity H_2, the amount of arsenic lost from the GaAs surface is relatively small via dissolution in an evaporation from the liquid phase. Evidence that this is significant for longer heating times is shown by the rivulet path of a migrating droplet as can be seen in Fig. 4. The track of the droplet should depend on relative dissolution rates of GaAs along differing crystallographic directions and the gas-flow patterns.

As indicated in Fig. 2 and 5, the relative drop densities were nearly the same, $\sim 3 \times 10^8$ cm^{-2}, but the mean drop size was somewhat larger for the sample with the thicker oxide. Detailed conclusions regarding relative drop sizes must be tempered by the disappearance of drops upon longer heating or at higher temperatures. Comparison of Fig. 2 with Fig. 3 illustrates this trend.

As the time of annealing in H_2 is increased, the droplet density decreases and the size initially grows and then decreases. In sufficient time the drops disappear. This behavior is attributed to the reaction of water as an impurity in the H_2 with Ga in the saturated liquid phase with GaAs. Although the chemical potentials of Ga in the liquid phase and in the solid GaAs are identical, the rate of reaction with water is faster at the liquid phase interface. In summary, reaction [7] proceeds faster than [8] until the liquid solution is exhausted. Reaction [8] then becomes the significant one for further surface errosion

$$2Ga\ (\text{saturated liquid solution}) + H_2O(g) \rightarrow H_2(g) + Ga_2O(g) \quad [7]$$

$$2GaAs(s) + H_2O(g) \rightarrow H_2(g) + Ga_2O(g) + \tfrac{1}{2}As_4(g) \quad [8]$$

It is implied that the consumption of Ga in [7] is accompanied by the vaporization of As from the solution or its precipitation as GaAs so that the liquid solution is saturated until exhausted.

Applications

Epitaxial growth.—We have noted a consistent pattern of smoother films grown on GaAs substrates which were first anodized after chemical polishing relative to ones without chemical polishing. Furthermore, the anodized ones require a minimum of precleaning before insertion in the epitaxy reactor. These are stored in polyethylene bags and simply blown off with N_2 gas. Anodization was done immediately after chemical polishing and water rinsing. Optimum oxide thicknesses are within the range, 400-600Å. The CVD epitaxy system is based on a $H_2/AsCl_3$ gaseous source which is first passed over a boat containing a Ga solution which has an encrusted surface of GaAs. The pregrowth treatment of the substrates in this process is to flush them in a pure purging H_2 gas stream while the necessary operating temperatures are being established and the separate $H_2/AsCl_3$ stream is adjusted for normal growth. During the warm-up stage, the anodic oxide on substrates is reduced and leaves a Ga residue as droplets saturated with GaAs. These droplets serve several useful functions. First, etching of the substrates due to traces of H_2O in the backflushing H_2 is circumvented since the H_2O reacts preferentially with the liquid droplets. Secondly, the high density ($\sim 5 \times 10^8$ cm^{-2}) of freshly etched regions on the substrate near the Ga droplets is expected to be excellent nucleation sites. Finally, the reaction of Ga droplets with HCl favors the rapid equilibration of H_2, HCl, As_4, and GaCl in the gas phase with the substrate. The rate of equilibration is enhanced because of the faster gas-liquid interface reaction than the corresponding gas-solid GaAs reaction. (Note that the chemical potential of Ga is the same in the substrate as it is in the saturated Ga solution.)

High temperature encapsulant.—Schwartz *et al.* have noted the satisfactory use of anodic oxides in weakly oxidizing atmospheres as diffusion masks (2). The oxides are currently under evaluation as surface protecting films for post-ion implantation annealing at temperatures between 700°-900°C under slightly oxidizing atmospheres. After heating, the oxides are frequently difficult to dissolve in mineral acids.

They can be reduced and removed during the last few minutes of the annealing period by replacing the slightly oxidizing atmosphere (N_2) with a reducing one such as H_2. The residual Ga droplets can be readily removed with aqueous HCl or by dissolution in Hg. They can be also vapor etched by adjusting the H_2O/H_2 ratio in the inlet H_2 stream and thus be removed *in situ* at the end of the anneal.

Summary

It has been shown that anodic and thermally grown native oxides on GaAs can be reduced by annealing in H_2 atmospheres to yield GaAs surfaces with upwards of 10^8 Ga droplets cm^{-2}. These droplets tend to grow in size with decreased densities upon continued annealing in high purity H_2 and are preferentially removed from the GaAs surface by reaction with traces of H_2O in the H_2.

Chemically polished GaAs substrates with anodic oxides 400-600Å thick are superior to those without the oxide for the growth of thin epitaxial films from the vapor phase using a H_2-$AsCl_3$-Ga system. Advantages are attributed to (*i*) easier cleaning of the anodic oxide surfaces, (*ii*) the high density of nucleation sites generated by the preliminary reduction of the oxide, and (*iii*) the enhanced rate of initial equilibration of the growth atmosphere with the substrate through the rapid reaction of the liquid droplets with the vapor.

Anodic and thermally grown oxides on GaAs used as encapsulants during annealing in oxidizing atmosphere can be removed by annealing in H_2 to form droplets or removed *in situ* by annealing in H_2 containing a controlled amount of H_2O.

Brief Communications

A Study of the Phosphorus Gettering of Gold in Silicon by Use of Neutron Activation Analysis

S. P. Murarka*

Bell Laboratories, Murray Hill, New Jersey 07974

Gold is probably the most important impurity acting as a very effective recombination center in both n- and p-type silicon (1-3). Keeping the concentration of gold (and that of other similar impurities) to a minimum is a must for those devices where high minority carrier lifetime is desirable. The reduction in the concentration of such impurities is routinely achieved by introducing a so-called gettering step (4-13) [phosphorus diffusion (1-3, 5, 10-13), mechanical damage (4, 6, 7), or implantation damage (8-10), all on the back surface of the wafers] in the processing sequence. As a result of this treatment, impurities like gold, which have fast diffusivities in silicon, diffuse toward and become trapped in the back surface of the wafer. This phenomenon of trapping impurities in the region away from the active regions of the devices has been called impurity gettering.

A variety of techniques (1-10) has been used to investigate the phenomenon of impurity gettering induced by phosphorus diffusion or mechanical or ion implantation damage. In these investigations the semiconductor was first equilibrated with an external source of impurity (so as to increase the concentration). Subsequently, the gettering was carried out and the bulk and the surface of the semiconductor were analyzed for the impurity content. To the best of the author's knowledge, no attempt other than the diode studies of Meek and Gibbon (5) has been made to study the gettering in as-received silicon wafers where the concentration of the impurities is relatively low. We have used neutron-activation analysis to study the effectiveness of gettering in as-received silicon wafers. Neutron activation analysis provides a very sensitive and generally specific method of analysis. Coupled with autoradiography, this technique offers a very powerful analytical means by which to learn the nature of impurities, and their concentration and spatial distribution in a given material. For the detection of impurities in silicon, this method (14-18) is ideal because of the very low thermal neutron capture cross section of ^{30}Si and the short half-life of the radioactive product ^{31}Si. In the present work neutron activation analysis was used to determine the concentration of gold in silicon wafers before and after phosphorus gettering. It may be mentioned that Tasch *et al.* (19) did use neutron activation analysis to look for the gettering of impurities on slip lines, but found that the impurity concentrations were below detection limit.

For each experiment at least two wafers from each crystal were used. To avoid any significant differences arising due to uneven distribution of impurities along the length of the boule, wafers cut adjacent to each other were selected. The slices were degreased, cleaned, and weighed. The degreasing and cleaning were done in accordance with the standard cleaning process used in semiconductor device development. Immediately thereafter, one of the slices was given the standard phosphorus gettering treatment, *i.e.*, 30 min in PBr_3 at 1000°C with 1% O_2-99% N_2 as the carrier gas. The slices were then individually placed in specially made and cleaned high purity quartz petri dishes with covers. The covered dishes were then wrapped in aluminum foil and placed in an aluminum container. Irradiations were carried out with thermal neutrons at fluxes $\approx 1 \times 10^{13}$ cm^{-2} sec^{-1} for a time period of 5 hr. In a few cases small pieces cut off the silicon slices were used instead of the whole wafers. Such pieces received identical cleaning treatment and were sealed in clean quartz tubes under vacuum ($\sim 10^{-3}$ Torr). Since the primary interest of this investigation was to determine the concentration of gold in silicon slices, no chemical separation was done prior to counting of the γ-ray activity. The counting of the samples was purposely delayed to let the ^{31}Si activity (half-life 2.6 hr) decay out so that it made a negligible contribution to the γ-spectrum. The counting was thus done about 40 hr after the irradiation. The samples were counted (in a fixed-reproducible geometry) with a Ge(Li) detector attached to a 1024 multichannel analyzer and data printed on a Teletype. The complete detection and counting assembly was calibrated[1] by use of a National Bureau of Standards source of γ-rays of energies varying from 0.0877 MeV of Cd^{109} to 1.836 MeV of Y^{88}. Attempts were made to identify only the 0.412 MeV peak of Au^{198} (half-life 64.7 hr) and in arsenic-doped crystals the 0.56, 0.66, and 1.22 MeV peaks of As^{76}. As^{76} energies served as the internal standards, since the doping levels of these wafers were known from the electrical measurements. In all cases, calculated concentrations of arsenic compared very well with those obtained by electrical measurements.

The following routine was followed to demonstrate that due to phosphorus gettering of the silicon wafers gold atoms had diffused away from the bulk and were trapped in the phosphorus-rich silicon near the surface. (*i*) Each of the irradiated samples was ultrasonically

[1] In another standardization, a solution contained a known amount of Au as a blank and activity thus produced was used to calibrate the counter.

Table I. Effect of phosphorus gettering on the gold concentration in silicon

Sample number	Gold concentration, cm^{-3} Ungettered wafer	Gettered wafer: After P-glass etched off	Gettered wafer: After surface Si layer (~2-4 μm) etched off
1	2.9×10^{13}	2.0×10^{13}	1.2×10^{12}
2	0.9×10^{14}	2.1×10^{14}	3.0×10^{12}
3	1.2×10^{14}	2.2×10^{14}	6.1×10^{12}
4	1.4×10^{14}	6.6×10^{14}	10.7×10^{12}
5	3.2×10^{13}	5.7×10^{13}	5.3×10^{11}
6	2.5×10^{13}	3.6×10^{13}	1.0×10^{12}
7	0.9×10^{14}	2.6×10^{14}	4.2×10^{12}
8	$0.4\text{-}4 \times 10^{12}$**	1.3×10^{12}	BDL*
9	0.9×10^{12}	1.0×10^{12}	BDL*
10	0.6×10^{12}	1.0×10^{12}	BDL*

* BDL = Below detection limit for given irradiation conditions.
** Sample broken.

cleaned in water and in methanol, dried, and counted. (*ii*) After this first counting, each sample was placed in agitated buffered hydrofluoric acid solution for 2 min to remove any oxide or glass layer on the surface, then washed, dried, and counted. (*iii*) The wafer was then etched to remove approximately 1 μm of silicon from the surface. The etchant was diluted Sirtl etch which consisted of a 1:1 mixture of CrO_3 [50 weight per cent (w/o) in water] and HF (49%) diluted with equal volume of water. A third counting was carried out. (*iv*) The sequence of etching and counting was repeated until the count rate of the gold activity per unit mass of silicon did not show any appreciable change. It was found that for the gettered wafers the count rate per unit mass did not show any appreciable change after about 2 μm of silicon had been etched off the surfaces. For the nongettered wafers, the count rate per unit mass was constant.

The amount of gold in the phosphorus glass which was formed on the surface of silicon during phosphorus diffusion and which was etched off in buffered hydrofluoric acid after first counting was determined (*i*) by counting the etchant solution containing etched-off glass and (*ii*) from the difference in the gold count rates between first and second countings. But for one exception where the sample was apparently contaminated during the etching sequence, the amount of gold in phosphorus glass was found to be negligible compared to the total in the silicon wafers.

Table I lists the results of this investigation. All concentrations are estimated to be within a factor of two of the true values. Figure 1 shows a plot of the residual gold concentration in the gettered silicon wafers from the surface of which the phosphorus-diffused region of ~2 μm has been etched off *vs.* the gold concentration in the ungettered ones. It is apparent that the gettering has resulted in an average reduction of the concentration by a factor of 50. Most of the gold initially present was trapped in the approximately 2 μm thick phosphorus-rich region near the surface and was etched off when this layer was removed. It may be mentioned here that no significant amount of gold was detected in the phosphorus glass which demonstrates that the phosphorus glass did not getter gold. Although Lambert and Reese (3) did report the presence of Au in glass, results similar to those reported here were obtained by several workers (4, 10, 20) who have investigated the phosphorus diffusion gettering in intentionally doped silicon wafers or in fabricated devices.

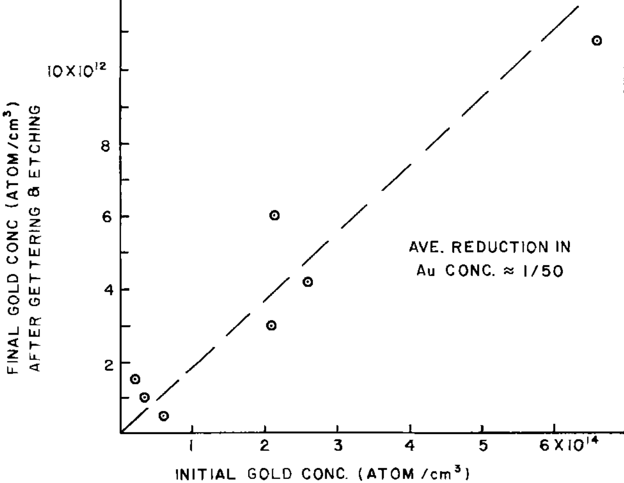

Fig. 1. Effect of phosphorus gettering on the gold concentration in silicon wafers.

A careful examination of the total gold concentration (Table I) in both gettered, but unetched, and ungettered samples shows that the gold concentration was higher in almost all gettered wafers, although after removal of 2 μm of silicon by etching the concentration goes down considerably. It has been observed (3, 21-24) that during high temperature anneals the impurities from the surroundings diffuse into the semiconductor material. The observed higher amounts of gold on gettered but unetched samples may have thus resulted due to external contamination during the 1000°C/PBr_3 treatment. The possibility of any appreciable gold contamination due to irradiation of samples in quartz containers (22) is ruled out since all samples, gettered or ungettered, were irradiated in identical quartz containers. It may be emphasized that this increase $\left(\text{by a factor of } 2\,{}^{+3}_{-2.6}\right)$ in the amount of gold due to external contamination during PBr_3 treatment is relatively insignificant and of secondary importance since the phosphorus gettering has been very effective in leading to a reduction of gold concentration by a factor of $20\,{}^{+40}_{-6}$ (Table I).

Recently, Seidel and Meek (10, 25, 26) have proposed that the gettering mechanism for phosphorus diffusion is solubility enhancement and ion pairing (26) of the substitutional metal ion (acceptor). At lower gold concentrations, such as those in our silicon wafers, essentially all gold could be expected to be paired with phosphorus in the phosphorus-rich ($\sim 10^{20}\text{-}10^{21}$ cm^{-3}) silicon surface, resulting in very effective gettering of gold. The good gettering observed in the present case (Fig. 1) thus very well supports the enhanced solibility mechanism.

Effect of Heat-Treatment of GaAs Encapsulated by SiO_2

B. Molnar*

Naval Research Laboratory, Washington, D. C. 20375

There is considerable interest in the ion-implantation doping of GaAs, especially in its application to device structures which require submicron-thick doped layers. For most of the applications of ion implantation, it is necessary to heat-treat GaAs at about 800°C in order to remove the irradiation damage (1) and to increase the electrical activity of the implanted ions (2). However, GaAs begins to undergo significant dissociation (3) at temperatures $\geqq$ 600°C. In addition, there is evidence (4) that implanted GaAs begins to dissociate at an even lower temperature $<$500°C. In order to prevent the dissociation, coating materials such as SiO_2, Si_3N_4, or AlN have been applied prior to high temperature annealing. However, Ga is relatively fast diffusing in SiO_2 (5), and it has been shown with backscattering measurements (6) that Ga accumulates at the surface of SiO_2 or Si_3N_4 layers on GaAs substrate following anneals at 700°-800°C. The loss of As or Ga from the surface of GaAs can give rise to large changes in the electrical properties. The affected surface layer may considerably influence the electrical properties of the implanted thin layers.

The purpose of this communication is to report the results of the investigation on the protective quality of rf-sputtered SiO_2 thin films. In order to avoid the complication of implanted layers, the protective quality of SiO_2 on unimplanted GaAs substrates was investigated. The protective quality of the SiO_2 was measured by its ability to maintain the background doping concentration.

The GaAs substrates used were Te doped, n-type with an electron concentration of $2 \times 10^{17}/cm^3$. Prior to loading in the sputtering system, the substrates were etched. An oxide film of about 2000Å thick was deposited on room temperature GaAs substrates by rf sputtering of a SiO_2 target. Etching rates, which indicate the quality of the films, were about 15 Å/sec in P etch. The encapsulated GaAs samples were sealed in a high purity ampul in order to avoid Cu contamination. Vacuum heat-treatment was performed between 500° and 900°C, and after the anneal the ampuls were quickly cooled to room temperature. After heat-treatment, the back side of the samples was etched, and the oxide was removed by HF. For electrical evaluation the back side was provided with a Sn-Au spot-welded ohmic contact. Schottky barrier metal contacts were sputtered Au delineated by the standard photolithographic technique.

The carrier concentration *vs.* depth data obtained by using the Schottky barrier technique while successively etching away thin layers are shown in Fig. 1. Before annealing the distribution of carriers was uniform, at the $2 \times 10^{17}/cm^3$ level. After heat-treating the GaAs at 800°C for 1 hr, the electron concentration decreased rapidly to around a few times $10^{15}/cm^3$ below the surface and then increased to the background doping level at a depth of approximately 1μ. After a 900°C anneal treatment the carrier concentration distribution moved deeper into the sample. The experimental carrier concentration could be regarded as the Te compensation by indiffusing acceptors. The indiffusing acceptors are represented by a complementary error function distribution. The experimental data are, therefore, the superposition of the n-type back-

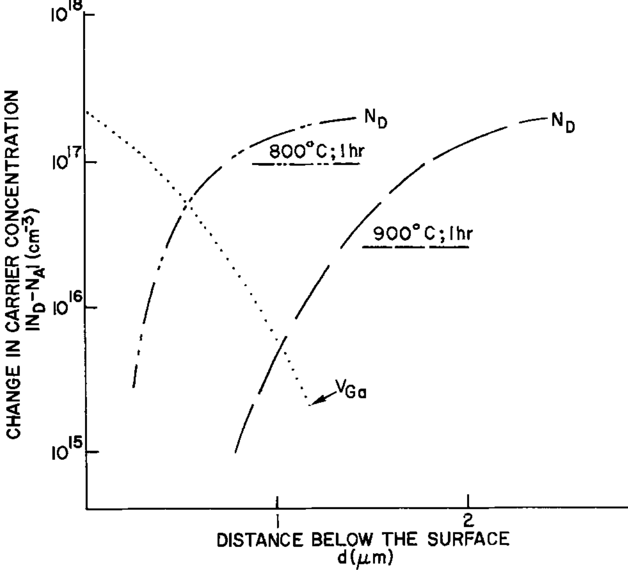

Fig. 1. Change in carrier concentration as a function of depth. Before annealing the distribution is uniform at $2 \times 10^{17}/cm^3$. The distribution of gallium vacancies (V_{Ga}) after 1 hr annealing at 800°C is also indicated.

Key words: annealing, GaAs, silicon dioxide, electrical activity, gallium vacancy.

ground doping and a p-type complementary error function distribution. From the appropriate complementary error function, a diffusion coefficient of about 3×10^{-13} cm²/sec at 800°C was deduced. By considering the possible out- and in-diffusing species, *i.e.*, Si, O, Te, Ga, and As, it has been found that only Ga vacancies (7) are p-type, have diffusion coefficients in the neighborhood of the deduced one, and an adequate equilibrium concentration for the proposed in-diffusing species. A similar conclusion was reached by S. Y. Chiang and G. L. Person by examining heat-treated, but unencapsulated GaAs (7). In conclusion, it has been found that heat-treatment produces significant changes in the surface carrier concentration on the SiO_2 encapsulated GaAs. Furthermore, the results of this experiment present strong evidence that the acceptors formed by the heat-treatment of SiO_2 encapsulated GaAs are due to Ga vacancies.

We are presently carrying out similar type investigation of Si_3N_4 and AlN films deposited by different methods.

A New Aqueous Solution for the Anodic Oxidation of GaAs

D. Law and C. A. Lee*

Department of Electrical Engineering, Cornell University, Ithaca, New York 14850

A number of reports have recently appeared (1, 2) concerning the anodic oxidation of GaAs which utilize nonaqueous solvents. These solutions purport to give higher quality oxide films, in terms of density and resistivity, than previously proposed aqueous solutions (3, 4). The deficiencies of these aqueous solutions variously involved dissolution of the oxide during growth, stability of the solution against impurities, and a tendency to produce a porous oxide of relatively low resistivity and dielectric strength.

In this communication we present a new aqueous solution for the anodic oxidation of GaAs which produces films of equal quality compared to those produced by solutions containing nonaqueous solvents and which is advantageous in a number of other respects (5). This new solution utilizes a common salt that is quite inexpensive compared to solutions containing ethylene glycol, or N-methylacetamide, and is quite safe to handle as opposed to solutions of 30% hydrogen peroxide. Moreover, this new aqueous solution is more versatile in that it has been found to produce high quality anodic oxide films on silicon (6), indium antimonide, and indium phosphide (7). A particular advantage of this new solution applied to silicon is that the anodic oxide films can be made virtually free of alkali ions by treating the solution with ion exchange resins. An assessment of the inversion layers produced by such a treated solution was made by measuring the photoresponse adjacent to a metallurgical junction with a fine light probe. No inversion layers were observed by this light probe technique even for resistivities of a couple of thousand ohm-cm. More conventional steam-grown oxides were limited to resistivities of less than 100 ohm-cm in this context.

The basic electrolyte is a 0.1M solution of dibasic ammonium phosphate in distilled water. Although this solution may be used directly for silicon, InSb, or InP, the pH of the solution is adjusted to a value of 4 by the addition of phosphoric acid when used with GaAs to prevent dissolution of the oxide film. In a neutral solution, 3600Å of oxide was observed to dissolve in approximately 25 min, whereas there was no detectable dissolution in a buffered solution (pH≈4) for periods up to one day.

The experimental arrangement for preparing the films described below was to immerse an appropriately masked sample into a beaker of the solution and record the breakdown voltage of the film as a function of the time for a specified current. The masking technique employed was to anodize a polished sample of GaAs and mask it with Apiezon wax leaving a window of known area. The window and a contacting area were then cleared of oxide with hydrochloric acid prior to anodizing the area in the window. The GaAs wafers used in these experiments were of heavily doped n-type substrate material. The anodization was carried out with the sample illuminated by a microscope lamp which served to reduce the contact potentials, but was otherwise not deemed necessary to obtaining good anodic films.

The first films were formed in an unbuffered solution (pH≃7) and the cell voltage *vs.* time for several current densities is shown in Fig. 1. Note that for the lowest current density the cell voltage does not increase linearly with time, indicating a slight dissolution of the oxide.

Buffering the solution to a pH of 4 with phosphoric acid reduces the solubility of the film to a completely negligible value. The cell voltage *vs.* time for this buffered solution, as shown in Fig. 1 for 0.3 mA/cm², is quite linear down to the lowest measured current densities (~20 μA/cm²). Figure 2 shows that the rate at which the oxide film is formed is linearly proportional to the current density and is, in addition, quite reproducible.

Hydrochloric acid was intentionally added to the buffered solution without readjustment of the pH and the stability of the oxide growth process was studied. Uniform oxide films could be grown in a solution with HCl contamination up to 1×10^{-3} *N*. Further addition of HCl will slowly change the process to etching. As

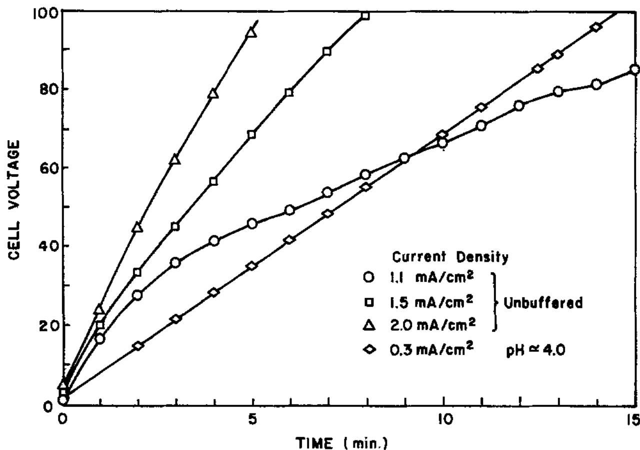

Fig. 1. Cell voltage *vs.* time as a function of current density for buffered and unbuffered solutions.

compared with the aqueous H_2O_2 solution (3), which was sensitive to a few ppm contamination, this solution is much more stable.

Interference microscope measurements of film thicknesses formed at 60 and 90V agreed within experimental error with published data (1, 3, 8). The breakdown field in these oxide films was observed to be at least 5×10^6 V/cm, which is equal in dielectric strength and compactness to that obtained with the best of the other anodizing solutions. Uniform films could be grown to a maximum thickness of 3600Å (180V). Beyond 3600Å, however, the film became uneven in color. Somewhat thicker films could be grown in a boiling solution (4), but again uniformity of the film was a problem. A preliminary estimate of the surface-state density obtained from MOS capacitance indicates a density between 10^{11} and $10^{12}/cm^2$ for unannealed films.

Anodic Behavior of Lithium in Aqueous Electrolytes

I. Transient Passivation

E. L. Littauer* and K. C. Tsai*

Lockheed Missiles and Space Company, Incorporated,
Lockheed Palo Alto Research Laboratories, Palo Alto, California 94304

ABSTRACT

Lithium manifests a transient passivation when it is anodically polarized to ~ −2.66 NHE in LiOH electrolytes. The duration of the passivation ranges from seconds to hours. The occurrence of the passivation is independent of electrolyte concentration, flow velocity, anode-cathode contact pressure, and of the polarization technique used. The duration of the transient is proportional to electrolyte concentration, the more dilute the solution the shorter the time. The passivation is believed due to the formation of an insulating, but unstable aggregate of Li_2O which nucleates at active Li sites at the base of the pores in the protective LiOH film. The recovery of the surface to the active state is due to the conversion of the Li_2O to LiOH in the presence of water at the Li surface.

The recent discovery of ways to electrochemically harness the lithium-water reaction (1) has prompted basic studies of the electrochemical reactions of lithium in aqueous electrolytes. Attempts to minimize polarization effects and to attain high current efficiency have been the subject of an ongoing program. Electrochemical characteristics of the lithium-water cell have been treated in a recent paper (2).

The chemistry of the lithium-water reaction is relatively simple, but the electrochemistry of the system is complex because (*i*) the reaction rate between lithium and water is very fast and the major portion of the lithium electrode is always covered with thick oxide films

$$Li + H_2O \rightleftarrows LiOH + 1/2\, H_2 \quad [1]$$

and (*ii*) the hydrogen evolution at the metal surface always creates pores within the film and this in turn complicates the electrochemical reaction

$$Li + X^- \rightleftarrows LiX + e^- \quad [2]$$

where X^- = anions in the aqueous electrolyte. These simultaneous processes result in a porous electrode comprising randomly formed and moving pores with active reaction sites existing only at the extremity of the pores at the metal-film interface.

The anodic oxide film is of such a form that it permits the inert cathode structure to be pressed against it without shorting. The oxide film acts, in principle, as a battery separator and serves as a conducting medium for the mass transport of ionic species to and from the anode surface. Through control of the anode-cathode applied pressure, exceptionally reproducible anodic polarization curves can be obtained.

In the lithium-water system, the rate-limiting process is the oxidation of lithium rather than the reduction of water at the cathode. It has been found that under anodic polarization, within certain ranges of hydroxyl ion concentration and electrolyte flow, two types of passivation are manifested. First, transient passivation is observed at a specific electrode potential. As is described in this paper, it is apparently related to the formation of an intermediate oxide. Second, actual mechanical passivation occurs and is presented in Part II of this subject title. Part III deals with the influence of electrolyte flow velocity on the surface coverage of the lithium anode.

Experimental

A general setup of the electrochemical cell is shown in Fig. 1. It was designed with the following requirements: rapid assembly, minimum electrical contact resistance between anode holder and the lithium anode, precise control of anode-cathode contact pressures, a

wide range of flow rates, and a sealed construction to prevent electrolyte and hydrogen loss.

Figure 2 gives an exploded view of this 11.4 cm^2 (projected electrode area) test cell constructed from Plexiglas and equipped with a fixed cathode and a movable anode.

The anode holder comprised a 0.64 cm diam pushrod, for pressure transference, with an 11.4 cm^2 steel disk affixed. The disk was studded with a large number of steel needles onto which the lithium anode was pressure-bonded.

The lithium anode (99.9% purity) elements were obtained from Foote Mineral Company. Samples were precast into disks 39 mm in diam and 12.7 mm thick. The disks were stored in an argon atmosphere thus eliminating cleaning prior to being pressure-bonded onto the anode holder. The side and back of the assembled anode were insulated with Miccroflex stop-off lacquer. The electrode was cleaned with methyl ethyl ketone (MEK) and methanol until a bright shiny surface was obtained.

The inert cathode matrix was composed of a wire screen spot-welded to a ribbed iron back plate. This cathode matrix serves at least four functions: (*i*) it acts as the counterelectrode during the anodic dissolution of lithium, (*ii*) it provides the reaction path for the mass transport of ionic species to and from the active anode surface, (*iii*) it serves as a means to control the anodic film thickness because it is actually pressed against the anode, and (*iv*) it provides a flow path for electrolyte between the ribs in the interelectrode cavity. A circular, rather than a square or rectangular, electrode was used throughout the experiments simply because (*i*) it was easier to assemble and disassemble, and (*ii*) it permitted more uniform control of anode-cathode contact pressure. The possible uneven distribution of electrolyte with the flow channels was compensated by positioning the inlet electrolyte nozzle right at the bottom of the middle portion of the cathode matrix. Due to high electrolyte flow rate coupled with short flow distance, the electrolyte concentration gradient along the flow path was minimal. Based on the geometry of the cathode matrix, the Reynolds number was calculated to be from 45 to 270 for the flow velocities, *i.e.* 6-36 $cm\text{-}sec^{-1}$, used in this study. It is expected that the hydrogen gas bubble evolution at the electrode surfaces will alter the values somewhat but is believed that laminar flow maintained in all the experiments.

Anode-cathode contact pressure was precisely controlled by an air pressure cylinder linked to the anode pushrod by an insulator. Elimination of the hydraulic pressure component was accomplished by a thrust balance cylinder connected to the inlet and outlet lines of the cell. This cylinder has a piston attached to the air piston, thus negating the hydraulic piston effect on the anode. Electrolyte hydraulic pressure could be varied by a control valve on top of the test cell.

Lithium hydroxide electrolytes were prepared using reagent grade chemicals and deionized water. The electrolyte was thoroughly mixed for several hours. A small portion was introduced into the reservoir, thoroughly circulated throughout the system, and then dumped. The remaining electrolyte was introduced into the reservoir and circulated to attain thermal equilibrium within the system while presaturating with hydrogen gas.

During runs, electrolyte was circulated from the reservoir, maintained at a constant temperature within $\pm$ 0.1°C through a constant temperature heat exchanger, through the cell and returned to the reservoir by a voltage-controlled Micropump Model 10-41-316. The flow rate was measured with a Brooks Model 1110 250-mm full-view rotameter calibrated for flow rates up to 2.1 liters/min.

Anode polarizations were mostly carried out by the constant load method using a carbon pile resistor. For certain experiments galvanostatic and potentiostatic control was needed and a special fast response high current potentiostat/galvanostat was assembled for this study. The unit had the following capabilities: current capacity, 0-10A; voltage range, 0-10V; response time, 60 μsec (from no load); and input impedance, 1.5 $\times$ 10^{12} ohm (potentiostatic mode). Voltage stability in the potentiostatic mode was 2.5% of the set value. Current stability in the galvanostatic mode was 3.5%.

The unit was built around an integrated circuit voltage regulator. Power to load the cell was provided by a lead-acid battery. The magnitude of the power was controlled by a power Darlington transistor. A metal oxide semiconductor field effect transistor operational amplifier was used to achieve the high input impedance in the potentiostatic mode.

The cell voltage and current were recorded on a Hewlett-Packard Moseley Autograph Model 7001 AM X-Y recorder and also monitored through a pair of Systron Donner Model 7004A digital multimeters. A cadmium/cadmium hydroxide reference electrode ($E°$ $= -0.809V$ *vs.* NHE) positioned within the interelectrode cavity within 2 mm of anode was used to record the electrode potentials.

Results

Figure 3 gives polarization curves of Li in 4M LiOH. In the original studies of the system (2), cell perform-

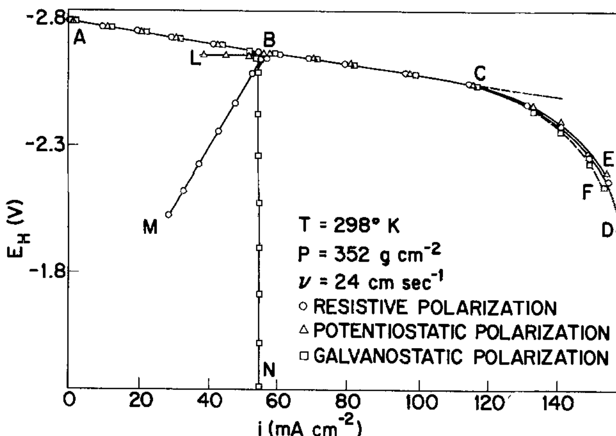

Fig. 3. Transient passivation of lithium in 4M LiOH by various polarization techniques.

ance data were obtained via constant load or resistive polarization. This form of polarization is represented by curve ABCD with the transient passivation phenomenon being shown as BM. The portion of the polarization curve shown as ABC is exclusively resistive and corresponds to transport across the anodic film.

In the region CD the film formation rate exceeds the film dissolution rate and this leads to mechanical passivation. This type of passivation is manifested by many metals when made anodic in aqueous electrolytes (3). It is the result of the formation of sparingly soluble coherent films at the metal surface or the plugging by precipitation or electrocrystallization of imperfections and pores in nonhomogeneous anodic films. In either way, the metal surface tends to become isolated from the electrolyte. Generally Li-H_2O cells are operated at or near to point C because it has been found in practice that optimum faradaic efficiency is thereby attained. As has been explained previously (*op.cit.*), the cell is adjusted for different operating current densities at more or less constant potential by adjusting the hydroxyl ion concentration of the electrolyte. Thus, for high rate discharge, the electrolyte concentration would be set at 3.5M LiOH and point C would occur at *ca.* 300 mA/cm². To operate at low current densities the polarization curve in, say, 4.8M LiOH would place point C at *ca.* 45 mA/cm².

To characterize the transient passivation effect occurring at point B, and to determine if it could be isolated as a kinetic or thermodynamic phenomenon, galvanostatic and potentiostatic polarization techniques were used. It was postulated that, if the effect had exclusively a kinetic basis, its onset would occur at different potentials according to the experimental conditions. On the other hand, the electrochemical formation of a new phase would be revealed potentiostatically. ABCE in Fig. 3 represents the potentiostatic polarization curve with the transient passivation being shown as BL. Curve ABCF represents the galvanostatic polarization, the transient passivation is BN.

It should be pointed out here that exceptional experimental reproducibility was obtained with this system provided the anode was momentarily placed at OCV prior to performing a polarization. It was necessary to maintain experimental conditions constant, such as anode-cathode contact pressure, electrolyte composition, temperature, and flow rate. Reproducibility from run to run of within 10 mV was easily attained, and generally a steady-state reading at any point was achieved almost instantaneously ($<10^{-1}$ sec). The exception to this was the sequence of events representing the actual transient passivation.

Under constant load polarization, the carbon pile resistor was adjusted slowly but continuously until point B was reached as indicated by a sudden decrease of current and voltage. At this point, the load was not altered until the recorder pen returned to B. Polarization was then continued as before. The time for the sequence BMB was about 30 sec under the specified experimental conditions. (At higher flow rates or at lower electrolyte concentration, the time would be less and vice versa.) A similar 30 sec sequence BLB occurred under potentiostatic polarization. Under galvanostatic polarization, the transient passivation became permanent, shown by BN, but on interruption of the current the potential returned to B, and on reimposing current the polarization curve followed BF.

It was observed that the process leading to transient passivation is irreversible since upon reversing the polarization from D, E, or F, toward open circuit, no discontinuity appeared at B or elsewhere on the curve. It should also be noted that for transient passivation to occur the anode did not have to be returned to OCV (2.76 NHE). It was only necessary that it be returned to a point slightly negative to B.

Figure 4 shows the influence of electrolyte flow velocity on transient passivation at constant load. At the lowest flow rate tested, 6 cm-sec^{-1}, the sequence took longer than 1 min. At the maximum flow rate, 36 cm-sec^{-1}, no passivation was manifested. It was observed that the transient passivation sequence time was more or less inversely proportional to the flow velocity. Exact quantitative data of this was not, however, obtained. The potential for the onset of passivation was found to be virtually independent of flow velocity, *i.e.*, −2.64 NHE at 6 cm-sec^{-1} and −2.67 NHE at 27 cm-sec^{-1}. Experiments at very low flow rates, *i.e.*, <3 cm-sec^{-1}, were not carried out because it became difficult to maintain uniform flow and because at low flow rates, anodic corrosion will be stimulated and concomitant heating occur.

It will also be noted from Fig. 4 that the onset of mechanical passivation at high current densities was significantly influenced by the electrolyte flow rate.

The effect of electrolyte concentration is shown in Fig. 5. It was found that the lowest concentration at which the phenomenon could be observed was 3.8M

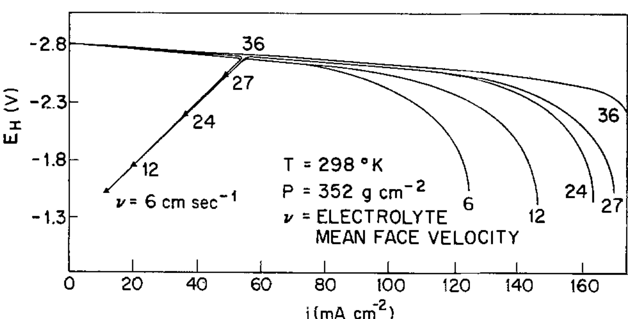

Fig. 4. Influence of electrolyte flow velocity on the transient passivation of lithium in 4M LiOH.

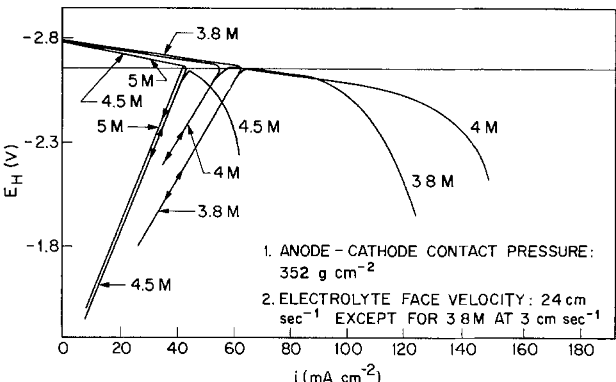

Fig. 5. Effect of electrolyte concentration on the transient passivation of lithium at 25°C.

LiOH, and here it was necessary to reduce the flow rate to 3 $cm\text{-}sec^{-1}$ for the passivation to appear.

It was also observed that the duration of the passivation sequence was proportional to electrolyte concentration. In fact, in 5M LiOH, the anode required more than 1 hr to recover to the active state. On the other hand, if the anode was in its passive state and the electrolyte was suddenly diluted from, say, 5 to 4M, recovery occurred almost immediately. Alternatively recovery could be accelerated by increasing the flow velocity or raising the electrolyte temperature. In these experiments, the potentials for the onset of transient passivation were virtually independent of electrolyte concentration.

Discussion

The anodic behavior of Li in aqueous alkaline electrolytes is unlike any other metal. Provided the hydroxyl ion concentration is sufficient, a film forms on the anode which prevents violent direct reaction of Li with H_2O. In order to harness with good faradaic efficiency the very high potential energy possessed by Li, it is generally necessary to utilize electrolytes in the range 3.5-5M LiOH. In electrolytes such as these, the anodic film tends to act as a barrier. It isolates much of the lithium surface, and reaction of the metal with the electrolyte occurs at the base of pores which permeate the film. High flux rates are supported with little polarization. Because of the reactivity of Li with H_2O, no activation overvoltage is manifested. Thus the anodic polarization curve is characterized by a straight line which suggests that the polarization is predominantly an *IR* drop across a constantly forming and dissolving porous film. However, a transient passivation is superimposed upon it at low current densities, and at fairly high current densities mechanical passivation occurs when the rate of film formation exceeds the rate of dissolution. Mechanical passivation similar to this is manifested by many other metals when made anodic in aqueous electrolytes (3). The properties of the mechanically passivating film are very important to the operation of the battery and they are described in Part II. Under normal conditions the transient passivation is not encountered, because the cell is operated within a region of the polarization curve well removed from that where it occurs. It is examined in detail here because if such passivation can be reproducibly controlled, it offers a method to essentially terminate reaction while electrolyte remains in contact with the Li. This, then, could be an effective means to turn off a Li-H_2O battery without the need to drain the electrolyte.

The transient passivation which may have a duration of many seconds, minutes, or hours depending on the experimental conditions has been shown to occur at an essentially fixed potential. Its duration and extent is influenced by electrolyte concentration, flow rate, and the polarization technique employed.

In the absence of this passivation, the Li is covered with a porous film of LiOH. No doubt, at the base of the pores adjacent to the Li, a complex situation exists because the activity of water is very low. Thus a series of layers of Li compounds of different levels of dehydration would be expected to exist in between the LiOH at the film solution interface and the metal surface. (A treatment of the composition of the anodic film on lithium and of the dominating mass transport processes across it is in preparation.) The fact remains, however, that in order for Li to exhibit extremely low anodic polarization at high current densities (the resistance of the film has been calculated to be 0.136 ohm at an electrolyte face velocity of 24 $cm\text{-}sec^{-1}$ in 4M LiOH) it is necessary that mass transport occur predominantly through the pores. It was noted above that once the transient passivation sequence has run its course, further polarization is a continuation of the curve which existed prior to passivation. Also, on reversing polarization, it does not reappear. It follows that the phenomenon is caused by the formation of a compound within the pores which can effectively insulate the active metal from the electrolyte for periods ranging from seconds to hours. It has been shown conclusively via three different electrochemical techniques that the onset of transient passivation occurs at a specific potential $E_{TP} = -2.66$ (NHE) and thus must represent the electrochemical oxidation of Li or a Li-containing species within the pores. This oxidation is presumably independent of the normal formation and dissolution of LiOH for the reasons given above. To obtain an insight into the problem, a *p*H-potential diagram for the Li-H_2O system was constructed using thermodynamic (4) and solubility (5) data. The diagram comprises the following elements

Table I. Calculated *p*H values

LiOH(M)	$a\pm$	*p*H
3.8	1.850	14.267
4.0	1.924	14.284
4.5	2.122	14.327
5.0	2.281	14.358

$$Li^+ + e \rightleftarrows Li \quad [3]$$

$$E = E° + 0.059 \log [Li^+]; \quad E° = -3.045V$$

$$LiOH + e^- \rightleftarrows Li + OH^- \quad [4]$$

$$E = E° + 0.059 (14 - pH); \quad E° = -2.95V$$

$$1/2\, Li_2O + 1/2\, H_2O + e^- \rightleftarrows Li + OH^- \quad [5]$$

$$E = E° + 0.059 (14 - pH); \quad E° = -2.51V$$

$$LiOH \rightleftarrows Li^+ + OH^- \quad [6]$$

$$K_{sp} = [Li^+] [OH^-]; \quad K_{sp} = 0.25$$

$$Li_2O + H_2O \rightleftarrows 2Li^+ + 2\, OH^- \quad [7]$$

$$K_{sp} = [Li^+]^2 [OH^-]^2; \quad K_{sp} = 625$$

Mean activities are given in the literature for LiOH at concentrations up to 4M (6). Extrapolation of the data to 5M permits calculation of the *p*H values, given in Table I, of all the electrolytes of interest in this study.

Inspection of Fig. 6 shows that at the average electrolyte *p*H, *i.e.*, 14.3, the thermodynamically stable phase is Li^+. In practice, the Li electrode does initially dissolve rapidly with formation of Li^+. Then, to retain electrical neutrality, hydroxyl ions migrate to the surface at a rate equal to the rate of ionization of Li

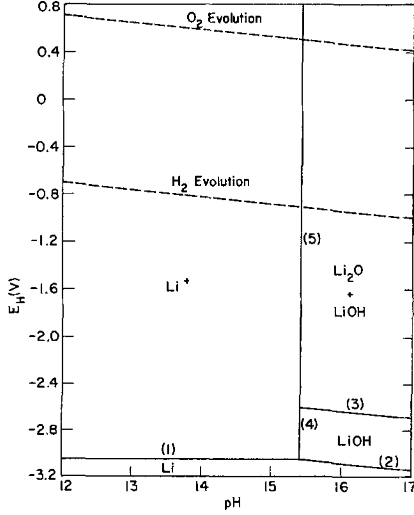

Fig. 6. *p*H-potential diagram for the Li-H_2O system ($[Li^+] = 1$)

and, at the same time, water is repelled from the surface. A situation then develops such that the solubility of LiOH is exceeded and the salt precipitates. It follows that directly adjacent to the Li, the water activity will be very low and it is believed that the film actually forms as a series of compounds. These compounds will be proportionately rich in Li at the metal-film interface, and moving away from the metal there will be increasing hydration until LiOH predominates. The film, which is in a state of quasi-equilibrium when the anode is in the active state, dissolves at the film solution interface at the same rate as it forms at the metal surface. The fact that LiOH does form a stable product on Li indicates that the *p*H within the film at the active surface must exceed *ca.* 15.5. Of interest to this study is Eq. [3], namely the electrochemical formation of Li_2O. It is apparent that, as Li is polarized beyond line 3, LiOH and Li_2O are both thermodynamically stable phases. The observed potential at the onset of passivation $E_{TP} = -2.66V$ which falls on line 3 at a *p*H of *ca.* 16. The chemical significance of such *p*H values is open to question, the data does however confirm that when dealing with a system as reactive as lithium-water, extreme compositional variations exist.

As was shown in Fig. 4, the extent of passivation and the corresponding time to recovery is directly affected by the electrolyte flow velocity. Analogously, as shown in Fig. 5, electrolyte concentration influences the extent of passivation and the recovery time. The explanation for these related observations is the fact that at higher flow rates and lower hydroxyl ion concentration, the equilibrium for LiOH formation and dissolution is shifted such as to lead to a thinner film. The converse will of course also follow. If the anode surface coverage is assumed essentially constant, as may be inferred from the invariant slope of the prepassivation polarization curves at varying flow rates in Fig. 4, then the mass transport processes across the film will be more rapid as the thickness is reduced.

The variation of E_{TP} as a function of flow rate from 6-36 $cm\text{-}sec^{-1}$ was 30 mV. This is ascribed to the slightly lower *IR* drop across the LiOH films of reduced thickness. Also the measured values of E_{TP} as a function of M LiOH did not vary significantly which is to be expected since the *p*H at the reactive metal surface is essentially constant and extremely alkaline.

In the process of transient passivation, the active surface diminishes because of the Li_2O pore blockage. The active surface potential during transient passivation is described by

$$E = E_{TP} - IR = E_{TP} - \frac{l}{k}\frac{I}{A} \qquad [8]$$

where l is the thickness of the porous film, k the conductivity of electrolyte within the pores, and A the active surface area.

Under the resistive polarization where neither surface current nor potential are controlled both E and current density I/A decrease at a constant rate corresponding to the slope $(-\ l/k)$, shown by BM in Fig. 3. During recovery from the transient passive state, the active surface area increases as well as the total anodic current and the surface potential recovers at a constant rate $(+\ l/k)$ with respect to the actual current density. This then serves to explain why the line describing transient passivation and the line for recovery are identical but of opposite direction.

Under potentiostatic polarization $E = E_{TP}$ in Eq. [8] and $I \rightarrow 0$ which is depicted by BL in Fig. 3. Under galvanostatic polarization the constant current at the surface when E_{TP} is reached is such as to force the metal to become permanently passivated. The actual active surface area rapidly decreases and based on Eq. [8], E also decreases rapidly and leads to polarity reversal, BN in Fig. 3.

From the above, the conclusion is reached that the occurrence of transient passivation is an essentially spontaneous, thermodynamically controlled process. Its onset is solely a function of the potential of the Li surface. However, recovery of the anode to an active state from the passivated state is a kinetic phenomenon.

Li_2O has physical properties dissimilar to LiOH. It is more dense (2.013 *vs.* 1.46 $g\text{-}cm^{-3}$) and it has a cubic structure *vs.* tetragonal for LiOH. It is hypothesized that, whereas LiOH forms as a porous loose film on the metal, Li_2O may form as a compact insulating layer at active Li sites. If this is the case, the formation of Li_2O would cause a sudden shift in the equilibrium for the anodic film formation and dissolution at E_{TP}. This shift would simultaneously lead to an imbalance between the rates of film formation and film dissolution, such that the former would exceed the latter and lead to passivation.

It is known that Li_2O is unstable in contact with water

$$1/2\ Li_2O_{(c)} + 1/2\ H_2O \rightleftharpoons LiOH_{(c)} \qquad [9]$$

$$K = 2.05 \times 10^6$$

but, as mentioned above, at the location where it initially forms, *i.e.*, at the active Li sites, the water activity is low.

On the other hand, the Li_2O in contact with alkaline electrolyte at the pore solution interface will be unstable according to reaction [9] and will convert to the final stable reaction product LiOH. LiOH is readily soluble in the electrolyte and this could account for the disappearance of the passivation as the equilibrium between film formation and dissolution once again dominates.

The fact that the transient passivation is observed only when Li is polarized from a potential slightly negative to E_{TP} suggests that a subtle but permanent change takes place on the anode's surface during the passivation sequence. The slope of the polarization curve is apparently unaltered after passivation which shows that the predominantly changing polarization component is the *IR* across the film. Thus, any changes which occurred within the anodic layer are obscured making it difficult to examine the phenomenon diagnostically. It may be that once the potential for formation of Li_2O has been reached, even though this compound dissolves into the electrolyte as discussed above, a certain amount is incorporated into the anodic layers. This then could influence the subsequent formation and dissolution kinetics of the anodic reaction products. On the other hand, at potentials more negative than E_{TP}, Li_2O is thermodynamically unstable and the equilibrium which maintains is solely that for the formation and dissolution of LiOH.

It is clear that additional work is needed to fully explain the irreversibility of polarization leading to transient passivation. The present paper has served to introduce the phenomenon, to explain the mechanism of passivation, and to point out the salient features of the $Li\text{-}H_2O$ system.

Conclusions

Lithium when anodically polarized in aqueous electrolytes forms a protective film of LiOH. In 3.8-5M LiOH this film exists in a state of quasi-equilibrium over an appreciable range of current densities. When the anode is polarized to a fixed potential, $\sim -2.66V$ *vs.* NHE, a transient passivation phenomenon of from seconds to hours is manifested. The duration of the transient is proportional to electrolyte concentration, the more dilute solution giving the shorter passivation times. The effect is believed to be associated with the formation of an insulating, but unstable aggregate of Li_2O which nucleates at active Li sites at the base of the pores in the protective film. Over a period of time,

determined by the rate of transport of water and/or hydroxyl ions through the film, most of the Li_2O reverts to LiOH and a state of quasi-equilibrium at the anode surface is recovered. However, as a result of the passivation process, the surface state of the Li is altered.

By understanding the mechanism of the passivation and by defining the ranges of electrolyte concentrations and flow rates within which it occurs, a means may be found to place a lithium-water battery in a standby mode without the need to drain electrolyte from it.

Exhaust Gas Compositions and Fuel Efficiencies of Hydrazine-Air Fuel Cells

Kohki Tamura and Toshiki Kahara

Hitachi, Limited, Hitachi Research Laboratory, Hitachi, Japan

ABSTRACT

High fuel efficiency and clean exhaust gas are the two most important requirements in hydrazine-air fuel cells. Four anodes of sintered nickel plaque were studied for these purposes, each one containing either cobalt, nickel, palladium, silver, or platinum as a catalyst. Exhaust gases were determined with a gas chromatograph, the consumption of hydrazine in the anolyte was analyzed chemically, and fuel efficiencies and unreacted product gases were evaluated based on these data. Consequently with the silver catalyzed electrode, 97% fuel efficiency was attained at 50 mA/cm² at 25°C.

Hydrazine-air type fuel cells are the ones most promising for special uses such as unmanned stationary electric sources, because they possess advantages over other types, for example, a high current density is obtainable and a liquid fuel which is easier to handle than other formal fuels can be used. But they have disadvantages, that is, fuel is very expensive and their exhaust gas contains nonnatural materials such as hydrogen and ammonia. For this reason, practical applications have been limited.

Thus, the two most important requirements for the wide acceptance of these fuel cells are (*i*) cleanness of exhaust gas and (*ii*) high fuel efficiency.

Extensive research and development has been done in the world on hydrazine-air fuel cells, especially their electrodes (1-4). This paper presents the results which were obtained in experiments using a complete cell. The influences of the kinds and amounts of electrode catalysts and the operating conditions were examined for the purpose of attaining the two requirements of clean exhaust gas and high fuel efficiency.

Experimental

Figure 1 shows details of experimental cell construction. The cell has one anode and one cathode, each 50 × 50 mm. These two electrodes and three Lucite frames form an anolyte, an electrolyte, and an oxidant chamber. Silicon rubber gaskets are placed between frames. Narrow holes for exhaust gas are opened at the upper walls of the anolyte chamber frame and the electrolyte chamber frame. The width of each chamber is 10 mm. Four anodes of sintered nickel plaque were constructed, each one containing either cobalt, palladium, silver, or platinum as a catalyst. Cobalt (II) chloride was reduced to cobalt by dipping in 1M sodium bicarbonate and 2M sodium hydroxide solutions, and silver nitrate to silver by 2M sodium formate. Palladium was precipitated in porous plaque from palladium (II) chloride by dipping in a palladium (II) chloride solution, and platinum from chloroplatinic acid. 1-2.5 × 10^{-5} mol/cm² of catalyst was loaded onto each nickel plaque. The thickness of the anode is about 0.95 mm and the porosity is 67% before adding the catalyst. The cathode is Teflon-bonded catalyzed carbon with a nickel screen.

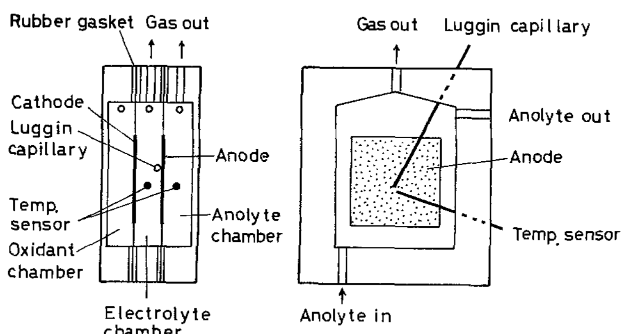

Fig. 1. Experimental cell construction

Key words: fuel cell, hydrazine-air fuel cell, hydrazine.

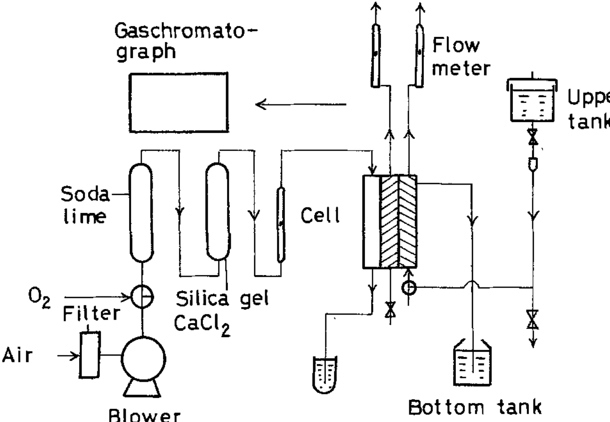

Fig. 2. Layout of the apparatus

A Luggin capillary was inserted in the electrolyte chamber to measure the anode potential. The capillary tip was in contact with the center of the anode surface. The potential of the saturated calomel electrode was used as the standard potential. Temperature sensors were enclosed in the anolyte and the electrolyte chambers.

Figure 2 shows the layout of the apparatus. Anolyte dropped and flowed from the upper tank to the anolyte chamber in the cell, overflowed from the top of the chamber, and was stored in the bottom tank. The flow rate of anolyte was 0.6-0.8 ml/min. Hydrazine concentrations in the anolyte were 0.5, 1, and 3%, and the electrolyte was 30% potassium hydroxide solution. A part of the hydrazine in the anolyte was spent in the anolyte chamber. Air was introduced by a small blower; its flow rate was 1.7 liters/min. About 150 min were expended for each measuring point, and the anolyte and the electrolyte were discharged whenever the measurement of one point was finished.

Hydrazine in the anolyte and the electrolyte was analyzed by the iodine titration method of Eq. [1]

$$N_2H_4 + 2I_2 \rightarrow 4HI + N_2 \quad [1]$$

or by the absorption photometric method using p-dimethylaminobenzaldehyde as the indicator.

The flow rate of the exhaust gas was measured by a soap bubble flow meter. The exhaust gases were taken out of the exhaust gas holes of the anolyte chamber and the electrolyte chamber separately and determined with a gas chromatograph. The concentration of hydrazine in the anolyte was analyzed chemically. The coulombic fuel efficiency and the cleanness of the gases were evaluated using these data.

Results and Discussion

Effect of catalyst.—The distribution of the catalyst in the anode was examined by surface analysis and line analysis, with an electron probe microanalyzer, as a first step in the experiments.

Figure 3 shows the results of analysis of the palladium catalyzed anode. The light areas in Fig. 3 (a) are the places where the characteristic x-ray of palladium is strong. The dark areas are the places where it is weak or not radiated. But the dark areas do not mean that palladium is absent, because the sintered nickel plaque has an uneven surface, and the characteristic x-ray of palladium is not radiated from concave areas or if it is, it cannot be observed because of its weakness. The peaks pointed toward the bottom of the photograph in Fig. 3 (b) are considered to be the concave areas in the plaque. The same results were obtained for the other catalyzed anodes. Therefore, it is concluded that the catalyst distributes uniformly on and in the sintered nickel plaque.

Figure 4 shows potentials of catalyzed anodes as a function of current density. All potentials are approximately the same except for the silver catalyzed electrode. The difference between the potentials was slight. The potential of the cobalt catalyzed anode was $-1.2V$ (*vs.* SCE), palladium $-1.18V$, platinum $-1.19V$, and silver $-1.12V$, at a discharge current density of 50 mA/cm^2. While it cannot be said that these results will always be obtained, as the potentials vary with the amount and state of the catalyst or with the operating conditions, still it is considered that they describe a relationship that exists among these four catalysts.

The gas evolution rate of each catalyzed electrode was measured as a function of current density; gases from the anolyte and electrolyte chambers were collected separately.

Figure 5 shows the results of analysis of the platinum catalyzed anode. The line of theoretical nitrogen in the figure corresponds to the coulombic amounts calculated by reaction [2]

$$N_2H_4 + 4\,OH^- \rightarrow N_2 + 4H_2O + 4e^- \quad [2]$$

The gas evolution rate obtained with platinum was higher than that obtained with cobalt, palladium, or silver.

Figure 6 shows the results of analysis of the silver catalyzed anode. The evolution rate of hydrogen and nitrogen from wasted hydrazine is very low, compared with the platinum catalyzed electrodes. The gas evolution rate obtained with silver was lower than that obtained with platinum, cobalt, or palladium.

So, it is clear that (*i*) the total nitrogen evolution rate increases and the total hydrogen evolution rate decreases linearly with increasing current density, (*ii*) both nitrogen and hydrogen occur in the largest amounts in the catalyzed platinum, and in the smallest amounts in the catalyzed silver, and (*iii*) a large amount of gas evolution from the electrolyte chamber can be observed.

The quantities of hydrogen in the exhaust gas were 15.0% with the platinum catalyzed anode, 8.8% with cobalt, 1.8% with palladium, and only 0.2% with silver at a current density of 50 mA/cm^2.

Attempts were made to detect ammonia in exhaust gases by Nessler's reagent, spectrophotometer, and gas chromatograph, but none could be detected.

Figure 7 shows the coulombic hydrazine efficiency calculated from the results of analysis of hydrazine

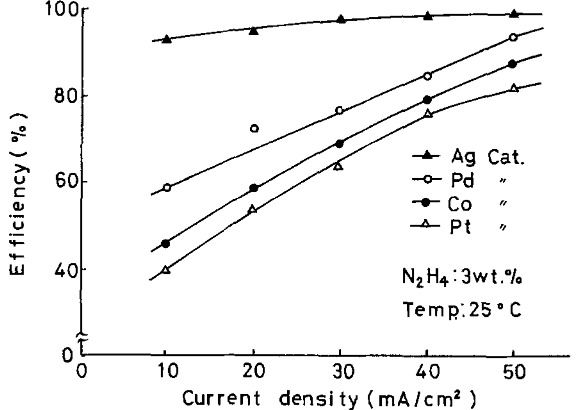

Fig. 7. Coulombic hydrazine efficiency with different catalysts as a function of current density.

concentration in the anolyte and electrolyte chambers after a constant current discharge for 2.5 hr. This is in agreement with the result calculated from the ratio of theoretical to actual nitrogen evolution. The efficiency of the silver catalyzed anode was highest. It was more than 90% even in the low current density area and, for example, was 96% at a current density of 30 mA/cm² with a silver catalyzed anode. On the other hand, it was 58% with platinum. The coulombic hydrazine efficiency always increases with increasing current density.

Influences of anode catalyst concentrations, 1×10^{-4}, 1×10^{-5}, and 1×10^{-6} mol/cm², on polarization curves, gas evolution rate, and efficiency were examined. For polarization curves, no difference existed between anodes with 1×10^{-4} and 1×10^{-5} mol/cm², but the polarization curve was unstable with 1×10^{-6} mol/cm². This might be considered to be because of the characteristics of the sintered nickel plaque. For such low catalyst loading, the techniques used in these experiments could not make the catalyst work effectively.

The effect of palladium catalyst concentration on gas evolution rate is illustrated in Fig. 8. Nitrogen and hydrogen evolution rates are high in high catalyst concentrations. This means that the decomposition of hydrazine which is not used effectively for electrochemical reaction increases with increasing anode catalyst concentration.

When the palladium catalyst concentration was 1×10^{-5} mol/cm², the coulombic efficiency was 93% at a current density of 50 mA/cm², but, when the concentration was 1×10^{-4} mol/cm², it was 73%. Therefore, it is known that excessive catalyst concentrations increase the useless consumption of hydrazine.

Effect of hydrazine concentration.—Effects of a hydrazine concentration of 0.5, 1, and 3 weight per cent (w/o) on polarization curves, gas evolution rate, and coulombic hydrazine efficiency were studied. Polarization curves of the hydrazine anode were independent of hydrazine concentration at a current density less than 30 mA/cm², but were influenced at a higher current density, and the potential of the anode became more noble with decreasing hydrazine concentrations because the supply of hydrazine decreased to the point where a reaction could no longer be maintained.

Figure 9 shows the effect of hydrazine concentration on gas evolution rate at a current density of 50 mA/cm². The behavior of gas evolution was similar at other current densities. From this figure it can be seen that the total nitrogen evolution rate increases, but that nitrogen from the anolyte chamber decreases and nitrogen from the electrolyte chamber increases with increasing hydrazine concentrations.

From these results, it is considered that the electrochemical reaction of hydrazine occurs at the anolyte chamber side of the anode in the case of dilute hydra-

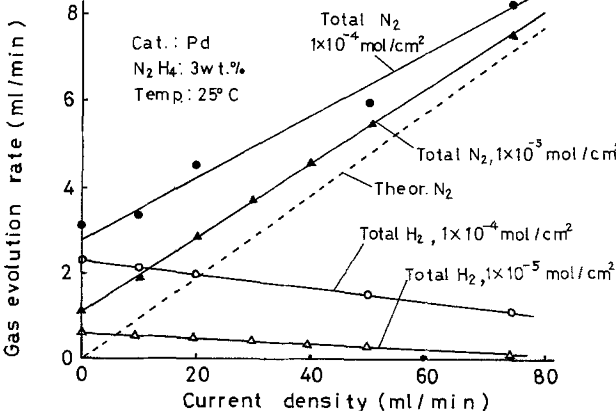

Fig. 8. Effect of catalyst concentration on gas evolution rate

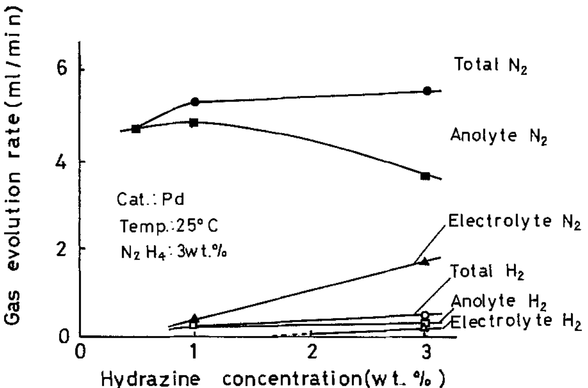

Fig. 9. Effect of hydrazine concentration on gas evolution rate at current density of 50 mA/cm².

zine concentrations and that the reaction area spreads to the electrolyte side of the anode with increasing hydrazine concentrations.

The quantities of hydrogen in the exhaust gas were 0.8% in 0.5 w/o hydrazine, 3.9% in 1 w/o, and 7.9% in 3 w/o, at a current density of 50 mA/cm². It is obvious that hydrogen in the exhaust gas increases with increasing hydrazine concentration.

Coulombic efficiency was about 100% in 0.5 w/o hydrazine, and about 90% in 1 and 3 w/o, at a current density of 50 mA/cm². At a low current density, for example, at 25 mA/cm², the efficiency was 91% in 0.5 w/o hydrazine, 75% in 1 w/o, and 70% in 3 w/o. Therefore, it is obvious that efficiency increases with dilution of the hydrazine and with increasing current density.

Effect of temperature.—Effects of temperatures of 25°, 40°, 60°C in the chamber on polarization curves, gas evolution rate, and coulombic hydrazine efficiency were studied.

The potential of the hydrazine anode moved into less noble areas with increasing temperature. For example, the difference of potential was about 15 mV for each 10°C at a current density of 50 mA/cm².

Figure 10 shows the behavior of gas evolution at a current density of 25 mA/cm². Total nitrogen and total hydrogen evolution rates increased with increasing temperature. Especially, total hydrogen increased very rapidly with increasing temperature. Nitrogen from the anolyte chamber was more than that from the electrolyte chamber, but the hydrogen evolution rate was opposite that of the nitrogen evolution rate. Then, at a current density of 25 mA/cm², hydrogen in the exhaust gas was 14% at 25°C, 35% at 40°C, and 49% at 60°C. Only at 60°C, did the exhaust gas make Nessler's reagent turn slightly yellow.

A small amount of ammonia might have existed in the exhaust gas. However, because the amount was negligible, quantitative analysis of it was impossible.

Figure 11 shows the effect of temperature on the coulombic hydrazine efficiency. It is obvious that the efficiency increases with decreasing temperature and with increasing current density.

Anode reaction.—When reaction [2] occurs, anode potential is about −1.2V (*vs.* NHE) in 30% potassium hydroxide solution electrolyte. The best value in this paper is −1.03V, namely about 0.2V more noble than the theoretical value.

Many reactions are expected regarding the hydrazine anode:

(*i*) Hydrazine decomposes to hydrogen and nitrogen, and this hydrogen reacts electrochemically

$$N_2H_4 \rightarrow N_2 + 2H_2 \quad [3]$$

$$2H_2 + 4\,OH^- \rightarrow 4H_2O + 4e^- \quad [4]$$

(*ii*) Hydrogen atoms in hydrazine are absorbed on the electrode surface and react with hydroxyl ions in the electrolyte, or become hydrogen molecules

$$N_2H_4 \rightarrow N_2 + 4H_{(ads.)} \quad [5]$$

$$4H_{(ads.)} + 4\,OH^- \rightarrow 4H_2O + 4e^- \quad [6]$$

$$4H_{(ads.)} \rightarrow 2H_2 \quad [7]$$

(*iii*) Hydrogen in hydrazine reacts gradationally with hydroxyl ion in the electrolyte, as reaction [8]

$$N_2H_4 + OH^- \rightarrow N_2H_{3(ads.)} + H_2O + e^- \quad [8]$$

(*iv*) Reversal reaction occurs and mixed potential is observed

$$4H_2O + 4e^- \rightarrow 2H_2 + 4\,OH^- \quad [9]$$

In this paper, because all exhaust gases have hydrogen gas in them either (*i*), (*ii*), or (*iv*) is presumed.

The calculated value of electrochemical potentials of hydrogen reaction [4] is −0.925V in 30% potassium hydroxide solution, but the anode potential in this paper is less noble than this value, not only at open circuit but in the low current density regions. It appears that reaction [2] will occur to a minimum extent, simultaneously with the hydrogen evolution reactions [3], [7], or [9] and their accompanying reactions. In the silver catalyzed electrode reaction the amount of evolved nitrogen is almost the same as the theoretical amount, with very little hydrogen. The reason is the low activity of the catalyst and the efficient use of the small volume of hydrogen.

Summary

1. The coulombic fuel efficiency is influenced by the kind of catalyst. That of the silver catalyzed anode

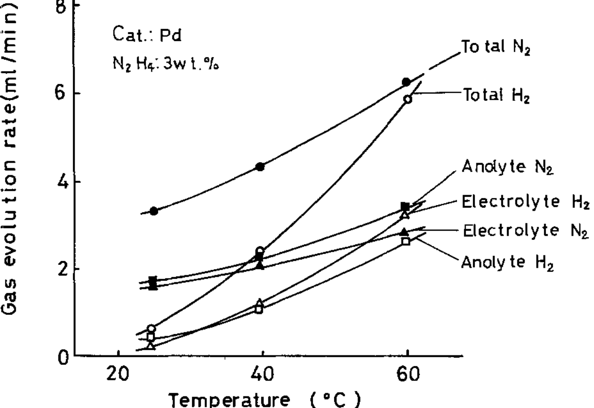

Fig. 10. Effect of operating temperature on gas evolution rate at current density of 25 mA/cm².

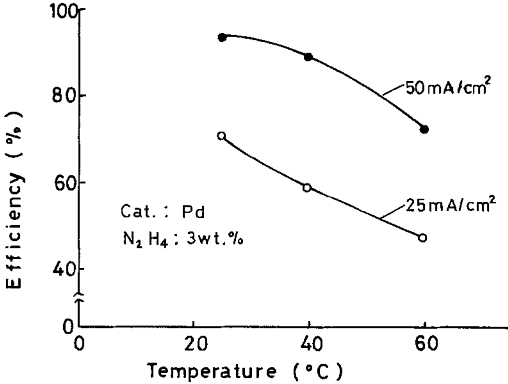

Fig. 11. Effect of operating temperature on coulombic hydrazine efficiency.

cell was the best, and that of the platinum was the worst.

2. The main components of the exhaust gas were nitrogen and hydrogen. A little ammonia was detected when the operating temperature was 60°C.

3. The hydrogen content of the exhaust gas decreases and fuel efficiency increases in accordance with increases in the current density. At a high current density, it is presumed that hydrogen which is produced by side reaction is caught by the anode and is used for further reaction.

4. The hydrogen content of the exhaust gas increases and fuel efficiency decreases with increasing hydrazine concentration. It seems that the decomposition of hydrazine which is not used effectively for electrochemical reaction increases with increasing hydrazine concentrations.

5. The hydrogen in exhaust gas increases and fuel efficiency decreases with increasing cell temperatures.

An X-Ray Diffraction, Scanning Electron Microscopy Study of Separator Failure

J. R. Dafler,* A. A. Garwood, F. W. Wentzel, Jr., Barbara Campbell, and D. L. K. Chu

ESB Incorporated Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

Resin-bonded paper separators suffer some loss of crystalline material on extended storage in battery grade H_2SO_4. Similar separators from cycled batteries suffer order of magnitude losses of crystallinity. Scanning electron microscopy has found Pb-salts of two kinds; those grown in regions of high and low supersaturation. The latter often obtain crystal dimensions larger than 30μ. Comparison with other separator materials used in Pb/acid batteries has led to a model of separator failure based on mechanical abrasion, fluid motion, and crystallization in large pores. The separator matrix is weakened by brittle fracture of the fiber network, accompanied by minor hydrolytic loss of material. These lead in turn to pore enlargement that can enhance the growth of large, well-ordered crystals. A somewhat speculative mechanism for perforation failure of large-pored separators is given.

Paper separators for use in automotive batteries perform beyond ordinary expectation in well-made, well-maintained batteries. Their use yields distinct cost savings when compared to microporous rubber or polymer separators (1). Made by typical paper-forming techniques and impregnated with thermosetting resins, they exhibit exceptional resistance to sulfuric acid (1.25-1.32 sp gr). When subjected to deep cycling at high, steady currents, they regularly exhibit what has come to be called "perforation" failure. Figure 1 shows representative perforation failures found in automotive batteries discharged at high rates.

Perforation spots are generally very rich in Pb-salts. Direct chemical analysis by area has shown these spots to have, frequently, more than twice the total Pb per unit weight as the rest of the matrix. On occasion, direct analysis found 22-23% Pb at a perforation spot, while the rest of the separator had accumulated ~ 10% Pb (analyzed as per cent Pb-metal/unit area). The onset of this particular kind of failure is generally signaled by quite low end-of-charge voltage (ECV) so that perforation spots are regarded as high resistance short circuits.

Key words: cellulose, crystallization, hydrolysis, mechanism, porosity, supersaturation.

It was natural to evaluate paper separators for electric and auxiliary vehicle (golf cart) use. The discharge rates are quite high compared to automotive practice, and discharges are much deeper: in the latter cases, ~ 100%. Regular discharge testing of automotive-type batteries using the accepted method (SAE J240a) does little to characterize separators, while the formerly used SAE test (Schedule K) quickly illuminates separator weaknesses. In J-240a testing, resin-bonded paper separators yield excellent results. In testing typically used for golf cart and electric vehicle batteries, paper has proved much less successful.

Paper separators tend to fail after a few hundred cycles if discharged at the 2-5 hr rates. The mechanism of failure has not been defined, but is certainly related to chemical and physical stability. The over-all mode of failure is associated with the physical strength of separators and the average pore size. The failure discussed most in this paper is so-called perforation failure, and this kind of failure is sometimes seen in separators possessing greater chemical and physical stability than resin-bonded paper.

Cellulose matrixes for separators are usually impregnated (phenol formaldehyde resins are common), then die-stamped or roll-died to form a rib structure. The paper is then baked to complete the polymeriza-

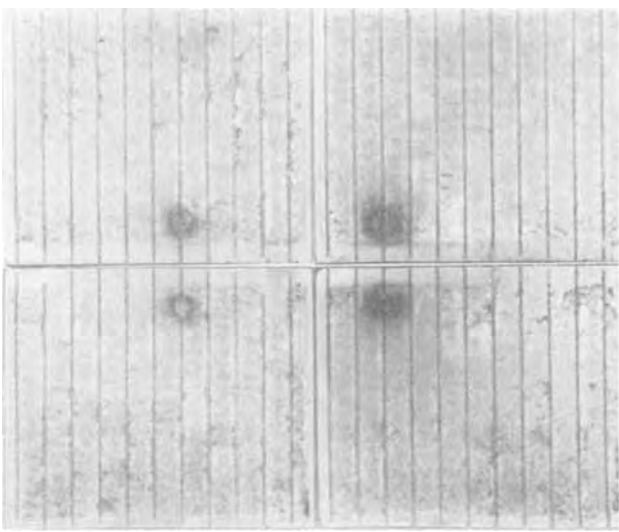

Fig. 1. Perforation failure typically seen in failed cells having low end-of-charge voltage.

tion. In some separators, the ribs are reinforced with polymers such as polyvinyl chloride (PVC). The powdered PVC fuses during the polymerization step, forming a hard surface over the ribs.

Finished separators made in this way have good wicking action, can act as a useful electrolyte reservoir, but fail to provide good retention of positive material; they usually are 60-70% porous. They possess adequate conductivity. The pores in such separators are large. Figure 2 shows scanning electron micrographs of a typical paper separator fiber matrix. The interfiber distances are of the order 20-30μ. It is clear, therefore, the average pore size of the fiber matrix is large, compared with the average pore diameters found in many other separators. A summary of typical pore sizes is indicated in Table I. To approach an understanding of the mode of failure we were led to measure the stability of the separator material, *per se,* then to investigate the nature of the Pb-salts present in cycled and failed separators, using scanning electron microscopy (SEM). The key to empirical understanding was cross-characterization of paper with respect to those separators that do not exhibit this particular kind of failure (microporous rubber and polymer).

X-ray measurement of crystallinity.—Our investigation of stability was based on x-ray diffraction measurements of the crystalline cellulose present in the separator matrix, assuming that long-lived crystallinity was to be equated with matrix stability. Hermans and Weidinger have explored the question of crystallinity and recrystallization in a series of papers (2-4). The question of order of crystallinity of cellulose has been discussed at some length (5-8). For the purpose of this study, the term crystallinity serves well.

We did not use the Hermans and Weidinger technique which requires careful fabrication of a compressed plug of sample (2). Instead, following the practice of Venkateswaran (9), we used sheet stocks and have concentrated on direct x-ray comparisons of the crystalline material in unimpregnated paper, finished and used separators. Using typical diffractometer techniques and postsample monochromated Cu-radiation (λ = 1.543Å), we obtained patterns similar to those Hermans and Weidinger (2) obtained with microcamera, and a carefully compressed plug of sample. As in the case of Hermans and Weidinger and others (2-4, 6, 9), all samples tested gave diffuse peaks in the region, 8°-15° 2θ, and a much taller, less diffuse peak in the neighborhood of 22° 2θ. All samples tested were derived from the same source of α-cellulose. A representative spectrum can be seen in Fig. 3.

A technique for indexing the amount of crystalline cellulose present in the fiber matrix was developed to serve as a measure of matrix stability as it compared, directly, to the starting material. The important quantity is the number of diffractors present in the target zone. For papers made by the same controlled process, this should be, reasonably, the same. For a standard of comparison, a chip of raw material α-cellulose (Cellulose-I) before pulping and formulating, is used. A correction is applied to normalize all the samples (papers

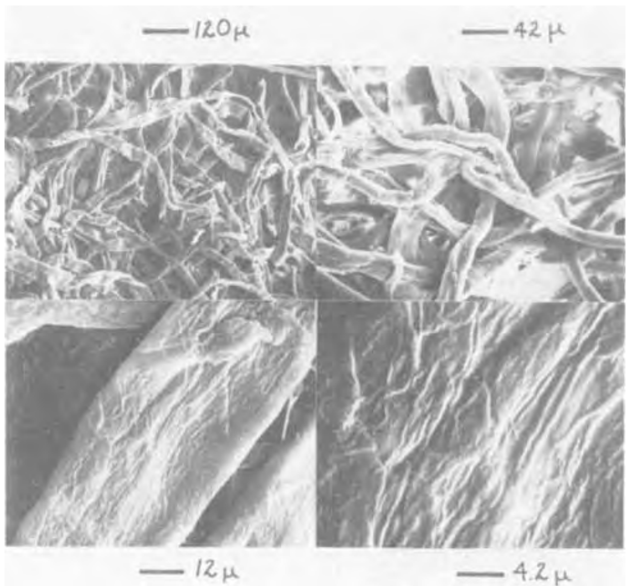

Fig. 2. Scanning electron micrographs of phenol-formaldehyde-bonded cellulose separator matrix.

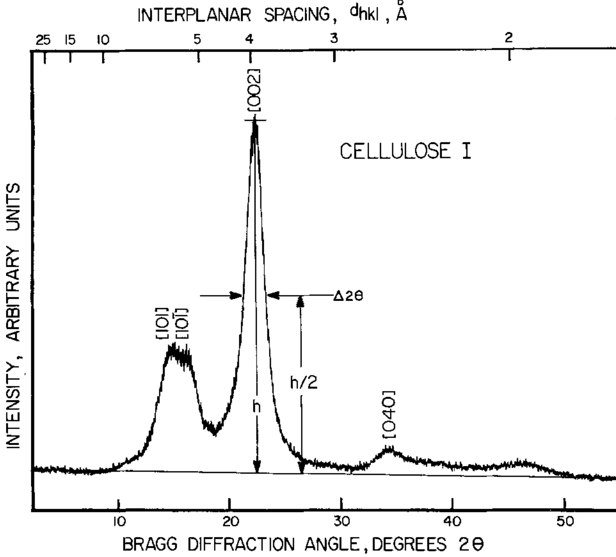

Fig. 3. X-ray diffraction spectrum of Cellulose-I stock used in formulation of separators. The I_{std} value used in calculating J_x is calculated by triangulating the [002] diffraction maximum as shown.

and pulp) to the same number of diffractors per unit area. The integrated intensity, I_x, of the peak measured is given by

$$I_x = An_x \quad [1]$$

where n_x is the number of diffractors/unit area, and A is the beam target area. The value of n_x is proportional to the density, ρ_x, of species and a constant, k_x related to their crystalline nature. Therefore, for the comparison standard $I_{std} = Ak_{std}\rho_{std}$. Setting target areas equal, and rearranging, the crystallinity index, J_x, is resolved

$$J_x = (k_x/k_{std}) = (\rho_{std}/\rho_x)(I_x/I_{std}) \quad [2]$$

Figure 3 indicates the way the ratio (I_x/I_{std}) is measured. An arbitrary base line is established from 10° 2θ to 30° 2θ. The primary I_{100} peak (10) is then triangulated to arrive at an "integrated" intensity value. This is used to calculate the index of crystallinity of the material after correcting for any differences in density between sample and standard. The density of raw material pulp was 1.352 and the density of the separators was 1.505. Before beginning x-ray procedures, tests to insure "saturation" of the refracted beam were done (9). Single thicknesses of ~ 25 mil back web material yielded the same diffraction maxima as 2-3 thicknesses. Because direct comparisons were made to the source material, no corrections for absorption were used (2).

The index of crystallinity used here and as used in an earlier note (11) differs from the crystallinity index of Segal (6) and others (2-9). This value, the J-value, is an extensive measure of retained crystallinity where in Segal's case, the measurement was a true degree of crystallinity, that is an intensive measurement. A decrease in J-value, as used here, represents a measure of the relative degradation of the crystalline cellulose matrix and therefore is a measure of relative stability.

Experimental Procedures

A large number of separator pieces were stored in H_2SO_4 of varying specific gravities. The acids used were 1.260, 1.280, 1.325, and 1.260 saturated with $PbSO_4$.

Forty to sixty 2 in. square chips were made up for each concentration of acid and shuffled before distributing into the acid baths. The samples were put into 1 lb ointment jars of the solutions and these thermostated at 52°C (125°F) in an oil bath. At the end of specific storage times, 4-7 samples were taken from each jar and rinsed in tap water and then distilled water until free of sulfate. The chips were vacuum dried at 40°C, examined by x-ray diffraction, and the crystallinity index of each sample calculated. The storage time varied from 690 to 2400 hr.

A set of Group 24 batteries was assembled with single cell covers to facilitate cell-to-cell removal of separators and elements. The cells were tested as part of a separator test program that included removal of separators at regular intervals. Our interest was, principally, in the condition of the separators after known periods of cycling. The discharge scheme, a 25% overcharge program, using the 2 hr rate (formerly SAE Schedule K) was: 20A discharge for 1 hr, 5A charge for 5 hr, and no rest at open circuit.

For indexing the cellulose crystallinity in cycled cells, separators were removed, in order, from cells and immediately washed in running water. After clearing excess acid, the separators were brushed free of loose, active material with a 2 in., soft paint brush and washed 1 hr in cold, running tap water and then soaked repeatedly in distilled water until free of sulfate. After removing excess water, the separators were dried, in vacuo, at ~40°C. Representative pieces were taken for x-ray analysis. Cells that refused to accept charge after a definite number of cycles, characteristically, had "perforation" spots (cf. Fig. 1), and exhibited short-circuit-like behavior.

Samples of cycled separators, prepared as for x-ray studies, were gold coated and examined, using SEM techniques, for types of Pb-salt accumulation.

Reagent grade chemicals were used throughout this program, and acid concentrations were determined by controlled-temperature hydrometry. Separator materials were standard phenol-formaldehyde-impregnated stocks from the Texon Corporation of South Hadley, Massachusetts. The α-cellulose stocks were also obtained from Texon.

A Philips Electronics Mark II x-ray diffractometer was used to obtain x-ray intensity data. All analyses were done at Cu-target parameters of 35-40 kVA and 15-20 mA x-ray current. Each series of measurements was concluded by analysis of a chip of α-cellulose at the same current-voltage settings. Scanning electron microscopy was done on a JEOL microscope. Use-time on this instrument was purchased from The Franklin Institute Materials Research Department.

Pore volume measurements were made using an Aminco-Winslow, mercury filled pore volume analyzer.

Results and Discussion

X-Ray diffraction.—There is a decrease in crystallinity upon storage in H_2SO_4. It is not large, in fact, smaller than the difference between the raw material Cellulose-I and the finished virgin separators. The process of pressing and baking of separators reduces the J-value of separators to 59.6 ± 6.5%, while storage in 1.280 sp gr H_2SO_4 lowers the J-value to 48% after 2400 hr. The calculated indexes of crystallinity (J-values) are summarized in Table II.

Dried samples of separators from batteries cycled 5 and 9 weeks were x-rayed and their crystallinity indexes calculated. Some difficulty is experienced in measuring line widths because of interference by Pb-salts in the separator matrix. In the brief summary in Table III, we have indicated the crystallinity indexes of separators analyzed after 5 and 9 weeks of cycling (28 cycles per week).

The use of celluosic separators in batteries is accompanied by a very large reduction in index of crystallinity, as it is defined in this study. Separators cycled 5-9 weeks suffered a much greater loss of crystallinity than separators stored in battery acid for much longer periods. This loss is not easily explained; however, the x-ray patterns of cycled cellulosic separators are not unlike these found by Segal *et al.* when they subjected Cellulose-I fibers to ball milling and found large losses of crystallinity (6). This suggests that either strenuous physical processes such as stretching and abrading of the fiber matrix, or strong chemical action causes the deep loss of crystallinity of cycled batteries.

The larger losses of crystallinity suffered during storage in acid saturated with $PbSO_4$ suggest that physical processes such as the abrading and exercising of the matrix no doubt experienced by separators during

Table II. Index of crystallinity: acid-treated separators

H_2SO_4, sp gr	Hours of immersion (52°C) 691	1360	2400
1.260	0.49	0.52	0.49
1.280	0.47	0.55	0.48
1.260 sat'd with $PbSO_4$	0.39	0.39	0.29
1.325	0.48	0.48	0.43

Table III. Crystallinity indexes

Cycle life, weeks	J (index of crystallinity)
5	0.063
9	0.080

cycling lead to increases in crystallinity loss. Segal *et al.* (6) ball milled highly crystalline Cellulose-I powder and found complete loss of crystallinity after 1 hr of milling. Knife-milling has been shown by Segal (6) and others (9) to cause only a slight lowering of crystallinity. Both processes, then lead to a reduction of crystallinity; that caused by compressive (ductile) processes being far greater than caused by tensile (brittle) processes on the fibers. In the environment of the cycling battery, we expect to see both ductile and brittle fracture contributing to loss of crystallinity.

The possible role of oxidative hydrolysis was briefly tested by 100°C extraction of separators with 10% HNO_3. The index of crystallinity was affected less than by 3500 hr in 1.325 H_2SO_4. Ant-Wuorinern and Lehtinen (12) hydrolyzed Cellulose-I in dilute H_2SO_4 and found material loss, but little change in degree of crystallinity unless the acid was hot and the concentration above 2*N* (sp gr ~ 1.12). At 25°C, Ant-Wuorinen and Visapaa (13) found that neither index of crystallinity nor degree of polymerization of cellulose was affected by hydrolysis with 0.1-2*N* H_2SO_4 or other mineral acids. In this laboratory, storage of separators in 1.325 H_2SO_4 did not result in large loss of *J*-value, and the work of McKeown and Lyness (14) and of Gjonnes *et al.* (15) indicate hydrolysis, whether heterogeneous or homogeneous, is not an unequivocal tool for interpreting the intensive degree of crystallinity of cellulose matrixes. In this laboratory, hydrocelluloses were made by hydrolysis in 1.400 H_2SO_4 at 53°C that had intensive and extensive crystallinities within 10% of that displayed by raw material α-cellulose.

Other possible causes of the decrease in *J*-value are: (*i*) thermal effects due to local heating, temperature cycling, and nonuniform spacing between separators and electrodes; and (*ii*) physical effects due to growth and dissolution of lead salts, a kind of exercising, stretching, and abrading of the fiber matrix by the electrodeposited salts.

Prevailing opinion in this laboratory is that loss of *J*-value is more likely due to thermal effects (hot spots) and simple physical effects (abrading), with hydrolytic losses much smaller than the former. Rusznak and Tanczos (16) found that thermal treatment at 190°C for up to 10 min brought about large increases in the rate constants for acid hydrolysis to occur, but as we have seen, long term storage of separators in quiet battery acid at 52°C led to very little relative loss of crystallinity.

Examination of separators that had so-called perforations, indicates they were all close to the cell tops, where the spacing is confined. Most of the dark spots are centered on ribs and are facing the positive electrode. The most intense darkening, even in the rare cases where the perforation is not centered on a rib, is always on the two raised faces that adjoin the positive plate. The symmetry, or match-up, on the two separator pieces is always very marked. These dark spots are very rich in Pb-salts.

SEM examination.—SEM examination found two kinds of salt accumulations: large well-formed crystals and collections of much smaller indistinct growths, rather like handfuls of wet sand in appearance. The well-formed crystals, often, were as large as 30μ on their long axis. This is quite large with respect to average pore size of cellulose separators, ~25μ. Figure 4 shows both kinds of growth. The poorly defined crystals are quite small and even in SEM pictures, indistinct.

The chemical nature of the crystals imbedded in the paper matrix is not known, since they had been modified by washing and drying procedures to prepare them for SEM analysis. If the material in perforation spots provided a high resistance short-circuit path, then they contained Pb or a form of PbO_2, both excellent electronic conductors. Their nature surely was changed by experimental treatment. The origin of the crystals, that is, whether seeded by positive material or spontaneously nucleated from supersaturated solution (see next discussion) is not known, but both origins would probably lead to the same species during extended cycling.

Spontaneous nucleation is clearly a possibility. SEM examination of separator chips stored for 2400 hr in 1.260 H_2SO_4 saturated with $PbSO_4$, showed crystals imbedded in the matrix. These solutions were, in all cases quiescent, so that stirring did not provide seeds.

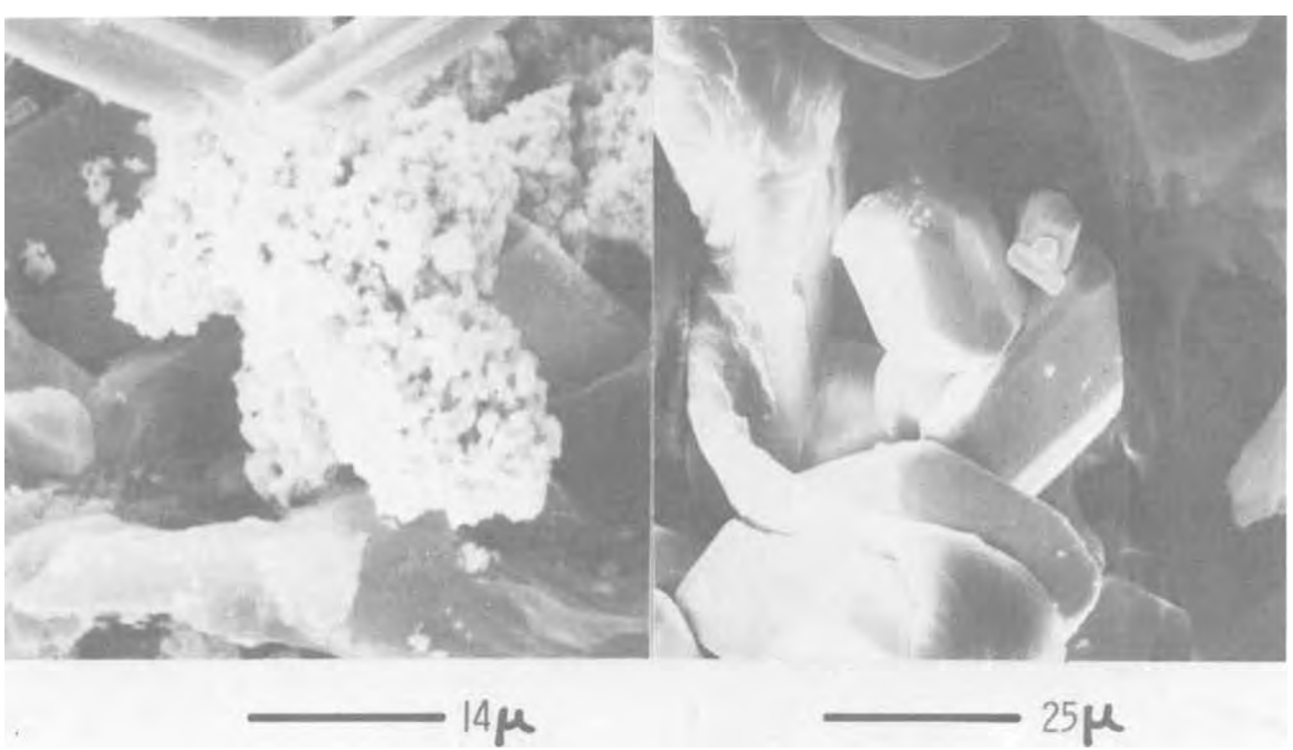

Fig. 4. Scanning electron micrographs of two kinds of crystal growth found in paper separator matrices

The SEM findings are very illuminating. Crystallization and nucleation are very dependent on the degree of supersaturation, S. The finding of two distinct crystal populations shows the ongoing presence of regions in the separator matrix where the degree of supersaturation is different, despite regular changes in solvated species concentration due to battery cycling. The presence of collections of small "cauliflower-like" growths and faceted, well-defined crystals is dependent on (17-19) what are essentially competing processes, nucleation and crystal growth.

Both processes are dependent on the same driving force, the supersaturation, S where

$$S \equiv (C_B/C_E) \quad [3]$$

with C_B the solute concentration in the bulk and C_E the equilibrium saturation concentration of solute.

The growth rate R, and nucleation rate N, are of the form (see Appendix)

$$R = AS^n \quad [4]$$

$$N = BS^m \quad [5]$$

with $m > n$. This means that as S increases in value, what we may call the average crystal size decreases, and the finding of cauliflower clusters indicates we are examining a region of high supersaturation (cf. Fig. 5).

Regions of low supersaturation lead to crystal growth that is slow and orderly, perhaps extending over hundreds of battery cycles (cf. Fig. 6).

Since there is a common electrolyte and soluble Pb-salt species are presumably of the same concentration, the only agency that can create regions of different S-value is the structure of the pore volume distribution of the separator.

The large pores and pore volumes present in paper separators make it possible for regions of low S-value to persist, since in large pores, convective mixing is less inhibited by viscosity and diffusivity effects. Convection can be thermally generated whenever the "cell" or pore under consideration is large. For the case of a cell or pore heated from below, Rayleigh showed no convection could take place if the Rayleigh number R, were less than a critical value R_c, where

$$R \equiv g\beta G_L L^4/\alpha\eta \quad [6]$$

with g, β, G_L, L, α, and η the gravitational constant, the volume expansivity, the thermal gradient at the interface inside the cell, the cell dimension, the thermal diffusivity, and the viscosity (20). This means that for values of R below a critical value ($R_c \sim 1700$), there is no convective mixing.

For battery separators, this indicates that the average pore size plays the crucial role in the mechanism of short-circuit development. In this study, cells which refused charge after some period of cycling invariably had perforation spots and the spots were very rich in total Pb.

This is very suggestive. Hard rubber separators and microporous polyethylene separators do not suffer this kind of failure. Large crystals of Pb-salt were not found in microporous polyethylene separators, while the pores were sometimes occluded with small crystals as shown in Fig. 7.

In an effort to understand these differences, mercury porosimetry was done on separators according to type. The oversize summaries are plotted in Fig. 8. Both paper separators and sintered PVC separators have quite large pores ($\sim 25\mu$) and both have exhibited perforation failure while microporous rubber and microporous polyethylene have not. A visual understanding of pore size differences may be gotten from Fig. 9, a 300X scanning micrograph of four widely used separator matrixes.

Sundberg (21) has related the pore volume distribution of separators to other properties such as resistivity, compressibility when wetted and wettability, and apparent barrier properties for antimony transfer. Since, however, antimony transfer is wholly a diffusion phenomenon (22), the pore size distribution of the separator cannot be a critical factor in preventing antimony transfer, except to the extent convection currents can penetrate the pores or interstices of the separator.

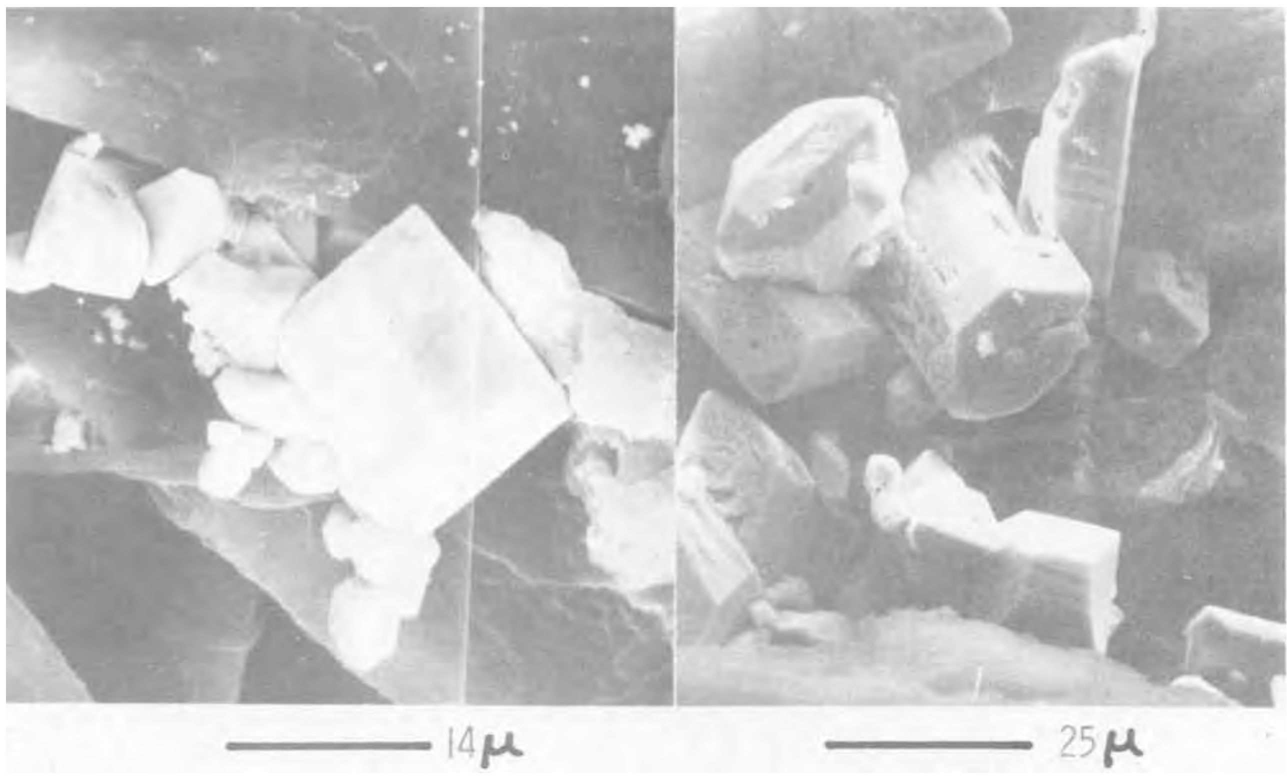

Fig. 6. Scanning electron micrographs of large, faceted diffusion-controlled growth forms of crystals found in paper separator matrix

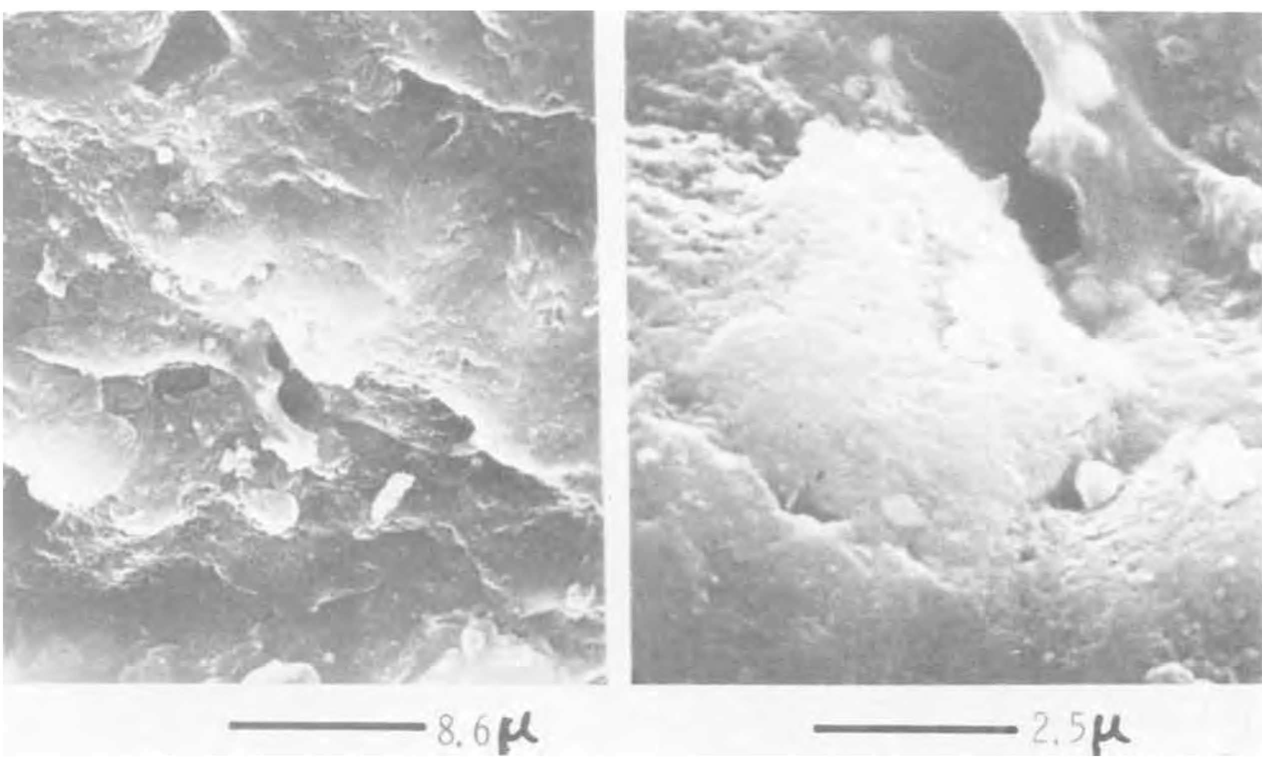

Fig. 7. Scanning electron micrographs of microporous polyethylene separator matrix. Note smallness of pores compared to scattered crystals found in matrix.

A mechanism for perforation failure.—The phenomenon of very large crystal growth in large-pore separators had led us to formulate a speculative mechanism for buildup of Pb-salts and subsequent short-circuit failure. Basic to the mechanism is that larger, well-defined crystals have higher conductivities because there are fewer salt/solution interfaces in the short-circuit path. Then, if a crystal has grown in an orderly fashion inside a large pore or cell, it will certainly provide sites for nucleation-controlled growth when the pore in which it has grown is reduced in size, so that the calculated Rayleigh number is less than the critical value. In Fig. 10 we indicate the basic character of the mechanism: (*i*) A large, diffusion-controlled crystal forms in a large pore, where, since L_{pore} is large, there is convective mixing and the supersaturation is low. (*ii*) After continued, slow growth, the pore dimension is decreased until L_{pore} is small enough. The

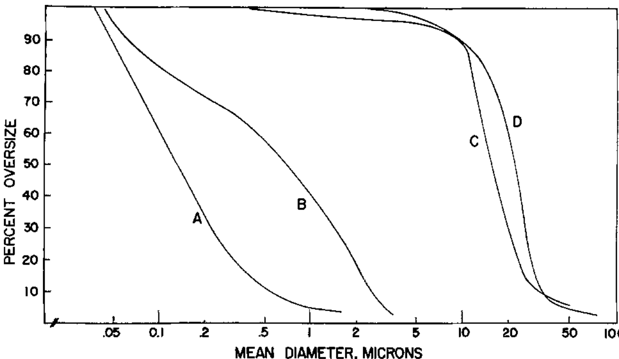

Fig. 8. Pore size distribution curves for four commonly used separator matrices. A, microporous polyethylene; B, hard rubber separator; C, sintered PVC powder separator; and D, resin-bonded paper separator.

Rayleigh number drops below the critical value R_c and nucleation controlled growth ensues until the boundaries of this pore, or cell, are bridged to a neighboring pore. In this way, a bridge of interconnection of low resistivity is formed through the body of the fiber matrix.

Speculative as this mechanism is, there is evidence in SEM studies for its correctness. Figure 11 shows scanning micrographs of nucleation-controlled growth over large crystals. This means that in these neighborhoods the degree of supersaturation went from a period of low values to a period of high value, suggesting the partial correctness of the speculations above.

SEM investigations also help confirm earlier speculations concerning the decrease in crystallinity of the paper matrix of cycled cells. Study of many SEM photos revealed a large number of brittle fractures of separator fibers in regions where there was large crystal growth, confirming, in part, that growth and dissolution processes stretched, and exercised the matrix to a considerable degree.

Large scale brittle fracture should result in broadening of the most intense x-ray diffraction peak, the [002] diffraction maximum. The fiber direction of cellulose coincides with the long axis of the cellulose unit cell (23-25). The main structural element of cellulose, the fibril, has its long axis parallel to the unit cell axis, and as fibers are structured from very large collections of fibrils (8), brittle fracture must reduce crystallite size on the b axis. Fiber rupture, whether brittle fracture across the fibrils or ductile fracture parallel the fibrils, yields an increased accessibility to chemical attack. This is true whether the cellulose model one uses is the crystalline/amorphous model of Clark (23) and others (26, 27), the fringed-micelle model (8), or the protofibril model of St. John Manley (28). As shown by Ant-Wuorinen and his co-workers (12, 13), hydrolysis of knife-milled cellulose leads to limited material loss and some decrease in crystallinity index.

What likely occurs during brittle fracture and knife-milling is creation of end groups with labile hydroxyl groups newly accessible to hydrolytic agents. Rowland, Roberts, and Bose (29) have shown the accessibilities of $-OH$ groups of cellulose structures are related to the state of order of these groups on the surfaces of crystalline regions, with highly crystalline regions possessing fewer accessible $-OH$ groups. Microscopic evidence of brittle fracture, therefore, supports physical and physical/chemical mechanisms leading to the large decreases in crystallinity found in cycled separators. Scanning micrographs of brittle fracture are shown in Fig. 12 and 13. It is noteworthy that brittle fracture was found in the neighborhood of large, regular crystal growth. Such crystal growth will cause both brittle fracture, as seen, but will abrade and compress fiber matrixes due to growth and dissolution of crystal bodies. The brittle fracture and ductile fracture will, certainly, lead to depressed values for the crystallinity.

Other failure mechanisms.—It was suggested that antimony transfer may contribute to failures evidenced by low end of charge voltage. It is well known that antimony diffusion to the negative grid will lower the hydrogen overpotential and lower end-of-charge voltages (21). It is also understood that in a 25% over-

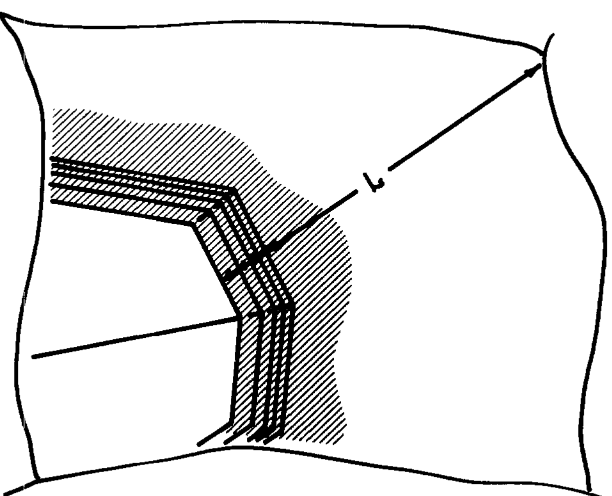

Fig. 10. Diagram of large pore in separator matrix. As the large crystal grows, the pore or cell dimension decreases until nucleation-controlled growth may ensue over the surface of the crystal.

charge program, much of the antimony corrosion capability is removed through stibine evolution during overcharge (30).

In the cycling program used here, starting ECV's were in the neighborhood of 2.85V. Cells with ECV's in the neighborhood of 2.35V invariably had one or more perforation spots (cf. Fig. 1).

In Holland's work (30), older batteries of extremely large capacities (~ 2000 A-hr) were discharged once a week at the 5 hr rate. They were given a quasi-constant potential charge after overnight, open-circuit stand. The degree of overcharge was 10%, and in this very bad case for antimony transfer, after three years or more of cycling, the ECV fell 0.130V; from 2.60-2.47V. Holland's cells, cycled about 180 times, at high rates, with extensive open-circuit stand had no ECV-drops of the order of 0.5V as seen in our studies. There is, however, no clear-cut manner of measuring the degree to which antimony transfer did contribute to failure in this program. We chose to disregard the possible contribution of antimony transfer because of the protective effect of the 25% overcharge used, and because of the 1:1 correspondence between low ECV's and perforated separators. In one case, a battery cycled (Schedule K) for 5 weeks (140 cycles) had end-of-charge voltages of 2.42, 2.81, 2.82, 2.79, 2.78, and 2.46V. The two cells with low voltages had perforated separators, while none of the other four cells had such failures.

Conclusions

The perforation failures of resin-bonded paper separators are high-resistance short circuits, caused, mainly, by a complex mechanism of crystal growth in the large pores of such separators. Resin-bonded paper separators and other separators with large pores (~ 30μ) can provide sites for the growth of large, faceted crystals, and are the only separators that exhibit this kind of failure under working conditions. The growth of well-formed crystals in such matrices is made possible because the pores are large enough to permit convective mixing which sustains the low degree of supersaturation necessary for well-ordered, large crystal growth.

APPENDIX

If we plot the concentration/temperature relationship for a species crystallizing from solution, we obtain, in general, a simple monotonic curve, with the plane divided into two regions: (*i*) unsaturated (inactive) region, and (*ii*) the supersaturated (active) region. What is important is:

There can be no crystallization activity in the unsaturated region,

Spontaneous nucleation can take place, without nuclei or seeds in the active or supersaturated region.

In the active region, in the neighborhood of the curve, nucleation without nuclei is not possible (sometimes called the metastable region).

Growth is possible over the entire active region, and the relationships are summarized in Fig. 14.

The situation is complex, of course, but from a simplified point of view, crystallization is seen as the result of two, competing processes: nucleation and growth. Growth, in turn, is controlled by the rates of integration and diffusion of crystallizing species.

What follows is a simplified treatment of the processes important to crystallization.

Nucleation.—Recalling Eq. [3], we define the degree of supersaturation S according to

$$S = C_B/C_E \quad \text{[A-1]}$$

where C_B is the concentration of crystallizing species in solution far from the interface, and C_E is the equilibrium saturation concentration. According to Kelvin (31)

$$\log_e S = 2M\sigma/RT\rho r \quad \text{[A-2]}$$

where M, σ, ρ, and r are the molecular weight, surface energy, density, and crystal radius. R and T are the gas constant and absolute temperature. From simple principles, the Gibbs free energy change for homogeneous nucleation (32) is given by

$$\Delta G = 4\pi r^2\sigma/3 \quad \text{[A-3]}$$

and if we eliminate the crystal radius r, between these two expressions we arrive at

$$\Delta G = 16\pi\sigma^3M^2/3\ (RT \log_e S)^2 \quad \text{[A-4]}$$

Clearly, the free energy change for nucleation is profoundly affected by S. To see the role of nucleation, competing for labile species in the solution phase, we can set up an Arrhenius rate expression of the form $N = B\exp(-\Delta G/RT)$ where N is the nucleation rate, and B, a constant. Substituting from Eq. [A-4], we obtain

$$N = B\exp(-Z/\log_e{}^2S) \quad \text{[A-5]}$$

with $Z = 16\pi\sigma^3M^2/sR^3T^3\rho^2$ and the rate of nucleation is seen a very strong function of S (17).

Growth.—It is generally assumed growth depends on the difference in concentration at the crystal interface, C_I. We have, then, a growth rate R, given by

$$R = A(C_I - C_E) \quad \text{[A-6]}$$

with $A = A(T, \sigma, \rho)$.

Recalling Fick's law, we can assume, ignoring, for now, the integration process

$$R = V_M D(dC/dx)_I \quad \text{[A-7]}$$

where V_M, D, and $(dC/dx)_I$ are the molar volume, the

Fig. 13. Electron micrographs of brittle fractures. Because of the nature of the growth, it is clear there are compressive stresses in a direction perpendicular to the plane of the paper.

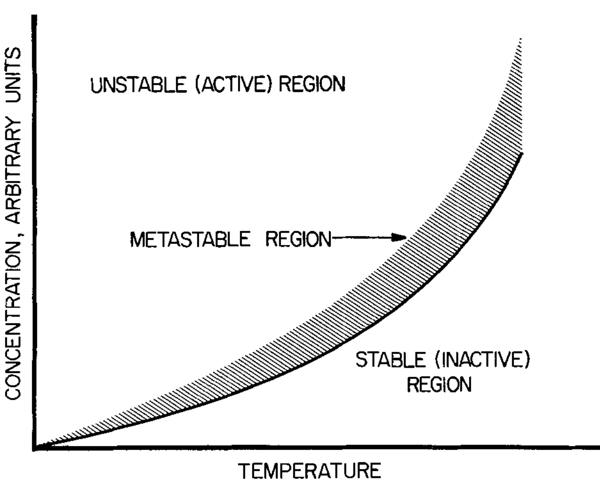

Fig. 14. Concentration/temperature relationship for a dissolved solute crystallizing from solution.

diffusion coefficient, and the concentration gradient for crystallizing species at the interface. We can approximate $(dC/dx)_I$ by $(C_B - C_I)\delta$, where δ is a boundary layer thickness at interface. By rearranging and eliminating C_I, we arrived at the expression

$$R\delta/V_M D + (R/A)^{1/n} = C_B - C_E = (S - 1) \quad \text{[A-8]}$$

The interesting cases of Eq. [A-8] are the well-stirred and the unstirred case. In the well-stirred case, δ/D is quite small, and as $(\delta/D) \rightarrow 0$

$$R = A(S - 1)^n \quad \text{[A-9]}$$

and growth is rapid, competing with the nucleation process itself. This is the situation in industrial crystallizers. In the unstirred case, the boundary layer is thick, and as $(\delta/D) \rightarrow \infty$

$$R = \frac{V_M D}{\delta}(S - 1) \quad \text{[A-10]}$$

and in the static case, growth is a slower, diffusion-controlled process. A graphic summary of these processes is shown in Fig. 15.

Integration.—The over-all rate of growth at the interface depends on two rates: the rate of integration

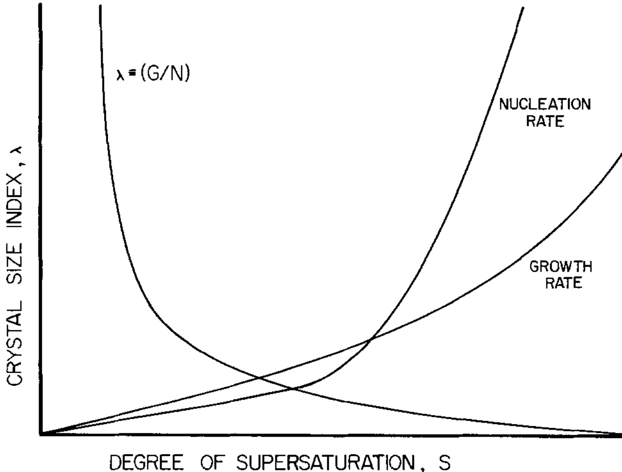

Fig. 15. Crystalline size index as a function of the degree of supersaturation. As the degree of supersaturation increases, growth passes from diffusion control (G), to nucleation control (N). The curves N and G demonstrate the functional dependence of these growth modes on S.

into the crystal and the rate of movement of species to the interface. We can write (17, 32)

$$1/R = 1/r_i + 1(r_o + bu) \quad \text{[A-11]}$$

with r_i the rate of integration, r_o the growth rate if integration is infinitely rapid and $u = 0$, and u is the relative velocity of crystallizing species at the interface. For this study, the unstirred case $(u = 0)$ is of interest. As $u \rightarrow 0$, we obtain

$$R = kr_i r_o/(r_i + r_o) \quad \text{[A-12]}$$

and this produces two limiting cases ([A-13] and [A-14])

$$r_i << r_o, \quad R = k^1 r_i \quad \text{[A-13]}$$

and the rate of integration controls the net growth process

$$r_i >> r_o, \quad R = k^{11} r_o \quad \text{[A-14]}$$

and diffusion controls the process of growth.

Anodic Oxidation of Copper in Alkaline Solutions

I. Nucleation and Growth of Cupric Hydroxide Films

D. W. Shoesmith, T. E. Rummery, D. Owen, and W. Lee

Atomic Energy of Canada Limited, Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba, R0E 1L0, Canada

ABSTRACT

The anodic oxidation of copper in LiOH solution has been investigated by galvanostatic, potentiostatic, and voltammetric sweep techniques. The structure and composition of the films were determined by x-ray and electron diffraction, and by scanning electron microscopy. $Cu(OH)_2$ forms in two layers: a base layer grown by a solid-state mechanism and an upper layer of individual crystals nucleated and grown from solution. The size and number of upper layer crystals are dependent on electrode potential. More anodic potentials produce a large number of randomly deposited crystals, whereas less anodic potentials result in fewer, more highly developed crystals. Increased stirring results in a greater loss of material into solution, and in the extreme, nucleation and growth are completely prevented. For sufficiently low crystallization rates, produced galvanostatically, the thermodynamically stable phase, CuO, is formed. At higher rates the formation of $Cu(OH)_2$ dominates. A nucleation and growth mechanism is given and discussed with reference to other metal systems.

Although the electrochemical behavior of copper metal in alkaline solutions has been extensively studied (1-16), no general agreement has been reached pertaining to the phases formed during anodic polarization in the Cu(II) region. Furthermore, disagreement persists as to the mechanism of formation of the major Cu(II) passivating phases (12, 15, 16).

Halliday (5) has claimed, on the basis of electron diffraction studies, that galvanostatically formed films at room temperature are on a mixture of CuO and $Cu(OH)_2$. This agrees with the results of x-ray diffraction studies of Bouillon *et al.* (6, 7) who also found CuO and $Cu(OH)_2$ in films formed galvanostatically at 25°C. At low anodic current densities, < 0.5 mA/cm², only CuO was detected. Between 0.5 and 0.8 mA/cm², a mixture of CuO and $Cu(OH)_2$ was observed, while at greater current densities, only the hydroxide was detected.

Macdonald (16) observed fine structure in his cyclic voltammograms in the Cu(II) oxidation region, and suggested, based on the work of Bouillon *et al.*, that this is indicative of the formation of both CuO and $Cu(OH)_2$. On the other hand, Ambrose *et al.* (14) concluded that the first peak is due to Cu^{2+} oxidation, whereas the second peak is due to nucleation and solid-state growth of a passivating layer, thought to be $Cu(OH)_2$.

Two mechanisms have been postulated for the passivation of copper in alkaline solutions. Miller (12), on the basis of rotating split-ring disk experiments, claimed passivation by a dissolution-precipitation mechanism. Ambrose *et al.* (14) claimed passivation by a solid-state nucleation and growth mechanism.

In this work, the identity and mechanism of formation of the passivating film has been extensively investigated by a number of electrochemical techniques, coupled with x-ray and electron diffraction and scanning electron microscopy. A detailed reaction scheme for copper passivation is presented and is discussed with respect to other metals exhibiting similar passivation behavior.

Experimental

Measurements were made on copper electrodes (99.99% purity) of 5.0 cm² geometric surface area. Rotating disk experiments were made on 2.5 cm² copper disks embedded in Teflon. Samples were polished with a series of SiC papers and finally with 1 μm diamond paste. Before immersion in the cell, the electrodes were washed in alcohol, acetone, and doubly distilled water. All experiments were performed at 21.0° ± 0.2°C, with one exception as noted below, and in 1 mol/kg LiOH solution. Solutions were prepared from AR lithium hydroxide monohydrate and doubly distilled water.

The electrochemical cell was of the conventional, three electrode design with the working, counter, and reference electrodes separated into compartments by porous glass frits. Platinum foil was used as a counter-electrode and all potentials were measured against a calomel reference electrode at 21.0° ± 0.2°C. The capacity of the cell was ≈ 400 ml. This ensured that during the course of an experiment, the buildup of Cu^{2+} in the bulk of the solution was insignificant.

Potentiostatic experiments were performed with a Wenking Model 70HC3 potentiostat, programmed with a PAR Model 175 universal programmer. Galvanostatic experiments utilized a Hewlett Packard Model 6186B d-c current source with a Dana Model 5330 digital voltmeter coupled to an analog recorder. Electrodes were rotated with a Pine Instruments Model ASR analytical rotator.

Prior to surface examination, electrodes were removed from the cell, washed with doubly distilled water and acetone, and dried in a stream of nitrogen. The changes which might occur after removal of the electrodes from the cell are dehydration of $Cu(OH)_2$ to CuO, and interconversion of CuO and Cu_2O. However, since both $Cu(OH)_2$ and Cu_2O have been identified as single phases on different specimens, and since no oxidation or reduction of specimens has been detected after exposure to air for various lengths of time, it seems unlikely that any significant phase changes occurred after removal from the cell.

X-ray diffractograms were obtained with a Philips vertical goniometer diffractometer and graphite monochromator. Copper K_α radiation and a scan speed of ⅛° 2θ/min were used throughout. Grazing incidence electron diffraction was performed using a Hitachi HU-11A transmission electron microscope at 100 kV. A Cambridge Model 2A stereoscan was used for morphological examination.

Results

Potentiostatic oxidation.—Anodic films grown at potentials between −330 and −170 mV, [Fig. 1(a) and

Key words: corrosion, surface films, crystal growth, dual film formation.

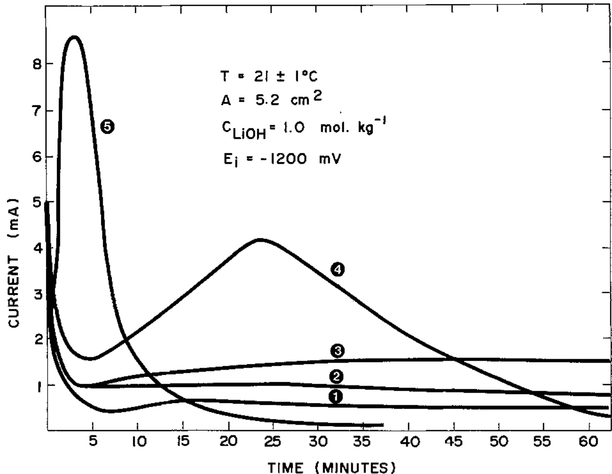

Fig. 1(a). Potentiostatic current-time transients recorded after application of a potential pulse from $E_i = -1200$ mV to: curve 1, -295.0 mV; curve 2, -282.0 mV; curve 3, -276.0 mV; curve 4, -270.5 mV; and curve 5, -265.0 mV.

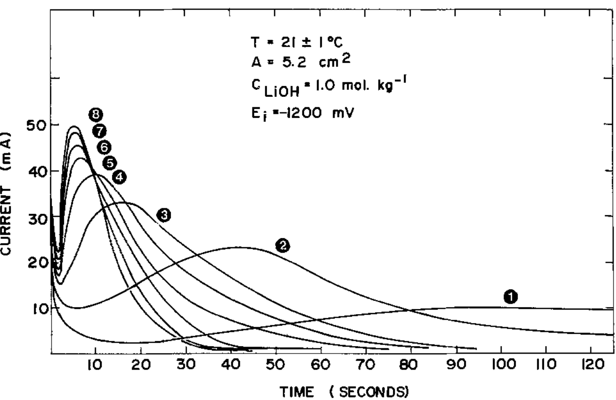

Fig. 1(b). Potentiostatic current-time transients recorded after application of a potential pulse from $E_i = -1200$ mV to: curve 1, -260.2 mV; curve 2, -250.1 mV; curve 3, -239.7 mV; curve 4, -230.0 mV; curve 5, -220.0 mV; curve 6, -210.2 mV; curve 7, -201.0 mV; and curve 8, -182.1 mV.

(b)] show the shape of the current-time transient for a series of potentials between -295 and -182 mV. Films grown potentiostatically for up to 8 hr at potentials between -330 and -280 mV contain only Cu_2O; at -276 mV, the film is mainly Cu_2O with a small amount of $Cu(OH)_2$. For potentials more anodic than -265 mV (up to -170 mV), only $Cu(OH)_2$ could be detected. The appearance of $Cu(OH)_2$ corresponds to the appearance of a peak in the transient curve after the initial sharp decrease.

Scanning electron microscope (SEM) photomicrographs show that the final film grown at potentials > -276 mV comprises crystals having a morphology suggestive of nucleation and growth from solution (Fig. 2).

The charge consumed during oxidation, Q_A, where

$$Q_A = \int_{t=0}^{t=t_p} i_E \cdot dt \quad [1]$$

is independent of potential for $E \gtrsim -220$ mV. In this potential range, SEM results show that the size and morphology of the surface crystals are independent of potential [Fig. 2(c) and (d)]. For more cathodic potentials, a steep increase in Q_A was observed (Fig. 3). SEM results show an increase in size and a decrease in surface density, with the acicular morphology remaining essentially the same [Fig. 2(a) and (b)].

The change in surface coverage for various times at constant potential (-264.9 mV) is shown in the SEM photomicrographs in Fig. 4(a)-(f). The time in the transient at which electrolysis was terminated, and the sample removed for examination, is shown in Fig. 5. Figures 4(a) and (b) show the development of a continuous, apparently porous base film. The surface shown in Fig. 4(a) was demonstrated by electron diffraction to be $Cu(OH)_2$.

The first appearance of individual surface crystals was observed at the minimum in the current-time transient (point b, Fig. 5) as shown in Fig. 4(b). As the current increases toward the maximum, the population and size of the surface crystals increase such that at the maximum (point e, Fig. 5), the surface is approximately 50% covered [Fig. 4(e)]. Beyond the maximum, crystal growth continues until surface coverage is complete [Fig. 4(f)]. Continued electrolysis for periods up to 2 hr after passivation results in no change in the crystal form, although a small constant residual current persists. It should also be noted that an increased porosity in the base layer occurs around the minimum in the current-time curve [cf. Fig. 4(a), and (b) and (c)].

The effect of stirring on the current-time transient is shown in Fig. 5, and the corresponding effect on the nucleation and growth of surface crystals is illustrated by comparison of Fig. 6 and Fig. 2(b). If stirring is vigorous enough, the solution at the electrode surface does not reach saturation, and nucleation and growth are prevented. This is demonstrated in Fig. 7 for a transient recorded at a rotating disk electrode. For the first 30 min of electrolysis, passivation is prevented by rotation at 41.7 Hz (Fig. 7). The absence of upper layer crystal growth on the rotated electrode is obvious even by visual observation. This same effect holds for rotation speeds as low as ~ 5 Hz. As seen in Fig. 7, as soon as rotation is ceased, the current-time transient is of the same form as previously discussed. The greater breadth and smaller value of maximum current shown in Fig. 7, as compared to Fig. 1, are due to residual convection in the solution after rotation is stopped.

If the potentiostatically grown film is reduced at -1300 mV, the charge in the reduction transient, Q_C, is always less than Q_A, indicating loss of material by dissolution during anodic oxidation. This loss is not too reproducible, being dependent on the convective conditions at the electrode surface. Figure 8 shows the charge lost by dissolution, $Q_{diss} = Q_A - Q_C$.

Galvanostatic oxidation.—Current densities from 0.10 to 0.50 mA/cm^2 were used. The majority of experiments were terminated only after the potential had switched to a value at which oxygen evolution occurred. In order to determine the stages of oxidation, a number of runs were terminated at times prior to the switch to oxygen evolution. Figure 9 shows the potential-time transients recorded.

In the current density range 0.12-0.50 mA/cm^2, a mixture of $Cu(OH)_2$, CuO, and Cu_2O was observed when the potential was allowed to progress to the oxygen evolution range. Between 0.12 and 0.20 mA/cm^2, the predominant phase is Cu_2O. Between 0.20 and 0.50 mA/cm^2, the proportion of $Cu(OH)_2$ and CuO increases. At 0.50 mA/cm^2, $Cu(OH)_2$ is the major phase. These results can be correlated to the form of the potential-time transient (Fig. 9). The transients all show the same features. On application of the current, the potential rises to the region $-270 \text{ mV} > E > -280$ mV (region I) and stays in this region for varying lengths of time depending on the current density: the higher the current density, the shorter the time. Subsequently, the potential rises to the region $-260 \text{ mV} > E > -270$ mV (region II). If oxidation is stopped at any point prior to the end of region II, only Cu_2O is formed. The charge measured coulometrically up to the end of region II shows more extensive Cu_2O growth at lower current densities. This conclusion is borne out by

Fig. 2. Surface of copper electrodes potentiostatically oxidized to passivation at (a) −276.0 mV, (b) −265.0 mV, (c) −221.3 mV, and (d) −201.0 mV.

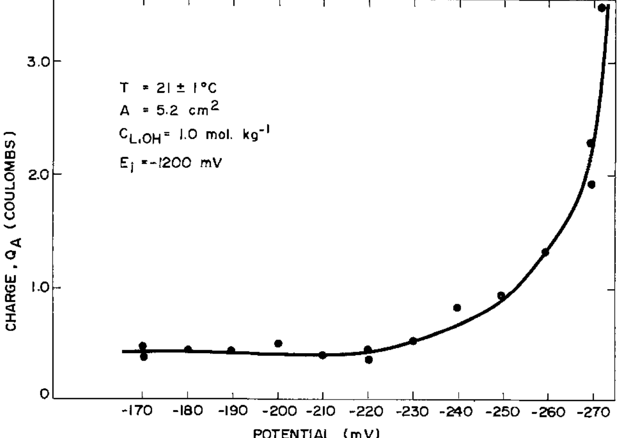

Fig. 3. Anodic charge obtained by integration of the transients in Fig. 1 as a function of applied potential.

x-ray diffraction intensity measurements. The morphology of the Cu_2O film is shown in Fig. 10(a).

Upon entering region III, the potential initially decreases, goes through a minimum, and then increases sharply. This final rise corresponds to passivation and occurs at shorter times for higher current densities. In region III, a mixture of $Cu(OH)_2$ and CuO crystals form [Fig. 10(b)].

If the temperature is increased from 21.0° to 25.8°C, for a current density of 0.16 mA/cm^2, the time to passivation increases (Fig. 9) and the potential in region III falls to −275 mV (compared to −263 mV for a similar current density at 20°C). In this case, only CuO and Cu_2O were detected. The morphology of the film formed at 25.8°C is shown in Fig. 10(c).

Voltammetric oxidation.—Electrodes were oxidized voltammetrically using sweep speeds between 1 and 8.3×10^{-3} mV/sec. Figures 11(a) and (b) show the voltammograms recorded at 1 mV/sec and 8.3×10^{-3} mV/sec, respectively. At slow scanning speeds [Fig.

on the cathodic side of peak III was detected. For sweeps which have progressed into the passive region beyond peak III, the amount of Cu_2O in the film is greater for lower sweep rates and is the predominant phase at 8.3×10^{-3} mV/sec. If the sweep is stopped just beyond the maximum of peak II [Fig. 11(b)], at −265 mV, the major phase is Cu_2O, with a minor trace of $Cu(OH)_2$. At slightly more anodic potentials, around the minimum between the two peaks, the major phase is still Cu_2O, but the proportion of $Cu(OH)_2$ has increased. In neither of these two cases are individual upper layer surface crystals observed. Once the sweep progresses into the region of peak II, a progressively increasing proportion of $Cu(OH)_2$ surface crystals are observed. The passive range, *i.e.*, $E > -250$ mV, corresponds to complete coverage of the surface with individual $Cu(OH)_2$ crystals.

Discussion

Dissolution and passivation mechanisms.—The evidence, both electrochemical and microscopic, shows the nucleation and growth of two different layers of $Cu(OH)_2$ in the potential range −276 to −170 mV, as opposed to the simple dissolution and precipitation model proposed by Miller (12).

In region I, Fig. 5, metal dissolution and base layer growth of $Cu(OH)_2$ occur. The morphology of this layer indicates that growth is via a solid-state reaction [Fig. 4(a)]. No attempt was made to obtain electrochemical data in region I which would allow an exact time dependence of the current to be calculated. However, the SEM results demonstrate that a film growth mechanism is occurring. Also, since the current is very sensitive to solution agitation, it must contain a major metal dissolution component.

Previous work (14) with a rotating disk electrode showed that dissolution occurs as Cu^{2+} and is controlled by the diffusion of Cu^{2+} species away from the electrode surface in the range −320 to −280 mV. For

potentials more anodic than −280 mV, dissolution is consistent with the behavior expected for a partially blocked surface (14). This work has shown that the surface blockage is due to the formation of a porous $Cu(OH)_2$ base layer [Fig. 4(a)-(d)].

In region II, an upper layer is nucleated and grown [Fig. 4(b)-(e)]. Dissolution in region I eventually leads to local saturation close to the electrode surface. At some degree of supersaturation, nucleation occurs. Depending on conditions close to the surface, nucleation could be initiated on the surface, or at an impurity in the solution close to the surface. In principle, homogeneous nucleation in solution is possible but is unlikely to occur without some degree of heterogeneous nucleation. Once nucleation has occurred, crystals grow from the saturated solution, thereby acting as a sink for soluble Cu^{2+}.

The current increase which accompanies this crystal growth can be explained in terms of Eq. [A-7] of the Appendix, which can be written[1]

$$R(t)_{\text{diss}} - R(t)_{\text{depos}} = \frac{i}{n\mathbf{F}A} = (j_b)_{o,t} + R(t)$$

$$= (i_a - i_c)(1 - \theta(t))/n\mathbf{F}A \quad \text{[A-7]}$$

As the crystal growth process proceeds, $R(t)$ increases due to the expanding crystal surface area. This leads to a decrease in the cathodic deposition current, i_c, and hence an increase in the over-all current, i. For this to be the case, the electrochemical supply of Cu^{2+} $[R(t)_{\text{diss}}]$ must be much greater than the rate of incorporation of material at the crystal growth site; *i.e.*, the condition $i_a \sim i_c >> i$ must apply, and crystal growth must be the rate-controlling step.

The term $R(t)_{\text{diss}}$ is the maximum attainable dissolution rate from the base layer. It is the anodic component of the current (neglecting the contribution of the base layer growth).

The over-all dissolution necessary to maintain crystal growth results in an increase of porosity of the base layer (Fig. 4). Whether these pores penetrate to the metal surface, thereby allowing further active metal dissolution, is not known.

Eventually, the crystals begin to impinge upon one another (Fig. 4), and the dissolution reaction is impeded. This leads to a fall in the current due to surface passivation by the upper layer crystals (Fig. 5, region III).

The current at long times (Fig. 5, region IV) can be attributed to residual dissolution, as demonstrated by comparison of chemical and coulometrical analyses in which it was shown that ~90% of the charge in region IV has been used to produce soluble copper. The remaining 10% must have been used to produce further base layer growth.

The above description of the behavior observed in the potential range −265 to −182 mV can be summarized in the following equations in which the subscript "Surf" designates a mobile surface species

$$Cu \rightleftarrows Cu^{2+}_{\text{Surf}} + 2e \quad [2]$$

$$\begin{array}{ccc} Cu^{2+}_{\text{Surf}} & \overset{A}{\rightleftarrows} & Cu^{2+}_{\text{Soln}} \\ B \downarrow\uparrow 2\,OH^- & & A \downarrow\uparrow nOH^- \\ Cu(OH)_{2\,\text{lattice}} & \underset{C}{\overset{(n-2)OH^-}{\rightleftarrows}} & Cu(OH)_n^{(2-n)} \end{array} \quad [3]$$

$$xCu(OH)_n^{(2-n)} \underset{D}{\rightarrow} [Cu(OH)_2]_x + x(n-2)OH^- \quad [4]$$

$$[Cu(OH)_2]_x + Cu(OH)_n^{(2-n)} \underset{F}{\overset{E}{\rightleftarrows}} [Cu(OH)_2]_{(x+1)} + (n-2)OH^- \quad [5]$$

where A represents active metal dissolution; B, base layer formation; C, base layer dissolution; D, nucleation; E, crystal growth; and F, crystal dissolution.

In a previous paper (14), the growth of the electrode film was discussed in terms of a model due to Armstrong (17). The process involves the solid-state nucleation, growth, and overlap of conical centers. No account was taken of the dissolution process, and agreement with the predicted current-time form was obtained only around the current maximum where the nucleation and growth processes dominate the current. In the Appendix, a simplified but more realistic model of the present situation is given. This model can be used to describe the observed behavior qualitatively.

Effect of potential on the crystal growth process.— The characteristic parameters of the current-time transient (i_m, t_m, Q_A) change very little in the potential range −180 to −230 mV [Fig. 1(a) and Fig. 3]. The form of the crystals and the large number produced [Fig. 2(c) and (d)] indicate extensive nucleation (18). This would require a high degree of supersaturation close to the electrode surface. The major limitation on the crystal growth process is probably the passivation of the electrode, leading to a rapid decrease in the rate of supply of material by anodic dissolution. The random nature in which the crystals are deposited on the electrode would suggest that they were grown in solution and subsequently deposited.

For sufficiently anodic potentials, the maximum dissolution rate ($i_a/n\mathbf{F}A$) in Eq. [A-7] will be very large due to its exponential dependence on potential. This maximum rate may be somewhat less than expected due to the presence of the base layer, but must be sufficient to ensure that local supersaturation with soluble copper species is quickly attained, leading to rapid nucleation and growth. The nucleation rate is dependent on the degree of supersaturation attained if initiated in solution, or on the degree of supersaturation and the overpotential if initiated heterogeneously on the electrode surface.

For a rapid nucleation and growth process in quiescent solution, Fig. 8 shows that very little material is lost to solution by diffusion (~10-15%). This corresponds to the condition in Eq. [A-7] where

$$(j_b)_{o,t} << R(t) << R(t)_{\text{diss}} \quad [6]$$

Figure 1(a) shows that the i-t profile is becoming independent of potential at the most positive values. Since the growth rate $R(t)$ determines the current rise, this indicates that a limiting rate of nucleation and growth is attained. This would be expected for both precipitation in solution from very supersaturated solutions and for heterogeneous surface nucleation if all the potentially active sites on the electrode are used for nucleation above $E \simeq -230$ mV.

At less anodic potentials, nucleation and growth are much slower processes [Fig. 1(a) and (b)], implying that the degree of supersaturation attained is much less at these potentials. For $E < -230$ mV, the transient characteristic parameters [Fig. 1(a), (b), and Fig. 3], show significant changes with potential as do the form and number of crystals (Fig. 2). Figure 4 shows that the rate of appearance of crystals on the electrode surface at −265 mV is relatively low. The crystals at this potential have the form expected from fast crystal growth (18). Their opportunity to grow before passivation is large compared to those grown at $E > -230$ mV. This leads to an increase in the total charge accumulated on the electrode surface (Fig. 3). The slower passivation of the electrode also allows

[1] A list of symbols is given at the end of the article.

greater loss of material by diffusion into solution (Fig. 8); *i.e.*, in Eq. [A-7]

$$(j_b)_{o,t} \sim R(t) < R(t)_{diss} \quad [7]$$

Tapering of the crystals begins once the processes have passed the transient peak and entered region III, Fig. 5 [cf. Fig. 4(e) and (f)]. This is probably due to a limitation on the amount of material reaching the growing crystal faces as the surface coverage increases, *i.e.*, for

$$E = -265 \text{ mV, and } \theta(t) > 0.5$$

$$k_a a_s (1 - \theta(t)) < R(t) \quad [8]$$

at the outer extremities of the crystals.

At anodic potentials between -265 and -270 mV, the current-time transient becomes almost symmetrical about the peak. The analysis of Armstrong (17) shows that this corresponds to centers progressively nucleating at a constant rate. A process of progressive nucleation is maintained by a steady supply of material from the electrode as shown by the appearance of the surfaces in Fig. 4.

At $E = -276$ mV, the film is mainly Cu_2O, and $Cu(OH)_2$ no longer forms the passivating layer [Fig. 2(a)]. Now only a relatively small number of nuclei are formed and crystal growth leads to more tabular crystals, indicating a much slower growth process. Loss of material to solution is $\approx 30\%$, *i.e.*

$$(j_b)_{o,t} \sim R(t) \sim R(t)_{diss} \quad [9]$$

The crystals tend to form in clumps, suggesting that the supply of cupric ions from the electrode surface is now uneven and occurring mainly from faults in the underlying layer of Cu_2O. The change in shape of the crystals in going from condition [7] at -265 mV to condition [9] at -276 mV can be explained in terms of the relative growth rates of individual crystal faces. When the metal dissolution process is fast, growth of crystal faces is unimpeded by material limitations and the crystals grow with an acicular geometry ($E = -265$ mV). When the supply of material is limited by slower metal dissolution, the supersaturation is not maintained at the surface of the fast growing faces and the growth rate is correspondingly limited. There may also be a change in the order p in the growth equation (Eq. [A-3], Appendix).

For potentials less than -276 mV, the amount of material lost by diffusion increases markedly, up to 70% at $E = -298$ mV (Fig. 8). The surface is now only composed of Cu_2O, local supersaturation at the electrode surface with Cu^{2+} never being attained.

Effect of Stirring on the Crystal Growth Process.—If artificial convection is introduced into the system, a steady-state diffusion layer will be rapidly established. Figure 5 shows that the current increase due to the crystal growth process is now obscured by the current contribution from material flux away from the electrode surface. The crystal form is much more regular (Fig. 6), indicating that the rate of growth on different crystal faces is now approximately equal. The regular form of the crystals indicates that growth is fairly slow, and that the supersaturation at the individual faces is now low.

For the thin diffusion layer obtained at the rotating disk electrode ($w = 41.7$ Hz, $\delta = 4.9 \times 10^{-4}$ cm), the concentration of Cu^{2+} at the electrode surface is reduced below the solubility limit: *i.e.*

$$(j_b)_{o,t} \sim R(t)_{diss} - R(t)_{depos} \quad [10]$$

Therefore $C_{o,t} < (C_{o,t})_{sat}$, and $R(t) \rightarrow 0$. Under these conditions, no crystal growth is observed, and steady-state dissolution of the metal occurs. For large enough rotation speeds, $C'_{o,t} \rightarrow 0$ and, therefore, $R(t)_{depos} \rightarrow 0$, and the limiting rate of surface dissolution is attained. This condition was investigated previously (14) and dissolution was shown to occur from a blocked surface. This blockage has now been demonstrated to be caused by a base layer of $Cu(OH)_2$. The rise in current when the disk is rotated (Fig. 7) is probably due to the restructuring of the base layer caused by its continuous dissolution and regrowth.

Once the electrode is held stationary again, the current falls as Cu^{2+} builds up at the electrode surface and the reverse rate of deposition (i_c) begins to increase. Eventually supersaturation is attained and nucleation and growth are again observed.

Effect of crystallization rate.—Comparison of free energies of formation of CuO and $Cu(OH)_2$ shows that CuO is more thermodynamically stable than $Cu(OH)_2$ under the conditions of our experiments (19). Hence the formation of $Cu(OH)_2$ in these experiments must have been kinetically controlled. If the current is controlled by growing films at constant currents < 0.3 mA/cm^2, CuO can be obtained in addition to $Cu(OH)_2$ and a large amount of Cu_2O. These currents correspond to low crystallization rates as indicated by the time required for the potential to switch to the oxygen evolution region (Fig. 9, curves 1-4). This is in agreement with the galvanostatic work of other authors (4-7), although Bouillon *et al.* (6, 7) did not report the formation of Cu_2O. The size and morphology of the crystals grown galvanostatically at <0.3 mA/cm^2 are comparable to those of crystals grown under potentiostatic conditions at -276 mV [cf. Fig. 10(b) and 2(a)] where the maximum current density attained in the growth region [Fig. 1(b), curve 3] was 0.29 mA/cm^2.

At 21°C, for low crystallization rates, the rate of dehydration to yield CuO is competitive with the rate of crystallization of $Cu(OH)_2$ and a mixture is obtained. These processes can be represented by the following equations

$$x\text{Cu(OH)}_n^{2-n} \xrightarrow{G} [\text{CuO}]_x + x(n-2)\text{OH}^- + \text{H}_2\text{O} \quad [11]$$

$$[\text{CuO}]_x + \text{Cu(OH)}_n^{2-n} \overset{H}{\rightleftarrows} [\text{CuO}]_{x+1} + (n-2)\text{OH}^- + \text{H}_2\text{O} \quad [12]$$

where the nucleation and growth steps G and H, respectively, are comparable to the equivalent steps D and E for hydroxide crystallization (Eq. [4] and [5]). At 25°C, steps G and H predominate, and only CuO, with a different morphology, is observed [Fig. 10(c)]. The alternative mechanism of CuO formation, by thermal degradation of $Cu(OH)_2$ crystals, is judged to be insignificant at this temperature. Further work with respect to the formation of CuO as a function of temperature is in progress.

Identification of peak doublet in Cu(II) region.—The data of Fig. 11, in combination with the structural and microscopic observations given in the Results section, show that the formation of two peaks in the voltammograms is not due to the formation of a mixture of CuO and $Cu(OH)_2$. The observation of small amounts of $Cu(OH)_2$ around peak II in Fig. 11(b) and the absence of upper layer crystals on the surface up to this point can be attributed to the formation of a base layer of $Cu(OH)_2$. This leads to the inhibition of the anodic dissolution and the generation of peak II. The presence of upper layer crystals on the surface as the current begins to rise into peak III demonstrates that this peak is due to $Cu(OH)_2$ nucleation and growth as previously claimed (14).

Comparison to other metals.—A number of other metal systems exhibit potentiostatic current-time transients similar to that observed here for copper. How-

ever, in some cases, the participation of soluble material is negligible.

For cobalt (20), the current-time transient was interpreted in terms of a solid-state nucleation and growth. This conclusion was confirmed using a rotating ring-disk electrode (25) which showed that the participation of soluble material is negligible in the passivation step.

A simple metal dissolution-hydroxide precipitation process was claimed for cadmium (21) on the basis of rotating ring-disk experiments, even though a current-time transient was observed. Armstrong (26) has pointed out that such evidence does not conclusively prove that a dissolution-precipitation mechanism is operative. Since the *i-t* transients were recorded at an electrode rotation speed of 35 Hz, it seems unlikely that the formation of the film involved participation of a soluble intermediate. However, under less vigorous stirring conditions, the surface concentration of soluble Cd^{2+} could build up sufficiently to produce precipitated material.

The necessity of having accurately controlled convective conditions has been pointed out in the case of zinc in alkaline solution (27-29), and has also been demonstrated previously with copper (14). Potential sweep profiles with zinc under quiescent conditions showed two peaks for very low sweep rates (29) [cf. Fig. 11(b) of this paper], and it is possible that a precipitation and crystal growth process is also involved here. The current-time transient did not show a peak however (28), probably due to the very high metal and hydroxide solubilities.

With aluminum, the rise in current after the early falling transient has been attributed to the nucleation and propagation of pores in a base layer of Al_2O_3 (24). These pores gave increased, field-assisted, dissolution of the base layer as Al^{3+}, and on saturation, a precipitate of $Al(OH)_3$ was formed. This mechanism is based on the claim that the base layer is free of pores during the initial stages. Pore formation is thought to be due to the aggressive action of the proton and the electrolyte anion (22). There is some doubt however, whether such pores are nucleated or are present from very short times in the base layer (23). This behavior could be equally well explained using the arguments presented here for copper. Hence, $Al(OH)_3$ could be formed by precipitation from a locally supersaturated solution and the rise in current due to the growth of precipitate. A similar explanation has been given by Vedder and Vermilyea (30) to describe the corrosion of aluminum. One would expect upper layer formation to be more pronounced in electrolytes in which Al^{3+} is more soluble, such as oxalic and sulfuric acids, and this is borne out by the experimental evidence (22).

APPENDIX

Mass Balance at the Electrode Surface in the Presence of Crystal Growth

The over-all rate of production of Cu^{2+} species at the electrode surface is given by the current, i, where

$$\frac{i}{n\mathbf{F}A} = (k_a a_s - k_c c_{o,t})(1 - \theta(t)) \quad \text{[A-1]}$$

$$= \frac{(i_a - i_c)}{n\mathbf{F}A} \quad \text{[A-2]}$$

k_a, k_c are exponentially dependent on potential. In this simplified model, the current due to base layer growth is neglected.

The rate of crystal growth can be expressed, for one crystal face, by the equation

$$R_n = k_n A_n(t)(c_{o,t} - (c_{o,t})_{sat})^p \quad \text{[A-3]}$$

where p varies between 1 and 2 depending on the degree of supersaturation (31).

For n crystal faces and a nucleation rate dN/dt, the over-all crystal growth rate will be given by

$$R(t) = \int_0^t \left(\frac{dN}{dt}\right)_{t-u} \sum_{i=1}^{n} R(n)\,du \quad \text{[A-4]}$$

where u is the age of a nucleus.

If material used in crystal growth is considered to remain in the plane $x = 0$, *i.e.*, close to the electrode compared to the thickness of the time-dependent diffusion layer, then the condition for the material balance at the electrode surface can be written as follows

$$\frac{i}{n\mathbf{F}A} = D_{Cu^{2+}}\left(\frac{\delta C_{o,t}}{\delta x}\right)_{x=0} + \int_0^t \left(\frac{dN}{dt}\right)_{t-u} \sum_{i=1}^{n} R(n)\cdot du \quad \text{[A-5]}$$

Combining [A-1] and [A-5] yields

$$k_a a_s(1-\theta(t)) = k_c c_{o,t}(1-\theta(t)) + D_{Cu^{2+}}\left(\frac{\delta C_{o,t}}{\delta x}\right)_{x=0} + \int_0^t \left(\frac{dN}{dt}\right)_{t-u} \sum_{i=1}^{n} R(n)\cdot du \quad \text{[A-6]}$$

In abbreviated terms

$$R(t)_{diss} = R(t)_{depos} + (j_b)_{o,t} + R(t) \quad \text{[A-7]}$$

where $R(t)_{diss} = k_a a_s(1 - \theta(t))$; and $R(t)_{depos} = k_c c_{o,t}(1 - \theta(t))$.

The terms on the right-hand side of Eq. [A-7] are interrelated but the relative rates of each process can be seen to be determined by the parameters k_c, $D_{Cu^{2+}}/\delta$, dN/dt, A_n, and k_n.

This statement represents only one condition in the complicated boundary value problem for the system but can be used to explain the effects of a variety of experimental conditions. A more detailed description of the system will be presented in a later communication.

LIST OF SYMBOLS

A	electrode surface area (cm^2)
A_n	surface area of the nth crystal face (cm^2)
a_s	surface activity (mol/cm^2)
$c_{o,t}$	surface concentration of Cu^{2+} species at time t (mol/cm^3)
$(c_{o,t})_{sat}$	equilibrium saturation concentration of Cu^{2+} (mol/cm^3)
$D_{Cu^{2+}}$	diffusion coefficient of $Cu(OH)_4^{2-}$ in solution (cm^2/sec)
E	electrode potential (V)
E_i	initial electrode potential (V)
$\mathbf{F}$	Faraday (coulomb)
i	current (mA)
i_m	current maximum in the potentiostatic transient (mA)
i_a	anodic metal dissolution current (mA)
i_c	cathodic metal deposition current (mA)
$(j_b)_{o,t}$	flux of Cu^{2+} species out of the plane of the electrode surface ($mol/cm^2/sec$)
k_a	potential dependent rate constant for active metal dissolution (cm^2/sec)
k_c	potential dependent deposition rate constant (cm^2/sec)
k_n	rate constant for the growth of the nth crystal face (cm^2/sec)
N	number of nuclei

n number of electrons transferred
Q_A charge consumed during oxidation (coulomb)
Q_C charge consumed during reduction (coulomb)
Q_{diss} charge due to dissolved material (coulomb)
R_n growth rate for the nth crystal face (mol/cm²/sec)
$R(t)_{diss}$ time dependent metal dissolution rate (mol/cm²/sec)
$R(t)_{depos}$ time dependent metal deposition rate (mol/cm²/sec)
$R(t)$ over-all crystal growth rate (mol/cm²/sec)
t time (sec)
t_m time of the current maximum in the potentiostatic transient (sec)
t_p passivation time (sec)
u age of a nucleus (sec)
v potential scan rate (mV/sec)
x distance from electrode (cm)
δ diffusion layer thickness (cm)
$\theta(t)$ degree of electrode coverage

The Anodic Behavior of Gold in Sulfuric Acid Solutions

Effect of Chloride and Electrode Potential

R. P. Frankenthal* and D. E. Thompson

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The anodic behavior of gold has been studied in 1M H_2SO_4 containing 0, 1, and 10 mM HCl at potentials in the passive and in the transpassive regions. The reaction products are soluble Au(III) and an $Au(OH)_3$ film. Their rates of formation and the potential dependence of the rates are functions of the chloride concentration. Chloride promotes the dissolution of gold and reduces the rate of film formation. The composition of the film and the mechanism of its formation are not affected by the presence of chloride in solution. Two mechanisms of oxygen evolution exist. At low potentials, oxygen is evolved on the metal surface; at high potentials, the process occurs on the $Au(OH)_3$ film. At high potentials, the film formation and the oxygen evolution reactions have the same rate-determining steps. The implications of this study to the corrosion of gold conductors on electronic circuits are discussed.

The corrosion of gold is of concern to the electronics industry in the design and manufacture of certain thin film and integrated circuits (1). Although the phenomenology of corrosion failures has been reported, little is known about the basic electrochemical processes that occur. In electronic circuits, the applied voltages between adjacent conductor paths may be greater than 10V. Most of this voltage is dissipated as *IR* drop across the insulating substrate. The fractions of the applied voltage that appear across the anode/substrate and across the cathode/substrate interfaces and that are therefore available for the electrochemical reactions are unknown. Thus, it would be helpful to know the reactions that may occur and the conditions of environment, *e.g.*, temperature and relative humidity, and potential under which they do occur.

The electrochemistry of gold in aqueous solutions is a reasonable starting point for obtaining this information. The subject has been studied by many investigators at potentials below the oxygen evolution potential. The literature up to 1972 has been reviewed by Schmid and Curley (2); more recent publications include Ref. (3-10). Studies of the oxygen evolution reaction on gold have been reviewed by Hoare (11).

* Electrochemical Society Active Member.
Key words: anodic dissolution, chloride, gold, oxide film, oxygen evolution, potential.

In sulfuric acid and in perchloric acid solutions, gold is anodically oxidized between 1.1 and 1.4V (SCE). The passivating film has been estimated to be one to two monolayers in thickness at potentials below the oxygen evolution region (2). At higher potentials, a thicker, poorly adherent film of hydrated Au_2O_3 or $Au(OH)_3$ grows (12). Barnartt (12) and Whitton and Davies (13) observed a linear rate law for growth of the film at constant current. Whitton and Davies also reported that 1.5% of the oxidized gold appears in the solution, with the remainder appearing in the film. The rate of film growth and the rate of gold dissolution have not been studied as a function of potential.

The addition of chloride ions to sulfuric acid or to perchloric acid solutions enhances the rate of gold dissolution but does not affect the potential of passivation (14, 15). There appear to be no studies on the effects of chloride ions on the composition of the films formed or on the rate of film formation and gold dissolution at potentials in the passive and in the oxygen evolution regions.

The mechanism of the oxygen evolution reaction on oxidized gold surfaces in sulfuric acid and in perchloric acid solutions is not fully understood (11). It has not been studied in the presence of chloride ions.

We report here a study of the composition of the anodic films formed on gold and of their rate and mechanism of formation, as well as the rate of gold dissolution, as a function of potential in sulfuric acid solutions with and without added chloride ions. In addition, the results provide further insight into the mechanism of the oxygen evolution reaction.

Experimental

The test specimens were gold foils, 2.7 cm long and 1.2 cm wide. To the top of each was spot welded a gold wire lead. The specimen was immersed in the electrolyte solution so that the air/solution interface was on the wire just above the foil. A two-compartment, three-electrode cell was used. The main compartment, 6.7 cm in diameter, housed the test electrode and two gold-plated platinum foil counterelectrodes spaced 3.5 cm apart and parallel to the gold foil surfaces. A Luggin capillary connected the main cell compartment to a saturated calomel reference electrode. The capillary tip was just below the center of the lower edge of the foil. All potentials are reported relative to the saturated calomel electrode (SCE).

Three solutions were used. The basic electrolyte and one of the solutions was 1M H_2SO_4 (pH 0.0) made from electronic grade concentrated acid that contains < 50 ppb Cl^-. To this was added sufficient HCl to make solutions 1 and 10 mM in HCl. The solutions were stirred with a magnetic stirrer at a reasonably constant rate. They were not deaerated or saturated with any gas, other than those evolved at the electrodes. The solution volume was approximately 250 cm^3. All experiments were conducted at room temperature.

A PAR Model 173 potentiostat with the PAR Model 176 current-to-voltage converter was used. The latter is equipped with an IR-compensator, which was needed because of the high current densities encountered in the oxygen evolution region. The amount of compensation required is a function of the precise positioning of the gold electrode relative to the tip of the Luggin capillary. In a typical experiment, the compensated resistance was 1 ohm. The resistivity of all the solutions is 2.7 ohm-cm.

A Mettler H54 semimicrobalance with a precision of ± 10 μg was used for all weighings. A Marshall tube furnace with a quartz furnace tube and an alumina boat to hold the specimen was used for thermal reduction of the anodic films; nitrogen was passed over the specimen during the reduction process.

The experimental procedure was as follows: The specimen was etched for 15 sec in aqua regia, rinsed with distilled water and then with methanol, and dried in a stream of nitrogen, and its weight, W_1, was measured. The specimen was inserted into the cell and any adsorbed oxygen or thin oxide film was reduced cathodically at -0.5V[1], after which the potential was switched to that to be studied. The time for which each specimen was held at potential ranged from 10^3 to 2×10^4 sec. The times were chosen to give reasonable weight changes in the intermediate potential range, to avoid thick spalling films at high potentials in pure sulfuric acid solution, to avoid excessive dissolution of the gold at high potentials in the chloride-containing solutions, and to give sufficient time to estimate low corrosion rates at low potentials. It was shown that the corrosion rates were independent of time at potential, as long as spalling was avoided. After anodic polarization, the specimen was rinsed and dried, and its weight, W_2, was recorded. Alternate specimens were dipped into 5M HCl for 15 sec and weighed, W_3, or baked at 570°K and weighed, W_4. The HCl dip dissolves the anodic film quantitatively but does not attack the gold (12, 13); this was verified by observing no additional weight loss during exposures to the HCl for times up to 1 hr. At temperatures above 523°K, the anodic film decomposes to metallic gold (16).

Results

The anodic polarization curves of gold in the three electrolyte solutions are shown in Fig. 1 and 2. The addition of chloride ions increases the anodic dissolution rate up to the passivation potential, 1.35V, which is independent of the chloride ion concentration. In the passive and early transpassive regions, the current is also markedly increased by chloride, but the effect diminishes with increasing potential and above 1.9V the current appears to be independent of solution composition.

The data were analyzed in the following manner: From the weights, $W_1, \ldots, W_4$

$W_a = W_2 - W_1 =$ weight change during anodic polarization

$W_f = W_2 - W_3 =$ weight of anodic film

$W_f^O = W_2 - W_4 =$ weight of nongold portion of anodic film

[1] Any weight change due to cathodic reduction was less than the precision of the balance.

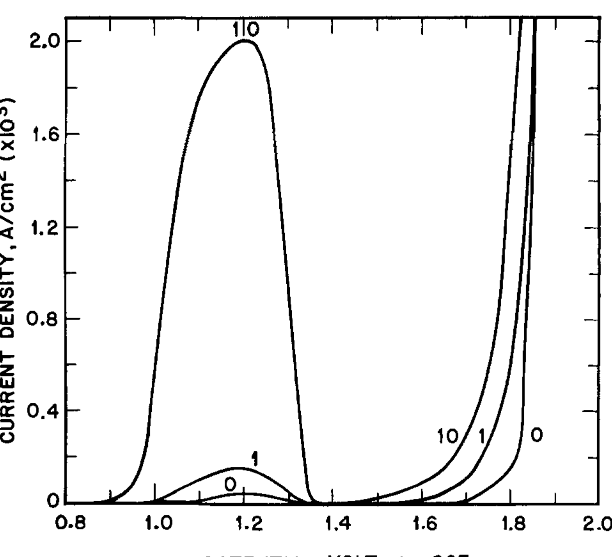

Fig. 1. Anodic polarization curves for Au in 1M H_2SO_4 with and without HCl additions. HCl concentrations (mM) shown on each curve.

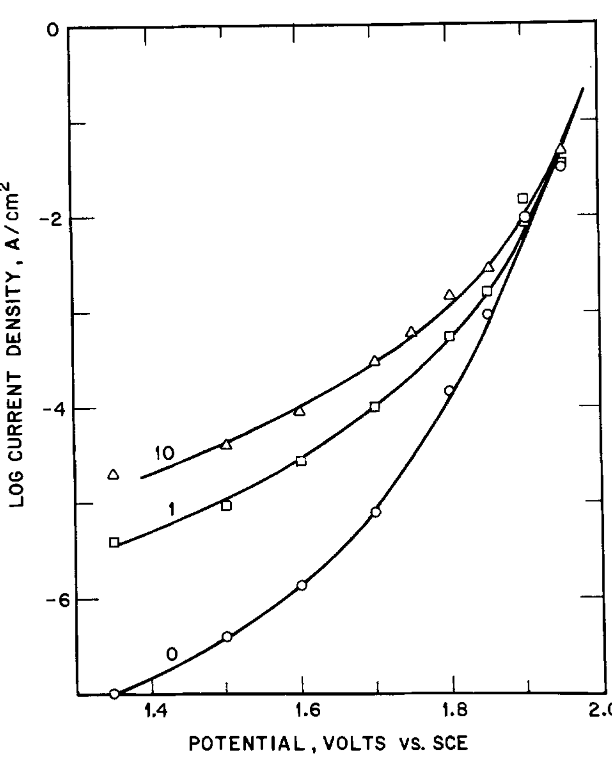

Fig. 2. Anodic polarization curves of Au in 1M H_2SO_4 with and without addition of HCl at potentials in the passive and transpassive regions. HCl concentrations (mM) shown on each curve.

$W_f - W_f^o = W_4 - W_3 =$ weight of gold in anodic film
$W_a - W_f^o = W_4 - W_1 =$ weight of anodically dissolved gold.

From $W_f - W_f^o = W_a - W_f^o$, the known polarization times, and assuming Au(III) as the reaction product, the rates of film formation and anodic dissolution were calculated as current densities and plotted as a function of potential (Fig. 3-5). The reproducibility of the data was ±5% for current densities greater than 1×10^{-5} A/cm^2, decreased to ±10-20% at 1×10^{-6} A/cm^2, and was approximately ±100% for current densities less than 4×10^{-7} A/cm^2.

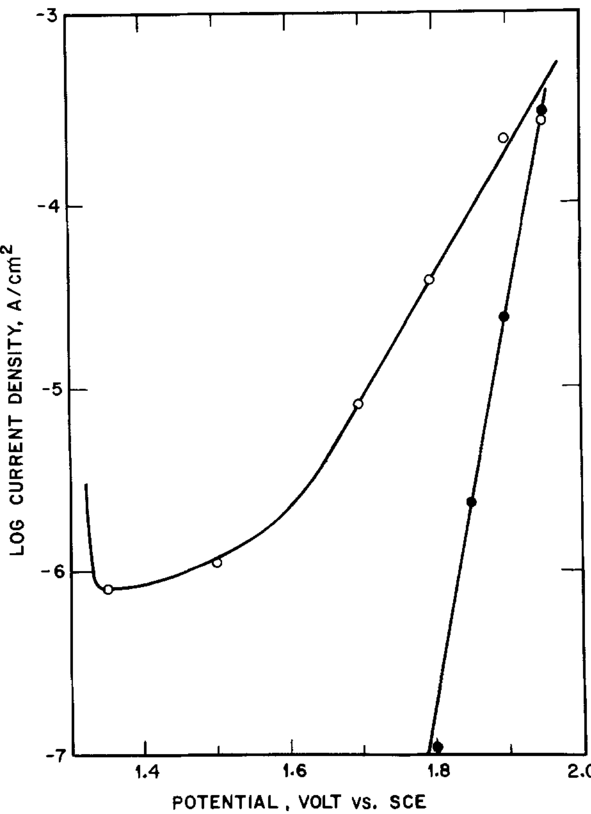

Fig. 4. Anodic oxidation rate of Au in 1M H_2SO_4 + 1 mM HCl as a function of potential. ○, Gold dissolution; ●, film formation.

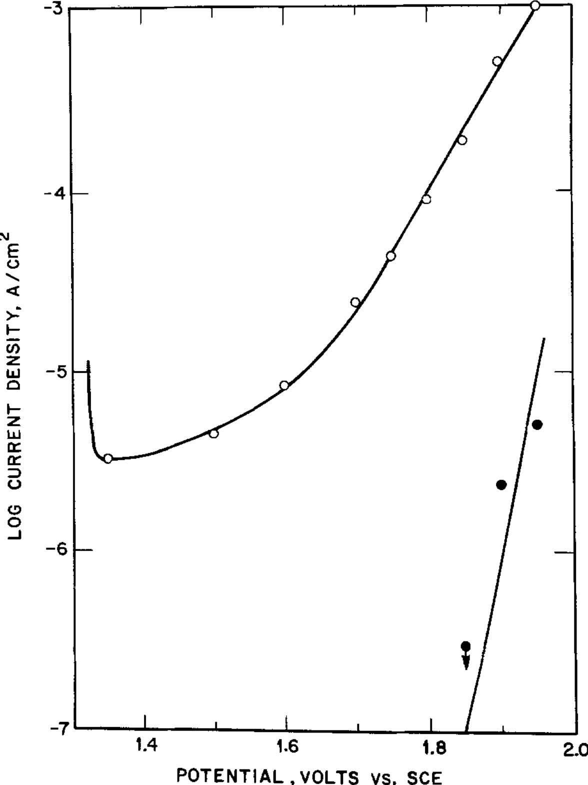

Fig. 5. Anodic oxidation rate of Au in 1M H_2SO_4 + 10 mM HCl as a function of potential. ○, Gold dissolution; ●, film formation. Arrow indicates value less than that shown, which was limit of detection.

Anodic dissolution is observed in each solution. However, chloride clearly increases the rate of dissolution, the Tafel lines shifting 60 mV with a tenfold change in concentration. The Tafel slopes are 147 mV/decade in the two solutions containing chloride and 245 mV/decade in the solution that does not contain chloride.

Anodic film growth is also observed in each solution. The potential at which it begins appears to increase with increasing chloride concentration. Since a current density of 10^{-7} A/cm^2 flowing for 10 ksec corresponds to the oxidation of approximately one monolayer of gold and since the passivating film on gold is one to two monolayers in thickness, it is assumed that a film thicker than the passivating film grows only above a potential E_f° at which the film growth rate is 1×10^{-7} A/cm^2. This potential and the slope of the $E - \log i$ plots for film growth are given in Table I. At 1.85V in the 10 mM chloride ion solution, film growth was not detected, indicating that the growth rate was less than 3×10^{-7} A/cm^2. The line through the data (Fig. 5) was drawn to intersect 1.85V at 1×10^{-7} A/cm^2.

Some of the films formed in 0 and 1 mM chloride ion solutions at 1.90V were subjected to evolved gas analysis, in which the specimen is slowly heated (*ca.* 2°K/min) and the evolved gases are analyzed in a mass spectrometer. For films prepared in either solution, water vapor was evolved continuously at all temperatures from room temperature to about 520°K. Oxygen evolution began at about 410°K; the rate increased greatly above 470°K and peaked at about 530°K. Only traces of $SO_4^=$ and Cl^-, measured as H_2S^+, HCl^+, and Cl^+ in the mass spectrometer, were detected. The last two species were detected only on samples exposed to the solution containing chloride ions. From the weight change measurements, the ratio $(W_f - W_f^o)/W_f^o$, which is the ratio Au/(O + H_2O), was calculated for each experimental condition. The median and the average were both 3.4. The ratios for Au_2O_3 and $Au(OH)_3$ are 8.21 and 3.86, respectively.

By subtracting the sum of the currents for gold dissolution and film formation from the observed current (Fig. 2), the anodic gas evolution current is obtained (Fig. 6). The data are best fit by two lines, as shown previously by Hoare (17). In the low potential region, the rate is markedly increased by chloride, but the slopes of the plots are the same, 163 mV/decade. Hoare (17) obtained a slope of 158 mV. The difference is attributable to the correction for gold oxidation applied in the present study. At high potentials, the current is independent of chloride ion concentration and the slope is 52 mV/decade. Hoare obtained a slope of 50 mV potentiostatically (17) and 47 mV galvanostatically (18). Barnartt (12) and MacDonald and Conway (19) obtained slopes of 45 mV galvanostatically. These other investigations were performed in sulfuric acid without any chloride additions. The points of intersection of the high and the low potential regions are given in Table II. Hoare's (17) data are given for comparison.

Discussion

Gold dissolution.—Gold dissolution is observed in every solution. However, the rate is a function of chloride ion concentration, as well as potential (Fig. 3-5). In the passive potential region ($E < 1.7$V), dissolution and passivation proceed in parallel, probably due to a competitive adsorption between chloride and an oxygen species. The former leads to dissolution, the latter produces passivation. In the transpassive region, a pseudo-Tafel behavior is observed, that is, $\log i$ varies linearly with potential. In the two chloride-containing solutions, the slope is 147 mV/decade, while in the chloride-free solution the slope is 245 mV/decade. The significance of these slopes is not clear. They are probably influenced by at least two factors. First, different reaction products form in the two types of solutions. A chlorogold complex, *e.g.*, $AuCl_4^-$, forms in the solutions containing chloride, while an aquogold complex is the principal product in the other solution. Second, the anodic film may influence the rate of dissolution. The thickness and porosity of the film are, most likely, functions of potential and of chloride ion concentration.

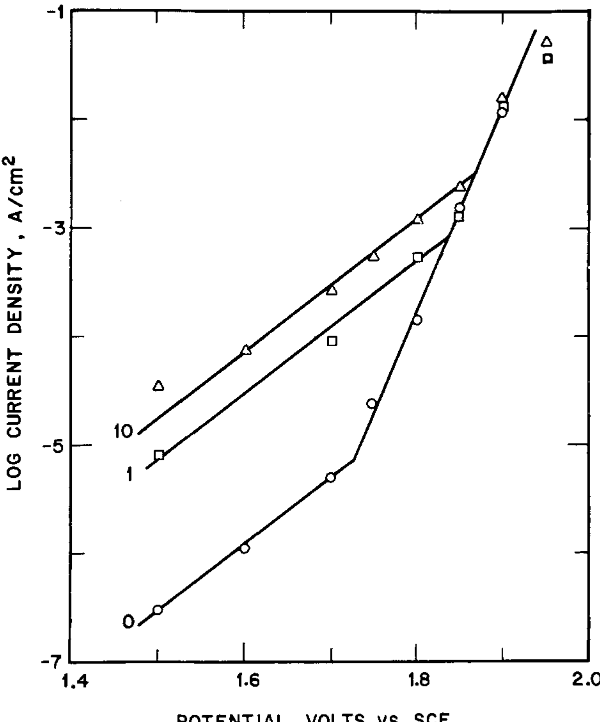

Fig. 6. Anodic gas evolution rate as a function of potential in 1M H_2SO_4 with and without addition of HCl. HCl concentrations (mM) shown on each curve.

Film formation.—The evolved-gas analysis decomposition spectra of films formed in both solutions are those of gold oxide or hydroxide (16). The measured ratio Au/(O + H_2O) indicates the film is $Au(OH)_3$ with some occluded water, in agreement with Barnartt (12). From these analyses and from the lack of dependence of the Tafel slope on chloride-ion concentration, it is concluded that the film composition and film growth mechanism are unaffected by chloride in solution. However, E°_f, the potential at which film growth begins, is shifted in the anodic direction by chloride, thereby reducing the rate of film growth at constant potential.

The effect of potential on the film growth rate is consistent with the "blister" mechanism of growth proposed by Barnartt (12). He, as well as Whitton and Davies (13), observed that the films grew linearly with time at constant current density and proposed

Table I. Characteristics of anodic film growth as a function of chloride ion concentration

(Cl-), mM	E°_f, V	$dE/d \log i$, mV
0	1.75	50
1	1.79	48
10	1.85	50

Table II. Points of intersection of gas evolution plots

(Cl-), mM	E(V)	i(A/cm^2)
0	1.73	8×10^{-6}
0 [Hoare (17)]	1.71	9×10^{-6}
1	1.82	4×10^{-4}
10	1.86	3×10^{-3}

that separation of the film from the substrate occurs locally, permitting access of solution to the film-free surface for further oxidation. Since oxygen evolution should increase the rate of separation, increasing the current density or the potential should increase the rate of film growth (12), as is observed.

Gas evolution.—In each solution, the E-i relation for the gas evolution reaction(s) exhibits two distinct Tafel regions (Fig. 6). In the low potential region, the Tafel slopes are independent of chloride ion concentration; in the high potential region, the current densities are independent of chloride ion concentration. These data are consistent with the measurable evolution (in these experiments) of only one gas, namely oxygen. The simultaneous evolution of chlorine from the 10 mM HCl solution would most likely change the observed E-i pattern. The absence of an observable chlorine evolution reaction is not surprising since the chloride ion concentration in the 10 mM HCl solution is only 2×10^{-4} of the water concentration.

Hoare (17, 18) suggests that in the low potential region oxygen evolution takes place on a gold surface partially covered with adsorbed oxygen, while in the high potential region it occurs on Au_2O_3. The present study verified this suggestion because the potential at which film growth begins, $E°_f$ (Table I), and the potential of intersection (Fig. 6 and Table II) are approximately the same. However, as indicated above, the film is $Au(OH)_3$.

The high potential region is characterized by (*i*) a polarization curve for oxygen evolution that is not affected by the addition of chloride ions to the solution, (*ii*) the presence of an $Au(OH)_3$ film that begins to form at the same potential at which this region begins, and (*iii*) the same Tafel slopes for film formation and oxygen evolution. From (*i*) it is concluded that chloride ions do not participate in the oxygen evolution reaction, just as they do not participate in the film formation reaction. Observations (*ii*) and (*iii*) are consistent with mechanisms for film growth and oxygen evolution that have the same rate-determining step. Further, this step must take place on the film. If it occurred on the film-free surface, the Tafel line should be an extension of the one observed at low potentials and exhibit the same effects of chloride ions.

The most likely rate-determining step, common both to oxygen evolution and to film formation, is the oxidation of water to an intermediate O or OH radical adsorbed on the film. Such radical can react to produce O_2 or $Au(OH)_3$. For the latter to occur, the radical must diffuse to the metal/film interface or Au(III) must diffuse to the film/solution interface. The suggested rate-determining step is similar to the one proposed by MacDonald and Conway (19) for the oxygen evolution reaction without consideration for film formation. They explained the Tafel slope of 45 mV by postulating a dual potential barrier consisting of a film, which was not identified, and the double layer at the film/solution interface.

Corrosion of electronic circuits.—Sufficient relative humidity and ionizable impurities on the insulating substrate surface will reduce the insulation resistance between conductors. This will lead to an increase in the current and in the potential available for the anodic and the cathodic reactions. This study shows that an increase in the potential (or current) increases the oxidation rate of gold. Chloride ions increase the quantity of dissolved gold that may migrate to the cathode and be redeposited to form dendrites that can create short circuits (1). In the absence of chloride, a hydroxide film is the main corrosion product. This will not lead to dendrite formation. On the other hand, the film is not self-limiting, and, given sufficient time, much gold could be consumed. Also in the absence of chloride, some gold does dissolve at very high potentials. Given sufficient time, this could also lead to dendrite formation. Clearly, chloride must be rigorously excluded from electronic circuits with gold metallizations and the insulation resistance must be maintained at a level high enough to prevent the various processes cited above from degrading the gold conductors.

Conclusions

1. In sulfuric acid solutions, with and without added Cl^-, gold is oxidized to a soluble Au(III) species or to a film of $Au(OH)_3$ at potentials in the passive and transpassive regions. The rates of formation of these reaction products and their potential dependence are a function of (Cl^-) in the solution.
2. Chloride promotes the dissolution of gold and reduces the rate of film formation. However, both dissolution and film formation occur at sufficiently high potentials in all solutions studied.
3. The potential dependence of the film growth rate is consistent with the "blister" growth mechanism of Barnartt (12). Neither the mechanism of growth nor the composition of the film are affected by the presence of chloride ions in solution.
4. Two potential regions are defined for the oxygen evolution reaction. At low potentials, the reactions occur on a metal surface that is film free or only partially covered by an adsorbed layer. The rate in this region is a strong function of (Cl^-). At high potentials, the rate is independent of (Cl^-) and the reaction occurs on the surface of the $Au(OH)_3$ film.
5. The formation of $Au(OH)_3$ and the oxygen evolution reaction appear to have the same rate-determining step. This is postulated to be the oxidation of water to an intermediate O or OH radical.
6. To prevent corrosion of electronic circuits, chlorides must be rigorously excluded and insulation resistance must be maintained at a high level.

Acknowledgments

We thank Messrs. Barry Miller and P. C. Milner for many fruitful discussions and P. K. Gallagher for the evolved gas analyses. We are grateful to Professor G. M. Schmid of the University of Florida for putting his chapter on the electrochemistry of gold at our disposal before publication.

Manuscript submitted Nov. 26, 1975; revised manuscript received Jan. 29, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Bell Laboratories.

Mechanism of Anodic Deposition and Cathodic Stripping of PbO_2 on Conductive Tin Oxide

H. A. Laitinen*[,1] and Noel H. Watkins[2]

Roger Adams Laboratory, School of Chemical Sciences, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Deconvolution of potentiostatic current-time curves during anodic deposition of PbO_2 from nitric acid solutions onto antimony-doped tin oxide electrodes permitted three processes to be delineated, viz., double layer charging, formation of nuclei, and growth of nuclei. The formation and growth laws are similar to those previously observed on platinum. Cathodic stripping voltammetry revealed a sharp peak due to reversible reduction of crystalline PbO_2 followed by a rounded hump or irreversible secondary peak attributed to the first fractional monolayer of PbO_2. Electron microscopy revealed randomly sized hemispherical deposits at constant and high overpotential, and well-formed crystals upon prenucleation followed by slow growth. Electron spectroscopy (ESCA) revealed a characteristic sharp Pb $4f_{7/2}$ binding energy peak attributable to Pb(IV) attached to SnO_2, and different from crystalline PbO_2.

In connection with the study of cathodic stripping coulometry as an analytical method for traces of lead (1), it became important to understand the mechanisms of nucleation, growth, and cathodic stripping of PbO_2 on a substrate of polycrystalline, antimony-doped tin oxide.

Fleischmann and co-workers (2-6) have carried out extensive studies of the kinetics of deposition of α- and β-PbO_2 onto platinum surfaces from perchloric acid, nitric acid, and acetate solutions. By choosing conditions appropriately, they were able to focus upon the nucleation and growth steps separately. Thus, if random nucleation occurs at a limited number of nucleation sites, N_0, at a rate proportional to the number of available sites at a given time, the first-order nucleation law is

$$N = N_0[1 - \exp(-At)] \quad [1]$$

where N is the number of nuclei per unit area at time t and A is the potential-dependent nucleation rate constant. For short time intervals at constant potential, this reduces to a linear nucleation law

$$N = N_0 At \quad [2]$$

The corresponding growth law for nuclei preformed at a high overpotential and grown at a lower overpotential is of the form

$$i = at^2 \quad [3]$$

It is assumed that no new nuclei are formed and that the preformed nuclei grow nonpreferentially. Such a current-time relationship was verified for the growth of preformed α-PbO_2 from acetate solutions (2).

If simultaneous nucleation and growth occur at constant overpotential, Eq. [2] and [3] lead to the expectation that the current should be proportional to t^3. Experimentally, the initial current increased with a power of the time greater than 3, unless an induction period t_0 was subtracted from the elapsed time, in which case the expected third-order dependence was observed for short time intervals. Electron micrographs of the lead dioxide deposited at an overpotential of 300 mV showed the hemispherical shapes expected for nonpreferred growth (5). The rate constants for nucleation and growth were evaluated as a function of potential and pH from the current-time curves, and a stepwise mechanism involving the specific adsorption of hydroxyl radicals and lead (IV) hydroxy species was proposed.

Hampson, Jones, and Phillips (7) used a galvanostatic technique to study the PbO_2/Pb^{2+} mechanism on platinum substrates in perchloric acid and acetate media. They concluded that the charge transfer mechanism changes from a single two-electron step at low overpotential (8, 9) to two successive single electron steps at higher overpotentials (7). They regarded the existence of free Pb^{4+} ions in solution as unlikely, and postulated an adsorbed Pb(IV) species which accepts an electron to form an adsorbed Pb(III) hydroxy intermediate, [HO-Pb-OH^+], which rapidly accepts the second electron to form $Pb(OH)_2$.

In the present investigation, the use of a tin oxide substrate, with its high oxygen overpotential and low residual current, permitted the deconvolution of the potentiostatic current-time curves into components due to nucleation, growth, and double layer charging. The use of a ring-disk geometry permitted a direct search for soluble intermediates during the formation and stripping steps.

Experimental

Tin oxide electrodes were prepared by spraying a solution 3*M* in $SnCl_4$, 0.0675*M* in $SbCl_3$, and 1.5*M* in HCl onto a Pyrex glass substrate heated to 550° (10)

[2] Present address: Monsanto Company, Pensacola, Florida 32501.
Key words: lead dioxide, anodic deposition, cathodic stripping, tin oxide, ESCA.

to form deposits 0.75-1.0 μm in thickness. Care was taken to avoid excessive cooling of the surface during bursts of spraying. Three different electrode geometries, namely cylindrical, rotating disk, and rotating ring-disk, were used as previously described (1, 11).

Linear potential sweep experiments were performed with a conventional three-electrode polarograph in conjunction with a linear sweep generator (12) and x-y recorder. Apparatus for double pulse potentiostatic experiments, potentiostatic electrodeposition followed by linear voltammetric stripping, integration of coulombic charge between two preselected potentials, and a four-electrode bipotentiostat for use with the ring-disk electrode have been described (1, 11). Special precautions were taken to prevent loss of potentiostatic control in switching between potentiostatic electrodeposition and linear sweep voltammetry, as well as to minimize interaction between ring and disk currents.

Scanning electron microscopy, using Cambridge Stereoscan and JEOLCO instruments, required minimal sample preparation because both the tin oxide substrate and lead dioxide deposit were conductive enough to render vapor deposition of a metal film unnecessary. The samples were air-dried and electrical contact was made to the tin oxide film by means of conductive silver paint.

Electron spectroscopy (ESCA) experiments were carried out by Dr. Nicholas Winograd, of Purdue University, using a Hewlett-Packard 5950 ESCA spectrometer with monochromatic Al Kα x-rays from a quartz crystal disperser. The spectra were deconvoluted using a du Pont 310 curve recorder.

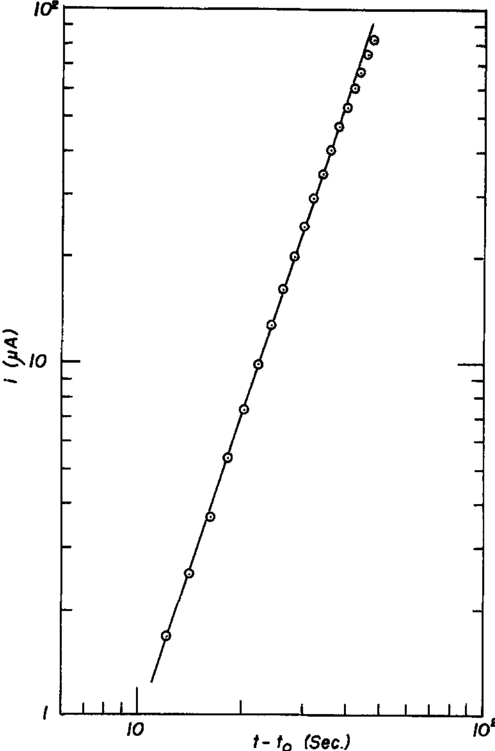

Fig. 1. Variation of log i with log $(t - t_o)$ for potentiostatic deposition at constant overpotential. 1M Pb $(C_2H_3O_2)_2$ in 1M $NaC_2H_3O_2$-1M $C_2H_3O_2H$. $\eta = +0.302V$ vs. PbO_2/Pb^{+2}; $A = 0.2\ cm^2$; $t_o = 12$ sec.

Results and Discussion

Soluble intermediates.—Using the ring-disk electrode, Pb(II) was oxidized to PbO_2 at the disk while simultaneously holding the ring at +0.2V *vs.* saturated calomel electrode (SCE) to observe any current due to the reduction of soluble Pb(III) or Pb(IV) species. With 0.25M $Pb(NO_3)_2$ in 0.01-1*M* nitric acid, no soluble intermediates could be detected. If it is assumed that a soluble intermediate hydrolyzes or oxidizes to form the lead dioxide deposit, a lower limit can be estimated for the homogeneous reaction rate (13, 14). For a soluble intermediate to escape detection at the maximum rotational speed used (211 radians sec^{-1}) we estimate that the first-order reaction rate constant must be greater than $3 \times 10^2\ sec^{-1}$.

In sufficiently acid solution, in the presence of orthophosphate, a soluble intermediate could be detected. With 0.25M $Pb(NO_3)_2$ in 0.08*M* H_3PO_4, a soluble intermediate was detected using 1*M* HNO_3 but not 0.01*M* HNO_3.

These observations are consistent with the findings of Fleischmann and co-workers (2-6) and Hampson, Jones, and Phillips (7), who postulated adsorbed, but not soluble, intermediates of Pb(III) and Pb(IV). They are also consistent with reports of soluble and relatively stable lead (IV)-phosphate species prepared electrochemically in phosphoric acid and sulfuric acid-phosphoric acid mixtures (15-17).

Kinetics of nucleation and growth.—To compare tin oxide with platinum as a substrate, preliminary experiments were carried out under conditions comparable to those used by Fleischmann and co-workers (2, 3). Similar results were found: the current is initially limited by an induction period, followed by nucleation and growth, and finally a steady state due to growth alone. For example, using 1*M* lead acetate in 1*M* acetic acid-1*M* sodium acetate, at an overpotential of 302 mV, an induction period of 12 sec was found to give a best fit for a cubic growth law valid from 15 to 50 sec (Fig. 1). When the surface was prenucleated at high overpotential, the current increased with the square of time. The quantity AN_o (Eq. [2]) was in reasonable agreement with that reported by Fleischmann and Liler (3). While this does not necessarily prove that the number of nucleation sites N_o and nucleation rate constant A are both identical on tin oxide and platinum, the experimentally measured nucleation rates are comparable.

At an overpotential of 600 mV it proved possible to resolve the potentiostatic current-time curve into four distinct regions, corresponding, respectively, to double layer charging, nucleation, crystal growth, and mass transport limited currents. For short time intervals, the mass transport limited current is negligible, as illustrated by the current-time curve for the first 30 msec in Fig. 2.

Neglecting the mass transport limited current, the current-time curve can be represented as the sum of currents due to double layer charging, nucleation, and crystal growth, or

$$i = k_1 \exp(-t/RC) + k_2 N_o (1 - \exp(-At)) + k_3 B N_o (t - t_{nucl})^2 \quad [4]$$

where k_1, k_2, and k_3 are proportionality constants and t_{nucl} is the time required for nucleation. It is assumed that double layer charging occurs quickly compared to nucleation and that nucleation is complete before significant crystal growth has occurred.

Deconvolution of the charging and nucleation currents was facilitated by the plot of log i *vs.* t shown in Fig. 3. The growth current was deconvoluted from the nucleation current by plotting $i^{1/2}$ *vs.* $(t - t_o)$ and selecting t_o for the best fit. The resulting component currents, when summed, are in reasonably good agreement with the observed current (Fig. 2) except in the region of 11-15 msec probably because nucleation is not complete before growth begins, contrary to the assumption made in curve fitting.

Voltammetric stripping.—According to Fig. 2, lead dioxide deposited during the first 10 msec should predominantly exist as crystal nuclei, whereas lead di-

Curve A, experimental current; B, sum of deconvoluted currents; C, double layer charging current; D, nucleation current; and E, crystal growth current.

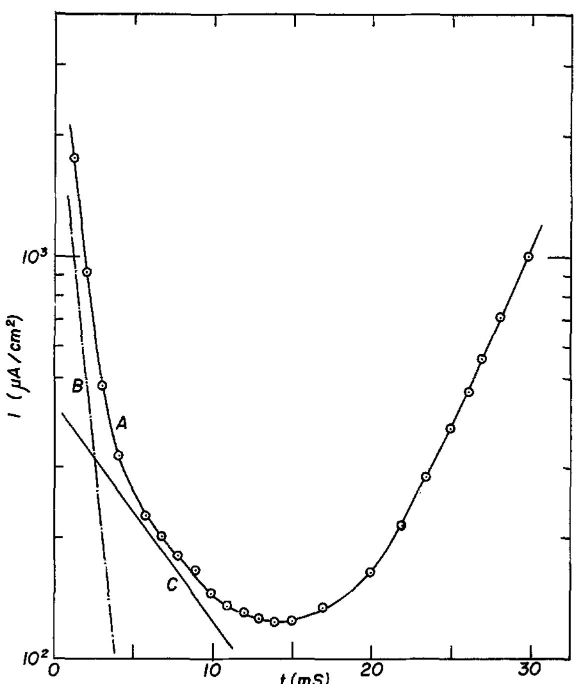

Fig. 3. Variation of log i with time for potentiostatic deposition of lead dioxide on tin oxide at high overpotential. 0.25M $Pb(NO_3)_2$ in 1M HNO_3. $\eta = +0.60V$; $A = 1\ cm^2$. Curve A, experimental; B, double layer charging; and C, nucleation.

oxide deposited for 30 msec should include both the crystal nuclei and the developed crystals. This expectation is fully realized in the stripping peaks observed in linear scan voltammetry (Fig. 4). A primary peak occurring near the reversible potential can be ascribed to the developed crystals, whereas the crystal nuclei appear as a broad secondary peak. Evidently a small amount of nucleation has occurred, in addition to crystal growth, in the time interval of 10-30 msec. On a platinum substrate, the reduction of surface

oxides during the cathodic sweep experiments would completely obscure any observation of secondary reduction peaks such as those observed on tin oxide.

Anodic and cathodic charges are compared in Table I. The anodic charge, obtained by integrating the resolved curves of Fig. 2, was consistently higher than the experimental cathodic stripping charge. This was expected, because the nucleation process is delayed during the double layer charging time, which is not negligible.

To test the nucleation law expressed in Eq. [1], we rewrite it as

$$2.303 \log \left[1 - \frac{Q}{Q_0} \right] = -At \qquad [5]$$

where the ratio N/N_0 has been replaced by Q/Q_0, where Q and Q_0 are the coulombic charges represented by the secondary stripping peak areas observed at time t and long time intervals. The substitution applies to the condition that all nuclei are of the same age and therefore that the crystallites are of uniform size.

A relatively high overpotential (902 mV) was chosen to facilitate the formation of the maximum number of nuclei, and a high lead concentration (0.25M) was used to minimize the anodic current due to oxidation of water and to prevent limiting the deposition by mass transport. A high nitric acid concentration (1M) was chosen to achieve a good separation between reversible and secondary peaks. Figure 5 shows a series of linear sweep stripping curves for deposition times from 0.5 to 10 msec. Each deposition experiment was repeated three times to check reproducibility. At the longer deposition times, the crystal growth had become so pronounced that the secondary peak area had to be

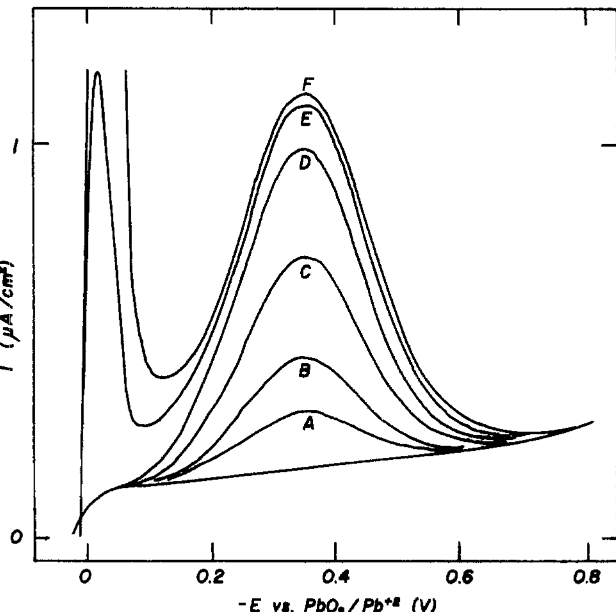

Fig. 5. Voltammetric stripping of lead dioxide deposited at constant overpotential. 0.25M $Pb(NO_3)_2$ in 1M HNO_3. $\eta = +0.902V$; $V = 50$ mV/sec. Time (msec): curve A, 0.5; B, 1; C, 2.5; D, 5; E, 7.5; and F, 10.

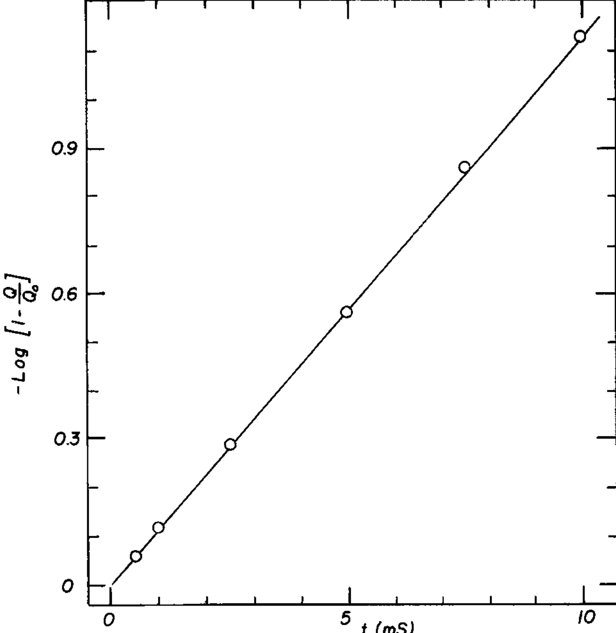

Fig. 7. Variation of log $(1 - Q/Q_0)$ with deposition time for the secondary peak deposited at constant overpotential. 0.25M $Pb(NO_3)_2$ in 1M HNO_3. $\eta = +0.902V$.

estimated by extrapolation, assuming the secondary peak to be symmetrical.

To determine Q_0, a plot of secondary peak charge density *vs.* deposition time (Fig. 6) was extrapolated to long time intervals. The maximum charge density $Q_0 = 8.3$ μcoulomb/cm². This corresponds to approximately 3% of monolayer coverage, which is estimated from the unit cell dimensions of PbO_2 to be 261-315 μcoulomb/cm², depending upon the crystal orientation, if the roughness factor is taken to be unity. Even a smaller fractional coverage would be estimated if a larger roughness factor were used.

A plot of log $(1 - Q/Q_0)$ *vs.* t is shown in Fig. 7. The plot is linear with zero intercept, indicating that at this high overpotential the induction period, if it exists, is less than 50 μsec. The nucleation rate constant A, as determined from the slope, is 208 sec^{-1}. This is to be compared with an extrapolated value of approximately 100 sec^{-1} from a graph of Fleischmann and Thirsk (3) of log A *vs.* $1/\eta^2$ for 0.25M $Pb(ClO_4)_2$ in 0.1M $HClO_4$, in which the highest overpotential used is about 250 mV.

Brainina (19), in a review of film stripping voltammetry, considered the stripping of both thick and thin films at stationary and rotating electrodes. For fractional monolayers, the activity was expressed by an empirical equation

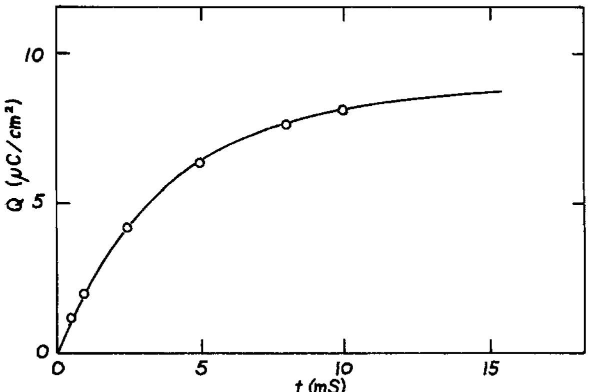

Fig. 6. Variation of secondary peak charge density with deposition time at constant overpotential. 0.25M $Pb(NO_3)_2$ in 1M HNO_3. $\eta = +0.902V$.

$$\alpha = \alpha_\infty [1 - \exp(-\gamma Q)]$$

where α is the activity of the pure phase, Q is the amount of substance deposited, and γ is an empirically determined constant. For the thin film case ($\gamma Q << 1$), a convenient diagnostic test for reversibility is a comparison of stripping peaks obtained under stationary and rotating conditions.

For a reversible cathodic film stripping process, rotation of the electrode should shift the stripping peak potential in an anodic direction by an amount

$$\Delta E_m = \frac{RT}{2F} \ln \frac{1}{\delta^2} \frac{DRT}{nFV} \quad [6]$$

where δ_1 = diffusion layer thickness, cm, and V = rate of potential change, V-sec^{-1}, while the peak current is increased by a factor of about 1.23 for convective mass transport at the rotating electrode as compared with diffusional mass transport at the stationary electrode. For an irreversible process, the back reaction would be negligible and no effect of rotation should be observed.

Experimentally, for the sharp primary reduction peak, the peak current increased by a factor of 1.2 as compared with the theoretical 1.23 and the peak potential shifted anodic by 25 mV as compared with the calculated value of 26.8 mV for the conditions used ($\delta = 1.14 \times 10^{-3}$ cm, $V = 50$ mV/sec). In contrast, the rounded secondary peak showed no shift in peak potential or peak current upon rotation, even under more extreme conditions ($\delta = 1.14 \times 10^{-3}$ cm, $V = 1$ mV/sec) when a peak voltage shift of 82.2 mV would have been expected for reversible stripping.

Other tests of reversibility for the secondary peak (variation of peak current with Q, peak potential with Q, peak potential with V, and peak current with V) likewise indicated qualitatively that the reduction process is irreversible (11).

Scanning electron microscopy.—A deposit of PbO_2 on tin oxide formed at a relatively high overpotential (240 mV) without prenucleation consisted of randomly placed hemispheres of a wide variety of sizes, indicating that nucleation is occurring concurrently with growth, and that growth is nonpreferential (Fig. 8). Preformation of nuclei by a pulse at 900 mV followed by growth at 240 mV gave rise to hemispherical crys-

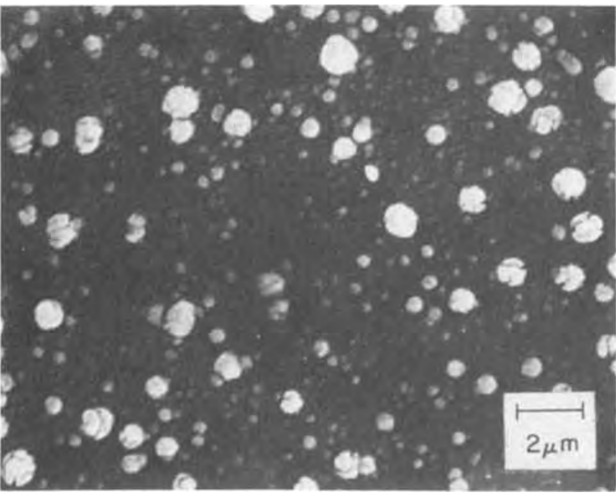

Fig. 8. Scanning electron micrograph of lead dioxide deposited on tin oxide without preformation of nuclei, high magnification. 0.25M $Pb(NO_3)_2$ in 1M HNO_3. $\eta = +0.24V$; $Q = 3 \times 10^4$ $\mu coulomb/cm^2$.

tallites of uniform size. These observations are similar to those of Fleischmann and Thirsk (5) on platinum.

At low overpotential there was evidence for preferred growth orientation of crystallites. As shown in Fig. 9, a deposit grown at a constant current density of 1 $\mu A/cm^2$ upon nuclei preformed at 600 mV overpotential for 50 msec is characterized by clearly discernible crystal faces. This observation is at variance from the statement of Fleischmann and Thirsk (5) that lead dioxide is formed without preferred orientation at high overpotential and also from nitrate solution.

ESCA studies of lead dioxide.—The technique of x-ray photoelectron spectroscopy (ESCA) was applied to monolayer deposits of lead dioxide on tin oxide to gain structural information about the SnO_2-PbO_2 interaction.

Monolayer deposits were made from two solutions, 0.25*M* $Pb(NO_3)_2$ in 1*M* HNO_3 and in 0.08*M* H_3PO_4-1*M* HNO_3, prepared from reagent grade acids and $Pb(NO_3)_2$. Orthophosphate was added to inhibit the formation of reversibly reduced PbO_2 (1). To minimize the reduction of monolayer deposits, the solutions were pretreated by dispersing PbO_2 in them, boiling for several minutes, filtering through a fine porosity glass crucible, and storing the solutions in the dark to prevent photochemical decomposition. The amount of deposit was monitored several times by trial deposition and stripping before the actual sample was prepared. After the deposit was formed and the potentiostat was disconnected, the electrode was rinsed with 1*M* HNO_3 and distilled water and demounted. Within 30 sec from the time of disconnecting the potentiostat the electrode was placed in a vacuum to dry. After drying 20 min the sample was sealed under vacuum in a Pyrex vial. In this manner, samples of one monolayer equivalent could be transferred to vacuum vials with only approximately 20% loss of the original reducible lead. Spectral assignments for Pb $4f_{7/2}$ binding energies are listed in Table II.

Table II. Pb $4f_{7/2}$ spectral assignments

PbO_2 type	Pb $4f_{7/2}$ B.E. (eV)	Assignment
Reversible	137.5	PbO_2, Pb_3O_4
	138.7	Pb_3O_4
Secondary	138.1*	PbO_2-SnO_2

* Width at half height is 1.2 eV.

The spectrum of "reversible" lead dioxide was complicated by the fact that it was especially susceptible to reduction during preparation and may have been present partially as PbO or Pb_3O_4. Winograd (18) has pointed out that Pb_3O_4 gives two Pb $4f_{7/2}$ lines attributable to a structure such as $PbO_2 \cdot 2PbO$. The ratio of the spectral time intensities in the present work varied from one sample to another, due to variation in the amount of PbO_2 reduced.

The spectrum of "secondary" lead dioxide, *i.e.*, that reduced in the broad secondary cathodic peak, had a single sharp $4f_{7/2}$ line which was definitely not attributable to bulk phase PbO_2. We conclude that the initial monolayer of PbO_2 bonded directly to SnO_2 has a perturbed Pb-O bonding insensitive to the crystal face of cassiterite to which it is bonded, inasmuch as the tin oxide layer is known to have a randomly oriented polycrystalline structure. It should be noted that α- and β-PbO_2 do not have significantly different Pb $4f_{7/2}$ electron binding energies, so that the possibility that the initial layer is α-PbO_2 and the bulk is β-PbO_2 is excluded on the basis of the ESCA observations.

An incidental observation was that no phosphorus ESCA spectrum was detected in the samples prepared in the presence of phosphate. Thus the initial "secondary" PbO_2 layer is not a Pb(IV)-phosphate compound, even though subsequent layers formed under these conditions can be described as a basic phosphate of lead (IV) (1). Another observation was that the tin ESCA spectrum was almost completely obscured by the "secondary" monolayer, whereas the "reversible" lead oxide, present as isolated crystallites showed a tin peak as intense as that exhibited by the original tin oxide surface. This is because ESCA has a sampling depth of only 10-20Å and the "secondary" monolayer is a continuous one.

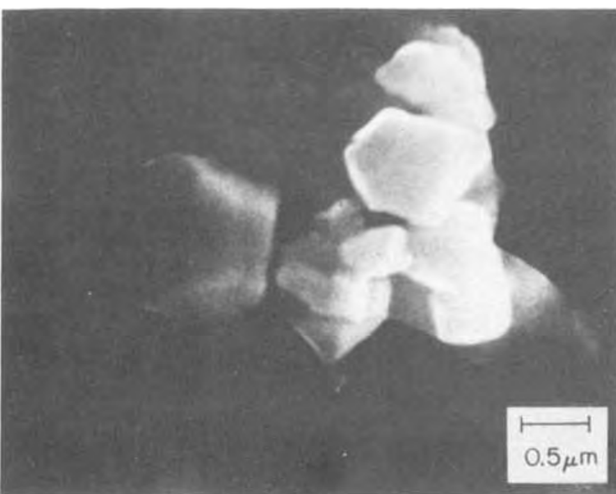

Fig. 9. Scanning electron micrograph of lead dioxide deposit formed at low current density on tin oxide. 0.25M $Pb(NO_3)_2$ in 1M HNO_3. Nuclei preformed at $\eta = +0.6V$ for 50 msec. Grown with constant current density of 1 $\mu A/cm^2$.

Paired Electro-Organic Syntheses

I. Cathodic Adipate with Anodic Bimalonate

Manuel M. Baizer* and R. C. Hallcher

Corporate Research Department, Monsanto Company, St. Louis, Missouri 63166

ABSTRACT

A procedure is reported for the co-electrolysis of ethyl acrylate and diethyl malonate using CH_3CN/Bu_4NI as solvent/electrolyte system to yield diethyl adipate and tetraethyl ethane-1,1,2,2-tetracarboxylate in high (95%) yield and good (60%) current efficiency. A convenient cell which allows experimentation in the 2-5g range was fabricated from a hollowed-out graphite cylinder (optionally lined with lead) which served as one electrode and a graphite rod machined and held so as to be counterelectrode and mechanical stirrer. General aspects of paired organic syntheses are discussed as well as the specific problems that are involved when the paired reactions are hydrodimerization-dehydrodimerization.

It is a truism, of course, that all electrolyses require the simultaneous occurrence of cathodic and anodic reactions. Almost always, however, a synthesis of interest is carried out at only one electrode (the "working" electrode) and a "sacrificial" reaction, without recovery of products, is allowed to proceed at the second (the "secondary," "auxiliary," or "counter") electrode. Ordinarily, in aqueous media, hydrogen or oxygen evolution is used as the respective cathodic or anodic sacrificial reaction. In electro-organic syntheses much ingenuity has been applied in order to assure that the sacrificial reaction produces innocuous products when undivided and even when divided cells are used.

The economic (now including environmental) advantage of devising electrochemical synthetic schemes which employ both electrodes gainfully has often been pointed out (1, 2) along with the difficulties associated with this concept (2). The success of the chlor-alkali industry presents an unending challenge (and frequent taunt) to the organic electrochemist.

Both electrodes are gainfully employed if (*i*) the sacrificial product may be recovered for sale (1) or preferably for synthesis of the starting material of interest, as, *e.g.*, in the reductive coupling of certain organic halides (3); (*ii*) reactions at both electrodes[1] are necessary to produce one given product, *e.g.*, propylene → propylene halohydrin (anode) → propylene oxide (cathode) (4); (*iii*) at least one useful product is produced at each electrode. We suggest that the latter category be denoted "paired syntheses."[2]

As has already been pointed out (2) there is, in addition to the horrendous technical difficulties involved in devising paired electro-organic syntheses, the question of providing outlets for two products formed in equivalent amounts. Even the chlor-alkali and the cumene → phenol + acetone industries face this problem. However, if one of the products of a paired organic synthesis is sold in huge quantities, *e.g.*, aniline, adipic acid derivatives, terephthalic acid, and can be made advantageously electrochemically, it can be used as a "sink" which allows ad lib adjustment of the scale of production of the coproduct.

We report here a detailed laboratory investigation of a paired synthesis (acrylate → adipate + malonate → bimalonate) which was recently described briefly in the literature (6). In the reported procedure[3] graphite electrodes were used in an undivided cell. The solvent/electrolyte system was acetonitrile/potassium iodide. Methyl acrylate and diethyl malonate were present in 10% concentration. The apparent current density was 0.004 A/cm² with an applied voltage of 5-7. The yields of dimethyl adipate and tetraethyl ethane-1,1,2,2-tetracarboxylate[4] were "high."

* Electrochemical Society Active Member.

Key words: paired syntheses, hydrodimerization, oxidative coupling, indirect electrolysis.

[1] This includes both faces of a bipolar electrode.

[2] There has already been occasional reference to this category as "coupled" reactions. Since the latter term has already received widespread use in connection with reactions immediately consequent upon an electron-transfer step (5), we should like to see this practice stopped before it generates confusion.

[3] Supplemented by a personal communication from Professor H. G. Thomas.

[4] The oxidation of malonate to bimalonate by anodically generated iodine but without providing a cathodic organic coproduct had been previously reported (7).

Experimental

Two similar cells constructed of graphite were employed in most of the work reported here. A cylinder 12 cm high × 6 cm in diameter was hollowed out to provide a cylindrical cell 10 cm high × 3 cm diameter. A small copper screw was machined into the top surface of the wall to permit connection to one of the leads from the power source; a threaded opening in the cell wall 9 cm from the bottom allowed attachment of a threaded polypropylene elbow which held a water-cooled condenser. A threaded Teflon part into the top end of the cell served as a bearing for the counterelectrode; a small copper shim screwed into the Teflon provided for electrical contact with the counterelectrode. The counterelectrode, which also served as a mechanically driven stirrer, was constructed from a graphite rod which was machined down to provide two sets of four vanes 15 mm high, one set at the bottom and the second beginning 3.5 cm from the bottom. The maximum diameter of the rod (at the vanes) was 1.7 cm, the minimum (above the vanes) 1.0 cm. One of the cells was lined with lead, leaving an electrolyte chamber 2.2 cm in diameter. The pores of the all-graphite cell were filled with polyethylene by repeatedly soaking the cell in a hot xylene solution of the polymer and then applying light vacuum to pull the solution through the cell wall. The inside was then carefully reamed out to remove surface polymer. The components of the cell are shown in Fig. 1. Direct current was supplied by Sorensen's Nobatron Model RC 150-7.5. For runs in which current efficiencies were determined a calibrated Lectrocount (Royson Engineering Company, Hatboro, Pennsylvania) was used. Electrode potentials were not controlled.

Analytical glc determinations were made using a Hewlett-Packard 5750 instrument. Two different columns and conditions were employed in the analyses: (*i*) 6 ft × ⅛ in., 3% OV-17 on Chromosorb W (80-100 mesh), 50° → 290° at 20°/min; (*ii*) 6 ft × ⅛ in., 1% $AgNO_3$ + 18% Carbowax 20M on Chromosorb W (80-100 mesh), 50° isothermal. Ethyl acrylate and ethyl propionate were determined by method (*ii*), while method (*i*) was used for the remainder of the products.

Identification of the products was made by comparison of the glc retention times under identical conditions and always included the peak enhancement method. Diethyl malonate was used as standard in the quantitative analyses. Structures were confirmed by glc-mass spectra analyses.

The experimental data are assembled in abbreviated form in Table I. A typical procedure (runs 29-34) follows. The cell was charged with 1.0g Bu_4NI and 12 ml of MeCN. The buret for addition of the reagents through the top of the condenser contained diethyl acrylate and diethyl malonate in the quantities indicated together with 5.5 ml of MeCN as solvent. The addition took about 30 min; the electrolysis was continued for 5 min longer. The cell contents were rinsed out quantitatively with MeCN and the solution stored over a trace of hydroquinone.[5] The weighed solution was analyzed by vpc.

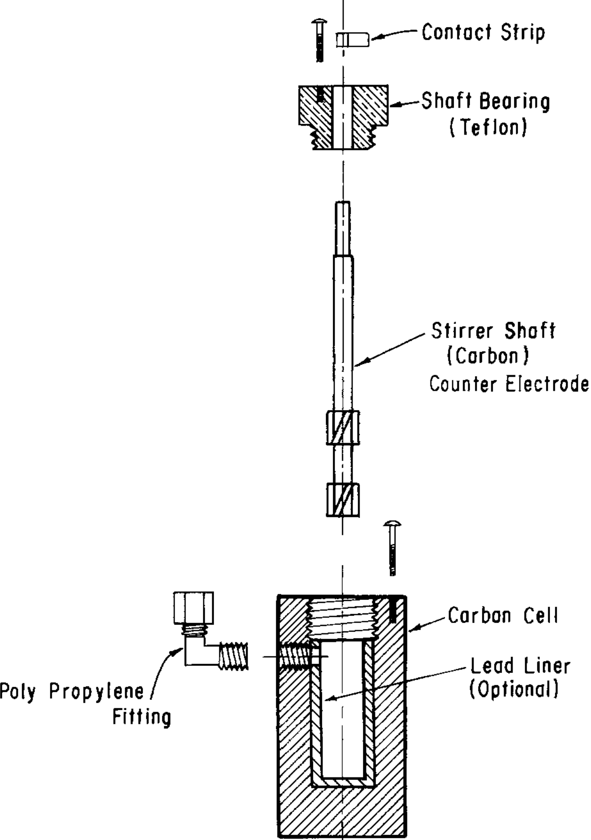

Fig. 1. Cell components

Results

This study of the co-electrolysis in an undivided cell of ethyl acrylate and diethyl malonate in acetonitrile has resulted in a laboratory procedure for obtaining diethyl adipate and tetraethyl ethane-1,1,2,2-tetracarboxylate in *ca.* 95% yield at 87-88% conversion and at *ca.* 60% current efficiency. The only significant by-products were ethyl propionate (3% yield requiring *ca.* 3% of the current input) and the Michael adduct[6] (1% yield); the latter could be degraded by base catalysis to its components (Eq. [7] below). It was concluded that 40% of the current input was consumed in the wasteful iodine-iodide cycle (Eq. [5]).

The quantitative data obtained by analysis of the product solutions of experiments 33 and 34[7] are given in Table II; the chemical yields and current efficiencies based on these same experiments are given in Table III.

Discussion

Co-electrolysis in an undivided cell of acrylate and malonate esters in an inert solvent with an iodide supporting electrolyte involves the following major reactions.

At the anode

$$2I^- - 2e^- \rightarrow I_2 \quad [1]$$

At the cathode[8]

$$2CH_2{=}CHCOOR + 2e^- \rightarrow [ROCOCH(CH_2)_2CHCOOR]^{=} \quad [2]$$

In solution

$$[ROCOCH(CH_2)_2CHCOOR]^{=} + 2CH_2(COOR)_2 \rightarrow ROCO(CH_2)_4COOR + 2[CH(COOR)_2]^- \quad [3]$$

$$2[CH(COOR)_2]^- + I_2 \rightarrow 2[\cdot CH(COOR)_2] + 2I^- \quad [4]$$
$$\downarrow$$
$$[-CH(COOR)_2]_2$$

In addition, the following principal side reactions occurring at or near the electrode or in the bulk of solution can lead to by-products or decrease of current efficiency

$$I_2 \underset{-2e^-}{\overset{+2e^-}{\rightleftharpoons}} 2I^- \quad [5]$$

[5] In many "screening" experiments only ratios of products and by-products were determined.
[6] Table I, footnotes p and q.
[7] Similar results of lesser precision were obtained in experiments 29-32.
[8] We are omitting from this discussion, since it is irrelevant to the results, the still moot question of whether the adipate ester dianion arises by an ec (*i.e.*, dimerization of two acrylate anion radicals) or ece mechanism (*i.e.*, attack of acrylate ester anion radical upon acrylate ester followed by reduction of the dimer ester anion radical).

Table I. Co-electrolyses of ethyl acrylate and diethyl malonate

Expt. No.	Cell[a]	Anode	Cathode	V	mA	mF	Electrolyte (g)	Solvent (ml)	Acrylate (mM)	Malonate (mM)	Product ratios[b]			Other

The challenge of maximizing the yield of and the current efficiency for only two products, adipate, the hydrodimer, and bimalonate, the dehydrodimer, in the midst of a welter of co-existing obnoxious reaction courses requires confrontation by weapons assembled from several fields of current interest to organic electrochemists: reductive coupling (8), oxidative coupling (9), indirect organic electrochemical reactions (10), pK_a's of electrogenerated anion radicals and dianions (11) and of carbon acids (12), rates of proton transfer by carbon acids (13), catalysis of the Michael reaction by electrogenerated bases (14), addition of electrogenerated radicals to vinylic compounds (15), and others. In all cases (Eq. [1]-[14]) rate data are of the essence; in most cases these data are lacking, particularly for competitive reactions and in an environment in which intermediate electrophoric molecules can undergo not only chemical reactions but electron transfers with the appropriate electrode or with other intermediate species. These considerations may previously have served as a deterrent to vigorous activity in the area of paired organic electrochemical syntheses.

The following salient points emerge from an examination of the results summarized in Table I:

1. In our hands the procedure of Thomas and Lux yielded about equimolar amounts of adipate and bimalonate but the Michael adduct was a very important by-product (Expt. 1). The situation was improved (Expt. 3) if the reaction was conducted at reflux.
2. Slow addition of the acrylate to the electrolysis mixture (Expt. 5) reduced the relative yield of Michael adduct considerably, even though KI was still used as electrolyte.
3. Changing the electrolyte to Bu_4NI drastically improved the yield of desired products (Expts. 7-9) provided the rotating rod rather than the cylinder was used as anode. This may be due to less tight ion pairing of R_4N^+ with the anions or to the greater separation of Bu_4N^+ discharge (compared to K^+ discharge) from the acrylate reduction potential.
4. There is an optimum current density (Expt. 8 *vs.* 7 and 9).
5. There is no advantage here in using Pb as cathode instead of graphite (Expt. 12).
6. Other undivided laboratory cells, which do not allow as rapid mixing as Cell B, gave poorer results (Expt. 14-19).
7. A divided cell gave the poorest results of all.
8. Ethyl acrylate gave better results than methyl acrylate (Expt. 8 *vs.* Expt. 10).
9. Expt. 22-27: None of these gave as good results as were previously obtained (Expt. 8) using the same all-graphite cell. The cathode surface, particularly the porosity, had apparently changed due to gradual removal of the polyethylene filler which had been applied.
10. Expt. 28: Applying a new filler treatment, this time with polytetrafluoroethylene, improved matters somewhat but did not restore the good performance that had been found in Expt. 8. It was concluded that, since the cathode surface (Pb) was less likely to have changed in Cell C than the graphite surface had changed in Cell B, it was desirable to proceed using only Cell C.

11. Expt. 29-32: Very favorable reproducible results were obtained. The $< 100\%$ current efficiency is, undoubtedly, due to the unproductive reaction $I^- \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} I^\circ$. In an undivided cell this can be minimized by control of temperature, rate of stirring, distance between the electrodes, etc., *i.e.,* mass transfer of I° from anode to cathode, charge-transfer from cathode to I°, and rate of reaction of I° with malonate anion must be determined and optimized.

12. Expt. 33-34: These were done under approximately the same conditions as Expt. 29-32, but greater care was taken in measuring the inputs, making quantitative transfers, calibrating the ammeter, etc. The material balances and current efficiencies are shown in Tables II and III.

13. Expt. 35: Reconfirmed that charging all acrylate and malonate before electrolysis gave unfavorable results.

14. Expt. 36: Reconfirmed that direct anodic oxidation of malonate anion (using a BF_4^- electrolyte) gave much poorer results than indirect oxidation via anodically generated I_2.

Experiments, not detailed here, on the co-electrolysis of acrylonitrile and diethyl malonate showed that the expected products (adiponitrile and bimalonate tetraester) were, indeed, obtained but that control of byproduct formation (propionitrile and Michael adduct) was more difficult. The use of proton donors (*e.g.,* acetylacetone) as precursors of dehydrodimers would also be anticipated to present problems (9).

The extension of hydrodimerization-dehydrodimerization as a class of paired syntheses similar in scope to reductive and oxidative couplings alone would be greatly accelerated when the rate data referred to above become available.

Acknowledgment

We wish to thank Dr. John Wagenknecht and Kenneth Koncki for supervising the fabrication of the graphite cells and David Hemmerly for polymer treatment of these cells.

Electrogenerated Chemiluminescence

XXVI. Systems Involving Tetraarylpyrroles, Tetraphenylfuran, and Tetraphenylthiophene

Michel Libert and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The production of light upon the electron transfer reaction of electrogenerated radical ions of tetraarylpyrroles [aryl = anisyl (TAP), phenyl (TPP), tolyl (TTP), p-chloro-phenyl (TCPP)], tetraphenylfuran (TPF), and tetraphenylthiophene (TPT) in systems containing these compounds alone in acetonitrile solutions or in mixed systems containing naphthalene, 2,5-diphenyl-1,3,4-oxadiazole, benzophenone, and tri-p-tolylamine is reported. Emission which corresponds to the fluorescence of the TAP, TPP, TTP, TPF, and TPT, as well as longer wavelength emission attributed to exciplex emission for some mixed systems, is observed. The singlet and triplet level energies of the compounds of interest are estimated and their cyclic voltammetric behavior described briefly.

The usual basic requirements for a system which produces light upon the electron transfer reaction of electrogenerated species, *e.g.*, $A^{\overset{-}{\cdot}}$ and $D^{\overset{+}{\cdot}}$ (electrogenerated chemiluminescence or ECL), include the formation of stable radical ions, the fluorescence of at least one of the parent species (A and D), and sufficient free energy release in the $A^{\overset{-}{\cdot}}/D^{\overset{+}{\cdot}}$ reaction to form an excited state. Moreover, efficient ECL systems, such as those involving 9,10-diphenylanthracene and rubrene, involve bulky molecules in which steric effects appear to hinder formation of complexes between the reactant species. Previous studies (1-6) have shown that tetra-aryl substituted five-member ring compounds (pyrroles, furans, and thiophenes)

$X = NH$	$Ar = p\text{-}C_6H_5$
	$Ar = p\text{-}C_6H_4OCH_3$
	$Ar = p\text{-}C_6H_4CH_3$
	$Ar = p\text{-}C_6H_4Cl$
$X = O$	$Ar = C_6H_4$
$X = S$	$Ar = C_6H_4$

form stable radical cations upon electrochemical oxidation. Although their luminescent properties and their behavior upon reduction have not been previously investigated, they appeared to be interesting compounds for ECL studies either as the source of both radical ions or as the radical cation source in mixed systems.

tetraphenylpyrrole	(TPP)
tetraanisylpyrrole	(TAP)
tetratolylpyrrole	(TTP)
tetra-p-chlorophenyl-pyrrole	(TCPP)
tetraphenylfuran	(TPF)
tetraphenylthiophene	(TPT)

Experimental

The preparation and purification of the pyrrole, furan, and thiophene compounds has been described (1-6). Tri-p-tolylamine (TPTA), naphthalene (NAP), benzophenone (BP), 2,5-diphenyl-1,3,4-oxadiazole (PPD), acetonitrile (ACN), and tetra-n-butylammonium perchlorate (TPAP) were obtained and treated as previously reported (7, 8). The benzene was treated with sodium for 48 hr and then distilled and degassed by four freeze-pump-thaw cycles. All solutions were prepared in an inert atmosphere glove box. Solution preparation, experimental procedures, apparatus, and instrumentation were as previously described (7, 8).

Results and Discussion

Fluorescence spectra of these compounds have not been previously described. These were obtained for millimolar solutions in acetonitrile and the position of the emission maxima are listed in Table I along with the u.v. absorbance maxima obtained in previous studies (1-6). The observed emission spectra were not as well defined as those reported for similar, less sterically hindered compounds, such as 4,5-diphenylimidazole (14) so that location of the 0—0 band was not possible. The reported singlet energies (E_s) in Table I were obtained by averaging the energies of the emission spectra and absorbance maxima. This method gives $E_s = 3.45$ eV for TPF as compared to a value of 3.55 eV for 2,5-diphenylfuran as obtained from the well-resolved 0—0 band in the spectrum given by Berlman (14). Cyclic voltammetry (CV) and ECL experiments were generally performed in 2-3 mM solutions of the compound of interest in 0.1*M* TBAP-ACN. For TTP and TCPP, which were not soluble in ACN, a 1:1 mixture of ACN-benzene was employed as solvent. A typical cyclic voltammogram, that for TPP, is shown in Fig. 1. The CV results, given in Table I, show that the radical cations of the pyrroles are very stable while those of the furan and thiophene are moderately stable

Table I. Electrochemical and spectroscopic data[a]

	Cyclic voltammetry[b]				Spectroscopy		
	Oxidation		Reduction

during the time scale of the experiment. For the pyrroles the reductions occur close to the background reduction process with no anodic current observed on scan reversal. For TPF and TPT a clear anodic peak is observed in CV, with $i_{pa} = i_{pc}$ (where i_{pa} and i_{pc} are the anodic and cathodic peak currents).

One series of ECL experiments consisted of electrogeneration of the radical cations of the compounds of interest ($R^{\cdot +}$) and observing the emission during generation of the radical anion of the same molecule ($R^{\cdot -}$) or of NAP, PPD, or BP ($A^{\cdot -}$) (all of which form relatively stable anion radicals). In another series of experiments, the emission from the reaction of the compound radical anion ($R^{\cdot -}$) with the stable electrogenerated radical cation of TPTA (7, 12) ($D^{\cdot +}$) was studied. The ECL results for typical systems are shown in Fig. 1-3, and the results are summarized in Table II. Except for TCPP, the systems involving the pyrrole, TPF, or TPT alone, *i.e.*, as the source of both $R^{\cdot -}$ and $R^{\cdot +}$, showed emission similar to that of the fluorescence of the parent compound. The reaction enthalpy (13), ΔH°, in these cases was about the same as E_S so that direct population of the excited singlet state upon electron transfer is possible. In reactions with NAP, PPD, or BP as acceptors or with TPTA as a donor, as well as for TTP, TPF, and TPT alone, emissions at longer wavelengths were also observed. These will be discussed in more detail for a few of the cases investigated.

TPP(−)/TPP(+).—The cyclic voltammogram of TPP in 0.1*M* TBAP/ACN (Fig. 1) illustrates the stability of $TPP^{\cdot +}$ and the instability of the radical anion. After a cathodic scan in which the radical anion is produced, a reverse scan shows the appearance of a reversible system of −0.23V *vs.* SCE. The nature of this system, probably originating from a reaction of the radical anion, was not investigated further, but was observed with all of the pyrroles investigated in this study, The ECL emission observed in this case was quite bright and stable with time for a frequency of pulsing of 500 Hz (Fig. 1).

NAP(−)/TPP(+).—The reaction enthalpy for the reaction of the rather stable NAP radical anion with $TPP^{\cdot +}$ is somewhat less than E_S of TPP and much less than E_S of NAP. The observed emission consists of a band at 400 nm, where TPP fluoresces, and a longer wavelength band at 445 nm. The former could originate via triplet-triplet annihilation of ^{3}TPP while the latter band can be ascribed to a TPP-NAP exciplex. NAP has been shown to form exciplexes with various donors in ECL in ACN solutions with the energy of the exciplex emission, E_{ex} correlating with the E_{pa} of the donor according to Eq. [1] [note that the same spectrophotofluorometer and photomultiplier tube were employed in this study and the previous one (7)]

$$E_{ex} = 1.27E_{pa} + 1.60 \quad [1]$$

The E_{pa} of TPP of 0.90V *vs.* SCE yields an E_{ex} of 2.73 eV (equivalent to emission at 450 nm) with this equation, which is very close to the experimentally observed value. The longer wavelength emission observed for the PPD(−)/TPP(+) can probably also be ascribed to an exciplex. To examine if TPP-NAP exciplexes could be observed in photoexcitation experiments, the quenching of NAP fluorescence by TPP was investigated. Although TPP was an effective quencher of NAP fluorescence in both ACN and CH_2Cl_2 solutions, no longer wavelength emission was observed. Thus, as has been observed previously (7), formation of the exciplex on direct reaction of the radical ions is

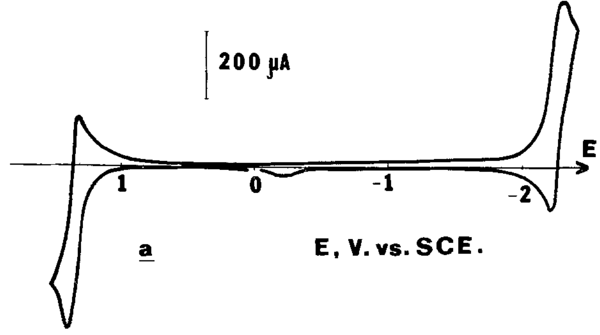
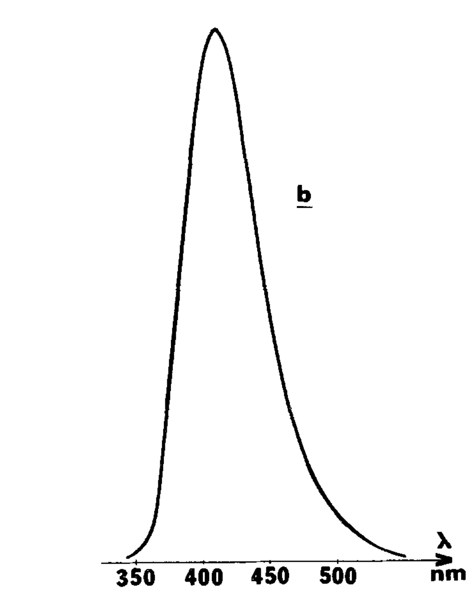
a more efficient route than production via photoexcitation. The low intensity of the ECL in this case probably results from dissociation of the exciplex to the ions or to ^{3}TPP which undergoes quenching and triplet-triplet annihilation reactions.

TTP(−)/TTP(+).—A cyclic voltammogram of TTP (Fig. 2) shows formation of a stable radical cation but the reduction of TTP can hardly be distinguished from the background reduction at *ca.* −2.85V, and the TTP radical anion is quite unstable. Just as with TPP, a new reversible system appears during CV at −0.26V following a reduction scan. In spite of the instability of the anion, the system shows quite stable ECL consisting of two peaks (Fig. 2). The more intense at 410 nm corresponds to ^{1}TTP* formed directly upon the energy sufficient radical ion reaction; this peak consists of emission during the cathodic pulses and shows maximum intensity at higher frequencies (*ca.* 500 Hz). The second peak consists of emission only on anodic pulses and appears only at low frequencies, showing a maximum intensity at 1 Hz. After about 1 hr of ECL experiments, the CV and the fluorescence spectrum are essentially the same as the starting solution. While the longer wavelength peak could be attributed to an excimer, this doesn't appear to be reasonable since it is only found on anodic pulses, it disappears at higher frequencies, and it is not observed for the structurally similar TPP. A better explanation for this emission invokes the production of a reactant during the cathodic pulse which reacts with radical cation to produce light. At high frequencies the extent of the $TTP^{\overline{\cdot}}$ decomposition reaction would be small, but at lower frequencies appreciable side-product would be produced. Evidence of this side-product is not obtained by fluorescence measurements after extended ECL, as is usually found for cases in which emission is observed from radical ion decomposition products (15, 16), so that the side-product, if formed, decomposes during or after the electron transfer reaction.

TPT(−)/TPT(+).—Both radical cation and anion of TPT are stable on the CV time scale (Fig. 3) and the ECL emission which results from the radical ion electron transfer reaction is rather intense with an emission maximum located between 412 and 438 nm, varying from experiment to experiment. Similar results are obtained when NAP, PPD, or BP are the sources of the radical anions. For the BP(−)/TPT(+) system two separate peaks at 418 and 433 nm can be distinguished. In all cases the electrodes are filmed after extended ECL experiments (*ca.* half-hour), resulting in changes in the CV. This filming might account for the lack of reproducibility of the observed emission peak location, if the ECL intensity was changing with time while the spectrum was being recorded. The emission at 410-415 nm is probably that of ^{1}TPT* formed either directly, or for the case of NAP and BP, via triplet-triplet annihilation. The emission at 437 nm could be from a





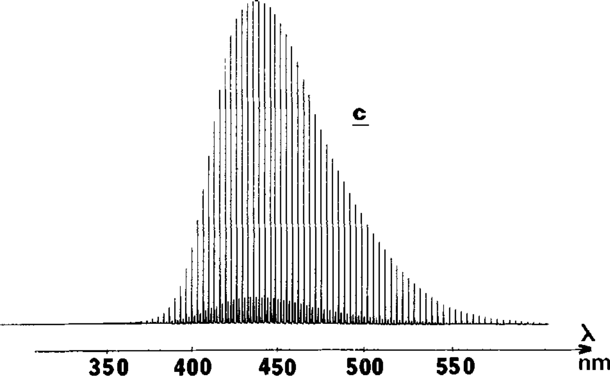


Fig. 3. TPT(−)/TPT(+) system (a) Cyclic voltammogram of 3.4 mM TPT in 0.1M TBAP-ACN at Pt electrode; scan rate, 200 mV/sec. (b) Fluorescence spectrum of 1.8 mM TPT in ACN. (c) ECL of 3 mM TPT in 0.1M TBAP-ACN at 0.25 Hz.

decomposition product of $TPT^{+\cdot}$. Previous studies (6) have shown that *cis*-dibenzoylstilbene can form from decomposition of the radical cation. A solution of this species, prepared by a previously published procedure (17) did not show fluorescence, however.

TPT(−)/TPTA(+).—The ECL in this case shows two distinct peaks: one at 418 nm for anodic pulses and one at 520 nm for cathodic ones. The first peak is again attributable to $^1TPT^*$ formed on triplet-triplet annihilation while the longer wavelength emission can be attributed to an exciplex. The emission maximum observed in this case agrees quite well with the relation found for exciplexes formed in ECL resulting from reaction of $TPTA^{+\cdot}$ with various acceptors (7)

$$E_{ex} = -0.65E_{pc} + 0.86 \quad [2]$$

Triplet levels.—Although TPF and TPT show ECL with BP as the source of radical anion, none of the pyrroles do. One possible explanation might be that the enthalpy of the radical ion reaction (2.4-2.6 eV) is insufficient to produce the corresponding pyrrole triplet. To estimate the triplet energies, phosphorescence measurements of TPP and TTP contained in an ethanol glass at 77°K were performed. The triplet energies found for TPP and TTP, 2.48 and 2.46 eV, respectively (with corresponding lifetimes under those conditions of 2.9 and 2.7 sec), demonstrate that the triplets could be formed in the BP(−)/TPP(+) and BP(−)/TTP(+) systems.

A more probable explanation is suggested by the CV of the pyrrole/BP systems. Upon addition of TPP or TTP to a system containing BP, the reverse current following a reductive sweep forming $BP^{-\cdot}$ is strongly decreased compared to the behavior of $BP^{-\cdot}$ in the absence of these species (Fig. 4). The reversible system centered at −0.23V appears when BP is reduced in the presence of TPP (just as it does for the TPP alone system) even when the negative limit of the cathodic sweep is not sufficiently negative to cause TPP reduction. Thus $BP^{-\cdot}$ reacts in some way with TPP decreasing its lifetime and preventing ECL. Although we did not investigate the nature of this reaction, a possible one involves abstraction of a proton by the $BP^{-\cdot}$

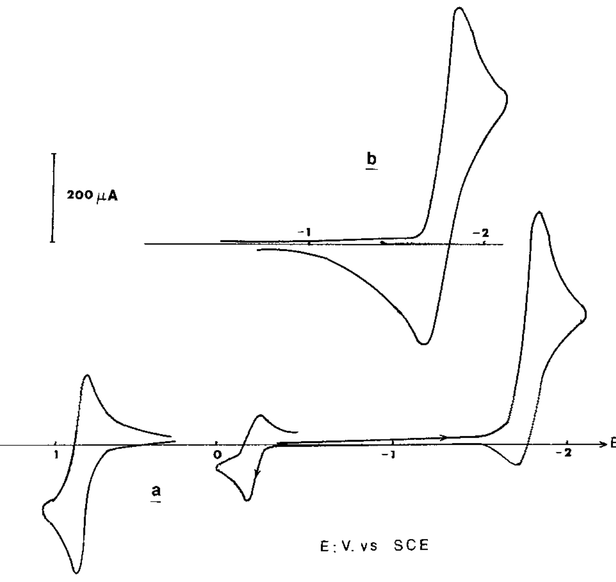

Fig. 4. Cyclic voltammetry of 1.8 mM BP in 0.1M TBAP-ACN at PT electrode with scan rate of 100 mV/sec (a) in presence of 1.7 mM TPP and (b) in absence of TPP.

$BP^{-\cdot}$ + [pyrrole, N–H] → $BPH^{\cdot}$ + [pyrrole, N^-] [3]

with the reversible system at −0.23V then being

[pyrrole anion, N] $\underset{+e}{\overset{-e}{\rightleftarrows}}$ [pyrrole radical, N] [4]

This system could also be formed by reaction of TPP with $TPP^{-\cdot}$, thus explaining the appearance of the reversible systems upon reduction of TPP in the absence of BP. This proton abstraction reaction could not occur, however, with TPF or TPT. Moreover, this explanation is consistent with a previous study (18) which showed that in the presence of a base, *e.g.*, acetate, CV of a TPP solution results in the appearance of a reduction peak at −0.3V, attributed to the reduction of the neutral radical.

Conclusions

A number of systems involving the compounds of interest are capable of producing ECL. While several rather intense systems were found, the lifetime of the systems under the conditions used here were not particularly good and electrode filming frequently occurred. We might note that Zweig *et al.* (19) noticed that the ECL from simple arylfurans was less satisfactory than that obtained from isobenzofuran derivatives. Exciplex formation has been demonstrated on direct radical ion reaction in ACN solutions under conditions where photoexcitation does not produce exciplexes, in agreement with previous results (7, 12). The results here are especially interesting, since the compounds where exciplex emission appears established, TTP and TPT, are rather sterically hindered.

Anodic Oxidation of Anhydrous Methanol

G. Bélanger*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

ABSTRACT

The electrooxidation of anhydrous methanol was studied with several electrochemical techniques. The effect of controlled amounts of water in the nonaqueous system was followed. The product analysis confirmed the production of formaldehyde as the predominant reaction product in this nonaqueous system. The addition of controlled quantities of water brings about changes in the polarization curves presumably owing to the formation of oxides on the platinum surface and to the production of formate ions. Strongly adsorbed species are observed at low anodic polarizations in the completely anhydrous system as well as in the presence of water. The exact nature of these species could not be identified but the formation of a polymeric inert film is suspected. The effect of adsorbed sulfur on the platinum working electrode was also examined; the adsorbed sulfur layer is unstable at high anodic potentials and causes an inhibition of the anodic oxidation of methanol or methoxide ion.

Electrooxidation reactions in nonaqueous solvents have been widely studied, in particular with respect to high energy density batteries and electroorganic synthesis. The electrooxidation of methanol in aqueous solutions has been extensively investigated since this material can be a very attractive fuel in a methanol-air fuel cell (1-3). However, relatively few studies have been carried out to elucidate the anodic reactions of pure anhydrous methanol. Recently such work has been published by Sundholm (4) and Iwakura *et al.* (5); the residual water content was rather high (120 ppm) in the work of Iwakura, and also appreciable in the experiments reported by Sundholm. No special procedures seem to have been undertaken to remove the last traces of water and also to work under conditions where the reacting solutions could be kept anhydrous (4,5). In the present work the residual water content was kept as low as possible (below 10 ppm) and the experiments were carried out in a controlled atmosphere enclosure where the anhydrous conditions remained unchanged.

In recent years, attempts have been made to increase the electrochemical activity of electrodes for the electrooxidation by adsorbing sulfur, among other materials, on the working electrode (6-9). Here, the effect of this additive on the electrooxidation of methanol is explored further.

Experimental

The purification of methanol and the electrochemical polarization experiments were carried out in a controlled atmosphere chamber supplied by Vacuum/Atmospheres Corporation, Model HE454. Under a dynamic flow of argon, the residual water and oxygen content could be maintained in the few ppm range. The methanol was dehydrated according to the following procedure (10): commercial spectro-grade methanol was distilled once after the dissolution of metallic sodium in it; this distilled methanol was then refluxed for one day over magnesium turnings with traces of iodine; this solution was then distilled and the distillate kept in a glass bottle in the controlled atmosphere chamber. All these procedures were carried out under controlled atmosphere. Determination of the residual water was performed with a modified automatic Karl-Fischer titration apparatus, the Aquatest II; the result of this analysis indicated a residual water content below 10 ppm. The desired concentration of sodium methoxide (the electrolyte solute) was obtained by the dissolution of metallic sodium in the purified methanol.

The steady-state automatic polarization curves were obtained for 20 mV potential steps using electrochemical apparatus and method described previously (11); the electronic apparatus were located outside the controlled atmosphere chamber and the electrical contacts were made via appropriate feedthroughs. A separate electrochemical system was used outside the chamber to carry out the electrode coverage experiments in aqueous solutions. This second electrochemical cell was equipped with a system allowing the electrode to be rinsed thoroughly with deoxygenated 1*N* Ultrex sulfuric acid. This second aqueous system is required to provide a source of oxygen in the oxidation of the species adsorbed on the electrode in the nonaqueous medium. The transfer of the electrode from the dry box to the aqueous system was performed under argon atmosphere, keeping the exposure of the electrode to the ambient air to a strict minimum.

The description of the instruments and the method used for the determination of the electrode coverage are described elsewhere (12). The integration of the current for the determination of the electrode coverage during anodic or cathodic potential sweeps was performed either by a manual method or electronically as described previously (12).

The analysis of formaldehyde in concentrated methanol requires a method different from the one

* Electrochemical Society Active Member.

Key words: methanol, nonaqueous, electrooxidation, fuel cells.

used when the product is analyzed in water or air. Due to the presence of concentrated methanol in the solution, gas chromatography proved to be inadequate in the separation of these compounds in the concentration range used (<100 ppm). The only spectrophotometric method that yielded adequate results was based on the use of the Hantzsch reaction with 2,4-pentanedione as the reagent and the procedure described by Yablochkin (13).

In the experiments, when the electrodes were covered by sulfur, the procedures described by Loucka (8,9) for carrying out the adsorption of sulfur on the electrode were used.

All potentials in anhydrous methanol are referred to a reference electrode of Ag/AgCl in KCl-saturated methanol solution. The potential value of this reference electrode *vs.* the RHE in the same solution was observed at +0.55V. This reference electrode proved to be stable as a function of time and unaffected by the difference in water content of the methanol solutions.

A Beckman Model 188501 platinum disk rotating electrode was used in experiments requiring controlled convection conditions. The disk electrode was polished on a felt with methanol, rinsed in methanol, and dried under vacuum. All electrodes were polarized galvanostatically with a cathodic current in a separate cell to reduce any adsorbed oxygen or oxides, prior to the actual polarization experiments (steady-state, potentiodynamic, or galvanostatic charging curves). The experiments were carried out at room temperature (24° ± 1°C).

Results

Product analysis.—The constant current polarizations (5 $mA\text{-}cm^{-2}$) in a small volume cell (15 cm^3 for the working compartment) were carried out in anhydrous methanol and in solutions with controlled additions of water. The quantitative product analysis was performed only for formaldehyde. No other detectable products could be found by gas chromatography or by mass spectroscopy for the electrolysis time and current density used, typically 300μ equivalents. No specific tests for formate were carried out.

The results are presented in Table I. It is observed that for the solutions used, the water content as well as the concentration of electrolyte played a very minor role in the over-all product formation. When the water content becomes greater than 10%, the formaldehyde production decreases somewhat: these results are in general agreement with the ones reported previously (4,5). In the above experiments, the solutions were not stirred in any manner.

Electrode coverage in anhydrous methanol.—The electrode was polarized potentiostatically at a given potential or was brought to a given potential in a quasi steady-state manner by applying successive potential steps of 20 mV and maintaining each potential step value for 2 min. After this polarization procedure, the electrode was removed from the anhydrous methanol solution and taken out of the controlled atmosphere chamber. It was then transferred rapidly into another cell where the electrode was washed with water and deoxygenated 1*N* Ultrex sulfuric acid. After several (five) washings the electrode was polarized potentiostatically at 0.4V (*vs.* RHE) and was then swept to 0.0V with a potential ramp. The current-voltage curve was recorded and the integration of the resulting curve gave us a measure of the electrode coverage θ by the following relationship

$$\theta = \frac{{}^{S}Q_H - Q_H}{{}^{S}Q_H}$$

where Q_H is the charge between 0.4 and 0.04 V (*vs.* RHE) in the presence of adsorbed species and ${}^{S}Q_H$ is the equivalent hydrogen deposition charge in the absence of such species.

A strongly adsorbed organic entity was observed that could be completely oxidized following an anodic polarization of 1.8V (*vs.* RHE) for several minutes.

In Fig. 1, we illustrate the adsorption behavior of this strongly adsorbed methanol species as a function of the polarization potential, both in anhydrous methanol and in presence of controlled amounts of water. We note a partial desorption of the strongly adsorbed species as the potential increases and this decrease is concomitant with a change of electrode reaction as is discussed below when the polarization curves for these solutions are presented. We must point out, however, that the absolute values of the coverage are not totally representative of the complete adsorption reactions because it is impossible to perform the coverage experiments *in situ* in the nonaqueous medium since the hydrogen ion adsorption current is not observed in the nonaqueous medium. This hydrogen ion deposition current is clearly resolved only in acidic aqueous solution.

The oxidation of this strongly adsorbed species was also studied. This was done by recording the current during anodic sweeps from 0.4 to 1.6V (*vs.* RHE) in aqueous solutions. A typical current potential curve is illustrated in Fig. 2 as obtained from oscillographic traces. To oxidize completely the adsorbed species the anodic limit must be raised to at least 1.8V (*vs.* RHE) and the sweep rate decreased to allow the slow reaction to take place.

Steady-state polarization data.—*Reaction order.*—Steady-state polarization studies were carried out on a rotating platinum disk electrode in anhydrous methanol and in solutions containing controlled amounts of water. An aim of these experiments was to study the order of the reactions with respect to the methoxide concentrations at different potentials. At anodic polarizations of 0.4 and 1.0V (*vs.* Ag/AgCl), the order of the reaction, $(\partial \log i/\partial \log c)_E$, was found to be 0.90 and 0.82, respectively, as determined by a least square treatment of the data, for methoxide concentrations ranging from 0.05 to 0.5M (in anhydrous methanol). These reaction orders were obtained at an electrode rotation rate of 3000 rpm.

Effect of rotation.—No definite relationship between the rate of rotation and the current at different

potentials could be established for electrode rotation speeds ranging from 600 to 6000 rpm, for several concentrations of methoxide (0.5, 0.1, and 0.5M CH_3ONa). This would establish the reaction to be entirely activation controlled as assumed in the current-potential and the reaction order plots.

Effect of water—Anhydrous methanol.—In the steady-state polarization curve in anhydrous methanol (0.05M CH_3ONa as electrolyte) shown in Fig. 3, there are several interesting features. At −0.35V (*vs.* Ag/AgCl) an oxidation current commences and a well-defined peak is observed at −0.2V. This peak formation is very dependent on the residual water content. The maximum current or limiting current at −0.2V is also very much dependent on the rotation speed of the electrode; the current value decreases drastically as the rotation increases. At higher potentials (above 0.1V) a rather long Tafel region is observed with a slope ranging from 110 to 130 mV/decade. Finally, a limiting current potential range from approximately 0.6 to 2.0V is observed. This limiting current value decreases with rotation speed only by a negligibly small extent.

The *iR* drop between the tip of the Luggin capillary and the working electrode cannot account for the above limiting current or the curvature observed in the polarization curves, the resistance determined by the interruption technique is of the order of 20-30 ohm and the *iR* drop would account for only 50 mV, even at the highest potentials attained.

Water addition.—In Fig. 4 we show the steady-state polarization curves for 0.05M methoxide solutions containing 100 and 1000 ppm (0.01 and 0.1%) water.

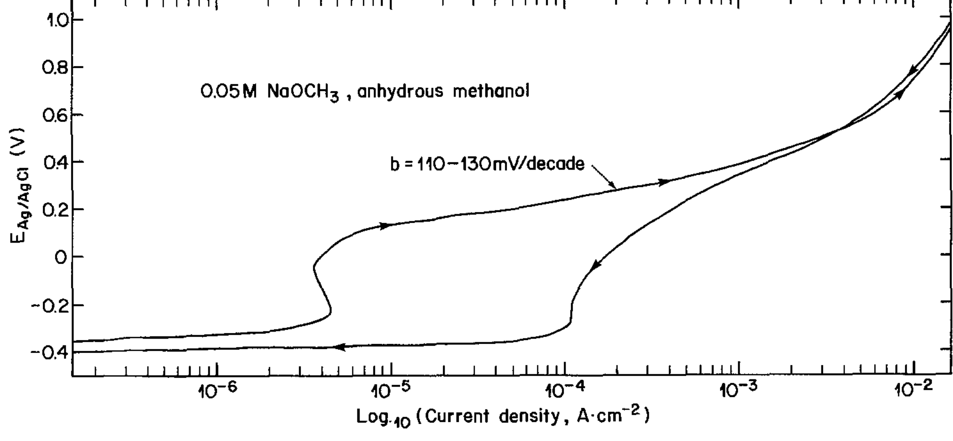

Fig. 3. Steady-state polarization curve for anhydrous methanol (<10 ppm) with 0.05M $NaOCH_3$ as the electrolyte solute; rotating disk platinum electrode of 0.28 cm^2 area at 3000 rpm. Experimental points obtained for 20 mV intervals; each potential was held constant for 2 min before recording the data

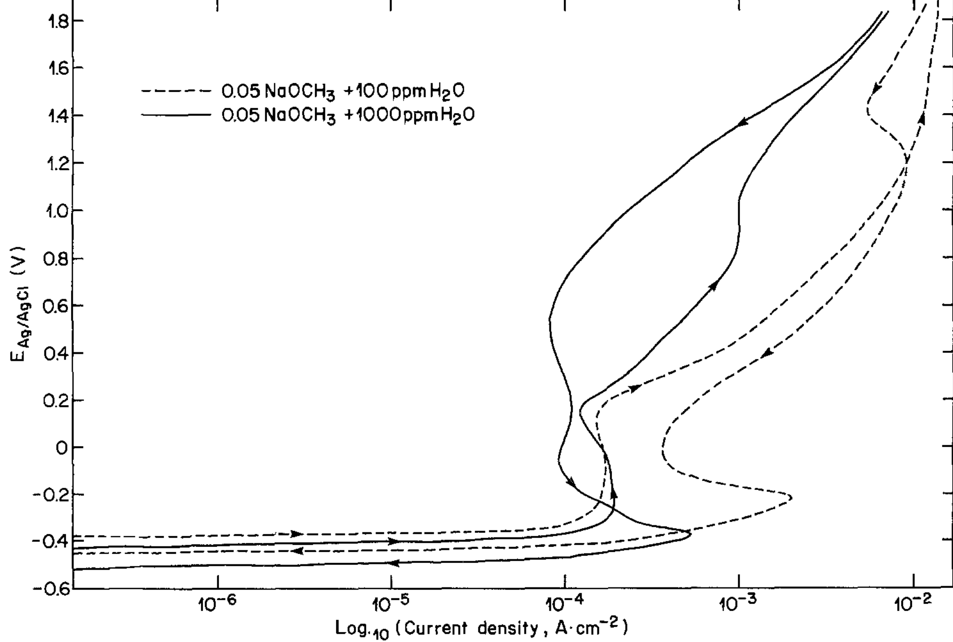

Fig. 4. Steady-state polarization curve for 0.05M $NaOCH_3$ solution in methanol with 100 (- - -) and 1000 (———) ppm H_2O; rotating disk platinum electrode of 0.28 cm^2 area at 3000 rpm. Same experimental procedure as in Fig. 3.

One can observe at first glance very profound differences between these polarization curves and the ones observed for the anhydrous case (Fig. 3). The main differences are the higher Tafel slopes (200-300 mV/decade) and the limited range where the Tafel relation is obeyed. The qualitative difference in the ascending and descending curves is also more pronounced: very well-defined inhibition peaks are observed and some modification in the current limiting potential range (>1V *vs.* Ag/AgCl) behavior is also apparent.

In these solutions the rotation speed of the working electrode had a minimal effect; the effect was in the opposite direction to what is generally observed, *i.e.*, here, the current decreases as the rotation speed increases, presumably owing to the increased concentration of the traces of water (and thence the inhibiting surface oxides) in the vicinity of the electrode at the higher rotation speeds.

The current behavior at relatively high anodic potentials (above 1.0V *vs.* Ag/AgCl) is quite different in the presence and absence of residual water. In completely anhydrous methanol a true limiting current behavior is observed at or near 1.0V. In the presence of 1000 ppm of water, an inhibition peak is observed at 0.6V, followed by an oxidation current that does not show any definite limiting current up to the highest potentials reached (*i.e.*, 2V *vs.* Ag/AgCl). The reaction at these high anodic potentials is probably a mixed process involving the methoxide ion and water or the hydroxide ion.

Galvanostatic charging data.—In the presence of water some interesting phenomena occur in the cathodic charging curves triggered from anodic potentials. In the completely anhydrous methanol no arrest or structure is observed as a cathodic current is applied to the electrode held at an anodic potential. For a 1000 ppm water content such an arrest appears and a complete analysis of this arrest for a 1% water content (1000 ppm) was carried out because of the better resolution in this solution. A linear relationship between current density and the reciprocal of the arrest period ($1/\tau$) is observed for different rotation speeds and for current densities ranging from −0.05 to 4 mA-cm^{-2}. This arrest is observed at approximately −0.5V (*vs.* Ag/AgCl). A typical cathodic charging curve as well as the derivative, dE/dt, of this curve is shown in Fig. 5. A second arrest is clearly observed as the charging current density reaches values higher than 2 mA-cm^{-2}. The high cathodic potential value for this arrest (−1V *vs.* Ag/AgCl) is related to the hydrogen deposition prior to the hydrogen gas evolution reaction.

A similar arrest is also observed in the galvanostatic anodic charging curves. However, the arrest is observed on a different time scale; *i.e.*, this arrest is a much slower phenomenon than the electrode process at −0.05V (*vs.* Ag/AgCl). Here again, a linear relationship between the current and the reciprocal of the arrest period is obtained indicating an activation-controlled process. The arrest occurs at 0.8-1.0V (*vs.* Ag/AgCl) and involves more than the surface oxidation; it lasts several seconds compared to milliseconds in the reduction case for the same current density. For the anodic arrest, the charges involved are of the order of 940 mcoulomb-cm^{-2} for the 1% H_2O solution (at 6000 rpm) and only 0.8 mcoulomb-cm^{-2} for the galvanostatic reduction charge in the same solution.

Potentiodynamic polarizations in the methanol system.—Some potentiodynamic profiles were reported by Iwakura *et al.* (5) for sodium methoxide in anhydrous methanol. In the present study, we have extended the potential sweep rates and examined the effect of controlled amounts of water in the anhydrous system.

For anhydrous methanol no structure (peaks) is observed, at all the sweep rates (10-500 mV-sec^{-1}) investigated. A typical potentiodynamic profile is illustrated in Fig. 6A. However, as water is added to the system some structure becomes apparent particularly at low (10 mV-sec^{-1}) sweep rates, as shown in Fig. 6B for the 1000 ppm H_2O solution. As the sweep rate increases to 100 mV-sec^{-1}, the peaks are no longer observed and a curve similar to the one for the anhydrous case is obtained.

Effect of adsorbed sulfur on the anodic oxidation in anhydrous methanol.—Two main series of experiments were carried out to study the effect of sulfur adsorption on the methanol oxidation reaction. In the first series, the electrode was fully covered by sulfur in an aqueous sulfide solution and the electrode was then taken in the controlled atmosphere chamber where a complete steady-state polarization curve was recorded from the open-circuit potential, *ca.* −0.6-2.0V (*vs.* Ag/AgCl). The electrode coverage was measured before and after these curves. From the latter experiment we noted that the sulfur underwent a desorptive reaction as the electrode was polarized to 2.0V. Also as shown by the steady-state polarization curves in Fig. 7, the descending curve is identical to the one obtained in the absence of sulfur adsorption. Examination of electrode coverage at different points on the polarization curves showed that this desorption occurred above 0.8V (*vs.* Ag/AgCl).

The main effect brought about by the adsorbed sulfur is the inhibition of the first reaction, *i.e.*, the oxidation of methoxide to formate ions, from open circuit to 0.2-0.4V. This effect was observed more clearly in the next series of experiments where the polarization was carried out from open-circuit potential to only 0.6V (*vs.* Ag/AgCl). For an electrode on which the coverage by sulfur was near 100%, the inhibition occurs quite clearly, as shown in Fig. 8. In the presence of water, the inhibition is also observed but only for the ascending anodic potentials; for the descending potential, the oxidation reaction (formation of formate) was observed. Coverage experiments have also shown that the sulfur is more readily desorbed in the presence of

water than in the completely anhydrous methanol solution.

Discussion

Reaction mechanism.—From the product analysis data, the effect of water in the methoxide oxidation becomes significant on the current efficiency only at water concentrations higher than 10%. As the water or hydroxide ion concentration increases mixed reactions can proceed according to the following reactions

Main reaction

$$2CH_3O^- \rightarrow CH_2O + CH_3OH + 2e$$

Side reaction

$$4CH_3O^- + OH^- \rightarrow CHOO^- + 3CH_3OH + 4e$$

or

$$CH_3O^- + 4\,OH^- \rightarrow CHOO^- + 3H_2O + 4e$$

However, the over-all reaction equations as well as product analysis bear no direct indication as to the effects of water on the actual kinetics of the reaction.

The reaction order of nearly one with respect to the methoxide concentration as well as the Tafel slope of 110-130 mV/decade in the anhydrous methanol tends to indicate a discharge reaction as the rate-determining step (rds), namely

$$CH_3O^- \rightarrow CH_3O_{ad} \text{ or } CH_3O\cdot + e$$

where CH_3O_{ad} is an adsorbed intermediate and $CH_3O\cdot$ a radical near the electrode. For a rds implying a discharge reaction from a reactant in solution, one expects (14) a linear relationship between $1/i$ and $1/\sqrt{\omega}$ (where ω is the angular rotation speed of a disk electrode). Such correlation is absent for the methoxide-methanol system. In fact the current is invariant with the rotation speed for potentials 0.4 and 1V (*vs.* Ag/AgCl). This independence of i on ω could indicate the formation of an intermediate that is swept away from the electrode as the solution is stirred. This conclusion is corroborated by the observation that the current decreases as the electrode passes from a standstill to any rotation speed.

A proposed reaction mechanism to account for the above fact could be illustrated as

$$CH_3O^- \xrightarrow{\text{rds}} CH_3O_{ad} \text{ or } CH_3O\cdot + e$$

$$CH_3O_{ad} \text{ or } CH_3O\cdot + CH_3O^- \xrightarrow{\text{fast}} CH_2O + CH_3OH + e$$

Hysteresis between the ascending and descending potential direction in the anhydrous methanol indicates an irreversible surface electrode phenomenon. This observation can be associated with the formation of an electrochemically inert film as indicated by the higher Tafel slopes observed (300 mV/decade). The occurrence of these higher slope values arising from surface films was discussed previously (15,16). The electrode surface modification could also be deduced from the irreproducibility of the steady-state polarization data: the curves exhibited large differences between successive scannings. The original curve (the first one) was restored by cleaning and polishing the electrode. The results presented above (Fig. 3 and 4) are the data from the first potential scan.

Oxide effects.—The presence of water brings about new phenomena. The most important is the formation of an oxide film as indicated by several observations:

1. Inhibition peaks in the steady-state polarization curves as illustrated in Fig. 4 are similar to the ones observed for the methanol oxidation in aqueous medium (1, 2, 17).

2. Arrest in the anodic and cathodic galvanostatic charging curves. The arrest at −0.5V (*vs.* Ag/AgCl) in the cathodic charging curve can be associated with the reduction of the oxide film formed at high anodic potential. The oxide reduction can proceed according to the following reaction scheme

$$Pt[O] + CH_3OH + 2e \rightarrow Pt + OH^- + CH_3O^-$$

or

$$Pt[O] + H_2O + 2e \rightarrow Pt + 2\,OH^-$$

The arrest observed in the anodic charging curve can be associated with the formate formation since it does not occur in absence of water. The following reactions can be involved

$$5CH_3O^- + H_2O \rightarrow CHOO^- + 4CH_3OH + 4e$$

or

$$4CH_3O^- + OH^- \rightarrow CHOO^- + 3CH_3OH + 4e$$

3. In the potentiodynamic current-potential curves, current peaks are obtained in the presence of water

and a very pronounced hysteresis between the anodic and the cathodic sweep is observed illustrating the inhibitive character of the oxide film formed in the presence of water. The inhibition brought about by the oxide film is similar to the one observed in similar experiments (18, 19) for the electrooxidation of sodium formate or formic acid.

Sulfur effect.—The promotion in the anodic oxidation of methanol is not observed in the presence of an adsorbed sulfur film on the electrode. This conclusion is not definite since we could not convert our data to true-platinum-site basis, since in the nonaqueous medium we do not have the hydrogen ion discharge peaks to indicate the true and active surface area. One observation worth noting is the instability of this sulfur film which undergoes a desorptive reaction at high anodic potentials. The steady-state polarization curve (Fig. 7) in the descending potential steps is identical for the electrode that has been covered with a sulfur film and for the bare electrode. This indicates complete desorption of sulfur at potentials of around 1.2V (*vs.* Ag/AgCl). This type of behavior is not observed if the upper anodic potential limit does not exceed 0.8V (*vs.* Ag/AgCl), as illustrated in Fig. 8. The main consequence of sulfur adsorption is a general poisoning effect: the methanol oxidation currents are decreased drastically by the presence of such an adsorbed film.

Conclusions

The influence of surface oxides on platinum electrodes in the polarization curves of anhydrous methanol containing controlled amounts of water has been investigated. The main effect of these surface oxides (formed in the presence of water at anodic potentials) is to inhibit the oxidation of methoxide to formaldehyde. The other effect of the presence of water is to change the reaction products at low potentials where formate ions can now be produced in presence of water or hydroxide ions. However, at high anodic potentials (above 1V *vs.* Ag/AgCl) the reduction in the formaldehyde production is observed for high water content (1-10% only).

At open circuit a very strongly adsorbed species is formed on the electrode: The removal of this adsorbed film can be brought about by anodic polarization in the nonaqueous medium where the coverage by this adsorbate decreases as the anodic potential increases.

The main effect of a sulfur-covered platinum electrode is to inhibit the reaction: This sulfur adsorbate is unstable at anodic potentials and the sulfur coverage decreases as the anodic polarization is increased to 2V *vs.* Ag/AgCl in a nonaqueous medium.

Acknowledgment

The author thanks Mr. G. Trudel for his assistance in the experimental part of this work. Dr. A. K. Vijh's encouragement and advice in course of the study and in the preparation of the manuscript are also acknowledged.

Manuscript submitted May 4, 1975; revised manuscript received Jan. 26, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Hydro-Quebec Institute of Research.

Slow Potentiodynamic Studies of Porous Alkaline Iron Electrodes

Bo Andersson[1] and Lars Öjefors[1]

Department of Chemical Technology, Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

ABSTRACT

A slow potentiodynamic method where a porous iron electrode is fully discharged and charged has been used to study the reactions of the alkaline iron electrode. Electrode thickness, temperature, average porosity, number of armor nets, electrolyte concentration, and carbonate contents have been varied. The experiments show that high temperature, porosity, and KOH concentration increases the charge efficiency of the electrodes. High KOH concentration promotes the direct oxidation of Fe to FeOOH, and K_2CO_3 concentrations up to 250 g/liters do not influence the reactions of the electrode considerably.

In spite of high theoretical Ah density, low price, and stability to both mechanical and electrochemical mistreatment, the iron electrode has gradually been replaced by its cadmium counterpart in alkaline accumulators. This change depends mainly on the low hydrogen overvoltage for iron which means poor charge efficiency as hydrogen evolution competes with the charge process. The hydrogen overvoltage also causes comparatively high self-discharge as this process can be characterized as hydrogen-evolving corrosion. Another negative factor is the poor performance at low temperature when compared to its cadmium competitor.

During recent years iron has been the focus as a negative active material in metal-air batteries and, since many of the bad qualities have been overcome, this electrode material is of interest together with nickel oxide positive electrodes to make iron-nickel batteries.

Theoretical Background

Apart from its cadmium competitor, several discharge reactions can occur at the alkaline iron electrode (1)

$$3Fe(OH)_2 + 2H_2 \rightleftharpoons Fe_3O_4 + 2H^+ + 2e^- \qquad E_o = -0.197 - 0.0591 \times pH \quad [1]$$

$$3Fe + 4H_2O \rightleftharpoons Fe_3O_4 + 8H^+ + 8e^- \qquad E_o = -0.085 - 0.0591 \times pH \quad [2]$$

$$Fe + 2H_2O \rightleftharpoons Fe(OH)_2 + 2H^+ + 2e^- \qquad E_o = -0.047 - 0.0591 \times pH \quad [3]$$

$$Fe + 2H_2O \rightleftharpoons FeOOH + 3H^+ + 2e^- \qquad E_o = 0.059 - 0.0591 \times pH \quad [4]$$

$$Fe(OH)_2 \rightleftharpoons FeOOH + H^+ + e^- \qquad E_o = 0.271 - 0.0591 \times pH \quad [5]$$

$$Fe_3O_4 + 2H_2O \rightleftharpoons 3FeOOH + H^+ + e^- \qquad E_o = 1.208 - 0.0591 \times pH \quad [6]$$

The discharge reactions of the iron electrode have been the subject of several investigations (2-6) which show no uniform results according to the products of the discharge processes. The discharged active material has been reported as FeO, $Fe(OH)_2$, Fe_3O_4, Fe_2O_3, FeOOH, and $Fe(OH)_3$. Figure 1 shows constant current discharge curves in 4.5M KOH solution at 0°, 25°, 50°, and 70°C. Investigations by x-ray diffraction and SEM techniques (16) show that $Fe(OH)_2$ is the main discharge product of the first level, while FeOOH is produced on the second discharge level. Consequently, reactions [3] and [5] are dominating. At temperatures above 50°C a third interposed level appears representing the direct oxidation of Fe to FeOOH in dissolved phases (reaction [4]).

During development work with iron-air batteries at the Royal Institute of Technology and the Swedish National Development Company, the aim has been to find optimal structures of the sintered iron electrode and good separation between the charge and hydrogen evolution reactions. In order to study these variables, a slow potentiodynamic method has been adapted (Fig. 2). The electrode potential is scanned slowly from −1.050 to −400 mV and, as the rate is very slow (5.3 mV/min), the curves thus obtained are actually those of the electrode discharge. Integration of the area under the curves gives the same magnitude of capacity as a constant current discharge during the same time (Fig. 1). In Fig. 2 the different discharge and charge reactions are better separated than in Fig. 1 and it is evident that the interposed direct oxidation to FeOOH is more favored by high temperature than the other reactions. Of particular interest is the separation between the charge reaction and hydrogen evolution which is difficult to study with the constant current technique.

Experimental

For the experiments a Beckman Electroscan 30 has been used together with an external motor to provide the low scanning rate. Figure 3 shows the test cell in Plexiglas, temperature controlled by a HAAKE thermostat. The electrodes were turn-formed disks (Table I) connected to a platinum wire. For every potentiodynamic discharge and charge, a new electrode disk was used. Before the discharge the electrodes were charged at constant current (100 mA/g) for 1 hr in

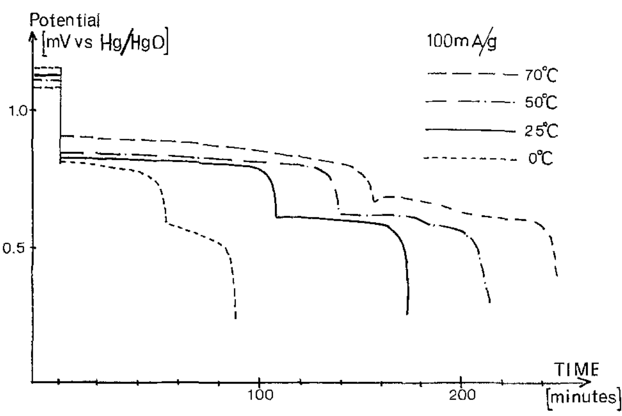

Fig. 1. Constant current discharge curves at different temperatures, 4.5M KOH.

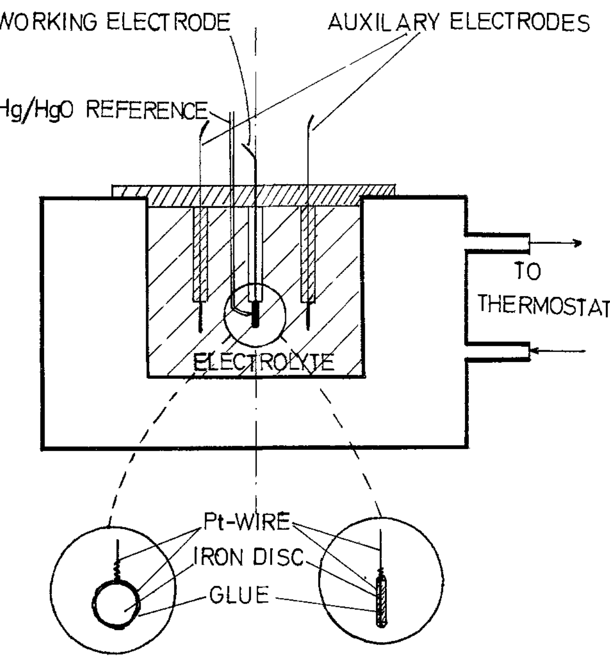

Fig. 3. Test cell

the actual electrolyte. Degassing of the electrodes was not necessary due to the slow discharge rate.

Experiments have shown that a scanning rate of 5.3 mV/min, which should be compared to that generally used (more than 0.5 V/min), for planar electrodes gives good separation of the different reactions at a porous iron electrode while it is charged and discharged to the same degree as in normal battery applications (Fig. 1 and 2). These curves also give information on current densities for different porosities and thicknesses of the electrode.

Experiments have shown that curves thus obtained are fully representative for the electrodes studied and do not differ from curves of electrodes cycled in the electrolyte considered. A calculation of the capacities in Fig. 1 and 2 shows that the results obtained with potentiodynamic discharge are very close to those of constant current discharge with 100 mA/g.

Table I. Physical properties of the electrodes

Electrode number	Thickness (mm)	Diam (mm)	Weight (g)	Surface (mm^2)	Volume (mm^3)	Average pore diam (μm)	Number of nets

Manufacture of the Electrodes

Manufacture of sintered iron anodes is a complex process where many parameters influence the electrochemical behavior of the final electrode. Parameters such as basic material, spacer, compacting pressure, sintering temperature, and time affect the porosity, pore diameter, surface area, mechanical strength, conductivity, and electrochemical performance. In the present work the porosity, thickness, and the number of armor nets are varied to relate these variables to electrochemical behavior. The electrodes presented should not, in terms of capacity per weight and volume, be compared to those of the battery project mentioned, since they have been made from well-defined carbonyl iron with the aim of getting reproducible electrodes suitable for this test.

The manufacture of the test electrodes has, in principle, been made in accordance with Ref. (7). As basic material, a carbonyl iron powder GS 6 from General Aniline & Film Company with the following specifications has been used: average particle diameter, 3-5 μm; apparent density, 1.2-2.2 g/cm^3; Fe min, 99%; C max, 0.1%; O max, 0.3%; N max, 0.1%.

A homogenous mixture of iron powder and the spacer was obtained by sieving and mixing after which it was compressed to circular plates with 1-3 mm thickness. For some electrodes a 20 mesh iron net was placed in the middle or on top and below the powder bed before compressing. The compressed plates were sintered in a tube furnace under a protective atmosphere. After solving out the spacer with water, the structure with very well-defined porosity was stabilized at another succeeding heat-treatment. The electrodes used in this test are presented in Table I.

Results

The results are presented in Fig. 2 and 4-8. As expected, the polarization decreases and the maximum current density increases with temperature and porosity for all electrodes and electrolyte concentrations tested.

Figure 2 shows the influence of temperature on charge and discharge processes of the alkaline iron electrode. Both the first and second plateau reactions are favored by higher temperatures, especially between 0° and 25°C. The interposed peak appearing at 50° and 70°C represents the direct oxidation in dissolved phases of iron to FeOOH, which also can be seen from the constant current discharge curves in Fig. 1. At charge no counterpart to this interposed reaction appears. At 50°C there is good separation between the peaks representing reduction of $Fe(OH)_2$

and hydrogen evolution which in practice means good charge efficiency in battery applications. At 0°C these reactions, however, seem to overlap each other.

Figure 4 shows clearly that the different reactions are better separated with higher porosity which also favors current density and capacity per weight. Of interest is that high porosity increases the separation between hydrogen evolution and the charge process.

Figure 5 shows the influence of electrode thickness on potentiodynamic curves at 25°C, where the step from 1 to 2 mm seems to be especially important. Experiments show that this effect is more pronounced at lower temperature, while at 50°C the maximum current density per area is the same for all thicknesses. Variations in this dimension do not affect the charge efficiency very much.

The influence of one iron net (20 mesh) in the middle of the electrode and two identical nets on each side of the sintered disk on the potentiodynamic curves is shown in Fig. 6. The two nets have a shielding effect on the active material which is identical to a decrease in porosity. The single net in the middle has a very small effect. It should be pointed out that improvements in conductivity and mechanical stability of the electrode are not registered by the test since small electrode pieces are used.

Decrease in concentration of the electrolyte seems to have the same influence on electrode performance during discharge as a decrease in pore volume (Fig. 7). This probably depends on the fact that lower porosity causes a higher deficit of OH^- ions during discharge. The charge step is not influenced in the same manner in terms of maximum current for temperatures lower than 25°C. At higher temperatures the negative influence of 3M KOH is pronounced for both the charge and discharge reactions.

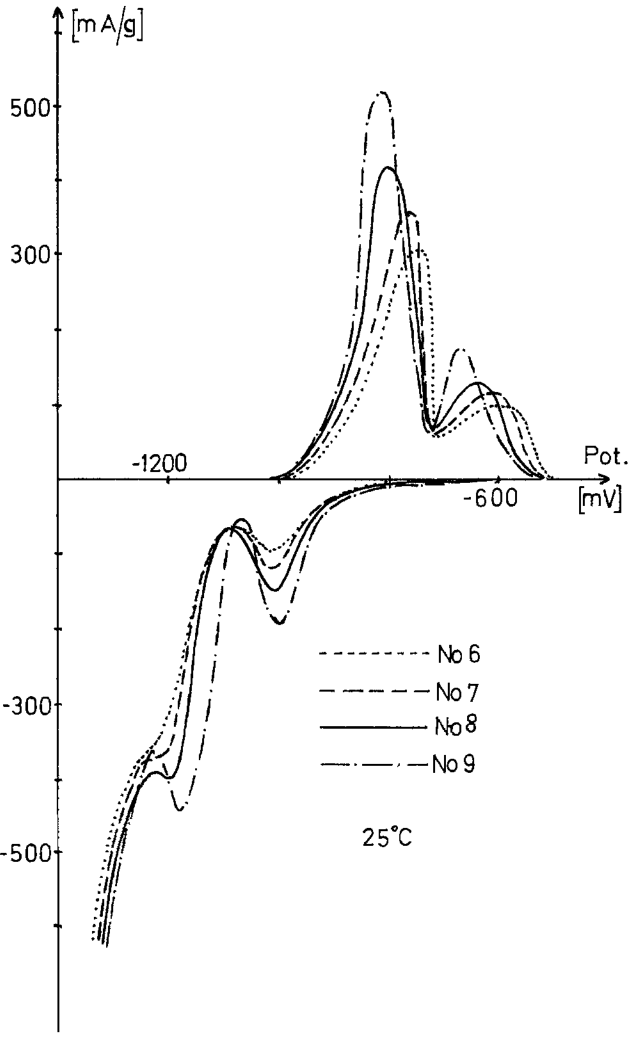

Fig. 4. Influence of different porosities on potentiodynamic discharge and charge at 25°C.

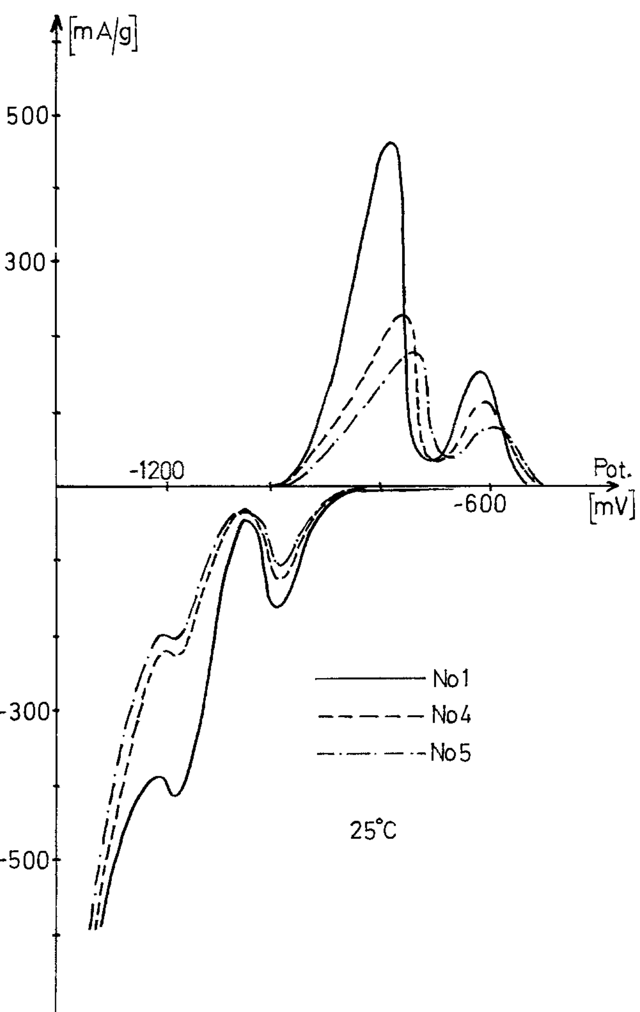

Fig. 5. Influence of thickness on potentiodynamic discharge and charge at 25°C.

High concentration electrolyte (12M) has a negative influence on capacity at 0° and 25°C. For 50°C the capacity does not differ from that of 6M except for the direct oxidation to FeOOH which is favored by this high concentration. The separation between the hydrogen evolution and charge reactions is clearly favored by high molarity.

Carbonization of the electrolyte (Fig. 8) seems to have an identical influence as a decrease in molarity, which probably depends on the lower *p*H caused by the carbonate. The decrease in conductivity which is important for batteries is not registered in this test. Carbonate has, apart from many other additives to the electrolyte (8, 9), no other influence on the different electrode reactions except for the hydrogen overvoltage which is increased.

Discussion

Several investigators have shown that the charge and discharge reactions proceed over dissolved intermediates according to Ref. (4, 6, 11)

$$Fe \rightarrow HFeO_2^- \rightarrow Fe(OH)_2$$

$$Fe(OH)_2 \rightarrow HFeO_2^- \rightarrow FeO_2^- \rightarrow FeOOH$$

Ring-disk studies by Armstrong *et al.* (11) clearly indicate that at high temperatures and in more concentrated electrolytes bivalent iron species are produced in the solution. On the anodic cycle they arise solely from active dissolution of the iron, while on

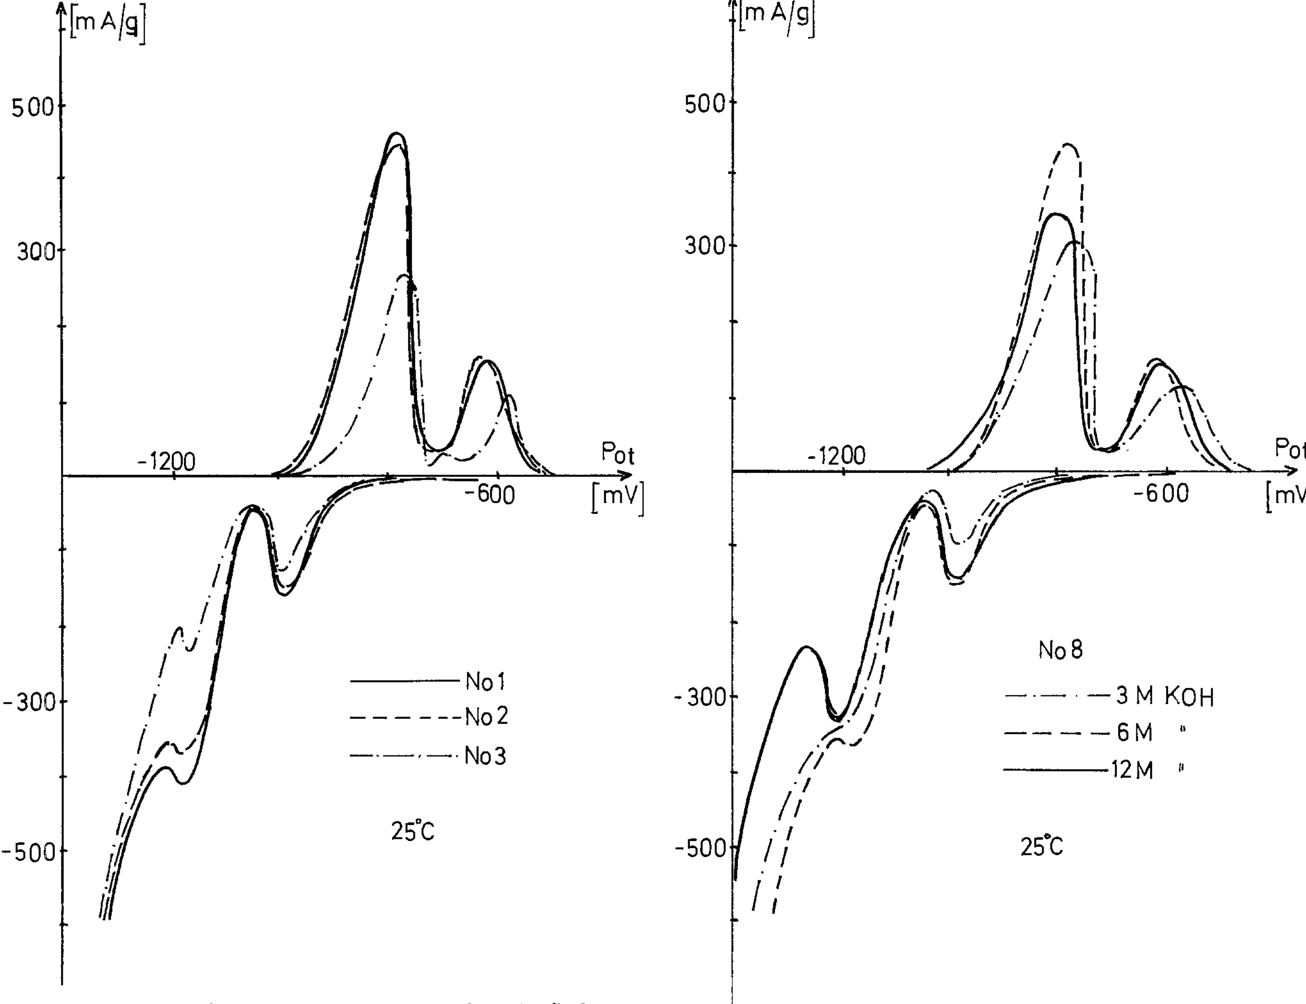

Fig. 6. Influence of 1 and 2 nets on potentiodynamic discharge and charge at 25° and 50°C. No. 1, no net; No. 2, 1 net; No. 3, 2 nets.

Fig. 7. Influence of electrolyte molarity on potentiodynamic discharge and charge at 25°C.

the cathodic cycle they are formed through the reductive dissolution of the anodic film. The measurements give, however, no evidence for solution soluble Fe(III) intermediates at a concentration above 10^{-6}M.

The strong temperature dependence, especially below 10°C, when compared to the cadmium electrode is explained in Ref. (10) with differences in solubilities of the intermediates. When the solubility surpasses $\sim 10^{-5}$M, it is found to have a limiting influence on the reaction rate. Theoretical calculations in Ref. (10) show that the solubility of FeO_2^- is more temperature dependent than the other intermediates while it is difficult to determine the exact value.

The second discharge step has been studied in more detail (13, 14). In Ref. (14) the authors state that the absolute and relative extent of the second anodic step at constant current of a porous iron electrode is highly dependent on temperature and current density while electrolyte concentration has relatively little effect. They also notice that when a discharged electrode stands on open circuit it regains some capacity especially on the second step. The observed results are explained with a solid-phase mechanism and an intraelectrode interaction between trivalent and metallic iron

As shown by Fig. 1 and 2, the relative increase of the second anodic level found by Flerov *et al.* (14) depends probably on the interference of the intermediate reaction appearing above 40°C, where metallic iron via $HFeO_2^-$ and FeO_2^- goes directly to its trivalent oxide state. The strong influence of temperature on the solubility of the trivalent intermediate explains this phenomena.

Lindström (12) proposes the intermediate reaction to be a combination of the first and second discharge steps caused by an opening of structure at the commencement of the second step. The opening-up procedure should be caused by the trivalent products having a higher density compared to that of bivalent reaction products. The waves in Fig. 2 are too separated to interfere with each other and the increase in porosity observed at the beginning of the second level can be explained with the dissolution of the anodic film. $Fe_2O_3 \cdot nH_2O$, which is supposed to be the trivalent anodic product, has a density of 2.4-3.6 g/cm^3 which should be compared with 3.4 g/cm^3 for $Fe(OH)_2$ (15). Fe_3O_4, which has been proposed by some investigators as a discharge product, has a density of 5.2 g/cm^3 but SEM investigations on discharged electrodes show only the gelatinous precipitation characteristic for $Fe_2O_3 \cdot nH_2O$ (16).

During charge, the reactions are separated into only two waves which can be explained by a slow dissolution of the Fe(III) discharge products causing a limited conversion to $Fe(OH)_2$ since these peaks are comparatively small. The following waves representing temperatures above room temperature are bigger than corresponding ones during discharge which means that direct reduction of Fe(III) species to iron interacts with that of $Fe(OH)_2$.

The solubility of the intermediate species are also highly pH dependent which explains the decrease in performance of charge and discharge reactions with smaller average pore diameter, lower in electrolyte concentration, increasing thickness, and shielding nets. The improved separation between hydrogen evolution

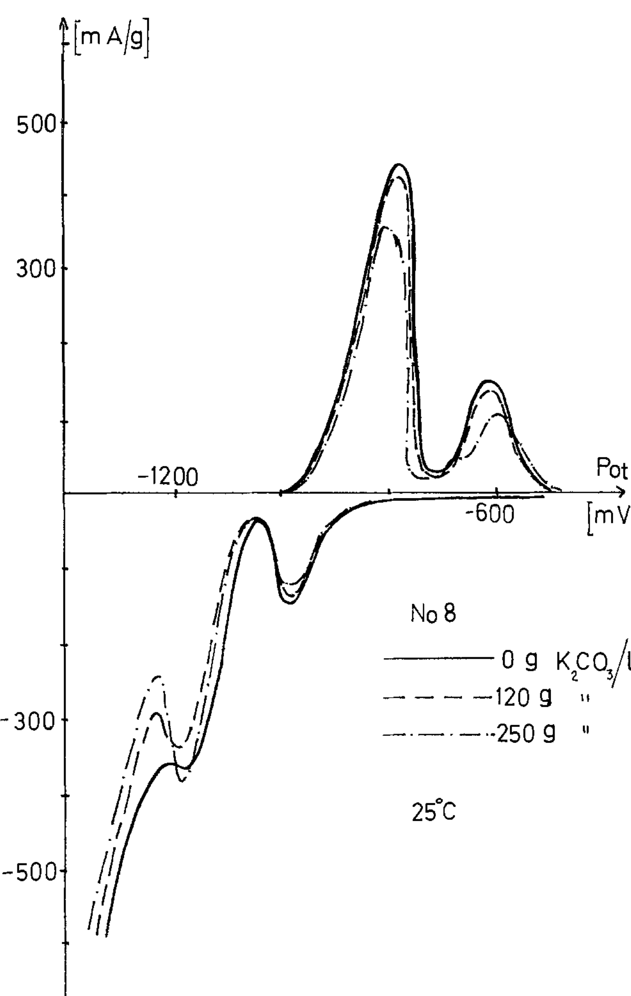

Fig. 8. Influence of carbonization of electrolyte on potentiodynamic discharge and charge at 25°C.

and the charge step with higher porosity depends on easier diffusion of the products of the latter process which is mostly influenced.

A decrease in molarity of the electrolyte has a negative influence on the performance, while a higher concentration changes the hydrogen evolving potential toward more negative values which has a positive effect on charge efficiency and self-discharge (9).

On the effect of carbonate in the electrolyte to the performance of the alkaline iron electrode, very little has been published and the maximum permissible amount of carbonate is considered to be 50g K_2CO_3/liter. The results presented here indicate that performance of the iron electrode is not influenced even at much higher carbonate concentration. However, on repeated cycling and with time, the cells become sluggish with more than 50 g/liter which has a negative influence on the performance.

By slowly discharging and charging a porous electrode, data are obtained which give more information on the processes appearing in the electrode than what is given by constant current techniques. It is, however, necessary to investigate in more detail the relationship between this method of charging and discharging the electrodes to that of normal use in batteries.

Electrochemical Reduction of Chromate in the Presence of H_2O in Molten Lithium Chloride-Potassium Chloride Eutectic

I. Uchida*,[1] and H. A. Laitinen*

Department of Chemistry, University of Florida, Gainesville, Florida 32611

ABSTRACT

The chronopotentiometric reduction of K_2CrO_4 was studied in molten LiCl-KCl eutectic at 450°C in the presence of $CaCl_2$ and/or water. The vapor pressure of H_2O was varied in the range of 0-22.5 Torr. Under highly dehydrated conditions, a single wave occurs at −1.18V *vs.* Pt(II), 1*M*/Pt reference electrode, and Ca(II) ions have no effect on the reduction wave. However, in a moist melt and in the presence of insufficiently dehydrated $CaCl_2$, two reduction waves are observed. The first reduction wave occurs at −0.6V and the second at −1.18V. $LiCrO_2$ is formed as an insoluble product at the first reduction step. The same product is produced chemically by decomposition of synthesized Li_3CrO_4 in a moist melt. Coulometry and chronopotentiometry revealed that three electrons and two water molecules are consumed per chromate ion and the first step is controlled by H_2O diffusion. A reduction path consistent with these observations is proposed.

Laitinen and Bankert used chronopotentiometry to study the electrochemical reduction of chromate ions, CrO_4^{2-}, in LiCl-KCl eutectic melt in the absence and in the presence of Mg(II) and Ca(II) ions. They showed that the presence of divalent cations lowered the reduction potential of chromate and gave extraordinarily stable deposits (1). In the case of Mg(II) the electrochemical reduction product has been shown to be a single unstoichiometric compound of formula $Li_xMg_yCrO_4$, where $x + 2y = 5$ (2). This empirical formula, $Li_xM(II)_yCrO_4$, was found to be applicable to other deposits obtained in the melts containing other divalent cations such as Ni(II), Zn(II), and Co(II) (3-5). On the other hand, the reduction of chromate in the presence of Ca(II) ion has been the most irreproducible system encountered. Bankert observed that the addition of $CaCl_2$ caused a positive shift of reduction potential (1), but Nezu did not obtain a product corresponding to $Li_xCa_yCrO_4$ (6). Further investigations were unsuccessful in establishing a definite formula and reproducibility of potential shift (7). There were no self-consistent data concerning the Ca(II)-CrO_4^{2-} system, although there was a suggestion that the presence of trace quantities of moisture or hydroxide ion in the melt affect the nature of the reduction (5).

Recently Niki and Laitinen have shown that Li_3CrO_4, which is believed to be the initial intermediate product in the course of chromate reduction, undergoes a disproportionation reaction in the melt and gives $LiCrO_2$ (8). This compound was encountered in the early studies (6) when the electrolysis was carried out with a high ratio of Ca^{2+}/CrO_4^{2-}.

The present investigation was initially undertaken to clarify whether the reduction of chromate is affected by the presence of $CaCl_2$ in a highly dehydrated condition and to establish the composition of the reduction product. In the course of the investigation it was found that dehydrated Ca(II) ion does not have any special effect on the reduction mechanism but that a trace of water associated with hygroscopic $CaCl_2$ has quite a remarkable effect. The main purpose of this work was then turned to elucidation of the reduction mechanism of the H_2O-CrO_4^{2-} system and characterization of the electrode deposit.

Key words: molten salt, chromate reduction, chronopotentiometry, lithium chromite.

Experimental

Apparatus.—A Hevi-Duty MK 3012-S vertical split tube furnace (Hevi-Duty Electric Company, Watertown, Wisconsin) was used. The temperature was regulated with a Wheelco Panel-Mount Capacitrol temperature controller (Wheelco Instrument Company) and a Chromel-Alumel thermocouple. All experiments were performed at 450° ± 1°C. A Sargent Model IV coulometric current source was used in the preparation of electrode deposits and for generation of the Pt(II)/Pt reference electrode. The constant current source employed for chronopotentiometric studies has been described previously (2). A Tektronix 502A oscilloscope served to record the chronopotentiograms.

The procedures employed for cleaning glassware and handling the molten eutectic with special glass devices were described in detail by Johnston (9).

Electrodes.—All potentials shown in this work are given with respect to the Pt(II), 1*M*/Pt reference electrode, construction and properties of which were already described (10). A spectroscopic carbon rod constructed according to the procedure described by Propp (2) was used as the counterelectrode.

The platinum flag electrodes used in the chronopotentiometry and the platinum gauze electrodes used in the preparative work were detachable. The construction of the platinum gauze electrodes and the electrode holders have been described (2). The platinum flag electrodes were constructed by punching a platinum foil (0.06 mm thick) with a paper punch (6.37 mm in diameter) and by spot welding 3 cm of 36 gauge platinum wire to the platinum flag as an electrical lead. The geometric area of each flag was 0.637 cm^2 without correction for the lead wire.

Reagents.—Reagent grade $CaCl_2 \cdot 2H_2O$ (Mallinckrodt) was recrystallized. The resulting $CaCl_2 \cdot 6H_2O$ was dried to $CaCl_2 \cdot 2H_2O$ in a vacuum desiccator at room temperature. Then the $CaCl_2 \cdot 2H_2O$ was further dehydrated by slow heating up to the melting point (772°C) under an HCl atmosphere followed by bubbling the resulting melt with dry HCl for 1 hr. After scrubbing with dry argon gas for 2 hr and filtration through a Vycor glass frit, the purified $CaCl_2$ was al-

lowed to solidify and was sealed in vacuum in a small Vycor vial provided with a break-sensitive tip. The anhydrous $CaCl_2$ was introduced into the molten system without moisture contamination from the laboratory atmosphere by breaking the tip in a cell container filled with dry argon. The $CaCl_2$ prepared by this method contained 99.9% of the theoretical amount of chloride. Commercially available anhydrous $CaCl_2$ (J. T. Baker) and $CaCl_2$ dried according to the procedure outlined by Bankert (1) were also used purposely to ascertain the difference between fused-dried $CaCl_2$ and vacuum-dried $CaCl_2$.

Anhydrous K_2CrO_4 was prepared by drying reagent grade material (J. T. Baker) at 180°C in vacuum for 24 hr and stored in a vacuum desiccator.

The LiCl-KCl eutectic was supplied from Anderson Physics Laboratories Inc., Champaign, Illinois.

Experimental techniques.—Moist argon with various vapor pressures of H_2O was prepared by passing dry argon through a series of two gas washing bottles containing 2 liters of aqueous sulfuric acid of known concentration prepared from 96.4% H_2SO_4 (Baker Analyzed Reagent) maintained at a known temperature in a constant-temperature bath. The partial pressures of water in equilibrium with aqueous H_2SO_4 are tabulated at various temperatures (11)

Chronopotentiometry of chromate reduction was performed in the absence and presence of H_2O. After the measurements in the dry melt, the moist argon was introduced into two separate compartments containing about 4 ml melt, one of which had chromate and the other no chromate, and the melt was bubbled for at least 30 min. After bubbling was stopped in one of the two compartments, the measurement was carried out within 3 min. A blanket of the moist argon was kept on the melt all the time to maintain the partial pressure of water constant. All measurements were carried out alternately in this way with electrochemical monitoring of the water concentration in the melt.

The samples of the electrode deposit resulting from the reduction of chromate in the presence of water were prepared by constant current electrolysis using platinum gauze electrodes with bubbling of moist argon. Without stirring, the electrode potentials would not have been restricted to the potential range of the first wave.

The procedures of weighing the electrode deposit, dissolving the deposit in hot perchloric acid, and determining chromium and lithium contents have been described in detail (2-4).

The x-ray powder diffraction pattern of the deposit was obtained by using an 11.47 cm Debye-Scherrer camera exposed to Ni-filtered Cu-Kα radiation from a Norelco x-ray generator. The x-ray powder samples were prepared in the manner mentioned above with platinum coil electrodes (1 mm in diameter and 10 cm length). The spiral was uncoiled over a mortar, and then the electrode deposits were easily peeled off.

Results and Discussion

Reduction of K_2CrO_4 in the presence of $CaCl_2$.—The pure melt used here was highly dehydrated as shown in Fig. 1, curve 1, where the initial rising portion is quite linear. Figure 1, curve 2 shows a chronopotentiogram of chromate reduction in the presence of fused-dried $CaCl_2$. There was no difference between the results for chromate reduction in the presence and absence of $CaCl_2$, both cases giving the same $E_{1/4}$ [= -1.19 ± 0.01V *vs.* Pt(II), 1M/Pt] and transition time constant (= 998 ± 18 A-sec$^{1/2}$ cm/mole). However, the reduction wave split into two waves in the presence of commercially available $CaCl_2$ or the vacuum-dried material as shown in Fig. 2, curve 2. In this case the residual charging curve was no longer the same as that of the dry melt as can be seen in Fig. 2, curve 1.

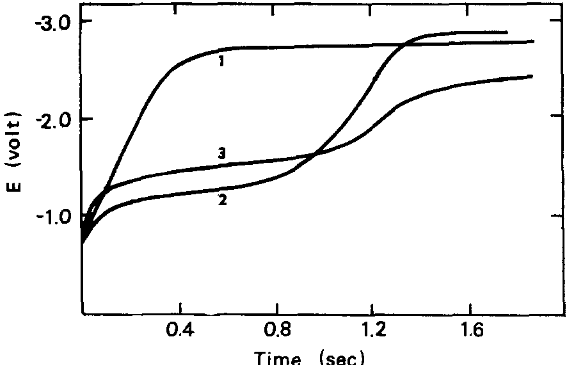

Fig. 1. Potential-time curves for the residual charging in the absence and presence of H_2O, and for the chronopotentiometric reduction of K_2CrO_4 in the presence of $CaCl_2$. Curve 1, in a pure dry melt, I = 0.755 mA/cm^2. Curve 2, in a dry melt containing $CaCl_2$, [$CaCl_2$] = 0.19M, [K_2CrO_4] = 6.20 mM, I = 6.04 mA/cm^2. Curve 3, in a moist melt, P_{H_2O} = 15.4 Torr, I = 1.98 mA/cm^2.

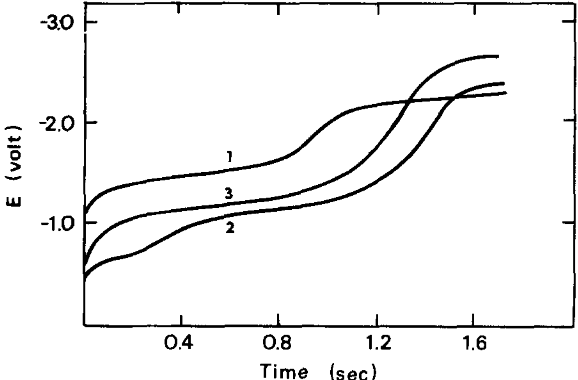

Fig. 2. Potential-time curves for the residual charging and chronopotentiometric reduction of K_2CrO_4 in the presence of insufficiently dried $CaCl_2$. Curve 1, in a pure melt containing commercially available $CaCl_2$, [$CaCl_2$] = 0.47M, I = 4.94 mA/cm^2. Curve 2, taken after addition of K_2CrO_4, [K_2CrO_4] = 5.67 mM, I = 4.88 mA/cm^2. Curve 3, taken 30 min after the curve 2. I = 4.94 mA/cm^2.

Figure 2, curve 1 agreed with the chronopotentiogram of H_2O reduction in Fig. 1, curve 2 ($E_{1/4} = -1.39$V). The prewave observed in the presence of insufficiently dried $CaCl_2$ decreased with elapsed time and seemed to disappear finally. Figure 2, curve 3, which was taken 30 min after curve 2 showed basically the same pattern as Fig. 1, curve 2. This experiment was done under a dry argon atmosphere so that the water introduced with $CaCl_2$ was free to escape from the melt. This is the reason why reproducible results were not obtained in CrO_4^{2-}-Ca^{2+} (H_2O) systems in the previous investigations (6, 7).

Reduction of K_2CrO_4 in the presence of H_2O.—The effect of H_2O on the reduction of chromate was demonstrated by successively decreasing the concentration of chromate at a constant vapor pressure of H_2O. Figure 3, curve 3 shows that at P_{H_2O} of 15.4 Torr, two transitions were obtained; one, at -0.60V and the other at -1.18V. With decreased chromate concentration the first wave at -0.60V increased and the second wave at -1.18V decreased relatively as shown in Fig. 3, curves 2 and 1, while a new wave, which was not well defined, appeared between -1.25 and -1.55V. It corresponds to the reduction wave of H_2O in Fig. 1, curve 3. On the other hand, a further increase of chromate concentration simply caused the second wave at -1.18V to grow larger and showed no influence on the first reduction step.

The product of I and $\tau^{1/2}$, is shown as a function of chromate concentration in Fig. 4, where I is current

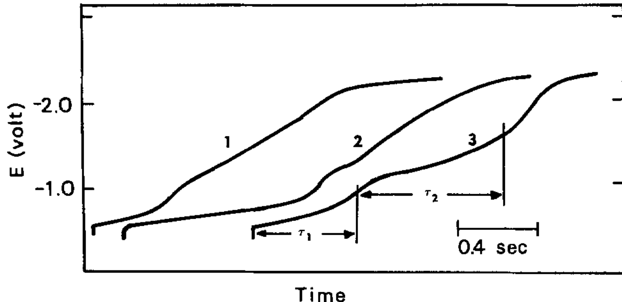

Fig. 3. Effect of H_2O on the chronopotentiometric reduction of K_2CrO_4 at P_{H_2O} = 15.4 Torr. Curve 1, $[K_2CrO_4]$ = 1.10 mM, I = 1.98 mA/cm^2. Curve 2, $[K_2CrO_4]$ = 2.98 mM, I = 2.96 mA/cm^2. Curve 3, $[K_2CrO_4]$ = 4.10 mM, I = 3.94 mA/cm^2.

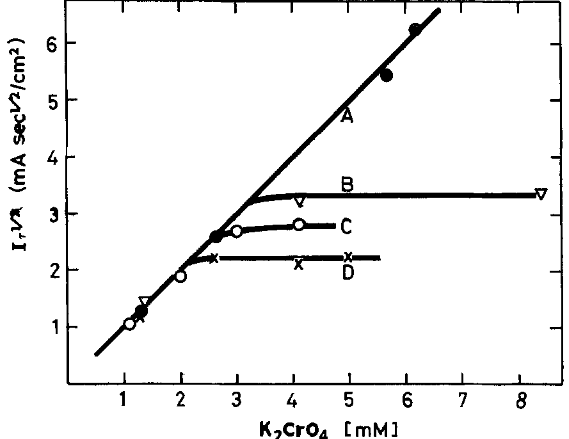

Fig. 4. Dependence of $I\tau_1^{1/2}$ on chromate concentration at different vapor pressures of H_2O. Curve A, P_{H_2O} = 0. Curve B, P_{H_2O} = 20.3 Torr. Curve C, P_{H_2O} = 15.4 Torr. Curve D, P_{H_2O} = 11.4 Torr.

density and τ_1 is the transition time of the first wave. This relationship confirms the above observation. At a given vapor pressure, $I\tau^{1/2}$ becomes independent of chromate concentration when the latter exceeds a certain value (curves B, C, and D). On the other hand, with the decrease of chromate concentration, presumably when $[H_2O] > [CrO_4^{2-}]$, $I\tau^{1/2}$ follows the zero H_2O concentration line (curve A), yielding a transition time constant ($I\tau_1^{1/2}/C$) identical with that in the absence of water. Apparently, under water-sufficient conditions the diffusing species is the chromate ion, and all the chromate ions reaching the electrode are reduced in the first reduction step. The limiting values of $I\tau^{1/2}$, observed under water-deficient conditions, mean that the first reduction step is controlled by the diffusion of water. All the water in the vicinity of the electrode is used up in a time interval (τ_1), and then the second reduction wave develops at the potential observed in the absence of water. Hence the limiting values of $I\tau^{1/2}$ at different vapor pressures are expected to be proportional to the vapor pressure as long as the solubility of water obeys Henry's law.

Data on the solubility of water in molten mixtures of LiCl-KCl are available (12), and the reciprocal Henry's law constant in LiCl-KCl eutectic at 450°C was estimated; k^{-1} = 0.26 mM/Torr where $[H_2O] = k^{-1} P_{H_2O}$. For instance, the water concentration in the melt

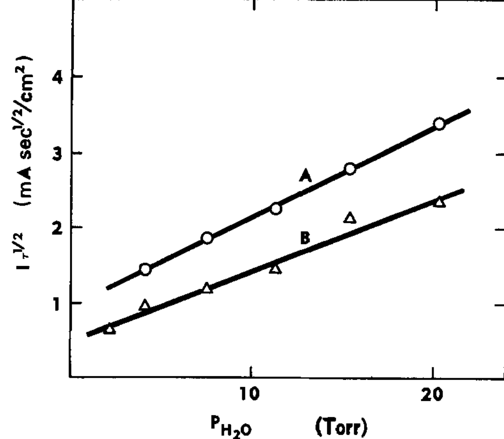

Fig. 5. Comparison of $I\tau^{1/2}$ for H_2O and first wave of CrO_4^{2-} in presence of deficiency of H_2O. Curve A, limiting values of $I\tau_1^{1/2}$ measured at each P_{H_2O} in excess of chromate. Curve B, $I\tau_{H_2O}^{1/2}$ measured at each P_{H_2O} without chromate.

at P_{H_2O} = 15.4 Torr is 4.0 mM. According to the literature (12) Henry's law holds at vapor pressures lower than 18 Torr.

The dependence of $I\tau^{1/2}$ on I was examined for the first reduction step of chromate ($I\tau_1^{1/2}$) and for H_2O reduction ($I\tau_{H_2O}^{1/2}$). The experiments were carried out only under the condition of low vapor pressures where the concentration of H_2O in the melt is believed to obey Henry's law. It was found that the Sand equation is applicable to both reductions within the time interval investigated.

Figure 5 shows linear relationships of $I\tau_1^{1/2}$ and $I\tau_{H_2O}^{1/2}$ *vs.* P_{H_2O}. The linear regression analysis for $I\tau_{H_2O}^{1/2}$-P_{H_2O} relation by the least squares method gave a transition time constant of water reduction ($I\tau_{H_2O}^{1/2}$ = 0.094 P_{H_2O} + 0.49, γ = 0.985); $I\tau_{H_2O}^{1/2}/C_{H_2O}$ = 0.36 × 10^3 sec$^{1/2}$ cm/mole using k^{-1} = 0.26 mM/Torr. Assuming n = 1, the diffusion coefficient of water was calculated as $D_{H_2O} = 1.77 \times 10^{-5}$ cm^2/sec at 450°C.

Because the first reduction wave is governed by mass transport of H_2O in excess chromate, the following relation is obtained under water-deficient conditions from the Sand equation

$$I\tau_1^{1/2} = \frac{n\mathbf{F}\pi^{1/2}D_{H_2O}^{1/2}C_{H_2O}}{2a} = \frac{n}{a} I\tau_{H_2O}^{1/2} \qquad [1]$$

where a is the number of water molecules required for the reduction of a chromate ion. As can be seen in Fig. 5, the ratio of $I\tau_1^{1/2}/I\tau_{H_2O}^{1/2}$ is about 1.5 at each value of the vapor pressure. Using n = 3 determined from coulometric experiments described later, the number of moles of H_2O consumed per mole of chromate was found to be 2.

Characterization of electrode deposit prepared in the presence of H_2O.—During the electrolysis the potential of the working electrode was monitored and was never allowed to become more cathodic than −0.7V. The deposits were insoluble in the melt and adhered to the electrodes. Chemical analysis and coulometric data showed that three electrons are consumed per mole of chromate, and that the empirical formula of the deposit is $LiCrO_2$. Typical results are shown in Table I.

Table I. Analytical results of deposit as a function of current density

$[K_2CrO_4]$ = 0.0194M		P_{H_2O} = 15.4 Torr			Temperature = 450°C		
I, mA/cm^2	Current passed, μequiv.	Deposit obtained, mg	Cr found, μmoles	n	Li found, μmoles	% wt found (as $LiCrO_2$)	Empirical formula
1.5	150.04	4.76	49.8	3.01	50.1	95.2	$Li_{1.01}CrO_{2.00}$
3	150.04	4.94	51.1	2.94	54.0	94.9	$Li_{1.06}CrO_{2.03}$
6	150.06	4.82	49.7	3.02	50.1	93.9	$Li_{1.01}CrO_{2.00}$
				n = 2.99			$LiCrO_2$

The experiments of Table I were performed in Vycor cells and done in relatively short time. Pyrex glassware was seriously attacked by alkali arising from the electrolysis after prolonged contact with the melt.

X-ray powder diffraction studies.—X-ray powder diffraction data are compared in Table II with those of synthesized $LiCrO_2$ and a decomposition product of Li_3CrO_4 in the moist melt, which is identified as $LiCrO_2$ (8).

Electrochemical reduction mechanism of chromate in the presence of H_2O.—Electroreduction of chromate in the dry melt was considered to involve consecutive electron transfer steps followed by a chemical reaction (1, 4, 5)

$$CrO_4^{2-} + 2e^- = CrO_4^{4-}$$

$$CrO_4^{4-} + e^- \rightarrow CrO_4^{5-} \rightarrow CrO_3^{3-} + O^{2-} \quad [2]$$

Recently Niki and Laitinen made a potential-pO^{2-} diagram of chromate based on the stability of Li_3CrO_4 and Ba_2CrO_4 in LiCl-KCl eutectic (8). The diagram predicts that the stability of Li_3CrO_4, which is believed to be the initial product of the reduction, is strongly dependent on the basicity of the melt; if the melt is acidic, Li_3CrO_4 decomposes to $LiCrO_2$ by a disproportionation reaction

$$3Li_3CrO_4 \rightarrow 2CrO_4^{2-} + LiCrO_2 + 2\,O^{2-} + 8Li^+ \quad [3]$$

and if it is basic, Li_3CrO_4 is stable in the melt. According to this explanation, the presence of acidic species in the melt is expected to promote the disproportionation reaction, and to shift the reduction potential to positive value.

The over-all reduction process in the moist melt was concluded to involve two water molecules and three electrons

$$CrO_4^{2-} + 3e^- + 2H_2O \xrightarrow{Li^+} LiCrO_2(\text{solid}) + 4\,OH^- \quad [4]$$

and electrochemical measurements showed kinetic complications to be involved. In current-reversal chronopotentiometry, no reoxidation process was found. However, the irreversible type logarithmic plots [E *vs.* log $(\tau_1^{1/2} - t^{1/2})$] were not linear for the reduction process. Therefore this irreversibility must come from an irreversible chemical reaction. The $E_{1/4}$ depended on current density and chromate concentration, but simple diagnostic criteria (13) were not applicable.

The chemical reaction involved here occurs between H_2O and Li_3CrO_4 which is a much stronger base than CrO_4^{2-}. The initial electron transfer process, $CrO_4^{2-} + e^- = CrO_4^{3-}$, seems to be reversible because Li_3CrO_4 (solid)/Pt electrodes showed stable equilibrium potentials (14). Hence, the following reaction sequence can be written

$$CrO_4^{2-} + 3Li^+ + e^- = Li_3CrO_4\ (\text{solid}) \quad [5]$$

$$3Li_3CrO_4 + 2H_2O \rightarrow 2CrO_4^{2-} + LiCrO_2\ (\text{solid}) + 4\,OH^- + 8Li^+ \quad [6]$$

Table II. X-ray data of the electrode deposit prepared in the presence of H_2O (P_{H_2O} = 15.4 Torr)

Electrode deposit		Decomposition product of Li_3CrO_4		Synthesized $LiCrO_2$	
d, Å	Intensity	d, Å	Intensity	d, Å	Intensity
4.73	m	4.73	90	4.812	100
2.45	w	2.45	50	2.476	28
		2.39	10	2.405	5
2.35	w	2.35	20	2.374	9
2.04	s	2.07	100	2.062	48
		1.88	50	1.895	9
		1.59	60	1.590	12
		1.46	70	1.466	15
1.44	s	1.44	70	1.488	15
1.38	s	1.38	50	1.389	7
		1.20	40	1.198	—

This reaction scheme was confirmed by direct study of the chemical reaction between Li_3CrO_4 and H_2O in the melt. Chemical analysis and x-ray diffraction data for the decomposition products of Li_3CrO_4 in the moist melt proved that the disproportionation reaction takes place and gives the product $LiCrO_2$. In the dry melt the Li_3CrO_4/Pt electrodes showed stable equilibrium potentials corresponding to the half-reaction [6] over a few hours, but once H_2O was introduced into the melt, the potential started to decay rapidly. Apparently the presence of H_2O strongly accelerated the decomposition of Li_3CrO_4. $LiCrO_2$ was not oxidized electrochemically.

In order to account for the shift of over 600 mV in $E_{1/4}$ in the moist melt in comparison with the dry melt, we can compare the fate of Li_4CrO_4, which is formed as a primary product in both paths by a reversible electron transfer process. In the moist melt, reaction [6] is so rapid that the surface concentration of CrO_4^{3-} is reduced to a vanishingly small value, whereas in the dry melt, the initial decomposition of Li_3CrO_4 according to reaction [3] releases O^{2-} ions in the vicinity of the electrode surface. Then Li_3CrO_4 becomes stable and requires two more electrons to complete the reduction. The decomposition of Li_5CrO_4 is so slow that Bankert obtained Li_5CrO_4 as a primary product (1). Thus the reaction sequence in the dry melt involves a three electron transfer process with high polarization overvoltage. On the other hand, in the proposed path the initial intermediate is short-circuited to the final product by the rapid disproportionation reaction with a large positive shift of $E_{1/4}$, because water has enough buffer action to act as an acid.

Conclusions

The positive shift of reduction potential reported previously (1) for chromate reduction in the presence of $CaCl_2$ is attributed to the effect of water introduced with hygroscopic $CaCl_2$. Addition of water alone produces the same splitting of the reduction wave. Chronopotentiometric and coulometric studies indicated that the first step consumes two water molecules per chromate ion, which is reduced with three electrons in the presence or absence of water.

The diffusion coefficient of water in molten LiCl-KCl eutectic was calculated from the transition time constant for the reduction of water alone, as well as from that of the first reduction step of chromate in the presence of a deficiency of water.

The first reduction step in the presence of water produces $LiCrO_2$ as an insoluble product. The same product is obtained by the disproportionation reaction of Li_3CrO_4, the initial electron transfer intermediate. This reaction is greatly accelerated by the presence of moisture.

Brief Communications

H_2 and H_2O Oxidation at a Pt/Na^+-Beta Alumina Interface

Gregory C. Farrington*

General Electric Company, Research and Development Center, Schenectady, New York 12301

In concept, a Pt/Na^+-β alumina interface should approximate an ideally polarizable electrode over a potential range limited only by Na^+ reduction at one extreme and O^{--} oxidation at the other. This is a broader range of ideal polarizability than is encountered with typical Pt/liquid electrolyte interfaces.

Both H_3O^+-β alumina (1) and H^+-β alumina (2) have been reported and are prepared by diffusional replacement of the entire Na^+ content of Na^+-β alumina. It is reasonable, therefore, that adsorbed H_2O or H_2 should limit the range of ideal polarizability of a Pt/Na^+-β alumina interface since each can be oxidized to an ion mobile within the β alumina structure. The purpose of this communication is to describe preliminary electrochemical examinations of H_2O and H_2 oxidation at a Pt/β alumina interface.

Experimental

Pt electrodes, 1000Å thick, were sputtered onto both faces of a 1.2 cm diameter, 4 mm thick, polished disk of single phase polycrystalline β alumina of 98% theoretical density, containing approximately 1% MgO and 1% ZrO_2. A reference electrode hole, 0.6 mm in diameter, was drilled 3 mm into the disk from its edge.

Two series of experiments were carried out: (*i*) constant potential polarization between each Pt electrode in vacuum and in the presence of trace amounts of H_2 and H_2O, and (*ii*) cyclic voltammetry in H_2O vapor using a Au wire dipped in Tl(Hg) as reference electrode. A small amount of propylene carbonate electrolyte was injected into the reference electrode hole to insure good electrode/β alumina contact. The reference electrode established a potential satisfactorily stable for these measurements. Its specific potential was not determined.

Results and Discussion

Figure 1 plots current *vs.* time during constant 5.00V polarization of a Pt/β alumina/Pt cell at 23°C. Before analysis, the cell was baked at 350°C at 10^{-3} Torr for 2 hr. Polarization in vacuum (A) reveals the presence of residual oxidizable species, presumably H_2O. The supply is rapidly depleted and cell current approaches zero.

When H_2 gas, dried by passage through molecular sieves, is introduced, current increases (B) and then decreases (C) when vacuum is again established. The most reasonable electrode reaction occurring is

$$H_2 \rightarrow 2H^+ + 2e^- \quad [1]$$

with injection of H^+ into β alumina at the positive electrode. Extended electrolysis for 2-5 min beyond that shown in Fig. 1 produces a gradual decrease in current indicating that exchange of H^+ for Na^+ is accompanied by a decrease in bulk β alumina conductivity.

Introduction of H_2O vapor produces a response similar to B in Fig. 1 but with a current approximately ten times larger. This may indicate that oxidation of H_2O at a Pt/β alumina interface is a faster electrochemical process than oxidation of H_2. The electrochemical reaction of H_2O adsorbed at a Pt/Na^+-β alumina interface was examined in greater detail by cyclic voltammetry. Experiments were carried out at 23°C in a flowing stream of N_2 saturated with H_2O. Results are shown in Fig. 2.

Little cell current is observed upon initial polarization at 0V *vs.* Tl°/Tl^+. Positive potential sweep encounters several oxidation peaks (A-C) which can be attributed to H_2O oxidation to H_3O^+ and O_2. Sweep reversal produces one significant peak at D which can be associated with reduction of a product, presumably O_2, formed at A-C.

At potentials less than −0.40V, a second major reduction peak appears (E). The current increases dramatically beyond −0.75V. Sweep reversal reveals peak F, not observed on initial cell polarization. The rapid decay of current in F suggests it corresponds to depletion of a particular species previously produced in peaks D or E.

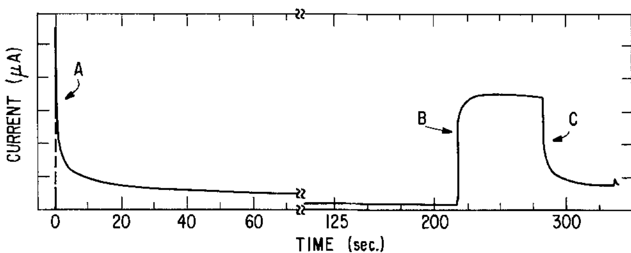

Fig. 1. Controlled potential 5V polarization of Pt/β-alumina/Pt cell. A, initial polarization in vacuum; B, introduction of dry H_2; C, evacuation of H_2; 23°C; electrode area = 0.78 cm^2; current scale is 25 μA/major division.

Key words: polarization, solid electrolyte, water, β alumina.

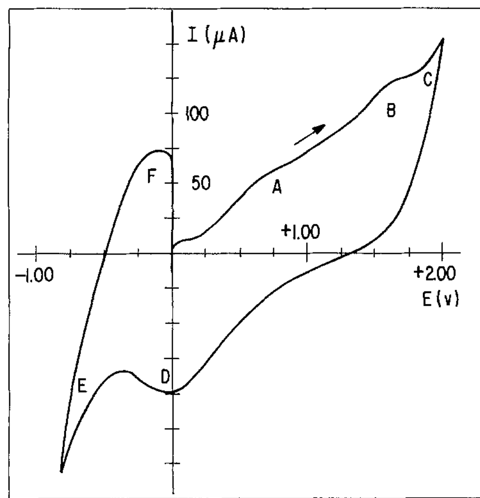

Fig. 2. Cyclic voltammogram of reaction of gaseous H_2O at Pt/β alumina interface. Sweep rate = 200 mV/sec; 23°C; electrode area = 0.78 cm^2; peaks A, B, C, and F represent oxidation; peaks D and E reduction.

The characteristics of peaks E and F are consistent with the hypothesis that E corresponds in part to reduction of adsorbed H_2O with simultaneous Na^+ migration out of the solid electrolyte to the surface. The over-all reaction is

$$4H_2O + 4Na^+_{beta} + 4e^- \rightarrow 2H_2 + 4NaOH \quad [2]$$

Peak F, then, represents reoxidation of H_2 and reinjection of Na^+ into β alumina. Both H_2 and Na^+ exist at the interface only as the result of electrochemical production at E.

This illustrates several of the peculiarities of cyclic voltammetry at a β alumina interface. For an electrochemical oxidation to occur, it must produce ions mobile within the β alumina structure. An ionic flow substituting new ions in β alumina also produces gradual changes in its bulk resistivity which must be considered in interpretation of any I/V sweep data. Correction for *IR* drop in cyclic voltammetry, for example, becomes difficult.

Conclusions

It is clear that H_2O and H_2 can be oxidized at a Pt/β alumina interface to ionic species mobile within the β alumina structure. Oxidation of H_2O, in particular, must be considered in any experimentation assuming blocking behavior at a Pt/β alumina interface or its equivalent. The presence of trace water is surely responsible for the satisfactory behavior of Pt and Au contacts in low frequency impedance measurements on Na^+-β alumina (3-5).

Effect of Water on Beta Alumina Conductivity

F. G. Will*

General Electric Company, Research and Development Center, Schenectady, New York 12301

Water or its cations have recently been shown by several groups to enter the crystal lattice of sodium β alumina. By repeatedly treating small β alumina crystals in boiling concentrated H_2SO_4, Saalfeld *et al.* (1) could show that most of the 4% sodium was replaced by hydronium ions, accompanied by an increase of the c-axis by 0.125Å. The larger part of the water, associated with the protons, desorbed when heating to between 400° and 700°C and adsorbed reversibly when cooling to 160°C in moist air. A gradual increase of the c-axis, amounting to 0.09Å in 96 hr, was also observed by Roth and Mitoff (2) when exposing β alumina powder to moist air.

Supporting evidence for the penetration of β alumina by protonated species also comes from infrared spectra (3). Beta alumina exposed to moist air for several hours shows a broad absorption band indicative of molecular water. The band disappears when heating to 300°C in dry argon. Furthermore, NMR results on β alumina powder exposed to moist air (4) suggest the presence of both water and mobile protons in the conducting planes, in agreement with Saalfeld's results. The characteristic ^1H NMR absorption peaks disappear on heating to 230°C in dry nitrogen, indicating desorption of the water.

While there is clear evidence for the penetration of β alumina by protonated species, no detailed information is available regarding its effects on resistivity. Yet such effects are expected and are significant for the efficient use of β alumina in batteries, in particular, those operating near ambient temperature (5).

The present paper establishes for the case of dense sintered β alumina (*a*) the role of water *vs.* that of hydronium ions and the mechanism by which these species enter, (*b*) the magnitude of the resistivity changes, and (*c*) the effects of water exposure on intragrain and grain boundary conductivity.

Experimental

Experiments were carried out on sintered sodium β alumina disks of 3 cm diameter and 0.15-0.3 cm thickness. The material has the approximate composition $Na_2O \cdot 8.5\ Al_2O_3$, contains 0.5% MgO and 0.5% Y_2O_3 by weight and has a density of about 99% of the theoretical value 3.24 g/cm^3. It has an average grain size of 10μ and is nonpermeable to helium. Details regarding the ceramic processing are published elsewhere (6).

* Electrochemical Society Active Member.

Key words: solid electrolyte, β alumina, ionic conductivity, hydronium ion exchange.

The a-c impedance was measured by placing the β alumina disk between two circular platinized platinum electrodes of 2.5 cm^2 area and porous polypropylene spacers of 0.05 cm thickness, saturated with 1*N* I_2 in a solution of 1*N* NaI in quartz-distilled propylene carbonate. The contribution of the electrodes and spacers to the impedance was established separately and corrected for. The d-c resistivity was determined from the linear polarization curves between 0 and 10 $\mu A/cm^2$ and the a-c impedances were obtained either with an a-c impedance bridge or with a setup described elsewhere (7). Determinations of *p*H were made in N_2-stirred quartz-distilled water, using a *p*H meter. Finally, dynamic water vapor absorption was carried out with a thermobalance in flowing nitrogen with a precision of ± 10 μg.

Results and Discussion

Occlusion of water.—Curve 1 in Fig. 1 shows the occlusion of water by a β alumina disk of 0.15 cm thickness during exposure to a stream of water vapor (23 Torr) in N_2 at 25°C. The disk had been previously dried by heating to 900°C in air for 16 hr. The two salient features of this curve are: (*i*) No straight-line portion is obtained in the $\sqrt{t}$ plot and (*ii*) saturation is essentially reached in 30 min to the extent of $1.5 \cdot 10^{-5}$ moles H_2O/cm^2 β alumina, equivalent to a weight increase of 0.1%. The same weight increase is observed when exposing the β alumina to liquid water for equivalent lengths of time. Dynamic water absorption at 50°C leads to only half the weight increase. By heating the β alumina to 900°C in air, all the water is removed and the original state regenerated.

The absence of a $\sqrt{t}$-relationship (or $[1 - a \exp(-bt)]$-relationship for times approaching saturation) shows that the observed fast occlusion of water by β alumina is not determined by a lattice or grain boundary diffusion process. This conclusion is substantiated by the fact that unreasonably large diffusion coefficients for water in β alumina ($\sim 5 \cdot 10^{-5}$ cm^2/sec) would have to be assumed to explain the short time to reach saturation. The rapid occlusion of water may be rationalized by the penetration of micropores and cleavage planes, followed by adsorption and possibly capillary condensation. Water-induced cleavage of lattice planes may be an important aspect of this mechanism. We have observed water-induced cleavage on β alumina single crystals, and the phenomenon is also known to occur on other layer structures, such as mica.

Hydronium ion exchange.—The *p*H of water rises distinctly with time when β alumina, previously air-dried at 900°C, is exposed to water. The *p*H increase is a quantitative and sensitive measure for the exchange of H_3O^+ in the water against Na^+ ions in the crystal lattice. This ion exchange should be accompanied by a slight decrease in the weight of β alumina. Actually, this effect is masked by the increase in weight due to the occlusion of water, occurring simultaneously.

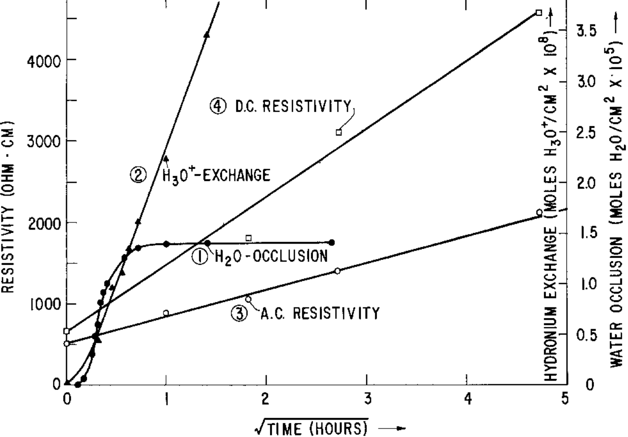

Fig. 1. Water occlusion and hydronium ion exchange (right ordinate) and d-c and a-c resistivity (left ordinate) of sintered dense β alumina as a function of time of exposure to water.

Curve 2 in Fig. 1 shows the number of moles H_3O^+ exchanged for Na^+ in a 3 mm thick β alumina disk during exposure to distilled water at 25°C. In contrast to the penetration of β alumina by water, the penetration by H_3O^+ ions is proportional to $\sqrt{t}$, the rate of penetration is three order of magnitude smaller ($1.5 \cdot 10^{-8}$ moles/cm^2 in 1 hr) and no saturation is observed in days.

This behavior is characterisic of a nonsteady-state diffusion process. The slope of the straight line, curve 2 in Fig. 1, is given by $2c_s \sqrt{D/\pi}$ (8), where c_s and D are the solubility and diffusion coefficient of H_3O^+ in β alumina. Values for c_s and D individually are presently not known. An upper limit of $D_{max} = 3.5 \cdot 10^{-8}$ cm^2/sec is established by the absence of saturation in 140 hr. This is a reasonable value as it falls into the range of the known self-diffusion coefficients of Na^+ and K^+ in β alumina at 25°C, namely, $4.0 \cdot 10^{-7}$ and $9.6 \cdot 10^{-9}$ cm^2/sec (9). For uniform H_3O^+ distribution in the β alumina, the solubility corresponding to D_{max} is $1.8 \cdot 10^{-6}$ moles H_3O^+/cm^3, equivalent to a mole ratio $H_3O^+ : Na^+ \sim 1:4000$. The extent of ion exchange in H_2O at 25°C is thus very small compared to the ratio $H_3O^+ : Na^+ = 1:1$ obtained by repeated treatment in boiling H_2SO_4 (1).

Resistivity changes.—The exchange of H_3O^+ against Na^+ ions is expected to affect the resistivity of β alumina. We have determined the changes in d-c and a-c resistivity (at 1 kHz) that accompany the exposure of dry sintered β alumina to water or water vapor for increasing lengths of time. Curves 3 and 4 in Fig. 1 show that both resistivities increase significantly and proportional to $\sqrt{t}$ without showing evidence for saturation. This behavior parallels that found for the H_3O^+ exchange and is radically different from that observed for H_2O occlusion. For the dry sample ($t = 0$), the d-c resistivity is only slightly larger than the a-c resistivity. However, with increasing exposure to water, the former rises considerably faster, indicating increasing capacitive effects due to H_3O^+ diffusion. The original low resistivity values can be re-established by air drying at 900°C.

Assuming the resistivity increase to be caused by H_3O^+ diffusion into the lattice, one arrives at a model of a band of high-resistivity material penetrating into low-resistivity material with the thickness of the latter progressively decreasing. Treatment of this simple model of two resistivities in series yields the expression $\rho(t) = \rho_\beta + 2\pi\rho_{H\beta} \sqrt{Dt}/d$, with ρ_β and $\rho_{H\beta}$ the resistivities of dry and hydrated β alumina and d the sample thickness. The agreement between observed and predicted behavior indicates that H_3O^+ diffusion into the lattice, not water occlusion, causes the resistivity increase of β alumina when exposed to water. Since identical effects are observed on exposure to water vapor, it appears that multi-molecular adsorption and capillary condensation [see, for example, Ref. (10)] in micropores and cleavage planes are necessary precursors for H_3O^+ exchange. Only after liquid water has been formed, can ion exchange proceed with concurrent formation of NaOH in pores and rifts.

The effects of water vapor on resistivity are consistent with the long-term increase of the c_o lattice parameter (2). This and the fact that complete H_3O^+ exchange leads to an even larger increase in c_o (1) is additional evidence that H_3O^+ exchange causes the observed resistivity increases.

Grain boundary vs. intragrain effects.—The mathematical treatment of H_3O^+ diffusion employs a con-

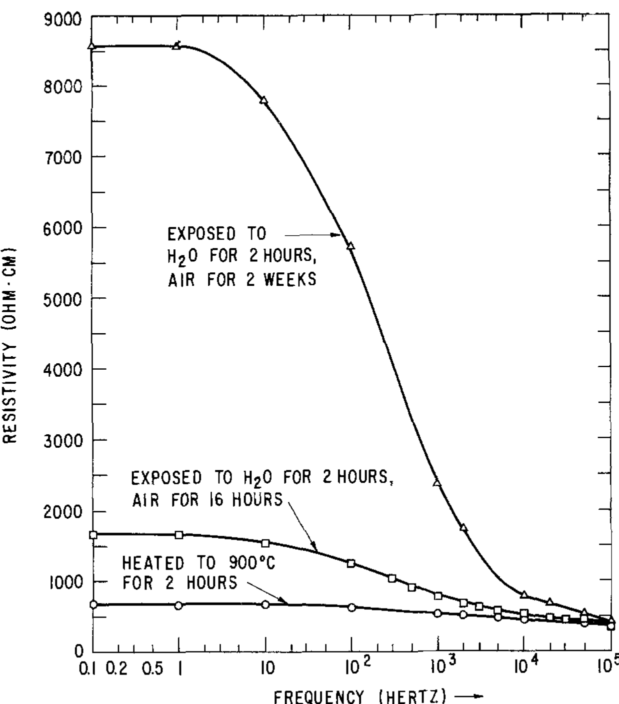

Fig. 2. Specific impedance of dry and moist sintered β alumina as a function of frequency.

tinuum model with effective resistivities. As such it averages over intragrain and grain boundary effects. However, it is of interest to know whether the large resistivity increase is mainly associated with hydronium ions in the lattice of the crystal grains or their boundaries.

The frequency dependence of the β alumina impedance (7, 11) allows a distinction between these two effects. Figure 2 shows the absolute value of the specific impedance plotted against the logarithm of the frequency. All three curves exhibit an upper limit of the impedance at low frequencies, a decrease in a range from 1 to 10^4 Hz and a lower impedance limit at frequencies larger than 50 kHz. The impedance limit at high frequencies is relatively insensitive to water exposure of β alumina, increasing from 440 ohm-cm for a dry disk (lower curve) to 530 ohm-cm for the same disk after long-term exposure to water and water vapor (upper curve). On the contrary, the specific impedance at its low-frequency limit is exceedingly sensitive to water exposure: It increases from 675 ohm-cm for the dry disk to 1780 ohm-cm after 2 hr in water and 16 hr in moist air and to 8600 ohm-cm after an additional 2 weeks in moist air.

Powers and Mitoff (7) studied the impedance of sintered β alumina with different grain size. They found that (*a*) the high-frequency limit is essentially identical to the grain or crystal resistivity, ρ_c, (*b*) the low-frequency limit is determined by both the crystal and grain boundary resistivity, ρ_b, and (*c*) the crossover frequency is inversely proportional to the grain boundary capacity, C_b. Due to the random orientation of the crystal grains, the high-frequency limit of the specific impedance is about 30% larger than the crystal resistivity. Hence, we obtain for ρ_c values of 290 ohm-cm for dry and 350 ohm-cm for moist β alumina. With a measured average grain size of 10^{-3} cm and an assumed grain boundary width of $5 \cdot 10^{-8}$ cm, we have computed the following values for ρ_b and C_b; ρ_b increases from $4.7 \cdot 10^6$ ohm-cm for dry β alumina to $2.5 \cdot 10^7$ ohm-cm for short-term exposure to moisture and to $1.6 \cdot 10^8$ ohm-cm for long-term exposure; the grain boundary capacities C_b/A for the three cases are 460, 160, and 33 $\mu F/cm^2$. The effect of hydronium ions, diffusing into sintered β alumina when exposed to water, is such as to significantly raise the grain boundary resistivity and lower the grain boundary capacity. The concurrent rise in crystal resistivity is relatively minor, *i.e.*, only 20%.[1] The association of H_3O^+ ions with the grain boundaries explains why relatively small amounts ($H_3O^+:Na^+ = 1:4000$) have such significant effect on the resistivity of sintered β alumina.

On β alumina tubes of very much different processing history, Powers and Mitoff obtained typical values of ρ_c between 80 and 90 ohm-cm, ρ_b between 1.5 and $4 \cdot 10^7$ ohm-cm, and C_b/A between 50 and 100 $\mu F/cm^2$.[2] The agreement with the values of ρ_b and C_b/A obtained in this study is good, considering the strong effect of β alumina composition (7) and moisture. However, ρ_c in this study was found considerably larger (290 ohm-cm) than the above values or the 72 ohm-cm obtained on Monofrax single crystals (12). These discrepancies may be due to the different Na-content of the different samples, *i.e.*, Na:Al = 1:8.5 in the present study *vs.* 1:7.9 in Ref. (7) and 1:9.4 in Ref. (12).

Conclusions

When sintered β alumina is exposed to water or water vapor, two processes occur simultaneously: (*i*) the rapid exothermic occlusion of water, probably by micropores and cleavage planes, reaching saturation within a fraction of an hour and (*ii*) the slow diffusion of hydronium ions into the crystal lattice, leading to ion exchange with the sodium ions in the conducting planes, with no evidence for saturation within days. A pronounced increase in the β alumina resistivity accompanies the exchange of even a small fraction of the sodium ions. The effect of hydronium ions is such as to raise the resistivity and lower the capacity of the grain boundaries by more than an order of magnitude. The concurrent rise in intragrain resistivity amounts to only 20%.

[1] Whittingham and Huggins (12) believe to have evidence for a lowering of the resistivity of Monofrax β alumina crystals due to moisture.

[2] The capacities C_b' reported by Powers and Mitoff (7), *i.e.*, 0.012-0.02 $\mu F/cm$, pertain to an equivalent circuit and are related to the grain boundary capacity C_b by $C_b = C_b' A/d_c$, where d_c = average grain size.

Dopant Effects on D-C Dynamic Scattering in a Liquid Crystal: Microscopic Pattern Studies

Hong Sup Lim* and J. David Margerum

Hughes Research Laboratories, Malibu, California 90265

Our studies on the microscopic patterns of d-c dynamic scattering (DS) show that the electrochemical properties of dopants determine the dominant charge injection reaction, direction of liquid crystal (LC) flow, and location of the LC turbulence. This report compares different dopants (an electron acceptor, an electron donor, and a nonreactive salt) in an ester LC. These results differ substantially from earlier microscopic observations (1,2) of d-c DS in other LC's, but are consistent with our studies (3) showing that redox dopants (donors and acceptors which readily undergo reversible electrochemical reactions in the LC) give d-c DS at lower threshold voltages as well as giving higher scattering levels and much longer lifetimes than salt dopants.

A nematic LC (4) designated as HRL-2N10 is used. It has a nematic range of about 18°-55°, a dielectric anisotropy of $\epsilon_a = -0.12$ (25°C, 500 Hz) and a birefringency of $\Delta n = 0.14$ (25°, 545 nm). In the undoped state, it is highly resistive ($\rho_\perp = 3.8 \times 10^{11}$ ohm-cm at 100 Hz) and does not show DS effects. The salt dopant used is tetrabutylammonium trifluoromethanesulfonate (TBATMS); the acceptor is (2,4,7-trinitro-9-fluorenylidene)malononitrile (TFM); and the donor is di-*n*-butylferrocene (DBF).

Electrochemical studies (5) in solvents containing 0.1M tetrabutylammonium perchlorate show decomposition potentials (*vs.* saturated calomel electrode) of the LC components at about +1.7V (in acetonitrile) for oxidation and −2.2V (in dimethylformamide) for reduction. The formal reduction potentials (in acetonitrile *vs.* SCE) for the reversible electrode process of the redox dopants are quite low, *e.g.*, 0.03V for TFM and 0.32V for DBF. Thus when the LC contains TFM or DBF, the electrochemical reactions of these dopants should be a dominant factor in the passage of current through the LC (6). This is confirmed by using a polarizing microscope to observe the direction of LC flow between electrodes. Test cells (Fig. 1) are made by sandwiching the LC between a substrate containing two thin-film transparent electrodes and a glass cover plate with a 51 μm thick Mylar spacer. This cell geometry is chosen to allow space for the back flow of the LC outside the area of observation, *i.e.*, in the periphery of the cell where the field is low. The LC is aligned parallel to the surface of the glass and perpendicular to the electric field by a rubbing technique. With TFM added, the LC flow is predominately from the negative to the positive electrode, while with DBF added the predominant LC flow is from positive to negative. When equimolar mixtures are added, the LC flow in each direction is approximately balanced, which is also the case when the salt dopant is used. These flow patterns are observed by the movement of dust particles in the LC. The flow directions are also confirmed by studies in tubular cells with screen electrodes and sidearm capillaries to indicate the pressure effect of the LC flow.

The direction of the LC flow is consistent with a unipolar space charge injection followed by the propagation of the space charge under the influence of the applied electric field, as previously observed (2) or discussed (7) by others. Our results indicate that in the presence of TFM unipolar injection of negative ions is probably dominant ($TFM + e^- = TFM^-$), followed by the reverse reaction at the positive electrode. Similarly with DBF, unipolar injection of positive ions is probably dominant ($DBF = DBF^+ + e^-$) followed by the reverse reaction at the negative electrode. A simultaneous bipolar injection occurs when both redox dopants or when the salt is present. However, when the dopant is a nonreactive salt, LC radical ions (8,9) are probably formed at the electrodes.

Scattering patterns with the different dopants at various applied voltages are shown in Fig. 2. (No scattering was observed with the salt dopant at 40V.) With the salt dopant, the scattering pattern has a line structure which contains alternating lines originating from each electrode. Thin flow lines of LC are initiated from each electrode at the same time and propagate toward the opposite electrode. Dust particles move along the lines in the direction of the propagation, indicating that the lines are caused by LC flow. These effects are similar to Williams domains (10), in which the source of the LC hydrodynamic motion has been well analyzed (11-13). However, with a redox dopant the general appearance of the scattering pattern is quite different. Turbulent motions of LC are observed at lower voltages, without formation of a regular line structure. The turbulence is initiated from one electrode and propagates toward the other. Except at very high voltages, the turbulence does not reach the opposite electrode but remains localized near the electrode where it was initiated. The most interesting observation is that the turbulence is initiated from the negative electrode when the dopant is the donor and from the positive when the dopant is the acceptor, while the charge injection and the liquid crystal flow are in the opposite directions. Dust particles move from the rear of the nonturbulent electrode toward the turbulent electrode and travel across it.

When the redox dopant is a balanced mixture of the acceptor and donor, the turbulence occurs more randomly. At low voltages turbulence begins at both

electrodes and also between them, although to a lesser extent. Regions of flow may appear, but the over-all effect is more like a combination of pictures from the individual redox dopants than that of the salt dopant finger patterns. The onset of turbulence occurs at lower voltages with redox dopants (single or mixed) than with salt dopants, and the LC turbulence is greater at a given voltage. Similar results are observed with the same LC between transparent electrodes in conventional flat panel cells (3).

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 118, No. 1; January 1971; and Vol. 122, No. 7, 9, 10, 11, and 12; July, September, October, November, and December 1975.

Electrochemical Properties of $RbAg_4I_5$ Solid Electrolyte I. Conductivity Studies

B. Scrosati, G. Germano, and G. Pistoia (pp. 86-89, Vol. 118, No. 1)

K. Shahi:[1] In the above paper the authors have reported some thorough and systematic investigations on a greatly interesting solid electrolyte, $RbAg_4I_5$. They have reported the specific conductivity also as a function of pellet compression pressure in the range 0-5600 kg/cm². The conductivity increases, as expected, with increasing compression pressure and becomes highest ($\sigma = 0.243 \pm 3\%$ ohm^{-1} cm^{-1} at 25°C) at the pressure of 1200 kg/cm². At pressures higher than 1200 kg/cm², they have observed a uniform decrease in conductivity up to the highest pressure (5600 kg/cm²) employed, and attribute it to a certain decomposition of the electrolyte or some possible phase changes.

[1] Department of Physics, University of Gorakhpur, Gorakhpur 273001, India.

We, in our series of measurements on high conductivity solid electrolytes,[2] have found for all the solid electrolytes including $RbAg_4I_5$, that the conductivity increases as the compression pressure increases and attains a maximum value (0.26 ± 3% ohm^{-1} cm^{-1} at 30°C for $RbAg_4I_5$ pellet compressed at 1500 kg/cm^2) as usual, and remains constant for the higher pressures, examined up to 3900 kg/cm^2, unlike that observed by Dr. Scrosati.

The conductivity of polycrystalline $RbAg_4I_5$ has also been measured by Dr. Owens[3] and Dr. Raleigh.[4] Owens reports a conductivity of 0.30 ohm^{-1} cm^{-1} at 30°C for a pellet which was compressed at ~3600 kg/cm^2 while Raleigh reports 0.28 ± 0.3% ohm^{-1} cm^{-1} at 25°C for the pellets compressed in the pressure range 1600-3200 kg/cm^2. Both results are free from any contact resistance and are in excellent agreement if the temperature dependence factor of 1.04% per °C[5] is considered.

If the electrolyte $RbAg_4I_5$ undergoes some phase changes or dissociates to some nonconducting material when compressed at pressures higher than 1200 kg/cm^2, as observed by Scrosati *et al.*; the latter investigations,[3,4] should seldom give the highest values of conductivity, and, furthermore, which are in excellent agreement, because in these investigations the pellets used are compressed at much higher pressures. As such there appears no evidence of dissociation of $RbAg_4I_5$ at higher pressures, at least up to 3900 kg/cm^2 and, therefore, the observation of Scrosati *et al.* would seem unlikely.

B. Scrosati:[5a] I thank Dr. Shahi for having brought my memory back to a paper published in 1971 and work performed in the now-far 1970 when studies on $RbAg_4I_5$ and on solid electrolytes in general were in a very preliminary stage.

In 1976, after the large amount of systematic work which has been carried out on the structural and thermodynamic properties of $RbAg_4I_5$, it is clear how the hypothesis of a decomposition or of a possible phase change of the electrolyte under moderate pressure appears unrealistic. To anyone just a little familiar with work on solid ionic conductors it is obvious how the slight change in conductivity reported in our paper was probably due to electrode/electrolyte contact effects.

I would like to remark here how a discussion of a paper to be really proficient and scientifically stimulating should be reported within a year of its publication, as, on the other hand, has always, to my knowledge, been the custom of the JOURNAL.

Catalytic Decomposition of Nitric Oxide on Zirconia by Electrolytic Removal of Oxygen

S. Pancharatnam, R. A. Huggins, and D. M. Mason
(pp. 869-875, Vol. 122, No. 7)

K. J. Lim and M. Boudart:[6] In the paper under discussion, Pancharatnam, Huggins, and Mason compared the rates of nitric oxide decomposition on platinum reported by a number of investigators. They concluded that the agreement between data obtained by very different methods was quite good, except for data of Amirnazmi *et al.*,[7,8] obtained in a flow system, in the absence of oxygen in the feed.

In fact, the reported discrepancy disappears if the data are correctly extrapolated to the chosen standard comparison condition of 48 Torr NO. A careful analysis of the original papers shows that the data of the batch studies should all be extrapolated using a second-order dependence on NO rather than by the first-order extrapolation of Pancharatnam *et al.* The early data of Green and Hinshelwood,[9] though reported to be first order in NO, were actually fitted better by a second-order expression, as shown by Bachman and Taylor[10] whose own results were also second order. In addition, the recent batch study of Pancharatnam, Lim, and Mason[11] presented evidence for a second-order dependence. When their results at three different NO pressures (400, 800, and 2260 Torr) were extrapolated to 48 Torr using first-order kinetics, three different curves resulted. However, extrapolation using their reported second-order rate expression yielded a single straight line for all the data. Furthermore, Amirnazmi *et al.*[7,8] have shown that NO decomposition on an oxygen-free Pt surface at high temperature follows second-order kinetics.

With the proper extrapolation carried out where needed, all the data summarized in Fig. 11 of the paper under discussion are shown in our Fig. 1. It can

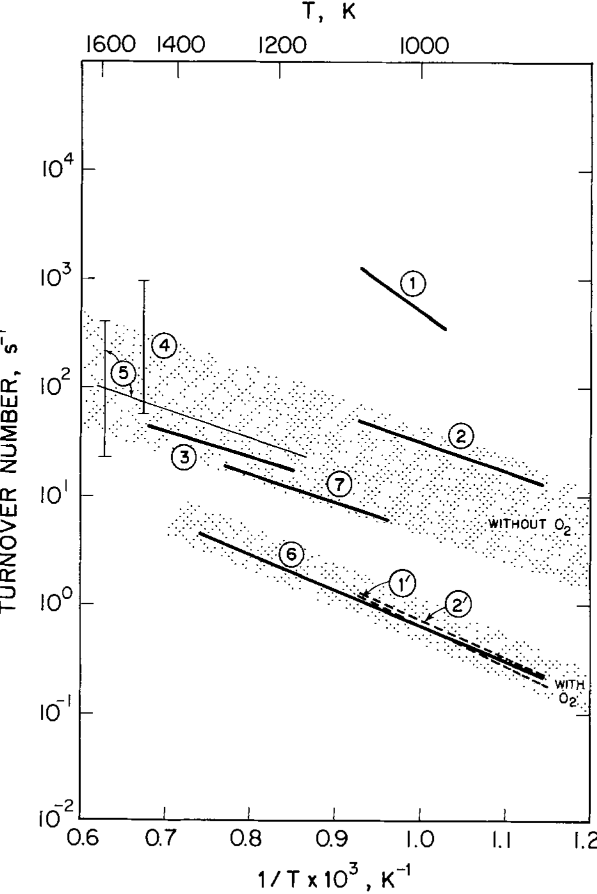

Fig. 1. Comparison of various studies of the decomposition of nitric oxide on platinum, with initial rates expressed as turnover numbers, all data extrapolated to 48 Torr NO. Curve 1': porous Pt, open circuit; 2': nonporous Pt, open circuit (paper under discussion). Curve 1: porous Pt with electrolytic pumping of oxygen (paper under discussion); curve 2: nonporous Pt with electrolytic pumping (paper under discussion); curve 3: heated Pt wire (Ftn[11]); curve 4, heated Pt wire (Ftn[10]); curve 5, heated Pt wire (Ftn[9]); curve 6, supported Pt/Al_2O_3 and Pt foil with O_2 in feed, extrapolated to zero (O_2) (Ftn[7,8]); curve 7, Pt foil without O_2 in feed, extrapolated to zero (O_2) (Ftn[7,8]).

be seen that there is good agreement for the case of oxygen-free platinum between the batch studies (curves 3, 4, and 5), the flow experiments with no added oxygen (curve 7), and the electrochemical results (curve 2). There is excellent accord for the oxygen-covered platinum case, curves 1′ and 2′ from the electrochemical results, and curve 6 from the flow experiments, but this is expected since Pancharatnam *et al.* chose a reasonable surface-roughness factor to conform their data to that of Amirnazmi *et al.*[7,8]

In conclusion, the agreement in the NO decomposition rates among the various investigators is significantly better than presented by Pancharatnam, Huggins, and Mason. Indeed, the agreement is remarkable considering the widely different NO partial pressures studied (10-2260 Torr), forms of platinum catalyst (platinum wire, platinum foil and platinum crystallites supported on alumina, and sputtered platinum films on zirconia), and methods of analysis (batch pressure drop technique, differential flow reactor analysis using gas chromatography, and electrochemical monitoring using an oxygen pump). More importantly, the agreement between data reinforces the conclusion of Amirnazmi *et al.*[7,8] that oxygen is an inhibitor of the decomposition of NO on platinum, and the conclusion of Pancharatnam *et al.* that this inhibition can be removed by electrochemical pumping.

Techniques for the Measurement of the Viscosity of a High Vapor Pressure Organic Electrolyte

H. Y. Kang and P. Bro (pp. 1155-1160, Vol. 122, No. 9)

C. R. Schlaikjer and N. Marincic:[12] We would like to call attention to Fig. 5 in the paper under discussion, where the authors present data for the density of electrolytes prepared by mixing liquid sulfur dioxide with various portions of acetonitrile-propylene carbonate-lithium bromide. The measured specific density of pure liquid sulfur dioxide is reported[13-17] in Table I. Somewhere between 90 w/o SO_2 and pure SO_2, the specific gravity of the electrolyte would have to decrease with increasing SO_2 content in order to correspond with the literature values for the specific gravity of pure liquid SO_2 (see Table II). Based on the reported data of Kang and Bro, we have calculated the partial specific density of liquid sulfur dioxide as a function of the SO_2 content of these mixtures. According to Kang and Bro, the specific gravity of the electrolyte is proportional to the square of the weight fraction of SO_2

$$\rho = kX^2 + C$$

where ρ = solution specific gravity, g cm^{-3}; X = weight fraction of SO_2 (0.3-0.9); k and C are constants. We wish to find $\partial V/\partial M$ cm^3 g^{-1} where V = volume, cm^3 and M = weight of SO_2, g for liquid sulfur dioxide based on the data of Fig. 5, and compare the results with the literature values for pure SO_2. Since

$$X = \frac{M}{S+M} \quad \text{and} \quad M = \frac{SX}{1-X} \qquad [1]$$

where S = weight of AN, PC, and LiBr, g (LiBr:AN:PC = 3:10:5.13)

$$V = \frac{S+M}{\rho} = \frac{S+M}{kX^2+C} = \frac{\left(\frac{SX}{1-X}\right)}{kX^2+C} = \frac{S}{(1-X)(kX^2+C)} \qquad [2]$$

$$\frac{\partial V}{\partial M} = \frac{\partial V}{\partial X} \times \frac{\partial X}{\partial M} \qquad [3]$$

$$\frac{\partial M}{\partial X} = \frac{S}{(1-X)^2}; \quad \frac{\partial X}{\partial M} = \frac{(1-X)^2}{S} \qquad [4]$$

$$\frac{\partial V}{\partial X} = \frac{-S(-3kX^2+2kX-C)}{(1-X)^2(kX^2+C)^2} \qquad [5]$$

$$\frac{\partial V}{\partial M} = \frac{3kX^2-2kX+C}{(kX^2+C)^2} \qquad [6]$$

Using the data presented in Fig. 5 and $C = \rho$ when $X = 0$ and $k = \Delta\rho/\Delta(X^2)$ we find the results as indicated in Table III.

Table I

Temp °C	−40	−20	0	20	30	50	70
Specific density cm^3 g^{-1}	0.6523	0.6739	0.6974	0.7231	0.7375	0.7722	0.8137
Specific gravity g cm^{-3}	1.533	1.484	1.434	1.383	1.356	1.295	1.229

Table II

Temp °C	Electrolyte specific gravity at 89.1% SO_2	Specific gravity of liquid SO_2	Per cent difference
−40	1.570 g cm	1.533	−2.4
−20	1.525	1.484	−2.7
0	1.490	1.434	−3.8
20	1.443	1.383	−4.2
30	1.415	1.356	−4.2
50	1.366	1.295	−5.2
70	1.32	1.229	−6.9

Evaluating Eq. [6] for various values of X and temperature, we find the results in Table IV.

The values of $\partial V/\partial M$ most nearly match those of pure liquid SO_2 for low values of X. At higher values of X, $\partial V/\partial M$ becomes smaller than the specific density of the pure solvent ($1/\rho$). If the data in Fig. 5 are correct, they would suggest that the lithium bromide, acetonitrile, and propylene carbonate occupy spaces between the SO_2 molecules in solutions with high SO_2 content.

The reported data are not necessarily inconsistent with the literature values for pure liquid sulfur

Table III

dioxide, but the most interesting part of Fig. 5 has been omitted. Perhaps the authors could have included specific gravity measurements for pure SO_2 along with the rest of their data, if their original purpose made it unnecessary to measure electrolyte specific gravities for values of X above 0.9. With the specific gravities for pure SO_2, the proposed quadratic function cannot be valid above $X = 0.9$.

On the Kinetics of the Breakdown of Passivity of Preanodized Aluminum by Chloride Ions

Z. A. Foroulis and M. I. Thubrikar
(pp. 1296-1301, Vol. 122, No. 10)

J. Augustynski and J. Painot:[18] In the paper under discussion, Foroulis and Thubrikar propose a model of passivity breakdown of aluminum by chloride ions, supported essentially by their investigation of the induction times for pitting nucleation on preanodized aluminum in neutral chloride solutions. The postulated mechanism involves adsorption of Cl^- ions on the aluminum oxide-solution interface at the critical potential and the subsequent localized dissolution of the oxide film via formation of a soluble, basic aluminum chloride salt. These suggestions, substantially different from models of the passivity breakdown discussed earlier in literature,[19-23] call for comment. The mechanism proposed by Foroulis and Thubrikar implies that at potentials more negative than the critical pitting potential the interaction between chloride ions and the hydrated oxide film is restricted to the oxide-solution interface. However, direct experimental evidence exists that chloride ions become included in the oxide film on aluminum before the critical pitting potential (E_{cr}). In our study[24,25] by x-ray photoelectron spectroscopy (XPS or ESCA) of the oxide-covered aluminum exposed to chloride solutions we show that the chlorine content of the aluminum oxide film increases from *ca.* 3 a/o Al atom at the open-circuit potential (E_{st}) to 16 a/o at E_{cr} −0.01V (Table I: 0.1N NaCl solution). These XPS analyses were performed on samples prepolarized both in weakly acid (pH 3) and in neutral solutions; the results were similar. The film thickness being, in the former case, less than the XPS effective depth (*ca.* 20-25Å),[26] the relative Cl concentrations given in Table I are, in fact, the mean Cl concentrations in the whole oxide film covering passive aluminum. Consequently these results should be considered as evidence for chloride ion incorporation into the aluminum oxide film at the potentials more negative than E_{cr}. Indeed, the mean Cl concentration of 16

a/o is much too high to be assigned to ion adsorption on the hydrated oxide-solution interface, especially if one takes into account that the chloride ion action is localized in certain selected sites in the oxide film. Our XPS results also throw some light on the nature of the Cl bonding inside the oxide film. As shown in Table II, the binding energy of the Cl $2p^{3/2}$ electrons for Cl included in the oxide film is somewhat lower than the corresponding value for $AlCl_3$, suggesting that Cl^- ions entering the aluminum oxide lattice may form an aluminum oxychloride AlOCl. We would like to mention that our XPS results concerning natural, thin, aluminum oxide films go in the same direction as an earlier work of Heine *et al.*[20] who investigated the Cl^- and SO_4^{2-} incorporation into the aluminum oxide film formed by anodization. These authors have observed a marked decrease of the ionic resistance of the oxide film on the aluminum samples exposed to 1N sodium chloride solution. Turning to the paper of Foroulis and Thubrikar, we draw attention to the fact that the different pretreatment (anodization) conditions of aluminum may alter its anodic behavior, not only because of the variation in the film thickness, but also owing to the modifications in the chemical composition of the film. As a matter of fact, the SO_4^{2-} anion is incorporated (up to 17%) into porous anodic films formed in sulfuric acid.[27] Thus, the increase of the critical pitting potential reported in the paper under discussion for the aluminum sample preanodized in 15% H_2SO_4 could be alternatively explained by an inhibiting action of sulfate ions included in the oxide lattice.

Z. A. Foroulis:[29] We appreciate the comments by J. Augustynski and J. Painot and the summary of their recent ESCA data on the composition of thin aluminum surface oxide films formed by exposing freshly polished aluminum specimens in electrolytes containing 0.33M $Al_2(SO_4)_3$ + 0.1M NaCl solutions at various potentials.[30] We believe that their results do not contradict our postulated mechanism[31-33] of passivity

breakdown involving adsorption of chloride ions on the aluminum-oxide solution interface and subsequent localized dissolution of the oxide film via formation of a soluble basic aluminum chloride salt.

Under the experimental conditions used by Augustynski and Painot, it is not surprising as their ESCA data indicate that the oxide surface films formed on aluminum either as a result of natural immersion or by anodic polarization containing chloride ions. In their experiments, the aluminum specimens, prior to being immersed in solutions containing $Al_2(SO_4)_3$ + NaCl, were freshly polished with emery paper, and under these conditions, it is reasonable to assume that the aluminum electrodes were covered with a thin (about 25Å) air-formed oxide film which is generally considered to be an amorphous γAl_2O_3.[34] On exposure to aqueous electrolytes, these thin films are known to thicken at a rate which depends, among other factors, on potential and solution composition.[34-37] It is reasonable to expect that during the film-thickening process, which may initially involve at least partial dissolution of the thin air-formed film,[38] anions including chloride ions from the electrolyte are likely to be incorporated within the oxide lattice formed during the oxide-thickening process. In addition, a higher concentration of chlorides is likely to be incorporated in the oxide film when film thickening occurs at higher potentials.

It is therefore our view that the chloride ions found in the oxide films studied by Augustynski and Painot have their origin not in a passivity breakdown process but in a process of oxide film formation in solutions which contain chloride ions. This explains why chloride ions were found within the oxide film at potentials lower than the critical pitting potentials, at which pitting is not expected to occur.[39,40] The chloride ions, in the case of their experiments, were incorporated during the oxide formation (growth) process, which occurred at potentials lower than the critical pitting potential.

In the case of our experiments,[32,33] the kinetics of the passivity breakdown process was investigated using preanodized aluminum specimens with barrier oxide films of considerable thickness and reasonably well-known structures. The barrier oxide films were formed in solutions which did not contain chloride ions and therefore chloride ions could not be incorporated in the oxide film during formation of these oxide films. In this case, the reasonably thick barrier-type oxide films are likely to be "stable" upon immersion in the test electrolyte during the passivity breakdown experiments, and no further growth of the oxide film is likely to occur. The interaction of such an oxide film with Cl^- in solution during passivity breakdown experiments, according to our proposed passivity breakdown mechanism, should be restricted primarily to the oxide solution interface and no significant chloride concentration should be expected within the oxide film material.

This explanation is in accord with the recent findings of G. C. Wood *et al.*,[41] who investigated the interaction of preanodized barrier oxide-covered aluminum surfaces with solutions containing chloride ions at different potentials using secondary ion mass spectrometry. These authors reported that chlorides were abundantly present on the oxide-solution interface, but they found no measurable chloride within the oxide film material, either as a result of natural immersion or by anodic polarization.

It is our view that whether or not chloride ions are likely to be incorporated in the oxide film will very much depend on the thickness and structure of the oxide film pre-existing on the aluminum specimen prior to immersion in aqueous solutions containing chlorides.

When an oxide-covered aluminum specimen is immersed in an aqueous solution, the rate of migration of aluminum ions toward the oxide-solution interface and therefore thickening of the pre-existing oxide film will depend on the over-all potential drop (pd) between the bulk metal and the bulk solution which is controlled either by an external power source (*e.g.*, a potentiostat) or by local action currents. Adsorption of anions such as Cl^-, OH^-, etc. from solution on the oxide surface will also create an electrostatic field (due to image charges) which will also tend to accelerate the outward migration of aluminum cations and thus the thickening of the oxide film.

When aluminum covered with thin oxides, such as air-formed films or even thin films formed by anodization,[42] is immersed in an aqueous electrolyte containing Cl^-, the electrostatic field strength across the oxide film at constant over-all pd is sufficiently high, the rate of outward migration of aluminum ions through the film is considerable, and film thickening occurs until the oxide film reaches a thickness at which, for the given over-all pd, further migration of aluminum ions through the oxide film becomes negligible. During the surface oxide film thickening process, inclusion of solution anions such as Cl^-, $SO_4^=$, etc. in the oxide lattice is very likely to occur.

However, when aluminum covered with relatively thick oxide films, such as the barrier films used in our work[32-33] as well as those used by G. C. Wood, *et al.*,[41] is immersed in chloride-containing solutions, at constant over-all pd, because of the higher thickness of the pre-existing oxide film the electrostatic field strength across the oxide film is lower and thus the outward migration of aluminum cations is negligible, and thickening of the oxide film does not occur. This mechanism explains the results by Wood and coworkers[41] who found no measurable chloride within a preanodized barrier-type oxide film (of about 720Å) after it was exposed to 1M KCl at different potentials. It also explains the results of Painot and Augustynski[30] and M. A. Heine *et al.*[42] who reportedly found measurable amounts of chloride ions within thin oxide films.

Sulfate ions incorporated in the oxide film during anodization may have some influence on the behavior of oxide films during the passivity breakdown process. However, on the basis of results available to date,[32,33] we feel that the oxide film thickness is likely to be more important as far as the critical pitting potential than the presence of sulfate ions in the film as suggested by Augustynski and Painot.

Finally, it should be stated that the passivity breakdown model proposed in the paper under discussion should be applicable to aluminum whether or not the passive surface oxide film is "contaminated" with chloride ions which may have been incorporated in the oxide lattice during the process of oxide film formation.

[43] 383 South Lexington Avenue, White Plains, New York 10606.

device described. The apparatus produces hydrogen and oxygen via a photoelectrolytic process involving water, and the authors compute its conversion efficiency as the ratio of the heat of combustion of the hydrogen it produces to the time-integrated insolation at its photoanode array. What is overlooked, however, is that the system does not merely electrolyze water. Since the anodes operate in 1.0*M* NaOH and the cathodes in 0.5*M* H_2SO_4, the electrode reactions are

$$2H^+ + 2e^- \rightarrow H_2$$

at the cathode, and

$$2\,OH^- \rightarrow H_2O + \tfrac{1}{2}\,O_2 + 2e^-$$

at the anode, from which one finds that the actual cell reaction is

$$2H^+ + 2\,OH^- \rightarrow H_2O + H_2 + \tfrac{1}{2}\,O_2$$

It is clear, therefore, that 1 mole of water is produced per mole of hydrogen, and that the enthalpy of the neutralization, which is essential for spontaneous operation of the cell, is provided not by the sun, but rather by the power plants of the firms that produce the NaOH and H_2SO_4.

The heat of combustion of hydrogen to water vapor is -57.8 kcal/mole, while the heat of neutralization of H^+ by OH^- is approximately -13 kcal/mole. From these values one finds that, at best, the energy conversion efficiency calculated by the authors is overstated by $\sim$25%. This alone is significant, but perhaps more so is the fact that remote energy consumption has not been acknowledged. I feel it is necessary that any new energy production technique be scrutinized to determine to the greatest extent practical not only the amount of energy that is produced, but the amount consumed in hardware fabrication, operation, and maintenance.

A. Fujishima,[44] **K. Kohayakawa,**[45] **and K. Honda:**[44] We agree with the comments given by Bezman in relation to the contribution of the neutralization energy to the formation of hydrogen. This contribution was already pointed out in our previous paper[46] where the neutralization energy was expressed in the form of the electromotive force due to the difference in *p*H between the anolyte and the catholyte. As the electromotive force is 59 mV for unit *p*H difference in comparison with the thermodynamic decomposition voltage of water of 1.23V, the contribution of neutralization energy to the decomposition of water will be about 5% for each one unit *p*H difference.

As the integrated incident solar energy was not measured on the day of experiments in the present paper, the reported value of solar energy in Japan of 3000 kcal/m^2/day was referred to and taking into consideration the above-mentioned contribution and the actual weather conditions of the day of experiments, the rough estimate of the conversion efficiency of 0.4% was given for a simple example.

A Limitation to the Mixed Potential Concept of Metal Corrosion

T. N. Andersen, M. H. Ghandehari, and H. E. Eyring
(pp. 1580-1585, Vol. 122, No. 12)

F. M. Donahue:[47] The paper under discussion is extremely valuable (in my opinion) for two reasons: (*i*) the authors have correctly identified a mixed potential system where interaction between the partial processes occurs, and (*ii*) they have supplied sufficient tabular data to allow a quantitative evaluation of their interpretations.

Let us consider the first point in some detail. Both the title of the paper and the text seem to indicate that they have somehow "discovered" something which has not been observed previously. Nearly two decades ago Heusler[48] (and he was probably not the first to note this!) showed that the kinetics of the reaction

$$Fe = Fe^{2+} + 2e^- \qquad [1]$$

in acid solution was dependent upon the hydrogen ion concentration, *i.e.*, the reactant in the cathodic partial process in the corrosion reaction. Since then numerous other authors[49-52] have verified this interaction. This kind of interaction occurs with such frequency in mixed potential systems that this author wrote a paper indicating how the reaction orders for the interacting species (as well as the reaction orders for the "normal" species) could be determined from data at the mixed potential.[53] Therefore, the point the authors of the paper under discussion make that interdependence among the partial processes "does not seem to have been stressed previously" is in error. Admittedly, the interactions were not always indicated in the titles of the papers mentioned above (Ftn[48,53] are exceptions to this), but the text of these papers clearly speaks to such interactions.

The authors are correct in their critical remarks concerning the "superposition" approach. However, they seem to have drawn too much from Vetter's remark concerning the independence of the partial processes (Ftn[54], p. 732) when the key point in mixed potential theory is "the important 'principle of additive combination of all partial processes'"[54] which Vetter correctly ascribes to Wagner and Traud.[55] Mathematically, this may be written

$$i_{\text{net}}(E) = \sum_j i_j(E) \qquad [2]$$

where $i_{\text{net}}(E)$ is the observed (measured) current density flowing at a polyelectrode at an electrode potential (*vs.* some reference electrode), E, and $i_j(E)$ represents the current associated with all electrochemically active species in the solution at that same potential. Equation [2] is merely a statement of the law of conservation of charge; no such law exists for the "conservation of polarization curves for partial processes."

In order to ascertain the presence of interactions, certain experiments are required. The authors have noted that experiments performed somewhat removed from the mixed potential (as in the case of Ftn[48-52]) may be in error due to changes in the "catalytic properties of the surface." This author agrees with this contention and, consequently, developed a scheme for studies at the mixed potential.[53] The authors have chosen a "middle ground" and provided sufficient data to allow an assay of their interpretations.

For the sake of uniformity, the subscripts for current density used by the authors in the paper under discussion will be adopted here. Further, since their reactions [1], [2], and [4] are associated with charge transfer processes (reaction [3], it would seem, is a liquid-phase, homogeneous reaction and cannot have an associated current density as the authors have done), Eq. [2] for the experiments in the presence of oxygen at a fixed electrode potential is

$$i_a(O_2) = i_1 + i_2 + i_4 \quad [3]$$

A material balance on copper metal yields

$$i(Cu, O_2) = i_1 + i_2 \quad [4]$$

Substituting Eq. [4] in Eq. [3] and rearranging

$$i_4 = i_a(O_2) - i(Cu, O_2) \quad [5]$$

Table I shows the values of i_4 computed from the data in Table I of the subject paper. Three points are obvious from this analysis: (*i*) the numbers are different from those given by the authors, (*ii*) i_4 is more-or-less constant, and (*iii*) all of the current densities are negative. Since the reduction of oxygen is a cathodic partial process operating about 1V from its equilibrium potential, one would expect its current density to be constant (at the value of the limiting diffusion current density) and, by convention, negative (see Ftn[54], p. 8). The analysis given here corroborates that expectation while the authors' analysis does not. The apparent error is their treatment of the material balances (their Eq. [6]-[9]). The computed average value for i_4, *i.e.*, 1.38 mA/cm^2, agrees favorably with the authors' limiting diffusion current for oxygen of 1.6 mA/cm^2.

The magnitude of the interaction can be obtained from

$$i_{inter} = i(Cu, O_2) - i(Cu, N_2) \quad [6]$$

Table II shows the values for this interaction as a function of potential. It is not obvious what conclusion(s) can be drawn from this information. If a Tafel line is drawn through these data, one obtains a slope of about 100 mV. If the data at 80 mV are ignored (there seems no justification for this, however), one concludes that the interaction is a constant. If the homogeneous reaction is invoked, *i.e.*, the authors' reaction [3], one anticipates that the rate of this homogeneous reaction would be proportional to the interfacial concentration of cuprous ion. However, one anticipates a Tafel slope for this to be 59 mV at 25°C since (from their model)

$$[Cu^+] = K \exp\left[\frac{FE}{RT}\right] \quad [7]$$

where $[Cu^+]$ is the concentration of cuprous ion and K is a constant which includes the standard electrode potential and the "equilibrium" concentration of Cu^+ at the standard potential. The singular conclusion which does seem evident from the discussion presented here is that the authors' contention that the homogeneous oxidation of cuprous ion as the source of the "interaction" is incorrect. Hopefully, more work in this area will lead to a fuller understanding of the phenomenon.

T. N. Andersen, M. H. Ghandehari, and H. Eyring:[56] Dr. Donahue's criticism appears to have two points. He believes (*i*) that the Cu/O_2-H_2SO_4 system is not unique in the mixed potential sense, as the authors claimed, and (*ii*) that the authors' theory for the observed results is incorrect. In both cases Donahue missed the point of our paper which careful reading should have made clear. These points shall be rebutted separately, although they are both related to the same misunderstanding.

The first point of our paper was that the corrosion system at hand differs from most in that the anodic and cathodic rates, as determined independently, are not applicable when the reactions are coupled (allowed to occur simultaneously). Thus the reactions are not independent in the mixed potential sense, as defined by Wagner and Traud[55] and reiterated by most other electrochemists (see Ftn[54]). If the reactions were independent, the rate of copper dissolution would be equal in N_2- and O_2-saturated solutions at the same potential.

In the case of the system referenced by Donahue (Fe in acids), both the isolated anodic (Fe dissolution) and cathodic (H_2 evolution) reactions have H_3O^+ or OH^- ions as reactants. Authors who have chosen to couple these reactions in explanation of corrosion phenomena (*e.g.*, see Ftn[51]) have done so successfully using the conventional mixed potential theory, *i.e.*, by adding the rates of the isolated reactions at each potential. In the Cu/O_2-H_2SO_4 system this could not be done consistent with the observed corrosion rate.

Hence Donahue's references reaffirm the uniqueness of the present system, and his own paper[53] acknowledges agreement with the conventional theory of mixed potentials in the lead-off statement, "Interactions between the anodic and cathodic partial processes in mixed potential systems ... can be ascertained from extensive studies of the electrode kinetics of the respective partial processes."

The second point of our paper was to provide an explanation for the atypical behavior of the Cu/O_2-H_2SO_4 system, *i.e.*, for the observation that the copper dissolution rate in O_2-saturated solution, $[i(Cu, O_2)]$ is greater than the corresponding rate in N_2-saturated solution $[i(Cu, N_2)]$ at the same potential. Our discussion section focuses on developing a suitable theory which is consistent with the various parametric test results obtained as well as with the above observation. Donahue's explanation of our data obliges him to ignore the very point of our paper, that $[i(Cu, O_2)/i(Cu, N_2)]_E > 1$. He passes off this significant observation in his concluding paragraph as unexplicable. Inasmuch as Donahue's theory (his Eq. [3] and [4]) is nothing more than conventional mixed potential theory, it is not surprising that he has no explanation for the above inequality. The first step in our interpretation was to abandon that approach and find a satisfactory one.

Further amplification of the disagreement between our model and Donahue's follows from carrying through the arithmetic of the two differing theories. The discusser's conventional theory of mixed potentials puts all the oxygen consumption into one term, i_4. The authors' theory obviously deduces the same total rate of O_2 consumption, which is given by $i_3 + i_4$ in Table III in the paper under discussion. The reviewer should have noted that there is no sign problem with i_4, which is defined in its absolute sense by Eq. [7] of the paper.

A final point of misunderstanding on Donahue's part is with regard to the rate of Cu dissolution via the different routes of steps [1], [2], and [3] in the authors' theory. The rate of Cu dissolution is measured as the

[56] Department of Chemistry, University of Utah, Salt Lake City, Utah 84112.

$$i_a(O_2) = i_1 + i_2 + i_4 \quad [3]$$

A material balance on copper metal yields

$$i(Cu, O_2) = i_1 + i_2 \quad [4]$$

Substituting Eq. [4] in Eq. [3] and rearranging

$$i_4 = i_a(O_2) - i(Cu, O_2) \quad [5]$$

Table I shows the values of i_4 computed from the data in Table I of the subject paper. Three points are obvious from this analysis: (*i*) the numbers are different from those given by the authors, (*ii*) i_4 is more-or-less constant, and (*iii*) all of the current densities are negative. Since the reduction of oxygen is a cathodic partial process operating about 1V from its equilibrium potential, one would expect its current density to be constant (at the value of the limiting diffusion current density) and, by convention, negative (see Ftn[54], p. 8). The analysis given here corroborates that expectation while the authors' analysis does not. The apparent error is their treatment of the material balances (their Eq. [6]-[9]). The computed average value for i_4, *i.e.*, 1.38 mA/cm^2, agrees favorably with the authors' limiting diffusion current for oxygen of 1.6 mA/cm^2.

A final point of misunderstanding on Donahue's part is with regard to the rate of Cu dissolution via the different routes of steps [1], [2], and [3] in the authors' theory. The rate of Cu dissolution is measured as the

[56] Department of Chemistry, University of Utah, Salt Lake City, Utah 84112.

number of Cu^{+2} ions dissolved from the metal per unit time, which is the sum of reactions [2] and [3]. Inasmuch as $i(Cu, O_2)$ was defined as this rate multiplied by $2\mathbf{F}$ ($\mathbf{F}$ is Faraday's constant), Eq. [8] follows. The anodic electric current contributed by Eq. [3], which contributes to the total anodic electric current $i_a(O_2)$, is i_3 because reaction [1] precedes i_3 and occurs once for each occurrence of i_3. Path i_2 contributes 2 electrons, one for its own occurrence and one for the preceding step, i_1.

The coupling of i_1 and i_3 is the reason the Tafel slope for i_3 is larger than $2.3\ RT/\mathbf{F}$ (59 mV). The step i_3 is fed through our step [1] which Donahue takes into account in desiring a Tafel slope of 59 mV; i_3 is also fed by slow-diffusing O_2 which also adds to the potential dependence and which the discusser has ignored.

The Erosion of Materials in Molten Silicon

R. E. Chaney* and C. J. Varker*

Motorola Incorporated, Semiconductor Products Division, Phoenix, Arizona 85008

ABSTRACT

The erosion rates and mechanisms are discussed for several materials in contact with molten silicon near its melting point. Vitreous materials, *e.g.*, vitreous carbon and fused silica, behave similarly and erode primarily by dissolution. Pressed-powder materials, *e.g.*, silicon carbide and silicon nitride, degrade by a combination of dissolution and particulate erosion (intergranular corrosion).

The resistance to degradation is an important property to consider when choosing materials for hardware applications with molten silicon. Many materials have been investigated in the past, but the literature is not consistent with respect to experimental conditions or interpretation of results. Here, we are reporting the results of some preliminary work which directly compares some materials and gives insight into criteria which should be applied to future investigations.

Material selection criteria.—One of the basic problems in silicon technology to which this project addresses itself is the high concentration of oxygen in crystals grown from crucibles (1, 2). If a material can be found which does not supply high levels of oxygen or any other impurity to the melt, that would be ideal. But the application of a material which supplies an electrically inactive impurity such as carbon or nitrogen in place of oxygen may solve the problem in a satisfactory manner. For this reason a systematic investigation of silicon nitride, silicon carbide, and carbon was undertaken. The nitride and carbide were obtained in the most convenient form available, hot-pressed rods of high purity powder, from Cerac/Pure Incorporated with no binders used in fabrication. A single sample of nitride from Norton Corporation was also tested (NC 350). Vitreous carbon was the carbon form tested because of its ability to take a high polish, the absence of voids in the bulk, and its hardness (6-7 on Mohs scale). The problems associated with porous materials (penetration of the surface by the melt and high surface-to-volume ratio) precluded the use of other forms of carbon in the early stages of this investigation. The vitreous carbon samples were obtained from Beckwith Carbon Corporation.

Experimental

The procedure used to test the selected materials is simple, but direct. A sample, usually a rod from 0.6 to 1.3 cm in diameter, was prepared by centerless grinding, dry polishing, and cleaning. After its diameter profile was taken, it was mounted in a seed chuck of a standard Czochralski crystal growth furnace. After flushing with helium, a 2 kg charge was melted in a silica crucible. The temperature was adjusted to about 5°C above the melting point so that crystallization on the sample was prevented. The rod is either immersed about 4 cm into the melt and then withdrawn by stages (termed pulling) or immersed by stages into the melt (termed pushing). Figure 1 shows schematically the process. No difference in results was noted for pushed and pulled samples. After the experimental testing is complete, the sample is removed, adhering silicon is removed with an appropriate etch if necessary, then the diameter measurements are repeated. The difference in diameter gives a measure of the erosion rate. This is translated directly into the rate at which the surface is removed by the melt.

During the experiment the crucible and sample are both rotated slowly so that the effects of any thermal asymmetry are removed. Because one of the proposed

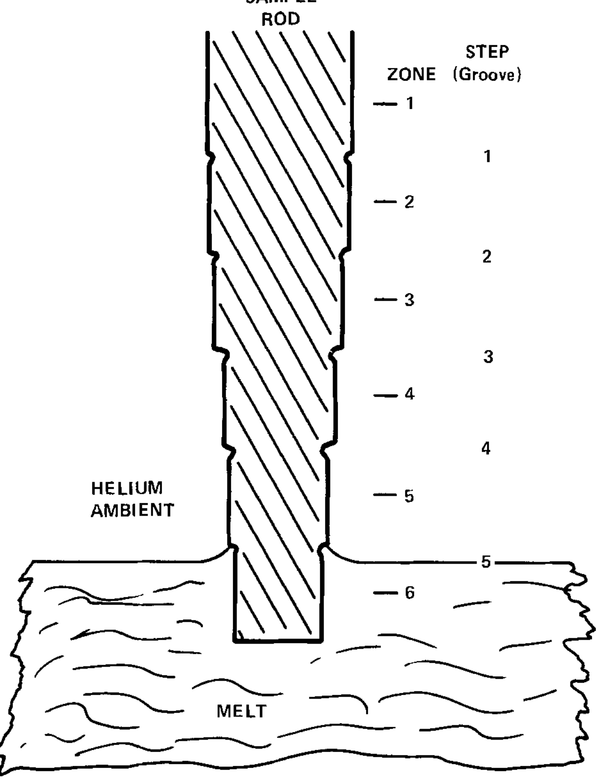

Fig. 1. Schematic diagram of the cross section of samples produced by erosion testing. Note the grooves formed at liquid-solid-ambient interface.

Key words: crystal growth, vitreous carbon, silicon nitride, silicon carbide, silicon.

uses for these materials is for forming dies in ribbon crystal growth processes, the crucible and sample rotation rates are set differently so that the resulting fluid flow on the sample surface approximates the flow conditions in forming dies at a representative growth rate of 5 cm/min (3).

Results and Discussion

Figure 1 illustrates the type of samples produced. Zone 1 is the area of the rod which was not exposed to the melt. Zones 2-6 were exposed for increasing lengths of time. At the surface of the melt, surface tension-driven flow causes convection currents which accelerate the erosion at the liquid-solid-ambient interface (4). These convection currents are stronger than those caused by stirring or thermal gradients in this region. The accelerated erosion produced grooves which were found in all interface zones of all of the samples tested. All depths were measured with respect to the surface of the same numbered zone, *i.e.*, the depth of groove 1 was measured with respect to the surface of zone 1. Data on the depth of these grooves and their variation with exposure time have been gathered by use of a metallographic microscope. It is presented in this report, but the analysis of this effect is outside the scope of this study.

Table I summarizes the data for all of the samples tested. Results for fused silica are included in the tabulation because it is the currently used crucible material throughout the industry. It is used here as a standard for comparison. For clarity in interpreting the results, the depth of erosion and the grooves is listed for 100 and 60 min, respectively. Thus samples which have erosion curves which do not intersect the axis can be compared in terms of absolute erosion depth.

Vitreous carbon.—In this study two sets of experiments with vitreous or glassy carbon were conducted. Samples 1 and 2 were tested in the as-received condition. Samples 3 and 4 were polished prior to testing. Figure 2 shows the results of the erosion testing. The change in sample radius *vs.* exposure time yields the erosion rate or the rate at which the surface recedes with exposure time, $\Delta r/\Delta t$.

All samples yield a linear curve, but the results of samples 3 and 4 show that surface polishing yields a surface which erodes less and more reproducibly than the as-received samples. Figure 3 shows an area of a sample after treatment and a light etch. The light area to the left is a fracture surface showing the void-free nature of the bulk. The gray area to the right is the surface which was exposed to the melt for 4 hr. The tiers are very shallow. The grainlike structure suggests a crystalline surface. X-ray diffraction shows no identifiable crystalline SiC structure for the surface. The diffraction spectra for bulk vitreous carbon and the sample surface differed only in relative peak heights and width, but not in peak position or number. Figure 4 shows a cross section of a similar sample. In this case a silicon drop adhered to the bottom of the sample rod. The sample was cut to reveal the vitreous carbon-silicon interface.

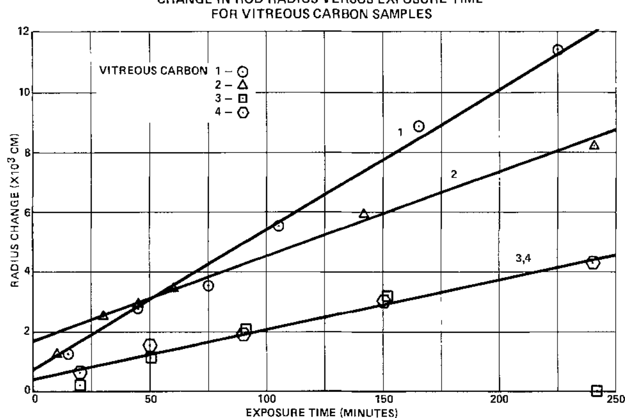

Fig. 2. Graph of radius change with respect to time for various vitreous carbon samples: 1 and 2 were in as-received condition, 3 and 4 were polished prior to treatment.

Table I. Tabulation of erosion results

Sample	Erosion rate (surface) $\Delta r/\Delta t$	Erosion depth 100 min	Erosion rate (groove) $\Delta x/\Delta t$	Erosion depth 60 min	Comments
SiO_2	1.15×10^{-5} cm/min	1.2×10^{-3} cm	8.4×10^{-5} cm/min	6×10^{-3} cm	(6)
Vitreous carbon					
1	4.7	5.4	18	11	Pushed
2	2.8	4.5	44	27	Pulled
3	1.7	2.1	6.8	7.3	Pushed
4			0	5	Pulled-flat grooving curve
SiC					
1	5.7	6.8		~16	Pulled
2	7.9	4.1		1.2	Pushed Groove data uncertain
3	1.1	1.1		5	Pushed
Si_3N_4					
1	3.1 (same curve as 5)	1.7	15	9	Pushed
2	1.2	2.0	11	6.6	Pulled
5	3.1	1.7	11	8.0	Pushed
NC350	4.9	4.9	11	7.0	Pulled

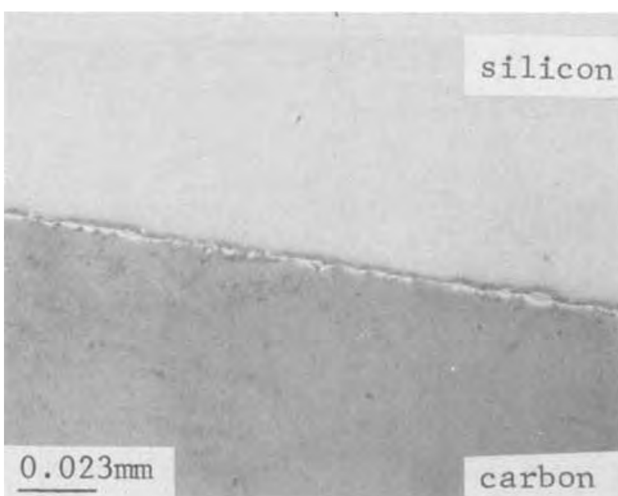

Fig. 4. Optical photomicrograph showing the interface layer formed when molten silicon solidifies on to a vitreous carbon surface.

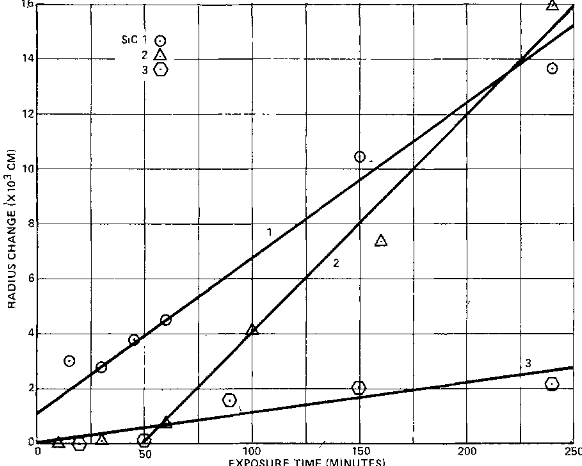

Fig. 5. Radius change vs. exposure time for SiC samples

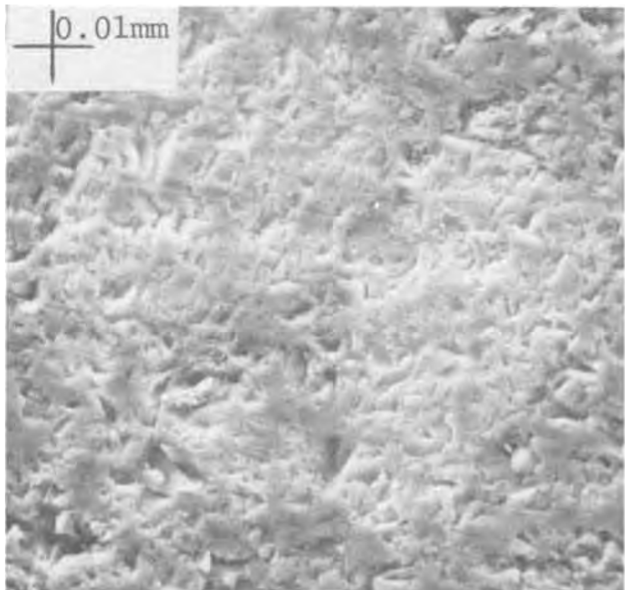
The transition area is clearly indicated, but very thin (2-5 μm) This may in fact be the SiC layer reported in the literature as being a product of the dissolution mechanism (5). Cowland and Lewis report a 6 μm layer formed between a Si melt and carbon crucible which has been identified by x-ray diffraction (6).

The groove formation was not consistent for samples 1 and 2. However, the data were more reproducible for the polished samples 3 and 4 indicating that the surface morphology is important in determining the erosion characteristics of materials.

Silicon carbide (SiC).—The SiC sample rods in the as-received condition had a very rough surface and non-circular cross section which necessitated centerless grinding to make reliable samples. The resulting surface was porous and uneven, but sufficient for the purpose of this work.

Figure 5 shows the erosion results plotted for three samples, but severe pitting of the surface leads to some uncertainty in the erosion rates. The very low rate of sample 3 may be due to low melt temperature. Due to heat conduction up the rod, the temperature at the surface may in fact be lower than the melt temperature. This may allow a layer of silicon to freeze onto the sample which protects it from erosion. But in all cases the breakdown of the material was too great to allow its application for hardware such as crucibles and forming dies.

Further evidence of particulate erosion and pitting was obtained from the next two sets of micrographs. Figure 6 shows SEM photos of the interior of a sample rod before treatment. The two samples were obtained by halving a wafer taken from the end of a rod. The section shown in 6(a) was untreated after cutting. The half in 6(b) was etched in $HF:HNO_3$ solution to remove any excess silicon (SiC dissolves much less rapidly in the acid etch). Etching reveals the material to be a loosely packed array of SiC particles which probably breaks down by particulate erosion or intergranular corrosion. The next set of photos in Fig. 7 verifies this conclusion. The sample shown was obtained by cross sectioning the end of sample 2 to which a drop of silicon was frozen. In 7(a) only a very slight coating of Au was deposited on the surface to reduce surface charging in the SEM. It is clearly shown that particles were trapped as they were being lifted out of the sample as indicated by the arrow. Figure 7(b) shows the same sample after a heavier layer of Au was applied. The smooth area to the right is the silicon drop, while the raised areas to the left are the particles of SiC. The arrow shows a particle which has apparently been lifted out of the SiC matrix and lies at the mouth of a long channel penetrating the bulk of the sample rod. Figure 7(c) shows the intricate network of channels



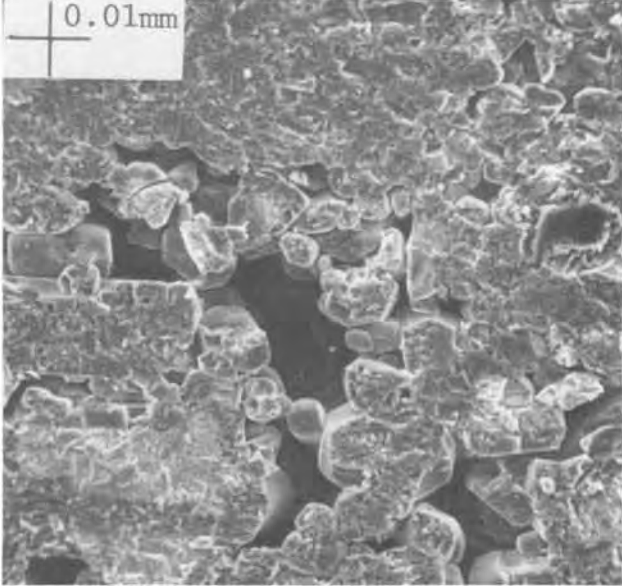


Fig. 6. SEM micrographs of the cross section of SiC sample 4: (a, left) as cut, (b, right) after etching.

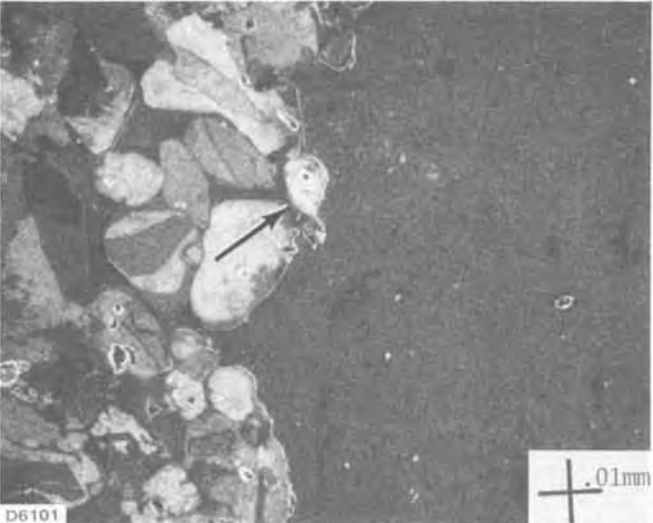

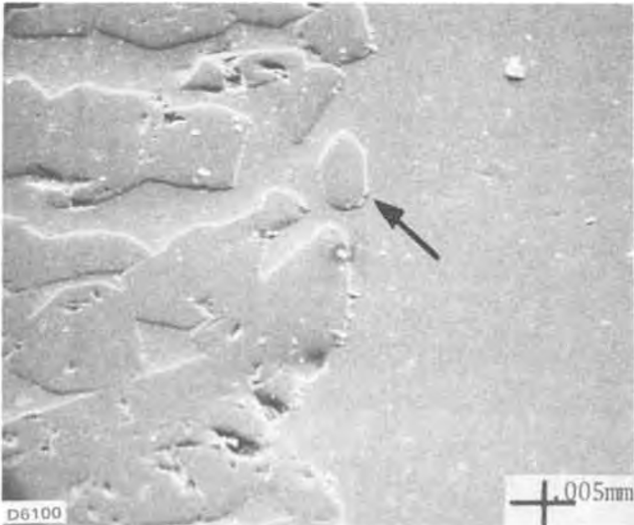

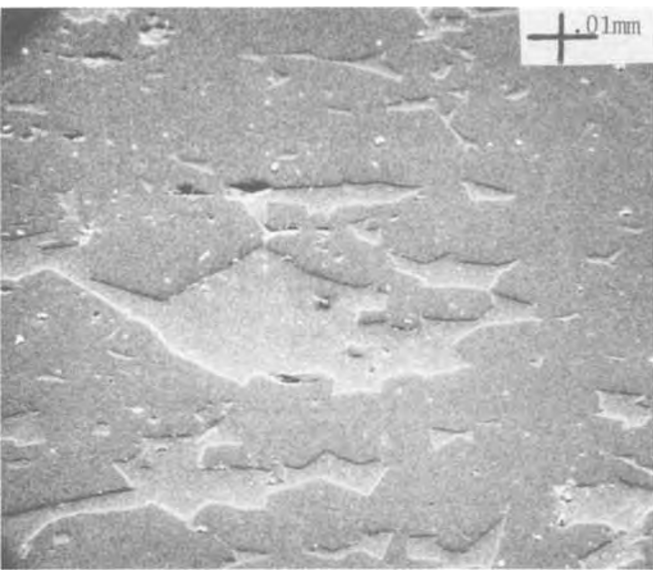

Fig. 7. SEM micrographs of vertical cross section of the end of SiC sample 2: (a, top left) small amount of Au coating, arrow indicates particle detaching from rod (left), Si on right; (b, top right) heavier Au coating changes appearance, but porticulate erosion is apparent; (c, left) this micrograph shows the channels opened up in the SiC rod interior.

opened up in the interior of the rod by the molten silicon.

These experiments reveal that the predominant mode of breakdown of pressed powders of SiC in molten silicon is particulate erosion (intergranular corrosion). The ability of the material itself to resist dissolution is not clear. This can be determined by testing other forms of SiC. Sampling the melt after a run may be misleading because the fine particles of SiC may be trapped and lead to an apparently high value for the carbon concentration.

No groove depth rates were calculated for the SiC due to the nonlinear nature of the data points. This may be due to acceleration of particulate erosion caused by the material breakdown process and opening of interior channels. It is clear that the convection currents do cause significant material degradation in silicon carbide pressed-powder materials.

Silicon nitride (Si_3N_4).—The Si_3N_4 samples discussed in this section are all formed from powders. Si_3N_4 samples 1, 2, and 5 are Cerac hot-pressed rods made from >99.9% pure powders with no binders. NC/350 is a sample of reaction-bonded material from Norton Company in the form of a square rod. Samples were cleaned with TCE and acetone. Figures 8 and 9 show the erosion behavior of these samples. NC/350 has the highest erosion rate of the four samples tested and this material is considered unsuitable for use with molten silicon. Si_3N_4 2 shows the lowest erosion rate, but the curve is offset from the abscissa indicating the rapid removal of a surface layer 3×10^{-4} cm thick. This is difficult to understand because samples 1 and 5 do not exhibit this behavior even though they were received in the same shipment and were treated in the same manner. The erosion of samples 1 and 5 is shown in Fig. 8. Little or no erosion took place up to 50 min exposure, subsequently the erosion rate was linear with time. This again may be due to low melt temperature. The two sets of data appear to curve slightly with time,

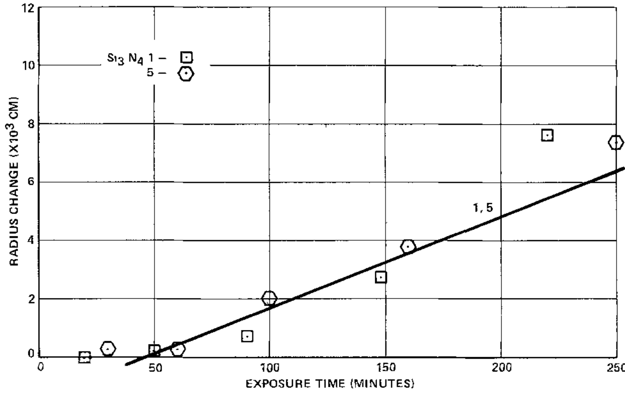

Fig. 8. Radius change vs. exposure time for Si_3N_4 samples 1 and 5.

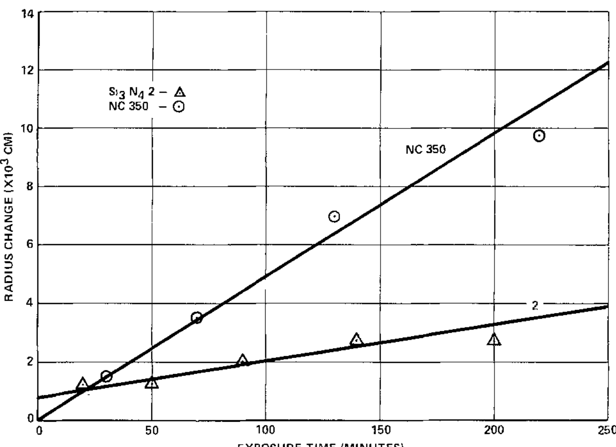

Fig. 9. Radius change vs. exposure time for Si_3N_4 samples 2 and NC 350.

however, there is some error in the last two points (time 200 min). The source of this error may be due to a short zone length. These rods were deeply immersed and then withdrawn from the melt. It is often difficult to be precise in setting the zone length. The last zone of samples 1 and 5 is clearly very short. In the experimental setup there is severe turbulence near the surface. This convective flow is responsible for the grooves. Therefore, the measurements of the diameters of the short zones may include not only the normal erosion processes, but also a part due to these convection currents. For this reason, these points were not included in the erosion rates. Without these points there is no justification for concluding anything but a linear erosion rate.

The groove depth data for Si_3N_4 samples seemed to be independent of the source. The grooving action was consistent and reproducible from sample to sample.

The mechanism of degradation for these pressed powders appears to be due to both dissolution and

Fig. 10. Cross section of a Si_3N_4 rod (as-received) treated to reveal internal structure: (a, top left) untreated after cutting (note the saw marks), the light area is a void; (b, top right) the same material after etching, note the light and dark areas; (c, bottom left) closer view of a light area. The fibers may be formed by the cooling of gas-filled voids after the hot-pressing process; (d, bottom right) closer view of a dark (silicon-rich) area.

particulate erosion processes. Figures 10 and 11 illustrate the structure of the material before and after treatment with molten silicon. Figure 10(a) shows a typical interior revealed by sawing. The white area is a void. Figure 10(b) shows the same area after an HF:HNO_3 etch. The etching process reveals very dark and white regions shown at higher magnification in 10(c) and (d). The dark areas appear to be a silicon-rich phase. The white areas are made up of very loosely packed fibers, which appear white due to the higher yield of secondary electrons in this region. This structure may form upon cooling of gas-filled voids in the material after the hot-pressing process.

Figure 11(a) shows a typical area of a Si_3N_4 sample which has been exposed to the melt, then etched to remove adhering silicon. Again, light and dark areas are observed. Figures 11(b) and (c) show more detailed views of these areas. The dark regions appear as voids. The relatively large particles on the interior of the holes are the same as shown for the untreated sample [Fig. 10(d)]. No silicon-rich regions were observed. It is evident that the solid crystalline spots melt, dissolve, or erode more rapidly than the bulk material to form these cavities. Figure 11(c) shows a view of a white area. This appears the same as the untreated bulk material [Fig. 10(c)].

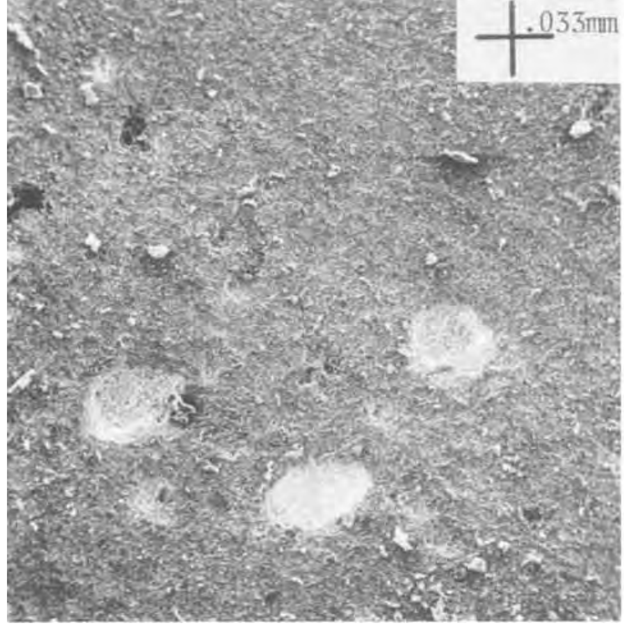
From the photographic evidence it is concluded that these samples of hot-pressed Si_3N_4 degrade by a combination of particulate erosion and dissolution. The material is quite porous which enables the melt to penetrate the surface, dissolve, or melt away the binding material between the particles or fibers and lift them away from the rod.

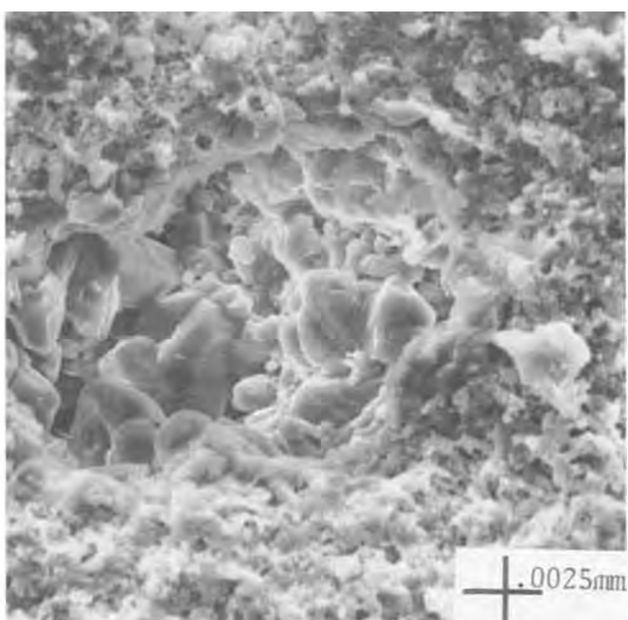
Summary

Based on the results of this study several conclusions can be reached.

1. Many of the materials studied have erosion rates similar to SiO_2 (refer to Table I).

2. The mechanism of the erosion varies according to the type of material. Vitreous materials (SiO_2 and glassy carbon) erode by a single dissolution mechanism. The pressed powders (SiC and Si_3N_4) erode by both dissolution and particulate erosion (intergranular corrosion). This combination of mechanisms is due to the particulate nature of the bulk materials which allows penetration of the melt below the sample sur-





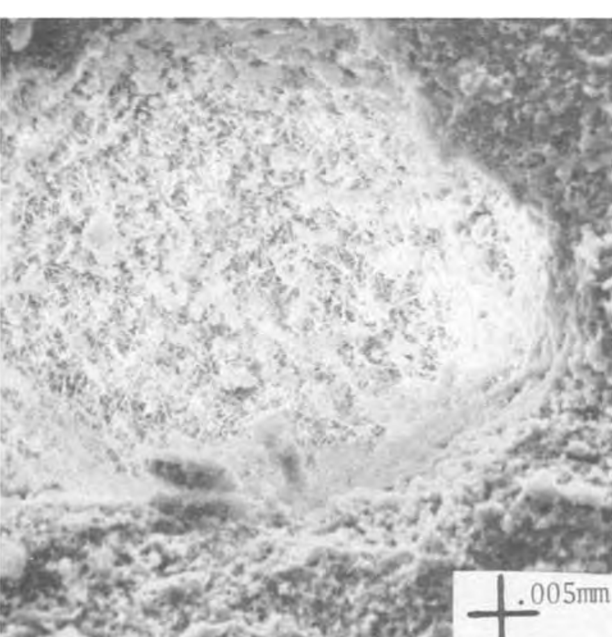


Fig. 11. Si_3N_4 sample 1 after treatment with molten silicon. These SEM photomicrographs are all of the exposed surface. (a, top left) etched after treatment, note light and dark areas; (b, top right) closer view of dark area, possibly formed by melting or dissolution of silicon-rich phase; (c, left) closer view of a light area, appears the same as for untreated bulk samples.

face or nonstoichiometry which causes voids to open up as unreacted silicon melts.

3. Surface preparation has a strong influence on the erosion levels attained as shown by polishing the vitreous carbon samples. The erosion rates were reproducible and suppressed due to reduction of the surface-to-volume ratio by polishing. This process will allow prediction of the wearing characteristics of materials used in the fabrication of precision components such as forming dies.

Activities of SnO in the $SnO\text{-}SiO_2$ System

A. E. Grau and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The activities of SnO in the binary melts $SnO\text{-}SiO_2$ have been investigated by emf measurements using the cell

$$\underset{(-)}{Sn_{(l)}},\ (SnO\text{-}SiO_2)_{(l)}\ |\ \underset{\text{solid electrolyte}}{ZrO_2\text{-}CaO}\ |\ NiO_{(s)},\ \underset{(+)}{Ni_{(s)}}$$

The results indicate positive deviations from an ideal "molecular" model and it is suggested that SnO is one of the more acidic oxides with respect to silica.

The measurement of the thermodynamic activities of SnO in $SnO\text{-}SiO_2$ liquid solutions has been the subject of several investigations (1-3). The reported results, however, are in total disagreement, thus emphasizing the need of reinvestigating the system.

Experimental

In the present work, the activities of SnO with respect to the pure liquid oxide as the standard state, a_{SnO}, were calculated from the emf's measured in electrochemical cells of the type

$$\underset{(-)}{Sn_{(l)}},\ (SnO\text{-}SiO_2)_{(l)}\ |\ \underset{\text{solid electrolyte}}{ZrO_2\text{-}CaO}\ |\ NiO_{(s)},\ \underset{(+)}{Ni_{(s)}} \quad [1]$$

The cell reaction is

$$Sn_{(l)} + NiO_{(s)} \rightarrow (SnO)_{\text{in slag}} + Ni_{(s)} \quad [2]$$

and the corresponding form of the Nernst equation may be written as

$$E = E^\circ - \frac{RT}{2\mathbf{F}} \ln a_{SnO} \quad [3]$$

where E is the cell emf measured at T°K and E° is the emf measured at the same temperature in a cell where the slag phase has been replaced by pure liquid SnO. R and $\mathbf{F}$ denote the gas constant and the Faraday constant, respectively.

The "closed" cell design employed in the present investigation was identical to that described in a previous publication from this laboratory (4, 5, 6). The main characteristic of the "closed" cell design is that the two electrode compartments are completely isolated from each other through the use of a CaO-stabilized zirconia tube 24 in. long and closed at one end. In addition, each half-cell compartment containing an electrode is sealed under vacuum at the open end which is located outside the furnace. In this manner, both electrode compartments are operated under the equilibrium partial pressures of oxygen corresponding to the metal-metal oxide system present at the temperature of the measurement. As discussed earlier (5, 6), the "closed" cell design yields emf measurements free of mixed potential effects.

The electrical contact for the $Sn/SnO + SiO_2$ electrode consisted of a 2 mm diameter iridium wire connected to platinum leads. Thermoelectric emf's due to the Ni-Pt-Ir junctions were measured separately using the same geometric cell arrangement and the same furnace; all reported cell emf values have been corrected for such effects.

The major experimental difficulty found in the SnO system is the instability of this oxide. In a recent investigation, Carbo and Richardson (7) have found that both the solid and liquid SnO are unstable below 1373°K and that they disproportionate according to the reaction

$$2SnO \rightarrow SnO_2 + Sn \quad [4]$$

It is clear, then, that the $SnO\text{-}SiO_2$ solutions do not correspond to a truly binary system but rather to a ternary containing SnO, SiO_2, and variable amounts of SnO_2. The amount of SnO_2 present in the solution

Key words: silicate melts, activities in SnO-SiO, emf measurements of SnO.

coexists in equilibrium with SnO and in a closed system it is determined by the temperature and composition of the melt.

Four slag samples of different composition were prepared by thoroughly mixing "Baker Analyzed" SnO powder with SiO_2 obtained by dehydrating silicic acid at 1250°-1300°K for periods of 18-24 hr. The components were always mixed in the amounts corresponding to a total sample of 10g and loaded into a small ZrO_2 crucible provided with a lid of the same material. The ZrO_2 crucible was contained in an Inconel crucible which was placed in a 45 mm bottom-closed quartz tube. Argon gas was continuously flowed during the melting of the slag by means of quartz tubes passed through a rubber stopper at the upper end of the 45 mm quartz tube. The samples were rapidly melted in an induction furnace and kept at temperature for about 15 min. After this time, the power to the induction furnace was shut off, and the samples were allowed to cool while still under argon. The slag obtained was then removed from the zirconia crucible (which had to be destroyed), ground, and stored in a dessicator. There was no indication of chemical interaction between the slag and the crucible, nor visible cracks due to the thermal shock of the zirconia.

The slags were analyzed for both stannous and total tin by the iodimetric method. The total tin was determined by dissolving samples weighing 0.2g in 20 ml conc HCl. The solution was then filtered and the filter paper containing the undissolved silica saved for the SiO_2 determination. 100 ml of distilled water followed by 50 ml of conc HCl were then added to the filtrate. Reduction was affected by the addition of nickel powder and gentle boiling of the solution under an argon atmosphere. After all the nickel had dissolved, the solution was cooled in running water and titrated at once (under A) with 0.1*N* iodine solution using starch as the indicator.

Stannous tin was determined by dissolving, under an argon atmosphere, 0.2g samples in 20 ml conc HCl, 100 ml distilled water, and 50 ml conc HCl were then added and the solution was immediately titrated as described previously. The amount of Sn^{4+} present in the slags was calculated as the difference between total tin and stannous tin.

Results and Discussion

The results of the chemical analysis are given in Table I together with some information concerning the physical appearance of the slags. In the next to last column, the compositions indicated by the analysis have been proportionally adjusted to 100% in order to provide a basis for the calculation of the molar concentrations. As expected, the amount of stannic oxide found in the slags increases as the silica content decreases. Since the slags were cooled slowly in argon (about 10 min to reach room temperature), it is possible that due to the SnO disproportionation, the concentrations of SnO_2 reported in Table I are somewhat higher than the actual equilibrium values. This is also suggested by the presence of small tin spheres found dispersed in the slag which may have been produced during the cooling of the melts. In any case, it appears that the disproportionation of the SnO dissolved in the slag proceeds fairly slowly as compared to the pure liquid oxide.

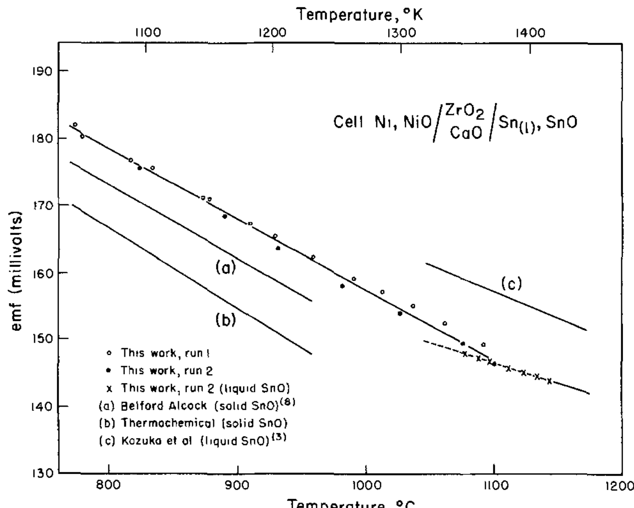

Fig. 1. Temperature dependence of emf for the cell Ni, NiO/ZrO_2-CaO/SnO, Sn.

The results for pure SnO are shown in Fig. 1, and for the purpose of interpretation may be separated into two groups.

Results obtained in the temperature range 1050°-1373°K.—The open and filled circles in Fig. 1 indicate a high degree of reproducibility, as evidenced by the agreement between the results of runs 1 and 2. However, the information available on the stability of SnO indicates that these results should not correspond to the presence of this oxide. The same comments should apply to the tentative electrochemical results of Bedford and Alcock (8) represented by line (a). The thermochemical line (b) has been obtained under the assumption that the heat capacities of SnO are equal to those of SnO_2 (9) and has been included for comparison purposes only.

Data obtained in the temperature range 1350°-1420°K.—This is the temperature range (x's in Fig. 1) for which liquid SnO is the stable phase in equilibrium with tin, and, therefore, these data are taken to represent the desired $E°$ results. Some of the points obtained in the lower part of the temperature interval may correspond to metastable SnO. The results of Kozuka and co-workers (3) for liquid SnO are represented by line (c) in Fig. 1, and are seen to be in poor agreement with the present results. These authors used a galvanic cell employing a solid electrolyte in the shape of a short ZrO_2-CaO crucible open at the upper end. The crucible contained the $Sn_{(l)}/SnO_{(l)}$ electrode while the reference electrode consisted of a Ni/NiO pellet pressed against the outer wall of the crucible. In this type of "open cell," due to continuous diffusion in the gaseous phase, the oxygen partial pressures in the two electrode compartments are not at their equilibrium values, and the emf results are incorrect (5, 6).

In the present work, errors can also arise, mostly from the presence of small amounts of SnO_2 in SnO. Although the x-ray analysis of samples quenched from 1423°K indicated the presence of SnO only, it is possible that a small amount of SnO_2 dissolved in liquid SnO remained undetected by the x-ray technique.

Table I. Chemical analysis of the $SnO-SiO_2$ slags

Sample	Calculated composition m/o SiO_2	Physical appearance	Analysis w/o SnO	Analysis w/o SnO_2	Analysis w/o SiO_2	Adjusted w/o SnO	Adjusted w/o SnO_2	Adjusted w/o SiO_2	Composition m/o SnO	Composition m/o SnO_2	Composition m/o SiO_2
1	55	Yellow, transparent glass	59.50	4.27	34.70	60.42	4.34	35.24	42.17	2.71	55.12
2	50	Yellow, transparent glass	62.86	5.20	29.83	64.21	5.31	30.47	43.40	3.20	53.40
3	40	Yellow, transparent glass	68.69	6.50	22.20	70.53	6.67	22.79	55.29	4.67	40.04
4	30	Gray, opaque glass	73.41	8.29	16.60	74.68	8.43	16.89	62.19	6.28	31.53

However the degree of disproportionation of SnO decreases with increasing SiO_2 content, which explains why the present work was limited to the more acidic solutions. Also, some error could arise from the chemical attack of the solid electrolyte by SnO. Although very stable and reproducible measurements were made during the first few hours in the life of the experiments, it is difficult to predict to what extent the behavior of the solid electrolyte is affected by the action of SnO.

From the experimental results presented in Fig. 1, it is concluded that the temperature dependence of the emf corresponding to the cell reaction

$$NiO_{(s)} + Sn_{(l)} \rightarrow Ni_{(s)} + SnO_{(l)} \quad [5]$$

in the temperature range 1350°-1420°K is given by the equation

$$E^\circ = 225.5 - 0.0575T \text{ (mV)} \quad [6]$$

The electrochemical data reported by Charette and Flengas (5) for the cell reaction

$$Ni + \tfrac{1}{2} O_2 \rightarrow NiO \quad [7]$$

are given as

$$E^\circ_{NiO} = 1210.8 - 0.4399T \text{ (mV)} \quad [8]$$

Since the reaction

$$Sn_{(l)} + \tfrac{1}{2} O_2 \rightarrow SnO_{(l)} \quad [9]$$

is obtained by the addition of reactions [5] and [7], the emf corresponding to the cell reaction [9] in the temperature range 1350°-1420°K is $E^\circ_{SnO} = E^\circ + E^\circ_{NiO}$. That is

$$E^\circ_{SnO} = 1436.3 - 0.4974T \text{ (mV)} \quad [10]$$

Thus, the standard free energy of formation of liquid SnO in this temperature range is calculated as

$$\Delta G^\circ_{SnO(l)} = -66{,}242 + 22.940T \frac{\text{cal}}{\text{mole}} \quad [11]$$

The emf data obtained for samples 1-4 representing $SnO-SiO_2$ solutions are shown in Fig. 2. The cells were operated on increasing and decreasing temperature cycles and the emf's were recorded every 20° or 30°K at equilibrium. The time interval between readings usually was 45 min-1 hr. These cells were run for periods of 18-24 hr. Figure 2 also shows the results obtained for pure liquid SnO (E°). For this system, because of the instability of SnO, emf results for solid SnO are not shown. The life of the experiments was reduced to a period of 5 or 6 hr after which the emf readings became unstable. This was attributed to the attack of the solid electrolyte by liquid SnO, as evidenced by the black stains found on the external surface of the ZrO_2-CaO tube after the cell was cooled and disassembled. The summary of the experimentally obtained emf data and the calculated standard error of estimate and the maximum deviations are presented in Table II.

Table II. Summary of the experimental emf data for the $SnO-SiO_2$ system

X_{SiO_2}	Temp range °K	$E = A - BT$ (mV) A	B	Standard error of estimate (mV)	Maximum deviation (mV)
0.551	1270-1350	169.5	−0.0002	±0.4	0.7
0.534	1230-1350	152.7	−0.0133	0.3	0.5
0.400	1160-1370	154.6	−0.0074	0.3	0.5
0.315	1300-1365	264.5	0.0780	0.6	0.9
"Pure SnO"	1350-1420	225.5	0.0575	0.1	0.2

It may be seen in Fig. 2 that the emf *vs.* temperature lines show important slope variations at well-defined temperatures. This type of variation is commonly interpreted as accompanying the appearance of either a solid phase or of liquid immiscibility and, when the phase diagram of the system under study is available, it provides a good check of the accuracy of the experimental determinations. Unfortunately, in the case of the $SnO-SiO_2$ system, the phase diagram is practically unknown, the only information available in the literature being that reported by Keysselitz and Kohlmeyer (9) which is reproduced in Fig. 3. It is very likely that the phase diagram suggested by these authors is an oversimplification of the actual phase relations in the system because of the absence of both the intermediate compounds and the liquid immiscibility region, which are characteristic of the metal oxide-silica systems.

The activities of SnO, referred to the pure liquid oxide as the standard state, were calculated by means of Eq. [3] and the results at 1373°K are shown in Fig. 4.

The activities of silica at 1373°K, referred to the pure solid as the standard state, were calculated from the Gibbs-Duhem equation written in the form

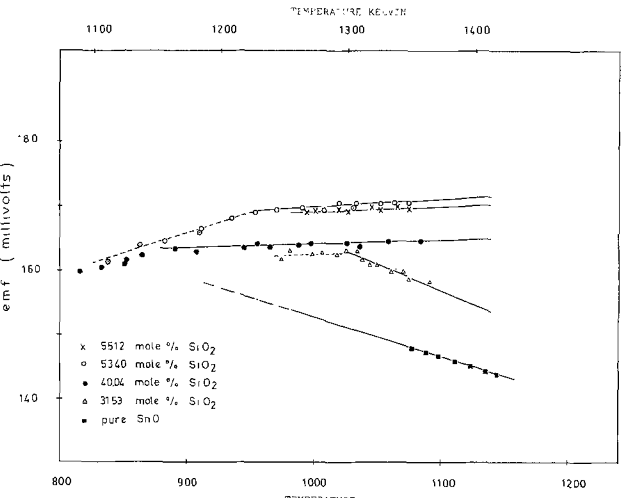

Fig. 2. Temperature dependence of emf for the cell Ni, NiO/ZrO_2-CaO/Sn, ($SnO + SiO_2$).

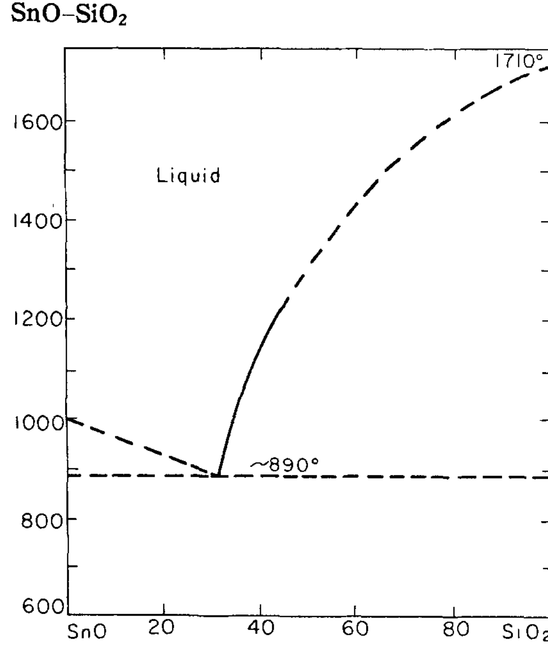

Fig. 3. Phase diagram of the $SnO-SiO_2$ system, Ref. (9)

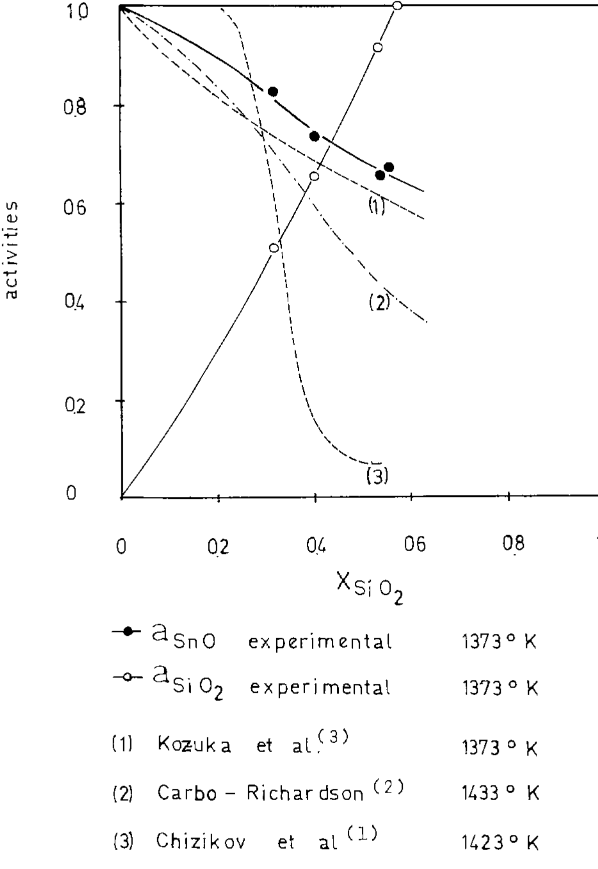

Fig. 4. Activities of SnO and SiO_2 vs. mole fraction of SiO_2 at 1373°K.

$$\int_{\gamma_{SiO_2} \text{ at } SiO_2 \text{ saturation at } X_{SiO_2} = 0.565}^{\gamma_{SiO_2}} d \ln \gamma_{SiO_2} = - \int_{\gamma_{SnO} \text{ at } SiO_2 \text{ saturation at } X_{SiO_2} = 0.565}^{\gamma_{SnO}} \frac{X_{SnO}}{X_{SiO_2}} d \ln \gamma_{SnO} \quad [12]$$

In this equation, γ_{SiO_2} is the activity coefficient of SiO_2 with respect to the pure solid and γ_{SnO} is the activity coefficient of SnO referred to the pure liquid oxide.

This integration, in order to be accurate, requires precise knowledge of the temperature-composition coordinates at which SiO_2 saturation takes place. In this regard, the only information available is the phase diagram due to Keysselitz and Kohlmeyer (9) (Fig. 3) which, as mentioned earlier, requires further confirmation. Therefore, the activities of silica calculated on this basis which are shown in Fig. 4, should be considered as approximate values only.

It may be readily seen in Fig. 3 that the results of the present work are in disagreement with those reported in previous publications (1, 2, 3).

Chizikov *et al.* (1) used the emf method with cells of the type Sn, $SnO/Al_2O_3/Sn$, $(SnO\text{-}SiO_2)$. However, Al_2O_3 does not behave as a purely oxide-ion conducting membrane, and therefore, accurate results cannot be expected from cells of this type.

In the work of Carbo and Richardson (2), the activities of SnO were established by measuring the oxygen dissolved in liquid tin brought into equilibrium with the slag through a gas phase. The slag samples contained as much as 10 mole per cent (m/o) Al_2O_3 which originated from the Al_2O_3 crucibles used for these experiments. Thus, the activities of SnO determined by this method should correspond to ternary melts containing SnO, SiO_2, and Al_2O_3, and were obtained by extrapolation to the $SnO\text{-}SiO_2$ binary system on the assumption that the Al_2O_3 had no effect on the activity of SnO in the concentration range covered by the experiments. This last assumption, however, was not experimentally founded, and it should be expected that Al_2O_3 would behave in a way similar to SiO_2 tending to complex the silicate structure and further decrease the activity of the stannous oxide in the melts.

The electrochemical cells of Kozuka *et al.* (3) may be represented as Sn, SnO $/\frac{ZrO_2}{CaO}/$ Sn, $(SnO\text{-}SiO_2)$ and their characteristic is that of being "open" cells. The problems that are expected in this type of cells have been discussed elsewhere (6). In addition, the Sn, SnO reference electrode, due to both the attack of the SnO on the zirconia and the disproportionation of the oxide at temperatures lower than 1373°K, may have adversely affected the results. It is of interest to note that the activity results of Kozuka *et al.* (3) differ from the present work by about 10% and describe positive deviations with respect to the ideal molecular model.

The comparison between the activities of SnO reported in this work and those of other metal oxides dissolved in silica suggests that SnO is one of the more acidic metal oxides with respect to silica.

The potential E measured in the cells represented in Eq. [1] could also be interpreted as the potential which accompanies the electrochemical transfer of oxygen between the two-half-cell compartments, and is given as

$$E = -\frac{RT}{2\mathbf{F}} \ln \frac{(p_{O_2})_{Sn/(SnO\text{-}SiO_2)}}{(p_{O_2})_{Ni/NiO}} \quad [13]$$

where $(p_{O_2})_{Sn/(SnO\text{-}SiO_2)}$ and $(p_{O_2})_{Ni/NiO}$ represent the partial pressure of oxygen in equilibrium with $Sn_{(l)}$, $(SnO/SiO_2)_{(l)}$, and Ni, NiO, respectively. Since the temperature dependence of $(p_{O_2})_{Ni/NiO}$ is well known (6), Eq. [13] may be used to calculate $(p_{O_2})_{Sn/(SnO\text{-}SiO_2)}$ from the experimental emf data reported in Table II. The result of this calculation at 1373°K is shown in Fig. 5.

Preparation and Properties of Magnetic Garnet Films Containing Divalent and Tetravalent Ions

S. L. Blank, J. W. Nielsen, and W. A. Biolsi

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The relevant phase equilibrium data necessary to grow garnet films containing divalent and tetravalent ions by liquid phase epitaxy are presented. The effects of melt composition on film magnetic properties and film composition are presented as is the influence of growth kinetics on the film magnetic parameters. Work on the $(Y,Sm,Ca)_3(Ge,Fe)_5O_{12}$ system is stressed. A coupled distribution coefficient is defined which adequately describes the Ca^{2+}-Ge^{4+} substitution. The effect of melt depletion on magnetic properties is discussed and data presented to indicate the magnitude of the effect observed in the $(Y,Sm,Ca)_3(Ge,Fe)_5O_{12}$ system. An example of the propagation characteristics observed in the $(Y,Sm,Ca)_3(Ge,Fe)_5O_{12}$ system is also shown. A technique for controlling the temperature dependence of the collapse field in LPE films is presented. The use of Lu^{3+} as both a dodecahedral and octahedral substituent is shown to lead to a system flexible enough to meet most of the present device requirements.

The discovery that some flux-grown magnetic garnet platelets possessed sufficient uniaxial anisotropy to support bubble domains (1, 2) has led to a search for garnet compositions suitable for device use. A large number of magnetic garnet compositions have been suggested for use in bubble domain devices (3-11). Many of these compositions have served well as vehicles for circuit design and prototype device construction, but as the bubble domain memory comes closer to being a practical device for use in a variety of environments, its stability toward temperature changes becomes a major consideration. Along with temperature-stable operation, high operational frequencies are also a requirement. The considerations that lead to high speed materials have been discussed previously (11). To achieve stability toward temperature, the Curie temperature of the garnet film must be as high as possible. Because of the preference of the nonmagnetic tetravalent ions Si^{4+} and Ge^{4+} for tetrahedral sites, and partly because of their valence state, substitution of Si^{4+} or Ge^{4+} in a magnetic garnet to yield a given $4\pi M_s$ will exhibit a higher Curie temperature than the same garnet substituted with Ga^{3+} or Al^{3+} to achieve the same $4\pi M_s$. Although a divalent ion is necessary to charge compensate for the tetravalent substitution, the most convenient-sized ion, Ca^{2+}, is an S-state ion and has no negative effect on domain mobility. This divalent-tetravalent substitution permits bubble memory operation over a wider temperature range, and propagation margins in excess of 10 oe at 1 MHz and 100°C have been observed on Ca^{2+}-Ge^{4+} substituted garnets.

In compensation for their higher complexity, the divalent-tetravalent substituted garnets show considerable versatility in meeting a wide range of speed, temperature, and domain size requirements while at the same time holding to the restriction of matching the lattice parameter of $Gd_3Ga_5O_{12}$ substrates. For example, the 6 μm bubble diameter material, $Y_{2.62}Sm_{0.38}Ga_{1.2}Fe_{3.8}O_{12}$, can be adjusted to yield 3 μm diameter bubbles in two ways. The decreased nonmagnetic ion substitution, along with the increased anisotropy required, leads to a larger lattice parameter that can be adjusted downward through substitution of either Lu^{3+} or Si^{4+}, as in $Y_{1.46}Lu_{0.34}Sm_{0.28}Ca_{0.92}Ge_{0.92}Fe_{4.08}O_{12}$ or $Y_{1.68}Sm_{0.38}Ca_{0.94}Ge_{0.84}Si_{0.10}Fe_{4.06}O_{12}$. Fortunately, the same generalizations applied earlier in the handling of substituted garnets and the melts from which they grow still apply to these more complicated systems. Thus, melts containing magnetic garnet components plus Ca^{2+}, Ge^{4+}, and/or Si^{4+} behave very much alike from the standpoint of phase equilibrium and kinetics of growth. However, they do differ in some respects from melts containing only trivalent garnet components.

The purpose of this paper is to present some of the relevant phase equilibrium data necessary to grow garnet films containing Ca^{2+} and Ge^{4+} by LPE, to show the effects of melt composition on film composition and magnetic properties, to present the growth kinetics observed in the system along with their influence on magnetic properties, and to show the effect of octahedral substitution on the temperature dependence of the bubble collapse field of LPE films. Work on the $(Y, Sm, Ca)_3(Ge, Fe)_5O_{12}$ systems will be stressed because of a greater tendency for supercooled melts containing Si^{4+} to nucleate prematurely.

Experimental Procedure

All films discussed in this study were grown on $Gd_3Ga_5O_{12}$ substrates by the dipping technique using supercooled melts (13). Axial rotation was main-

Key words: liquid phase epitaxy, crystal growth, magnetic bubble materials, phase equilibria, growth kinetics.

tained constant at approximately 100 rpm during the growth period. The details of the apparatus and growth techniques have been discussed elsewhere (14, 15). Temperatures at saturation were restricted to 950° ± 25°C except in specific instances mentioned in the text. Lattice constant measurements were obtained using the HPM method and the 444 and 888 reflections (16). Magnetic property measurements were obtained using the standard techniques (17, 18).

Samples for composition analysis were taken from the uniform region of the LPE films. The analysis was performed on an ETEC Autoscan scanning electron microscope (SEM) using a Kevex-Ray lithium drifted silicon detector and an energy dispersive system. Intensity data were stored in channels 10 eV wide. Resolution is such that peaks separated by ~150 eV may be analyzed without significant interference. The x-ray lines used were YLα, PbMα, CaKα, SmLα, FeKα, and GeKα. The standards used were CaF_2, $Sm_3Ga_5O_{12}$, $Y_3Fe_5O_{12}$, Pb, and Ge. Electronics stabilization was achieved prior to analysis by allowing the beam (in reduced area mode) to scan the YIG standard for 2 hr. Drift over the analysis time was typically 1.0%. MAGIC IV (19), with appropriate modifications for the specimen geometry, was used to reduce the data.

Magnetic Properties vs. Composition

The major reason for the substitution of tetravalent ions in bubble garnets is that the Curie temperature per mole of substitution is higher. Geller *et al.* (20) have shown that both the site selectivity and the higher valence will serve to yield higher Curie temperatures over those expected with substitutions by Ga^{3+} or Al^{3+}. Figure 1 shows the Curie temperatures as a function of nonmagnetic ion substitution for the systems Ca^{2+}:YIG:V^{5+} (20), Ca^{2+}:YIG:Si^{4+} (21), Ca^{2+}:YIG:Ge^{4+} (21), YIG:Ga^{3+} (22), and YIG:Al^{3+}

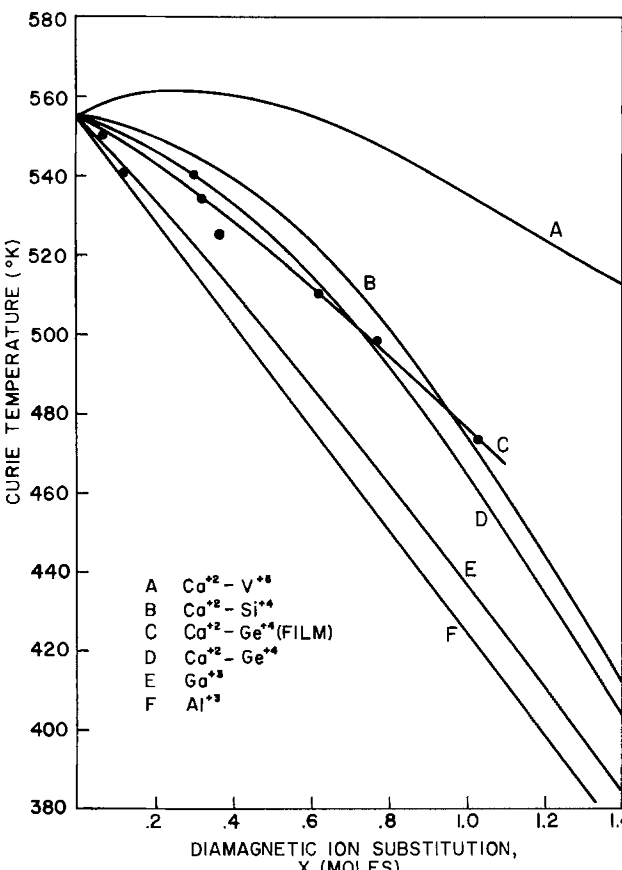

Fig. 1. Curie temperatures as a function of substitution (x) in the systems (A) Ca^{2+}:YIG:V^{5+}; (B) Ca^{2+}:YIG:Si^{4+}; (C) Ca^{2+}: 0.1Sm YIG:Ge^{4+} (film); (D) Ca^{2+}:YIG:Ge^{4+}; (E) Ga^{3+}:YIG; (F) Al^{3+}:YIG.

(22). For comparison, curve C is from SEM analyses and Curie temperature measurements taken on samples from the $\{Y_{2.9}Sm_{0.1}Ca_x\}(Fe_{5-x}Ge_x)O_{12}$ system. (All curves are normalized to $T_c = 555°K$ at $x = 0$.)

It can be seen that the effectiveness in lowering T_c goes as $Al^{3+} > Ga^{3+} > Ge^{4+} > Si^{4+} > V^{5+}$. The difference between Al^{3+} and Ga^{3+} arises mainly from the difference in site selectivity. Aluminum occupies more octahedral sites which are more effective in lowering T_c. Although site selectivity probably plays a small role in explaining the differences in T_c seen for Ge^{4+}, Si^{4+}, and V^{5+} substitution, these ions are highly selective, preferring tetrahedral sites. Therefore, the differences in T_c seen among Ge^{4+}, Si^{4+}, and V^{5+} substituted garnets are related mostly to size and charge.

Note that at $x = 1.0$, the T_c for Ge^{4+} substitution is 28° higher than for Ga^{3+} substitution. The difference between device films is even more striking because of the greater Ga^{3+} substitution required to achieve the same moment. For a 6 μm bubble diameter, the substitution level of Ga^{3+} in YIG:0.2Sm is about $x = 1.2$, and $T_c = 405°K$, while for Ca^{2+}-Ge^{4+}, $x = 0.95$ and $T_c = 480°K$, or 75° higher.

The course of curve C is of interest. The curve begins with lower T_c's than those exhibited by the polycrystalline samples of Winkler (21), then crosses the plot of his data for the Ca^{2+}-Ge^{4+} substitution. Since the films used to plot the data in curve C were also Ca^{2+} and Ge^{4+} substituted with the exception of two samples where the compensating ion was lead, the difference in the curves requires some explanation. We suggest that curve C indicates octahedral substitution. Geller (20) has shown similar curves for Ca^{2+}-Si^{4+} and Mg^{2+}-Si^{4+} substituted YIG, where the curve for octahedrally located Mg^{2+} compensated by Si^{4+} begins below the curve for Ca^{2+}-Si^{4+} substituted samples but then crosses over it, although the effect is more dramatic in that case. Two sources of octahedral substitution are suggested. First, it is possible that under the conditions of temperature and growth rate used for LPE, the substitution of Ge^{4+} on octahedral sites may be slightly higher than in the case of ceramic samples. Second, in the case of low and zero substitutions of Ca^{2+}, charge compensation occurs through Pb^{2+} incorporation. In these samples, lattice parameter measurements suggest Y^{3+} may be substituted in octahedral sites in small amounts, probably smaller than the Ge^{4+} octahedral substitution.

In Fig. 2 are shown two calculated curves showing room temperature $4\pi M_s$ *vs.* Ge substitution over the range $0.6 < x < 1.4$. The curves were generated by computer using the method of Dionne (23). In addition to assuming that the molecular field coefficients varied with diamagnetic ion substitution in YIG in the manner assumed by Dionne, an empirically determined factor was applied to account for the small

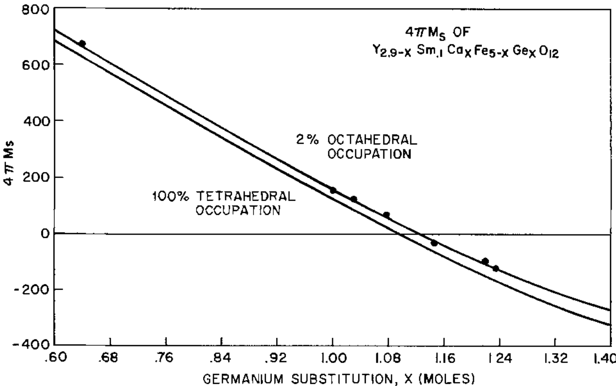

Fig. 2. $4\pi M_s$ of $Y_{2.9-x}Sm_{0.1}Ca_xFe_{5-x}Ge_xO_{12}$ for 0% and 2% octahedral substitution of Ge (— calculated; ● observed).

samarium substitution (24). The lower curve assumes that substitution is entirely tetrahedral, the upper curve assumes 2% of the Ge^{4+} is on octahedral sites. The measured values of $4\pi M_s$, indicated by the points, fall on or very near the upper curve, strongly suggesting that our samples had about 2% Ge^{4+} in octahedral sites. Considering the accuracy of measurements of this type, these data are consistent with Geller's (20) observation that although Ge^{4+} is strongly site selective, a small percentage, perhaps 1%, is octahedral at a substitution of $x = 1$. The higher substitution observed in the film is probably the result of kinetic effects.

The data are in disagreement with the conclusion of Shimada *et al.* (25) that for $x = 1$ approximately 14% of the Ge^{4+} ions are on octahedral sites. Our magnetic moment, lattice constant, and T_c data agree closely with the results obtained by Geller (20) and Winkler (21).

Data presented so far have been taken on samples of analyzed compositions from PbO-B_2O_3 fluxed melts. Although it is clear that melt compositions must be adjusted to grow varied film compositions, just how the growth parameters of composition and rate are adjusted to yield desired magnetic properties in films is not always obvious, and the establishment of a set of growth parameters that optimize film properties can be tedious. The effect of changing two ratios, Fe/Ge and Ca/Ge on the germanium content and hence T_c of $(YSmCa)_3(Ge, Fe)_5O_{12}$ films, strongly suggested that in order to make maximum use of the systems containing Ge^{4+} and Si^{4+} a broad investigation of phase equilibria, distribution coefficients, and kinetic effects was necessary.

Phase Equilibria Studies

In discussing the $(YSmCa)_3(FeGe)_5O_{12}$ system we define six atomic melt ratios

$$R_1 = \frac{Fe_2O_3}{\Sigma Ln_2O_3} = \frac{Fe}{\Sigma Ln}$$

$$R_2 = \frac{2Fe_2O_3}{GeO_2} = \frac{Fe}{Ge}$$

$$R_3 = \frac{PbO}{2B_2O_3} = \frac{Pb}{B}$$

$$R_4 = \frac{2\Sigma Ln_2O_3 + 2Fe_2O_3 + GeO_2 + CaO}{PbO + 2B_2O_3 + 2\Sigma Ln_2O_3 + 2Fe_2O_3 + GeO_2 + CaO}$$

$$R_5 = \frac{CaO}{GeO_2 + CaO}$$

$$R_6 = \frac{CaO}{2\Sigma Ln_2O_3} = \frac{Ca}{\Sigma Ln}$$

where Ln_2O_3 refers to the rare earth oxides. These ratios are atomic ratios in contrast to those defined previously (14, 15). In clarification, the ratio $R_3 = PbO/2B_2O_3$ reads one half the molar ratio of PbO to B_2O_3. In the $Ln_3Fe_{5-x}Ga_xO_{12}$ systems the ratio R_1 was chosen to place the melt composition within the garnet phase field in the pseudoternary Ln_2O_3-Fe_2O_3-flux somewhere between $R_1 = 14$ and $R_1 = 35$. In the $(YSmCa)_3(GeFe)_5O_{12}$ system three ratios are important in delineating the garnet phase field. As in the previous systems, $Fe_2O_3/\Sigma Ln_2O_3$ (R_1) must still be set to place the melt into the garnet field instead of the orthoferrite or magnetoplumbite fields. However, the ratios R_2 and R_5 must also be adjusted to prevent second-phase precipitation during garnet deposition. Figure 3 shows a portion of the pseudoquaternary YIG-Fe_2O_3-CaO-GeO_2 for $T_{sat} \approx 950°C$. The ternary represents a plane in the quaternary

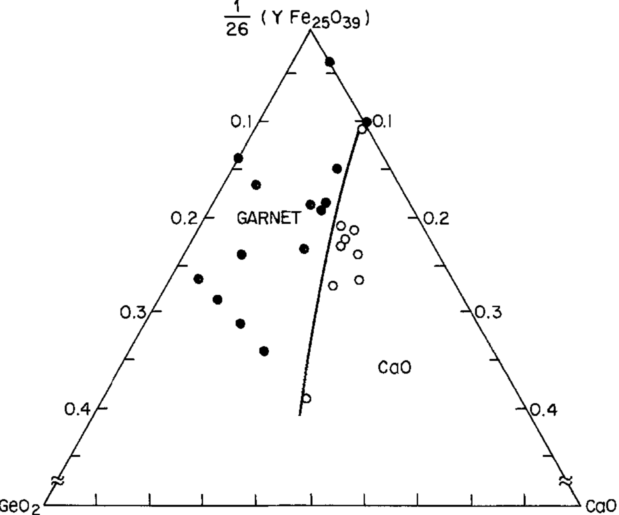

Fig. 3. Section of pseudoquaternary, YIG-Fe_2O_3-CaO-GeO_2 at $T_{sat} = 950°C$.

having $R_1 = 25$, hence the end members are written as $1/26(YFe_{25}O_{39})$-GeO_2-CaO. The 1/26 is a scaling factor for the compositional axis used in Fig. 3. The closed circles represent data points where the only phase present was found to be garnet. Open circles present points where the primary phase was observed to be a colorless parallelepiped which deposited before the iron garnet. Analysis of this colorless phase was performed in an SEM; the only cationic element present was calcium; hence, the phase is almost certainly CaO. In order to insure that garnet is the primary phase during crystal growth the ratios R_2 andR_5 must be adjusted to place the melt above the solid line in Fig. 3.

Once the approximate boundary to CaO formation was established it was informative to explore the concentration dependencies of Ca and Ge substitution. As had been done in the case of Ga, distribution coefficients between concentrations in the crystal and melt were defined as follows

$$k^{Ge} = \frac{\left(\frac{Ge}{Ge + Fe}\right)_{crystal}}{\left(\frac{Ge}{Ge + Fe}\right)_{melt}}$$

and

$$k^{Ca} = \frac{\left(\frac{Ca}{Ca + \Sigma Ln}\right)_{crystal}}{\left(\frac{Ca}{Ca + \Sigma Ln}\right)_{melt}}$$

where the symbols in the fractions represent the number of moles present.

These distribution coefficients are plotted against R_5 in Fig. 4 and 5 for a series of runs in which the concentrations of Ca and Ge ranged from zero upward. Note that at zero Ca concentration k^{Ge} is considerably less than 1, ~0.24, but rises sharply to over 1 as the Ca concentration rises. On the other hand, k^{Ca} is near 0.1 at high Ca and low Ge concentrations but rises to ~0.6 as the ratio R_5 decreases; *i.e.*, the concentration in the melt of Ca relative to Ge diminishes. The maximum in k^{Ca} at R_5 between 0.4 and 0.5 occurs because of the very large Pb^{2+} concentration in the melt which dominates the charge compensation process at low Ca concentrations. A comparable break in the k^{Ge} does not occur because tetravalent ions other than Ge, such as Fe^{4+}, have very low concentrations.

Additional details on Pb^{2+} incorporation will be presented later; however, the data in Fig. 4 and 5 show the great interdependence of the incorporations

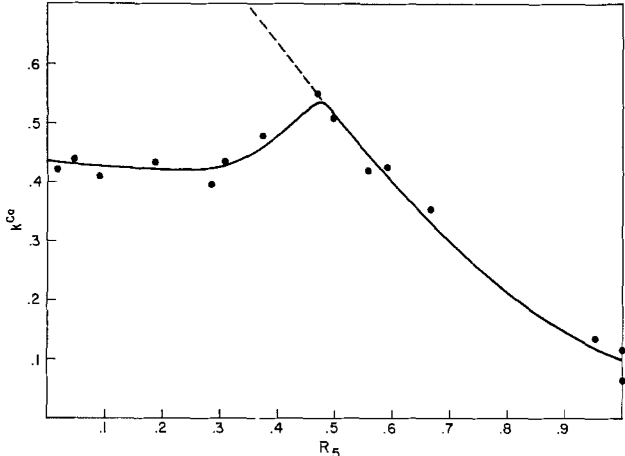

Fig. 4. $k^{Ca^{2+}}$ vs. R_5

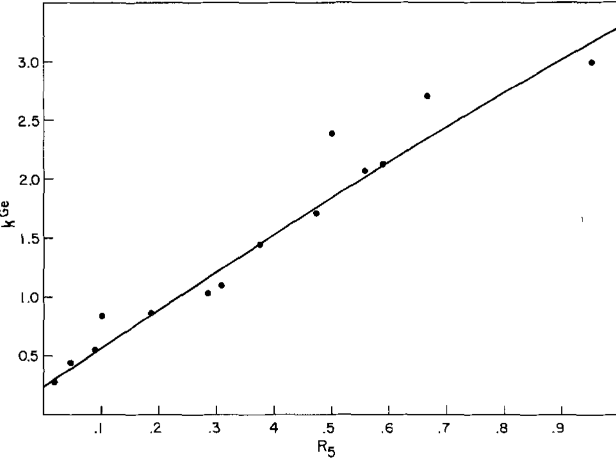

Fig. 5. $k^{Ge^{4+}}$ vs. R_5

of Ca and Ge into the crystal. At very low Ge concentrations, the total substitution is strongly influenced by the concentration of Ge and k^{Ge} is high, >1, in fact. At very low Ca concentrations the reverse is true; the substitution tends to be Ca controlled, but the presence of lead makes this effect less pronounced than the former case.

We have found it convenient in discussing the substitution of Ca and Ge to define a coupled distribution coefficient as follows

$$k^{Ca;Ge} = \frac{(X_{Ca} + X_{Ge})_{crystal}}{2(X_{Ca} + X_{Ge})_{melt}}$$

where the X's are mole fractions based on total garnet ions present.

We can view $k^{Ca;Ge}$ as a measure of the effectiveness of total substitution in the $(YSmCa)_3(GeFe)_5O_{12}$ system. In Fig. 6 are plotted values of $k^{Ca;Ge}$ against R_5. There it is seen that substitution becomes easier as Ca and Ge concentrations become comparable. It can be seen then, from Fig. 4, 5, and 6, that the incorporations of Ca and Ge are strongly controlled by the concentrations of the ions with valences other than three. In fact, separate experiments revealed that k^{Ge} and k^{Ca} are not nearly so sensitive to the temperature of growth as, for example, is k^{Ga}. Thus while the scatter in the points in Fig. 4, 5, and 6 can perhaps be partially attributed to differences in growth temperatures, it is likely that kinetic factors played a greater role. These will be discussed later.

The incorporation of Pb requires comment. With no Ca in the melt, films grown at the same temperature, 902° ± 2°C, and at a similar rate contained lead varying from 0.06 to 0.12 in the formula unit as R_2 changed

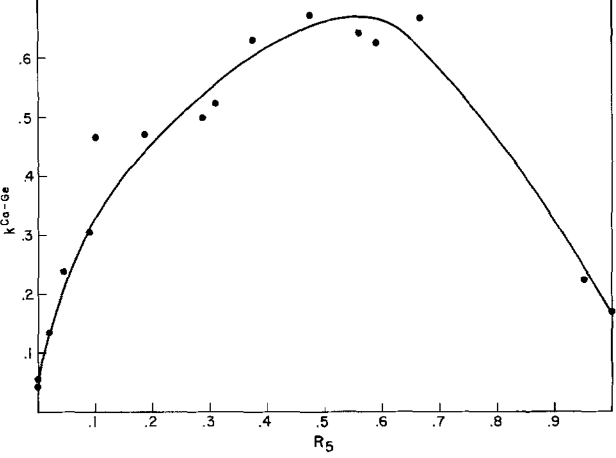

Fig. 6. $k^{Ca;Ge}$ vs. R_5

from 9.4 to 6.0, *i.e.*, as the ratio of Fe to Ge decreased. It was observed, however, that as calcium was added to the melt the lead content was sharply reduced. For example, analysis of films grown from a melt where R_1, R_2, and R_5 were 25, 6, and 0, respectively, yielded the formula $Y_{2.80}Sm_{0.09}Pb_{0.11}Fe_{4.88}Ge_{0.12}O_{12}$. Keeping R_1 and R_2 constant and raising R_5 to only 0.3 yielded a composition with Pb 0.01 in the formula unit. We conclude that because of its smaller size, calcium rapidly dominates the charge balancing process in the films even in the presence of large concentrations of divalent lead.

Growth Kinetics

Composition vs. growth rate.—Once the phase equilibria are known and a melt made which has the correct composition to insure that the desired iron garnet is the primary phase, kinetic effects must be considered. There is evidence that at higher temperatures the growth rate is greater for the $(YSmCa)_3(FeGe)_5O_{12}$ system than it is for the $(YSm)_3(GaFe)_5O_{12}$ system. For comparison, the growth rate for $(YSmCa)_3(FeGe)_5O_{12}$ at 908° and 955°C and 10° and 5°C supercooling, respectively, are 0.30 μm/min and 0.97 μm/min as compared to 0.26 μm/min and 0.25 μm/min for the Ga system at the same temperatures and degrees of supercooling (26).

Figure 7 shows the $4\pi M_s$ and Curie temperature as a function of growth rate for samples grown from the melt composition given below

$R_1 = 25$ $R_4 = 0.236$

$R_2 = 9.25$ $R_5 = 0.590$

$R_3 = 7.81$ $Sm/Y + Sm = 0.0416$

Note that the R_2-R_5 combination places the melt just inside the garnet field. The compensation temperature moves from below room temperature to above room temperature for growth rates from 0.80 to 2.10 μm/min. This corresponds to compositions ranging from $Y_{1.93}Sm_{0.10}Ca_{0.97}Ge_{0.97}Fe_{4.03}O_{12}$, for the lowest growth rate, to $Y_{1.75}Sm_{0.10}Ca_{1.15}Ge_{1.15}Fe_{3.85}O_{12}$ for the highest growth rate. Figure 7 predicts that for the melt composition listed above, a growth rate of ~1.52 μm/min would result in a material with a compensation temperature at room temperature having the approximate composition $Y_{1.8}Sm_{0.10}Ca_{1.1}Ge_{1.1}Fe_{3.9}O_{12}$. By interpolating between the measured lattice constants for samples grown at 1.06 and 1.58 μm/min, one predicts that the above composition should have a lattice parameter of ~12.3797Å. Correcting this lattice constant for the approximate Sm and Pb contents, one obtains a lattice constant for $Y_{1.9}Ca_{1.1}Ge_{1.1}Fe_{3.9}O_{12}$ of ~12.371Å. This compares well with the lattice constant reported by Winkler (21). We point out that the effect of rate

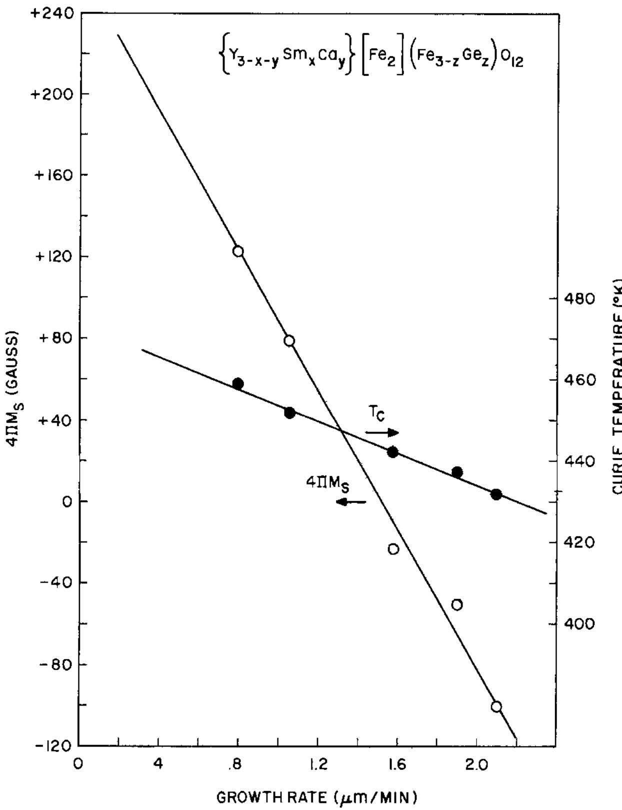

Fig. 7. $4\pi M_s$ and T_c vs. growth rate. ● = Curie temperature, ○ = $4\pi M_s$.

on $4\pi M_s$ can be large, and can be greater than in the trivalent substituted systems.

The question arises: Since the sensitivity of $4\pi M_s$ to growth rate is substantial, does the interdependence of the substitutions of Ca and Ge give a greater flexibility in controlling the rate sensitivity than is observed in the case of a single nonmagnetic ion substituent such as Ga? A series of runs was made to investigate the point.

The sensitivity of the measured $4\pi M_s$ to growth rate can be expressed by

$$\dot{M}\,(\text{G}/\mu\text{m/min}) = \frac{\Delta 4\pi M_s}{\Delta \text{Rate}}$$

For the melt listed above, $\dot{M} = -170$ G/μm/min. We show in Fig. 8 the relationship observed between $\dot{M}$ and R_5 for a fixed R_1 of 25 and for three values of R_2. Open circles represent R_2 values between 9.0 and 10.0, closed circles represent R_2 values from 6.5 to 8.0, and crosses represent R_2 values from 5.0 to 6.5. The data show that the growth rate sensitivity of the $4\pi M_s$ is a maximum at R_5 near 0.5. The values of $\dot{M}$ range from -260 G/μm/min for $R_5 = 0.5$ to approximately -90 G/μm/min for R_5 or either $R_5 = 0.167$ or 0.63. For comparison, in the system $Y_{2.6}Sm_{0.4}Ga_xFe_{5-x}O_{12}$ the average $\dot{M} = \sim +225$. Compositions can be used such that the rate sensitivity is at least no greater than it is in gallium-containing systems. Furthermore, the empirically observed growth-rate sensitivity of the $4\pi M_s$ confirms that the effective distribution coefficient of the Ca^{+2}-Ge^{+4} couple is less than unity. We postulate that, over the useful range of melt compositions studied, calcium is the controlling ion in establishing the effective distribution coefficient for the Ca-Ge couple.

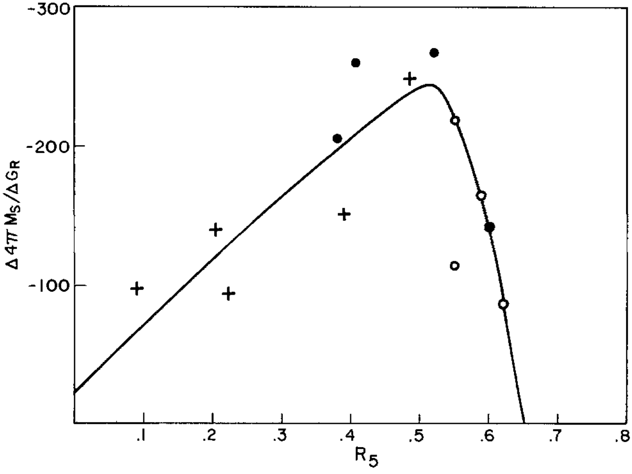

Fig. 8. Growth rate sensitivity vs. R_5

Melt Depletion Effects

From the data shown in Fig. 4, 5, and 6, one would expect that the effect of melt depletion would be to cause a considerable systematic variation in film composition as garnet is removed from the melt. To investigate this point as well as to establish the effect of temperature on rate sensitivity, a small melt ($\sim$250g) was used first to grow films on 12 0.8 in. diameter GGG substrates over the temperature range 953° ± 7°C, then flux ($PbO + B_2O_3$) was added to the melt and a second series of 14 samples was grown over a temperature range of 895° ± 5°C. The melt ratios were 31.6, 7.38, 0.386, and 2.70 for R_1, R_2, R_5, and R_6, respectively. A second melt, with the same composition as the first except for R_4, was then used to grow 12 samples over the temperature range 840° ± 10°C. Figure 9 shows the measured $4\pi M_s$ of these three sets of samples as a function of growth rate. Open circles represent the first set of samples, X the second set, and closed circles the third set. Note the large scatter in the points. No attempt is made to indicate the sequential nature of the points.

With a melt as small as 250g, removal of 1.9×10^{-2}g of garnet ($\sim$10 μm total thickness of film on 0.8 in. diameter substrate) changes the melt ratios significantly. The most important change occurs in R_6, since Y and Ca are removed from the melt in the ratio of 2/1, R_6 would increase. Increasing R_6 results in increased Ca-Ge substitution in the film. Experimentally, it is found that the $4\pi M_s$ of films grown from the above-described melt decreases by 4.8G upon removal of a 10 μm thickness of garnet. Correcting the mea-

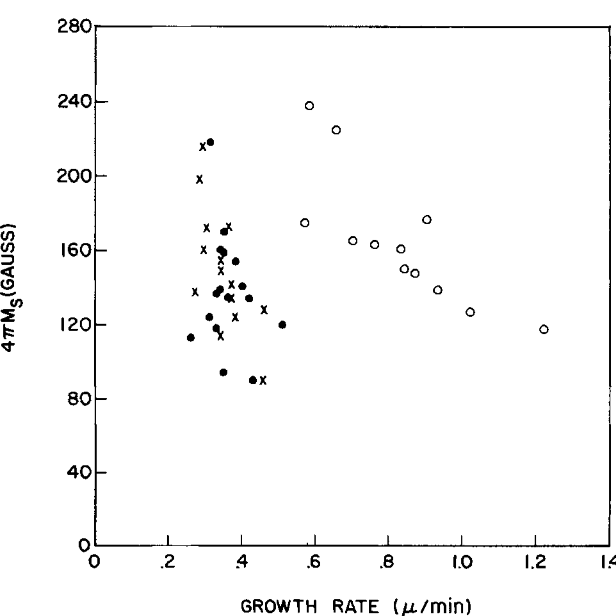

Fig. 9. $4\pi M_s$ vs. growth rate for $Y_{2.9-x}Sm_{0.1}Ca_xFe_{5-x}Ge_xO_{12}$ grown from a 250g melt. ○ = 953°C, × = 895°C, ● = 840°C.

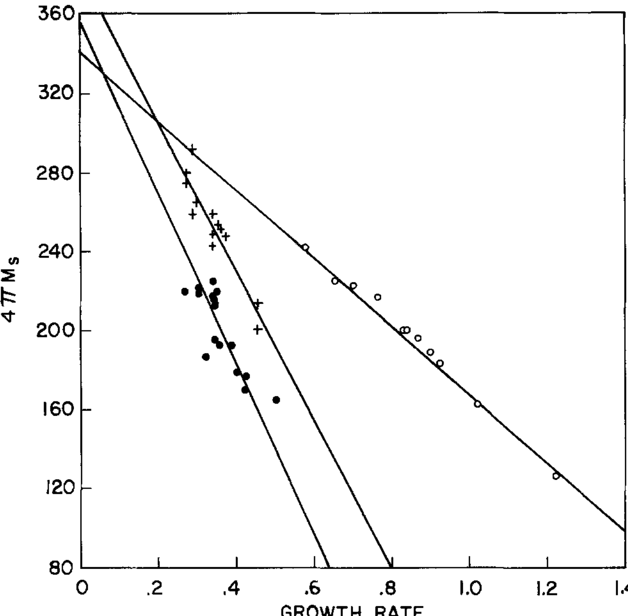

Fig. 10. $4\pi M_s$ vs. growth rate for $Y_{2.9-x}Sm_{0.1}Ca_xFe_{5-x}Ge_xO_{12}$ after correction for melt depletion. ○ = 953°C, + = 895°C, ● = 840°C.

sured $4\pi M_s$ of each sample by the above factor results in the data shown in Fig. 10. Note the smaller scatter and the trend of decreasing moment with decreasing temperature of growth. The latter effect could result from increased lead content (therefore increased Ge^{4+} acting as charge compensation) as the growth temperature decreases (15). The growth rate sensitivity of the $4\pi M_s$ varies from −173 G/μm/min at 953°C to −430 G/μm/min at 840°C. This increased growth rate sensitivity is also thought to be the result of increased lead content. Since the distribution coefficient of Pb is much less than unity, as the concentration in the film is increased the growth rate sensitivity of the $4\pi M_s$ would also be expected to increase.

Temperature Dependence of Magnetic Properties

Samples of $(YSmCa)_3(GeFe)_5O_{12}$ were grown with net moments parallel to the tetrahedral (positive) and octahedral (negative) iron sublattices. The positive material, with a composition $Y_{1.92}Sm_{0.10}Ca_{0.98}Ge_{0.98}Fe_{4.02}O_{12}$, exhibited a normalized slope of the collapse field vs. temperature curve $(\Delta H_o/H_o\Delta T)_{25°C}$ of −0.14%/°C. For the negative material, with a composition $Y_{1.67}Sm_{0.10}Ca_{1.23}Ge_{1.23}Fe_{3.77}O_{12}$, $(\Delta H_o/H_o\Delta T)_{25°C}$ = −0.51%/°C. Comparison of the two values on either side of the compositional compensation point indicates that the material with the net moment parallel to the octahedral iron sublattice has a temperature dependence ~3.5 times greater than that for the positive material. The change of collapse field with temperature is an important material parameter to consider because it directly affects the temperature sensitivity of circuit performance. To be thermally stable, the bubble garnet chip must be placed in a bias magnet structure where the temperature dependence of the bias field tracks the change in collapse field of the epi material. The most commonly used bias magnets are composed of barium ferrite whose $(\Delta H_o/H_o\Delta T)_{25°C}$ is ~ −0.20%/°C over the $-10 < T°C < 100$ range. A method by which the $(\Delta H_o/H_o\Delta T)_{25°C}$ could be varied is therefore of great importance in tailoring a bubble material to a specific application.

It is found experimentally that in the $(YSmCa)_3(Ge,Fe)_5O_{12}$ system the temperature dependence of the bubble collapse field is a function of growth temperature. Figure 11 shows $(\Delta H_o/H_o\Delta T)$ (%/°C) vs. growth temperature (°C) for four samples of $Y_{1.92}Sm_{0.10}Ca_{0.98}Ge_{0.98}Fe_{4.02}O_{12}$. The increased slope observed as the

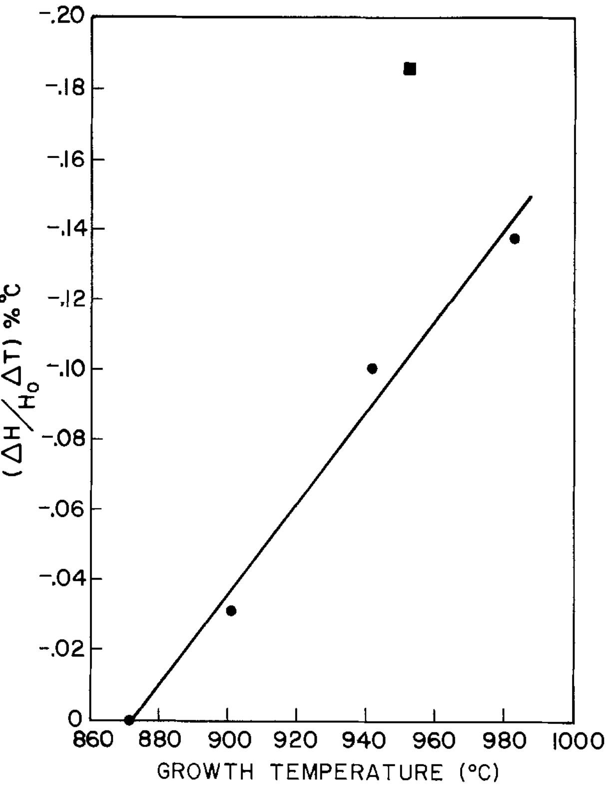

Fig. 11. Normalized collapse field temperature dependence vs. growth temperature. ○ = $(YSmCa)_3(Ge,Fe)_5O_{12}$, ■ = $(LuYSmCa)_3(Ge,Fe)_5O_{12}$.

growth temperature is increased is thought to be the result of increasing octahedral substitution. A sample of $Lu_{0.34}Y_{1.44}Sm_{0.28}Ca_{0.94}Ge_{0.94}Fe_{4.06}O_{12}$ was grown at 952°C and the $(\Delta H_o/H_o\Delta T)_{25°C}$ also plotted in Fig. 11 as the dark square. The increased value for the slope is consistent with the postulation that some small fraction of Lu^{3+} occupy octahedral sites. Curie temperature measurements confirm some octahedral occupation of Lu^{3+}. The measured T_c for the above composition is 471°K with a $4\pi M_s$ of 214G. The expected value of T_c is ~475°K. If the decrease in T_c of ~185°K per mole from octahedral substitution is assumed to be correct, the observed decrease in T_c of 4°K corresponds to ~0.022 moles of Lu^{3+} on octahedral sites or approximately 6.5% of the total Lu^{3+} content. Robertson *et al.* (27) have also reported rare earth ions on octahedral sites.

In order to investigate the effect of octahedral occupation of Lu^{3+}, a series of samples in the system $(Y, Sm, Lu, Ca)_3(Fe, Ge)_5O_{12}$ was grown. Figure 12 shows the measured Curie temperature of these samples as a function of the melt ratio Fe_2O_3/Lu_2O_3. The solid point indicates the measured Curie temperature for a sample grown from a melt where Fe_2O_3/Lu_2O_3 was 54.5 but where Sc^{3+} was added to the melt to incorporate 0.024 ± 0.002 additional moles of Sc^{3+} on octahedral sites in the epi film. Figure 13 plots the normalized collapse field (ΔH_o) defined as the change in collapse field from 0° to 100°C divided by the temperature interval and normalized to the collapse field at 50°C as a function of the octahedral Lu^{3+} concentration (mole). The substitution on octahedral sites is consistent with the Curie temperature, moment measurement, and film lattice parameter. The solid point again represents the sample containing both Lu^{3+} and Sc^{3+}.

Propagation Characteristics

In Fig. 14 (28) is shown the longevity plot (29, 30) of a bubble data pattern propagating around a reentrant loop composed of *TX* elements. The operating frequency is the parameter, and the limits of the bias

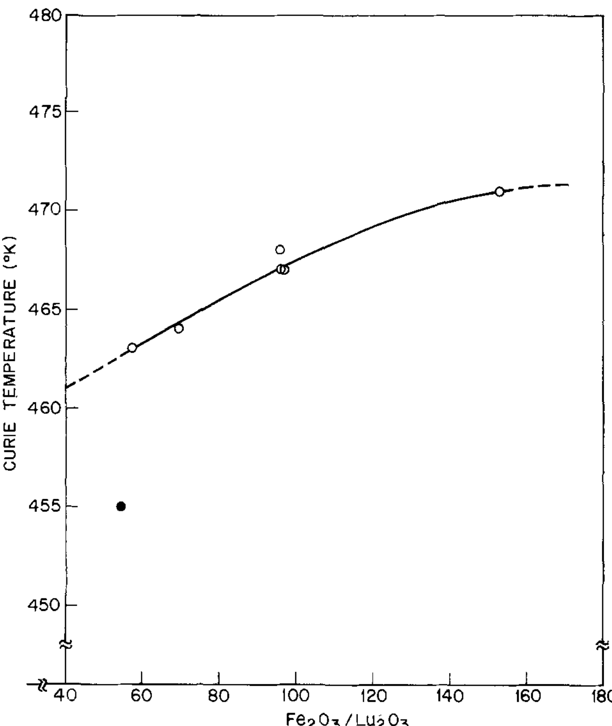

Fig. 12. Curie temperature vs. Fe_2O_3/Lu_2O_3 (molar ratio)

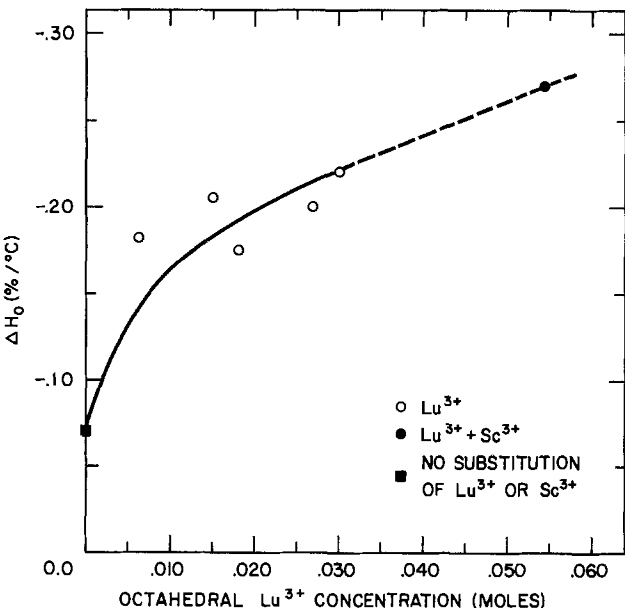

Fig. 13. Normalized collapse field temperature dependence vs. octahedral Lu^{3+} concentration.

field operating range are plotted as a function of the number of propagation steps. The circuit period was 28.8 μm and the separation between the epitaxial garnet film and the circuit was from 1.0 to 1.6 μm. The film composition was $Y_{1.92}Sm_{0.10}Ca_{0.98}Ge_{0.98}Fe_{4.02}O_{12}$. The magnetic properties of the sample are listed in Table I. It is seen in Fig. 14 that the bias field margins are independent of frequency until 1.1 MHz is reached. At 1.1 MHz, propagation still occurs for a relatively small number of steps but it is not possible to propagate more than 10^5 steps and retain the data pattern. At 1.2 MHz, propagation was not possible. Figure 14 illustrates the onset of dynamic conversion and implies that the dynamic conversion failure mechanism is the mechanism operative under the conditions presented.

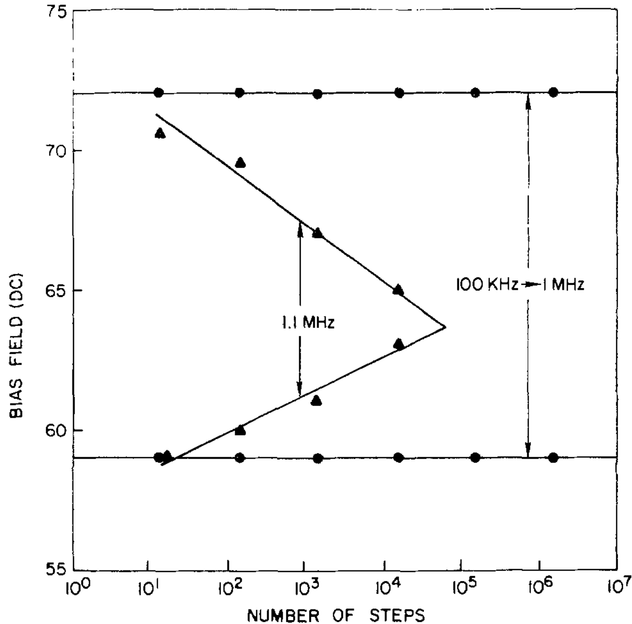

Fig. 14. Bias field operating range limits vs. number of propagation steps.

Discussion and Summary

Our work on the phase equilibria in the Y_2O_3-CaO-Sm_2O_3-Fe_2O_3-GeO_2-PbO-B_2O_3 system reveals two important differences between it and systems studied earlier (which contained only trivalent ions) that are important to note before depositing garnet films from the system by LPE. First, the distribution coefficients of the diamagnetic ions Ca^{2+} and Ge^{4+} can be varied over a much wider range by varying the concentration parameters than can the distribution coefficients of Ga^{3+} and Al^{3+}, *i.e.*, the solutions containing the ions Ca^{2+} and Ge^{4+} are less "ideal."

Second, the possible crystallization of CaO adds an additional complication to the LPE process. In systems containing trivalent garnet ions the spontaneous crystallization of only garnet, orthoferrite, or magnetoplumbite need be considered, and the elimination of problems with the latter two is a simple matter of controlling R_1. That is to say, the garnet primary field is readily defined and broad enough to permit a rather wide range of temperature and compositional changes. In the case of the melts containing Ca, the range of compositions available to the film grower is restricted by the formation of CaO within ranges of R_2 and R_5 that are close to the useful values of these ratios. Figure 5 shows that as R_5 increases the melt must become increasingly iron rich to avoid precipitation of CaO.

Returning to the first point, in contrast to Ga and Al, the distribution coefficients of both Ca^{2+} and Ge^{4+}, as single substituents, are less than unity and vary considerably with concentration. However, that variation is small compared to the change in k^{Ca} or K^{Ge} observed in melts containing both ions as the concentration of the compensating ion is increased. That is, a small amount of Ca added to a melt containing a substantial quantity of Ge, or a small amount of Ge added to a melt containing a large Ca concentration will sharply increase k^{Ca} or k^{Ge}, respectively. At low concentrations of Ge, in the presence of large

Table I

T_{growth}	h(μm)	SW(μm)	H_{coll} (oe)	$4\pi M_s$(G)	l(μm)	K_u(erg/cm^3)
947°C	4.0	5.2	70	163	0.66	4400

concentrations of Ca, k^{Ge} is over 2. On the other hand, the incorporation of Ca, at low concentrations of Ca in the presence of large concentrations of Ge, is influenced by the presence of Pb and k^{Ca} reaches a maximum at a value of R_5 a near 0.45. At that point, and at higher values of R_5 and higher temperatures (>925°C), Ca is substituted to the exclusion of Pb in spite of the large excess of the latter.

The composition of LPE films grown from solutions containing Ca and Ge is more strongly dependent on the rate of growth than the composition of films containing only trivalent ions when R_5 is near 0.5. However, this sensitivity decreases when an excess of either Ca or Ge is present. Apparently, in the presence of large amounts of Ca or Ge, the equivalent of a "buffering action" occurs which stabilizes the rate effect. Of course, high CaO concentrations increase the risk of CaO precipitation.

The temperature dependence of the bubble collapse field can be controlled by adjusting the degree of octahedral substitution, thereby changing the Curie temperature and degree of total diamagnetic ion incorporation. Increased octahedral substitution results in lower Curie temperature and increased values for ΔH_0. The use of Lu^{3+} as both a dodecahedral and octahedral substituent allows control of the temperature dependence of the bubble collapse field while simultaneously satisfying the other stringent device requirements.

In spite of the increased complexity of the Y_2O_3-CaO-Sm_2O_3-Fe_2O_3-GeO_2-PbO-B_2O_3 system and, perhaps, its high rate sensitivity, the garnets crystallized from it have high potential for use in high speed, temperature-stable, bubble memories. Propagation of 6 μm diameter bubbles at 1 MHz and 100°C with useful margins has already been demonstrated.

Potential-Induced Impedance Variations in Barrier-Type Aluminum Oxide Films in Aqueous Sodium Sulfate

T. A. Libsch*[,1] and O. F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Negligible changes occur in the dielectric properties of barrier-layer anodic aluminum oxide films exposed (50 hr) to neutral aqueous sodium sulfate at the open-circuit potential and −725 mV *vs.* SCE, indicating little film-environment interaction. Transmission electron micrographs of films exposed for this time to the same chemical environment at 10 and 20V show the presence of a deposit on the surface of thinned anodic oxide; this deposit is presumably hydrated aluminum oxide. Significant changes observed in the dielectric properties of films tested at these two potentials have been analyzed by means of an a-c impedance model yielding dielectric constant and resistivity values, and thickness-time profiles for the anodic and hydrated layers.

The oxide film on aluminum acts as a barrier to mass transport between the metal and the environment creating the generally favorable corrosion resistance of aluminum and its alloys. Hence, it is important to determine the manner in which these films are affected by various environmental factors, *e.g.*, anionic constituents, electrolyte *p*H, and applied potential. Several investigators, *e.g.*, Pryor and co-workers (1-4), Richardson and Wood (5), and Libsch and Devereux (6), have examined the effects of anionic constituents and electrolyte *p*H upon barrier-layer anodic oxide films on aluminum at the open-circuit potential. Other investigators (7, 8) have studied the formation mechanism of such films. To date, however, few investigations have been directed toward the effect of applied anodic potentials less than the formation potential; these potentials are subsequently referred to as "reduced potentials." The work of O'Sullivan and Wood (9) concerning the effect of reduced potentials on porous anodic aluminum oxide films, and of Renshaw (10) and Libsch and Devereux (11) concerning the effects of reduced potentials on barrier-layer films has been described previously.

In this investigation, the authors chose to examine the effect of reduced potentials upon barrier-layer anodic aluminum oxide films in neutral aqueous sodium sulfate. This chemical environment was chosen for study because of its innocuous effect (4, 5) upon these films at the open-circuit potential, and because of its nonanodizing behavior (12).

Experimental Procedure

Cylindrical electrodes were machined from aluminum and platinum rods of 99.999 and 99.5% purities, respectively, and successively abraded with 240, 320, 400, and 600 grit metallographic papers. The aluminum surfaces were further prepared by chemical polishing, as outlined previously (11). Electrolytes were prepared from reagent grade chemicals and double-distilled water. The anodizing electrolyte was aqueous 3 weight per cent (w/o) ammonium tartrate adjusted to neutral *p*H by the addition of several drops of dilute ammonium hydroxide. The testing electrolyte was aqueous 1M sodium sulfate adjusted to neutral *p*H by the addition of dilute sulfuric acid or sodium hydroxide. The *p*H of this electrolyte was checked immediately prior to use in each case, and minor adjustments made when necessary.

The electrode assembly was identical to that described previously (6, 11); the electrochemical cell was also similar except for the introduction of a reference electrode by means of a salt bridge comprised of the testing electrolyte. Barrier-layer anodic films [~360Å thick (3)] were potentiostatically formed at 30V in the manner given previously (11). Cells with anodized electrodes were tested at −725 and 1000 mV *vs.* SCE for 2700 min, and at the open-circuit potential, 10 and 20V for 3000 min. At 2700 min, the potential of cells tested at −725 and 1000 mV *vs.* SCE was abruptly reduced to and maintained at −910 mV *vs.* SCE (the steady-state open-circuit potential) for 200 min. The potential of cells tested at 10 and 20V was abruptly removed at 3000 min; testing continued, however, for an additional 200 min. In each case, a new electrode was used with testing promptly following anodizing. Cells with platinum electrodes were tested at the open-circuit potential for 4000 min. All cells were maintained at 30.0° ± 0.1°C during anodizing and testing by means of a conventional water bath.

The dielectric properties of cells with anodized electrodes were measured at preselected times during the testing period at 0.5, 1, 5, 10, 20, 50, and 100 kHz utilizing the capacitance measuring assembly described previously (6, 11). Cells with platinum electrodes were connected in series with a capacitor (General Radio 1419-B). The dielectric properties of this combination were measured at the above frequencies after a lapse of 4000 min; it had been the authors' previous observation that the properties of these cells do not stabilize for at least 1500 min (6). The dielectric properties of the series capacitor with the same leads were also measured at these frequencies for subsequent correction of these data. This technique was found to be more accurate than that previously employed by the authors (6, 13). The data of cells with platinum electrodes were obtained in order to correct the data of cells with anodized electrodes for the presence of the electrolyte, as discussed below.

Following exposure to the testing electrolyte, the cells were prepared for transmission electron microscopy in the manner given previously (6, 11); in this investigation, however, it was necessary on occasion to sandwich the film between two copper grids to prevent curling upon drying. At 10V, films were tested for 660, 1320, 1980, and 2640 min in order to construct a time sequence of transmission micrographs.

Experimental Results

Time dependence of the open-circuit potential.—The average open-circuit potential value of several cells with anodized electrodes was observed to decrease from approximately −400 mV *vs.* SCE initially to a nearly constant value of −910 mV *vs.* SCE after 500 min of testing (14). Cells tested at potentials more

20V	2.16

* Parameter definitions can be found in the list of symbols.

positive than the latter value were, therefore, considered to be anodically polarized.

Calculation of electrolyte and film parameters.—Electrolyte parameters were determined by two of the methods proposed by Young (15), *i.e.*, by substitution of a dummy electrode of low impedance for the anodized electrode, and by extrapolation of a plot of the initial series resistance of the cell *vs.* reciprocal frequency to infinite frequency. The parallel capacitance (Cp_2) and resistance (Rp_2) of cells with platinum electrodes were calculated from the measured series capacitance (Cs_4) and dissipation factor (D_4) of the cell-capacitor combinations, and from the measured series capacitance (Cs_5) and dissipation factor (D_5) of the capacitor, as discussed previously, by

$$Cp_2 = Cs_5\, Cs_4\, (Cs_5 - Cs_4)/[(Cs_5 - Cs_4)^2 + (Cs_5\, D_4 - Cs_4\, D_5)^2] \quad [1]$$

$$Rp_2 = [(Cs_5 - Cs_4)^2 + (Cs_5\, D_4 - Cs_4\, D_5)^2]/\omega\, Cs_5\, Cs_4\, (Cs_5\, D_4 - Cs_4\, D_5) \quad [2]$$

where ω represents the angular frequency in rad/sec. The series resistance (Rs_2) of these cells was calculated from Cp_2 and Rp_2 by

$$Rs_2 = Rp_2/[1 + (\omega\, Rp_2\, Cp_2)^2] \quad [3]$$

The average values of Cp_2, Rp_2, and Rs_2 calculated as above from three cells are listed, normalized for the electrode area (A), in Table I, part A.[2] These parameters are regarded as characteristic of the electrolyte since the platinum electrodes, in series with the electrolyte, may reasonably be expected to possess negligibly high capacitance and negligibly low resistance. The tabulated values compare favorably with those reported by Heine and Pryor (3) for near-neutral aqueous 1M sodium chromate. The series resistance (Rs_2) of the testing electrolyte was calculated by the latter of the aforementioned methods in the manner outlined previously (11). The average series resistance *vs.* reciprocal frequency plots were linear at each potential reflecting good cell geometry, as suggested by Smyth (16). The average electrolyte resistance values determined in this manner are listed *vs.* potential in Table I, part B. In Table I, the series resistances of the testing electrolyte determined by both methods are observed to be similar, particularly at the higher frequencies.

Cells with anodized electrodes were modeled as a series combination of two parallel RC circuits; one parallel RC circuit representing the electrolyte, the other the anodic film. Utilizing this analog, the bridge measurements of these cells, *i.e.*, the series capacitance (Cs_1) and dissipation factor (D_1), and the electrolyte parameters determined from cells with platinum electrodes (Table I, part A), the series capacitance (Cs_3) and resistance (Rs_3) of the film were calculated by

$$Cs_3 = Cs_1\, [1 + (\omega\, Rp_2\, Cp_2)^2]/[1 + Cp_2\, (\omega\, Rp_2)^2\, (Cp_2 - Cs_1)] \quad [4]$$

$$Rs_3 = [D_1 + \omega\, Rp_2\, (\omega\, Rp_2\, Cp_2^2\, D_1 - Cs_1)]/\omega\, Cs_1\, [1 + (\omega\, Rp_2\, Cp_2)^2] \quad [5]$$

The cell analog and procedure for calculating film parameters from the data of cells with anodized electrodes and the series resistance of the electrolyte as determined from plots of the initial series resistance of the cell *vs.* reciprocal frequency have been discussed previously (11). In both models, the parallel film capacitance (Cp_3) and resistance (Rp_3) were calculated from Cs_3 and Rs_3 by

$$Cp_3 = Cs_3/[1 + (\omega\, Rs_3\, Cs_3)^2] \quad [6]$$

$$Rp_3 = [1/(\omega\, Cs_3)^2\, Rs_3] + Rs_3 \quad [7]$$

Film values calculated by both methods were compared at the 10V potential and found to be negligibly different. The maximum difference in parallel film capacitance ($\Delta Cp_3/A$) was 0.010 μf/cm² (50 kHz, 3000 min), while the maximum difference in parallel film resistance (ΔRp_3A) was 10,000 ohm · cm² (0.5 kHz; 0 min). Hence, film values at the other testing potentials were calculated only from the data of cells with anodized electrodes.

Cell and film values.—The average parallel capacitance (Cp_1) and resistance (Rp_1) of three cells tested at open circuit, −725 and 1000 mV *vs.* SCE, and 10, and 20V are presented, normalized for the electrode area, in Fig. 1-5. Cp_1 and Rp_1 values were calculated from the bridge measurements Cs_1 and D_1 by

$$Cp_1 = Cs_1/(1 + D_1^2) \quad [8]$$

$$Rp_1 = (1 + D_1^2)/\omega\, Cs_1\, D_1 \quad [9]$$

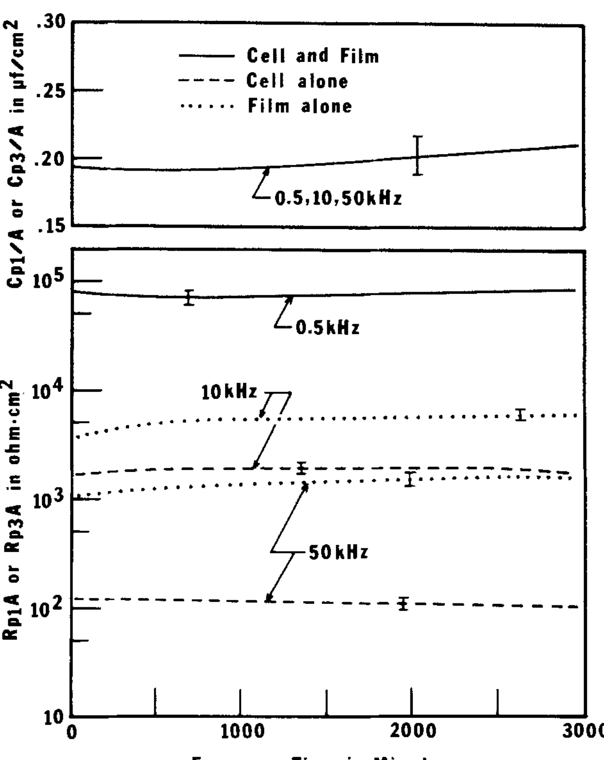

Fig. 1. Time dependence of the average parallel capacitance and resistance of cells having anodized electrodes and of films tested at the open-circuit potential. Error bars typical.

[2] Data at 100 kHz have not been reported throughout this article due to significant errors introduced by the inductance and resistance of the leads and bridge windings (14).

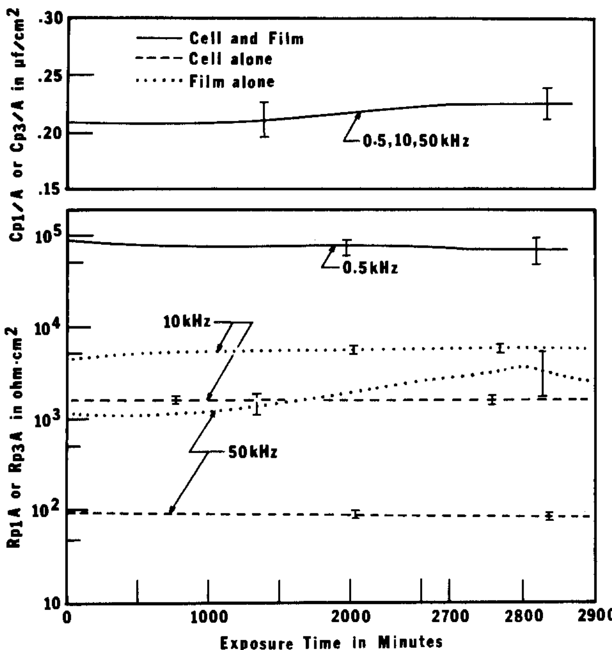

Fig. 2. Time dependence of the average parallel capacitance and resistance of cells and films tested at −725 mV vs. SCE. The potential was reduced to −910 mV vs. SCE at 2700 min, coincident with the expansion in the time scale. Error bars typical.

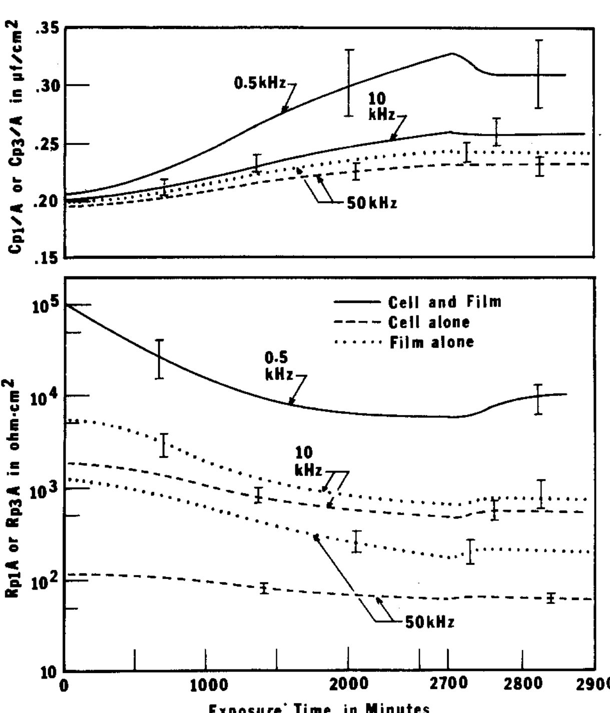

Fig. 3. Time dependence of the average parallel capacitance and resistance of cells and films tested at 1000 mV vs. SCE. The potential was reduced to −910 mV vs. SCE at 2700 min. Error bars typical.

The corresponding film values, calculated as above, are also illustrated in these figures. Data points are not shown in these figures; error brackets have been included solely for the purpose of illustrating typical scatter. The time scale has been expanded by a factor of five at 2700 min in Fig. 2 and 3 and at 3000 min in Fig. 4 and 5 corresponding to the time when the potential was reduced or removed. Significant changes in dielectric parameters are observed only for cells and films tested at 1000 mV *vs.* SCE and 10 and 20V; a large frequency dispersion of capacitance is also observed at these potentials.

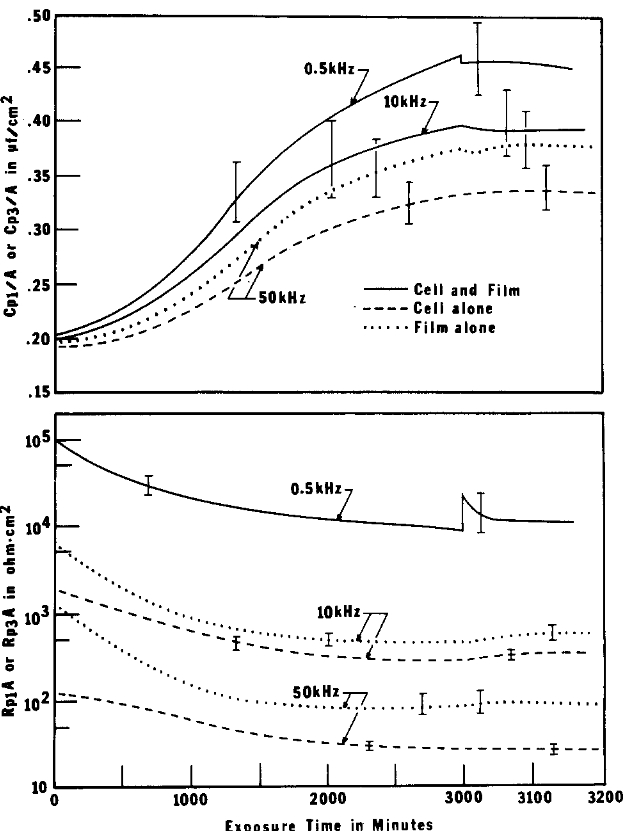

Fig. 4. Time dependence of the average parallel capacitance and resistance of cells and films tested at 10V. The potential was removed at 3000 min, coincident with the expansion in the time scale. Error bars typical.

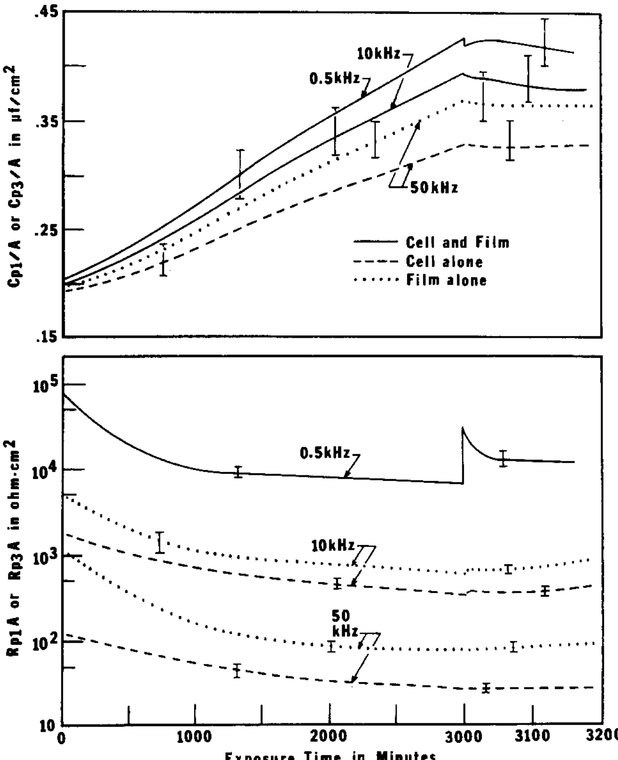

Fig. 5. Time dependence of the average parallel capacitance and resistance of cells and films tested at 20V. The potential was removed at 3000 min. Error bars typical.

Microscopic examination of films.—Typical transmission electron micrographs of films tested at each anodic potential are presented in Fig. 6. Films tested at −725 mV *vs.* SCE appear essentially featureless, except for

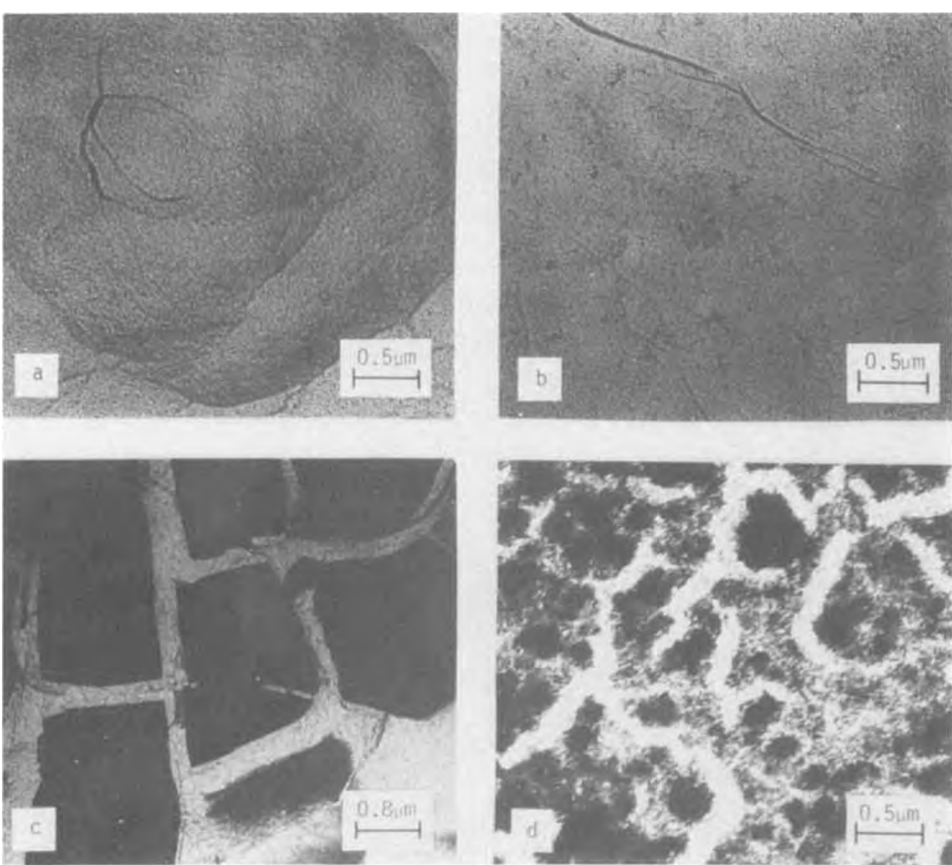

Fig. 6. Transmission electron micrographs of films tested at the anodic potentials: (a) −725 mV vs. SCE, (b) 1000 mV vs. SCE, (c) 10V, and (d) 20V. (a) and (b), 2700 min; (c) and (d), 3000 min.

a scalloped appearance due to the replication of the irregular topography of the substrate, created by the chemical polishing procedure (17). Films tested at 10 and 20V show the presence of a deposit on the surface of thinned anodic oxide. This deposit is observed to mask the majority of the anodic oxide, to be considerably thicker than the anodic oxide, and to be permeated by channels. Some tendency toward this behavior is seen in films tested at 1000 mV *vs.* SCE. The appearance of channels in tested films led to the investigation of the development of this phenomenon. Typical transmission electron micrographs of films tested for various times at 10V are presented in Fig. 7; channel development, as observed in these micrographs, is discussed in a subsequent section.

Discussion

Film values.—Heine, Keir, and Pryor (4) and Richardson and Wood (5) have previously reported the dielectric properties of barrier-layer anodic aluminum oxide films tested in near-neutral aqueous sodium sulfate at the open-circuit potential to remain essentially unchanged for a prolonged period. In the current study, the dielectric properties of films tested under similar conditions (Fig. 1) remained nearly constant during 50 hr, a result in agreement with that of the aforementioned investigators. The purpose of determining these data was to establish a standard against which the dielectric properties of films subjected to the anodic potentials could be compared. Minor changes in film properties occur at −725 mV *vs.* SCE (Fig. 2); in view of the micrograph of the film tested at this potential (Fig. 6a), these changes are credited to minor uniform film dissolution.

Significant changes in film dielectric properties were observed at 1000 mV *vs.* SCE and 10 and 20V (Fig. 3-5). Micrographs of these films (Fig. 6b-6d) show these changes to result from the thinning of the anodic oxide film and the concurrent thickening of an outer deposit, believed to be hydrated aluminum oxide. The hydrated oxide appears as the dark regions due to its substantial thickness.

Several workers (18-20) have investigated the reaction between boiling water and barrier-layer anodic aluminum oxide films, and reported the simultaneous thinning of the anodic oxide, and thickening of a hydrated oxide. Borate and phosphate ions were found to impede this reaction; sulfate, chromate, and oxalate ions had little effect. The reaction product was identified as pseudoboehmite, a poorly crystallized substance containing considerably more water than stoichiometric aluminum monohydrate (boehmite); it was observed to form in randomly oriented platelets which extended far out into the electrolyte.

The authors believe the hydrated oxide observed in this investigation "cracked" upon drying at the conclusion of the test period. This belief is supported by the following observations: (*i*) after 660 min at 10V (Fig. 7b), the hydrated oxide appears uniform; (*ii*) the channeled area is relatively small (26% in Fig. 6c) and appears to be related to the thickness of the hydrated oxide; and (*iii*) a model considering the growth of channels *in situ*, described subsequently, proved unrealistic.

Potential-dependent changes were observed in the dielectric properties of films tested at the higher anodic potentials (Fig. 3-5). The authors (11) have previously observed similar changes which were explained by the flow of ionic defects to the oxide/electrolyte interface. The potential-dependent changes in film values in the current investigation can be credited in part to the same phenomenon; the situation is complicated, however, by the presence of the hydrated layer, and these data are presented without further explanation.

The hydration model.—The micrographs in Fig. 7 show that the thinned anodic layer is essentially uniform; the film, therefore, was modeled as a series combination of two parallel RC circuits; one circuit representing a uniform (in thickness) anodic layer, the other a uniform hydrated layer. This model was analyzed only for films tested at 10V, and only for the time during which this potential was applied (0-3000 min). The dielectric constants and resistivities of both

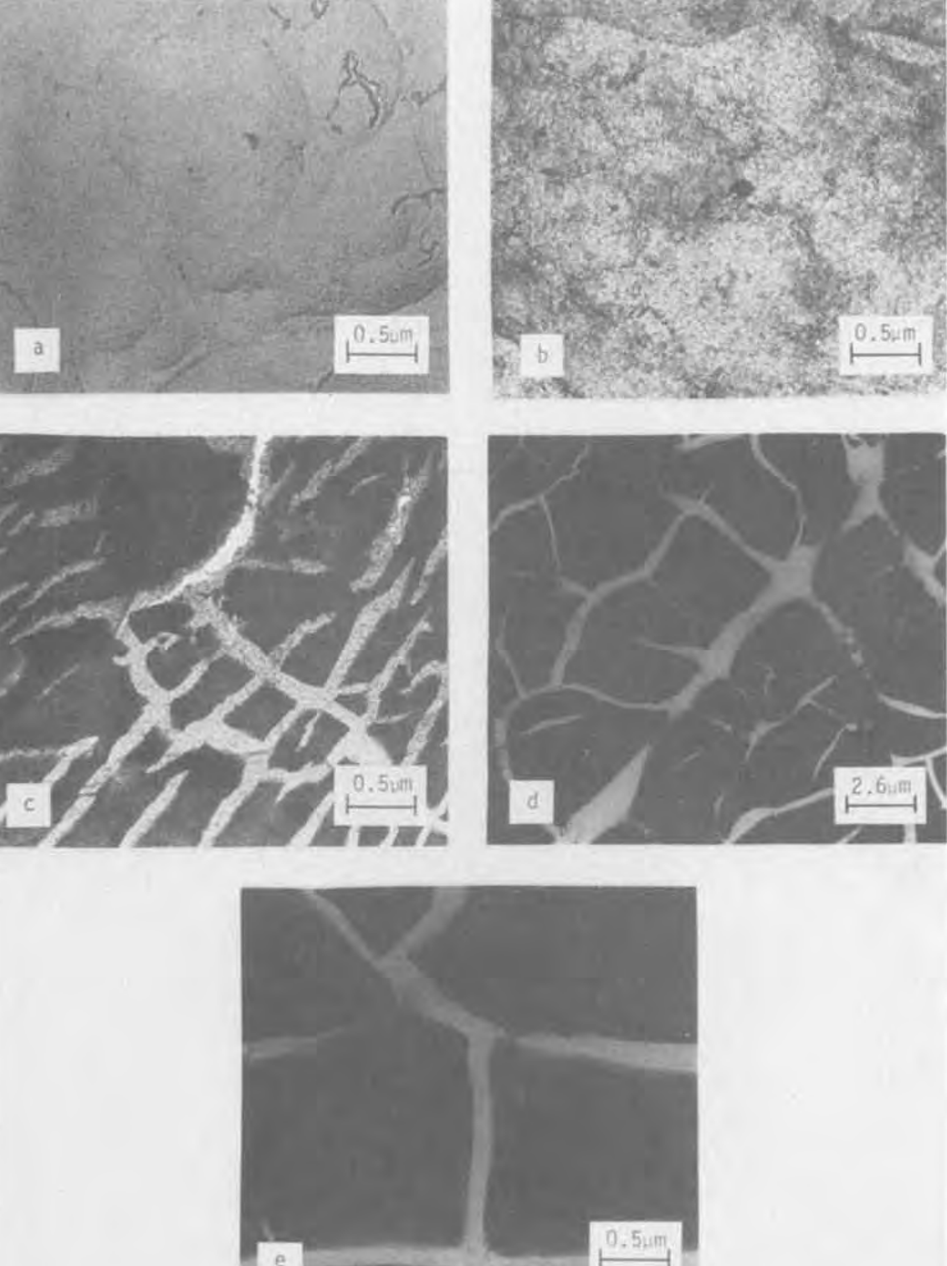

Fig. 7. Transmission electron micrographs of films tested at 10V for: (a) 0, (b) 660, (c) 1320, (d) 1980, and (e) 2640 min.

oxides were assumed independent of layer thickness, and values were assigned for the thickness of each layer at 3000 min. Several final thickness assumptions were examined, each of the form $d_6:d_7$, where d_6 and d_7 in this form represent the final thicknesses of the anodic and hydrated layers in angstroms.

The series dielectric constant (κs_6) and resistivity (ρs_6) of the anodic oxide were calculated by

$$\kappa s_6 = Cs_3\, d_o/\epsilon_o A \quad [10]$$

$$\rho s_6 = Rs_3\, A/d_o \quad [11]$$

where d_o and ϵ_o represent the initial film thickness and the permittivity constant, respectively. κs_6 and ρs_6 were determined from initial film values since the layer thicknesses are known to be 360 and 0Å at this time. The values of these parameters are listed *vs.* frequency in Table II, part A.

The series dielectric constant (κs_7) and resistivity (ρs_7) of the hydrated layer were calculated by

$$\kappa s_7 = \kappa s_6\, Cs_3\, d_7/(\kappa s_6\, \epsilon_o\, A - Cs_3\, d_6) \quad [12]$$

$$\rho s_7 = (Rs_3\, A - \rho s_6\, d_6)/d_7 \quad [13]$$

A problem was encountered in supplying data for these expressions since d_6 and d_7 are known only at time zero, which is not useful. Utilizing the dielectric constant and resistivity values of the anodic layer (Table II, part A), and the final values of film capacitance and resistance, κs_7 and ρs_7 were arbitrarily calculated at 3000 min for each of the following final thickness assumptions: (*i*) 20:2000, (*ii*) 20:2500, (*iii*) 60:2000, and (*iv*) 60:2500. These values are listed *vs.* frequency in Table II, part B. The dielectric constant and resistivity of the hydrated oxide are observed to be greater and less than, respectively, the same parameters of the anodic oxide. It is also observed both when the assumed hydrated layer thickness is increased at constant anodic layer thickness and when the assumed anodic layer thickness is increased at constant hydrated layer thickness that the dielectric constant increases; at the same time the resistivity of the hydrated oxide decreases.

The thicknesses of the anodic (d_6) and hydrated (d_7) layers have been determined at any time by

$$d_6 = \kappa s_6 \{\omega\, \kappa s_7\, \epsilon_o\, A\, Rs_3 - [1 + (\omega\, \kappa s_7\, \epsilon_o\, \rho s_7)^2]^{1/2}\, d_7 \cos\theta_2\}/\kappa s_7\, [1 + (\omega\, \kappa s_7\, \epsilon_o\, \rho s_6)^2]^{1/2} \cos\theta_1 \quad [14]$$

and

$$d_7 = \kappa s_7 \, \epsilon_0 \, A(\cos \theta_1 - \omega \, Cs_3 \, Rs_3 \sin \theta_1) / Cs_3 \, [1 + (\omega \, \kappa s_7 \, \epsilon_0 \, \rho s_7)^2]^{1/2} \sin (\theta_2 - \theta_1) \quad [15]$$

where θ_1 and θ_2 are given by

$$\theta_1 = \tan^{-1} (1/\omega \, \rho s_6 \, \kappa s_6 \, \epsilon_0) \quad [16]$$

$$\theta_2 = \tan^{-1} (1/\omega \, \rho s_7 \, \kappa s_7 \, \epsilon_0) \quad [17]$$

Utilizing the dielectric constant and resistivity values of both oxides (Table II) and the capacitance and resistance values of the film at 0.5 kHz,[3] d_6 and d_7 were calculated at several times for each of the aforementioned final thickness assumptions. These thickness profiles are illustrated in Fig. 8; to locate the anodic and hydrated layer profiles for any final thickness assumption, choose the two curves labeled with the values of that assumption. Regardless of the final thickness assumption employed, the anodic layer thins at a nearly constant rate during the initial portion of the test; the rate then slows and assumes a nearly constant value of ~ 10% of the initial rate. More specifically, for the 20Å curve the initial and final rates are 0.267 and 0.030 Å/min; for the 60Å curve the rates are 0.211 and 0.027 Å/min. This change is attributed to a reduction in the reaction rate at the anodic oxide/hydrated oxide interface due to thickening of the hydrated layer. Regardless of the assumption, the hydrated layer thickens to approximately its final value during the initial 1000 min of testing, and remains essentially constant after that. The initial growth rate of this layer is 2.85 Å/min for the 2000Å curve and 3.56 Å/min for the 2500Å curve. Using the initial rates cited above, the thickness of hydrated oxide formed per angstrom of anodic oxide consumed is found to be dependent on the final thickness assumption, increasing from 10.7Å for the 20:2000 assumption to 16.9Å for the 60:2500 assumption. These values are greater than that of 2.5Å reported by Hunter, Towner, and Robinson (18) for the reaction between boiling water and nonporous anodic aluminum oxide.

[3] Layer thickness is independent of frequency, hence, film data at 0.5 kHz were arbitrarily chosen.

The parallel capacitance and resistance of the anodic and hydrated layers, *i.e.*, Cp_6, Rp_6, Cp_7, and Rp_7, respectively, have been calculated *vs.* time and frequency by

$$Cp_6 = \kappa s_6 \, \epsilon_0 \, A/d_6 \, [1 + (\omega \, \epsilon_0 \, \rho s_6 \, \kappa s_6)^2] \quad [18]$$

$$Rp_6 = d_6 \, [1 + (\omega \, \rho s_6 \, \kappa s_6 \, \epsilon_0)^2]/(\omega \kappa s_6 \, \epsilon_0)^2 \, A \, \rho s_6 \quad [19]$$

$$Cp_7 = \kappa s_7 \, \epsilon_0 \, A/d_7 \, [1 + (\omega \, \rho s_7 \, \kappa s_7 \, \epsilon_0)^2] \quad [20]$$

$$Rp_7 = d_7 \, [1 + (\omega \, \rho s_7 \, \kappa s_7 \, \epsilon_0)^2]/(\omega \, \kappa s_7 \, \epsilon_0)^2 \, A \, \rho s_7 \quad [21]$$

Utilizing the dielectric constant and resistivity values of both layers (Table II) and the thickness profiles (Fig. 8), the capacitance and resistance curves of each layer were determined for each of the aforementioned final thickness assumptions. The capacitance *vs.* time curves are illustrated in Fig. 9; these curves have been condensed into bands for graphical clarity. This figure clearly shows the large increases in film capacitance observed in Fig. 4 to result from the thinning of the anodic oxide, and the large frequency dispersion of capacitance to result from the large frequency dispersion of capacitance of the hydrated oxide. The resist-

ance *vs.* time curves are illustrated in Fig. 10; clearly, the large decreases in film resistance observed in Fig. 4 result from the thinning of the anodic oxide.

Alternate treatment of the data.—Using a similar series of steps, the authors have also analyzed the case where the channels are assumed present *in situ* (14). In this analysis, the anodic layer was assumed to thin uniformly, and the channeled area was considered to be a linear function of the thickness of the hydrated layer. Utilizing the film values at 10V and assuming a value of 2000Å for the final thickness of the hydrated layer, it was determined that the final thickness of the anodic layer must necessarily be greater than 115Å. It is apparent from the electron micrograph (Fig. 6c) that the anodic layer is considerably thinner than this at the end of the test, indicating conclusively that the channels are, in fact, an artifact induced during drying of the electrodes.

Summary and Conclusions

Barrier-layer anodic aluminum oxide films were exposed to neutral aqueous sodium sulfate for 50 hr at the open-circuit potential and at anodic potentials of −725 and 1000 mV *vs.* SCE and 10 and 20V. These films were examined by a-c impedance measurements and transmission electron microscopy. Film dielectric data, calculated from electrochemical cell data by two of the techniques suggested by Young (15), were found to be in excellent agreement.

Significant changes in film dielectric properties were observed only at 1000 mV *vs.* SCE and 10 and 20V. Transmission electron micrographs of these films show the presence of a deposit, believed to be hydrated aluminum oxide, on the surface of thinned anodic oxide. The authors' belief that the observed "cracked" morphology of the hydrated oxide is not present *in situ*, but rather is an artifact of drying at the conclusion of the test period, is supported by a time sequence of transmission electron micrographs of films tested at 10V, and by consideration of an a-c impedance model in which channels were assumed present *in situ.*

The average dielectric properties of films tested at 10V have been analyzed by representing the film as a series combination of two parallel RC circuits. The following conclusions have been drawn from this model: (*i*) the dielectric constant and resistivity of the hydrated oxide are considerably greater and less, respectively, than the same parameters of the anodic oxide; (*ii*) the anodic oxide thins at a nearly constant rate (~ 0.3 Å/min) during the initial 1000 min of the test period, but approaches a linear thinning rate of 10% of that value during the final portion of the test; (*iii*) the hydrated oxide layer thickens (initial rate ~ 3 Å/min) to approximately its final value during the initial 1000 min of the test, and remains essentially constant after that; and (*iv*) the changes in the film's dielectric properties are primarily attributable to thinning of the anodic oxide layer.

Investigation of Magnetic Anisotropy of Electrodeposited Magnetic Films by Measurement of the Magnetoresistance Effects

M. Perakh*

Graduate School of Applied Science, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

It is suggested that the magnetic texture in films may be estimated by using the characteristic angles azimuthal ψ and polar β, the first being the integral characteristic of uniaxial texture in a film plane, and the second of "perpendicular" anisotropy. An experimental procedure for determining the characteristic angles on the basis of measurement of galvanomagnetic effects in the film plane is suggested and has been found satisfactory in practice. An algorithm is developed to calculate the constant of perpendicular anisotropy and its components, as well as the demagnetizing factor along the normal of the film plane starting from experimental values of β. The addition of certain materials (saccharin, for instance) to the electrolyte causes a large increase in the perpendicular anisotropy which is found to be due to microstresses and their variations under the influence of the additional organic compounds. According to hysteresis loops and powder domain patterns observed, while the values of the polar angle are $\beta > 45°$, the "stripe" film state is achieved.

Magnetic texture is one of the most important properties of ferromagnetic films conditioning their use (1). The concept of texture is meant as a totality of all preferable directions of magnetization regardless of their physical origin. Two especially important kinds of magnetic anisotropy are: first, the uniaxial anisotropy in the film plane and, second, the so-called "perpendicular" anisotropy which appears only in films, the thickness of which exceeds a definite "critical" value. These films are called "transcritical" or "stripe" films. The latter name is due to stripe-shaped domain patterns observed (2) on the film surface while using a powder technique (3).

For investigation of uniaxial texture in the thin film plane, several methods are used although the magnetometer (4) is often most suitable. For measurement of perpendicular anisotropy only a few methods are suggested. The use of a rotation magnetometer, for instance, does not enable one to measure anisotropy, the constant of which is less than 10^4 erg/cm^3. Furthermore, the value of the anisotropy constant, which is an energetical characteristic, does not give the obvious image about the shape of anisotropy. Finally, use of the magnetometer is connected with experimental difficulties. Therefore, the development of new methods for the investigation of anisotropy, especially in "stripe" films, is still being sought.

Integral Characteristics of the Magnetic Texture in Films

Let us consider a film (Fig. 1) having a certain distribution of local easy axes in its plane. Let the fraction $\rho(\alpha)\,d\alpha$ of local easy axes be contained within the angle from α to $\alpha + d\alpha$. The distribution function $\rho(\alpha)$ is normalized by the condition

$$\int_0^{\pi/2} \rho(\alpha)\,d\alpha = 1 \qquad [1]$$

If the film has been magnetized to saturation along the x-axis, the magnetic moments lying within the angle $d\alpha$, rotate through an angle of α to the x-axis.

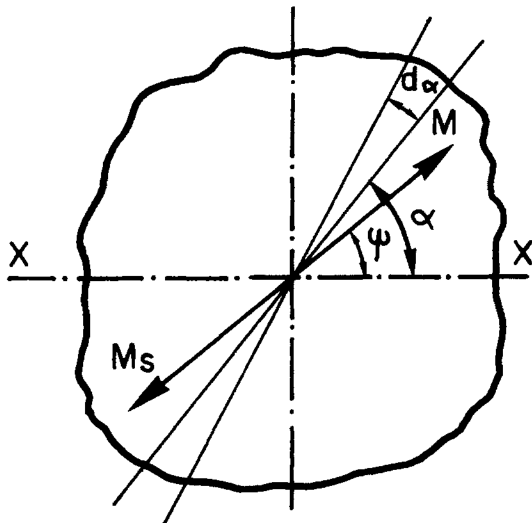

Fig. 1. Diagram showing how the galvanomagnetic effect is calculated with allowance for the dispersion of local easy axes.

It is known (5) that the galvanomagnetic effect (GE), *i.e.*, the change of electroresistance while applying a magnetic field, is proportional to the increment of square magnetization. If the electrical resistance is measured along the x-axis, and the magnetic field acts along the same axis, the contribution of the vectors of magnetic moments, contained before the applying of a field within the angle $d\alpha$, to the measured longitudinal GE, will be (neglecting the amplitude dispersion of magnetization)

$$dg^{xx} = [k_{\parallel} M_s^2 - k_{\parallel} (M_s \cos\alpha)^2]\rho(\alpha)\,d\alpha = k_{\parallel} M_s^2 \sin^2\alpha\rho(\alpha)\,d\alpha \quad [2]$$

where g^{xx} is the value of the longitudinal GE (the first superscript at g indicates the direction in which the conductivity is measured and the second superscript the direction of magnetic field); $k_{\parallel}$ is the coefficient of proportionality between longitudinal GE and the square of magnetization, M_s^2. Hence the total longitudinal GE

$$g^{xx} = k_{\parallel} M_s^2 \int_0^{\pi/2} \sin^2\alpha\rho(\alpha)\,d\alpha \quad [3]$$

Now we introduce a characteristic angle ψ by means of the relation

$$\sin^2\psi = \int_0^{\pi/2} \sin^2\alpha\rho(\alpha)\,d\alpha \quad [4]$$

The physical sense of the angle ψ is as follows. If all the magnetic moments in the film plane had been at an angle of $|\psi \pm k \cdot \pi/2|$, where $k = 0,1,2,\ldots$, to the mean easy axis, then the measured longitudinal GE for this axis would be identical to the one observed at the real distribution of magnetic moments described by the function $\rho(\alpha)$. Therefore ψ could be used as the integral characteristic of uniaxial anisotropy in the film plane. If the distribution of local easy axes in the film plane is isotropic ($\rho(\alpha) \equiv 2/\pi$), then from [4] we obtain $\psi = \pi/4$. While a definite degree of anisotropy exists, we have either $\psi < \pi/4$ (mean easy axis coincides with x-axis) or $\psi > \pi/4$ (mean easy axis along y); the derivation ψ from $\pi/4$ is the measure of anisotropy.

The above consideration relates to the distribution of magnetic moments in the film plane. However, in so-called "transcritical" or "stripe" films, the magnetization vectors "withdraw" from the film plane (5, 7). Carrying out a consideration similar to the one described above, for the distribution of magnetic moments in the plane perpendicular to the film we introduce the characteristic angle β

$$\cos^2\beta = \int_0^{\pi/2} \sin^2\epsilon\,\rho_{\perp}(\epsilon)\,d\epsilon \quad [5]$$

where β is read from the plane of the film, the variable angle ϵ is read from the z-axis, being perpendicular to the film plane, and $\rho_{\perp}(\epsilon)$ is the distribution function of the magnetization vectors in the plane, perpendicular to the film plane, normalized by 1. Hence, the angle β is the angle of inclination of the magnetization vectors to the film plane, averaged over GE; it can be used as the integral characteristic of "perpendicular anisotropy" (PA).

Determination of the Integral Characteristics of Magnetic Texture from Galvanomagnetic Effects

In Fig. 2 the vector M_s is a resultant vector of magnetization reduced to a unit of volume and representing the magnetization vectors, directions of which lie within the first octant. The vector M_s is inclined towards the plane of the film through an angle of β; the projection of M_s to the plane xy is at an angle of ψ to the x-axis.

From geometrical considerations one obtains

$$\sin\gamma = \cos\psi \cos\beta \quad [6]$$

where γ is the angle between vector M_s and the yz-plane.

Generalizing Eq. [2] to the case of nonplanar distribution of magnetic moments yields for a longitudinal GE

$$g^{xx} = k_{\parallel} M_s^2 (1 - \cos^2\beta \cdot \cos^2\psi) \quad [7]$$

The expression [7] was derived by dividing the rotation of vector M_s to the x-axis in the process of magnetization into two stages: rotation through the angle β to the xy-plane, and afterwards through an angle of ψ in the xy-plane, to the x-axis.

Now let us consider the transverse GE. The rotation of vector M_s from its initial position to the y-axis during the process of magnetization along this axis can be divided into two stages: rotation through an angle of γ to plane yz, and then the subsequent rotation through a certain angle in the plane yz to the y-axis. However, while rotating in the yz-plane, the angle between M_s and the x-axis along which the measuring current is flowing, makes no contribution to the change in conductivity. Hence, the transverse GE g^{xy} (when magnetization is over y and the conductivity measured over x) is controlled by the angle γ. Taking into ac-

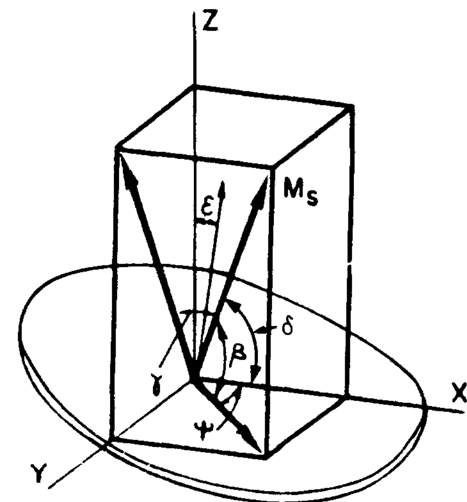

Fig. 2. Diagram illustrating calculation of the relation between the characteristic angles ψ and β and the magnitudes of longitudinal and transverse galvanomagnetic effects.

count [6], one gets

$$g^{xy} = k_{\perp} M_s^2 \cos^2\psi \cos^2\beta \quad [8]$$

where $k_{\perp}$ is the coefficient of proportionality between the transverse GE and the square of magnetization.

Analogously, when conductivity is measured along the y-axis, the longitudinal g^{yy} and transverse g^{yx} GE are

$$g^{yy} = k_{\parallel} M_s^2 (1 - \cos^2\beta \sin^2\psi); \quad g^{yx} = k_{\perp} M_s^2 \sin^2\psi \cos^2\beta \quad [9]$$

If the magnitudes g^{xx}, g^{yy}, g^{xy}, and g^{yx} are measured experimentally, one gets Eq. [7]-[9] containing the unknown coefficients $k_{\parallel}$ and $k_{\perp}$.

Let us use the II rule of even effects (8), according to which, in the case of isotropic distribution of magnetization

$$g^{xx}_{\text{isotr}} = g^{yy}_{\text{isotr}} = -2g^{xy}_{\text{isotr}} = -2g^{yx}_{\text{isotr}} \quad [10]$$

In the isotropic case, one has simultaneously $\psi = \beta = \pi/4$. Thus, we obtain from [8]-[10]

$$\frac{k_{\perp}}{k_{\parallel}} = -\frac{3}{2} \quad [11]$$

Combining Eq. [7]-[11] yields

$$\tan^2\psi = \frac{g^{yx}}{g^{xy}}; \quad \cos^2\beta = \frac{2\eta}{\cos\psi\ (2\eta - 3)} \quad [12]$$

where

$$\eta = \frac{g^{xy}}{g^{xx}} \quad (13)$$

Formulas [12] and [13] can be used for computing values ψ and β, the integral characteristics of magnetic texture, from measurement of longitudinal, g^{xx} and g^{yy}, and transverse, g^{xy} and g^{yx}, GE. The use of the azimuthal angle by itself, as the characteristic of magnetic texture in the film plane, may prove to be a convenient method of estimating uniaxial texture because of comparative simplicity and great accuracy of the GE measurements. Furthermore, separate determination of ψ may provide a means of verifying information about texture in the film plane obtained by other methods. As regards the polar angle β, one can scarcely find another characteristic of the PA, which combines clarity, ease of determination, and availability regardless of the magnitude of PA as is inherent in β. Finally, as will be subsequently demonstrated, the induced anisotropy actually obtained in films grown in a magnetic field can only be characterized using both characteristic angles ψ and β.

Connection Between the Polar Angle β and the Constant of Perpendicular Anisotropy

Let us assume (without restricting the generality of the consideration) that the film is isotropic in its own plane. Furthermore, let us divide all the factors influencing the PA into two groups. First, the spontaneous microstresses σ (the GE are measured on films separated from substrates, macrostresses being thus eliminated), and, second, all other possible factors, OF. The OF can be connected, for example, with the conditions of magnetic flux closure (9) with "columnar" structure of film (10), with an axial crystallographic texture (11), etc.

The contribution of microstresses σ to the PA may be represented by the constant

$$K_{\perp\sigma} = -\frac{3}{2}\lambda\sigma \quad [14]$$

where λ is the coefficient of magnetostriction. The contribution of OF to PA is characterized by the constant $K_{\perp\sigma}$.

Let us imagine a hypothetical case in which there are neither stresses nor a demagnetizing factor along the normal to the film plane ($N_z = 0$). In this case, the angle of inclination of magnetization vector M to the film plane is $\beta_0 < \beta$, where β is this angle observed experimentally (Fig. 3). In the case in which microstresses act, as well as OF, but, as before $N_z = 0$, the angle of inclination is $\beta^* > \beta$.

Let us consider an axis x_0 as an effective axis of anisotropy, created by OF, with a corresponding anisotropy constant K_0. Thus, the free energy of unit volume, for $N_z = 0$, is

$$E_0 = K_{\perp\sigma} \cos^2\beta^* + K_0 \sin^2(\beta^* - \beta_0) \quad [15]$$

Minimizing [15] with respect to β^*, we get

$$K_0 = K_{\perp\sigma} \frac{\sin 2\beta^*}{\sin 2(\beta^* - \beta_0)} \quad [16]$$

In a real film vector of magnetization, M is inclined to the film plane at an angle β, determined experimentally. Allowing for the demagnetizing fields, the free energy of a unit volume equals

$$E = \frac{N_z M^2}{2} \sin^2\beta + K_0 \sin^2(\beta - \beta_0) + K_{\perp\sigma} \cos^2\beta \quad [17]$$

Using the condition of minimum of energy E yields

$$K_0 = \frac{K_{\perp\sigma}\left(1 - \frac{N_z M^2}{2K_{\perp\sigma}}\right)\sin 2\beta}{\sin 2(\beta - \beta_0)} \quad [18]$$

Equations [16] and [18] contain three unknowns: K_0, β_0, and β^*. A third equation may be obtained, considering an axis x* (Fig. 3) as the nominal anisotropy axis with a corresponding anisotropy constant K^*. The free energy of unit volume in this form is thus

$$E^* = K^* \sin(\beta^* - \beta) + \frac{N_z M^2}{2} \sin^2\beta \quad [19]$$

The magnitude K^* may be expressed in terms of $K_{\perp\sigma}$ and K_0. Let us consider the rotation of M under the influence of a field H acting along the axis x_i, lying at an angle ψ to the anisotropy axis ξ (Fig. 3b), and characterized by the anisotropy constant K_{ψ}. The

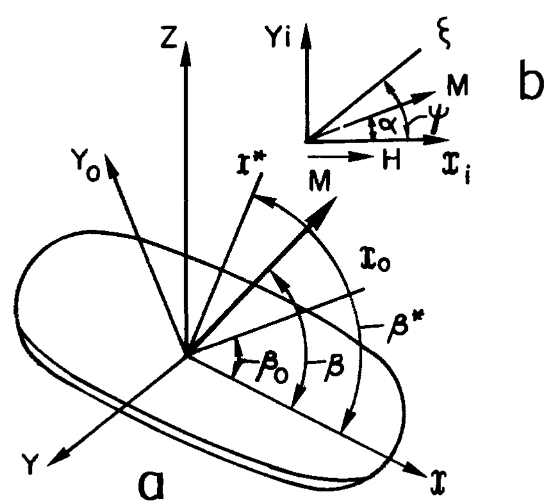

Fig. 3. Diagrams: (a) angles of inclination of magnetization vector M to film plane and (b) illustrating the calculation of anisotropy constants at magnetization's rotation.

energy of a body magnetized along the axis x_i in the absence of demagnetizing fields is

$$E_i = K_\psi \sin^2(\psi - \alpha) - HM \cos\alpha \qquad [20]$$

The equilibrium value of α may be found from the condition for the minimum of E_i

$$H = \frac{K_\psi \sin 2(\psi - \alpha)}{M \sin\alpha} \qquad [21]$$

Since $dM = -M\sin\alpha\, d\alpha$, the work of magnetizing along the axis x_i is

$$A_{xi} = \int_\psi^0 H dM = -\int_\psi^0 \frac{K_\psi \sin 2(\psi - \alpha)}{M \sin\alpha} M \sin\alpha\, d\alpha = K_\psi \sin^2\psi \qquad [22]$$

The anisotropy constant for the new nominal anisotropy axis x_i equals

$$K_{xi} = A_{yi} - A_{xi} = K_\psi \cos 2\psi \qquad [23]$$

Formula [23] relates two anisotropy constants K_ψ and K_{xi}, which are both due to the same source, but which refer to the true and nominal anisotropy axis ξ and x_i, respectively, and which are separated by angle ψ. With regard to K^*, K_o, and $K_{\perp\sigma}$, relation [23] enables us to write the following relationship which allows for the additivity of the energy

$$K^* = -K_{\perp\sigma} \cos 2\beta^* - K_o \cos 2(\beta^* - \beta_o) \qquad [24]$$

Substituting [24] into [19], and using the condition of minimum energy, yields

$$K_o = -K_{\perp\sigma} \left[\frac{\cos 2\beta^*}{\cos 2(\beta^* - \beta_o)} + \frac{N_z M^2 \sin 2\beta}{2K_{\perp\sigma} \cos 2(\beta^* - \beta_o) \sin 2(\beta^* - \beta)} \right] \qquad [25]$$

To solve the system of Eq. [16], [18], and [25], the following algorithm was developed. From equations [16], [18], and [25] one can get

$$\frac{\sin 2\beta^* \sin 2(\beta - \beta_o)}{\sin 2(\beta^* - \beta_o)} = \left(1 - \frac{N_z M^2}{2K_{\perp\sigma}}\right) \sin 2\beta \qquad [26]$$

$$-\frac{\sin 2\beta^* \sin 2(\beta^* - \beta)}{\tan 2(\beta^* - \beta_o)} - \cos 2\beta^* \sin 2(\beta^* - \beta) = \frac{N_z M^2}{2K_{\perp\sigma}} \sin 2\beta \qquad [27]$$

The order of computation is as follows:

1. For a film with specific values of β and σ (determined experimentally), one specifies a series of values of $\beta_{oi} < \beta$; for each β_{oi} one plots the left side of Eq. [26] as a function of β^*. On the latter graph the value of β^*, satisfying Eq. [26], is to be found. Thus, the function $\beta^*(\beta,\beta_o)$ is determined.
2. The left side of Eq. [27] is plotted as a function of β_o; the values of β^* having been substituted into [27] from the previously constructed $\beta^*(\beta_o)$ relationship. On the latter graph, the values of β_o, satisfying relationship [27] are to be found.
3. Using the determined values of β_o, one can use any of Eq. [16], [18], or [25] to find K_o.

The computation described requires a knowledge of N_z, the demagnetizing factor along the normal to the film plane. It is possible to estimate N_z as follows. From Eq. [18] one gets for $\beta = \beta_o$

$$K_{\perp\sigma} = \frac{N_z M^2}{2} \qquad [28]$$

Relation [28] has a simple physical meaning: if PA created by the stresses is exactly compensated for by the demagnetizing field, the angle of the departure of M from the film plane is controlled only by OF, *i.e.*, $\beta = \beta_o$. To use [28] one must substitute into this relation $K_{\perp\sigma} = -(3/2)\cdot(\lambda\sigma)$ for $\beta = \beta_o$. This may be done by successive approximations. As a zero approximation, $\beta_{oo} = \pi/4$ is to be selected. Extrapolating the experimental data, we find the value of σ, for which $\beta = \beta_{oo} = \pi/4$. From Eq. [28] the zero approximation $N_z = N_{zo}$ is next to be calculated. Furthermore, using the proposed algorithm, which is based on Eq. [26] and [27], the first approximation $\beta_o = \beta_{o1}$ is to be determined, etc. By using the procedure described, a good convergence was often established without proceeding further than the second approximation $(N_{z2} - N_{z1})/N_{z2} \lesssim 0.05)$.

Hence, the procedure described enables us to determine the constant of perpendicular anisotropy and the demagnetizing factor along the normal to the film plane as well, starting from experimental values of β, determined as proposed above. The total constant $K_\perp$ of PA is to be calculated using the following equation (12)

$$K_\perp = K_{\perp o} + K_{\perp\sigma} - \frac{N_z M^2}{2}; \quad (K_{\perp o} = K_o \sin^2\beta_o) \qquad [29]$$

The magnitudes $K_\perp$, $K_{\perp\sigma}$, $K_{\perp o}$, and N_z are important characteristics providing useful information about the magnetic structure and areas of use of magnetic films.

Verification of the Experimental Procedure

The GE were measured by the potentiometric method (13). The films were deposited on copper substrates, the cell was thermostated (±0.5°C), and the current density was maintained galvanostatically. An electromagnet provided a uniform magnetic field up to 10^3 oe in the zone of deposition. Cuts in the shape of the future U-shaped specimens had previously been made on the substrate; one way orientated along the lines of field and the other, across. After deposition the substrate was removed in a 250 g/liter solution of GrO_3 and 100 g/liter of $(NH_4)_2SO_4$. The copper was left at the ends of the U-shaped specimen to serve as contacts and at the bridge connecting both branches of the U-shaped specimen. The appearance of uncontrollable internal stress which might have arisen during the cutting of the specimen, was avoided by making the cuts in advance. The final shapes of specimen oriented both (*i*) along and (*ii*) across the lines of a magnetic field are schematically presented in Fig. 4. The shape and method of attaching the specimens were such as to avoid error due to magnetostriction and thermo emf. Before measuring, the specimens were demagnetized in a diminishing variable magnetic field. While measuring the conductivity, specimens were

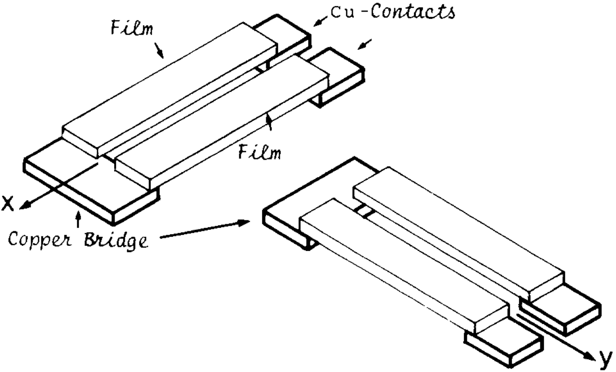

Fig. 4. Schematic representation of U-shaped specimen oriented along x- and y-axes, respectively.

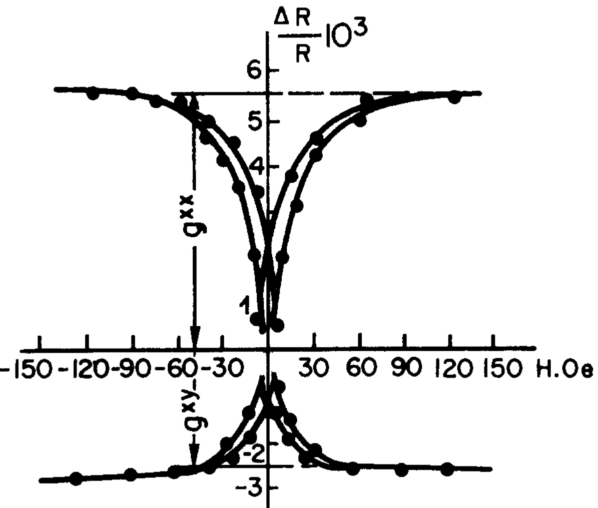

Fig. 5. Examples of the hysteresis loops of the galvanomagnetic effects in film (5 ± 0.2 μm) of an iron-nickel alloy (80% Ni). The values g^{xx} and g^{xy} are the measured longitudinal and transverse galvanomagnetic effects at saturation, which are used to calculate the characteristic angles.

fixed with one side in a perspex clamp supplied with current leads and positioned in an oil thermostat between the poles of an electromagnet. The measuring current was 4 mA. The longitudinal and transverse GE were measured at technical saturation (Fig. 5).

The GE were measured and the angles ψ and β calculated in a rolled plate of nickel (0.5 mm) which had been vacuum annealed at 10^{-5} mm Hg and 1200°C and cooled for 12 hr. As expected, in this definitely isotropic specimen, $\psi = \beta = 45 \pm 1.5°$. Furthermore, the method was verified on electrodeposited nickel film 5 μm thick, vacuum annealed in 10^{-3} mm Hg at 900° for 3 hr and cooled at the rate of 50°/hr. In this film it was found that $\psi = 50° \pm 1.5°$ and $\beta = 38° \pm 1.5°$. The film was stretched in a special device to a stress of $\sigma = 3.3 \times 10^3$ N/cm². As a result of the negative magnetostriction of nickel, the uniaxial extension over the x-axis should cause the magnetic moments to rotate towards the perpendiculars to the x-axis (8), that is, towards the y-axis and z-axis. Increases in ψ and β were to be expected as a result of extension. The experiment showed that in extended state $\psi = 53° \pm 1.5°$ and $\beta = 58° \pm 1.5°$. Thus, our procedure revealed changes in magnetic texture due to the elastic stretching of the film.

The additional verification of the method proposed, based on the use of Crowter's method (14), has been previously described (15). Finally, the method was verified by comparing the values of β with domain patterns and hysteresis loops, as described below.

Several Experimental Results

Influence of organic additives on perpendicular anisotropy of Ni-Fe films.—It was found that the introduction of several organic substances into the electrolyte causes a significant increase of the angle β, *i.e.*, of the PA. In Fig. 6 the corresponding data are presented for nickel films electrodeposited from the solution containing 294 g/liter $NiSO_4{\cdot}7H_2O$, 30 g/liter H_3BO_3, 25 g/liter Rochelle salt, and organic compounds, saccharin or sulgin, at 2 A/dm², 20°C, *p*H = 2.3. As the concentration of saccharin or sulgin in the electrolyte increased, the angle β increased monotonically up to ~75° ± 5°; when the concentration of additives exceeded ~4 × 10^{-3}M, a "saturation" was observed, probably connected with the "saturation" of an adsorbed layer on the growing crystals of the film.

The investigation by means of x-rays, electron diffraction, and electron microscopy showed that the increase of β is connected neither with crystallographic texture nor with "columnar" structure of the deposit.

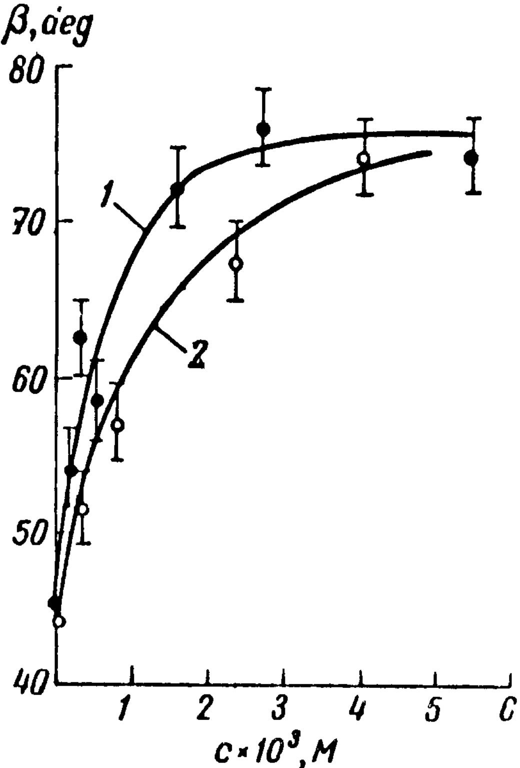

Fig. 6. The angle β in nickel films as a function of concentration of (1) saccharin and (2) sulgin in the electrolyte. Thickness of the film: 5 ± 0.2 μm. Composition of electrolyte 294 g/liter $NiSO_4 \cdot 7H_2O$, 30 g/liter H_3BO_3, 25 g/liter Rochelle salt. D_k = 2 A/dm²; pH = 2.3; T = 20°C.

Although the macrostresses in films were eliminated while separating the substrate, it was impossible to exclude in advance the existence of an "inherited" anisotropy, caused by planar macrostresses (appearing during the deposition) and "frozen" in the deposit after separation. The macrostresses in deposit were measured using the two-cantilever method, as described in Ref. (16, 17); the absolute values of macrostresses were calculated by means of formulas (18). No connection was found between the macrostresses and angle β. An assumption was proposed that the influence of organic matter on PA is connected with the role of microstresses. In Fig. 7 the characteristic angle β is depicted in its dependence on microstresses in nickel films, determined by means of the x-ray technique. The details of microstress determination were reported elsewhere (19). The various values of microstresses were obtained by adding several organic compounds to the electrolyte. It is seen that between the angle β and the microstresses there is an evident correlation.

In Fig. 8 angle β is presented as a function of film composition (*i.e.*, of nickel content). In the region of negative magnetostriction ($\gtrsim$ 80% Ni), the increase of microstresses under the influence of saccharin (19) is accompanied by an increase of angle β (curve 2). In films with 60-80% Ni (positive magnetostriction), saccharin increases the microstresses and simultaneously reduces β. The curves of β *vs.* composition, obtained with and without saccharin, cross at approximately 80% Ni, *i.e.*, in the range of composition where the sign of magnetostriction is reversed. These facts fall in with the assumption that the increase of PA is due to microstresses.

Constants of perpendicular anisotropy and the demagnetizing factor of Ni-Fe films.—In Table I, the values of the effective demagnetizing factor (7) of Ni-Fe films are presented, determined by means of the algorithm described above and based on relations [26]-[28]. The decrease of N_z along with an increase of Fe

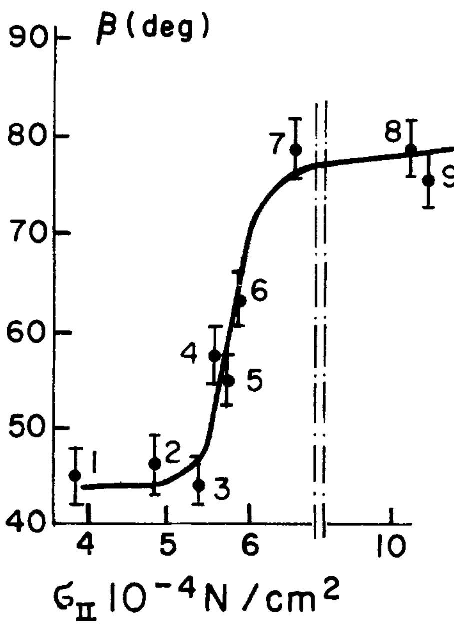

Fig. 7. Characteristic angle β in nickel films as a function of microstresses, determined using x-ray technique. 1, Butine-diol; 2, streptocide; 3, without additive; 4, sulphodimezine; 5, ethanol; 6, sulfacyl; 7, saccharin; 8, benzene sulfamide; 9, sulgin. Thickness of film: 5 ± 0.2 μm. Conditions of deposition as in Fig. 5.

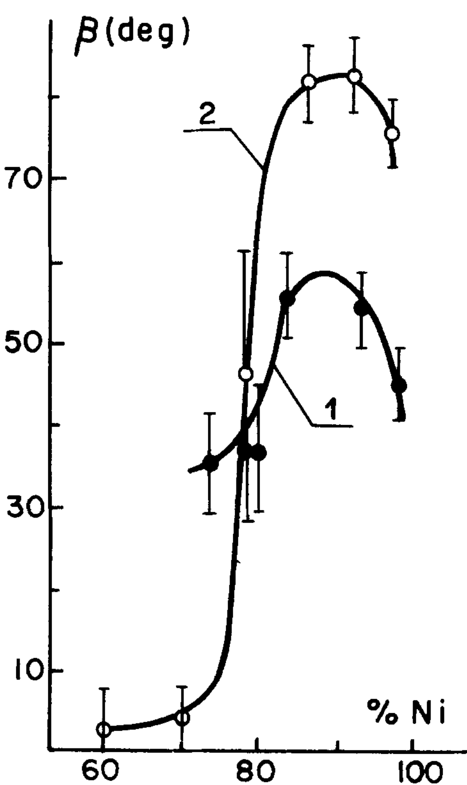

Fig. 8. The angle β in iron-nickel film as a function of their composition. Thickness of films 5 ± 0.2 μm; composition of electrolyte: 1, 294 g/liter ($NiSO_4 \cdot 7H_2O$ + $FeSO_4 \cdot 7H_2O$) [the ratio Ni/Fe varies accordingly (23) to get an alloy of required composition]; 30 g/liter H_3BO_3; 25 g/liter Rochelle salt. 2, The same plus 1 g/liter saccharin. $D_K = 2$ A/dm²; pH = 2.3; $T = 20$°C.

content in alloy is apparently connected with the change in domain structure. In films with ~83% Ni and especially in Fe films, the values of N_z are so small that they may be explained only by the appearance of a closed domain structure (9). In such cases. the angle β characterizes the position of M in internal domains; in surface domains M lies in a film plane (9).

Table I. Effective demagnetizing factor of iron-nickel films 5 ± 0.2 μm thick

Composition of film, w/o	N_z	Composition of film, w/o	N_z
100 Ni	2 ± 0.1	87 Ni-13 Fe	0.55 ± 0.05
95 Ni-5 Fe	1.6 ± 0.1	83 Ni-17 Fe	0.17 ± 0.02
90 Ni-10 Fe	1 ± 0.07	100 Fe	0.055 ± 0.001

In Fig. 9 the anisotropy constants, determined as described above on the basis of Eq. [14] and [26]-[29] are presented. From these curves it is seen that the contribution of OF to PA is small; the main contribution to PA is due to the spontaneous microstresses. The nondependence of β_0 and $K_{\perp o}$ on β indicates that the division of the total PA constant into the components $K_{\perp\sigma}$ (depending on microstresses) and $K_{\perp o}$ (depending on OF), has a real physical essence.

Dependence of PA on current density and film thickness.—It was found that the PA increases in correlation with film thickness increase. In order to explain the phenomenon observed, let us consider once again Eq. [18], which, in combination with [14], can be written as follows

$$\frac{\sin 2(\beta - \beta_0)}{\sin 2\beta} = \frac{3/2\,\sigma|\lambda| - E_d}{K_o} \quad [30]$$

where $E_d = N_z M^2/2$ is the energy of the demagnetizing field.

The angle β_0, being controlled by OF, does not depend considerably on the film thickness. On the other hand, in the thickness range of 1.5-5 μm, in which the increase of β was observed, the microstresses σ are almost constant (20). Thus, the increase of β accompanying the growth of the film may be due only to a change of E_d. This magnitude, according to theory (7), in the case of a stripe domain structure may be expressed as

$$E_d = \frac{1.7\,M^2 d}{t}\ (\text{erg/cm}^3) \quad [31]$$

where t is the film thickness and d the width of domain. The stripe domain structure was disclosed in films under experimental investigation (see below). From theory (7), it is known that the domain width increases proportionally to $t^{1/2}$. This theory's prediction has been confirmed experimentally (17). Thus, if at a "critical" thickness t^*, ensuring the transition from "thin film" state to "stripe film" state, the domain width is d^*, then at an arbitrary thickness t the domain width is thus

$$d = d^* \sqrt{\frac{t}{t^*}} \quad [32]$$

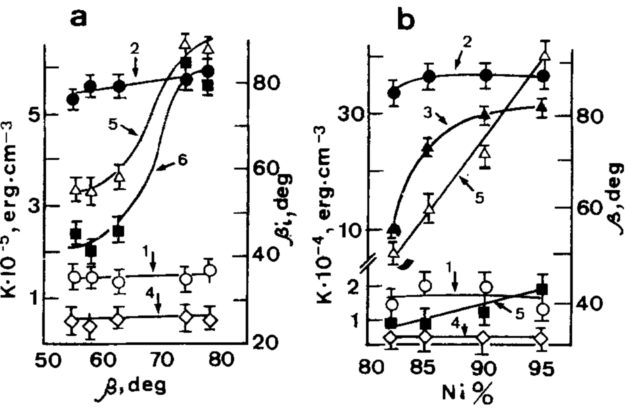

Fig. 9. Angles of inclination of magnetization vector and PA constants for films 5 ± 0.2 μm thick. (1, β_0; 2, β^*; 3, β; 4, $K_{\perp o}$; 5, $K_{\perp\sigma}$; 6, $K_{\perp}$). a, For a nickel film; b, for iron-nickel film.

Substituting [31] and [32] into [30] yields

$$\frac{\sin 2(\beta - \beta_0)}{\sin 2\beta} = A - Bt^{-1/2} \qquad [33]$$

where

$$A = \frac{3/2\,|\lambda| \cdot \sigma}{K_0}; \quad B = \frac{1.7M^2 d_0}{K_0\sqrt{t^*}} \qquad [34]$$

Hence, according to the assumption that the increase of β along with film thickness is due to the decrease of demagnetizing field, the linear dependence of the function $f(\beta) = \sin 2(\beta - \beta_0)/\sin 2\beta$ on $t^{-1/2}$ is expected to be observed.

In Fig. 10 the experimental data for Ni film are presented confirming the proposed assumption. From the cutoff segment on the vertical axis, the value of K_0 can be found using Eq. [33] and [34]. In our case $K_0 = 0.85 \times 10^5$ erg/cm³. The average value of K_0 according to data presented in Fig. 8 is $K_0 \equiv 0.73 \times 10^5$ erg/cm³, which means a good agreement.

If the current density increases, β is enlarged as well. The theoretical consideration similar to the one presented above and based on the assumption that the reason for an increase of β in this case is the increase of microstress, predicts that the following dependence is to be observed

$$\sin 2(\beta - \beta_0)/\sin 2\beta \propto \sqrt{\ln D_c}$$

This prediction is also well fulfilled, as is seen from curve 2 in Fig. 10.

Fluctuations of anisotropy and compensation effect.—It was found that in a series of film prepared under identical conditions, there was a considerable scatter of β and ψ from film to film. In Fig. 2 three angles are depicted, ψ, β, and δ, the latter being the angle between the vector M of magnetization and mean easy axis x. The self-explanatory relation

$$\cos\delta = \cos\beta \cos\psi \qquad [35]$$

enables us to determine δ while ψ and β are measured. It was discovered that there is a compensation effect. If for random reasons angle ψ in one film is reduced, then there will be a definite increase in β, while the angle δ remains practically unaltered.

Several typical results are presented in Table II.

Fluctuations of ψ and β, as has been demonstrated (21), are due to the fluctuations in spontaneous internal microstresses. The compensation effect, according to Ref. (21), is due to the demagnetizing field:

Table II. Values of the angles ψ, β and δ in series of nickel films deposited on copper bases with different microrelief

Method of generating base microrelief	Angle	Value, deg max	min	mean
Chemical polishing	ψ	46	29	37
	β	54	46	50
	δ	61	59	60.7
Treatment with emery paper in the direction of the x-axis	ψ	60	30	43
	β	56	18	40
	δ	62	61	61.5
Rolling in direction of x-axis	ψ	48	41	43
	β	48	42	43
	δ	60	60	60
Grooves made by a scalpel in the direction of x-axis	ψ	48	40	43
	β	47	40	43.5
	δ	60	60	60

Note: There is an error of ±1.5° in determination of angles ψ and β on a specific specimen.

when ψ_i grows (due to random differences of σ_{xi} and σ_{yi}, for instance), we get a demagnetizing field which reduces β_i, until obtaining again the closed magnetic flux. This keeps δ constant.

Obtaining of "stripe" films.—In Fig. 11 and 12, the magnetic hysteresis loops and powder diagrams, respectively, are presented. There is an obvious correlation: in films having typical 'transcritical" hysteresis loops (b and c in Fig. 11) and a stripe-shaped domain structure, the angle $\beta \gtrsim 45°$; if $\beta \lesssim 45°$, we obtain a "thin film" state (a and d in Fig. 11).

The width of domains in the film of ~82% Ni alloy of thickness $t = 5$ μm was found to be $D \cong 1.1$ μm, and for the thickness $t \cong 10$ μm, $D \cong 2.3$ μm. This shows quantitative agreement with data (22) for vacuum condensates.

Acknowledgment

The author wishes to express his sincere gratitude to B. S. Zolotkovskii, who took a significant part in the experiments.

Manuscript submitted June 16, 1975; revised manuscript received Jan. 5, 1976. This was Paper 122 presented at the New York, New York, Meeting of the Society, Oct. 14-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Cathodization Luminescence of Silicon

S. Ogura,[1] T. Odajima, and C. R. Viswanathan*

Electrical Sciences and Engineering Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Luminescence during the cathodization of silicon and other materials was observed. In the cathodization of silicon in 0.04*N* KNO_3/ethylene glycol, the luminescence was found only when the oxide film was thin. It was observed that the cathodization of silicon resulted in removal of the oxide film. However, in the presence of water, the luminescence occurred without any requirement of an oxide layer.

The galvanoluminescence during anodization has been reported for aluminum by Braun in 1898 (1). Since then, the emission of light on anodization has long been known for other metals such as Ta, Zn, Mg, and W. The luminescence for semiconductors has been reported for silicon by Gee (2) and Waring *et al.* (3). In our study of the anodization process for silicon, the luminescence was observed not only during the anodization but also during the cathodization of silicon. The luminescence during cathodization was also observed in various metals as Al, Zn, etc.

Characteristics of Electroluminescence

0.04 KNO_3-ethylene glycol solution and silicon wafers were used for the investigation of electroluminescence characteristics in a silicon-electrolyte system. p-and-n-type (111)-orientation silicon wafers, each having a different resistivity, were used.

* Electrochemical Society Active Member.
[1] Present address: IBM, Raleigh, North Carolina.
Key words: silicon oxidation, reduction, luminescence during cathodization.

After being polished and chemically etched, the silicon samples were held on a Teflon sample holder. The back of the wafer was in contact with mercury, while the front side was in contact with the solution. A platinum wire immersed in the solution formed the counterelectrode. The emission from silicon wafers was picked up by a photomultiplier (EMI 9558B) tube with an S-20 photocathode characteristic.

Two x-y recorders were used; one, in which the output from the PMT was connected to the y-terminal, and the other, in which the cell current was connected to the y-terminal. The cell voltage was fed to the x-terminals of both the x-y recorders. In this manner, the relative light intensity and the cell current are measured simultaneously as a function of light voltage.

When d-c voltage across the cell was swept at a rate of 1 V/sec, the cell current and the luminescent signal shown in Fig. 1 and 2 are obtained. A positive cell voltage corresponds to anodization of silicon, while a negative voltage on the silicon electrode corresponds to cathodization. When the cell voltage is increased as indicated (curve I) in Fig. 1 and 2, the cell current increases and luminescence appears around 10V. It is known that in 0.04*N* KNO_3-ethylene glycol solution the thickness of oxide film growth on silicon is proportional to anodization forming voltage and the growth rate of oxide is 4-5 Å/V. Our result indicates almost parabolic increase of luminescence current against forming voltage, which agrees with the data by Waring *et al.* (3). But our experiment was carried out below their breakdown voltage at which the "spark" discharge appeared. The efficiency of forming silicon dioxide is reported to be about 2% (4).

When the cell voltage was reduced at a rate of 1 V/sec from a large positive value, the cell current and the luminescent signal that were obtained as a function of the cell voltage are labeled II in Fig. 1 and 2.

Next, the polarity of the applied voltage was reversed. When the applied voltage was increased in the negative direction up to −25V at a rate of 1 V/sec, the cell current labeled III in Fig. 1 was obtained. A weak luminescent signal was also obtained beyond −15V as shown by curve in Fig. 2. It was also observed that the cell current characteristics (curve III in Fig. 1) approached another curve (IV in Fig. 1) if at each value of the reverse voltage, sufficiently long time was allowed. The applied voltage was frozen at −25V by stopping the sweep, and if was found that the cell current increased reaching a saturation value. At the same time, the luminescent signal decreased to zero. Then the applied voltage was swept to zero volt at the same rate as before and the cell current dropped to zero as indicated by curve IV in Fig. 1. During this sweepback, no luminescence was observed.

The voltage sweep was next applied in the positive direction (anodization) and the measured cell current followed the curve I in Fig. 1. However, if sufficient time was not allowed for the previous cathodization process at −25V, the cell current during the anodization process will follow a curve intermediate between curves I and II in Fig. 1. This shows that when sufficient time is allowed at −25V during the cathodization, the oxide film on the silicon electrode is completely removed. Since the luminescent signal during cathodization goes to zero when the cell current saturates (corresponding to complete removal of the oxide film), it appears that the weak luminescence occurs only during the process of reduction or dissolution of the oxide film in cathodization. After repeated anodization and cathodization, the silicon surface was observed to be nonuniform and volcanic.

In order to find out more about the cathodization luminescence, an a-c bias voltage was superimposed on the d-c bias as shown in Fig. 3. The amplitude of the a-c bias at a frequency of 70 Hz was varied while the

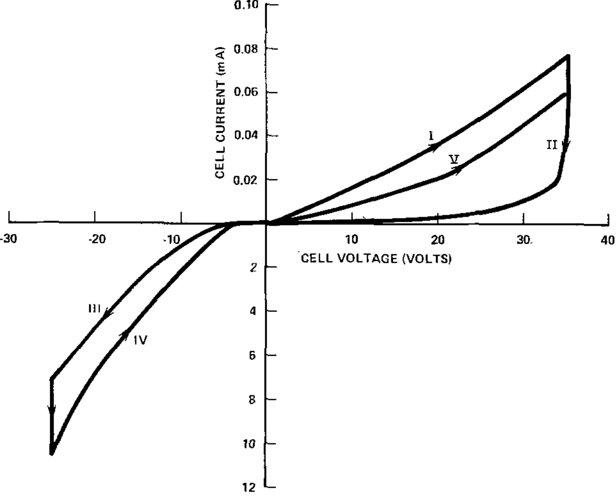

Fig. 1. Cell current vs. cell voltage

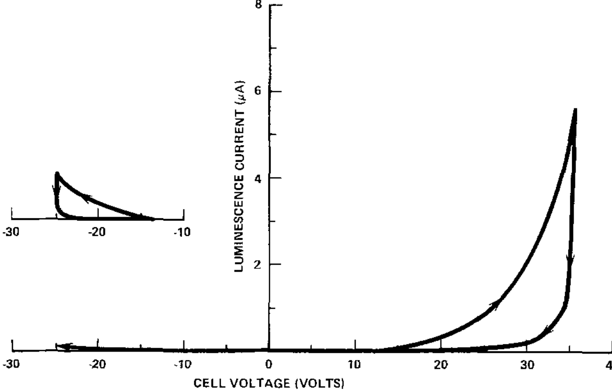

Fig. 2. Luminescence current vs. cell voltage

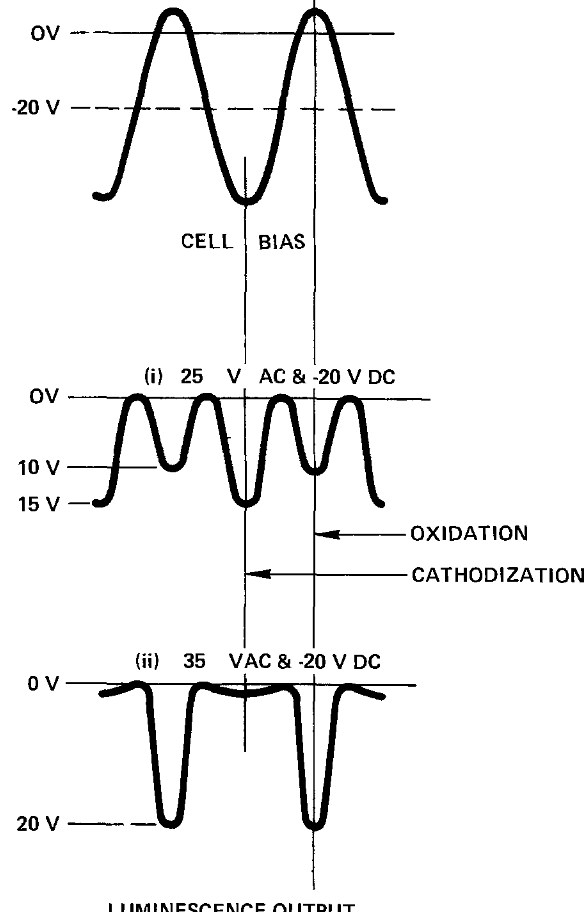

Fig. 3. A-C characteristics of luminescence

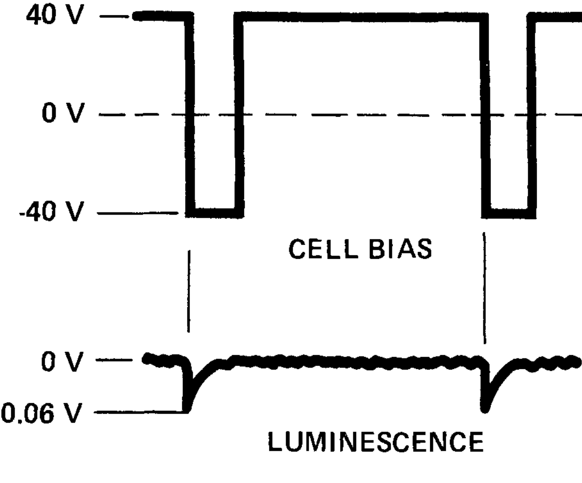
d-c bias was kept at −20V. The anodization occurs only during that portion of the a-c bias voltage cycle during which the net voltage is positive. On the other hand, cathodization (*i.e.*, reduction or dissolution) occurs during the rest of the a-c bias voltage cycle during which the net voltage is negative. The output of luminescence on oscilloscope as detected by the photomultiplier is also shown in Fig. 3(i) and (ii). The peak of the luminescence output at the anodization process corresponding to the bias which is above zero was 10V while that at cathodization was 15V. It was observed that whenever the luminescence output during the anodization process was smaller than that during the cathodization process, the luminescence output on the oscilloscope was very unstable. When there was a thin oxide film, the luminescence output during cathodization was higher than that during anodization. However, as time went on, and the oxide layer was removed in the cathodization process, the luminescence output of both processes became close to each other. When the a-c bias voltage was increased to 35V as shown in Fig. 3(ii), the luminescence output of the anodization process increased while that of the cathodization process decreased. When the a-c bias voltage was increased further, the luminescence output of the anodization process became completely dominant.

When the bias voltage in excursion (I) in Fig. 2 is increased up to 70V or higher, the thick oxide layer is formed. After this process, although reverse cell voltage was increased to 25V and was maintained at the voltage, cell current did not increase and luminescence was not observed. This indicates that the luminescence during cathodization is observable only when the oxide film is thin and the cathodization of silicon results in removal of the oxide film. The reaction in the cathodization process is suggested to be a reduction of the silicon dioxide layer to silicon by the cations or a dissolving of silicon dioxide to give a compound such as K_2SiO_3, etc.

In order to separate more clearly cathodization luminescence from anodization luminescence, a square wave negative voltage was superimposed on the d-c positive bias as shown in Fig. 4(i). In the figure is shown a value of 40V for the d-c positive bias with a negative pulse of amplitude 80V. In the luminescence output corresponding to the cell bias, the cathodization luminescence can be seen as a spike while anodization luminescence is almost negligible compared to cathodization luminescence. Thus cathodization luminescence can easily be separated from anodization luminescence, which is a very useful technique to measure luminescence spectra. The spectral response of the luminescence can be determined by using phase sensitive detector which gives a high S/N ratio. The luminescence intensity can easily be kept constant while spectrum measurement is carried on. For comparison the anodization luminescence is shown in Fig. 4(ii) corresponding to the bias condition of d-c bias −15V and positive pulse height 80V.

Once water is added into the $0.04N$ KNO_3-ethylene glycol or in $0.04N$ KNO_3-H_2O, the luminescence of cathodization was observed without any cycle of anodization. Also, the luminescence intensity for cathodization is much higher for these systems than that for $0.04N$ KNO_3-ethylene glycol. The instability such as observed in the process of removing the oxide in KNO_3-ethylene glycol was not observed. Thus the luminescence for the system with water molecules is understood to be different from the previous system. It may be suggested that this luminescence of cathodization with water molecules is associated with the reaction of Si and H^+ or H_3O^+.



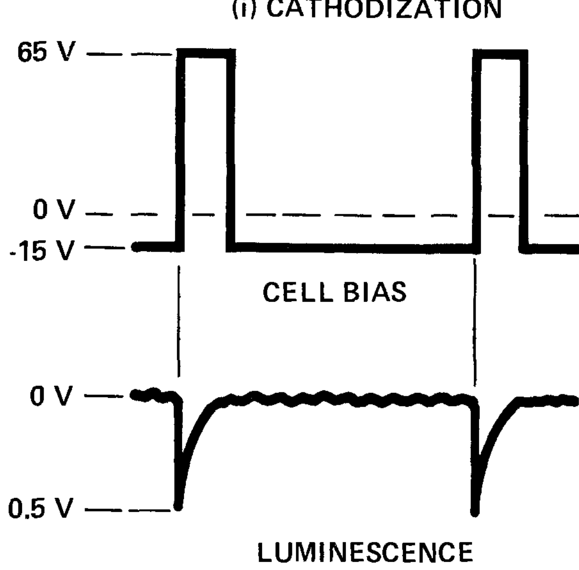


Fig. 4. (i) Cathodization luminescence in $KNO_3(0.04N)$-ethylene gycol. Pulse cycle; 70 Hz and pulse width, 1 msec (ii) Anodization luminescence in $KNO_3(0.04N)$-ethylene glycol.

Also luminescence for cathodization of such metals as Al, Zn, Cu, etc. was observed.

In a subsequent paper, the spectra, resulting from anodization and cathodization luminescence in different solutions, and their interpretation will be given.

Manuscript received Sept. 2, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Influence of Precipitating Conditions on the Cathodoluminescence of Zinc Sulfide:Silver Phosphors

R. A. Brown[*,1] and F. J. Hinnenkamp

RCA Electronic Components, Lancaster, Pennsylvania 17604

ABSTRACT

A study has been carried out on the properties of zinc sulfide obtained by precipitation from aqueous zinc sulfate solution with gaseous hydrogen sulfide. The influence of three factors, namely H_2S flow, temperature, and initial concentration of the zinc solution, on (*i*) the rate of precipitation of zinc sulfide, and (*ii*) the cathodoluminescent efficiencies of the resultant ZnS: 0.015% Ag phosphors has been investigated. Experimental results were interpreted by an empirical method, using a correlation and regression analysis performed by computer procedures. This approach has established quantitative relationships on the behavior of both the rate of formation of ZnS and the phosphor efficiency as changes occur in the three variables which influence the conditions of precipitation.

A study on the preparation and fundamental properties of zinc sulfide is of considerable importance in the technology of the manufacture of luminescent materials. Although there are numerous reports in the literature (1-5) concerning the influence of firing conditions and composition on the properties of zinc sulfide phosphors, there appears to be comparatively little published work on the precipitation of this compound, especially from the viewpoint of the effect of precipitating conditions on the characteristics of the resultant phosphors.

For many years the precipitation of zinc sulfide from acidic, or slightly acidic, solutions of a soluble zinc salt has been used extensively for the analytical separation and determination of zinc (6-8). Hydrogen sulfide (9, 10) appears to be the usual precipitant, although more recently analysis from homogeneous solution by the acid hydrolysis of thioacetamide (11, 12) has been reported. Ortmann and Piwonka (13, 14), Lendvay and coauthors (15), and Brown (16) appear to be among the few investigators to have studied the preparatory conditions of ZnS with the object of obtaining luminescent materials.

Ortmann and Piwonka (13, 14) demonstrated that a slow reaction with rapid stirring at an H_2S pressure of 1.5 atm yielded crystallites up to 30 μm in size. In addition, precipitation at reduced hydrogen sulfide pressures was studied, and produced good phosphors. These investigations (13, 14) showed that the luminescent properties of the materials were dependent largely on the precipitation in the initial stages of the reaction. In all cases, ZnS prepared in strongly acid solution separated in the sphalerite form, the particles being well defined and sufficiently crystalline to give an x-radiogram identical with that obtained from zinc sulfide luminophors recrystallized at 900°C. Lendvay *et al.* (15) prepared ZnS crystals 100-200 μm in size by slowly interacting hydrogen sulfide with an acidic solution of a zinc salt. What was more interesting, perhaps, was that phosphors could be obtained directly from solution under ambient conditions without subsequent activation and firing at elevated temperatures. Studies on the particle size and morphology of zinc sulfide precipitates have been reported by Brown (16). This worker demonstrated that preparation of ZnS in strongly acid solution gave irregularly shaped aggregates of the order of 1-5 μm, and that the dimensions of these agglomerates influenced the particle size of the final phosphor.

Two principal methods have been used for the large-scale manufacture of luminescence-grade zinc sulfide, and these lead to somewhat different products. In the so-called "alkali" process (17), a purified solution of $ZnCl_2$ is treated with ammonium hydroxide solution until the initial zinc hydroxide precipitate redissolves. Subsequently, ZnS is formed by the addition of hydrogen sulfide or ammonium sulfide. Under these conditions, some hydrolysis of the zinc salt may occur, and this in turn gives rise to oxygen band fluorescence (18) in the ultimate phosphor. Alternatively, the "acid" process (17, 19) may be used. In this method ZnS is synthesized by the interaction of a solution of a zinc salt with hydrogen sulfide in acidic media. This latter procedure was employed in the present study; zinc sulfide precipitates were obtained by the straightforward addition of gaseous hydrogen sulfide to aqueous zinc sulfate solution.

The objective of this work was to carry out a laboratory-scale investigation on the influence of various factors, such as rate and duration of hydrogen sulfide flow; temperature; initial concentration of the zinc solution; on the precipitation of zinc sulfide, from the viewpoint of determining what effect, if any, these variables had on the cathodoluminescent efficiencies of the resultant phosphors. With this object in mind, an attempt was made to determine the important factors affecting (*i*) the rate of precipitation, and (*ii*) the peak efficiencies of the various zinc sulfide phosphors under cathodoluminescent excitation. Phosphor preparations were carried out with ZnS: 0.015% Ag, 2% sodium chloride as flux, and 1% sulfur as the starting material. Note that these compositions are weight per cent (w/o) values. The results obtained were interpreted with the aid of a regression and correlation analysis carried out by means of an RCA 301 computer program.

Experimental

Precipitation of zinc sulfide.—A detailed description of the starting materials and experimental procedures employed in the preparation of zinc sulfide precipitates has been given previously (16). For the sake of completeness, a brief account of the method used is given below.

The apparatus consisted of a 3 liter glass precipitation flask equipped with necks to provide ports for the gas inlet, gas outlet, and stirrer. A single blade glass paddle was used to agitate the solution; temperature was controlled to within ± 0.5°C. In a typical preparation, 2 liters of 1M zinc sulfate solution were placed in the precipitating vessel and stirred by an electrically driven glass paddle. Hydrogen sulfide at a flow

Key words: ZnS:Ag phosphors, correlation and regression analysis, Weibull distribution.

rate of 0.82 liter/min was passed into the solution through a gas dispersion tube for a period of 3 hr, the flask and its contents being maintained at 25°C. During a precipitation, samples were removed at regular intervals of time, filtered, and the filtrates analyzed for zinc and hydrogen ion contents. Zinc was determined colorimetrically by means of dithizone, using a method which was essentially that of Snell and Snell (20). For the determination of the free acid content, aliquots were titrated against standard sodium carbonate solutions (21) utilizing either methyl orange as indicator, or a potentiometric method to determine the end point. After being left for approximately 18 hr to attain equilibrium, the white precipitate of zinc sulfide was filtered in a Buchner funnel, washed with deionized water until the washings were free from sulfate ions, and dried at 100°C for 6 hr.

Initially, the speed of stirring of the reacting mixture was varied from 50 to 350 rpm. At speeds up to 200 rpm, there was a direct relationship between stirring rate and amount of precipitation. The reaction processes appeared to be independent of agitation for stirring speeds greater than 200 rpm. Consequently, throughout this work a speed of approximately 300 rpm was employed.

Precipitations were carried out with zinc sulfate concentrations from 0.25 to 2.0M, using hydrogen sulfide flows between 0.082 and 5.75 liter/min, and with temperatures in the range 0°-70°C.

Preparation and measurement of phosphors.—In order to obtain reproducible results, phosphor samples were prepared by a dry blending process, following the usual procedures. The over-all composition of the starting material was ZnS: 0.015% Ag, 2% sodium chloride, with 1% sulfur. A series of experiments to determine the temperature and duration of firing showed that optimum luminescent efficiencies could be attained on heating at 800°C for 1 hr. A brief description of a typical firing cycle is given below.

Test samples of approximately 10g of ZnS: 0.015% Ag, 2% NaCl, with 1% sulfur were heated in 10 cm^3 covered "Vitreosil" crucibles for 1 hr at 800°C. Each heating operation involved the firing of six separate specimens. After removal of excess flux by washing with deionized water, the products were dried at 100°C.

Cathodoluminescent efficiencies and emission spectra were determined with a defocused electron beam having a current density of 1.5 $\mu A/cm^2$ and an accelerating potential of 8000V, following the procedure of Hardy (22). Peak efficiencies and spectral distribution of energy were measured by means of a recording, grating-type spectroradiometer. An eye-corrected, Weston selenium barrier layer photocell was used for the measurement of visual efficiencies.

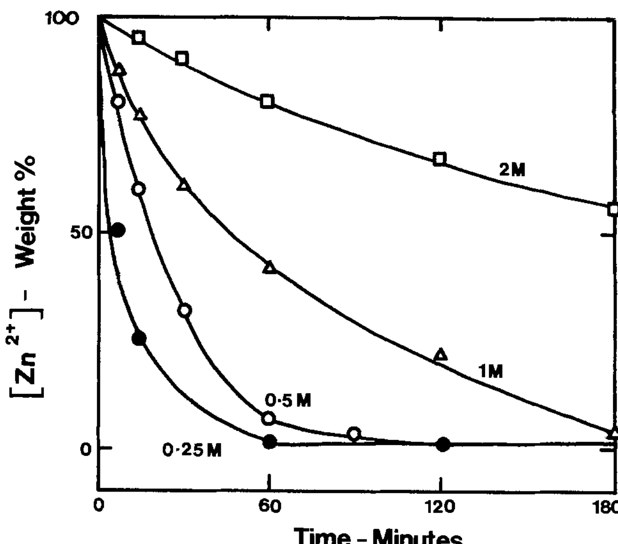

Fig. 1. Influence of initial $ZnSO_4$ concentration on precipitation of ZnS. 0.82 liter/min H_2S at 25°C.

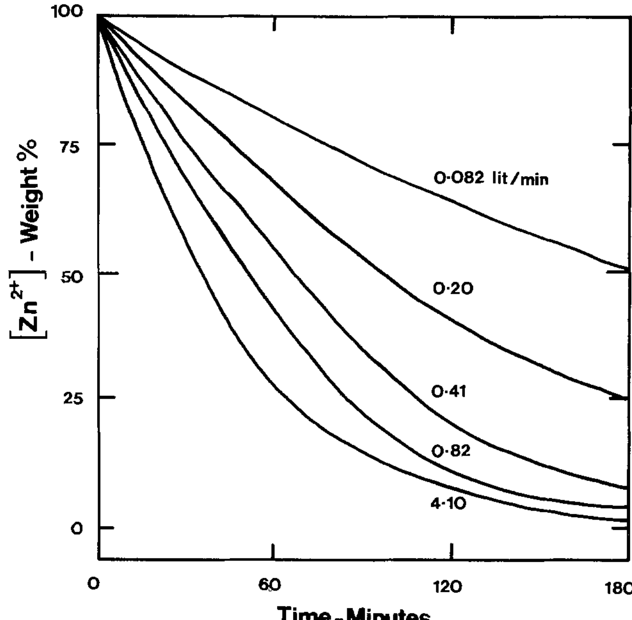

Fig. 2. Influence of H_2S flow (liter/min) on precipitation of ZnS. 1M $ZnSO_4$ at 25°C.

Results

The influence of initial zinc sulfate concentration on the rate of precipitation of zinc sulfide is demonstrated in Fig. 1. In order to make the comparison more straightforward, the results are plotted in the form of w/o zinc remaining in solution as a function of time, t. Hydrogen sulfide flow was maintained at 0.82 liter/min, temperature at 25°C, and the $ZnSO_4$ level varied between 0.25 and 2.0M.

A typical set of curves showing the influence of hydrogen sulfide flow on 1M $ZnSO_4$ solutions at 25°C is presented in Fig. 2, again in the form of w/o zinc *vs.* time.

In general, a plot of logarithm of the zinc concentration, log $|Zn^{2+}|$, as a function of precipitation time showed a linear dependence over all of the preparative conditions employed in this present study. Thus, the zinc sulfate-hydrogen sulfide reaction follows pseudo-first order kinetics with respect to the zinc ion. At temperatures in the region of 0°C, there was initially a fast precipitation accounting for approximately 40% of the product, followed immediately by a slower process. Both stages of the reaction followed this same straight-line, semilogarithmic behavior. These findings are demonstrated in Fig. 3, which shows the influence of various factors on the relationship between log $|Zn^{2+}|$ and precipitation time.

Figure 4 is a typical set of curves in which log $|Zn^{2+}|$ is plotted *vs.* t for experiments carried out in 1M zinc sulfate solution at 10°-40°C, using a hydrogen sulfide flow of 0.82 liter/min. These data confirm that a linear relationship does, in fact, exist. Measurement of the slopes of these semilogarithmic plots provided the specific rate constants, k, and these values were used to express the rate of precipitation of ZnS. In practice, k was calculated by the least squares method, utilizing the computer program which is outlined below.

A plot of log $|H^+|$ as a function of log (time) for temperatures of 25° and 0°C, in the case of 1M $ZnSO_4$ at 0.82 liter/min H_2S, is given in Fig. 5. At 25°C there is a straight-line dependence with a slope of 0.94, whereas the 0°C plot shows a departure from linear behavior.

A summary of the experimental results obtained on the preparation of zinc sulfide precipitates, together with peak efficiencies under cathodo-excitation of the final ZnS: 0.015% Ag phosphors, is presented in Table

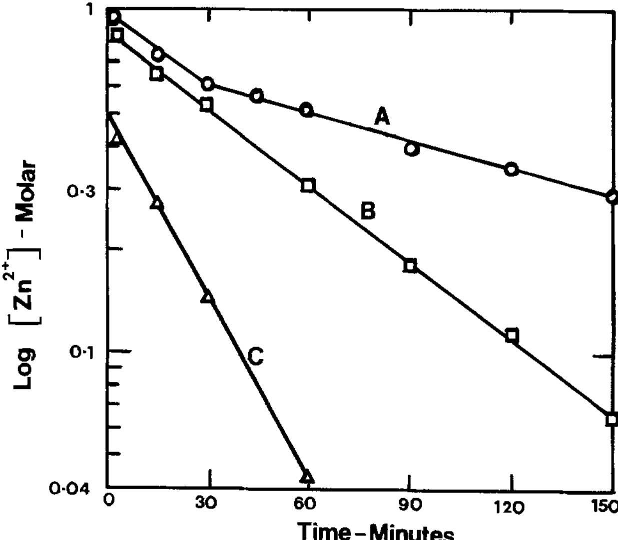

Fig. 3. Log $|Zn^{2+}|$ vs. time for ZnS precipitations: (A) 1M $ZnSO_4$ at 0°C and 0.82 liter/min H_2S; (B) 1M $ZnSO_4$ at 25°C and 4.1 liter/min H_2S; (C) 0.5M $ZnSO_4$ at 70°C and 0.82 liter/min H_2S.

Discussion

For convenience, the results obtained are discussed in terms of (*i*) rate of precipitation, and (*ii*) cathodoluminescent efficiencies.

(*i*) *Rate of precipitation.*—Since it was desirable to relate the rate of precipitation of ZnS with the preparative conditions, each of the 36 experimental tests was submitted to analysis by the RCA 301 correlation and regression computer program in a multiple and polynomial regression study. The specific rate constant, k, was taken as the dependent variable and various combinations of temperature, duration of precipitation, initial zinc sulfate concentration, and hydrogen sulfide flow as the independent variables. Generally, the mathematical model employed was of the form

$$Y = b_0 + b_1X_1 + b_2X_2 + b_3X_3 + b_4X_4 + b_5X_1^2 + b_6X_2^2 + b_7X_3^2 + b_8X_4^2 + b_9X_1X_2 + b_{10}X_1X_3 + b_{11}X_1X_4 + b_{12}X_2X_3 + b_{13}X_2X_4 + b_{14}X_3X_4 \quad [1]$$

where Y is the dependent variable, X the independent variable, and b is an estimate of the unknown population parameter. In addition to the above terms, the

variables used were expressed as logarithmic, reciprocal, and ratio functions. This analysis showed that the experimental results obtained for the reaction rate could be represented best by the expression

$$\log_{10}k = -2.597 + 0.00575T + 0.000174FT - 1.433\,|Zn_o| + 0.303\,|Zn_o|^2 \quad [2]$$

where k = reaction rate constant (min^{-1}); T = temperature (°K); F = hydrogen sulfide flow (liter/min); and $|Zn_o|$ = initial concentration of the zinc sulfate solution (M).

A measure of the fit of a plot to the data it represents is given by the correlation coefficient squared, R^2 (23), which is often expressed as a per cent value. This parameter is defined as the amount of variation of the dependent variable Y, which can be associated with variations in X, the independent variable. A perfect fit would give R^2 = 100%, whereas a complete nonfit would have R^2 = 0%. For Eq. [2], a value of R^2 = 91% was calculated. This result indicates that the reaction rate data are represented very well by the given expression.

The type of curve obtained on plotting the three variables, initial zinc concentration, gas flow, and temperature, in accordance with Eq. [2] is given in Fig. 6. This curve is in a hyperbolic form. Note that for purposes of convenience the surface represented in Fig. 6 corresponds to a specific rate constant of $\log k = -2.0 \times 10^{-2}$. The advantage of such a plot is that it presents in a relatively straightforward manner a quantitative treatment of the behavior of the precipitation rate as changes occur in the three parameters which influence the preparatory conditions. By setting the first derivative with respect to $|Zn_o|$ equal to zero, an inflection point is obtained at a concentration level of 2.36M. Since this point is a minimum in the curve, this observation suggests that the slowest reaction rate should be attained with an initial concentration of 2.36M zinc sulfate. Increase in either the temperature, or the hydrogen sulfide flow, or in both of these parameters will give faster rates of reaction.

(*ii*) *Cathodoluminescent efficiency results.*—A further part of this study was an attempt to relate peak efficiencies of the phosphors obtained from the various precipitates to the conditions of precipitation. These experimental results were less straightforward to analyze than the reaction rate data. A regression and correlation analysis similar to that already described was

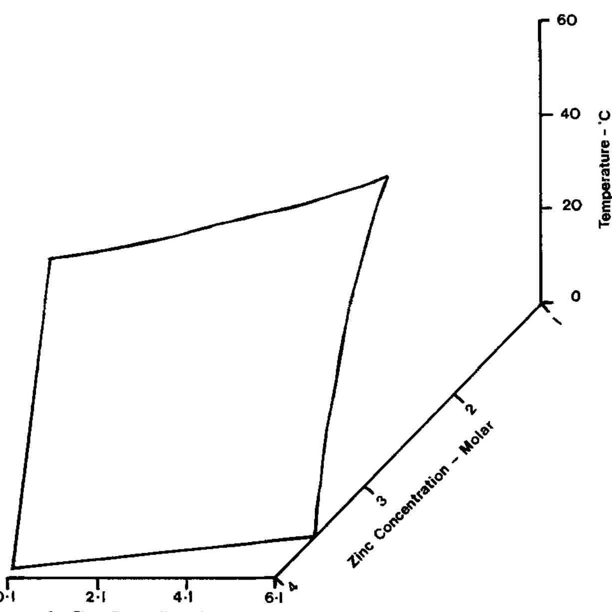

Fig. 6. Reaction rate (log k) as a function of precipitation variables. Surface represents $\log k = -2.0 \times 10^{-2}$.

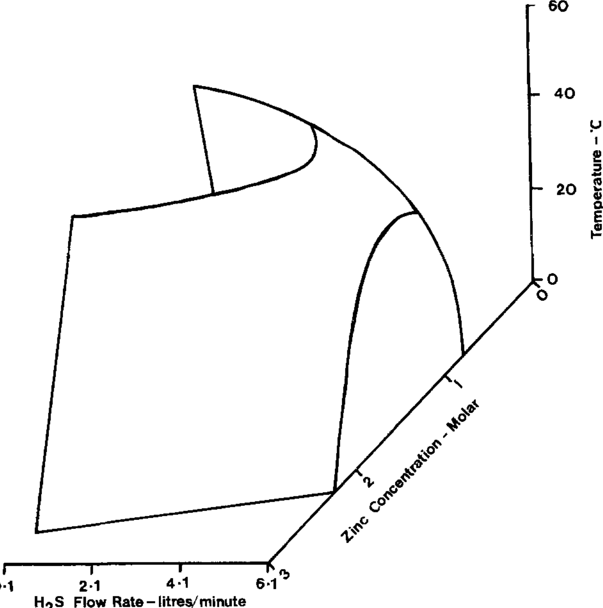

Fig. 7. Phosphor peak efficiency (P_E) as a function of precipitation variables. Surface represents P_E = 100.

carried out for the phosphor brightness results obtained in the 36 experimental tests. In this case, peak efficiency of the phosphor under cathodo-excitation was the dependent variable, and various combinations of reaction temperature, duration and rate of hydrogen sulfide flow, and initial zinc concentration were the independent parameters.

This treatment showed that the experimental data obtained for phosphor efficiency under cathodoluminescence can be described best by the expression

$$P_E = 107 + 46.2\,|Zn_o| - 15.2\,|Zn_o|^2 - 1.64F - 0.00031T^2 \quad [3]$$

where P_E is the relative luminescent peak efficiency of a specimen, measured against a standard phosphor[2] sample taken as 100, and the other symbols have the meanings given above. For Eq. [3], a value of R^2 = 65% was calculated. This result indicates that the above relationship describes the experimental data reasonably well. The form of curve obtained on plotting the three variables, initial zinc level, H_2S flow, and temperature in accord with Eq. [3] is illustrated in Fig. 7. The curve describes an elliptical paraboloid. Note that the surface represented in this figure corresponds to a peak efficiency of 100.

On the basis of Eq. [3] and Fig. 7 the following can be deduced:

(*a*) A decrease in temperature of precipitation and a lower hydrogen sulfide flow both lead to a rise in peak efficiency of the resultant phosphor.

(*b*) The inflection point occurs at a zinc concentration of 1.52M. This concentration region corresponds to the initial zinc sulfate level which provides the optimum phosphor brightness, on the basis of the experiments actually carried out.

(*c*) It is interesting to note that the conditions of precipitation which give the fastest rate of formation of ZnS are those which result in poor phosphor efficiencies. Conversely, those preparatory conditions which give the highest peak efficiencies involve very slow precipitations. This latter finding appears to be in accord with an observation made by Ortmann and Piwońka (13, 14).

It has already been pointed out that this work was undertaken with the object of providing quantitative relationships between the principal factors affecting the rate of precipitation of zinc sulfide, and the cathodoluminescent efficiencies of the final phosphor. The

[2] JEDEC designation, P22 Sulfide; RCA Phosphor No. 33-Z-265.

empirical relationships derived so far, as expressed in Eq. [2] or [3], have gone a long way toward achieving this objective in that these do describe fairly well the behavior of the precipitation rate and phosphor brightness.

It might be worthwhile illustrating the usefulness of this approach by considering a typical application. Rapid precipitations are desirable from an economic viewpoint, since these give maximum utilization of the precipitating vessels. This work has demonstrated that fast reaction rates require elevated temperatures and high H_2S flows. In addition, the initial zinc sulfate level should be low, for example 0.5M, or high, namely >2.36M, since a 2.36M solution was shown to provide the slowest rate of reaction. To take one further example, it is well known that optimum phosphor efficiency is a prerequisite for many applications involving luminescent materials so as to obtain desirable product quality. The preparatory conditions required for optimum peak efficiencies are: low precipitation temperatures, a diminished gas flow, and an initial zinc sulfate concentration of 1.52M.

A logical development of this type of approach would be to combine the information obtained from Eq. [2] and [3]. For example, it should be possible to choose precipitating conditions which would give the highest attainable level of phosphor brightness consistent with a practicable rate of reaction. Or, alternatively, to fix conditions for the synthesis of ZnS precipitates which would provide the fastest rates of precipitation consistent with reasonably good luminescent efficiency. Table III illustrates results of some typical calculations involving the combination of Eq. [2] and [3]. These data represent some of the points of intersection of the curves in Fig. 6 and 7. Consequently, the data correspond to a peak efficiency in the region of 100, and a reaction rate of the order of $\log k = -2.0 \times 10^{-2}$. Evidently, a fairly wide range of precipitating conditions is available, even within these limitations.

It was pointed out above that the data on phosphor efficiency did not give as good a correlation as those on reaction rate. A possible explanation for this behavior would be that the chosen variables were insufficient to describe completely the phosphor brightness results. For example, it is not unlikely that factors such as the impurities occluded on a precipitate (24), or the particle size and morphology of the zinc sulfide powders (16), may be important in determining the final phosphor brightness. An attempt was made to allow for the sulfate ion content of the precipitates, but this did not improve the correlation coefficient parameter for phosphor efficiency. No direct attempt was made to incorporate the size and habit of the zinc sulfide crystallites in the analysis, although the work of Brown (16) suggests that the precipitation variables chosen should reflect on these parameters. An alternative possibility is that the reproducibility of the precipitation, washing and drying stages, together with that of the phosphor preparation and measurement, may have varied. The results presented in Table II appear to indicate fairly good reproducibility.

As a consequence of this discrepancy, an additional method of analyzing the phosphor brightness results was sought. One procedure employed frequently in the analysis of the statistical distribution of empirical data is that due to Weibull (25). This method is reviewed

Table III. Relationship between phosphor efficiency and reaction rate

Peak efficiency (P_E)	Reaction rate (log k)	Zinc concentration (M)	Temperature (°C)	H_2S flow (liter/min)
94	-1.4×10^{-2}	0.5	0	5.6
100	-2.0×10^{-2}	1.7	34	7.5
106	-1.8×10^{-2}	0.7	0	1.6
106	-2.0×10^{-2}	1.3	13	6.2
112	-2.4×10^{-2}	1.7	0	4.0

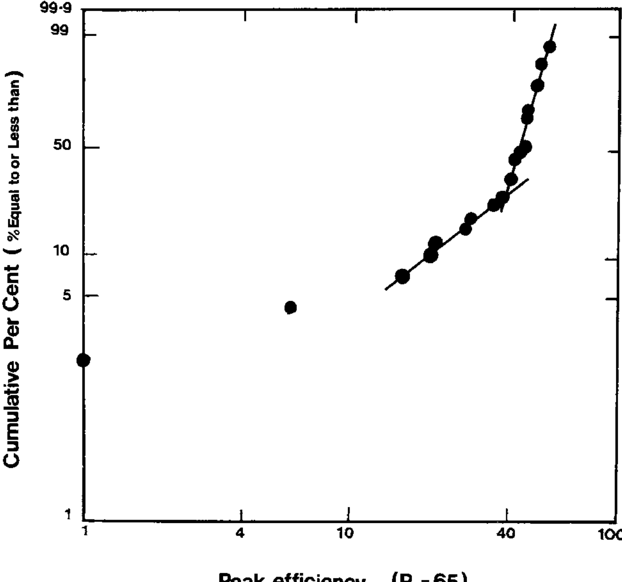

Fig. 8. Weibull distribution plot for phosphor efficiency data. Cumulative per cent vs. peak efficiency (P_E − 65).

briefly in the Appendix. Such a technique has proved useful in a wide variety of applications, as pointed out by Berrettoni (26). A Weibull plot of the phosphor efficiency results is given as Fig. 8. The curve shows the relationship between cumulative per cent (*i.e.*, per cent samples less than a given peak efficiency) as the ordinate, and peak efficiency (P_E − 65) as the abscissa. Evidently, the slope of the line changes at a peak efficiency of 100. This result indicates the occurrence of a mixed statistical distribution. Thus, samples with a peak efficiency value greater than 100 have a different distribution than those with 100 or less. The occurrence of two distributions suggests that there are probably also two different sets of parameters, or parameter levels, which best describe the two areas. Accordingly, the observed brightness measurements were submitted for correlation and regression analysis in two parts, namely $P_E \leq 100$ and $P_E > 100$. The best-fitting curve, which had an R^2 value of 78%, was obtained for peak efficiencies of 100 or less. This relationship was described by the equation

$$P_E = 62.5 + 58.2\,|Zn_o| - 22.1\,|Zn_o|^2 \qquad [4]$$

This expression indicates that for phosphor efficiencies not greater than 100, the most important factor in the precipitation process is the concentration of the initial zinc sulfate solution.

In summary, this work has shown that numerical relationships can be established between the preparatory conditions used for the zinc sulfide precipitates (especially initial concentration of zinc solution, temperature, and hydrogen sulfide flow), and both the rate of precipitation and the cathodoluminescent efficiency of the final phosphors. As a consequence, precipitating conditions can be specified which would either (*i*) give very fast reaction rates, such as are economically desirable for maximum utilization of precipitation vessels, or (*ii*) provide optimum phosphor brightness, in order to improve product quality.

It should be pointed out that these studies have involved a ZnS:Ag phosphor prepared in a particular manner, and with sodium chloride as flux. In addition, only the peak efficiency has been chosen as the phosphor parameter. In fact, many other properties of a zinc sulfide luminophor are important in any given application. For example, utilization in a color kinescope would require such additional features as a given spectral distribution of emitted light, particular size and distribution of the particles of phosphor, and stability during screening operations. It would be of interest to ascertain whether the general method de-

veloped here is applicable to a variety of luminescent materials, and whether it could be employed to describe other parameters of phosphor systems.

Acknowledgments

The authors express their gratitude to W. G. Rudy for the measurement of phosphor efficiencies, to Mrs. E. D. Martin, who performed the analyses, and to E. W. Bomgardner for assistance with the preparatory work. For helpful discussions and suggestions, especial thanks are due to Dr. A. L. Smith.

Manuscript submitted Oct. 28, 1975; revised manuscript received Jan. 16, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

APPENDIX

The Weibull Distribution

The cumulative distribution function $|F(x)|$ of the Weibull distribution is defined as

$$F(x) = 1 - \exp\left| -\frac{(x-\gamma)^\beta}{\alpha}\right|$$

where γ = a location parameter; β = shape parameter (Weibull slope); and α = scale parameter.

Since the value of γ only determines the position of the curve with respect to the abscissa, it is set to zero for the present purpose. On taking logarithms twice we obtain

$$\ln|1 - F(x)| = -(x/\alpha)^\beta$$

$$\ln \ln |1 - F(x)| = -\beta(\ln x - \ln \alpha)$$

$$\text{or,} \quad \ln \ln |1/\{1 - F(x)\}| = \beta \ln x - \beta \ln \alpha$$

Thus, on plotting $\ln \ln |1/\{1 - F(x)\}|$ as a function of $\ln x$, a straight line of slope β and intercept-$\beta \ln \alpha$ is obtained. This is the Weibull plot.

For exponential distribution, a value of $\beta \simeq 1$ is obtained; in the case of normal distribution $\beta \simeq 3.5$.

Theoretical and Experimental Efficiencies of X-Ray Screens

A. L. N. Stevels and A. D. M. Schrama-de Pauw

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

Measured relative light outputs ($CaWO_4$ is used as a standard) of the x-ray powder phosphors Gd_2O_2S:Tb, Y_2O_2S:Tb, BaFCl:Eu^{2+}, CsI:Na, and CsI:Tl are lower than the figures calculated from CR efficiencies. This might be due to a systematic difference between the radiant efficiencies of phosphors under cathode-ray and x-ray excitation, but probably is related to a large extent to the present sample preparation technology. Comparison of the light outputs under x-ray excitation of powders and screens indicates that the powder screen technology of Gd_2O_2S:Tb and BaFCl:Eu^{2+} is less developed than that of $CaWO_4$. The vapor-deposition technologies of CsI:Na and CsI:Tl seem to be well established.

In earlier papers (1, 2), we have evaluated the properties of new and traditional x-ray phosphors. The potentialities of each material were explored by calculating the x-ray quantum detection efficiencies (QDE) of x-ray screen/detector combinations. In fact these calculated figures do not represent actual realiza-

Key words: luminescence, x-ray phosphors, x-ray screens, efficiency.

tions of phosphor screens but rather give an indication what maximum performance will be found under ideal powder- and screen-making conditions.

The purpose of the present paper is to compare some measured data on powders and screens with calculated ones. In this way more insight is gained into the present state of the art of the x-ray screens.

Results of Calculations

For a given x-ray energy, the x-ray QDE is defined as follows

$$QDE_E = A_E \cdot \eta \cdot \lambda_{Em} \cdot C_E \cdot D_\lambda \quad [1]$$

where A_E = the x-ray absorption of the screen (in per cent); η = the luminescence radiant efficiency under cathode-ray excitation of the phosphor (in per cent) (in contrast to efficiencies under x-excitation, these are fairly accurately known); λ_{Em} = the mean wavelength of the detected emission; C_E = a factor representing the energy losses in the screen; and D_λ = the efficiency for detection of the screen luminescence, I_λ, by a detector with response R_λ. D_λ is defined as $\int_\lambda I_\lambda R_\lambda d\lambda / \int_\lambda I_\lambda d\lambda$.

In Fig. 1 we show the QDE figures calculated with the above-mentioned equation [for details on the calculations see Ref. (1) and (2)] for powder screens of Gd_2O_2S:Tb, Y_2O_2S:Tb, BaFCl:Eu^{2+}, CsI:Na, and CsI:Tl and for vapor-deposited CsI:Na and CsI:Tl screens. In order to have a direct comparison of the performance of various phosphors in a particular energy range, a relative scale is used in which the QDE of a reference phosphor is taken as equal to 1, independent of the x-ray energy. In the present case we have chosen $CaWO_4$ as the reference, since this material is the traditional phosphor in x-ray intensifying screens. In Fig. 1, QDE data are presented for 200 μm thick screens. The packing density of the powder screens is put equal to 50%, whereas for screens which can be made by vapor deposition 100% density is assumed. The efficiency, D_λ for the detection of the screen luminescence has been taken equal to 1. This means that the calculated QDE are in fact calculated light outputs.

We conclude from Fig. 1 that as far as calculated data are concerned, the newly developed screen materials considered have higher QDE numbers than $CaWO_4$. This conclusion holds for the complete 30-100 keV energy range. Due to their high packing density

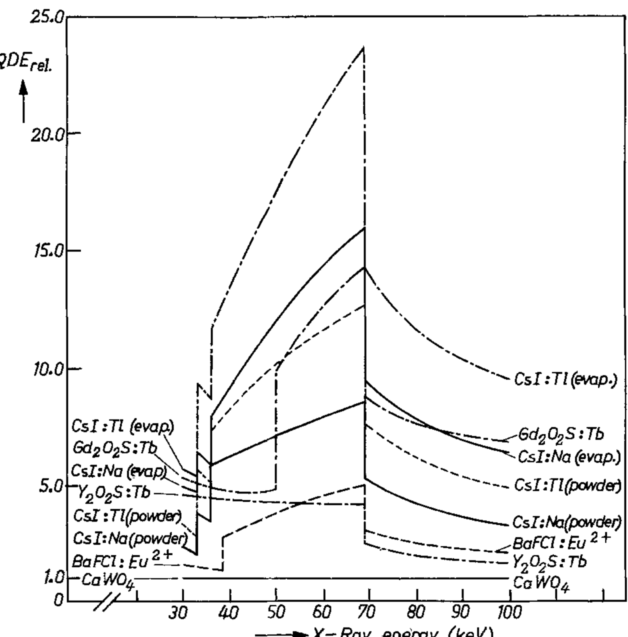

Fig. 1. Calculated relative quantum detection efficiency vs. x-ray energy for 200 μm thick phosphor screens ($CaWO_4$ = 1).

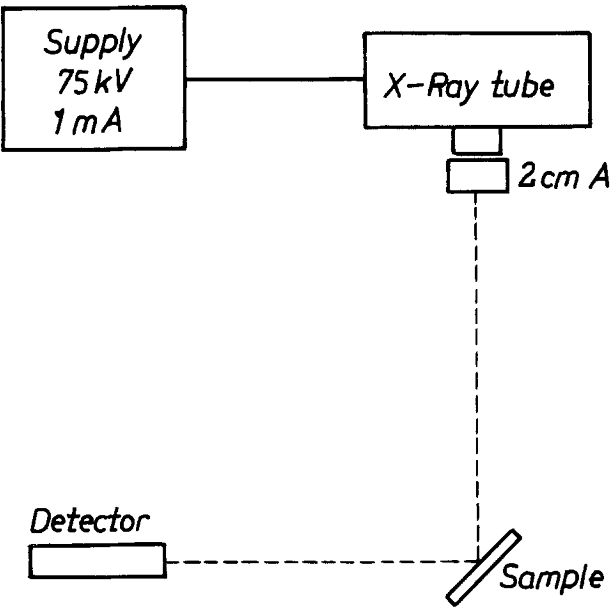

Fig. 2. Schematic diagram of the light output measurement

the vapor-deposited CsI:Na and CsI:Tl have the highest QDE figures. This suggests that these materials are very promising for applications. In fact, CsI:Na is already used on a wide scale as the input screen phosphor of x-ray image intensifier tubes.

Measurements on Phosphor Powders

Let us now consider how the measured results compare with the calculated ones. The measurements were carried out in the arrangement sketched in Fig. 2. The x-ray source was a Philips Practix tube, operated at a voltage of 75 kV and a tube current of 1 mA. An aluminum filter with a thickness of 2 cm was placed in front of the tube to make the spectral bandwidth narrower. The spectral power distribution of this x-ray source is given in Fig. 2 of Ref. (3).

In order to compare properly with the $CaWO_4$ reference, it is necesary to correct the results for the spectral sensitivity of the photomultiplier detector, for differences in phosphor layer thicknesses and for differences in the mean grain size. In the last two cases this was done with the aid of Hamaker's formulas (4) for light emission of luminescent screens irradiated by x-rays. The correction factor for the layer thickness was derived by comparing the light output calculated for the sample thickness and that of the standard thickness (200 μm). The samples considered had mean grain sizes ranging between 1 and 5 μm. In this range the scattering coefficient is about proportional to $\sqrt{1/d}$ where d = mean grain size [see Ref. (5)]. Assuming this proportionality and a standard mean grain size of 3 μm, corrections (which did not exceed 15%) can be determined in a similar way as for differences in layer thickness.

Table I gives data corrected in these ways for powders either prepared with our own production facilities or commercially obtained from others. It is concluded that for all new phosphors the measured light output is below the calculated one. This result might be explained by the observation of de Poorter and Bril (3) who found that the actual efficiency of $CaWO_4$ under x-ray excitation is much higher than under cathode-ray excitation, whereas for all other phosphors considered by these authors the difference was much less. Since we have used for our calculations the fairly accurately known CR radiant efficiencies (rather than the inaccurate x-ray efficiencies), this would imply an underestimation of the calculated light output of

Table I. Measured and calculated relative light outputs of powder phosphors

Phosphor	Measured light output*	Calculated light output
$CaWO_4$	1.0	1.0
Gd_2O_2S:Tb	4.7-5.6	8.6
Y_2O_2S:Tb	3.4-3.7	4.1
BaFCl:Eu^{2+}	2.9-3.6	3.8
CsI:Na	4.3-6.3	6.6
CsI:Tl	4.9-7.3	9.8

* In this column we give the maximum and minimum figures found for the various samples considered.

$CaWO_4$ and so would introduce a systematic error into our calculations.

However, a few measurements using the well-known (Zn, Cd)S:Ag phosphors as a standard indicated to us that no such systematic error was involved in the discrepancies which are found in Table I. This point of view is supported by data of Ludwig (5) who found, especially for $CaWO_4$, a fairly good agreement between the radiant efficiencies of cathode-ray and x-ray excited screens. This makes it probable that the discrepancies in Table I are, to a large part, caused by the fact that, with the present bulk production technology, the performance level of these phosphors under x-ray excitation has not yet reached that of laboratory samples under cathode-ray excitation (the last named figures have been used in the calculations). This may apply more particularly to phosphors that have recently gone into production.

If we consider the phosphors more specifically, the hygroscopic nature of CsI:Na may give rise to lower light outputs of this material. In CsI:Tl the appropriate incorporation of the Tl dope and the avoidance of a yellow body color seem to be the main snags. Due to the hexagonal platelike form of the crystallites, anomalous scattering effects in Tb-doped Gd_2O_2S and Y_2O_2S may give rise to a lower light output. There are also indications (7) that the control of the grain size of these phosphors is a cumbersome task, which may end in compromising at the cost of the light output. In BaFCl:Eu^{2+} the incorporation and reduction of the Eu activator pose the main problem (2).

Measurements on Screens

In order to get an indication of the present state of the art of screen making we define a relative screen performance (RSP) in the following way

$$RSP = \frac{\text{light output of phosphor screen/light output of } CaWO_4 \text{ reference screen}}{\text{light output of phosphor powder/light output of } CaWO_4 \text{ reference powder}}$$

In all cases 200 μm thick phosphor layers are considered.

If the RSP of a screen is equal to 1, this means that losses due to screen making are equal to those of $CaWO_4$ phosphor for which the screen technology was developed decades ago and is well established by now. For recently developed phosphor screens we therefore expect RSP figures below 1.

Due to its high packing density, the RSP of a vapor-deposited screen is significantly higher than that of powder screens; with the present figures, by a factor of 2. Vapor-deposited screens have the additional advantage that no binders have to be used, so that no excitation energy is lost in them and also screen processing may be less harmful to the phosphor efficiency.

Table II. Measured data on relative screen performance (RSP)

Phosphor	RSP	
$CaWO_4$	1.00	powder screens
Gd_2O_2S:Tb	0.80	powder screens
Y_2O_2S:Tb	0.45	powder screens
BaFCl:Eu^{2+}	0.50	powder screens
CsI:Na	2.40	vapor-deposited screens
CsI:Tl	2.20	vapor-deposited screens

These points combined with the fact that layers can be produced with less scatter (and hence less self-absorption) of the generated light make it possible to find RSP figures even higher than 2.

The measurement of the light outputs of the screens and the grain-size correction of the results in order to put them on a comparable basis were performed in the same way as for the powder phosphors discussed above. In Table II we summarize some data on relative screen performance. For the powder screens of Gd_2O_2S:Tb, Y_2O_2S:Tb, and BaFCl:Eu^{2+}, the RSP figures are clearly below 1, which makes it likely that their screen technologies will be improved. On the other hand, it should be noted that screens produced by methods used in the present state of the art already have given very good application results (2, 8, 9) so that, in fact, our conclusion is that further gains may be expected. For CsI:Na and CsI:Tl screens we find a relative screen performance of more than 2. As we have explained above, this is not unexpected for vapor-deposited layers. A rough estimate of the maximum RSP figure that can be found for vapor-deposited CsI:Na or CsI:Tl is 2.5-2.6. We conclude, therefore that the technology of making these vapor-deposited screens is already well advanced.

Optical Properties of Tantalum Oxide Films on Silicon

A. G. Revesz, J. H. Reynolds, and J. F. Allison

COMSAT Laboratories, Clarksburg, Maryland 20734

ABSTRACT

Tantalum oxide films on silicon were prepared by thermal oxidation of vacuum-deposited Ta films. The optical absorption of these noncrystalline films resembles closely that of crystalline Ta_2O_5, indicating a strong similarity in their short-range order structures. For given oxidation conditions, the refractive index of the oxide films increases from ~1.93 to 2.34 as the thickness increases from 12.5 to 111.7 nm. For a given tantalum film thickness, higher oxidation temperatures result in thicker oxides of lower refractive index. Additional oxide growth occurs during postoxidation heat-treatment in oxygen while the refractive index decreases. The refractive index of a given oxide film increases from the Si/oxide interface toward the outer surface, *e.g.*, from 2.08 to about 2.4. These phenomena are attributed to the incorporation of silicon into the Ta oxide during its growth. However, the estimated amount of silicon in the oxide is not sufficient to explain the observed values if it is assumed that the lowering of the refractive index is due simply to mixing Ta_2O_5 with SiO_2. Thus, it is concluded that the structure of noncrystalline Ta_2O_5 has a great flexibility which is further enhanced by incorporating silicon; the polarizability of the Ta-O bond is then strongly affected by silicon. This oxide has been applied as antireflection film in recently developed shallow junction silicon solar cells of increased conversion efficiency.

Based on fundamental considerations (noncrystallinity with high degree of short-range order, emphasis on growth rather than deposition techniques, etc.) (1), tantalum and niobium oxides have been developed as antireflection (AR) films (2) for silicon solar cells of increased conversion efficiency (corresponding to a power output $\geqq$ 18 mW/cm^2). These oxides have been prepared by thermal oxidation of vacuum-deposited Ta or Nb films. In the course of that work, we have observed that the refractive index of Ta oxide films on silicon exhibits a gradient (3). This has been attributed to the incorporation of silicon in oxidized form into the oxide during its growth. Rutherford backscattering (RBS) analysis has shown that the Ta oxide films on silicon are, in the first approximation, stoichiometric Ta_2O_5; however, the substrate-film interaction has been considered as a possible reason for the increase of their apparent density with thickness (4). The results of gravimetric and secondary ion mass spectroscopy (SIMS) analysis (5) and MOS capacitance measurements (6) also indicate that some interaction takes place in Si/Ta (Ta_2O_5) structures.

The purpose of the work presented here was to study in detail the optical properties of Ta_2O_5 films on silicon and, to some extent, on silica substrates. It will be shown in this paper that the optical absorption of noncrystalline thermally grown Ta oxide films on silicon resembles closely that of crystalline Ta_2O_5, indicating a strong similarity in their short-range order structures. However, the refractive index of these oxide films exhibits a surprisingly large variation that is attributed to the structural flexibility of noncrystalline Ta_2O_5 as well as to modification of the Ta-O bond and/or short-range order by incorporation of silicon from the substrate into the oxide film.

Experimental

Polycrystalline tantalum films (having the β-tetragonal structure) from ~10 to 50 nm thick were deposited at a rate of 0.1-1.0 nm/sec on silicon substrates by electron beam evaporation from a high-purity source. Very smooth silicon surfaces were obtained by the cupric ion polishing technique (7). The vacuum was 10^{-6} Torr. In a few cases, Ta films were also deposited by rf sputtering, but these specimens were not investigated in detail. Oxidation was performed in oxygen using a resistance heated silica tube furnace. The temperature range was 350°-700°C. Most oxidation experiments were carried out at 525°C. For comparison, a deposition (instead of growth) technique was also used. In this case the oxide film was obtained by vacuum evaporation of high purity Ta_2O_5 using electron beam heating.

The refractive index and thickness of the oxide films were determined with ellipsometry at 546.1 nm wavelength. In the computer evaluation of the Δ and ψ values (8), n = 4.06 and k = 0.102 were used as the optical constants of silicon. These optical constants were determined experimentally. The n value is close to published values, *e.g.*, n = 4.05 (9). The published k values vary significantly, but its actual value has little effect on the refractive index and thickness of dielectric films on silicon. The possibility of having a discrete SiO_2 film between the Si substrate and Ta oxide film has already been eliminated on the basis of ellipsometric measurements performed at two different wavelengths (3). This result has also indicated that the Ta oxide film is nonabsorbing between 435.8 and 546.1 nm wavelengths. Independent absorption increments (see below) also demonstrate that Ta oxide films do not absorb at 546 nm wavelength. Thus, the ellipsometric results for these films are unambiguous. In some cases the ellipsometric measurements were combined with a stepwise etching of the oxide film in HF so that a possible gradient in the refractive index could be revealed.

Optical absorption as a function of wavelength was determined by measuring the reflected and transmitted light using an integrating sphere attached to a spectrometer. For this purpose, the oxide films were produced on fused silica substrates.

Results

As has been shown previously, the Ta oxide films, even those obtained at 700°C, are noncrystalline and morphologically (as judged by optical and electron microscopy) very uniform (3). They all exhibited bright, continuous interference colors.

The absorption spectra of ~60 nm thick thermally grown (curve 1) and vacuum-deposited (curve 2) tantalum oxide films are shown in Fig. 1. It can be seen from this figure that, similarly to a crystalline

Key words: solar cells, Ta_2O_5 on Si, Ta_2O_5 optical properties, antireflection film.

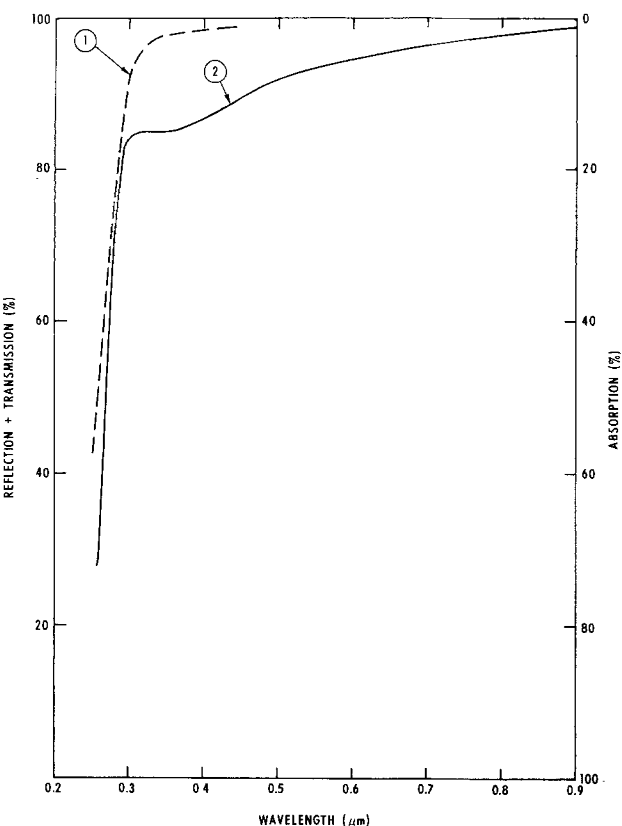

Fig. 1. Absorption of Ta oxide films. The absorption was determined as described in the text. Curve 1: Ta_2O_5 film obtained by thermal oxidation, Curve 2: Ta oxide obtained by vacuum deposition.

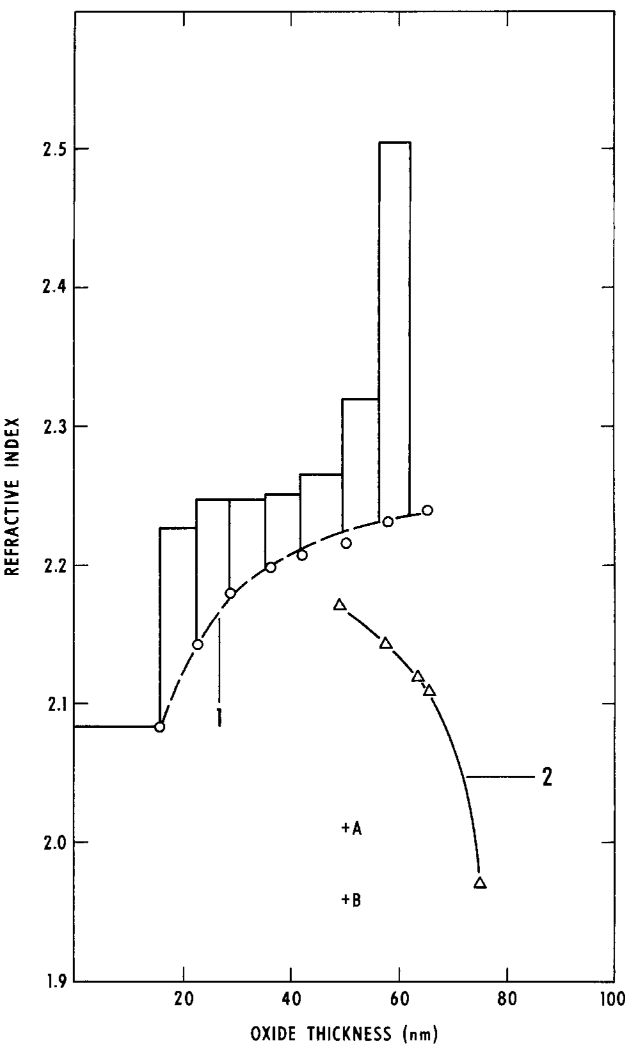

Fig. 2. Refractive index of various Ta oxide films. Curve 1 refers to a Ta oxide film on silicon obtained at 525°C. The film was etched stepwise in HF; the circles indicate the measured refractive index of the remaining film after each step (average refractive index). The superimposed bars give the refractive index of each segment (see text). The refractive index of the outermost segment may be unrealistically high. Curve 2 shows the stepwise etching behavior of a Ta oxide film on GaAs. Points A and B show the refractive indices of two samples for which the Ta film was obtained by sputtering on silicon rather than by vacuum deposition.

solid, the absorption of the thermally grown noncrystalline Ta oxide film is quite sharp. From this curve, the bandgap can be estimated as 4.1 eV. This value is comparable to 4.2 eV reported for chemically deposited polycrystalline β-Ta_2O_5 (10) and for noncrystalline Ta_2O_5 films (11). This result demonstrates that the thermally grown Ta oxide film on silicon can be considered, at least in the first approximation, as stoichiometric Ta_2O_5. A similar conclusion has been reached from the RBS analysis (4).

On the other hand, the absorption curve of vacuum-deposited tantalum oxide (curve 2) is distorted; this behavior is typical of noncrystalline solids with large structural disorder. These results demonstrate that, in accordance with the fundamental considerations outlined in Ref. (1), the grown oxide has a higher degree of short-range order and, hence, less unsaturated valences and/or Ta-Ta bonds than the deposited one.

As was already mentioned above, the substrate for the absorption measurement was silica rather than silicon. However, the reflectance spectrum of thermally grown Ta_2O_5 film on a silicon substrate as well as the characteristics of solar cells fabricated with such an oxide as the AR films shows that the oxide film on a silicon substrate is also essentially nonabsorbing above ~0.35 μm wavelength (2). Thus, from the viewpoint of the optical absorption, there is no significant difference between Ta_2O_5 films on Si and SiO_2 substrates.

Since the observation of a gradient in the optical index of thermally grown Ta_2O_5 on silicon was one of the first signs of an unexpected substrate-film interaction (3), the stepwise etching of the oxide film and determination of its refractive index was repeated. The results confirmed those reported previously (3); *i.e.*, the refractive index decreases from the outer surface toward the Si/oxide interface as shown in Fig. 2. In this figure, the open circles along curve 1 indicate the average value of the remaining film after each etching step, *i.e.*, it was assumed that each segment of the film is homogeneous and that the reflecting surface is silicon. The bars superimposed on curve 1 were obtained by approximating the graded film with a series of discrete homogeneous layers. The lowest average value was taken as the refractive index of the first layer on silicon (assumed to be a homogeneous film 16.0 nm thick), the refractive index and thickness of the second layer were then obtained by reevaluating the ellipsometric data using a multilayer model consisting of the substrate, the first layer, and the unknown second layer. This calculation was repeated for each successive layer; for details of the calculation see Ref. (8).

Since the refractive index change within each layer is small, and the layer thickness (~10 nm) is a small fraction of the wavelength, this method provides a reasonably accurate approximation of the refractive index profile. It can be seen from Fig. 2 that the greatest inhomogeneity occurs near the two surfaces. We have observed that the refractive index of Ta oxide films obtained by partial oxidation of relatively thick Ta films, *i.e.*, Ta oxide on Ta rather than Si substrate, is higher than 2.4 (this value is, however, somewhat

uncertain due to possible absorption). Thus, Fig. 2 indicates that, with increasing thickness, the Ta oxide film on silicon is becoming more similar to thermally grown oxide film on tantalum.

Another aspect of this behavior is exhibited in Fig. 3, which shows the refractive index values of a series of Ta oxide films on silicon. These samples were obtained by depositing a varying amount of tantalum which was then fully oxidized. It is obvious that the average refractive index of these samples shows a trend which is similar to that seen in Fig. 2, *i.e.*, it increases with increasing oxide thickness. The apparent densities of the oxide films were obtained by using the RBS technique to determine the number of Ta atoms per cm^2, then converting this value to the corresponding amount of Ta_2O_5 and using the ellipsometric thickness value (4). It has been pointed out in Ref. (4) that the ratio of Ta to O atoms in these films corresponds, to a first approximation, to that of Ta_2O_5; this justifies the use of this procedure. However, it is very likely that these density values are unrealistically low (hence they are designated as apparent) since some nontantalum constituent, *e.g.*, Si, may not have been detected by the RBS technique.

It is clear from these observations that the refractive index of thermally grown Ta_2O_5 films on silicon depends largely on the preparation conditions. If these conditions are properly chosen, then its value as averaged across the film can be very close to 2.3, which is the optimum refractive index for an AR film in a silicon solar cell; also, the film thickness can be adjusted according to the optical matching requirements. In a typical application as AR film, the refractive index of the ~60 nm thick Ta_2O_5 film is 2.23; the reflection loss from a silicon surface covered with such a film and a fused silica coverslide is about 2% at 540 nm wavelength (primarily due to coverslide reflection). These aspects are discussed in detail in Ref. (2).

It should be mentioned that the behavior of the refractive index, as shown by curve 1 in Fig. 2, is not universally characteristic of thermally grown Ta oxide films. To wit, stepwise etching of a Ta oxide film formed under identical conditions on a GaAs substrate has revealed a gradient which is the opposite of that observed for Ta oxide on silicon (see curve 2 in Fig. 2). There is a possibility that the Ta oxide films on GaAs are not completely transparent. Neglecting the absorption in the evaluation of ellipsometric data results in apparent refractive indices that are higher than their true values. Consequently, the true gradient in the refractive index may be lower than that indicated by curve 2 in Fig. 2.

These observations demonstrate that the gradient in the refractive index of Ta oxide films depends largely on the substrate on which the film was formed. This means that, at least in some cases, a significant interaction with the substrate occurs during deposition of the Ta film and/or thermal oxidation. The extent of this interaction apparently depends on various process parameters resulting in a range of refractive index values. This range is much wider than that of the reported values for Ta oxide films produced by anodic oxidation of Ta foils [n = 2.22 (12)] by thermal oxidation of sputtered Ta films on glass or silica [n = 2.14-2.25 (13, 14)], and on Li-tantalate [n = 2.21 (15)] substrates, as well as that obtained by chemical deposition [n = 2.3 (11)], even though these films exhibit a much larger thickness range (80-800 nm) than the films described herein. It is important to note that no gradient in the refractive index has been reported for Ta_2O_5 films on glass and similar substrates.

Oxidation of Ta films prepared by sputtering resulted in significantly lower refractive index values than those characteristic of oxides obtained with vacuum-deposited Ta films (see Fig. 2, points A and B). These values are also lower than those quoted above for oxides on insulator substrates although the latter were also obtained by oxidizing sputtered Ta films. It is conceivable that, similar to the reaction resulting in metal-silicide films (16), the film-substrate interaction is easier for sputtered than for vacuum-deposited Ta films. However, it should be mentioned that the vacuum-deposited Ta oxide film also had a relatively low refractive index (~2.1).

Another aspect of the effect of process parameters is demonstrated in Fig. 4: the refractive index decreases with oxidation temperature, even though the various Ta oxide films obtained on silicon substrates in the

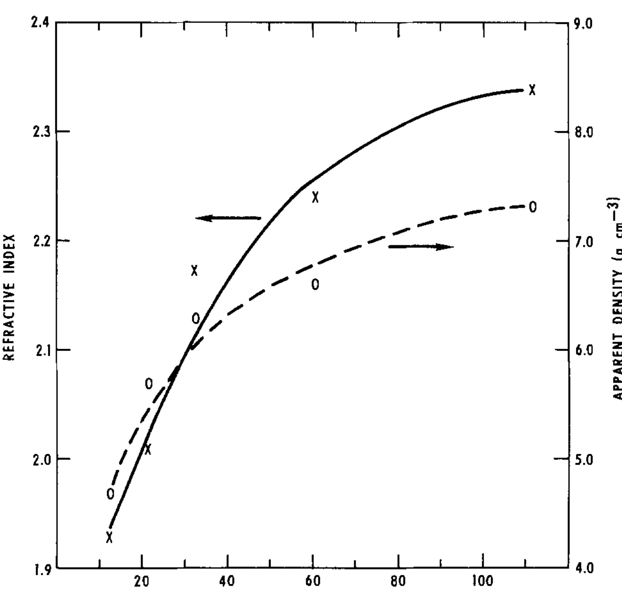

Fig. 3. Average refractive index and apparent density of a series of Ta oxide films on silicon. The thickness of Ta and hence Ta oxide films was varied. The oxidation was done at 525°C for 15 min for each sample. The apparent density was determined from Rutherford backscattering analysis as described in the text.

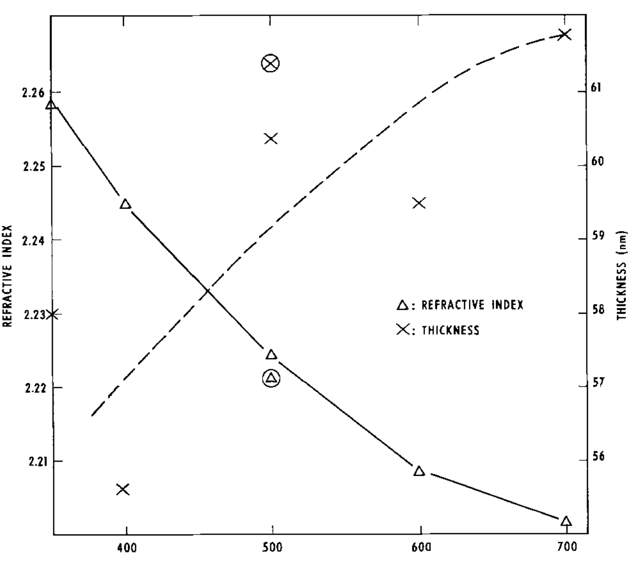

Fig. 4. Refractive index and thickness of Ta oxide films on silicon. The thickness of the Ta film before oxidation was roughly the same for all samples. The oxidation time varied from 5 min at 700°C to 65 hr at 350°C. The Ta film was fully oxidized in each sample. The encircled values refer to an oxide film which was obtained by oxidization at 350°C and then it was heat-treated in oxygen at 500°C for 16 hr.

temperature range 350°-700°C appeared to be morphologically and structurally identical. The increase in the oxide thickness with oxidation temperature was not so well defined, but a trend was discernible. Note that, as demonstrated by the encircled symbols, the refractive index of the oxide film formed at 350°C changed during a subsequent 16 hr heat-treatment in oxygen at 500°C to that characteristic of a film obtained at 500°C in about 15 min and that the thickness also increased significantly. As was pointed out earlier, a similar trend, *i.e.*, increase in thickness and decrease in refractive index, was observed in determining the end point of oxidation of Ta film on silicon (3).

The behavior exhibited in Fig. 4 shows that the oxide composition and/or density depends on the oxidation temperature and subsequent heat-treatment. If it is assumed that the variation in thickness is due to a change in density only, this change is about 9%. The refractive index also decreases as the density decreases and, correspondingly, the mol. polarizability decreases by about 9%. This means that the nature of the Ta-O bond has changed as reflected in the polarizability. Another possibility is, of course, that some chemical change involving a nontantalum component has occurred. Such a chemical change may be, for instance, the incorporation of silicon into the Ta oxide film.

A somewhat similar effect of heat-treatment has also been observed with sputtered Ta films on insulator substrates. Oxidation of 800 nm thick Ta film on glass substrate at 550°C for 16 hr yielded an oxide film with $n = 2.213$, whereas a 40 hr treatment resulted in $n = 2.203$ (13). It has been hypothesized that the change indicates the beginning of crystallization of the noncrystalline oxide. However, the possibility of an interaction with the substrate cannot be excluded. Indeed, discoloration effects in $LiTaO_3$ were attributed to some interaction with the deposited Ta film during its oxidation (15).

These heat-treatment effects are the opposite to those usually observed with porous films: increase in refractive index and decrease in thickness. The heat-treatment behavior is also opposite to that of anodic Ta_2O_5 films on Ta substrates for which the dielectric constant increases during heat-treatment in air, but the thickness does not increase (17). The increase in the dielectric constant has been attributed to the creation of an oxygen deficit, *i.e.*, suboxide formation, and to an increase in the long-range order (beginning of crystallization).

The dielectric constant at 1 MHz was determined from MOS capacitance measurement (6) and its value for a ~60 nm thick oxide film was found to be 11.6.

Discussion

Since the refractive index and mol. polarizability values for these Ta_2O_5 films on silicon are higher than for SiO_2 and lower than for Ta_2O_5, the gradient in the refractive index as well as the effects of oxidation and heat-treatment conditions have been attributed qualitatively to the incorporation of silicon in oxidized form into Ta oxide (3). The results of gravimetric and SIMS analyses have also indicated the presence of silicon in these Ta_2O_5 films (5), thereby strengthening the above interpretation. In addition, it has been observed that the quantum yield at short wavelengths of shallow junction solar cells using this oxide as AR film is very high. This results from the low surface recombination velocity of minority carriers, indicating that the silicon-oxide interface is reasonably perfect (2). Recent MOS capacitance measurements are also in accordance with this conclusion since they reveal that the interface state density is relatively low, about 10^{12} cm^{-2} $(eV)^{-1}$ (6).

These results indicate that some interaction with the silicon substrate has occurred during the oxidation of the Ta film. It is a general observation that low interface state densities are characteristic of grown rather than deposited oxide (or other insulator) films on semiconductors.

Interpretation of the data shown in Fig. 3 gives some insight into the structure and composition of Ta oxide films on silicon. Since the oxide films can be considered, in the first approximation, to be Ta_2O_5, the mol. polarizabilities can be calculated with the Lorentz-Lorenz equation using the molar weight of Ta_2O_5. If it is assumed that the apparent density values in Fig. 3 are true, then their mol. polarizability changes from 1.85×10^{-23} to 1.43×10^{-23} cm^3 as the thickness increases from 12.5 to 110.7 nm. On the other hand, if it is assumed that the density is constant and equal to 7.9 g/cm^{-3} (which is the value for noncrystalline Ta_2O_5 film obtained by anodic oxidation), then the corresponding change is from 1.05×10^{-23} to 1.30×10^{-23} cm^3. Since the mol. polarizability of anodic Ta_2O_5 is about 1.262×10^{-23} cm^3 (using $n = 2.22$), this latter range seems to be more realistic than that calculated from the apparent density values.

Both assumptions concerning the density lead to a large variation (about 25%) in the mol. polarizability. As a comparison, the mol. polarizability of SiO_2 increases by only 5% (from 2.85×10^{-24} to 2.96×10^{-24} cm^3) when its structure changes from coesite ($d = 2.87$ gcm^{-3}, $n = 1.596$) to vitreous [$d = 2.20$ gcm^{-3}, $n = 1.458$ (18)]. Thus it is very unlikely that the 25% variation can be attributed solely to some small change in the short-range order of noncrystalline Ta_2O_5. Some profound change in the polarizability and, hence, in the nature of the Ta-O bond must occur and/or incorporation of silicon into the Ta oxide must be responsible for this effect.

Lowering of the refractive index, albeit to a much lesser extent, was observed for oxide films obtained by anodic oxidation of a sputtered Ta film which contained 23 atom per cent (a/o) aluminum (19). The composition of the oxide film was determined with the Lorentz-Lorenz equation

$$\frac{n_0^2 - 1}{n_0^2 + 2} = \frac{4\pi}{3}(N_1\alpha_1 + N_2\alpha_2) = (1 - q)\frac{n_1^2 - 1}{n_1^2 + 2} + q\frac{n_2^2 - 1}{n_2^2 + 2} \quad [1]$$

where N, α, and n are the number of molecules/cm^3, molecular polarizability, and refractive index, respectively; and subscripts 0, 1, and 2 refer to the composite film, anodic Ta_2O_5, and anodic Al_2O_3, respectively. The parameter q is the volume fraction occupied by anodic Al_2O_3. For $n_0 = 2.12$, q was determined as 14% (using $n_2 = 1.66$) which in turn gave 21 mole per cent (m/o) for Al_2O_3, in good agreement with an independent analysis of the composite oxide film, This result demonstrates that the composite oxide can be considered to be a mixture of Ta_2O_5 and Al_2O_3 in which no significant interactions between the Ta-O and Al-O bonds occur.

A similar analysis could be also applied to the films described herein, but the refractive indices of oxide films thicker than 32.2 nm are higher than the values reported for anodic Ta_2O_5 films. Also, as pointed out above, the refractive index of Ta_2O_5 film grown by thermal oxidation on Ta substrates is somewhat uncertain. Thus, the value of n_1 to be used in Eq. [1] is not quite clear. However, it can be seen from Fig. 5 that the lowest value of the refractive index as extrapolated to infinite thickness is about 2.37. This value is comparable with the mean refractive index (~2.39) calculated from the two indices of the optically biaxial β-Ta_2O_5 crystal (10).

In order to test the validity of such an analysis, the volume fractions occupied by SiO_2 in the films represented in Fig. 3 and 5 were determined by using 2.37 for n_1 and 1.458 for n_2 in Eq. [1]. The corresponding mole fractions of SiO_2 were calculated by using 7.9

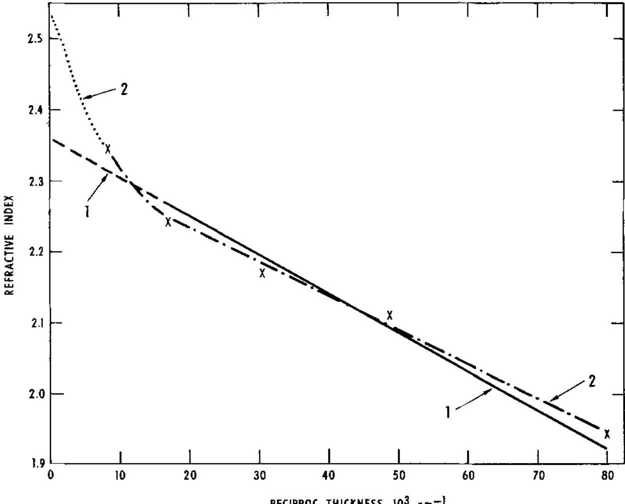

Fig. 5. Refractive index as a function of reciprocal thickness. The samples are the same as in Fig. 4. Curves 1 and 2 represent two possible relationships among the data. The smallest value of the refractive index as extrapolated to zero reciprocal thickness is about 2.37.

and 2.2 g/cm^3 as the densities of Ta_2O_5 and SiO_2, respectively. The calculated values are given in Table I. This table indicates that, in general, a substantial amount of SiO_2 is present in the oxide films (using $n_1 > 2.37$, this amount would be even larger). However, according to sensitivity estimates of the RBS analyses of these same films, the maximum Si/Ta ratio is 0.16, corresponding to 0.24 mole fraction of SiO_2. This value is significantly less than most of the values in Table I, indicating that the application of the analysis, as outlined above, is not justified. Accordingly, these films cannot be regarded as simple mixtures of SiO_2 and Ta_2O_5, and the values shown in Table I are unrealistic.

Another possibility is that some amount of silicon in the oxide film is present in unoxidized form, *i.e.*, in addition to Ta-O-Si bonds, Ta-Si bonds are also present. However, it is expected that such a structure would absorb light, whereas these films are practically nonabsorbing at 546.1 nm wavelength. Thus, it is very probable that the nature of the Ta-O bonds, and hence their polarizability, varies significantly in the Ta oxide films, and that this variation depends on the amount of silicon incorporated into these films. This is the reason that, as opposed to the composite Ta_2O_5-Al_2O_3 anodic films, these films cannot be considered to be simple mixtures of Ta_2O_5 and SiO_2. Consequently, their chemical composition cannot be determined from simple polarizability considerations.

This point is further strengthened by the following argument. The dielectric constant of a ~60 nm thick tantalum oxide film on silicon at 1 MHz is 11.6. The average refractive index of this film is 2.24; this value is almost identical to the refractive index of anodically grown Ta_2O_5 film even though its dielectric constant is about 27. If ϵ is substituted for n_2 in Eq. [1] and $\epsilon_1 = 27$ and $\epsilon_2 = 3.8$ (for SiO_2), then the volume occupied by SiO_2 is 0.28 and the mole fraction of SiO_2 is 0.57. These values are significantly different from

Table I. Composition of Ta oxide films on silicon as determined from the refractive index

Refractive index	Volume fraction occupied by SiO_2	Mole fraction of SiO_2
2.34	0.030	0.06
2.24	0.111	0.22
2.17	0.167	0.34
2.11	0.220	0.45
1.94	0.387	0.79

those given in Table I (0.111 and 0.22, respectively). In contrast, it has been found that the mole fraction of Al_2O_3 in the Ta_2O_5-Al_2O_3 film, as determined from the dielectric constant at 1 kHz, is the same as that determined from the refractive index (19).

The behavior of Ta oxide film on silicon indicates that the frequency dependence of the polarizability is different in these films than in Ta_2O_5 and SiO_2. This means that the ionic and dipole contributions to the over-all polarizability and hence the nature of the bonds are also different from those characteristic of anodic Ta_2O_5 and vitreous SiO_2.

It is interesting to note that anodic oxidation of a mixed Ta (65 a/o) and Si (35 a/o) sputtered film proceeds under a field of 5×10^6 V/cm (20). This field is lower than the field across growing anodic Ta_2O_5 (5.6×10^6-6.2×10^6 V/cm) and SiO_2 (2×10^7 V/cm). Since the stoichiometry has been reported to be consistent with an oxide composed of Ta_2O_5 and SiO_2, the anodization field should be between the two extreme cases. The fact that it is outside of this range is an additional indication that even in the anodically formed mixed oxide the Ta-O and Si-O bonds are different from those present in the pure oxides. Since the refractive index of the mixed anodic oxide is not known, no comparison can be made with the film described herein.

It is concluded from the above discussion that noncrystalline Ta_2O_5 exhibits a great structural flexibility. Incorporation of silicon (at least partially in oxidized form) during thermal oxidation of Ta film on silicon apparently increases this flexibility as shown by the enhanced stability of the noncrystalline structure. To wit, Ta oxide films on silicon produced even at 700°C are noncrystalline, whereas anodic oxide films usually crystallize at lower temperatures, *e.g.*, at 450°C, at which temperature they also lose their remarkable ductility (21).

Conclusions

As inferred from the optical absorption spectrum, noncrystalline tantalum oxide films obtained by thermal oxidation of vacuum-deposited tantalum exhibit a great similarity to crystalline Ta_2O_5 with respect to stoichiometry and short-range order. However, the refractive indices of thermally grown Ta oxide films on silicon vary from $n = 1.94$ to $n = 2.34$ as the film thickness increases. Also, the refractive index of a given film has a gradient; the lowest value is in the vicinity of the Si/oxide interface and the highest value is at the outer surface. Since anodic Ta_2O_5, chemically deposited Ta_2O_5, and Ta oxide film on insulator substrates do not exhibit such a large variation in their refractive indices and no significant gradients have been observed, a substrate-film interaction resulting in the incorporation of silicon into the Ta oxide film is thought to be responsible for these unique effects.

This conclusion is also supported by the heat-treatment behavior which is opposite to that expected for a porous film and that observed with anodic Ta_2O_5 films on Ta substrate as well as by the results of gravimetric and SIMS analyses. The extent of the film-substrate interaction depends on the thickness of Ta film, oxidation conditions, and postoxidation treatments. Polarizability considerations and Rutherford backscattering analysis of these films indicate that silicon alone cannot account for the observations. Hence, it can be concluded that thermally grown Ta oxide films exhibit a great structural flexibility, resulting in significant variation in the polarizability of the Ta-O bond; this is further enhanced by incorporating Si atoms from the substrate into their noncrystalline structure.

As a result of the flexibility of the noncrystalline structure and the film-substrate interaction, the Si-Ta_2O_5 interface is reasonably perfect. This interface perfection together with the structural and optical

properties of this Ta_2O_5 film led to its successful application as antireflection film in shallow junction silicon solar cells.

Acknowledgments

Thanks are due to B. Free for providing the sputtered Ta samples and to M. Penrose for assistance with the ellipsometric measurements. We also wish to thank Dr. J. Hirvonen (Naval Research Laboratory) for helpful comments on the manuscript. We are indebted to Dr. L. Young (University of British Columbia) for drawing attention to the ductile behavior of anodic Ta_2O_5.

Evolution and Current Status of Aluminum Metallization

Arthur J. Learn*

Fairchild Camera and Instrument Corporation, Research and Development Laboratory, Palo Alto, California 94304

ABSTRACT

The requirements which have been placed on metallization for silicon integrated circuits are listed and their origins are traced. Physical models relating to various requirements are discussed. Among these are oxygen activity as a criterion for adherence, slope etching, impurity effects on resistivity, self-shadowing effects on step coverage, and Schottky barrier formation and tunneling as a determinant of contact resistance. The procedures necessary for optimization of some of these properties are considered. Physical vapor deposition methods are reviewed and compared. The more demanding problems of interaction with silicon at contacts, electromigration-induced failure, two-level metallization processing, and corrosion are discussed at length. Approaches designed to allow a basically aluminum metallization to meet all requirements are presented. It is concluded that the use of aluminum alloys is the most generally beneficial technique and that additional effort must be devoted to defining a fully satisfactory method for corrosion protection.

The metallization step in silicon device and integrated circuit processing is one of the last to be performed. Since the value of wafers steadily increases throughout the course of processing, the metallization step is therefore among the more critical ones. The required properties for metallization were relatively simple and few for discrete devices and early integrated circuits. The design of new types of devices and circuits together with processing refinements during the last decade have, however, resulted in increasingly more stringent demands on metallization.

The initial metallization requirements were comfortably met by aluminum and, consequently, it was used for this purpose. Certain problems have subsequently arisen with aluminum, notably those associated with silicon interaction at contacts, electromigration, corrosion, and multilevel metallization. There are essentially two approaches to the solution of such problems. Nonaluminum metallizations which have comparable resistivity such as molybdenum-gold (1), titanium-platinum-gold (2), or titanium-palladium-gold (3) have been developed. Since the preparation of such metallizations is inherently more difficult, and hence more costly, than aluminum they have found only specialized application. The alternative approach is to attempt improvement by techniques which allow retention of basically aluminum metallization. It is activities in the latter area which will be reviewed here.

The paper is organized as outlined below. A list of requirements for metallization will first be presented.

* Electrochemical Society Active Member.
Key words: silicon IC metallization, metallization processing, metallization reliability, metallization optimization, aluminum and aluminum alloys.

Each of the requirements will be discussed in turn and in detail. Where it is not obvious, the origins of the requirements will be traced. The properties of aluminum will be compared with this list. Models to explain why good matches are achieved in some cases will be given. Where there is substantial disparity in ideal and actual properties, the methods investigated to more closely approach the ideal will be discussed. Conclusions as to the best over-all approach at this time and areas for further study will be given. It is hoped that the present review will serve to both update and expand other such reviews (4-6). Many volumes or series relating in part to various aspects of metallization are also available (7).

Metallization Requirements

A list of requirements for metallization on present-day silicon devices and integrated circuits must include the following:

1. Compatible deposition methods
2. Good adherence to dielectrics
3. Selective etchability
4. Low electrical resistivity
5. Complete coverage of surface topography
6. Bondability
7. Low contact resistance
8. Contact stability
9. High electromigration resistance
10. Multilevel capability
11. Resistance to oxidation and corrosion

Requirements 7 and 8 relate specifically to the properties of metallization as a contact material and the remainder primarily to the properties as an interconnection or external connection.

Additional requirements could certainly be considered, such as the ability to solder to or plate onto the metallization and resistance to mechanical abrasion. The latter is readily achieved by deposition of dielectric layers over the metallization (8). Multilayered metal systems have been developed to allow soldering (9) or plating (10, 11) over aluminum metallization. These properties while desirable do not, however, represent basic limitations on the use of aluminum. Accordingly, the above list will be used as a basis for discussion of aluminum metallization.

Discussion

Deposition methods.—The formation of high quality aluminum by chemical vapor deposition has not been achieved, or at least has not been reported. Therefore, physical vapor deposition processes are used. Applicable methods of deposition are listed in Table I and compared with a checklist of desired characteristics when used for providing metallization.

Evaporation of aluminum from tungsten or tantalum filaments is among the earliest techniques used (12, 13). Aluminum will alloy with these materials at evaporation temperatures and filament life is short. Also the deposit thickness is limited by the amount of aluminum which may be loaded on the filament. Perhaps the most serious drawback to filament evaporation is the inability to consistently obtain alkali-free material (14). The consequences as regards MOS devices are especially grave although bipolar device processing is also developing comparable sensitivity (15) to the various charges in the oxide (16), such as positive fixed surface-state charge or mobile ionic contamination (Q_o). Radiation damage effects (N_{ot}) are not present with filament evaporation. Porous aluminum carbide rod filaments have been used for aluminum evaporation and reportedly (17) are relatively free of sodium. The development of intermetallics, such as a mixture of boron nitride and titanium diboride, which better resist attack by aluminum also makes evaporation from a boat feasible.

Flash evaporation from a heated bar composed, for example, of the above intermetallic offers several attractive features. Materials can be continuously fed to the bar in the form of pellets (9) or wire (18). The deposition of thick films is therefore intrinsic to this approach and also there is freedom from radiation damage. In addition, the deposition of a variety of aluminum alloys requires only a simple substitution of the appropriate alloy pellets or wire (18).

Inductively heating an aluminum charge held in a crucible of the intermetallic material (19) previously mentioned or boron nitride (20) offers high deposition rates. It should be noted that, with the possible exception of sputtering, the other methods listed yield rates sufficiently high that there is little impact on throughput time for metallization processing. Alloy deposition is possible in a controlled way with inductive heating only by utilizing multiple sources.

Electron beam evaporation (20) has a number of shortcomings. The deposition of thick films or alloys is not inherent in this method and is achieved only at the expense of more complicated and difficult-to-control procedures. Thick films can be considered, just as for other methods, if material is supplied to the molten evaporant pool. This technique (21), heating of a continuously fed rod of material (22-24), or use of multiple sources either operated simultaneously (25) or sequentially can be used for alloy deposition. Consideration must be accorded the possible effects of radiation damage (26).

The boat, flash, and inductive-heating methods typically exhibit flux distribution characteristics approaching a surface (cosine law) source (27). This characteristic is normally assumed in designing rotating or planetary fixturing (28) to yield a deposit of uniform thickness. Unless the deposition conditions are carefully controlled, the distribution from electron beam sources can exhibit beaming or directionality effects (29) and deposits of nonuniform thickness can result.

Although sputtering is listed as useful for thick-film deposition, excessive times may result as a consequence of relatively low deposition rate. In order to sputter aluminum effectively and obtain near-bulk resistivity, d-c bias sputtering (30) or RF sputtering (31, 32) is required. This results in considerably increased cost for the apparatus. The attainment of low Q_o is somewhat questionable in view of the tendency for the sputtering process to redistribute and activate mobile ionic contamination (33, 34). Likewise, the extent of the effects arising from radiation damage has not been fully defined. Sputtering is, however, attractive for the deposition of alloys and promising new techniques offering increased deposition rates are evolving (35-37).

It may be noted that the limits on Q_o can be relaxed through the use of layers prior to metallization which inhibit the motion of ionic contaminants or "getter" them. Such layers include silicon dioxide incorporating phosphorus (38) or chlorine (39), silicon nitride (40), and aluminum oxide (41). On the other hand. the presence of nitride restricts the annihilation of fast surface states (16) which normally occurs upon heating in an ambient of hydrogen (42) or with aluminum metallization present (43). This effect must

Table I. Characteristics of metallization deposition techniques

Deposition method	Low cost	High deposition rate	Thick films	Alloy deposition	Low Q_o	No N_{ot}
Filament	Yes	No	N	N	N	Y
Flash evaporation	Y	N	Y	Y	Y	Y
Inductive heating	N	Y	N	N	Y	Y
Electron beam heating	N	Y	N	N	Y	N
Sputtering	N	N	Y	Y	?	N

then occur by lateral penetration and diffusion of hydrogen under the nitride (44). Such effects are of interest because surface states can appear with those deposition methods for which x-radiation or energetic secondary electrons are prevalent. The preparation of wafers before metallization is also important in minimizing Q_o. In particular, dilute acid rinses followed by the liberal use of distilled water can remove alkali ion contaminant from the wafer surface (45).

Adherence to dielectrics.—The heat of formation for metal oxides has been proposed as a qualitative measure of the adherence of metals to oxide (46-48). If the heat of formation is large and negative, then the tendency of the metal to reduce the oxide onto which it is deposited is pronounced. A strong chemical bond at the interface should therefore result. Bonding of this type was recently reviewed (49, 50).

The oxide heats of formation for aluminum and silicon are −399 and −205 kcal/mole, respectively. Therefore, good adherence of aluminum to silicon dioxide would be expected, as has been universally observed. This inequality in heats of formation also indicates that reduction of residual silicon dioxide in contact windows covered with aluminum would occur upon heating. Such a phenomenon is the basis for the "alloying" or sintering step in silicon device processing where the intent is to promote more intimate metallization contact and thereby lower contact resistance. Rates of silicon dioxide reduction by aluminum have been measured and recorded (52). As an example, a typical 5 min "alloying" period at 500°C would reduce 25Å of oxide.

Silicon nitride is finding more widespread application in device processing, particularly as an oxidation mask in recently developed oxide isolation techniques (53). Frequently the surface of nitride layers is thermally oxidized to provide an etch mask for the nitride delineation. With oxide present, adherence of aluminum metallization should be as discussed above. For deposition directly on nitride it is not certain that an adherence mechanism involving nitride heats of formation can be invoked. The heats of formation for AlN (51) and Si_3N_4 (54) are −131 and −180 kcal/mole, respectively. In any case, the adherence of aluminum to silicon nitride is found to be completely satisfactory.

Etching properties.—Aluminum is readily etched in either basic or acidic solutions. Basic solutions may also etch silicon and their use would necessitate the complete coverage of contacts. In addition, the risk of alkali ion contamination is naturally more pronounced with such solutions. Accordingly, acidic etchants are preferred for aluminum etching. Typically, phosphoric acid is the primary ingredient used. Phosphoric acid will etch underlying nitride layers (55) as well but the etch rate is significant only at temperatures much higher than those employed in etching aluminum.

Normally, the etching is nearly isotropic so that the edge profile of the metallization will be represented by a quarter circle. If the metallization is overetched, *i.e.*, if the etch time exceeds that required to etch through the metallization thickness, then nearly vertical edges will result (56). At least two methods exist for providing a more favorable slope or taper at the metallization edge. If an appropriate ingredient, such as nitric acid, is added to the conventional etchant, loss of adherence of the photoresist will result. If the photoresist lifting is initiated at its edge and increased inward in a controlled manner, suitable profiles can be obtained (57). A second technique utilizes double layers having different etch rates in a given etchant. Both anodic (58) and deposited oxide overlayers (59) were found, in buffered etches, to have larger etch rates than aluminum and therefore to allow attainment of low angle steps.

Electrical resistivity.—The resistivity, ρ, for metallization is normally determined either using a four-point probe (60) or from a resistor pattern of known dimensions. The metallization thickness, t, is commonly measured by using multiple-beam interferometry (61) or a stylus-type surface profilometer (62). Values of ρ at room temperature are typically in the 2.7-3.0 $\mu\Omega$cm range for aluminum of 1μ thickness. This compares quite favorably with the value of 2.7 $\mu\Omega$cm for bulk aluminum. Unless very poor vacuum practices are followed, ρ is quite tolerant to the conditions of deposition. For example, for work done in our laboratory the ratio of total pressure, P, to deposition rate, R, was increased up to a value of about 3×10^{-6} Torr sec/Å in an oil diffusion-pumped vacuum chamber. This would correspond to deposition at a pressure of 3×10^{-4} Torr for a typical rate of 100 Å/sec. It might be anticipated that P/R would be a meaningful parameter as regards film properties since it is a measure of the relative impingement rates of impurities and evaporant. As indicated in Fig. 1, there is a substantial effect of P/R on grain size of the deposits. No correlation of ρ with P/R was observed, however, over the range shown in Fig. 1.

More precisely, the effect on ρ of the reactive gases oxygen and water vapor rather than total pressure should be considered. Table II lists minimum values of P/R which were found to result in increased ρ for a number of separate investigations. The relevant deposition parameters also appear including those relating to Fig. 1. In the latter case, the ratio between total pressure and partial pressure of water vapor during deposition was constant at about 30 (63), as indicated in Table II, and no significant effect on ρ was noted for $P(H_2O)/R$ up to 1×10^{-7} Torr sec/Å. In one study (64), the critical value of $P(H_2O)$ for water vapor was approximately 1×10^{-7} Torr sec/Å above which resistivity increased significantly. In another case (65), only the total pressure was monitored and the critical P/R indicated is in the range $0.5\text{-}5 \times 10^{-8}$ Torr sec/Å. The situation here should be similar to the case for Fig. 1 since filament evaporation was employed. This would imply, however, a greater sens-

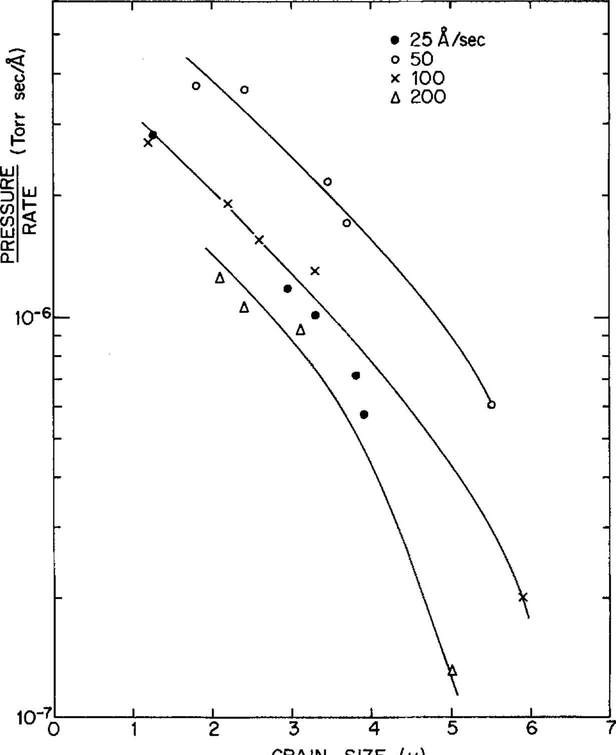

Fig. 1. Aluminum grain size resulting from deposition at different values of P/R and various rates.

Table II. Deposition parameters for various studies of aluminum film properties

Source	Thickness (μ)	Temperature (°C)	Deposition rate, R (Å/sec)	$P(H_2O)$* (Torr)	$P(O_2)$* (Torr)	P(total) (Torr)	Critical P/R (Torr sec/Å)	Reference
Inductively heated $BN \cdot TiB_2$	0.5	200	20	$\lesssim 3 \times 10^{-5}$ (M)	$1\text{-}2 \times 10^{-7}$ (C)		$0.5\text{-}1 \times 10^{-8}$ (O_2)	20
W-filament	1	350	100	$\lesssim 1 \times 10^{-5}$ (M)		$\lesssim 3 \times 10^{-4}$		63
Radiatively heated BN	2	~200	~10	$\sim 1 \times 10^{-6}$ (C)	$\sim 1 \times 10^{-7}$ (C)		1×10^{-7} (H_2O) 1×10^{-8} (O_2)	64
W-filament	1	Unheated	~200			$1\text{-}10 \times 10^{-6}$	$0.5\text{-}5 \times 10^{-8}$	65
W-filament		100					3×10^{-6} (O_2 ?)	66

* Critical (C) partial pressures or maximum (M) partial pressures investigated.

itivity of ρ to water vapor partial pressure. It is possible that the pressure monitored was not a true measure of pressure within the deposition chamber. Also the lower deposition temperature may increase sensitivity to water vapor because of an increased sticking coefficient. Consistent with this, an increase in the ratio of room temperature to low temperature resistivity with increasing deposition temperature has been noted (20). In a study (66) with filament evaporation purportedly concerning the effects of oxygen on ρ, it appears that total pressure was monitored. A critical P/R of 3×10^{-6} Torr sec/Å was found. Assuming the factor of 30 relating total pressure and water vapor partial pressure, the critical P/R would be 1×10^{-7} Torr sec/Å, as above.

Two studies (20, 64) where oxygen was the known residual gas led to a critical $P(O_2)/R$ of about 1×10^{-8} Torr sec/Å. Thus ρ is about one order of magnitude more sensitive to oxygen than to water vapor. This is a fortunate happenstance since water vapor is the primary residual gas in oil diffusion-pumped vacuum systems (63).

Geometrical size effects result in increased ρ for thin aluminum films. Substantial increase is found (65) only for films thinner than approximately 1000Å, even for single crystal aluminum (67). Standard metallization is normally thicker than 0.5μ, in order to provide sufficiently low sheet resistance, so that size effects are of little consequence.

Step coverage.—The completeness of the metallization coverage at steps or irregularities in the substrate is basically determined by geometrical considerations during the course of deposition. In the case of two sources, the metallization profile near vertical steps may be constructed by considering deposition of thin layers alternately from each source. Even when line of sight is possible from one source to each step, a discontinuity or microcrack will still occur (68). The deposit from each source shadows the deposit from the other source leading to a self-shadowing mechanism for crack formation.

The construction method has been generalized to a larger number of sources (68) and, in the limit, to a distributed or extended source (69, 70). The latter is somewhat analogous (70) to the case where there is substrate movement, such as planetary motion (71), during deposition. It is found (69, 70, 72) that cracks nevertheless occur with an extended source and that (*i*) the bottom edge contour determines the crack depth with the depth being inversely related to the radius of curvature; (*ii*) the top edge contour has little effect; and (*iii*) at an undercut step with a reentrant angle a crack pointing toward the bottom of the undercut portion occurs.

The most straightforward method of avoiding cracks is therefore to control the contour of the step to be covered by maintaining a positive slope and avoiding sharp corners. It has also been found that if the step profile is not too severe, heating of the substrate during deposition promotes improved coverage (18, 68). Such an effect is illustrated in Fig. 2 for aluminum deposition onto an undercut step. This type of step results when a composite layer of phosphorus-doped oxide on thermal oxide is etched because of the differing etch rates for the two materials (18). At the lower substrate temperatures, microcracks form with an increasing tendency to seal over the crack with increasing temperature. When a film of the latter type is etched, however, etchant can penetrate into the crack and a tunnel (64, 73), or complete removal of metallization at the step, results. The situation is probably aggravated by the strong capillary forces tending to draw etchant into the crack. Temperatures of approximately two-thirds the melting point temperature are required, or about 300°C for aluminum, to yield acceptable coverage [Fig. 2(c)].

Calculations have indicated that the use of vertical planetary platens and an eccentrically positioned source would minimize crack formation (74). It is not known, however, to what extent this has been verified experimentally. The application of negative bias to the substrate during deposition (75-77) to allow some resputtering has also been employed to obtain coverage on rather severe test steps. There is some question as to the role of substrate heating in this case (78). Calculations for a sputtering source (78) generally indicate the same propensity for crack formation as for evaporation sources.

It is interesting to note that the shadowing effect has been turned to advantage in certain cases. Geometrical shadowing was utilized in the fabrication of closely spaced (submicron) metallization (79, 80) on integrated circuits. Small-dimensioned metal grids were formed by deposition of a thin continuous overlayer on agglomerated films and subsequent etching of the agglomerated material (81). Contrast enhancement in electron microscope replicas is also achieved by shadowed deposition (82).

Bonding.—Aluminum wire, usually with small (~1%) silicon additions, may be readily bonded to aluminum metallization by ultrasonic means (83). In this way the surface of the metallization is scrubbed to break up native oxides and the two bonding surfaces are made to conform so that a strong bond results. The failure modes of such bonds have been investigated extensively (84). Generally their reliability is found to be excellent.

With thermocompression wedge or ball bonding (85) of gold wire to aluminum, the potential exists for reduced reliability because of possible intermetallic formation and concomitant void formation (1, 86-88). It was proposed that silicon has the effect of accelerating such interaction and that a black ternary product so formed (89) is more detrimental than the $AuAl_2$ intermetallic which is purple in color. This effect of silicon was corroborated (90) in another investigation. Recent work (91) has firmly established that reliable gold-aluminum bonds are also achievable.

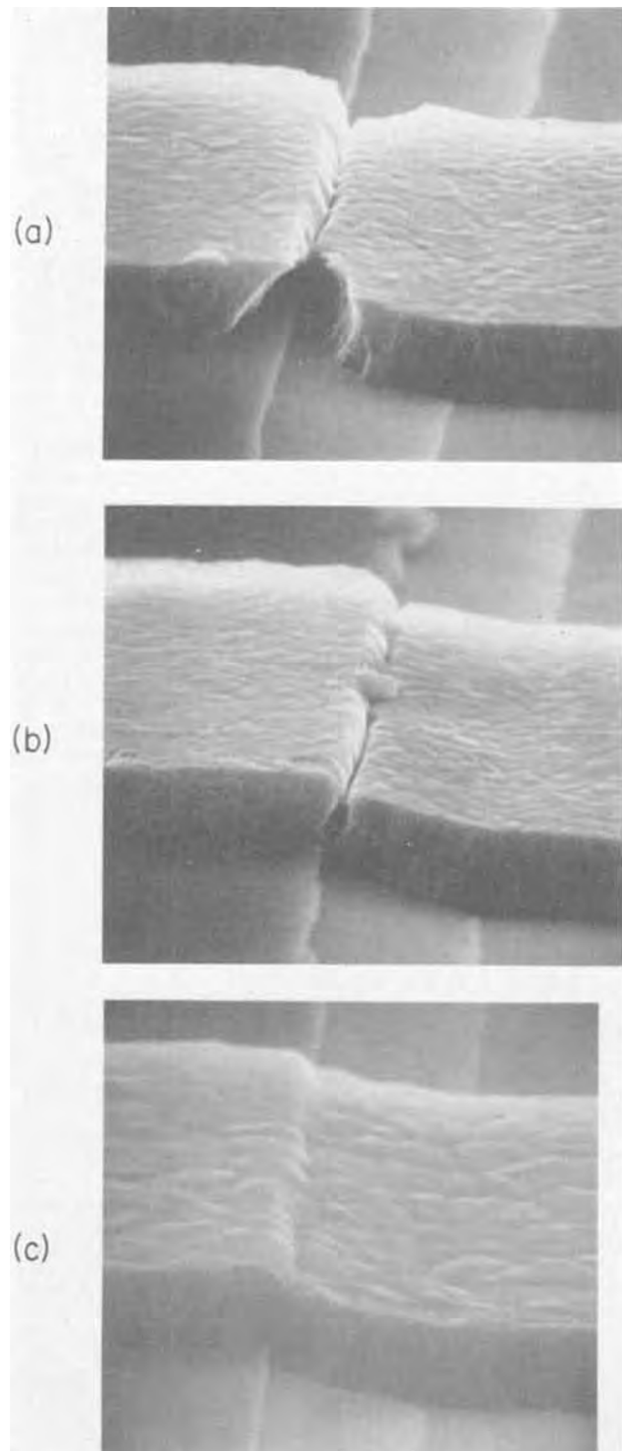

Fig. 2. Metallization coverage and tunnel formation at an undercut step as a function of deposition temperature; (a) 200°C, (b) 250°C, (c) 300°C.

Careful attention must, however, be accorded the amounts of each material available for intermetallic formation, the bonding and postbonding temperatures and the time at temperature.

Contact resistance.—When aluminum and n-type silicon having clean surfaces are brought into contact a Schottky barrier occurs (92) of height, ϕ_{Bn}, in the range of 0.68-0.76 eV (93-99). This ϕ_{Bn} is approximately two-thirds of the silicon forbidden gap, E_g, (100) and is thought to arise from the presence of acceptor states at the silicon surface which fix the Fermi level at the level of the surface states. For silicon, such states occur at an energy of 0.48 eV above the valence band edge (101). The situation is completely analogous for aluminum to p-type silicon contacts except that the barrier height, ϕ_{Bp}, is then $E_g - \phi_{Bn}$. Barrier heights of 0.94 eV (102) and 0.58 eV (103) have been measured, but it is not known to what extent the values were affected by silicon surface conditions.

The mechanism of current flow in a Schottky barrier depends on the width of the barrier, *i.e.*, on the dopant concentration, N. In the thermionic emission range, with dopant concentrations $\lesssim 10^{16}$ cm^{-3}, barrier width is relatively large and charge carriers must surmount the barrier in order to move between metal and semiconductor. For large dopant concentrations $\gtrsim 10^{19}$ cm^{-3}, barrier width is sufficiently small that quantum mechanical tunneling of charge carriers through the barrier, rather than emission over the barrier, becomes dominant.

The present interest is in metal-semiconductor contacts which exhibit ohmic characteristics. An ohmic contact shall be considered synonymous with a linear current-voltage characteristic. A figure of merit used to describe such contacts is the specific contact resistance (104)

$$R_c \equiv \left.\frac{dV}{dJ}\right]_{V=0} \quad [1]$$

If R_c is small then a contact can support a large current density, J, at low voltage, V.

In the thermionic emission range

$$R_c = \text{const.}\ e^{q\phi_B/kT} \quad [2]$$

where T is absolute temperature, q is the electronic charge and k is the Boltzmann constant. Note that ϕ_B and T determine the value of R_c and there is no dependence on N, as would be expected for emission over the barrier. In the tunneling range

$$R_c = \text{const.}\ e^{[1/N]^{1/2}} \quad [3]$$

and R_c is strongly dependent on N but approximately independent of T.

Calculation of R_c in the above ranges, as well as the intermediate one, has been performed (105-107). Experimental values of R_c for aluminum on n-type silicon are in substantial agreement with the calculated values, both in terms of functional behavior and absolute value (105-109). Somewhat more complete calculations (110), taking into account the penetration of charge carriers into the depletion layer, also yield results coinciding with experiment. Theoretical results are shown in Fig. 3 for [111] silicon and ϕ_B equal to 0.40 eV, presumably (111) characteristic of aluminum contacts to p-type silicon. An experimental curve of R_c for contact to p-type silicon (112) is also presented in Fig. 3. The values of R_c are those obtained subsequent to heat-treatment ("alloying") at 500°C for 10 min. There is substantial disparity between experimental and calculated values, particularly for smaller N. A probable explanation involves aluminum doping of the silicon as a consequence of heating. If N were increased by about 1×10^{19} cm^{-3} in this way, the experimental values would coincide more closely with calculation. The solid solubility of aluminum in silicon at 500°C could be of this order of magnitude (113). A similar result regarding doping level is inferred (114) from heat-treatment experiments at 550°C. On [100] rather than [111] silicon, R_c should be reduced by about one-half (107). It is unlikely that this difference could be readily detected experimentally.

An additional application of the Schottky barrier, other than providing ohmic contact, utilizes the diode properties which arise for contact to lightly doped silicon (104, 115). In particular, such a diode is used in parallel with the collector-base junction of n-p-n transistors in saturated logic circuits to increase switching speed. Ideally, this can be implemented by

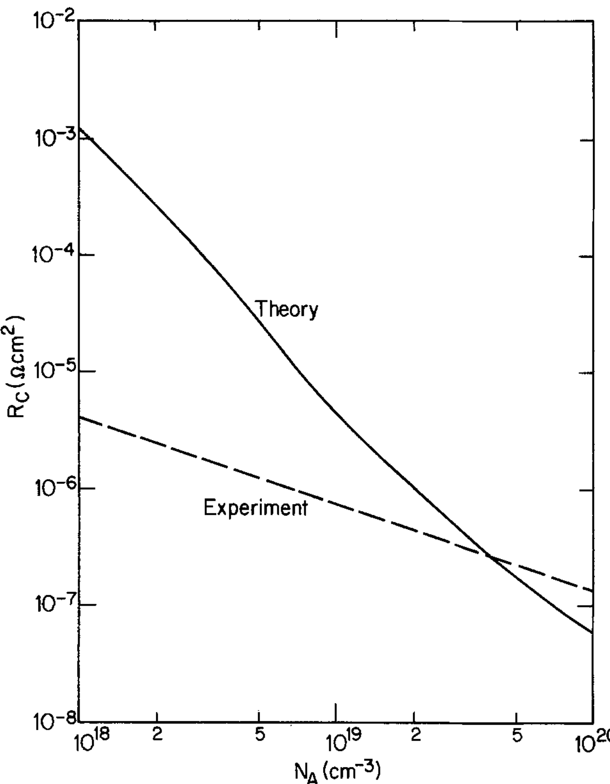

Fig. 3. Specific contact resistance as a function of acceptor concentration. Solid line: theoretical; dotted line: experimental results for contact to p-type silicon following heat-treatment at 500°C for 10 min.

depositing aluminum over the region where the collector-base junction intersects the silicon surface. Such an approach is possible because the aluminum can form ohmic contact to the p-type base and rectifying contact to the n-type collector as discussed above.

Problems were encountered with this simple structure related to effects at the edges of the contact cut in the oxide (104) or to variable ϕ_B upon "alloying" the Schottky diode (96, 97). The latter has been attributed to dissolution and reprecipitation of aluminum-doped silicon in the form of islands or a continuous layer at the metal-silicon interface (97, 99). In order to prevent the silicon dissolution or interaction during "alloying," platinum silicide can be formed in contact areas prior to aluminum metallization (116). The barrier heights ϕ_{Bn} and ϕ_{Bp} for platinum silicide on silicon (116-118) are about 0.15 eV higher and lower, respectively, than for aluminum so that contact properties are similar to those discussed earlier. An additional problem with the platinum silicide-aluminum structure arises as a consequence of an aluminum-platinum intermetallic formation leading to unstable ϕ_B (119, 120). This logically suggests incorporation of a diffusion barrier, such as tungsten (121, 124), between the silicide and aluminum to allow attainment of a stable Schottky diode.

Contact stability.—Postmetallization processing such as "alloying," deposition of a scratch protection layer, assembly, and packaging will typically involve temperatures higher than the metallization deposition temperature. During such periods, after breakup of residual oxide at contacts, interdiffusion of the aluminum and silicon will occur. The problem of increased junction leakage or shorting as a consequence of the aluminum-silicon interaction was recognized and the mechanism was elucidated (9). Basically, silicon is dissolved in the aluminum up to the solid solubility limit at a given temperature, e.g., 0.8% at 500°C. Silicon subsequently diffuses out into the aluminum interconnection (125) thus resulting in additional silicon dissolution at the contact. Consistent with this is the frequent observation that the most pronounced dissolution occurs where the aluminum leads out of the contact (126), *i.e.*, where there is an aluminum sink. At the same time, aluminum diffuses into the silicon or along the silicon-silicon dioxide interface. As shown in Fig. 4, this results in the growth of spikes or shallow spears in these two areas (127-130) for [100] and [111] oriented silicon, respectively. If the process continues for a sufficient period of time, junctions will be shorted by the spikes growing through them or covering them where they intersect the silicon surface. The silicon dissolution in the metallization is further evidenced by enhanced recrystallization of the aluminum and by the presence of silicon precipitates remaining after removal of the aluminum (131).

Junction shorting can be avoided by limiting the temperature and duration of postmetallization processing, but in some cases this is not a feasible approach. In particular, with the advent of shallow junctions, such as occur in devices for emitter coupled logic circuits (132), another solution is required. Three methods have been used to minimize silicon dissolution.

Just as with Schottky diodes, a diffusion-barrier layer such as titanium (133) or nichrome (134) can be interposed between the silicon and aluminum. Consideration must then be given the possible interaction of this material with either or both the aluminum and

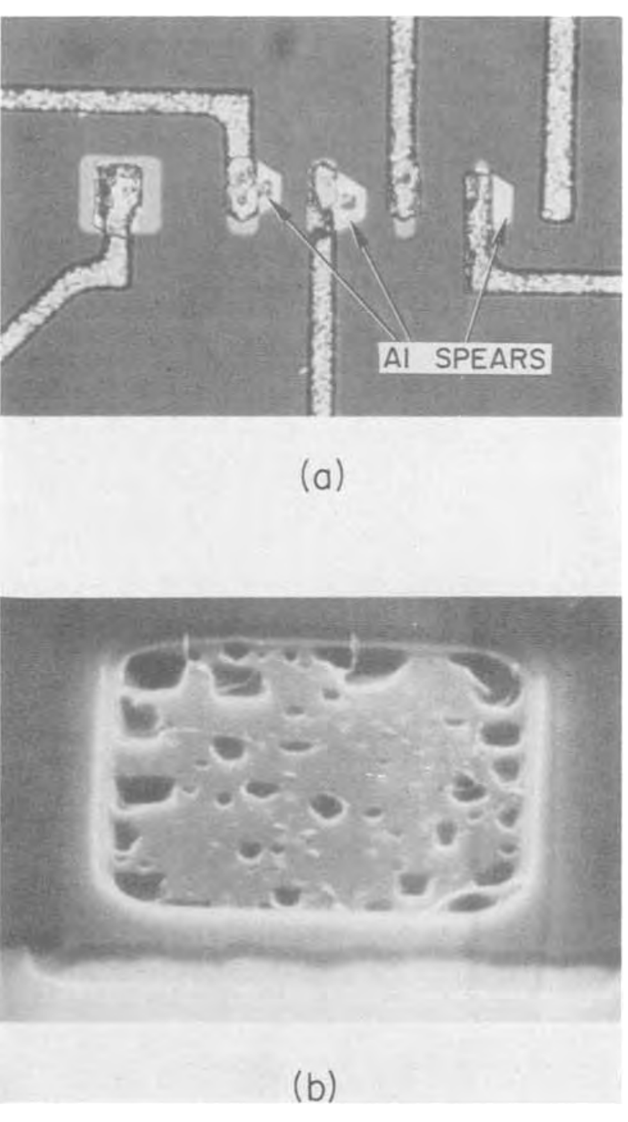

Fig. 4. Structures resulting from overextended heat-treatment of aluminum-silicon contacts; (a) [111] silicon and (b) [100] silicon after metallization removal.

silicon and the contact resistance. As regards the latter, platinum silicide can be utilized. Some care must be exercised in avoiding degradation during the platinum deposition (usually by sputtering) and the sintering to form the silicide. The over-all consequence is, in any case, that a fairly complex structure with more difficult processing results. It should be noted that such a structure is normally present if platinum silicide Schottky diodes are used in the integrated circuits.

Alternatively, a layer of silicon can be deposited prior to the aluminum. The thickness of the silicon film is chosen such that the solid solubility limit is satisfied when the film is fully dissolved in the aluminum (135, 136). For a temperature of 500°C, where the solid solubility is about 0.8 atomic per cent (a/o) and for an aluminum thickness of 1μ, the silicon thickness required is approximately 90Å. The silicon thickness, although typically small and difficult to control, is quite critical. If it is too large, then not all of the silicon will be dissolved and R_c may be increased. If it is too small, the silicon will not fully perform the intended function.

The solid solubility limit can also be satisfied by adding silicon to the aluminum during the course of the metallization deposition (9). As discussed in connection with deposition methods, aluminum-silicon alloy metallization of this type can be prepared by simultaneous evaporation of aluminum and silicon from separate sources, by flash evaporation or sputtering.

Electromigration.—For polycrystalline aluminum metallization it has been fairly conclusively established that diffusion occurs primarily in grain boundaries (137). Evidence indicates that as for bulk material (138) a vacancy mechanism is still relevant, at least for copper (139) and silver (140). Consequently, certain grain boundary structures can lead to localized accumulation or depletion of material during electromigration. Examples of such structures are grain boundary triple points (141), with other than 120° angles, and contiguous clusters of large and small grains (142). The net effect of electromigration in an aluminum film is to produce voided areas and hillocks more or less uniformly distributed along the length of the film. If temperature gradients exist in the direction of electron flow, then voids will form in the region of increasing temperature and material accumulation will occur in the region of decreasing temperature (143). Also, at contacts, depletion or accumulation can occur because of the differing diffusion coefficients for silicon and aluminum (144). The depletion of metallization where electrons flow from a contact and the accumulation in the form of whiskers where there is electron flow into a contact are illustrated in Fig. 5.

Of most practical importance is the lifetime, τ, before electrical opens occur in interconnections or before electrical contact is lost to silicon. As regards interconnections, it has been assumed (145) that τ is inversely proportional to the electromigration flux and directly proportional to the conductor cross-sectional area, wt, because of the need to remove a certain volume of material before a void reaches across the entire interconnection width. This would imply that

$$\tau = \text{const.} \frac{tw}{J} e^{E_a/kT} \qquad [4]$$

where J is the current density and E_a is the activation energy for self-diffusion. There has been some discussion as to whether a J^{-1} or J^{-2} dependence should result (146, 147). Another treatment of the electromigration-induced failure time indicates (148) a J^{-n} dependence where n is 1 with diffusion gradients present, *e.g.*, at contacts, and is 3 with temperature gradients present. Other treatments (149-151) considering self-heating lead to the result that n should increase, with increased J, from a value of 1 to large values on the order of 10. It has also been suggested (152-153) that current crowding effects are more important than such self-heating. An attempt to unify the dependence on geometrical parameters through a more basic consideration of grain size and grain size distribution leads to (154) approximately the dependency on w appearing above, an $e^{\text{const}/L}$ dependence on interconnection length, L, and an approximately linear dependence on grain size. The length dependence arises because there is a higher probability of finding weak spots, *i.e.*, more severe grain boundary inhomogeneities, for depletion of material with increased length. Similar consideration was given grain characteristics in a discussion of electromigration at rectangular contacts (155). An expression for τ in this case is

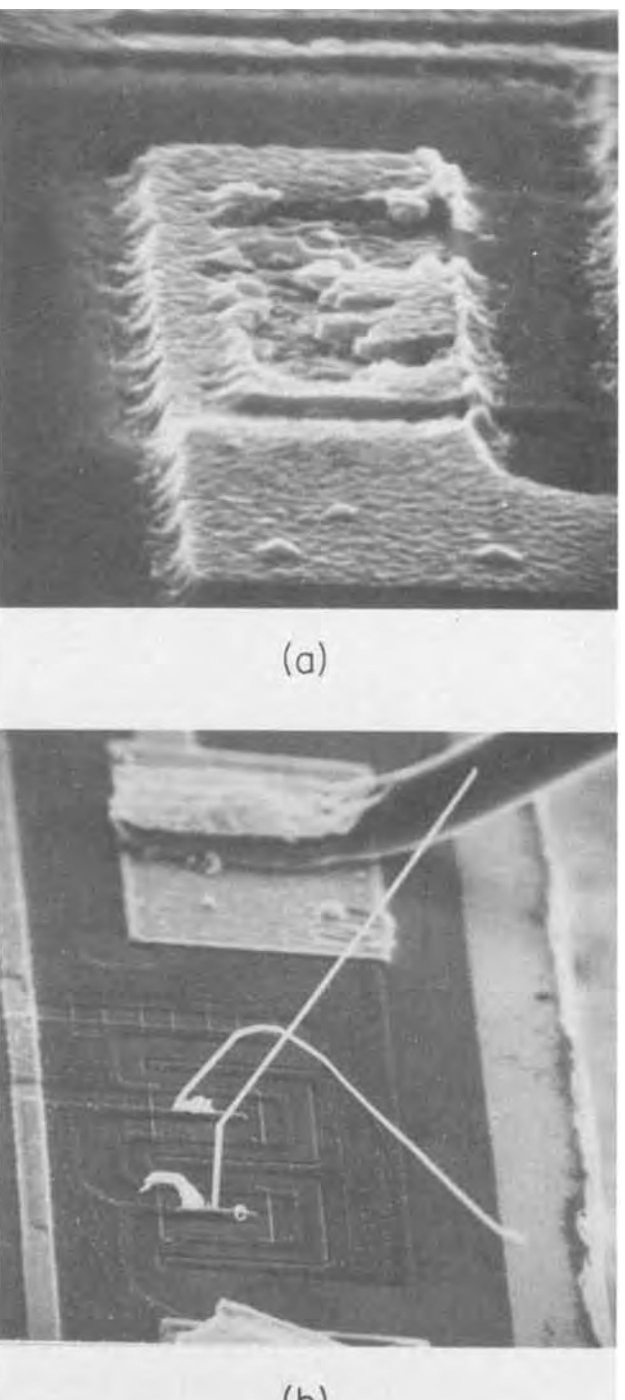

Fig. 5. Electromigration effects at contacts to silicon for electron flow from the contact (a) and electron flow into the contact (b).

$$\tau_c = \text{const.}\, \frac{tw'}{J'}\, e^{E_a/kT}\, e^{\text{const.}/l} \qquad [5]$$

where w' is the contact dimension parallel to electron flow from the contact, l is the other contact dimension, and J' is the average current density over the contact area.

The general features of expressions [4] and [5] are supported by experimental studies. The methods of examination and the potential pitfalls associated with lifetesting and the use of data so generated, in particular, have been thoroughly discussed (156). The early results served primarily to establish the consequences of electromigration in thin films (157-163). A vast store of more quantitative data has been accumulated for aluminum interconnections, in particular. In this case, an exponential dependence on temperature is generally observed. The values of E_a found are listed in Table III. Many values of E_a were obtained by lifetesting (142, 144, 164-168). Measurement of transported volumes (141, 169-172) and resistance changes (173, 174) were also used and resultant E_a values are included. There is considerable spread in the values obtained by different investigators. The generally low values of E_a are, however, consistent with grain boundary diffusion. In addition, it appears that values, within a given study, are less for aluminum having smaller grain size (142, 144, 167) and significantly large for very large grain size (172). Values of n (144, 165, 167, 175-177) also appear in Table III. Again, the values exhibit a wide range from 2 to 7. Probably a value of about 2 for n is most commonly observed and therefore generally used in estimating τ. The dependence on interconnection cross-sectional area is approximately supported by an experimental study (144). More specifically, a linear dependence on w has been observed (178). Decreased τ with increased L was observed in two instances (178, 179). In one case (178), the functional dependence was well represented by $e^{\text{const.}/L}$. Other investigations, primarily involving measurement of mass transport, have yielded specific values for diffusivity (141, 169, 171, 180, 181). A Berg-Barrett x-ray topographic technique has also been employed for this purpose (182).

Data are much sparser for electromigration failure at contacts to silicon. The phenomenon has frequently been observed but generally only in a qualitative manner (183-185). In the one exceptional case (186), quantitative lifetime measurements resulted in essentially expression [5] for τ_c.

The use of expressions such as [4] and [5] to assess lifetimes under typical operating conditions can sometimes reveal marginal values at best. This is particularly true for aluminum-silicon metallization, in large part due to a low value of E_a for such material (165, 187). Consideration must therefore be given techniques for extending lifetime. It may be recalled that certain phenomena are necessary to electromigration-induced failure in aluminum. Self-diffusion, via a vacancy mechanism, and grain boundary structures are involved. Vacancies are also necessary in sufficient concentration to allow void formation and growth (188-191).

The relative effect of grain boundaries may be reduced by increasing grain size since this reduces the grain boundary volume per unit cross-sectional area of the conductor. It has already been noted that this results in increased E_a and, therefore, increased τ. If carried to the extreme where no grain boundaries are present, *i.e.*, with a single crystal film, unlimited τ is exhibited (192). At the other extreme where grain size is much less than metallization thickness, increased τ is also observed (193). It appears that this is a consequence of the multiplicity of diffusion paths through the film thickness rather than any reduction in electrotransport rate. A minimum in τ for intermediate grain size has been predicted (194). The increased τ observed (195) for low rates of deposition may be explained in this way in light of Fig. 1. The improvement in τ obtained through incorporation of aluminum oxide (196) may also be partially attributable to a very small grain size. In another case (197), incorporation of increased amounts of residual gases (presumably actually meaning Al_2O_3) reduced τ which may again be related to decreased grain size.

A second approach is designed to limit the vacancy density and thus inhibit diffusion and void formation. Use of a tightly adherent overcoat to seal the metallization surface and eliminate this source of vacancies is suggested. Somewhat contradictory results have been obtained with silicon dioxide layers deposited by chemical vapor deposition (144, 175). In cases where τ was increased, some of the improvement may be attributable to grain growth (176) during oxide deposition and hence the dependence on grain size discussed above. Using anodization at room temperature to provide an alumina overcoat resulted in improved lifetime (167, 179). The increases in τ were interpretable on the basis of E_a increases of up to 0.15 eV. It is of interest that periodic oxidation of aluminum under electrical stress also prolonged τ (198). Increases in τ as a consequence of dielectric overcoating have also been interpreted as a consequence of pressure-inhibiting effects on diffusion (199).

Another approach involves the addition of small concentrations of metals to aluminum which can segregate to grain boundaries and inhibit diffusion of solvent atoms (166, 200). Very substantial increases in τ were attained through copper (166, 201-205), nickel (206), magnesium (206-209), chromium (206, 210), or titanium (211) additions. It appears that copper has won the most widespread application for this purpose. Difficulties can arise using the other additives. For example, for magnesium, low temperature reactions with silicon dioxide and resistivity increases render such metallization less useful (208). Resistivity increases are also quite substantial with chromium additions (210). Ternary and quaternary alloy metallizations such as aluminum-copper-magnesium and aluminum-copper-nickel-magnesium have also been investigated (212). Lifetime improvements, however, would not appear to be sufficiently greater than with copper to merit full consideration, particularly in view of side effects such as those with magnesium. As with pure aluminum, many qualitative studies of the effects of electromigration in aluminum-copper have been performed. It is found that the copper is a more rapid diffuser and that failure frequently occurs in regions depleted of copper (166, 202, 213, 214). The film struc-

* Thickness dependent.

ture per se and distribution of second-phase precipitates are also found to be important (166, 203, 205, 214-217). Increases in E_a up to approximately 0.3 eV have been measured (166) for aluminum-copper metallization and these are sufficient to account for the increased τ. Values of the exponent n in the range of 2 to 3 were determined (201, 202). Lifetime is found to reach a minimum when the film width is about twice the grain size (218). For larger ratios of width-to-grain size, τ varies approximately linearly with w. Other fundamental quantities such as copper ion velocity (219) or effective charge and diffusivity parameter for copper (220-224) were also measured for aluminum-copper. The addition of copper to aluminum-silicon metallization results (187) in τ increases comparable to those with aluminum-copper. Consequently, the use of aluminum-copper-silicon metallization simultaneously protects against junction shorting and premature electromigration-induced failure.

Multilevel capability.—In order to exploit fully the sophisticated device structures and processing which have resulted in substantial reductions in device size, it is frequently necessary to employ at least two levels of metallization (225). The two levels are in contact through vias in the insulator which electrically isolates the levels in all other regions. Several dielectrics have been utilized including anodized aluminum (226), silicon nitride (227), sputtered quartz (228, 229), and polyimide (230). By far, the most widely used (231) is a phosphosilicate glass ($SiO_2 \cdot P_2O_5$) obtained by the simultaneous oxidation of silane and phosphine (232, 233) at temperatures in the vicinity of 400°C The addition of phosphorus serves to reduce stress and to yield a more compatible thermal expansion coefficient (175, 234), both of which aid in limiting cracking or crazing of such layers.

The presence of a second level of metallization requires careful attention to the vias and to crossover areas for the two levels. The via must be free of foreign layers and relatively free of oxide in order to achieve intimate contact between metallization levels and yield acceptably low resistance (235). As with contact to silicon, some small thickness of silicon dioxide can be reduced by heating. With proper processing of vias, a specific via resistance of less than 1×10^{-7} Ωcm^2 is readily obtained.

The electrical integrity of the insulator at metallization crossovers is determined primarily by the uniformity of the coverage of edges or irregularities, such as hillocks, occurring in the first level of metallization. Deposited phosphosilicate glass tends to grow preferentially at sharp corners and nodule formation can result (18, 175, 236). Nodules formed over hillocks are difficult to cover with photoresist and may therefore be removed during via etching. In addition, such nodules may be broken off when a mask is brought into contact with wafers. In either case, the net result is shorting between levels when the second level of metallization is deposited. The occurrence of nodular growth at metallization edges both thins the insulator along the vertical surface and renders more difficult the deposition of continuous second-level metallization. The problems associated with edges can be avoided by slope etching of the first level. Insulator coverage is then of reasonably uniform thickness. It is also desirable to slope etch the vias (237-239) thereby promoting better second-level metallization coverage at the vias. The phenomenon of hillock growth bears some analogy to electromigration in that both involve movement of material by diffusion. The driving force in hillock growth is compressive stress (240, 241) rather than forces exerted by charge carriers, as in electromigration. Consistent with this analogy, it is found that those approaches leading to increased lifetime are also applicable to limiting hillock growth. The density of annealing hillocks in aluminum is reduced for larger grained films (242-243). In addition, anodization (243) or copper (244, 245) and other (246) additions were demonstrated to be very effective in minimizing hillock growth. It is of interest that no electromigration effects were noted with second-level metallization present which were not predictable on the basis of measurements with a single level of metallization (229).

Oxidation and corrosion.—The oxidation of aluminum is normally a self-limiting process and is therefore not a cause for concern. For example, in room temperature air the maximum oxide thickness formed is less than 50Å (247). Moreover, in a water-free ambient, corrosion of aluminum is not observed. Consequently, corrosion of aluminum metallization on silicon devices placed in hermetically sealed packages is virtually nonexistent. In plastic encapsulation which water vapor can penetrate, however, corrosion of an electrochemical nature is frequently prevalent (248).

In addition to water vapor, an impurity which will combine with the water to form an electrolyte is required. Finally, an electric field larger than some threshold value is necessary between adjacent conductors. A common impurity, in the above sense (249), which is frequently present is phosphorus or phosphorus oxide. This can arise from a scratch-protection layer over the metallization, from the insulating layer between two levels of metallization, or from films under the metallization, such as are formed in silicon dioxide masking layers during phosphorus diffusion. Corrosion in this type of environment has been thoroughly investigated (250) and it is found that the corrosion rate is increased with increased relative humidity, phosphorus content, electric field, and temperature. Rather than failure at the anode, as with ordinary anodic dissolution, it occurs initially at the cathode. This is a consequence of the formation of aluminum hydroxide. Other impurities such as chlorine or sodium (251) have been demonstrated to cause similar corrosion effects. The corrosion rate for aluminum-alloy metallization is found to be no greater than that of pure aluminum (252). Such behavior is entirely unexpected on the basis of results for bulk specimens (253) of aluminum-copper or aluminum-copper-silicon. Since it has been observed (254) that corrosion of aluminum metallization occurs preferentially at grain boundaries, the improved corrosion properties of the alloys, as for electromigration, may be related to the altered structure of the boundaries.

Summary and Conclusions

The properties of aluminum as they relate to the requirements for metallization on silicon devices were discussed. It was found that in most instances there is a suitable match between properties and requirements. In those cases where it is an aid to the full understanding of a property, suitable physical models exist. Examples of such properties are adherence, step coverage, and contact resistance.

Pure aluminum was found lacking in some aspects of contact stability, electromigration resistance, multilevel capability, and corrosion resistance. Although more than one alternative is available to improve performance in the first three areas, the use of aluminum alloy metallization is beneficial for all. The conversion from aluminum to aluminum-copper or aluminum-copper-silicon metallization involves little change in processing or design. Versatile deposition methods, such as flash evaporation, are available which are equally simple for aluminum or aluminum alloys. In addition, the adherence, etching, step coverage, bonding, and contact resistance properties for the above alloys remain essentially the same as for aluminum while resistivity is increased only about 15%. Care must be exercised in postmetallization heat-treatments because of the reduced eutectic temperatures of the

alloys (255). With one possible exception, it may therefore be stated that the employment of aluminum alloy metallization has allowed the requirements for metallization on silicon to be met and has greatly extended the usefulness of a basically aluminum process.

The most notable area in which additional work remains to be done is in providing more effective corrosion protection for aluminum metallization. The solution may again lie in the use of aluminum alloys. For example, it is known that the corrosion resistance of aluminum-chromium alloys is superior (256) to that of aluminum, at least in bulk form. Alternatively, a satisfactory approach may involve the use of hermetic deposited overlayers such as silicon nitride, aluminum oxide, or a combination of nitride and aluminum oxide (257). Low temperature deposition processes for silicon nitride and aluminum oxide are being investigated and characterized (258-262). It appears highly probable that a suitable solution will be forthcoming and that aluminum metallization will long remain the standard of the semiconductor integrated circuit industry.

Finally, it may be noted that, as in other semiconductor processing steps, the move toward more complete automation of metallization would be highly desirable. Among the deposition methods included in Table I, sputtering is perhaps most amenable to such an approach. As mentioned earlier, new sputtering techniques (35-37) are being investigated in order to increase deposition rates and minimize radiation damage. It is hoped that these types of development will continue and will be expanded in scope and effort. Complete characterization of the metallization obtained by the various deposition methods must, in any case, be performed. This becomes necessary since many properties are structure sensitive and structure is in turn dependent on the details of the deposition process.

Acknowledgments

The author wishes to thank Dr. Bruce E. Deal for his encouragement in the organization of material for and writing of this review.

Manuscript submitted Dec. 9, 1975; revised manuscript received Jan. 28, 1976. This was Paper 190 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Fairchild Camera and Instrument Corporation.

The Growth of Uniform Submicron GaAs Layers by Liquid Phase Epitaxy

Hadis Morkoc and L. F. Eastman

School of Electrical Engineering, Cornell University, Ithaca, New York 14853

ABSTRACT

Very close agreement between theory and experiment in the growth of submicron layers has been achieved. Difficulties in obtaining uniform wetting have been overcome by growing a porous and amorphous oxide layer on the substrate and stripping it off in 50% aqueous HCl immediately before it is loaded into the reactor. By the introduction of a source-seed crystal, precise saturation of the melt has been obtained. It has been observed that slow growth rates (800 Å/min) and lower growth temperatures yield nearly featureless FET layers.

Early successful use of liquid phase epitaxy (LPE) in the preparation of GaAs laser diodes stimulated a very intense research program to provide a wide variety of microwave and optical materials and devices. Since the original application of LPE to compound semiconductor technology using a tilting boat by Nelson (1), dipping and slider boats have been developed to generate material for high performance devices. In particular, the bottom-of-the-melt method in which the growth is initiated from the bottom and the melt is saturated from the top surface has met stringent tolerances required by state-of-the-art devices. This technique has been widely applied specifically to generate materials for such complete and complicated devices as Read structures, double heterostructure lasers, Gunn logic devices, and microwave field effect transistors.

Small and Barnes (2) reported on the diffusion-limited LPE growth model and on the solution of the diffusion equation involved for a set of simplified boundary conditions. Later, Crossley and Small (3) presented a numerical calculation method to compute the precise As profile, with somewhat more accurate boundary conditions at the growth interface, which advances into the solution as the growth progresses. Minden (4) reported on a closed form solution of the diffusion equation with the semi-infinite melt approximation. Finally, Rode (5) gave a series solution of the LPE diffusion in a bounded melt including the temperature dependence of the diffusion coefficient of As in a Ga solution.

Little is present in the literature concerning the LPE growth of the submicron layers required for microwave FET's. It is therefore the intention of this paper to discuss the particular difficulties involved in the growth of such layers by LPE. The dominant problems associated with submicron-thick epitaxial layers are thickness uniformity and reproducibility, which are common to both LPE and vapor phase epitaxy (VPE) techniques. We will show that in the case of LPE these problems are predominantly caused by nonuniform wetting, which can be overcome by techniques to be described. Nonsimultaneous wetting, in the very beginning moments of growth, which is, in general, caused by a residual or deposited oxide layer on the surface of the substrate, results in nonuniform layer thickness. In our experiments oxide layer formation is prevented by making the system vacuum tight and limiting the water vapor content in the reactor. Any native oxide and surface impurities present are imbedded in an intentionally grown porous oxide layer and are removed when it is stripped off with 50% aqueous HCl. Stripping just prior to placing the substrate into the boat allows us to start with an oxide-free surface. A source-seed crystal is located on the slider forward of the main substrate to assure precise saturation of the melt; only such saturation

* Key words: liquid phase epitaxy, submicron, GaAs.

permits a uniform growth rate over the total surface of the substrate. By following the above techniques, submicron FET layers can be grown by LPE with as good thickness uniformity as by VPE and with significantly better reproducibility. Wetting, thickness control, reproducibility, and the surface morphology will be discussed in detail in following sections. In addition, the predictions of computer calculations which include a temperature dependent As diffusion coefficient will be compared with experimental results.

The System

The reactor consists of a horizontal sliding boat inside a 64 mm OD quartz tube heated by a three-zone resistive furnace. The fused quartz tube is cleaned in aqua regia approximately every 50 runs in a negative pressure tube cleaning hood (Air Control, Incorporated, Norristown, Pennsylvania). Hydrogen is purified by passing it through a Matheson Model 8361 Pd diffuser. The high purity hydrogen is introduced into the vacuum-tight reactor via high purity stainless tubing and fittings. On the output end, the hydrogen passes through a Panametrics Al_2O_3 water vapor sensor to monitor quartz dissociation and any leaks. The exhaust end is located in a laminar flow loading station where positive pressure is maintained to eliminate particle migration from the room into the reactor during loading and unloading. The reactor is purged with high purity gaseous nitrogen before and after loading to prevent explosive gas mixtures. In addition, the gaseous nitrogen flow was maintained during loading to inhibit particle diffusion into the reactor. Before the first growth attempt made, the fused quartz reactor is baked at an elevated temperature, such as 1000°C for 5-6 hr before the graphite boat is inserted. This boat has previously been outgassed at 1400°C in a vacuum chamber with an rf induction heater down to 10^{-7} Torr. A second bakeout at 850°C in hydrogen atmosphere with the boat wells filled with Ga lasts 10 hr and in the end this Ga is discarded. Skipping the outgassing step and the last bakeout causes a 10^{17} cm^{-3} impurity level, particularly for a freshly fabricated boat.

Figure 1 is a 3-D diagram of the graphite boat used in the experiment. The slider boat setup has been chosen because the only objective of this work was to grow material for high performance devices. It is similar to that described by Rode (5) except that the body of this boat consists of two pieces held together with precision graphite pins, with the upper part resting on the slider with the force of gravity. This configuration allows practically negligible clearance between the bottom surface of the upper half and the substrate. The resultant wiping action upon removal of the substrate after growth eliminates localized GaAs deposition from Ga-rich melt droplets on the grown layers. This feature is of great importance in obtaining uniform thicknesses and a sharp, flat interface between successive layers, in the case where a buffer layer is to be grown.

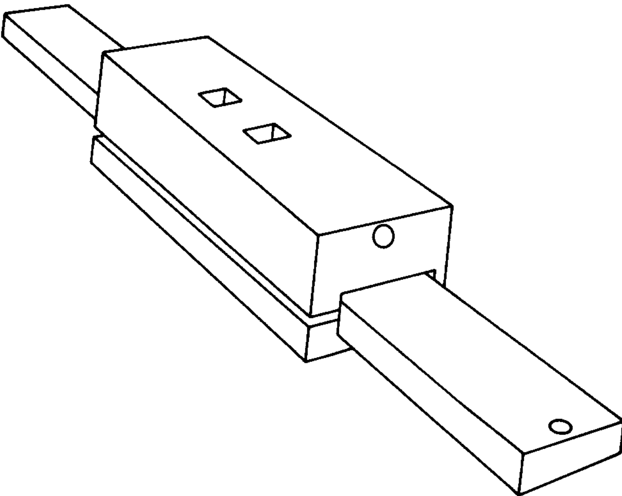

Fig. 1. Diagram of the double-bin gravity-type boat. The area of wells is 1 × 1 cm, the height is 15 mm, the spacing between the wells is 20 mm, the wall thickness at the wells is 15 mm.

A hydrogen flow rate of 600 cm^3/min (quartz tube bore is 60 mm ID) has been found to be the minimum adequate level for uniform wetting and has been standardized upon. Measured water vapor content is less than 0.2 ppm when the furnace is hot. The furnace (Lindberg Model 54357) has three separately controlled zones which keep the temperature uniform within ±1°C over a length of 50 cm.

Substrate Qualification and Preparation

The substrate material has been obtained from three different suppliers within the United States (Laser Diode, Crystal Specialties, and Texas Materials). Both (100) and 3° off (100) toward (110) oriented Cr-doped substrates have been used and our experiments with submicron and 5-10μ thick layers showed no apparent disadvantage of using 3° off (100) substrates (made available to us by Wright Patterson Air Force Base Laboratories, Ohio). A small piece from each shipment is subjected to a qualification process similar to that described by Barrera (6) with the aid of evaporated Al Schottky barriers. Since there are very few qualifiable Cr-doped substrates available, work on growing a 5μ thick buffer layer underneath the active layer is already underway. To date, we have achieved high purity layers with repeatable levels of mobility of 170,000 cm^2/V-sec at liquid nitrogen temperature and a total ionized impurity density of 1.9×10^{14} cm^{-3}, with a net donor density of less than 1×10^{14} cm^{-3}; the details of this project will be reported elsewhere.

In processing microwave FET's, the pattern geometry is created by electron beam lithographic or photolithographic exposure techniques. In any case, it is necessary to have an extremely flat surface to be able to achieve sharp geometry and high yield. This in a sense puts strong requirements on the preparation of the substrates. We should therefore examine the details of substrate preparation in light of two main requirements: cleanliness and planar surface achievement.

To obtain a planar layer requires an initial planar substrate surface because any corrugations on the substrate are closely replicated on the epilayer. The substrate thickness uniformity should also be within reasonable tolerances. Thus the polishing and etching techniques should be optimized to result in flat and parallel surfaces.

To achieve a flat surface, we removed the saw damage by lapping on both sides with 5 μm grit and then mechanical-chemical polishing both sides down to 250μ final thickness. The pressure and chemical flow rate during polishing are adjusted to obtain the best resulting surface. The chemical etch before the substrate is loaded into the reactor is done in H_2SO_4:H_2O_2:H_2O (5:1:1) at room temperature for 4 min; note that H_2SO_4 must be added slowly to prevent boiling, and thus turbulence in the liquid, which may be responsible for corrugations on the substrate surface.

Wetting

As stressed earlier, wetting is the single most dominant factor in achieving uniform submicron epitaxial layers. Once simultaneous wetting on the surface is achieved, it is then only a question of parameter selection and control (growth rate, growth temperature, and saturation technique) to accomplish not only a repeatable thickness but also close agreement with the predicted thickness values from the diffusion-limited growth theory we have mentioned. Any irregularities in the wetting during the early part of the growth will have a magnified effect in the thick-

ness, because the locally wetted areas of the melt will be deficient in As concentration relative to the non-wetted areas (where deposition does not take place). This in turn allows a relatively longer growth time and larger growth rate on the nucleation centers, with a transverse surface diffusion of As to the deposition sites near the interface.

Barrera (7) has indicated that he achieved better wetting when the reactor was leak tight. He also urged that high hydrogen flow rates improve the wetting. He then concluded that in a leaky reactor, oxide deposition on the substrate surface prior to epilayer deposition has the prime responsibility in preventing uniform wetting. Clearly, higher hydrogen flow rates reduce the amount of oxygen in the reactor, among other benefits. One then concludes that the oxide deposition must be avoided by vacuum sealing the reactor. The second important aspect related to the oxide layer is that the native oxide and the remaining organic impurities should be removed from the surface of the substrate. The etch in 5:1:1 for 4 min removes approximately 5μ of material from each side to assure that minor work damage from polishing is eliminated. We have observed that this etch leaves a thin oxide layer (about 30-50Å) and does not remove some organic based impurities. Experiments at 735°, 750°, and 780°C have been carried out to investigate the initial growth phase and the degree of wetting. Shown in Fig. 2 is a layer grown at 735°C on a substrate which had undergone a standard cleaning process. Supercooling of 1/4°C was applied to initiate a downward temperature ramp and the substrate was quickly slid under the melt, being kept there for 5 sec while the slope of the ramp cooling was maintained at 1 °C/min. It is clear that the growth was only initiated on small islands; moreover, this photograph is of the region of highest density of these nucleation centers. There was no growth at all on most of the substrate. Similar experiments (at 750° and 780°C) indicated that the wetting becomes better as the growth temperature increases. This indicates that the residual oxide layer is removed during the relatively high temperature bakeout period and the transverse expansion of the nucleation centers is aided by the faster growth rate.

Shaw (8) has found that an oxide layer on Ga and GaAs remains below approximately 700°-750°C and disappears above this critical temperature, in strong agreement with our observations.

Dawson (9) mentioned that his substrates were cleaned in HCl without giving any particular reason. Spitzer *et al.* (10) and Rode *et al.* (11) reported that aqueous HCl is used to remove the oxide layer after it has been grown by anodic oxidation and, especially in the former paper, it is pointed out that HCl would not remove the oxide layer after it had gone through a heat-treatment in dry nitrogen atmosphere. Cho (12) has also indicated that employing a combination of amorphous oxide layer growth followed by removal in aqueous HCl helps achieve flatter layers. Schwartz (13) presented the results he achieved concerning the oxidation of GaAs and GaP during various types of chemical etching. For instance, on a (100) surface he found that in room temperature water Ga_2O_3, and in warm water (60°C) GaO, growth takes place.

In light of all this background, we began to look into improving the technique of removing oxide layers (including the native oxide) during the preparation phase. We have found that the best results are achieved by growing an approximately 150Å amorphous and porous oxide layer in room temperature DI water for 20 min. The thickness of such an oxide layer has been measured using a Talystep which also demonstrated the spongy nature of the surface. The same thickness can be obtained in warm water in a shorter period of time. However, precaution must be taken as the oxide layer tends to become polycrystalline at higher temperatures and cannot be easily and uniformly removed in HCl.

The stripping process, which uses 50% aqueous HCl for a minimum of 5 min, not only removes the freshly grown porous oxide layer but also removes any residual native oxide along with much of the organic impurities on the outer surface. A very quick DI water rinse is applied and the substrate is loaded into the reactor after the water is blown off with high purity gaseous nitrogen. The substrate is not exposed to free air for more than about 20 sec (gaseous nitrogen flow in the reactor is maintained during loading as well).

Experiments similar to those described earlier have been carried out to study the early growth phase and therefore the effect of HCl treatment. In Fig. 3 a photomicrograph of a layer grown at 735°C on a substrate which had gone through porous oxide-HCl treatment is shown. Growth was initiated after a supercooling of 1/4°C and 5 sec growth time at a cooling rate of 1 °C/min was allowed. Notice the remarkable improvement in the wetting; it is very uniform and the layer is nearly featureless. The layer thickness is estimated to be below 150Å. The same experiment has been repeated at 750° and 780°C.

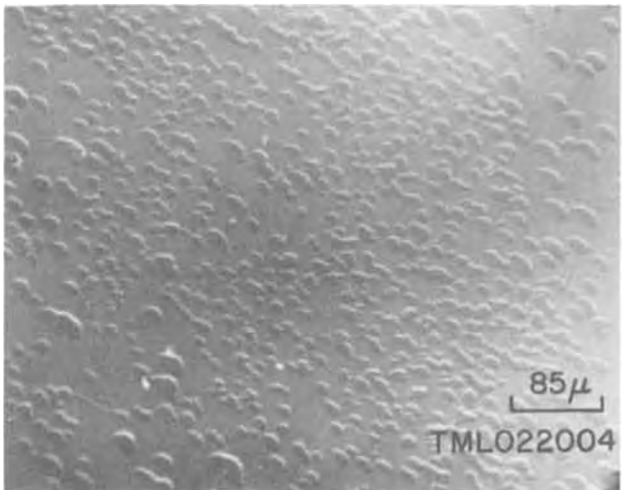

Fig. 2. Photomicrograph (Nomarski phase contrast) of a layer grown at 735°C on a substrate which had undergone only a standard cleaning procedure. The growth time $t = 5$ sec; linear cooling $\alpha = 1$ °C/min, supercooling 1/4°C. Notice the formation of nucleated growth centers and nonuniform wetting.

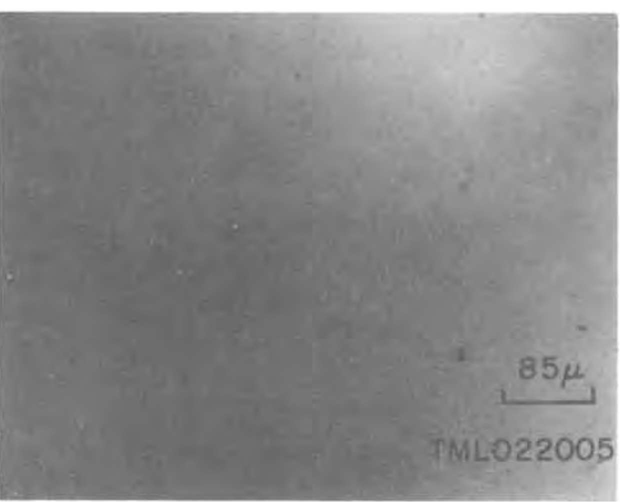

Fig. 3. Photomicrograph (Nomarski phase contrast) of a layer grown at 735°C on a substrate that had undergone a porous oxide-HCl treatment in addition to standard cleaning. Growth parameters were unchanged from that shown in Fig. 2. The improvement in the wetting is remarkable.

It can be concluded that to achieve uniform submicron epilayers for FET's, the crucial "wetting" parameter can be controlled with the porous oxide-50% HCl process.

As Profile, Growth Rate, and Layer Thickness

We have pointed out earlier that once the wetting is controlled, the other important parameters are the perfect saturation of the melt solution and the growth rate. We now examine the effect of these parameters and compare the experimental results with theoretical predictions.

In the growth of thick layers such as Gunn diode layers, a deviation of about ±1°-2°C in the saturation of the melt with As will have a small effect on the final layer thickness since a total temperature drop of around 20°C takes place. By contrast, for the growth of submicron (0.2μ) epilayers, the total temperature drop can be as low as 1.5°C (780°C, with cooling rate $\alpha = 1$ °C/min, supercooling $\Delta T = 0$). Therefore, it is clear that one cannot afford any under- or oversaturation of the melt. Our observations show that the wetting is best when the melt is saturated from the top. Experimentally we have found that bakeout times about twice as long as the diffusion time are not necessarily long enough to establish equilibrium. (To check this point, a GaAs source 10 mg heavier than that found from Rubenstein's data (14) was weighed and added to the melt.) The saturation was studied by placing a polished source-seed crystal beneath the melt after a bakeout time of 2 × (melt height)^2/diffusion coefficient during which the temperature was kept practically constant. The source seed was removed after 10 min and examination showed that a very nonuniform backdissolving occurred. Nonuniformity can be caused by strains and imperfections in the bulk material but, nevertheless, it is very likely that the bottom of the melt was undersaturated and in a nonuniform manner. Therefore, we find that it is necessary to have a source-seed crystal [first used by Dawson; see Ref. (5) and (9)] preceding the main substrate to trim out the As concentration of the melt at the bottom. Only then can one achieve repeatable thicknesses by controlling the growth rate on oxide-free substrates. The layers grown without a source-seed crystal have thicknesses ranging from negative values (backdissolving) up to the intended values.

The growth rate is the third mechanism that is of vital consequence to the parameters of the grown layer. Submicron layers with thicknesses of about 0.2μ have been grown at temperatures of 780°, 750°, 735°, and 700°C. The ramp cooling rate was in all cases $\alpha = 1$ °C/min and in certain cases supercooling of $\Delta T = 3$°C was applied. Our experiments show that with high growth rate, control over the thickness repeatability becomes poorer. Moreover, surface imperfections, such as cusps and undulations become more pronounced in contrast to Crossley and Small (15) and Hsieh (16). Illustrated in Fig. 4 is a layer grown at 780°C for 15 sec after a supercooling of 3°C. The wetting is adequate but the surface features make such a layer useless. In this case no source-seed crystal was used. The growth rate in the early moments of the growth is fairly high and decreases with time. The growth rate has been calculated at 780°C from the numerical analysis including the temperature dependence of As diffusion coefficient and is shown in Fig. 5, both with and without a supercooling of 3°C. It is very clear that the difference between the two conditions is very large. The much higher growth rates associated with supercooling place nearly impossible requirements on the actual growth time, especially for submicron layers. For example, a small hesitation of 2 sec pushing the slider will mean about 2 sec of traveling time under the melt and 13 sec of actual stationary contact time (at 780°C with $\Delta T = 3$°C). During this 2 sec, about 15% of the total growth

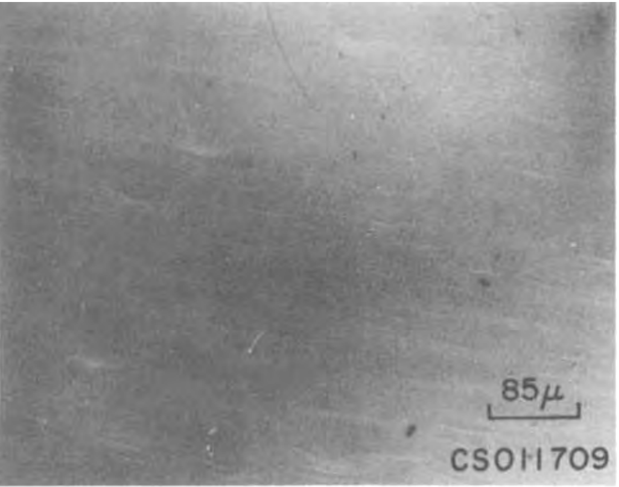

Fig. 4. Steps caused by a fast growth rate. This particular layer is about 0.2μ thick and grown at 780°C. The growth parameters are: supercooling $\Delta T = 3$°C, linear cooling rate $\alpha = 1$ °C/min, and the growth time $t = 15$ sec.

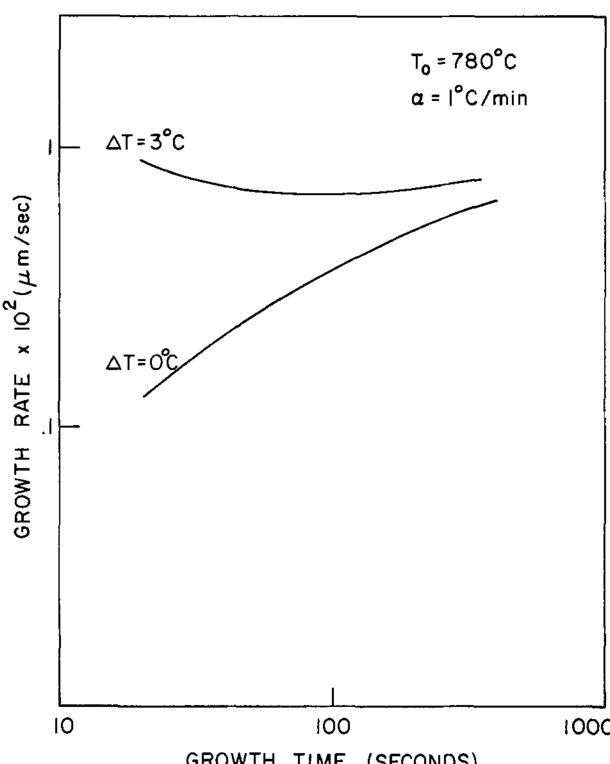

Fig. 5. Plots of growth rate at 780°C as a function of growth time both with and without a supercooling of 3°C.

would take place causing steps in the thickness similar to meniscus lines to form [first observed by Crossley and Small (15)]. In addition, a faster growth rate may cause steps.

We have done experiments at 780°C with only ramp cooling ($\alpha = 1$ °C/min) and observed considerable improvement in thickness control and surface morphology. A further improvement in both occurs when a 0.2μ (or less)-thick layer is grown on the source seed and subsequently a 0.2μ layer is grown on the main substrate.

These phenomena can be explained by examining the As concentration profile, the slope of which at the substrate-solution interface determines the growth rate. Shown in Fig. 6 is a set of calculated As profiles *vs.* segment number at 780°C. Segment number 0 corresponds to the substrate-liquid interface at $t = 0$ and segment number 50 corresponds to the opposite surface

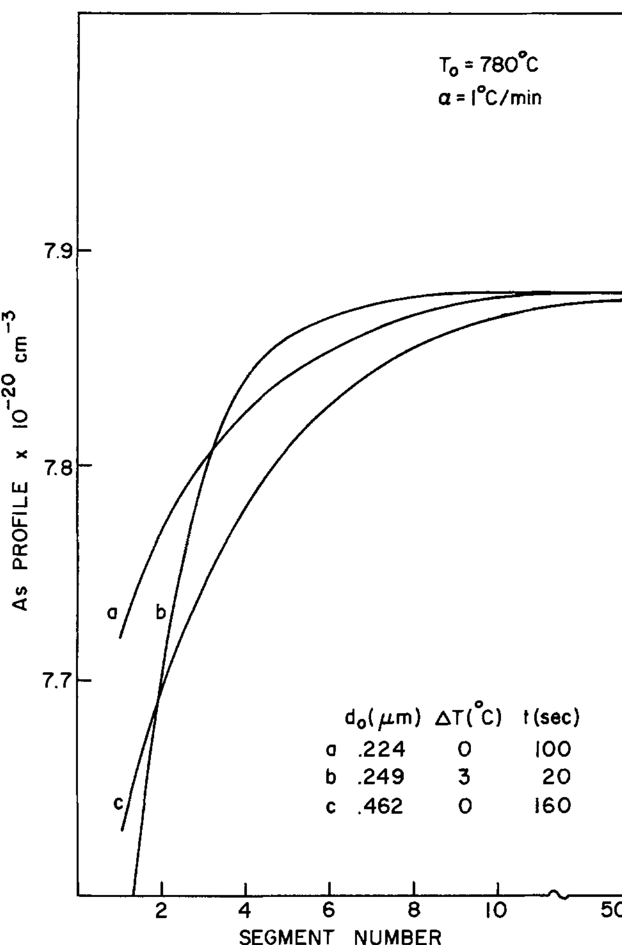

Fig. 6. Predicted As profile in Ga melt at the end of growth with various growth parameters at 780°C. d_0 represents the grown layer thickness after a time interval t at a cooling rate of 1 °C/min with and without a supercooling of ΔT.

of the solution (the melt height = 1 cm); As profile is calculated for each segment every 2 sec of growth time. Figure 6b shows the As profile at the end of a 0.25μ layer growth when a supercooling of 3°C was applied. The As profile at the beginning of the growth is much steeper than at the end; even then, the profile is very steep, making the thickness very hard to control. Shown in Fig. 6a is the As profile at the end of the growth of the 0.22μ thick layer on the source seed with no supercooling. The profile is not steep even during early growth because there are no sudden excess As concentrations. Shown in Fig. 6c is As profile at the end of the 0.24μ layer grown on the main substrate (as opposed to the beginning profile in Fig. 6a). It is clear that the As profile follows a very nice and controllable variation from the beginning to the end. To still further decrease the growth rate (and hence improve controllability), the growth temperature was dropped from 780°C which had been the normal growth temperature, down first to 750°C, later 735°C, and presently to 700°C. We are able to lower the growth temperature so much because with the HCl treatment the substrates wet very uniformly even at 700°C.

Preliminary studies show that the layers can be grown more repeatably at 700°C than at higher growth temperatures. The optimum average growth rate to achieve minimum cusp density has been experimentally determined to be about 800 Å/min. The density of the cusps decreased considerably [10^5 cm^{-2} at 780°C and 10^2 cm^{-2} or less at 700°C (17)], as well as timing errors, because the growth rate is slower (it now takes almost 3 min to grow 0.2μ thick layers).

Thickness and doping profiles have been deduced from C-V measurements done with the aid of a phase-locked amplifier and by using an automatic profiler. To do this, Al Schottky barriers of 3000Å thick and 250μ in diameter have been evaporated through a mask under high vacuum (~6×10^{-8} Torr). Lehovec and Zuleeg (18) have argued that the C-V method of determining impurity concentration and distribution becomes less accurate as the depletion layer expands toward the substrate interface. Near pinch-off conditions, the channel resistivity becomes so high that the resistivity between the two back-to-back biased Schottky barrier diodes becomes very large. To reduce the effect of the forward-bias resistance, a large-area Al pad has been evaporated and biased. This diode is forward biased during the measurement. Wiley and Miller (19) have reported on the effect of series resistance in C-V profiling, how to reduce it, and how to interpret the measurement when a large series resistance is present. It is clear that one can only be specific about the thickness of submicron epitaxial layers deduced from C-V plots after the errors associated with the measurements have been analyzed. An alternative way would be to actually fabricate FET's to evaluate the layers, which is time consuming and uneconomical.

Nevertheless, illustrated in Fig. 7 is the measured doping profile of a layer grown at 735°C using a source-seed crystal. Notice that the doping profile is flat and the total thickness variation is small.

Layers with thicknesses ranging from 2 to 5μ have been grown at 700°, 735°, 750°, and 780°C. The experimental thickness data have been compared against numerical calculations, which included the temperature dependence of As diffusion coefficient determined by Rode (5), and close agreement within measurement errors has been achieved. Therefore, we completely agree about not only the diffusion-limited growth model, but the diffusion coefficient of As as a function of temperature in Ga solution as presented by Rode. Moon and Long (20) have recently used the solution of the diffusion equation reported by Small and Barnes (2) in 1969. In the 1969 article C_0 appears (equilibrium As concentration in the melt) in the denominator of the thickness equation. This was changed correctly to C_s (As concentration in the solid) in the article by Crossley and Small (3) in 1971. Hseih (16) has reported on the growth relations from supercooled, linearly cooled, and a combination of both types, which was a restate-

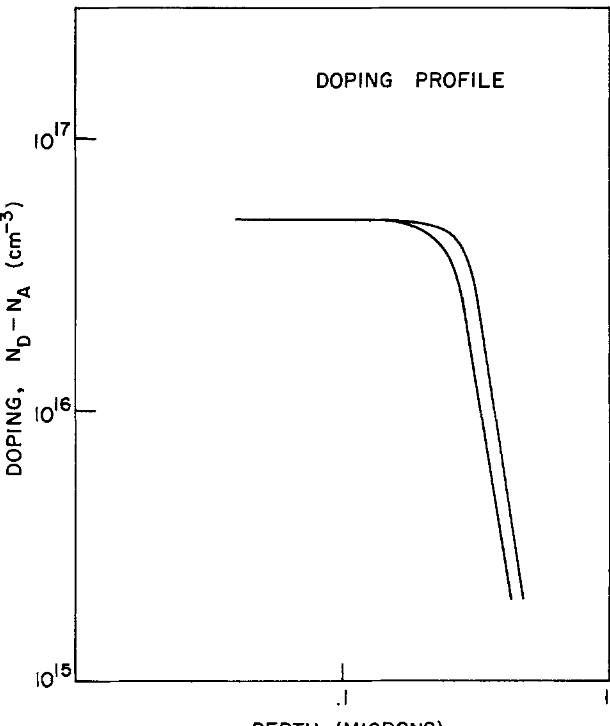

Fig. 7. Doping profile of a layer grown at 735°C using a source-seed crystal with no supercooling.

ment of those originally reported by Small and Barnes (2) and Crossley and Small (3). The main point made by Moon and Long (20) was that the diffusion coefficient appears to be relatively constant for the large temperature drop of 30° used by them. This result is in complete contrast with our work and that of Rode's for smaller temperature drops. It is clear that the simplified theory they used is only realistic for short growth times and small temperature drops; these limits vary with the growth temperature due to the solubility curve. Therefore, since their theory predicts thicker layers than actually grown, and since a 30° temperature drop, at 1 °C/min, exceeds the realistic range, the semi-infinite melt approximation becomes a questionable assumption. It is possible that minute crystallites as shown by Hsieh (16) and Crossley and Small (3) competed for As during growth in their experiments to yield their results.

The layers grown at 780° and 750°C with and without a supercooling and at 735°C with a supercooling have been selected out to have *C-V* measurements performed on them. Thus the data points for these cases do not show much spread in the thickness *vs.* growth time curves to be described. But the measurements on layers grown at 735°C preceded by a seed crystal have been done with no selection. Therefore the displayed spread in data points for this case is much greater even though it is actually almost the same as the others. In Fig. 8, the calculated thickness *vs.* growth time at 780°C is shown. Four data points with and without a supercooling are also shown. Two distinct methods of numerical calculations were used to predict the thickness. The technique reported by Rode (5) with temperature-dependent As diffusion coefficient has been primarily used. The boundary conditions are identical to those reported by him (zero excess As concentration at the interface and zero spatial derivative of excess As concentration at the top of melt). The melt height in our experiments is 10 mm. The alternate calculation uses Crossley and Small's (3) model modified to include Rode's As diffusion coefficient. In the latter case, the semi-infinite melt approximation was made. For growth periods negligible compared to diffusion time across the melt, which is true for all the experiments reported here, both techniques have agreed quite closely. However, the semi-infinite melt approximation cannot be relied upon for longer growth intervals.

In Fig. 9 and 10 the same curves as those shown in Fig. 7 are repeated for 750° and 735°C, respectively. We believe that a thickness reproducibility from layer to layer of $\pm 0.015\mu$, and a thickness uniformity as low as ±4% over a portion of the layer that excludes the edge lip, can be achieved with these techniques whereas at higher temperatures these figures must at least be doubled.

We are now concentrating on growing these layers at 700°C with no supercooling. We reduced the cooling rate, in an attempt to lower the growth rate and the edge growth, which should enable us to make use of more of the area and achieve better thickness uniformity. But, much slower growth rates increased the density of cusps remarkably. Preliminary results at 700°C show that about ±4% thickness uniformity can be achieved repeatably. It has also been demonstrated that with slower growth rate (about 800 Å/min) at lower growth temperature, one can achieve reproducible submicron layers when any oxide layer present is removed with aqueous HCl and the melt saturation is trimmed with a source-seed crystal.

Summary and Conclusions

The controlled-growth mechanism and the factors affecting it, along with the necessary countermeasures, have been examined in detail for the growth of submicron FET layers. Remarkably good agreement between theory and experiments has been achieved. The temperature dependence of the As diffusion coefficient determined by Rode has been reaffirmed. It has also been demonstrated that with slower growth rate (about 800 Å/min), at lower growth temperature, one can achieve reproducible submicron layers when any oxide layer present is removed with aqueous HCl and the melt saturation is trimmed with a source-seed crystal.

ABSTRACT

Unusual effects are seen when heavily p-doped polycrystalline Si is deposited via the $H_2/B_2H_6/SiH_4$ system. For example, material resistivity does not diminish monotonically as B_2H_6 abundance is increased; also, resistivity variation due to subsequent layer oxidation is not monotonic. Manipulation of these and associated effects, such as variation in the volumetric conversion ratio to the oxide, can result in product improvements.

There are many cases in current semiconductor technology in which doped polysilicon layers find utility, such as gate electrodes and device field shields (1, 2). In general, applications make demands on poly-Si properties, such as etch characteristics, material resistivity, and material response to oxidation cycles. Since satisfying these requirements is not always possible with a standard material, several compromises are usually necessary.

In this paper, we describe some unusual effects that are present when B_2H_6 is used to heavily dope the poly-Si layer during deposition. By properly manipulating these effects, one can effectively gain several distinct processing advantages.

Description of Experiments

The poly-Si layers were deposited on 2¼ in. p-type, 2 ohm-cm substrates, upon which about 300Å of Si_3N_4 had been previously deposited. SiH_4, diluted to 5% in N_2, was the silicon source used. In general, poly-Si layer thickness was intended to be near to 4500Å; however, tests in other thickness ranges gave similar results.

Poly-Si thickness measurements were most often made by mechanical methods, although some data were taken using reflectance spectra techniques. Resistivity data were calculated from four-point probe measurements. Oxide thickness over the poly-Si was generally derived from reflectance spectra.

Most experiments consisted of several runs, with B_2H_6 flow rate as the variable between runs; dummy runs were made, as needed, to stabilize the reactor background doping levels. The samples thus generated were then subjected to a variety of tests (*e.g.*, thickness, R_s and etch rate determinations) as well as to several additional processing sequences, such as oxidation under various conditions and pattern etching.

Experimental sets were processed over the temperature range of 750°C to about 1000°C, using different carrier gases (N_2 or H_2), and in different reactor types. While the effects to be discussed showed some sensitivity to such processing changes, these influences were relatively minor compared to the effects described below.

Discussion

Preliminary experiments: as-deposited material resistivity.—Assuming that the fraction of electrically active B incorporated into the growing poly-Si film is reasonably independent of boron availability, one expects that the boron concentration in the film will be approximately linearly dependent on B_2H_6 input flow rate, at least insofar as the flow rate is much less than the total rate of flow in the reactor

$$N_a \sim K|B_2H_6| \quad [1]$$

where K is some constant and $|B_2H_6|$ is the flow rate of the dopant. If this were true, one should be able to plot the (average) material resistivity against $|B_2H_6|$ (and thus N_a, by virtue of [1]) and achieve a functional dependence similar to published data (3). This type of functional dependence is approximately given by

$$\bar{\rho} \simeq A|B_2H_6|^{-B} \quad [2]$$

in which $\bar{\rho}$ is the average poly-Si resistivity, and where A and B are positive constants over some range of $|B_2H_6|$. This approximation had previously been shown to be reasonable in the range of $\bar{\rho} \sim 1$ ohm-cm for n-type dopants. In this study, the first several runs also showed $\bar{\rho}$ to depend on $|B_2H_6|$ in approximately this manner, as shown in Fig. 1.

Certainly, $\bar{\rho}$ is expected to be a monotonically decreasing function of $|B_2H_6|$; the fact that this assumption fails at high values of $|B_2H_6|$ is shown in Fig. 2. The anomalous increase in $\bar{\rho}$ at high B_2H_6 flow rates is

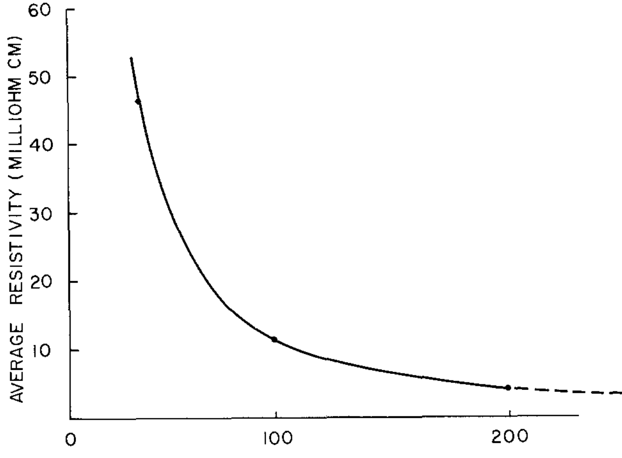

Fig. 1. Expected behavior of $\bar{\rho}$ on $|B_2H_6|$

attributed to the formation of a new phase, possibly one of the silicides of boron.

The anomaly noted above was the first of several which appeared over the course of additional study. In general, these effects were somewhat responsive to changes in processing conditions and reactor type, but not extremely so. The process reported in Table I was chosen as the vehicle for additional experiments. Table II displays B_2H_6 flow rate values for a typical four-run experimental set.

Poly-Si deposit rate.—Typical material deposit rates are also shown in Table II. In some experiments, qualitative agreement with published data was noted (4). In other cases, the growth rate showed a complicated, nonmonotonic dependence on B_2H_6 flow rate and other process variables. Since the range of variation from run to run in an experimental set was generally less than ±15%, extensive study of deposit rate phenomena was not undertaken.

Poly-Si oxidation rate.—Wafers from one experimental set were subjected to oxidation in steam at 1050°C. These samples were prepared as noted in Tables I and II.

After initial characterization, the wafers were oxidized for 7.5 min, cooled, and halved. One half was retained for measurements and the other half was processed further. This procedure was repeated twice, the second oxidation being for 7.5 min, and the final cycle having 15 min of oxidation.

Poly-Si thickness was measured on each sample. The most convenient plot of poly-Si thickness over oxidation time is on semilog scales, as illustrated in Fig. 3. The same information is displayed in Fig. 4, in which the amount of poly-Si consumed by the oxidation step is plotted against oxidation time. The data show the following features: (*i*) heavily doped samples oxidize somewhat faster than lightly doped samples; (*ii*) the variation in oxidation rate is about ±15%; and (*iii*) the per cent variation in material removal rate diminishes as oxidation time increases.

These data can be summarized with the statement that poly-Si oxidation rate (under the aforementioned conditions) is not very dependent on the B_2H_6 flow rate during deposition. While this conclusion does not seem unusual, it is quite important in regard to the results of the next section.

Table I. Process for boron-doped poly-Si experiments

H_2	65 S.L./min

Poly-Si to SiO_2 volume conversion factor.—Another parameter of interest is the amount of oxide generated when a unit thickness of the deposited poly-Si layer is consumed during oxidation. We define the characteristic quantity, conversion ratio (C.R.), as

$$\text{C. R.} = \frac{T_{\text{ox}}}{\Delta T_{\text{poly-Si}}} \quad [3]$$

where T_{ox} is the oxide thickness measured over the the poly-Si, and where $\Delta T_{\text{poly-Si}}$ is the amount of deposited material consumed by the oxidation process. Since we are dealing with a very boron-rich material, we should expect that the C.R. observed is not equal to that obtained from pure silicon. If the material has average stochiometry given by Si_xB_y, then the expected value for C.R. would be

$$\text{C.R.}_{\text{(expected)}} = \frac{x}{x+y} \cdot \text{C.R.}_{\text{Si}} + \frac{y}{x+y} \cdot \text{C.R.}_{\text{B}} \quad [4]$$

where C. R.$_{\text{Si}}$ and C.R.$_{\text{B}}$ are the respective C.R. values for Si and B. C.R.$_{\text{Si}}$ is about 2.1, and C.R.$_{\text{B}}$ is expected to be between about 3.0 and 5.0. The observed value of

C.R. for the composite material should then asymptote to about 2.1, for small values of $|B_2H_6|$ during deposition, and should approach 4.0 or greater for samples deposited with high diborane flow rates. Measurements of sample C.R. show exactly this type of behavior, as shown in Fig. 5 and 6. The data suggest an effective C. R. for the boron component of about 4.5. Extending the analysis a bit further allows an expression to be generated for the ratio x/y, in terms of the observed sample C.R.

$$\frac{x}{y} = \frac{4.5 - \text{C.R.}_{(\text{sample})}}{\text{C.R.}_{(\text{sample})} - 2.1} \quad [5]$$

Material resistivity after oxidation.—Another effect noted during these experiments dealt with the response of $\bar{\rho}$, in samples prepared as described above, to oxidation cycles. It is a well-known fact that boron tends to segregate into the SiO_2 layers formed on the silicon during oxidation. Since less dopant then remains in the silicon, this effect is generally evidenced by an increase in $\bar{\rho}$. As illustrated in Fig. 7, the expected response is, in fact, observed on lightly doped samples: resistivity increases markedly as a function of oxidation time. Heavily doped samples, however, exhibit anomalous behavior, as ilustrated in Fig. 8. On these samples, it can be observed that $\bar{\rho}$ actually diminished as oxidation time increased. In Fig. 9, $\bar{\rho}$ is plotted against B_2H_6 flow rate, with oxidation time as a parameter. Note that if the poly-Si deposition is performed with $|B_2H_6|$ value near about 550 S.C.C./min, the material resistivity is almost insensitive to oxidation time, at least over the range of variation explored.

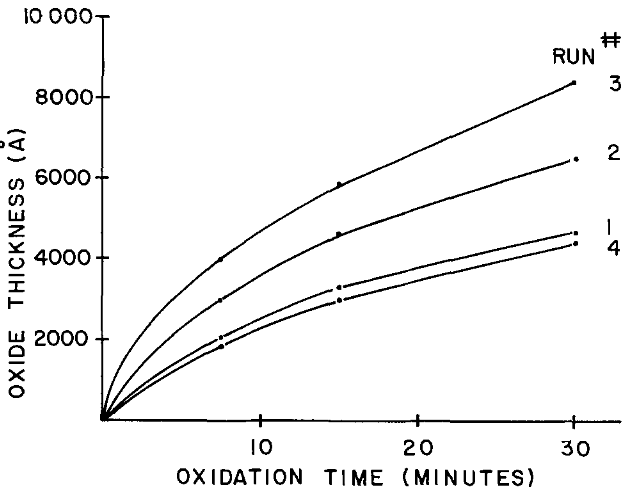

Fig. 5. Amount of oxide grown from the poly-Si as a function of oxidation time for several values of $|B_2H_6|$.

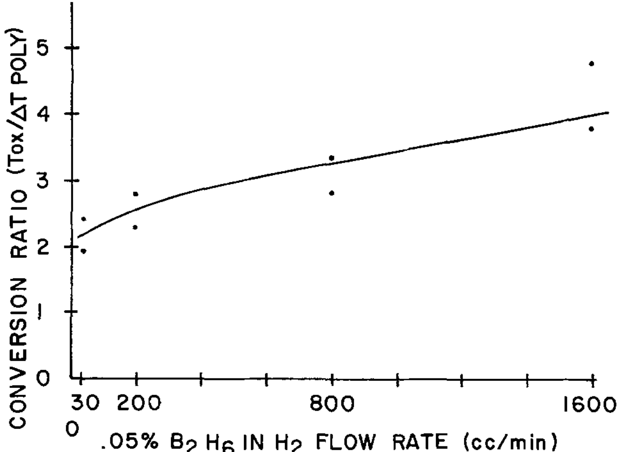

Fig. 6. Poly-Si to oxide conversion ratio as a function of $|B_2H_6|$

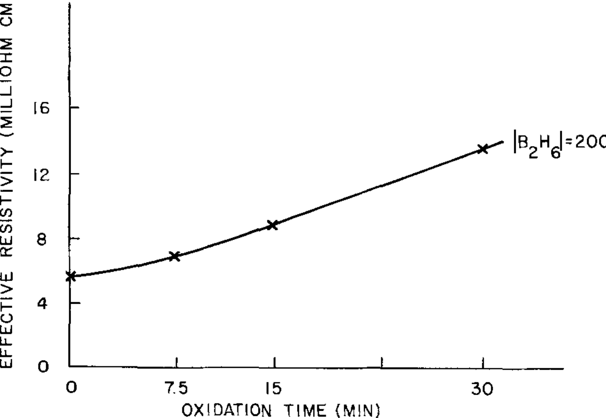

Fig. 7. Average resistivity as a function of oxidation time for a lightly doped sample.

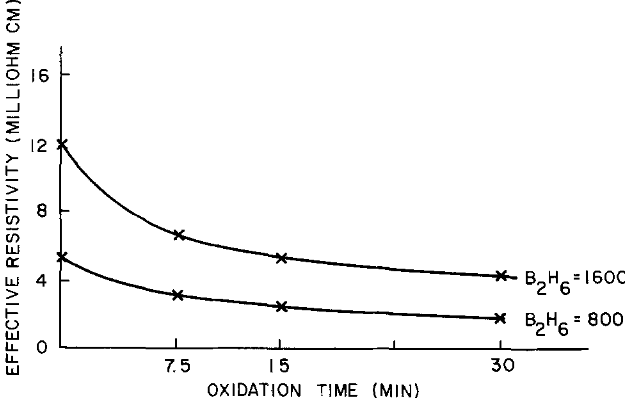

Fig. 8. Average resistivity as a function of oxidation time for heavily doped samples.

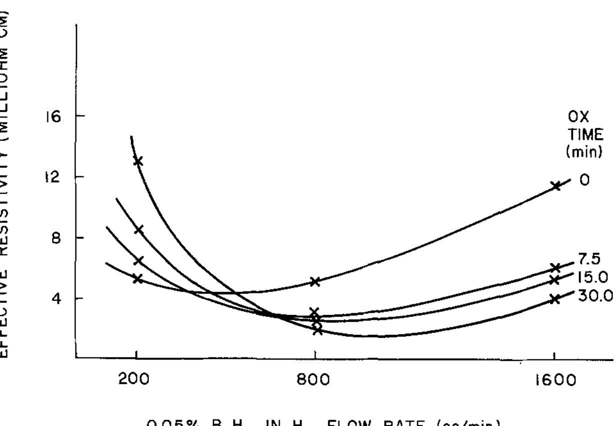

Fig. 9. Dependence of $\bar{\rho}$ on B_2H_6 flow rate for several oxidation times.

This phenomenon is apparently due to at least the following three simultaneous effects: (*i*) grain growth in the poly-Si; (*ii*) depletion of the boron into the already boron-rich oxide; and (*iii*) decomposition of the hypothesized new phase in such a manner as to keep the B concentration in the poly-Si layer near the solubility limit. In contrast, simple heat-treatment of similar samples caused little, if any, change in average resistivity. In such cases, the phase decomposition can apparently occur only to the extent that grain growth also occurs; the phase must continue to exist unless a "sink," such as oxide, is available to accumulate excess boron.

Poly-Si etch rate.—Poly-Si etch rate as a funccion of $|B_2H_6|$ was also investigated. The etchant used here

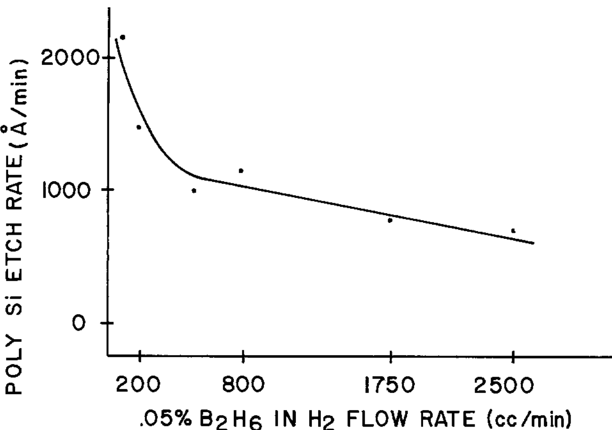

Fig. 10. Poly-Si etch rate as a function of $|B_2H_6|$

was composed of HF, HNO_3, and acetic acid in proportions 1:26:33. The etch rate of undoped poly-Si in this solution is generally near 1500 Å/min, increasing slightly with p-doping near the 0.05 ohm-cm range of resistivity.

When the poly-Si is boron doped into the low 10^{-3} ohm-cm region, however, the etch rate decreases rapidly, as shown in Fig. 10. This behavior is also attributed to the hypothesized silicide phase within the composite material.

Conclusion

The various types of anomalous behavior discussed above were found to be fairly reproducible, and the existence of such effects is now quite well established. Similar tests made with AsH_3 and PH_3 showed no anomalies, at least in the resistivity regions of interest here. To this time, no attempt has been made to more precisely identify the apparent new phase in the B_2H_6 case.

It is not difficult to imagine many cases in which proper manipulation of such effects can result in significant processing advantages. In the cases attempted to date, results have followed expectations rather well.

Acknowledgments

The authors wish to acknowledge J. Doulin and D. Doney for much of the experimental work. Also, I. Dolgov, T. Litz, and C. Liu performed many of the etch rate experiments.

Effect of III/V Ratio on the Properties of Vapor Phase Epitaxial GaP

G. B. Stringfellow* and H. T. Hall, Jr.

Hewlett-Packard, Palo Alto, California 94304

ABSTRACT

The effect of III/V ratio in the gas stream on the properties of GaP grown by the vapor phase epitaxial (VPE) technique has been studied. At the substrate temperature of 840°C, the nitrogen distribution coefficient is found to increase strongly with increasing III/V ratio. Equilibrium thermodynamic calculations explain the dependence well. On the other hand, the residual doping level, believed to be due to S, has the opposite dependence on III/V ratio which is not understood. The minority carrier lifetime and diode efficacy are observed to increase with III/V ratio. An analysis of this behavior indicates the dominant nonradiative recombination center in this material may be a deep acceptor residing on the Ga sublattice, such as Cu or Fe.

The family of III-V compounds is generally very stoichiometric because of the strong covalent bonding. This characteristic is important for many of the properties of these semiconductors, including the ability to be doped both n- and p-type and the very slow substitutional diffusion observed in them.

There are few reliable studies on the actual degee of nonstoichiometry, but recent studies on the Ga compounds have indicated that the stability range is largely on the Ga-rich side of perfect stoichiometry (1-4), the dominant defect probably being vacancies on the Group V sublattice which may exist with concentrations of up to 10^{19} cm^{-3} (1-4). In GaAs and GaP, these vacancies are apparently electrically and optically inactive, but in GaN they render the material always n-type (5, 6). The Ga vacancy, although present in smaller numbers, appears to be a deep acceptor, and there are many reports that it acts either alone or paired with various donor impurities as a nonradiative recombination center which reduces the minority carrier lifetime and recombination efficiency (7-11). Photoluminescence and absorption peaks in the infrared are sometimes ascribed to such defects (12-14). Arsenic interstitials rather than Ga vacancies have also been implicated in these effects (15, 16).

The experiments usually considered to give the most reliable indication of the effect of Ga vacancies on ma-

* Electrochemical Society Active Member.
Key words: GaP, stoichiometry, light emitting diodes, vapor phase epitaxy.

terials properties are those in which the activity of Ga, a_{Ga}, is changed systematically in a series of growth runs while monitoring the change in some property which depends on the gallium vacancy concentration. In LPE experiments, this requires changing from the V-rich to the Ga-rich side of the liquidus at a fixed temperature (8) or changing the temperature. In VPE, the III/V ratio, which is defined as the ratio of HCl to PH_3 in the input gas stream, is simply changed. However, as discussed later, a_{Ga}, the quantity which will be used to specify the gas phase stoichiometry at the solid-vapor interface, is not linearly proportional to the III/V ratio as is normally assumed (14, 17-19). The problem with this type of experiment is that the results are always ambiguous. The defect responsible for changes in the property being monitored cannot be identified with certainty because changes in a_{Ga} affect the distribution coefficients for Ga site impurities and V_{Ga} in the same way (20).

In VPE GaP similar to that to be described in the present study, the major residual donor impurities have been identified and the donor and acceptor concentrations were found to be $<10^{16}$ cm^{-3} for nitrogen-doped material (21). In this study, we have systematically varied the III/V ratio during a series of VPE runs and observed the effects on N_D, N_A, E_D, and the nitrogen doping level. Taking these effects into account, we have then attempted to understand the influence of vapor phase stoichiometry on the minority carrier lifetime and diode efficiency.

Experimental

The PH_3-HCl-Ga-H_2 system was used to grow the GaP layers. The details have been presented elsewhere (22), but the important feature is that the system is rf heated so all the hot elements which the gases contact are high purity graphite. The LEC GaP substrate, either n^+ sulfur doped or semi-insulating Cr doped, was oriented 4° off the (100) plane. The substrate temperature was 840°C for all experiments.

The GaP doped only with N was characterized by measuring: (*i*) the photoluminescent spectrum which yields the nitrogen concentration (22) and information about deep levels in the material; (*ii*) the minority carrier lifetime by photoluminescent decay measurements (23); and (*iii*) the diode efficacy, B/J. All of these measurements are standard and have been described in previous publications. The efficacy measurements were made on diodes with absorbing back contacts without epoxy encapsulation. The electrical properties of this material, which is always observed to be n-type under the conditions described, were measured by making van der Pauw measurements *vs.* temperature, which can be interpreted to yield N_D, N_A, and E_D (21).

Results

The growth conditions used for the series of runs are listed in Table I. For runs 611-618, an attempt was made to keep as many parameters, including growth rate and nitrogen concentration in the solid, as constant as possible. Thus for high III/V ratios, where the PH_3 flow rate controls growth rate, the PH_3 flow rate was held at a value giving a growth rate of ~1 μm/min. At low III/V ratios, the HCl flow rate was held at this value and the PH_3 flow rate increased, to again maintain ~1 μm/min growth rates. The NH_3 flow rates were varied to give what was calculated to be an approximately constant nitrogen concentration.

Table I. Growth conditions for runs with varying III/V ratio. All runs were carried out with a substrate temperature of 840°C.

619	6.6	68.0	1100	23.0	5.20	1.8	0.067

One problem with trying to cover such a wide range of III/V ratios is that the morphology becomes bad at both high (pyramids) and low (pits) III/V ratios (24). However, the morphology was sufficiently good to allow fabrication of van der Pauw samples and LED's over the entire range of III/V ratios from 0.3 to 10.

Nitrogen incorporation.—The most easily interpreted parameter found to vary with III/V ratio is the nitrogen distribution coefficient. As reported previously (22), at 840°C the experimental solid/vapor distribution coefficient agrees with an equilibrium thermodynamic calculation. The calculation basically consists of using the N incorporation reaction

$$GaCl(g) + NH_3(g) = GaN(s) + HCl + \frac{3}{2}H_2 \quad [1]$$

to calculate X_{GaN}/p_{NH_3} using the data of Thurmond and Logan (25) for $\Delta G_f^o(GaN)$, a value of 23,000 cal/mole for Ω^s used to calculate the activity coefficient of GaN in the GaP-rich solid (26-28) and values of p_{GaCl} and p_{HCl} at the solid-vapor interface which must be calculated. The mass action relations for the two reactions

$$GaCl(g) + \tfrac{1}{2} P_2(g) = GaP(s) + HCl(g) \quad [2]$$

and

$$2P_2(g) = P_4(g) \quad [3]$$

are used with the conservation conditions

$$p_{PH_3}^o - 2p_{P_2} - 4p_{P_4} = p_{GaCl}^o - p_{GaCl} \quad [4]$$

$$p_{HCl}^o = p_{HCl} + p_{GaCl} \quad [5]$$

to determine the four parameters p_{GaCl}, p_{HCl}, p_{P_2}, and p_{P_4} given the input conditions $p_{PH_3}^o$ and p_{HCl}^o and the substrate temperature. The experimental data are compared with the calculated distribution coefficient *vs.* III/V ratio in Fig. 1. The calculation describes the re-

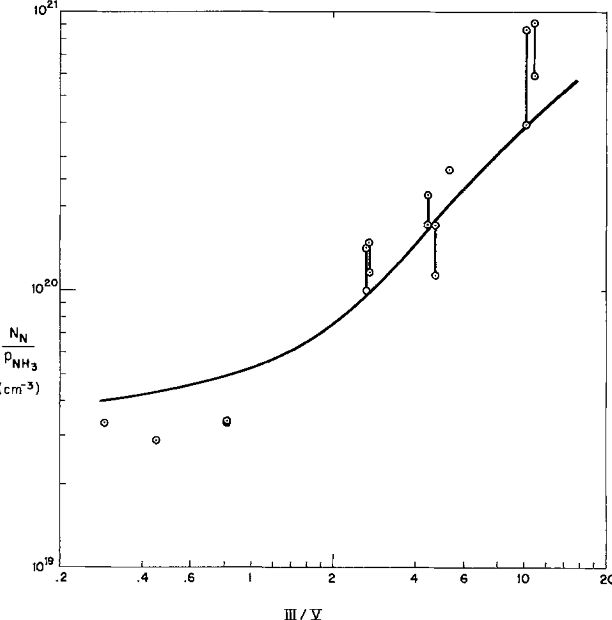

Fig. 1. Distribution coefficient of nitrogen, N_N/p_{NH_3}, *vs.* III/V ratio in the input gas stream, $p_{HCl}^o/p_{PH_3}^o$. The solid line was calculated assuming thermal equilibrium at the growth interface as described in the text.

sults very well. Notice that the distribution coefficient does not vary linearly with III/V ratio. This is because the actual III/V ratio at the growing interface $p_{GaCl}/2p_{P_2} + 4p_{P_4}$ is of course not equal to the "III/V ratio" defined as $p_{HCl}^0/p_{PH_3}^0$. For a linear relationship between dopant concentrations and III/V ratio, the III/V ratio at the gas-solid interface must be used. This is an important point generally ignored by many papers dealing with the III/V ratio effects on VPE materials (14, 17-19). In fact, a very convenient quantity for expressing stoichiometry is a_{Ga} defined as $p_{Ga}^{(g)}/p_{Ga}^{ol}(T)$. This can be used to compare the stoichiometry of the solid with that obtained by LPE. For the high III/V ratios used in this work, a_{Ga} is nearly equal to that for LPE. The equilibrium values calculated for a_{Ga} are listed in Table I along with the III/V ratio to give an idea of the relationship between the two. In applying these thermodynamic calculations to N incorporation, it must be acknowledged that the incorporation need not be thermodynamically controlled, as is the case for S doping to be discussed below. In fact, at 820°C the N concentration in the solid is substantially higher than the solid solubility limit (26). However, the success achieved in calculating the absolute magnitude of the distribution coefficient and its dependence on III/V ratio at 840°C, all with no adjustable parameters, indicates that the solid-vapor equilibrium is the determining factor in this case.

Doping level.—Since the residual donor in nitrogen-doped GaP has been identified as S in previous investigations (21), one would expect a relationship between N_D and III/V ratio similar to that for nitrogen, since both reside on the P sublattice so both should be proportional to a_{Ga}. However, the results have the opposite dependence. As seen in Fig. 2, N_D, N_A, and $N_D - N_A$ decrease as the III/V ratio and a_{Ga} increase. This is similar to the results of Enstrom *et al.* (29) on GaAs, which they attributed to kinetic effects, namely the change in the sticking coefficient with III/V ratio. If the residual donor were a Group IV impurity, rather than S, we could understand the effect thermodynamically, but the ionization energy and previous optical absorption experiments seem to rule out all donors except S. Because of the dependence of N_A on a_{Ga}, one might conclude that the acceptor resides on the Ga site, but this is uncertain in light of the results for the donor. An interesting observation is that the ratio N_D/N_A remains nearly constant. Similar results have been reported by Okamoto *et al.* (17) and Ashten *et al.* (30) for VPE GaAs. A similar trend is also observed in the data for VPE GaP of Craford *et al.* (31).

Minority carrier lifetime and quantum efficiency.—A very significant effect of the III/V ratio is on the minority carrier lifetime. In Fig. 3, the reciprocal of the photoluminescent decay time is plotted *vs.* III/V ratio. A trend to longer lifetime at high III/V ratio is observed, similar to the results reported by Wessels (19) for charge storage times measured in VPE GaP over a much narrower range of III/V ratio. For comparison, we include the solid line given by the expression

$$1/\tau = A/a_{Ga} \quad [6]$$

where a_{Ga} is the activity of Ga calculated at the growing interface and the parameter A is adjusted to give the best fit to the data.

A number of studies of deep nonradiative recombination centers (NRC's) have been performed recently. Hamilton *et al.* (32) observed that in undoped LPE GaP the lifetime is inversely proportional to the concentration of a NRC observed at 0.75 eV above the valence band. Other workers have presented evidence attempting to identify specifically the point defect responsible for determining the lifetime. In heavily n-type samples, the complex V_{Ga}-$(D_P)_3$ (11, 14) is believed to dominate. Other complexes, such as Si_{Ga}-O_P, C_{Ga}-O_P (34), V_{Ga}-Te_2 (35), and $V_{Ga}P_{Ga}V_{Ga}$ (36) have also been suggested to be NRC's. Smith and Abbott (37) found in undoped LPE GaP that L_P was proportional to $n^{-1/2}$ and implied from this that Si_P was the dominant NRC. In fact, any deep center binding two carriers such that it can produce Auger recombination is a possible NRC (38). A number of possible NRC's are tabulated in Table II for convenience.

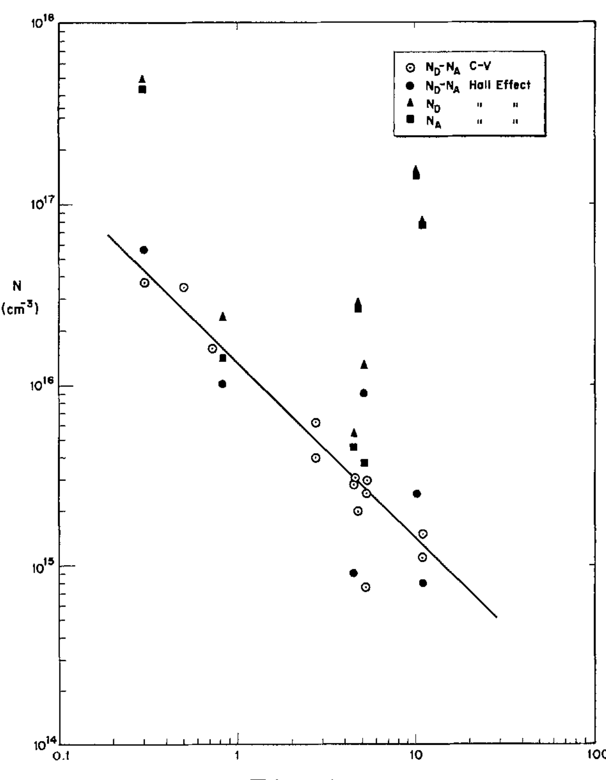

Fig. 2. N_D (▲), N_A (■) and $N_D - N_A$ (⊙) plotted *vs.* III/V ratio in the input gas stream.

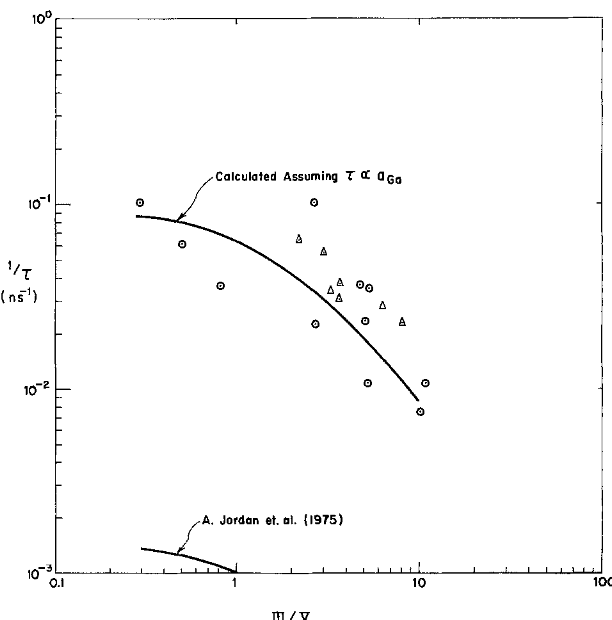

Fig. 3. Reciprocal minority carrier lifetime obtained from photoluminescent decay measurements *vs.* III/V ratio in the input gas stream. The solid line was calculated assuming $1/\tau \propto V_{Ga}$, with V_{Ga} assumed proportional to a_{Ga}^{-1} and the proportionality constant adjusted to fit the experimental data. The lower curve is the calculated result using the proportionality constant from Ref. (10). The data are from the present work (⊙) and for charge storage times in VPE samples reported by Wessels (19) (△).

Table II. Behavior of several postulated NRC's as a function of III/V ratio. In the table n = $d(\log[\mathrm{NRC}])/d(a_{Ga})$. Experimentally n = −1.

NRC	Reference	n	Comparison with experiment	Possible NRC
Si_P	(37)	+1		
V_{Ga}	(10)	−1	τ 100X too small	
D_P (Group VI)		−1*	Shallow, not NRC	
D_{Ga} (Group IV)		−1	Shallow, not NRC	
A_{Ga} (Group II)		−1	Group II—not NRC	
Cu or Fe	(40)	−1	Good	X
V_{Ga}-O_P	(34)	0		
Si_{Ga}-O_P	(33, 34)	0		
C_{Ga}-O_P	(34)	0		
V_{Ga}-Te_2	(35)	1(−3*)		
V_{Ga}-$(D_P)_3$	(11, 14)	2(−4*)		
$(V_{Ga})_2$-P_{Ga}	(36)	−4		

* If D_P incorporation is kinetically controlled as described in the text.

For our system, several possible NRC's can be eliminated immediately, based on the dependence of τ on stoichiometry. Since the concentration of the NRC is apparently proportional to $1/a_{Ga}$, if the defect is an isolated point defect, it must reside on the Ga site. This assumes equilibrium incorporation, of course, and thus the Group VI P-site donors are an exception and must also be considered; however, they are common shallow donors and hence have not been reported to act as NRC's. Since the NRC must reside on the Ga sublattice, all Group IV acceptors, including Si_P must be eliminated. Furthermore, none of the complexes listed in Table II have the proper dependence on a_{Ga}. For example, the V_{Ga}-$(D_P)_3$ complex should have a concentration proportional to $(a_{Ga})^2$ for equilibrium incorporation, or $(a_{Ga})^{-4}$ for kinetically limited incorporation of D_P. Similarly, the V_{Ga}-Te_2 complex can be eliminated. The concentrations of Si_{Ga}-O_P, C_{Ga}-O_P, and V_{Ga}-O_P should be independent of stoichiometry. This leaves V_{Ga}, D_{Ga}, and A_{Ga} as the remaining possibilities. The lifetime associated with Ga vacancies can be predicted from the results of Jordan *et al* (10). The resultant lifetimes are 100 times longer than observed in this study.

The Group IV elements are the major Ga-site donors. They are well established to form shallow levels and are not believed to be NRC's. In our present system, in fact, the concentration of Si in the GaP epilayer can be reduced by adding NH_3 (21) with little change in lifetime. This indicates the Si_{Ga} at the 10^{17} cm^{-3} level is not the dominant NCR. Similar results were reported by Wessels (19). The effect of Sn doping is not clearly established but preliminary results indicate that at a concentration of 10^{17} cm^{-3} Sn does not affect the lifetime in N-doped GaP (39).

The Group II and IIB acceptors, Mg, Cd, and Zn, are common dopants in III-V compounds and at the concentrations considered here do not decrease the lifetime. This leaves the transition metals, such as Fe or Cu, which are deep acceptors and are believed the most logical choice. However, one possible inconsistency observed is that the Cu acceptor level has been determined to be 0.55 eV (40) above the valence band while Hamilton *et al.* (32) found the ionization energy of the dominant NRC to be 0.75 eV for LPE GaP. However, it is possible that the dominant NRC is different for the present VPE GaP than for the LPE material used by Hamilton. The results of this analysis are summarized in Table II.

One other possibility which could make the simple thermodynamic analysis invalid would be the redistribution of point defects during cooling. This situation is impossible to analyze but, as suggested by Van Vechten (36), it could result in the concentration of $V_{Ga}P_{Ga}V_{Ga}$ centers being proportional to a_{Ga}^{-1}, as observed experimentally. If indeed the association reaction continues until all Ga vacancies are used up, any of the defects involving one Ga vacancy are possibilities.

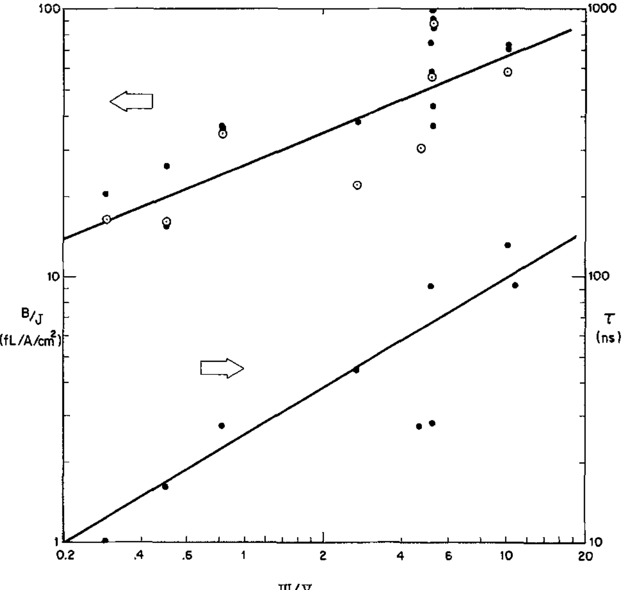

Fig. 4. Diode efficacy (fL/A/cm²) measured at J = 10 A/cm² and minority carrier lifetime (nsec) *vs.* III/V ratio in the gas stream.

The change in minority carrier lifetime is also manifest as a change in the efficacy of LED's fabricated in this material. The efficacy is plotted along with the lifetime *vs.* III/V ratio in Fig. 4. In spite of the scatter, a clear trend to increasing efficiency for samples grown at high III/V ratios is observed. More scatter is observed for efficacy than lifetime measurements partly because the nitrogen concentration, an important factor in the determination of efficacy (22), is not completely constant.

Stewart (14) reported in GaAs,P with $N_D - N_A > 10^{17}$ cm^{-3} the presence of a photoluminescent peak at ~ 9500Å the intensity of which was observed to vary with III/V ratio. In the VPE GaP samples used in the present study, the only photoluminescent peak observed in the infrared (out to 12,000Å) was a small peak at ~ 7000Å. The intensity of this peak was small, about 1% of the green peak and independent of III/V ratio.

Conclusions

A carefully controlled set of experiments was performed where the III/V ratio in the input gas phase was varied systematically from 0.3 to 10. In these experiments, the flow rates were varied in such a way as to keep the growth rate and nitrogen concentration in the solid as nearly constant as possible. The samples were then characterized by measuring N_D and N_A, the nitrogen concentration, the majority carrier lifetime (photoluminescent decay time), and the efficacy of LED's fabricated by Zn diffusion in the material.

The nitrogen incorporation is found to increase with increasing III/V ratio and to be well described by thermochemical calculations. The donor and acceptor concentrations and $N_D - N_A$ are found to decrease as the III/V ratio is increased. The lifetime and diode efficacy are both found to increase with increasing III/V ratio. This is thought to indicate that a deep impurity, probably a transition metal acceptor residing on the Ga sublattice, is responsible for the nonradiative recombination in this material.

Epitaxial Deposition of $Pb_xSn_{1-x}Te$ on $Pb_xSn_{1-x}Te$ Substrates in a Closed System

Sidney G. Parker*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Epitaxial films of $Pb_{0.79}Sn_{0.21}Te$, which were p-type with carrier concentrations in the $10^{17}/cm^3$ range were deposited on $Pb_{0.79}Sn_{0.21}Te$ (100) substrates in a closed system at a rate of 1.5-3.0 μm/hr. The epitaxial films were deposited from stoichiometric or slightly metal-rich charges at 425°-525°C. Those films which were deposited n-type contained metal inclusions. The morphology of the films was influenced by defects in the substrates, substrate temperature, and charge composition. Films up to 100 μm in thickness were obtained. Infrared detector arrays with blackbody detectivities of 10^{10} cm $Hz^{1/2}/W$ at 77°K were made on the epitaxial films using a Schottky barrier technique.

Epitaxial films of PbTe and $Pb_xSn_{1-x}Te$ have been deposited for fabrication of infrared detectors, which are used for various thermal imagery applications. These films have been grown by vacuum evaporation techniques, vapor transport in flow reactors, and from liquid phases (1-12). Films deposited by vacuum evaporation may vary in composition because of the nonequilibrium conditions which are inherent in this process. Vapor transport in a flow system has given good quality films but with film thickness limited to 10-20 μm (8). Epitaxial growth from liquid phases can give elemental inclusions unless great care is taken. The substrates used for epitaxial deposits have included BaF_2, NaCl, PbSe, PbTe, and $Pb_xSn_{1-x}Te$. Most of the epitaxial films have been made on NaCl or BaF_2 substrates because of the unavailability of good quality PbTe or $Pb_xSn_{1-x}Te$ substrates. Use of BaF_2 and NaCl as substrates causes cracks and strains to develop in the epitaxial films because of differences in thermal coefficients of expansion of the substrate and the epitaxial layers.

In an effort to avoid some of these problems, epitaxial growth of $Pb_xSn_{1-x}Te$ films on single crystal substrates of $Pb_xSn_{1-x}Te$ by vapor transport in a closed system was studied. This approach was taken

* Electrochemical Society Active Member.

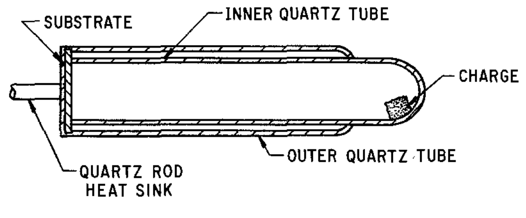
Key words: IV-VI compounds, infrared detectors, carrier control, vapor phase epitaxial growth.

because of our success in growing large single crystals of PbTe and $Pb_xSn_{1-x}Te$ by vapor transport in a closed tube (13). Further, it was hoped that epitaxial growth in a small quartz tube sealed under vacuum would give films under more equilibrium conditions than those existing in dynamic vacuum evaporations or in flow systems. The large, single crystals were grown at temperatures 800°-895°C while the epitaxial films were to be made at substrate temperatures of 425°-525°C. The lower substrate temperatures were selected in an attempt to obtain low carrier concentrations in the epitaxial films which was not always possible using other vacuum evaporation methods. Further, it was hoped that deposition conditions could be established such that epitaxial films of $\geqq 30$ μm thickness could be laid down in a few hours with a carrier concentration of $10^{17}/cm^3$. To avoid the Burstein shift with subsequent decrease in the wavelength cutoff and efficiency of $Pb_xSn_{1-x}Te$ infrared detectors, the carrier concentration must be $\leqq 10^{17}/cm^3$. Slices from bulk crystals of $Pb_xSn_{1-x}Te$ as-grown have carrier concentrations of $3 \times 10^{19}/cm^3$ and require one month of metal-rich annealing to bring the carrier concentration down to the low $10^{17}/cm^3$ range.

Experimental

The quartz reactor that was used for the growth of epi films is illustrated in Fig. 1. The apparatus was similar to that used in crystal growth with the exception that a constant diameter, larger opening to the seed was utilized (13). The quartz tubes were made in various diameters to accommodate substrates from 1 to 2.5 cm in length.

The substrates, which were {100}, were cut from single crystals of $Pb_{0.79}Sn_{0.21}Te$ with a string saw. Surface irregularities from the sawing operation were removed from the substrates by lapping with a slurry of 600 mesh SiC. The substrates were then polished on a Pellon pad with concentrated HBr solution containing 5 volume per cent (v/o) Br_2 until about 400 μm had been removed; removal of this amount of material was necessary to insure removal of saw damage. The substrates were then removed from the polishing block and etched in HBr-Br_2 solution for 2 min to remove small scratches introduced on the polishing pad. The substrates were then electrolytically etched for 1 min to reveal damage. If no scratches were still present and if the number of dislocations was less than 10^5/cm, the substrates were used for the growth studies. The substrates were etched in HBr-Br_2 solution again by swirling for 1-2 min following the electrolytic etch. The substrates were 9-29 mm in length, 5-15 mm in width, and approximately 1.5 mm thick.



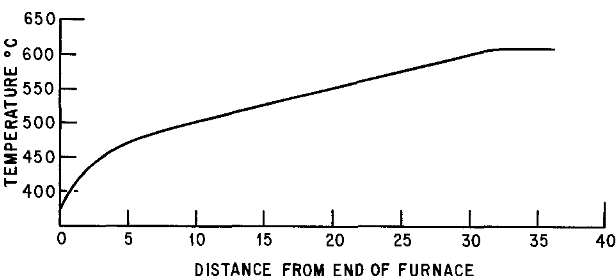


Fig. 1. Diagram of quartz apparatus used for epitaxial growth and a temperature profile used in one growth run.

The charges varied in composition from those which were stoichiometric to those containing 0.1 mole per cent (m/o) excess metals; these charges were compounded as described for crystal growth (13). Pieces weighing 2-3g were used as charges for the epitaxial growth experiments. After placing the charge in the growth tube, the system was sealed off at 10^{-6} Torr.

Figure 1 also gives a temperature profile with respect to the growth tube which was used during an epitaxial growth experiment. Although the temperature of the substrate for the experiment in Fig. 1 was 500°C with the charge at 610°C, substrate temperatures of 425°-525°C were used with temperature differences between the substrate and charge of 15°-200°C. To initiate epitaxial growth, the growth tube was inserted into a vertical, resistance heater already at the desired growth temperature and with the necessary thermal difference between the substrate and the charge. The length of a growth run was from 4 to 100 hr. At the conclusion of a run the growth tube was removed from the furnace and air quenched. The substrates were removed from the growth tubes by sawing the quartz.

Microscopic examination and x-ray diffraction were used to evaluate the crystalline quality of the epitaxial deposits. Electron microprobe was used to determine the composition of the films and their uniformity. The carrier type was determined by thermal probe. Schottky barriers were used to determine the carrier concentration of the epitaxial films.

Results and Discussion

The morphology of the deposits was greatly influenced by the substrate temperature. With a substrate temperature $\geqq$ 520°C the deposits had blocklike features as shown in Fig. 2(a). Figure 2(b) illustrates the surface of a continuous, smooth deposit approximately 50 μm thick which was laid down with the substrate at 490°C. Both deposits were made from charges of $Pb_{0.791}Sn_{0.211}Te$ at 590°C over a period of 24 hr. All deposits laid down at 425°-490°C from a charge of $Pb_{0.791}Sn_{0.211}Te$ were similar in appearance to that shown in Fig. 2(b). At the higher temperature $\geqq$ 520°C nucleation and growth probably occur at fewer sites than at lower temperatures. Thus, at the lower temperature the increased number of nucleation sites for growth probably leads to continuous deposits. It is also possible that more two-dimensional growth occurs at lower temperatures. Changes in morphology with temperature have been observed for many substances (14-16), and it has been the general conclusion that different growth mechanisms predominate at different temperatures. Deposition periods $\geqq$ 72 hr with substrate temperatures of 520°-525°C also gave continuous deposits but the surfaces were still covered with blocklike structures. For epitaxial growth at 800°-850°C, which is the temperature range used for growth of large single crystals (13), the deposit surfaces were smooth and featureless. Nearly all deposits had regular-shaped crystallites or blocklike structures on their surface when removed from the growth tube. However, these were loosely adhering crystallites which

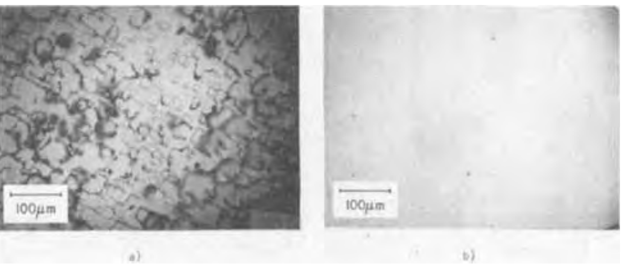

Fig. 2. Deposit surfaces at different substrate temperatures. (a) Substrate at 525°C, (b) substrate at 490°C. 350X magnification.

formed by rapid condensation of vapors during cool-down and were easily wiped off with a wet swab.

The surface quality of the substrate together with internal crystalline perfection affected the morphology of the epitaxial film as has been observed with numerous systems. Scratches and areas containing dislocations $\geqq 10^6/cm^2$ lead to irregular or blocklike features on the deposit surface. Figure 3 shows the surface of an epitaxial film with blocklike structures growing from scratches on the substrate. These structures extend about 20 μm above the epitaxial surface and demonstrate the effect of more rapid growth at dislocations or damaged regions. Usually these damaged regions could not be seen on the polished surfaces even under high magnification, however, the polished substrates were electrolytically etched to bring out these damaged areas. The presence of small angle grain boundaries and dislocations $\leqq 10^5/cm^2$ seemed to have no effect on the quality of the epitaxial film. The epitaxial films contained 3-10 times fewer dislocations than the substrates on which they were deposited.

The composition of the charge also had an influence on the morphology of the deposits. Charges ranging in composition from $Pb_{0.790}Sn_{0.210}Te$ to $Pb_{0.791}Sn_{0.211}Te$ gave smooth deposits while charges containing more excess metal gave irregular growth surfaces with needlelike projections. The needlelike projections were found to be metal rich by microprobe and metal-rich inclusions were found in the interior of the epitaxial layers deposited from these metal-rich sources. Chemical polishing of these epitaxial films with HBr-Br_2 resulted in holes being formed at the metal-rich inclusions. Similar growth features have been observed by others when using metal-rich charges in other growth methods (20-24). The tops of the needlelike projections are rounded and suggest that a vapor-liquid-solid type growth mechanism is involved when excess metal is present. These metal inclusions cause electrical shorts in the epitaxial films. The use of Te-rich charges gave irregular deposits which contained Te inclusions that were etched out during processing to leave holes.

Good quality epitaxial films were grown by proper control of charge stoichiometry, substrate surface preparation, and deposition temperature. A scanning x-ray topograph of a good quality epitaxial film is illustrated in Fig. 4. Topographs of the substrates before and after deposition of epitaxial films showed no changes in crystalline perfection. That the deposits were single crystal was also shown by x-ray diffraction using the large area Laue technique. The x-ray topograph in Fig. 4 shows the epitaxial film to be rather uniform in texture and free of strains. The white areas correspond

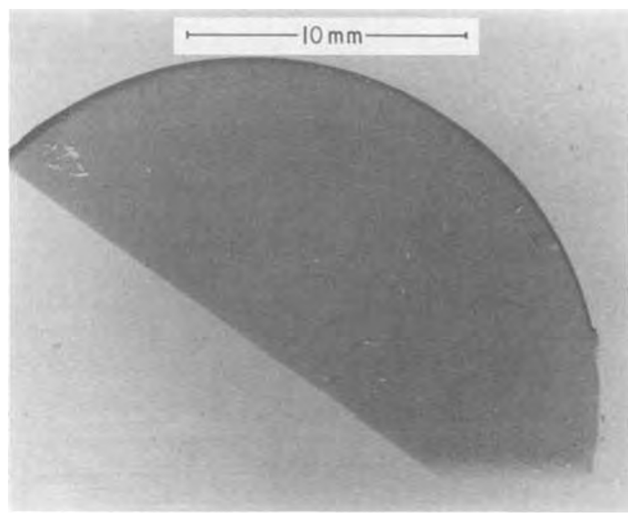

Fig. 4. Scanning x-ray topograph of an epitaxial film. 4.5X magnification.

to scratches and small holes introduced during the handling operations. This epitaxial layer was deposited with the substrate at 490°C and with the $Pb_{0.791}Sn_{0.211}Te$ charge at 590°C. The epitaxial layer shown in Fig. 4 was 60 μm thick and was deposited over a 24 hr period.

The epitaxial growth rate was varied by changing the temperature of the substrate and the composition of the charge. The deposition rate with the substrate at 420°C and the charge of $Pb_{0.790}Sn_{0.210}Te$ at 590°C was 1.5 μm/hr. With the substrate at 480°C and the charge at 590°C the deposition rate was 2.6 μm/hr. Figure 5 shows a photomicrograph of a cleaved substrate with the epitaxial layer deposited under these conditions. The epitaxial layer is clearly defined. The pits in the surface of the epitaxial layer were caused by material breaking away during the cleaving operation. Material also condensed on the walls of the growth tube and grew into small crystals but this material was not analyzed for its composition. This condensation occurred over about half the length of the growth tube but represented only a few per cent of the total charge weight. With stoichiometric charges the deposition rates were 30-50% less than for the slightly metal-rich charges used above. This suggests that uncombined metal may be involved in the growth mechanism and influences the growth rate.

The composition of the epitaxial films at their surfaces was rather uniform as determined by electron

microprobe analysis. Typical results are shown in Table I. The initial charge, which was used in the run described in Table I, was weighed out to give a stoichiometric charge of $Pb_{0.79}Sn_{0.21}Te$ or 10.5 atomic per cent (a/o) Sn, 39.5 a/o Pb, and 50 a/o Te. The composition of the charge after the deposition run was the same as that of the initial charge within the limits of experimental error. There was enrichment of SnTe in the epitaxial film which has also been observed in regular crystal growth at 850°C. This enrichment of SnTe is caused by the slightly greater vapor pressure of SnTe over that of PbTe (25). No microprobe measurements were made to determine if the compositions of the epitaxial films were uniform throughout their entire depth.

The type of dominant carrier in the epitaxial films was determined by thermal probe both at 77° and 300°K. The carrier concentration in the epitaxial films was determined by the Schottky barrier technique (26). Both carrier type and concentration showed variations with deposition temperature and with the feed composition as shown in Table II. It is doubtful that useful n-type films could be made because the n-type or mixed type material contained metal inclusions, which resulted in nonuniform etching during device fabrication and electrical shorts. It was necessary to use stoichiometric charges to obtain p-type deposits free of metal inclusions for substrate temperatures below 480°C. No deposition runs were made with stoichiometric charges for substrates below 425°C. The p-type carrier concentration decreased as the substrate deposition temperature decreased as expected based on annealing studies for $Pb_{0.79}Sn_{0.21}Te$ (27). Usually 10 μm were lapped and etched from the epitaxial layers before fabrication of the Schottky barriers so surface effects were eliminated.

A Schottky barrier infrared detector array was made on a 50 μm thick film deposited at 510°C from a charge of $Pb_{0.791}Sn_{0.211}Te$ at 600°C. The 22 element detector array had an average blackbody detectivity of 1×10^{10} cm $Hz^{1/2}/W$ at 77°K and varied by no more than ±10% from the average detectivity. The responsivity was about 10^4 V/W with a spectral cutoff at 12 μm. The properties of this array were very similar to those of Schottky barrier arrays made on annealed, bulk material (28). Only a few hours were required to obtain these epitaxial films while annealing the bulk material required a minimum of three weeks.

Depositions of PbTe on $Pb_xSn_{1-x}Te$ substrates as well as $Pb_xSn_{1-x}Te$ on PbTe substrates were also made using the closed-tube method. However, the deposition temperatures and the charges used were different from the ones described here and will not be further discussed.

Summary

Epitaxial films of $Pb_xSn_{1-x}Te$ were deposited on $Pb_{0.79}Sn_{0.21}Te$ substrates at 425°-525°C in a closed system at 10^{-6} Torr. Good quality, p-type films with carrier concentrations in $10^{17}/cm^3$ range were obtained. The n-type films produced contained metallic inclusions. The quality of the deposits was greatly influenced by the charge composition, substrate temperature, and defects in the substrate. Deposition rates ranged from 1.5 to 3.0 μm/hr.

Acknowledgments

The author gratefully acknowledges the help of Jack E. Pinnel in the experimental work. Appreciation is expressed to Henry Morris for making the Schottky barrier for determining carrier concentration and for fabrication of detector arrays. The discussions with Rowland E. Johnson and Richard A. Chapman were very helpful.

ABSTRACT

The first part of the study deals with the influence of CVD titanium carbide and titanium nitride coatings on the transverse rupture strength of M10 and P40 cemented carbide. The rupture strength is noticeably reduced by the coating, the extent of this decrease depending on coating thickness, coating structure, and the presence of a decarburization or brittle phase in the surface zone of the substrate material. Furthermore, it was found that a thin intermediate nickel layer does not have any positive effect on the rupture strength. The second part deals with investigations on the effect of substrate composition on the structure of the TiC and TiN coatings. In presence of nickel-containing substrates, the TiN forms dendritic structures, the TiC coarse-grained structures. Nickel is also incorporated into the coating. Increasing the reactant concentration in the gas phase intensifies these effects. Finally, the mechanisms underlying these effects are briefly discussed.

Titanium carbide, titanium nitride, and titanium carbonitride are currently widely employed in the form of homogeneous coatings and as multiple coatings to improve the wear resistance of cemented carbide tools and also to achieve decorative effects (1). The increase in wear resistance caused by these coatings is of particular importance in machining. The excellent stability and hardness as well as the attractive colors of some hard materials are gaining importance for decorative purposes.

Materials used in machining must have adequate toughness in addition to maximum wear resistance. For coated materials the adhesion to the substrate is another important factor. The wear resistance and toughness requirements of cemented carbides are mutually contradictory so that a compromise must be sought in each particular application.

If, for example, a cemented carbide grade with great wear resistance but insufficient toughness is employed in a certain machining application, fracture may occur. If, on the other hand, the toughness is greater than required, the cutting speed must be reduced in order to prevent softening or plastic deformation of the cutting edge.

The optimum utilization of coated materials thus requires a knowledge of their toughness behavior. In cemented carbide technology, the transverse rupture strength is taken as a measure of toughness and we have carried out a number of experimental studies on the effect of hard coatings on the transverse rupture strength.

Key words: transverse rupture strength, thickness of coatings, structure of coatings, composition of base material.

Coated TiC cemented carbide with Ni-Mo binder is of interest for wear parts as well as for decorative purposes. In decorative applications, the coating should not only exhibit good adhesion and corrosion resistance but should also be smooth so that a bright polish can be achieved. Coating experiments have shown, however, that the TiC-Ni-Mo grades, in contrast to the WC-Co grades, tend to form rough coating structures. This different behavior of the substrate material has induced us to carry out an investigation on the effect of the substrate on the coating structure.

Investigations on the Effect of the Coating on the Transverse Rupture Strength

A study carried out by Lee and Richman (2) has shown that a TiC coating on C2 and C4 cemented carbide reduces the transverse rupture strength by approximately 45%. The authors suppose that this decrease is due to the columnar coating structure; an equiaxed structure would presumably eliminate this deficiency.

We have first carried out preliminary studies on the effect of TiC and TiN coatings on two different grades of cemented carbide. The effect of a thin metallic intermediate layer was also investigated. This led to the necessity to investigate the dependence of the transverse rupture strength on the coating thickness, the effect of a decarburization zone between substrate and coating, and the behavior of coatings with different structures.

Test procedure and evaluation of results.—Transverse rupture strength rods of ISO groups M10 and P40 were coated with TiN and TiC by CVD (M10: 6%

Co, 10% TiC + Ta(Nb)C, remainder WC; P40: 13% Co, 10% TiC + Ta(Nb)C, remainder WC). Two lots of M10 rods were sintered. The rods cut from presintered blocks were sintered and then tumbled in a barrel with a boron carbide containing slurry for edge rounding and removal of the sintering skin and were then sand blasted. This preparation was essential in order to have the same conditions as with normal disposable tips.

The coating was carried out in a medium frequency induction furnace with graphite susceptor which was coated on the inside and had an internal diameter of 120 mm. The nickel-containing TiC coating was obtained by first depositing the TiC, then applying a nickel layer by electrolytic deposition and then again a layer of TiC. The coating conditions are summarized in Table I.

Figure 1 shows the arrangement for the measurement of the transverse rupture strength in accordance with ASTM B 405-70 standard (3) (corresponds to ISO standard DIS 3327, Type B) with the only difference that the specimen thickness was reduced. The specimen dimensions were 6.5 × 3.6 × 20 mm with a distance between supports of 14.5 mm. In accordance with the above standards, the supports consisted of cemented carbide rolls having a diameter of 6 mm and the load was applied in the center of the specimen by means of a 10 mm diameter cemented carbide sphere.

In transverse rupture testing, a considerable scatter is normal (the Swedish standard SIS 112618 considers a standard deviation of 12% of the mean value with 10 specimens as normal) so that a statistically significant result requires a correspondingly large number of specimens. Hence, 19-20 specimens were used for each test; some supplementary tests were carried out on only 14 or 15 specimens. The arithmetic means and the 95% confidence limits were determined for each test series. In order to permit conclusions on the effect of the coating structure, we prepared SEM (scanning electron microscope) micrographs at 3300X magnification at the specimen bottom where the material is subjected to tensile stress. Additionally, optical micrographs at 1500X magnification were also prepared.

Results.—Table II contains the results on the rods of lot 1 and Table III those of lot 2. In addition to the number of rods tested for each variant, the tables indicate the variation of the transverse rupture strength with the coating. The arithmetic mean of the uncoated rods was defined to 100%. The individual values fit fairly well into a normal distribution. Figure 2 shows as an example the distribution of the individual values for different coating thicknesses in the probability grid. Figure 3 (a-d) shows the coating structures at the fracture surface for the TiC, TiN, and TiC-Ni-TiC coating on M10 and for the TiN coating on P40 cemented carbide; Fig. 3 (e-g) the corresponding optical micrographs.

Further coating structures of fracture surfaces are shown in Fig. 5(a) and 5(b) for a thin and a thick TiC layer, Fig. 6(a) and 6(c) for 6-7μ thick TiC layers with and without decarburized phase, and Fig. 6(b) for a TiC layer with grainy structure. A comparison of the results permits the following conclusions.

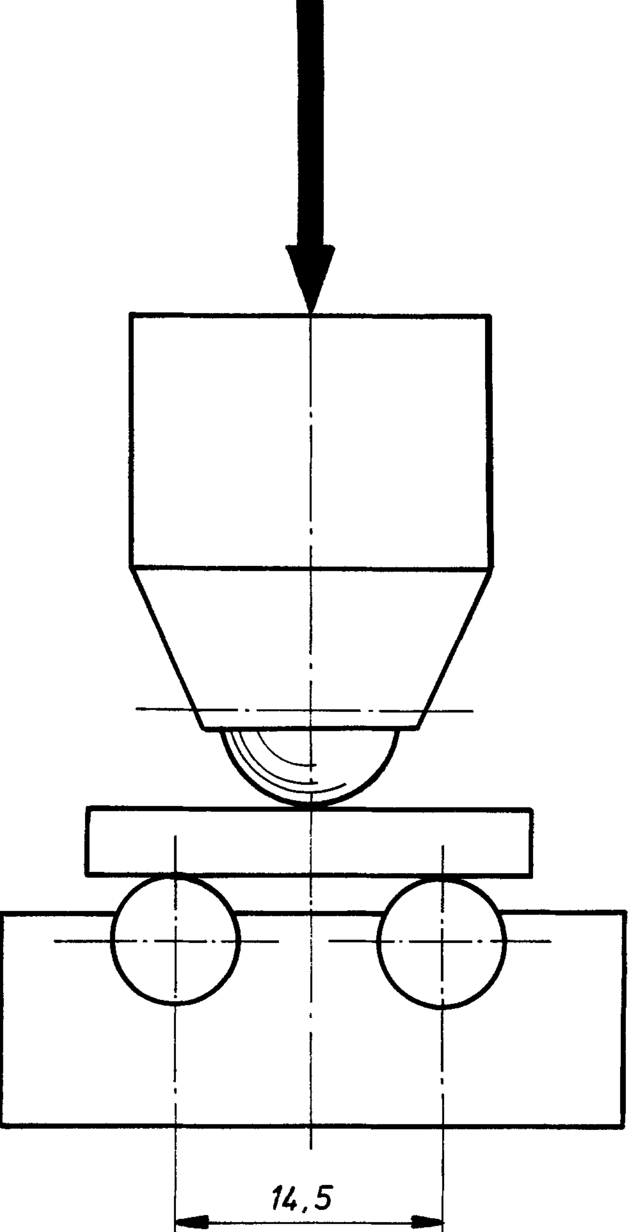

Fig. 1. Arrangement for the TRS measurement

Effect of TiC and TiN layers on M10 and P40 cemented carbide.—TiC and TiN layers over 10μ thick lower the transverse rupture strength of M10 and P40 grades by approximately one-third. These layers have a columnar structure [SEM micrographs Fig. 3(a-c)]; although this structure is thicker and more pronounced in the TiN coating, there is no difference in their effects.

Table II. Transverse rupture strength (TRS) of the rods of lot 1

Coating	Base material	No. of specimen	TRS kp/mm²	%
Uncoated	M10	20	182.4 ± 7.6	100
9 μm TiC	M10	18	126.1 ± 9.8	69.1 ± 5.4

* Base material M10 hardmetal.

Effect of coating thickness.—The transverse rupture strength as a function of the TiC coating thickness is shown in Fig. 4. With thin layers (up to 5μ), the coating thickness has a great influence. With increasing coating thickness, this influence is less pronounced. The fracture micrographs Fig. 5(a) and (b) show that in the thicker coatings, a very fine-grained structure is present near the substrate, with a transition to a columnar structure. The latter seems to be absent in the thin coatings.

Effect of the decarburization zone (eta layer).—Figure 4 also gives values for two different TiC layer thicknesses combined with an approximately 3μ thick decarburization zone (W_6Co_6C etc.). The curve showing the influence of the coating thickness is slightly shifted to lower rupture strengths, *i.e.*, the decarburization zone has the same effect as a thicker coating.

Influence of the coating structure.—By variation of the coating parameters it was possible to produce a grainy (equiaxed) structure [see Fig. 6(b)]. This structure gives a higher rupture strength but at 7μ coating thickness, the decrease still amounts to about 22%.

Incorporation of a thin nickel layer in a TiC coating.—It was found that the incorporation of an intermediate nickel layer alters the structure of the TiC coating and causes a further decrease in rupture strength [Fig. 3(d)]. Thus, an intermediate layer does not act as a crack barrier.

Fracture mechansim.—Cemented carbide and TiC differ considerably in Young's modulus and transverse rupture strength.

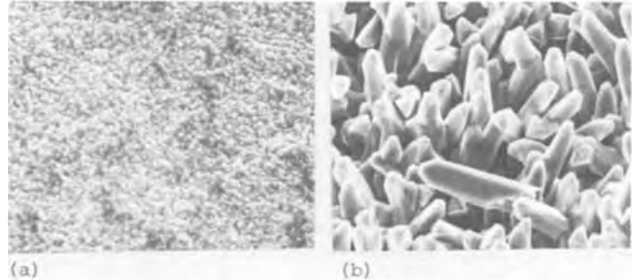

Fig. 7. SEM of the surface of (a) P40 and (b) TiC-Ni-Mo cemented carbide coated simultaneously with TiN.

On the basis of these values one would expect that the coating cracks on the side subjected to tension in the transverse rupture test without the crack propagating immediately into the cemented carbide. This crack could act as a notch. Coatings of different thickness would have to give notches of different depth. Further investigations are underway and will show whether this model adequately accounts for the dependence of the transverse rupture strength on the coating thickness and for the effects of different coating structures.

Conclusions.—The following inferences can be derived from the above results. The transverse rupture strength of cemented carbide is noticeably lowered by coating with tightly adhering hard materials, with the following factors being of importance: (*i*) the coating thickness, particularly with very thin coatings; (*ii*) the coating structure, with grainy structures being preferable to columnar structures; and ((*iii*) a decarburization or brittle phase in the surface zone of the substrate. Hence, these factors must be included in any investigation on the strength of coated materials. A thin, electrolytically deposited nickel layer does not have any positive effect on crack propagation.

Influence of the Substrate on the Coating Structure

Hintermann, Gass, and Lindström (5) have shown that in TiC coating of cemented carbide, the composition of the substrate has an important effect on the coating structure. As mentioned above, we obtained dendritic structures in coating of TiC cemented carbide with Ni-Mo binder under certain conditions, whereas on WC-Co cemented carbide, finely crystalline, smooth coatings resulted. Figure 7 shows the surfaces of a 10μ thick TiN layer on P40 and on TiC-Ni-Mo hard metal, which were coated simultaneously. As it was not clear at first whether these structure effects were produced by the TiC or the Ni binder, we have coated P40 hard metal with 5-7μ thick TiC and then nickel-plated them electrolytically. We have carried out structure investigations on TiC and TiN coatings at normal and double reactant concentration.

Experimental conditions and results.—The coating conditions are given in Table IV. Figure 8 shows surface textures of TiN coatings deposited at normal and double concentration. The TiN deposition on TiC, *i.e.*, a nickel-free substrate, always gives finely crystalline coatings such as are obtained on WC-Co hard metals. Doubling of the concentration does not affect the structure. Conversely, the nickel-plated specimens ex-

hibit a pronounced dendritic crystal growth, particularly so at double reactant concentration. In the TiC deposits made under the same conditions, pronounced dendritic structures are absent, but the coating is more coarse grained in presence of nickel.

Figure 9 shows TiC deposits obtained at double reactant concentration. On the nickel-plated specimen, a new phase is observed in the form of inclusions, particularly at higher concentrations. These inclusions were identified by EDAX as finely divided nickel.

Figure 10 shows polished sections of TiC and TiN coatings on nickel-plated substrates with finely divided nickel inclusions in the coating; a Ni and Ti analysis by means of EDAX and a fracture structure. The latter shows the typical dendritic crystal growth. As it appeared logical that this crystal habit is due to heterogeneous nucleation at the Ni surface, we have carried out short-time coating tests in order to observe the processes taking place during the initial coating phase. Figure 11 provides a comparison of the surface structures obtained in short-time and normal coating. With the nickel-plated specimen, a greatly inhibited nucleation can be observed, resulting in a columnar to dendritic structure with longer coating durations. In contrast, specimens not nickel plated exhibit intense nucleation at the surface during the initial coating stage, thus yielding finely crystalline, smooth coatings.

Discussion.—The following inferences can be drawn with regard to the influence of different substrate compositions on the coating structure. TiC and WC-Co cemented carbide substrates always give smooth coatings under our coating conditions. Nickel-plated or

nickel-containing substrates, on the other hand, particularly when TiN is deposited, exhibit intense dendritic crystal growth. Doubling the concentration in this case has a much greater effect than in TiC coating, when the Ni merely causes a slight coarsening of the structure. It is possible, however, that under different coating conditions this effect will be more intense even for the TiC deposition. Nickel incorporation into the coating can be observed in TiC and TiN coating; in TiN coating, the effect of the nickel probably consists in a reduction of the number of nuclei in the initial stage. Thus, coarser coatings will result. At the same time, preferred growth directions develop. The coating conditions probably also affect

the result; for example, in our case, a higher concentration results in faster growth in one direction and thus also in an intensification of dendritic growth.

Concerning the Ni incorporation, the following transport mechanisms may be assumed: (*i*) a gas phase transport via nickel chlorides resulting in a constant nickel chloride concentration in the deposition zone and in continuous nickel deposition at certain points; (*ii*) surface diffusion of the nickel during the growth of the TiC or TiN crystallites; and, (*iii*) formation of a liquid phase which penetrates cavities formed during deposition.

In the system Ti-Ni, the lowest temperature of the liquid phase is about 950°C, representing an eutectic containing 70 weight per cent titanium. Which of these theoretically possible transport mechanisms is actually operative, cannot be decided at this time.

ABSTRACT

The effect of composition, microstructure, and preferred orientation upon the oxidation of iron-nickel-cobalt alloy was investigated. Decarburized samples were oxidized at various temperatures and times. Decarburization at 1100°C in wet hydrogen enhances the (200) orientation. The oxidation rate depends on the alloy grain size and minor alloy constituents and is enhanced at the grain boundaries. The oxide is predominantly spinel with increased amounts of α-Fe_2O_3 appearing in fine-grain alloy oxidized at lower temperatures and longer times.

Variations in the oxidation behavior of iron-nickel-cobalt alloy under constant production conditions have been observed from heat to heat and from vendor to vendor. These variations cause processing difficulties in the production of components requiring glass-to-metal seals, consequently lowering the production yield. The problem is especially severe (*i*) where close process control is used to achieve a standard oxide weight gain on the parts prior to the glass fusing operation and/or (*ii*) where continuous processing is desired.

The purpose of the present investigation was to determine the causes of the differences in the oxidation characteristics of the ASTM F-15 glass-sealing alloy so that its oxidation behavior could be predicted.

Very little work has been done on the oxidation characteristics of the ternary alloy, iron-nickel-cobalt. Abendroth (1) studied the oxidation of the iron-nickel-cobalt alloy having a chemical composition similar to ASTM F-15 at 700°-900°C and concluded that the oxidation product is predominantly Fe_3O_4 with some cobalt and nickel present. He attributed oxidation below 800°C to iron ion diffusion through Fe_3O_4 and above 800° to iron ion diffusion through FeO. However, the wustite phase (FeO) was not detected by x-ray diffraction.

Abendroth's work is inconclusive pertaining to the mechanisms of oxidation of the iron-nickel-cobalt alloy and provides no information on the variation of oxidation characteristics with respect to inherent material variables. Therefore, it was decided to investigate the effects of the composition, microstructure, and preferred orientation on the oxidation rate, oxide composition, and structure as a function of temperature and time.

Materials and Experimental Procedures

Materials for this investigation were chosen from three vendors referred to as I, II, and III. Two heats of the alloy were chosen from each supplier according to their chemistry, microstructure, and texture. All materials were stamped into rectangular coupons 2.54 × 2.39 cm with an average thickness from 0.015 to 0.041 cm. The chemical compositions as provided by the manufacturers of the materials (unless otherwise noted) are given in Table I.

The materials were oxidized in dry air (dew point at −70°C) at 787°, 850°, and 900°C for periods of 4-20 min. These oxidation conditions were chosen because previous experimental work indicated that the optimum production conditions for oxidizing parts to be glass sealed fell within this time and temperature range.

Prior to decarburization and oxidation, the metal coupons were chemically cleaned by hydrochloric acid and degreased. After the cleaning operation, groups of ten coupons of each material were weighed on a Mettler analytical balance to ±0.1 mg. They were then loaded in a sand-sealed retort which was placed in a Lindberg box furnace for decarburization and oxidation. A total of six materials was arranged in groups of

ten coupons in the retort. Platinel thermocouples were placed at the front and rear of the retort to monitor the temperature. The reported temperatures are accurate to better than ±5°C. The materials were decarburized at 1100°C for 25 min in wet hydrogen (dew point at room temperature). They were then cooled to the desired oxidation temperature under a dry argon blanket (dew point at −72°C). The furnace temperature was stabilized, and dry air was introduced into the system at a flow rate of 1600 cm^3/min. The chamber volume was 2122 cm^3. When oxidation had taken place for the desired time, the air was switched off and the samples were cooled to room temperature under an argon blanket. After cooling, each material was then weighed in groups of ten coupons on the analytical balance to obtain the group oxide weight gain. The average surface area of each material was determined from the coupon dimensions, and, subsequently, weight gain in mg/cm^2 was obtained.

The oxides were characterized by x-ray diffractometry and spectroscopy. Calibration samples having predetermined ratios of Fe_2O_3 to Fe_3O_4 were used to prepare a calibration curve for quantitatively determining the oxide phases formed. Selected decarburized samples and oxidized samples were also examined with a Cambridge scanning electron microscope. The iron, cobalt, and nickel concentrations in the oxide were obtained with an energy dispersive x-ray analyzer attachment on the SEM. The microstructure of the oxide/metal interface was studied by examining tapered sections under a metallurgical microscope.

The preferred orientation of the material was determined by comparing the relative intensities of the x-ray diffraction peaks for the (111), (200), and (220) planes of face-centered cubic (fcc) alloy. A Phillips diffractometer was employed with copper Kα radiation as the source. Preferred orientation was determined on both the as-received materials and on samples which had been decarburized.

Results and Discussions

It is known that oxidation behavior is dependent on substrate orientation (2-5). For this reason, the preferred orientation of each material was determined.

The results of the metal preferred orientation measurements are summarized in Table II. As-received material showed preferred orientation of the (111), (200), and (220) planes for different heats of material, but the decarburization treatment at 1100°C strongly enhanced the (200) cube face orientation in the roll plane. Thus, the decarburization process eliminates the orientation variable, *i.e.*, the effect of substrate crystal plane orientation on the oxidation characteristics of the six materials should be the same. No significant evidence of oxide orientation or residual stress was detected within the limits of experimental error. This is probably due to the thickness of the oxide formed.

The average grain size of the materials after decarburization at 1100°C was found to vary from 9 to 132 μ as shown in Table I. The grain size was determined by the line intercept method.

For fixed time and temperature, the oxide weight gain varied as much as 54% among the six materials. The weight gain is plotted as a function of the oxidation time in Fig. 1. The calculated rate constants are shown in Table I. The oxide weight gain is found to increase parabolically.

High temperature parabolic oxidation indicates that the rate-determining step is a thermal diffusion process (6). Abendroth (1) also observed parabolic oxidation rates for iron-nickel-cobalt alloy in the range 700°-900°C.

Logarithms of the rate constants are plotted as an inverse function of temperature in Fig. 2. The activation energies for oxidation were obtained from a least squares fit to the Arrhenius plots in Fig. 2.

The activation energies observed for oxidation of materials IA and IB are close to the value of 54-55 kcal/mole obtained for iron diffusion in Fe_3O_4 (7). The activation energies obtained for materials IIC, IID, IIIE, and IIIF are approximately 46 kcal/mole. The difference in activation energy between the two groups appears to be related to chromium content (Table I). These two values are found to be substantially greater than the activation energy (30.9 kcal/mole) reported by Abendroth (1).

The x-ray diffraction results are summarized in Table I. The spinel form predominated in all cases. Nickel and cobalt were detected in the oxide by x-ray

spectroscopy. Hematite (α-Fe_2O_3) was present in some cases. The percentage of α-Fe_2O_3 in the oxide was found to increase at lower oxidation temperatures and longer times. Graham and Cohen (8) also observed the formation of α-Fe_2O_3 after the oxidation of pure iron at longer periods of time, but not after short-time oxidation.

This can be explained in terms of the diffusion of iron, cobalt, and nickel. The oxide scale formed on the iron-nickel-cobalt alloy is basically a diffusion couple with the alloy on one side and oxygen on the other side. The separate monoxides (FeO, NiO, CoO) will immediately react on the surface to form the spinel [(Fe) (Fe, Co, $Ni)_2O_4$]. This spinel is stable over a wide range of cation and oxygen anion concentrations. The diffusivities of iron, cobalt, and nickel cations vary considerably so that the cation ratios will change with the oxide film thickness. Mayer and Smeltzer (9) and Dalvi and Smeltzer (10) have shown that $D_{Fe} = 1.6\ D_{Co}$ at 1200°C and $D_{Fe} = 3D_{Ni}$ at 1000°C in (Co, Fe)O and (Ni, Fe)O scales, respectively. Similar trends were observed in spinel layers by Abendroth (1). His measurements of oxide chemical composition of iron-nickel-cobalt alloy indicated that iron diffused more rapidly than cobalt which also diffused more rapidly than nickel in the temperature range 750°-900°C. His measurements also indicated that the difference in relative diffusivities decreased as the oxidation temperature increased. Therefore, longer times at lower temperatures will result in the formation of more α-Fe_2O_3 with the iron cation concentration building up at the oxide/air interface. The tendency for iron ion to diffuse faster than nickel ion in iron-nickel-cobalt alloys was also noted by Ikeda and Sameshima (11). Thus, at suitably long times, the diffusion couple will consist of alloy/spinel/α-Fe_2O_3/O_2 (air). The α-Fe_2O_3 is also found to form in thicker oxide scales which are favored by smaller grained alloy substrates. The smaller grained substrates appear to be related to higher silicon content. SEM x-ray analysis was performed on some of the materials decarburized at 1100°C. The analysis showed that the over-all silicon concentration was greater on the surface of the decarburized material than on the as-received material. Silicon-rich precipitates were observed along the grain boundary and in the grain matrix of the decarburized alloy. These silicon-rich precipitates appear to be oxides and may be inhibiting grain growth of the alloy. They are easily seen in Fig. 3, a SEM photomicrograph of a smaller grained alloy, material 1B (15 μ). Douglas (12) also observed these silicon-rich precipitates after heat-treating the Fe-51 weight per cent (w/o) Ni alloy which contained up to 0.10 w/o silicon at 1150°C for 30 min in hydrogen.

Figure 4 shows the effect of the grain boundary area on the parabolic rate constant, pointing out the strong contribution of grain boundary oxidation to the formation of oxide scale. The total grain boundary surface area per unit volume of metal is inversely proportional to the average grain diameter, D (13). From a least squares fit to the plot of the parabolic rate constant of the materials containing less than 0.11 w/o chromium *vs*, $1/D$, the oxidation rate constants at 787°, 850°, and 900°C were obtained; (i) the oxidation rate at the grain surface only, k_{gs}, which is the value of k at

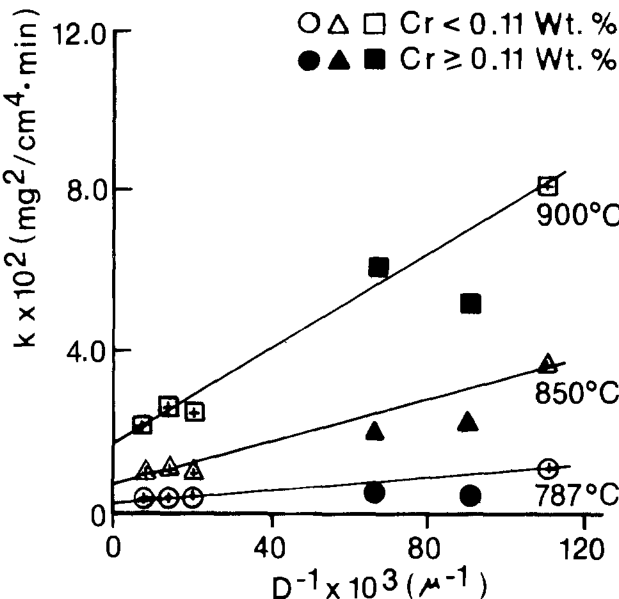

Fig. 4. Oxidation rate as a function of grain boundary area

$1/D$ equal to zero (grain boundary area is zero) and (*ii*) the oxidation rate per unit grain boundary area, k_{gb} which is obtained from the slope of the plot. These values are given in Table III.

The effect of chromium (≧0.11 w/o) on the oxidation rate is also shown in Fig. 4. The oxidation rates of the materials with higher chromium concentrations are lower as is indicated by the points falling below the line (with one exception at 900°C which may be due to experimental error). This would indicate that a chromium content of less than 0.06 w/o will not substantially affect the oxidation rate; whereas, chromium greater than 0.11 w/o will inhibit it.

Logarithms of the rate constants are plotted as an inverse function of temperature in Fig. 5. A least squares analysis of the plots shows the activation energy for oxidation on the grain surface to be 48.5 kcal/mole and for oxidation on the grain boundary to be 41.3 kcal/mole, a decrease of 7.2 kcal/mole.

Thus, for material IIIE (Table I) where the grain size is small (9μ), the activation energy for oxidation, 43.1 kcal/mole, is close to the value obtained for pure grain boundary oxidation (41.3 kcal/mole). As the grain size is increased, the activation energy increases to 46.6 kcal/mole where it levels off (Fig. 6). This value is approaching that for pure grain surface oxidation (48.5 kcal/mole). As shown in Fig. 6, the leveling begins at approximately 50μ grain diameter indicating the smaller contribution of the grain boundary to the oxidation of the larger grained alloys.

The taper sections which were prepared indicate a major contribution of the metal grain boundaries to oxidation as illustrated in Fig. 7 (material IIC, grain size, 78μ). Oxide grain boundaries extend from the metal grain boundaries. The oxide grain boundaries are of different composition than the oxide formed on the metal grain surfaces. SEM x-ray analysis shows that the surface of the grain boundary oxide is richer in iron and depleted in nickel as compared to the oxide formed on the metal grain surface (Table IV). Thus it appears that iron is being preferentially oxidized at the grain boundary compared with the grain surface. Preferential oxidation of iron has been observed in iron-nickel alloys (14). This in turn results in a gradual enrichment of nickel at the alloy/oxide interface. The SEM micrograph of material in Fig. 8 also illustrates the more rapid oxide growth (sometimes described as extrusion of oxide at metal grain boundaries) occurring at the grain boundary.

Table III. Parabolic rate constants

T°C	Oxidation rate at grain surface, $k_{gs} \times 10^2$ (mg²/cm⁴ · min)	Oxidation rate per unit grain boundary area $k_{gb} \times 10^2$ (mg²/cm⁴ · min)
787	0.189	8.881
850	0.719	27.281
900	1.716	58.523

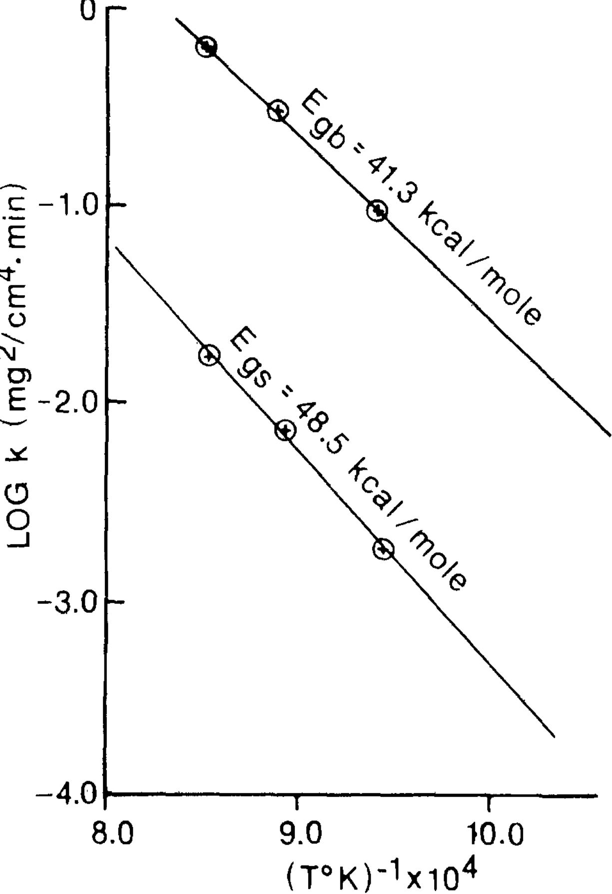

Fig. 5. Activation energy for grain boundary and grain boundary oxidation.

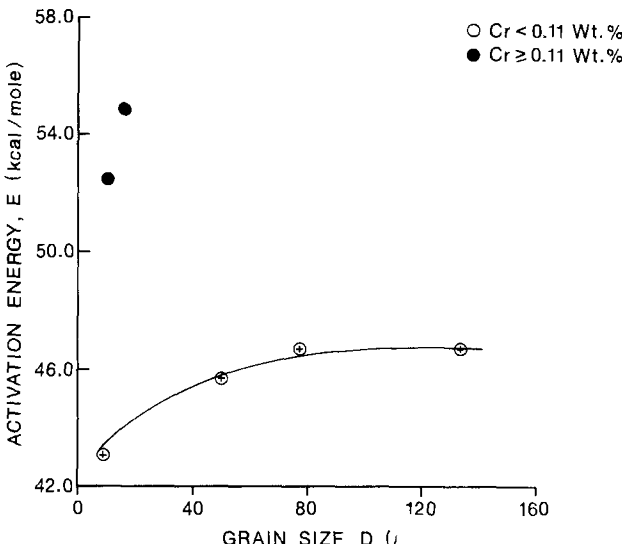

Fig. 6. Activation energy as a function of grain size

Conclusions

The six as-received materials had different preferred orientations, either (111), (200), or (220). Decarburization at 1100°C in wet hydrogen produces the (200) preferred orientation in all the materials.

The rate of oxidation of the iron-nickel-cobalt alloy follows parabolic kinetics. The grain size of the alloys strongly affects the oxidation rate; the smaller the

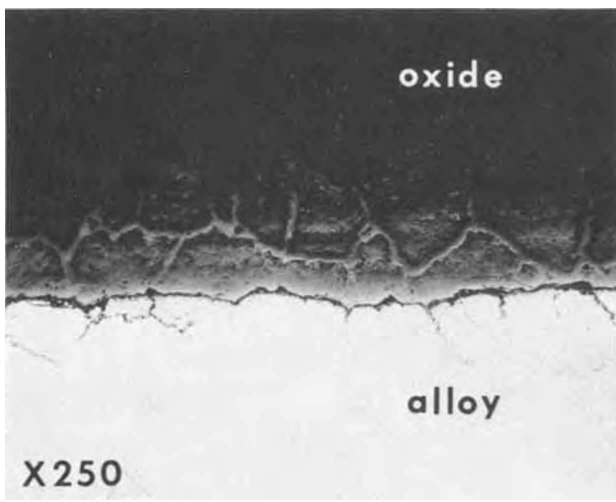

Fig. 7. Taper section of oxide/alloy interface

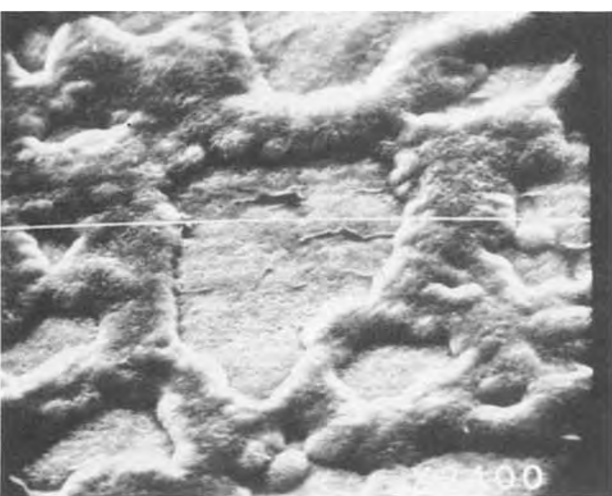

Fig. 8. SEM photograph of oxide/air interface

grain size, the higher the oxidation rate. The activation energy for the oxidation of the material having the smallest grain size (9μ) is 43.1 kcal/mole close to the value, 41.3 kcal/mole, calculated for grain boundary oxidation. As the grain size increases, the activation energy for oxidation increases to 46.6 kcal/mole becoming constant for materials having an average grain size greater than 50μ. The value is approaching that calculated for grain surface oxidation (48.5 kcal/mole). Thus, the effect of grain size becomes less pronounced when the grain diameter is greater than 50μ.

Higher silicon content appears to inhibit grain growth and hence produces a higher oxidation rate. Where the grain size is similar, high concentrations of chromium (0.11 w/o) retard the oxidation rate and increase the activation energy for oxidation from 46 to 55 kcal/mole. It appears that a chromium content of less than 0.06 w/o will not substantially affect the oxidation rate or the activation energy for oxidation.

A mixed spinel containing iron, nickel, and cobalt [$(Fe, Ni, Co)_3O_4$] is initially formed at the metal/

Table IV. SEM analysis of oxide formed at 787°C at 8 min

Area	Material	% Metal content Fe	Co	Ni
Grain boundary	IA	69.13	16.29	6.21
	IIIE	69.83	16.73	4.33
Grain surface	IA	56.10	17.45	25.11
	IIIE	57.00	19.60	19.89

oxide interface. The formation of α-Fe_2O_3 at the oxide/air interface is favored by low oxidation temperatures and long times because iron ions diffuse faster than nickel or cobalt ions, particularly at lower temperatures. Higher concentrations of α-Fe_2O_3 are formed on the fine-grained alloy due to its higher oxidation rate (thicker scale).

The oxide forms more rapidly on the alloy grain boundary and has a different chemical composition from that of the oxide formed on the grain surfaces. The grain boundary oxide is more enriched in iron and depleted in nickel with respect to the oxide formed on the grain surface.

Structural Principles of α-AgI and Related Double Salts

J. C. Phillips

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The structures of $RbAg_4I_5$ and related superionic conductors are discussed, and quantitative measures of chemical bonding are proposed which explain the formation of double salt compounds. Alternative diffusing cation candidates are proposed.

The α-phases of AgI, CuI, and CuBr are perhaps the most remarkable binary solids known. Although the anions form a bcc lattice, the cations are distributed among many nearly equivalent sites; the distribution is so nearly uniform that the cations may be said to form a liquid (1-3). The temperatures, T_α for the β (wurtzite) $\rightarrow$ α transition and the melting points, T_m, for these three crystals are listed in Table I. For CuI and CuBr, T_α and T_m are close enough together (especially for CuBr) that one might say that the cation sublattice has merely melted (or premelted) just before the anion sublattice. However, no other single phase compounds are known to melt in stages, and general theories of first order phase transitions do not suggest that such phenomena should occur. Moreover, the α-phase of AgI is stable over a very wide range of temperature (Table I).

A second explanation for these extraordinary phases is that they are in some way peculiar to Ag and Cu salts. Apart from its alchemical character, this explanation is not satisfactory because AgCl and AgBr do not form α-phases. However, Tubandt and co-workers showed long ago that Cu_2S, Ag_2S, Ag_2Se, and Ag_2Te all have ionic conductivities much higher than in ordinary salts. A particularly interesting case, studied by Ketelaar (4), is $(Ag, Cu)_2HgI_4$. This compound has essentially the zinc blende structure, but only three of the four cation sites in cubic unit cell are occupied. In principle, this may give rise to a tetragonal structure, and in the Cu case it does ($c/a - 1 = 0.010$), but in the Ag case the structure remains cubic ($c/a - 1 = 0.000$). The disordering temperature, T_d, for Ag_2HgI_4 is 50°C, considerably lower than $T_\alpha = 146$°C in AgI.

Double Salts

One may regard Ag_2HgI_4 as a double salt, *i.e.*, $(AgI)_2HgI_2$. One may also hypothesize, as Bradley and Greene (5) and Owens and Argue (6) apparently did independently, that forming double salts has a eutectic effect on T_α, and that a more judicious choice of the second salt to be combined with AgI might lower T_α further. Of course, such qualitative reasoning may not be rigorously justified, but, in fact, new double salts were discovered (5, 6), such as $RbAg_4I_5$, which have an ionic conductivity of 0.27 ohm^{-1} cm^{-1} at ambient temperatures.

The discovery of $RbAg_4I_5$ has stimulated further investigations which have shown that there are many compounds with the majority of the cations exhibiting high mobility. All of the highly mobile majority cations in compounds prepared so far are Ag or Cu. However, it seems possible that alternative cations may exhibit similar behavior. Moreover, the crystal structures of many of the new compounds can be said to be as novel as α-AgI, or perhaps even more novel.

To see why the structure of $RbAg_4I_5$ is extraordinary, it is instructive to compare it with Ag_2HgI_4. The latter structure is a superstructure of sphalerite, with a unit cell four times as large, analogously to the chalcopyrite compounds which have a unit cell twice as large as the sphalerite cell. Both structures may have the cations ordered by a tetragonal distortion, or remain cubic with disordered cations. In the chalcopyrite structure the tetragonal distortion can be explained (7) in terms of dielectric electronegativities (for II-IV-V_2 compounds such as $ZnSnAs_2$), but no simple pattern has been established for the tetragonal distortions in (Ag, Cu)-III-VI_2 compounds because of the complications introduced by the (Cu, Ag) d electrons.

Key words: solid electrolytes, soft lattices, addition compounds, double salts.

Exotic Structures

The mechanism of ionic conductivity in Ag_2HgI_4 is easy to understand. When the cations are disordered the cation defect sites (created by replacement of two Ag^+ ions in Ag_4I_4 by a Hg^{++} ion and a neutral vacancy) can form conducting paths through the lattice, the ions passing from one tetrahedral site to the next by means of shared tetrahedral faces. This nomenclature has been adopted to describe conductivity in $RbAg_4I_5$ and many other of the new and novel double salts synthesized in the last decade. However, here I argue that while this description is not incorrect, it does not really exhibit the remarkable structural character of these compounds, which in my opinion is closely related to that of the single salt prototype, α-AgI. In fact, unlike Ag_2HgI_4, the new double salts have exotic crystal structures which are not variants or superstructures of any known single salt. Thus the most basic question regarding these materials is the nature of the microscopic interactions responsible for their exotic structures.

An argument can be made at the outset that these interactions cannot be analyzed or explained. Many of these ternary structures are stable over narrow temperature ranges; the compounds readily disproportionate. The unit cells often are large, containing several formula units and dozens of atoms. Certainly from quantum mechanics it is not possible to calculate free energies accurately enough to deduce these structures.

Crystal Chemistry

The answer to this argument, and the theoretical basis for this paper, lies in the emerging science of crystal chemistry which has successfully accounted for the systematics of phase transitions, heats of formation, dielectric properties, and interatomic forces in many binary compounds. Many of the basic ideas in this field are old and can be traced back to Goldschmit, Pauling, and earlier workers, but their de-

Table I*

Compound	T_α(°C)	T_m(°C)
AgI	146	555
CuI	440	602
CuBr	470	488

* The low temperature (β) phases of these binary salts are tetrahedrally coordinated, while they undergo a transition at T_α to the α-phase where the cations are in a "liquid" state. Also listed are the melting temperatures T_m.

velopment in quantitative form has been more rapid recently with the acquisition of a vast amount of experimental data.

More specifically, we can hope to identify (at least semiquantitatively) the interactions which stabilize exotic double-salt structures just because there are so many of them. In the double-salt formula $MX(AgI)_p$ ($4 \lesssim p \lesssim 7$), M may be Ag, an alkali ion, or any one of many organic cations with very large molecular weights (8-12). Also X may be S (8) or a radical such as CN (13) or $(P_2O_7)_{1/4}$ (14). An increasing number of double salts $MX(CuX)_p$ with X = Cl, Br, or I and M an even larger organic cation have been reported (14, 15).

Preview

Our discussion is divided into four parts. First, we consider macroscopic changes in density which show that $RbAg_4I_5$ is more closely related to α-AgI than are defect compounds such as Ag_2HgI_4. Second, we indicate the degree of covalent-ionic mixed bonding which makes it possible to form the α-AgI and related exotic double salt structures. Third, we connect the lattice dynamics of the parent single salts AgI and CuX with the general theory of soft lattices, which applies not only to insulators but also to intermetallic compounds, many of which are high temperature superconductors. Fourth, we discuss the role played by vibrational entropy in stabilizing exotic structures near their Debye temperatures but well below their melting points.

Covalent Melting

The transformation of Ag_2HgI_4 from the β-phase (ordered cations in a slightly tetragonally distorted sphalerite superstructure) to the cubic α-phase at 50°C is accompanied by negligible volume change (16), but in AgI the $\beta \rightarrow \alpha$ transition gives (3)

$$\frac{\Delta V_t(\text{AgI})}{V_t} = -0.05 \qquad [1]$$

with the sign corresponding to a reduction in molar volume. A typical value for the reduction in molar volume of all tetrahedrally coordinated partially covalent semiconductors upon melting is (17)

$$\frac{\Delta V_m(A^N B^{8-N})}{V_m} = -0.15 \qquad [2]$$

Comparison of [1] and [2] shows that the picture of α-AgI as "half-melted" is qualitatively satisfactory.

We can now compare the molar volume of $RgAg_4I_5$ with the volumes of RbI and 4AgI with (18) $\Omega(4RbAg_4I_5) = (11.24)$ (3) and (19) $a_{AgI} = 6.473$ A and $a_{RbI} = 7.342$ A we find a contraction ΔV_{ds} for the double salt

$$\Delta V_{ds} = \frac{V(RbAg_4I_5) - V(RbI) - 4V(AgI)}{V(RbAg_4I_5)} = -0.04 \qquad [3]$$

Note that in α-AgI all the cations are liquid, whereas in $RbAg_4I_5$ only four-fifths of them are liquid. Correspondingly

$$\frac{\Delta V_{ds}}{V_{ds}} = \frac{4}{5}\,\frac{\Delta V_t(\text{AgI})}{V_t(\text{AgI})} \qquad [4]$$

which shows the close macroscopic relationship between α-AgI and $RbAg_4I_5$. Note that in $RbAg_4I_5$ each cation complex has the same coordination configuration as in the single salt, *i.e.*, each Rb minority cation is octahedrally coordinated with six I anions, while each "liquid" Ag majority cation is tetrahedrally coordinated with four I anions. In the large cubic unit cell for α-AgI it was suggested (3) that there were 30 possible sites for $4Ag^+$ ions (none of them tetrahedrally coordinated, as the I anions form a bcc lattice). For $RbAg_4I_5$ there are 52 possible quasi-tetrahedrally coordinated Ag sites per unit cell containing 16 Ag ions (15). The question of whether the Ag sites are strictly tetrahedral is probably of secondary importance because as we shall see the Ag coordination complexes are soft; of more importance are the density changes [1]-[4], which are characteristic of the melting of fourfold coordinated complexes.

Microscopic Models

Macroscopic density changes $\Delta V_m/V_m$ upon melting are nearly constant (17) for all tetrahedrally coordinated binary compounds $A^N B^{8-N}$. We therefore ask next what is special about AgI, CuCl, CuBr, and CuI that leads to the formation of exotic double salts. We note that each of these compounds is tetrahedrally coordinated, and that octahedrally coordinated AgCl and AgBr do not form exotic double salts. This can be explained by the density argument discussed above; for octahedrally coordinated halides $\Delta V_m > 0$ and therefore formation of an exotic, liquid majority cation structure with $\Delta V_{ds} < 0$ is excluded.

A simple explanation for the proclivity of AgI, CuCl, CuBr, and CuI to form double salts is the presence of easily polarized d electrons on Ag and Cu atoms, which make the atoms "soft" and therefore can more easily accommodate the changes ΔV_m (or ΔV_{ds}) needed to form exotic double salts. The weakness in this explanation is that the Cu d electrons are much more easily polarized than the Ag d electrons. Indeed the color of Cu stems from the d absorption threshold at 2 eV, while the color of Ag is related to the fact that the d absorption threshold at 4 eV is well outside the visible part of the spectrum. Yet the exotic structures are much more easily formed from AgI than from the Cu halides, and the α-modification of AgI is stable (Table I) at much lower temperatures than the α-modifications of the Cu halides.

A macroscopically accurate explanation of the relative softness of AgI and the Cu halides can be obtained from the general theory of noncentral (bond-bending) interatomic forces. The idea was stated originally (20) before the synthesis of most of the double salts based on the Cu halides, and it permits one to draw distinctions between them in accord with more recent experiments and also in contradiction with the qualitative trends between CuBr and CuI shown in Table I. Thus it may be said that the interatomic force criteria have already demonstrated some predictive value.

Binary Phase Transitions

The microscopic criteria have evolved from the study of phase transitions of homologous binary compounds. For primarily intermetallic compounds the balance between metallic and ionic energies often determines phase transitions between competing structures (21). For the fairly polarizable bonds of insulators and semiconductors pertinent to the present compounds, the energies to be balanced are covalent and ionic. These energies can be determined spectroscopically with almost no adjustable parameters (20), and they provide a quantitative basis (see Fig. 1) for understanding the free energy differences between fourfold and sixfold coordinated $A^N B^{8-N}$ binary octet compounds (22). (A less precise but more general discussion of phase transitions in this family has recently been given (23) in terms of atomic parameters only.) The emerging science of crystal chemistry has thus provided us, with its theory of the effect of chemical bonding on crystal structure, with a quantitative basis for the following discussion.

Scaffolded Structures

The characteristic feature of double salts

$$MX(NY)_p \qquad [5]$$

where NY may be AgI, CuCl, CuBr, or CuI, is the large value of p which occurs in spite of the fact that N is the diffusing cation. Thus the structure is stabilized by the minority cation M (which is 10-20% as numerous as N). This is the structural feature that distin-

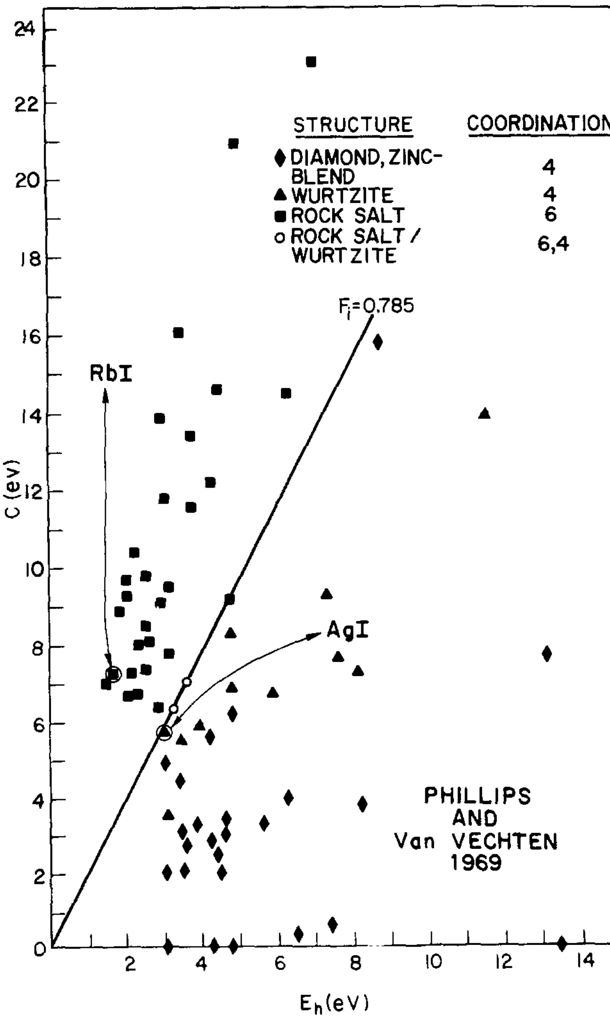

Fig. 1. Distribution of A^NB^{8-N} compounds in the E_h (covalent energy) C (ionic energy) plane. The line $F_i = E^2_h/(E^2_h + C^2) = 0.785$ successfully separates compounds with fourfold and sixfold coordination. Of particular interest are the locations of AgI and RbI, which are indicated in the figure.

guishes these double salts from, for example, sodium β-alumina, which contains (24) about eleven stabilizing Al cations for every diffusing Na ion. Because of the large value of p, the entropy associated with disorder among the diffusing cations is large, and this entropy may play an important role in stabilizing these double salts. This leads to the picture of a compound which has compromised between two coordination configurations by forming a scaffolded structure, with a skeletal framework of minority cation complexes. The framework is decorated by loosely bound, quasi-interstitial majority cations which supply a neutralizing charge sheath enveloping the over-all structure.

This structural description can be visualized more easily in the case (19) of the layer compound $(C_5H_6N)Ag_5I_6$. The organic minority cation, pyridinium, has a planar structure which gives rise to the layered skeletal framework, again illustrating the determinative role played by the minority cation. The pyridinium ion is at the center of the unit cell, and it is sandwiched between staggered hexagonal rings of iodine ions. Outside the iodine rings and coplanar with the minority pyridinium ions, are Ag dodecadons, with every site occupied. At $-30°C$ no Ag was found in planes halfway between sandwiches, although these sites may be occupied temporarily when ion transport takes place. In contrast to $RbAg_4I_5$, the Ag ions occupy both smaller tetrahedral sites (where two rings contact) and larger octahedral sites (in the free volume between three rings). Here the principle of alternating charge sheaths is more easily visualized, as the structure consists of an hexagonal array of coaxial capacitative cylinders, with Ag ions making up the outer cylinder, iodine ions the inner cylinder, and pyridinium ions forming the skeletal axes. Also, the near equality in energy of octahedrally and tetrahedrally coordinated Ag ions clearly helps to stabilize the structure.

Chemical Bonding

We can now identify the characteristic properties of the NY chemical bonds which produce scaffolded structures. While the minority cation complexes MX_6 must form stable units (such as RbI_6), the NY_s complexes must be "soft" in the sense that the bond-bending energy differences which determine whether s is four or six (or some intermediate value) are small. This is the case most dramatically for AgI, where the difference in energy (22) of the two configurations is $\lesssim$ 0.5 kcal/mole, but it also holds for the Cu halides (see Fig. 2). Bond-bending energies can also be analyzed quantitatively by comparing the noncentral force constant, β, with the central force constant, α, (see Fig. 3). The appropriate values of these quantities, together with the spectroscopic ionicity f_i, are collected in Table II. Both the free energy differences and β/α tend to zero as $f_i \rightarrow F_i = 0.785$, the characteristic ionicity of the bond in A^NB^{8-N} compounds associated with the transition from fourfold to sixfold coordination (20).

We have also listed in Table II the transition temperatures, T_α, for cation "melting" (the $\beta \rightarrow \alpha$ AgI transition) in CuBr and CuI. Note that the disordering temperature, T_α, for CuI is lower than for CuBr, although the ionic conductivity (14) of the organic double salt based on the former is 20 times less than that of the latter, indicating that the reaction to produce a scaffolded structure is much more complete at 150°C in the latter. This ordering is consistent, however, with the chemical bonding parameters f_i and β/α quoted in Table II. This shows that it is these bonding parameters (and not the disordering temperature, T_α) which are relevant to the realization of new scaffolded structures.

We are not in a position at present to calculate the absolute energies of A^NB^{8-N} compounds in either four-

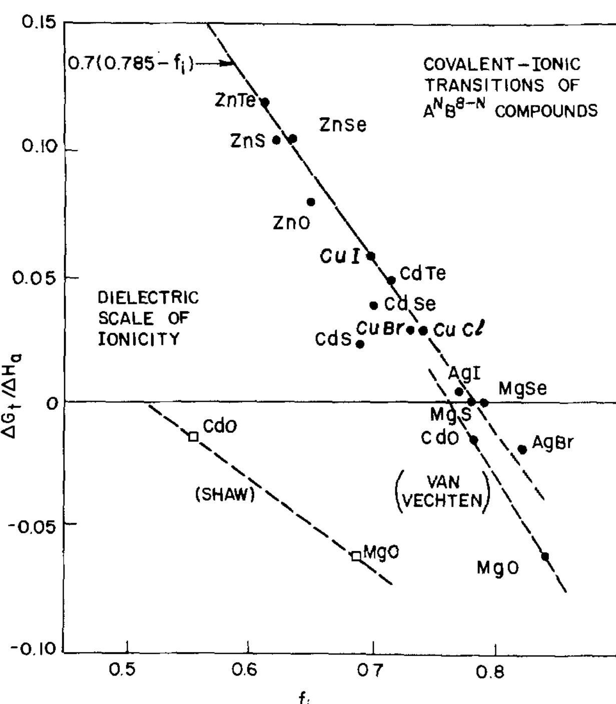

Fig. 2. Differences, ΔG_t, in Gibbs free energy between A^NB^{8-N} compounds in fourfold and sixfold coordinated structures. For normalization reasons the ratio $\Delta G_t/\Delta H_a$ is plotted where ΔH_a is the enthalpy of atomization of the compound.

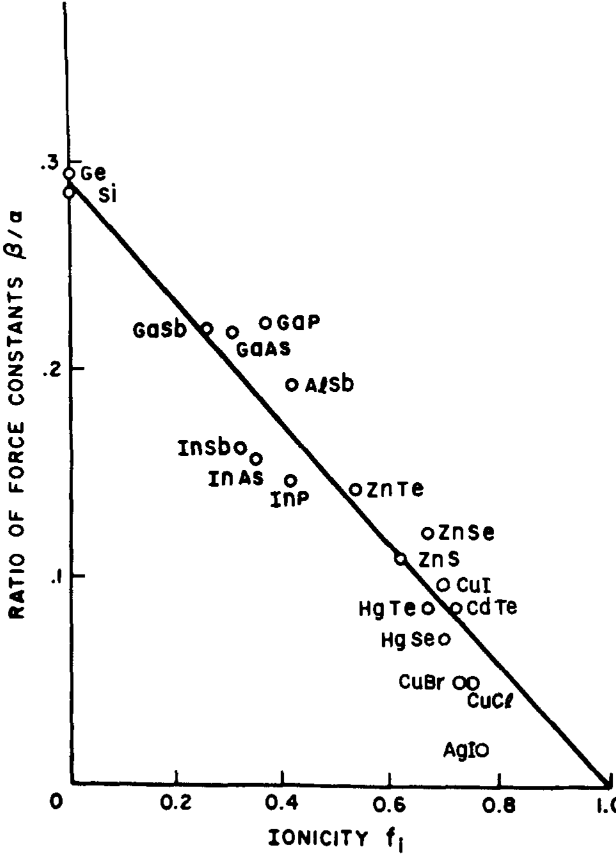

Fig. 3. Ratio of noncentral bond-bending force constant, β, to central bond-stretching force constant, α, as a function of spectroscopic ionicity, f_i. As $\beta \rightarrow 0$ the transverse acoustic frequencies $\rightarrow 0$.

fold or sixfold coordinated structures with sufficient accuracy near $f_i = 0.8$ to locate the critical ionicity F_i at which the covalent-ionic phase transition takes place (20), but there is an interesting electrostatic explanation for the value of F_i as the one at which the bond charge is centered on the anion (22, 25). Thus one can understand in balancing internal energies, U, how the macroscopic electrostatic sheath energies can be competitive with microscopic coordination energies when f_i (NY) is near F_i, but not otherwise. The balance is very delicate, for at low temperatures disproportionation may take place, *e.g.*, in $RbAg_4I_5$ (10), which may be contrasted with the stable condensation of Ag ions in layered AgI double salts (19). Evidently the entropy associated with fractional occupancy of Ag sites is essential to the stability of $RbAg_4I_5$, this stabilization arising from the distribution of the Ag ions among the available sites. One has here an ionic realization of Pauling's concept of resonating bonds: the resonating ions stabilize the structure when the minority cation is a single alkali ion.

Organic Minority Cations

The obvious defect of a sheath structure is that the attractive interactions between oppositely charged sheaths may tend, in general, to be smaller than the repulsive interactions between ions belonging to the same sheath. However, it appears that with the cations on the outer sheath the two energies nearly cancel, leaving the determination of the structure to the small coordination energies and the resonating ion entropies. One way to shift the balance in favor of the scaffolded structure is to increase the size of the minority cation, *e.g.*, by replacing Rb by tetramethylammonium, an almost spherical ion (10). This increases the distance from the common axis to the outer majority cation and inner anion sheaths, thereby reducing the repulsive interactions within the sheaths, without substantially altering the spacing or the capacitative attraction between the other oppositely charged sheaths. It also predicts an increase in p, and this is usually observed [Rb, p = 4; tetraalkylammonium (26), p = 6.5; N-alkyl hexamethylenetetramine (14), p = 7; but for organic ions with planar substituents or containing sheath-warping N-H dipoles no consistent pattern for p has been found (12)].

As the radius of the central minority cation increases, the stability of the (larger circumference) sheaths against wavelike (spinodal) decomposition (buckling) is reduced, and one would expect to find a maximum radius, R_{max}, beyond which the scaffolded structure becomes unstable. For the nearly spherical tetraalkylammonium ions this discontinuity (which can also be correlated with molecular weight) is particularly striking (10), but if one allows for nonhomologous differences between cubic and layer structures there appears to be (12) a R_{max} for all AgI-based double salts, which occurs near a molecular weight of 110 for the spherical ions and 290 for the planar ions.

If we now consider the Cu halide-based double salts, then in addition to balancing the ionic resonance and residual sheath energies, we have a much larger coordination energy difference to deal with (about ten times larger in CuBr than in AgI, see Table II). This means that we may expect to find a R_{min} as well as a R_{max} and that R_{max} should be much larger than in AgI; moreover, we expect both R_{min} and R_{max}, respectively, to be larger for double salts based on CuI than for double salts based on CuBr. The lowest molecular weight for the nearly spherical tetraamine [adamantane family (27)]-based cations which form conducting double salts with CuBr is about 140, *i.e.*, slightly larger than 110. Thus it appears that R_{min} (CuBr) > R_{max} (AgI), but studies of more cases are needed to confirm this point.

In addition to the electrostatic contribution to the enthalpy, the entropy contribution of the partially ordered diffusing majority cations may be changed when the size of the minority cation is increased. Naively, one would expect there to be more sites available to the majority cation with increasing radius of the minority cation, which would tend to stabilize the double salts with large minority cations. This is also a plausible explanation for the existence of a $R_{min} > 0$ in the Cu-halide-based double salts.

The coordination configuration plays a vital role for the stabilizing minority cations just as much as it does for the "soft" majority cations. On a gross level this is obvious from the fact that $(C_5H_5NH)Ag_5I_6$ has a layer structure whereas $RbAg_4I_5$ is cubic. However, that the balance of energies associated with the stabilizing majority cation is just as delicate as for the minority cations is evident from the ions M which form MAg_4I_5: these are (6) K and Rb, but not Li, Na, or

Cs, although M = Cs does form solid solutions with M = K or Rb. Originally this was explained (6) merely as a size effect, *i.e.*, $R(Cs) > R_{max}$ and (presumably) $R(Li) < R(Na) < R_{min}$. With the later discovery (10, 12), however, of stabilization of scaffolded structures by giant organic cations, the nonexistence of $CsAg_4I_5$ became puzzling. The most likely explanation is that CsI is normally eightfold coordinated, but is unstable toward a rearrangement toward sixfold coordination. The volume change, ΔV_t, between eightfold and sixfold coordination is only a few per cent, however, and thus CsI cannot fill a stabilizing role.

Connection with Lattice Dynamics

Because of the open, low density nature of tetrahedrally coordinated A^NB^{8-N} salts with zinc blende and wurtzite structures, the lattice vibration frequencies in short wavelength transverse acoustic (shear) modes are anomalously low even in Si and Ge. With increasing ionicity the noncentral, bond-bending force constant β decreases compared to the nearest neighbor (central) bond-stretching force constant α. This decrease, which is shown in Fig. 3, becomes catastrophic in the Cu halides and AgI. While β/α measures the softening of the shear elastic constants, the effect at short wavelengths (Brillouin zone boundary phonons) is even greater. In zinc blende compounds the transverse acoustic mode frequencies are low at the centers of the L = (111) and X = (100) Brillouin zone faces; in wurtzite structures the doubling of the unit cell (in effect) folds back the former to $k = 0$, where it is observable by Raman scattering.

In Table III the frequencies $\nu(E^1_2)$ are shown, together with their pressure derivatives where known. (By E^1_2 we mean the low frequency transverse optic phonon at $k = 0$ in wurtzite structures, or its transverse acoustic analogue at k = L in zinc blende structures.) The most noteworthy feature of Table III is the low value of $\nu(E^1_2)$ in β-AgI. The significance of this result has been discussed elegantly (28) from the present point of view, with emphasis on the $\beta \rightarrow \alpha$ transition in AgI. In particular, the connection of the low frequency with low values of β/α and with the proximity of f_i(AgI) to F_i has been stressed (28). Also, the character of the iodide ion motion and its relation to a transformation from hcp to bcc is noted for the first time (28).

The success of the lattice dynamical interpretation (28) of the $\beta \rightarrow \alpha$ phase transition in AgI increases our interest in $\nu(E^1_2)$ as a possible configuration coordinate for describing the formation of scaffolded double salts. We therefore show in Table III these frequencies for the Cu halides and ZnO and CdS. Clearly, the Cu halides are next most favorable after AgI, while CdS is a better candidate than ZnO. Also, CuBr is significantly better than CuI. (The same conclusion was reached on the basis of Table II, in agreement with experiment, but in contradiction with the overly simple T_α trends in Table I.)

Table III. Soft phonon frequencies and their shifts with pressure in some A^NB^{8-N} compounds

Compound	$\nu(E^1_2)$ (cm^{-1})	$\Delta\nu$(10 kbar) (cm^{-1})
Si	150[a]	−0.7[a]
ZnO	99[b]	−1.3[b]
CdS	42[b]	−2.0[b]
CuBr	31[c]	
CuI	34[d]	
AgI (β)	15[e]

Vibrational Entropy

The low lying frequencies $\nu(E^1_2)$ listed in Table III give rise to very large (strongly anharmonic)) vibrations at ambient temperatures, primarily of iodine ions in AgI, which correspond to a mean phonon occupation number $\overline{n}(E^1_2) \sim 12$ in AgI. [This explains, incidentally, the very large Debye-Waller damping for the iodine ions which puzzled Hoshino (16).] Such large phonon occupation numbers increase the vibrational entropy of AgI_4 complexes, thereby helping to stabilize $RbAg_4I_5$ against disproportionation (20) down to 27°C. As $\nu(E^1_2)$ increases, the vibrational amplitudes decrease, which tends to destabilize the CuX double salts compared to the AgI ones. The same effect may explain the tetragonal distortion which is present in Cu_2HgI_4 but absent in Ag_2HgI_4: in the latter case the motional Jahn-Teller effect has "averaged out" the tetragonal distortion.

Synthesis at High Pressures?

The pressure derivatives in Table II are interesting. One can ask, is it not possible, by applying pressure, to bring the spectroscopic ionicity, f_i, of the Cu halides or CdS close enough to f_i (AgI) so that one could form scaffolded structures involving the former? But one must be careful in interpreting Fig. 2, for the effect of pressure is to change both f_i (AB) and the critical ionicity, F_i, *i.e.*, both $\partial f_i/\partial_p$ and $\partial F_i/\partial_p$ must be considered. To make this distinction, consider CuBr, which transforms to the rock salt structure (14) at 43 kbar. Assume that $\partial\nu/\partial_p$ is about the same in CuBr as it is in CdS; then ν(CuBr, 40 kbar) $\cong 31 - 8 = 23$ cm^{-1}. Thus about half of the difference between ν(CuBr) and ν(AgI) can be removed by application of pressure, but half cannot. An even less favorable case is CdS, where the transition pressure is (14) anomalously low (25 kbar); thus ν(CdS, 20 kbar) = 38 cm^{-1}, which is more than twice the AgI value.

Two-Phase Behavior

Highly conductive single crystals with mole ratios near the optimum value have been grown from several double salts (18, 19) based on AgI. However, Takahashi, Yamamoto, and Ikeda (14) usually were unable to prepare single phase double salts based on Cu halides, and do not report the structure of their "single phase" samples. Sammels, Gougoutas, and Owens have similarly reported (15) that while the optimum Cu_p/organic NH_4 halide mole ratios for high ionic conductivity ranged from p = 4 to p = 7, the only single crystals which they have grown correspond to p = 2.5. While the latter is reported to be conductive, it seems unlikely that it has high ionic conductivity comparable to that achieved for the larger optimal values of p. Our model for formation of scaffolded structures suggests that two-phase behavior may be intrinsic to all but the AgI-based double salts. The two-phase behavior may correspond to intrinsic disproportionation, for example, into a phase with high ionic conductivity (α) and one with much lower ionic conductivity (α'). The fraction of the α-phase may be unity in AgI-based salts, near 0.5 for CuX-based salts (and somewhat larger for X = Br than for X = I) and may be near zero, *e.g.*, in CdS-based salts.

Two-phase behavior is especially common in soft lattices; Ketelaar, in his early work (4), mentions that the surface of AgI undergoes the $\beta \rightarrow \alpha$ transition (with an accompanying change in color) before the interior does. This behavior can occur because of the strain field at the sample surface. Ferroelastic crystals are especially sensitive to strain fields, and it seems that many soft lattices may be equally sensitive to shape and surface effects. In some cases, such as quasi-one-dimensional molecular crystals, the coexistence of two phases may be necessary to relieve internal strain fields (30), and in the case of KCP such

coexistence has been observed by neutron scattering (30).

The basic factor limiting the formation of double salts may well be internal strain fields. In the case of quasi-one-dimensional materials this is obvious because of the problem of lattice-constant mismatch between the two chains (30). For the Cu-halide based double salts the presence of the second salt apparently tends to produce a uniaxial (quasi-tetragonal) distortion of CuX_4 complexes. On the other hand, the symmetry (and lattice constants) of the minority scaffolded structure may not be consistent with slightly tetragonally distorted majority cation complexes. This produces internal strain which can be relieved by two-phase behavior. In the quasi-one-dimensional materials at low temperatures the two phases may be replaced by a single phase with a much larger unit cell; the low temperature phases (31) of $RbAg_4I_5$ may arise in this way. However, in other crystals the two phases may coexist in practice without ordering at low temperatures.

Alternative Majority Cations

The discovery (14) of the solid-solid reaction between [...]X and CuX (instead of AgI) raises the possibility of forming double salts based on A^NB^{8-N} compounds with N = 2. Two candidates, Mg and Cd, are considered in Table II.

Considering only ΔG_t, we are tempted to choose MgS or MgSe. However, strictly speaking, at room temperature ΔG_t is probably slightly negative (as indicated in the table), so that the fourfold coordinated form is only metastable. Under compaction to form a double salt these two compounds transform to the denser rock salt structure, which will probably block the reaction to form the scaffolded structure.

We must therefore consider the Cu salts and the Cd salts. From the discussion given above, the configuration coordinates ΔG_t, β/α, and $\nu(E^1{}_2)$ of the Cu salts are substantially more favorable than those of the Cd salts, with or without pressure. However, it may still be possible to prepare double salts based on CdS, CdSe, or CdTe.

A more remote possibility is to combine a tetrahedral A^NB^{8-N} binary compound (such as CdS) with an octahedral C^NB^{10-N} compound (such as PbS). This appears unlikely, because Pb, for example, usually would be tetravalent rather than divalent. However, some early work indicated (32) the existence of $Cd_4Ge(S \text{ or } Se)_5$, with a nearly cubic unit cell containing four formula units, in strong similarity to $RbAg_4I_5$. However, later work on Cd-Ge-S (33) and A^2-C^4-S [with C = Si or Ge and A = Cd or Hg (34)] showed that the correct formula is $A_4{}^2C^4S_6$, *i.e.*, with C = Si or Ge the C atoms are indeed tetravalent. In general, the ability to form divalent states increases with increasing atomic weight in the fourth column, so it still might be possible to prepare Cd_4PbS_5. The existence of a number of compounds of formula $A_4{}^2C^4B_6{}^6$ (*i.e.*, the proper ratio, 4:1, of tetrahedral to possibly octahedral cations) suggests that this is an interesting possibility, but so far no such compounds have been reported.

Alternative Anions

The principles that govern anion substitution are less clear-cut than those that govern cation substitution. Early work (8, 9) showed that Ag_3SI transformed to a cation-disordered perovskite structure at T_c = 235°C, while Ag_3SBr transformed (35) at 430°C. It is interesting that Pauling's table of elemental electronegativities (36) gives $X(S) = X(I) = 2.5$, while $X(Br) = 2.8$; this may explain the lower value of T_c in the iodide. The heats of formation ($-\Delta H_f$ in kcal/mole) are (37) 7.8 (Ag_2S), 15 (AgI), and 24 (AgBr), and this, together with (20) f_i (AgBr) = 0.79 + 0.06 (AgBr has the NaCl structure) also supports the higher value of T_c in the bromide compared to the iodide. Again we see that strongly ionic interactions hinder cation disorder, primarily because they favor octahedral sites over tetrahedral ones, whereas nearly equal site energies make possible cation disorder at low values of T_c.

Microscopic Models

Most theoretical models of superionic conductors have emphasized the activation energy, ΔH_a, for ionic diffusion as derived from an Arrhenius plot of $\sigma(T)$. Such a discussion is appropriate, *e.g.*, for ionic conduction in sodium β-alumina (24). However, in cation-disordered salts such as α-AgI, and equally in scaffolded double salts such as $RbAg_4I_5$, this hopping model appears to be irrelevant to understanding the very high ionic conductivities (small values of ΔH_a) that are actually observed. With a number of sites available to the diffusing cations, all in closer proximity than cation sites in the majority cation single salt, it is clear that the nature of the structure (cation-disordered or scaffolded, as the case may be) is such that the near equality in energy of inequivalent sites is accompanied by a very substantial anharmonic softening or lowering of barrier heights ΔH_a from what one would calculate from the uncorrelated hopping ion picture. This is the essential common feature of both cation-disordered and scaffolded structures. It can be pictured as lopping off the barrier between two equivalent sites and putting between them an inequivalent site with only a slightly higher energy than that of the lowest site. This picture has been implicit in the experimental discussions for some time (6), but it seems to have been omitted from most microscopic models. The present discussion takes this model for granted and utilizes the data for the copper-ion conductors (14, 15) to elucidate differences between ionic conduction in the cation-disordered and scaffolded salts. In particular, our model shows why scaffolded CuBr double salts can be more conducting than scaffolded CuI double salts, although the latter have the lower cation disordering temperature, T_c.

An amusing example of an oversimplified hopping model has been presented in terms of small polaron theory (38). These authors do not discuss scaffolded structures at all, but they do assert that ΔH_a does not change much upon cation disordering, thereby ignoring the change in conductivity of several orders of magnitude at T_c and ignoring what most experimentalists use to distinguish ordinary ionic conductivity from superionic conductivity. They also claim to explain "for the first time" why CuCl is not a good superionic conductor. (The hopping energy in CuCl is calculated to be 2.5 times that of CuBr, which in turn is twice that of CuI.) But, as we have seen, scaffolded CuBr double salts are better ionic conductors than scaffolded CuI double salts. Moreover, one does not need many-body theory to explain why CuCl is not a superionic conductor. From the values of T_c in CuI and CuBr, it is clear that T_c increases with the Debye temperature, and a reasonable guess for T_c in CuCl is 530°C, or about 100°C above the melting point, T_m (see Table II).

The reason why the polaron coupling constant $\lambda = (1/\epsilon_\infty - 1/\epsilon_0)$ is not a relevant configurational coordinate for superionic conductors is that it measures the longitudinal ionic forces responsible for the difference in frequency of longitudinal and transverse optic modes at $k = 0$. However, as we have seen, it is the frequencies of the $E^1{}_2$ modes (essentially transverse acoustic zone-boundary phonons) that measure the softness against shear that is the characteristic feature of AgI and the Cu halides. Indeed, of all the configuration coordinates, the polaron coupling parameter is the one that is least relevant to cation disordering and to the formation of superionic structures.

Conclusions

The structural principles which make possible the formation of scaffolded superionic conductors were discussed. Primary emphasis was laid on the necessity for "soft" majority and "rigid" minority cation coordination configurations, which were shown to be of greater structural significance for the scaffolded double salt than the possibility of cation disorder in the majority cation salt, although the latter is also, of course, related to the "soft" majority cation configuration. Alternative majority cation salts were discussed.

Postscript.—Studies of ionic conductivity in (Zn, Cd, Hg, Cu, and Pb)S have been reported (39) that indicate mixed ionic and electronic conductivity, possibly caused by the presence of stacking faults in (Zn and Cd)S.

Second postscript.—An elegant and convincing demonstration of the transferability of the 4-6 coordination isomerism discussed here (and illustrated by the abscissa intercepts of Fig. 2 and 3) has been obtained recently by Teo and Calabrese (40) and Churchill and co-workers (41). They have studied the structural variations in metal clusters $(R_3Y)_4M_4X_4$ where R is C_6H_5 or C_2H_5, Y is P or As, and the metal core salt atoms M are Cu or Ag while X is a halide. In crystals the M_4X_4 core may have either a cubane structure (right-angle M bonds, analogous to sixfold coordination in MX salts) or a chair structure (distorted tetrahedral M bonds, as in fourfold coordinated MX salts). Only with M = Ag and X = I is an unprecedented isomerism present. However, with M = Cu conversion from the cubane form with X = Cl to the chairlike configuration with X = Br and I is established. Considering that each cluster has a large surface area, the general similarity of these isomeric transformations to the quantitative "softness" criteria discussed in this paper is striking.

The Preparation and Properties of Tin Oxide Films Formed by Oxidation of Tetramethyltin

B. Jayant Baliga*,[1] and Sorab K. Ghandhi*

Electrical and Systems Engineering Department, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

A new technique is described for the deposition of SnO_2 films based upon the pyrolysis of tetramethyltin (TMT) in oxygen at relatively low temperatures ($\approx$450°C). As a tin source, TMT has the advantages of being stable in air and moisture and of being a liquid with a relatively high vapor pressure at room temperature. Thus, a simple bubbler system is used to transport its vapors to the reaction chamber. The deposition technique is characterized by (*i*) high and controllable growth rates (more than 300 Å/min), (*ii*) high conductivity layers [more than 30(ohm-cm)$^{-1}$ undoped], and (*iii*) highly transparent layers in the visible range (more than 95% transmission for 1500Å layers). In addition, the films can be doped to achieve conductivities as high as 200(ohm-cm)$^{-1}$ without loss in transmission. Finally, fast, low temperature anneals with forming gas in an open-tube system can be effectively used to result in an additional twofold increase in conductivity.

Tin oxide has the unusual properties of high transparency in the visible spectrum, combined with a high conductivity. These properties are shared with only a few other materials, and many techniques for its deposition have therefore been developed. Among these, the most commonly used are reactive sputtering (1, 2) and chemical vapor deposition using $SnCl_4$ (3-7). Substrate temperatures ranging from 500° to 750°C are necessary in the $SnCl_4$ process. Although lower temperatures are used in reactive sputtering, the properties of the resulting films are difficult to control in spite of elaborate target preparation procedures (1). In this paper, a new technique is described for the chemical vapor deposition of SnO_2 films based on the oxidation of tetramethyltin (TMT) at relatively low temperatures (450°-550°C).

The growth of electronic materials using organometallic compounds as sources was pioneered by Manasevit and co-workers, who have used TMT to obtain films of SnTe, SnS, and PbSnTe chalcogenide glasses (8). TMT has the advantages of being stable in air and moisture which allows its handling in glass containers with no hazard to the user, of being a liquid at room temperature, and of having a relatively high vapor pressure at room temperature (100 mm of Hg). The last two properties readily allow vapor transport to the reaction zone by bubbling an inert gas through liquid TMT.

Undoped SnO_2 films have high conductivity; nevertheless, the conductivity can be improved by doping with Sb_2O_5 (4, 7) and by annealing in a vacuum (3, 6). In this paper we report the results of doping SnO_2 films with P_2O_5 and the effects of forming gas anneals in an open-tube system. These techniques are substantial simplifications on the previously available methods for increasing the conductivity of the SnO_2 films.

Experimental Conditions

Apparatus.—The deposition of SnO_2 films was performed in an open-tube reactor similar to that described by Goldsmith and Kern (9). In this reactor, a stainless steel susceptor was maintained at the deposition temperature (to within ±5°C) by conventional resistance heating. UHP argon gas was bubbled through the TMT[2] at 30°C to transport its vapors to the heated substrate. All depositions were conducted using an argon carrier gas flow of 2.0 liter/min.

Deposition procedure.—Deposition of SnO_2 films was simultaneously conducted on 8 mil glass slides (Corning Cover Glass No. 1½) and silicon wafers. These substrates were degreased in a 1:1:1 solution of isopropyl alcohol, trichloroethylene, and acetone, cleaned in Caro's etch [1:1 solution of H_2SO_4 (97%) and H_2O_2 (47%)], and given a final rinse in methanol prior to loading into the reactor. After the substrate reached the deposition temperature in the argon ambient, silane[3] and oxygen[4] were introduced to obtain a 2000Å layer of SiO_2 on the substrate surface. All SnO_2 layers were deposited on this freshly prepared SiO_2 layer.

A Dektak thickness gauge was used to measure the film thickness. Since layer thickness was found to increase linearly with time, the deposition rate was calculated by dividing film thickness by deposition time. A film thickness of 1600Å was used to characterize the growth rate and to obtain the conductivity of the resulting films.

Deposition Characteristics

Temperature.—The temperature dependence of the growth rate of SnO_2 films was studied using an argon flow of 15 ml/min through the TMT bubbler and an oxygen flow of 48 ml/min. As shown in Fig. 1, the growth process was reaction-rate controlled over the temperature range used in this study and had an activation energy of 1.64 eV/molecule (37.8 kcal/mole). The effect of decreasing the TMT transported to the chamber by reducing the argon flow through the TMT bubbler to 0.75 ml/min is also shown in Fig. 1. The growth rate is still reaction-rate controlled at lower temperatures, but the effects of mass-transport limited kinetics begin to appear at 530°C.

Oxygen flow.—The effect of changing the oxygen flow on deposition rate was measured at 500°C using an argon flow of 15 ml/min through the TMT bubbler. The growth rate was seen to increase linearly with oxygen flow, over the range from 0 to 48 ml/min. It was found that sufficient air was present in the open-chamber arrangement in our apparatus to produce deposition rates of 55 Å/min of SnO_2 in the absence of oxygen flow.

TMT flow.—Experiments were also conducted at 500°C to determine the effect of changing the TMT concentration in the chamber while maintaining an oxygen flow of 48 ml/min. Figure 2 shows the results

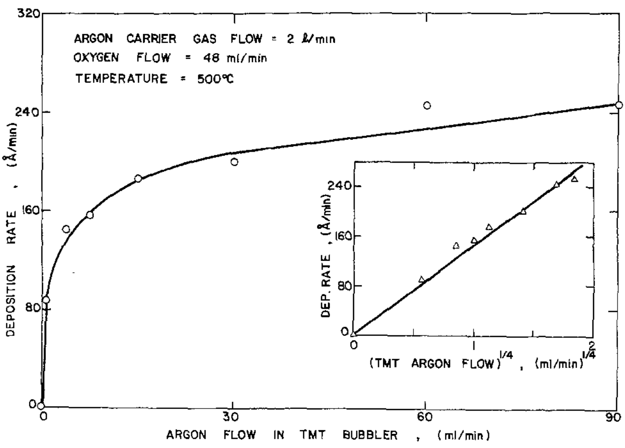

Fig. 2. Variation of tin oxide deposition rate with TMT concentration.

of increasing the argon flow through the TMT bubbler from 0 to 90 ml/min. The growth rate increases rapidly as argon flow is increased from 0 to 7.5 ml/min but is not a strong function of the TMT concentration at higher flows. The variation of growth rate with temperature (Fig. 1) at argon flows of 15 and 0.75 ml/min through the TMT bubbler shows that the kinetics of the growth are reaction-rate controlled and have the same activation energy over the entire range of TMT concentrations studied in Fig. 2 at a substrate temperature of 500°C. The observed variation cannot, therefore, be ascribed to a change in reaction kinetics. Indeed, the insert in this figure shows that the observed growth rate behavior can be explained if the reaction is assumed to be of one-quarter order with respect to TMT concentration.

These results show that, using the TMT-O_2 system, SnO_2 films can be deposited at rates in excess of 300 Å/min. These rates compare well with those observed by CVD using $SnCl_4$ and exceed those normally observed in reactive sputtering. In comparison with these methods, the system described here has the advantage of requiring lower substrate temperatures and the capability of depositing uniform layers over a large area. Furthermore, repeated deposition of films under standardized conditions (substrate temperature = 500°C, argon flow in TMT bubbler = 15 ml/min, oxygen flow = 48 ml/min) results in less than ±5% variation in growth rate.

Electrical Properties

SnO_2 is a wide bandgap (> 3.5 eV) semiconductor with predominantly n-type conductivity (3). The electron concentration in the conduction band primarily arises from lack of stoichiometry produced by an oxygen deficiency (4, 5). It is, therefore, important to examine the effect of the TMT/O_2 mole ratio upon conductivity. Further, the addition of antimony oxide has been found to enhance the conductivity of SnO_2 films (4, 7). In this section, we examine the effect of the addition of phosphorus pentoxide to these films.

Undoped films.—As expected, increasing the oxygen flow while maintaining a constant concentration of TMT resulted in layers with decreasing conductivity. On the other hand, SnO_2 films grown using increasing TMT flow while maintaining a fixed oxygen flow had increasing conductivities. The conductivity of SnO_2 films grown in this study was, therefore, controlled by an oxygen deficiency. The proportionality between conductivity and the TMT/O_2 flow ratio is shown in Fig. 3 for TMT/O_2 mole ratios up to 0.25. An oxygen excess was used in all these experiments.

Changing the deposition temperature was found to have a strong influence on the conductivity of the layers. Under fixed TMT and oxygen flows, the conductivity was found to decrease rapidly as the deposition temperature was increased. As seen from Fig. 1, this decrease in conductivity is accompanied by a rapid increase in growth rate. We, therefore, conclude that increasing substrate temperature results in the oxidation reaction proceeding further to completion, and leads to a fall in the conductivity.

Doped films.—Since SnO_2 is a semiconductor in which the conductivity is derived from lack of stoichiometry, its conductivity can be enhanced by the addition of oxides of Group V elements. We have studied the effect of the addition of P_2O_5, using phosphine gas[5] as a source. Phosphine is readily available in a wide range of concentrations due to its common usage

[5] Electronic grade 99.999% purity, Matheson Gas Products, East Rutherford, Massachusetts.

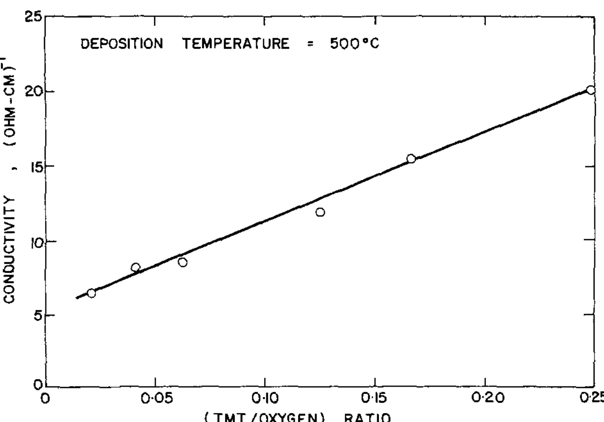

Fig. 3. Variation of the conductivity of tin oxide films with (TMT/oxygen) mole ratio.

as a n-type dopant for silicon, and its oxidation at low temperatures has been well studied (10, 11).

The effect of the addition of P_2O_5 to SnO_2 layers was studied at a deposition temperature of 500°C, using an argon flow of 15 ml/min through the TMT bubbler and an oxygen flow of 48 ml/min. A source of 460 ppm of phosphine in argon was used to obtain a wide range of low phosphine concentrations in the reactor. Figure 4 shows the change in conductivity as a function of the PH_3/TMT mole ratio over a range of three decades. The TMT concentration was computed using a vapor pressure of 100 mm of Hg at room temperature and assuming equilibrium transport from the bubbler. As seen from Fig. 4, the addition of phosphine increases the conductivity of the SnO_2 layers by more than a factor of twenty. The highest conductivities were observed in our system for a PH_3/TMT ratio of 0.01. Increasing the phosphine concentration beyond this value produced a rapid decrease in conductivity. All of these layers exhibited a transmission coefficient of greater than 95% over the visible spectrum.

Annealing behavior.—The conductivity of SnO_2 films has been increased by annealing the films in a vacuum (3, 6). In this work, we present results of annealing studies, performed on both doped and undoped samples, in a reducing ambient. Annealing the films in forming gas (20% hydrogen, 80% nitrogen) for relatively short periods (5 min) was found to produce a twofold increase in conductivity. This technique allowed fast, effective annealing in a simple open-tube apparatus as compared to the more complex vacuum annealing processes.

Typical results of isochronal anneals (5 min time intervals) are shown for both a doped and an undoped sample in Fig. 5. Little change in conductivity occurred below 200°C. The highest conductivity after annealing occurred for temperatures between 300° and 350°C. At higher temperatures the conductivity decreased until visible signs of the reduction of SnO_2 to Sn were observed at 500°C and above. Extended anneals at 500°C resulted in complete reduction of the SnO_2, as evidenced by the appearance of tiny balls of Sn on the sample. These results indicate an optimum anneal temperature of 300°C. Isothermal anneals performed at this temperature showed that the anneal is complete within 5-10 min (12).

The depositions in our study were performed by the pyrolysis of tetramethyltin in oxygen. Consequently, conductivity changes caused by the presence of incorporated methyl groups during annealing have also been considered. Annealing in a dry nitrogen atmosphere at 300°C showed no conductivity change. Hence, we conclude that the reducing effect of these groups, if incorporated into the films, is negligible.

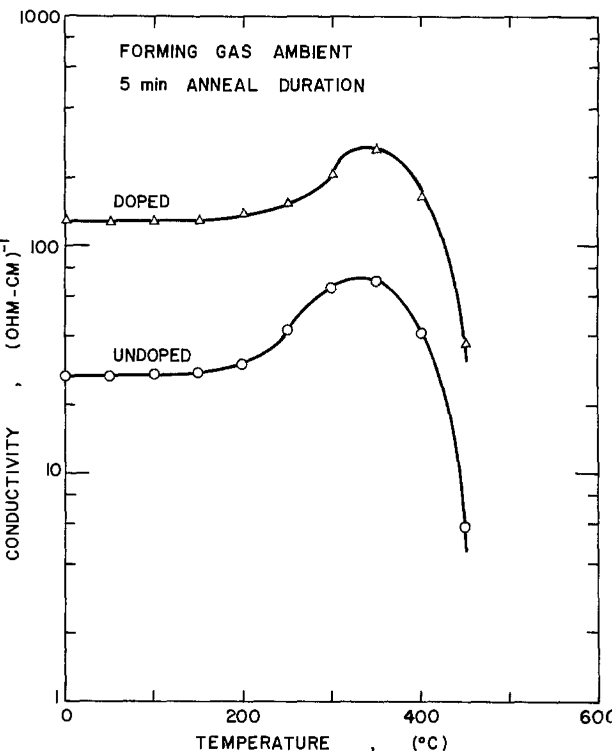

Fig. 5. Effect of isochronal annealing in forming gas upon the conductivity of tin oxide films.

Discussion and Conclusions

Repetitive deposition of SnO_2 films under standard conditions (deposition temperature = 500°C, argon flow in TMT bubbler = 15 ml/min, oxygen flow = 48 ml/min) produced layers whose conductivities varied by less than ±10%. This reproducibility partially stems from the deposition of the SnO_2 layers on the freshly deposited SiO_2 layers, which makes the properties of the SnO_2 films insensitive to the substrate cleaning procedure.

In our experiments, undoped layers could be grown with conductivities as high as 30 (ohm-cm)$^{-1}$. The conductivity is found to increase with increasing TMT/O_2 ratio and is also increased by annealing the layers in a reducing ambient. This confirms that the conductivity arises predominantly from an oxygen deficiency and not from the presence of impurities in the TMT source.

The addition of P_2O_5 to the SnO_2 increases the conductivity of our films from 8 (ohm-cm)$^{-1}$ for undoped films to as high as 180 (ohm-cm)$^{-1}$ for films grown under an optimum PH_3/TMT mole ratio of 0.01, and the conductivity falls rapidly at higher ratios. A similar behavior, observed in the doping of SnO_2 films with Sb_2O_3 (7), has been attributed to a measured decrease in electron mobility. It is likely that the decrease in conductivity of our films for PH_3/TMT ratios above 0.01 is also due to this effect.

Annealing these films in forming gas at 300°C for 5 min produces a twofold increase in conductivity for both undoped and P_2O_5-doped films. In this study the highest conductivity observed after annealing was 320 (ohm-cm)$^{-1}$. Annealing at higher temperatures can result in sample destruction by reduction of SnO_2 to Sn.

In conclusion, this paper introduces a new CVD process for the deposition of high conductivity SnO_2 films based on the oxidation of tetramethyltin. Growth rates exceeding 300 Å/min are achievable, with film quality comparable to that obtained by either reactive sputtering or chemical vapor deposition using $SnCl_4$. This new deposition technique, however, offers the advantages of simplicity of apparatus, low deposition temperatures, and good reproducibility.

Technical Note

Particle Morphology and Lamp Maintenance of $(1-x)YPO_4 \cdot xYVO_4$ Phosphors Containing Eu^{3+}

R. C. Ropp and B. Carroll

Department of Chemistry, Rutgers University, Newark, New Jersey 07102

In a prior paper (1), a study of solid solution formation between YPO_4 and YVO_4 was presented. Complete solid solution was observed only if the two were coprecipitated or if the salt, $YPO_4 \cdot 5/3\ H_3O$ was employed as a reaction base. The use of any other phosphate resulted in an apparent deviation from Vegard's law due to incomplete solid-solution formation caused by competing side reactions. These side reactions were shown to result in the formation of polyvanadates [*e.g.*, $Y(VO_3)_3$] in the high phosphate region, or polyphosphates [*e.g.*, $Y(PO_3)_3$] in the high vanadate region. It was further demonstrated that the salt, $YPO_4 \cdot 5/3\ H_2O$, exhibits an acicular crystal habit, and if used in a solid-state reaction, produced solid-solution particles of $(1-x)YPO_4 \cdot xYVO_4$ which were also acicular (pseudomorphism). A similar circumstance was noted (2) several years ago for the case of $CaHPO_4 \cdot 2H_2O$ where the original particle morphology was carried through to form pseudomorphic calcium halophosphate phosphor.

If Eu^{3+} is included as a coprecipitate in either of the two (or both) salts, $YPO_4 \cdot 5/3\ H_2O$ and YVO_4, a phosphor results with an acicular crystal habit. This phosphor exhibits a marked improvement in light output and light maintenance when incorporated into a 400W high pressure mercury vapor lamp, as shown by the data in Table I. Whether this improvement in light output is due to improved packing of the acicular particles in the phosphor coating as in the case of halophosphate, or is due to a greater resistance to surface degradation of the particles under the influence of the photon flux as a function of time is not fully understood at this time.

Key words: morphology, phosphors, yttrium, phosphate-vanadate.

Table I.

Moles PO_4	Moles VO_4	Particle habit	Lumens	Red (due to phosphor)		
			0 hr lamp	0 hr	100 hr	%M
0.60	0.40	acicular	26,294	3837	3792	98.8
0.60	0.40	normal*	25,510	3672	2872	78.2

* The "normal" particle habit is a sort of irregular dodecahedron.

Brief Communication

Elimination of Stacking Faults in Silicon by Trichloroethylene Oxidation

Takeshi Hattori

Sony Corporation Research Center, Hodogaya-ku, Yokohama 240, Japan

There has been an increasing interest in recent years in the advantages of SiO_2 films thermally grown in the presence of small amounts of a chlorine-bearing species in a dry oxygen atmosphere (1). Until recently, most procedures have introduced chlorine into the oxidizing ambient in the form of HCl or Cl_2 (2-9), while a more manageable chlorine source has been sought to avoid its corrosive and deleterious effects (10-12). The author and co-workers reported in a previous paper (11) that the use of trichloroethylene (C_2HCl_3), which is far less corrosive and much easier to handle, results in the excellent characteristics of MOS devices.

Thermal oxidation of silicon at high temperatures is well known to result in the generation of extrinsic stacking faults in the surface layers of the crystal (13-19). These stacking fault defects frequently increase the reverse current of planar p-n junctions (19-20) and/or give rise to bright spots or lines in the image of silicon vidicons (21), charge coupled imagers (22), and related image-sensing devices. Very recent reports (23-24) indicate that both standard oxidation at extremely high temperatures above 1200°C (or 1300°C in steam) and HCl oxidation at 1200°C cause stacking faults to vanish from the surface of silicon. The purpose of this article is to present the effects of trichloroethylene (TCE) oxidation on the elimination and shrinkage of stacking faults in silicon wafers.

For the present studies, dislocation-free silicon wafers [grown by the Czochralski method, chem-mechanically polished, (100) oriented, 40 mm in diameter, n-type, 2-3 ohm-cm] were used. These were cleaned by a standard process for MOS LSI's and oxidized at temperatures ranging from 1000° to 1200°C in a dry oxygen flow of 1500 cm^3/min (constant) in a quartz furnace. TCE oxides were grown under the same condition, but with varying flows of dry nitrogen through a quartz bubbler filled with purified liquid C_2HCl_3. The temperature of the bubbler was controlled constantly at 27°C.

Virtually no difference between standard and TCE oxide films was observed in refractive index, dielectric constant, maximum dielectric strength, etch rate in buffered HF, and wavelength of infrared absorption peak, but the oxidation rate of silicon (11) was considerably increased in the presence of C_2HCl_3. Both Auger electron spectroscopy (AES) and ion microprobe mass analysis (IMMA) showed that the chlorine profile in the TCE oxide was sharply peaked near the Si-SiO_2 interface (12) as well as in the HCl oxide (4-6).

After these oxide films were removed in hydrofluoric acid, oxidation-induced stacking faults contained in the silicon wafers were revealed by Secco etching (25). Stacking faults were extrinsic in character and consist of an extra plane of silicon atoms on the (111) plane. The defect size, taken as the largest length on the wafer surface, was measured by optical microscopy. Stacking fault densities were about 10^2 defects/cm^2 through these experiments, except for the case of the complete elimination.

Figure 1 shows the dependence of stacking fault length on the oxidation conditions. The size was plotted as a function of the flow rates of nitrogen through a bubbler filled with TCE. No oxidation-induced stacking faults appeared at the flow rate of more than 15 and 200 cm^3/min for 1200° and 1100°C, respectively, while 10-20 μm long stacking faults were generated by standard oxidation without TCE-N_2 flow. The relationship between temperatures and the minimum C_2HCl_3/O_2 ratio at which stacking faults could be completely eliminated is shown in Fig. 2. This ratio increased considerably with decrease of oxidation temperature, and, at 1000°C and below, elimination was virtually not observed, though the oxidation-induced stacking fault length was very short due to comparatively low temperatures.

Elimination or shrinkage of existing stacking faults could also be obtained by using TCE oxidation. Wafers having oxidation-induced 34 μm long stacking faults generated by standard oxidation in dry O_2 for 2 hr at 1200°C were subjected, with the initial oxides left intact, to additional oxidation containing TCE vapor for various times. As shown in Fig. 3, the existing stacking faults shrank and were finally eliminated within 2 hr at 1200°C. The defects shrank gradually after slight expansion at 1100°C. Significant shrinkage phenomena could not be observed below 1100°C. Almost the same elimination phenomena have been reported for the use of HCl (24), and were observed also when the initial oxides were revealed prior to TCE oxidation.

The exact mechanism by which the TCE vapor acts to eliminate or shrink the stacking faults is not known. Generation of vacancies at the surface of silicon and their flow to the fault might occur under the influence

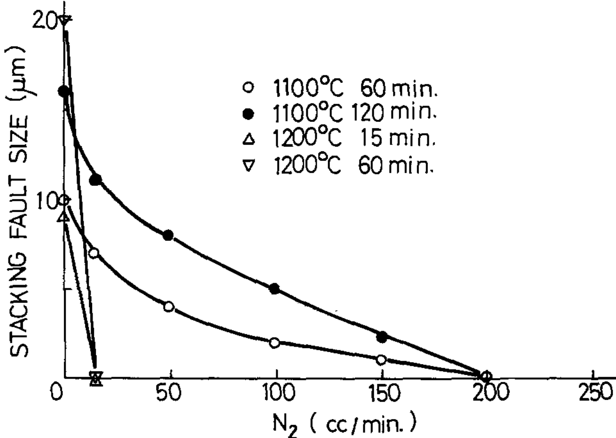

Fig. 1. Stacking fault size vs. C_2HCl_3-N_2 flow during oxidation

Key words: silicon processing, chlorine incorporation, thermal oxidation, lattice defect, C_2HCl_3.

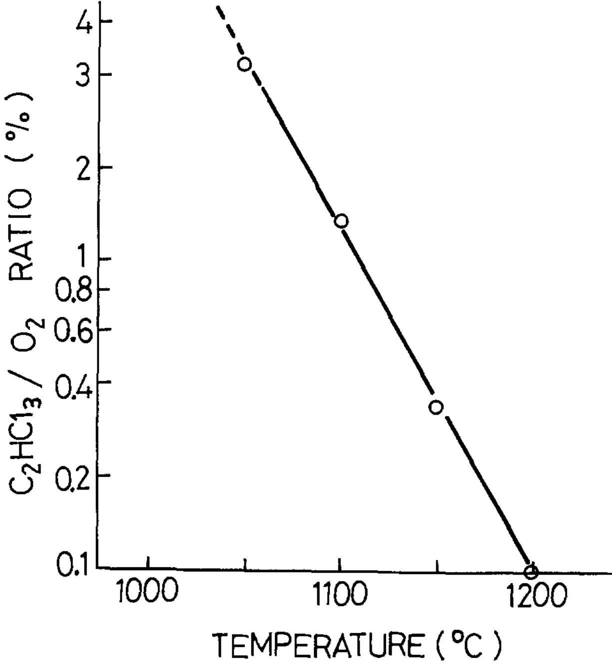

Fig. 2. Oxidation temperature vs. C_2HCl_3/O_2 ratio whereby stacking faults could be completely eliminated.

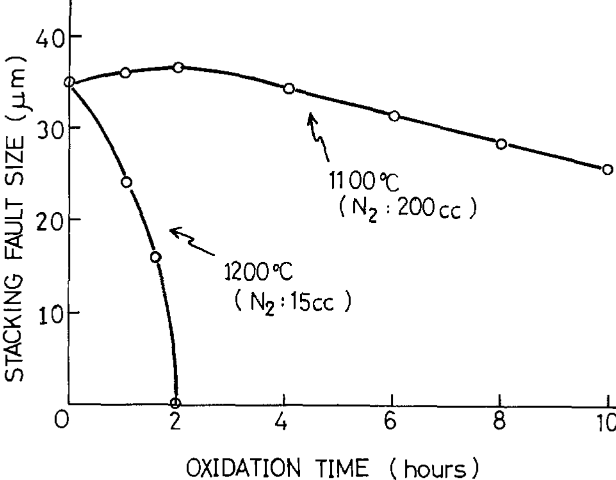

Fig. 3. Shrinkage of existing stacking faults during additional oxidation in the presence of C_2HCl_3.

of the pyrolytic product of C_2HCl_3, chlorine, and it will therefore result in the elimination or shrinkage of these defects. Further experiments are required to establish the validity of the inference.

It may be expected that TCE oxidation has great potential for silicon devices, particularly image-sensing devices like charge coupled imagers requiring very high quality oxides and crystals.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 122, No. 8, 10, and 11; August, October, and November 1975.

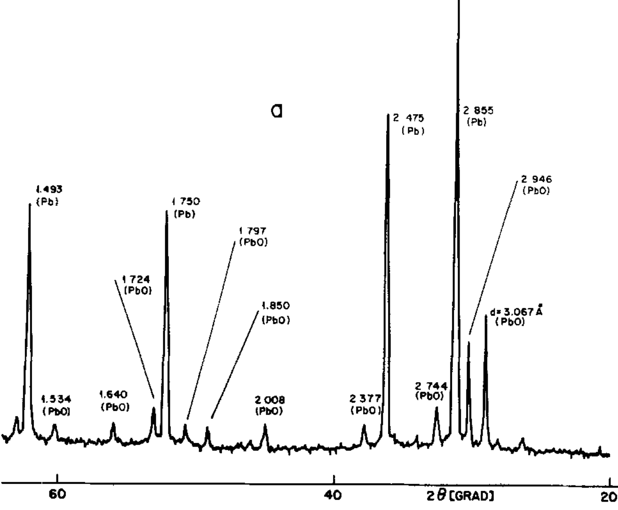
A Note on the Chemistry of Lead Sulfide Sensitization for Infrared Detection

G. M. Wolten (pp. 1149-1150, Vol. 122, No. 8)

O. A. Kunze:[1] In the technical note under discussion it is proposed that the effect of oxidants on the deposition of photoconductive lead sulfide films is the formation of a solid solution of $PbSO_4$ in PbS. The initial presence of sulfate is regarded as being responsible for the observed sensitizing effect. In support of this the author has presented chemical arguments which differ substantially from the results obtained in our laboratory.

The general acceptance of the role of oxygen and oxygen compounds in the photoconduction of lead sulfide is based on electrical measurements. Attempts to

[1] C.S.I.R., National Physical Research Laboratory, Pretoria 0001, South Africa.



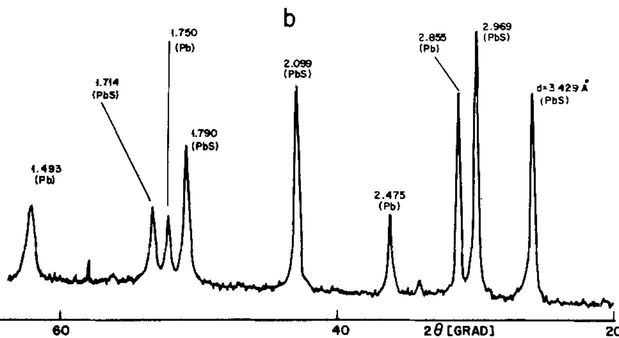


Fig. 1. Powder diffractograms, copper $K\alpha$ radiation: (a) plumbite + AIMSA, (b) plumbite + AIMSA + thiourea.

relate the sensitizing action of oxidants (or reducing agents) directly to the actual oxygen concentration in the layers have failed so far. For example, we have found that mass spectrographic analyses of PbS layers formed with and without hydroxylamine[2] show the same low oxygen concentration for both cases. Another example is the data by Blount *et al.*[3] which show the lowest oxygen value for the sample formed with the highest amount of oxidant.

From our results given below we consider reduction rather than oxidation as the crucial step involved in sensitization. Further we conclude that the initial formation of lead sulfate can be excluded.

Thiourea is oxidized easily in aqueous alkaline solution of the type used in the deposition of PbS films. We have determined polarographically that the half-wave potential for thiourea in 0.3*N* sodium hydroxide solution is close to 0V. We have also found that in place of oxidants, aminoiminomethanesulfinic acid (AIMSA) and several other reducing agents have a pronounced sensitizing effect on PbS layers.

In a strongly alkaline medium AIMSA reduces plumbite to elemental lead in a slow reaction. This is shown in Fig. 1(a), which is part of a powder diffractogram of the reaction product of an aqueous solution 0.03*N* in $Pb(NO_3)_2$, 0.3*N* in NaOH, and 0.009*N* in AIMSA. The diffractogram shows the presence of lead and lead(II) oxide. Figure 1(b) is the diffractogram of the reaction product of a similar solution which in addition was 0.013*N* in thiourea. In this case the precipitate was found to consist of lead sulfide and lead. In both cases formation of lead sulfate did not take place. This is in agreement with Bennett and Durrant who give sulfite as the oxidation product of sulfoxylate in an alkaline medium.[4] This also excludes the possibility that added sulfite is responsible for the formation of sulfate according to

$$Pb^{++} + SO_3^{--} + OH^- \rightarrow Pb + SO_4^{--} + H^+ \quad [1]$$

(completed reaction [4] in the discussed note). As expected, no formation of sulfate in a plumbite solution containing sodium sulfite was observed in an experiment designed to test reaction [1]. On the contrary, sulfite was found to induce the photochemical oxidation of plumbite to lead(IV) by dissolved oxygen, as reported by Kunze *et al.*[5]

Finally, it should be pointed out that the easy substitution of sulfate for sulfide in the PbS lattice as suggested by Wolten appears to be doubtful. The effective ionic radius of $[SO_4]^{--}$ is not 1.49Å as quoted but of the order of 2.2Å.[6]

Instead of allowing the formation of excess lead in the layers, which has thus far been supposed, the action of those reducing agents which are effective sensitizers might well be to inhibit the oxidation of sulfide to sulfur due to the presence of dissolved oxygen. Lead sulfide formed by the plumbite thiourea reaction is known to contain an excess of sulfur.[7] The presence of reducing agents would thus result in the formation of deposits with improved stoichiometry. This reasoning is supported by our finding that PbS layers deposited without a reducing additive show very little if any photoconductivity. Their photoconductive response can, however, be enhanced if the deposition is conducted in an inert atmosphere using chemicals and solvent from which the adsorbed and dissolved oxygen have carefully been removed.

The Transport of Chromium in Cr_2O_3 Scales in Sulfidizing Environments

G. Romeo, H. S. Spacil, and W. J. Pasko
(pp. 1329-1333, Vol. 122, No. 10)

F. A. Kröger:[8] This paper explains the marked effect of sulfur on the diffusivity of Cr in Cr_2O_3 scales by donor action of sulfur dissolved in the Cr_2O_3. The donor is supposed to be sulfur at an oxygen site. Such a donor would have a donor level S_O^x somewhat above the valence band of Cr_2O_3. Although such a center may trap a hole, it will not do so very efficiently. It seems more likely that sulfur acts as a reducing agent by reacting with oxygen with the formation of SO_2. The same reaction has been proposed to explain the reducing effect of sulfur on ZnO[9] and of oxygen on ZnS[9] and CdS.[10] Owing to the large negative Gibbs free energy of the reaction

$$\tfrac{1}{2}S_2(g) + H_2O(g) \rightarrow H_2(g) + SO_2(g) \ (\Delta G)_{1000^\circ C} = -45.25 \text{ kcal/mole} \quad [1]$$

this reaction is even effective in reducing the low oxygen activities established by H_2-H_2O mixtures. Reaction with Cr_2O_3 can be formulated

$$1/4S_2(g) + O_O^x + 2/3V_{Cr}''' + 2h^\cdot \rightarrow 1/2SO_2(g) \quad [2]$$

and thus leads to a reduction in the concentrations of holes and Cr vacancies. The increased mobility of chromium in the scale can be explained by the increase of interstitial Cr caused by the decrease of the Cr vacancy concentration. This is seen from Eq. [I-A] of the paper under discussion which represents a modi-

fied Frenkel disorder reaction. It can also be explained by normal Frenkel disorder of chromium

$$Cr_{Cr}^x + V_i^x \rightarrow Cr_i^{\cdot\cdot\cdot} + V_{Cr}''' \quad \text{leading to } [Cr_i^{\cdot\cdot\cdot}][V_{Cr}'''] = K_F$$

Formation of CrS at the interface Cr_2O_3-Cr metal indicates that sulfur penetrates the oxide layer. This must occur either by bulk diffusion or by grain boundary diffusion. In the former case, some sulfur must be dissolved in the Cr_2O_3, either at oxygen sites (S_O^x) or at interstitial sites (S_i). It is known for the chalcogenides of lead, cadmium, and zinc that chalcogen diffusion occurs by neutral interstitials at low metal activities but by a nonmetal vacancy mechanism at high metal activities. If the bulk diffusion of S is involved in the present case, it is probably of the latter type.

G. Romeo,[11] **H. S. Spacil,**[12] **and W. J. Pasko:**[12] Kröger has suggested that our experimental results may be due to the reducing action of sulfur, in the gas phase, rather than sulfur actually dissolved in the oxide. His reaction [2], however, can be combined with the dissociation of gaseous SO_2

$$\tfrac{1}{2}SO_2(g) = \tfrac{1}{4}S_2(g) + \tfrac{1}{2}O_2(g)$$

to yield, using Kröger-Vink notation

$$O_O^x + 2/3V_{Cr}''' + 2h^{\cdot} = \tfrac{1}{2}O_2(g)$$

which is identical to, though reversed in direction from, our reaction [I-B]. Whether modified or normal Frenkel defects are also considered to exist, the Cr defect concentration would depend only on oxygen activity, and be independent of sulfur activity. Sulfur could then influence chromium transport under our experimental conditions only by changing the oxygen activity or by acting as a sink for chromium moving across the scale.

While sulfur does act as a reductant in the systems cited by Kröger, its effect as a reductant in our system is best considered in terms of the relative effects of sulfur and hydrogen on the oxygen potential of a hydrogen-sulfur-oxygen gas containing a fixed amount of oxygen. Table I gives the oxygen potential in such a gas as a function of the atomic sulfur to hydrogen plus sulfur ratio, for an atomic fraction of oxygen equal to 10^{-5}, at 900°C and 1 bar.[13]

Thus the addition of sulfur to a gas initially containing only hydrogen and oxygen can only increase the oxygen potential and activity, and could not increase chromium mobility through an increase in interstitial concentration as proposed by Kröger.

Prior investigators [see Ref. (13) and (14), in the paper under discussion] have shown that oxidation rates of chromium in oxygen-containing gases have either increased or remained relatively constant with oxygen activity. Such results imply that chromium mobility in Cr_2O_3 would show a similar dependence on oxygen activity. Our Fig. 2, however, illustrates the increase in chromium transport through the oxide in going from an O_2 atmosphere to a H_2-10% H_2S mixture. If the oxygen activity were the only controlling factor of chromium mobility in Cr_2O_3, this quantity should remain the same or decrease as a consequence of changing the atmosphere from O_2 to H_2-10%H_2S. Since actually an increase is observed, sulfur does not appear to function only as a sink for chromium, but can also be a factor of enhancement of the chromium mobility by affecting the defect equilbria in the Cr_2O_3.

We do not advance any mechanism by which sulfur penetrates Cr_2O_3 to form the internal sulfide layer observed in our experiments. While we have proposed that sulfur enters the oxide as an electron donor on oxygen sites, with subsequent effects on chromium mobility, simultaneous sulfur transport through the oxide may occur as a result of gaseous transport in cracks or the mechanism mentioned by Kröger.

Doping of Silicon by Neutron Irradiation

H. A. Herrmann and H. Herzer (pp. 1568-1569, Vol. 122, No. 11)

J. Burtscher:[14] Herrmann and Herzer write about the chances of neutron-irradiated silicon perhaps somewhat too cautiously, finishing their paper with the statement, "Further work must be undertaken to establish whether transmutation doping will play a dominant role in addition to the standard methods for growing silicon crystals."

The use of neutron-irradiated silicon for manufacturing large-area devices (especially high power devices) is by no means a question of the future. In 1973, Schnöller[15,16] had already presented rectifiers and thyristors which were made from Siemens silicon irradiated in the swimming pool reactor FRJ1 in Jülich (Germany). By observation of the avalanche radiation[17] it was shown in Schnöller's work that the breakdown in these structures was much more homogeneous than in devices made from conventional doped crystals. In addition to the homogeneity of the resistivity across the area, it is also important that the desired mean value of the resistivity can be reached more exactly by neutron irradiation than by any conventional doping method, at least in the range 10-200 ohm-cm n-type which is currently the most important one for high power, high voltage devices. This finer fitting of the resistivity value made it possible to improve the always necessary compromises between breakdown voltage, current capability, and dynamic properties.[18,19] This point has been discussed somewhat more exactly in the meantime.[20]

Details about the reached resistivity tolerances when using different reactors were reported in Ftn[21-24]. Also, the safety questions connected with the storing and handling of bigger quantities of irradiated material have ben examined; the required waiting times for the radioactivity to decay are of the order of days.[25] The use of neutron-irradiated silicon for the production of high voltage, high power devices has become standard in the meantime.

H. A. Herrmann and H. Herzer:[26] Neutron-irradiated silicon, we agree, is not only a question of the future, but has grown up to be a very important technique for high power device technology since writing our publication in **This Journal**. The interest in this material now overflows nearly all applications in the resistivity range above 20 ohm-cm n-type.

The meantime from our first publication[27] up to now can be characterized by three typical features: (*i*) the rapid increase in fundamental work,[28-34] (*ii*) the rapid increase in R&D work,[35] and (*iii*) the rapid increase in demand for production quantities.[36] The latter point always judges whether a technological progress has been received or not. The cautious question which we put up in the communication regarding whether transmutation doping will play a dominant role can only be answered by both scientific-technical arguments and economic facts. From the point of view of a silicon supplier with a leading position in polysilicon quality and floating-zone technique as well, this question can be answered positively also under economical aspects. Many important power device producers have published exciting, good results. Therefore the list references cited by J. Burtscher has to be completed.

So neutron transmutation-doped silicon, which we call Waso-ND, seems to give us a nice example for the mutual stimulation between nuclear and semiconductor physics, in spite of a delay of several years, we have seen: (*i*) a nearly closed understanding on a physical process,[37] (*ii*) material in education books,[38] (*iii*) rediscovery as a doping-technique, and (*iv*) rapid turnover of a section of semiconducting applications.

The Reduction of Manganese Dioxide in Leclanché-Type Dry Cells as Displayed by Derivative Discharge Functions

C. R. A. Clauss and H. E. L. G. Schweigart

Council for Scientific and Industrial Research, Chemical Engineering Research Group, Pretoria, South Africa

ABSTRACT

The derivative discharge curves for β- and γ-MnO_2 down to ~0.7V open cell voltage were resolved into one characteristic set of four normal distribution functions (peaks). Only peak positions shift to lower voltages for β- compared to γ-MnO_2. When the ratio of electrolyte to MnO_2 is increased, the first peak increases while the other peaks decrease (the second passes through a maximum) and at a mass ratio above 14 only the first peak remains. The first peak represents direct reduction of Mn^{4+} to soluble Mn^{2+} which ends at *p*H 7.5, the second is attributed to the formation of $Mn(OH)_2$, and the third to the formation of MnOOH. Each reaction takes place throughout the depolarizer pellet before the next becomes significant. Electrochemical tests for the evaluation of the dry cell activity of MnO_2 samples should be performed at the same mass ratio of electrolyte to MnO_2 as used in commercial dry cells. Higher ratios lead to an overestimation of samples with low activity.

The complex reaction mechanism in a Leclanché-type dry cell manifests itself in the mode of potential drop during cell discharge. Brenet (1) proposed considering the derivative of the function coulombs produced per gram of MnO_2 *vs.* cell voltage for characterization and interpretation of the reactions in the manganese dioxide cathode. This paper presents the results obtained by this method from a large number of discharge curves measured as open-circuit potential during short current interruption. Different types of manganese dioxide were tested varying the ratio of electrolyte to manganese dioxide in the depolarizer mixes, the length of the depolarizer pellet formed therefrom, the mass current density, and the superficial current density.

Experimental

Manganese dioxide samples.—Three different types of manganese dioxide were used in the experiments. Their properties are given in Table I. The two ores were of South African origin: the β-MnO_2 had an activity which was too low for use in commercial dry cells, whereas the Nsutite ore showed an acceptable activity. X-ray diffraction analysis indicated that the Nsutite ore consisted mainly of Nsutite 1.65, following the classification given by Sorem and Cameron (2), and a small amount of β-MnO_2.

The samples were crushed in a jaw crusher and dry ground in a sintered corundum mortar until the whole material would pass a 100 BSM sieve and 85% of it a 200 BSM sieve on a ROTAP sieve shaker.

X-ray diffraction analyses.—A Philips x-ray diffractometer Model PW 1310 with unfiltered Cu radiation was used. The diffracted beam was monochromatized by a curved carbon crystal (AMR focusing monochromator E 202) and measured with a pulse height discriminator. This device gave very low background values so that lines of low intensity could easily be detected.

Preparation of black mixes (depolarizers).—The black mix compositions used in tests with β-MnO_2 are given in Table II. Mixes containing the other types of MnO_2 had similar compositions.

The indicated proportions of the dry components were mixed by hand. The required amount of electrolyte solution was sprayed over the dry mixture which was then kneaded by hand to give a homogeneous black mix (3).

Discharge tests.—The cell used in all tests with black mixes is shown schematically in Fig. 1. The cylindrical pellets of the black mixes were discharged at constant current. After each 199 msec the current was interrupted for 1 msec and the voltage between the zinc reference electrode and the cathode was measured during the last 200 μsec of the interruption period using a

pulse galvanostatic analyzer (4, 5). These voltages were recorded as a function of time and the discharge curves obtained are virtually identical to those obtained under continuous discharge conditions, excluding ohmic resistances, since the recovery potentials during interruption periods up to 1 msec do not exceed 10 mV (5).

Conducting-foil tests (1, 6).—A strip of carbon-filled conducting plastic foil, 10 × 20 mm (Nikolaus Branz, Berlin, Germany) was glued with hexane on to the end of an equally wide but longer strip of gold foil and kept for 30 min at 70°C. After cooling, the composite strip was weighed and a certain amount of manganese dioxide particles (85 BSM > size > 100 BSM) spread evenly over the plastic foil. The particles were hydraulically pressed into the foil which was warmed underneath to 110°C by a preheated support. Any loose particles were washed off with a jet of water. After drying for 30 min at 70°C and cooling the strip was reweighed.

The cathode thus prepared was placed into a beaker containing 50-200 ml of electrolyte solution. At the low discharge current applied (1 mA) polarization of the zinc anode can be neglected and this electrode can be used also as reference electrode. The electrolyte solution was stirred magnetically. For discharging this cell was connected to the pulse galvanostatic analyzer.

Evaluation of the discharge curves (7).—The discharge period of time was read off the recorder chart in 0.02V steps of decreasing cell voltage and converted to specific capacity Q given as coulomb/gram MnO_2 (MnO_2 determined as active oxygen) taking black mix composition and discharge current into account.

The numerical resolution of the discharge curve entailed the finding of a stable derivative of the empirically defined function and the separation of a sum of Gaussian peak functions into components.

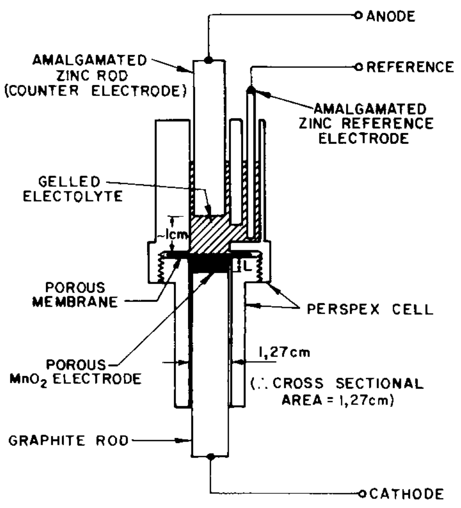

Fig. 1. Cross section of test cell

For a given set of readings (Q_i, V_i) an estimate σ_i of the expected error in Q_i is made that is proportional to the tangent of the graph at the given point. The graph is now approximated by a spline function which passes through the points ($\hat{Q}_i$; V_i) where $\hat{Q}_i$ is the smoothed value for Q_i. The $\hat{Q}_i$ are determined such that the approximation is the smoothest for which the restriction

$$\sum_{i=1}^{i=n} \left[\frac{Q_i - \bar{Q}_i}{\sigma_i} \right]^2 \leq n$$

is satisfied.

Since the spline function is mathematically given by a formula of the form

$$Q(V) = Q_i + a_i(V - V_i) + b_i(V - V_i)^2 + C_i(V - V_i)^3$$

for $V_i \leq V \leq V_{i+1}$ the derivative at V_i is simply a_i.

For the separation of the peaks, a nonlinear least squares fit is now used on the obtained values of the derivative at V_i.

Calculation of pH in the electrolyte solution.—For interpretation of the results knowledge of the pH changes in the electrolyte solutions during the initial discharge period was desired.

For these computations the molar concentrations of NH_4Cl and $ZnCl_2$ in the electrolyte before the discharge tests were calculated from the black mix compositions taking the amount of solid ammonium chloride, being part of the mixture of the dry components, as dissolved in the electrolyte. The coulomb/gram MnO_2 values were converted to Faraday/liter electrolyte (**F**/l) based on the known black mix compositions.

Protons are consumed in the reduction of manganese dioxide as well as in the dissolution of the reduction products. For the range of peak A it is assumed that manganese dioxide is reduced to manganous ions which are dissolved in the electrolyte. According to reaction [1] (see below) 2M protons are used per **F**/l. Until the end of peak A ammonium ions are considered to be the only proton donors. Any quantity of protons consumed produces therefore an equivalent amount of ammonia, most of which will be bound by zinc ions according to Eq. [3] and [4] as long as enough zinc ions are available.

Some of the derivative discharge curves show a small peak, O, at cell voltages higher than peak A. As it is assumed that this peak is related to adsorbed oxygen, only one equivalent of protons is consumed per **F**/l in this range.

The ammonium ion concentration in the cathode mix decreases due to the discharge reactions and increases by migration and normal diffusion from the free electrolyte adjacent to the black mix pellet. Changes due to this diffusion were neglected in the calculations. The electrolyte in the black mix contains during the initial discharge period, besides water, essentially the following seven species: $ZnCl_4^{2-}$, Cl^-, NH_4^+, Zn^{2+}, NH_3, $Zn(NH_3)_2^{2+}$, $Zn(NH_3)_4^{2+}$.

Of these the last three do not exist in the free electrolyte and only the first three species must be considered for ion migration through the free electrolyte-black mix interface. Since the concentration of Zn^{2+} ions in the free electrolyte is always low due to formation of the $ZnCl_4^{2-}$ complex at high chloride concentrations (8), Zn^{++} ion transport can be neglected. The $Zn(NH_3)_2^{2+}$ and $Zn(NH_3)_4^{2+}$ ions being formed only in the black mix do not migrate toward the zinc anode.

Results and Discussion

Mass ratio of electrolyte to manganese dioxide.—Derivatives of discharge curves for the β-MnO_2 are shown in Fig. 2a-f. Figure 2a represents the curve ob-

tained from a black mix composition normally used in commercial Leclanché-type dry cells. The curve can be described essentially as the sum of four normal distribution functions (peaks A, B, C, and D). These peaks appear at different cell voltages and they differ in half-maximum width and surface areas.

Comparison between Fig. 2a and b shows that the areas of peaks A and B increase while that of peak C decreases with increasing mass ratio of electrolyte to manganese dioxide. Furthermore a slight shift in the position of the four peaks can be observed. Peak B shifts, *e.g.*, about 0.04V toward lower and peak C 0.01V toward higher cell voltages when the mass ratio increases from 0.64 to 2.7 (Table III). At the next higher mass ratio examined (Fig. 2c) only three peaks appear. Taking into account the observed shifts one can assume that the middle peak consists of peaks B and C, the upper and lower peaks being A and D, respectively. Figures 2a-f show that with increasing mass ratio of electrolyte to manganese dioxide peak A increases, peak C and D decrease and tend to disappear at a certain mass ratio, whereas peak B increases at first and then also decreases at the higher mass ratios studied. At a mass ratio of about 24 all peaks but A have become insignificant.

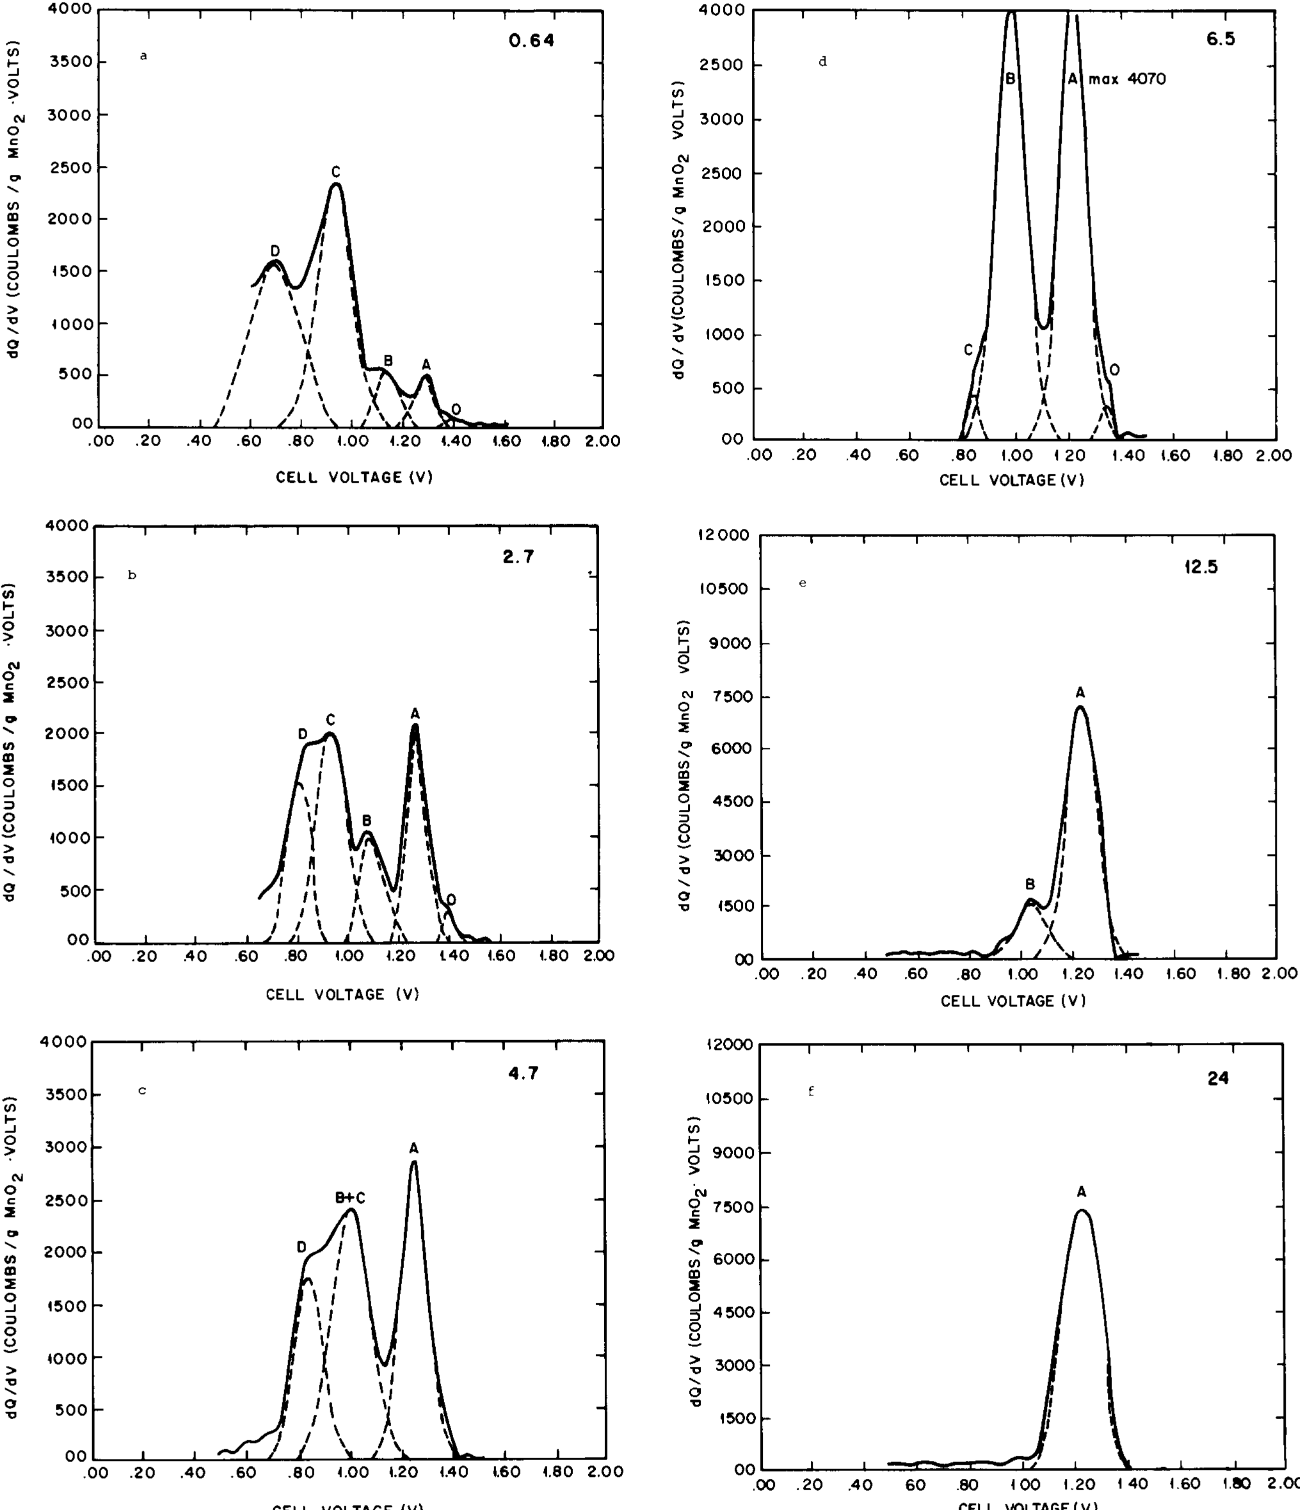

Fig. 2 a-f. Derivative discharge curves obtained with β-MnO_2 in black mixes of increasing mass ratio of electrolyte to manganese dioxide. Values in figures indicate the mass ratios of electrolyte to manganese dioxide in pellets. The corresponding black mix compositions are given in Table II.

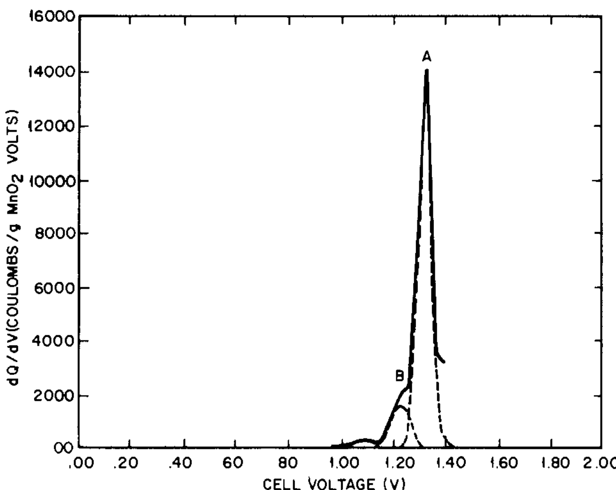

Fig. 2g. Derivative discharge curve of β-MnO_2 obtained by cathodic reduction (1.03 mA) of a thin layer of 25.6 mg manganese dioxide impressed on a conducting plastic foil immersed in well-agitated electrolyte solution.

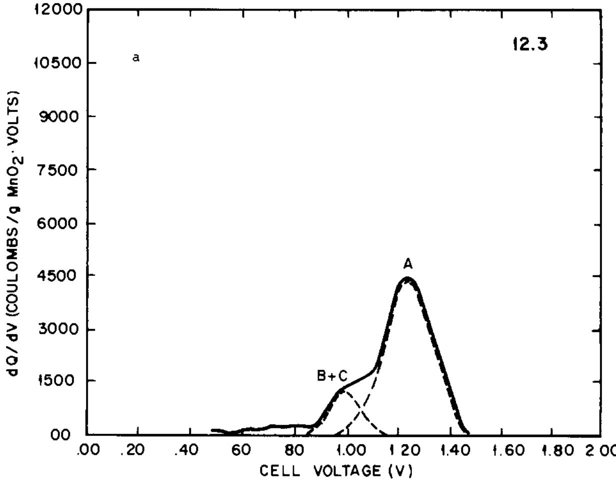
This finding was confirmed by discharge experiments in which a thin layer of manganese dioxide was cathodically reduced in the presence of a large excess of well-stirred electrolyte solution. Figure 2g shows that under these conditions essentially one sharp peak at 1.30V is obtained. A minor peak at somewhat lower cell voltages may be assigned to peak B and/or C.

The observed increase of peak A with increasing mass ratio of electrolyte to manganese dioxide could also be due to the simultaneous increase in the carbon black to manganese dioxide mass ratio of the mixes used in the discharge tests. The carbon black content had to be increased in the mixes in order to achieve the desired uptake of electrolyte. The conducting-foil tests (6) did not exclude a possible influence of carbon because the MnO_2 particles were in contact with the carbon filler of the plastic foil. To distinguish between the influence of carbon black and of electrolyte, two mixes were prepared in which about half of the carbon black was replaced by Aerosil 380 as electrolyte carrier. The shapes of the derivative discharge curves obtained in these experiments (Fig. 3a-b) are similar to those of equal mass ratio of electrolyte to manganese dioxide where only carbon black is used as carrier for the available electrolyte (Fig. 2e-f). Curves for equal ratios of carbon black to manganese dioxide but different electrolyte to manganese dioxide mass ratios differ significantly (Fig. 2d and 3a). This indicates that the mass ratio of carbon black to manganese dioxide in



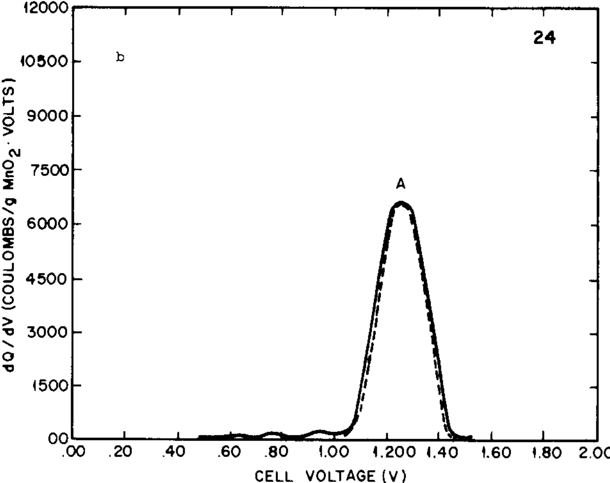


Fig. 3 a-b. Derivative discharge curves of β-MnO_2 in black mixes where part of the carbon black is substituted by Aerosil 380. Values in figures indicate the mass ratios of electrolyte to manganese dioxide in the pellets.

the black mix composition is not the shape-determining factor in the range examined.

The areas under the derivative discharge curves as well as those of the peaks represent the electrical charge in coulomb/gram of manganese dioxide exchanged within the ranges of the cell potentials considered. The size of the peaks obtained under various discharge conditions, presented as coulomb/gram MnO_2, and the positions of the peak maxima for the curves

shown in Fig. 2a-g and 3a-b are listed in Table III. The values in Table III clearly show the increasing predominance of peak A as the mass ratio of electrolyte to manganese dioxide increases. The last column shows the over-all increase in discharge capacities, expressed as sum of peak areas, with increasing mass ratio of electrolyte to manganese dioxide. Above a ratio of about 6.5 the discharge capacities are higher than the theoretical value for complete reduction to the trivalent state. The results, therefore, indicate that above a certain mass ratio the reduction proceeds beyond the trivalent state of the manganese ions. Complete reduction to the bivalent state, however, has never been observed in our experiments. The values obtained in conducting foil tests were surprisingly lower than the highest values found in the discharge tests of long pellets. The reason for this discrepancy may be explained either by insufficient contact between some of the manganese dioxide particles and the electron-conducting plastic foil or by inaccessibility of electrolyte solution to some of the imbedded manganese dioxide particles.

Electrolytic MnO_2.—Figures 4a-e and the values compiled in Table IV show the corresponding results obtained from discharge tests of electrolytic γ-MnO_2. Again it is possible to interpret the derivative discharge curves essentially as sums of four or less peaks. The peak positioned at the highest cell voltage behind the small peak O increases with increasing mass ratio of electrolyte to manganese dioxide and remains practically the only one at and above a mass ratio of 7. For γ-MnO_2 the peak maxima A, B, and C occur at higher cell voltages than for β-MnO_2. Peak D cannot be lo-

cated accurately and it is therefore not possible to decide whether the position of its maximum is related to the type of MnO_2 or to the black mix compositions. The sums of the peak areas are about the same for both types of manganese dioxide.

Nsutite.—Table V presents the results of an analogous series of experiments using a Nsutite-type manganese dioxide ore which showed a relatively high activity in dry cell tests. The over-all picture compares fairly well with the results of the other series with the exception of the existence of another peak (designed as A1) which is situated at about the same cell voltages as peak A of the γ-MnO_2. With regard to its position and behavior the following peak A can be compared to the peak A of β-MnO_2. The area of peak A1 is quite independent of the mass ratio of electrolyte to manganese dioxide. These observations can be explained by assuming that the Nsutite-type ore contains a small amount of a more active component.

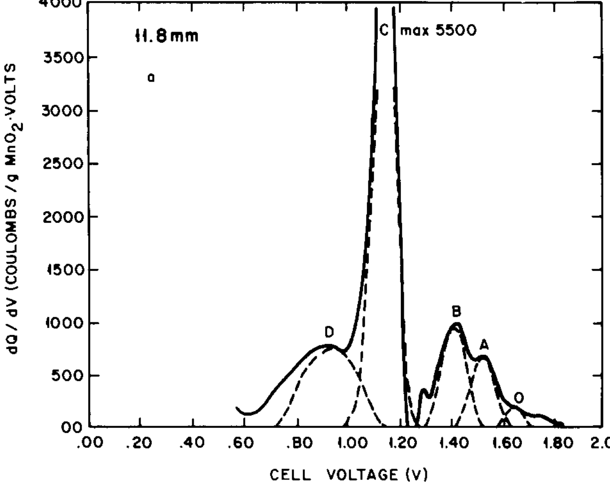
In performing the conducting foil test with the Nsutite-type ore it was found that virtually all (96%) of the coulombs exchanged were used to produce Mn^{2+} going into solution.

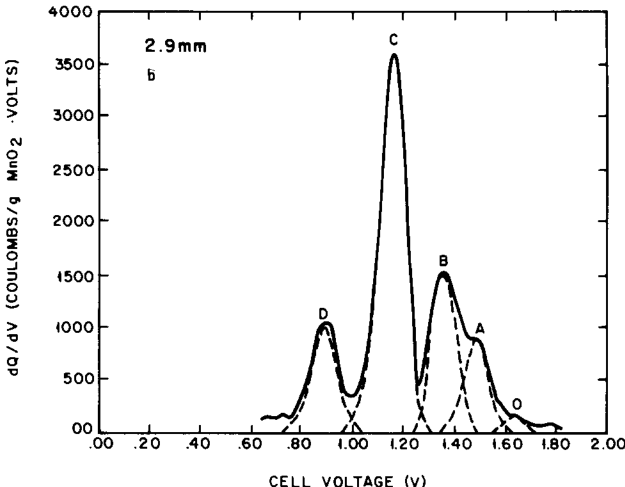
Discharge current densities and length of the black mix pellet.—The influence of the discharge conditions on the shape of the derivative discharge curves was studied for one black mix composition close to those used in Leclanché-type dry cells. Under the prevailing test conditions the following parameters were varied: (*i*) length (millimeters) of the cylindrical black mix pellet; (*ii*) superficial current density (milliampere/square centimeter), *i.e.*, the discharge current divided by the basal area of the black mix pellet; and (*iii*) mass current density (milliampere/gram MnO_2) which is the quotient of the discharge current and the mass of manganese dioxide (calculated as active oxygen) in the black mix pellet.

These three parameters are interdependent and in a series of experiments with one black mix composition only one parameter can be kept constant while the others vary.

Derivative discharge curves obtained by discharging pellets of various lengths, containing γ-MnO_2 as an example, are shown in Fig. 5. The positions and areas of the peaks forming these curves and those obtained at higher current densities are given in Table VI. From the results of a large number of experiments the following general rules can be deduced: (*i*) The shorter the black mix pellet and the lower the discharge current the greater is the resemblance of the derivative discharge curves to those obtained from experiments with higher mass ratios of electrolyte to manganese dioxide. The sum of the peak areas increases in the same manner as observed for increasing electrolyte to MnO_2 mass ratios. (*ii*) The longer the pellet the better are the peaks resolved. (*iii*) The mass current density has little influence on the shape of the derivative discharge curves within the examined range from 1.8 to about 70 mA/g MnO_2 as long as diffusion does not interfere [rule (*i*)].

If one expects that each peak is related to a specific reaction in the black mix it can be concluded that the peaks A and B belong to reactions related to the electrolyte composition while peak C and possibly peak D are linked to reactions which become significant only after certain changes of electrolyte composition. The observation that the resolution of the peaks improves with increasing length of the black mix pellet [rule (*ii*)] leads to the conclusion that each type of reaction proceeds essentially through the whole length of the black mix pellet before the next type of reaction starts. The resolution decreases under conditions where diffusion becomes significant and only then different types of reactions may take place simultaneously at different depths in the black mix pellet.





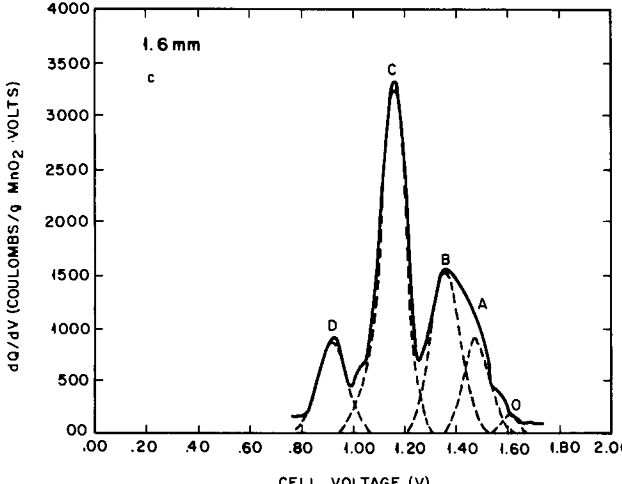


Fig. 5 a-c. Derivative discharge curves obtained with electrolytic γ-MnO_2 in black mixes of standard composition at various lengths of the black mix pellets discharged at 2.5 mA/cm^2.

Consequences with respect to test methods.—The type of manganese dioxide seems to have little influence on the shape of the derivative discharge curves when black mix compositions, geometry of the black mix pellet, mass, and superficial current densities are comparable. The same peaks appear, however, at different cell voltages. For active types of manganese dioxide the peaks are positioned at somewhat higher cell voltages than for the less active types and for this reason the energy available from a dry cell down to a certain cell voltage is higher if it contains the active material.

It has been stated by several authors that under certain conditions battery-inactive types of manganese dioxide, *e.g.*, β-MnO_2, can become as active as the most active types (9, 10). Our work shows that this happened at high electrolyte to manganese dioxide mass ratios when only the electrolyte-dependent reaction (peak A) exists. Tests where high mass ratios of electrolyte to manganese dioxide are used such as conducting-foil tests (1, 6) or the Kornfeil test (11) cannot give reliable values because in these tests the reaction of type A is overemphasized and a material of low dry cell activity would be judged too favorably. The same argument is valid for conditions where diffusion of reaction products from the black mix into adjacent electrolyte and of NH_4^+ ions in the opposite direction is significant. It follows that in activity tests the electrolyte volume between the black mix and the zinc counterelectrode should be kept as small as in commercial dry cells and the black mix composition should be the same as used in batteries in order to get the best relation between the fast laboratory tests and the behavior of MnO_2 in batteries.

Assignment of peaks.—As it is likely that each of the observed peaks belongs to a specific reaction taking place in the black mix during the cathodic reduction

Table VI. Positions of maxima [cell voltage (volt)] and surface areas (coulomb/gram MnO_2) of the peaks forming the derivative discharge curves of electrolytic γ-MnO_2 obtained from black mix pellets of different lengths for discharge currents of 3 and 12 mA. (Standard black mix composition: 62.3% MnO_2 sample, 7.7% carbon black, 13.4% NH_4Cl, 2.1% $ZnCl_2$, 14.5% H_2O; mass ratio of electrolyte to manganese dioxide: 0.53.)

of the manganese dioxide the following assignments are proposed.

The relative predominance of peak A depends mainly on the quantity of electrolyte available per mass unit of manganese dioxide. Conducting-foil tests at low discharge current densities give essentially only one peak (1) situated at about the same cell voltage at which peak A appears in the pulse galvanostatic analyzer tests. Under conditions of the conducting-foil tests a stoichiometric cathodic dissolution of the manganese dioxide has been found by us in agreement with the results obtained by Chreitzberg, Allenson, and Vosburgh (12) under comparable conditions at somewhat higher superficial current densities. The conditions in Cahoon's "utilization test" (13) agree with those in our tests at highest mass ratios of electrolyte to manganese dioxide, *i.e.*, with excess electrolyte. In the example quoted in this paper the stoichiometrical amount of Mn^{2+}, as expected from Eq. [1], has been found in solution when discharging manganese dioxide to $MnO_{1.6}$ in an electrolyte of 33% $ZnCl_2$, 20% NH_4Cl, and 47% water. Therefore peak A can be related to the cathodic dissolution of manganese dioxide following the over-all equation

$$MnO_2 + 4H^+ + 2e^- \rightarrow Mn^{2+} + 2H_2O \quad [1]$$

This reaction predominates in acid electrolyte (14-17) but is also observed in neutral electrolytes up to about pH 8, (12, 18-20). It was assumed that in neutral electrolyte (pH 6-8) the dissolution reaction and solid-state diffusion occur simultaneously (17), while in alkaline electrolyte only a solid-state diffusion mechanism is envisaged (9, 17, 21-24). Under conditions where peak A prevails the ammonium ion should, directly or indirectly, be the proton donor (17) for reaction [1]

$$NH_4^+ \rightleftharpoons NH_3 + H^+ \quad [2]$$

The ammonia formed in this way is bound to the zinc ions to form di- and tetrammine complexes (25) following the equations

$$Zn^{2+} + 2NH_3 \rightleftharpoons Zn(NH_3)_2{}^{2+} \quad [3]$$

and

$$Zn^{2+} + 4NH_3 \rightleftharpoons Zn(NH_3)_4{}^{2+} \quad [4]$$

In this way, the system acts as a buffer solution and the pH only starts to increase rapidly after practically all the available Zn^{2+} ions are used up by reactions [3] and [4].

As reaction [1] is dependent on the pH of the electrolyte in the black mix it is to be expected that the reaction is practically terminated when the pH has reached a specific value. The pH values of the electrolytes were therefore calculated using Eq. [1], the equilibrium constants (26, 27) corresponding to Eq. [3] and [4], and also considering the electric transport of NH_4^+ ions into and $ZnCl_4^{2-}$ ions out of the electrolyte of the black mix. For nearly all discharge experiments for which a diffusional exchange with the electrolyte paste adjacent to the black mix was negligibly small, a pH value of about 7.5 was computed for the intersection points of the outlines of peaks A and B. For electrolytic γ-MnO_2 and Nsutite at relatively low mass ratios of electrolyte to manganese dioxide, pH values between 8 and 9 were computed. Under all conditions in which the derivative discharge curve contains only peak A the calculated pH does not reach 7.5 during the entire discharge test.

Curves obtained in correlating pH and cell voltage (28) show a sharp kink at this particular pH. This is the point where 0.12 V/pH intersects with 0.06 V/pH indicating that the two-electron four-proton process changes into the one-electron one-proton process.

Cahoon *et al.* (18) pointed out that the primary (electrochemical) reaction consumes protons (Eq. [1]), consequently increasing the pH, and the secondary (chemical) reaction ($MnO_2 + Mn^{2+} + 2\ OH^- \rightarrow 2MnOOH$) consumes OH^-, thus increasing acidity in the electrolyte at the surface of the depolarizer and that this increase will be faster for the more active types of MnO_2. This could explain why for the end of peak A of electrolytic MnO_2 and Nsutite the calculated pH is higher than would be expected and that the actual surface pH of the active MnO_2 particles is, in fact, similar to that found in tests with less active material or with excess electrolyte.

Peak B increases at first with increasing mass ratio of electrolyte to manganese dioxide and decreases again at the higher mass ratios examined. This points to this peak being related also to the composition of the electrolyte. Since peak B starts at a pH where peak A ends, the chemical reaction corresponding to peak B should become predominant at and above pH 7.5. The precipitation of manganous hydroxide could be a possible reaction

$$Mn^{2+} + 2H_2O \rightleftharpoons Mn(OH)_2 + 2H^+ \quad [5]$$

and can act as a proton-donating buffered system for a possible electrochemical reaction

$$MnO_2 + 2H^+ + 2e^- \rightleftharpoons Mn(OH)_2 \quad [6]$$

which may be related to peak B. Under these conditions the area of peak B should approximate that of peak A since all manganous ions produced in the chemical reaction related to peak A would be consumed by the reaction related to peak B. Diffusion of NH_3 into, and electrical transport of NH_4^+ ions from, the adjacent paste electrolyte into the depleted black mix can explain the relatively larger surface areas of peak B observed in some cases. Furthermore, it is not necessary to assume that reaction [6] is terminated when most of the manganous ions are consumed.

If the manganous hydroxide formed by reaction [6] would be attached to the surface of the manganese dioxide particles as a dense monolayer of manganous hydroxide so that reaction [6] could not proceed further, much lower areas of peak B are to be expected. In order to explain the observed larger capacities one has to accept that the manganous hydroxide precipitation forms a separate detached phase in such a way that the manganese dioxide surface remains accessible to further reaction.

Peak C may be attributed to the well-known solid-state reduction of manganese dioxide (9, 17, 21-24) represented by the equation

$$MnO_2 + H^+ + e^- \rightleftharpoons MnOOH \quad [7]$$

This reaction starts only once the electrolyte composition prevents continuation of the reactions ascribed to peaks A and B, *i.e.*, at higher pH values than normally described in literature.

Peak D is often difficult to separate from peak C and its surface areas cannot be clearly defined so that its dependence on the experimental conditions is uncertain. Attempts to relate the occurrence of peak D to the formation of hetaerolite, which has been described as the most significant reaction product in battery discharge (28-30), failed. Practically no hetaerolite could be detected by x-ray diffraction in black mixes which had been discharged slightly below the cell voltage which indicates the end of peak D. Hetaerolite could be identified only in black mixes after discharging to 0.0V cell voltage. The formation of hetaerolite appears to be a secondary (chemical) reaction (25, 31) and is found mainly in black mixes exposed to low current, long term discharge conditions (32).

The sequence of peaks into which the area under the derivative discharge curve can be resolved follows the scheme laid out for the depolarization of manganese dioxide implied from magnetic susceptibility measure-

ments by Ghosh and Brenet (33, 34). These authors found that during the first stage of discharge no Mn^{3+} was formed but that the Mn^{4+} lattice remained while reduction proceeded to Mn^{2+} (peaks A and B). On further reduction MnOOH (peak C) and finally Mn_3O_4 (peak D) could be identified.

Conclusion

Consideration of the derivative discharge curves shows that the discharge mechanism of the cathode of Leclanché-type dry cells is more complicated than implied by the models previously proposed. From the experimental results presented in this work it follows conclusively that composition and quantity of electrolyte and changes in the electrolyte during discharge have a pronounced influence on the form of the discharge curves. The discharge curve obtained under the conditions of commercial Leclanché-type dry cells represents a variety of different reactions and it is not possible to consider only one type of reaction, as for instance the solid-state diffusion model.

The dissolution reaction and manganous hydroxide formation occur first before the solid-state diffusion reaction becomes predominant. Resolution of the peaks of the derivative contour line increases as diffusional exchange of reaction products and salts between the electrolyte in the black mix and the electrolyte in the compartment diminishes. This indicates that each type of reaction proceeds throughout the length of the black mix pellet before the next reaction becomes significant.

For these reasons electrochemical tests for the evaluation of dry cell activity of manganese dioxide should be carried out at the same mass ratios of total electrolyte quantity to manganese dioxide as used in commercial dry cells. In particular the activities of manganese dioxide ores with low depolarization capacity are overestimated if the values obtained from tests with excess electrolyte, terminated at a predetermined cell voltage, are taken as criteria for the activity, because the values of the areas of peaks A and B which occur at higher cell voltages are higher in the presence of more electrolyte.

Acknowledgment

The authors wish to express their appreciation to Mr. D. P. Laurie and Dr. R. Rösel of the National Research Institute for Mathematical Sciences-CSIR for establishing computer programs for the evaluation of the discharge curves and the pH calculations.

The Chemistry of TiS_3 and $NbSe_3$ Cathodes

Donald W. Murphy* and Forrest A. Trumbore*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The cell discharge reactions of $NbSe_3$ and TiS_3 cathodes in nonaqueous lithium cells have been shown to involve three lithiums per MX_3. Using reaction with n-BuLi as a model for cell discharge we show that cell discharge involves topochemical reactions in which the basic strucutre of the MX_3 is maintained. Both $NbSe_3$ and TiS_3 are chain structures containing X-X bonds. The $(X_2)^{2-}$ groups are reducible as well as the M^{4+} ion, accounting for the stoichiometry. The cell reaction is reversible for $NbSe_3$, but only partially reversible for TiS_3. Irreversibility in TiS_3 is suggested to be due to a change in coordination geometry of Ti^{4+} from trigonal prismatic to octahedral.

Recent reports have described the use of MX_3 (M = Ti, Nb, Ta; X = S, Se) compounds as cathodes in secondary nonaqueous lithium batteries (1-5). The reversibility of these cathodes, especially $NbSe_3$, led us to embark on a study of the chemistry of cell discharge in the hope that an understanding of the chemistry would lead to improved performance and suggest other potential secondary cathode materials.

The trichalcogenides of the groups IVB and VB transition metals have similar structures. The group IVB compounds are typified by $ZrSe_3$ (6) with which TiS_3 is isostructural (Fig. 1). The structure is monoclinic and may be thought of as consisting of chains of trigonal prismatic $[TiS_6]$ units sharing opposite faces. The sulfur atoms are not equidistant from each other, but two of the three are closer to each other and form a disulfide linkage. A more informative formula then is $TiS(S_2)$, a compound of Ti^{4+}. The sulfide sulfur of one chain is also loosely coordinated to titanium ions of two adjacent chains to give a bicapped trigonal prismatic coordination about titanium and making the compound pseudo two-dimensional rather than one-dimensional. The group IVB compounds have a d^0 configuration and are semiconductors (7).

* Electrochemical Society Active Member.

Key words: nonaqueous batteries, chalcogenides, secondary batteries, lithium batteries.

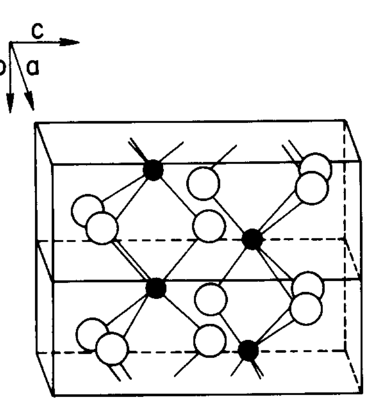
The group VB compounds $NbSe_3$ (8) (Fig. 2) and $TaSe_3$ (9) have structures similar to the group IVB compounds, but slightly different. The planes of connected chains are somewhat puckered, apparently due to some Se-Se bonding between chains as well as intrachain diselenide formation. The puckering is slightly different in the two compounds. The compounds are formally d^1 and are metallic (10). All of the MX_3 compounds grow in a fibrous morphology elongated in the b direction (the direction of the metal chains). It is very difficult indeed to obtain crystals of $NbSe_3$ more than a few microns in the a and c directions while over a centimeter in the b direction.

Experimental

The starting TiS_3 and $NbSe_3$ were prepared by reaction of the elements in sealed quartz tubes. Excess sulfur (S:Ti = 3.5:1) was used with titanium powder (325 mesh, 3*N* pure) at 500°C, and stoichiometric amounts of niobium powder (30μ, 3*N*5 pure) and selenium shot (5*N* pure) were reacted at 680°C (8). Crystals of TiS_3 were grown by I_2 vapor transport at 500°-550°C.

The thin needlelike crystals of TiS_3 tend to aggregate at one point much like a fan, while $NbSe_3$ forms long hairlike fibers which intertwine to form physically connected (electrically conductive) mats much like miniature steel wool pads, as illustrated in Fig. 3.

Simple cells were constructed with lithium foil anodes (15 mil × 0.5 cm × 1.5 cm), a 1.0*M* $LiClO_4$ in propylene carbonate (PC) electrolyte (~ 3 mil), and



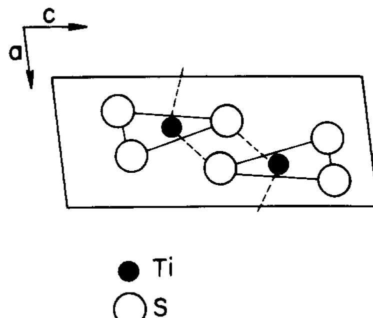


Fig. 1. The monoclinic structure of TiS_3 (6)

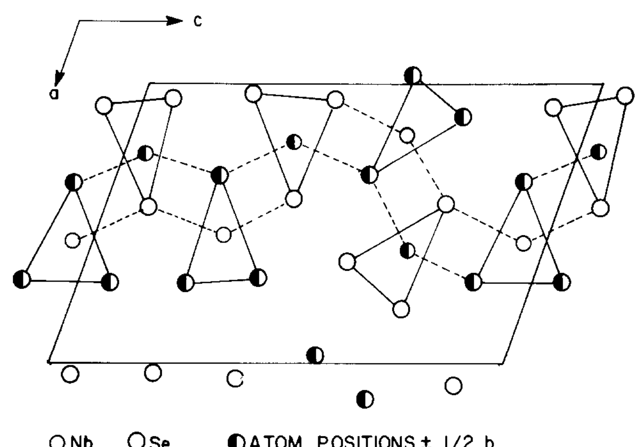

Fig. 2. The monoclinic structure of $NbSe_3$ (8)

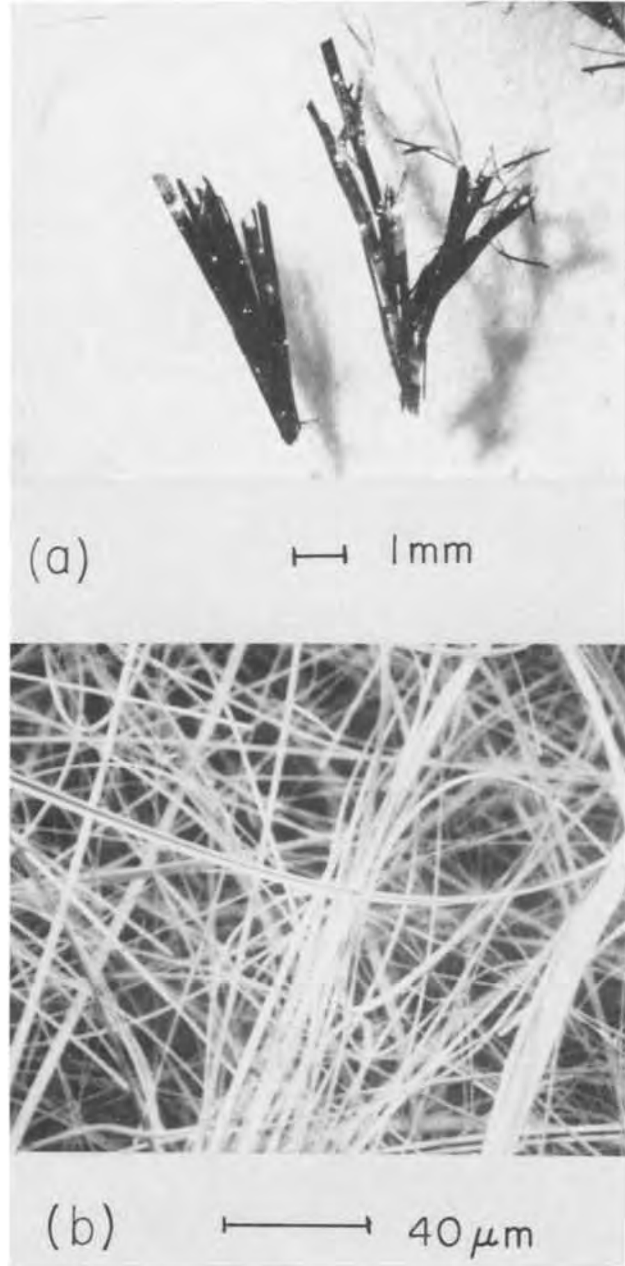

Fig. 3. (a) Fanlike aggregates of TiS_3 crystals formed by iodine transport. (b) Typical fibrous nature of $NbSe_3$.

cathodes prepared by crimping gold wire onto either a fan of TiS_3 crystals or a matte of $NbSe_3$. Cathode sizes varied from 0.05 to 10.0 mg for TiS_3 and 0.1 to 200 mg for $NbSe_3$. The anodes and cathodes were suspended via gold wires into the electrolyte so that they were approximately 0.5 cm apart. The cells were discharged under a constant load and the area under the voltage *vs.* time curve allowed determination of the number of coulombs. Then, knowing the weight of pure cathode material, the number of lithium atoms involved per MX_3 unit could be calculated. Representative initial discharge curves are shown in Fig. 4 (TiS_3) and Fig. 5 ($NbSe_3$). Some cells were set up with a reference and a working lithium electrode to determine the part played by anodic processes on the discharge behavior. In each case the potentials of the working and reference electrodes were the same.

Cells were recharged by applying a 3V battery across the cell. The total charge was found by measuring the voltage across a known resistor in the circuit and integrating the voltage-time curve.

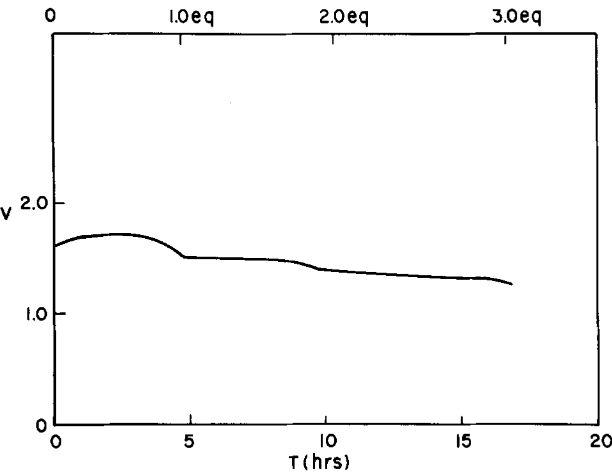

Fig. 4. Initial discharge curve for an aggregate of pure TiS_3 (0.63 mg) crystals in PC with 1M $LiClO_4$ and a load of 68 kohms ($i = 0.02$ mA at 1.5V).

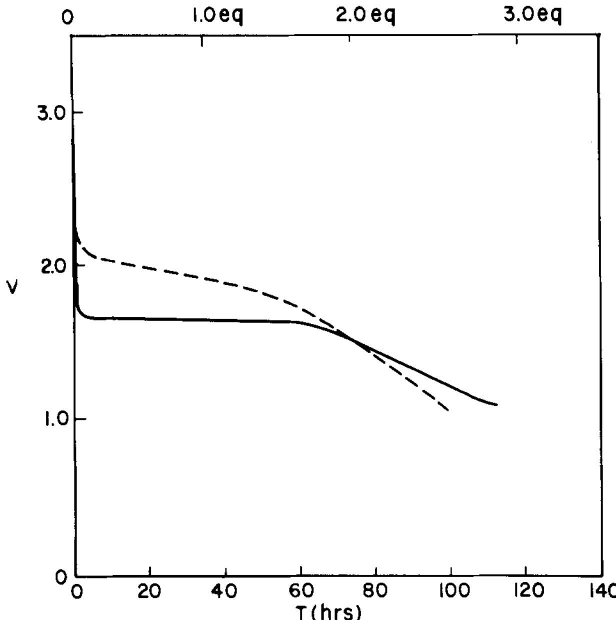

Fig. 5. Initial discharge curve for a fibrous matte of pure $NbSe_3$ (10.4 mg) in PC with 1M $LiClO_4$ and a load of 68 kohms, ——— ($i = 0.02$ mA at 1.5V). Second discharge, - - - -.

Reactions of TiS_3 and $NbSe_3$ were also run with sodium and lithium in liquid ammonia and with n-butyl lithium (n-BuLi) as a model for the cell reaction. All such reactions were run under anhydrous conditions in argon. Completion of reactions with stoichiometric amounts of n-BuLi was verified by observation of no color change when a drop of the solution was added to 1,10-phenanthroline. Excess n-BuLi could be determined by titration of the n-BuLi (after filtration) with butyl alcohol in xylene using 1,10-phenanthroline as indicator (11). All transfers of discharged products were carried out in an inert atmosphere box.

Powder x-ray photographs were taken on a Debye-Scherrer camera with CuKα radiation. Debye-Scherrer capillaries were loaded inside the dry box, sealed with wax, then with a flame outside the box.

Results and Discussion

Cells discharged with known amounts of pure TiS_3 (Fig. 4) and $NbSe_3$ (Fig. 5) indicate that approximately three lithiums per formula unit are used on discharge to approximately 1V. The discharge curve

for $NbSe_3$ shows a definite break at two equivalents while TiS_3 shows breaks at one and two equivalents.

Cells discharged with pure $NbSe_3$ cathodes maintained fibrous morphology and could be recharged to over 90% of capacity for several cycles [four is the maximum we have tried with pure $NbSe_3$ in this study, while thin film cathodes have been cycled several hundred times (12)]. Cells using pure TiS_3, however, readily exfoliate (splinter), and only about a third of the charge is regained on regeneration.

Several chemical schemes are possible to account for the observed reaction with three lithiums. First, a decomposition to the MX_2 compound followed by intercalation of lithium into the MX_2 compound as in Eq. [1]

$$MX_3 + 3Li \rightarrow LiMX_2 + Li_2X \qquad [1]$$

Decomposition to the MX_2 was originally proposed as the cell reaction (1).

Second, ternary compounds simliar to the known $BaTaS_3$ (13) (Fig. 6) could be formed. These compounds have the same kind of chain structures as the MX_3 compounds except that the Ta is octahedrally coordinated and the chains are isolated from adjacent chains by Ba ions. The Ta ions are formally 4+ in $BaTaS_3$. Lithium ions could occupy sites between chains as do the barium ions, and the third lithium could be thought of as reducing the metal ions to the 3+ state with the same structure. The switch from trigonal prismatic to octahedral coordination could be accomplished by a simple twist without any gross atomic rearrangement. Whittingham (14, 15) has suggested that such topochemical reactions with retention of the main structural features leads to reversibility in a number of systems including the MX_3's.

A third possibility suggested by the two-dimensional nature of the compounds is a simple two-dimensional insertion similar to that of graphite and the layered MX_2 compounds (16). Three lithiums could be accommodated by reduction of the dichalcogenide linkage (2Li) and reduction of the 4+ ion to the 3+ ion (1Li). The dichalcogenide linkages form the surface of the van der Waals gap between layers. Intercalation has been suggested by Holleck *et al.* (5) as the possible cell reaction.

The first of these possibilities, decomposition to MX_2 and intercalation of lithium, seems untenable in view of the maintenance of the fibrous morphology of the cathode on discharge. In addition, the formation of MX_2 would require severe atomic reorganization, and it is difficult to imagine such a process being reversible at room temperature.

We had hoped that examination of x-ray powder patterns of the discharged cathodes would distinguish between the various possible discharge products. However, the discharged TiS_3 gave a powder pattern with very large d spacings (top of Fig. 7) unlike any of the expected products, and the discharged $NbSe_3$ gave only a very weak pattern containing only a few broad lines. Poor quality x-ray powder patterns are often found in solids formed near ambient temperature even if the compound is crystalline. The large d spacings for the discharged TiS_3 suggested the possibility of solvent incorporation on discharge and, indeed, combustion analysis of the discharged TiS_3 and $NbSe_3$, after washing with PC and ether then vacuum drying, showed 17 and 12% C, respectively. This solvent incorporation does not appear to be detrimental to cycle behavior, but may change the cell voltage slightly, and could cause swelling problems in a real battery.

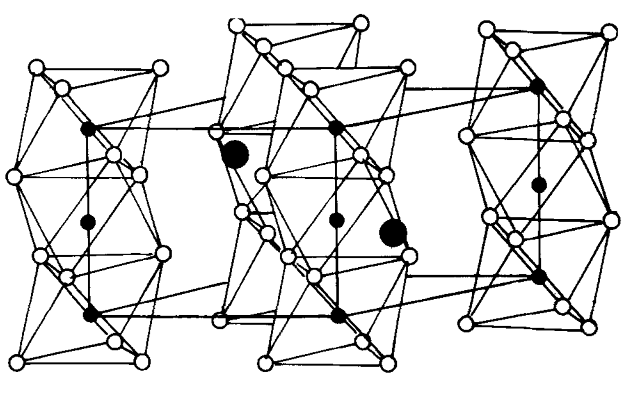

Fig. 6. Crystal structure of $BaTaS_3$ (13)

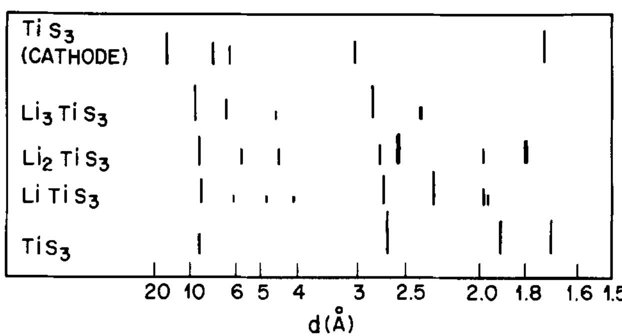

Fig. 7. Diagram of x-ray powder pattern of TiS_3 cathode discharged in PC (top), and products of TiS_3 treated with n-butyl lithium.

To avoid complications from solvent incorporation we investigated model reactions for cell discharge. The simplest model reaction is the treatment of the cathode compound with a solution of the alkali metal in liquid ammonia. Analysis of x-ray powder patterns (Fig. 8) of TiS_3 treated with sodium in liquid ammonia are consistent with a two-dimensional topochemical addition of sodium (and ammonia) into the TiS_3 structure. Addition of one sodium (two ammonia molecules are also incorporated as determined by weight gain) increases the c axis by ~ 4.3Å. The b axis remains unchanged [(020) at 1.70Å] and the strong (012) peak shifts appropriately from 2.68 to 2.74Å. No lines associated with the a axis were observed. Addition of a second sodium causes only a slight increase in c while the (020) peak becomes weak and broad. The third sodium gave a product with no powder pattern.

Treatment of $NbSe_3$ with sodium in liquid ammonia gave Na_2Se as the only product giving an x-ray powder pattern. With lithium in liquid ammonia Li_2Se was the only product observable in the x-ray powder pattern. When this $NbSe_3$ treated with lithium in liquid ammonia, which was hoped would correspond to the discharged $NbSe_3$, was placed in a cell it recharged only slightly (about 0.1 of expected); thus it is unlikely that these products correspond to those of cell discharge.

We suspected that the ammonia might be responsible for the decomposition of $NbSe_3$ with lithium. This could occur by catalytic formation of $LiNH_2$ which might displace Se in the compound as in Eq. [2] below,

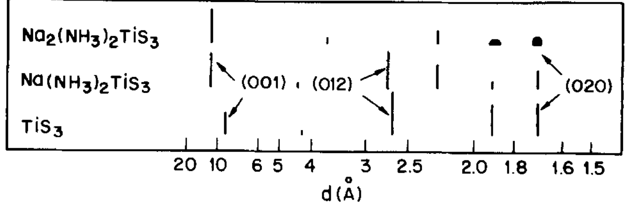

Fig. 8. Diagram of x-ray powder patterns of TiS_3 cathode discharged with sodium in liquid ammonia.

or by amminolyses of Nb-Se-Li linkages to form Li(H)Se which could then react with another lithium in solution to give Li_2Se as shown in Eq. [3]

$$2Li + 2NH_3 \xrightarrow{NbSe_3} 2LiNH_2 + H_2$$

$$\xrightarrow{NbSe_3} NbSe(NH_2)_2 + Li_2Se \quad [2]$$

$$Nb\text{-}Se\text{-}Li \xrightarrow{NH_3} Nb\text{-}NH_2 + Li(H)Se$$

$$\xrightarrow{Li(NH)_3} Li_2Se + \frac{1}{2} H_2 \quad [3]$$

In order to eliminate complications from ammonia we used reaction with n-butyl lithium in hexane as a model reaction for cell discharge. This reaction has been described in detail elsewhere (17, 18) and has been suggested as a model for cell discharge (19-21). Reaction of 3n-BuLi with $NbSe_3$ gave a product (Li_3NbSe_3) whose x-ray powder pattern (Debye-Scherrer photographs) showed no Li_2Se, but also showed very little else (Fig. 9). When this Li_3NbSe_3 (the product maintained fibrous morphology) was placed in a cell the potential was $\sim$ 1V *vs.* lithium, the same as the discharged $NbSe_3$. Furthermore, recharging to 3V required the charge expected for three lithium atoms per niobium, evidence that this Li_3NbSe_3 is analogous to the cell discharge product. Reaction with one and two equivalents of n-BuLi gave more discernible products. Powder patterns of the one and two lithium products (Fig. 9) are very similar to $NbSe_3$ itself and demonstrate that the cell reaction (at least for the first two lithiums) is a topochemical reaction. The x-ray powder pattern for $LiNbSe_3$ is very similar to $NbSe_3$, while in Li_2NbSe_3 a number of small peaks are missing, those that remain are broadened and the intensities of corresponding peaks have changed, as well as some small changes in the d spacings. The third lithium causes the diffraction pattern to be almost totally obliterated. Only three very weak, broad peaks are observed which are not obviously related to any peaks in $NbSe_3$. Chianelli and Dines (22) have obtained similar data for lithiated $NbSe_3$, but also report a distinct pattern for Li_3NbSe_3 very similar to $NbSe_3$, which they were able to index. This discrepancy may be due to a slight difference in reaction conditions. Addition of NH_3 to Li_3NbSe_3 did indeed cause decomposition with Li_2Se being observed in the x-ray powder pattern.

After recharging Li_3NbSe_3 the resulting "$NbSe_3$" also shows only a weak diffuse x-ray diffraction pattern, indicating a high degree of disorder, conceivably a different or a random arrangement of the $NbSe_3$ chains. In line with this observation, discharged cathodes do not track the original discharge curve on subsequent cycles, but higher, gradually decreasing voltages are observed (Fig. 5).

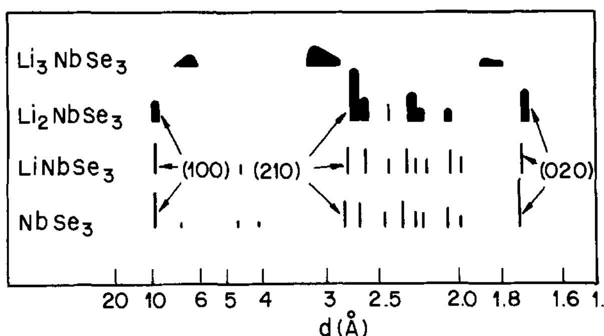

Fig. 9. Diagram of x-ray powder patterns of $NbSe_3$ treated with n-butyl lithium.

Lithiation of TiS_3 with n-BuLi gives rise to a phase of higher symmetry (possibly hexagonal) as indicated by the x-ray powder pattern (Fig. 7) and also observed by Chianelli (22). Lengthwise splitting of TiS_3 crystals occurs during reaction with n-BuLi. This change in crystal symmetry implies a more drastic change in the local coordination as well, compared to $NbSe_3$.

We have also measured d-c conductivities of the lithiated $NbSe_3$ and TiS_3 compounds by a four-probe method on pressed powders. The conductivity of $NbSe_3$ is progressively lowered from about 300 to 10^{-1} (ohm-cm)$^{-1}$ for Li_3NbSe_3, while TiS_3 and all the Li_xTiS_3 have conductivities near about 0.2 (ohm-cm)$^{-1}$ (7). Formation of a nonconducting discharge product cannot be the cause of irreversibility in TiS_3. The larger d spacings in the powder pattern of the discharged TiS_3 cathode are due to the inclusion of PC coordinated to the lithium ions.

Comparing and contrasting the lithiated compounds of TiS_3 and $NbSe_3$ provides a rationale for the differences in reversibility. For $NbSe_3$ the structure remains virtually unchanged on going to Li_2NbSe_3. Such maintenance of structure allows for easy reversibility of the cell reaction as suggested in other systems (14, 15). With TiS_3 a higher crystal symmetry is likely indicative of a greater structure change. The most likely change is the simple twist to octahedral coordination noted earlier for $BaTaSe_3$. Octahedral coordination is expected to be favored for [TiS_6] units as it is in TiS_2 (23). The trigonal prismatic coordination of TiS_3 is stabilized by the short S-S bonds and the coordination of sulfides from adjacent chains to give an eight coordinate Ti^{4+}. When the S-S bonds are broken and the interchain bonding disrupted the Ti^{4+} is free to assume its favored coordination. This change is irreversible. By contrast [$NbSe_6$] units prefer trigonal prismatic coordination in $NbSe_2$. Thus when $NbSe_3$ chains separate they need not change coordination geometry, but if they do, such a change could be reversible at room temperature. The weak x-ray powder pattern of Li_3NbSe_3 can be explained as a highly disordered aggregation of chains.

Conclusions

Both TiS_3 and $NbSe_3$ undergo topochemical reactions with lithium on discharge in nonaqueous cells to form compounds of the formula Li_3MX_3. This cell reaction is completely reversible for $NbSe_3$, but only partially reversible with TiS_3. The basic chain structure of both compounds is maintained on lithiation. Reversibility has been equated with maintenance of microstructure. We suggest that TiS_3 changes from trigonal prismatic to octahedral coordination on lithiation and that this change is irreversible. Perhaps the investigation of other structures capable of remaining basically the same following lithiation will lead to new secondary cathode materials.

Acknowledgments

We would like to thank Professor J. Rouxel for communication of the structure of $NbSe_3$ prior to publication, J. Broadhead, F. J. Di Salvo, and D. O. Feder for helpful discussions, and T. M. Putvinski for technical assistance.

Anodic Behavior of Lithium in Aqueous Electrolytes

II. Mechanical Passivation

E. L. Littauer* and K. C. Tsai*

Lockheed Palo Alto Research Laboratories, Lockheed Missiles and Space Company, Incorporated, Palo Alto, California 94304

ABSTRACT

The anodic passivation of lithium in flowing alkaline electrolytes was studied chronopotentiometrically. The experimental results reveal that the passivation follows the classical diffusion-limited process. An empirical relationship similar to the Sand equation, but including a term for the critical current, i_c, is observed

$$(i - i_c) = kt_p^{-1/2}$$

A theoretical model of the dissolving lithium anode has been formulated to explain the dependence of the time to passivation, t_p, on the experimental variables. This model involves the diffusion of the soluble species through a fixed porous solid layer on the electrode surface and through the electrolyte diffusion layer. The assumption made for the initial boundary condition requires the existence at OCV of a concentration gradient within the porous oxide layer. It has led to an analytical solution which can successfully represent the $i - t_p$ relationship for metals in highly corrosive media.

Lithium, when in a strongly alkaline aqueous electrolyte at open circuit or under anodic polarization, is always covered with a fairly thick film. It is believed that the film has a complex structure comprising a thin, coherent lithium oxide layer of unknown stoichiometry directly adjacent to the metal surface which is overlaid by a pored oxide/hydroxide layer. At the film-solution interface, gray anhydrous LiOH has been identified by x-ray, intermixed together with white $LiOH \cdot H_2O$. Under anodic dissolution, high flux rates are supported across the film with little polarization.

A previous paper (1) showed that in a Li-H_2O battery the anode-to-cathode contact pressure, electrolyte concentration, flow rate, and polarization level have to be controlled for the Li to dissolve with near to 100% faradaic efficiency. This paper indicates that if the Li is polarized beyond a critical C.D. it becomes passivated. A passivated anode in a multicell battery may require considerable time (*ca.* 1-5 min) to return to the active state. It is therefore important to understand the processes which lead to passivation in order to prevent its occurrence as power demands from the battery are changed.

It is believed that in the process of passivation, Li conforms to the classical theory (2) which postulates that pores and imperfections in an anodic film become blocked. This blocking effect occurs when a critical concentration of reacting species is exceeded within the film and/or at the metal-film interface or the film-solution interface. The passivation is then a reflection of the increase in overvoltage for cation transport from the metal surface into the bulk solution.

Electrochemically, Li has features similar to other reactive metals, *e.g.*, Zn and Cd, which form insulating films when under anodic polarization in alkaline solution. It also has certain unique characteristics. The protective oxide film has been found to be considerably

* Electrochemical Society Active Member.

Key words: mechanical passivation, lithium, diffusion, porous oxide layer, diffusion layer, Sand equation.

thicker (*ca.* 0.3 mm) than is usually observed on reactive metals, and the corrosion rate at OCV is far higher (*i.e.*, >10 kA/m^2 in 3M LiOH and ≈2.5 kA/m^2 in 4.5M LiOH).

Frequently studies of passivation are hampered by difficulties in achieving an identical electrode surface condition from one experiment to the next. However, in this system, the high corrosion rate of Li at OCV causes the electrode to return always to the same state without surface preparation (provided electrolyte composition and temperature remain constant) and excellent experimental reproducibility results.

This paper examines the processes leading to and controlling mechanical passivation at various electrolyte flow velocities and concentrations keeping anode-cathode contact pressure constant.

Experimental

The experimental arrangement described in the previous paper (1) was used. This comprised 1.14×10^{-3} m^2 electrode area cell with means to control anode to cathode contact pressure, electrolyte temperature, flow rate, and concentration. Experiments were performed to determine (*i*) the critical C.D.'s at three electrolyte concentrations and (*ii*) the influence of electrolyte flow velocity on the time to passivation in the same electrolytes.

The three concentrations were 3.1, 4.1, and 4.6M LiOH. For the critical current density experiments, the flow rates were controlled at 0.24 and 0.6 m/sec, and for the time to passivation studies, flow rates ranging from 0.12 to 0.72 m/sec were used.

Initially, a series of resistive polarization runs were made in the three electrolytes. The point at which the *E-i* curve changed slope to indicate the onset of the passivation region was taken to be the critical C.D. These C.D.'s are depicted by point b in Fig. 1. In this figure, line b-c represents the mechanical passivation region. Point c which corresponds to 1.95V polarization was arbitrarily selected as the cutoff level. A minimum of five C.D.'s were chosen between b and c for the passivation experiments. These experiments were performed chronopotentiometrically. The time to passivation, t_p, was measured from the *E-t* curves using a Tektronix No. 549 storage oscilloscope. In an analogous way, t_p values were obtained as a function of electrolyte flow rate at a C.D. intermediate between b and c for the three electrolytes of interest.

Experiments were performed in triplicate. The reproducibility of the *E-i* curves was within 2% and the reproducibility of t_p was within 5%. During each run, the temperature and anode-cathode contact pressure were maintained constant.

Results

The *E-i* plots of Fig. 1 indicate that for the electrolytes of interest, a critical C.D. i_c shown as point b has to be exceeded before passivation will occur. The values for i_c taken from the curves are approximately 0.25, 2, and 6 kA/m^2 in 4.6, 4.1, and 3.1M LiOH, respectively. It was found that in the most dilute electrolyte, the flow rate had to be reduced from 0.60 to 0.24 m/sec for passivation to appear within a reasonable C.D. range. The relationship between C.D. and time to anodic passivation for electrochemical systems which follow the classical diffusion limited process is

$$i = k't_p^{-1/2} \text{ (Sand equation)} \quad [1]$$

where k' is a constant. Plots of i *vs.* $t_p^{-1/2}$ are given in Fig. 2.

It is evident that the curves do not pass through the origin which would have been the case if Eq. [1] was implicitly obeyed. Extrapolation of the linear plots to $t_p^{-1/2} = 0$ gives intercepts of 0.20, 1.92, and 5.90 kA/m^2. It will be noted that these values are very close to those obtained for i_c in Fig. 1. Accordingly, for the Li-H_2O system an empirical equation may be written

$$(i - i_c) = k't_p^{-1/2} \quad [2]$$

Figure 3 shows that a linear relationship exists between mean electrolyte face velocity υ and $t_p^{-1/2}$. This would be expected since the experimental conditions maintained the anode-cathode contact pressure and film thickness constant for each value of υ.

Discussion

Passivation Time-Current Density Relationship

The classical Sand equation (3)

$$i = k't_p^{-1/2} \quad [1]$$

where $k' = \frac{1}{2} nFA(\pi D)^{1/2}\Delta C$, A is the active surface

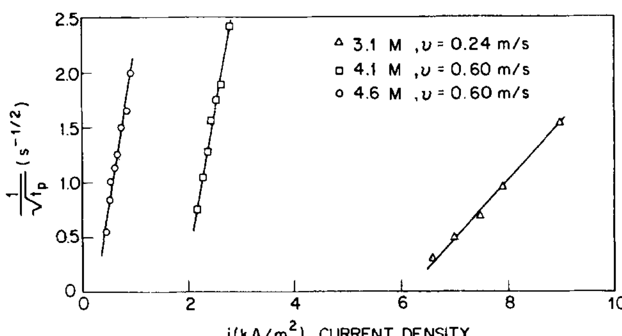

Fig. 2. Variation of time to passivation with current density at various LiOH concentrations.

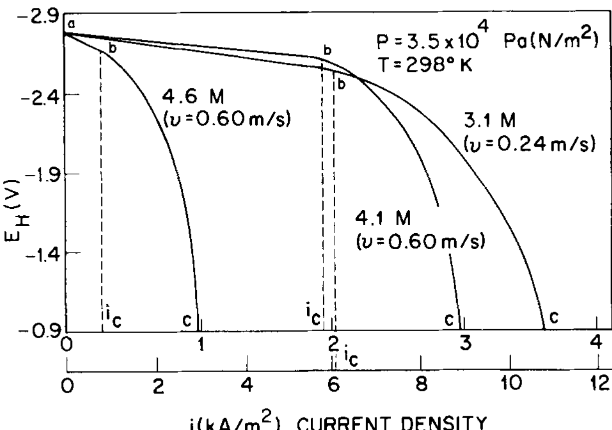

Fig. 1. Anodic polarization of lithium in LiOH showing the critical current density i_c.

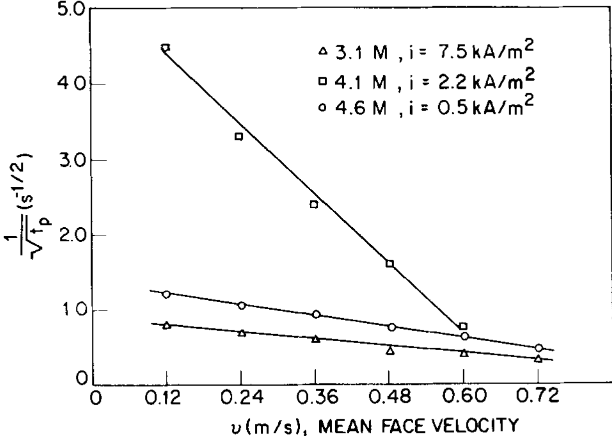

Fig. 3. Relationship between time to passivation and electrolyte flow velocity υ at various LiOH concentrations.

area and ΔC is the concentration difference between reactive species at the metal surface and the bulk solution, satisfactorily describes the response of metals which form sparingly soluble and thin protective films. Examples are Fe, Ni, Au, Cr, and Cr-Fe alloys (4). Here, the basic assumption is that the passivation C.D. i_p is equivalent to the limiting diffusion C.D. i_d at t_p. This assumption generally requires an initial boundary condition such as $C(x,o) = C^*$ or $C(x,o) = 0$, where $C(x,o)$ is the initial concentration of the corroding metal cations within the transport medium and C^* is the bulk concentration. However, for a metal which forms a protective film in a strongly corroding medium, such as Li or Zn in alkaline solution or Ni in acid solution (5), $C(x,o) \neq C^*$ and a concentration gradient will exist even at OCV. In this situation the Sand equation will not hold. To resolve this, it is necessary to include an additional term γ in Eq. [1] to account for the initial concentration gradient across the film. Obviously, the OCV corrosion rate will influence the value of γ.

An empirical equation

$$(i - \gamma) = k' t_p^{-1/2} \quad [3]$$

where γ is a constant, was first proposed to account for the passivation behavior of Zn in flowing (11) and tranquil (6-10) electrolytes. The previous investigators attributed the constant γ to either nondiffusional mass transport (predominantly convection) or to varying rates of film growth (11). These explanations do not offer an analytical solution to the existence of the critical current density i_c.

Lithium unlike Zn does not form complex ions in alkaline solution. It is much more reactive than Zn and forms considerably thicker films at the metal surface. An analysis of the controlling processes between the Li surface and the electrolyte may therefore be undertaken. Figure 4 represents a one-dimensional model for a filmed Li anode surface in a flowing electrolyte. In this model it is assumed that mass transport of Li^+ occurs exclusively via diffusion across a porous oxide layer of constant thickness (x_o) and through an adjacent diffusion layer of electrolyte of thickness δ. In a flowing electrolyte system operating under laminar flow, mass transport can be assumed to occur exclusively across these two layers. The transport of Li^+ away from the diffusion layer is controlled by convection (12).

The diffusion equation for the oxide layer can be described as

$$D_1 \frac{\partial^2 C(x,t)}{\partial x^2} = \frac{\partial C(x,t)}{\partial t} \quad [4]$$

where D_1 is the diffusion coefficient of Li^+ in the porous oxide medium and $C(x,t)$ the concentration of Li^+ within the medium. It is subject to the following boundary conditions

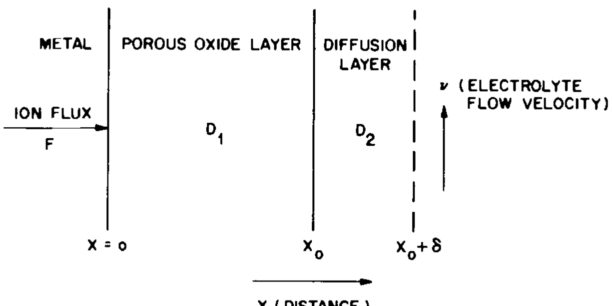

Fig. 4. One-dimensional model of the electrode/porous oxide layer/diffusion layer (electrolyte) system D_1 = diffusion coefficient of Li^+.

$$C(o,o) = C^*_1, \text{ (the initial concentration of } Li^+ \text{ at the metal surface at OCV)} \quad [5]$$

$$C(x,o) = C^*_1 e^{-\rho_1 x}, \text{ (the initial concentration gradient at OCV)} \quad [6]$$

where ρ_1 is a constant

$$D_1 \left(\frac{\partial C(x,t)}{\partial x} \right)_{x=0} = \frac{-i(t)}{n\mathbf{F}A} \text{ (the ion flux at the metal surface)} \quad [7]$$

Using the Laplace transform technique and considering galvanostatic polarization, *i.e.*, $i(t) = i$ (constant), Eq. [4] can be solved for $C(x,t)$.[1]

$$C(x,t) = C^*_1[\exp(-\rho_1 x + \rho_1^2 D_1 t) - \tfrac{1}{2}\exp(-\rho_1 x + \rho_1^2 D_1 t) \operatorname{erfc}(x/2\sqrt{D_1 t} - \rho_1\sqrt{D_1 t}) + \tfrac{1}{2}\exp(\rho_1 x + \rho_1^2 D_1 t)\operatorname{erfc}(x/2\sqrt{D_1 t} + \rho_1 \sqrt{D_1 t})] - \frac{i}{n\mathbf{F}AD_1}[x \operatorname{erfc}(x/2\sqrt{D_1 t}) - 2\sqrt{D_1 t/\pi}\exp(-x^2/4D_1 t)] \quad [8]$$

Equation [8] represents the concentration profile of Li^+ within the porous oxide medium and satisfies all the boundary conditions given under [5], [6], and [7].

It can be shown that, when $t = t_p$, the active Li surface is passivated due to the precipitation of LiOH on the electrode; thus the surface concentration of LiOH reaches its saturation. Therefore, at $t = t_p$

$$C(o,t_p) = C_s \quad [9]$$

Equation [8] can then be written in terms of i

$$i = \frac{n\mathbf{F}A(\pi D_1)^{1/2}}{2}(C_s)t_p^{-1/2} - \frac{n\mathbf{F}A(\pi D_1)^{1/2}}{2}C^*_1 \exp(\rho_1^2 D_1 t_p)\{1 - \tfrac{1}{2}[\operatorname{erf}\{\rho_1(D_1 t_p)^{1/2}\} - \operatorname{erf}\{-\rho_1(D_1 t_p)^{1/2}\}]\}t_p^{-1/2} \quad [10]$$

For small t_p, the error function and exponential function can be approximated by a series expansion

$$\operatorname{erf}(\pm x) = \pm\frac{2}{\sqrt{\pi}}\left(x - \frac{x^3}{3} + \frac{x^5}{5.2!} - \frac{x^7}{7.3!} + \dots\right)$$

and

$$e^y = 1 + y + \frac{y^2}{2!} + \frac{y^3}{3!} + \dots$$

Since in actual practice

$$x = \rho_1(D_1 t_p)^{1/2} << 1$$

and

$$y = x^2 = \rho^2 D_1 t_p <<< 1$$

then

$$\operatorname{erf}(\pm x) \simeq \pm\frac{2}{\sqrt{\pi}}x$$

and

$$e^y \simeq 1$$

Therefore, [10] can be further simplified as follows

$$i - (n\mathbf{F}A\, D_1\rho_1)C^*_1 = \left\{\frac{n\mathbf{F}A(\pi_1 D_1)^{1/2}}{2}(C_s - C^*_1)\right\} t_p^{-1/2} \quad [11]$$

Let

$$i_c = (n\mathbf{F}A\, D_1\rho_1)C^*_1 \quad [12]$$

and let

$$k' = \frac{n\mathbf{F}A(\pi D_1)^{1/2}}{2}(C_s - C^*_1) \quad [13]$$

Then [11] may be expressed

[1] A detailed treatment of the following mathematical development is given in the Appendix.

$$i - i_c = k' t_p^{-1/2} \quad [14]$$

Equation [14] derived here theoretically, is identical to [2] which empirically satisfied the experimental results obtained in the investigation. It is obvious from [12] that the magnitude of the critical C.D. is proportional to the product of surface concentration (at OCV) and the concentration gradient, ρ_1, within the oxide film which in turn is determined by the corrosion rate of Li. Unlike other metals such as Fe, Au, Cr etc., Li corrodes rapidly in aqueous media. Therefore, a distinct i_c is observed at various concentrations of LiOH. The reason that the term i_c is not observed with Fe, Au, Cr, etc., is that their corrosion rates at OCV (more specifically, their exchange current densities) are small in comparison to the applied current density. Then within experimental error, Eq. [1] rather than [14] is observed. In the case of Zn, the corrosion rate at OCV is generally enhanced by complex formation. Thus, as with Li, there is a significant critical current density. The slopes of the $i - t_p^{-1/2}$ curves shown in Fig. 3 may be predicted from [13]; at higher bulk electrolyte concentration, the surface concentration would be anticipated to be higher, and the difference between C_s and C^*_1 would be smaller. Therefore, a smaller k' value would result.

The concentration at the active metal surface, C^*_1, is related to the bulk electrolyte concentration, C^*, in the following manner. At OCV ($t = o$), the concentration gradient within the diffusion layer, $x_o \leq x \leq x_o + \delta$, can be described as

$$C(x, o) = C^*_2 \, e^{-\rho_2(x - x_o)} \quad [15]$$

where

$$C^*_2 = C(x_o, o) = C^*_1 e^{-\rho_1 x_o} \quad [16]$$

Equation [16] describes the boundary condition for the concentration continuity across the oxide/electrolyte interface when $x \geq x_o + \delta$ and $C(x_o + \delta, o) = C^*$. Then, from [16]

$$C^*_1 = C^* \, e^{(\rho_1 x_o + \rho_2 \delta)} \quad [17]$$

For the simplest case in which $\rho_1 = \rho_2 = \rho$, [17] becomes

$$C^*_1 = C^* \, e^{\rho(x_o + \delta)} \quad [18]$$

with

$$0 \leq \rho \leq \frac{\ln(C_s/C^*)}{(x_o + \delta)}$$

Equation [18] indicates the relationship between surface concentration and bulk concentration under any experimental condition where the film thickness and diffusion layer thickness can be determined. This equation also demonstrates that the initial surface concentration can be ascertained without knowledge of the details of the concentration profile within the diffusion layer. A comprehensive analytical treatment of the mass transport of Li^+ through a finite region of oxide film and diffusion layer is in preparation.

Electrolyte Flow Velocity-Passivation Time Relationship

The anodic polarization is predominantly an IR drop across the porous film and it is considered reasonable to suppose that the film resistance and the film thickness are linearly related. Inspection of the E-i curves as a function of flow rate in the active polarization region (1), and subsequent experiments to examine this aspect in more detail, show that the resistance and hence the film thickness are linearly related to the electrolyte flow velocity. If x_o is the film thickness and υ the flow velocity then

$$x_o = x_o^o - \xi \upsilon \quad [19]$$

where x_o^o is the film thickness at $\upsilon = o$ and ξ is a constant. In this system, $x_o >> \delta$ (*i.e.*, the film thickness is *ca.* 0.3 mm and the diffusion layer thickness is assumed to be *ca* 0.01 mm) then since $\rho(x_o + \delta) << 1$, [18] becomes

$$C^*_1 = C^* \, [1 + \rho x_o^o - \rho \xi \upsilon] \quad [20]$$

In practice, and as is shown in a subsequent paper (13), the parasitic reaction is fairly independent of υ within the range of conditions of interest in this study. Hence

$$C_s - C^*_1 \simeq \text{constant}$$

Then [14] can be written as

$$\chi - \psi \upsilon = k' t_p^{-1/2} \quad [21]$$

with

$$\chi = i + (n\mathbf{F}A \, D_1 \rho C^*) \, [1 + \rho x_o^o]$$

and

$$\psi = n\mathbf{F}A \, D_1 \rho^2 \xi C^*$$

Equation [21] gives the relationship between the electrolyte face velocity and the passivation time. Figure 3 shows that the experimental results confirm this relationship. It is apparent that increasing face velocity shortens the distance for the mass transport of Li^+ from the anode surface, and thus makes it more difficult for the electrode surface to become passivated. The practice of increasing the electrolyte face velocity to prevent Li passivation during cell operation can therefore be understood.

Conclusions

When Li is anodically polarized to a level just prior to the critical current density, the film existing on its surface is in a state of dynamic equilibrium with the electrolyte. The thickness of the film is fixed by the electrolyte flow rate, anode to cathode contact pressure, and molarity. At the critical polarization level, the direct parasitic reaction is essentially zero while the electrochemical reaction rate is near to its maximum. (At open circuit the converse holds.)

As the C.D. exceeds the critical level, the dynamic equilibrium is disturbed as precipitation of reactive species occurs within the film and the active sites diminish and eventually disappear entirely. It is not known where the precipitation occurs within the film. It could be adjacent to the oxide film at the base of the pores, within the matrix comprising the overlaying film(s), or both. The diminution of active sites is reflected as a sudden increase in polarization and within a short period the cell potential decreases to zero at constant load or, under galvanostatic conditions, polarity reversal occurs.

The onset of passivation can be controlled by either altering the rate of mass transfer of the cations into the bulk electrolyte via adjustment of the electrolyte concentration or temperature, or by changing the thickness of the mass transfer medium, i.e., changing the film thickness.

An analytical solution for the passivation phenomenon has been predicted on the mass transport of Li^+ through the anodic oxide film and through the diffusion layer. The experimental data support the model which is based on the assumption that at OCV there exists a concentration gradient of Li^+ across the film. It is this premise which differs from the classical basis of the Sand equation. This leads to Eq. [14] which relates C.D. and passivation time and includes a term for the critical current i_c. It is believed that [14] will apply to the passivation of other metals which have a high OCV corrosion rate, *e.g.*, Zn. The analytical solution permits calculation of i_c and of the slope of the current density-time to passivation curve at any concentration.

Further, the fact that the anode-cathode contact pressure is held constant has led to the development of an analytical treatment to describe the effect of electrolyte flow velocity on time to passivation. This information, coupled with the ability to calculate i_c, may be used to guide the selection of control parameters for the Li-H_2O battery.

APPENDIX

$$D_1 \frac{\partial^2 C(x,t)}{\partial x^2} = \frac{\partial C(x,t)}{\partial t} \qquad [A-1]$$

is to be solved for $C(x,t)$, subject to the following boundary conditions (B.C.'s)

$$C(o,o) = C^*_1 \qquad [A-2]$$

$$C(x,o) = C^*_1 e^{-\rho_1 x} \qquad [A-3]$$

and

$$D_1 \left(\frac{\partial C(x,t)}{\partial x} \right)_{x=o} = \frac{-i(t)}{n\mathbf{F}A} \qquad [A-4]$$

First, taking the Laplace transform (L.P.T.) of [1] with respect to t, yields

$$D_1 \frac{\partial^2 \overline{C}(x,s)}{\partial x^2} = s\overline{C}(x,s) - C(x,o) \qquad [A-5]$$

where

$$\overline{C}(x,s) = L_t[C(x,t)] = \int_o^\infty e^{-st} C(x,t)\,dt \qquad [A-6]$$

Rearranging [5] and using the B.C. given by [3] yields

$$\frac{\partial^2 \overline{C}(x,s)}{\partial x^2} - a^2 \overline{C}(x,s) = -b\, e^{-\rho_1 x} \qquad [A-7]$$

in which $a = \sqrt{s/D_1}$ and $b = C^*_1/D_1$. For simplicity, the variable s is temporarily dropped and [7] reads

$$\frac{\partial^2 \overline{C}(x)}{\partial x^2} - a^2 \overline{C}(x) = -b\, e^{-\rho_1 x} \qquad [A-8]$$

Taking the L.P.T. of [8] with respect to x, gives

$$P^2\overline{C}(p) - pA - B - a^2\overline{C}(p) = \frac{-b}{p + \rho_1} \qquad [A-9]$$

where A and B are arbitrary constants with respect to P and

$$\overline{C}(p) = L_x[\overline{C}(x,s)] = \int_o^\infty e^{-px}\overline{C}(x,s)\,dx \qquad [A-10]$$

Rearranging [9] and using partial fractions yields

$$\overline{C}(p) = \frac{b/(a^2 - \rho_1^2)}{p + \rho_1} + \frac{A'}{p + a} - \frac{B'}{p - a} \qquad [A-11]$$

where A' and B' are constants with respect to p.

Taking the inverse L.P.T. of [11] gives an expression for $\overline{C}(x)$

$$\overline{C}(x,s) = \frac{b}{a^2 - \rho_1^2} e^{-\rho_1 x} + A'(s)\, e^{-ax} + B'(s)\, e^{ax} \qquad [A-12]$$

Since the boundary condition requires that $\overline{C}(x,s)$ remains bounded as $x \to \infty$, $B'(s) = 0$, and [12] becomes

$$\overline{C}(x,s) = \frac{b}{a^2 - \rho_1^2} e^{-\rho_1 x} + A'(s)\, e^{-ax} \qquad [A-13]$$

$A'(s)$ can be evaluated by differentiating [A-13] with respect to x, setting $x = o$, and substituting the result into the transform with respect to t of boundary condition [A-4]. When this is done and the values of a and b are inserted, [A-13] becomes

$$\overline{C}(x,s) = \frac{C^*_1}{s - D_1\rho_1^2} e^{-\rho_1 x} - \left[\frac{\rho_1 D_1^{1/2} C^*_1}{s^{1/2}(s - D_1\rho_1^2)} - \frac{\overline{i}(s)}{n\mathbf{F}AD_1^{1/2} \cdot s^{1/2}} \right] \cdot e^{-\sqrt{s/D_1}\cdot x} \qquad [A-14]$$

Under galvanostatic polarization, $i(t) = i$ (a constant), thus $\overline{i}(s) = i/s$ and [A-14] becomes

$$\overline{C}(x,s) = \frac{C^*_1}{s - D_1\rho_1^2} e^{-\rho_1 x} - \left[\frac{\rho_1 D_1^{1/2} C^*_1}{s^{1/2}(s - D_1\rho_1^2)} - \frac{i}{n\mathbf{F}AD_1^{1/2} s^{3/2}} \right] e^{-\sqrt{s/D_1}\cdot x} \qquad [A-15]$$

Finally, the concentration profile $C(x,t)$ can be obtained by taking the inverse L.P.T. of [A-15]. The inverse L.P.T.'s of the first term and of the second term in the bracket of the right hand side of [A-15] can be obtained readily from a table.[2] The inverse L.P.T. of the first term in the bracket of the right hand side of [A-15] was obtained as follows

Let

$$J(t) = L_s^{-1}\left(\frac{e^{-ns^{1/2}}}{s^{1/2}(s - m^2)} \right) \qquad [A-16]$$

with

$$m = \rho_1 D_1^{1/2} \text{ and } n = xD_1^{-1/2}$$

Since

$$f(t) = L_s^{-1}\left(\frac{e^{-ns^{1/2}}}{s^{1/2}} \right) = \frac{1}{\sqrt{\pi t}} e^{-n^2/4t}$$

$$h(t) = L_s^{-1}\left(\frac{1}{s - m^2} \right) = e^{m^2 t}$$

we have by the Law of Convolution

$$J(t) = \frac{e^{m^2 t}}{\sqrt{\pi}} \int_o^t \exp\,[-m^2\tau - n^2/4\tau] \frac{d\tau}{\sqrt{\tau}}$$

$$= \frac{1}{2m} \exp\,(m^2 t - mn)\, \text{erfc}\,(n/2\sqrt{t} - m\sqrt{t}) - \frac{1}{2m} \exp\,(m^2 t + mn)\, \text{erfc}\,(n/2\sqrt{t} + m\sqrt{t}) \qquad [A-17]$$

Therefore

$$c(x,t) = C^*_1 [\exp\,(-\rho_1 x + \rho_1^2 D_1 t) - \tfrac{1}{2} \exp\,(-\rho_1 x + \rho_1^2 D_1 t)\, \text{erfc}\,(x/2\sqrt{D_1 t} - \rho_1\sqrt{D_1 t}) + \tfrac{1}{2} \exp\,(\rho_1 x + \rho_1^2 D_1 t)\, \text{erfc}\,(x/2\sqrt{D_1 t} + \rho_1\sqrt{D_1 t})] - \frac{i}{n\mathbf{F}AD_1} \left[x\, \text{erfc}\,(x/2\sqrt{D_1 t}) - 2\sqrt{D_1 t/\pi} \exp\left(-\frac{x^2}{4D_1 t} \right) \right] \qquad [A-18]$$

Pore Volume and Density of Unformed Pastes of Lead-Acid Battery Plates

C. W. Fleischmann* and W. J. Schlotter

C&D Batteries, an Eltra Corporation, Plymouth Meeting, Pennsylvania 19462

ABSTRACT

The specific pore volume, v, and solids' density, d, were determined for the pastes of unformed lead-acid battery plates by a simple laboratory technique. v was found to vary linearly with the apparent density of the dry paste, D, according to $v = 0.356 - 0.0569D$ for pastes cured to develop $4PbO \cdot PbSO_4$ and $v = 0.271 - 0.0415D$ for pastes otherwise cured. d was determined from the relationship $d^{-1} = D^{-1} - v$. d decreased continually with decreasing D for all plates except those cured to develop $4PbO \cdot PbSO_4$. For the latter plates d went through a maximum as D decreased. This maximum is explained in terms of the differing crystalline perfections of the $4PbO \cdot PbSO_4$ crystals in the plates.

The method of preparing lead-acid battery plates from pastes of acidified lead oxides is well known (1, 2) and good practical instructions for making the pastes are available (3). The commercial oxides which are employed to make such pastes may contain, in addition to PbO, various amounts of Pb or Pb_3O_4 (4). In brief, to prepare an unformed battery plate, the paste is pressed into a lead alloy grid, and the plate is then allowed to stand or "cure" to oxidize most of the free lead and to develop various basic sulfates. The chemistry of basic sulfates has received considerable attention. The thermodynamics of these compounds were discussed by Barnes and Mathieson (5), and the phase changes and the chemistry of the curing processes were reviewed by Ritchie and co-workers (2), and have been discussed and reviewed by others (1, 6, 7). Specific curing techniques and practical instructions are available (1, 2, 6) and it has been generally summarized (1, 2, 6, 7) that plates cured by drying at ambient conditions or at slightly elevated temperatures and humidities develop $PbO \cdot PbSO_4$ and $3PbO \cdot PbSO_4 \cdot H_2O$ as the principal basic sulfates while those cured at higher temperatures (above 70°C) and humidities principally develop $4PbO \cdot PbSO_4$. After curing, the plates are electrochemically "formed" to produce positive plates, composed of PbO_2, or negative plates, composed of Pb (1). Because the porosity of the plates ultimately affects battery performance (1, 8), it is an important parameter of battery production.

Experimental

Pastes were made using three different commercial oxides: a leady oxide (26% free Pb) made by a ball-milling process; a leady oxide (19% free Pb) made by a Barton process; and a nonleady oxide, made by a Barton process followed by a mechanical furnace. The latter contained 9.5% Pb_3O_4. The procedure for preparing the paste mix was to blend together 9.07 kg of commercial oxide with 1-1.3 liters of water and then to add, slowly, 460-960 ml of 7.02M H_2SO_4 The wet paste density decreased, as expected (2, 3), with the total fluids, principally with the amount of acid. Since it is well known that variations in the method of grid pasting affect the relationship between the density of the dry paste obtained from a given wet density (3), all the pasting was done by hand and by the same operator. The plates ranged in thickness since four different grid thicknesses were employed, 0.18, 0.41, 0.68, and 0.79 cm.

After pasting, some of the plates of the different oxides and grid thicknesses were selectively cured in order to develop or not to develop $4PbO \cdot PbSO_4$. The predominance of $4PbO \cdot PbSO_4$ in certain pastes was confirmed by x-ray analysis. The pastes of the other plates contained $3PbO \cdot PbSO_4 \cdot H_2O$, $PbO \cdot PbSO_4$, but no $4PbO \cdot PbSO_4$ as the principal sulfated species.

For each dry, cured plate, the dry paste density, D, (gram/cubic centimeter) and the specific pore volume, v, (cubic centimeter/gram) of the paste were determined. The fractional porosity, a frequently used parameter, is the product of D and v.

The specific pore volume was determined from the mass of water that the plate absorbed under low vacuum. The pore volumes so obtained were found to agree within 2% with those using an hydraulic oil as the absorbed medium and within 15% with pore volumes obtained by mercury intrusion. The range of pore diameters for samples tested by mercury intrusion was 2.5×10^{-5}-5×10^{-4} cm. Mercury intrusion measurements and the measurements of solids' density by gas pycnometry were services purchased from Micromeritics Instrument Corporation, Norcross, Georgia.

The volume of the paste on a plate was determined from the total volume of the plate minus the grid volume. The volume of each plate was obtained, using Archimedes principle, from the difference in mass of the water-impregnated plates when weighed in air and in water. The volume of each grid was obtained from the density of the alloy and an estimate of the mass. This estimate was obtained from the measured mass of cast twins which were subsequently separated. The uncertainty in the single grid mass due to this

* Electrochemical Society Active Member.
Key words: battery plates, electrode porosity, basic lead sulfates, electrode density.

estimate led to an uncertainty of less than 1% in the final calculated value of the dry paste density.

The wet paste density, W, or "wet cube" of the paste, in gram/cubic centimeter, was taken to be the mass of paste which could be pressed flush into a cup of known volume (3).

Optical examinations were by metallographic techniques similar to those described by Simon (7, 9). Crystal volume estimates were from photographs of the paste structure at magnifications at 600X.

Linear fits to the data points were obtained using the program routines in the Texas Instruments Calculator, Model SR-51A.

Results and Discussion

Relationships between wet paste density, dry paste density, void volume, and solids' density were derived from the experimental data.

Wet paste density vs. dry paste density.—The density of the dry paste, D, varied with the density of the wet paste W. The following relationship was observed

$$D = 1.23W - b \quad [1]$$

where b was between 0.34 and 1.07. Low magnitudes of the intercept, b, generally correspond to the data for the thinner plates and to the data for the pastes which did not contain $4PbO \cdot PbSO_4$.

Specific void volume vs. dry paste density.—The specific void volume, v, measured for each paste is plotted against the value of the dry paste density in Fig. 1. The data fell into two groups: those for pastes in which $4PbO \cdot PbSO_4$ was developed, and those for the other pastes. Each set of data define a different linear relationship between v and D. The pastes in which $4PbO \cdot PbSO_4$ was developed had greater specific void volumes than the other pastes at the same dry paste density. The data points are not identified according to oxide or plate thickness because correlations to these parameters were not observed. The data for the pastes containing $4PbO \cdot PbSO_4$ were fitted by Eq. [2] (with a correlation constant of 0.995) while the data for the other pastes were fitted by Eq. [3] (with a correlation constant of 0.959)

$$v = 0.356 - 0.0569D \quad [2]$$

$$v = 0.271 - 0.0415D \quad [3]$$

The solids' density vs. the dry paste density.—The relationship between v and D in terms of the density of the solids in the paste, d, is given by Eq. [4]. This equation simply states that for one gram of paste, the total paste volume, D^{-1}, must be the sum of the void volume, v, and the volume d^{-1}, occupied by the solids

$$D^{-1} = d^{-1} + v \quad [4]$$

Expressing Eq. [2] and [3] by the general form of Eq. [5], in which g and p are the slope and intercept constants, respectively

$$v = p - gD \quad [5]$$

and solving in terms of d from Eq. [4], Eq. [6] is obtained

$$d = D(gD^2 - pD + 1)^{-1} \quad [6]$$

This function is plotted in Fig. 2 for each of the two sets of data given in Fig. 1. The function goes through a maximum value of d when the value of D is equal to $g^{-1/2}$. For the data for the pastes in which $4PbO \cdot PbSO_4$ was developed, the maximum occurs at $D = 4.19$ g/cm^3 as shown in Fig. 2. The data for the other pastes do not exhibit a maximum in Fig. 2, because it would be calculated to occur beyond the experimental range at $D = 4.93$ g/cm^3. The solids' density of some pastes were independently measured by gas pycnometry. Samples containing $4PbO \cdot PbSO_4$ were specifically chosen to range about the maximum. The values obtained by gas pycnometry were all in agreement within $\pm 6\%$ of those obtained by the method described above.

The density of each and every element or compound that is present in the lead oxides is greater than each and every element or compound that is expected to occur in the sulfated pastes, *e.g.*, see the list of densities given by Burbank (10). Because of that difference in the densities, it would be expected that d would decrease with increased sulfation. Increased sulfation corresponds to decreased values of the wet (W) and corresponding dry (D) paste densities because, as

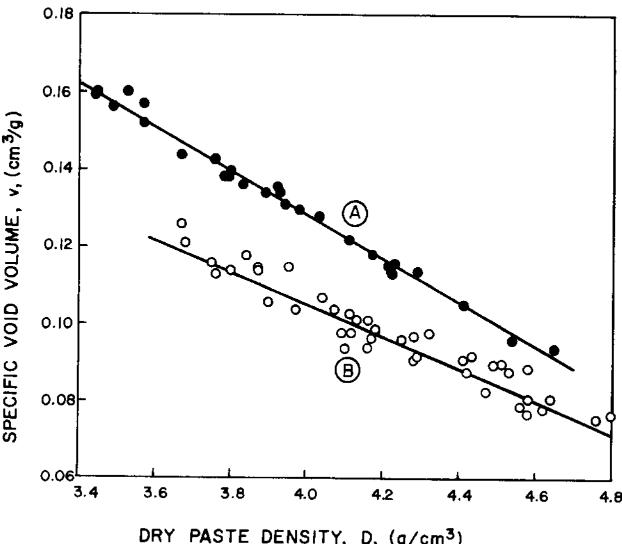

Fig. 1. Specific void volume of cured pastes plotted against the dry paste density. Curve A for plates which were treated to develop $4PbO \cdot PbSO_4$; curve B for plates in which $4PbO \cdot PbSO_4$ was not developed.

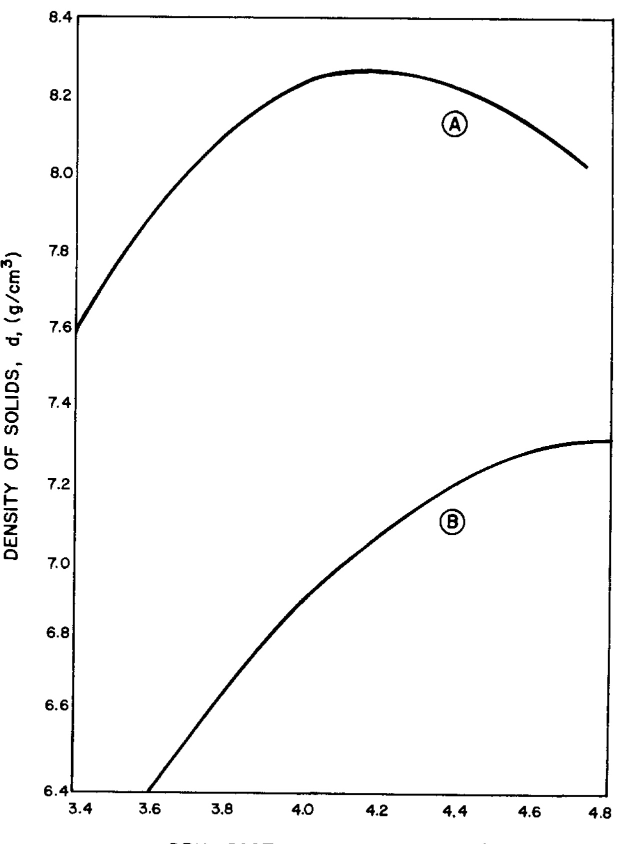

Fig. 2. Density of the solids in the dry paste plotted against the dry paste density. Curve A for plates cured to develop $4PbO \cdot PbSO_4$; curve B for plates in which $4PbO \cdot PbSO_4$ was not developed.

pointed out above, these parameters are experimentally adjusted principally by the acid addition. Therefore a general decrease in d with a decrease in D would also be expected. In this study, sufficient acid was added to sulfate 8-17 mole per cent of the PbO. Such sulfations may be calculated to produce solids' densities for the pastes containing $4PbO \cdot PbSO_4$ within the range 8.33-8.88 g/cm^3. Similarly the solids' densities of the other pastes would be expected to range within 7.90-8.98 g/cm^3. Specific calculated densities were not determined for each paste because quantitative analyses were not obtained for the constituents. The density values generated according to Eq. [6] (see Fig. 2) generally fell below the predicted ranges. Such lower values may be expected if the crystals of the starting materials and products are imperfect, *i.e.*, they contain occluded voids whose volumes are not included in v. However, from the known composition of the starting oxides and the solids' density values of these oxides as determined by gas pycnometry, it was estimated that the density of the starting oxides was high, about 95% of the theoretical values. Therefore, it is assumed that the deviations of the crystalline densities of the products from their theoretical values caused the observed lower solids' densities. As an aid to interpret the particularly unexpected behavior of the pastes containing $4PbO \cdot PbSO_4$, these pastes were subjected to optical examinations.

Optical examinations.—From the optical examinations, it was found that the largest crystals of $4PbO \cdot PbSO_4$ were developed in those pastes in which the sulfate concentration was low (high values of D). On the other hand, a larger number of smaller crystals developed when the sulfate concentration in the pastes was high (low values of D). Figure 3 illustrates the relative volumes of the crystals of $4PbO \cdot PbSO_4$ developed in pastes of three different densities.

Presumably, the larger crystals of $4PbO \cdot PbSO_4$ which formed at the lowest sulfate concentrations occluded significantly more voids than the smaller crystals which formed at the highest sulfate concentrations. This difference in crystalline perfection is believed to be responsible for the maximum observed in the relationship between d and D for plates containing $4PbO \cdot PbSO_4$.

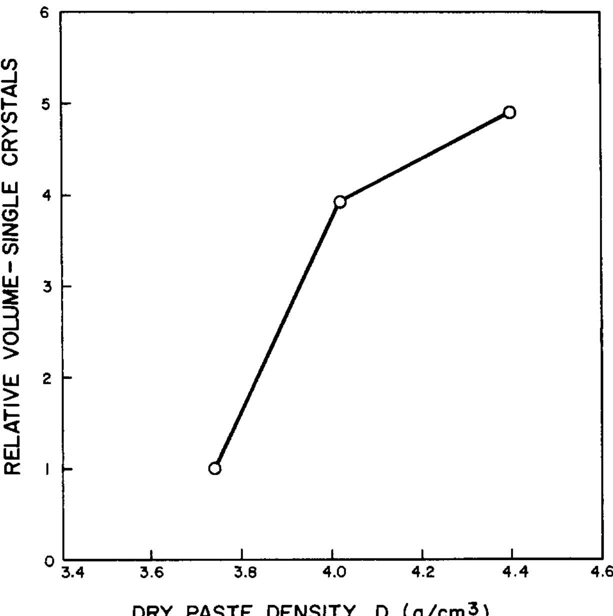

Fig. 3. Relative volumes of $4PbO \cdot PbSO_4$ crystals in cured pastes plotted against the dry paste density.

Conclusions

A simple laboratory method has been used to determine the specific void volumes and the dry paste densities of battery pastes, and to permit calculations of the densities of the solids within the paste. The void volumes were greater for pastes cured to develop $4PbO \cdot PbSO_4$ than for the other pastes. A linear relationship was found between the void volumes and the dry paste densities. Different linear relationships were found for the pastes cured to develop $4PbO \cdot PbSO_4$ and for the pastes cured otherwise. These relationships were not affected by the type of oxide nor the thickness of the plate but only by the method of cure. The degree of sulfation affected the size of $4PbO \cdot PbSO_4$ crystals in plates cured to develop that species with the largest crystals formed at the lowest sulfations and, correspondingly, the highest dry paste densities.

An unexpected result was that the calculated density of the solids' portion of the dry paste went through a maximum value within the experimental range of dry paste densities for those pastes which contained $4PbO \cdot PbSO_4$. In contrast, the solids' densities of the other pastes fell off smoothly as the dry paste density was reduced. The maximum was interpreted to be a result of the difference in the crystalline perfections of the $4PbO \cdot PbSO_4$ within the pastes of different dry paste densities.

Acknowledgments

This work was supported, in part, by the Prestolite Battery Division, an Eltra Company, and the authors are grateful to Mr. John P. Badger, of that Division, for useful technical discussions. In addition, the authors are anxious to acknowledge their gratitude to Mr. D. Kemble Bauman, of C&D Batteries, who conducted much of the experimental work.

Manuscript received Jan. 23, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were partially assisted by C&D Batteries.

LIST OF SYMBOLS

- b intercept constant of the linear relationship between D and W, g/cm^3
- d density of the solids in the dry, cured paste, g/cm^3
- D density of the total dry, cured paste, g/cm^3
- g slope constant of the linear relationship between v and D, cm^6/g^2
- p intercept constant of the linear relationship between v and D, cm^3/g
- v specific void volume of dry, cured, paste, cm^3/g
- W density of wet paste mix, g/cm^3

Effect of Base Lead Composition on Metallurgical Properties of Maintenance-Free Battery Alloys

T. W. Caldwell and U.S. Sokolov*

NL Industries, Incorporated, Central Research Laboratory, Hightstown, New Jersey 08520

ABSTRACT

The effects of trace element additions on the microstructure and age-hardening properties of Pb-Ca and Pb-Ca-Sn alloys for maintenance-free batteries are reported. A specific laboratory casting procedure duplicating grid solidification conditions and the solidification-cast property relationships upon which it is based are discussed. It was found that bismuth, antimony, copper, and silver in amounts typical of high bismuth primary and refined secondary base leads have little or no influence on microstructure in Pb-0.085Ca and Pb-0.085Ca-0.8Sn. The addition of trace elements increased the early hardness of Pb-0.085Ca-0.8Sn but had no effect in Pb-0.085Ca.

Maintenance-free batteries are designed to be sealed and require no periodic addition of water. This restriction requires new, low gassing, grid alloy compositions, as the conventional Pb-Sb alloys contribute heavily to hydrogen evolution (1). The Pb-Ca system has been employed for many years in float service (2). Consequently, grid alloy development for SLI maintenance-free applications has focused on the Pb-Ca and Pb-Ca-Sn systems.

It has been reported that "the presence of bismuth is assumed to be disturbing" (3), and that bismuth and other common trace elements decrease strength and castability (4). In the latter study, it was postulated that bismuth or other trace elements interacted with calcium, reducing the effective calcium content. Other studies have indicated no interaction between bismuth and calcium (5), or interaction only at high bismuth levels (6). Davey found that below 0.034 weight per cent (w/o) bismuth, no interaction with calcium could occur, based on the Pb-Ca-Bi phase diagram (7). This level is above that found in typical commercial base leads. This study reports the effects of trace elements on the metallurgical properties of lead, Pb-Ca, and Pb-Ca-Sn alloys for maintenance-free applications.

Certain important properties of grid alloys are best measured under controlled conditions in the laboratory, and in some cases, on samples different in shape and size from cast grids. Laboratory tests also enable the screening of a large number of alloys without the difficulties of preparing alloys in grid form. Certain metallurgical aspects must be considered when measuring material properties of laboratory samples and relating results to actual cast grids. These aspects are discussed as applied to the alloy properties of interest. A technique is presented for preparing laboratory samples having properties equal to cast grids.

Cast Structure—Property Relationships

Figure 1(a) illustrates the typical microstructure of a Pb-Ca-Sn grid. A rodlike morphology is evident within each grain, with the rodlike structure having a single orientation within a given grain. Occasionally, these structures "break down" into branched structures. This branched structure is termed a dendrite, and the rodlike or unbranched morphology is termed fibrous dendritic. These well-known structural morphologies of alloys are discussed elsewhere in detail (8). The fibrous dendritic structure is similar to another morphology which is termed cellular (9). Cells grow in the heat flow direction while dendrites grow at some small angle to it. The importance of the distinction between cells and fibrous dendrites is that segregation of alloying and trace elements is generally more severe in dendritic solidification.

The cellular and fibrous dendritic morphologies are typically found in alloys of low solute content, such as the Pb-Ca and Pb-Ca-Sn compositions studied herein. Alloys of higher solute content, *e.g.*, antimonial lead grid alloys, typically exhibit more fully developed dendritic structures as shown in Fig. 1(b). A fully developed dendrite is seen clearly in the center of the photograph. Around the periphery, only portions of dendrite arms are visible as the plane of polish intersects those dendrite axes at an angle. These peripheral areas are actually portions of other grains, as dendrite orientation is constant within a given grain. The dendrite is single phase solid solution surrounded by material of essentially eutectic composition.

* Electrochemical Society Active Member.
Key words: lead-acid battery, lead-calcium alloys, grid casting, microstructure, mechanical properties.

The dominant feature of the intragranular microstructure of many alloys is the spacing between dendrite arms. In most cases, properties have been related to the spacing of secondary dendrite arms, *i.e.*, arms branching directly from the main or primary dendrite stalk or axis. At constant composition, tensile strength, fatigue strength, and elongation increase as dendrite arm spacing decreases (10, 11). It has been shown that antimonial lead corrosion is influenced by dendrite arm spacing (12). Furthermore, the rate of solidification of Pb-Ca alloys, and the rate of cooling through the single phase region of the Pb-Ca phase diagram were found to significantly affect tensile strength (13). It has also been determined that microstructure has a considerable influence on the rate of hydrogen evolution on a number of lead alloys (14).

Dendrite arm spacing and solidification rate are directly related as shown in Fig. 2. Data are shown for a number of alloys in different alloy systems. The relationship is usually expressed as secondary dendrite arm spacing *vs.* local solidification time, defined as the time between passage of the start-of-freezing and end-of-freezing isotherms at a given point in a casting (16). On a log-log scale, the relationship is linear, only the slope and ordinate intercept differing with alloy composition. Because of the manner in which local solidification time is defined, the relationship is independent of the amount of undercooling occurring before solidification is initiated. The relationship applies to all alloy systems as it is a characteristic of the mechanism of dendritic solidification.

For a given alloy, two castings having identical local solidification times at a given location will exhibit identical dendrite arm spacings. All the properties influenced by either of these two parameters (alternate expressions of the same phenomenon) will be equal at the given location in the two castings. With this concept, it is observed that duplicating the properties of a cast grid in laboratory samples requires the reproduction of conditions in the solidifying metal. Any combination of mold and metal temperatures, mold coat, and section size can be employed, as long as the combination yields the same local solidification time as found in the cast grid. The dendrite arm spacing provides a means of comparing solidification rates of laboratory samples and cast grids.

Alloy Composition

Laboratory castings of lead, Pb-0.085Ca and Pb-0.085Ca-0.8Sn were prepared from three commercial base leads. Calcium and tin compositions were chosen as typical of those which may ultimately be employed in maintenance-free battery grids. The base lead compositions were determined by spark source mass spectrometry and are shown in Table I. Only those elements which differed in concentration among the three base leads are shown, with all other elements < 0.001 w/o each. Comparison of the two primary base leads essentially measures the effect of bismuth, with a small increase in copper. Comparison of the high bismuth primary and the refined secondary lead essentially measures the effect of small combined additions of antimony, copper, and silver. A comparison of the low bismuth primary and the refined secondary lead measures the combined effect of all four trace elements, the major element being bismuth. It is recognized that after addition of calcium, the antimony content will decrease due to the interaction of these two elements (17). The compound Ca_3Sb_2 is 33 w/o calcium. It is obvious that the 5 ppm loss of calcium due to compound formation with 10 ppm antimony is negligible for a Pb-0.085Ca alloy (850 ppm Ca), even if the reaction went to completion.

Table I. Base lead composition, ppm(wt)

	Bi	Sb	Cu	Ag
LOW Bi PRIMARY	<10	<.03	.3	6
HIGH Bi PRIMARY	180	<.03	5	5
REFINED SECONDARY	160	10	10	10

Sample Preparation

A technique for casting lead alloy samples under solidification conditions identical to those encountered in actual grid casting was developed. Figure 3 illustrates an eight-cavity carbon steel mold. The mold was preheated to 365°C, and the molten alloy, also at 365°C, was poured into each of the eight 2.54 cm diam × 0.65 cm deep cavities. The alloy, of course, remained molten at this mold temperature. A signal was sent to a solenoid valve on a high pressure water line, allowing water to enter the mold through the water lines shown, rapidly cooling the mold, and solidifying the alloy samples. Approximately 600g, twice the weight of the eight cast samples, was melted in a resistance-heated, graphite-coated Armco iron crucible for each experiment. A new crucible was used in each experiment. The molten metal surface was covered with powdered charcoal during melting and alloying. The mold was coated with Chemco J-500, a graphite mold spray. Conditions and button geometry were chosen so that the start-of-freezing and end-of-freezing isotherm velocities were constant and essentially equal as the iso-

Table II. Average tertiary dendrite arm spacing of Pb-6Sb-0.5As-0.5Sn

	AVERAGE SPACING, μ
GRID WIRE	12.3
BUTTON	11.1
BUTTON/CORK MOLD COAT	15.4

therms moved across the thickness of each button during solidification. From the definition given previously, it is clear that under these conditions, local solidification time and hence dendrite arm spacing will be constant throughout the buttons. The heat flow condition resulting in constant isotherm velocity near a mold surface is often termed "h-controlled" heat flow, where h is the interface heat transfer coefficient. The mold coat then becomes the major barrier to heat flow in the system. These conditions apply when casting thin sections in metal molds, as in grid casting.

The chill surface of each sample was flat and free of cold shuts and porosity. The cast samples, called buttons, solidified in a substantially unidirectional manner perpendicular to the mold/metal interface.

Alloy Microstructures

The microstructures of the eight buttons simultaneously cast of each alloy were identical, and were reproducible in subsequent castings of the same alloy. To verify that the castings were produced under the conditions present in solidifying grids, the average tertiary dendrite arm spacings of a Pb-6Sb-0.25As-0.25Sn button and grid were compared, as shown in Table II. The average dendrite arm spacings of the grid and the button cast in the manner previously described were identical, within the accuracy of the measurement technique. These structural comparisons were performed on a Pb-Sb alloy as Pb-Ca and Pb-Ca-Sn alloys do not exhibit well-defined dendrite arms.

To illustrate the sensitivity of the dendrite arm spacing to changes in solidification conditions, the use of a cork spray in place of the graphite mold coat normally employed in the button mold resulted in a proportionally large difference in dendrite arm spacing, as shown. In other words, when the bottom mold was coated with the graphite spray, dendrite arm spacings were identical to those found in cork-sprayed grid casting molds. When the button mold was coated with a cork spray, however, dendrite arm spacings increased. This illustrates that it is the combination of mold and metal temperatures, mold coat, and section size which determines the resultant structure.

The specially prepared alloy and base lead samples were examined metallographically to determine the influence of both alloy additions and trace elements on cast structure. The bottom face of each button examined was polished and etched to reveal the microstructure. An acetic acid-hydrogen peroxide attack polish and an ammonium molybdate etchant were employed. In many cases, the samples required overetching, with resultant pitting, to provide enough contrast for photographic reproduction.

Figure 4 shows the structure of the three base leads employed. A grain boundary is observed in Fig. 4(a), while the other photographs show portions of a single grain. The fine structure is the fibrous dendritic morphology. Although not shown, the grain size was approximately equal in all three base leads. Areas of elongated cells were occasionally observed, but the structure consisted mostly of "regular" cells, with some breakdown into true branched dendrites. In some areas the distinction between structures was not clear. The growth conditions in the castings were therefore in the range of the cellular-dendritic transition for these alloys, where local thermal perturbations or slight differences in over-all cooling rates between castings can alter the shape and size of cells (18). Figure 5 presents a side view of the structure in Fig. 4(a). The rodlike fibrous dendritic morphology is readily apparent. The dendritic segments are actually much longer than observed, as the dendrite axes intersect the sample surface at an angle, giving a shortened appearance.

Figure 6 illustrates the structure of Pb-0.085Ca alloys prepared with each base lead. The addition of calcium to the base leads has decreased the grain size in all cases. Figures 6(a) and (b) illustrate that the addition of bismuth does not measurably affect grain size. However, the addition of the other trace elements de-

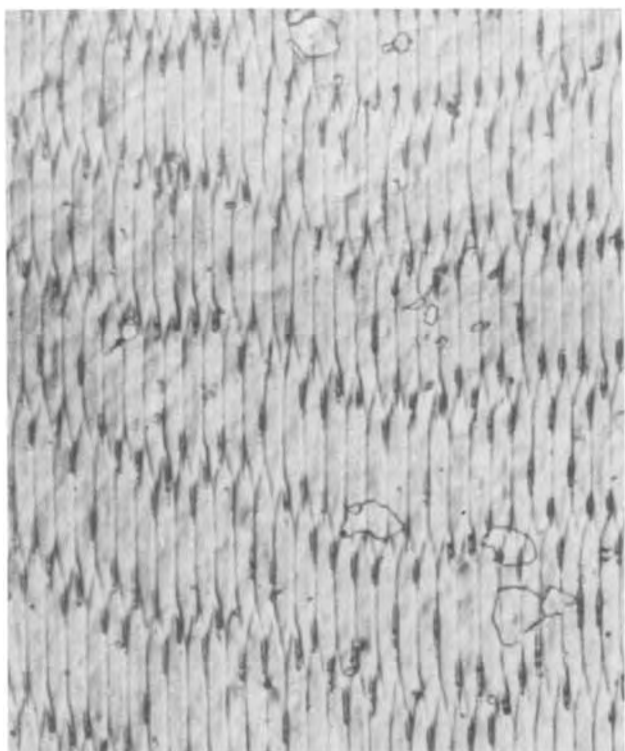

Fig. 5. Side view of casting in Fig. 4(a) showing fibrous dendritic morphology, 120X.

creases grain size slightly, comparing Fig. 6(b) and (c). The underlying fibrous dendritic structure is still visible. Some of the small grainlike features observed on the surface are remnants of the deformed surface layer produced during sample preparation. This can be demonstrated by successively polishing and photographing the same area. When a particular grain is initially absent, then appears, and finally disappears from within an underlying grain without touching a third grain, while the underlying structure remains the same, Euler's law (19) for polyhedral bodies in a space-filling aggregate is violated. The disappearing grain is an artifact. Artifact grains cut across fibrous dendrites in Fig. 5.

The addition of 0.8Sn to form Pb-0.085Ca-0.8Sn modifies the structure as shown in Fig. 7. The structure closely resembles that found in the base leads shown in Fig. 4, *i.e.*, a larger grain size and pronounced fibrous dendritic morphology are again evident. Local variations in cell size are again evident in all three alloys. Comparison of the three alloys indicates that the structure is unaffected by the addition of bismuth, or combined additions of bismuth, antimony, copper, and silver.

Age Hardening

The hardness of the cast buttons was measured as a function of time after casting. While hardness is only an indirect measure of mechanical properties, reasonably good correlation between hardness and tensile strength in Pb-Ca alloys has been obtained (13). A crossplot of yield strength *vs.* hardness from data in this reference also indicates a reasonable correlation. Hardness was measured on the Rockwell Superficial 15Y scale. Cast buttons were given a minor surface preparation consisting of filing the surface smooth on a fine file. This treatment did not affect the hardness measurement, as a button prepared in this manner every day before testing for three days was identical in hardness to a button of the same composition filed and tested for the first time at three days after casting, *i.e.*, after substantial age hardening. Five hardness readings were averaged to determine the hardness at each time of measurement.

As further verification of the sample preparation technique, Pb-Ca-Sn alloy buttons cast of metal taken from the melting pot of a grid casting machine exhibited a hardness close to that of grids from the same alloy, shown in Fig. 8. Hardness was measured with a Barber-Coleman 936 Impressor, a device suitable for measuring the hardness of small sections such as found in cast grids (20).

Figure 9 illustrates the age-hardening behavior of the Pb-Ca and Pb-Ca-Sn alloys studied. For the Pb-Ca alloys, age hardening is observed in the first 24 hr after casting. Hardness continues to increase at a very low rate as evidenced by the increased hardness at 60 days after casting. The differences between alloys of differ-

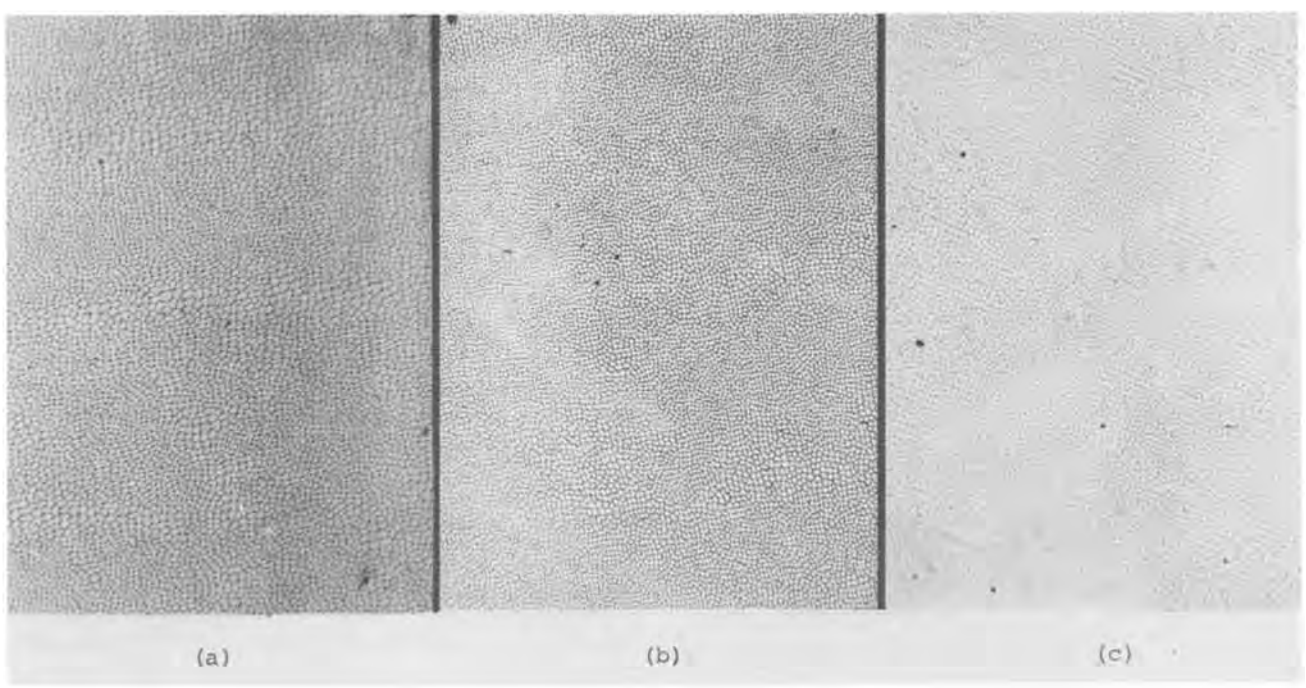

Fig. 7. Cast microstructure of Pb-0.085Ca-0.8Sn with three base leads; (a) low Bi primary, (b) high Bi primary, and (c) refined secondary, 52X.

ent base leads are not considered statistically significant, as the range of individual hardness readings at each time are as large as the differences between alloys.

The hardness curves of the Pb-Ca-Sn alloys indicate a very large age-hardening effect shortly after casting, compared to the Pb-Ca alloys. The hardness is initially much lower in Pb-Ca-Sn than in Pb-Ca alloys, but it increases rapidly, approaching the Pb-Ca hardness after 2 days. Thereafter, age hardening continues at a slow rate. At 60 days after casting, the hardness has increased to the level found in the Pb-Ca alloys. It appears from the slopes of the curves that the Pb-Ca-Sn alloy hardness will surpass that of the Pb-Ca alloys. This has been observed previously (21, 22). Significant differences in hardness are observed as a function of base lead composition, for up to 2 days after casting. In the initial 2 day period, hardness increases with the addition of bismuth, and increases further

Fig. 8. Comparison of grid and button hardness

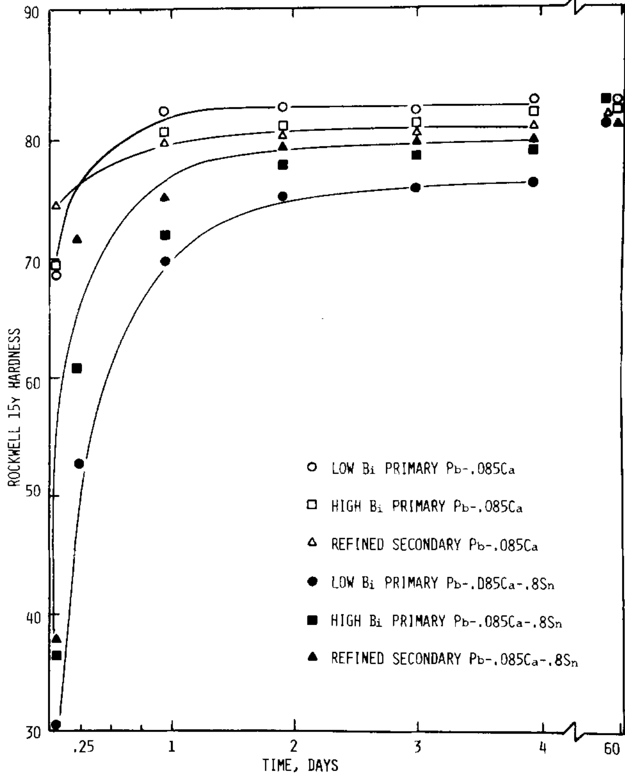

Fig. 9. Hardness vs. time after casting for three Pb-Ca and Pb-Ca-Sn alloys.

with combined additions of bismuth, antimony, copper, and silver. After 2 days, differences between alloys are not statistically significant with the measurement technique used.

Discussion

General relationships between solidification parameters and resultant microstructural features have been presented. When studying laboratory specimens for the purpose of screening potential grid alloys, or even for quality control of established grid alloys, it is evident that the duplication of actual cast grid properties requires the duplication of conditions in the solidifying metal. A special casting technique has been presented for this purpose. The procedures employed to evaluate the accuracy of this technique can be employed to design casting procedures for other sample configurations as well.

Metallographic examination of Pb-0.085Ca and Pb-0.085Ca-0.8Sn alloys made from the three base leads has shown that bismuth, in the range studied, does not alter grain size or the fibrous dendritic morphology. In Pb-0.085Ca, the combined addition of antimony, copper, and silver does promote some grain refinement, but no grain refinement is observed when these additions are made to Pb-0.085Ca-0.8Sn. The grain-refining agent is most likely copper. These observations are in qualitative agreement with previous work on the effect of calcium, tin, and bismuth at similar levels (23).

The addition of tin, at the level studied, masks the microstructural effects of both calcium and trace element additions, as the microstructure of Pb-0.085Ca-0.8Sn is essentially indistinguishable from the base leads. The masking effect of tin on metallurgical and electrochemical properties is discussed in detail elsewhere (20). Some of the effects observed when tin is added to Pb-Ca alloys can be understood as calcium being added to Pb-Sn alloys, as the tin content is usually many times greater than the calcium content.

The effects of additions of bismuth antimony, copper, and silver on hardness are observable only at relatively low hardness values, only during the initial 2 day aging interval in Pb-0.085Ca-0.8Sn, and not at all in Pb-0.085Ca. At the higher hardness levels, the influence of these trace elements on hardness presumably still exists, but the net effect is not measurable on the Rockwell 15Y scale and may be of no significance. The contribution of calcium to the hardness overshadows the effect of these trace element additions at these high hardness levels.

Recently, it has been shown (23) that bismuth additions greater than 220 ppm increase the initial age hardening rate of Pb-0.06Ca but have no effect on Pb-0.09Ca, a composition close to that used herein. In the same study it was observed that the additions of 0.5 and 1.0% tin delayed the onset of age hardening regardless of bismuth content. The hardening mechanism was shown to be at least partly due to grain refinement by calcium and bismuth in the absence of tin. However, it is not clear from the microstructures observed and the trace element levels used in this study what the hardening mechanism is that distinguishes alloys of differing trace element levels at less than 2 days of aging in Pb-0.85Ca-0.8Sn. Trace elements may contribute to solid solution hardening and/or change the precipitation kinetics of age hardening.

Conclusions

The conclusions of this study are summarized as follows:

1. A specific sample preparation technique has been developed to duplicate solidification conditions in cast grids. Castings so produced exhibit cast grid microstructures and hardness values.

2. Addition of 180 ppm bismuth does not influence the microstructure of Pb-0.085Ca or Pb-0.085Ca-0.8Sn.

3. Combined additions of 160 ppm bismuth, 10 ppm antimony, 10 ppm copper, and 4 ppm silver to Pb-0.085Ca have a slight grain-refining effect.

4. In Pb-0.085Ca-0.8Sn, the combined additions of 160 ppm bismuth, 10 ppm antimony, 10 ppm copper, and 4 ppm silver have no visible effect on microstructure.

5. Additions of bismuth, and combined additions of bismuth, antimony, copper, and silver in the above contents do not influence the age hardening behavior of Pb-0.085Ca. Significant increases in hardness and the rate of hardening of Pb-0.085Ca-0.8Sn in the period 0-2 days after casting are found with the above element additions.

Electrochemical Properties of Sodium Beta-Alumina in $ZnCl_2$-NaCl Melts

David R. Flinn[*,1] **and Kurt H. Stern**[*]

Naval Research Laboratory, Chemistry Division, Washington, D.C. 20375

ABSTRACT

On the basis of membrane potential measurements, sodium β-alumina is shown to be almost completely selective for sodium ions in NaCl-$ZnCl_2$ melts. However, the continuous electrolysis of β-alumina in these melts decreases its conductivity. These results are interpreted in terms of the movement of mobile sodium ions becoming impeded by nearly immobile zinc ions introduced into the ceramic under the applied electric field. Beta-alumina is therefore not useful in battery applications where ions other than sodium are present. It can, however, be used in the construction of sodium ion specific membrane electrodes.

In recent years an enormous amount of work has been done on sodium β-alumina (SBA), primarily because of its potential applicability as a sodium-ion-conducting ceramic separator in the sodium-sulfur battery. Other possible uses of the material have been much less explored. For example, it was conceivable that the material might be useful for selectively passing sodium from one compartment to another in a molten salt battery containing a mixture of molten salts, and in the construction of ion-selective electrodes. The present work was undertaken with these applications in mind.

Several years ago Yao and Kummer (1) reported ion exchange equilibrium constants for single crystals of SBA in a variety of molten salts. They found that the exchange was particularly unfavorable for divalent cations, *i.e.*, in some cases no exchange of these cations for sodium ions in SBA could be detected by weight change methods when diffusion, *i.e.*, a chemical potential gradient, was the only driving force.

We therefore chose a representative melt, $ZnCl_2$-NaCl, for this study. It has a sufficiently wide liquid range at temperatures low enough for the vapor pressure of $ZnCl_2$ not to be prohibitively high, and zinc electrodes are reversible to zinc ions in these melts. Thermodynamic activity data for these melts are available, although they are not as accurate as is desirable.

The major object of this study was to find out whether sodium would continue to be the only current-carrying species in SBA as current was passed through it from one $ZnCl_2$-NaCl melt to another, and whether the composition of the SBA remained constant as evidenced, for example, by the electrical conductivity.

Experimental

Commercially prepared SBA tubes from two sources were examined. Tubes purchased from GEC Power Engineering, Ltd., London, England, (GEC) were 8 mm ID, 10 mm OD, and 17 cm in length. Other tubes examined were manufactured by Tokyo Shibaura Electric Co., Ltd. (TSE), and were provided to us by Mr. Roy Rice of the Naval Research Laboratory. These tubes were 13 mm ID, 15 mm OD, and 15 cm in length. X-ray analysis of the tubes showed the presence of ~8 volume per cent α-Al_2O_3 in the GEC tubes, with none detectable in the TSE tubes. The GEC tubes were found to contain more than 0.5% Zr and several per cent Si by emission spectrographic analysis; the TSE tubes contained several per cent Si and Mg.

The zinc metal used was NBS freezing point standard 43e. Reagent grade NaCl was vacuum dried at 300°C. Reagent grade $ZnCl_2$ was purified by bubbling HCl gas through the molten salt followed by helium.

All experiments were carried out in a helium-filled Vacuum Atmospheres Corporation dry box, with water and oxygen content maintained at less than 1 ppm by a recirculating purification system. High purity alumina crucibles, McDanel 998, were used to contain the molten salts. Molten zinc electrodes were held in small silica cups, suspended in the melt by small silica tubes, through which tantalum wires contacted the molten zinc.

Potentials were measured with an Orion Model 801 digital pH meter or a Corning Model 12 pH meter, used in the millivolt mode. Current was integrated with a Koslow Scientific Coulometer, Model 541. Current was maintained approximately constant by manual adjustment of the power supply voltage. Resistance of the SBA was measured either by a General Radio Type 1608A impedance bridge at 1 kHz or at d.c., or by measuring the potential drop across the cell for a given current. The resistance, rather than the resistvity, is reported, since the area of melt contact with the tubes was not known accurately.

The first experiment, illustrated in Fig. 1, was carried out to determine the ion selectivity of SBA in $ZnCl_2$-NaCl mixtures. In this experiment a GEC tube was used to separate a known, constant composition $ZnCl_2$-NaCl mixture from a variable mixture, initially concentrated in $ZnCl_2$. Zinc electrodes, contained in Pyrex tubes, with tantalum contact wires, were used as reference electrodes in each melt mixture. A zinc electrode was also used in direct contact with the variable melt mixture. Open-circuit potentials were re-

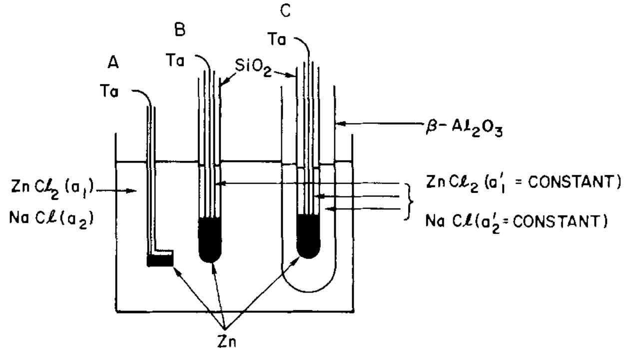

Fig. 1. Galvanic cell used to determine ion selectivity of SBA. For a description of the method see text.

Key words: electrolysis, β-alumina, molten salts, galvanic cells, conductivity.

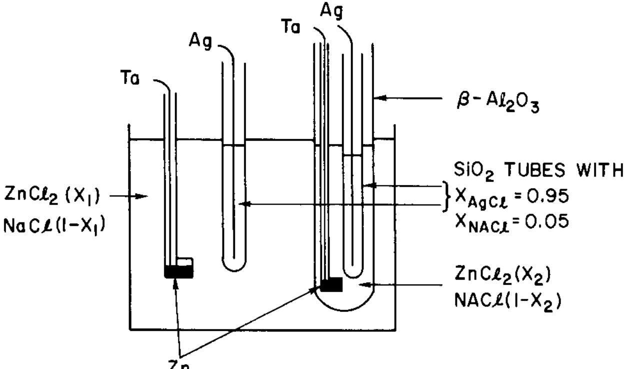

Fig. 2. Galvanic cell used for electrolysis of SBA. For a description of the method see text.

corded following NaCl additions to the variable mixture side.

In the other experiments (Fig. 2), a potential was applied across the SBA tube separating two $ZnCl_2$-NaCl mixtures. Zinc electrodes were in direct contact with the melt mixture on each side of the SBA. Also, a Ag/AgCl-NaCl reference electrode inside a Pyrex membrane was used as a reference electrode in the outer compartment when the smaller GEC tube was used, and on each side when the larger TSE tubes were used. From the amount of charge which passed through the SBA the amount of sodium transferred from one compartment to the other was calculated, assuming that sodium ion carried all of the charge. This assumption was tested by comparing the melt composition thus calculated with the composition obtained potentiometrically. All measurements were carried out at 500°C.

Results

The cell illustrated in Fig. 1 is actually a double cell in which two glass reference electrodes, one in the inner, the other in the outer compartment, can be measured against a zinc electrode in the melt of variable composition. For clarity we write the two cells separately

$$(Ta)Zn \mid NaCl(a_2'), ZnCl_2(a_1') \mid Pyrex \mid NaCl(a_2), ZnCl_2(a_1) \mid Zn(Ta) \quad \text{[Cell A-B]}$$

$$(Ta)Zn \mid NaCl(a_2'), ZnCl(a_1') \mid Pyrex \mid NaCl(a_2'), ZnCl_2(a_1') \mid SBA \mid NaCl(a_2), ZnCl_2(a_1) \mid Zn(Ta) \quad \text{[Cell A-C]}$$

where $a_2' = 0.301$, $a_1' = 0.699$, and a_1 and a_2 are variable. (Sources of activity data for $ZnCl_2$-NaCl melts are discussed below.)

The chief function of the Pyrex membrane inside the SBA tube (cell A-C) is to prevent direct contact between metallic zinc and SBA. Since the inside and outside of this Pyrex tube are in contact with melts of the same composition (this is also the composition in electrode B), no net membrane potential is developed across this glass, and the inner zinc electrode thus behaves as if the Pyrex were absent. Since Pyrex is highly selective for sodium ion in NaCl-$ZnCl_2$ melts (2), the emf expected for cell A-B is (3)

$$E_{A\text{-}B} = \frac{RT}{2\mathbf{F}} \ln \left[\left(\frac{a_1'}{a_1} \right) \left(\frac{a_2}{a_2'} \right)^2 \right] \quad [1]$$

If SBA were also highly selective for sodium ion compared to zinc ion, Eq. [1] should also be the emf of cell A-C, and $E_{B\text{-}C}$ should be zero for all $ZnCl_2$-NaCl compositions in the outer compartment.

Figure 3 shows a plot of the observed potentials $E_{A\text{-}B}$ (□) and $E_{A\text{-}C}$ (○) *vs.* the potentials predicted from Eq. [1]. The line shown is drawn through the 0,0 origin with a slope of unity. Activity coefficients were

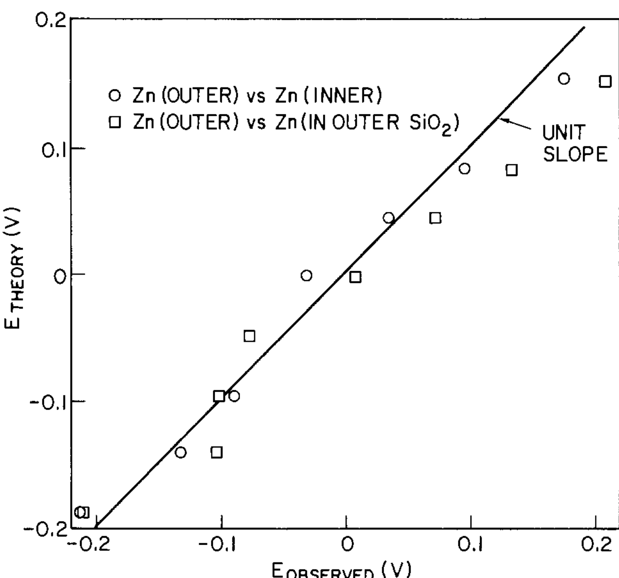

Fig. 3. Experimental test of Eq. [1], using the cell in Fig. 1. □ $E_{A\text{-}B}$, ○ $E_{A\text{-}C}$.

taken from Bloom *et al.* (4), and were determined by a transpiration technique. The results shown in Fig. 3 indicate that SBA shows nearly the same selectivity for sodium ion over zinc ion as that shown by Pyrex.

The experimental cell used in the second set of experiments is shown in Fig. 2. This cell consists of two complete cells of the form

$$(Ta)Zn|NaCl, ZnCl_2|Pyrex|AgCl, NaCl|Ag$$

with the NaCl-$ZnCl_2$ melts separated by a SBA membrane.

The predicted potentials between the zinc electrodes are the same as those given by Eq. [1], assuming a high sodium ion selectivity for the Pyrex and β-alumina. The emf expected between the zinc electrode and silver electrode pair on each side of the SBA may be expressed by the equation

$$E_{Zn/Ag} = E^\circ_{ZnCl_2/AgCl} - \frac{RT}{2\mathbf{F}} \ln \frac{a_{AgCl}{}^2}{a_{ZnCl_2}} - \frac{a_{NaCl}\ (\text{in AgCl})}{a_{NaCl}\ (\text{in } ZnCl_2)} \quad [2]$$

where $E^\circ_{ZnCl_2/AgCl}$ is that for the reaction: $2Ag + ZnCl_2 = 2AgCl + Zn$, and is $-0.707V$ at 500°C (5).

A potential was applied between the two zinc electrodes of the cell shown in Fig. 2 and the current was continuously integrated. At selected times the applied potential was disconnected and the SBA resistance and the open-circuit potentials were measured as a function of charge passed. Occasionally a weighed amount of NaCl was added to the outer melt compartment to maintain a reasonable concentration of NaCl in the melt.

The concentrations and activities of NaCl and $ZnCl_2$ were calculated for both compartments for each potential measurement by assuming that all of the charge passed through the SBA was carried by sodium ions. Figure 4 shows a comparison of the emf measured (for both GEC and TSE tubes) between the zinc electrodes and the emf predicted by Eq. [1]. Both dashed lines are drawn through the respective sets of points with unit slope, and with best visual fit, to illustrate the asymmetry between the measured and predicted cell potentials. This asymmetry is in the same direction as the applied potential (▼), even though the potentials were measured at open circuit. For the TSE tube, two emf's were also measured after electrolysis in the opposite direction, and the resulting values are shown

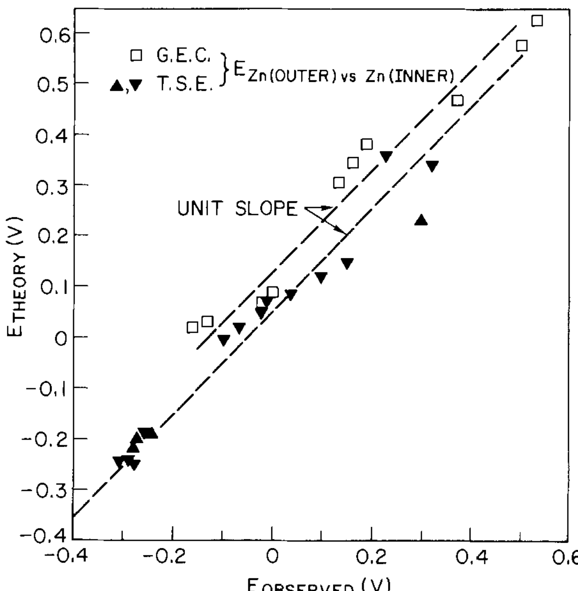

Fig. 4. Experimental test of Eq. [1] using the cell in Fig. 2

in Fig. 4 by the symbol ▲. Although only one potential was recorded for a long reverse electrolysis period (uper right-hand portion of the figure), its value suggests that the asymmetry potential in the SBA is reversible.

For the TSE tube cells, other potentials were also recorded. The potential between the two silver electrodes was observed to be nearly zero for all concentrations, as would be expected for analogous reasons that $E_{B\text{-}C}$ is zero for the cell in Fig. 1. This result can easily be calculated from Eq. [1] and [2] by computing

$$E_{Zn(I)/Zn(II)} - E_{Zn(I)/Ag(I)} - E_{Zn(II)/Ag(II)} \equiv E_{Ag(I)/Ag(II)} = 0$$

The emf's observed between the pairs of zinc and silver electrodes on each side of the SBA were also measured for most concentrations. These results are compared in Fig. 5 to those predicted from Eq. [2]. The observed potentials are about 100 mV more positive than those predicted.

The resistance across an effective area of 4.7 cm^2 of the TSE tube observed during the electrolysis is shown in Fig. 6. The number to the right of each point is the mole fraction of the NaCl in the side of the cell which is supplying sodium ions to the membrane. During the initial electrolysis (at 42.6 mA-cm^{-2}) the cell resistance increased rapidly after the passage of ~18.5 mequiv.-cm^{-2}. Additional sodium chloride was added to the side from which sodium was being electrolyzed. Although these additions did result in a lower resistance, the original low resistance value for the same mole fraction was not regained.

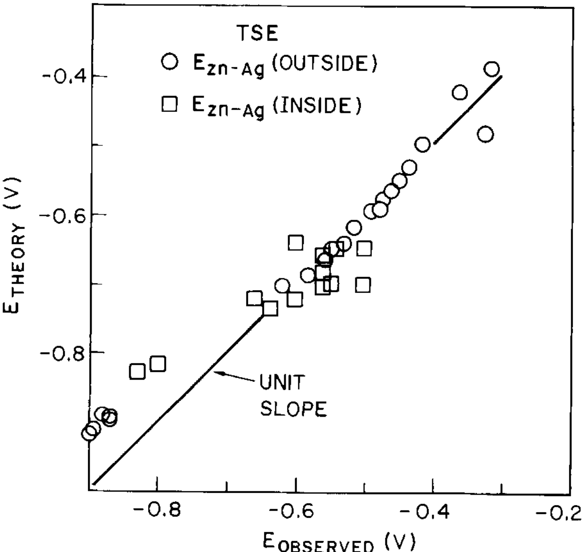

Fig. 5. Experimental test of Eq. [2] using the cell in Fig. 2

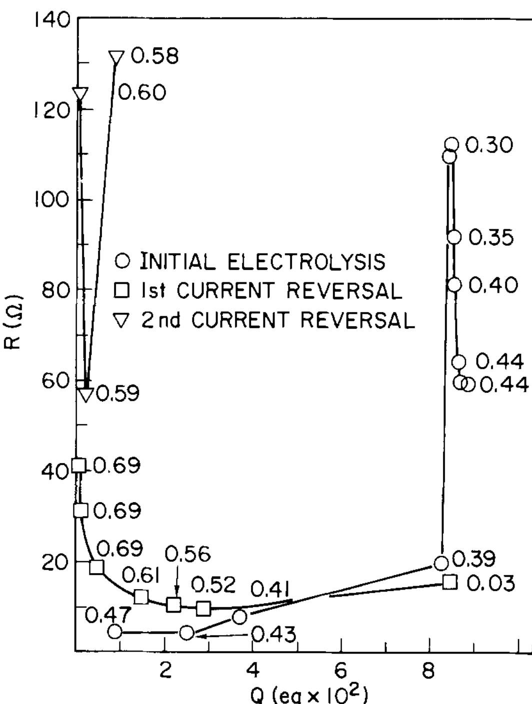

Fig. 6. Resistance of TSE tube as a function of charge passed during electrolysis. For details see text.

When the current was reversed, the resistance fell to a value which was approximately twice that originally observed, and slowly rose with increasing charge passed. The resistance did not rise to the high value observed in the initial electrolysis direction, even at low NaCl mole fractions. The current was then again reversed to the original direction and after a short-lived decrease, the resistance increased again, rising to approximately 500 ohms in a very short time. Further additions of zinc, $ZnCl_2$, and NaCl to the cell did not lower the membrane resistance.

When the GEC tube was electrolyzed, high resistances were noted for both electrolysis directions after about the same amount of charge (per unit area) was passed as in the TSE tube case.

Discussion

Equation [1] is a simplified form of the Eisenman equation (6) which holds when the membrane is highly selective for a given cation in a mixture of two different cations, and includes the Nernst potential arising from the electrode reactions. A complete discussion and development of Eq. [1] is given in Ref. (3).

The results of the open-circuit experiments shown in Fig. 3 indicate that SBA is highly selective for sodium ion in the presence of zinc ion in the mixed chloride melt. The selectivity constant of the Eisenman equation (6) includes a thermodynamic equilibrium constant of ion exchange at the membrane surface and the mobility ratio of the two exchanging ions in the membrane. The selectivity constant may thus be large because the equilibrium constant is large, the mobility ratio is large, or because both are large. Unfortunately, the open-circuit experiment does not discriminate between the two possibilities.

The results shown in Fig. 4 suggest that the SBA ceramic itself may be polarized as a result of an electric field applied across it, and that this polarization

may be reversed by reversing the field. However, some doubt is cast on this interpretation by the apparent asymmetry exhibited by the separate pairs of Zn-Ag electrodes for which SBA is not in the circuit being measured. An alternate explanation may lie in the poor activity data available for $ZnCl_2$-NaCl melts. This system deviates highly negatively from Raoult's law and calculated emf's are thus quite dependent on activities. The data used (4), the only ones available at 500°C, were obtained from transpiration experiments and disagree with data obtained by other methods at higher temperatures (7). Nevertheless, the data in Fig. 3-5 show clearly that SBA acts as a sodium-selective membrane in $ZnCl_2$-NaCl melts.

The question of ion mobility in SBA is apparently answered by the electrolysis experiments. Figure 6 shows that continued electrolysis through the SBA in a given direction results in increasing cell resistance. Reversal of the electrolysis direction is unable to remove the cause of the increased resistance, since when the current was again reversed, the high resistance persisted. Apparently the zinc ion, which is present to some extent at the melt/SBA interface due to the ion exchange equilibrium at the interface, becomes trapped in the SBA structure as it is transported by the applied electric field and inhibits sodium ion migration. Current reversal is not effective in removing the zinc ion from the SBA in any reasonable time period.

An attempt was made to test the above hypothesis by direct Auger analysis of an SBA tube that had been electrolyzed in a $ZnCl_2$-NaCl melt. Over a depth of ~3000Å the Zn concentration decreased progressively by at least a factor of four from its value at the surface. Because of surface inhomogeneities and sputtering angles, this value represents an upper limit and the actual concentration in the bulk SBA may have decreased more. Since the concentration of sodium in SBA is low to begin with, meaningful changes of the sodium concentration with sputtering distance could not be obtained. The Auger results are, however, at least qualitatively, consistent with our interpretation.

Even though the resistance of the SBA increased with the amount of charge passed through it, the zinc ion within the SBA did not affect the ability of the material to continue to function as a sodium ion selective electrode. The high mobility of sodium ion in the SBA continues to control the potential.

The conductivity was noticeably affected only after an amount of charge was passed through the SBA equivalent to the total amount of sodium initially in the material. This observation indicates that the ion exchange equilibrium constant also apparently favors sodium ion over zinc ion exchange from the chloride melt into SBA, just as the mobility of sodium is greater than that of zinc in SBA. Both these factors cause SBA to exhibit high sodium selectivity in the presence of zinc ions in a chloride melt.

Conclusions

We have shown that sodium is favored over zinc in the SBA structure. However, when zinc ion moves into the structure under the influence of an applied electric field, it has such a low mobility that the over-all conductivity of the SBA is greatly impaired. Current reversal is apparently not effective in removing the zinc ion once it has entered the structure. The presence of zinc ion in the SBA does not alter the high selectivity for sodium ion, so that even though SBA would not be a good separator in battery applications using molten NaCl-$ZnCl_2$ mixtures, it could be used as an accurate monitor of sodium ion activity in such melts over a wide range of sodium ion activity. Most likely, the sodium ion selectivity of SBA would hold in any mixture of a sodium salt with salts of higher valent cations.

Acknowledgment

We would like to thank Dr. James Murday and Mrs. Elaine Shafrin for carrying out the Auger analysis.

The Electrical Properties of Protective Polymer Coatings as Related to Corrosion of the Substrate

Martin W. Kendig and Henry Leidheiser, Jr.*

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

The effective electrical permittivity of polymer-coated steel was measured between 200 Hz and 100 kHz as a function of time of exposure to 0.52M NaCl. The real and imaginary parts of the permittivity increased over the entire frequency range as a consequence of electrolyte penetration. The development of a -1 slope on the log loss *vs.* log frequency curve suggested localized penetration of the dielectric coating by a conducting phase. This behavior correlated with the onset of visible localized corrosion. Results were discussed in terms of a metal/metal oxide/penetrated-coating model.

The mechanism by which a polymer coating protects a metal substrate against corrosion is of great interest. The coating serves as a mass transport barrier to reactants, but this role does not describe completely the phenomena that are observed in some systems (1). This study was undertaken with the recognition from previous work that the electrical properties of the electrolyte/coating/substrate composite can be correlated with corrosion behavior. In this communication the electrical response and a parallel observation of the corrosion potential of polymer-coated steel exposed to a model 0.52M NaCl corrosive medium will be presented. Particular attention is given to the ability of these measurements to elucidate the mechanism of corrosion of polymer-coated steel. Of subsidiary interest is the applicability of the measurements to provide a means for appraising the corrosion protection properties of the coating.

Many studies of the electrical properties of protective polymer coatings reported in the past include measurements of the current response of an isolated film or a coated metal to an applied potential. Mayne and co-workers have extensively investigated the d-c conductivity of free polymer films (2, 3) while the a-c response has been treated and discussed recently by several workers in terms of equivalent resistances and capacitances (4-6). In this laboratory, polybutadiene coatings on steel substrates have been observed to show a decrease in both in-phase and out-of-phase impedance after exposure to a NaCl solution. There is a rapid change at the point where the coating fails completely (5). Under the assumption that it is only the "dielectric" coating which is probed by the a-c measurement, and that the penetrating aqueous phase is distributed within the coating as random aggregates, the per cent water uptake may be determined from the equivalent parallel capacitance (4, 5, 7). While these estimates of water uptake may be valid for the early stages of coating exposure to an aqueous environment and for relatively thick coatings, the estimates have limitations. Indeed, porous penetration of conducting phase (8, 9), interfacial impedance (10), and Maxwell-Wagner and/or Debye losses within the polymer and interface may all contribute to the observed electrical response of a polymer/substrate system (11). In a theoretical discussion, Shmirev and Egorov (12) consider the coating to be represented by a three-element network which may be experimentally determined by a measurement of the impedance at three different frequencies. Likewise, Tomashov *et al.* (10) suggest that a frequency dependence of the impedance may illuminate the nature of coating breakdown. Preliminary results in this laboratory suggest that the frequency-dependent response of a coating is related to its corrosion protective properties (8).

To explore further the nature of the electrical response which develops temporally during exposure of the coating to 0.52M NaCl, the coating impedance between 0.2 and 100 kHz has been followed as a function of time and of coating thickness.

The second electrical property of polymer-coated substrates which provides useful information germane to the mechanism of corrosion is the corrosion potential. Since the potential of a corroding substrate is determined by the relative importance of the separate cathodic and anodic rates, changes in this measured quantity with time provide significant insights into the rate-determining steps. Recently, a review of the corrosion potential as applied to painted steels has appeared (13).

Experimental

Substrate preparation.—Common blackplate 0.026 cm thick, in 10 by 15 cm pieces, was obtained from Bethlehem Steel Corporation. The samples were cleaned by soaking in mineral spirits and rubbing dry with a lint-free cloth prior to application of the coating (5). Confirmation that macroscopic dust particles were removed was obtained by sighting the steel plate at a low angle while whisking the plate with a lint-free cloth. Immediately following this procedure, the coating was applied to the samples, and cured as described below. Chromated steel substrates were produced using the procedure of Bancroft, Mayne, and Ridgway (14).

Coating preparation.—The coating which was primarily used in this study was a polybutadiene denoted PB (15). An epoxy (16), denoted EX, a methylmethacrylate copolymer, denoted AB (17), and a polybutadiene stabilized acrylic copolymer nonaqueous dispersion, denoted CLX (18) were also used. The solutions, PB, EX, AB, were passed through a 5 μm millipore filter prior to application. The nonaqueous dispersion was used as received. AB was used as a polymer solution; the other coatings were fully formulated.

The coatings were drawn onto the substrate with wire bars. The thickness of the cured coatings was controlled by use of wire coating bars of different gauge. Freshly coated samples were immediately placed in a hot, covered ceramic container and maintained in an oven for the appropriate cure time. The cover of the container was positioned so as to allow solvent vapors to escape. Information about the samples is presented in Table I. The temperature represents the average temperature of the atmosphere in the oven during curing. The oven temperature rose slightly after closing the door. Optimum cure for the polybutadiene was considered to be obtained when the

samples exhibited a slightly green hue, an overbake leading to a yellow color and the underbake leading to a gray color.

The coating thicknesses were determined by micrometer measurements of the panels before and after coating. Results are expressed as an average of eight or more measurements. Typical scatter in these measurements was 10% (see Table I).

Cell description.—Experimental cells were constructed from the coated sample by cementing the ground end of 17-18 mm ID tubes onto the coating surface with epoxy cement. A guard ring surrounded the cell to minimize stray capacitances. Mercury was placed in the cell and the equivalent parallel capacitance and loss tangent measurement was made between 200 Hz and 100 kHz prior to any exposure to the corrosive medium. The cell was then filled with 1 ml of air-saturated aqueous 0.52M NaCl solution and allowed to stand for the desired period of time. The sodium chloride was decanted and clinging drops were wiped free of the surface with an absorbent, lint-free tissue. The mercury electrode was again placed over the coating and the equivalent parallel capacitance and loss tangent were measured across the mercury/electrolyte penetrated coating/substrate interface. The mercury was removed and the sodium chloride electrolyte was reintroduced for an additional period of time.

Cells used for the potential measurements were constructed as described by Leidheiser and Touhsaent (5). The potential was measured between the metal substrate and a saturated calomel reference (SCE) electrode.

Electrical measurements.—Capacitance and loss tangent measurements across the substrate/coating/mercury interface were accomplished with a General Radio 716C Shering Bridge and 716-P4 guard circuit. The bridge was driven by a variable frequency Rhode and Schwartz oscillator at 1V peak-to-peak between 200 Hz and 100 kHz. The signal to be nulled was detected by a Rhode and Schwartz tuned indicating amplifier or a PAR Model 129 lock-in amplifier. The response of the coating to an applied oscillating field, $V_0e^{j\omega t}$ was determined by bridge balancing of the response to that of an equivalent parallel resistor and capacitor. The bridge elements were linear and the detector was tuned only to the fundamental frequency, so it is the first-order response which is observed by this method. These data may be represented in a variety of ways: (*i*) real and imaginary conductivity, (*ii*) equivalent parallel resistance and capacitance, (*iii*) effective in-phase and out-of-phase permittivity, (*iv*) capacitance and loss tangent. For this discussion, the in-phase and out-of-phase effective permittivity will be used to account for the current response across the coating/metal interface. The real and imaginary components of the permittivity (ϵ'', ϵ') are related to the equivalent parallel resistance and capacitance by the following

$$\epsilon'' = \frac{d}{A\epsilon_0\omega R_{xp}}$$

$$\epsilon' = \frac{d}{A\epsilon_0} C_{xp}$$

where ϵ_0 = absolute permittivity of free space, A = apparent coating area, d = coating thickness, ω = frequency in radians, R_{xp} = equivalent parallel resistance, and C_{xp} = equivalent parallel capacitance. The equivalent parallel resistance and capacitance of a complex element may be calculated from bridge balances. Then, by the above equation and the film and cell dimensions, the effective complex permittivity (ϵ'', ϵ') of the coating may be determined.

Potential measurement.—The corrosion potential was measured between the coated substrate and the SCE reference electrode using a Keithley 600A electrometer and a cell, 50 mm ID. Since the electrometer input impedance was significantly greater than the impedance of the coated interface, virtually no current was drawn on the system under observation. The potential was measured at intervals over a period of about 40 days. Every time the potential was measured the 25 ml of 0.52M NaCl was renewed.

Visible underfilm corrosion was assessed via ASTM Standard D610 (19) in two ways. First, by observing the area covered by dark spots of corrosion product, and second by estimating the surface area that was delaminated. The appropriate ASTM D610 designation was assigned to these two types of areas. These designations run from 1, representing 50% destruction, to 10, representing no change. As an example, Fig. 1 shows a photograph of a sample which was treated with 0.52M NaCl and had commenced to corrode. The two types of areas are readily apparent with the delaminated areas well outlined around the dark corrosion spots.

Inflicted defect.—One sample, PB44, was purposely damaged, and the damaged spot was exposed to the 0.52M NaCl solution. The damage was accomplished by pressing the coating with a tapered 0.7 mm OD stainless steel syringe needle. Approximately 0.3 ml of 0.52M NaCl was placed on this spot for 1 hr after which

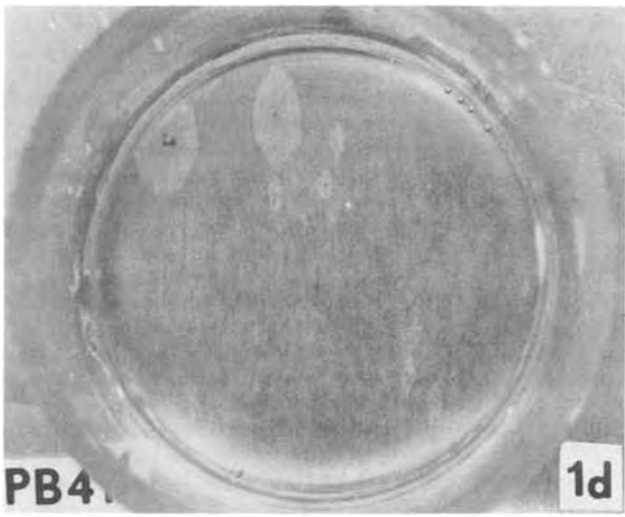

Fig. 1. Photograph of a polybutadiene-coated steel sample after exposure to 0.52M NaCl for one day. Corrosion appears in upper left as dark spots surrounded by a light region.

it was wiped off and the electrical response of the sample was measured in the manner previously described.

Inert atmosphere.—An inert atmosphere of dry nitrogen purified by passage over hot copper wire was produced within a polyethylene glove bag by maintaining a positive pressure of nitrogen in the system. The electrometer cables were fed through a bulkhead sealed to the polyethylene bag. The 0.52M NaCl electrolyte was flushed with nitrogen for 20 min, stoppered, and placed within the nitrogen-flushed bag. The sealed bag containing cells, SCE reference, electrometer cable and electrolyte was allowed to equilibrate for 3 hr with nitrogen. The electrolyte was then introduced into the cells and the potential measurements were commenced.

Results

Figures 2-5 illustrate the log loss *vs.* log frequency results for several polymer coatings (20-30 μm) on steel at different times of treatment in 0.52M NaCl. The onset of corrosion coincided with the development of the -1 slope at low frequencies in the log ϵ'' *vs.* log f plots. The sample which showed no low frequency slope, Fig. 5, showed no corrosion on exposure time of 30 days.

In a second set of experiments a series of polybutadiene-coated steel samples, having a range of coating thicknesses between 5 and 24 μm, was treated with 0.52M NaCl and the effective complex permittivities over the 200 Hz to 100 kHz range were measured periodically. The thin coatings did not achieve the -1 slope in the frequency range studied as may be seen in Fig. 6 where the 21 day result for this series of

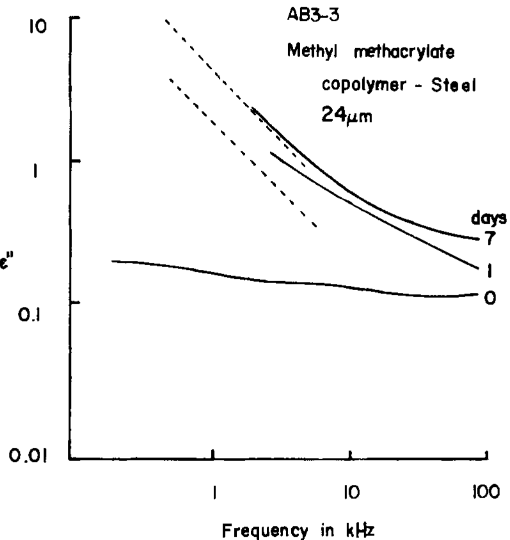

Fig. 2. Log loss *vs.* log frequency for a methylmethacrylate copolymer-coated steel exposed for 0, 1, and 7 days to 0.52M NaCl.

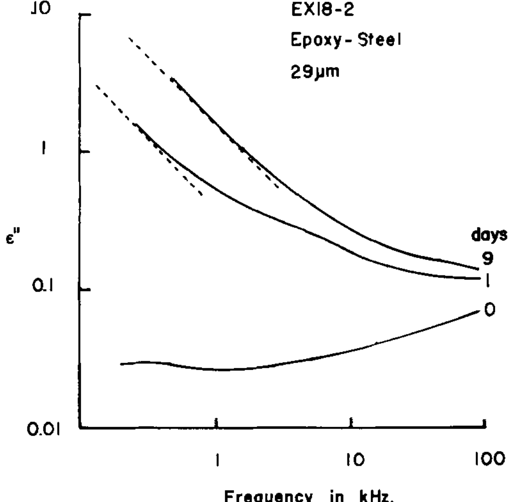

Fig. 3. Log loss *vs.* log frequency for an epoxy-coated steel exposed for 0, 1, and 9 days to 0.52M NaCl.

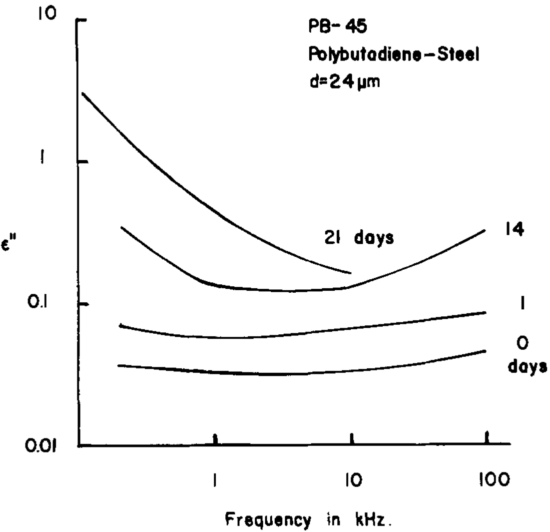

Fig. 4. Log loss *vs.* log frequency for a polybutadiene-coated steel exposed for 0, 1, 14, and 21 days to 0.52M NaCl.

Table II. The relationship between the slope of the ϵ'' vs. log f plots at low frequency and the rate of corrosion of polybutadiene-coated steel in 0.52M NaCl

Ranking on basis of corrosion rate	Sample designation	Low frequency slope After 7 days	After 20-22 days
1 (greatest	PB39	−1.0	Totally corroded
2	PB41	−0.37	−0.44
3	PB45	0	−1.0
4	PB42	−0.48	0
5	PB40	0	0
6 (least)	PB43	0	−0.18

Table III. The slope of the log ϵ'' vs. log f plots at low frequency for chromated steel samples coated with polybutadiene and exposed to 0.52M NaCl

Sample	Low frequency slope after two weeks	% Surface corroded after two weeks
785-19-14	−1.0	35
785-28-15	−0.1	5
785-22-15	−0.1	1
785-17-13	0	0

samples is recorded. There is nonetheless, a correlation of the low frequency slope with corrosion as illustrated by Table II. Similarly the correlation of the low frequency data is also indicated for chromated samples in Table III.

That the onset of a −1 low frequency log ϵ'' *vs.* log frequency slope may be associated with a path of continuous conductivity through the coating is illustrated by the results depicted in Fig. 7 which shows the log ϵ'' *vs.* log frequency results for a polybutadiene-coated steel sample in which the coating was punctured with a needle and allowed to equilibrate with 0.52M NaCl solution for 1 hr. The −1 slope at low frequencies of the log ϵ'' *vs.* log frequency plot is seen.

The out-of-phase component of the effective complex permittivity does not vary as rapidly with frequency. If one were to assume that the out-of-phase effective permittivity were a true permittivity of the composite coating and dispersed aqueous phase, its value would be a function of the volume fraction of the dispersed phase (5, 7). The assumption neglects the fact that there may be a contribution from the substrate/polymer interface. Nevertheless, it is important to note the increase of this effective permittivity with time of exposure. Barring interfacial effects and for small volume fraction of the dispersed phase, the function $(\epsilon'_t/\epsilon'_{t,o} - 1)$ is proportional to the volume fraction of the dispersed phase.[1] The proportionality constant is dependent upon the particular geometry of the dispersed phase (11). This quantity, $(\epsilon'_t/\epsilon'_{t,o} - 1)$, is tabulated for the series of polybutadiene coated steel samples in Table IV. Using the treatment of Leidheiser and Touhsaent (5) and previous work where a random distribution of aqueous phase is assumed, the "calculated per cent water uptake" after two weeks is between 10 and 13% and with minor dependence upon coating thickness.

steel. The potential is anodic initially and moves to more cathodic potentials with time. This movement to more cathodic potentials correlates with the increase in the delaminated area which occurs around the dark corrosion spots (Fig. 1). After a length of time depending upon the thickness of the sample, there is complete failure of the coating as observed by the formation of a black to orange corrosion film over the entire surface. The transition occurs quite rapidly, usually within one day, and is followed by an equally fast plunge of the substrate potential to the vicinity of −650 mV, a potential approximating that at which mild steel actively corrodes in aerated NaCl.

The initial corrosion potentials were more cathodic with decreasing coating thickness as illustrated in Fig. 11. This relationship suggests that it is the cathodic half-reaction which is rate controlling in active underfilm corrosion in the polybutadiene-steel system. The relative rate of oxygen penetration of coatings of different thickness explains the greater degree of cathodic depolarization in the thinner samples than in the thicker samples.

Further evidence for the importance of the cathodic half-reaction is provided by the results of corrosion potential measurements carried out in an oxygen-free environment. Neither significant corrosion nor delamination occurred for samples held under nitrogen. Accordingly, the corrosion potential of the metal substrate remained near −650 mV, not trending toward more positive potentials as the aerated delaminating samples did. A comparison is shown in Fig. 12. Curve A is the typical behavior of an aerated sample in which the positive movement of the potential follows the delamination. The samples held in an oxygen-free environment yield an approximately constant potential of −600 to −650 mV as shown by the lower two curves. Upon exposure of the samples to air, the thinner samples remained at −600 to −700 mV, but the 24 μm sample equilibrated at −250 mV. Many small corrosion spots became visible soon after exposure to the air.

Discussion

In discussing the electrical properties of a polymer coating, it is convenient to describe the coating/metal oxide interface/metal in terms of a circuit analog having an equivalent frequency response.

The frequency dependent response of a coating impedance which is electrically equivalent to a parallel resistor and capacitor yields a −1 slope for the variation of log ϵ'' *vs.* log frequency. While this slope has been observed for many samples in which corrosion processes have become visible under the coating, it is not by any means general for a polybutadiene-coated steel treated with aqueous 0.52M NaCl. Specifically, Fig. 2-5 show that prior to exposure to the electrolyte, log ϵ'' does not change greatly with frequency, but after exposure for several days there is an increase in the low frequency loss. Shmirev and Egorov (12) suggest an equivalence of the coating to a parallel resistor and capacitor circuit which itself is connected in series with a capacitor representing the interface. This equivalent circuit cannot generally represent the coating impedance since for this network, the expected response would have a −1 log ϵ'' *vs.* log frequency slope at frequencies below this characteristic frequency. Clearly, in the initial stages and for several of the observed samples presented in Fig. 5, this is not the case. As mentioned above, the loss is rather flat over the measured frequencies. It does not reach a sharp maximum.

A general equivalent circuit may be represented by a distribution of series resistors and capacitors in parallel as illustrated schematically in Fig. 13. Physically, this picture represents what will be referred to as a heterogeneous assembly of electrolytically conducting paths. The heterogeneous nature of the electrical properties of several polymer films has been previously noted by Mayne (2).

There are two types of behavior. In some localized areas, the coating does not behave as a dielectric, but

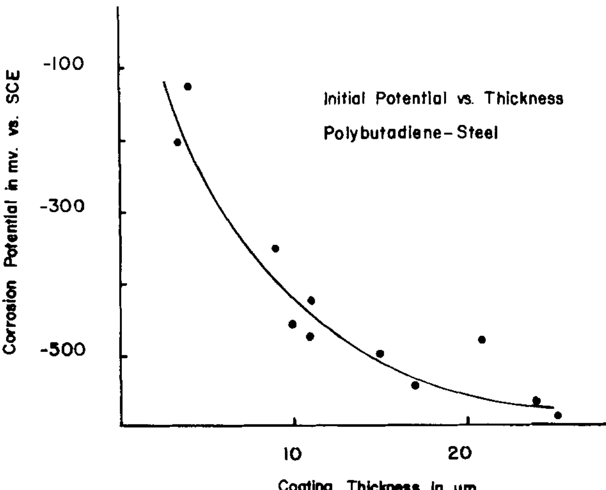

Fig. 11. Extrapolated initial corrosion potential of polybutadiene-coated steel substrate vs. coating thickness.

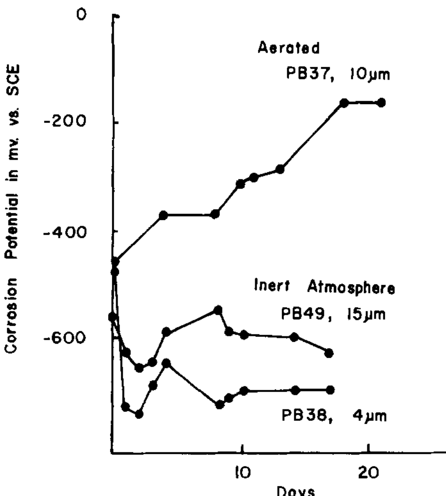

Fig. 12. Comparison of typical corrosion potential vs. time curves of polybutadiene-coated steel in a deaerated and aerated environment.

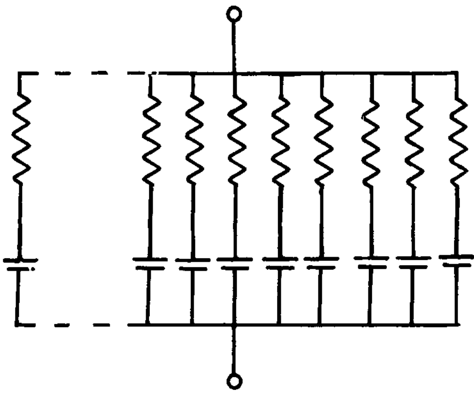

Fig. 13. The electrical analog of a polymer coating heterogeneously penetrated by a conducting phase.

exhibits electrolytic conductivity as a consequence of polymer breakdown such that electrolyte is dissolved within a hydrolyzed region, or because of penetration by the electrolyte through pores. In other localized areas, the coating remains a highly cross-linked, relatively inert, dielectric material. The entire coating/metal oxide/metal system may be considered to consist of electrolytically activated, conducting regions penetrating the coating randomly over the surface with respect to depth. In terms of Fig. 13, each parallel path is a resistor in series with a lossy capacitor. The lossy capacitor is a series connection of the dielectric polymer and the very lossy metal oxide interface. From this model, the effective permittivity of the whole coating may be formulated (see Appendix). The coating is divided into regions having a given conductive length, l, which is related to an effective dielectric thickness d_i

$d_i = d_o - l$

d_o = the macroscopically determined coating thickness

The observed effective complex permittivity of the whole coating will be a weighted sum of the complex permittivities of each region defined by a particular d_i

$$\epsilon_{\text{obs}} = \sum_i P(d_i)\epsilon(d_i)$$

Here $P(d_i)$ is the fraction of the surface where the coating has an effective dielectric thickness d_i, and effective dielectric permittivity $\epsilon(d_i)$.

In order to make a test of the above concept, the following assumptions are made:

1. The fraction of the surface having an effective dielectric thickness d_i is a function of the effective thickness, $P(d_i)$, and decreases exponentially with differences $(d_i - d_o)$

$P(d_i) = Ne^{(d_i - d_o)/D}$
N = normalization factor
d_i = the effective dielectric thickness
d_o = apparent coating thickness
D = penetration factor

2. An oxide with an electrical response similar to α-Fe_2O_3 is considered to represent the interfacial phase. An oxide reported by Hilborn (20) and certain modifications thereof (Table V) are also considered. These are the only iron oxides of interest for which data are available.

3. The conductivity of the penetrating phase is considered to be equivalent to that of bulk electrolyte. In the case of 0.52M NaCl the specific conductance is 0.047 mho/cm.

4. The oxide thickness at the interface is considered to be 50Å.

The model, as formulated in the Appendix, is calculated by computer with the above parameters, and

Table V.

	K_I*	K_s*	10^{-5} sec,* τ	γ*	σ_{d-c}, mho/cm
Oxide #1	30	670	1.2	0.22	$5.39(10)^{-10}$**
Oxide #2	30	670	1.2	0.22	$5.39(10)^{-9}$
Oxide #3	30	670	1.2	0.22	$5.39(10)^{-8}$

* The parameters may be defined as follows from (20): $\epsilon'' = (K_s - K_I)(\cos\phi)^{\gamma}\sin\gamma\phi + C/\omega$; $\epsilon' = K_s - (K_s - K_I)(\cos\phi)^{\gamma}\cos\gamma\phi$; $\cot\phi = \omega$; τ is a characteristic time related to the distribution of the oxide resistivity and γ is related to the breadth of the distribution of the oxide resistivity; $C = \sigma_{d-c}/\epsilon_o$.

** An oxide observed by (20).

for several penetration factors. Factors between 1.4 and 2.5 μm yield both in-phase and out-of-phase permittivities which are qualitatively similar to experimentally determined frequency response for the early stages of treatment with electrolyte. Figure 14 shows log ϵ'' *vs.* log frequency for the two penetration factors, 1.4 μm and 2.0 μm. They are also values which yield experimentally reconcilable values of $(\epsilon'/\epsilon'_{t,o} - 1)$ in Fig. 15. Furthermore, for these penetration factors, the permittivity ϵ' remains relatively constant with frequency.

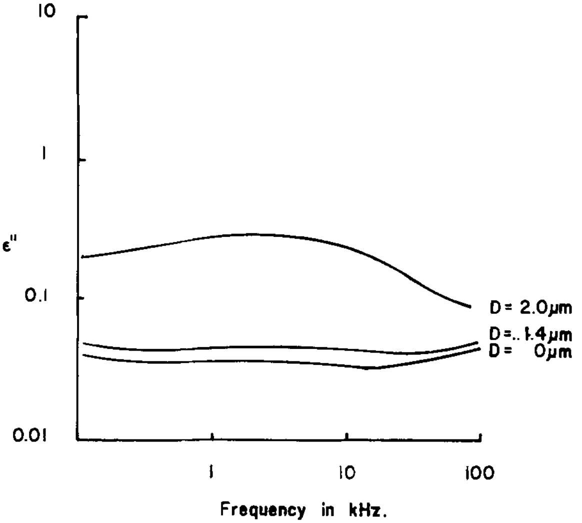

Fig. 14. The calculated log loss vs. log frequency for a polybutadiene coating on a 50Å α-Fe_2O_3 oxide. The coating is penetrated by a conducting phase of conductivity 0.047 mho-cm to various depths characterized by the penetration factor *D*.

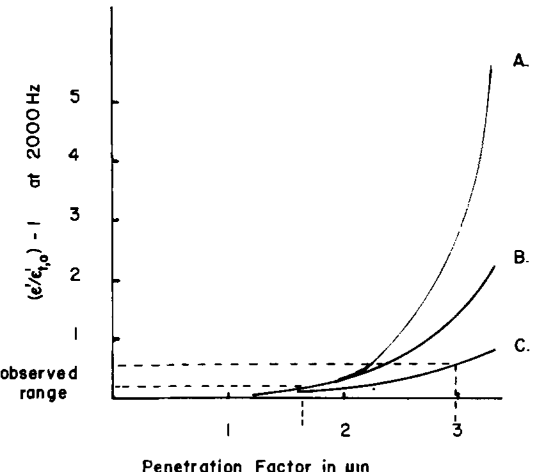

Fig. 15. The change in the complex permittivity, expressed as $([\epsilon'/\epsilon'_{t,o}] - 1)$ at 2000 Hz as a function of penetration factor for conducting phases of: A, 0.047 mho/cm; B, 0.0047 mho/cm; and C, 0.00047 mho/cm conductivities.

In this model, the loss, ϵ'', is very sensitive to the structure and nature of the oxide interface. The oxide may become either thinned or it may become more conductive. In either case, the value of log ϵ'' increases toward lower frequencies as either of these changes occur in the oxide. Figure 16 illustrates this point for the case where the oxide described by (20) is thinned, while in Fig. 17, the oxide is modified with respect to its d-c conductivity (Table V) to yield also a loss that increases at low frequency.

There are two basic stages in the development of the electrical response of the electrolyte-impregnated, coated steel. First, the coating is heterogeneously penetrated by the conducting electrolyte phase. At a statistical number of points, this phase is in contact with the metal oxide interface whose properties will largely determine the low frequency in-phase electrical response of the coating/metal oxide/substrate couple. A metal oxide that becomes conductive will result in the development of a -1 slope of the log ϵ'' *vs.* log frequency curve corresponding to an effectively short-circuited coating, while an insulating oxide will present a rather flat log ϵ'' *vs.* log f curve. In spite of the fact that there is significant uncertainty in the precise electrical nature of the metal oxide interface and the precise bulk conductivity of the conducting phase within an electrolyte treated polymer, there is qualitative agreement of typical behavior of the polymer-coated steel to that modeled by this treatment.

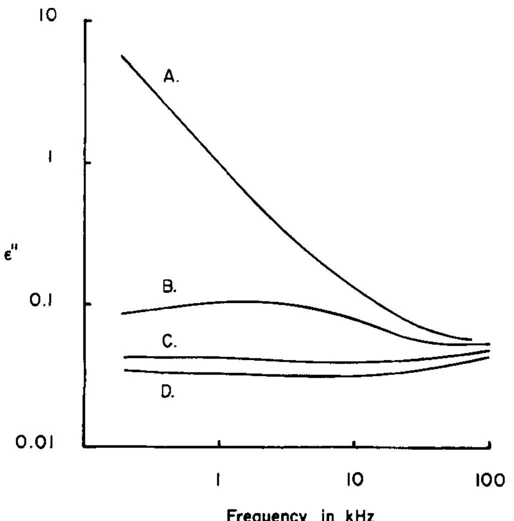

Fig. 16. Calculated log loss *vs.* log frequency for a 20 μm polybutadiene coating on a steel substrate. A, No oxide interface; penetration factor of 1.43 μm. B, Penetration factor 1.43 μm; 0.5 nm α-Fe_2O_3 (19) oxide interface. C, Penetration factor 1.43 μm; 5 nm α-Fe_2O_3 (19) oxide interface. D, No penetration of electrolyte.

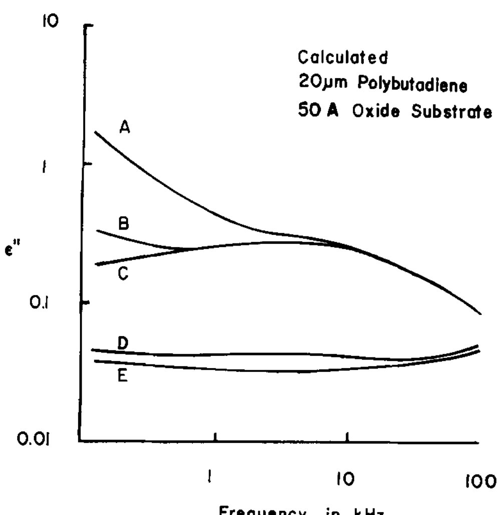

Fig. 17. Calculated complex permittivity for 20 μm polybutadiene on steel with 5 nm oxide interface. Shown is the effect of penetration of electrolyte and change in oxide properties. A, 2.00 μm penetration factor, oxide #3 (Table IV). B, 2.00 μm penetration factor, oxide #2. C, 2.00 μm ppenetration factor, oxide #1. D, 1.43 μm penetration factor, oxide #1. E, Initial, no penetration.

The model qualitatively interprets the behavior of the coating whose electrical response as a function of time is shown in Fig. 4. First, there is a frequency-independent increase of the loss as seen for the 1 day exposure. This increase corresponds to the random penetration of the conducting electrolyte phase into the polymer coating. After 14 days, penetration of the conducting electrolyte to the interface becomes apparent with the initiation of the -1 log ϵ'' *vs.* log frequency slope at low frequencies.

Relation of the Electrical Response to the Mechanism of Corrosion (22)

Initially, the electrolyte penetrates the coating and sets up conducting paths to random depths over the coating surface. The initial stages of exposure of PB45, as shown in Fig. 4, are representative of the resultant electrical response. Both the in-phase and out-of-phase permittivity increase in a similar manner more or less uniformly over the frequency range observed. Paths of complete penetration develop with time, however, which allow the electrolyte phase to meet the metal oxide interface and a corrosion cell is activated. The first visual signs of corrosion are green-gray to black spots around which regions of delamination subsequently grow. The growth of the delaminated region correlates with an increase in corrosion potential. The spots represent points of anodic attack electrochemically coupled to the oxygen depolarized cathodic delamination region. For the thicker films, the local dissolution reaction increases the conductivity of the interfacial oxide and the coating, and the -1 slope of the log ϵ'' *vs.* log frequency plot is observed.

It is to be pointed out that the cathodic half-reaction is self propagating in the sense that the alkaline products formed at the interface aid in the hydrolysis of the interface and cause further delamination. It has been observed that delamination of an externally polarized defect occurs only for cathodic currents (23).

At the point of final breakdown, the cathodic region becomes active because deterioration of the film in the presence of alkali occurs in the cathodic region. Further support for this point is found in the previous observation that increased alkalinity has an accelerating effect upon the degradation of the polybutadiene film (6).

APPENDIX

Model for Coating Impedance

The region at the base of a pore is electrically represented by the impedance Z_I, which is a series combination of the impedances of the respective polymer and oxide phases

$$Z_I = Z_{poly,I} + Z_{oxide,I} \quad [A\text{-}1]$$

Referring to Fig. A-1,

d_i = unpenetrated polymer dimension
A^1 = area of the pore
d_{ox} = oxide thickness
r_1 = d_{ox}/d_o, d_o = total polymer thickness

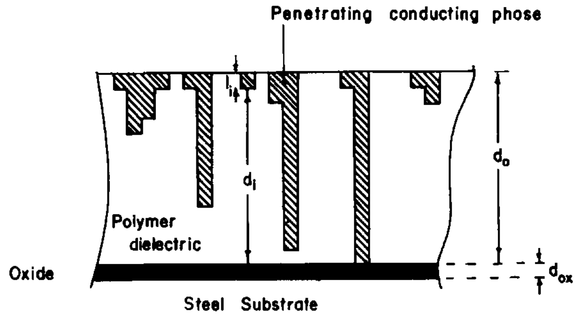

Fig. A-1. Schematic of polymer coating heterogeneously penetrated by a conducting phase.

considering the following definitions [A-2]

$\epsilon_p', \epsilon_p'' =$ bulk polymer permittivity

$\epsilon_{ox}', \epsilon_{ox}'' =$ oxide permittivity

$den = (\epsilon'')^2 + (\epsilon')^2$ of respective oxide and polymer

Z_I may be more explicitly stated

$$Z_I = \frac{d_i}{\omega A'\epsilon_o}\left(\frac{\epsilon_p''}{den(\text{poly})} + \frac{r_1\epsilon_{ox}''}{den(\text{ox})} + j\left\{\frac{\epsilon_p'}{den(\text{poly})} + r_1\frac{\epsilon_{ox}'}{den(\text{ox})}\right\}\right) \quad \text{[A-3]}$$

The impedance of the penetrating conducting phase, Z_p, is

$$Z_p = \frac{d_o - d_i}{A'\sigma^*} \quad \text{[A-4]}$$

where σ^* is the conductivity of the porous phase. Since the pore impedance is in series with that of the interface, the total impedance, Z_T, will be the sum

$$Z_T = Z_p + Z_I \quad \text{[A-5]}$$

Therefore the respective real and imaginary components of Z_T are

$$Re(Z_T) = \frac{d_i}{\omega A'\epsilon_o}\left\{\frac{d_o - d_i}{d_i}\cdot\frac{\omega\epsilon_o}{\sigma^*} + \frac{\epsilon_p''}{den(\text{p})} + r_1\frac{\epsilon_{ox}''}{den(\text{ox})}\right\}$$

$$Im(Z_T) = \frac{d_i}{\omega A'\epsilon_o}\left\{\frac{\epsilon_p'}{den(\text{p})} + r_1\frac{\epsilon_{ox}'}{den(\text{ox})}\right\} \quad \text{[A-6]}$$

Defining the complex quantity

$$Z_x = \frac{\omega A'\epsilon_o}{d_i} Z_T \quad \text{[A-7]}$$

The effective permittivity of the region having a penetration d_i is

$$\epsilon(d_i) = \frac{1}{X \cdot Z_x} \quad \text{[A-8]}$$

where $X = \dfrac{d_i}{d_o + d_{ox}} =$ unpenetrated fraction. Since the coating may be thought of as a parallel combination of such regions, the observed complex permittivity, $\epsilon_{obs.} = P(0)\epsilon(0) \sum_{i=1}^{n} P(d_i)\epsilon(d_i)$ where $P(d_i)$ is the fraction of the coating area which is conductively penetrated to within d_i of the oxide.

The total penetration term $P(0)\epsilon(0)$ must be treated separately since terms in $1/d_i$ in the above formulations are undefined. Furthermore, thinning of the oxide and delamination (effective increase in oxide area) must also be considered for $d_i = 0$.

A Model for Copper Electroplating of Multilayer Printed Wiring Boards

Thomas Kessler*,[1]

Bell Laboratories, Whippany, New Jersey 07981

and Richard Alkire*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

An analytical model is developed for predicting electroplated copper thickness distributions on multilayer printed wiring boards. Plated copper thickness distributions are predicted within a plated-through hole (PTH) by coupled solutions of the potential, kinetics, and mass diffusion equations. The model establishes: (*a*) correlation parameters including geometric, charge transfer, mass transfer, and ohmic solution effects, and (*b*) the minimum electrolyte convection required in a PTH to avoid rough or powdery deposits. Predictions are compared with experimental data obtained over a wide range of operating scales from breakers to full-scale production tanks.

The production of reliable multilayer printed wiring boards (MLB's) containing plated-through holes (PTH's) requires many carefully controlled process steps. One of the most important steps is the electroplating of copper in holes drilled through the board (PTH's) in order to provide electrical connections among the various circuit layers. MLB's are electroplated with copper in large multiple-cell tanks with cell geometries typified by the schematic in Fig. 1. The electrolyte used in these tanks is a high conductivity acid-copper sulfate bath containing proprietary organic additives. The electrolyte is stirred by air, sparging pipes being located in the bottom of the tank. The air bubbles rising from the spargers are intended to minimize electrolyte concentration gradients and provide some electrolyte convection in the PTH's.

MLB's are manufactured in panels which are physically larger than the final MLB product. Diagonally opposite corners of these panels contain test coupons which are, hopefully, representative of the MLB or MLB's closer to the center of the panel. Some of these test coupons are destructively tested to assure reliability of the MLB product in each panel. In order that the test coupons properly represent the rest of the panel, it is important to obtain uniformly plated copper throughout the panels. In addition the plated copper must be sufficiently uniform and ductile within each individual PTH to enable the PTH to withstand the strains encountered in a forty year design life. For coupons to be truly representative of panels, the copper plated in the coupon PTH's and in any PTH in the panel must have identical thickness distributions and mechanical properties.

The purpose of the investigation is to develop the analytical models to provide scaling information for predicting PTH copper thickness distributions. These models, supported by experimental data, can be used to establish necessary operating conditions for producing uniformly plated MLB's.

The characteristics of electroplated metals in plated-through holes have been determined experimentally by several authors. A brief summary of the results for electroplated copper is contained in Ref. (1). Several experiments by Dini (2) indicate the difficulty of plating into deep plated-through holes. Dini also observed that additives in a fluoborate bath refine the grain

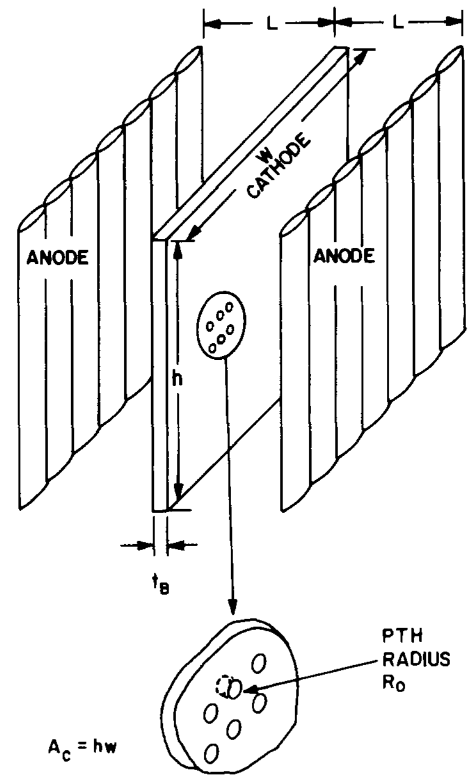

Fig. 1. Schematic of a typical MLB electroplating cell

structure in the deposit, but they do not affect the thickness distribution in the hole. An extensive set of experiments with several plating baths by Rothschild (3) have shown that the plated thickness distribution becomes more nonuniform as the ratio of the board thickness (t_B) to the hole radius (R_o) increases. For each plating bath Rothschild found the resulting plated thickness on the board surface for a specified minimum thickness in a hole to be a function only of t_B/R_o. A simple qualitative calculation by Irvine (4) has shown that some electrolyte agitation is required for satisfactory plating of through-holes. This is the only modeling, prior to the present work, that the authors are aware of regarding this problem. Saubestre and Khera (5) plated circuit boards in several copper plating baths including standard and high-throw cop-

Key words: current distribution, multilayer circuit board, mathematical model, copper deposition.

per sulfate baths with additives. Jawitz (6) has presented results for printed circuit board plating with various copper plating baths including a standard copper sulfate bath. The phenomenon of skip plating, *i.e.*, locally thin plating near the outer corner of a PTH, which sometimes occurs when plating with additives has been discussed by Luke (7). Experiments by Dini, Johnson, and Brown (8) with copper pyrophosphate solutions show that such skip plating can be eliminated by increasing either the current density or the agitation.

Several auxiliary experimental studies, not directly related to the PTH geometry, were essential to the development of the present analytical models. Rotating disk electrode kinetics experiments by Rudy (9) established that the Cubath® M and Cubath® 1 additives in use do not cause significant changes in either the copper kinetics or the diffusion coefficient of the copper ions in solution. Similar results were obtained by Turner and Johnson (10, 11) for copper sulfate solutions with several different additives; although their work shows that some additives can affect kinetics. These results are consistent with the review papers by Kardos (12-14) which discuss the effects of additives in several plating systems. In many cases, additives only affect the deposit morphology and what Kardos calls "microleveling" over small roughnesses the order of 5 mils or less in size. It is recognized that additive baths sometimes cause dishing or skip plating (thin plating) near the outer edges of the holes (8). These observed effects basically do not affect the plated copper distribution down in a smooth hole which is of primary interest here.

The theoretical model developed in the following section characterizes the region in and close to a PTH. Current distributions in this region are obtained by a solution of the coupled equations for conservation of charge and species, along with a reaction rate law. Additive effects have been neglected in this model. Details of the model and comparisons with experimental results are included in the next two sections.

Theoretical Model

Many salient features of the PTH system are similar to the tubular electrode (TE) system for which a fundamental investigation has recently been conducted (17). Figure 2 shows, in the upper portion, a schematic diagram of a single PTH; the lower portion illustrates a TE for which the analysis is available. A comparison of the two drawings indicates that the TE is geometrically similar to the PTH except insofar as the characterization of the external surface is concerned. The PTH has a sharp exterior edge at the mouth along

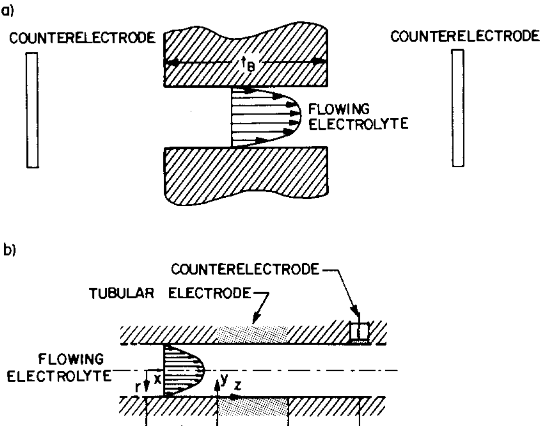

Fig. 2. Schematic diagram of a PTH and the model tubular electrode. (a) PTH, (b) tubular electrode; counterelectrode downstream.

with a cathodic conductor on the external MLB surface, whereas the TE does not. The PTH has counterelectrodes on both sides whereas the TE has but one counterelectrode. Within the TE, steady laminar flow will prevail provided that Re $<$ 2100, while the Lèvêque approximation will be valid provided that $lD_j/2\bar{v}R_o^2 << 0.01$. The hydrodynamic flow pattern in the two systems will be somewhat different owing to end effects in the PTH. However, for the particular system at hand these effects are negligible since the foregoing restrictions on flow rates correspond to the range of $0.2 < \bar{v} < 180$ cm/sec, which is the range of practical interest in the PTH problem. For plating with the acid copper system, the effect of cupric ion migration is negligible owing to the high acid concentration; the system is also characterized by a large value of the Schmidt number.

Plated copper thickness distributions in the vicinity of a PTH are complex to predict because there are many different effects which control electrode behavior. The above brief comparison of the PTH system and the TE system has shown that the two systems are similar in many ways with respect to geometric, mass transfer, hydrodynamic, and kinetic characteristics. On this basis, the TE model has been used in order to estimate behavior in the PTH system. The analysis predicts the current distribution dependence on geometry, electrolyte conductivity, charge transfer characterisics, electrolyte convection, and electrolyte composition. To be sure, a detailed comparison of TE theory with experimental data may reveal differences, but it is to be expected that the qualitative trends and intuitive feeling gained by study of the TE system will be helpful in understanding the PTH system.

The tubular electrode system, depicted in Fig. 2(b), consists of an electrode of length, l, positioned between two long cylindrical sections of insulating material. Electrolytic solution flows through the assembly in fully developed laminar flow. The counterelectrode may be either downstream, as shown, or upstream; in either case, the counterelectrode is sufficiently far away that its precise position does not affect TE behavior. At the electrode surface, the TE model (17) assumes that the rate of electrochemical reaction obeys the Butler-Volmer kinetic rate expression (24). Mass transfer limitations should they arise, are assumed to be confined to a thin shell near the tube periphery. Because concentration differences are confined near the electrode surface, two distinct regions may be identified within the electrolytic solution flowing through the electrode: (*a*) the diffusion layer region within which concentrations vary, and (*b*) the bulk region which fills the central region of the tube. The TE model employs separate equations for these two regions and develops a procedure for solving them simultaneously. Details of the mathematical treatment may be found in Ref. (17).

It is worthwhile to review the dimensionless parameters which arise from the TE analysis. There are four parameters: Φ_A, γ_o, ξ, and N. Φ_A is the dimensionless applied potential, and γ_o is the aspect ratio. The interpretation of ξ and N is more complex. The quantity

$$\xi_\kappa = \frac{2n\mathbf{F}l^2}{R_gTR_o\kappa} i_o \qquad [1]$$

is essentially the linear form of the polarization parameter in that it denotes the relative importance of ohmic to charge-transfer resistances in the linear region of polarization. Provided that mass transfer effects are absent, the value of ξ_κ indicates whether the current distribution within the TE is uniform or not. Qualitatively, values of $\xi_\kappa > 1$ indicate that the ohmic resistance is greater than the charge-transfer resistance so that the portions of the TE nearest the counter-

electrode will have a greater deposition rate than portions farther from the counterelectrode. Values of ξ_K less than unity indicate that the current distribution will be uniform along the surface. For application to the PTH system, it is more convenient to use a different form of ξ which is applicable to the Tafel (18) charge-transfer rate equation

$$\xi_{TK} = \frac{2\alpha_c \mathbf{F} l^2 \bar{j}}{R_g T R_o \kappa} \quad [2]$$

ξ_{TK} contains kinetic information about the Tafel slope whereas ξ_K contains information about the exchange current density. ξ_{TK} is also related to the dimensionless average current density in the TE

$$\beta_a = 4\xi_{TK} \quad [3]$$

Note that the only kinetic parameter contained in ξ_{TK} is α_c, the cathodic transfer coefficient, which has been shown to be independent of the presence of plating additives. $\xi_{TK} << 1$ implies that charge transfer resistance predominates and a uniform current density distribution results. $\xi_{TK} >> 1$ implies that solution ohmic resistance dominates in the hole, and nonuniform primary current distributions are expected.

The parameter N is the dimensionless average limiting current density; N also contains the ratio $D_j c_\infty/\kappa$ and thereby indicates the relative importance of concentration overpotential to ohmic overpotentials

$$N = \frac{3n^2 \mathbf{F}^2 l^2 D_j c_\infty}{s_j R_g T R_o \kappa \Gamma(4/3)} \left(\frac{2v_{max}}{9D_j R_o l} \right)^{1/3} \quad [4]$$

A large value of N indicates that the limiting current is high so that mass transfer proceeds with relative ease with respect to ohmic resistance effects. For small values of N, the concentration overpotential tends to be the largest overpotential so that limiting current behavior is approached. The lowest value which N can take on is the dimensionless average limiting current density

$$\beta_{a,lim} = N \quad [5]$$

Two additional quantities are useful; J the dimensionless current

$$J = \frac{j}{\bar{j}} \quad [6]$$

and the average current density divided by the average limiting current density

$$\frac{\bar{j}}{\bar{j}_{lim}} = \frac{\beta_a}{N} \quad [7]$$

Theoretical Results and Discussion

MLB's are typically electroplated with copper at average current densities from 26.9 to 32.2 mA/cm^2 (25-30 A/ft^2) in high-throw acid copper sulfate solutions. These solutions, which contain 0.27M $CuSO_4$, 1.76M H_2SO_4, 30 ppm of Cl^- and proprietary additives, are assumed to consist of the following major ionic concentrations: $c_j = (Cu^{+2}) = 0.27M$, $(H^+) = 1.49M$, $(HSO_4^-) = 2.03M$.

The PTH system for which calculations have been made is defined by the parameters in Table I (15, 16, 24). Two sets of calculations will be presented in order to arrive at tentative criteria by which boards may be designed to assure uniform deposits of high quality. These criteria have been tested against experimental data as discussed in subsequent sections.

In the absence of mass transfer limitations ($N = \infty$), the effect of ξ_{TK} on the TE current distribution is shown in Fig. 3. These calculations are based on a one-dimensional approximation to Laplace's equation (17). Because a PTH has counterelectrodes on both sides of the board, the current distribution will be symmetric about the centerline (that is, $l = t_B/2$). Consistent with the comments above, acceptably uniform current distributions will be obtained provided that

$$\xi_{TK} < 1 \quad [8]$$

The numbers given in parenthesis in Fig. 3 indicate the plating rates (milliampere/square centimeter) in the PTH system; it is seen that the common plating rate of 25-30 mA/cm^2 is in a crucial region where the current distribution within the holes is very sensitive to seemingly minor variations in applied current.

It is known that the acceptable morphology of copper deposits depends strongly on maintaining sufficient electrolyte agitation to insure that mass transfer effects do not arise. Therefore, the TE model has been used to estimate the importance of electrolyte convection in a PTH. For this purpose the electrolyte length l was chosen to be board thickness t_B; since the TE system has but one counterelectrode, the predicted current distributions will represent the extreme case. Figure 4 illustrates how the total overpotential within the TE varies with N (flow rate) for a given value of β_a (applied current density of 25 mA/cm^2). The quantity Φ^*_m is the potential in the solution at the mouth of the electrode nearest the counterelectrode; this quantity is a sensitive indicator of concentration overpotential. Recall that for $N = \infty$, the convection rate is so large that concentration overpotential effects are negligible. As the flow velocity is decreased, the total overpotential increases because of the onset of concentration overpotentials which arise in the electrolyte. As N approaches the lowermost limiting value of $\beta_{a,lim} = 12$,

Table I.

$c_j = 0.27 \times 10^{-3}$ g-mol/cm^3
$\kappa = 0.55$ (ohm-cm)$^{-1}$
$i_o = 10^{-3}$ A/cm^2
$R_o = 0.058$ cm (23 mils)
$t_B = 0.305$ cm (120 mils)
$D_j = 0.55 \times 10^{-5}$ cm^2/sec
$n = 2$ g-equiv./g-mol
$\nu = 1.22 \times 10^{-2}$ cm^2/sec

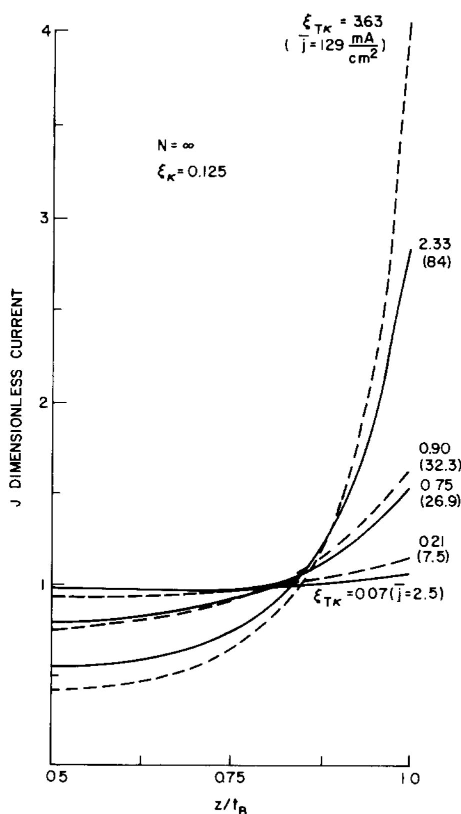

Fig. 3. Current distributions in a PTH for various ξ_{TK}

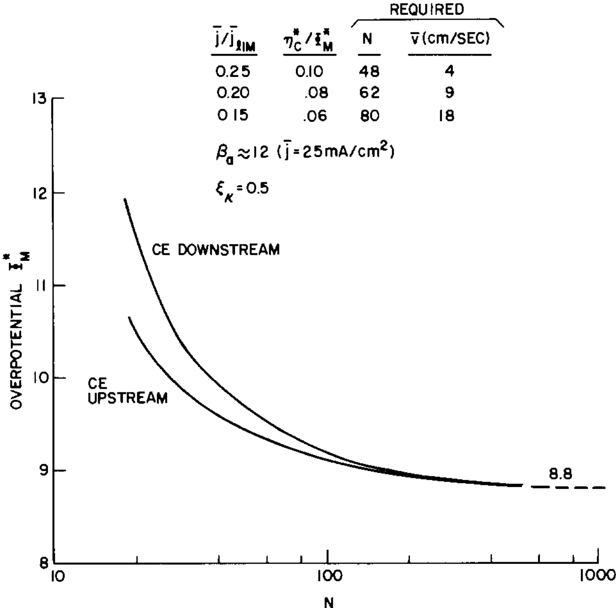

Fig. 4. Effect of average limiting current density on overpotential

the limiting current distribution is obtained and the total overpotential increases sharply. Figure 4 contains two curves, one for an upstream counterelectrode and one for a downstream counterelectrode. Although they differ slightly, it is seen that convective mass transfer does not significantly influence electrode behavior for values of N greater than 50. As indicated in the inset in Fig. 4, the concentration overpotential comprises only 10% of the total overpotential at a value of $N = 48$ (25% of the average limiting current density).

For the PTH system parameters at 30 mA/cm^2 ($\beta_{a,lim} = 14.5$), current distributions have been estimated for several values of N as shown in Fig. 5. It is seen that for $N = 14.5$, the limiting current distribution is obtained whereby upstream portions of the electrode are most reactive; for $N = \infty$, the downstream portion of the electrode, nearest the counterelectrode, is most reactive. For this particular system, the current distribution for $N = 50$ is for the most part within 20% of the current distribution for $N = \infty$. Therefore, as a rough estimate of the conditions under which concentration overpotentials are relatively uninfluential in controlling electrode behavior, one has $N > 50$ for the system at hand, or

$$N > 4\beta_{a,\,lim} \quad [9]$$

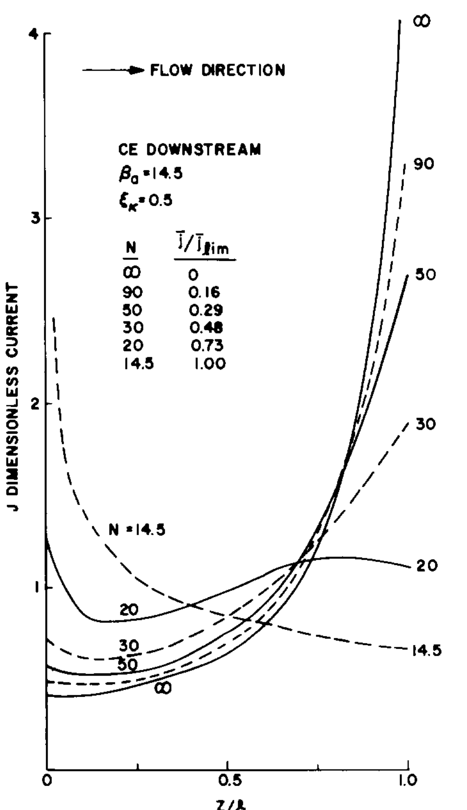

Fig. 5. Current distributions for various fractions of the limiting current density.

MLB's are typically copper plated at average currents between 25-30 mA/cm^2. It is clear from Fig. 3 that the present systems therefore operate in the critical region where the current distributions within the holes are very sensitive to seemingly minor increases in current. For example, it is known that nonuniform plating current distributions on MLB's can cause the test coupons near the outer edges of panels to receive current densities that are a factor of two to three larger than the current densities near the panel center. Therefore, the current distribution in a coupon PTH may look something like the curve labeled 78 mA/cm^2 while the PTH's near the panel center might exhibit current distributions which are similar to the curve labeled 25 mA/cm^2. The copper thickness in the coupon PTH will always be greater than in interior panel PTH's since the J in Fig. 3 is made dimensionless with the local average current density. In order that the electrodeposited copper in coupon PTH's be representative of the copper plated in the interior PTH's, one of two situations is necessary: Either (*i*) $\xi_{T\kappa} < 1$ and $N > 4\beta_a$, or (*ii*) $\xi_{T\kappa}$ and N must have constant values over the entire panel.

Comparison Between Predictions and Experimental Results

Experiments have been conducted by several investigators to determine the electroplated copper thickness distributions in and around PTH's in MLB's. In all cases, the inside of the holes and the outer copper planes received a thin coating of approximately 20 μin. of electroless copper prior to electroplating. Table II gives a summary of the experimental conditions for each investigation. Comparisons between model predictions and results from these experiments indicate that the model provides good qualitative agreement with the experiments for the wide range of conditions tested.

Effects of the $CuSO_4/H_2SO_4$ ratio on the electroplating of PTH's have been determined experimentally in a systematic study by Turner and Havens (20). The experiments were conducted in a 1500 ml beaker with air agitation provided by a sparger located under the cathode. The $CuSO_4/H_2SO_4$ ratio was varied by keeping the total concentration of $CuSO_4 \cdot 5H_2O$ and H_2SO_4

Table II. Range of parameters for PTH plating experiments

No.	Ref.	Parameters
1	20	t_B (mils) = 108 R_o (mils) = 15.5, 23, 44.5, 82 $\bar{j}$ (mA/cm^2) = 16.1, 26.9, 37.7 c_j (M) = 0.14, 0.28, 0.52, 0.8 Agitation: air sparged
2	20	t_B (mils) = 108; R_o (mils) = 23 $\bar{j}$ (mA/cm^2) = 16.1, 26.9, 53.8, 80.7, 107.6 c_j (M) = 0.27 Agitation: forced flow (24 ≤ $\bar{v}$ (cm/sec) ≤ 83)
3	21	t_B (mils) = 111, 187; R_o (mils) = 23 $\bar{j}$ (mA/cm^2) = 10.8, 14, 21.5, 43.1, 86.1 c_j (M) = 0.27 Agitation: air sparged, tranverse MLB motion, or forced flow
4	21	t_B (mils) = 93, 123; R_o (mils) = 23 $\bar{j}$ (mA/cm^2) = 5, 25, 40, 100 c_j (M) = 0.34 Agitation: forced flow $\bar{v}$ (cm/sec) = 0.16, 25, 87)
5	MLB product	t_B (mils) = 160; R_o (mils) = 23 $\bar{j}$ (mA/cm^2) = 25; c_j (M) = 0.27 Agitation: air sparged

constant at 250 g/liter. For easy comparison of results, the total number of coulombs transferred was identical for each experiment. PTH resistances were determined with a commercially available four-point probe system (Caviderm® by Unit Process Assemblies, Incorporated). Figure 6, which has been taken from Ref. (20), shows that the PTH resistances are near a minimum for typical high-throw solutions at about 70 g/liter $CuSO_4 \cdot 5H_2O$. The experimental results shown are for additive-free solutions; however, additional experiments (20) conducted with proprietary additives produced negligible changes in resistance. Turner and Havens report (20) that the high PTH resistances for high copper concentrations are caused by poor copper thickness distributions in the holes. At low copper concentrations they found that the high resistances were due to the poor quality of the plated copper in the hole. The present model supports the view that poor distributions result from large ohmic effects ($\xi_{TK} > 1$) and poor deposit quality is a consequence of inadequate mass transport ($N < 4\beta_a$). The following paragraphs outline three experimental methods which were used to establish this interpretation.

High Copper Concentrations

An explanation for the observations in Ref. (20) is found by recasting the data in terms of the dimensionless parameters defined by the foregoing model. For the moment, let us focus discussion on copper concentrations above 70 g/liter of $CuSO_4 \cdot 5H_2O$. Since the PTH resistance is inversely proportional to the hole radius R_o, it is convenient to define an equivalent PTH resistance as $\mathcal{R}_H[R_o \text{ (mils)}/23]$. A plot of equivalent PTH resistance *vs.* the parameter ξ_{TK} is shown in Fig. 7. The average PTH resistance for the center 5 holes in the flow cell experiments (20) are also included on this plot. The good correlation shown for the wide range of parameters studied confirms the utility of the parameter ξ_{TK}. Higher resistances occur for larger values of ξ_{TK} because the ohmic solution resistance in the hole is large; leading to more nonuniform current distributions in the holes.

A second useful measure of the uniformity of the plated copper in a hole is the throwing power, t_s/t_H;

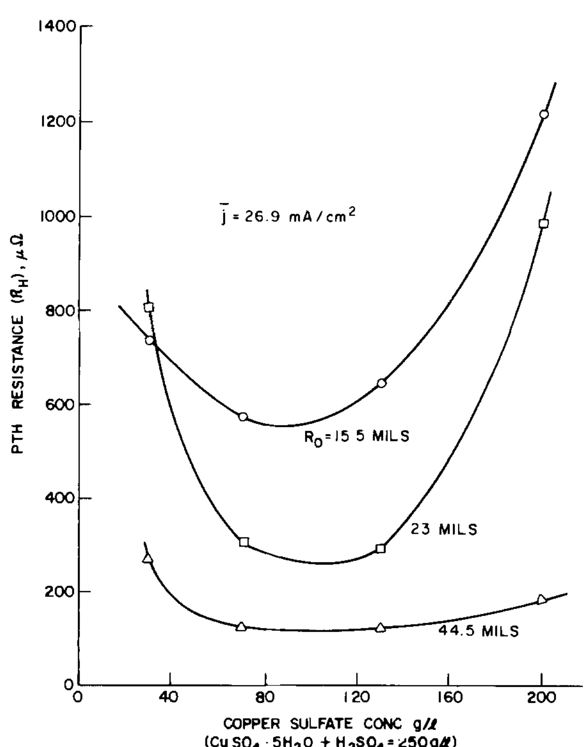

Fig. 6. Effect of copper-acid ratio on PTH resistance [Figure supplied by Turner and Havens (20)].

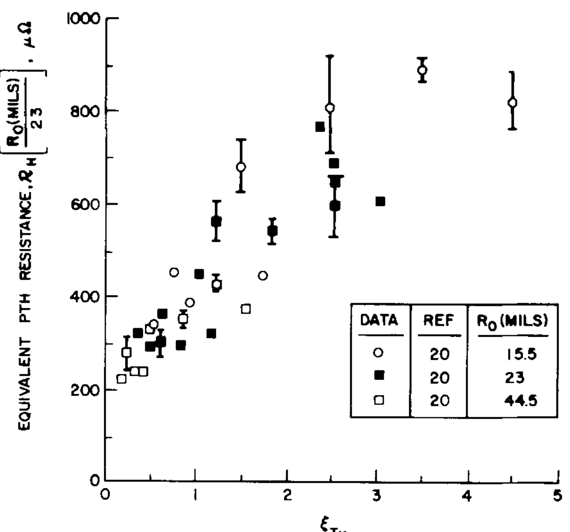

Fig. 7. Dependence of the equivalent plated-through hole resistance on the parameter ξ_{TK}.

where t_s is the plated copper thickness at the outer edge ($z = 0$ or t_B) of the hole and t_H is the plated thickness in the center ($z = t_B/2$) of the hole. This ratio has been determined from microscopic examination of PTH cross sections. A plot of the throwing power *vs.* the parameter ξ_{TK} is presented in Fig. 8. Turner and Havens (20) actually measured the plated copper thickness on the outer surface of the MLB next to the PTH; however, these thicknesses are close enough to t_s values for the purpose at hand. Note the agreement, considering the scatter in the data, among the experiments conducted at widely different scales. The data in Fig. 8 are representative of the following wide range of experimental conditions: (*i*) Experiments were conducted with and without additives. (*ii*) Experiments were conducted in full size production plating tanks, small beakers (1 and 4 liters) (20, 21) and 77 liter flow cells (21). (*iii*) Experiments were conducted with air sparger agitation, transverse agitation of the MLB's, and with forced electrolyte convection through the holes.

The predicted throwing power agrees with the data for $\xi_{TK} < 1.5$. For values of $\xi_{TK} > 1.5$, the applicability of the simplified model for the potential distribution breaks down most likely because the geometry of the PTH "mouth," where the reaction rate is largest, is not taken into account. Nevertheless, the qualitative features of the model continue to be valid even for

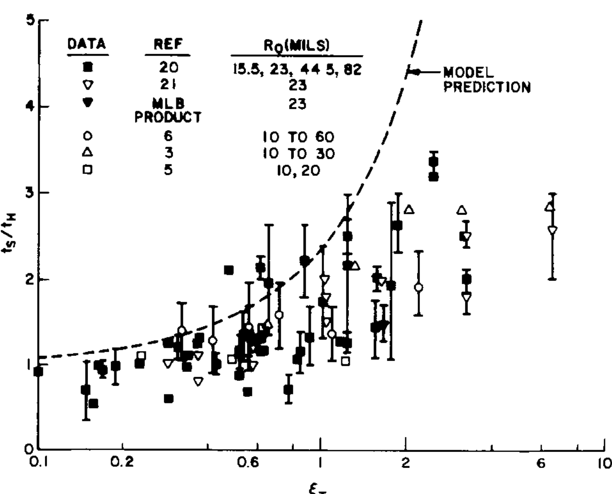

Fig. 8. Dependence of the throwing power (t_S/t_H) on the parameter ξ_{TK}.

Table III. Specific experimental conditions for the data presented in Fig. 9-13, and 15

$\xi_{T\kappa}$	Ref.	t_B (mils)	R_o (mils)	c_j (molarity)	$[H_2SO_4]$ (molarity)	Additives	$\bar{v}$ (cm/sec)	$\bar{j}$ (mA/cm²)	Plating time (min)

large values of $\xi_{T\kappa}$. The model provides a conservative estimate of conditions under which satisfactory distributions may be obtained. The data show that increasingly poor distributions are obtained as $\xi_{T\kappa}$ increases above unity. It is clearly desirable to maintain $\xi_{T\kappa} < 1$ to assure uniform copper distributions in the holes.

The correlation of throwing power with $\xi_{T\kappa}$ has important implications regarding the relevance of the copper plated in test coupon PTH's to the copper plated in the PTH's nearer to the center of the panel. The higher current densities that frequently exist near panel edges, where the coupons are located, will cause larger $\xi_{T\kappa}$ values at the coupons than near the panel centers (19). Consequently, the copper thickness distributions in coupon PTH's can be expected to be less uniform than corresponding distributions in PTH's near the panel center. For this reason, the current density throughout panels should be made more uniform, and board thicknesses and/or average current densities should be decreased to reduce $\xi_{T\kappa}$.

The third and most direct method is to compare distributions with actual copper thickness distributions determined from PTH cross sections. Such comparisons are shown in Fig. 9 through 11. It should be emphasized that the model contains no unknown parameters which may be arbitrarily adjusted to force agreement with experimental data. The agreement between predictions and the measurements (20, 21) is good for $0.57 \leq \xi_{T\kappa} < 2.48$. Details of the experimental conditions for the data used in Fig. 9 through 14 are contained in Table III. Figure 9 shows that small values of $\xi_{T\kappa}$ produce relatively uniform deposits. The experimental curves for $\xi_{T\kappa} = 0.57$ in Fig. 9 are for two different holes from a single plating experiment; these curves illustrate typical reproducibility for rough hole walls. The results in Fig. 10 show that at intermediate values of $\xi_{T\kappa}$ the distributions become nonuniform. This nonuniformity increases with $\xi_{T\kappa}$, but the agreement between measurements and predictions is still excellent. Figure 11 shows a highly nonuniform deposit distribution for $\xi_{T\kappa} = 2.48$ which is typical of large values of $\xi_{T\kappa}$. Measured thickness distributions from three separate additive-free experiments are shown to indicate experimental reproducibility. As discussed previously, the analysis is conservative in the sense that larger nonuniformities are

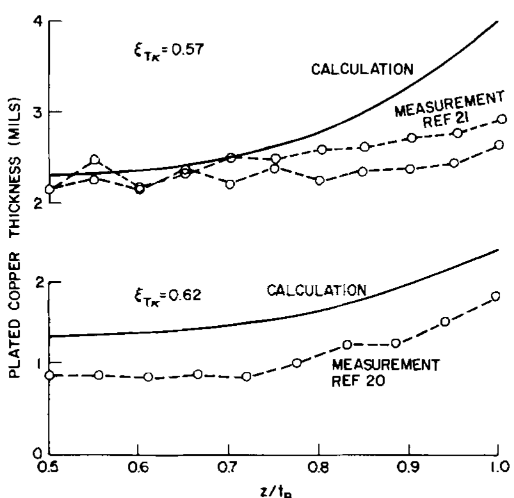

Fig. 9. Comparison between predicted copper thickness distributions in a PTH and measurements for $\xi_{T\kappa} < 1$.

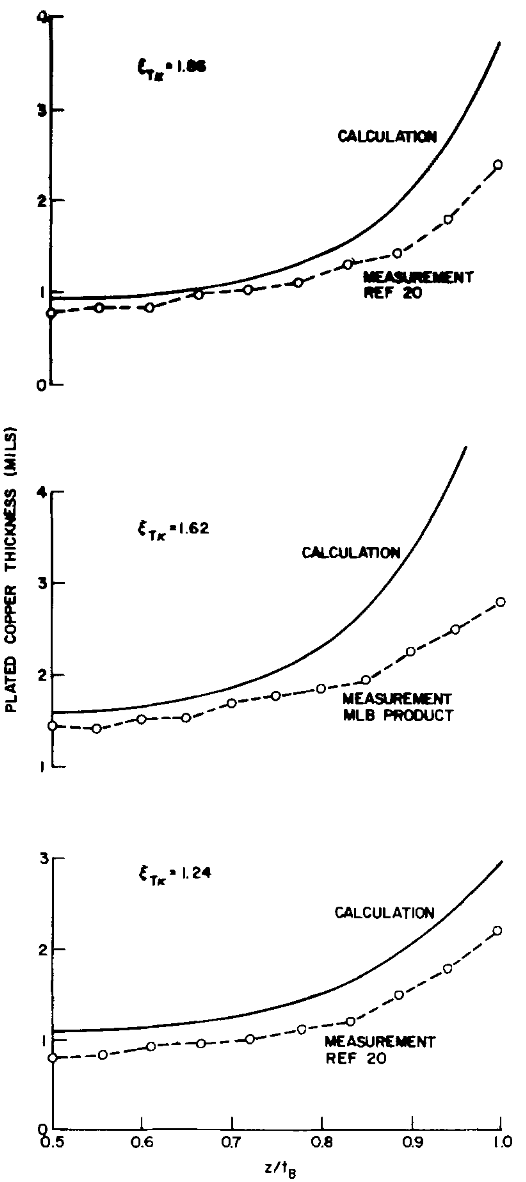

Fig. 10. Comparison between predicted copper thickness distributions in a PTH and measurements for $1 < \xi_{T\kappa} < 2$.

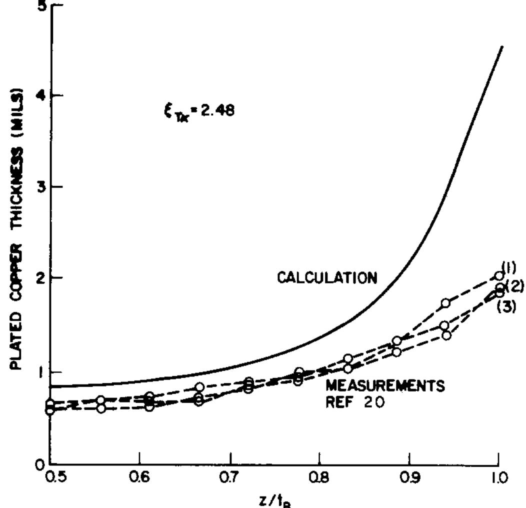

Fig. 11. Comparison between predicted copper thickness distribution in a PTH and measurements for $\xi_{TK} = 2.48$.

predicted than are found experimentally. Nevertheless, the over-all agreement between experiments and predictions confirms the salient features of the model.

The experimental results from Ref. (20) in Fig. 9 through 11 were conducted with electrolyte pumped through the seven holes in a small MLB to provide controlled and uniform agitation in the holes. The results in Fig. 11 show little difference in plated copper thickness distributions for average convection velocities in the holes from 49 to 83 cm/sec. The parameter β_a is approximately 39 for these experiments, and the calculated value of N is between 110 and 131. As shown in Fig. 4, the model predicts the observed insensitivity for values of N several times larger than β_a.

The foregoing threefold comparison of data and predictions supports the view that nonuniform deposit thickness distributions are the consequence of large ohmic effects ($\xi_{TK} > 1$). Further evidence of this is shown in the photographs of PTH cross sections in Fig. 12 and 13 for $\xi_{TK} = 0.15$ and 2.96, respectively. As can be seen in Table III, both of these PTH's were plated with the same average number of coulombs in an additive-free solution with controlled agitation in the holes (21). The symmetry of the copper thickness distributions in the holes indicates that flow direction and development effects in the holes are not important. The desirability of $\xi_{TK} < 1$ for uniform thickness distributions in PTH's is apparent.

Low Copper Concentrations

Let us now turn to a discussion of the data in Fig. 6 for low copper concentrations. Turner and Havens (20) report that the higher PTH resistances at 35 g/liter of $CuSO_4 \cdot 5H_2O$ were caused by excessively rough copper deposits in the holes. Since the electrolyte velocity in the holes was neither measured nor controlled for these air sparged experiments, the ratio of $\bar{j}/\bar{j}_{lim}$ can only be crudely estimated. Such an estimate indicates that $\bar{j}/\bar{j}_{lim}$ exceeds 0.35 for all cases where rough copper was deposited in the holes.

The importance of adequate electrolyte convection in the through-holes during plating has been established by experiments (20, 21). Figure 14 presents PTH resistance data (21) as a function of average plating current density and average electrolyte velocity in the PTH's. The error bars indicate the resistance range for at least ten PTH's plated in an additive-free bath at the conditions shown. For $\bar{j} \leq 40$ mA/cm², the resistances are insensitive to variations in solution velocity from 25 to 87 cm/sec. Nevertheless, convection effects are significant at $\bar{j} = 100$ mA/cm². For $\bar{j} = 100$

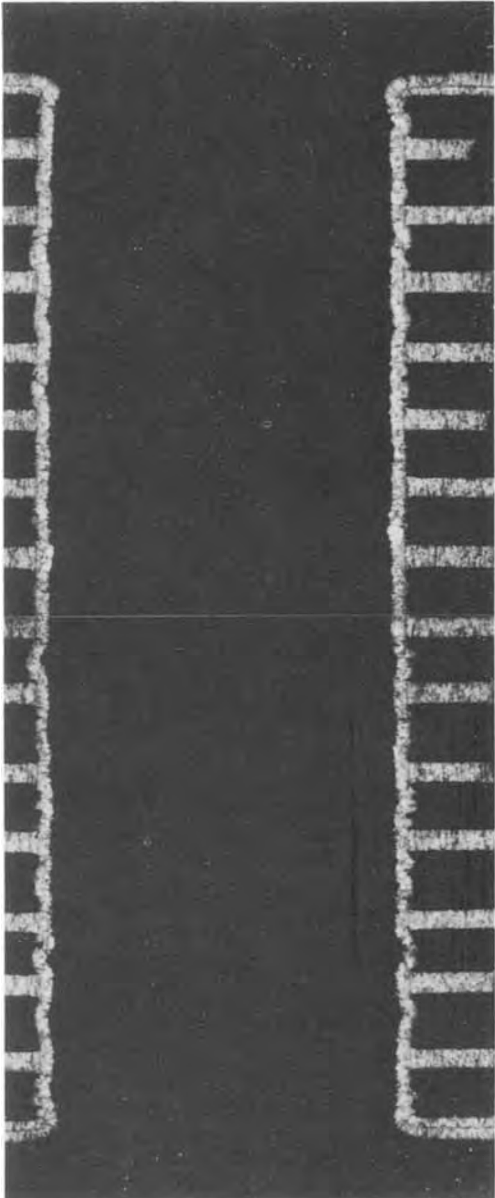

Fig. 12. Cross section of a plated-through hole in a multilayer board. Plating parameters: $\xi_{TK} = 0.15$, $\bar{v} = 87$ cm/sec, $\bar{j}/\bar{j}_{lim} = 0.015$.

mA/cm² and $\bar{v} = 87$ cm/sec, which results in a ratio $\bar{j}/\bar{j}_{lim}$ of approximately 0.28, convection is sufficient to produce good quality copper in the holes as shown in Fig. 13. However, for $\bar{v} = 25$ cm/sec, $\bar{j} = 100$ mA/cm², and $\bar{j}/\bar{j}_{lim} = 0.43$, the higher resistance in Fig. 14 is indicative of poor quality copper in the hole (or on the board surface). The cross section shown in Fig. 15 shows that the copper quality is indeed poor at these plating conditions. Similar results have been obtained with additive-free baths (20). Plating at $0.3 \leq \bar{j}/\bar{j}_{lim} \leq 0.36$ produced good quality copper, whereas plating at $\bar{j}/\bar{j}_{lim} = 0.45$ produced significantly rougher coarse grained coper. Since rough deposits are usually encountered under limiting current conditions, these data suggest that the current density $\bar{j}$ was too close to the average limiting current density $\bar{j}_{lim}$.

The observations that poor quality copper deposits for plating at $\bar{j} > 0.35\ \bar{j}_{lim}$ are also in agreement with observations in the literature (22, 23). Rotating cylindrical cathode studies by Gabe and Robinson (22) suggest that rough copper deposits may occur above $\bar{j}/\bar{j}_{lim}$

Fig. 13. Cross section of a plated-through hole in a multilayer board. Plating parameters: $\xi_{T\kappa} = 2.96$, $\bar{v} = 87$ cm/sec, $\bar{j}/\bar{j}_{lim} = 0.28$.

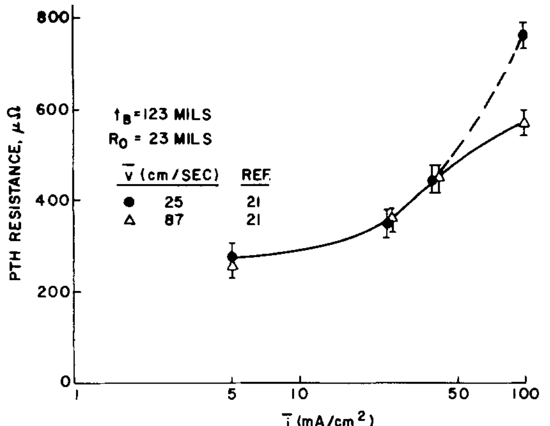

Fig. 14. Dependence of PTH resistances on average current density and convection in the PTH's.

$= 0.4$; in practice they found very rough copper above $\bar{j}/\bar{j}_{lim} = 0.7$. Measurements of deposit surface roughness from acid-sulfate baths by Ibl and Braun (23) indicate

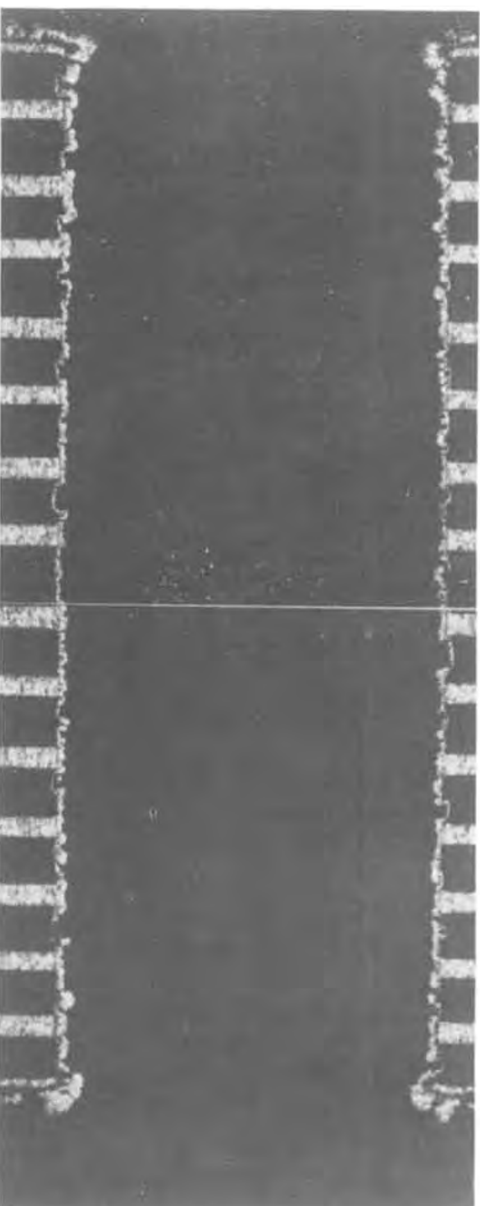

Fig. 15. Cross section of a plated-through hole in a multilayer board. Plating parameters: $\xi_{T\kappa} = 2.96$, $\bar{v} = 25$ cm/sec, $\bar{j}/\bar{j}_{lim} = 0.43$.

that rough deposits occur for $\bar{j}/\bar{j}_{lim}$ exceeding 0.7. In the plating experiments of Ref. (20) and (21), it is possible that the initiation of rough copper actually occurred because $\bar{j}/\bar{j}_{lim}$ was too large on the board surface outside of the hole. Since the convection on this outer surface is unknown, no quantitative estimates of this ratio for the outer surface are possible.

The above interpretation of the experiments in Ref. (20) and (21) may now be used to make a rational choice for the required minimum electrolyte convection in a PTH. Figure 4 has shown that the overpotential Φ^*_m asymptotically approaches a limiting value of N, but a criterion is needed for choosing a minimum acceptable value for N. Since poor plating quality has been found at values of $\bar{j}/\bar{j}_{lim}$ exceeding 0.35, a recommended maximum value for operating conditions is $\bar{j}/\bar{j}_{lim} = 0.25$. This value of $\bar{j}/\bar{j}_{lim}$ requires a minimum N value of $4\beta_a$ and implies (see Fig. 4) that η_c contributes no more than 10% of Φ^*_m. Note also that this value of N is sufficient to eliminate convective effects on copper distribution as shown in Fig. 5.

For the system at hand (Table I) where $\beta_a \simeq 12$, the requirement $N > 50$ implies a minimum average solution velocity of 4 cm/sec in the holes. Further agitation experiments are required to determine if such convection velocities exist uniformly throughout production plating tanks. To guarantee uniform copper plating on panels, the minimum convection velocity in PTH's as well as the primary current distribution across the panel must be controlled.

Summary and Conclusions

A program of experimental and theoretical studies has provided a consistent interpretation of the processes which control copper electroplating of PTH's. The studies have clarified how ohmic resistance, charge transport, cell geometry, plating additives, and mass transport effects can all contribute toward determining the electrochemical behavior during PTH deposition. Engineering design of a plating system for MLB's is complex because the relative importance of these several phenomena may vary widely from place to place along the MLB surface. The following paragraphs summarize the over-all picture which has emerged from this program of engineering analysis. The analysis provides design criteria for assuring uniform high quality plating.

The model establishes the importance of two dimensionless parameters ($\xi_{T\kappa}$ and N), which are essentially independent of additive effects, for characterizing current distribution effects in and close to a PTH. $\xi_{T\kappa}$ is shown to control the copper thickness distribution within PTH's for sufficient agitation. $\xi_{T\kappa}$ is proportional to l^2/R_o; that is, the geometrical scale-up is not l/R_o as might have been anticipated. N determines the effectiveness of the electrolyte convection in the holes. It is important to recognize that both of these parameters can be obtained without solving the equations of the model. Furthermore, only a minimum amount of theoretical calculations were needed to establish the following desirable ranges for these parameters:

1. $\xi_{T\kappa} < 1$ or else uniform $\xi_{T\kappa}$ throughout a panel. The uniformity of $\xi_{T\kappa}$ may be controlled by adjusting the cell geometry to provide a more uniform primary current distribution throughout a panel.

2. $N > 4\beta_a$. This minimum value for N is needed to assure the elimination of concentration overpotential effects on either the deposit morphology or the thickness distributions. This criterion implies a minimum average electrolyte convection of 4 cm/sec in each PTH. This minimum convection is required in all PTH's in the panel to assure that test coupons are representative of the panel interior.

For these conditions of $\xi_{T\kappa}$ and N, a test coupon from the panel edge will accurately represent the state of electrodeposition in the panel interior.

The criterion that $\bar{j}/\bar{j}_{lim}$ not exceed 0.35 should be regarded as a preliminary result. A more refined determination of this ratio, both with and without additives in the electrolyte, could be made with the use of rotating disk and/or rotating cylinder electrodes for which the current ratio can be determined precisely. In addition, at various predetermined ratios, optical observations of deposit quality could be made.

LIST OF SYMBOLS

c_j	cupric ion concentration, g-mole/cm^2
D_j	diffusion coefficient of species j, cm^2/sec
$\mathbf{F}$	Faraday's constant, 96,500 coulombs/g-equiv.
h	cathode (panel) height, cm
i_o	exchange current density, A/cm^2
j	current density, A/cm^2
$\bar{j}$	average current density, A/cm^2
j_{lim}	limiting current density, A/cm^2
$\bar{j}_{lim}$	average limiting current density, A/cm^2
J	$j/\bar{j}$ normalized local current density, dimensionless
l	length of tubular electrode, cm
l_1	distance from counterelectrode to edge of tubular electrode, cm
l_2	distance from rear edge of tubular electrode to rear plane of equipotential, cm
L	anode to cathode spacing, cm
n	number of electrons taking part in electrode reaction
N	$\frac{3n^2\mathbf{F}^2l^2D_jc_\infty}{s_jR_gTR_o\kappa\Gamma(4/3)}\left(\frac{2v_{max}}{9D_jR_ol}\right)^{1/3}$ average limiting current density, dimensionless
r	spatial variable in radial direction, cm
$\mathcal{R}$	resistance, μohm
Re	Reynolds number, $2R_o\bar{v}/\nu$
R_g	gas constant, 8.31 joules/g-mole deg
R_o	through-hole radius, cm
s_j	stoichiometric coefficient of the reaction species
Sc	Schmidt number $= \nu/D_j$
t_B	MLB panel thickness, cm
t_H	plated copper thickness at the center ($z = t_B/2$) of the hole, cm
t_s	plated copper thickness at outer edge ($z = 0$ or t_B) of hole, cm
T	temperature
v_{max}	electrolyte velocity along tube axis, cm/sec
$\bar{v}$	average electrolyte velocity in tube, cm/sec
w	cathode (panel) width, cm
x	spatial variable in axial direction, cm
y	spatial variable normal to electrode surface, cm
z	spatial variable in axial direction, cm
Z	z/l, spatial variable along electrode surface, dimensionless
α_c	cathodic transfer coefficient in reaction rate expression
β_a	average current density, Eq. [3], dimensionless
γ_o	aspect ratio: l/R_o
$\Gamma(4/3)$	Gamma function
η_c	concentration overpotential, V
η^*	$(n\mathbf{F}/R_gT)\eta$ overpotential, dimensionless
κ	electrolyte conductivity, ohm^{-1}-cm^{-1}
ν	electrolyte kinematic viscosity, cm^2/sec
ξ_κ	$2n\mathbf{F}l^2i_o/R_gTR_o\kappa$, ratio of ohmic resistance to linear charge transfer resistance, dimensionless
$\xi_{T\kappa}$	$2\alpha_c\mathbf{F}l^2\bar{j}/R_gTR_o\kappa$, ratio of ohmic resistance to Tafel charge transfer resistance dimensionless
ϕ	potential in electrolyte phase, V
ϕ_A	potential applied across cell, V
Φ^*_m	average overpotential at the mouth of the hole nearest the counterelectrode, dimensionless
Φ^*	$(n\mathbf{F}/R_gT)\phi$ potential in electrolyte phase, dimensionless

Investigations of an Electrodeposited Tin-Nickel Alloy

I. Thermal Stability by Differential Thermal Analysis and X-Ray Diffraction

J. E. Bennett and H. G. Tompkins

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

The equiatomic (65 weight per cent Sn) tin-nickel alloy, which can only be produced by electrodeposition, has found various practical applications. This plated alloy is a nonequilibrium metastable phase since the equilibrium configuration of such an alloy should be a mixture of the two compounds Ni_3Sn_2 and Ni_3Sn_4. Previous investigations have reported that the alloy decomposed at temperatures ranging from 250° to 500°C. This work was conducted to better define the transition point since it can be a deciding factor for many applications. By means of differential thermal analysis it was found on heating at a rate of 5°C/min the alloy decomposed exothermally over the range 350°-380°C with a maximum at 365°C. This was confirmed by x-ray diffraction analyses (powder and diffractometer methods) of samples heated to just below and just over the transition range. From additional isothermal heat-treatments and x-ray diffraction analyses it was concluded that caution should be taken when applications with service temperatures over 300°C are expected.

The electrodeposited equiatomic [65 weight per cent (w/o) Sn-35 w/o Ni] tin-nickel alloy[1] continues to be of considerable scientific and technological interest. A commercially usable technique for plating this equiatomic alloy was first demonstrated by Parkinson (1) and colleagues (2). Electrolytically formed binary alloys may or may not be identical in phase constitution with alloys of identical chemical composition formed by conventional metallurgical processes (3). Tin-nickel electrodeposit is a case in point as Rooksby originally found it to be a single-phase, intermetallic compound, with a NiAs-type unit cell (4). However, the published equilibrium diagram (Fig. 1) of the binary nickel-tin system, based upon metallurgically prepared alloys, shows that an alloy of equiatomic chemical composition is composed of a mixture of the two intermetallic compounds Ni_3Sn_2 and Ni_3Sn_4 (5, 6). Thus, the electrodeposited equiatomic single-phase alloy can be considered a nonequilibrium metastable phase (4). However, on the basis of their x-ray (7) and calorimetric results (8), Dutta and Clarke argue that the alloy is in fact a new compound which is a stable phase at its usual temperature of formation (70°C).

The 65/35 tin-nickel alloy plating has found various practical applications, *e.g.*, coating of automotive ignition components and pistons in thermostatic and shower mixing valves (9). It has also been recommended as a substitute, or as an underplating for gold on copper printed circuit boards (9-11). Certain fundamental characteristics of the alloy which have technological importance are its corrosion resistance or passivity, and its thermal stability. Although several studies of these properties have been conducted in the past, there is still uncertainty as to the temperature at which the alloy becomes unstable and transforms to the equilibrium phases, and as to what is the nature of the surface which leads to the exceptional passivity of this alloy. This paper reports on a study to clarify some of these matters using differential thermal analysis (DTA), x-ray diffraction, and the electron microprobe. A companion paper (12) by the authors deals with the surface passivity of the alloy.

Key words: metastable, passivity, plating.

Alloy Preparation

Material for this investigation was prepared from the plating bath formulation in Table I. The electro-

Table I. Tin-nickel plating bath composition

Stannous chloride ($SnCl_2 \cdot 2H_2O$)	20 g/liter
Nickel chloride ($NiCl_2 \cdot 6H_2O$)	250 g/liter
Ammonium bifluoride (NH_4HF_2)	40 g/liter
Ammonium hydroxide (NH_4OH)*	35 ml/liter of bath

* Utilized with HF to maintain bath at 2.5 < pH < 3.0.

lyte was continuously filtered and maintained at 72° ± 2°C. Separate anodes of 2 nickel to 1 tin were used on a common anode rail. Anodes were bagged to prevent sludge formation in the bath and the anodes were removed from the bath when not in use. Current density during plating was 0.0215 A/cm^2 (20 A/ft^2). The freshly prepared bath was initially operated using a nickel screen cathode to remove impurities from the bath. Strips of type 301 stainless steel were used as cathodes for obtaining experimental samples. By severe flexing of the plated cathodes, large flakes of the alloy plating were obtained for subsequent evaluations. The plating was analyzed with a scanning electron microscope-microprobe using pure elements as standards and found to contain 34.97 w/o Ni. An independent gravimetric analysis using dimethyl glyoxime found 34.41 w/o Ni.[2]

Background

Since this alloy should not be single phase according to the equilibrium diagram (5), it is understandable that its as-plated stability should be a matter of concern for practical applications. Several investigations (2, 4, 7, 13) have dealt with this matter. The procedure used in all these investigations has been the same, *i.e.*, isothermal heat-treatments of the alloy plating with x-ray diffraction analysis of the samples before and after treatment. In his original work (4) Rooksby stated that "up to about 350°C no appreciable change was observed but heating at 400°C for one hour in either air or vacuo was sufficient to effect substantial decomposition." It was subsequently reported by Rooksby and co-workers (2) that heat-treatments up to temperatures of about 300°C (for an unspecified length of time) produce no detectable change, but above this temperature decomposition begins and various mixtures of the normal γ'-Ni_3Sn_2 phase and the Ni_3Sn_4 phase form, depending upon the chemical composition of the electrodeposit. By heat-treating in air for 1 hr at various temperatures, Smart and Robins (13) found their deposits to be "structurally stable at temperatures up to at least 500°C but at 700°C and above decomposition into a mixture of two phases, Ni_3Sn_2 and Ni_3Sn_4, takes place." They attribute the difference in their results from those of Rooksby to differences in plating conditions. In metallographic sections they found no evidence of compound formation at the interface between plating and substrate even after heat-treatment at these elevated temperatures and suggest that this further indicates the high stability of the tin-nickel compounds. A similar lack of interaction at 50°C has been previously reported by Thwaites (14). Finally, Dutta and Clarke (7) annealed electrodeposit samples covering the composition range from 24.41 to 42.90 w/o Ni for periods of 150 hr at 250°, 300°, 350°, and 450°C. They found the appearance of additional lines in the x-ray patterns of all their alloys at all the temperatures, indicating that the alloys were unstable even at 250°C. They reported that the decomposition increased sharply above 300°C, as judged by the number of new lines which appeared.

Results

As mentioned above, all previous studies have employed heat-treatments at specific temperatures thereby permitting estimates of the temperature at which transition of the alloy plating to the stable equilibrium compounds occurs. This investigation utilized the technique of DTA which consists of recording the difference in temperature between a substance and a reference material against temperature as the two specimens are subjected to identical temperature regimes in an environment heated or cooled at a controlled rate. Thus, the temperature of the alloy plating could be monitored continuously and that temperature at which the transition to the equilibrium compounds occurs could be observed by virtue of the enthalpy or heat change associated with the reaction. The equipment used was a CSI-R. L. Stone DTA System with a palladium cell employing ring-type differential thermocouples and a monitoring thermocouple of Pt/Pt-10% Rh. Samples and reference material, pure α-Al_2O_3, were contained in small aluminum pans which fit inside the ring-type differential thermocouples. The temperature axis was calibrated using the peak points for the transitions of National Bureau of Standards DTA Standards of Sn (237°C), $KClO_4$ (309°C), and Ag_2SO_4 (433°C). A cover gas of flowing (0.075 SCFH) argon (99.999%) was used for all experiments.

In Fig. 2 are representative DTA curves for heating of the NBS calibration materials through their transition points and for heating of the alloy plating up to 460°C, at a rate of 5°C/min. Duplicate runs of plating samples exhibited the same broad exothermic peak ranging from 350°-380°C with maximum at 365°C. Exothermic effects upon heating correspond to the liberation of energy during the decomposition of energy-rich substances which are metastable at lower temperatures (14).

Further confirmation and explanation of the decomposition peak was made from x-ray diffraction analyses of the following: (*a*) as-plated material, (*b*) DTA sample heated only to 340°C, (*c*) DTA sample heated only to 390°C, (*d*) DTA sample heated to 460°C, and (*e*) sample encapsulated in an argon-filled quartz container and heated at 500°C for 1 hr in a muffle furnace. All DTA:x-ray samples were cooled rapidly from the indicated temperature by removing the furnace from around the DTA cell; x-ray sample (*e*) was cooled rapidly by withdrawing it from the muffle furnace.

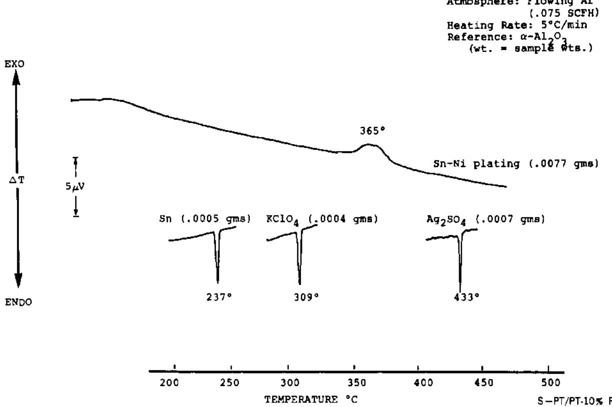

Fig. 2. DTA curves for heating of electrodeposited tin-nickel and NBS calibration materials Sn, $KClO_4$, and Ag_2SO_4.

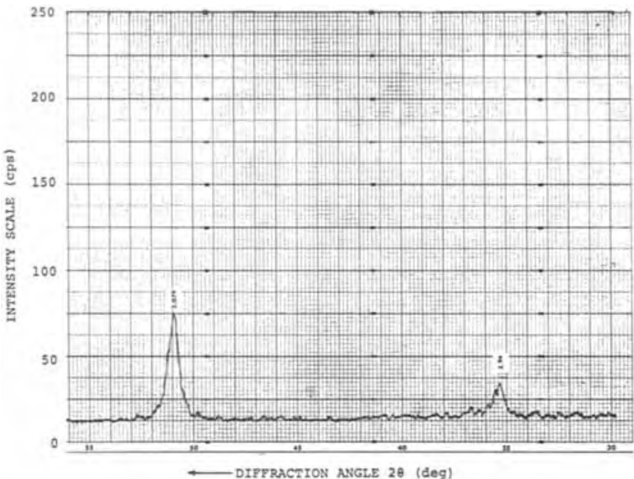

Fig. 3. X-ray diffraction pattern of electrodeposited tin-nickel flake. Filtered cobalt radiation 50 kV, 12 mA. Observed d spacings (angstroms) indicated at peaks.

The x-ray analyses were made by the Debye-Scherrer powder method and by the diffractometer method. Samples for the powder method were the actual DTA pan samples whereas those for the diffractometer were large flakes of the plating which had been placed separately in the bottom of the DTA cell and heated simultaneously with the actual DTA samples. X-ray results are listed in Table II and representative diffractometer patterns are illustrated in Fig. 3-6. Although diffractometer patterns were run from $2\theta = 30°$ to $2\theta = 100°$ for all samples, the reduced region (30°-55°) in Fig. 3-6 is sufficient to show the significant difference among the samples.

It can be seen from Fig. 3 and 4 or Table II that heating the plating to 340°C, *i.e.*, just below where the exothermic DTA peak is observed, resulted in no significant structural change. It has the same diffraction pattern as that for as-deposited plating corresponding to ASTM X-ray Diffraction File Card 7-256. However, the pattern in Fig. 5 for the sample heated to 390°C is distinctly different from Fig. 3 and confirms that the gradual exothermic reaction observed by DTA at 350°-

380°C corresponds to the transition of the metastable as-deposited structure to the equilibrium compounds Ni_3Sn_2 (ASTM Card 6-0141) and Ni_3Sn_4 (ASTM Card 4-0845). The encapsulated flake sample heated at 500°C for 1 hr yielded the pattern in Fig. 6, which is also that for the equilibrium compounds except that the peaks are sharper and better defined due to grain growth and/or more complete transformation from extended heating at a more elevated temperature.

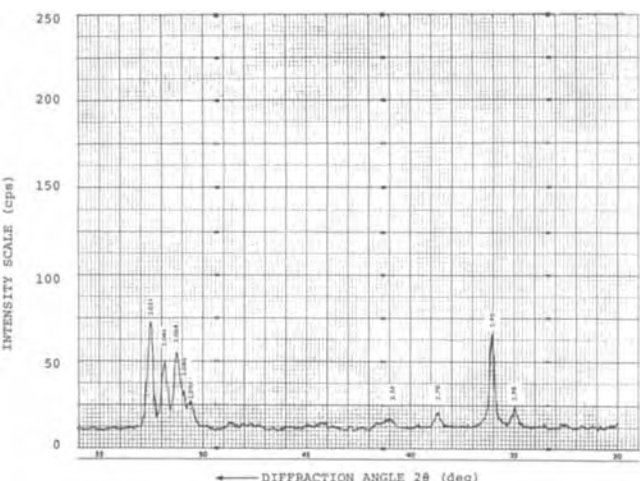

Fig. 6. X-ray diffraction pattern of electrodeposited tin-nickel flake encapsulated in quartz and heated at 500°C for 1 hr. Filtered cobalt radiation 50 kV, 12 mA. Observed d spacings (angstroms) indicated at peaks.

For further confirmation of the transition, experiments similar to those of other investigators (4, 7, 13) were also carried out. Samples of the plating were ground into powder and heated in air at various temperatures. As could be expected, a sample heated for 1 hr at 360°C was completely transformed to the equilibrium compounds. However, samples heated at 340° and 330°C for 1 hr were also completely transformed and at 320°C some faint new lines appeared. After 1 hr at 280°C or 100 hr at 200°C the pattern was still that of the as-plated alloy.

All of the results thus show that the electrodeposited tin-nickel alloy is indeed metastable. Heating at a slow rate of 5°C/min does cause the decomposition to occur at 365°C but the transition can be brought about at lower temperatures by holding for extended times. The DTA results indicate that under a constant heating rate there is a specific although broad range over which the reaction occurs. Under different heating rates this range may change in size or shift. The results from heating samples at the lower temperatures support the results of Rooksby *et al.* (2). The results of Smart and Robins (13) are in complete disagreement with those of this study and the other previous investigations. The results of this study and those of Dutta and Clarke (7) suggest that a study of the kinetics of the transition at various temperatures, particularly below 340°C, is needed. As Fig. 3-6 illustrate, appropriate heat-treatments of the plated alloy followed by x-ray analyses with the diffractometer could be used to study kinetics by following the behavior of the 2.076 line of the as-plated material since it splits into 3-5 different lines as decomposition occurs.

Summary

Electrodeposited tin-nickel alloy has been investigated with differential thermal analysis and x-ray diffraction. DTA and x-ray diffraction have shown that transformation from the metastable to the equilibrium structure for the equiatomic composition occurs as an exothermic reaction over a range of temperature centered at 365°C upon heating at a rate of 5°C/min. It has also been shown that extended heating at fixed temperatures between 300° and 365° can result in partial or complete transformation. Kinetic studies are needed for further elucidation of the transition at these lower temperatures.

From the standpoint of thermal stability, it is advisable that tin-nickel plating not be used if service temperatures are expected to exceed 300°C, for any period of time, and some caution should be taken if long periods ($>$100 hr) over 250°C are anticipated (7).

Acknowledgments

The authors wish to express their appreciation to the following individuals for their considerable assistance in this investigation: G. V. McIlhargie for preparing the alloy, D. E. Heath for microprobe and x-ray diffraction analyses, and T. M. Paskowski for differential thermal analyses. Also the encouragement and critical review of the manuscript by M. R. Pinnel and K. F. Bradford is appreciated.

Manuscript submitted Dec. 12, 1975; revised manuscript received *ca.* Feb. 1, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were partially assisted by Bell Laboratories.

Investigations of an Electrodeposited Tin-Nickel Alloy

II. Surface Passivity Studied with Auger Electron Spectroscopy

H. G. Tompkins and J. E. Bennett

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

The electrodeposited equiatomic tin-nickel alloy exhibits a strong corrosion passivity. There has been some conjecture as to why this alloy exhibits this passivity and as to the nature of the passive surface film. This work investigates the surface film which is formed in air, using Auger electron spectroscopy and depth profiling. The surface film appears to be primarily a tin-rich oxide which is several atoms thick. The passive film which forms may not depend on the metastable nature of the alloy.

The electrodeposited equiatomic [65 weight per cent (w/o) Sn-35 w/o Ni] tin-nickel alloy continues to be of considerable scientific and technological interest and has found various practical applications, *e.g.*, coating of automotive ignition components and pistons in thermostatic and shower mixing valves (1). It has also been recommended as a substitute, or as an underplating, for gold on copper printed circuit boards (1-3). Certain fundamental characteristics of the alloy which have technological importance are its corrosion resistance or passivity, and its thermal stability. Although several studies of these properties have been conducted in the past, there is still uncertainty as to the temperature at which the alloy becomes unstable and transforms to the equilibrium phases, and as to what is the nature of the surface which leads to the exceptional passivity of this alloy. A companion paper (4) deals with the thermal stability and the metastable nature of the alloy. This paper deals with the surface passivity which is studied with Auger electron spectroscopy.

Background

The alloy has found considerable use as a protective and decorative coating for less corrosion resistant materials. Such applications stem from the studies of Parkinson, Britton, and Angles (5, 6). They found that the electroplated alloy resists serious attack from many liquid and vapor reagents, including those which rapidly attack the component metals. It was suggested (6) that the exceptional corrosion resistance of the alloy was due to a protective film of oxide containing both metal components.

Clarke and Britton (7) reported that, in aqueous solutions, the alloy forms an oxide film of a special nature, that the film is remarkably stable over a wide range of *p*H and potential in the presence of many different anions, and that for solutions open to air three oxidation states of the film are observable. From electrochemical measurements of the passivation potential for the alloy, Clarke and Elbourne (8, 9) relate that it is considerably lower than those for the parent metals, which implies that the oxide formed on the alloy is more stable than either of the two lowest oxides of nickel or tin.

Key words: oxidation, metastable.

From a reassessment of the results of Clarke and coworkers, Hoar (10) concluded that the three oxidation states which had been observed correspond to three different passive films and that the films should be nickel stannite and stannates with nickel and tin in the same ratio as in the alloy.

More recently, Hoar, Talerman, and Trad (11) examined oxide films on the electrodeposited tin-nickel alloy by Auger spectroscopy where the films were formed either naturally in air or by potentiostatic anodic polarization in phosphate solutions of various *p*H values. For comparison, they chemically prepared nickel-tin hydrous oxides as precipitates from aqueous solutions. They conclude that their data strongly suggest that the oxide film which confers corrosion resistance on tin-nickel alloy is a glassy nickel polystannate containing water and hydroxyl ions This extrapolation from observations on precipitates found in aqueous solutions to the natural film is questionable. In addition, in contrast to their conclusions, their calculated atomic ratio data indicate that the natural film and one of the three films formed electrochemically have a 3 to 1 tin to nickel ratio rather than an equal amount of tin and nickel, as would be expected in a nickel stannate. Thus, their conclusion that the natural film is a glassy nickel polystannate is questionable and inconsistent with their data.

The conclusions in these and earlier studies regarding the nature of the air-formed film were reached essentially by comparison or analogy to the nature of films or precipitates formed in aqueous solutions. The investigation reported herein was intended to utilize the more recently developed Auger technique of depth profile analysis to clarify the nature of the passive air-formed film by direct measurements.

Results

The sample preparation has been described (4) previously. It is essentially a metastable alloy of equal

mole fractions of tin and nickel. The samples were made by electroplating onto a stainless steel substrate. When the substrate was then severely flexed, large flakes (1-5 mm) of the alloy were obtained for subsequent evaluations.

The Auger analysis (12) was made with a Physical Electronics Industries commercial instrument using a beam voltage of 3 kV and current of 15 μA (elliptical beam dimensions of 0.1 and 0.4 mm). Depth profiles were obtained by analyzing while sputtering with argon ions (gaussian beam with half-width of the order of 3 mm). The argon pressure during sputtering was 5×10^{-5} Torr with a titanium sublimation pump operating. A typical spectrum is shown in Fig. 1. This is the surface approximately four days after plating. The peaks observed are Sn, Ni, O, and C. Some carbon is typically seen on all samples exposed to the atmosphere for any significant length of time where the exposure occurs in an unprotected manner (dust, hydrocarbons, etc). A depth profile was then obtained and is shown in Fig. 2. The peak to peak height (dN/dE) is plotted *vs.* sputtering time. The sputtering rate (1.3 Å/min) for tin-nickel was calibrated by sputtering through a sample of known thickness. The initial rise of the Sn signal is probably due to the removal of the atmospheric carbonaceous material. The most notable part of this profile is the fact that the surface is Sn rich. After the surface region was removed exposing a new surface, the sample was exposed to the atmosphere for four days in a protected (clean) manner. A spectrum and a profile were again obtained. This surface was essentially bulk material exposed to air with all evidence of the as-plated surface removed. The profile is shown in Fig. 3 and is somewhat different from the profile in Fig. 2. (Other samples exposed for considerably less than four days showed basically the same results. This surface condition seems to be formed in less than 1 hr.)

The measured intensity profiles shown in Fig. 2 and 3 do not quite represent the actual concentrations of the various species present, for the following reason: Auger electrons escaping from the sensed volume are attenuated in an exponential manner (13). Characteristic depths of escape have been determined and published (12) and range from 4 to 50Å (the escape depth is the thickness of material which attenuates the escaping electrons by a factor of $1/e$). If the distance over which the concentration varies is large compared to the escape depth, the measured intensity profile corresponds closely to the actual concentration profile. If, on the other hand, the concentration varies significantly over distances on the order of the escape depth, the measured intensity profile must be deconvoluted to obtain the actual concentration profile. One result of this phenomenon is that a nonzero value for the peak height of nickel at the surface (time zero) in Fig. 3 does not necessarily imply nickel on the surface since the escape depth for nickel Auger electrons (840 eV) is 11Å.

Examination of both Fig. 2 and Fig. 3 shows that the tin concentration in the vicinity of the surface (the first couple of minutes of sputtering) is obviously higher than the nickel concentration.

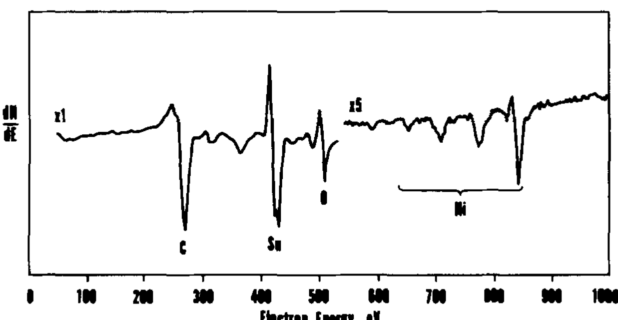

Fig. 1. Typical Auger spectrum of tin-nickel surface as-plated

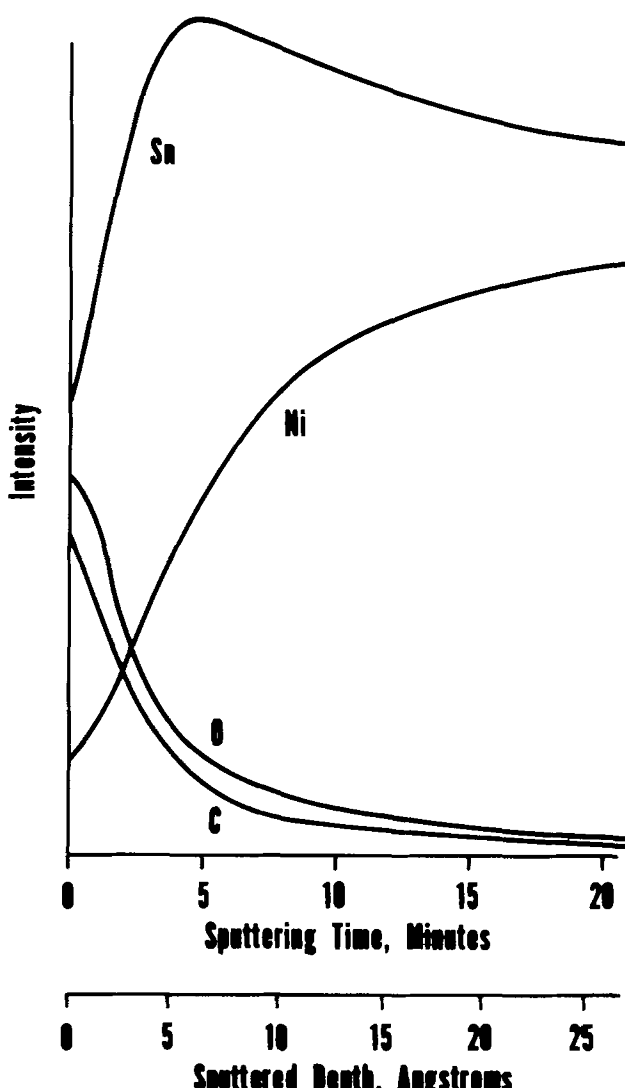

Fig. 2. Intensity profile of as-plated surface

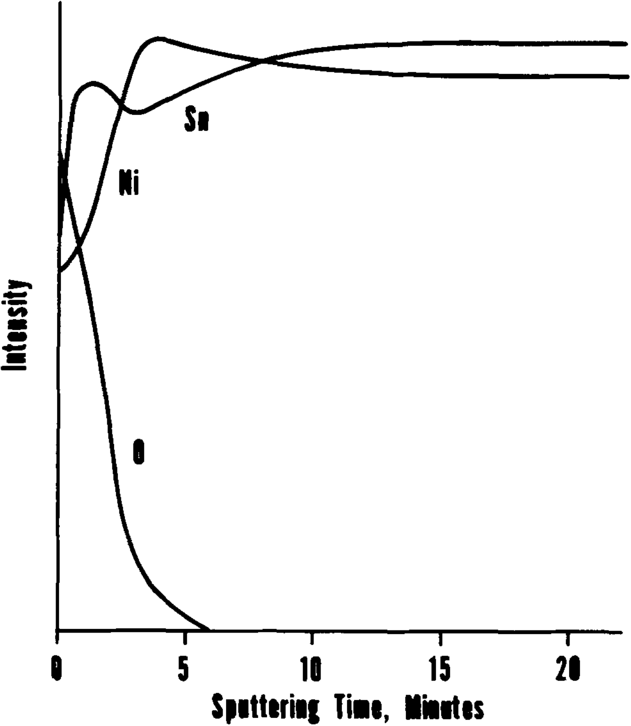

Fig. 3. Intensity profile of sputter-generated surface after oxidation.

A different method (14) of obtaining information about the homogeneity of a material and/or film thickness is by investigating the ratio of the high (840 eV) and low (60 eV) energy peaks of Ni. Electrons involved in these two transitions have escape depths of 11 and 4Å, respectively (12). The ratio of the peak heights in a homogeneous material (concentration does not vary with depth) will be different than in a layered (nonhomogenous) material where the layer thickness is of the order of the escape depths. The ratio of the low peak to the high peak for any homogeneous nickel-containing material was determined to be about 1.6 on the instrument used. The homogeneous material used for this determination was pure nickel. This ratio measured from a spectrum taken immediately prior to obtaining the profile in Fig. 3 was about 0.8, indicating that the low energy peak (with escape depth 4Å) was attenuated more than the high energy peak (with escape depth 11Å). This indicates a deficit of nickel at and near the surface. Using an exponential attenuation factor, it was calculated that a 4Å film of tin oxide (or anything else not containing nickel) would give the observed change in the ratio. The expression used is

$$\frac{I_l}{I_h} = \left.\frac{I_l}{I_h}\right]_H \frac{e^{-t/4}}{e^{-t/11}}$$

where I_l/I_h is the ratio of the low and high energy peak heights, the "H" refers to a homogeneous material, and t is the thickness of the film. This calculation, of course, assumes no tin in the film and cannot be used to conclude that there is no tin in the film. The 4Å value calculated in this manner is, however, consistent with the changes in the profile in Fig. 3. Most of the changes occur in the first 4 min (or 5Å since the sputtering rate is 1.3 Å/min).

Since the size of a tin atom is about 3Å, we clearly are dealing with one or two atomic layers. The film is, however, different from simply a chemisorbed layer of oxygen since the tin is extracted from the tin-nickel to form a layer of oxide on top of the tin-nickel. It must be kept in mind that AES cannot detect hydrogen so the layer may be a hydroxide rather than an oxide. It is clear, however, that the surface layer contains significantly more tin and oxygen than nickel and it appears to be on the order of 4Å thick.

Figure 2 was obtained from the as-plated surface. Using the calibrated sputtering rate, a distance axis has been added to Fig. 2. There is a tin-rich surface, oxygen which appears to extend deeper in the sample than in Fig. 3, and nickel which appears to rise gradually rather than abruptly to its bulk values. One significant difference in the profiles shown in Fig. 2 and 3 is the presence of carbon in Fig. 2. Some sputtering time is required to remove the carbonaceous material and if there is a range of thickness (*i.e.*, part of the carbonaceous material is thicker than another part), the thin underlying layer will not all be exposed at the same time. Features on a profile which would be sharp if there were no carbonaceous material will tend to be smeared out when the thin layer is covered with a carbonaceous material with a range of thicknesses. This might be one of the reasons that the profiles are different in the two figures. The possibilities are that there is either (*i*) a phase which contains tin, nickel, and oxygen, (*ii*) grains of tin oxide along with grains of tin-nickel, or (*iii*) a tin oxide film on top of tin-nickel.

Thus, in this work, methods not previously applied to the tin-nickel system were used to obtain additional information about the nature of the passive film. When the previously proposed model (7-11) is examined in light of the new data, it becomes clear that that model, of equal amounts of tin and nickel in the film, is contradictory to these results. There are, however, several models all involving a tin-rich oxide which are consistent with these data. The least complex of these is a simple tin oxide containing no nickel.

A sample annealed at 500°C for 1 hr in argon was analyzed in the same way as the previously described samples. The initial profile obtained after annealing was identical with Fig. 2. The sputtered surface was then oxidized as described previously (exposed to air for 4 days at room temperature) and the resulting profile was identical to Fig. 3. It would appear that the initial surface film does not significantly change or deteriorate with such treatment even though the alloy undergoes a transition from the metastable form to a mixture of the equilibrium compounds (4). By comparing oxidation behavior of freshly sputtered surfaces, it can be seen that the oxide formed on the as-plated material and on the annealed material is essentially the same. This suggests that the transformed material may be as passive in air as the metastable material and that the passivity of the as-plated alloy may depend not on its metastable nature but primarily on the presence of the two elements.

The true test of this possibility will be the comparison of passive films on Ni_3Sn_2, on Ni_3Sn_4, and on the metastable alloy described herein. These investigations are in progress. It should be emphasized that these studies deal with the air-formed film and do not deal with corrosion in aqueous solutions.

Summary

The passive film formed in air on the electrodeposited tin-nickel alloy has been investigated with Auger electron spectroscopy, and a concentration profile of the surface layer which is responsible for the alloy passivity has been displayed. An approximate thickness of the passive film was determined (approximately 4Å) and it was shown that the nickel content of the film is significantly less than the tin content. Previous investigators have proposed that the film is a nickel stannate of some kind. Their model seems to be based on analogy rather than observation and on the assumption that the film formed on an alloy "must contain the different metal cations in the same proportion as they exist in the metal" (9). Surface segregation (15-17) and selective reaction (17-18) have been shown to occur frequently, however. It has been proposed that components which segregate to the surface are those which are more readily oxidized (19). Observation in this work that the surface of electroplated tin-nickel is enriched in tin is consistent with that proposal since tin is more readily oxidized than nickel as can be seen from free energy/temperature diagrams for oxides (20). Thus it is concluded that the passivating film forms via a selective reaction with the oxygen in the atmosphere to form an oxide. The previous model (7-11) of equal amounts of tin and nickel in the film is contradicted by the results of the present work. There are several models, all involving a tin-rich oxide, which are consistent with these results. The least complex of these is a simple tin oxide containing no nickel.

The passive film which forms in air on the metastable plated material was found to be essentially unchanged after heating the alloy in argon at 500°C to produce the equilibrium structure. It was also found that the film formed on this equilibrium structure by oxidation after sputter cleaning was the same as that formed on a sputter-generated surface of the metastable alloy. This would suggest that from a corrosion standpoint the alloy could be used to at least 500°C. However, the metastable structure was shown (4) to have definitely transformed by 365°C with DTA; since the alloy could have concomitant changes in physical, chemical, mechanical, and electrical properties it is advisable that such possibilities be recognized when the alloy is used.

Acknowledgments

The authors wish to express their appreciation to the following individuals for their considerable assistance in this investigation. G. V. McIlhargie for preparing the alloy, and R. Schroeder for Auger analyses. Also, the encouragement and critical review of the manu-

script by M. R. Pinnel and K. F. Bradford is appreciated.

Conductivity and Other Transport Parameters in Ammonium Citrate Gold Baths

B. Miller* and S. Menezes Affonso

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Specific conductivity and the transport parameters of solution kinematic viscosity and gold species diffusion coefficient have been measured in ammonium citrate-potassium gold cyanide systems over the temperature range 25°-70°C. Diffusion coefficients were derived from rotating disk electrode limiting current results with lead ion catalysis of gold reduction. The dissociation constant of $HAu(CN)_2$ was also measured and found to be greater than 10^{-1}.

To support studies of the mechanistic and throwing properties of commonly applied gold plating systems, conductivity and transport parameters of some citrate baths and component solutions have been measured over the range 25°-70°C. Specific conductivity (κ) and kinematic viscosity (ν) were determined directly and diffusion coefficients (D) were calculated from rotating disk electrode (RDE) limiting current data. Schmidt numbers, $Sc = \nu/D$, are also given.

In addition, the dissociation constant, K_a, of $HAu(CN)_2$ was investigated with pH and conductometric analyses. The value of this pK_a is necessary to interpret the behavior of acid gold baths, and we have found the literature value underestimates the strength of the acid by several orders of magnitude.

Theoretical

The limiting current to an electrode of area A for the n-electron deposition of a species of bulk concentration C is written from a Nernst layer model as

$$i_D = n\mathbf{F}ADC/\delta \quad [1]$$

with δ the diffusion layer thickness. For the convective-diffusion limiting current at a disk rotating at speed ω, Levich's equation [1] for δ yields

$$i_D = 0.62n\mathbf{F}ACD^{2/3}\nu^{-1/6}\omega^{1/2} \quad [2]$$

This is numerically accurate to about 3% for $Sc = 1000$. A more exact analytical expression for i_D as $f(Sc)$ has been written by Newman (2). A convenient form for calculating D from the Newman computations and the experimental data for i_D and ν is given by Bruckenstein (3) as

$$D = \nu[(J^{-1} - 0.122939)^{1/2} - 0.1490]^{-3} \quad [3]$$

where

$$J^{-1} = \frac{0.62048n\mathbf{F}A(\omega\nu)^{1/2}C}{i_D} = \frac{K_L n(\omega\nu)^{1/2}C}{i_D} \quad [4]$$

Equations [3] and [4] have been used to obtain D values in this work.

However, this use of the Levich equation presumes that sufficiently concentrated additional electrolyte is present to suppress ionic migration contributions to transport of the electroactive species so that the measured limiting current, i_L, is equal to i_D. Another means of describing this "supporting electrolyte" case is to say that the transport number (fraction of the current carried) of the electroactive species (gold entity) is zero. This will, of course, also be accomplished if the transported electroactive species is neutral and carries no charge, e.g., $HAu(CN)_2$.

Supporting electrolyte conditions are usually achieved in typical "strike" gold baths, exemplified by solution VI below where $C_{KAu(CN)_2} = 0.0045M$ and $C_{(NH_4)_2H\,Citrate} = 0.22M$, nearly a fiftyfold concentra-

* Electrochemical Society Active Member.

Key words: rotating disk electrodes, diffusion coefficients, kinematic viscosity, plating.

tion ratio. However, ionic migration possibilities must be considered in the typical formulation with $C_{KAu(CN)_2} = 0.07M$ in the same citrate electrolyte, a concentration ratio of only about 3.

The calculation of such migration effects is much more complex (4, 5) than the classical models (6) indicate. In simplest form, these latter suggest that the contributions are separable and that the transport of an anion (as $Au(CN)_2^-$) to a cathode against the field reduces the limiting current, i_L, ratio to the pure convective diffusion value, i_D, by

$$\frac{i_L}{i_D} = \frac{1}{1 + t_-} \quad [5]$$

where t_- is the transport number of $Au(CN)_2^-$. Newman (4) has shown that a simultaneous solution considering transport by all means, diffusion, convection, and migration, is necessary in the general case. The resulting differential equations require that the products of the reaction and their charge must also be considered so that the ionic conductivities of all species are needed.

In citrate gold baths a further complication exists in identifying the migrating gold species. Maja (7), from the pH of $KAu(CN)_2$ solutions, obtained a K_a for

$$HAu(CN)_2 \rightarrow H^+ + Au(CN)_2^- \quad [6]$$

of $\cong 10^{-5}$. Since the pH of citrate baths is about 5, a pK_a of 5 suggests that comparable amounts of charged and neutral gold species exist. The determination of this pK_a and an estimate of the t_- of $Au(CN)_2^-$ are necessary for qualitatively assessing the contribution of migration and thus the significance of the apparent D value, when calculated from the Levich equation with its assumption of convective diffusion.

Experimental

Kinematic viscosity and conductivity vessel temperatures were controlled to ±0.1°C in a water thermostated bath. RDE limiting current data were obtained with a jacketed cell and circulation from the same bath.

The following solutions were prepared with triply distilled water and reagent grade chemicals, and will be identified below by number:

I. 20 g/liter $KAu(CN)_2$
II. 50 g/liter $(NH_4)_2SO_4$
III. 50 g/liter $(NH_4)_2HC_6H_5O_7$, diammonium citrate
IV. 20 g/liter $KAu(CN)_2$ + 50 g/liter $(NH_4)_2HC_6H_5O_7$ + 1 ppm Pb
V. 20 g/liter $KAu(CN)_2$ + 50 g/liter $(NH_4)_2HC_6H_5O_7$ + 50 g/liter $(NH_4)_2SO_4$ + 1 ppm Pb
VI. 1.3 g/liter $KAu(CN)_2$ + 50 g/liter $(NH_4)_2HC_6H_5O_7$ + 1 ppm Pb

In solutions IV, V, and VI the final concentration of 1 ppm Pb was obtained by the addition of a stock solution of Pb as PbO dissolved in the lead-free electrolyte of the final composition.

Kinematic viscosity, ν.—A Cannon-Fenske viscometer of size 25 calibrated against water over the temperature range of 25°-70°C was employed for kinematic viscosity measurements. The viscometer constant of 1.871×10^{-2} centistokes/sec was found to be independent of temperature over the range investigated. It is assumed for both ν and κ that the 1 ppm of Pb contained in solutions III, IV, and V does not affect these quantities.

Conductivity, κ.—A Beckman Conductivity Bridge RC-19 (accuracy ±0.25%) and Beckman H-100 cell were used. The cell was calibrated with 0.0100_0M KCl over the range of 15°-30°C for which detailed conductance data were available (8), and the cell constant of $100._0$ cm^{-1} did not vary outside the accuracy of the bridge. Hence it was assumed constant over the full range (to 70°C) investigated, as claimed by the manufacturer.

Limiting current, i_L, and diffusion coefficient, D.—The electrode was a gold disk of 0.061_5 cm^2 area in an epoxy insulated mantle. The cell (9), motor (10), and circuitry (11) have been described earlier. Limiting currents were obtained for the RDE from recorded current-potential curves with linear potential scans.

Solutions IV, V, and VI, which all contain 1 ppm Pb, were studied in this manner. The catalytic behavior of lead toward this deposition, discovered by Reinheimer (12), makes it generally possible to obtain a limiting current region for all solutions and temperatures. Without added Pb the current-potential curves vary in appearance from being virtually indistinguishable from the pure citrate electrolyte (blank) trace to exhibiting well-defined steps for gold reduction. Studies of this current-potential behavior are described elsewhere (13). The curves in 1 ppm Pb(II) containing solution have variable shapes and inflections before the limiting current is reached. These are partly due to the fact that the Pb(II) catalysis is time and coverage dependent. The region of limiting current may be poorly resolved from the supporting electrolyte reaction and be highly sloped. Thus a graphic procedure was followed to determine the limiting current. This consisted of simply extrapolating tangents to the current-potential plot from beyond the limiting current and at the upper part of the pre-limiting current region and taking their point of intersection as the limiting current estimate for that value of $\omega^{1/2}$.

The graphic method biases the current towards higher values. To compensate for this and other systematic errors, such as area uncertainties for the small disk [D depends on (disk radius)^3], the value of K_L in Eq. [4] was calibrated with $i_L - \omega^{1/2}$ data for ferrocyanide ion, employing a similar graphic technique. For these purposes 4.00 mM $K_4Fe(CN)_6$ in 1M KCl was run at 25°C, applying the accepted value (15) of $D_{Fe(CN)_6^{-4}} = 6.32 \times 10^{-6}$ cm^2/sec and solving Eq. [3] and [4] for K_L. Solution VI, for which Cheh (14) found $D = 1.67 \times 10^{-5}$ cm^2/sec at 60°C for the gold species in lead-free solutions by weighing a RDE deposit obtained at $i > i_D$, was run for comparison. This solution gives no definable current step in the Pb-free version.

Solution volumes of 150 ml maintained under nitrogen were employed. The electrode surface was repolished for each of the scans from which limiting current data were obtained, and at least two scans were used at each temperature. Scan rates of 10 mV/sec were employed and the rotation speed range of 400-6400 rpm was covered, where feasible. Lower ranges, such as 400-1600 rpm, were used whenever the catalyzed waves became insufficiently separated from supporting electrolyte reduction reactions at the higher currents (speeds) to apply the graphic technique.

Results and Discussion

Kinematic viscosity data for solutions III, IV, and V at five temperatures are given in Table I and plotted logarithmically *vs.* reciprocal temperature in Fig. 1. The values for solutions III and IV are very similar and

in fact show a small decrease in ν with the added $KAu(CN)_2$. When expressed as the $\nu^{-1/6}$ factor in the Levich equation, the change in kinematic viscosity from the addition of 20 g/liter $KAu(CN)_2$ to the citrate electrolyte amounts to only a maximum of 0.2% at 25°C and <0.1% at 70°C in RDE limiting currents. The increase in ν produced by the addition of 50 g/liter $(NH_4)_2SO_4$ (solution V) to the standard gold bath IV corresponds to approximately a 1% decrease in limiting current at a RDE over this temperature range. The activation energy calculated from the linear log ν *vs.* reciprocal temperature plot is 3-3.5 kcal and the corresponding variation of $\nu^{-1/6}$ from 25°-75°C is less than 14% for any of the solutions measured.

The conductivity results for solutions I-V are given in Table II and are plotted as log κ *vs.* reciprocal temperature in Fig. 2. Some numerical relationships can be gained by considering the κ values at one temperature, *e.g.*, 60°C, a normal operating level for gold baths such as IV and V. Taking the κ value for solution I as unity, the normalized figures from Table II are

	I	II	III	IV	V
κ	1	8.08	4.30	5.00	11.3

Pure additivity of components implies $\kappa_I + \kappa_{III} = \kappa_{IV}$ (found 5.30 and 5.00), $\kappa_I + \kappa_{II} + \kappa_{III} = \kappa_V$ (found 13.38 and 11.3), and $\kappa_{II} + \kappa_{IV} = \kappa_V$ (found 13.08 and 11.3). None of these comparisons contraverts usual concentration effects on equivalent conductivity. Addition of the conductivity salt, $(NH_4)_2SO_4$, more than doubles the bath conductivity at all temperatures.

The ratio κ_{III}/κ_I is 4.3 and, with an assumption that $Au(CN)_2^-$ is the gold species and that this anion and K^+ are equally mobile, t_- for $Au(CN)_2^-$ in bath IV can be approximated by 0.5/5.3 or 0.09. In the higher conductivity bath V, a comparable estimate of t_- is 0.04. If the electrode reaction is written as

$$Au(CN)_2^- + e = Au + 2CN^- \quad [7]$$

it resembles a redox reaction such as $Fe(CN)_6^{-3} + e = Fe(CN)_6^{-4}$ with anion reactants and products in the sense of ionic migration effects. The ferri-ferrocyanide reduction appears to be the only such anion reduction for which i_L/i_D values as a function of an added electrolyte (with one common ion) have been theoretically calculated (4). In the extreme case, pure $K_3Fe(CN)_6$ (no added salt), the minimum value of $i_L/i_D = 0.87$. In an equimolar $K_4Fe(CN)_6 - K_3Fe(CN)_6$ solution, doubling the K^+ concentration (with KOH) suffices to increase the i_L/i_D ratio to 0.97 from the zero added electrolyte ratio of 0.94.

These values suggest that, with the t_- estimates for the gold baths IV and V, the decrease in the limiting current due to transport against the electric field (anion reduction at a cathode) is at most a few per cent in IV and negligible in V.[1] Any effect of $i_L < i_D$ is amplified by the $i_D^{3/2} \propto D$ relation in calculating diffusion coefficients. However, from the experimental values of i_L that follow, other effects of the addition of the $(NH_4)_2SO_4$ apparently dominate any tendency for i_L to increase with electrolyte concentration. The D values calculated from the Levich equation with Sc corrections ought to be reasonable estimates of this parameter for the gold species in these baths even where the supporting electrolyte case is less than ideal.

The determination of D for the 4 mM ferrocyanide in 1M KCl solution at 25°C by the graphic method, gave a value of 7.67×10^{-6} cm²/sec. Von Stackelberg *et al.* (15) obtained 6.32×10^{-6} cm²/sec. As noted, the ratio of these values calibrates the system K_L to reduce graphic bias and the effect of other errors, *e.g.*, in area measurement at the 0.06 cm² level. A $\pm 3\%$ error in D corresponds to $\pm 14\mu$ error in disk radius. Since the kinematic viscosities of solutions III and IV were nearly identical, their average value was used for D and S_c calculations for solution VI.[2] Applying the calibrated K_L, the value then obtained for D at 60°C in solution VI was 1.72×10^{-5} cm²/sec, in good agreement with Cheh's value (14) of 1.67×10^{-5} cm²/sec for a weighed deposit.

Log plots of $i_L/AC\omega^{1/2}$ and of D and S_c *vs.* reciprocal temperature, are given in Fig. 3 and 4, respectively. The D values and S_c numbers are summarized in

Table II. Specific conductivity in ohm^{-1} cm^{-1} as a function of temperature

T°C	Solution I	II	III	IV	V
25	0.00744	0.0623	0.0316	0.0370	0.0857
35	0.00896	0.0740	0.0382	0.0445	0.103

[1] A reviewer has calculated the decrease, from Newman's theory, to be 0.8% in IV, the more sensitive case.

[2] The value used for ν at 60°C is within 1% of that measured directly by Cheh (14).

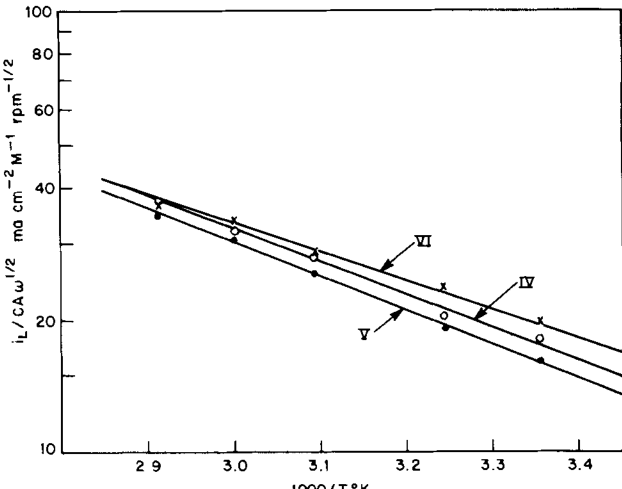

Fig. 3. $i_L/CA\omega^{1/2}$ plotted on log scale vs. reciprocal absolute temperature. Solutions as indicated.

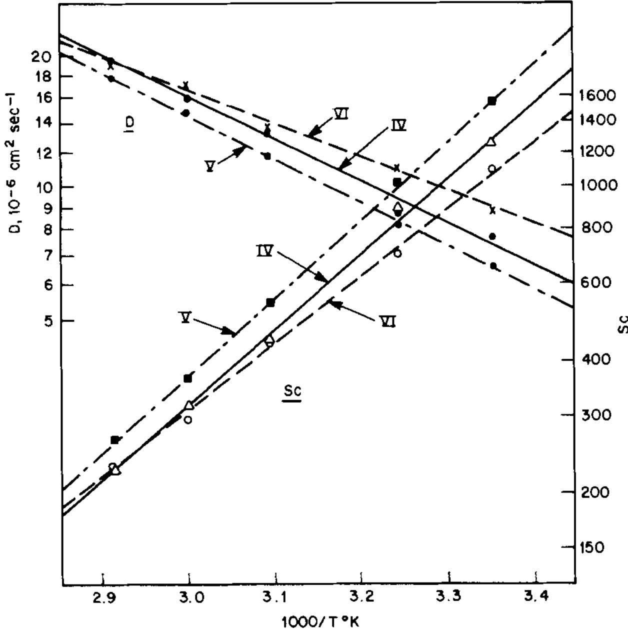

Fig. 4. Calculated D and S_c from Tables III and IV plotted on log scale vs. reciprocal absolute temperature.

Tables III and IV, respectively. The apparent activation energy for diffusion is 4 ± 1 kcal for gold baths IV, V, and VI.

The approximate additivities of the conductivity data above are not inconsistent with the pK_a of 5 for $HAu(CN)_2$ given by Maja (7). For example, the alternatives

$$Au(CN)_2^- + HCit^= \rightarrow \text{no reaction} \quad [8]$$

or

$$Au(CN)_2^- + HCit^= \rightarrow HAu(CN)_2 + Cit^{\equiv} \quad [9]$$

probably would not produce easily detectable conductivity differences. Accordingly, to establish the pK_a, $KAu(CN)_2$ was titrated with HCl in separate experiments with a glass electrode pH meter and conductometric monitoring. A known system, acetic acid with pK_a of 4.75, was treated in parallel experiments by titrating $KOOCCH_3$ solutions.

The pH titrations are shown in Fig. 5. The pH at half-equivalence ($f = 0.5$) of 4.7 for the acetate titration agrees with the pK_a; the behavior of $KAu(CN)_2$ is that expected of the salt of an acid with $pK_a < 2$. Similarly the conductometric titrations in Fig. 6 show

1. 0.100M $KAu(CN)_2$, 0.100M $HAu(CN)_2$, 0.100M KCl	1.12	0.26
2. 0.05M $KAu(CN)_2$, 0.05M $HAu(CN)_2$, 0.05M KCl	1.42	0.55

Solutions prepared from $KAu(CN)_2$ and HCl.
* $KAu(CN)_2$ is considered as essentially fully dissociated as K^+ and $[Au(CN)_2]^-$ in view of its conductivity shown in Table II.

the expected shape for $KOOCCH_3$ (Cl^- for $^-OOCCH_3$ substitution at $f < 1$, $H^+ + Cl^-$ dilution at $f > 1$), but no evidence of reaction for $KAu(CN)_2$ ($H^+ + Cl^-$ dilution for all f).

pH measurements on nominal $f = 0.5$ solutions of two different Au(I) concentrations are summarized in Table V with calculations of the pK_a, correcting for $HAu(CN)_2$ dissociation. The fraction dissociated is so high as to preclude accurate measurement of the pK_a, but a $pK_a < 1$ value is established. The significance of this acidity is that, in all practical gold baths including the hard gold usually deposited from lower pH, cobalt containing citrate formulations, gold is transported as the ion $Au(CN)_2^-$ and the pH change at the electrode is due to

$$Au(CN)_2^- + e \rightarrow Au + 2CN^- \quad [10]$$

rather than

$$HAu(CN)_2 + e \rightarrow Au + HCN + CN^- \quad [11]$$

Since CN^- is a strong base ($pK_{HCN} = 9.2$), the effect of [10] as opposed to [11] is to produce 2 OH^-/e rather than 1 OH^-/e.

In Maja's work only $KAu(CN)_2$ solution pH measurements are cited. When such measurements are made with the pure $KAu(CN)_2$ grade used in this work, drifting pH values of 7.5-8.3 are obtained at 0.1M concentration, corresponding to a calculated pK_a 2-3.6. Addition of only $2 \times 10^{-4}M$ KCN corresponding to a 0.04 weight per cent (w/o) impurity in the original $KAu(CN)_2$ salt raises the pH to 9.6 and the apparent pK_a to 6.2. The use of $KAu(CN)_2$ solutions only is obviously deceptive, as would be true for any strong acid salt.

The data presented in this work can be used to predict limiting current through Eq. [1] in any system for which δ can be estimated. Cheh's data (14) indicated that the value of D for $Au(CN)_2^-$ was similar in citrate, phosphate, and alkaline baths at 60°C. As a first approximation, the range of D values given here as a function of temperature can probably be applied to most gold baths in present use.

Aging Effects in Single Crystal Reduced Rutile Anodes

L. A. Harris and R. H. Wilson*

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

Single crystal samples of reduced rutile used as anodes in a photoelectrochemical cell with 1.0N H_2SO_4 show significant changes with use. Saturated photocurrent as a function of illumination wavelength and differential capacitance as a function of anode half-cell voltage were measured before and after varying periods of operation under intense illumination. Shifts in the photoresponse and capacitance are observed only when the illuminating photon energy exceeds the bandgap energy of rutile and when a field exists in the crystal. The changes, possibly indicating a motion of donors toward the crystal surface, are also accompanied by an eventual loss in quantum efficiency and striking alterations in surface morphology. Reduced rutile may not have sufficient stability for prolonged use as the anode in electrochemical cells.

The properties of reduced rutile (TiO_2) and its behavior as an anode in an electrochemical cell have received increasing attention recently (1-8). This interest stems from the work of Fujishima and Honda (9, 10) who suggested rutile as an agent for electrolyzing water with photons (sunlight) supplying the necessary energy. If rutile or some similar plentiful oxide in the polycrystalline state could be so employed successfully, it would greatly enhance the prospects for the economic utilization of solar energy.

Although the bandgap of rutile is fairly large [3.05 eV (11)] allowing it to usefully capture only a small fraction of the energy available in sunlight, it is one of very few semiconducting materials considered suf-

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, TiO_2, rutile, hydrogen, aging.

ficiently stable to resist corrosion when used as an illuminated anode in an aqueous electrochemical cell (7, 9). Previous investigators have been able to detect no change in weight of the material after considerable use (2) or evidence of Ti ions in the electrolyte (9).

We report here observations of changes in electrical behavior and surface structure of single crystal rutile anodes under the influence of light and electric field conditions that obtain when water is dissociated in an electrochemical cell of this type. These aging effects result in an eventual loss of quantum efficiency which seriously reduces the effective life of the material as a water-splitting agent, even though no obvious chemical dissolution occurs.

Experimental Procedures

Measurements.—The tests to be described were carried out in an electrochemical cell similar to those described by other workers (2, 10). The anode was a rutile crystal, about 0.5 cm^2 in area, and the cathode was a blackened platinum foil, about 14 cm^2 measured area. Two saturated calomel reference electrodes (SCE) were connected through appropriately placed Luggin capillaries to measure the half-cell voltages at each electrode. Hydrogen could be bubbled over the platinum black cathode to avoid depolarization effects, particularly when hydrogen was not being liberated there by the action of the cell.

All the electrodes were placed in a 400 ml Vycor beaker containing 250 ml of 1.0N H_2SO_4. The electrolyte was not stirred during the experiments, after earlier tests had shown the current and half-cell voltages to be independent of stirring.

The rutile anode could be illuminated, by either of two 150W Bausch and Lomb xenon light sources, by simply rotating the beaker appropriately as indicated in Fig. 1. The light from source 1 was separated into its components by a small Bausch and Lomb grating monochromator and focused to a spot 2 cm in diameter at the sample by a quartz lens. The light from source 2 was focused directly by another quartz lens to about the same size spot. The total power density at the sample from source 2 was about 1.4 W/cm^2.

Figure 1 also shows the circuit used to measure the volt-ampere relations of the two half-cells or the photoresponse of the anode half-cell; and the polarities of the voltages and currents are defined there. Capacitance of the cell was measured without illumination using the bridge circuit shown in Fig. 2. This bridge design assumes a series RC equivalent circuit for the cell, in which the capacitive reactance is associated primarily with a depletion layer in the semiconductor electrode (12-15). Differential capacitance as a function of anode half-cell d-c potential, V_1, was measured using an approximately 3 kHz square or triangular wave to excite the bridge and an oscilloscope as the balance detector. Even when perfect nulls could not be obtained because the RC circuit in the reference arm inadequately represents the cell (15), an unambiguous balance could be detected by the amplitude and symmetry of the detector wave form.

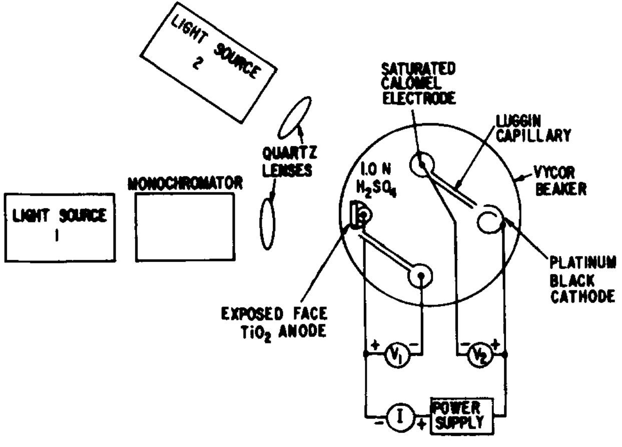

Fig. 1. Schematic of experimental arrangement for photocurrent measurements and aging.

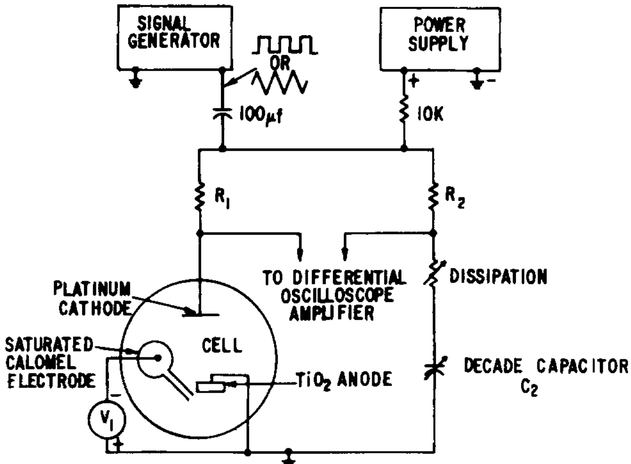

Fig. 2. Schematic of circuit for measuring differential capacitance *vs.* half-cell voltage.

Sample preparation.—All samples were sliced from a single crystal boule of rutile purchased from the National Lead Company. The most detailed tests were done on samples cut normal to the C axis of the crystal, exposing a (001) face, though some measurements were made on (100) and (110) faces. The slices were approximately 1 mm thick and were polished on one side with 0.3μ abrasive.

The crystals were insulating as prepared and were heated in a reducing atmosphere to make them conducting (11, 16). This treatment makes the crystals n-type. The usual reduction procedure was heating the polished slices in 1 atm of H_2 at 650°C for 15 min, a treatment we found to give about the optimum quantum efficiency. We shall indicate where results pertain to samples with other than (001) orientation or prepared with other reduction processes.

Ohmic contact was made on the rough, unpolished face of the crystal slice with a Ga-In or Ga-Ag alloy, and a wire was soldered to this face with a drop of In-Sn solder. The sample was then sealed to a glass tube and coated with epoxy cement so that only the polished face was exposed to the electrolyte. As noted earlier, sample areas were typically about 0.5 cm^2.

Results

A typical V-I curve for the illuminated anode (TiO_2) half-cell resembles those reported elsewhere (9, 10). For convenience the curve is shown in Fig. 3, along

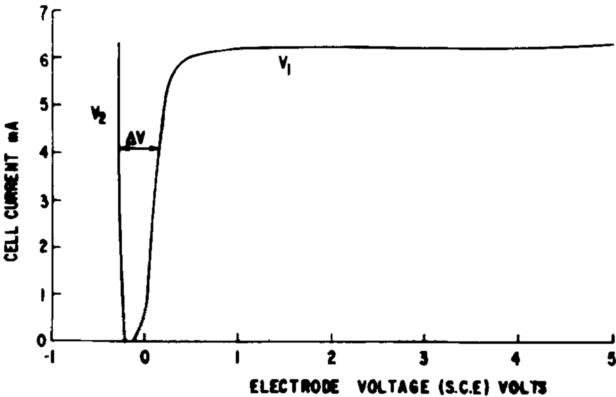

Fig. 3. Current *vs.* half-cell voltages ($V_1 \rightarrow TiO_2$; $V_2 \rightarrow Pt$)

with that for the platinum black cathode after it is saturated with hydrogen. These curves verify the conclusion of Wrighton *et al.* (2) that the short-circuited cell will not support an appreciable current, even when illuminated, unless the voltage deficiency indicated between the two half-cell characteristics is supplied from an external source.

The height of the current plateau at any given time is proportional to the intensity of the illumination (10), as determined with a set of calibrated neutral density filters, but the response was observed to vary with the sample history. Systematic measurements were made to clarify the nature of these changes with sample "age."

Standard reduction, (001) orientation.—Immediately after preparation and before any exposure to light from source 2, the cell capacitance as a function of V_1 and the saturated photocurrent at constant $V_1 = 2V$ were measured. Then, with V_1 held at the same constant value to draw the saturated current, the rutile anode was exposed to light from source 2 for a period of time, after which the C-V_1 and spectral response measurements were repeated. This sequence of exposure and measurement was continued for a number of aging intervals, all with exposure to the same light intensity, about 10 times that of unconcentrated sunlight. Although this high intensity undoubtedly accelerated the aging effects reported here, the rate of aging with different light intensities was not investigated.

The results of one such sequence of measurements on sample number 9b2 are summarized in Fig. 4, 5, and 6, in which age represents the total time the sample was illuminated by source 2 prior to the measurement indicated. Figure 4 shows the results of capacitance measurements plotted as A^2/C^2 *vs.* V_1, where A is the geometric area of the sample. The slope of this Schottky plot gives a measure of the net donor density for a flat surface if the changes in capacitance all occur in the semiconductor as is usually the case (12-14). Under these assumptions the initial donor density is about 7×10^{19} per cm^3. The calculated depletion widths using these assumptions are also shown in Fig. 4.

Figure 5 shows the photocurrent as a function of wavelength from source 1 for different ages. These curves are uncorrected for the spectral intensity dis-

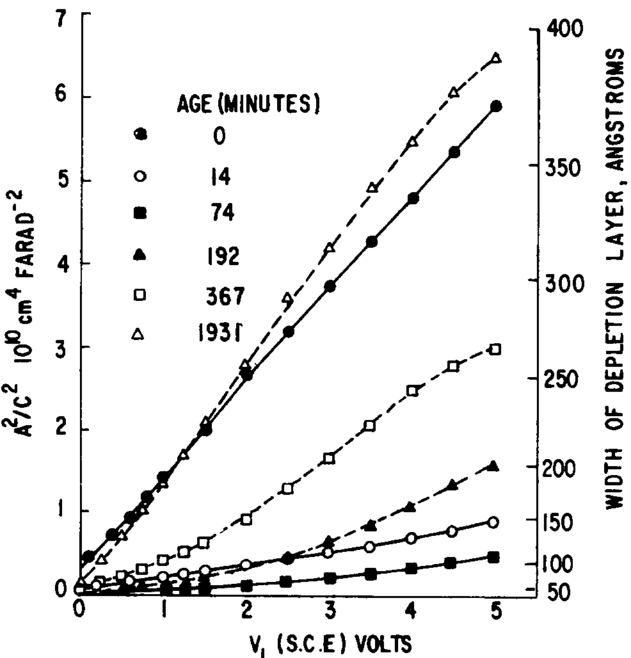

Fig. 4. Schottky plot of reciprocal of capacitance squared *vs.* half-cell voltage. Flat surface area assumed to calculate width of depletion layer. Sample number 9b2.

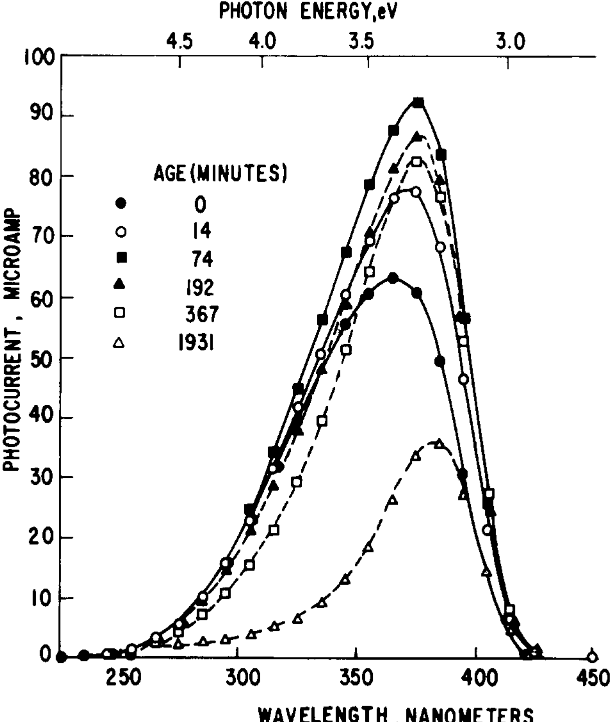

Fig. 5. Spectral dependence of photocurrent at different stages of aging for strongly reduced sample number 9b2.

tributed at the monochromator output. The wavelength resolution is quite broad because the monochromator slits were wide (4 mm) to give adequate intensity for measurement. (In an earlier test of a similarly prepared sample, correction of the spectral response curve for monochromator output distribution and absorption in the cell wall and electrolyte, but not for reflection at the sample surface, showed a quantum efficiency of about 0.74 electrons per photon with energy exceeding the bandgap of TiO_2.) The uncorrected curves adequately show the shift with age of the spectral response toward the longer wavelengths and the initial rise and subsequent fall of the peak current.

The rise and fall of current with age is also evident in the graph of saturation current (Fig. 6) under full illumination from light source 2. During the course of the experiment there were many interruptions when the sample remained inactive in the electrolyte. The capacitance and spectral response were always checked after such intervals and found to vary little from their values before the interruptions. Values of the saturation current taken immediately after resumption of the aging schedule tended to be lower than their previous values but came back to the value shown in the

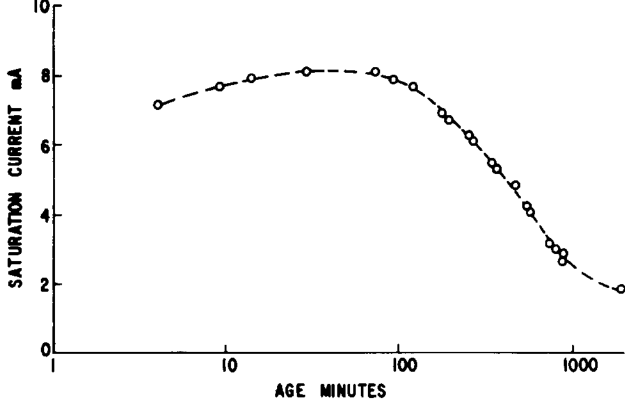

Fig. 6. Change in photocurrent with age. Sample number 9b2, full light from source 2.

figure within a few minutes. The age, defined as the total time of exposure to full illumination, appears to be the principal determinant of the changes in electrical properties reported here.

The aging effects just described for a reduced rutile crystal with the (001) face exposed raise questions regarding the conditions necessary for them to occur; in particular, the influence of crystal orientation, amount and method of reduction, light, and electric field. A number of additional experiments were done to answer some of these questions.

Other orientations and reductions.—Repetition of the aging experiments with crystals reduced in hydrogen at 650°C for 15 min but with the (100) and (110) faces exposed showed similar initial increases in capacitance and shifts of the spectral response toward long wavelengths. The capacitance increased for the full duration of the experiments and rose to higher values than in the (001) case, particularly with the (110) face exposed. Otherwise the behavior was qualitatively similar.

Figure 7 shows the photoresponse of an unreduced rutile crystal with the (001) face exposed. Although there is some growth of the peak current with age, its value is about three orders of magnitude below that measured in reduced crystals, and the response remains confined to a narrow region near the low energy absorption edge of TiO_2 (16-18). The sample capacitance was very small and independent of V_1 or age.

Another sample, number 9c, with (001) orientation was reduced by heating to approximately 580°C for 15 min in an ultrahigh vacuum system where the pressure was 3×10^{-9} Torr before heating and 5×10^{-7} Torr during heating. This treatment resulted in a very lightly reduced crystal (about 2×10^{16} donors/cm^3 based on the slope of an A^2/C^2 plot) which was subjected to the same sequence of aging experiments described earlier. It showed an increase in capacitance with aging similar to sample number 9b2.

The changes in photoresponse for sample 9c are shown in Fig. 8. Initially, this response peaks at about 325 nm but with age a second peak develops at about 375 nm while the shorter wavelength response de-

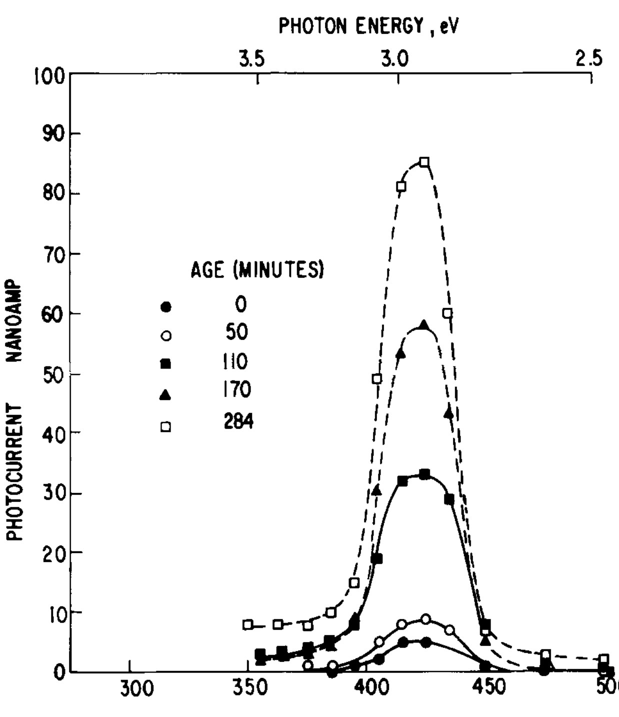

Fig. 7. Spectral dependence of photocurrent at different stages of aging for unreduced sample.

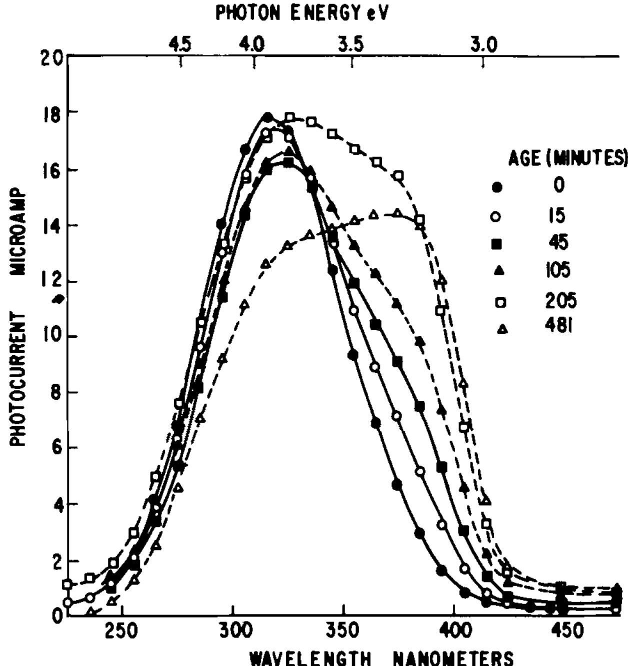

Fig. 8. Spectral dependence of photocurrent at different stages of aging for lightly reduced sample number 9c.

creases somewhat. These shifts are consistent with those of Fig. 5 but are much more obvious in the present case. It should be noted that the curves of current shown in Fig. 8, if plotted on the same scale as those of Fig. 5, would lie below the latter curves.

Influence of field and illumination.—After having examined the effects of aging on a variety of samples, we then examined the effects of varying the aging parameters, the illumination and applied voltage.

Sample number 12a was reduced in the standard way. It was then subjected to the sequence of aging tests already described, except that V_1 was held at 0.2V instead of the usual 2V. The results were similar in all respects to those of sample 9b2 except possibly for a lower rate of change with sample 12a, though differences in the initial level of reduction make this rate change uncertain.

The final sample to be discussed, number 12b, was reduced in the same process as sample 12a and underwent a series of aging tests. In the first of these the cell was short circuited, which set V_1 at about −0.27V. As can be seen from the intercepts of the A^2/C^2 curves (Fig. 4) this approximates the flatband condition in which there is no depletion region in the semiconductor. The aging tests, with the sample illuminated as usual by the full light from source 2, showed no significant changes in photoresponse or capacitance.

Since the sample was apparently unchanged, another aging test was made with $V_1 = 2V$ but with no illumination. Again no significant changes in the crystal were observed.

A third test was made on the same specimen with $V_1 = 2.0V$ and with illumination by filtered light from source 2. The light was passed through a Corning CS 3-37 filter which has a sharp cutoff for light of wavelengths less than about 430 nm. Since the transmitted light consisted of photons with insufficient energy to excite hole-electron pairs in the TiO_2, no change in current was observed with the light on or off. Once again, aging had no significant effect on the photoresponse or the capacitance.

As a final check, to ensure that this sample was a representative one, it was aged for 15 min with $V_1 = 2V$ and with full illumination. After this brief aging the striking increases in capacitance observed with other samples were evident.

Surface structure changes.—It was observed that the exposed surfaces of aged samples changed their visual appearances, usually from a shiny dark gray or black to a velvety matte surface. Some of these surfaces have been examined with the aid of a scanning electron microscope. At present, the information is too preliminary to report in detail, but striking changes in surface morphology do indeed occur with aging. Figure 9 shows some of the changes which occur on the (001) surface of rutile when it is reduced, and then the nature of subsequent changes when the surfaces were aged in the photoelectrochemical cell. The difference between Fig. 9a and 9b shows that some surface change occurs on reduction with hydrogen. Figure 9c shows the surface of sample 12b, the last to be discussed above, which, though in the electrolyte for a whole series of tests, underwent active aging for only 15 min. Figure 9d is a comparable micrograph of the surface of sample 12a which had been actively aged for a total of 360 min with $V_1 = 0.2V$. Micrographs of aged (100) and (110) crystal faces also show the development of considerable porosity but differ in detail from those shown in Fig. 9c and d.

Discussion

We have presented data which show changes in a reduced rutile crystal when it is used as an anode in a photoelectrochemical cell. Three major effects were observed: (*i*) the quantum efficiency decreases for high energy (greater than 3.6 eV) photons and increases for intermediate energy (3.0-3.6 eV) photons; (*ii*) the capacitance of the electrolyte-crystal junction changes; and (*iii*) the surface structure of the crystal changes. Whether these effects are independent or merely different aspects of a single process is not entirely clear at present.

One possible interpretation of the capacitance changes involves the accumulation of donors near the surface as a result of the combined action of bandgap radiation and applied field. This increased concentration at the surface would narrow the depletion region and increase the observed capacitance. The changes in spectral response, however, are not adequately accounted for on this basis without resorting to a number of other improbable assumptions.

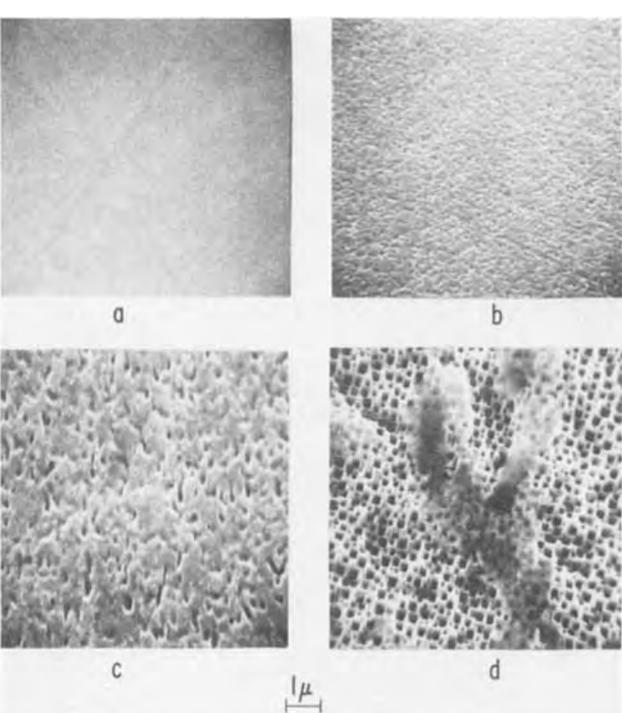

Fig. 9. Scanning electron micrographs of polished (001) rutile electrode surfaces at 10,000X. a: As polished; b: after reducing 15 min at 650°C in H_2; c: after 15 min aging $V_1 = 2V$ sample number 12b; d: after 360 min aging $V_1 = 0.2V$ sample number 12a.

Another possible explanation for the observations is a change in surface roughness giving rise to an increased contact area between electrolyte and crystal. A factor of three increase in area in the first 14 min of aging would explain the observations in Fig. 4, but such an increase is more than would be predicted from the appearance of surface roughness in Fig. 9c. This model could also explain increased quantum efficiency for intermediate energy photons by assuming the development of pores in the surface that provide collection surface deep in the crystal where the photons are absorbed. The model, however, does not provide an explanation for the large difference between the quantum efficiencies for the heavily and lightly doped crystals.

By the time the crystal is aged to the point corresponding to Fig. 9d, the quantum efficiency has begun decreasing. This decrease can be explained if the restructured surface is composed of an electrically inert layer that absorbs photons without contributing to the current. The layer could also affect the capacitance measurement by decreasing the contact area between the electrolyte and electrically active surface. The restructuring itself is possibly due to a current-driven migration of surface atoms. Only about one atom rearranged per thousand electrons through the circuit is necessary to cause the observed effects. This process may be related to that discussed by Vermilyea (19) for anodized Ta_2O_5 films.

Conclusions

We have shown that the quantum efficiency of a reduced rutile crystal used as an electrode for photoelectrolysis depends on the process used to reduce it. This quantum efficiency is subsequently changed in use. The long term result is a decrease in quantum efficiency apparently related to rearrangement of TiO_2 at the surface. Experiments have shown that both bandgap excitation and a strong field are necessary for these aging effects to occur. The influence of processing and experimental history on the behavior of this material could lead to the discrepancies in quantum efficiencies reported by different workers.

Aside from its too-wide bandgap, TiO_2 may prove to be unsuitable as a photochemical solar energy collector because of the instabilities reported here. Although these instabilities were demonstrated only for TiO_2 and only in a 1.0*N* H_2SO_4 electrolyte, they may well occur under a wider variety of operating conditions and with other semiconductor electrodes, particularly those made semiconducting by the introduction of lattice defects.

Further effort is necessary to clarify the fundamental nature of the instabilities so that their effects may be minimized or avoided by proper choice of material and operating conditions.

ABSTRACT

This report describes experimental and analytical methods of resolving frequently encountered problems of linearity, accuracy, reproducibility, reliability, and concentration polarization in characterization of membrane transport coefficients. An apparatus has been constructed for nonsteady-state characterization of membrane transport. This apparatus employs simultaneous monitoring of salt and volume transport in each half-cell, independently, to provide internal checks on accuracy. Sufficient data are generated from a single experiment to evaluate a complete matrix of coefficients (L_p, σ, ω). Ambiguities resulting from combining data from different experimental conditions in a single coefficient matrix are completely eliminated. Two analytical-experimetal methods are employed: the zero volume flux method (ZVFM) and the linearization of the flux equations leading to the least squares straight line method (LSM). Average reproducibility of a coefficient matrix, using ZVFM or LSM, is about 5%. Average accuracies for the LSM coefficients L_D, ω, and σ are 2.9, 0.5, and 4.8%, respectively. A quantitative measure is introduced for the over-all reliability of a coefficient matrix. The "reliability coefficient," R_J, demonstrates how well the experimental fluxes can be reproduced by the transport coefficient matrix over the range of thermodynamic forces. For these experiments $R_{J_v} \simeq 3 \times 10^{-8}$ cm-sec^{-1} and $R_{J_s} \simeq 2 \times 10^{-10}$ mole-cm^{-2}-sec^{-1}. The problems of linearity and concentration polarization are nearly solved, as evidenced by the reliability with which the experimental fluxes can be predicted by the transport coefficients.

The first complete characterization of membrane transport phenomena was achieved by Staverman, who demonstrated the inequality of osmotic and hydrostatic transmembrane pressures in producing volume flux (1, 2). By a simple application of the principles of nonequilibrium thermodynamics developed by Onsager (3, 4), Staverman showed that, in addition to water and solute permeabilities, a third transport coefficient is necessary for complete characterization of membrane transport. He named this additional term the "reflection coefficient" and described its physical significance.

Since Staverman's efforts, interest in elaborating the theoretical principles underlying membrane transport phenomena, and the choice of reference frames for

* Electrochemical Society Active Member.

Key words: reflection coefficient, hydraulic conductivity, membrane permeability, concentration polarization, irreversible thermodynamics.

membrane characterization, has resulted in voluminous literature contributions. Distinguished reviews of membrane biophysics have been published (5-7). Staverman's original concept of the reflection coefficient has been generalized by Zelman (8). Several research groups have developed specific apparatus and techniques for evaluating three or more transport coefficients for membrane-solution systems [true steady state, (9, 10); quasi-steady state, (11-18); nonsteady state, (19-21)].

In all of the methods thus far developed for complete characterization of membrane transport, both theoretical and experimental anomalies are introduced which place severe limitations on the evaluated coefficients. There are basically five problems thwarting complete characterization of a matrix of coefficients.

I. The linear form of the transport equations can be developed from either macroscopic or microscopic considerations (22). The two basic forms for the transport equations are

$$\vec{J}_i = -\sum_{j=1}^{N} L_{ij}\nabla\vec{\mu}_j \quad [1]$$

and

$$J_i = -\sum_{j=1}^{N} L'_{ij}\Delta\mu_j \quad [2]$$

The transport coefficients, L_{ij}, are in principle functions of hydrostatic pressure, solute concentration, and voltage. However, if the differential form, Eq. [1], is linear, then the difference form, Eq. [2], obtained by integration of Eq. [1], will be intrinsically nonlinear (23). Use of the macroscopic transport Eq. [2] must therefore be restricted to narrow regions of electrochemical potential difference where linearity is found experimentally to exist.

II. For a three component system consisting of a membrane, solute, and solvent, there are two independent flux equations and three independent transport coefficients. These three coefficients cannot be evaluated from a single state of the membrane-solution system. Consider two chemical species, denoted by subscripts 1 and 2, in a membrane-solution system whose state is denoted by a superscript prime

$$-J_1' = L_{11}\Delta\mu_1' + L_{12}\Delta\mu_2' \quad [3]$$

$$-J_2' = L_{21}\Delta\mu_1' + L_{22}\Delta\mu_2' \quad [4]$$

where, according to the principle of Onsager reciprocity, $L_{12} = L_{21}$. To generate a third equation and solve the system, one must alter some chemical potential and, thus, the mass fluxes which occur. The second state of the system is denoted by superscript double primes

$$-J_1'' = L_{11}\Delta\mu_1'' + L_{12}\Delta\mu_2'' \quad [5]$$

$$-J_2'' = L_{21}\Delta\mu_1'' + L_{22}\Delta\mu_2'' \quad [6]$$

Any three equations from [3]-[6] can be used to evaluate the independent coefficients. The important aspect, however, is that a second state of the chemical system, developed by altering the chemical potentials, was necessary to generate sufficient data to determine the complete matrix of coefficients. The transport coefficients, then, are not derived experimentally from a single state of the membrane-solution system, but they are functions of at least two different states. The magnitude of the coefficients will depend on the method of averaging the coefficients over these different thermodynamic states. Theoretical attempts at deriving the transport coefficients by integrating the differential flux equations across a single state of the membrane-solution system encounter intrinsic difficulties.

III. Concentration polarization is the nemesis of the membranologist. The boundary layer is, of course, impossible to eliminate completely (24). For systems with three or more transport coefficients, it becomes a monumental task to develop sufficient data to use the Wilson plot method of eliminating the boundary layer by extrapolation to infinite solution agitation. There are two alternatives. One can either manufacture a test cell with mathematically well-defined boundary layers, or one can design a stirring apparatus which makes the boundary layer an insignificant contribution to the transmembrane mass transfer resistance.

IV. From the standpoint of absolute accuracy, the transport coefficients can be evaluated most easily by performing separate experiments in different transport cells and even with different membrane samples. A set of experiments can thus be used to evaluate a single matrix of coefficients. This procedure introduces into a single matrix, however, coefficients which reflect different boundary layer conditions and inhomogeneity in the different membrane samples. They do not rigorously reflect the same membrane-solution system. Ideally, data should be collected from one experimental cell, and, if possible, during one experimental trial.

V. As discussed previously, transport coefficients are obtained from at least two different states of the membrane-solution system. However, in practice one uses the set of coefficients to generate the fluxes expected for a single state. Thus, it is essential for every report to examine the validity of the reported transport coefficients by including a comparison between the fluxes generated by the experimental transport coefficients and the actual measured experimental fluxes. This aspect of membrane characterization has been sorely neglected in the literature.

This discussion leads to the conclusion that the optimal characterization of a solution-membrane system requires a single matrix of coefficients evaluated from experiments which maintain a constant, negligibly small boundary layer. All measurements should be performed in the same transport cell with the same adequate stirring conditions. The apparatus should incorporate as many double checks on each measurement as possible to ensure accuracy and reproducibility. The coefficients should be "properly" averaged over the various states of the membrane-solution system used to evaluate the transport coefficients. Finally, the validity of the calculated transport coefficients should be demonstrated by reproducing the measured fluxes within experimental accuracy.

The purpose of this report is to describe a nonsteady-state system designed for complete membrane characterization for a membrane-aqueous salt solution system. In addition, we demonstrate the appropriate analytical methods necessary for evaluation of the transport coefficients from rigorously valid experimental data. The calculated transport coefficients can be used to reproduce the experimental fluxes over an extended range of solute concentrations.

Analytical Method

An apparatus has been constructed for nonsteady-state characterization of membrane transport phenomena. This system is unique in that every necesary experimental parameter can be determined, with precision, in each half-cell simultaneously. Thus, an entire matrix of transport coefficients can be obtained from a single experiment.

Temperature, solution concentration, and solution volume were monitored continuously in each half-cell. Experiments were designed such that the solute concentration in each half-cell varied with time while the solution temperatures and transmembrane hydrostatic pressure difference were maintained constant.

Figure 1 shows a hypothetical transport cell used to define the sign notations applicable to the thermodynamic forces and fluxes involved. Differences in the thermodynamic variables are taken right minus left.

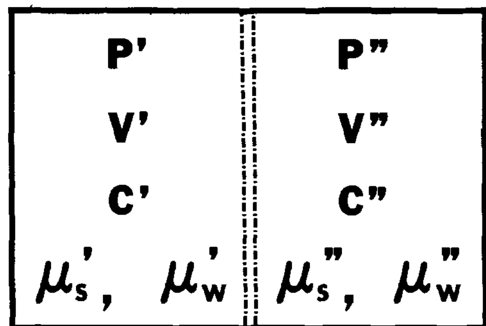

Fig. 1. Hypothetical cell for transport of salt and water across a permeable membrane.

Fluxes are taken to be positive when transport is from the left to the right half-cell.

The solute and volume fluxes are written as time derivatives of the experimentally accessible parameters; half-cell volume, $V(t)$, and solute transport, $n_T(t)$. Osmotic pressure and chemical potential are developed as time-dependent functions of concentration, $c(t)$. $V(t)$, $c(t)$, and $n_T(t)$ are developed as polynomial expressions in time using the Crout reduction method. The time-dependent equations for half-cell volume, solute concentration, and solute transport are

$$V(t) = \sum_{i=1}^{m} a_i t^i \quad [7]$$

$$c(t) = \sum_{i=1}^{n} b_i t^i \quad [8]$$

and

$$n_T(t) = \sum_{i=1}^{p} d_i t^i \quad [9]$$

Data points can in general be fitted to a polynomial with a vanishingly small standard deviation by increasing the degree of the polynomial. To gain a realistic function for these polynomials, however, we decreased m, n, and p until the standard deviation for the polynomial was about equal to the experimental imprecision ($m,n,p \simeq 4$, usually). Thus, the higher order terms which forced the polynomial to fit the data points were eliminated. Smooth, experimentally reasonable curves for $V'(t)$, $V''(t)$, $c'(t)$, $c''(t)$, $n_T'(t)$, and $n_T''(t)$ were obtained in this manner.

The volume flux, $J_v(t)$, is given by

$$J_v(t) = -(1/A)(dV'(t)/dt) = (1/A)(dV''(t)/dt) \quad [10]$$

where A is the exposed membrane area. The solute flux, $J_s(t)$, is given by

$$J_s(t) = -(1/A)(dn_T'(t)/dt) = (1/A)(dn_T''(t)/dt) \quad [11]$$

The time-dependent transport equations were written, for a single solute, as (2, 5, 8)

$$J_v(t) = -L_p(\Delta P - \sigma\Delta\Pi(t)) \quad [12]$$

and

$$J_s(t) = \bar{c}(t)(1-\sigma)J_v(t) - \omega\Delta\Pi(t) \quad [13]$$

where $\bar{c}(t)$ is a logarithmic average solute concentration defined by

$$\bar{c}(t) = \Delta\Pi(t)/\Delta\mu_s{}^c(t) \quad [14]$$

For a uni-univalent salt, the osmotic pressure and $\mu_s{}^c$ can be written

$$\mu_s{}^c(t) = 2RT \ln(\gamma_\pm(t) m_s(t))$$

$$\text{and } \pi(t) = \frac{18.016RT}{1000\bar{v}_w(t)}(2\Phi_s(t)m_s(t)) \quad [15]$$

This particular form of the transport equations was chosen because the coefficients L_p, the hydraulic conductivity, σ, the reflection coefficient, and ω, the solute permeability at zero net volume flux are reasonably independent of solute concentration (25). In Eq. [12] and [13], these coefficients may be treated as constants so long as $\Delta\Pi(t)$ is not "too large."

Two methods were used to evaluate the transport coefficients. The "zero volume flux" method uses relationships from Eq. [12] and [13] to evaluate the coefficients

$$\omega = -(J_s(t)/\Delta\Pi(t))_{J_v=0} \quad [16]$$

$$\sigma = (\Delta P/\Delta\Pi(t))_{J_v=0} \quad [17]$$

$$L_p = -(1/N)\sum_{i=1}^{N}(J_v(t_i)/(\Delta P - \sigma\Delta\Pi(t_i))) \quad [18]$$

In Eq. [18], the hydraulic conductivity is determined as an average over the number of experimental data points, N, collected at the times t_i during an experiment. In this analytical method, the per cent standard deviations of ω and σ are the sums of the per cent standard deviations of the terms which contribute to their calculation. The standard deviation of L_p was determined from

$$\text{s.d. }(L_p) = \left(\sum_{i=1}^{N}(L_p(t_i) - L_p)^2/(N-1)\right)^{1/2} \quad [19]$$

In this method, the coefficients ω and σ are determined for the single state of the membrane-solution system when the net volume flux is zero. The hydraulic conductivity is an average over the range of thermodynamic states produced in each experiment.

The second method of data reduction, the least squares straight line method, uses a linearization of the volume and salt flux expressions as follows. From Eq. [12], one obtains

$$J_v(t) = -L_p\Delta P + L_p\sigma\Delta\Pi(t) \quad [20]$$

which can be written as

$$Y(t) = Y_0 + SX(t) \quad [21]$$

The salt flux expression Eq. [13] can be rearranged to obtain

$$J_s(t)/(\bar{c}(t)J_v(t)) = (1-\sigma) + (-\omega)(\Delta\Pi(t)/(\bar{c}(t)J_v(t))) \quad [22]$$

or

$$Y'(t) = Y'_0 + S'X'(t) \quad [23]$$

Least square straight lines are determined for $Y(t)$ and $Y'(t)$. Since ΔP is an experimentally determined constant, the transport coefficients are obtained from

$$L_p = -Y_0/\Delta P \quad [24]$$

$$\sigma = -S/L_p = 1 - Y'_0 \quad [25]$$

$$\omega = -S' \quad [26]$$

The correlation coefficient, r, and the level of significance, p, were determined for all experimental data fit to a linear equation. The standard deviations of the slopes and intercepts of the straight lines were also determined (26).

Coefficients determined using the least squares straight line method are average values over all states of the membrane. Thus, these coefficients are unambiguously developed to characterize transport phenomena over a specified range of thermodynamic states.

Experimental Method

Figure 2 contains an illustration of the transport cell utilized in these experiments. The cell consisted of two 3 in. ID conical end Kimax glass pipe elbows connected with aluminum flanges (Kimax, Owens-Illinois Incorporated, Fluid Process Systems, Vineland, New Jersey). The membrane was supported between the glass elbows by two pieces of 0.062 ± 0.001 in. thick Plexiglas. Holes of diameter 0.250 ± 0.001 in. were arranged in a circular array to provide an exposed membrane area of 16.64 ± 0.07 cm^2. These holes were aligned using two stainless steel pins placed eccentrically in the plastic sheets and external to the half-cell solutions. Neoprene gaskets were used between connected parts.

The half-cells were closed at their outer ends with ½ in. thick Plexiglas fastened to the glass using aluminum flanges and Neoprene gaskets. Connections to the half-cells were either nylon "Swagelok" or "Ultra-torr" fittings (Crawford Fitting Company, Solon, Ohio). Combinations of "Tygon" and polyethylene tubing (Norton Plastics and Synthetics, Akron, Ohio) were used to connect conductivity cells, pumps, and devices for volume measurement to the half-cells.

Thermometers accurate to ± 0.01°C were placed in each half-cell (Model No. 41235, Brooklyn Thermometer Company, Farmingdale, New York). Temperature regulation was accomplished in two steps. First, the entire transport assembly was enclosed in a plywood box with the temperature maintained to ±0.1°C using an air temperature controller (Yellow Springs Instrument Company, Yellow Springs, Ohio). Second, the glass transport cell was placed inside a water bath. The bath temperature was regulated to ±0.02°C by a water

circulator-temperature controller (Model K-2/RD, Brinkmann Instrument Company, Westbury, New York). In all experiments, the temperature in each half-cell was maintained to ±0.04°C.

Concentration polarization at each membrane-solution interface was mitigated by two means. First, internal 1½ in. egg shaped Teflon coated magnets (Bel Art, Pequannock, New Jersey), directly next to each side of the membrane, were driven at 500 rpm by two external magnets directly under the cell. The external magnets were controlled by an a.c.-d.c. series motor (Model 2M057, Dayton Electric Manufacturing Company, Chicago, Illinois) run off of a variable voltage regulator (Superior Electric Company, Bristol, Connecticut) and synchronized using a gear train assembly. The second means of stirring the solution in each half-cell was provided by aiming the output of each circulating pump (Micropump Corporation, Concord, California) directly at the center of the membrane. The circulating pumps were magnet drive gear pumps. Pump heads were specially manufactured entirely from plastic components. The circulation rate of each pump, about 1 liter/min was controlled by a "Variac" voltage regulator (General Radio Company, Concord, Massachusetts).

Solution salt concentrations of NaCl were monitored using conductivity cells (Model JD20, Beckman Instruments Company, Cedar Grove, New York). The solution resistance in each half-cell was measured using an impedance comparator (Model 1654, General Radio Company, Concord, Massachusetts) and a standard decade resistance box (Model 1433-G, General Radio Company, Concord, Massachusetts). Conductivity cell constants were determined to ±0.1% using 0.1000M NaCl placed in the transport cell. In this manner, salt concentrations were measured in each half-cell with an accuracy of ±0.1%, reproducibility of ±0.04%, and sensitivity of 0.003% change in concentration.

Corrections for resistance changes due to temperature variations within the transport cell were obtained by establishing 25°C as a reference temperature. All resistance readings were corrected to 25°C using the expression

$$R_{25^\circ C} = R_T(1 + \beta(T - 25^\circ C)) \qquad [27]$$

where R_T was the actual resistance reading at temperature T. The temperature coefficient β was determined with data from the International Critical Tables (27). Concentration changes in the course of an experiment were calculated by linear extrapolation of conductivity-concentration data (27).

Volume measurement in the low pressure half-cell was made by allowing overflow into a stoppered glass weighing bottle. The weighing bottle was vented using a hypodermic needle to relieve pressure due to volume changes in the bottle and to prevent evaporation of the solution in the bottle. Weight changes measured to ± 0.2 mg were converted to volume changes in the half-cell using the known density of the solutions (27). On the high pressure side, volume changes were measured with a 10 ml Mohr pipette graduated in intervals of 0.1 ml and calibrated to ± 0.01 ml.

An estimate of the rate of solution loss of each half-cell was made prior to each experiment. Typical leak rates were 3 μl/hr. The measured leak rates were used to correct the experimental volume and salt transport measurements.

Hydrostatic pressures were measured by a Bourdon tube-type pressure gauge with 2000 Torr full scale deflection (Model CMM-8 1/2, Dresser Industries, Newtown, Connecticut) with an accuracy of ± 2 Torr, reproducibility of ± 0.4 Torr, and sensitivity of 0.2 Torr. An empty 5 liter gas storage bottle attached to the pressure system served as ballast. The pressure system

was attached to the pipette used for volume measurement in the high pressure half-cell.

An injection port was designed for each half-cell using an "Ultra-torr" fitting made for ⅜ in. OD tubing. The O-ring normally used in the fitting was replaced by a disk of soft natural rubber through which a hypodermic needle could be inserted to add or remove solution.

Each experiment is initiated by measuring conductivity cell constants and solution leak rates. Appropriate amounts of solutions are added to each half-cell to obtain starting solute concentrations. With the desired hydrostatic pressure applied, the system is allowed to come to mechanical equilibrium for 24 hr before taking the first readings of the experiment. Each data point taken requires reading temperature, volume, and solution resistance of each half-cell. These readings are accomplished without physically disturbing the conditions of the experiment.

Results

In each experimental trial, initial osmotic (NaCl) and hydrostatic pressure differences were first established across the membrane. As each experiment proceeded, the hydrostatic pressure was maintained constant while the osmotic pressure difference decreased with time. The experiments were primarily designed such that the net volume flux was initially in the opposite direction to the salt flux, then zero, and finally in the same direction as the salt flux. This sequence was a result of the decaying transmembrane concentration difference.

The low pressure half-cell, in which volume measurements were obtained using the weighing bottle, gave the most precise volume measurements. Volume fluxes were calculated from data taken from this half-cell. The volume data on the high pressure side was used as an internal check on the volume data taken from the low pressure half-cell. Experiments are not reported where the solute and solvent mass balances are not within 3%. Less than 20% of the experimental trials were discarded.

Figures 3 through 7 depict results from a single, typical experiment. Data were collected over a time span of almost eight days. Figure 3 shows the time-dependent half-cell concentrations and their polynomial fit. The data points shown are significantly larger than the actual experimental imprecision. For this transport apparatus, the half-cell volumes are approximately equal ($\simeq$ 1200 ml); thus, the concentration curves produced are very nearly mirror images of each other. This experimental design was developed to hold $\bar{c}$ as constant as possible, as shown in Fig. 3. In this manner, the concentration-dependent character of the transport coefficients should be kept to a minimum during a single experiment, but concentration dependence may be examined by choosing a series of average concentrations over which to evaluate the coefficients.

Figure 4 contains experimental data and polynomial fits for the time-dependent salt and volume transport in a single experiment. The slopes of these curves are equal to the fluxes through the membrane at any time t during the experiment. From the volume transport curve in Fig. 4 and the sign conventions previously assumed for chemical fluxes in the transport system, the net volume flux is first into the high pressure half-cell ($J_v > 0$), then zero, and finally into the low pressure half-cell ($J_v < 0$). From these data, individual sets of transport coefficients can be obtained from the zero volume flux method (ZVFM) and from the least squares method (LSM) of data analysis. Transport coefficients for the experiment shown in Fig. 3 through 7 are given in Table I under experiment 128.

The reflection coefficient from the solute flux expression was not calculated for these experiments. The sensitivity in concentration measurement necessary to

determine σ, from Eq. [13], accurately is 0.002% change in salt concentration per hour. The smallest sensitivity obtainable with our experimental apparatus was determined to be near 0.04% change in salt concentration per hour. Consequently, the reflection coefficients reported for the least squares method were obtained solely from the volume flux equation.

Linearity.—Figures 5 and 6 are plots of the linear forms of the transport Eq. [20] and [22]. The correlation coefficients, r, for the linearized solute and volume fluxes are always greater than 0.9909 in absolute magnitude. This high degree of linearity demonstrates the validity of assuming the transport coefficients to be independent of solution concentration during each experiment, at least so long as $\bar{c}$ is maintained nearly constant.

Accuracy.—Reporting the accuracy of the transport coefficient matrix is complicated by the fact that the

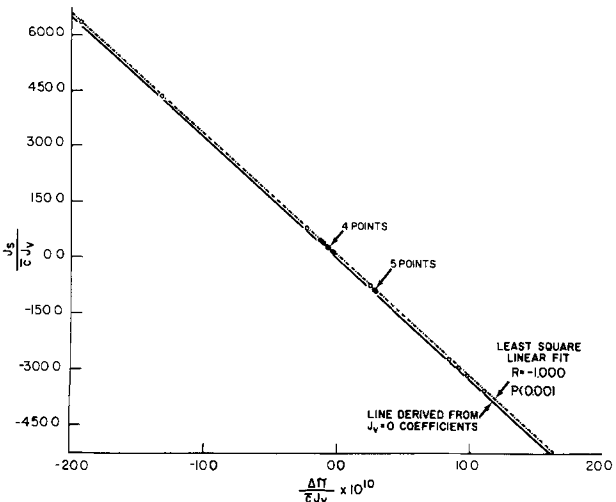

Fig. 5. Linearization of the solute flux equation. Experimental data are fit to a least squares straight line to produce the LSM transport coefficients. ZVFM produces coefficients which can reproduce the linear curve within experimental accuracy. Separation between lines is larger than actual for clarity. Experiment 128.

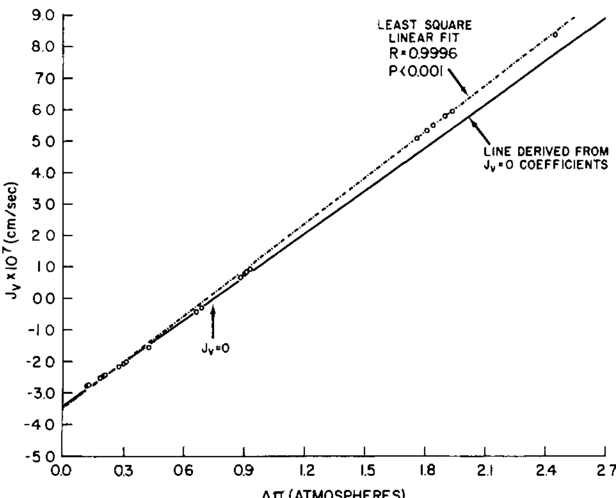

Fig. 6. Linearization of the volume flux equation. Experimental data are fit to a least squares straight line to produce the LSM transport coefficients. ZVFM produces coefficients which are less accurate at high $\Delta\Pi$ as a result of concentration polarization. Experiment 128.

coefficients are arrived at through an averaging process. In these experiments, accuracy is a composite of experimental imprecision and standard deviation over a set of experimental points. In the discussion, we shall propose a method of reporting coefficients which will alleviate this problem. The method of obtaining the standard deviation of the transport coefficients was outlined under analytical methods and the results are reported in Table I.

Theoretically, the LSM is intrinsically more accurate than the ZVFM. In order to determine the zero volume flux point, several data points must be included in the region near $J_v = 0$. However, as $J_v \rightarrow 0$, the precision of the volume flux measurement goes to zero. In the ZVFM, this greater imprecision in the volume flux is transmitted to the coefficients, calculation of two of which are directly based on determination of the time when $J_v = 0$. LSM avoids this problem by averaging the transport coefficients over all experimental points. As indicated in Table I, the standard deviations for ω and L_p obtained from the least squares method are significantly less than those calculated for the zero

volume flux method. These methods apparently have about equal accuracy for determining σ.

Reproducibility.—To determine reproducibility, sets of experiments were run without altering $\bar{c}$ significantly. In Table II, two groups of experiments are shown. For each group, $\bar{c}$ differs by nearly an order of magnitude. All of the experiments in Table II used the same membrane, without removing it from the membrane holder.

Reproducibility of the transport coefficients is slightly larger than experimental imprecision. The larger deviation for σ in experiments 128 and 130 was compensated for in later experiments by employing a more precise pressure gauge, as listed in experimental methods. For each average solute concentration, the set of coefficients has an average reproducibility of about 5%. It appears that both analytical methods, ZVFM and LSM, have about equal average reproducibility.

Reliability.—The experimental solute and volume fluxes, as well as curves calculated from the transport coefficients determined by both analytical methods, are shown in Fig. 6 and 7. It is not surprising that the LSM develops a line which follows the volume flux more closely than the ZVFM does, since the least squares coefficients are obtained directly from the J_v *vs.* $\Delta\Pi$ graph. Any effect of concentration polarization on L_p and σ is incorporated directly into the LSM coefficients. For the zero volume flux method, J_v tapers off at large values of $\Delta\Pi$ because the effect of concentration polarization is to decrease the actual osmotic pressure difference across the membrane. When $\Delta\Pi$ is small, the two analytical methods give essentially equal values of J_v. Even when $\Delta\Pi$ is at its maximum,

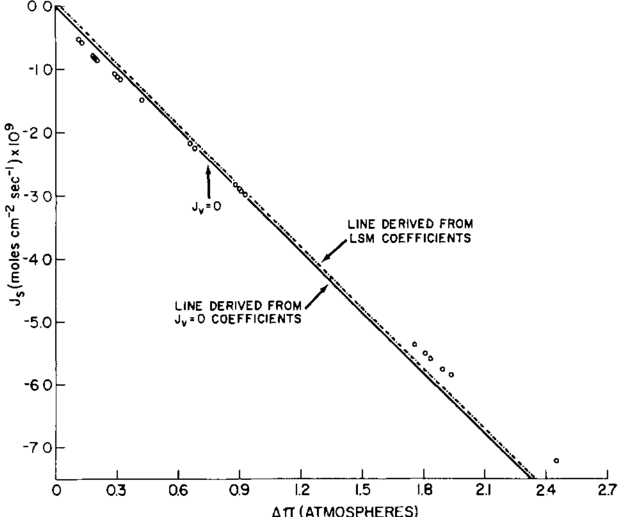

Fig. 7. Experimental data and predicted solute fluxes for both analytical methods. Separation between calculated curves is larger than actual for clarity. Experiment 128.

there is at most a 6% difference between the two calculated fluxes.

Figure 7 shows the experimental and calculated solute fluxes over the range of osmotic pressures in a single experiment. Initially, J_s and J_v are in opposite directions, in which case concentration polarization would tend to decrease $\Delta\Pi$ across the membrane and J_s is smaller than expected. The data points and calculated fluxes cross in the region where $J_v = 0$, where concentration polarization is minimized. Toward the end of the experiment, the net volume and solute fluxes are in the same direction. At this point, the effect of concentration polarization depends on the concentration of solution permeating the membrane, given by J_s/J_v. In these experiments, J_v was small and the solution concentration was higher than that of either half-cell solution. The boundary layer next to the membrane on the high hydrostatic pressure, high concentration side decreased in salt concentration whereas the boundary layer on the low hydrostatic pressure, low concentration side increased in concentration. The transmembrane osmotic pressure difference, induced solely by concentration polarization, tends to drive water in the same direction as the hydrostatic pressure difference and the volume flux is increased over that expected from ΔP and $\Delta\Pi$ alone. In turn, the experimental solute flux will be larger than predicted from the experimental data.

Since the least squares method averages the coefficients over both positive and negative J_v, the effect of concentration polarization is cancelled out to some extent. This is indicated by the fact that the zero volume flux method, where concentration polarization is least, develops essentially the same value transport coefficients as the least squares method of analysis.

Ranges of experimental variables and membrane types.—The apparatus was designed to measure, within 0.04%, a range of concentrations from 2 × 10^{-4} to 3M NaCl. The hydrostatic pressure difference across the membrane can be varied from 0 to 2.6 atm. Thus, a range of thermodynamic forces can be produced which is sufficiently large that any type of flat sheet membrane sample can be characterized.

Table I lists the transport coefficients for two extremes in membrane composition and osmotic pressures. Experiments 128-140 characterized a hydrophilic, nonionic cellophane membrane (No. 70160-3, 3-7/16 flat cellophane tubing, Central Scientific Company, Chicago, Illinois) with osmotic pressures from 0 to 22.5 atm. Experiment 146 characterizes a sample of a hydrophobic, ionic mosaic membrane. This particular membrane is a mosaic of anionic and cationic patches; however, the anionic regions dominate the over-all character of the membrane (28), with $t_+ \simeq 0.1$, and the reflection coefficient is positive.

Discussion

This paper has presented a rather complete methodology for obtaining very reliable and complete

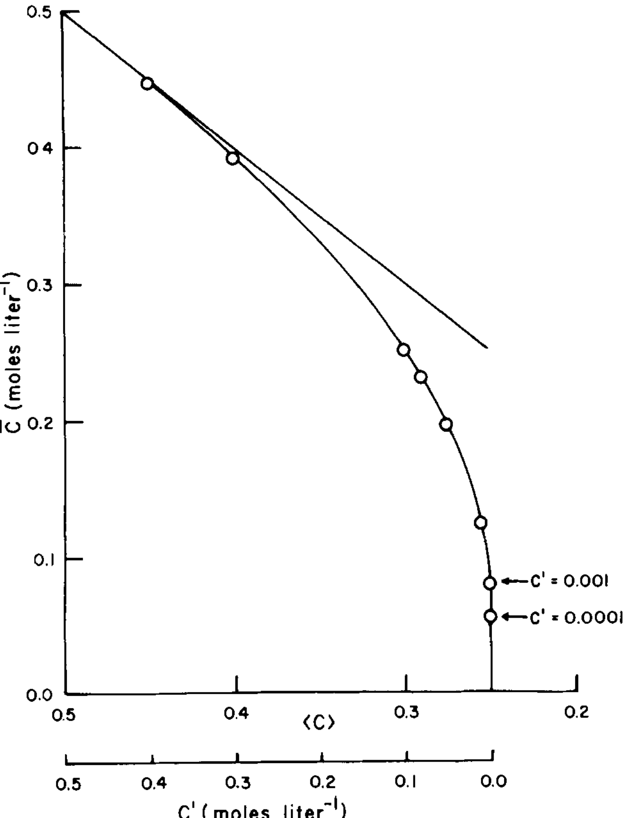

Fig. 8. Logarithmic and arithmetic average salt concentrations as the concentration in one half-cell approaches zero. Logarithmic average, $\bar{c}$, and arithmetic average, $\langle c \rangle = (c' + c'')/2$. $c'' =$ 0.5M. Upper line indicates $\bar{c}$ plotted numerically equal to $\langle c \rangle$.

characterization of transport coefficients where a single solute and solvent permeate a synthetic membrane. It is now appropriate to address ourselves to the five problems stated in the beginning.

It is clear that the problem of linearity of the macroscopic flux equations is nearly resolved, not by methodology but by happenstance. The coefficient matrix proposed by Staverman produced a set of coefficients which are nearly independent of concentration so long as the average concentration, $\bar{c}$, is maintained constant. However, the transport coefficients are very dependent on hydrostatic pressure differences due to stretching of the membrane matrix (29, 30). The transformation of the practical coefficients (L_p, σ, ω) into the conductance coefficients (L_{11}, L_{12}, L_{22}) involves $\bar{c}$. To the extent that $\bar{c}$ changes during the course of an experiment, so must the transport coefficients be concentration dependent. Since the conductance coefficients are simply linear combinations of L_p, σ, and ω with $\bar{c}$, constructing experiments such that $\bar{c}$ is constant ensures that the conductance coefficient matrix will not be concentration dependent.

There is an irregularity in $\bar{c}$ that should not be overlooked. $\bar{c}$ is close to the arithmetic mean of the half-cell solution concentrations only when Δc is small. Figure 8 is a plot of $\bar{c}$ *vs.* the arithmetic mean concentration, $\langle c \rangle$. As the concentration on one side of the membrane becomes small, the chemical potential tends toward infinity and $\bar{c}$ goes to zero. This would indicate, from Eq. [13], that convective transport would go to zero also. Zelman's derivation (8) of σ in terms of the conductance coefficients shows that σ contains a $\bar{c}$ term which cancels $\bar{c}$ in the solute flux equation. The complete term $\bar{c}\ (1 - \sigma) J_v$ is really independent of $\bar{c}$ except for indirect dependence of the L coefficients on concentration. Values of σ should not be tabulated without recognizing this special variance of σ with $\bar{c}$.

Another problem involved proper averaging of the coefficients over the various states of the membrane-solution system necessarily produced to obtain sufficient data to evaluate the transport coefficients. Both of the analytical methods, linearization of the transport equations leading to the least squares straight line method and the zero volume flux method, are "natural" extensions of the mathematical representation of the flux equations. If further justification be necessary, it must be noted that the coefficients obtained from these methods can be used to reproduce the measured fluxes within experimental reproducibility.

The problem of ambiguities resulting from data obtained from separate experiments or multiple experimental cells was resolved by engineering a single apparatus from which sufficient data would be obtained to determine all of the coefficients from a single experiment.

The final, and perhaps most difficult, problem was that of concentration polarization and the ubiquitous boundary layer. In as much as no experimental means can remove the boundary layer, and the solute concentration within the boundary layer is a stiong function of J_s/J_v, and the purpose of developing transport coefficients is to be able to evaluate J_s and J_v over extended ranges of thermodynamic forces, it should be clear that a more meaningful system for reporting uncertainties in the transport coefficients would be desirable. What is important to an engineer is how accurately a coefficient matrix can predict the solute and volume fluxes over a particular range of thermodynamic forces. A simple, yet adequate representation of accuracy is the standard deviation of the experimental fluxes from the calculated values. This quantity can be called the "reliability coefficient," R_J, and is given by

$$R_J = \left(\sum_{i=1}^{N} (J_{ic} - J_{ie})^2/(N-1) \right)^{1/2} \qquad [28]$$

where J_{ic} is the calculated flux of species i and J_{ie} is the experimental flux. If each report would characterize its coefficients both in experimental accuracy (Table I) and the reliability in reproducing the measured fluxes over a range of thermodynamic variables (Table III), the usefulness of reported values would be enhanced. Note that the reliability index, R_J, in Table III indicates that the uncertainty in the calculated solute flux can be much greater than that indicated from the accuracy of the transport coefficients as given in Table I, depending on the magnitude of the flux

Table III. Reliability coefficients, R_J, for typical experimental trials from Table I

Expt. No.	L_p (cm-sec^{-1}-atm^{-1})	ω (moles-cm^{-2}-sec^{-1}-atm^{-1})	σ	$\Delta c = c''(M) - c'(M)$	ΔP (Torr)	R_J: J_v (cm-sec^{-1})	R_J: J_s (moles-cm^{-2}-sec^{-1})
128	1.06×10^{-5}	3.30×10^{-9}	0.046	$\Delta c_{in} = 0.1540 - 0.1002$ $\Delta c_f = 0.1285 - 0.1260$	25	1.0×10^{-8}	2.5×10^{-10}
146	3.01×10^{-6}	1.54×10^{-9}	0.47	$\Delta c_{in} = 0.1571 - 0.0868$ $\Delta c_f = 0.1235 - 0.1210$	250	6.6×10^{-8}	1.0×10^{-10}

involved. This reliability coefficient takes into account all the errors of evaluation, both experimental and analytical, whereas the accuracy of each coefficient represents errors specific to that coefficient.

Accurate representation of the experimental characterization of membrane transport coefficients requires several types of indices by which to judge the value of the reported coefficient matrix. Essential parameters are accuracy and reproducibility, but more importantly the newly defined reliability.

LIST OF SYMBOLS

A	exposed membrane area, cm^2
c	solute concentration, mole-cm^{-3}
$\bar{c}$	logarithmic average solute concentration across the membrane, mole-cm^{-3}
$\vec{J}_i$	the vector molar flux of component i, mole-cm^{-2}-sec^{-1}
J_s	the scalar molar salt flux, mole-cm^{-2}-sec^{-1}
J_v	the volume flux, cm-sec^{-1}
L_p	hydraulic conductivity coefficient, cm-sec^{-1}-atm^{-1}
L_{ik}	linear phenomenological coefficient, general units of flux per unit thermodynamic force
n_T', n_T''	moles of salt transported across the membrane in an experiment, mole
m	molality, mole/kg water
N	number of experimental data points
p	level of significance of a linear fit of experimental data, dimensionless
r	correlation coefficient for linear regression analysis, dimensionless
R	molar gas constant, cm^3-atm-$mole^{-1}$-$°K^{-1}$
R_J	reliability coefficient; general units of flux, Eq. [28]
R_T	solution resistance recorded at temperature T, ohms
$R_{25°C}$	solution resistance corrected to 25°C, ohms
S, S'	slopes of general linear equations, Eq. [21] and [23]
t	time sec
T	temperature, °C
$\bar{v}_w$	partial molal volume of water, cm^3/mole
V	solution volume in one half-cell, cm^3
X, X'	independent variables for general linear equations, Eq. [21] and [23]
Y, Y'	dependent variables for general linear equations, Eq. [21] and [23]
Y_0, Y'_0	intercepts of general linear equations, Eq. [21] and [23]
β	fractional change in solution resistance with temperature, $°C^{-1}$
Δ	denotes difference, taken right minus left
$\gamma_\pm$	mean molal activity coefficient, dimensionless
μ_j	total chemical potential of species j, cm^3-atm-$mole^{-1}$
μ_i^c	concentration part of the electrochemical potential, cm^3-atm-$mole^{-1}$
Π	osmotic pressure, atm
σ	reflection coefficient, dimensionless
ω	solute permeability at zero net volume flux, mole-cm^{-2}-sec^{-1}-atm^{-1}
Φ	molal osmotic coefficient, dimensionless

Semiconductor Electrodes

V. The Application of Chemically Vapor Deposited Iron Oxide Films to Photosensitized Electrolysis

Kenneth L. Hardee* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The preparation of polycrystalline n-type Fe_2O_3 electrodes by the chemical vapor deposition (CVD) of iron oxide onto Ti and Pt substrates is reported. The behavior of these electrodes in aqueous solutions of different pH in the absence and presence of illumination is shown. Photoassisted electrolysis of water occurs at wavelengths longer than 400 nm and the current *vs.* wavelength curve for this process is compared to that of a CVD TiO_2 electrode.

Recently there has been much interest in the utilization of semiconductor electrodes for solar energy conversion by the photoassisted electrolysis of water (1-4). By illuminating an n-type electrode with light energy greater than the bandgap energy, holes are produced in the valence band which, under anodic polarization, migrate to the surface where they can react with a species in solution. Thus with a suitable semiconductor electrode it is possible to oxidize water to oxygen utilizing solar energy. However, only TiO_2 (1, 2, 4), SnO_2 (5, 6), and $SrTiO_3$ (7) have been shown to be capable of oxygen generation without decomposition of the electrode material. All of these materials have a large bandgap (greater than 3 eV) and thus require u.v. illumination for the reaction. Other semiconducting materials with smaller bandgaps (*e.g.*, GaAs, CdS, Si) decompose under anodic polarization and/or illumination. A nonreactive electrode which shows appreciable photocurrents at wavelengths longer than 415 nm (3.0 eV) has not been reported. Since the bulk of the solar radiation on the surface of the earth is found at longer wavelengths [only about 3% occurs in the 315-400 nm range (3, 8)], a practically useful material for solar energy conversion must be able to utilize this lower energy radiation.

We recently reported the preparation of n-type TiO_2 electrodes by chemical vapor deposition (CVD) (9). We report here the preparation of iron oxide (Fe_2O_3) electrodes by CVD and their use in the photoassisted oxidation of water at potentials less positive than those at platinum and at wavelengths longer than 400 nm. The unavailability of a single crystal of iron oxide prevented comparison of its characteristics with the CVD material, but based on our findings with CVD *vs.* single crystal TiO_2, we would expect generally similar behavior.

Experimental

The basic experimental setup for CVD has been described (9). The vapor source was iron acetylacetonate ($Fe(C_5H_7O_2)_3$) obtained from Alfa/Ventron. This was placed in a flask heated with a heating mantle. Prepurified nitrogen, the carrier gas, was passed over the heated compound, then through a glass tube situated approximately 1 cm above the substrate. A second line containing nitrogen which had been bubbled through heated water was attached to a side-arm on the inverted funnel over the substrate to provide a reactive atmosphere. Both Ti and Pt metal served as substrates. The Ti was cut into 1×1 cm squares after being polished to a mirror finish. The Pt was 0.002 in. thick foil cut into suitable squares. All substrates were cleaned in distilled water and ethanol prior to use. The substrate temperature was maintained at about 400°C, with a hot plate during CVD. The procedure used in depositing the iron oxide was as follows. A glass slide was placed on the hot plate and the nitrogen flow rate adjusted to give the desired film growth rate, determined by observing the change in interference colors. The rate of deposition did not appear to be critical and therefore no attempt was made to control this rate precisely. Typically a rate showing the formation of three sets of interference colors in 2 min was used. After the flow rate was adjusted, the desired substrate was positioned under the nozzle. When a suitable layer was deposited (usually in about 2 min), the substrate was placed in the flame of a Meeker burner for about 1 min. The substrate became almost white hot during this treatment and upon removal from the flame it was observed that the interference colors had disappeared. When cool the surface of the coated Pt had a reddish purple color, while with Ti the color was mostly gray, with some reddish patches. Several layers (between 3 and 7) were thus deposited on each substrate. With the Ti substrate some of the film flaked off of the electrode after the heat-treatment. In this case the affected portions were wiped off and deposition continued. Deposition on Pt produced no flaking problems. In fact, the best performing electrodes were made by continuing the deposition on Pt until no interference color change could be observed, indicating a fairly thick layer. The surface had a uniform steel-blue appearance. Heating produced a uniform red-purple coating. This was repeated 3-4 times. All films deposited on platinum exhibited a very low resistance, so that no vacuum treatment following CVD was used, as was necessary in the case of the TiO_2 electrodes. A copper wire was attached to the back of the substrate with silver epoxy (Epoxy Products Company, New Haven, Connecticut). The electrode was then mounted in a glass tube with Apiezon wax, exposing only the oxide-coated surface to the solution.

All electrochemical measurements were performed with a PAR Model 173 potentiostat (Princeton Applied Research Corporation, Princeton, New Jersey) controlled by a PAR Model 175 universal programmer. Current-potential curves were recorded on a Model 2000 X-Y recorder (Houston Instruments, Austin, Texas). A simple H-cell with a glass frit separating working and auxiliary compartments was used. A Pyrex window allowed illumination of the working electrode. Platinum wire served as the counterelectrode and a saturated calomel electrode (SCE) was the reference electrode. All potentials are reported *vs.* SCE.

The illumination system consisted of a 450 Watt Xenon lamp (Oriel Corporation, Stamford, Connecti-

cut) in an Oriel Model 6140 housing with an Oriel Model 6242 power supply. For current-wavelength curves, an Oriel Model 7242 grating monochromator with 12 nm band pass slits was used. The intensity of the incident light from the monochromator (in microwatts/square centimeter) was measured with a Model 550 radiometer (EG & G, Salem, Massachusetts). The intensity was normalized to the intensity at 470 nm and then used to correct the photocurrent *vs.* wavelength curves for variations in intensity with wavelength.

Results and Discussion

Current-potential curves for Fe_2O_3 films on Ti and Pt substrates in neutral unbuffered media (0.5*M* KCl for Ti and 0.5*M* Na_2SO_4 for Pt) are shown in Fig. 1. Qualitatively the two curves are similar. The dark current is slightly larger with the Ti substrate electrode, possibly because of some reaction at bare Ti, since the surface had a very patchy appearance. The cathodic currents in the dark can be attributed to the reduction of dissolved oxygen and of the Fe_2O_3. When nitrogen was bubbled through the solution, the current at potentials more positive than -0.4V markedly decreased; however the currents at more negative potentials were not affected appreciably. Continued scans to potentials negative of -0.4V gradually reduced the photoresponse of the electrode. The surface became lighter in color until the coating was virtually gone.

Under illumination there is a large rise in anodic current commencing at about $+0.2$V *vs.* SCE, with both Pt and Ti substrates. Gas evolution appears promptly with the anodic current and is quite noticeable on the electrode surface, implying that the reaction is the photoassisted oxidation of water to produce oxygen. Prolonged illumination in an unbuffered solution at $E = +0.800$V results in a decrease in *p*H. The current rise continues with increasing positive potentials to at least $+1.5$V without showing the current plateau characteristic of TiO_2 electrodes. However, even in the dark at *ca.* $+1.2$V (shifting to more negative potentials with increasing *p*H), the Fe_2O_3-coated substrates exhibit a large current rise with simultaneous gas evolution. This probably represents the direct oxidation of water at these potentials as a result of tunneling through the film. A similar gas evolution and current rise is observed in the dark on CVD TiO_2 electrodes, but at more positive potentials (*ca.* $+2$V). Thus at Fe_2O_3 the nonphotoassisted oxidation current at large positive potentials adds to the photoassisted current and thus masks the appearance of the photocurrent plateau.

There appears to be a small photocurrent beginning at about -0.4V *vs.* SCE under white light illumination with the Ti substrate. The current continues to rise gradually until the onset of the large photocurrent at $+0.2$V. This small photocurrent is probably due to the presence of some TiO_2 formed during the heat-treatment. Evidence of this is the gray color of the surface and the flaking problems encountered during preparation. This photocurrent appears at about the same potentials as those observed with CVD TiO_2 electrodes. On scan reversal from positive potentials with a Pt substrate electrode, a cathodic peak appears at about $+0.20$V (the shape and location of this peak vary somewhat with different electrodes). The peak shifts to negative potentials with increasing *p*H and does not appear on Ti substrates. This peak probably represents the reduction of adsorbed oxygen produced during the anodic scan under illumination. It does not appear in dark scans to potentials less positive than $+1.2$V, but is seen if an anodic scan is made to more positive potentials. It is also observed when the anodic scan is made under illumination and the light turned off during the cathodic scan. The cathodic current negative of 0.0V is also increased after anodic scans with light, representing an increase in the concentration of dissolved oxygen.

The potential for the onset of the photocurrent (E_L) shifts to more negative values with increasing *p*H. The current-potential curves for an Fe_2O_3-coated Pt electrode in solutions of several different *p*H values are shown in Fig. 2. The value of E_L varied somewhat (about 200 mV) for different electrodes.

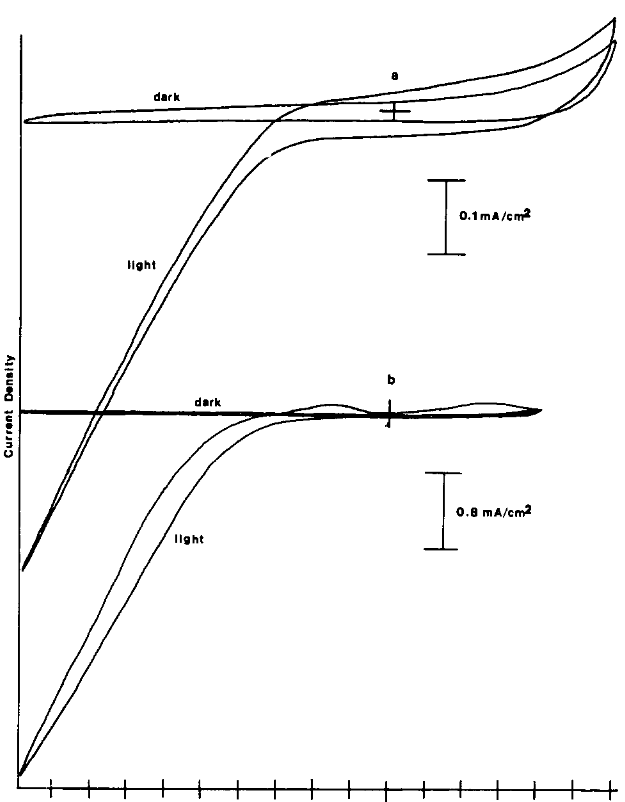

Fig. 1. Current density *vs.* potential for Fe_2O_3 films on (a) Ti, in 0.5*M* KCl, and (b) Pt, 0.5*M* Na_2SO_4.

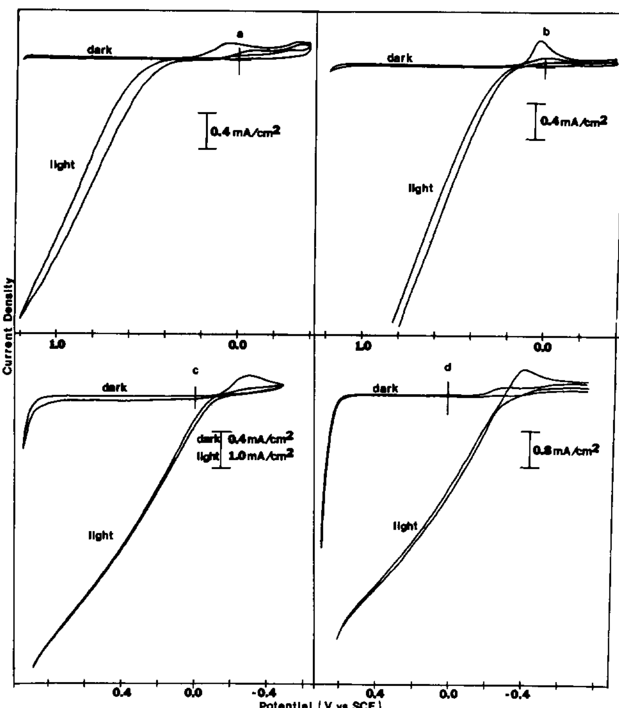

Fig. 2. Current density *vs.* potential for Fe_2O_3-coated Pt electrodes in 0.25*M* Na_2SO_4 solutions buffered to *p*H (a) 4.50, acetate, (b) 6.70, acetate, and (c) 10.36, ammonia. Curve (d) is for 1*M* NaOH.

The iron oxide electrodes appeared stable at open circuit in alkaline solutions up to 1*M* NaOH. Acid solutions (pH less than 4) slowly dissolved the oxide coating. Continuous potential scans between +1.0 and −0.6V in alkaline solutions produced no noticeable changes in surface appearance or *i-E* characteristics, although holding the electrode at potentials negative of −0.6V could possibly damage the electrode. There was no detectable change in behavior after holding the electrode at +0.600V at a pH of 10.4 (NH_4Cl-NH_3 buffer containing 0.25*M* Na_2SO_4) for 1 hr (current density, 4.7 mA/cm²); under these conditions the electrode was covered with gas bubbles. In pH 4.5 acetate buffer the Fe_2O_3 film gradually dissolved during a series of scans between +1.2 and −0.6V. However if the electrode was held at +0.600V in this buffer under illumination no decrease in photocurrent was observed.

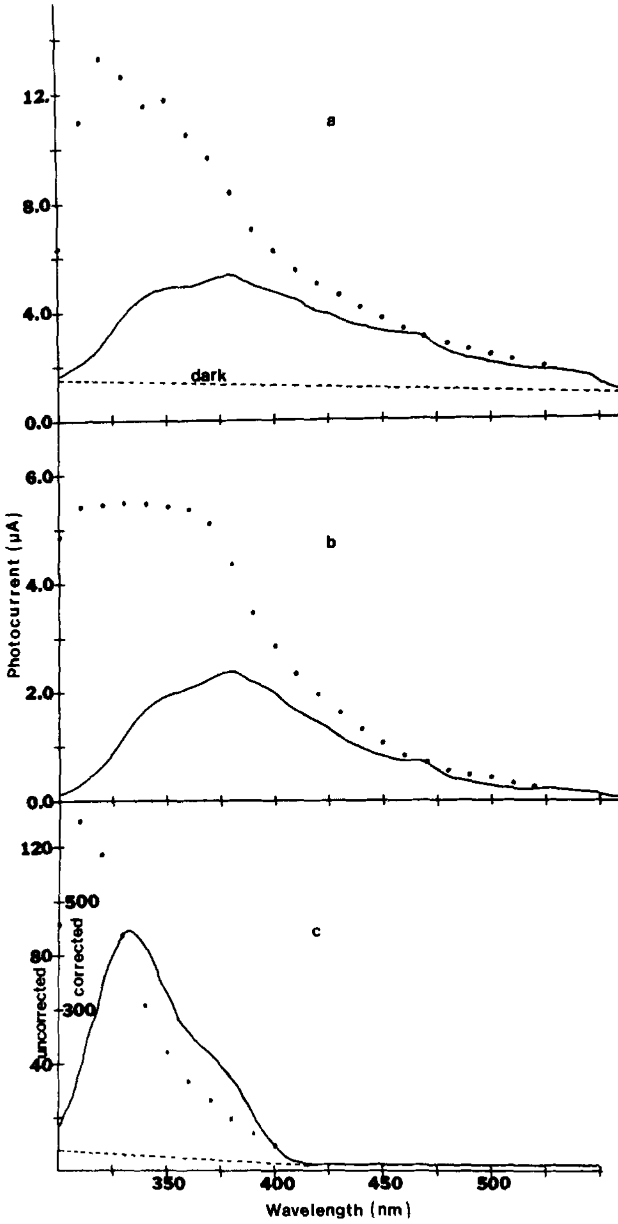

Fig. 3. Photocurrent vs. wavelength at a potential of E = +0.800V (vs. SCE) for Fe_2O_3 films on (a) Ti, in 0.5*M* KCl, (b) Pt, in 0.5*M* Na_2SO_4, and (c) CVD TiO_2 electrode in 0.5*M* KCl. Solid line is uncorrected for intensity variations; circles are the corrected curve.

On the other hand, holding it at −0.5V under the same conditions caused a rapid dissolution of the coating.

The spectral response of the Fe_2O_3 electrodes at E = +0.800V is shown in Fig. 3a (Ti substrate) and 3b (Pt substrate). Figure 3c is a spectral curve of CVD TiO_2 on Ti shown for comparison. Curves are given with and without corrections for lamp/monochromator output variations. The dark current for the Ti substrate decayed slowly during measurement resulting in a sloping base line. The spectral response curves for all of the Fe_2O_3-coated substrates were virtually identical in shape, indicating that the photoeffect is due to the Fe_2O_3 itself. A significant portion of the total photocurrent under the curve shown (approximately 20% of corrected curve) is at wavelengths longer than 400 nm, compared to virtually zero for TiO_2. Thus the Fe_2O_3 electrode could be operated at +0.400V in 1*M* NaOH with a yellow filter having <0.1% transmittance below 450 nm, yielding a current density of 700 μA/cm² with gas bubbles being observed on the surface.

The photocurrent for the iron oxide begins at about 550 nm which would correspond to the reported bandgap of Fe_2O_3, *i.e.*, 2.2 eV (10). A coating of the iron oxide was deposited on a quartz slide and heated in flame. Although the coating was quite adherent, it showed a high resistance. An absorbance *vs.* wavelength curve (taken with a Cary 14 spectrophotometer) of the Fe_2O_3 on quartz sample showed a steep rise in absorbance beginning at about 580 nm, with absorbance above 1.0 at 550 nm, again agreeing with the bandgap energy of Fe_2O_3.

The spectral response and reasonable stability of the iron oxide film electrode makes it suitable for use in photoelectrochemical experiments at longer wavelengths, as well as a possible electrode for the photoassisted electrolysis of water and in photoelectrochemical solar cells (3, 11).

Semiconductor Electrodes

VI. A Photoelectrochemical Solar Cell Employing a TiO_2 Anode and Oxygen Cathode

Daniel Laser and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

A photoelectrochemical cell for conversion of light to electrical energy based on the photosensitized oxidation of water at a chemically vapor deposited, thin film, n-type TiO_2 anode and the reduction of oxygen at a fuel cell-type cathode is described. The effect of load resistance on the current, cell voltage, and power was studied, and quantum and power efficiencies under short-circuit conditions for monochromatic light of about 365 nm was estimated as 26% and 1-2%, respectively. Open-circuit cell voltages of 0.89V were obtained. The cell is simple to construct and is capable of continuous operation with no apparent deterioration in performance.

Photoeffects at semiconductor electrodes received renewed attention when these materials were recognized as potential candidates for use in the conversion of light to electrical and chemical energy via some electrochemical process; this subject has been reviewed and discussed recently (1, 2). Of special interest are semiconductor electrodes which do not decompose or corrode during the photoelectrochemical process (*e.g.*, n-type TiO_2), so that the light exclusively induces charge transfer to selected species in solution. We describe here the construction and behavior of an electrochemical photocell which produces electrical power under illumination by light of suitable spectral characteristics. Although this electrochemical cell differs in operating mechanism from the familiar solid-state solar cell, the result, conversion of light to electrical energy, is the same. The cell is based on the photosensitized oxidation of water to oxygen at a chemically vapor deposited n-type TiO_2 anode and the reduction of oxygen at a fuel cell-type cathode and offers good quantum efficiency, simple construction, and continuous operation without renewal of electrolyte or electrode decomposition. Its major limitation for utilization of solar energy is its response only to the short wavelength (below 400 nm) portion of the spectrum.

Experimental

The cell, shown schematically in Fig. 1, consisted of an aqueous solution (acidic or basic) confined between a quartz window and the cathode. The cathode was the type employed in hydrogen-oxygen fuel cells (American Cyanamid experimental fuel cell electrode, 2.5 mg Pt/cm^2, deposited on a nickel-gold screen with Teflon backing). In parallel and spaced 12 cm away was fixed a bright Pt foil (0.2 mm thick) which was perforated by numerous pinholes (about 6 $holes/cm^2$) which reduced its geometric area only slightly and which was covered on both sides with a TiO_2 film produced by chemical vapor deposition (CVD) (3). The side facing the window served as the photoactive TiO_2 anode with ionic conductivity from this part of solution to the oxygen electrode being accomplished through the pinholes in the foil. The TiO_2 film on the other side of the membrane (facing the O_2 electrode) eliminated contact between solution and bare Pt surface. The procedure for the CVD of the TiO_2 film described by Hardee and Bard (3) was followed. The Pt substrate, after being punched, was cleaned in a 3:1 $HCl:HNO_3$ mixture; the film was then deposited and annealed. After about four successive coatings, each of them at the maximum thickness possible without causing the film to peel off, the resulting film was quite thick. It had a hazy gray appearance and interference fringes could no longer be observed; the adhesion of this film to the Pt was excellent. After the CVD the TiO_2 film was vacuum treated for 8 hr (750°C, 10^{-4} Torr). This procedure converted the dielectric TiO_2 film into a conductive n-type material.

Two inlets to the cell allowed the immersion of a saturated calomel reference electrode (SCE) and another Pt electrode into the cell for potentiostatic measurements. For these a Princeton Applied Research (PAR) Model 173 potentiostat was used. While operating as a galvanic cell, the voltage and current were determined with a standard resistance load connected across the cell terminals. A 450W Xenon lamp (Oriel Corporation, Stamford, Connecticut) was the light source. For spectral response and efficiency determinations an Oriel Model 7242 high intensity grating monochromator and a Model 550 (EG & G, Salem, Massachusetts) calibrated radiometer assembly were used.

Results and Discussion

Electrochemical photocells can be classified as two distinct types (1, 2). In the first, radiation is converted into chemical energy, *i.e.*, under illumination a normally endothermic chemical reaction will take place spontaneously or with an electrical energy input less than the reversible value for this reaction. In the second type, which is the one of interest here, no over-all chemical change occurs in the system and the absorption of light results in the generation of electrical power. Both electrochemical half-cell reactions which were

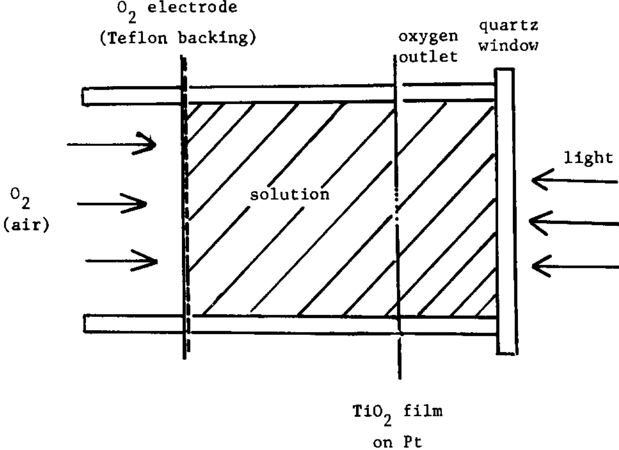

Fig. 1. Schematic representation of the n-TiO_2/Pt(O_2) photoelectrochemical solar cell.

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, semiconductors, solar cells, galvanic cells.

employed have been the subject of separate previous studies and so are not dealt with here in detail. The anode reaction was the evolution of oxygen at an illuminated n-type TiO_2 electrode. This reaction has been studied at both single crystal (4-7) and thin film (3) materials. With the omission of mechanistic details oxygen evolution from aqueous solution at an illuminated TiO_2 electrode can be represented as

$$2H_2O + 4h^+ \rightarrow O_2 + 4H^+ \quad \text{(acidic solution)} \quad [1]$$

$$4\,OH^- + 4h^+ \rightarrow O_2 + 2H_2O \quad \text{(basic solution)} \quad [2]$$

The holes (h^+) are produced by the appropriate band-gap illumination and the efficiency of the process depends on the electrical state of the semiconductor electrode. A sufficiently positive bias will result in an extended space charge region in which the recombination of the photogenerated holes with electrons (e^-) (the majority carrier) is minimized and an efficient separation of the photoproduced h^+/e^- pairs occurs, with the holes drifting to the electrode surface. The photooxidation of water takes place at a "negative overpotential" (8), *i.e.,* at a less positive electrode potential than the reversible one (thermodynamically independent of electrode composition), thereby allowing the utilization of the light energy. The cathode reaction, the well-known reduction of oxygen at a Pt catalyst fuel cell electrode

$$O_2 + 4H^+ \rightarrow 4e^- + 2H_2O \quad \text{(acidic solution)} \quad [3]$$

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \quad \text{(basic solution)} \quad [4]$$

is just the reverse of the anodic reaction, except that electrons participate in it instead of holes.

The behavior of the complete cell can be predicted from the individual current-potential curves for each electrode measured potentiostatically against a reference electrode; typical results for 5*M* NaOH and 5*M* $HClO_4$ solutions are given in Fig. 2. If the electrodes are shorted together (load resistance R_L, of 0) and solution resistive drop is negligible, they attain the same potential, at which the current at each is of the same magnitude and opposite in polarity (dashed line, Fig. 2). The less favorable situation in the acidic solution results from the less reversible behavior of the oxygen cathode, *i.e.,* its failure to shift to more positive potentials with decreasing *p*H by an amount equivalent to the anode shift (for a reversible reaction a shift of 60 mV/*p*H unit is expected). The open-circuit potential in alkaline solution is about 900 mV under illumination. The maximum current ($R_L = 0$) is about 85% of the saturation (plateau) current which represents the maximum current obtainable at a given light level for the photooxidation process at the TiO_2 electrode. Thus, even if the cathode could be shifted to more positive potentials [*e.g.,* at a silver/silver oxide cathode (9)] the maximum cell current would only increase by a small amount; the cell power would increase, however, because of the greater cell voltage. During operation oxygen is evolved at the TiO_2 electrode and the same amount of oxygen is incorporated from outside of the cell at the oxygen electrode. Because of the high concentration of reactant employed (water, OH^-, O_2), concentration polarization is negligible. A small outlet near the upper part of the TiO_2 electrode allowed escape of the electrogenerated oxygen. The solution on the dark side of the Pt/TiO_2 electrode was held at a pressure slightly greater than atmospheric so that the solution level remained constant throughout the cell.

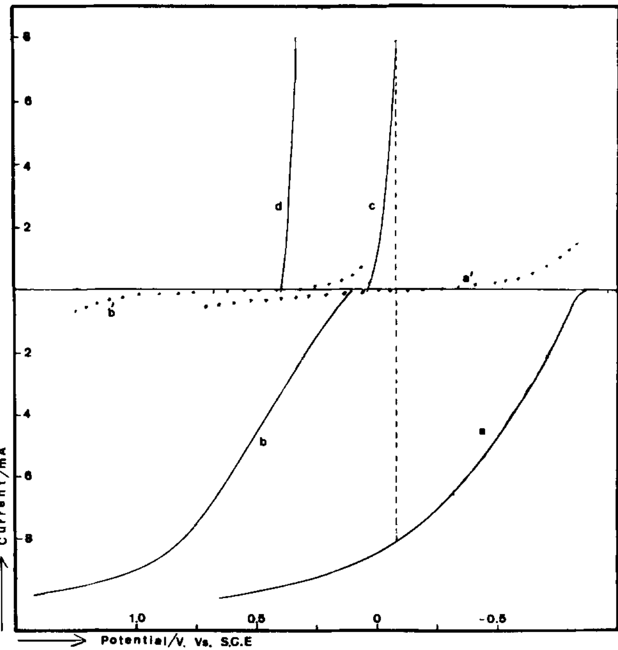

Fig. 2. Current-potential curves of the cell electrodes. (a) TiO_2 film electrode, 5*M* NaOH, under illumination and (a') in dark; (b) TiO_2 film electrode, 5*M* $HClO_4$, under illumination and (b') in dark; (c) oxygen cathode in 5*M* NaOH; (d) oxygen cathode in 5*M* $HClO_4$. Electrode areas, 20 cm^2. White (Xe) light illumination.

The voltage, current, and power curves of the cell for different R_L values at the same light levels as in Fig. 2 are given in Fig. 3. In bright sunlight about one-half to one-third of the power shown in Fig. 3 was obtained. The internal resistance of the cell was mainly due to that of the TiO_2 film, estimated to be 5-10 ohms. At the current density employed, little power dissipation due to internal cell resistance was observed. The spectral response of the TiO_2 film agreed with that of previous reports (3, 7, 10) with a maximum at about 365 nm (uncorrected for lamp output). The quantum or photon efficiency, n_ϕ (1), defined as the current density at the TiO_2 electrode divided by the flux of light at the wavelength of maximum response (or electrons flowing per photon impinging on electrode), determined under potentiostatic conditions for the saturation current, was 30 ± 5%. This figure should be regarded only as a representative one, since different TiO_2 films differ in their photoresponse depending on the method and conditions of preparation. A single crystal of TiO_2 was found to have an efficiency of 80 ± 10%, under similar conditions. Thus, if the film was sufficiently thick for the absorption of all the light, some other factors, such as enhanced surface e^-/h^+ recombination, may contribute to the lower efficiency of the TiO_2 films. In the operation as a galvanic cell with $R_L = 0$ about 85% of the saturation current is obtained for the same illumination condi-

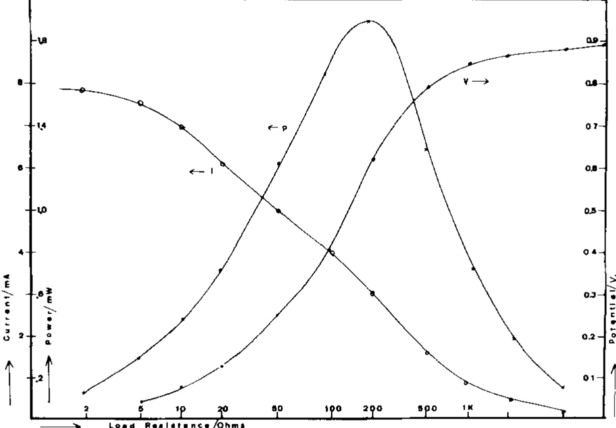

Fig. 3. Voltage *(V)*, current *(I)*, and power *(P)* of the cell as function of the load resistance. Under same white (Xe) light intensity as in Fig. 2.

tions. Thus the quantum efficiency under short-circuit conditions is about 26% for this cell. The maximum power efficiency takes into account the energy of the incident photons as well as their flux and depends on R_L. It will be defined as the maximum cell power per square centimeter electrode area over the light intensity at the wavelength which corresponds to the maximum response. This quantity could not be measured directly, because of the low intensity of the monochromatic light (produced using a slit width of about 2 mm to give a bandwidth of about 2 nm) resulting in an electrical power of less than 1 μW. Moreover, this power efficiency depended on the illumination intensity and R_L. If the white light intensity was varied, using neutral density filters in the ratio of 1:0.62:0.40:0.12, an over-all (polychromatic) maximum electrical power with a ratio of 1:0.6:0.46:0.15 at loads of 150, 200, 500, and 1000 ohm, respectively, was obtained. The corresponding saturation currents at the TiO_2 measured potentiostatically were, as expected, linear with white light intensity and were 10, 6.1, 4.1, and 1.2 mA for the intensity ratios given above. These observations are consistent with the fact that in general the current at the TiO_2 electrode is not exactly proportional to the light intensity at all potentials on the rising portion of the wave as it is for the saturation current. The maximum (monochromatic) power efficiency was estimated as follows. The cell power (0.22 mW/cm^2) and the TiO_2 potentiostatic saturation current (1.5 mA/cm^2) were measured under the same intensity white light concentrated on the center 1 cm^2 of the electrode. Then, using monochromatic light, the light intensity (96.4 μW/cm^2) and saturation current for the TiO_2 (9 μA/cm^2) were determined. Thus, for monochromatic light (367 nm) a saturation current of 0.093 μA/μW is produced. The saturation current found with the white light is thus equivalent to a monochromatic light intensity of 16 mW/cm^2. Thus the maximum power efficiency for monochromatic light is 1-2%. The efficiency for solar energy conversion is much lower, of course, because only about 3% of the solar spectrum would be utilizable at a TiO_2 electrode (1).

The cell appeared capable of operation either continuously or in on/off cycles with no deterioration in performance (*e.g.*, Fig. 4). The cell also could operate without a separate oxygen feed to the cathode (on the oxygen dissolving at the anode) or with air fed to the cathode. In the latter case the cell, besides producing energy, serves to separate oxygen from the air.

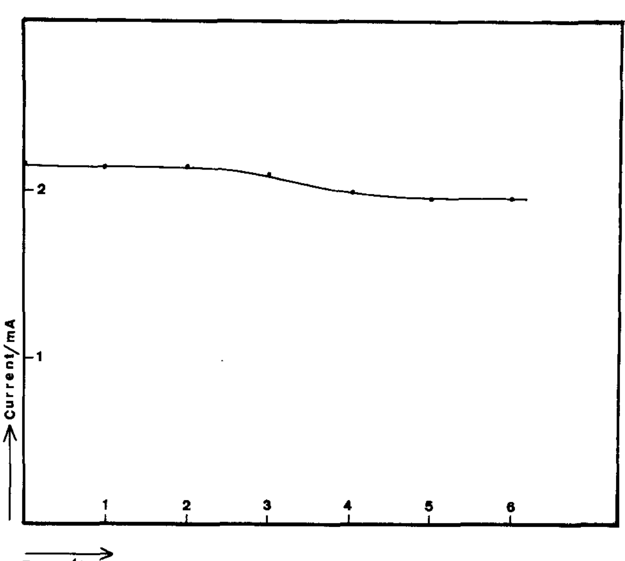

Fig. 4. Cell operation under white light illumination with time; load resistance, 100 ohms.

Although the described cell arrangement appeared satisfactory, *i.e.*, allowed full illumination of the photosensitive surface with a reasonable current density distribution and internal ohmic losses, some other cell configurations were also tried. Among these was a thin sandwich cell employing the same oxygen cathode and electrolyte solution but with the TiO_2 film deposited on a transparent SnO_2 film-on-glass substrate. Memming (10) previously showed that such TiO_2 films show light-induced electrochemical activity and that the SnO_2 is transparent to the wavelengths which generate photocurrents at the TiO_2 film. In this arrangement the TiO_2 film faces the cathode and is illuminated from the rear through the glass plate and the SnO_2 film. In this way the cell geometry is optimized and the distance between the electrodes, volume of solution, and its internal resistance are minimized. However, this cell performance was inferior to that of the previously described one; we attribute this mainly to the poorer efficiency of the TiO_2 film deposited on the SnO_2 substrate. We found it difficult to prepare a TiO_2 film which was thick enough to give good photosensitized electrochemical behavior and show good conductivity and at the same time obtain good light transmittance through the glass/SnO_2/TiO_2 system. The major problem was that the glass substrate system could not be subjected to the high temperatures needed in the CVD-coating procedure without deterioration of the SnO_2 film. The conversion of the TiO_2 to an n-type material in this case was accomplished by heating to 450° in a hydrogen atmosphere, since heating to high temperatures under vacuum was not possible.

We might also note that a recent paper by Mavroides *et al.* (11) utilized a platinized-Pt cathode of geometric area 50 times that of the anode operating on the reduction of dissolved oxygen to evaluate the performance of various semiconducting TiO_2 anodes. High quantum efficiencies were also obtained in that study for operation in a photogalvanic mode. Similarly Keeny *et al.* (6) effectively used a Pt-oxygen cathode in their laboratory cell.

While the photoelectrochemical cell here operates on the water-oxygen system, similar cells for conversion of light to electrical energy without a net chemical change in the system could operate with other redox couples (represented by Ox + $ne \rightleftarrows$ Red). The potential range of the TiO_2 anode would be limited to values near the flatband potential where sufficient band bending occurs to cause efficient separation of the h^+/e^- pairs. Thus for any redox couple the anodic i-E curve will probably be close to the one given for water oxidation. The cathode curve for reduction of Ox to Red will depend on the $E°$ and the reversibility of the reduction reaction. The more positive the values at which the i-E curve lies the greater will be the power of the cell at a given illumination level. Thus redox couples with more positive $E°$ values should lead to higher power efficiencies with the constraint that for couples with $E°$ values larger than that of the oxygen/water couple (adjusted to the appropriate pH value), species Ox will tend to be unstable in aqueous solutions. Moreover the work of Fujishima and Honda (12, 13), as well as our own recent studies (14) suggest that as the $E°$ of the redox couple becomes more positive water may compete more successfully with Red for the photogenerated holes, leading to an over-all irreversibility in the cell reaction. If one abandons an aqueous system, however, and uses a solvent with a wider available potential range, such as acetonitrile, for example (15), then even more positive redox couples can be employed. The most positive $E°$ value for a couple used in a solvent which participates in neither the anodic nor cathodic reaction is one located at about the position of the valence band of the n-type semiconductor, where Red is still capable of combining with holes at the electrode surface. Under

these conditions the maximum utilization of the energy of the incident photons should occur.

Primary Resistances for Ring-Disk Electrodes

Joseph J. Miksis, Jr., and John Newman*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A system consisting of a disk electrode, a concentric ring electrode, and a large counterelectrode at infinity has three independent resistance values describing the primary potential difference between any two electrodes when current is passed between any two electrodes. These resistance values are calculated and presented as dimensionless correlations as functions of the ratios of radii of the disk and ring.

A common electrode geometry in electroanalytical and research applications involves a disk electrode and a concentric ring electrode both embedded in an insulating plane and rotated about the axis of the disk. Species produced by an electrochemical reaction at the disk can frequently be detected quantitatively by electrochemical reaction at the ring (1-3). In some of these applications it is desirable to assess the ohmic potential drop in the solution. For example, to have a controlled electrode potential for the reaction at the disk one needs to know how a current to the disk and a current to the ring separately influence the potential in the solution in the neighborhood of the disk (4, 5). To ensure that a limiting current is maintained on the ring involves a similar question (6).

Experimental efforts to answer these questions involve abrupt changes in the current to either the ring or the disk followed by a measurement of the change in potential of both the ring and the disk as shortly thereafter as possible (4, 5, 7). Such rapid changes in potential and current are associated with the primary distributions of potential and current (8).

Consequently, we can define a mathematical problem in which the potential obeys Laplace's equation

$$\nabla^2\Phi = 0 \quad [1]$$

the potential is zero at infinity, and has a uniform value in the solution adjacent to each electrode. Corresponding to a zero current density, the normal component of the potential gradient is zero on the insulating annulus between the disk and the ring and on the plane surrounding the ring. This problem excludes consideration of the variation of conductivity within the thin diffusion layer adjacent to the electrodes and effectively regards the change in potential drop to be determined by the bulk of the solution. Also excluded from consideration is the effect of electrode kinetics, it being assumed that the double-layer capacity is sufficiently large that the potential difference across it does not change during the time of the measurement (8). [The course of events involving the change of the charge of the double-layer capacity has been examined by Nişancioǧlu and Newman (9-11).]

The problem thus defined is limited in scope since it involves only the geometry of the system, the conductivity of the solution, and the potentials and currents themselves. The principal result of the model is the expression of the disk and ring potentials in terms of the disk and ring currents

$$V_d = R_{dd}I_d + R_{dr}I_r \quad [2]$$

$$V_r = R_{rd}I_d + R_{rr}I_r \quad [3]$$

where I_d and I_r are the total currents to the disk and ring electrodes, respectively, and V_d and V_r are the potentials, presumed uniform, in the solution adjacent to the two electrodes. In the absence of concentration and surface overpotentials, V_d and V_r can be regarded to be the potentials of the electrodes themselves, and this is the usual manner of speaking when discussing primary-distribution problems. Bear in mind that in

* Electrochemical Society Active Member.

Key words: current distribution, potential distribution, Laplace's equation, interrupter techniques.

the applications discussed above these quantities I_d, I_r, V_d, and V_r probably represent instantaneous changes in the electrode currents and the corresponding instantaneous changes in the electrode potentials.

Equations [2] and [3] follow directly from the mathematical problem and the linearity of Eq. [1]. By the principle of superposition, the potential Φ in the solution can be expressed as the sum of two functions, one proportional to V_d and the other proportional to V_r. Since the current to an electrode is obtained from the integral over the area of the normal component of the potential gradient at the electrode, it is clear that both I_d and I_r are sums of two terms, one proportional to V_d and the other proportional to V_r. Inversion of these relations then leads to Eq. [2] and [3] and the corresponding definition of the resistances.

R_{dd}, R_{dr}, R_{rd}, and R_{rr} are the primary resistances defined by Eq. [2] and [3] for this ring-disk system. We can attach a physical meaning to them by the following considerations. When there is no ring current, $I_r = 0$, we see that R_{dd} represents the resistance between the disk electrode and a counterelectrode at infinity. This resistance will be lower in the presence of the ring than for the disk alone because current can find a path through the ring electrode to the disk, bypassing some of the resistance of the solution. This is true even though there is no net current to the ring. Under these circumstances, the potential of the ring will take on a definite, uniform value to satisfy the condition of no net current to the ring. This value is determined by R_{rd} in Eq. [3]. Thus, R_{rd} is a quantity having the dimensions of a resistance but which yields the potential on the ring due to a current on the disk.

In a similar manner, we see that when there is no disk current, R_{rr} is the resistance between the ring and a counterelectrode at infinity while R_{dr} reproduces the uniform potential on the disk due to a current on the ring. As shown below, $R_{dr} = R_{rd}$.

The geometry of the ring-disk system is defined adequately by the ratio r_0/r_1 of the disk radius to the inner radius of the ring and the ratio r_1/r_2 of the inner and outer radii of the ring. The resistances can be made dimensionless with the conductivity κ of the solution and a characteristic length, which we choose to be the outer radius r_2 of the ring. Therefore, the results of this study can be presented simply by correlating three dimensionless resistances ($R_D{}^D = \kappa r_2 R_{dd}$, $R_D{}^R = R_R{}^D = \kappa r_2 R_{dr}$, and $R_R{}^R = \kappa r_2 R_{rr}$) as functions of two geometric ratios (r_0/r_1 and r_1/r_2). This simplicity and generality is a further justification for restricting the problem to the primary resistances.

In a subsequent paper from this laboratory (12), we shall discuss some more complicated behavior of the ring-disk system in which concentration variations and electrode kinetics are considered in order to assess the current distribution on a sectioned electrode (composed of the ring and disk at the same potential) below the limiting current, the collection efficiency of the system when the current distribution on the disk is nonuniform due to the ohmic potential drop in the solution, and the anomalous diffusion coefficient for a redox couple measured by means of the limiting current to a ring electrode with zero current to the disk.

Symmetry of Resistances

Let us consider two cases: case 1 where $I_d = 0$ and case 2 where $I_r = 0$. For any two functions Φ_1 and Φ_2, Green's theorem says (13)

$$\int (\Phi_1 \nabla^2 \Phi_2 - \Phi_2 \nabla^2 \Phi_1) dV_o = \oint (\Phi_1 \nabla \Phi_2 - \Phi_2 \nabla \Phi_1) \cdot dS \qquad [4]$$

The integral over the volume V_o is zero here because both Φ_1 and Φ_2 obey Laplace's equation. The surface integral is over the entire area enclosing the volume V_o, which we shall take to be the entire half-space between the plane of the disk and the counterelectrode at infinity. The integral over the insulating surfaces is zero because the normal component of the potential gradient is zero there. The integral over a hemisphere at infinity is zero because each potential is inversely proportional to the radius, the potential gradient is inversely proportional to the square of the radius, and dS is proportional to the square of the radius.

This leaves us with integrals over only the surfaces of the electrodes

$$\int_d (\Phi_1 \nabla \Phi_2 - \Phi_2 \nabla \Phi_1) \cdot dS = - \int_r (\Phi_1 \nabla \Phi_2 - \Phi_2 \nabla \Phi_1) \cdot dS \qquad [5]$$

Now, by the definition of the primary distributions, the potential adjacent to each electrode is uniform and can be removed from the integral, with the result

$$V_{d1} \int_d \nabla \Phi_2 \cdot dS - V_{d2} \int_d \nabla \Phi_1 \cdot dS = - V_{r1} \int_r \nabla \Phi_2 \cdot dS + V_{r2} \int_r \nabla \Phi_1 \cdot dS \qquad [6]$$

Furthermore, the integral of the normal component of the potential gradient over the surface of an electrode is proportional to the total current to the electrode. Equation [6] becomes

$$V_{d1} I_{d2} - V_{d2} I_{d1} = - V_{r1} I_{r2} + V_{r2} I_{r1} \qquad [7]$$

For the cases chosen here, $I_{d1} = 0$ and $I_{r2} = 0$, and this reduces to

$$V_{d1} I_{d2} = V_{r2} I_{r1} \qquad [8]$$

Substitution of Eq. [2] and [3] for the electrode potentials, with $I_{d1} = I_{r2} = 0$, yields

$$R_{dr} I_{r1} I_{d2} = R_{rd} I_{d2} I_{r1} \qquad [9]$$

or

$$R_{dr} = R_{rd} \qquad [10]$$

Gabrielli *et al.* (7) state this result and provide supporting experimental results. Equation [10] could be considered to be an example of the Onsager reciprocal relation.

It should be emphasized that this demonstration of reciprocity is valid for an arbitrary geometry of the electrodes and insulators. For example, the presence of the Luggin capillary from a reference electrode can modify the values of the resistances but still $R_{dr} = R_{rd}$. Also, the counterelectrode does not need to be a hemisphere at infinity. By taking the third electrode to be the zero of potential, one can still reduce Eq. [4] to Eq. [5] and obtain the reciprocal relation for the primary resistances.

Analysis

Newman (14) reviewed methods of calculating current and potential distributions in ring or disk geometries. At first we thought that we could treat the ring-disk system as a composite disk of radius r_2 and use the method of separation of variables in rotational elliptic coordinates. Then the current density would be zero on the insulating annulus while the potentials would be specified on the ring and disk, and the coefficients of the series would be determined by trial and error or by matrix inversion so as to satisfy these boundary conditions. However, such a series is inadequate to represent the distributions of potential and current in this system because the current density approaches infinity at the inner edge of the ring and at the edge of the disk. [The coordinate system does allow treatment in a natural way of the infinite current density near the outer edge of the ring, just as it does for the primary distribution near the edge of a disk without a ring (15).]

As an alternative, the currents due to the ring and the disk were treated separately by different methods. First a series of ten cases was defined with prescribed current distributions on the ring. For cases 1 and 3, these current distributions were

$$i_{r1} = \frac{2}{\sqrt{1-x^2}} \quad [11]$$

and

$$i_{r3} = \sqrt{\frac{2}{1+x}} \quad [12]$$

where

$$x = \frac{2r - r_1 - r_2}{r_2 - r_1} \quad [13]$$

Case 2 has a zero current density everywhere on the ring but will have a current assigned to the disk as described below. Cases 4 through 10 (denoted by values of k from 4 through 10) were assigned the following current distributions on the ring

$$i_{r,k} = P_{k-4}(x) \quad [14]$$

where $P_k(x)$ is the Legendre polynomial.

It was felt that these cases would represent a complete set which could be superposed to reproduce any primary current distribution on the ring electrode. In particular, case 1 has an infinite current density at both the inner and the outer edge of the ring, and the current density approaches infinity in the manner required when an electrode is embedded in an insulating plane, namely, by being inversely proportional to the square root of the distance from the edge.[1] Case 3 involves an infinite current density only at the inner edge of the ring. A superposition of cases 1 and 3 should be able to match the way in which any primary current distribution goes to infinity at the inner and outer edges of the ring. The residual current distribution should be finite over the ring and adequately represented by a superposition of the remaining cases 4 through 10. For some values of r_0/r_1 and r_1/r_2 where the accuracy of the results was questionable, the number of cases was extended from 10 to 20.

[1] This means that the product of the current density and the square root of distance from the edge has a finite, nonzero limit as the edge is approached.

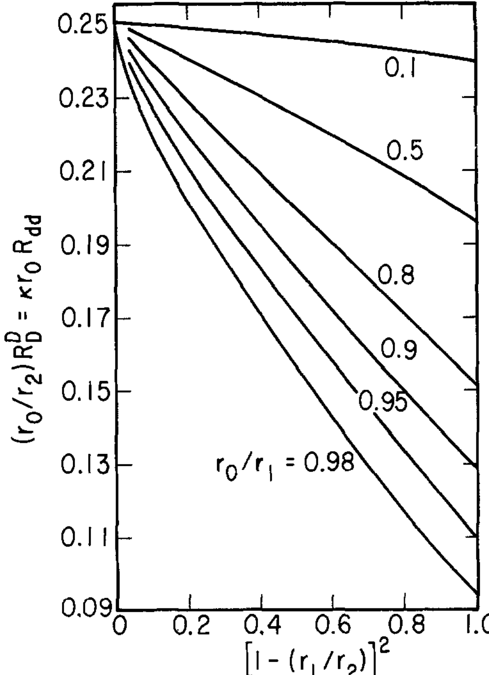

Fig. 1. Correlation of the disk resistance

The next step in the procedure is to evaluate the potential distribution on both the disk and the ring due to the current distribution on the ring for each of the cases described above. For this purpose, we use the formula for the potential in the plane of the disk (14)

$$\Phi_0(r) = \frac{2}{\pi\kappa}\int_{r_1}^{r_2} \frac{i(r')K(m)r'dr'}{r+r'} \quad [15]$$

where

$$m = \frac{4rr'}{(r+r')^2} \quad [16]$$

and $K(m)$ is the complete elliptic integral of the first kind

$$K(m) = \int_0^{\pi/2} \frac{d\alpha}{\sqrt{1-m\sin^2\alpha}} \quad [16a]$$

The potential due to a uniform ring current source of radius r', located in the plane $z = 0$ and of strength $2idr'$ (ampere per unit length), is

$$d\Phi = \frac{2ir'dr'}{4\pi\kappa}\int_0^{2\pi} \frac{d\theta}{[z^2 + (r - r'\cos\theta)^2 + (r'\sin\theta)^2]^{1/2}}$$

$$= \frac{ir'dr'}{2\pi\kappa}\frac{2}{\sqrt{z^2+(r+r')^2}}\int_0^{\pi} \frac{d\theta}{\left[1 - 2rr'\dfrac{1+\cos\theta}{z^2+(r+r')^2}\right]^{1/2}}$$

$$= \frac{ir'dr'}{2\pi\kappa}\frac{4}{\sqrt{z^2+(r+r')^2}}\int_0^{\pi/2} \frac{d\alpha}{\left[1 - \dfrac{4rr'}{z^2+(r+r')^2}\sin^2\alpha\right]^{1/2}} \quad [16b]$$

where $\alpha = (\pi - \theta)/2$. Integration for current rings between r_1 and r_2 and evaluation for $z = 0$ yield Eq. [15].

The evaluation of the integral in Eq. [15] for the potential distribution on the ring requires care, first of all, because the elliptic integral approaches infinity when $r' = r$, corresponding to the infinite potential at the ring itself produced by a ring of nonzero current but infinitesimal width. Additional difficulties are introduced for cases 1 and 3 where the current distribution approaches infinity at the inner or outer edge of the ring.

The potential distributions obtained above will be nonuniform on both the ring and the disk. For each case, the potential can be made uniform on the disk by superposing the potential distribution due to a current distribution introduced on the disk. Here we use rotational elliptic coordinates η and ξ based on the radius r_0 of the disk. The coordinate transformation reads

$$z = r_0\xi\eta \text{ and } r = r_0\sqrt{(1+\xi^2)(1-\eta^2)} \quad [17]$$

and the solution of Laplace's equation by separation of variables in this coordinate system is (14, 16)

$$\Phi = \sum_{n=0}^{\infty} B_n P_{2n}(\eta) M_{2n}(\xi) \quad [18]$$

where B_n represents arbitrary coefficients, $P_{2n}(\eta)$ is again the Legendre polynomial, and $M_{2n}(\xi)$ [called $M_n(\xi)$ in Ref. (14)] is a Legendre function of imaginary argument having properties described earlier. Selection of even Legendre polynomials in Eq. [18] ensures that the corresponding current distribution is zero in the plane outside the disk; hence, the current distribution is not modified on the ring by superposing a potential distribution of the type in Eq. [18].

In practice, Eq. [18] is truncated after a finite number of terms, say 20. For each case the B values are

then chosen so that the potential (including that due to the ring current) will be zero on the surface of the disk. Up to this point, case 2 has not been defined or modified. We now require that the potential Φ_0 be equal to unity on the surface of the disk, for case 2, which is equivalent to setting $B_0 = 1$. The superposition of the disk potential function in Eq. [18] will generate a nonzero net current and a uniform potential for the disk for each case.

Next, for each case, we should calculate the potential distribution on the ring due to the current distribution on the disk, and we should add this to the potential distribution previously obtained from the current distribution on the ring. This step involves the use of Eq. [18] with values of ξ greater than zero since

$$\Phi_0 = \sum_{n=0}^{\infty} B_n P_{2n}(0) M_{2n}(\xi) \qquad [19]$$

in the plane for r greater than r_0. The evaluation of $M_{2n}(\xi)$ has been necessary in earlier work (6), and we have introduced refinements here (17) to permit accurate calculation for large values of ξ and n.

The several cases that have been treated now each have prescribed current distributions on the ring and disk, known total currents, a uniform potential on the disk, and a nonuniform but finite potential distribution on the ring. The final step of the procedure is to superpose cases 3 through 10 onto cases 1 and 2, in turn, in such a way that the potential distribution on the ring is made uniform. More cases can be used to attain a higher degree of uniformity.

Cases 1 and 2 now satisfy all the requirements of a primary distribution: They have uniform potentials on the ring and the disk, and they satisfy Laplace's equation and all the other boundary conditions. Analysis of cases 1 and 2 according to Eq. [2] and [3] yields values of the resistances R_{dd}, R_{dr}, R_{rd}, and R_{rr}.

This solution for the primary potential and current distributions by superposition may seem involved and complicated, but it is economical and accurate, and it avoids any trial-and-error calculations. The functions chosen for superposition make special allowance for the geometry of the system and can treat the infinite current densities at the edges of the electrodes even when the insulating annulus is quite thin.

Results

In the computed results, R_{dr} and R_{rd} usually agreed to within 0.01%. Certain limiting situations could also be checked to ensure the validity of the results.

Figures 1, 2, and 3 show the values of the three independent resistances as functions of the geometric ratios r_0/r_1 and r_1/r_2. These results are also given in Table I. For a very thin ring, R_{rr} becomes infinite in a

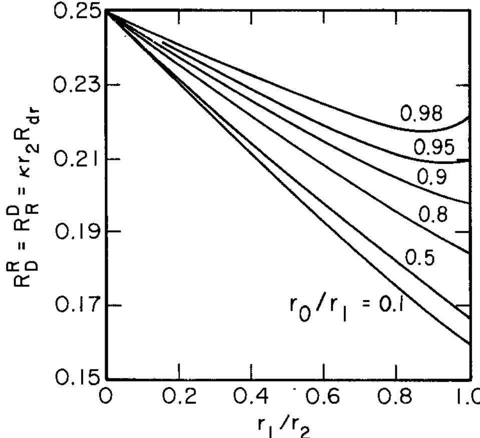

Fig. 2. Correlation of the interaction resistance

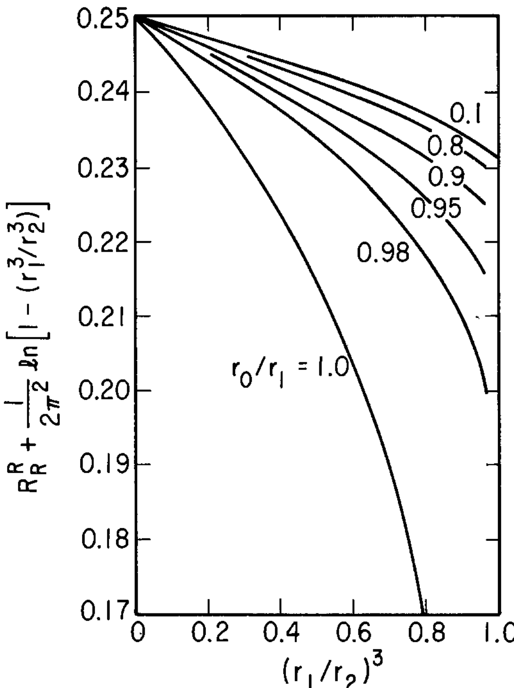

Fig. 3. Correlation of the ring resistance

manner which is discussed in the Appendix. Consequently, on Fig. 3 we have added a term which compensates for this and produces a finite limit as r_1 approaches r_2. An exception is the (unrealistic) limit of a zero gap distance. As r_0 approaches r_1, the value of $\kappa r_2 R_{rr}$ approaches 0.25, independent of the value of r_1/r_2.

Discussion

The results for R_{dd} can be comprehended in relation to the value $1/4\kappa r_0$ for the primary resistance (15) for a single disk in an insulating plane. The values for the disk resistance, as plotted in Fig. 1, therefore approach the value 0.25 as the influence of the ring becomes negligible, either for thin rings ($r_1 \rightarrow r_2$) or for wide gaps between the rings and the disk ($r_0 << r_1$). The influence of the ring is always to lower the resistance value $\kappa r_0 R_{dd}$ below the value 0.25 because the ring provides an alternative current path which can help the current get from infinity to the neighborhood of the disk. Figure 1 shows how this effect becomes more pronounced for wide rings and narrow gaps.

There are several ways of thinking about the coupling resistances $R_{dr} = R_{rd}$. First imagine a current to the disk with no current to the ring. Then the potential distribution will bear some resemblance to that for a single disk in an insulating plane, and the similarity will become exact in the limit of a thin ring. The ring, in addition to distorting this potential field, will acquire a potential corresponding to the single disk at some radial position r_* which lies between r_1 and r_2. Since

$$(r/r_0)^2 = 1 + \xi^2 \qquad [20]$$

on the ring and since

$$M_0(\xi) = \frac{2}{\pi} \operatorname{ctn}^{-1}(\xi) \qquad [21]$$

the potential in the plane at a radial position r_* due to the primary distribution on a single disk is

$$V_r = V_d \operatorname{ctn}^{-1}(\xi) = \frac{I_d}{2\pi\kappa r_0} \sin^{-1}\left(\frac{r_0}{r_*}\right) \qquad [22]$$

This leads to the resistance value

$$\kappa r_2 R_{rd} = \frac{r_2}{2\pi r_0} \sin^{-1}\left(\frac{r_0}{r_*}\right) \qquad [23]$$

This formula becomes rigorous for thin rings when we set r_* equal to r_2. Thus, the intercept on the right side of Fig. 2 is known with certainty. The limit for the ordinate is 0.25 for narrow gaps ($r_0 \rightarrow r_1$) and $\frac{1}{2}\pi = 0.1592$ for wide gaps ($r_0 << r_1$).

For thick rings, it is convenient to think of a zero current on the disk. Then the ring itself will look like a disk, with a small imperfection at the center, and the potential distribution will be nearly that for a disk of radius r_2 in an insulating plane. The small disk of radius r_0 can then sense only one potential, that approximately equal to the potential of the ring $V_r = I_r/4\kappa r_2$. This leads to the limit

$$\kappa r_2 R_{dr} \rightarrow 0.25 \text{ as } r_2/r_1 \rightarrow \infty \quad [24]$$

independent of the value of r_0/r_1.

By an analysis of the current deflected from the insulating region for $r < r_1$, one can find a correction to Eq. [24] for small disks

$$\kappa r_2 R_{dr} = \frac{1}{4} - \frac{1}{\pi^2}\frac{r_1}{r_2} \quad [25]$$

for $r_1 << r_2$ and $r_0 << r_1$. This limiting slope is verified in Fig. 2.

For rings which are neither thick nor thin, we can use the results in Fig. 2 to calculate the value of r_* according to Eq. [23]. It turns out that r_* varies from the arithmetic average of r_1 and r_2 for thin rings to a value of $2r_2/\pi$ for thick rings (in order to reproduce the limit in Eq. [24]). This suggests the method of correlation of R_{dr} shown in Fig. 4. Here a value of r_* is calcuated *a priori*, and the ratio of the left and right sides of Eq. [23] represents a deviation function which is close to unity. The only advantage of Fig. 4 over Fig. 2 is that the scale can be expanded because the minimum and maximum values now differ by a factor of 1.05 instead of a factor of 1.57.

Let us next turn our attention to the ring resistance R_{rr}. For wide rings, it is clear that the resistance value is given by

$$\kappa r_2 R_{rr} = 0.25 \quad [26]$$

the value for a single disk of radius r_2. In the other extreme

$$\kappa r_2 R_{rr} + \frac{1}{2\pi^2} \ln\left(1 - \frac{r_1^3}{r_2^3}\right) = \frac{\ln 96}{2\pi^2} = 0.2312 \quad [27]$$

for thin rings ($r_1 \rightarrow r_2$) and small disks ($r_0 << r_1$), a result which is developed in the Appendix.

Figure 3 was plotted so that the small disk case ($r_0 << r_1$) would show these limits clearly. According to this figure, the effect of a nonzero disk is always to lower the ring resistance, because an alternative path is provided between the counterelectrode at infinity and the ring electrode. The correction to Eq. [27] for small disks is very small, $-(r_0/r_2)^5/45\pi^2$. Thus, we see that the curve for $r_0/r_1 = 0.8$ is already very close to the curve for $r_0/r_1 = 0.1$.

Gabrielli *et al.* (7) have measured resistances for four ring-disk geometries. They verified the coupling relationship between R_{rd} and R_{dr}. A comparison between their measurements and our calculated values is made in Table II. For this purpose, $1/\kappa$ was given the value 2.25 ohms-cm for a $2N$ H_2SO_4 solution. The comparison cannot be regarded as satisfactory. Two experimental values of $\kappa r_0 R_{dd}$ are greater than 0.25, which should not be possible under any circumstances. The other two values of $\kappa r_0 R_{dd}$ show good agreement. Measured values of the coupling resistance are consistently lower than those calculated. One value of $\kappa r_2 R_{rr}$ is lower than 0.25, which again should not be possible

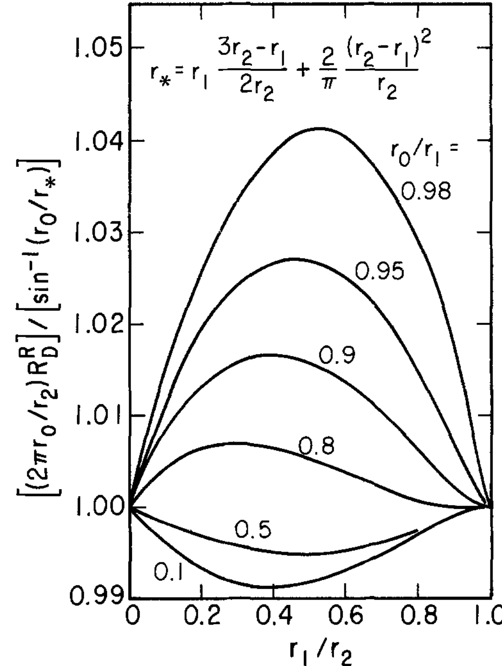

Fig. 4. Correlation of interaction resistance

Table II. Comparison of calculated resistances with those measured by Gabrielli *et al.* (7) for four ring-disk geometries

		$\kappa r_2 R_{rr}$		$\kappa r_2 R_{dr}$		$\kappa r_0 R_{dd}$	
r_0/r_1	r_1/r_2	Meas.	Calc.	Meas.	Calc.	Meas.	Calc.
0.952	0.42	0.244	0.252	0.211	0.228	0.307	0.192
0.968	0.62	0.272	0.261	0.194	0.22	0.217	0.216
0.976	0.82	0.311	0.273	0.189	0.218	0.231	0.238
0.976	0.976	1.213	0.342	0.177	0.219	0.262	0.2495

under any circumstances. The other measured values of $\kappa r_2 R_{rr}$ are significantly higher than the calculated values. It seems that some new experimental measurements are in order.

Shabrang and Bruckenstein (5) analyze their results in terms of equations of the form

$$V_d - V_T = R_D I_d + (I_d + I_r) R_C \quad [28]$$

and

$$V_r - V_T = R_R I_r + (I_d + I_r) R_C' \quad [29]$$

where R_D, R_R, R_C, and R_C' are resistances and V_T is the potential of the reference electrode and can be expressed as

$$V_T = R_{Aux} I_d + R_{Aux}' I_r \quad [30]$$

Comparison with Eq. [2] and [3] shows that we can make the associations

$$R_{dd} = R_D + R_C + R_{Aux} \quad [31]$$

$$R_{dr} = R_C + R_{Aux}' \quad [32]$$

$$R_{rd} = R_C' + R_{Aux} \quad [33]$$

and

$$R_{rr} = R_R + R_C' + R_{Aux}' \quad [34]$$

In view of Eq. [10], we can write

$$R_C - R_C' = R_{Aux} - R_{Aux}' \quad [35]$$

Shabrang and Bruckenstein take these differences to be zero. Indeed, if the counterelectrode is far away and the reference electrode is moderately far away from the ring-disk system, we can estimate (15)

$$R_{Aux} = R_{Aux}' = \frac{1}{2\pi\kappa\rho} \quad [36]$$

where ρ is the radial position of the reference electrode in spherical coordinates. However, the currents I_d and I_r do not, in general, need to have the same influence on the potential V_T in Eq. [30]; the difference will become accentuated the closer the reference electrode probe is to the ring-disk system.

In the extreme case, place the reference electrode adjacent to one of the working electrodes say the ring. Then $V_T = V_r$ and $R_{Aux} = R_{rd}$ and $R_{Aux}' = R_{rr}$. It is unlikely that $R_{rd} = R_{rr}$.

From Fig. 1, 2, and 3, we find $\kappa r_0 R_{dd} = 0.249$, $\kappa r_2 R_{rd} = 0.209$, and $\kappa r_2 R_{rr} = 0.3238$ for the geometry of Shabrang and Bruckenstein ($r_0/r_1 = 0.95$ and $r_1/r_2 = 8/8.4$). R_D corresponds approximately to $R_{dd} - R_{dr}$, and R_R corresponds approximately to $R_{rr} - R_{rd}$, whereas Shabrang and Bruckenstein came to the conclusion that R_R and R_D correspond to R_{rr} and R_{dd}, respectively. For the ratio $R_D/(R_D + R_R)$, they find values of 0.37, 0.35, 0.34, 0.39, 0.36, 0.34, and 0.31, whereas we calculate 0.366 for the corresponding ratio. (Here, we assume that the labels V_o/V_D and V_o/V_R are interchanged in their Table III.)

Because of uncertainties in the position of the reference electrode and the conductivity of the solution, we refrain from further comparisons with their data.

From the results of Miller and Bellavance (4) we deduce an experimental value of $\kappa r_2 R_{rd} = 0.192$. The corresponding value from Fig. 2 is $\kappa r_2 R_{rd} = 0.206$ for $r_0/r_1 = 0.909$ and $r_1/r_2 = 0.812$.

Conclusion

Computed values of the primary resistances for a ring-disk system, as presented here, should permit estimation of the uncompensated resistances when an attempt is made to control the potentials of the electrodes. There are few geometries for which this information is available.

Discrepancies between calculated and experimental values may lead to refined experiments or to considerations beyond the scope of the primary resistances.

APPENDIX

Thin Rings

The limiting resistance behavior for a thin ring (in the presence of only a small disk) can be obtained by application of Eq. [15] to case 1, where the current-density distribution is given by Eq. [11]. First note that the ring current for case 1 is given by $I_r = \pi^2 r_2^2 - r_1^2$. To evaluate the potential on the ring, we thus write

$$\Phi_0(r) = \frac{2}{\pi\kappa}\int_{r_1}^{r_2} \frac{2}{\sqrt{1-x'^2}} \frac{K(m) r' dr'}{r + r'}$$

$$= \frac{r_2 - r_1}{\pi\kappa}\int_{-1}^{1} \frac{K(m)}{\sqrt{1-x'^2}} \frac{1 + 2\epsilon x'}{1 + \epsilon(x + x')} dx' \quad [A\text{-}1]$$

where x has been introduced according to Eq. [13] and

$$\epsilon = \frac{1}{2}\frac{r_2 - r_1}{r_2 + r_1} \quad [A\text{-}2]$$

is a small quantity for a thin ring.

Now, m is close to 1. In fact

$$1 - m = \frac{\epsilon^2 (x - x')^2}{[1 + \epsilon(x + x')]^2} \quad [A\text{-}3]$$

and

$$K(m) \rightarrow -\frac{1}{2}\ln\frac{1-m}{16} + O(\epsilon^2 \ln \epsilon) \quad [A\text{-}4]$$

Equation [A-1] simplifies to

$$\Phi_0 = \frac{r_2 - r_1}{\pi\kappa}\left[-\frac{\pi}{2}\ln\frac{\epsilon^2}{16} - \frac{1}{2}\int_{-1}^{1}\frac{\ln (x - x')^2}{\sqrt{1-x'^2}} dx' + \pi x \epsilon \ln \epsilon + O(\epsilon)\right] \quad [A\text{-}5]$$

The integral in this equation has the remarkable property that it is a constant if $-1 < x < 1$. Then

$$\int_{-1}^{1}\frac{\ln (x - x')^2}{\sqrt{1-x'^2}} dx' = -2\pi \ln 2 \quad [A\text{-}6]$$

This property manifests itself, for example, in the primary current and potential distributions (18) for a strip electrode embedded in an insulating plane. Then the primary current distribution on the electrode is like case 1, treated here, and the constancy of the integral in Eq. [A-6] is required to produce a constant potential on the electrode.

By the introduction of Eq. [A-6], the ring current for case 1, and approximations valid for thin rings, Eq. [A-5] becomes

$$\Phi_0 = \frac{I_r}{2\kappa r_2 \pi^2} \left[\ln 32 - \ln \left(1 - \frac{r_1}{r_2} \right) - \epsilon(2 - x) \ln \epsilon + O(\epsilon) \right] \quad \text{[A-7]}$$

This potential distribution is nearly constant, and we see that case 1 alone provides an approximation to the primary current and potential distributions for thin rings. Equation [A-7] thus gives the basis for the limiting behavior of $\kappa r_2 R_{rr}$ (see Eq. [27] and Fig. 3).

Rapid Computation of Current Distribution by Orthogonal Collocation

Reinaldo Cabán and Thomas W. Chapman*

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT

Current distributions on two plane, parallel electrodes embedded in the walls of a flow channel have been computed by orthogonal collocation. Although the calculation includes the effects of mass transfer, electrode spacing, and complete Butler-Volmer kinetics, accurate computation of current density distribution requires only 2 sec of computing time. Cell polarization curves are readily generated with applied potential as the independent variable. It is suggested that the speed and efficiency of the collocation method can make possible the analysis of more complicated problems such as mixed-potential processes and can also facilitate the interpretation of experimental polarization data.

The design of electrolysis cells is primarily an empirical experimental endeavor because of the complex phenomena involved in electrochemical systems. Development and optimization of new industrial processes is a difficult and expensive task because of the multitude of parameters to be considered in cell design. The measurement of basic electrochemical properties such as kinetic parameters is also difficult for the same reason.

The application of systematic analysis to these problems requires that one be able to characterize current distribution and polarization behavior of a cell given a knowledge of the hydrodynamics and physical chemistry of the system. Newman (1) has outlined the basic problem of computing current distribution below the limiting current when both concentration and potential variations as well as electrode kinetics are important. Newman and others (2-7) have in recent years analyzed a number of geometries to show the effect of various parameters on the uniformity of the current distribution. Each one of the problems treated has required significant computational effort on a high speed digital computer. In this paper we present an alternative procedure for solving such problems. Although the method presented here yields only an approximation to the complete solution, it can be made quite accurate. Furthermore, since it generally requires relatively little computation time, it may be extended to more complicated problems such as the cal-

* Electrochemical Society Active Member.

Key words: current distribution, electrochemical mass transfer, electrode kinetics, cell polarization, orthogonal collocation.

culation of current efficiency or corrosion rates where multiple electrochemical reactions occur. It may also be useful for repetitive calculations in the statistical estimation of system parameters from experimental data.

Probably the most comprehensive treatment of a current distribution problem accomplished so far is the work of Parrish and Newman (4) on two plane, parallel electrodes in channel flow. Accordingly, we choose this example to illustrate our method as it provides a measure of the relative computational effort required to obtain current distributions and polarization curves.

Mathematical Formulation of the Problem

Parrish and Newman (4) have presented the mathematical formulation of the current distribution problem for two planar electrodes of equal length L which are located opposite one another in the walls of a channel of width h. The flow through the channel is laminar, and the Peclet number is large so that a thin diffusion layer approximation is valid.

The potential in the bulk solution can be written for this geometry (7) as

$$\phi(x,y) = \bar{\phi} - \frac{1}{2\pi\kappa_\infty}\int_0^L i_{\text{cath}}(\bar{x}) \ln\left\{\sinh^2\frac{\pi}{2h}(x-\bar{x}) + \sin^2\frac{\pi}{2h}(y-h)\right\}d\bar{x} - \frac{1}{2\pi\kappa_\infty}\int_0^L i_{\text{an}}(\bar{x}) \ln\left\{\cosh^2\frac{\pi}{2h}(x-\bar{x}) + \sin^2\frac{\pi y}{2h}\right\}d\bar{x} \quad [1]$$

where x is distance downstream from the leading edges of the electrodes, y is distance normal from the anode towards the cathode, and $i_{\text{cath}}(x)$ and $i_{\text{an}}(x)$ are the local current densities on the cathode and anode. The latter are taken to be negative and positive, respectively. The constant $\bar{\phi}$ represents the potential of the solution in the absence of current, relative to ground.

Parrish and Newman express the current distribution on the electrodes as an integral over the limiting current distribution and the actual surface concentration distribution. Stewart (8) has shown that the surface concentration can similarly be written as an integral of the current distribution on the electrode and the uniform-flux concentration distribution. This form is more convenient for our purposes so we write the surface concentration of a reactive solute on each electrode as

$$\frac{c_0}{c_\infty} = \frac{c_{\text{an;cath}}(x)}{c_\infty} = 1 - \left(\frac{Dh}{18<v>}\right)^{1/3}\frac{s_R(1-t_R)}{\Gamma\left(\frac{2}{3}\right)n\mathbf{F}Dc_\infty}\times\int_0^x \frac{i_{\text{an;cath}}(\bar{x})}{[x-\bar{x}]^{2/3}}d\bar{x} \quad [2]$$

For convenience we consider the same reaction to occur at each electrode, metal dissolution at the anode and deposition at the cathode ($s_R = 1$) with kinetics of the form

$$i(x) = i_o(c_\infty)\left[\frac{c_0}{c_\infty}\right]^\gamma\left[e^{\frac{\alpha_A\mathbf{F}\eta_s}{RT}} - e^{-\frac{\alpha_C\mathbf{F}\eta_s}{RT}}\right] \quad [3]$$

where c_0 is the surface concentration, $c_{\text{an}}(x)$ or $c_{\text{cath}}(x)$, on each electrode, and η_s is the surface overpotential of the electrode.

The applied cell potential V is the difference between the anode potential V_{an} and the cathode potential V_{cath}

$$V = V_{\text{an}} - V_{\text{cath}} \quad [4]$$

where

$$V_{\text{an}} = \phi_{0,\text{an}}(x) + \eta_{s,\text{an}}(x) + \eta_{c,\text{an}}(x) \quad [5a]$$

and

$$V_{\text{cath}} = \phi_{0,\text{cath}}(x) + \eta_{s,\text{cath}}(x) + \eta_{c,\text{cath}}(x) \quad [5b]$$

The electrostatic potential $\phi_0(x)$ is obtained by extrapolating the solution potential $\phi(x,y)$, given by Eq. [1] to the electrode surfaces, $y = 0$ or h. The concentration overpotential at each electrode is given by

$$\eta_c = \frac{RT}{\lambda\mathbf{F}}\left[\ln\frac{c_0}{c_\infty} + t_+\left(1-\frac{c_0}{c_\infty}\right)\right] \quad [6]$$

where

$$\lambda \equiv -n \quad [7a]$$

for a well-supported electrolyte and

$$\lambda = \frac{-z_+z_-}{z_+ - z_-} \quad [7b]$$

for a solution of a binary electrolyte.

Finally, the currents passing through the two electrodes must be equal so that

$$\int_0^L i_{\text{cath}}(x)dx + \int_0^L i_{\text{an}}(x)dx = 0 \quad [8]$$

In order to reduce the number of parameters in the problem we define the following dimensionless groups and variables

$$T = -\frac{n\lambda\mathbf{F}^2Dc_\infty}{4\pi\Gamma\left(\frac{4}{3}\right)(1-t_+)RT\kappa_\infty}\left(\frac{18<v>L^2}{hD}\right)^{1/3} \quad [19]$$

$$\zeta = x/L \quad [10]$$

$$\alpha = \alpha_A/\lambda \quad [11a]$$

$$\beta = \alpha_C/\lambda \quad [11b]$$

$$\psi = \pi L/2h \quad [12]$$

$$c^* = c_0/c_\infty \quad [13]$$

$$V^* = \frac{\lambda\mathbf{F}}{RT}V \quad [14]$$

$$\eta_c^* = \eta_c\frac{\lambda\mathbf{F}}{RT} \quad [15]$$

$$\eta_s^* = \eta_s\frac{\lambda\mathbf{F}}{RT} \quad [16]$$

$$\phi_0^* = \frac{\lambda\mathbf{F}}{RT}\phi_0 \quad [17]$$

$$\bar{\phi}^* = \frac{\lambda\mathbf{F}}{RT}\bar{\phi} \quad [18]$$

$$i_o^* = \frac{i_o(c_\infty)}{|<i_{\text{lim}}>|} \quad [19]$$

and

$$i^*(\zeta) = \frac{i(x)}{|<i_{\text{lim}}>|} \quad [20]$$

In these calculations we assume that the cathodic reaction is the reduction of a cationic solute species so that i_{lim} is taken to be the limiting current at the cathode

$$i_{\text{lim}} = \frac{n\mathbf{F}Dc_\infty}{(1-t_+)\Gamma\left(\frac{4}{3}\right)}\left(\frac{2<v>}{3Dhx}\right)^{1/3} \quad [21]$$

where $(-n)$ is the number of electrons required to reduce a cation. Therefore, the average limiting current used in the above definitions is

$$\langle i_{\lim}\rangle = -\frac{3}{2}\frac{nFDc_\infty}{(1-t_+)\Gamma\left(\frac{4}{3}\right)}\left(\frac{2\langle v\rangle}{3DhL}\right)^{1/3} \quad [22]$$

With these definitions the basic equations become

$$\phi_{0,\text{cath}}^*(\zeta) = \bar{\phi}^* - \Upsilon\left\{\int_0^1 i_{\text{cath}}^*(\bar{\zeta})\ln[\sinh^2\psi(\zeta-\bar{\zeta})]d\bar{\zeta} + \int_0^1 i_{\text{an}}^*(\bar{\zeta})\ln[\cosh^2\psi(\zeta-\bar{\zeta})]d\bar{\zeta}\right\} \quad [23]$$

$$\phi_{0,\text{an}}^*(\zeta) = \bar{\phi}^* - \Upsilon\left\{\int_0^1 i_{\text{cath}}^*(\bar{\zeta})\ln[\cosh^2\psi(\zeta-\bar{\zeta})]d\bar{\zeta} + \int_0^1 i_{\text{an}}^*(\bar{\zeta})\ln[\sinh^2\psi(\zeta-\bar{\zeta})]d\bar{\zeta}\right\} \quad [24]$$

$$c_{\text{cath}}^*(\zeta) = 1 + \frac{3\sqrt{3}}{4\pi}\int_0^\zeta \frac{i_{\text{cath}}^*(\bar{\zeta})}{[\zeta-\bar{\zeta}]^{2/3}}d\bar{\zeta} \quad [25]$$

$$c_{\text{an}}^*(\zeta) = 1 + \frac{3\sqrt{3}}{4\pi}\int_0^\zeta \frac{i_{\text{an}}^*(\bar{\zeta})}{[\zeta-\bar{\zeta}]^{2/3}}d\bar{\zeta} \quad [26]$$

$$\eta_{c,\text{cath}}^*(\zeta) = \ln c_{\text{cath}}^*(\zeta) + t_+(1 - c_{\text{cath}}^*(\zeta)) \quad [27]$$

$$\eta_{c,\text{an}}^*(\zeta) = \ln c_{\text{an}}^*(\zeta) + t_+(1 - c_{\text{an}}^*(\zeta)) \quad [28]$$

$$V_{\text{cath}}^* = \phi_{0,\text{cath}}^*(\zeta) + \eta_{s,\text{cath}}^*(\zeta) + \eta_{c,\text{cath}}^*(\zeta) \quad [29]$$

$$V_{\text{an}}^* = \phi_{0,\text{an}}^*(\zeta) + \eta_{s,\text{an}}^*(\zeta) + \eta_{c,\text{an}}^*(\zeta) \quad [30]$$

$$V^* = V_{\text{an}}^* - V_{\text{cath}}^* \quad [31]$$

$$i_{\text{cath}}^*(\zeta) = i_o^*[c_{\text{cath}}^*(\zeta)]^\gamma[e^{\alpha\eta_{s,\text{cath}}^*(\zeta)} - e^{-\beta\eta_{s,\text{cath}}^*(\zeta)}] \quad [32]$$

$$i_{\text{an}}^*(\zeta) = i_o^*[c_{\text{an}}^*(\zeta)]^\gamma[e^{\alpha\eta_{s,\text{an}}^*(\zeta)} - e^{-\beta\eta_{s,\text{an}}^*(\zeta)}] \quad [33]$$

and

$$\int_0^1 i_{\text{cath}}^*(\zeta)d\zeta = -\int_0^1 i_{\text{an}}^*(\zeta)d\zeta \quad [34]$$

The problem then is to solve Eq. [23]-[34] for i_{cath}^*, i_{an}^*, c_{cath}^*, and c_{an}^* as functions of ζ, the parameters α, β, γ, t_+, i_o^*, Υ, and ψ, and the applied voltage V^*.

Solution by Orthogonal Collocation

Parrish and Newman (4) solved the problem stated above by a numerical procedure which involved iterations within iterations. That is, for an assumed overpotential distribution the total applied potential was varied until the total current matched a specified level. Then the detailed overpotential distributions were adjusted until all equations were satisfied. Three to eight iterations were required for convergence in each inner loop, and up to 70 iterations on the overpotential distribution were required to obtain the complete solution. Numerical values of the functions at 100 to 180 points on an electrode were used, and the integrals were evaluated numerically. Note that two integrals must be evaluated at each mesh point on each iteration of the computation. Accordingly, the calculation was time consuming and expensive. Furthermore, it does not seem very feasible to extend the method to more complicated problems or to use it for routine, repetitive design or data-processing calculations.

An approximate numerical method suited to efficient calculation of complex problems is orthogonal collocation. Stewart has described collocation and its application to transport problems (9), and a variety of problems have been solved by the method (10, 11).

The basic idea of collocation is that a trial solution is postulated as a finite series of orthogonal polynomials. The N coefficients of this series are determined by making the trial solution satisfy the basic equations of the problem at N particular collocation points, where N is a small number. The collocation points are chosen according to some optimality criterion, such as the requirement that the trial solution should give the best possible quadrature estimate of the solution for a given N.

In electrochemical design problems, the most important characteristic of the system is probably the polarization curve. Therefore, we may not be as interested in the detailed structure of the current distribution or the current density at a given point as in the total current for a given applied potential. Accordingly, we seek here the best estimate of the total current, expressed as the dimensionless average current density $\langle i^*\rangle$ where

$$\langle i^*\rangle \equiv \frac{i_{\text{avg}}}{|\langle i_{\lim}\rangle|} = \int_0^1 |i_{\text{cath}}^*|d\zeta = \int_0^1 i_{\text{an}}^* d\zeta \quad [35]$$

We implement a collocation procedure by postulating current distribution functions of the form

$$i_{\text{cath}}^{*(N)}(\zeta) = \sum_{j=0}^{N-1} A_j\zeta^j \quad [36]$$

and

$$i_{\text{an}}^{*(N)}(\zeta) = \sum_{j=0}^{N-1} B_j\zeta^j \quad [37]$$

where N is the order of the approximation and the $2N$ coefficients A_j and B_j are to be determined. We obtain an optimal estimate of $\langle i^*\rangle$ by Gauss-Legendre quadrature (12, 13) for a given N by requiring that Eq. [36] and [37] satisfy Eq. [23] to [34] exactly at N collocation points ζ_i on each electrode. The collocation points ζ_i are chosen as the roots of $P_N^*(\zeta)$, the Legendre polynomial of degree N shifted to be orthogonal over the interval [0, 1] (13). After the coefficients A_j and B_j have been determined in this way, the average current may be estimated by the quadrature formula (12, 13)

$$\langle i^*\rangle \doteq \frac{1}{2}\sum_{i=1}^{N} w_i|i_{\text{cath}}^{*(N)}(\zeta_i)| \quad [38]$$

where w_i are the quadrature weights and $i_{\text{cath}}^{*(N)}(\zeta_i)$ are the cathodic current densities at the points ζ_i as computed from Eq. (36). According to the proper choice of the ζ_i, this Gauss-Legendre quadrature formula would be exact if i_{cath}^* could be represented exactly by a polynomial of degree $(2N - 1)$ or less. Thus, the estimate of the average current can be considerably more accurate than a local current density at any given order of approximation. Roots and quadrature weights for the shifted Legendre polynomials with $N = 6$, 7, and 8 are given in Table I.

Although Eq. [36] and [37] are written as truncated power series, they may be viewed as rearranged linear combinations of Legendre polynomials. Working in terms of the powers of ζ is equivalent to using a set of explicit polynomials but is easier computationally. Identification of these power series as the linear combination of orthogonal polynomials permits the use of Eq. [38] and determines the proper collocation points for the computation.

We proceed by substituting Eq. [36] and [37] into Eq. [23] to [34]. For example, Eq. [25] and [26] for the surface concentrations become

$$c_{\text{cath}}^*(\zeta) = 1 + \frac{3\sqrt{3}}{4\pi}\sum_{j=0}^{N-1} A_jE_j(\zeta) \quad [39]$$

Table I. Collocation points ζ_i as roots of shifted Legendre polynomials of degree N, and the associated Gauss-Legendre quadrature weights w_i [derived from Ref. (13)]

and

$$c_{an}^*(\zeta) = 1 + \frac{3\sqrt{3}}{4\pi}\sum_{j=0}^{N-1} B_j E_j(\zeta) \qquad [40]$$

where

$$E_j(\zeta) = \int_0^{\zeta} \frac{\bar{\zeta}^j d\bar{\zeta}}{[\zeta - \bar{\zeta}]^{2/3}} = 3\zeta^{j+1/3} \sum_{k=0}^{j} \frac{(-1)^{j-1}\binom{j}{k}}{3j - 3k + 1} \qquad [41]$$

Note that the assumed form has allowed analytic evaluation of the superposition integral.

Similarly, Eq. [23] and [24] for the potential may be rewritten

$$\phi_{0,cath}^*(\zeta) = \bar{\phi}^* - \Upsilon \sum_{j=0}^{N-1} [A_j R_j(\zeta) + B_j S_j(\zeta)] \qquad [42]$$

and

$$\phi_{0,an}^*(\zeta) = \bar{\phi}^* - \Upsilon \sum_{j=0}^{N-1} [A_j S_j(\zeta) + B_j R_j(\zeta)] \qquad [43]$$

where

$$R_j(\zeta) = \int_0^1 \bar{\zeta}^j \ln [\sinh^2 \psi(\zeta - \bar{\zeta})] d\bar{\zeta} \qquad [44]$$

and

$$S_j(\zeta) = \int_0^1 \bar{\zeta}^j \ln [\cosh^2 \psi(\zeta - \bar{\zeta})] d\bar{\zeta} \qquad [45]$$

Although these integrals cannot be determined analytically, we note that they need to be evaluated only at the N collocation points ζ_i and that for a given value of N the two $N \times N$ matrices, $R_j(\zeta_i)$ and $S_j(\zeta_i)$, need be evaluated only once and not repeatedly.

If all the system equations were linear, it would be a straightforward procedure to determine A and B by requiring that Eq. [29] and [30] be satisfied at each of the N collocation points on each electrode. Because of the nonlinear nature of the current-potential relationships, however, an iterative procedure is required. Fortunately the collocation formulation lends itself to a more systematic iterative scheme than is possible with a brute-force numerical method.

Computational Procedure

To obtain the coefficients A and B we must satisfy

$$f(\zeta_i) = i_o^* c_{cath}^{*\gamma}(\zeta_i) [e^{\alpha\eta_{s,cath}^*(\zeta_i)} - e^{-\beta\eta_{s,cath}^*(\zeta_i)}] - \sum_{j=0}^{N-1} A_j \zeta_i^j = 0 \qquad [46]$$

at each collocation point ζ_i on the cathode and similarly

$$g(\zeta_i) = i_o^* c_{an}^{*\gamma}(\zeta_i) [e^{\alpha\eta_{s,an}^*(\zeta_i)} - e^{-\beta\eta_{s,an}^*(\zeta_i)}] - \sum_{j=0}^{N-1} B_j \zeta_i^j = 0 \qquad [47]$$

on the anode, where the concentrations are given by Eq. [39] and [40] and the overpotentials are obtained from a combination of Eq. [27]-[31], [42], and [43].

At this point we recognize that in addition to the $2N$ coefficients A_j and B_j we must also evaluate $\bar{\phi}^*$. This can be done by including Eq. [34] with the $2N$ Eq. [46] and [47]. Equation [34] may be rewritten as

$$\int_0^1 \sum_{k=0}^{N-1} (A_k \zeta^k + B_k \zeta^k) d\zeta = \sum_{k=0}^{N-1} \left(\frac{A_k + B_k}{k+1} \right) = 0 \qquad [48]$$

This relationship completes the necessary set of $2N + 1$ equations.

We solve these nonlinear algebraic equations by Newton's method (12) by writing $f(\zeta_i)$ and $g(\zeta_i)$ as truncated (linear) Taylor series in the variables A_0, A_1, ... A_{N-1}, B_0, B_1, ... B_{N-2}, and $\bar{\phi}^*$ around trial values of these unknowns. The last coefficient B_{N-1} is determined by Eq. [48].

The computational algorithm proceeds as follows:

1. The applied potential V^* is specified. The value of V_{an}^* or V_{cath}^* is fixed arbitrarily and the other obtained from Eq. [31].
2. The degree of approximation N is chosen, and the collocation points ζ_i are obtained as the roots of $P_N^*(\zeta)$.
3. The coefficients $E_j(\zeta_i)$, $S_j(\zeta_i)$, and $R_j(\zeta_i)$ are computed for $j = 1, 2, \ldots N$ and $i = 1, 2, \ldots N$ from Eq. [41], [44], and [45]. These arrays need be determined only once for a given N.
4. Initial values of A_j and B_j are obtained by guessing a realistic current distribution and inverting the matrix Eq. [36] and [37] as written at the collocation points. $\bar{\phi}^*$ is set to zero, and B_{N-1} made consistent by use of Eq. [48].
5. The surface concentrations are calculated at the collocation points by Eq. [39] and [40].
6. The concentration overpotentials η_c^* are computed at the collocation points by Eq. [27] and [28].
7. The surface potentials ϕ_0^* at the collocation points are computed by Eq. [42] and [43].
8. The surface overpotentials η_s^* at the collocation points are computed from Eq. [29] and [30].
9. The current densities $i_{cath;\,an}^{*(N)}$ at the collocation points are computed from Eq. [32] and [33].
10. The local current densities are tested for convergence with respect to the previous values of the A and B coefficients. Specifically, the rms of the changes of the current densities at all collocation points relative to the values of the initial guess or the previous calculation is computed. The convergence criterion used here was a rms change less than 10^{-4}, where the current densities have been normalized by $\langle i^* \rangle$.
11. If the convergence criterion is not satisfied, the partial derivatives $\frac{\partial g(\zeta_i)}{\partial A_j}$ and $\frac{\partial f(\zeta_i)}{\partial A_j}$ for $j = 0, 1, \ldots N - 1$, $\frac{\partial g(\zeta_i)}{\partial B_j}$ and $\frac{\partial f(\zeta_i)}{\partial B_j}$ for $j = 0, 1, \ldots N - 2$, and $\frac{\partial f(\zeta_i)}{\partial \bar{\phi}^*}$ and $\frac{\partial g(\zeta_i)}{\partial \bar{\phi}^*}$ are computed at each of the collocation points. The equations for these derivatives can be obtained by differentiating Eq. [46] and [47] after the necessary substitutions have been made. Newton's method is applied to Eq. [46] and [47] to obtain new estimates of A_k, B_k, and $\bar{\phi}^*$; the algorithm then cycles back to step 5 and iterates until convergence is attained.

12. The foregoing procedure is repeated with increasing N until some characteristic quantity, say $<i^*>$ as obtained from Eq. [38], converges to a steady value within specified limits, taken here to be 0.01%. This criterion tests the accuracy of the polynomial approximation.

Results

Calculations have been done for a variety of parameter values. For total currents near the limiting current where the most nonuniform distributions are observed, as few as seven collocation points ($N = 7$) give satisfactory results for $<i_{an}^*>$ and $<i_{cath}^*>$, and 11 iterations on the polynomial coefficients give convergence within the specified limits. For small values of Υ, where the current distribution is fairly symmetrical, only four iterations were required. A typical problem required no more than 2 sec of computing time on a Univac 1110 computer to obtain current distribution curves.

In particular, calculations were done for $\Upsilon = 3$ and 15, and for $i_o^* = 0.05$ and 0.5; the other parameters α, β, γ, t_+, and h/L were set at 0.5. The applied potential V was varied from zero to more than 1V. These values were chosen to correspond to results published by Parrish and Newman (4).

Convergence was always obtained even for currents very near the limiting current ($<i^*> = 0.99$) although double precision computation (20-place accuracy) was required there. Figure 1 shows current distributions on the cathode at selected fractions of the limiting current for $\Upsilon = 15$ and $i_o^* = 0.05$ as computed with $N = 7$. The distributions at limiting current and at $<i^*> = 0.79$ for $h/L = \infty$ are also shown.

Figure 2 shows the reactant concentration distributions on the cathode surface corresponding to the curves in Fig. 1.

Figure 3 shows cell polarization curves at various combinations of Υ and i_o^*.

Discussion of Results

The parameters used to obtain Fig. 1 and 2 were chosen to correspond roughly with those represented by Fig. 7 and 9 in Parrish and Newman (4). Comparison with their work shows that our results for both anodic and cathodic current distribution and surface concentration are quite similar to the more detailed numerical computations. In fact, our calculations with seven points are even capable of reproducing the maximum in the local current density observed by Parrish and Newman (3) at currents near the limiting current with large h/L. (A similar but slight maximum is also observed around $<i^*> = 0.85$ for $h/L = 0.5$.)

The results for large h/L were obtained by reproducing the earlier calculations (3) for the case where a plane cathode could be considered separately from polarization behavior on the anode. In that case we obtained results in 1 sec of computing time and within four to seven iterations except at currents very near (99%) the limiting current where 15 iterations were required. This effort can be compared with Parrish and Newman's procedure which took 50 to 140 mesh points on the electrode and as many as 35 iterations. In their method the integral equations must be evaluated at each mesh point in each iteration so that almost 5000 numerical integrations might be required.

It should be noted that Parrish and Newman generally simplify the complete kinetics expression, Eq. [3], to either the linear or the Tafel form. Because the collocation method can handle any general kinetics

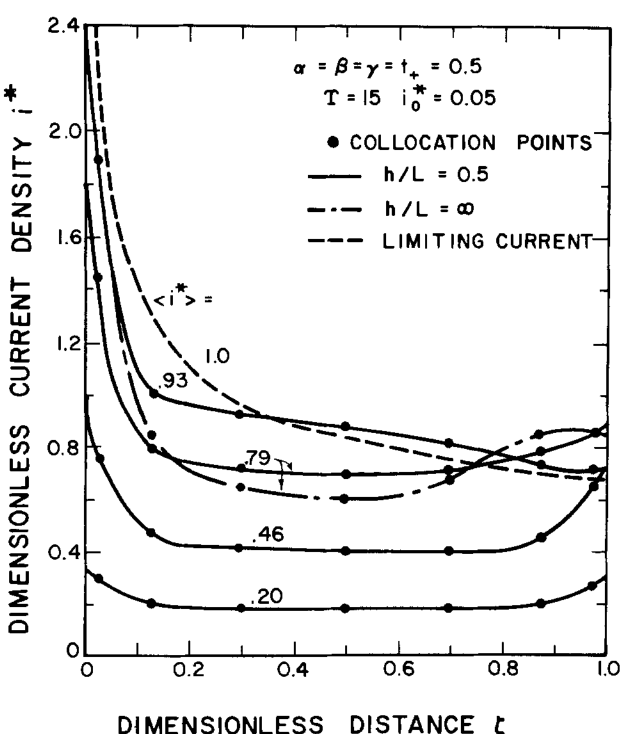

Fig. 1. Current density distributions on the cathode at various fractions of limiting current.

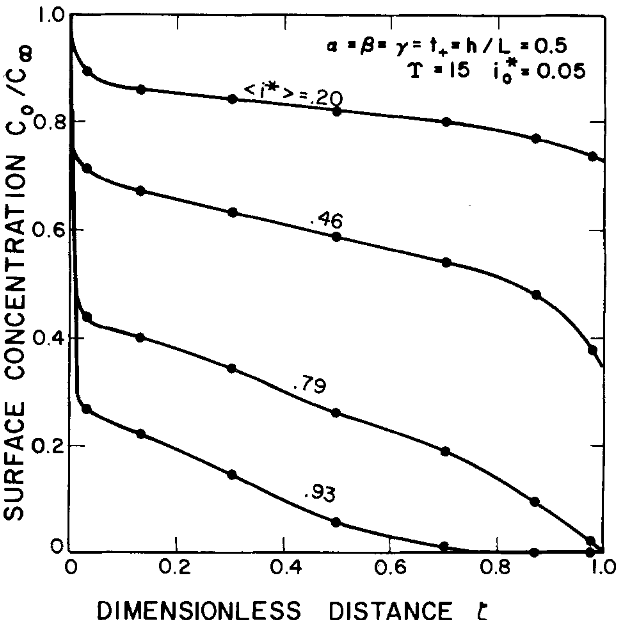

Fig. 2. Reactant concentration distribution on the cathode surface at various fractions of limiting current.

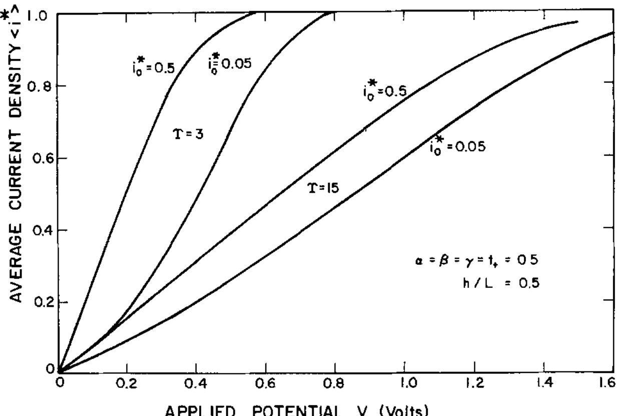

Fig. 3. Polarization curves plotted as average current density, relative to limiting current, vs. applied potential for various parameter values.

expression, there is no particular advantage to making such simplifying assumptions.

Parrish and Newman have already commented on the physical significance of the current distribution curves. We shall mention here only that we have chosen a slightly different nondimensionalization of the problem. We have defined Υ in Eq. [9] to represent the ratio of electrical resistance to mass transfer resistance in the solution; it is proportional to the parameter N used by Parrish and Newman. On the other hand, we have chosen i_o^* rather than J of Parrish and Newman to represent the importance of kinetic effects. Their parameter δ has no counterpart in our formulation because we specify V and compute the current. Their procedure is to specify δ, that is, the total current, as the independent variable.

The critical parameters in our calculations then are Υ and i_o^*. At large Υ the current distribution is determined by potential effects and approaches the secondary or primary current distribution according to i_o^*. At low values of Υ the current distribution approaches the limiting current distribution provided that i_o^* is large. At intermediate values of Υ and at small i_o^* the current distribution is more uniform than in either limiting case.

The important point of this work is that current distribution problems can be solved with good accuracy but nominal computational effort by means of orthogonal collocation. Because of the facility and speed with which the method converges we are encouraged to extend it to even more difficult problems. An obvious possibility is the treatment of mixed-potential processes where several electrode reactions occur on the same electrode.

The problem treated here was simplified considerably by the thin diffusion layer approximations. Thus, it was possible to satisfy the relevant differential equations for c_0 and ϕ by the integral Eq. [1] and [2]. The collocation procedure used here is required only to satisfy boundary conditions on the electrodes. This might be called boundary collocation (10). In the more general case one must solve coupled, nonlinear partial differential equations in the solution as well as to satisfy the nonlinear, coupled boundary conditions on the electrodes. Such a problem would be extremely difficult to solve by conventional finite difference methods. It may be reasonably tractable, however, by the method of mixed collocation (10) where collocation points are chosen both on the boundaries as well as at selected points in the interior of the electrolytic solution.

LIST OF SYMBOLS

A, A_j	coefficients defined by Eq. [36]
B, B_j	coefficients defined by Eq. [37]
c	concentration, mole/m³, or dimensionless surface concentration
D	diffusion coefficient, m²/sec
E_j	coefficient defined by Eq. [41]
$\mathbf{F}$	Faraday's constant, 96,487 C/equiv
f	function defined by Eq. [46]
g	function defined by Eq. [47]
h	distance between electrodes, m
i	current density, A/m²
i_o	exchange current density, A/m²
i_{lim}	limiting current density at cathode, A/m²
i^*	dimensionless current density, normal component
L	length of electrodes, m
N	number of collocation points on an electrode
n	number of electrons produced by electrode reaction when written as an oxidation. $n = -z_+$ for reaction considered here
P_i^*	shifted Legendre polynomial of degree i
R	universal gas constant, 8.3143 J/mole K
R_j	coefficient defined by Eq. [44]
S_j	coefficient defined by Eq. [45]
s_R	stoichiometric coefficient of the solute species, which is the reactant in the cathodic reaction
Sc	Schmidt number
T	temperature, °K
t_R, t_+	transference number of reactive solute, taken here to be a cation
$\langle v \rangle$	average flow velocity, m/sec
V	voltage or electrode potential, V
w_i	quadrature weight at collocation point ζ_i
x	distance along electrode m
z_i	charge number of species i

Greek Letters

α_A	anodic transfer coefficient
α	dimensionless anodic transfer coefficient
α_C	cathodic transfer coefficient
β	dimensionless cathodic transfer coefficient
γ	a dimensionless kinetic parameter, the order of the reaction
κ	conductivity, mho/cm
$\Gamma(x)$	gamma function of x
ζ	dimensionless distance, x/L
η_s	surface overpotential, V
η_c	concentration overpotential, V
λ	parameter defined by Eq. [7]
Υ	dimensionless parameter defined by Eq. [9]
ϕ	electric potential, V
$\bar{\phi}$	reference potential in solution, V
ψ	dimensionless electrode length, $\pi L/2h$

Common Subscripts

an	refers to the anode
cath	refers to the cathode
an; cath	applies to either anode or cathode
i	of species i or index of collocation points
0	evaluated at the electrode surface
∞	refers to bulk solution

Common Superscripts

*	dimensionless variable
(N)	refers to the Nth approximation

The Behavior of an Oscillating Solid Microelectrode for Voltammetric Studies in Aqueous and Molten Salt Solutions

P. Pint[1] and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario, Canada

ABSTRACT

An oscillating planar solid indicator microelectrode was developed for voltammetric investigations. An investigation of the variables which affect the limiting current using this particular microelectrode was conducted. The electrode was successfully used in aqueous electrolytes, in molten nitrate electrolytes up to 330°C, and in molten equimolar sodium and potassium chlorides at 700°C.

The dropping mercury electrode has proven to be useful and convenient in aqueous polarography and also in low melting molten salt systems. However, it cannot be used at temperatures higher than 200°C due to the volatility of mercury.

Several high temperature polarizable indicator microelectrodes have been proposed, namely, the dropping molten metal electrodes (1, 2), the stationary wire electrode (3, 4), gas flushed electrodes (5), mechanically rotated wire (6), and rotated disk electrodes (7). The rotating disk electrode has been extensively and successfully studied, and the fluid flow characteristics have been understood particularly after the rigorous treatment by Levich (8). In high temperature liquids the convection currents are unpredictable and the electroreducible species do not migrate to the indicator electrode solely by diffusion. In the forementioned techniques controlled convection in the electrolyte was a necessary requirement for the attainment of reproducible limiting currents. Similarly, mention should be made of Lindsey's high frequency vibrated platinum wire microelectrode (9-11), and of the various vibrating dropping mercury electrodes (12 ,13).

The electrode developed in this laboratory consists of a planar solid microelectrode, oscillated at low frequencies in a direction perpendicular to the surface of the electrolytic solution. The behavior of this electrode was studied in aqueous electrolytes where it could readily be compared to the dropping mercury electrode (DME), in molten nitrate melts at temperatures up to 330°C and in molten chlorides containing as the solvent the equimolar mixture of KCl and NaCl at 700°C. This electrode is particularly suited for fused salt systems because of its simplicity, the well-defined surface area, and its ability to operate in totally enclosed cells under a protective atmosphere and to yield reproducible and time-independent limiting currents.

Experimental

The experimental assembly shown in Fig. 1 consists of the solid indicator microelectrode dipping into the electrolyte and a calomel (Hg, Hg_2Cl_2, KCl saturated) electrode as a nonpolarizable reference. The solutions in the two sections of the Pyrex cell are separated from each other by means of a low resistance agar plug.

The indicator microelectrode was made out of platinum or tungsten wires, about 0.5 mm diameter sealed into Pyrex glass tubing having a diameter of approximately 0.5 cm. The tip of the electrode was polished flat so that the electrode was in effect a flat tungsten or platinum disk encased in glass sheathing. The wire protruding from the top of the glass sheath was connected to the negative terminal of the polarograph. The potentials to the cell were applied by means of the Fisher electropode (Model No. 65) and the resulting currents were recorded on the Fisher recorder (No. 66) which was coupled to the electropode. The potentials could be applied either automatically or manually. During the automatic operation the potential was applied at a rate of 200 mV/min corresponding to a chart speed of 10 divisions/in./min.

The mechanical oscillator consisted of a piston driven by a rotating off center disk. This arrangement imposed a harmonic vibrating motion on the electrode and the frequency of oscillation could be changed from zero to a maximum of about 350 oscillations/min. The amplitude of the stroke was constant at 0.5 cm.

For the experiments the cell assembly was immersed in a constant temperature water bath at 25°C. Prior to determining any I-V curves the solutions were flushed with argon gas which was bubbled through the side arm shown in Fig. 1 for approximately 10 min.

Key words: polarography, molten salt systems, vibrating microelectrode.

Lead, copper, and cadmium salts were used in the aqueous investigations with the bulk of the experiments being conducted with $Pb(NO_3)_2$ dissolved in 1*N* $NaNO_3$ supporting electrolyte. The limiting currents (i_L) in aqueous solutions were investigated as functions of the oscillation frequency ν, the concentration of the solution *C*, the temperature, and of the viscosity of the solution. In addition the dependence of i_L on geometric factors such as the ratio of the exposed cross-section area of the metal wire electrode to the total cross-section area of the indicator electrode, the diameter of the electrolyte container, and the positioning of the electrode in the electrolyte container were investigated, as well as the macroscopic appearance of the flow patterns around the electrode due to its motion.

The limiting currents were obtained from the experimental I-V traces by the standard graphical technique.

The high temperature cell employing molten nitrates shown in Fig. 2, had an indicator electrode of platinum wire 0.508 mm in diameter sealed into a 5.64 mm diameter Pyrex capillary, as opposed to tungsten wire which was used in aqueous voltammetry. Tungsten was found to be unacceptable in these oxidizing melts since very high erratic diffusion currents were produced. In all cases the seal between the platinum and Pyrex appeared to be adequate.

The electrode could be introduced into the melt by sliding it through a "Sargent Teflon Seal," which also served as a gas seal during oscillation. A ground glass joint made possible the removal of the electrode assembly from the cell.

A large platinum disk (1.54 cm^2) served as the depolarized reference electrode. Argon could be bubbled over this electrode in order to stir or flush the electrolyte if so desired. Another large platinum foil electrode was incorporated into the system which was used for electropolishing the indicator electrode. Thus the electrode did not have to be removed for cleaning and the possibility of introducing impurities into the melt was minimized.

The potential of the reference electrode is stable under these conditions, as indicated by the reproducibility of the decomposition potentials shown by the I-V curves. Although the complete anodic reaction cannot be defined from such data, it is expected that platinum immersed in a melt containing NO_3^- species should behave like an oxygen electrode.

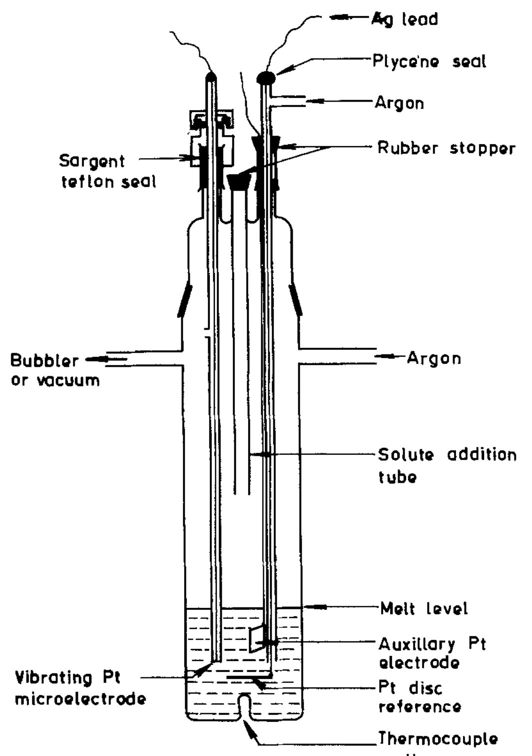

Fig. 2. Experimental cell assembly for high temperature voltammetry.

Solute additions could be made to the melt through a glass tube located at the top of the cell.

With molten nitrates, the supporting electrolyte was a low melting mixture containing 54 mole per cent (m/o) KNO_3 and 46 m/o $NaNO_3$ (mp 222°C). The electroactive species for all of these investigations was $AgNO_3$. The certified standard (A.C.S.) sodium nitrate and potassium nitrate, obtained from Fisher Scientific, were premixed and dried in air at about 120°C. These nitrates were loaded into a Pyrex cell and were vacuum dried and melted under argon. The silver nitrate (A.C.S.) from Johnson, Matthey, and Mallory was melted under vacuum and solidified under argon.

The cell containing about 250g of solvent electrolyte was heated in a resistance-type furnace, the temperature of which was kept constant to within ±3° by means of a Thermovolt controller. The furnace was partially lined with a heavy grounded Inconel sheath in order to minimize temperature gradients in the melt and eliminate external electrical interference.

All experiments were conducted under an argon gas atmosphere.

The variables investigated were the effect of temperature on the background current in the supporting electrolyte, the dependence of i_L on the concentration of $AgNO_3$, the dependence of i_L on temperature at constant concentration of $AgNO_3$, and the dependence of i_L on the frequency of oscillation.

The 1:1 molar NaCl-KCl (mp 660°C) was chosen as the solvent for high temperature voltammetric investigations. The electroactive Ag^+ species was added as AgCl. The reagent grade sodium and potassium chlorides containing less than 0.01% total impurities, obtained from Fisher Chemical Company, were premixed and dried under vacuum at about 100°C for 48 hr. The temperature was then slowly raised to the melting point while anhydrous HCl gas was passed through the salts. The salts were then alternately purged with argon and evacuated, and then finally solidified under vacuum. The reagent grade silver chloride was obtained from Fisher Chemical Company and was treated at 400°C with anhydrous HCl gas.

The high temperature cell employing molten alkali metal chlorides was similar to that shown in Fig. 2, with the main difference being that the tungsten wire electrode was sealed into quartz glass by using Corning GSC-1 and GSC-3 glass which gave leakproof glass to metal seals. Also instead of the Teflon seal structure a brass bellows was used for the oscillating electrode assembly. The cell was of silica glass.

The reference, depolarized electrode was a high purity graphite rod (16.5 cm^2 surface area) around which argon gas could be bubbled.

The cell containing 250g of the prepared solvent was heated in a furnace containing a heavy grounded Inconel sheath which was controlled by a Thermovolt temperature controller at 700° ± 3°C.

Results and Discussion

A typical I-V curve obtained for the reduction of divalent lead in a 1*N* $NaNO_3$ supporting aqueous electrolyte solution can be seen in Fig. 3(a). The sharp increase in current at about −0.75V is due to the low overvoltage of hydrogen on tungsten. Figure 3(b) indicates the trace obtained employing the DME. The trace from the oscillating electrode (OE) is well defined and does not indicate the maximum shown on the DME polarogram.

Figure 4 illustrates the dependence of the limiting current on frequency. It can be seen that the limiting current decreases linearly with a decreasing frequency.

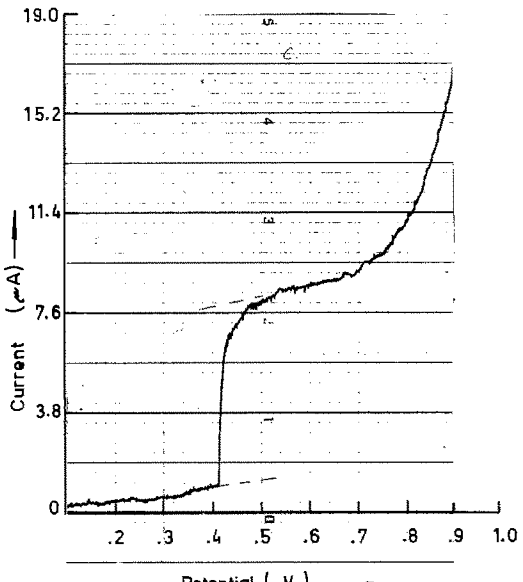

Fig. 3. (a) Typical I-V curve for the electroreduction of Pb^{2+} ions at the solid microelectrode at 25°C.

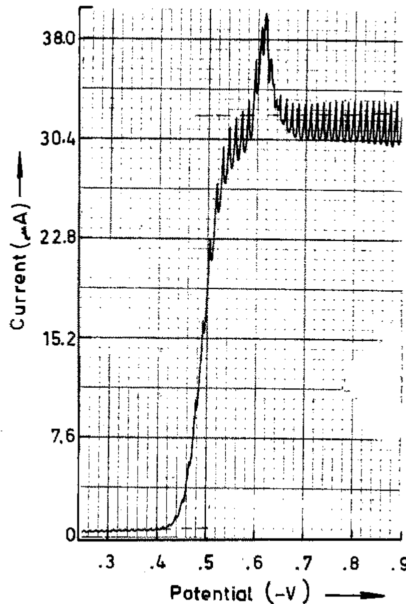

Fig. 3. (b) DME polarogram of $Pb(NO_3)_2$ in $NaNO_3$ at 25°C

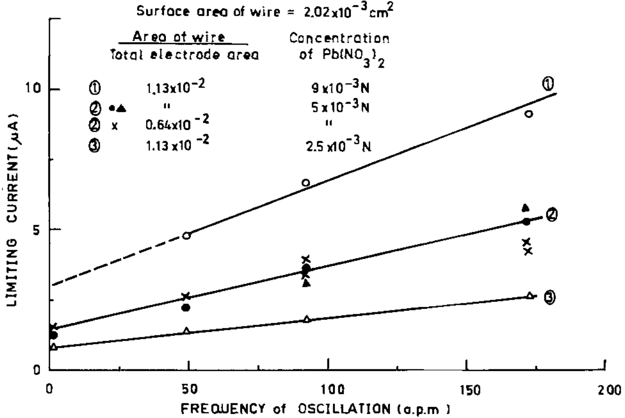

Fig. 4. The dependence of the limiting current on the oscillation frequency at 25°C.

The limiting current at zero frequency was determined from a single continuous I-V run. Generally the I-V curves at zero frequency were poorly defined, indicated a time dependence, and had irregular plateaus. The dependence of i_L on the surface area of the microelectrode is shown in Fig. 5(a) and it is seen that the limiting current is proportional to the surface area of the metal. It is also important to note that the ratio (R) of the cross-sectional area of the surface of the metal electrode to the total cross-sectional area of the entire electrode is an important variable, as is illustrated in Fig. 5b. This plot shows that i_L becomes independent of R at all concentrations when R exceeds about 1/100. Furthermore, the bulk concentration of $Pb(NO_3)_2$ and the limiting current are directly proportional as illustrated in Fig. 6.

The dependence of i_L on the temperature of the electrolyte appears to be linear. The ratio of i_L at 25°C to i_L at 20°C is 1.1 which is the value found for Pb^{2+} ions when employing the DME.

To increase the viscosity of the electrolyte, glycerin was added to aqueous solutions containing $Pb(NO_3)_2$. The limiting current decreases linearly with an increasing glycerin content and increasing viscosity as expected. Furthermore, it was found that the limiting current is independent of the dimensions of the container containing the electrolyte, providing that the oscillating electrode is not placed within a distance of about 3 cm from the bottom and the walls of the container.

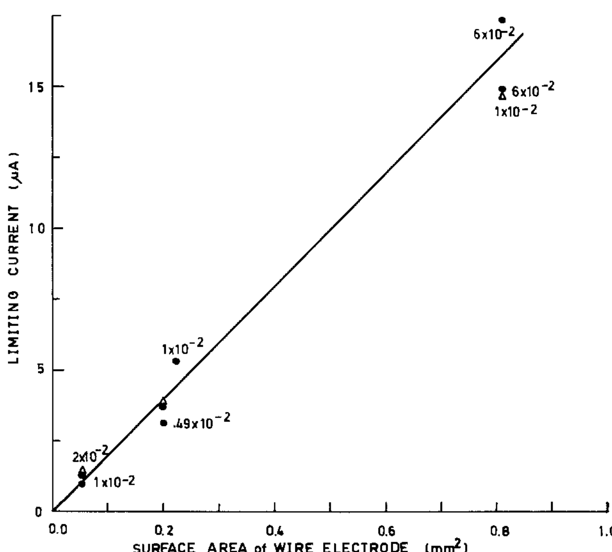

Fig. 5. (a) The dependence of the limiting current on the microelectrode surface area. Numbers along curve refer to the ratio R = area of wire electrode/total surface area.

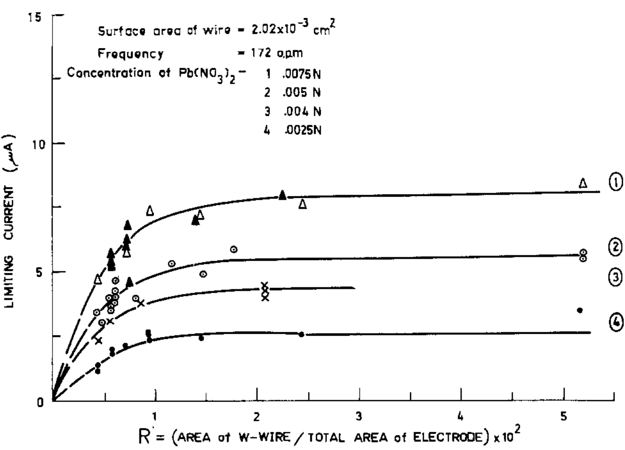

Fig. 5. (b) The dependence of the limiting current on the ratio of the area of tungsten wire to the total area of the electrode face, including glass sheathing at various concentrations of $Pb(NO_3)_2$ in solution.

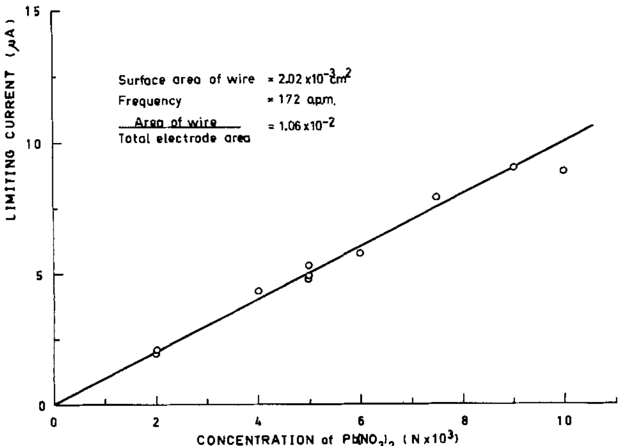

Fig. 6. The dependence of the limiting current on the concentration of $Pb(NO_3)_2$ at 25°C.

The results conducted in aqueous solutions of $CuSO_4$ in 1*N* $NaNO_3$ verified the relationships observed with Pb^{2+} as the electroactive species.

Figures 7(a) and (b) illustrate current plateaus for multiple reduction steps in aqueous solutions containing both Cu^{2+} and Pb^{2+} ions and Cu^{2+}, Pb^{2+} and Cd^{2+} ions, respectively. The approximate half-wave potential against the Pt-disk reference electrode for the deposition of Cu^{2+}, Pb^{2+}, and Cd^{2+} in aqueous solutions are −0.10, −0.45, and −0.6V, respectively.

The macroscopic flow patterns about the vibrating microelectrode in the present study were qualitatively determined by adding red dye to the proximity of the electrode and observing the resulting patterns on the upward and downward strokes of the electrode. On the upward stroke a suction is imposed on the fluid and fresh electrolyte is brought from the sides to the proximity of the electrode surface. The electrolyte at the center of the electrode remains relatively undisturbed with a stagnant layer appearing at the face of the electrode. This flow pattern appears to be laminar. During the instant of reversal of motion turbulent flow appears to be taking place at the electrode-electrolyte interface. However, during the downward motion the laminar flow appears to be established again and the solution behaves like an incompressible fluid. The linear dependence of the limiting currents on concentration indicates the establishment of a steady state in the electroreduction process at the electrode-electrolyte interface. The observed flow patterns indicate that both diffusive and convective processes are taking place. Because of this complicated behavior a rigorous solution of the over-all transport process has not been obtained and the theoretical treatment of diffusion and mass transport control under these conditions has not been found in the literature. In a recent paper by Podesta *et al.* (14) an expression for ionic mass transfer at horizontal disk electrodes under longitudinal vibrations has been derived.

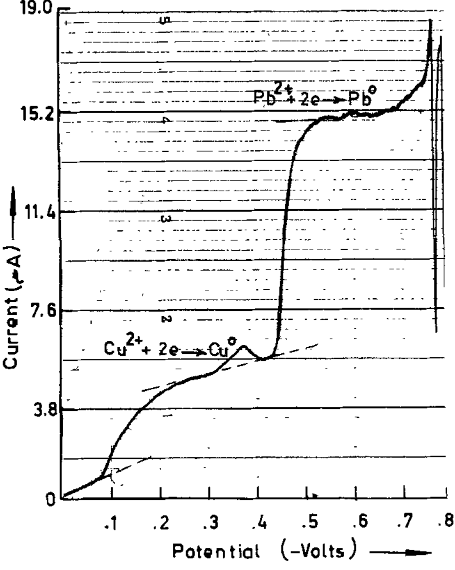

Fig. 7. (a) Limiting current plateaus for the electroreduction of Cu^{2+} and Pb^{2+} ions at 25°C.

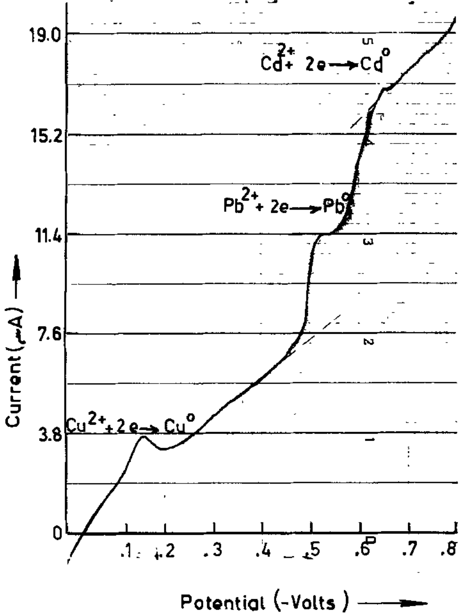

Fig. 7. (b) Limiting current plateaus for the electroreduction of Cu^{2+}, Pb^{2+}, and Cd^{2+} ions in aqueous solutions at 25°C.

The vibrating electrode in the above study consisted of a rather large bright platinum disk having a diameter between 0.3 and 1.5 cm, mounted on the end of an inverted, hollow, truncated cone made of insulating material. The entire electrode was connected to a 7 in. commercial loudspeaker and could be vibrated in the frequency range 20-200 Hz. Its optimum frequency was found to be about 50 Hz. The I-V curves obtained in aqueous solutions only, indicated a linear dependence of the current on the concentration of the electroreducible species in solution, a dependence on the ¾ power of the frequency, and a dependence on the ½ power of the electrode surface area.

The steady-state limiting currents obtained represented a mixed convective- and diffusion-type control mechanism and were dependent on the amplitude of the vibrations and possibly on the angle of the supporting hollow cone. The type of flow pattern prevailing at frequencies about 50 Hz indicated the establishment of an almost immobile cylindrical zone attached to the disk surface.

The vibrating microelectrode developed in the present study differs significantly from that investigated by Podesta *et al.* (14) in its over-all geometry, its current dependence on frequency and on electrode surface area, and on the over-all pattern of the fluid flow established at the electrode solution interface during the vibrations. It is evident that at the lower frequencies of about 3 Hz used in the present study, and for a geometry represented by a small metal disk surrounded by a large glass surface, the electrode solution interface is forced to follow the relatively slow vibrations of the electrode and the steady-state current is again the result of a mixed convective and diffusion-type control mechanism. However, the theoretical treatment of the mass transport problem for the two electrodes should be different.

The linear dependence of the limiting currents on oscillation frequency, concentration of solute species, and electrode surface area indicate that the empirical

expression for the limiting current should be given as

$$i_L = (K_1 + K_2\nu)AC \quad [1]$$

where K_1 and K_2 are constants, ν is the oscillation frequency, A is the area of the microelectrode, and C is the concentration of the electroactive species in the bulk phase.

A typical I-V curve obtained for the electroreduction of Ag^+ added as $AgNO_3$ to the equimolar melt of KNO_3-$NaNO_3$ is shown in Fig. 8.

From experiments it became apparent that the residual currents due to the $NaNO_3$-KNO_3 solvent were dependent on the temperature of the melt, increasing rapidly at temperature higher than 340°C. Hills (15) has investigated this problem in detail and has proposed that this sharp increase in currents is due to the irreversible cathodic reduction of nitrate ions to nitrite ions or nitrogen peroxide according to

$$NO_3^- + 2e^- \rightarrow NO_2^- + O_2^- \quad [2]$$

$$NO_3^- + e^- \rightarrow NO_2 + O_2^- \quad [3]$$

At higher temperatures these reactions are expected to be favored, and especially with a platinum electrode which is serving as a catalyst.

Thus the appearance of such high residual currents restricts the use of the platinum microelectrode in nitrate solvent melts to metallic cations which can be reduced at voltages below −0.5V.

It is of interest that I-V curves obtained in the $NaNO_3$-KNO_3 electrolyte employing a milliammeter as the current detection instrument, and two large stationary electrodes, 2.5 cm^2 in surface area, show a decomposition potential of 2.4V. This unusual behavior has been verified in several experiments and seems to indicate that reactions [2] and [3] are rather slow and can only appear as a residual current on a microelectrolysis experiment. The over-all decomposition reaction for the KNO_3-$NaNO_3$ molten electrolyte occurs at 2.4V and probably involves the reduction of the alkali metal ions to metal.

From the results in Fig. 9. it is seen that the limiting current is directly proportional to the concentration of the electroreducible silver ions. Furthermore, it was observed that the limiting current for the electroreduction of Ag^+ ions at the microelectrode increases by 0.058 μA/°C in the temperature range between 200° and 300°C. The limiting current for the reduction of Ag^+ ions in a nitrate melt also decreases with increasing frequency of electrode oscillation as observed in the aqueous solutions.

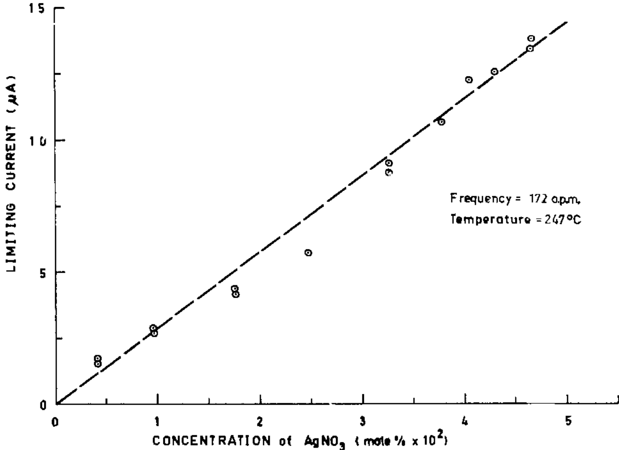

Fig. 9. The dependence of the limiting current on the concentration of $AgNO_3$ at 247°C. The solvent melt is an equimolar mixture of KNO_3 + $NaNO_3$.

For the electroreduction of Pb^{2+} ions in aqueous electrolytes plots of the well-known Heyrovsky-Ilkovic (16) and Kolthoff-Lingane (17) relationships give a straight line but the slopes differ from the theoretical expected slope of 0.0296 for a two-electron electrode process.

Even though the slope of the Heyrovsky-Ilkovic relationship is closer to the predicted slope for a two-electron reduction step, the Kolthoff-Lingane (17) equation should be the valid relationship for a reversible reaction. It is unlikely that at 25°C lead would alloy with tungsten at the indicator electrode. Hence, the deviation from the predicted slope of 0.0296 is probably due to irreversibility.

For the reduction of Ag^+ in the nitrate melts it was found that the reduction of Ag^+ ions obeyed the Kolthoff-Lingane relationship. This indicates that the deposit of silver must quickly reach unit activity and that the silver does not diffuse into platinum at least during the time of the experiment.

At more negative voltages the experimental points deviate from the linearity predicted by the Kolthoff equation.

From the results it appears that the half-wave potential for the silver deposition is about −0.05V with respect to the platinum disk reference electrode.

Typical I-V curves for the electroreduction of Ag^+ added as AgCl in the equimolar melt of KCl-NaCl are shown in Fig. 10. These curves are not as well defined as with the nitrate melts, but illustrate the dependence of the limiting current on the concentration of AgCl.

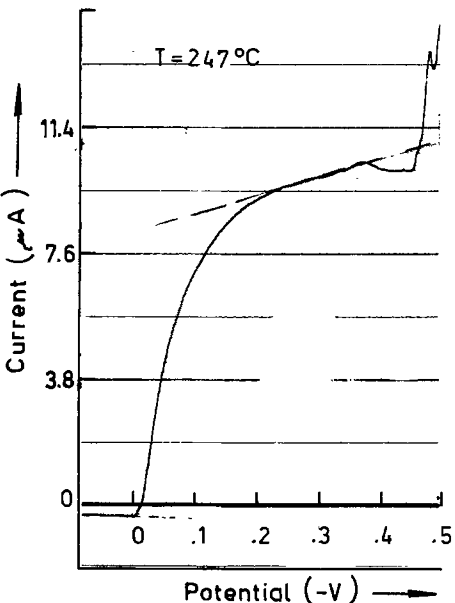

Fig. 8. A typical I-V curve for the electroreduction of Ag^+ ions in solution in the equimolar melt KNO_3 + $NaNO_3$ at 247°C.

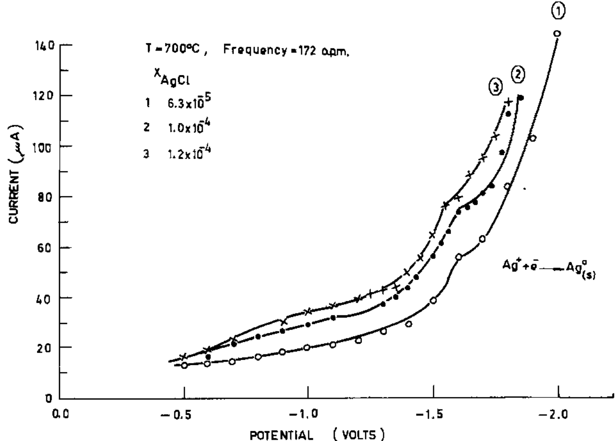

Fig. 10. I-V curves for the electroreduction of Ag^+ ions in solution in the equimolar melt at KCl + NaCl at 700°C at various concentrations of AgCl.

The half-wave potential for silver deposition in the chloride electrolytes is about −1.6V with respect to the graphite reference electrode. This is close to the theoretical values of −1.605 and −1.660V for the reversible decomposition potential of AgCl (18) in solutions containing 1.2×10^{-4} and 6.3×10^{-5} mole fraction of AgCl, respectively.

Conclusions

A low frequency vibrating solid planar indicator microelectrode was developed for voltammetric investigations in aqueous electrolytes and low temperatures nitrate melts. The electrode behaved well in aqueous electrolytes giving excellent voltammetric curves. The limiting current during electroreduction was related to the concentration of the electroreducible species, the area of the microelectrode, its geometric characteristics, the frequency of oscillation of the microelectrode, the viscosity of the electrolyte, and its temperature. The electroreduction of Pb^{2+} ions in aqueous electrolytes at 25°C was found to be irreversible.

This electrode also produced good voltammograms in nitrate melts and behaved predictably with respect to variables which define the limiting current. For the electroreduction of Ag^{+} ions in nitrate melts the Kolthoff-Lingane equation is obeyed.

Reasonably good voltammograms were also obtained for the electroreduction of Ag^{+} ions in the equimolar NaCl-KCl supporting electrolyte.

Recording Characteristics of Anodic Oxide Films on Aluminum Containing Electrodeposited Ferromagnetic Metals and Alloys

Satoshi Kawai and Ikuo Ishiguro

The Pilot Pen Company, Limited, Hiratsuka Works, Kanagawa, Japan

ABSTRACT

Fe, Co, Ni, Co-Ni, Fe-Ni, and Fe-Co were electrodeposited into the micropores of oxide films on aluminum anodized in a sulfuric acid bath. The coercive force of the Fe deposit reached about 2300 oe and the maximum value of 3200 oe was obtained by the Fe-Co alloy. Good squareness ratios were observed in the Fe, Ni, and their alloys. The magnetic recording characteristics were studied by measuring the frequency response. It was found that the films having vertical anisotropy showed better results than the films of horizontal ones. The recording density was calculated to be about 14,000 BPI in the Fe-Ni alloy at about 3 μm in thickness.

In a previous paper (1), it was revealed that anodic oxide films containing electrodeposited Co and/or Ni show very characteristic magnetic properties. The micropores of oxide film in which Co or Ni was precipitated showed magnetic anisotropy perpendicular to the substrate. In the Co-Ni (50%) alloy, the anisotropy turned to the horizontal direction of the surface. The coercivities ranged from about 500 to 1100 oe in the oxide films anodized under various kinds of electrolytes. A more recent report (2) disclosed that the electrodeposited metals were densely packed at the bottom of micropores and grew to the surface. In the oxide films obtained by a sulfuric acid bath, the deposits were observed as needlelike crystals of about 100Å in diameter. As the porosity of micropores was estimated to be about 10% of whole film, the strength of magnetization which depends on the amount of deposition indicated the lower value compared to a conventional thin film. However, when the thickness of oxide films was mechanically thinned by polishing, the densities of residual magnetization of the films containing Co and Ni reached about 1700 and 600G, respectively.

Since the fine particles of magnetic metals have been known to show a high coercive force, the evaluation stimulated an application for magnetic recording

Key words: anodic oxide film, coercive force, magnetic disk, frequency response.

Table I. Bath conditions

(a) Anodizing condition

Procedures	Remarks
Degreasing	5% NaOH, 60°C, 1 min
Desmut	5% HNO_3, 20°C, 1 min
Anodizing	15% H_2SO_4, 0.1% Al, 1.5 A/dm², 20°C, 20 min
Electrodeposition	15V (a.c. 50 Hz), 30°C bath compositions are indicated as follows*
Sealing	1% $Ni(CH_3CO_2)_2 \cdot 4H_2O$, 90°C, 20 min

(b) Electrodeposition composition

*Component (g/liter)	Fe	Co	Ni	Co-Ni	Fe-Ni	Fe-Co
$FeSO_4 \cdot 7H_2O$	50				25	30
$CoSO_4 \cdot 7H_2O$		50		20		20
$NiSO_4 \cdot 7H_2O$			50	80	250	
H_3BO_3	25	25	25	25	25	25
Glycerine	20	20	20	20	20	20
pH	4	5	5	5	4	4

devices (3), and the thin films of magnetic metals which are obtained by platings or evaporations are promising as a high density recording medium. In the study of digital recording, Bonyhard *et al.* (4) pointed out that the width of an isolated flux transition is proportional to the value of $Br \cdot t/2\pi \cdot Hc$, where t is the thickness of coating, Br is the retentivity of the medium, and Hc indicates the coercivity. Dudson (5) compared the iron oxide coating with the Co thin film, and explained that the Co plating gives an output which is at least three times greater than that of the iron oxide. Talke *et al.* (6) investigated the interface between a transducer and a magnetic disk, and reported that the readback pulse width can be reduced by decreasing the flying height of the magnetic head and the thickness of the film. The magnetic tapes and disks have been developed extensively for the last decade; according to the study of Mallinson (7), the ultimate density given by an information theory is demonstrated to be in the range of 10^8-10^9 bits per square inch.

Anodic oxide films containing magnetic metals have been considered as retaining the properties of either the fine particles or the thin films. The present paper studies the magnetic recording characteristics of the oxide films containing electrodeposited ferromagnetic metals and alloys.

Experimental Procedures

Specimens used for the experiment were prepared in two types. At the outset, for the measurement of magnetometer, rolled aluminum sheets (100 × 50 × 0.5 mm³) 99.99% in purity were used with no particular mechanical surface treatment. Then, aluminum disks (150ϕ × 5 mm) of the same purity, which had been previously stress relieved by a thermal treatment of *ca.* 250°C for about 500 min, were supermachined by a diamond bit in a lathe. After the disks were anodized in a sulfuric acid bath and electrodeposited in metal sulfate solutions, mirrorlike finishings were obtained by using a lapping machine with an abrasive of aluminum oxide powder in a size of about 0.1 μm. The surface flatness and roughness were checked at each step of polishing by an optical flatness meter and a stylus contact roughness meter. With a microscopic observation, the hardness of the anodic oxide films was measured along the depth on the cross sections.

As shown in Table I (a), a standard condition of electrolytic anodizing was introduced, and the thickness of films controlled to about 10 μm. Then, Fe, Co, and Ni metals and various ratios of Co-Ni, Fe-Ni, and Fe-Co alloys were electrodeposited into the micropores to be fully filled with arranging the electrolysis time. Table I(b) indicates the typical conditions of electrodeposition to the specimens for measuring the magnetic hysteresis loops which are shown in Fig. 1. The pH of electrolytes was adjusted by adding dilute solutions of ammonium hydroxide and sulfuric acid, and, in the case of baths containing ferrous sulfate, electrolytes were slightly acidified to prevent precipitation. The amount of deposited metals was determined with an atomic absorption spectroscopy. Magnetic hysteresis loops were recorded with a sample vibrating magnetometer which has been explained in a previous paper (1).

In order to find the recording property of the oxide films, frequency responses were measured between rotating disks and a magnetic head. The aluminum disks turned around at a speed of 9.5 m/sec (3600 rpm), while a flying head was positioned over the disk surface in a floating distance of 0.3 μm. The magnetic head was made from a ferrite core (Ni-Zn alloy) having 1.5 μm gap length and 16 turns in coiling. Square pulse of NRZ all-one signals were written into the magnetic film of disks, and readback responses in the most optimum voltage were recorded with varying the writing currents in the head.

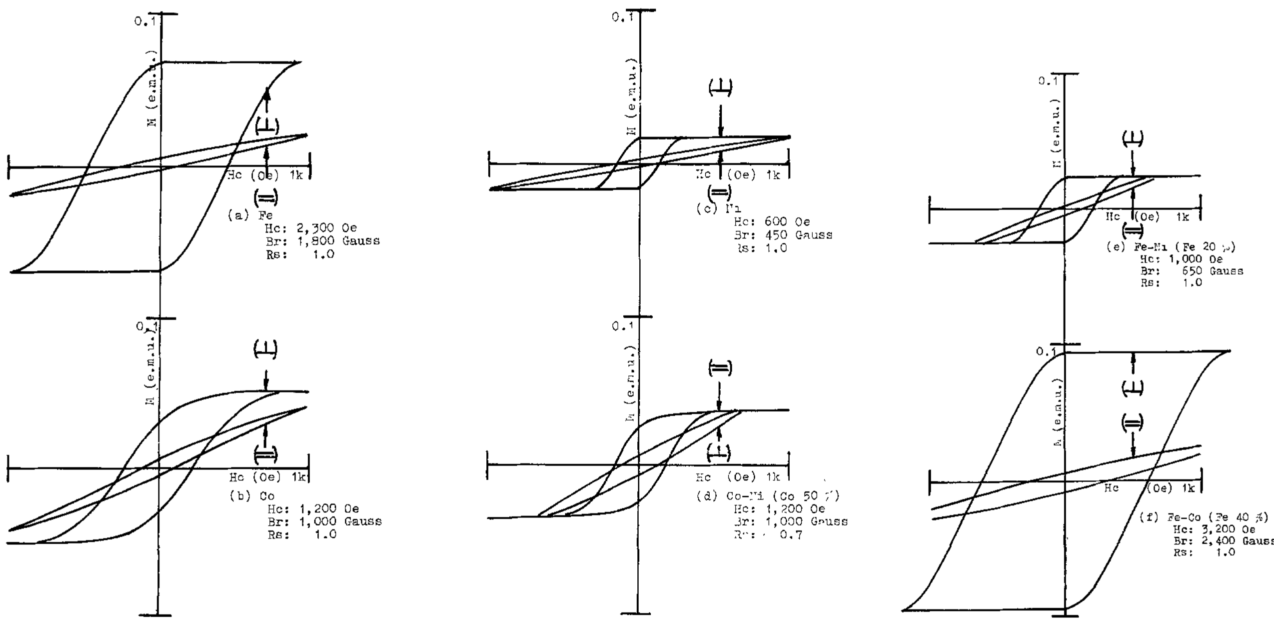

Fig. 1. (a)-(f) M-H hysteresis curves of anodic oxide films electrodeposited with ferromagnetic metals

Experimental Results

The hysteresis loops of the magnetic films containing Fe, Co, Ni, Co-Ni, Fe-Ni, and FeCo alloys are described in Fig. 1 (a), (b), (c), (d), (e), and (f), respectively. Strong magnetic anisotropies in the vertical direction to the substrate were observed; however, the anisotropy in the horizontal direction appeared in the Co-Ni (50%) alloy. Squareness ratios of *Mr/Ms* reached about 1.0, except Co and its alloy deposits which were calculated to be in the range of about 0.6-0.7.

In the Fe-Ni alloy, the coercivities increased almost linearly with enlarging the Fe content from about 700 oe of Ni to 2300 oe of Fe. On the other hand, in the Fe-Co alloy, the coercivities varied from about 1100 oe of Co to 2300 oe of Fe, while at the Fe content of about 20%, the coercivity peaked at about 3200 oe. The results are shown in Fig. 2 and 3.

The strength of residual magnetizations of Fe, Co, and Ni was measured to be about 200, 150, and 50 emu/g, respectively, and these values were nearly equal to the values of magnetic moments of the bulk metals.

As a result of mechanical finishing, the surface roughness of the base metals became about 0.2 μm, and that of the oxide films after the superpolishing reached about 0.02 μm as shown in Fig. 4(a) and (b). The final flatness of the surface observed by an interference fringe was about 2.0 μm per 100 mm. An excellent roughness of the disk surface can be obtained because of the brittleness of the oxide film. Figure 5 depicts the microhardness of the film which increased by degrees as approaching closer to the inner layer, and reached approximately 500 Hv (kg/mm²) at about 2 μm distance from the aluminum substrate. A schematic view of the cross section of the anodic oxide film containing metals is shown in Fig. 6.

On the measurement of frequency response, first, the relationship between writing currents of the head and reading voltages of the same head was recorded, while keeping the frequency constant at 2 MHz. The saturation currents attained 55 mA in the Ni and 100 mA in the Co-Ni and Fe-Ni deposits, respectively, as shown in Fig. 7. The wave forms of response pulse observed through an oscilloscope are shown in Fig. 8 in which (a) shows a typical form obtained from the films having horizontal anisotropy and (b) indicates a form of

the vertical one at a low frequency range. These forms, however, became a normal sine curve pulse (c) with increasing the frequency to 3 MHz. Then readback voltages from the stored disks under different frequencies were measured as shown in Fig. 9. The films containing Ni and Fe-Ni alloy deposits indicated better frequency response than the film of Co-Ni deposit Table II elucidates the comparison between the magnetic properties of the films and the estimated recording densities.

Coercivities of Oxide Films

In this experiment, the coercive forces varied from about 700 to 3200 oe. Luborsky (8) has shown that the

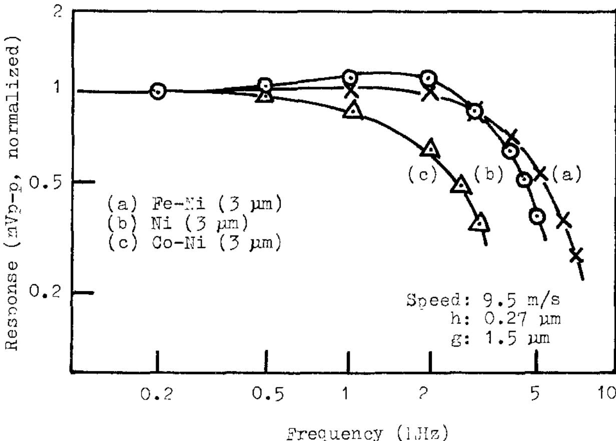

Fig. 9. Frequency response of various kinds of metals

coercive forces of fine particles of Fe and Co metals depend upon their particle diameters, and the maximum coercivity of about 1000 oe is obtained by the size of about 100-200Å. The deposits in the micropores of oxide films anodized in a sulfuric acid bath have a similar diameter to that of the particles, therefore, it is considered that the high coercivities of precipitations may be caused by the size of crystallization.

The magnetic anisotropies were dominated in the vertical direction and the excellent squareness ratios were recorded in the Fe and Ni deposits. In the single crystal of Fe. the easier magnetization axis has been reported to lie parallel to the cube edge and the same axis of Ni crystal orients to the cube diagonal (9), and,

frequently, these axes have been studied to coincide with the axes of crystal growing. In hexagonal Co, however, the variation of magnetizability with crystallographic direction is even greater than the Fe or Ni, and the c axis of crystal growth direction was reported to show harder magnetization than the other main axes. This may have a relation to the squareness inferiority in the hysteresis loop of the Co deposit.

Recording Characteristics

On the magnetic recording experiments, good output responses were recognized in the high frequency zone. From the values of rotation speed and frequencies at 0.5 mV of output voltage, the recording densities can be calculated to be 6000, 12,000, and 14,000 BPI with the deposits of Co-Ni, Ni, and Fe-Ni, respectively. The density obtained from the Co-Ni alloy seems to be almost equal to the values of iron oxide coatings in current use. On the other hand, the densities of the Ni and Fe-Ni deposits are considered much the same as the values of thin films which are now in trial use under experiment (10).

The highest readback voltage was measured in the Co-Ni deposit, and this might be due to the fact that this kind of magnetic head is designed to write and read the signals which are oriented in the lateral direction more effectively than those lined in the normal direction. In spite of the micropores being arranged perpendicular to the substrate, the oxide films of Co-Ni (50%) deposit indicate the magnetic anisotropy lying in the horizontal direction, and this proves the phenomenon of crystal anisotropy in which the easier magnetization axis progressed in the lateral direction. It has been known that this composition of deposit showed a lamellar structure and the axis of crystal growth was identical to the horizontal direction (1).

In the Ni and Fe-Ni (Fe 20%) deposits, the good responses lasted even in the range of high frequency, and it is assumed that the magnetic leakage flux developed in the normal direction may have the influence to more easily induce a current to the flying magnetic head.

Although the thickness of oxide films used in this experiment was somewhat greater than the films prepared by platings or evaporations, there are possibilities for obtaining the much higher recording density when the thickness could be reduced to very thin and flat. Also, the oxide films produced by a hard anodizing process have a practical application for the film of disks without any protective coatings.

The oxide films anodized in a sulfuric acid bath have been assumed to be a transparent medium, with the magnetic particles dispersed very uniformly into the film. This colloidal layer may have possible application for the magneto-optical Kerr or Faraday effect when a laser beam reflects or passes through the layer.

It may be concluded that the oxide films containing electrodeposited magnetic metals and alloys can be used for the magnetic memories of high bit density recording.

Conduction Mechanisms in Alkali Metal Vapor Electrolysis Cells

W. Y. Shiu, S. L. Ezer, D. J. Young,* M. J. Dignam,* and B. Rao

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A1

ABSTRACT

The operating characteristics of an alkali metal vapor plasma electrolysis cell, designed for ultrahigh vacuum vapor deposition of alkali metals, have been studied. The metal ions are generated at a tungsten anode in a gaseous plasma, following which they migrate through a glass envelope, on the far side of which they are discharged at a gold or platinum evaporated metal cathode, and thence enter the vacuum chamber. Many of the operating characteristics of the cells are explained in terms of the known behavior of gas discharge tubes. Some unexplained behavior remains, however, which appears to relate to nonlinear conduction behavior in the glass. Specifically, the units display voltage-time transients under constant current conditions, and certain units show a switching phenomenon, during which the current drops abruptly and spontaneously from ~10 mA to ~10 μA in $\lesssim$ 1 sec. No irreversible changes accompany these phenomena.

The vacuum evaporation of many metals is now a routine procedure, and commonly employed in the deposition of thin films of high purity. Alkali metals, because of their low melting points, are not suited to this technique.

A standard technique for the deposition of alkali metals involves electrolysis of the cation from a molten salt, through glass (1, 2). We have developed a procedure which is suitable for ultrahigh vacuum systems (3). In this procedure, metal ions are generated within the gaseous plasma. These migrate through the glass envelope, are then discharged at a gold or a platinum film cathode deposited on the far side of the envelope, and enter the vacuum space as a gas. A useful feature of this process is the purity of the metal passed through the glass, free (<2 ppm) of hydrogen and hydrocarbons (4). This purification is due primarily to the fact most impurities are in general very much less mobile in appropriately chosen glass than the desired metal cation (5).

In this paper we are concerned primarily with the conduction mechanism operating in these plasma electrolysis units. A number of surprising operating characteristics have been observed and some tentative explanations offered.

Construction

A standard deposition unit (Fig. 1) consists of a glass envelope containing a tungsten electrode, alkali metal vapor, and argon. For purposes of comparison some units were investigated in which no argon was present, others in which the gas plasma was replaced by a molten salt electrolyte $NaNO_3$. The envelope was made of appropriate glass, according to whether sodium or potassium was to be evaporated. This envelope was sealed to a central tube of the same glass which in turn was sealed to an ultrahigh vacuum flange. The central tube carried a small heating unit and thermocouple. Specifically, in the case of the unit containing the molten salt, the central tube was in direct contact with the electrolyte. Thus the cell temperatures measured in the case of the molten salt system closely represent the electrolyte temperature. The unit was activated by applying a potential difference between the tungsten anode and a metal film cathode deposited on the external surface. Additional details are given elsewhere (3).

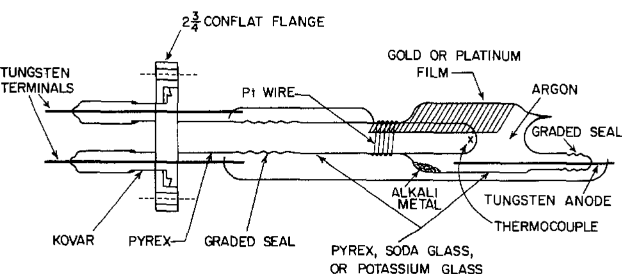

Fig. 1. Design of a typical plasma electrolysis unit

Operating Characteristics

In all, five different evaporation systems were studied. These were sodium in Pyrex (Na/Pyrex), sodium plus 0.1-1 Torr argon in Pyrex (Ar-Na/Pyrex), molten sodium nitrate in Pyrex ($NaNO_3$/Pyrex), sodium plus 0.1-1 Torr argon in soda glass (Ar-Na/Na glass), and potassium plus argon in potassium glass (Ar-K/K glass). The behavior of each of these units is presented in turn.

Na/Pyrex unit.—These units display close-to-ohmic behavior on increasing the voltage in small steps from 0 to 1200V over the temperature range 375°-500°C (Fig. 2) and settle rapidly to the new current (< 2 sec). The current-voltage (*C-V*) curves are both reversible and reproducible as long as the voltage is changed in small steps. However, transient behavior occurs when a unit is subjected suddenly to a high applied voltage.

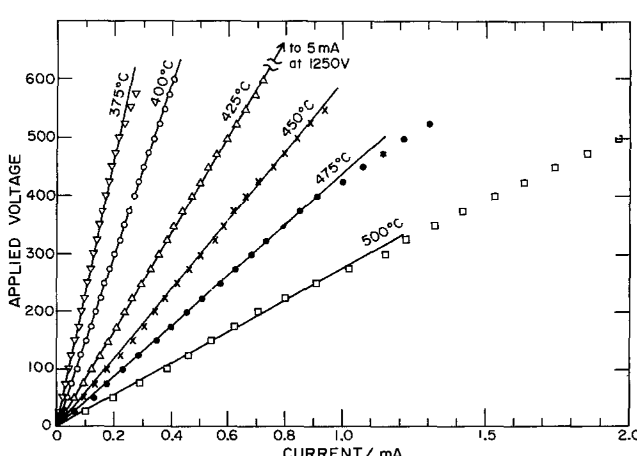

Fig. 2. Steady-state conduction data for a Na/Pyrex unit

The current increases over a period of about 10-20 sec to a value substantially larger than that obtained upon applying the voltage slowly, and is accompanied by a visible discharge; this situation may persist for a number of seconds, but ultimately the current falls off to ~10 μA in a period ~ 1 sec, and the visible discharge ceases. The transient can be repeated after holding the unit for a short period at zero applied voltage. Typical transients are shown in Fig. 3.

No difference in operating characteristics is observed for units constructed so that the tungsten anode makes contact with the molten sodium. However, if in addition the molten sodium is in contact with a portion of the Pyrex envelope which is coated with gold or platinum, much higher currents are obtained (50 mA for ~200V) and rapid puncture of the envelope results.

Ar-Na/Pyrex unit.—Addition of argon at a pressure from 0.1 to 1 Torr completely alters the *C-V* characteristics of the Na/Pyrex (Fig. 4 and 5). For such units, an intense discharge is observed which can be struck by the application of less than 200V. For voltages less than that required to sustain the discharge, these units displayed close-to-reversible ohmic behavior. Following the onset of the discharge, the current rises over a period of from 3 to 10 min to a value 10-100 times larger than the predischarge value. In the discharge region, the steady-state *C-V* relation is far from ohmic (Fig. 5). However, for a rapid change in the applied current, the instantaneous voltage change is approximately proportional to the current change, following which the voltage approaches its new steady-state value in a time which is of the order of 10-100 sec (Fig. 6).

On initiation of the discharge, the discharge is purple, and centered on the anode, changing over the few minutes required to establish steady-state conditions to the bright yellow characteristic of the sodium D lines. The spectrum of the emitted light contained in addition to the sodium D lines, three lines which appear to be due to Ar [568 mμ (strong), 514 mμ (intermediate), 499 mμ (weak)].

Units containing argon and constructed so that the tungsten anode makes contact with the molten sodium

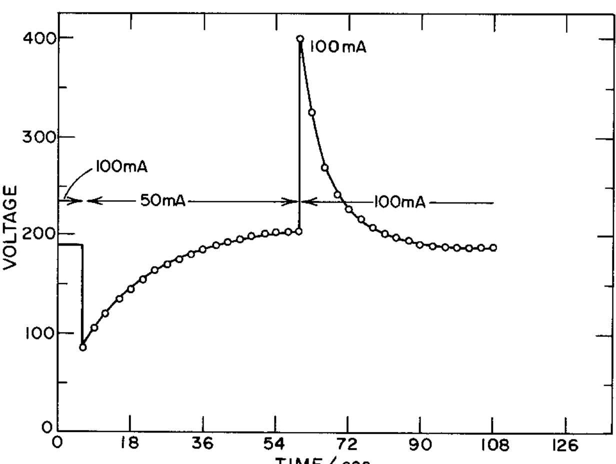

Fig. 6. Transient response for an Ar-Na/Pyrex unit in the discharge region.

generally give little or no visible discharge at any voltage, the current increasing smoothly as the potential is increased from zero to several hundred volts (Fig. 7).

At the higher voltage, the *C-V* behavior differs from that for units without anode-sodium contact (Fig. 5) mainly in that the curves are displaced to lower voltages.

$NaNO_3$/Pyrex unit.—These units were constructed somewhat differently from that depicted in Fig. 1. The envelope possesses a side arm to the atmosphere through which the molten salt is introduced, the anode inserted, and from which the oxides of nitrogen produced in the electrolysis are released. The portion of the Pyrex envelope which is coated with the gold or platinum film is in contact with the molten salt, which is in turn in contact with the anode.

The steady-state *C-V* behavior for these units (Fig. 8) is similar to the Ar-Na/Pyrex units with

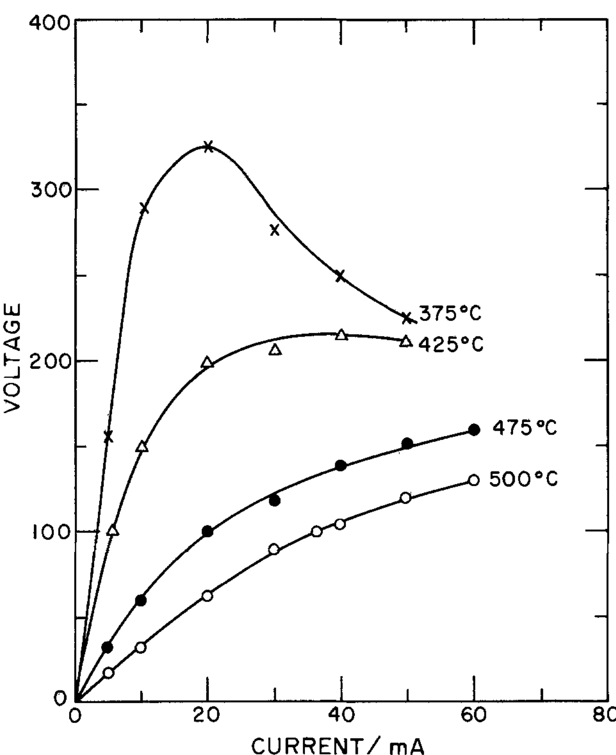

Fig. 7. Steady-state conduction data for an Ar-Na/Pyrex unit with Na-anode contact.

anode-sodium contact (Fig. 7) and to the standard Ar-Na/Pyrex units in the discharge region (Fig. 5). Their response to a sudden change in current is also similar (Fig. 9).

Ar-Na/Na glass units.—These units perform in a manner similar to the Ar-Na/Pyrex units except that they operate satisfactorily at a substantially lower temperature, and the conductances calculated from the slopes in the predischarge regions are very much larger.

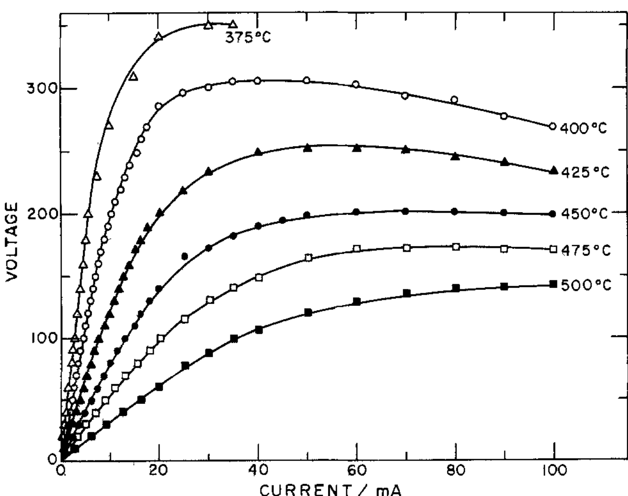

Fig. 8. Steady-state conduction data for a $NaNO_3$/Pyrex unit

Discussion

As most of the data obtained relate to units which involve sodium ion migration through Pyrex, we shall restrict discussion mainly to these units.

In Fig. 10, conductance data obtained from the initial Ohmic regions for the various Pyrex units are presented in the form of Arrhenius plots of approximately the same slope, corresponding to an activation energy of about 19 kcal/mole. Conductivity data for Pyrex (6) lead to a value of 19.8 kcal/mole.

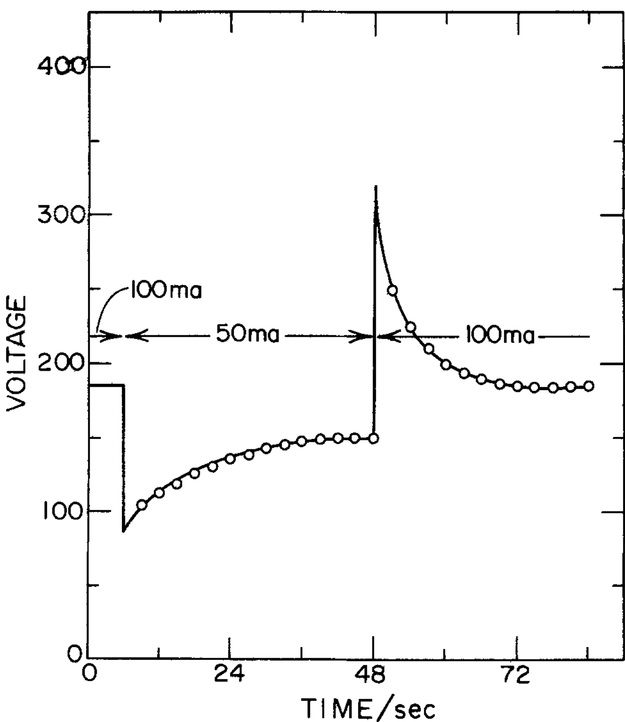

Fig. 9. Transient response for a $NaNO_3$/Pyrex unit in the region of high differential conduction.

Although the activation energies for the four units are nearly the same, the conductances themselves are not. The conductances of the units $NaNO_3$/Pyrex and Ar-Na/Pyrex with Na-anode contact are essentially the same, as are those of the Na/Pyrex, and Ar-Na/Pyrex without Na-anode contact, but the former have conductances about 50 times larger than the latter.

On the basis of the data presented, and the known properties of gas discharges, we offer the following account of the operating behavior of the various Pyrex units.

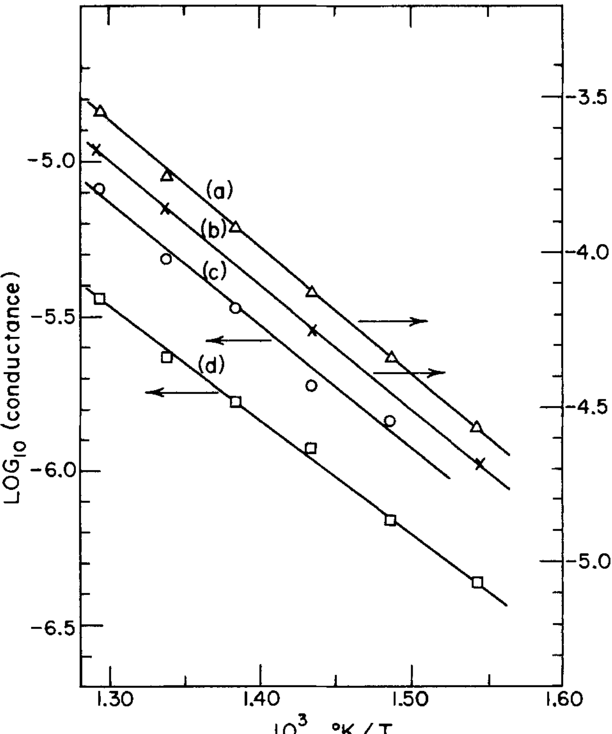

Fig. 10. Arrhenius activation energy plots of the conductance for the various Pyrex units; (a) $NaNO_3$/Pyrex units, (b) Ar-Na/Pyrex unit with Na-anode contact, (c) Ar-Na/Pyrex unit without Na-anode contact, (d) Na/Pyrex unit.

Na/Pyrex unit.—A comparison between the steady-state behavior of this unit and that of the $NaNO_3$/Pyrex unit will now be made. It may be presumed that Na^+ migration through Pyrex determines the i-V relationship for the latter unit. We assume here that the only charged particles present in significant numbers in the gas phase of the Na/Pyrex unit are sodium cations (when there is no discharge), the cations being generated on the tungsten anode via an adsorption-desorption process. For currents in the μA range, this anodic process is apparently not rate controlling, so that a positive space charge region is established close to the anode to equalize the net current at the anode with that at the cathode. Assuming now that the cathodic current is controlled by the field strength in the Pyrex glass, then on neglecting the thickness of the positive space charge region, and assuming no net surface or volume charge associated with the glass, one obtains for an ideal, one-dimensional current flow, the relation

$$i = (\sigma V/l)/[1 + KL/l] \qquad [1]$$

where i is the current density, V the total applied voltage, σ the glass conductivity, l and L the thicknesses of the glass and gas column, respectively, and K the dielectric constant of the glass. As the corresponding relationship for the $NaNO_3$/Pyrex unit is

$$i = \sigma V/l \qquad [2]$$

Eq. [1] predicts the conductance of the Na/Pyrex unit to be less than that of the $NaNO_3$/Pyrex unit by a factor of $(1 + KL/l)$, which for $K = 4.8$ (6), $l = 0.1$ cm, and $L \sim 1$ cm is about 50, in satisfactory agreement with observation. The results of the Arrhenius plots (Fig. 10) are also in agreement with Eq. [1] and [2]. The agreement obtained justifies the assumption that only sodium cations contribute to the current in the gas phase of the Na/Pyrex unit.

If a high voltage is applied suddenly to a Na/Pyrex unit, breakdown occurs in the gas and a discharge is established which leads to higher currents as described in the following section on the Ar-Na/Pyrex unit. This discharge is not stable, however, and is ultimately extinguished (see Fig. 3). It seems likely that as the discharge develops, more and more of the applied voltage appears across the glass until finally the discharge is extinguished. The details of the process, however, remain obscure. Thus, it appears necessary to assume that during this process the conductivity of the glass is reduced dramatically so that following extinction of the discharge the conductance of the unit is about 100 times less than it is for the same unit when the voltage is applied slowly.

Ar-Na/Pryex unit.—In the predischarge region, the operating characteristics are indistinguishable from those of the Na/Pyrex unit, the two mechanisms being therefore presumably the same.

Above the breakdown voltage, a situation analogous to that in a normal glow discharge appears to be established, in which positive ions and electrons are generated by collision in the region of the cathode fall. The role of the argon is undoubtedly to increase the probability of ionization by collision, possibly through a Penning effect. Neglecting the voltage drop within the positive column, and assuming no surface or volume charge associated with the glass, we obtain

$$i = [\sigma(V - V_a)/l]/[1 + Kd_c/l] \qquad [3]$$

where d_c is the effective length of the region of cathode fall and V_a the anode fall.

On comparing the behavior of Ar-Na/Pyrex units with and without Na-anode contact, it is apparent that the voltages required to sustain given currents are much less in the former. On the other hand, the conduction behavior of the Ar-Na/Pyrex unit with Na-anode contact is nearly the same as that of the $NaNO_3$/Pyrex unit over the entire range of currents studied. The most obvious explanation for these observations is that Kd_c/l is small compared to unity and V_a is essentially zero for the unit with Na-anode contact, while $\sim$ 100V for the unit without Na-anode contact. It appears, therefore, that in the absence of Na-anode contact, direct ionization of sodium at the tungsten anode cannot accommodate currents in the mA range, so that an anode fall is established in which positive ions, required for the positive column, are generated by collision. On this basis, one expects V_a to decrease with increasing current. On comparing Fig. 5 and 7, V_a appears to be about 100V at low currents, increasing to a maximum $\sim$ 180V at from 4 to 17 mA, depending on the temperature, then falling off rapidly to well below 100V at higher currents. Perhaps the initial increase in V_a with increasing current is due to a contribution to the generation of positive ions at the anode by field emission of sodium adsorbed on the tungsten anode. Thus Na^+ ion generation passes with increasing current through an equilibrium regime (V_a independent of i), a field emission regime (V_a increasing with i), and finally a collision ionization regime (V_a decreasing with increasing i).

If this explanation for the operating behavior of the two types of Ar-Na/Pyrex units is accepted, then we must conclude that most of the visible emission of light is associated with processes occurring close to the anode, since the units with Na-anode contact show little if any visible emission.

The transient behavior exhibited by both the Ar-Na/Pyrex unit (Fig. 6) and the $NaNO_3$/Pyrex unit (Fig. 9) must be due to a time dependence of the conductance of the glass, as the relaxation times are much too large to be associated with any likely gas phase phenomenon. The transients are very similar for the two units, as expected, since under constant current conditions, V_a should be constant, and is in any event substantially smaller than the voltage drop across the glass in the current range 50-100 mA.

The possibility that the nonlinear conduction behavior of the units, as well as the voltage transients (Fig. 6 and 9), is due to temperature nonuniformities is now considered. Both effects are of the correct general form to be accounted for by a temperature differential between the conducting glass and the thermocouple, the difference increasing with increasing power dissipation in the unit. To explain in this way the voltage value required to sustain a 100 mA current in the $NaNO_3$/Pyrex unit at a nominal temperature of 400°C would require assuming that the conducting part of the glass envelope was at a temperature about 125°C higher than that of the thermocouple.

The energy dissipation of this unit under the above conditions is about 30W. The thermocouple is situated inside a well which is immersed in the molten salt, and less than 1 cm from the conducting portion of the envelope which is also in contact with the molten salt. At the operating temperature for these units, the principle mechanism for heat loss to the surroundings is by radiation, rather than conduction, so that a substantial temperature gradient from the outside to the interior of the cell cannot be maintained as a consequence of power dissipation in the outer region. On the other hand, the conducting portion of the glass envelope is coated with metal, a material of low emissivity compared to glass.

It is difficult to rule out the possibility that a 125°C temperature differential could be maintained within the deposition unit under operating conditions, although such a large differential seems improbable. Perhaps the most convincing evidence against such a large thermal effect is provided by the very similar behavior of the $NaNO_3$/Pyrex and Ar-Na/Pyrex units, despite the great difference in conductivity between molten $NaNO_3$ and a low pressure gas. Finally, we note that the transients depicted in Fig. 3 are clearly not explicable solely in terms of nonuniformity of temperature. We believe that both transients, as well as the nonlinear conduction behavior, are due to nonlinear process with the glass.

Representing the current density in the glass by the relationship

$$i = envE \qquad [4]$$

where e is the charge on the proton, v the mobility and n the concentration of the current carriers (sodium ions), and E the electric field strength in the glass, then if the constant current transients are due to a time dependence of n, $1/V$ should display the same time dependence as does n. It is found from appropriate plots that within experimental scatter, $1/V$ decays according to first order kinetics, the relaxation times for a number of different runs being recorded in Table I. They are seen to be about the same for the two units, Ar-Na/Pyrex and $NaNO_3$/Pyrex, and essentially independent of temperature.

The observed kinetics are consistent with a conduction mechanism in which conducting ions are produced in the glass by an avalanche mechanism, and are destroyed by a first order process. Thus assuming that

$$\frac{dn}{dt} = ki - n/\tau \qquad [5]$$

we obtain with Eq. [4]

$$\log_e \left| \frac{E_\infty/E - 1}{E_\infty/E_0 - 1} \right| = -t/\tau \qquad [6]$$

$$E_\infty = k\tau/ev \qquad [7]$$

where E_0 is the field strength at time zero and E_∞ the final steady-state field strength, which is seen to be independent of i, in accord with the observed behavior in the limit of large i. For sufficiently small i, n is presumably constant and no longer varies according to Eq. [5].

Perhaps the main objection to this mechanism is that the precise nature of the first order process is obscure, and the lack of a significant temperature dependence for τ surprising. Additionally, it does not predict τ to be dependent on i.

A mechanism which eliminates both these objections can be formulated if one assumes generation of ion pairs by a "second order avalanche process," as proposed by Young (7) for ionic conduction in anodically formed Ta_2O_5, with ion recombination controlled by the current flow, a situation that could obtain if conduction in a glass were similar to the movement of charged bodies in a viscous fluid. This mechanism gives

$$\frac{dn}{dt} = k_1 i^2 - k_2 ni \qquad [8]$$

with k_2 essentially temperature independent, which again leads to Eq. [6] with $\tau = 1/k_2 i$ and $E_\infty = k_1/k_2 ev$. An objection to this mechanism is the lack of direct experimental or theoretical justification for a process of ion-pair generation which is proportional to i^2. Other mechanisms have been proposed to account for high field ionic conduction in anodically formed oxide films (8), however none of these appear to apply to the present systems.

Ar-Na/Na glass and Ar-K/K glass units.—In all important respects, these units behave as do the corresponding Pyrex units. Thus in the predischarge region, the Arrhenius activation energies for conduction in each of the units agree with those calculated from published data (6, 9). Not all of the experiments performed on the Pyrex units, however, were carried out for these units.

Table I. Relaxation times for $1/V$ (i constant)

Summary

The process of plasma electrolysis of alkali metal vapor, using a glass cathode and metal anode, has been studied over a range of temperatures and plasma conditions. The results are compared with the electrolysis of $NaNO_3$, also using a glass cathode.

At low currents, sodium ions are generated at a tungsten anode by a dischargeless process, which is not rate controlling. At high currents, they are generated by collision ionization in the anode fall region, the process being accompanied by the emission of light. If liquid sodium is used for the anode, sodium ions are generated by a dischargeless process at all currents studied.

The voltage-time transient under constant current conditions, and the switching phenomenon observed for Na/Pyrex units are probably due to nonlinear conduction processes within the glass cathode.

Thermoelectric Power in Pure and CaO-Doped ThO_2 Electrolytes

H. S. Maiti[1] and E. C. Subbarao

Department of Metallurgical Engineering, Indian Institute of Technology, Kanpur 208016, India

ABSTRACT

The Seebeck coefficient of the thermocells of the type

$$p_{O_2}, Pt \underset{T_1}{||} ThO_2 \text{ or } ThO_2 + 7 \text{ m/o } CaO \underset{T_2}{||} Pt, p_{O_2}$$

was measured in the temperature range 600°-1000°C with $p_{O_2} = 10^{-0.7}$ (air), 10^{-5}, and 10^{-23} atm. Electron holes are the charge carriers in the mixed-conduction region. The temperature dependence of the total Seebeck coefficient is accounted for by the variation of transference numbers and α_h (Seebeck coefficient due to electron holes) with temperature.

Recent studies (1) have shown that the electrical conductivity of ThO_2-CaO electrolytes is predominantly due to electron holes at oxygen partial pressures greater than about 10^{-6} atm and due to oxygen ions at lower p_{O_2} values, similar to the case of ThO_2-Y_2O_3 electrolytes. As a supplement to the electrical conductivity data, thermoelectric power measurements have been carried out over the temperature range of 600°-1000°C on sintered disks of nominally pure ThO_2 and ThO_2 doped with 7 mole per cent (m/o) CaO. The latter composition has a much higher conductivity than the former throughout the oxygen partial pressure range. These results are compared with those of Tallan and Bransky (2, 3) on pure ThO_2.

Experimental

The alumina tube sample holder, used earlier for electrical conductivity measurements (4), was utilized for the Seebeck coefficient measurements with the following modifications. The cylindrical sample used here (9 mm in diameter and 1 cm in length) was longer than that used for electrical conductivity study. The necessary temperature gradients up to 15°C were created across the specimen by supplying a d-c voltage to a platinum wire wound over the alumina pressing rod just above the specimen surface. The Seebeck coefficient was estimated from the slope of the straight line of the emf *vs.* the temperature gradient plot. The sign of the Seebeck coefficient, as determined from the polarity of the cold end of the specimen, was positive, indicating that the electron holes are the charge carriers. The experimental considerations in the measurement of Seebeck coefficient are discussed by Blumenthal and Seitz (5). The measurements were made at three oxygen partial pressures [$p_{O_2} = 10^{-0.7}$ (air), 10^{-5}, and 10^{-23} atm]. The desired low oxygen partial pressures were generated by using an electrochemical oxygen pump based on CaO-stabilized zirconia tube (1).

Results and Discussion

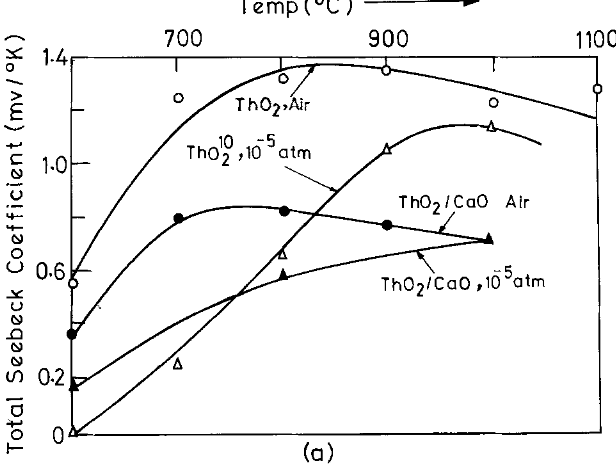
The total Seebeck coefficient (α_T) for the two samples in air and at $p_{O_2} = 10^{-5}$ atm is plotted in Fig. 1 as a function of temperature, together with the temperature variation of t_{ion}.

The Seebeck coefficient of pure ThO_2 increases with temperature reaching a maximum between 800° and 900°C in air and between 900° and 1000°C at $p_{O_2} = 10^{-5}$ atm. The α_T value at 1000°C in air is 1.25 mV/°K and is close to the 1.2 ± 0.1 mV/°K reported by Bransky and Tallan (2) at $p_{O_2} = 10^{-1}$ atm at 1000°C. The Seebeck coefficient at any fixed temperature is lower at the lower oxygen partial pressure. This is contrary to the slight increase in α_T reported by Bransky and Tallan (2) as the oxygen partial pressure is lowered to 10^{-5} at 1000°C. The reason for this discrepancy is not clear.

The total Seebeck coefficient (α_T) of a mixed (partially ionic and partially electron hole) conductor is given by

$$\alpha_T = t_i\alpha_i + t_h\alpha_h \qquad [1]$$

where t_i and t_h are the transference numbers for ions and electron holes and α_i and α_h are the corresponding Seebeck coefficients. The temperature coefficient of α_T depends on the temperature dependence of the four terms on the right-hand side of Eq. [1]. In air, t_i of pure ThO_2 decreases from 0.2 at 600°C to 0.05 at 700°C and remains constant at higher temperatures. The value at 1000°C is smaller than the 0.15 observed by



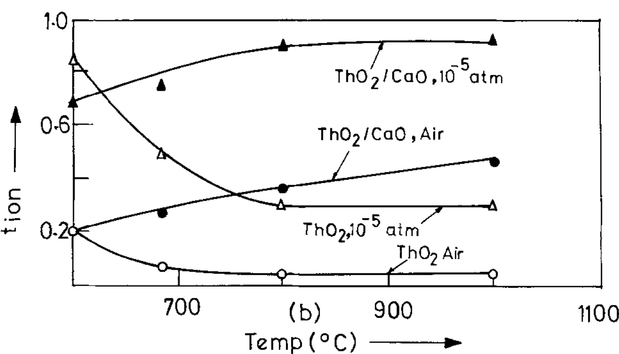


Fig. 1. (a) Seebeck coefficient and (b) t_{ion} of pure and 7 m/o CaO-doped ThO_2 specimens in air and at $p_{O_2} = 10^{-5}$ atm.

[1] Present address: Materials Science Center, Indian Institute of Technology, Kharagpur 721302, India.

Key words: Seebeck coefficient, temperature dependence, mixed conduction.

Bransky and Tallan (2) for their ThO_2 which is purer than the present sample. Thus $t_i << t_h$. Besides, α_i (0.45 mV/°K) is reported (2) to be less than α_h (1.4 mV/°K) at $p_{O_2} = 10^{-1}$ atm at 1000°C. As a result, the contribution of $t_i\alpha_i$ to α_T is negligible. The temperature coefficient of α_h was shown to be

$$\frac{d(\alpha_h)}{dT} = \frac{-K}{e}\frac{d(\ln p)}{dT} \quad [2]$$

for a p-type semiconductor; here K is the Boltzmann constant, e is the electronic charge, and p is the electron hole concentration. Therefore, α_h decreases slightly with increasing temperature. Since t_h increases from 0.8 to 0.95 as the temperature is varied from 600° to 800°C, $\alpha_h t_h$, and correspondingly α_T, increases with temperature in this range. On the other hand, t_h remains constant beyond 800°C and therefore $\alpha_h t_h$ and α_T decrease slightly with temperature above 800°C. Bransky and Tallan (2) have reported a similar decrease in α_T as the temperature rises from 900° to 1400°C.

Similar considerations explain the temperature variation of α_T of pure ThO_2 at $p_{O_2} = 10^{-5}$ atm. The large increase in t_h from 0.15 at 600°C to 0.7 at 800°C is reflected in the steep rise of α_T with temperature below about 900°C. At all temperatures, t_h is less at $p_{O_2} = 10^{-5}$ atm than in air. As a result, α_T is lower at $p_{O_2} = 10^{-5}$ atm than in air. In fact, at a very low oxygen partial pressure ($p_{O_2} \approx 10^{-23}$ atm) when the "pure" ThO_2 is exclusively an ionic conductor and the total conductivity was extremely low, the Seebeck coefficient was too small to be measured with certainty. This may be compared with a value of 0 ± 0.1 mV/°K observed by Tallan and Bransky (2) on pure ThO_2 at 1000°C and at p_{O_2} in the range of 10^{-11}-10^{-19} atm.

The t_h is considerably smaller for 7 m/o CaO sample than for pure ThO_2 in air and at $p_{O_2} = 10^{-5}$ atm at all temperatures (Fig. 1). Therefore, $t_h\alpha_h$, and consequently α_T, is smaller for the doped sample than for pure ThO_2, even though $\alpha_h > \alpha_i$. This was indeed the case in air at all temperatures and at $p_{O_2} = 10^{-5}$ atm above 800°C. The increase of α_T with temperature at lower temperatures must be due to the increase of t_i and slightly of α_i with temperature. At higher temperatures, t_i remains constant and therefore the influence of the negative temperature coefficient of α_h is seen in the decrease of α_T with temperature above 800°C in air. However, such a trend was not detected at 10^{-5} atm, since t_h is very small ($\simeq$0.1) in this case. A Seebeck coefficient of 0.25 mV/°K was measured in this sample at 1000°C at $p_{O_2} \simeq 10^{-23}$ atm, where the sample is a purely ionic conductor.

Adhesive bonding of aluminum alloys for use as primary structures of aircraft is becoming an important method of assembly. Present adhesive technology has increased the cohesive strength of bonding resins to the point where the adhesive-oxide interface now plays the major role in the durability of the bonded structure. This requires the oxide layer to play two important roles; (*i*) it must be a clean active surface that is suitable for bonding and (*ii*) it must be an adherent protective film for the metal. Therefore, the surface preparation of the metal becomes an important step in the procedure to obtain optimum bond strength, durability, and reproducibility. The fracture strength of the oxide layer is also an important property, however; a thin alumina layer (<5000Å) should not limit joint strength.

Key words: ion scattering spectroscopy, secondary ion mass spectroscopy, Auger electron spectroscopy.

Fulfilling the requirements stated in *i* and *ii* above is made difficult by the complex nature of the aluminum

alloy surface. The elements added for alloying purposes may appear in solid solution, as microparticles of the elements or be present as particles of intermetallic compounds. The stoichiometry of the oxide layer of a material as received from the manufacturer is usually dictated by the particular heat-treatment the alloy has received. In the case of 2024-T3, this surface layer has been shown to consist of a magnesium-rich layer (1). Minford (2) in his work on surface preparations has shown that 6061-T6 aluminum when only vapor degreased before bonding has reasonable initial strength but no durability when exposed to an aggressive environment. Smith (3) has reported that this alloy has a magnesium-rich surface after a heat-treatment. Vapor degreasing has little chemical effect on the surface of an alloy, therefore, it remains the same as that generated by the heat-treatment process. Some preliminary studies in our laboratory show that 2024-T3 bare aluminum has poor durability when only vapor degreased before bonding. These data indicate that a magnesium-rich surface on aluminum lends no durability to a bonded joint. In our studies we have observed that the aluminum alloys 7075, 6061, and 7050 all tend to have a magnesium-rich layer in their as-received state from the manufacturer. It is apparent from the literature that no correlation has been made between the surface chemistry of a vapor-degreased surface and its poor durability. The literature states only that the "old oxide" layer must be removed, so indirectly a magnesium-rich layer is avoided.

With aluminum alloys an acid cleaner (deoxidizer) is invariably used to remove the old oxide surface layer. After deoxidizing, another surface layer will be generated and in our opinion the surface chemistry of this layer is also important and needs to be analyzed. The chemical surface treatment for aluminum alloys usually consists of an acid-bath etch. The acid bath used worldwide, with a few exceptions, is a mixture of sulfuric-chromic acid (or sodium dichromate) solutions. In spite of this large usage, very few surface studies have been performed (4-6) on materials treated in these solutions. To a large extent these few studies have dealt mainly with the physical properties of the surface.

A number of instrumental techniques are now available that allow us to chemically analyze the surfaces of these treated materials. Particular to this study are ion scattering spectroscopy (ISS), secondary ion mass spectroscopy (SIMS), and Auger electron spectroscopy (AES).

This paper reports on the types of elements found in the surface layer of 2024-T3 aluminum after treatment by several acid cleaners. These data represent the initial phase in our program to correlate the surface chemistry of aluminum alloys to adhesive bond durability.

Experimental

Instrumentation.—Standard instrumental parameters were employed for the ISS, SIMS, and AES studies and have been reported previously (1). ISS and SIMS were obtained simultaneously. They are capable of uniquely identifying the elements in the first monolayer of a surface when using ^4He as the probe ion. AES probes somewhat deeper (~20-30Å), however, it is capable of sputtering through a film and recording a depth profile of the elements present. Each technique by itself suffers from some deficiency in sensitivity for various elements, however, the three instruments form a fine complementary technology base for surface analysis.

Chemical treatments.—All of the 2024-T3 samples were pretreated with an acetone wash, carbon tetrachloride ultrasonic cleaning, and a room temperature etch in 0.1*N* sodium hydroxide for 2 min.

Three acid solutions were used in this study: Solution 1. 300g sulfuric acid, 30g sodium dichromate per liter of solution (commonly known as FPL etch). Time and temperature were varied. Solution 2. 100g sulfuric acid, 30g chromic acid per liter of solution. Temperature was maintained at 50°C while time varied. Solution 3. 300g sulfuric acid, 40g chromic acid per liter of solution. Temperature was maintained at 60°C while time varied.

All samples were rinsed in tap water for 15 min and wiped dry.

Results and Discussion

2024-T3 aluminum is a high copper (4.5%)-magnesium (1.5%) alloy and in all cases a surface layer will be formed by the chemical interaction of the acid bath and the aluminum metal. The corrosion resistance of the metal will depend on the tenacity and chemical nature of the hydrated oxide layer placed on the surface. These two characteristics will depend on the nature of the alloy and the chemical treatment that is responsible for the film.

The artificial aging of this alloy causes the compound $CuAl_2$ to precipitate along the grain boundaries. This compound is highly cathodic if brought into contact with an aggressive environment. As mentioned previously, a magnesium-rich oxide layer does not appear to provide a durable surface (2) for bonding. Sulfate and chromate anions can both become part of the treated surface due to their presence in the acid etch solutions. Any sulfate left in the oxide layer could, under the proper conditions, form a white powdery product (6), namely $Al_2(SO_4)_3 \cdot 18H_2O$. The positive or negative effects of the chromate anion on the oxide layer-adhesive interface have not been studied in any detail.

The data presented in this paper are primarily concerned with the chemical nature of each surface film and the comparative results are based on the presence of copper, magnesium, chromium, sulfur, and the relative thickness of each film. We propose that the desired surface should contain a minimum amount of the elements presented above.

Figure 1 shows the intensity data for oxygen, copper and aluminum (1396 eV) obtained from an Auger profile. It is a typical example of the profile data obtained for this study. The intensity profile for each element was normalized and plotted through the use of a computer program. The oxide thickness was arbitrarily determined by extending the profile slope of oxygen directly to the baseline. The copper concentra-

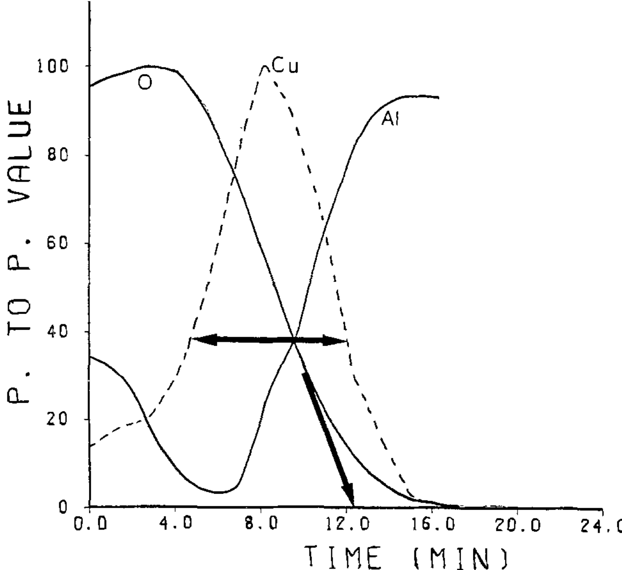

Fig. 1. AES intensity profile of oxygen, copper, and aluminum

tion was arbitrarily determined by measuring the width of the copper intensity profile curve at the oxygen-aluminum crossover. Both of these data points were left in the unit of time. Since copper is part of the bulk alloy its concentration can be greater than the thickness of the oxide layer.

Figure 2 shows the comparative oxide film thickness and copper concentration of the 2024-T3 aluminum surface for various time and temperature treatments in the FPL etch (solution 1). An etch temperature of 65°C leaves a relatively constant oxide layer and copper concentration regardless of the time in bath. At 55°C these values increase and at 45°C they are approximately double that of the 65°C etch.

Figure 3 shows the data obtained from the straight acid etches. The 100-30 mixture (solution 2) at 50°C averages almost 17 min sputter time in both film thickness and copper concentration. The 300-40 mixture (solution 3) at 60°C averages approximately 13 min for oxide layer thickness and 11 min for copper concentration.

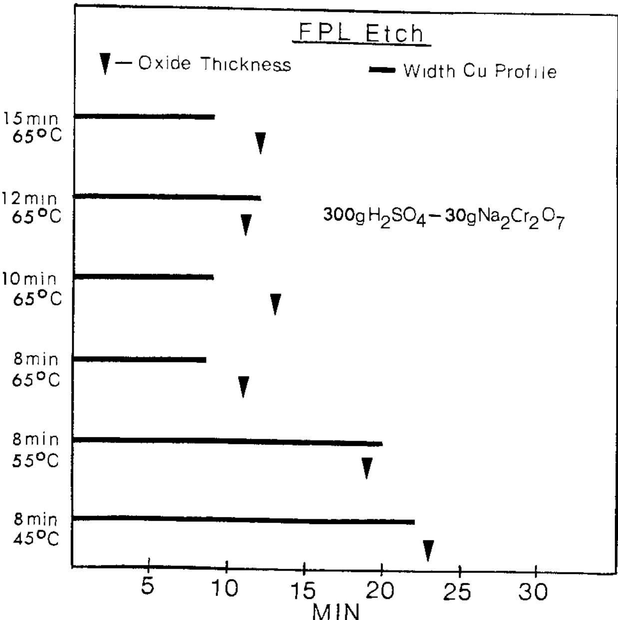

Fig. 2. Variations of oxide thickness and copper concentration on 2024-T3 generated by an FPL etch solution.

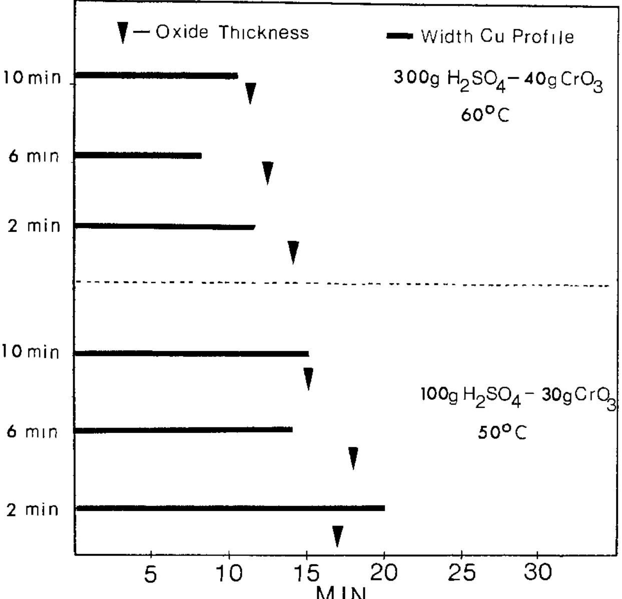

Fig. 3. Variations of oxide thickness and copper concentration on 2024-T3 generated by sulfuric-chromic acid solutions.

Magnesium was reduced to a minimum by these solutions and due to its low sensitivity by the Auger technique could not be profiled with any accuracy. Figures 4 and 5 show typical ISS-SIMS and Auger spectrograms, respectively. These curves were obtained from a sample treated for 6 min in solution 2. Oxygen, 510 eV, usually masks the chromium energy peaks at 489 and 529 eV (Fig. 5) making it impossible to obtain an intensity profile curve for this element.

Sulfur is observed in all of the Auger spectra at approximately 8% of the peak-to-peak intensity of oxygen. The Auger technique is sensitive to sulfur while the ISS and SIMS techniques are not. Several intensity profiles indicate sulfur is only part of the outer surface layer with its intensity falling almost to zero after 2 min. This is based on a sputtering rate of 10-15 Å/min. Carbon seems to be always present and follows the same discussion as that for sulfur, however, it should not have been placed there directly by our preparation techniques.

Since magnesium, chromium and sulfur are difficult to profile by Auger for this particular investigation, they are reported in Tables I and II as detected elements.

Copper was observed by ISS, SIMS, and AES for all of the solutions studied and is not reported in these tables. Magnesium will be masked by aluminum in the ISS technique but can be observed by SIMS (Fig. 4). Table I shows magnesium is detected on the metal surface for all of the FPL etch solutions by SIMS, how-

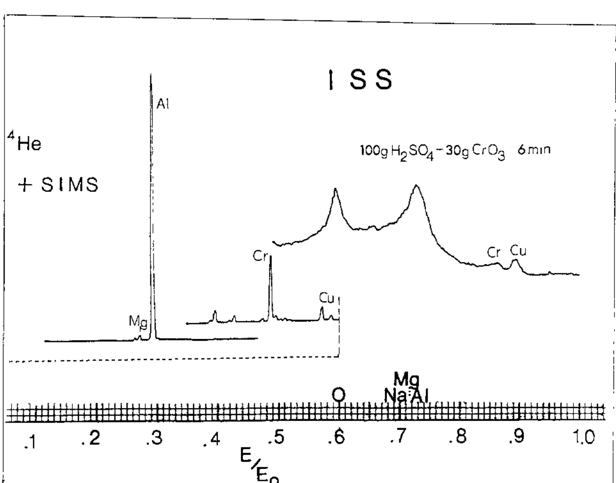

Fig. 4. ISS-SIMS spectra of a surface prepared from a 6 min etch in a 100-30 sulfuric-chromic acid solution.

10	S	I, S, A	A		I, S	A

ever, it must be remembered that the concentration at the surface has to be small since it was not observed in the Auger spectra. Chromium is detected by SIMS in most of the studies but not only by ISS or AES, indicating only a small amount is present.

Table II shows that the 100-30 mixture leaves the metal surface relatively chromium rich as it is detected by all three instrumental techniques. Magnesium is detected by SIMS and AES for the 2, 4, and 6 min etch times and SIMS for the 8 and 10 min periods. The 300-40 mixture removes all of the magnesium below detectable limits in the 4 through 10 min etch periods, while chromium is detected only by SIMS in the 4-10 min period and by ISS in only the latter.

Conclusions

In any electrochemical reaction the most negative or active half-cell will be oxidized. In order to help protect the aluminum surface from corrosion, the electrochemical potential of the surface oxide layer should be as small as possible. This can be achieved by maintaining an oxide layer just thick enough to do its job, and by keeping all other metal elements and anions in the oxide layer at a minimum.

All of the solutions studied form a thin oxide layer (200-300Å) on 2024-T3 aluminum. The 300-40 mixture (solution 3), with a time in bath of 6-8 min, gives a surface with the minimum amount of detectable elements for this study. From the electrochemistry viewpoint this oxide layer should form a good surface film. In order to determine the influence of the surface on the long-term properties of an adhesive joint, the authors propose that sufficient chemical data must be obtained not only on the surface of each alloy but on different lots of the same alloy as well. Using this data base all of these surfaces must then be correlated with environmental studies.

The Electrochemical Response of Nickel Electrodes in Aqueous Sulfuric Acid Solutions

J. R. Vilche[1] and A. J. Arvía*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, Universidad Nacional de La Plata, La Plata, Argentina

Two or more current peaks are associated with the potentiodynamic anodic dissolution of nickel in aqueous sulfuric acid solutions. Different explanations have been proposed to account for the occurrence of those current peaks which are related to the $Ni = Ni^{2+} + 2e$ reaction (1-6). But most of them are not fully consistent since the potentiodynamic response of nickel electrode depends on a large number of variables which usually are not systematically changed under comparable conditions. This is immediately concluded after a critical revision of the published results.

The aim of this report is precisely to call attention to the complexity of kinetic results related to nickel corrosion and passivity in acid aqueous media and the difficulty of deriving from them prompt mechanistic interpretations which are not fully substantiated.

* Electrochemical Society Active Member.
[1] Present address: División de Investigación y Desarrollo, Fate Electrónica, San Fernando, Buenos Aires, Argentina.
Key words: nickel, corrosion, passivation.

When a polycrystalline nickel wire electrode is polarized in a 1*N* $NiSO_4$ + 0.05*N* H_2SO_4 solution at 25°C, under a triangular potential sweep, the *E*/*I* profile depends upon the anodic as well as the cathodic potential limits reached, on the potential sweep rate, and on the number of repetitive potential cycles.

A freshly electropolished nickel electrode immersed in this solution exhibits a rest potential of −0.240V (*vs.* a SCE). When the electrode is polarized at 0.5 V/min from $E_i = -0.260$V up to 0.505V (anodic scan) the E/I contour (Fig. 1) presents a well-defined anodic current peak (I) at 0.065V which corresponds to metal passivation. This is revealed by the reverse cathodic potential scan where practically no current is recorded. The following successive potential scans confirm the onset of the passive state on the electrode. The current peak associated with passivity entails an anodic charge which largely exceeds that of a monolayer and its contour is appreciably asymmetric in shape. The latter

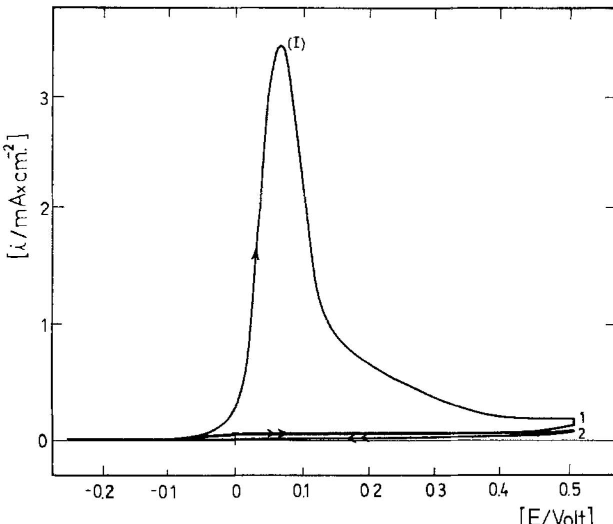

Fig. 1. *E*/I display obtained with a symmetric triangular potential sweep at 0.5 V/min in a 1*N* $NiSO_4$ + 0.05*N* H_2SO_4 solution. First scans 1 and 2 are shown. Arrows indicate the direction of the potential scan.

is due to the occurrence of at least two additional current peaks at the anodic side of current peak I. This is confirmed (Fig. 2) by carrying on the same experiment with an electrode previously potential cycled within the same potential range and left in contact with the solution until it attained the rest potential. Now the *E*/I profile shows a marked decrease in the height of current peak I and a better definition of the new current peaks located at *ca.* 0.15 and at *ca.* 0.35V, respectively.

The potentiodynamic *E*/I profile change during the initial cycles (Fig. 3) and the relative change of the *E*/I contours with the number of cycles strongly depends on the anodic potential limit reached. In the case of Fig. 3, both the height of the anodic current peak I and the amount of anodic charge involved decrease with the number of successive cycles, while the corresponding current peak potential becomes more negative.

During the cathodic scan an appreciable anodic current is also observed, which approaches a limiting value during the successive potential scans. At relatively low potential sweep rates (Fig. 4), the *E*/I characteristics recorded within a potential range which is anodic with respect to the hydrogen electrode potential exhibit during the first anodic scan the anodic current peak I together with a shoulder at *ca.* 0.1V, and the returning cathodic scan reveals another anodic current peak (II) at a potential very close to the nickel rest potential. Under these circumstances the potential

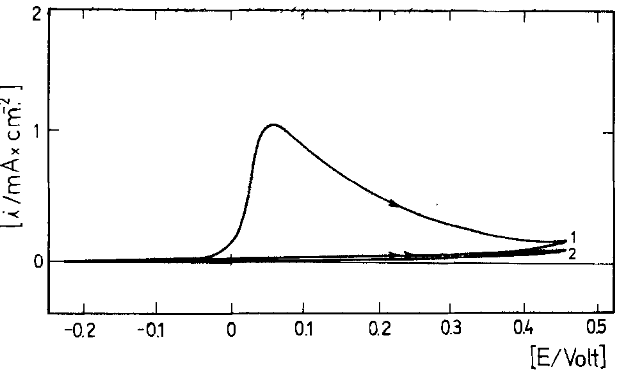

Fig. 2. *E*/I display obtained as indicated in Fig. 1, but with an electrode previously potential cycled and left in contact with the solution until attaining the rest potential.

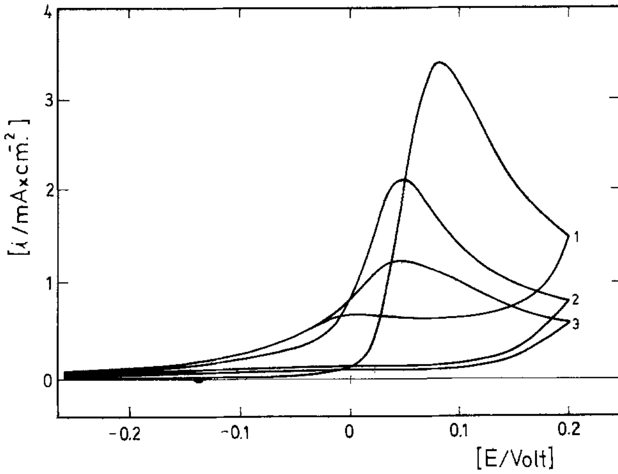

Fig. 3. *E*/I display obtained with symmetric repetitive triangular potential scans under the experimental conditions indicated in Fig. 1.

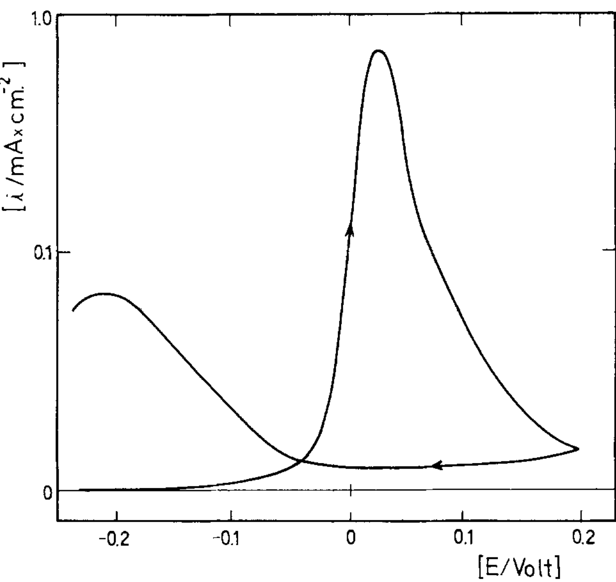

Fig. 4. *E*/I display recorded with a single symmetric triangular potential sweep at 0.05 V/min in 1*N* $NiSO_4$ + 0.05*N* H_2SO_4 solution.

of current peak I lies close to the potential attained at larger potential sweep rates after *n* cycles (Fig. 3).

A similar effect is observed (Fig. 5) when the cathodic potential limit extends towards the hydrogen evolution region. The potentiodynamic sweep starts

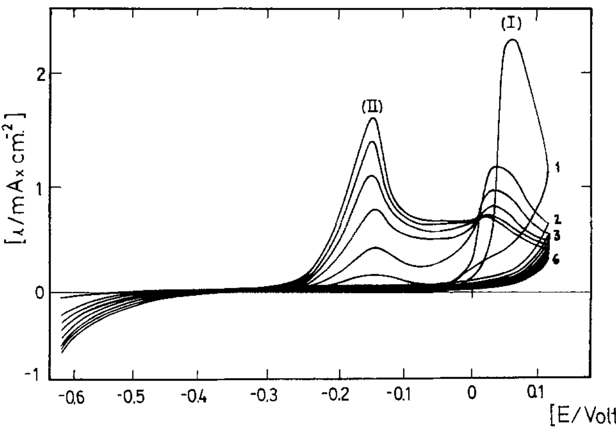

Fig. 5. Repetitive *E*/I displays at 0.5 V/min covering the hydrogen evolution region with the same electrolytic solution.

from the rest potential (−0.240V) going toward the cathodic potential region (down to −0.630V) and the following repetitive cycles run between −0.630 and 0.120V. Now, the first anodic sweep exhibits only the anodic current peak I at 0.080V, while no cathodic current is found during the returning half-cycle. The second anodic scan exhibits a well-defined anodic current peak II at −0.150V. The height of the latter increases during the successive cycles without an appreciable change of the corresponding potential.

Simultaneously, both the height and the potential of current peak I decrease. A well-defined limiting current region is also found between −0.1 and 0V, which increases during the repetitive potential cycling. The whole voltammogram attains a stable contour after a relatively large number of cycles ($n \geqq 20$).

At 0.010V, the E/I profiles exhibit a crossing point which probably corresponds to an isopotential point. Furthermore, the relative peak height distribution depends also on the potential sweep rate and the difference of the current peak potentials decreases as the potential sweep rate increases.

The multiplicity of current peaks depicted in Fig. 5 coincides with those recently reported (6) which were assigned to the effect of cathodic treatment of nickel and the bubbling rate of different gases (6).

The effect of stirring was determined with a nickel rotating disk electrode. For this purpose the electrode was first cycled until the E/I display attained a stable contour. A stable E/I profile run at 6 V/min, when the stirring rate is changed stepwise from 0 up to 2500 rpm, shows a net increase of the limiting current peak located between the anodic current and no appreciable influence of stirring on current peak I.

From this brief phenomenological description of the electrochemical behavior of nickel in sulfuric acid-containing solutions, one concludes that their potentiodynamic E/I characteristics depend both on the conditions of the potential perturbation and stirring. Their influence on the kinetic parameters of the process is probably more marked than that resulting from the crystallographic characteristics of the base metal (7).

The kinetics of nickel electrodissolution in H_2SO_4 solutions outstandingly depends on the state of the electrode surface either before or during anodic polarization, which must include the participation of the $SO_4^{=}$ anion adsorption process (8). The dependence of the kinetic characteristics of nickel in aqueous solutions on ionic composition should be correlated with the anion adsorption free energy. The latter will also explain the different behavior of nickel in electrolytes such as H_2SO_4 or HCl (9) or a mixture of both electrolytes (10).

Brief Communication

Cathodic Instability in Solid Copper Ion Battery Electrolytes: A Suggested General Mechanism

Douglas O. Raleigh*

Rockwell International, Science Center, Thousand Oaks, California 91360

There have now been reports of a number of solid room temperature copper ion conductors based on double salts of polar organic halides and CuI. Takahashi *et al.* reported copper ion conductivity in the N-alkyl (or hydro)-hexamethylenetetramine halide-copper halide system (1) and later in the N,N′-dialkyl (or dihydro)-triethylenediamine dihalide-copper halide system (2). Recently, Sammells *et al.* have reported room temperature copper ion conductivity in some nine substituted organic ammonium halide-copper halide compounds (3).

In each case, an interest in solid-state battery applicability presumably led to attempts to construct cells involving copper and a solid-state oxidant as electrodes. Indications to date, however, are that these compounds are all chemically unstable in contact with oxidant materials. Sammells and co-workers reported electrolyte deterioration in such cells for all electrolyte

Key words: solid electrolyte, copper battery, instability.

compositions, whether or not a current was drawn from the cell, for both oxide (V_2O_5, MoO_3) and organic polybromide cathode materials. No specific mechanism was offered. Takahashi and co-workers reported conductivities, but no galvanic cell results. The purpose of this communication is to suggest a general instability mechanism for a solid copper-ion conductor in contact with a solid oxidant.

Copper ion conductors are unique among solid electrolytes in that the current-carrying ion may be oxidized to a higher valence state by most common oxidants. In crystal ionic compounds, the presence of such a higher valence state in the crystal bulk should generally give rise to hole conduction, either of the hopping or valence band type, depending on whether the most energetic filled electronic states are localized or form energy bands (4). A third possibility is that the electron holes thus produced are immobilized by being in deep potential wells. This does not appear likely, however, for the copper ion conductors under consideration. Takahashi and co-workers (1, 2) found that in polarization cells of the type

$$Cu|Cu^+ \text{ conductor}|\text{graphite}$$

an observed low level electronic conductivity showed the exponential increase with voltage characteristic of hole conductivity. Thus, it appears that holes in these compounds are mobile.

The mobility of both Cu^+ ions and holes in these compositions suggests a general transport mechanism by which deterioration of electrolyte properties should occur in contact with practically any solid oxidant material. The polarization cell results of Takahashi *et al.* suggest that the electron energetics in these compounds may be represented by a straightforward energy band picture, with a bandgap $>> kT$. Figure 1(a) shows a schematic energy level diagram for a Cu^+ conductor as it is about to be brought in contact with a solid oxidant. The midbandgap position of Fermi level E_F corresponds to assuming exact cation-anion stoichiometry (effective Cu valence 1.00). A stoichiometric Cu excess would give rise to conduction electrons and a Cu deficit to valence band holes, in accordance with the usual Wagner picture (5). The Fermi level in the oxidant corresponds to the electron affinity in the equilibrium system $Ox + ne \rightleftharpoons Red$ appropriate for this oxidant. It is shown to lie deeper with respect to the vacuum level than the top of the valence band in the Cu^+ conductor, to indicate that the oxidant is more oxidizing than the Cu^+, Cu^{++} couple in the conductor.

In this picture, when electrolyte-oxidant contact is established, Cu^+ ions on the electrolyte surface should be oxidized to Cu^{++}. In addition, the greater electron affinity in the oxidant should cause an incipient influx of electrons from the electrolyte. In the absence of any mass transport, this would result in an interfacial electronic equilibrium with a local accumulation of holes in the electrolyte valence band, electrons in the oxidant phase, and an equilibrium interface potential that prevents further charge transfer. This situation, with the resultant band bending, is shown in Fig. 1(b).

In the presence of mobile Cu^+ ions, however, this situation is not time invariant. These ions should now move towards the oxidant phase under the influence of the interface potential, $V(x)$. On reaching the interface, they can be oxidized by the oxidant:

$$Ox + Cu^+ \rightarrow Cu^{++} \cdot Red$$

where $Cu^{++} \cdot Red$ is the reaction product. This motion of Cu^+ ions, however, reduces the diffuse space charge in the electrolyte, and thus draws more electrons into the oxidant phase to maintain the interfacial Fermi level equilibration. The net result should be matching countercurrent flows of valence band holes into the electrolyte and Cu^+ ions to the interface, with a small fraction of the bulk Cu^+ ions being replaced by holes in a "front" of the electrolyte that moves continually into the crystal bulk. Concurrent with this would be the buildup of a $Cu^{++} \cdot Red$ reaction layer at the interface. This is the situation shown in Fig. 1(c).

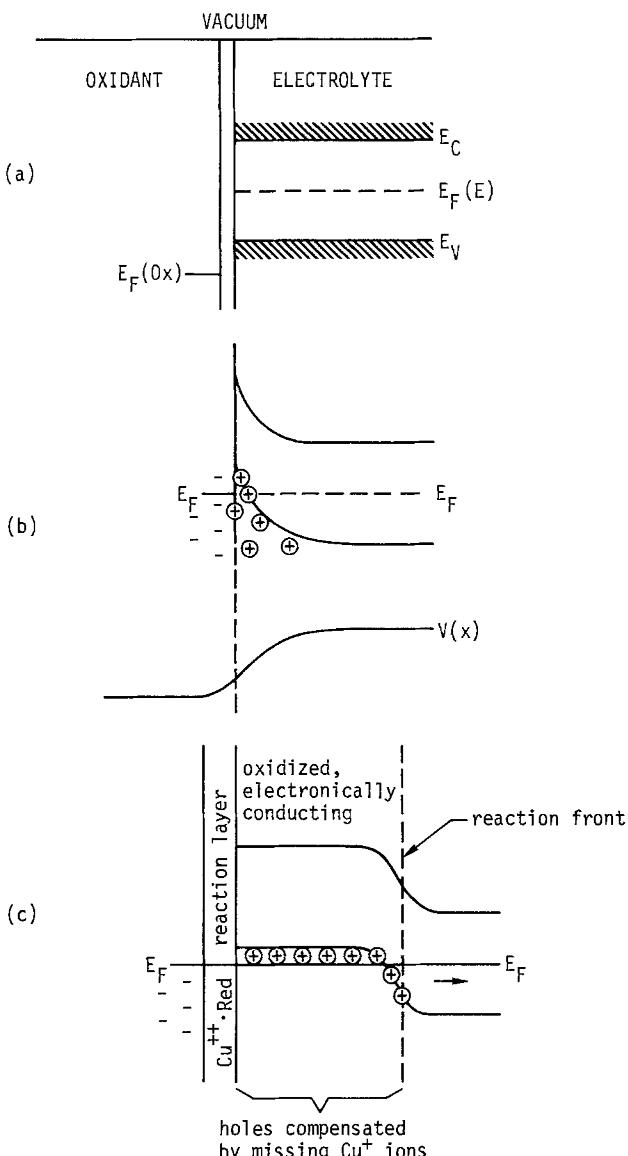

Fig. 1. Schematic of energy band structure of Cu^+ ion conductor in contact with solid oxidant: (a) prior to contact, (b) initial electronic equilibrium and interface voltage profile, (c) during subsequent bulk oxidation.

Note that this is simply the thermodynamically favored chemical oxidation of the electrolyte, which is enabled to occur in Cu^+ conductors by the existence of mobile electronic charge corresponding to the +2 valence state. In Ag^+ and alkali ion conductors, the absence of a higher cation valence state renders the electrolyte stable toward a number of oxidants.

We might ask whether electrolyte deterioration could be avoided by suitable ionic and electronic transport properties of the reaction layer or a suitable choice of the battery oxidant material. With respect to the former, low polarization in a battery requires that Cu^+ ions be mobile in this reaction layer, since this layer is the product of drawing current from a $Cu|Cu^+$ conductor|oxidant cell. The mobility of Cu^+ ions therein is the mechanism by which current could continue to be drawn. Since, in addition, the simultaneous presence of Cu^+ and Cu^{++} ions in this layer should insure significant hole conductivity, its transport properties would appear adequate to support the suggested de-

terioration mechanism. If the oxidant chosen is too weak to oxidize Cu^+, it must lie between the Cu°, Cu^+ and Cu^+, Cu^{++} couples in oxidizing strength, resulting in a maximum cell emf of only ~0.35V (6). For oxidants strong enough to be of interest in battery applications, the oxidizability of Cu^+ appears to insure a general anodic self-discharge mechanism that propagates across the electrolyte a compositional change resulting in electronic conduction.

The specific deterioration mechanism suggested is obviously the simplest of a number of possibilities. Sammells *et al.* reported that the use of oxide oxidants such as V_2O_5 and MoO_3 gave no electrolyte color change, while halide oxidants resulted in blackening as well as cell voltage loss. The blackening may reflect either a greater degree of oxidation within the original structure or actual chemical decomposition. The purpose of the present communication is not to "prove" a particular deterioration mechanism or even to prove that a copper ion electrolyte battery cannot be made. It is rather to suggest that the lack of success thus far is the result of something other than an unfortunate choice of the cathode material or an anomalous property of the particular copper electrolyte.

Manuscript submitted Dec. 29, 1975; revised manuscript received March 29, 1976.

Any discussion of this paper will appear in a Discusion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

The Active Oxidation of Si and SiC in the Viscous Gas-Flow Regime

J. W. Hinze*,[1]

Systems Research Laboratories, Incorporated, Dayton, Ohio 45440

and H. C. Graham

Air Force Materials Laboratory, Wright Patterson Air Force Base, Ohio 45433

ABSTRACT

The active oxidation of Si and SiC was investigated in the viscous gas-flow regime. Kinetics were measured as a function of temperature and oxygen partial pressure using thermogravimetric techniques. Active oxidation was initiated by exposing oxide-free samples to low oxygen partial pressures in O_2/Ar gas mixtures. Oxidation rates were found to be controlled by oxygen transport through the gaseous boundary layer. Active oxidation of Si was found to occur in two distinct stages rather than in only one as expected. Linear sample weight losses were observed during the first stage; however, in the second stage unusual and destructive behavior was observed in the form of extremely rapid sample weight gains. This phenomenon was interpreted in terms of a simultaneous SiO vaporization and SiO_2 condensation process. No such behavior was observed during SiC active oxidation.

Si-base materials such as Si_3N_4, SiC, and their composites have been proposed for a number of applications because of their exceptional high temperature properties, in particular, strength, oxidation resistance, and thermal-shock resistance. A number of investigators have studied the oxidation of these materials in environments where protective silica scales are formed on the substrate. Although the details of the oxidation mechanisms are still not well understood (1-8), the activation energies for oxidation and the extremely low oxidation rates found by various investigators are in reasonable agreement. An important limitation of Si-base materials is their tendency to form gaseous products during oxidation in reduced oxygen pressures at high temperatures. Instead of a protective SiO_2 scale being formed, the substrate surface either remains bare or, as we shall see later, nonprotective SiO_2 in the form of whiskers is grown. Under these conditions extremely rapid rates of material loss occur.

Active oxidation can be initiated at high temperatures by exposing the material to either pure oxygen at low total pressure (molecular gas-flow regime) or dilute oxygen/inert gas mixtures at or near atmospheric pressure (viscous gas-flow regime). Results from several investigations involving the active oxidation of Si and SiC in the molecular gas-flow regime have been reported (9-14), and the mechanisms of active oxidation are well understood. Solid SiO_2 was stable in the oxygen pressure and temperature environments used; however, active oxidation was initiated by decreasing the ambient oxygen pressure ($P_{O_2} = P_T$) below the equilibrium SiO pressure at the Si-SiO_2 or SiC-SiO_2 interface. Rapid attack ensued when the SiO_2 scale mechanically ruptured causing the escape of SiO(g) through pores and fissures in the scale (9, 12, 14). The steady-state rate of material loss by SiO evaporation was calculated by using the Hertz-Knudsen equation and by equating the rates of oxygen arrival and SiO removal (14) as follows

$$J_{SiO} = J_O = 2\alpha P^\circ_{O_2}/(2\pi M_{O_2} RT)^{1/2} \quad [1]$$

where J_{SiO} and J_O are, respectively, the fluxes of SiO and oxygen, $P^\circ_{O_2}$ is the ambient oxygen pressure, M_{O_2} is the molecular weight of oxygen, and α is the collision efficiency.

Unlike the molecular-flow regime, the active-oxidation mechanisms of Si and SiC in the viscous-flow regime are not well understood. Wagner (15) has offered a theory of active oxidation based on the experimental results of Kaiser and co-workers (16-17) who exposed liquid Si to an oxygen/inert-gas mixture of low P_{O_2} at high temperature. The Si getters oxygen in such a way that diffusion gradients for the oxygen and the inert gas become established. The oxygen partial pressure at the Si surface, $P^*_{O_2}$, is reduced below the stability limit for SiO_2 shown as a vertical line in Fig. 1 ($P^*_{O_2} \approx 10^{-20}$ atm at 1600°K). Because only gaseous oxides are stable below this P_{O_2}, the surface of the Si will remain free of solid oxidation products so long as $P^\circ_{O_2}$, the ambient P_{O_2}, is maintained at a sufficiently low value. Active oxidation then proceeds according to the reaction

$$Si(l) + 1/2\ O_2(g) = SiO(g) \quad [2]$$

$$P^*_{SiO} = K_2\ P^{*1/2}_{O_2} \quad [2a]$$

The steady-state rate of active oxidation is controlled solely by the rate of oxygen impingement at the Si

Key words: viscous gas flow, vaporization, mass-transfer coefficient, passive oxidation.

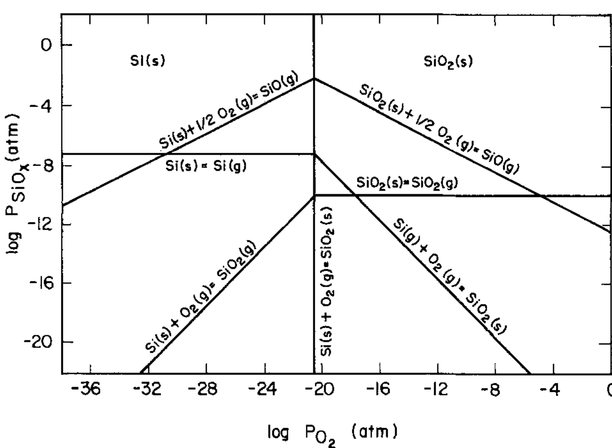

Fig. 1. Thermodynamics of the Si-O system at 1600°K using data of Zmbov et al. (21) and JANAF (23).

surface which, in the viscous-flow regime, is given by Fick's law of diffusion, whence

$$J_{SiO} = J_O = 2D_{O_2}\, P^\circ{}_{O_2}/\delta_{O_2}\, RT = 2h_{O_2}\, P^\circ{}_{O_2}/RT \quad [3]$$

where h_{O_2} is the average boundary-layer mass-transfer coefficient, $P^\circ{}_{O_2}$ is the ambient oxygen partial pressure, D_{O_2} is the oxygen/inert gas interdiffusivity, and δ_{O_2} is the effective thickness of the oxygen boundary layer. As $P^\circ{}_{O_2}$ is increased, $P^*{}_{O_2}$ increases until it reaches the critical value (vertical line in Fig. 1) corresponding to incipient SiO_2 formation. The Si surface becomes covered with a coherent, protective layer of SiO_2, and passive oxidation occurs. In Wagner's notation the ambient P_{O_2} corresponding to the transition from active-to-passive oxidation is given by

$$P^\circ{}_{O_2}(\max) = 1/2(D_{SiO}/D_{O_2})\,(\delta_{O_2}/\delta_{SiO})\, P^{eq}{}_{SiO} \quad [4]$$

where D_{SiO} and D_{O_2} are, respectively, the SiO- and O_2-inert gas interdiffusivities, δ_{SiO} is the effective thickness of the SiO-boundary layer, and $P^{eq}{}_{SiO}$ is the equilibrium SiO partial pressure calculated from the equation

$$1/2\, Si(l, s) + 1/2\, SiO_2(s) = SiO(g) \quad [5]$$

If the boundary layer is laminar, it can be shown that

$$(\delta_{SiO}/\delta_{O_2}) \approx (D_{SiO}/D_{O_2})^{1/2} \quad [6]$$

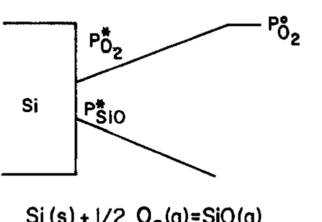
and Eq. [4] becomes

$$P^\circ{}_{O_2}(\max) = 1/2(D_{SiO}/D_{O_2})^{1/2}\, P^{eq}{}_{SiO} \quad [7]$$

The ratio D_{SiO}/D_{O_2} can be determined from well-known gas-kinetics equations. Because this ratio is virtually temperature and gas-flow velocity independent, a plot of log $P^\circ{}_{O_2}$(max) *vs.* $1/T$ is expected to give the enthalpy of formation of SiO according to Eq. [5].

While the Wagner model of active oxidation has been used to rationalize the experimental observations of Kaiser *et al.* (16-17) for the active oxidation of liquid Si, the model proposed by Turkdogan, Grieveson, and Darken (18) for the oxidation-enhanced vaporization of metals could be valid for the case of Si for certain temperatures and gas-flow characteristics. This model is compared to that proposed by Wagner in Fig. 2. In the Turkdogan *et al.* model metal atoms vaporize by desorption and diffuse through the diluent gas away from the surface. The metal vapor reacts with oxygen in the gas phase to give solid metal-oxide "fog." The metal-vaporization process is enhanced because the oxidation reaction increases the gradient for metal-atom diffusion. Turkdogan *et al.* have successfully applied this model to the oxidation-enhanced vaporization of such metals as Cr, Fe, Cu, and Co. As applied to the case of Si, the fog-formation reaction is

$$Si(g) + O_2(g) = SiO_2(s, fog) \quad [8]$$



TURKDOGAN, GRIEVESON, AND DARKEN MODEL

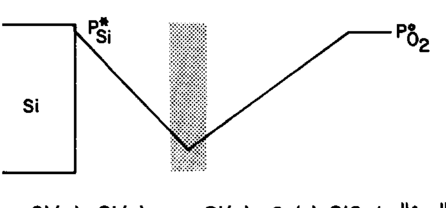


Fig. 2. Comparison between the Wagner model and the Turkdogan, Grieveson, and Darkin model applied to the active oxidation of Si.

The rate of Si removal is controlled by oxygen diffusion through the boundary layer in advance of the fog-formation front according to the equation

$$J_{Si} = J_{O_2} = h_{O_2}\, P^\circ{}_{O_2}/RT \quad [9]$$

The rate of Si consumption predicted by the Turkdogan *et al.* model (Eq. [9]) is one-half of that predicted by the Wagner model (Eq. [3]) for a given $P^\circ{}_{O_2}$ and h_{O_2}. As $P^\circ{}_{O_2}$ is increased, the fog-formation front approaches the Si surface. An abrupt transition from active-to-passive oxidation occurs when the front reaches the surface. The $P^\circ{}_{O_2}$ at the transition is given by (18)

$$P^\circ{}_{O_2}(\max) = \frac{P^*{}_{Si}}{h_{O_2}} \left(\frac{RT}{2\pi M_{Si}}\right)^{1/2} \quad [10]$$

where $P^*{}_{Si}$ is the vapor pressure of Si according to the equation

$$Si(l, s) = Si(g) \quad [11]$$

The mass-transfer coefficient for oxygen in both models is given by (18, 19)

$$h_{O_2} = 0.664\, (D_{O_2}{}^4/\nu_{O_2})^{1/6}\, (v_g/l)^{1/2}\ (\text{cm/sec}) \quad [12]$$

where D_{O_2} is as defined earlier, ν_{O_2} is the kinematic viscosity, v_g is the gas velocity in the vicinity of the sample, and l is the sample length in the direction of the gas flow. Both D_{O_2} and ν_{O_2} may be calculated from first principles (20), and vary as $T^{3/2}$. According to Eq. [12], at constant gas velocity $h_{O_2} \propto T^{3/4}$ and $\sqrt{T}/h$ in Eq. [10] is only weakly temperature dependent ($\sim T^{-1/4}$). Therefore, a plot of log $P^\circ{}_{O_2}$(max) as a function of $1/T$ is expected to give the enthalpy of vaporization or sublimation of Si according to Eq. [11]. Furthermore, because $h_{O_2} \propto v_g{}^{1/2}$, $P^\circ{}_{O_2}$(max) in Eq. [10] is expected to be strongly dependent upon gas-flow velocity in contrast to the Wagner model where no such dependence is expected.

The evidence presented by Kaiser *et al.* (16, 17), suggests that the Wagner model is valid for their experimental temperatures and gas-flow characteristics. Large concentrations of oxygen were found to be dissolved in the Si upon active oxidation; the concentration of dissolved oxygen being proportional to $P^\circ{}_{O_2}$. This could occur only if oxygen had access to the Si surface. In the Turkdogan *et al.* model the oxidant is consumed in advance of the Si surface, therefore, if this model were valid, the Si should remain free of dissolved oxygen.

For the Wagner model, a question remains concerning the stability of the liberated SiO molecule as it diffuses through the gaseous boundary layer away from the Si surface. In principle, the SiO should react with oxygen in the boundary layer to form SiO_2 when the P_{O_2} in the boundary layer reaches that value given by the vertical line shown in Fig. 1. Therefore, some of the oxygen should be consumed in advance of the Si surface in a manner similar to that proposed by Turkdogan *et al.* except that now SiO rather than Si would react with O_2 to give SiO_2 fog.

The purpose of this investigation is to determine the mechanism of Si and SiC active oxidation in the viscous-gas-flow regime (*i*) by studying the dependence of reaction rates upon time and $P°_{O_2}$, and (*ii*) by locating $P°_{O_2}(\max)$, *i.e.*, the $P°_{O_2}$ corresponding to the transition from active-to-passive oxidation, as a function of temperature. For Si a plot of log $P°_{O_2}(\max)$ as a function of $1/T$ is expected to have a slope corresponding to the enthalpy of formation of SiO [$\Delta H_f(SiO)$] according to Eq. [5] if the Wagner model applies. On the other hand, a slope corresponding to the enthalpy of vaporization or sublimation of Si [$\Delta H_{v,s}(Si)$] according to Eq. [11] is expected if the Turkdogan *et al.* model applies. Because $\Delta H_{v,s}(Si)$ is greater than $\Delta H_f(SiO)$ by ~ 27 kcal/mole (21) [$\Delta H_{v,s}(Si) \approx 110$ kcal/mole and $\Delta H_f(SiO) \approx 83$ kcal/mole] such a plot should indicate whether Si or SiO is the desorbed species at the Si surface during active oxidation.

For SiC a Turkdogan *et al.* mechanism seems unlikely in view of the very low vapor pressure of SiC (9). Therefore, active oxidation should obey a Wagner-type mechanism where both SiO and CO are desorbed at the SiC surface. A plot of $P°_{O_2}(\max)$ as a function of $1/T$ is expected to yield the thermodynamic equilibrium describing the transition from active to passive oxidation and, therefore, an indication of whether SiO or CO is the important desorbed species at the transition.

Experimental

High purity n-type Si having a resistivity of 3-8 ohm-cm was purchased from Crysteco (Wilmington, Ohio) in the form of single crystal disks having (111) faces. Polycrystalline β-SiC was provided by General Electric Company in the form of a hot-pressed billet, major impurities being B (1500 ppmw) and W (500 ppmw). Coupons ($\sim$ 1.5 $\times$ 0.6 $\times$ 0.1 cm) were cut from the larger pieces. The Si coupons were polished with 1μ diamond paste, and the SiC was ground with 220 mesh diamond abrasive. The coupons were cleaned ultrasonically in acetone and in methanol before each oxidation experiment. Undried commercial grade Ar and O_2/Ar mixtures were used.

Active oxidation kinetics were determined by monitoring sample weight changes continuously with a Cahn RH electrobalance having a sensitivity of $\pm$ 2 μg. Details of the furnace-balance system were given previously (22). The temperature of the furnace was controlled to within $\pm$ 0.5°C. Sample temperature was measured with a Pt 6 Rh-Pt 30 Rh thermocouple located within $\sim$ 1 cm of the sample. The specimen was situated in the center of a $\sim$4 cm long hot zone within the reaction tube. The lateral temperature gradient in the hot zone was no greater than 2°C. Experiments were initiated by lowering the Si or SiC coupon into Ar ($P_{O_2} \approx 10^{-8}$ atm) at the desired temperature. In early experiments an H_2 pretreatment was used to remove any oxide film initially present on the surface; however, this treatment was found to be unnecessary. An O_2/Ar gas mixture of low P_{O_2} was introduced into the reaction tube (inside diameter = 3.81 cm) to begin active oxidation. The $P°_{O_2}$ was varied by combining two different O_2/Ar mixtures with calibrated flow meters. To avoid cooling of the sample by the flowing gas, very low flow rates [$\sim$ 85 cm^3/min (STP)] were used. In all cases the total system pressure was maintained at 150 Torr. Because the room temperature flow rates were constant, linear gas-flow velocities in the sample region were linearly dependent upon the sample temperature.

Results

Si active oxidation.—The active oxidation of Si was investigated in the temperature range 1400°-1650°K. Results for a typical experiment are shown in Fig. 3 where sample weight change is plotted as a function of time. In this experiment $P°_{O_2}$ was increased in small increments, from 5.4 $\times$ 10^{-5} to 9.2 $\times$ 10^{-3} atm. Although the curve in Fig. 3 appears to be smooth, oxidation kinetics at each $P°_{O_2}$ were linear except in the transition regions. The most striking feature of this plot is the appearance of two distinct regions of active oxidation instead of the one expected on the basis of the Wagner (15) and the Turkdogan *et al.* (18) models. In the first region (stage I), the Si surface was found to be completely free of oxidation products. However, when the ambient P_{O_2} was increased to a critical value [$P°_{O_2}(\max)_I$], instead of passive oxidation occurring a transition from stage I to the second stage of active oxidation (stage II) occurred. In this stage active oxidation was characterized by extremely rapid, linear sample weight gains. When the ambient P_{O_2} was increased, stage II active oxidation continued until a second critical $P°_{O_2}$ [$P°_{O_2}(\max)_{II}$] was reached. At this point passive oxidation was initiated, resulting in low reaction rates (indicated by the horizontal line in the figure) governed by diffusion through a protective SiO_2 layer.

Figure 4 reveals the morphology of the oxide scale which formed in the Si specimen oxidized at 1500°K in the stage II active oxidation regime. The unusual whiskerlike oxide structure suggests that a vaporization-condensation process occurred. The whiskers were identified as SiO_2 by the energy shift of the Si peak upon microprobe analysis. X-ray analysis indicated that the SiO_2 was amorphous. Figure 5 illustrates the temperature dependence of the scale morphologies. Figure 5a is an SEM micrograph of the fractured cross section, whereas Fig. 5(b-d) are SEM micrographs of the sample surface. At the lowest temperature, Fig. 5(a), the scales consisted of extremely fine whiskers; at the highest temperature, Fig. 5(b-d), a thick spongy SiO_2 layer was formed (A) in addition to the whiskerlike structure (B). In the stage II oxidation mode, neither type of oxide structure was protective; *i.e.*, the oxygen had direct access to a significant area of the Si surface.

In order to determine whether the transition from stage I to stage II active oxidation is reversible, a Si coupon was oxidized in the stage II mode after which $P°_{O_2}$ was decreased. The chronology of this experiment is shown in Fig. 6 where a distinct hysteresis effect is

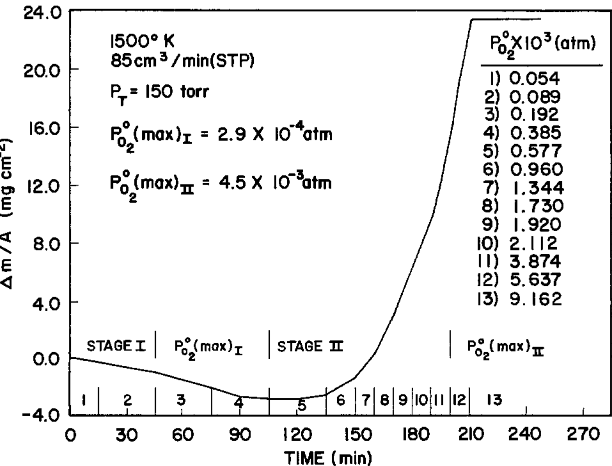

Fig. 3. Chronology of Si active oxidation at 1500°K. Vertical lines at figure base indicate an increase in P_{O_2}.

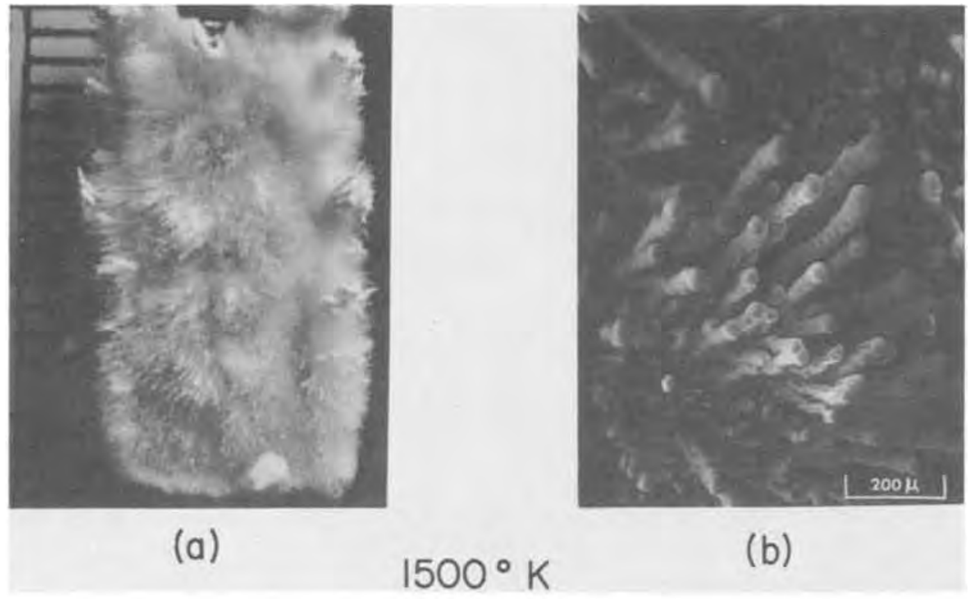

Fig. 4. Macrophotograph (a) and SEM micrograph (b) of a Si specimen oxidized at 1500°K in the stage II active oxidation regime.

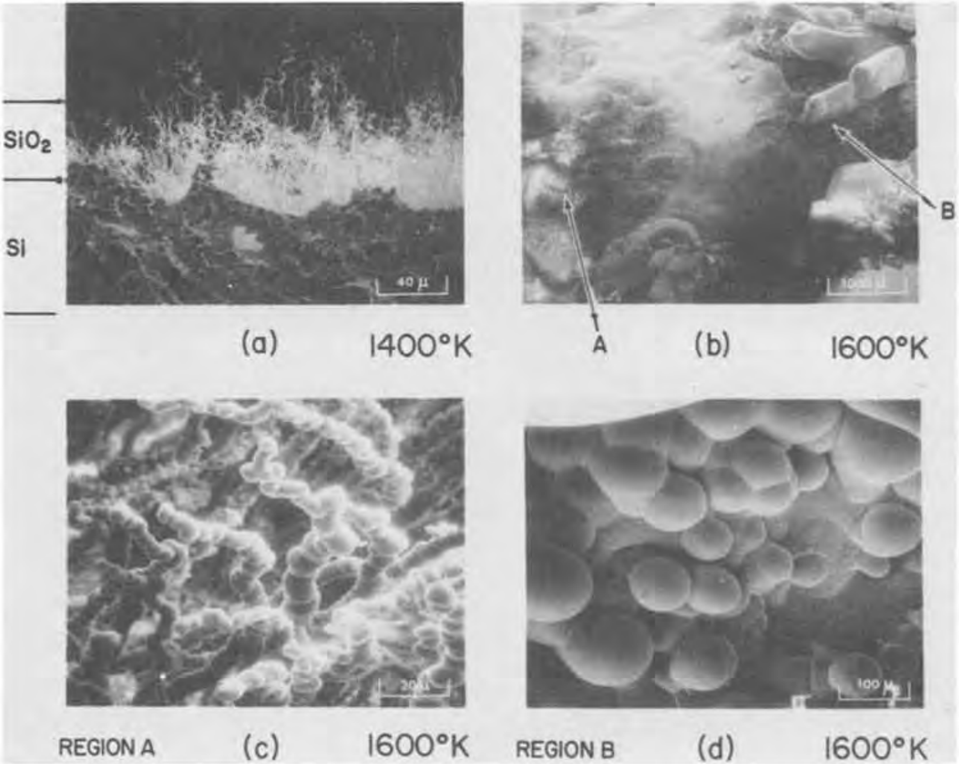

Fig. 5. SEM micrograph showing temperature dependence of the oxide morphologies for Si oxidized in the stage II regime: (a) cross section, 1400°K; (b)-(d) surface, 1600°K.

exhibited; stage II active oxidation, once established, continues even when $P°_{O_2}$ is lowered into the range where stage I active oxidation had occurred previously [see, for example, $P°_{O_2}$ steps 2-4 (15-120 min) and $P°_{O_2}$ steps 4-2 (240-280 min)]. Because Si is removed (as SiO) during stage I oxidation, and O_2 is gained (as SiO_2) during stage II oxidation, for a given $P°_{O_2}$

$$k_a(\text{stage I}) = -(M_{Si}/M_{O_2})\, k_a(\text{stage II}) \quad (\text{mg-cm}^{-2}\text{-min}^{-1}) \qquad [13]$$

where k_a is the linear rate constant for active oxidation.

Figure 7 is a plot of the absolute magnitude of the rate constants $|k_a|$ obtained from the slopes of the curves shown in Fig. 3 and 6 as a function of $P°_{O_2}$. The vertical line on the graph denotes the transition $P°_{O_2}$ from stage I to stage II active oxidation [$P°_{O_2}(\text{max})_I$]. The linearity of the data indicates that the reaction is controlled by oxygen diffusion through the gaseous boundary layer in both regimes. Since no discontinuity in the curve is exhibited at $P°_{O_2}(\text{max})_I$,

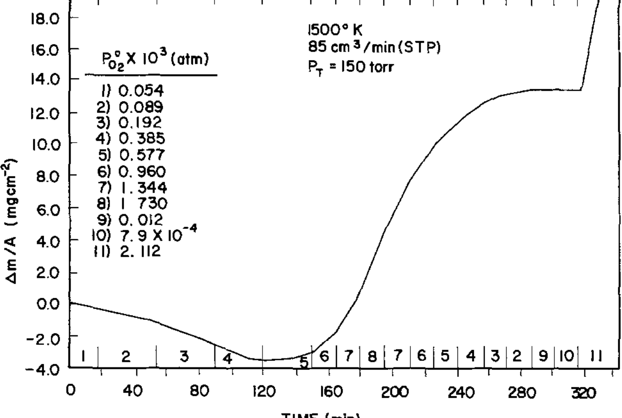

Fig. 6. Chronology of Si active oxidation at 1500°K showing irreversibility of the stage I to stage II transition.

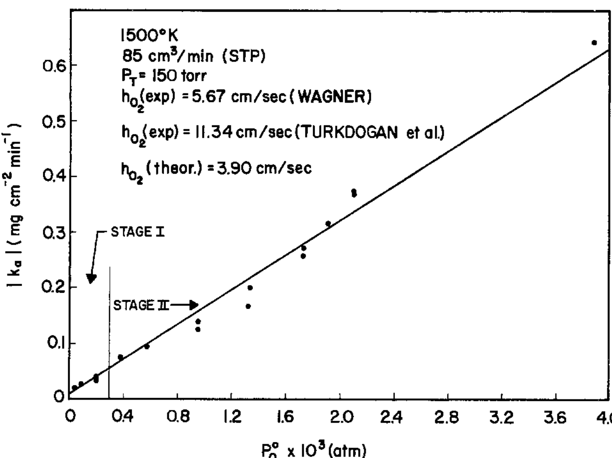

Fig. 7. Oxygen partial pressure dependence of the rate constant for Si active oxidation at 1500°K.

h_{O_2} is independent of the active oxidation mode. The slope of the curve is related to the boundary layer mass-transfer coefficient, h_{O_2}, by the equation

$$d|k_a|/dP°_{O_2} = nh_{O_2}/RT \quad [14]$$

where $n = 1$ or 2, depending upon which model [*i.e.*, the Turkdogan *et al.* (18) model ($n = 1$) or the Wagner (15) model ($n = 2$)] applies. The h_{O_2} calculated on the basis of the Turkdogan *et al.* model is a factor of three larger than the theoretical value calculated from Eq. [12], whereas h_{O_2} calculated on the basis of the Wagner model is less than a factor of two larger. Because of the low gas-flow rates used, the boundary layer thickness is greater than the radius of the furnace tube ($\sim$ 2 cm); therefore, slight deviations from the theoretical h_{O_2} were anticipated.

It is important to note that the curves which appear in Fig. 7 and later in Fig. 11 are linear, even in the low P_{O_2} regions. This implies that concentrations of impurities such as H_2O in the gas phase do not influence the oxidation kinetics. If the reactions had been impurity sensitive, the plots of $|k_a|$ as function of P_{O_2} would have exhibited upward curvature at low P_{O_2} until a lower limiting value of $|k_a|$ corresponding to P_{H_2O} in the gas was reached. No such curvature or limiting value of $|k_a|$ was seen.

Data of the type shown in Fig. 3 and 7 were obtained at six temperatures in the range 1400°-1650°K. Active oxidation was found to occur in two stages at each temperature. One experiment was conducted on polycrystalline Si; the behavior was identical to that of the single crystal material. The experimental $P°_{O_2}(\max)_I$ and $P°_{O_2}(\max)_{II}$ values are plotted in Fig. 8 and compared with predictions based on the Wagner and Turkdogan *et al.* models. Because these models predict only a single stage of active oxidation, only one $P°_{O_2}(\max)$ value was calculated. The predictions were made by inserting the recent thermodynamic data of Zmbov *et al.* (21) for P^*_{Si} and P^{eq}_{SiO} together with the calculated diffusivity ratio $D_{SiO}/D_{O_2} \approx 0.8$ into Eq. [7] and [10]. Values for $P°_{O_2}(\max)_I$ are in fair agreement with predictions from Wagner's theory for the transition from active to passive oxidation. A relatively large uncertainty in the value of $P°_{O_2}(\max)_I$ exists because the transition takes place gradually over several increments in $P°_{O_2}$, whereas a rapid transition from stage II to passive oxidation occurs. The activation energy for $P°_{O_2}(\max)_{II}$ is $\sim$ 83 kcal/mole which agrees with the 83 kcal/mole obtained by Zmbov *et al.* for the enthalpy of the reaction

$$1/2\,Si(l, s) + 1/2\,SiO_2(s) = SiO(g) \quad [5]$$

indicating that SiO(g) is the important desorbed species at the transition. The $P°_{O_2}(\max)$ predicted by the Turkdogan *et al.* model falls below the experimental

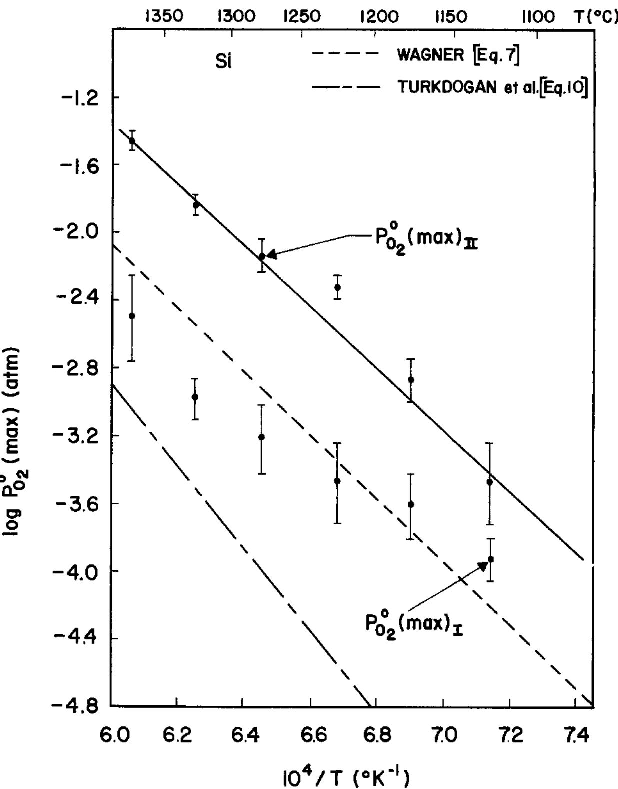

Fig. 8. Temperature dependence of $P°_{O_2}(\max)_I$ and $P°_{O_2}(\max)_{II}$ for Si active oxidation in the viscous gas-flow regime compared with predictions based on the Wagner model (15) and the Turkdogan *et al.* model (18).

data for $P°_{O_2}(\max)_I$ and has a much larger activation energy, suggesting that Si desorption from the surface during active oxidation is unimportant.

Mechanism of Si active oxidation.—The above results indicate that neither the Wagner model nor the Turkdogan *et al.* model completely describes the mechanism of Si active oxidation. Although the Wagner model correctly identifies the nature of the gaseous species as SiO at the Si surface, the existence of the stage II active oxidation mode was not suggested. The Wagner model predicts that once $P°_{O_2}(\max)_I$ is exceeded, the inward flux of oxygen (as O_2) at the Si surface will exceed the outward flux of oxygen [as SiO(g)] and that $SiO_2(s)$ will form and grow laterally on the surface. The first part of this prediction was found to be correct; however, lateral growth was not exhibited. Instead SiO_2 whiskers grew perpendicular to the Si surface, and only after a second critical $P°_{O_2}$ was exceeded did the SiO_2 grow laterally to form a protective layer.

In order to determine the conditions under which the stage II mode of active oxidation can become stable, consider the schematic representation of attack shown in Fig. 9. When $P°_{O_2} < P°_{O_2}(\max)_I$ [Fig. 9(a)], stage I active oxidation occurs and the Si surface remains bare in agreement with the Wagner model. The δ_{SiO} and δ_{O_2} are nearly equal because the ratio D_{SiO}/D_{O_2} in Eq. [6] ≈ 0.8. As $P°_{O_2}$ is increased, P^*_{SiO} increases according to the reaction

$$Si(s) + 1/2\,O_2(g) = SiO(g) \quad [15]$$

with

$$P^*_{SiO} \propto P^{*,1/2}_{O_2} \quad [16]$$

When $P°_{O_2}$ is increased to $P°_{O_2}(\max)_I$, P^*_{SiO} reaches the equilibrium value P^{eq}_{SiO} given by Eq. [5] and incipient SiO_2 formation takes place. Initially the SiO_2 forms as tiny islands [see Fig. 9(b)], with most of the surface remaining bare. From thermodynamic considerations, the tendency for SiO_2 and SiO formation is equal; SiO removal from the surface will continue as

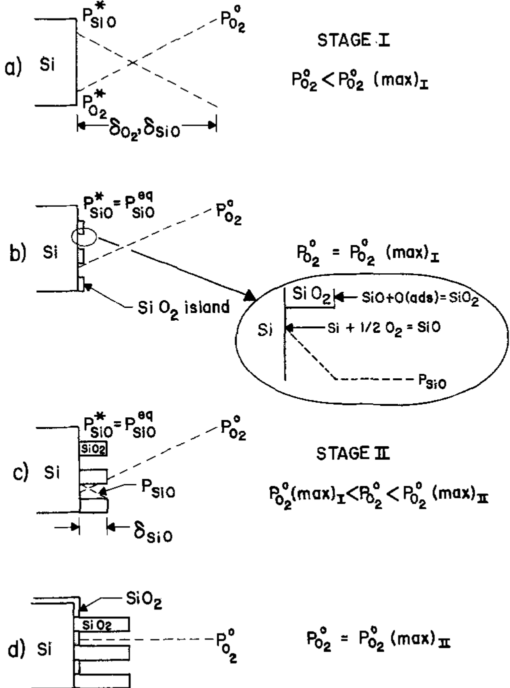

Fig. 9. Schematic representation of the mechanism of active oxidation of Si in the viscous gas-flow regime.

SiO_2 attempts to grow lateral to the surface. The SiO molecules will be exposed to as ever-increasing P_{O_2} as they diffuse away from the surface. Therefore, these molecules have a tendency to oxidize forming SiO_2 according to the reaction

$$2SiO(g) + O_2(g) = 2SiO_2(s) \quad [17]$$

This homogeneous reaction is relatively unfavorable because it requires a trimolecular collision of two SiO molecules and one O_2 molecule in the gas phase. However, the SiO_2 islands can serve as nucleation sites for heterogeneous reaction. Since the tip of the island is at a higher P_{O_2} than the edges, the availability of oxygen is greatest there. If oxygen is adsorbed at the tip, the islands will grow perpendicular to the Si surface to form the observed SiO_2 whiskers according to the heterogeneous reaction

$$SiO(g) + O(ads) = SiO_2(s) \quad [18]$$

According to the Wagner model when $P°_{O_2}$ exceeds $P°_{O_2}(max)_I$, the inward flux of oxygen will be greater than the outward flux of SiO and the surface becomes covered with a protective layer of SiO_2. In the present investigation, no such layer was observed, instead active oxidation was found to continue independent of time with rates being linearly dependent upon $P°_{O_2}$. The rates agreed well with those predicted from gas kinetic equations implying that oxygen transport through the boundary layer is rate controlling and that oxygen has direct access to the Si surface. In order for this to occur, either P^*_{SiO} must increase or δ_{SiO} must decrease in order to increase the removal rate of SiO given by the equation

$$J_{SiO} = D_{SiO}\, P^*_{SiO}/\delta_{SiO}\, RT \quad [19]$$

Once SiO_2 is formed at the surface, P^*_{SiO} is fixed at its equilibrium value P^{eq}_{SiO} given by Eq. [5]. Therefore, δ_{SiO} must decrease in order that J_{SiO} be maintained at a level which is sufficiently high to accommodate the inward flux of oxygen. Figure 9(c) shows the manner in which heterogeneous reaction at the tip of the whiskers reduces δ_{SiO}. This mechanism bears some resemblance to the Turkdogan *et al.* model in that some oxygen is consumed in advance of the Si surface, thereby increasing the diffusion gradient for the adsorbed species. However, in this case the reaction occurs at the tip of the SiO_2 whiskers and enables their growth. By decreasing δ_{O_2}, J_{SiO} becomes increased according to Eq. [19]. This allows active oxidation to continue until $P°_{O_2}$ reaches $P°_{O_2}(max)$ according to Eq. [4], where $P°_{O_2}(max)$ is the experimentally observed $P°_{O_2}(max)_{II}$. When $P°_{O_2} = P°_{O_2}(max)_{II}$, SiO cannot be removed at a sufficiently rapid rate and the Si surface becomes covered with a coherent, protective layer of SiO_2 [Fig. 9(d)].

SiC active oxidation.—The active oxidation of SiC was investigated to determine whether a stage II mode would be characteristic of other Si-base materials. Results of a typical experiment are shown in Fig. 10. Unlike the behavior of Si, no stage II active oxidation was observed for SiC. Instead, rates of weight loss increased with incremental increases in $P°_{O_2}$ until $P°_{O_2}(max)$ was reached after which extremely low rates of oxidation were observed, indicative of diffusion control through a protective SiO_2 layer. Subsequent increases in $P°_{O_2}$ did not cause the onset of stage II active oxidation. Lower ambient oxygen partial pressures or higher temperatures were required to establish the active oxidation process for SiC. Weight losses were linear with time, in agreement with stage I Si active oxidation.

The rate of active oxidation, $|k_a|$, is plotted linearly against $P°_{O_2}$ in Fig. 11, indicating that the reaction for SiC is also controlled by oxygen diffusion through the boundary layer. As with Si active oxidation, boundary layer mass-transfer coefficients, h_{O_2} (assum-

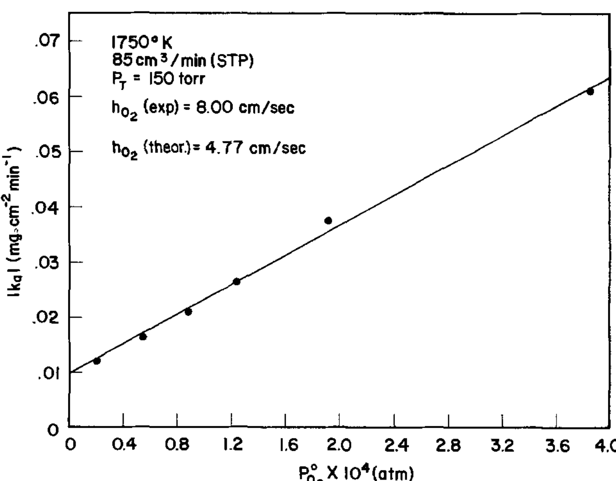

Fig. 11. Oxygen partial pressure dependence of the rate constant for SiC active oxidation at 1750°K.

ing SiO and CO to be the desorbed species), are ~ 1.5 times larger than the theoretical values calculated from Eq. [12].

Mechanism of SiC active oxidation.—The active oxidation process in SiC is believed to occur according to the reaction

$$SiC + O_2 = SiO + CO \quad [20]$$

where CO rather than CO_2 is desorbed at the SiC surface because of the low P_{O_2} which is established there. The rate of oxygen impingement at the SiC surface controls the reaction, the rate being given by the equation

$$J_{O_2} = D_{O_2}\, P^\circ{}_{O_2}/\delta_{O_2}\, RT \quad [21]$$

If it is assumed that the reaction proceeds stoichiometrically, then

$$J_{SiO} = J_{CO} = J_{O_2} \quad [22]$$

where J_{SiO} is given by Eq. [19] and J_{CO} is given by

$$J_{CO} = D_{CO}\, P^*{}_{CO}/\delta_{CO}\, RT \quad [23]$$

The thermodynamics describing the conditions for the transition from active to passive behavior are not so straightforward as those for Si oxidation where Eq. [5] is the only pertinent relation to be considered. A number of equilibria must be considered in the case of SiC, the most likely being

$$SiC(s) + 2SiO_2(s) = 3SiO(g) + CO(g) \quad [24]$$

$$SiC(s) + SiO_2(s) = 2SiO(g) + C(s) \quad [25]$$

$$2SiC(s) + SiO_2(s) = 3Si(l, s) + 2CO(g) \quad [26]$$

Combining Eq. [21], [22], and [23]

$$P^\circ{}_{O_2} = (D_{CO}/D_{O_2})\,(\delta_{O_2}/\delta_{CO})\,P^*{}_{CO} \quad [27]$$

and combining Eq. [21], [22], and [19]

$$P^\circ{}_{O_2} = (D_{SiO}/D_{O_2})\,(\delta_{O_2}/\delta_{SiO})\,P^*{}_{SiO} \quad [28]$$

If it is assumed that

$$(\delta_{CO}/\delta_{O_2}) = (D_{CO}/D_{O_2})^{1/2} \quad [29]$$

and

$$(\delta_{SiO}/\delta_{O_2}) = (D_{SiO}/D_{O_2})^{1/2} \quad [6]$$

Then Eq. [27] and [28] become

$$P^\circ{}_{O_2} = (D_{CO}/D_{O_2})^{1/2}\,P^*{}_{CO} \quad [27a]$$

and

$$P^\circ{}_{O_2} = (D_{SiO}/D_{O_2})^{1/2}\,P^*{}_{SiO} \quad [28a]$$

Depending on the thermodynamics of the transition, $P^\circ{}_{O_2}(max)$ will be given either by

$$P^\circ{}_{O_2}(max) = (D_{CO}/D_{O_2})^{1/2}\,P^{eq}{}_{CO} \quad [30]$$

or

$$P^\circ{}_{O_2}(max) = (D_{SiO}/D_{O_2})^{1/2}\,P^{eq}{}_{SiO} \quad [31]$$

where $P^{eq}{}_{CO}$ and $P^{eq}{}_{SiO}$ can be calculated from Eq. [24-26].

In Fig. 12 the experimental $P^\circ{}_{O_2}(max)$ values are compared with predictions based on Eq. [30] and [31], assuming that $D_{SiO}/D_{O_2} = 0.8$ and $D_{CO}/D_{O_2} = 1.02$ (20). Although only fair agreement was found, Eq. [26] and [30] best describe the transition behavior. This implies that CO rather than SiO is the important gaseous species in determining $P^\circ{}_{O_2}(max)$. The thermodynamics of the transition are in agreement with those found by Gulbransen and Jansson (9) for SiC under molecular gas-flow conditions. These results allow the following physical interpretation of the active oxidation of SiC to be made: When $P^\circ{}_{O_2} < P^\circ{}_{O_2}(max)$, the rates of both CO and SiO removal from the SiC surface are sufficiently large to accommodate the inward flux of oxygen, as evidenced by the linear P_{O_2} dependence of the reaction rate. However, when $P^\circ{}_{O_2} = P^\circ{}_{O_2}(max)$, CO (rather than SiO) cannot be removed at a sufficiently rapid rate and passive oxidation occurs. Unlike the case for Si where δ_{SiO} was reduced via a heterogeneous reaction [Fig. 9(c)] causing the onset of stage II active oxidation, the P_{CO} gradient adjacent to the surface cannot be increased by reducing δ_{CO}. Therefore, stage II active oxidation in SiC is impossible.

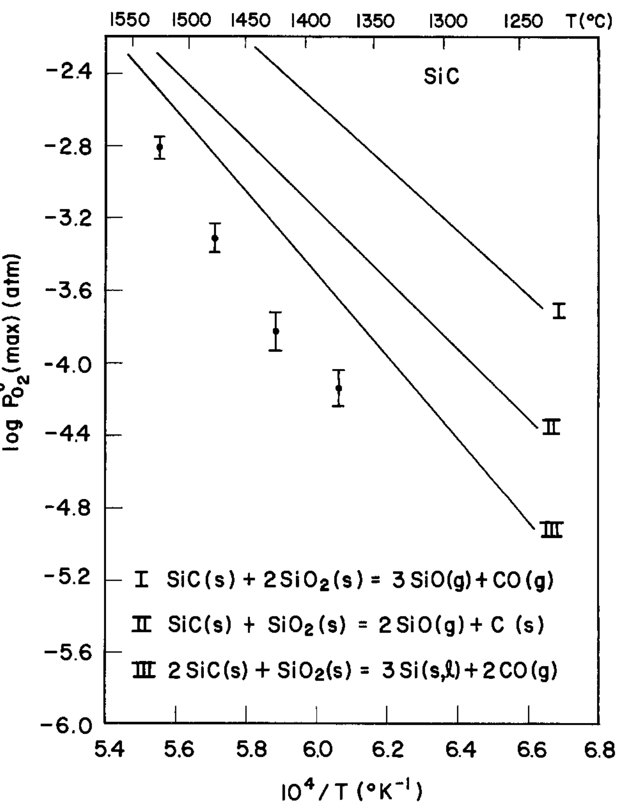

Fig. 12. Temperature dependence of $P^\circ{}_{O_2}$ (max) for SiC active oxidation in the viscous gas-flow regime.

The Criterion for Stability of a Planar Alloy-Oxide Interface upon Oxidation of Binary Alloys

D. P. Whittle,[1] D. J. Young,[*,2] and W. W. Smeltzer[*]

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada, L8S 4M1

ABSTRACT

Linear perturbation theory is used to analyze the stability of a moving planar alloy-oxide interface when oxidation of a binary solid solution alloy leads to growth of a superficial metal conducting oxide scale. The transport equations for metal and oxygen in the alloy and oxide phases are analyzed under limiting approximations consistent with ternary diffusion theory. If oxygen diffusion in the alloy occurs predominantly down its own gradient the stability criterion for a planar interface is

$$\frac{N_A^{I*}D_{OO}^{I} + 2(N_A^{Io} - N_A^{I*})\sqrt{D_{AA}^{I}D_{OO}^{I}}}{N_A^{I*}D_{AA}^{I} + N_A^{II*}D_A^{II*}V^{I}/V^{II}} > 1$$

This criterion becomes in the case of oxygen diffusion in the alloy occurring predominantly from its interaction with the metal gradient

$$\frac{N_A^{I*}V^{II}D_{AA}^{I}}{N_A^{II*}V^{I}D_A^{II*}}\left\{1 - N_A^{I*}\epsilon_O^{A}\frac{D_{OO}^{I}}{D_{AA}^{I}}\right\} > 1$$

In these expressions, D, N, and V represent self-diffusion coefficients, mole fractions, and molar volumes of the alloy and oxide phases denoted by superscript I and II, respectively. Asterisks on these parameters refer to values at a planar alloy-oxide interface. A and O refer to the selectively oxidized metal component and oxygen. N_A^{Io} is the initial concentration of A, and ϵ_O^A is the Wagner interaction coefficient between oxygen and A in the alloy.

The diffusion controlled oxidation of a binary alloy to form a superficial single-phase scale is characterized by the development of a planar or nonplanar interface between alloy and oxide. Wagner (1) has developed an equation defining a limiting criterion for planar interface stability under the assumptions that the solubilities of oxygen in the alloy and of the more noble alloy component in the oxide are negligible. More recently, Coates and Kirkaldy (2) have analyzed the conditions for the stability of planar phase interfaces in isothermal ternary systems making no assumptions about phase constitution with the alloy-oxide interface as a special case. The purpose of this paper is to examine the effects of removing the two solubility restraints introduced by Wagner on the criterion for planar interface stability. Although it is necessary to consider two limiting approximations of the ternary diffusion equations in order to obtain tractable mathematical solutions, we demonstrate that oxygen dissolution into the alloy with or without diffusional interactions leads to a less restrictive criterion for planar interface stability.

Planar Interface Stability Criterion

The ternary diffusion model employed in this analysis is shown schematically in Fig. 1. We consider the diffusional controlled growth by metal transport of the oxide $(AB)_rO$, in which r represents the atoms of metal per atom of oxygen, on alloy A-B with concurrent oxy-

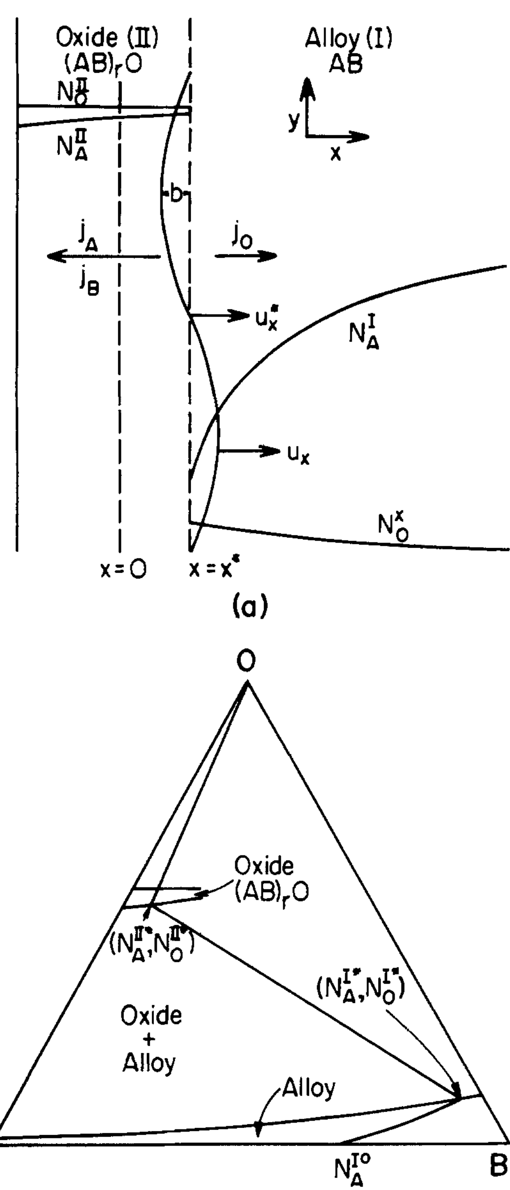

Fig. 1. The oxide scale-alloy model with symbols corresponding to those in text: (a) Cross-section of $(AB)_rO$ scale and AB alloy showing planar interface at $x = x^*$ moving at velocity $u_x{}^*$, sinusoidal interface $x = x^* + b\sin(w\,y)$ moving at velocity u_x, and the gradients of metal A and oxygen O in the alloy (I) and oxide (II). (b) The diffusion path for metal and oxygen, $N_A{}^{I0}$ — $(N_A{}^{I*}, N_O{}^{I*})$ — $(N_A{}^{II*}, N_O{}^{II*})$ — O, superimposed on the ternary A-B-O isotherm in the case of a planar oxide scale-alloy interface. The interfacial compositions of A in the alloy and B in the oxide are assumed to be very dilute.

gen diffusion into the alloy. Metal A which is preferentially oxidized and oxygen are chosen as the independent diffusing components. The composition path corresponding to the diffusion profiles is also shown superimposed on the ternary A-B-O isotherm in Fig. 1 to emphasize that we consider the case corresponding to small solubilities of metal B in the oxide and oxygen in the alloy. These latter restrictions are required in order to obtain a tractable mathematical analysis.

The instantaneous velocity of a planar alloy-oxide interface, $u_x{}^*$, is related to the mass boundary condition for either A or oxygen

$$u_x{}^*\left[\frac{N_i{}^{II*}}{V^{II}} - \frac{N_i{}^{I*}}{V^{I}}\right] = j_i{}^{II(x)*} - j_i{}^{I(x)*} \quad [1]$$

where j is a component flux, N represents a mole fraction, and V^I, V^{II} are the molar volumes of alloy(I) and oxide(II). To investigate the stability of this planar interface, we follow Wagner (1) in impressing a sinusoidal perturbation of infinitesimal amplitude b on the metal surface such that the locus of the interface is given by

$$x = x^* + b\sin(w\,y) \quad [2]$$

where $w = 2\pi/\lambda$ and λ is the wavelength satisfying $b << \lambda << x^*$. The instantaneous velocity of the perturbed interface, u_x, is described by an equation identical to [1] although the fluxes and concentrations now depend on y, the position along the interface. These quantities will be denoted by the absence of asterisks. One can conclude upon examining Fig. 1 that the perturbation decays if at points where the local oxide thickness exceeds the average value the local velocity of the interface is smaller than the average value, and if at points where the local oxide thickness is less than the average value the local velocity exceeds the average value. Thus the planar interface stability criterion is

$$(u_x - u_x{}^*)/\sin(w\,y) < 0 \quad [3]$$

In order to define this criterion as a function of diffusivities and concentrations, we must seek solutions for the diffusion equations coupled to the alloy and oxide phases and solve for the interfacial fluxes, compositions, and material balances.

Diffusion Equations

Diffusion in the alloy.—In the region $x > x^* + b\sin(w\,y)$, the diffusion equations for metal and oxygen can be written

$$j_A{}^{I(x)} = -\frac{D_{AA}{}^I}{V^I}\frac{\partial N_A{}^I}{\partial x} - \frac{D_{AO}{}^I}{V^I}\frac{\partial N_O{}^I}{\partial x} \quad [4a]$$

$$j_O{}^{I(x)} = -\frac{D_{OA}{}^I}{V^I}\frac{\partial N_A{}^I}{\partial x} - \frac{D_{OO}{}^I}{V^I}\frac{\partial N_O{}^I}{\partial x} \quad [4b]$$

Analogous equations hold for the y direction. These equations, with [4a] and [4b] and the continuity condition

$$\frac{\partial N_A{}^I}{\partial t} = \frac{\partial j_A{}^{I(x)}}{\partial x} + \frac{\partial j_A{}^{I(y)}}{\partial y} \quad [5a]$$

$$\frac{\partial N_O{}^I}{\partial t} = \frac{\partial j_O{}^{I(x)}}{\partial x} + \frac{\partial j_O{}^{I(y)}}{\partial y} \quad [5b]$$

may in principle be solved to yield $N_O{}^I$, $N_A{}^I$ as spatial functions. In view of the nontrivial nature of the problem, limiting approximations are sought. We use those introduced by Wagner (1) who has demonstrated that the steady-state approximation $\partial N_A{}^I/\partial t \simeq \partial N_O{}^I/\partial t \simeq 0$ can be used when $b << 2\pi/w << x^*$. Solutions of the coupled equations in [5] even with the above approximations still remain complex, particularly when $D_{AO}{}^I$ and $D_{OA}{}^I$ have to be treated as functions of composition.

We first consider the limiting case where $D_{AA}{}^I$ and $D_{OO}{}^I$ are approximately concentration independent and the cross diffusional effects are negligible. Under these assumptions, the solution of Eq. [4] and [5] are

$$N_A{}^I = N_A{}^{I*} + G_A{}^I\{(x - x^*) + \beta_A{}^I b\sin(w\,y)\exp - w(x - x^*)\} \quad [6a]$$

$$N_O{}^I = N_O{}^{I*} + G_O{}^I\{(x - x^*) + \beta_O{}^I b\sin(w\,y)\exp - w(x - x^*)\} \quad [6b]$$

where $G_A{}^I$ and $G_O{}^I$ are the gradients of A and oxygen at the planar interface, $\beta_A{}^I$ and $\beta_O{}^I$ are constants to be evaluated later. The exponentials in [6] may be approximated to unity at the perturbed interface $x = x^* + b\sin(w\,y)$ since b is small. Consequently, [6] leads to

$$N_A{}^{I,i} = N_A{}^{I*} + G_A{}^I b\sin(w\,y)\{1 + \beta_A{}^I\} \quad [7a]$$

$$N_O^{I,i} = N_O^{I*} + G_O^I\, b \sin(w\, y)\{1 + \beta_O^I\} \quad [7b]$$

A second limiting case occurs when cross diffusional effects prevail. Oxygen diffusion in alloys is commonly interstitial with $D_{OO}^I >> D_{AA}^I$ implying that $|\partial N_O^I/\partial x| << \partial N_A^I/\partial x$. If this solid solution is sufficiently dilute in A and oxygen, the diffusional cross term is (3)

$$D_{OA}^I = D_{OO}^I \epsilon_O^A N_O^I \quad [8]$$

where $\epsilon_O^A = (\partial \ln \gamma_O/\partial N_A)_{N_B \to 1}$ is the Wagner interaction coefficient (4). Thus [4a] and [4b] approximate to

$$j_A^{I(x)} = \frac{-D_{AA}}{V^I}\frac{\partial N_A^I}{\partial x} \quad [9a]$$

$$j_O^{I(x)} = \frac{-D_{OA}^I}{V^I}\frac{\partial N_A^I}{\partial x} \quad [9b]$$

whence

$$j_O^{I(x)} = \left(\frac{D_{OO}^I \epsilon_O^A N_O^I}{D_{AA}^I}\right) j_A^{I(x)} \quad [10]$$

The solution of [9a] is given by [7a] which together with [10] yields an evaluation of the oxygen flux.

Diffusion in the oxide.—A small degree of nonstoichiometry in the ternary metal conducting oxide phase $(AB)_rO$ is assumed such that the mole fractions of the components approximate to

$$N_A^{II} + N_B^{II} + N_O^{II} \simeq 1 \quad [11]$$

Following Wagner (5) and Coates and Dalvi (6), the flux equations for the oxide constituents relative to the x-coordinate in Fig. 1 may be written as

$$j_i^{II(x)} = -D_i^{II}\frac{N_i^{II}}{V^{II}}\frac{\partial \ln a_i}{\partial x} + u_x\frac{N_i^{II}}{V^{II}} \quad [12a]$$

$$j_O^{II(x)} = u_x\frac{N_O^{II}}{V^{II}} \quad [12b]$$

where i refers to metal A or B. From the Gibbs-Duhem equation, assuming ideal or Henrian behavior

$$d \ln a_i^{II} = d \ln N_i^{II} - d \ln a_O^{II} \quad [13]$$

Substitution of [13] in [12a] yields

$$j_i^{II(x)} = \frac{-D_i^{II}}{V^{II}}\left\{\frac{\partial N_i^{II}}{\partial x} - N_i^{II}\frac{\partial \ln a_O^{II}}{\partial x}\right\} + u_x\frac{N_i^{II}}{V^{II}} \quad [14]$$

An approximation must be sought to [14] since an analytical solution for N_i^{II} and a_O^{II} is not available. Frequently D_A^{II} and D_B^{II} in a ternary p-type oxide are of the same order of magnitude and near the interface (7)

$$\frac{\partial N_A^{II}}{\partial x} \simeq \frac{\partial N_B^{II}}{\partial x} \simeq 0 \quad [15]$$

whence [14] becomes

$$j_i^{II} = \frac{D_i^{II}}{V^{II}} N_i^{II,i}\frac{\partial \ln a_O^{II}}{\partial x} + u_x\frac{N_i^{II,i}}{V^{II}} \quad [16]$$

where $N_i^{II,i}$ is the mole fraction of A or B in the oxide at the alloy/scale interface. In order to use Eq. [16], one requires the functional relationship between D_i^{II} and a_O^{II}. An analytical form which has found application to the rock-salt structured (AB)O p-type oxides is (8)

$$D_i^{II} = D_i^{II(o)} \gamma^{(N_A^{II}-1)} (a_O^{II})^n \quad [17]$$

where $D_i^{II(o)}$ is the metal self-diffusion coefficient in pure AO or BO and γ is the ratio of the mole fraction of vacant cation sites in pure AO to that in pure BO. Equation [16] becomes upon substitution of [17]

$$j_A^{II(x)} = \frac{D_A^{II(o)}}{V^{II}} \gamma^{(N_A^{II,i}-1)} \frac{N_A^{II,i}}{n}\frac{\partial (a_O^{II})^n}{\partial x} + u_x\frac{N_A^{II,i}}{V^{II}} \quad [18]$$

An expression similar to [18] is found for the flux of A in the y-direction. Assuming that the oxide has a constant molar volume and that it deforms plastically, the velocity of the alloy-oxide interface is divergence free

$$\frac{\partial u_x}{\partial x} + \frac{\partial u_y}{\partial y} = 0 \quad [19]$$

Solution of [19] for $x < x^* + b \sin(w\, y)$ recalling that $\partial N_A^{II}/\partial t = 0$ is similar to the equivalent equations for the alloy and gives

$$(a_O^{II})^n = (a_O^{II*})^n + G_O^{II}\{(x - x^*) - \beta_O^{II}\, b \exp w(x - x^*) \sin(w\, y)\} \quad [20]$$

where G_O^{II} is the gradient $\partial(a_O^{II})^n/\partial x$ at the mean or planar interface and β_O^{II} is a constant to be evaluated. Knowing $a_O = F(x, y)$ the flux j_A^{II} can be computed from [18].

Boundary Conditions

Interfacial compositions.—Neglecting any capillarity effects, application of the Gibbs-Duhem equation to the local equilibrium concentrations in the alloy and oxide phases at their common interface gives

$$(N_A^{II} - N_A^I)(d \ln a_A - d \ln a_B) + (N_O^{II} - N_O^I)(d \ln a_O - d \ln a_B) = 0 \quad [21]$$

Since the oxygen solubility and the residual interfacial concentration of the element A in the alloy are very small, they are regarded as being sufficiently dilute to meet Henrian solution behavior. Accordingly

$$d \ln a_A = \frac{dN_A^I}{N_A^I}; \quad d \ln a_O = \frac{dN_O^I}{N_O^I};$$

$$d \ln a_B = -\, dN_A^I - dN_O^I \quad [22]$$

Substitution of [22] into [21] followed by integration yields

$$N_A^{II} \ln N_A^I + N_O^{II} \ln N_O^I = \text{constant} \quad [23]$$

where N_O^I, $N_A^I << 1$ is assumed throughout the calculation. Letting the standard states of the solute components be defined at infinite dilution and the oxide be considered as near stoichiometric, N_A^{II}, $N_O^{II} \simeq 1$, [23] yields

$$N_A^I N_O^I = a_A^I a_O^I = K \quad [24]$$

where K is an equilibrium constant.

a_O^{II} is evaluated from Eq. [20] by setting $x = x^* + b \sin(w\, y)$ and approximately the exponential to unity

$$(a_O^{II,i})^n = (a_O^{II*})^n + b\, G_O^{II}\,(1 - \beta_O^{II})\sin(w\, y) \quad [25]$$

Since only small deviations from a planar interface are considered, $a_O^{II,i} \simeq a_O^{II*}$ and $bG_O^{II}(1 - \beta_O^{II}) \sin(w\, y) << 1$. Equations [25] is expanded as a binomial series and truncated after two terms to yield

$$a_O^{II,i} = a_O^{II*}\left\{1 + \frac{bG_O^{II}}{n(a_O^{II*})^n}(1 - \beta_O^{II})\sin(w\, y)\right\} \quad [26]$$

Fluxes at the interface.—The flux of A in the oxide is found by substituting the derivative of [20] into [18] and approximating the exponential to obtain

$$j_A^{II,i} = \frac{D_A^{II(o)}}{V^{II}} \gamma^{(N_A^{II,i}-1)} \frac{N_A^{II,i}}{n} G_O^{II}\{1 - w\, b\, \beta_O^{II} \sin(w\, y)\} + u_x\frac{N_A^{II}}{V^{II}} \quad [27]$$

The oxygen flux is given simply by Eq. [12b] for the recession rate of the alloy.

On the alloy side of the interface, the distribution of A and its interfacial value, $N_A^{I,i}$, are given by Eq. [6a] and [7a], respectively. Differentiation of [6a] and substitution for $\partial N_A^I/\partial x$ in [9a] yields after approximating the exponential

$$j_A^{I,i} = \frac{-D_{AA}^I}{V^I} G_A^I (1 - w\, b\, \beta_A^I \sin(w\, y)) \quad [28]$$

The interfacial oxygen concentration, $N_O^{I,i}$, is found from Eq. [24]. The two previously given limiting cases are employed to describe the oxygen flux. In the situation where oxygen diffusion is controlled solely by the oxygen gradient, the oxygen profile is described by Eq. [6b], the interfacial concentration by [7b] and the oxygen flux by

$$j_O^{I,i} = \frac{-D_{OO}^I}{V^I}\frac{\partial N_O^I}{\partial x} = \frac{-D_{OO}^I G_O^I}{V^I}(1 - w\, b\, \beta_O^I \sin(w\, y)) \quad [29]$$

For the case of dominant diffusional interaction on oxygen transport, the oxygen flux at the interface is evaluated from Eq. [10] and [28]

$$j_O^{I,i} = \frac{-D_{OO}^I}{V^I}\epsilon_O^A N_O^{I,i} G_A^I (1 - w\, b\, \beta_A^I \sin(w\, y)) \quad [30]$$

Interfacial material balance.—This mass balance for element A is found from [1], [27], and [28]

$$u_x\left\{\frac{N_A^{II,i}}{V^{II}} - \frac{N_A^{I,i}}{V^I}\right\} = \frac{D_A^{II(o)}}{V^{II}}\gamma^{(N_A^{II,i}-1)}\frac{N_A^{II,i}}{n}G_O^{II}\{1 - w\, b\, \beta_O^{II}\sin(w\, y)\} + u_x\frac{N_A^{II}}{V^{II}} + \frac{D_{AA}}{V^I}G_A^I\,(1 - w\, b\, \beta_A^I \sin(w\, y)) \quad [31]$$

Also, the interface velocity can be found from [1] by considering the oxygen flux in the oxide and alloy. In the first limiting case where diffusional interaction in the alloy was neglected, substitution of [12b] and [29] into [1] gives

$$u_x\left[\frac{N_O^{II,i}}{V^{II}} - \frac{N_O^{I,i}}{V^I}\right] = u_x\frac{N_O^{II,i}}{V^{II}} + \frac{D_{OO}^I}{V^I}G_O^I(1 - w\, b\, \beta_O^I \sin(w\, y)) \quad [32]$$

or

$$u_x = \frac{-D_{OO}^I G_O^I}{N_O^{I,i}}(1 - w\, b\, \beta_O^I \sin(w\, y)) \quad [33]$$

Substitution of [33] into [31] using [7a] and [7b] to evaluate $N_A^{I,i}$ and $N_O^{I,i}$, respectively, gives

$$\{N_A^{I*} + G_A^I(1 + \beta_A^I)b \sin(w\, y)\}\left\{\frac{D_{OO}^I G_O^I}{V^I}(1 - w\, b\, \beta_O^I \sin(w\, y))\right\} = \{N_O^{I*} + G_O^I(1 + \beta_O^I)b\sin(w\, y)\}\left\{\frac{D_A^{II(o)}}{V^{II}}\gamma^{(N_A^{II,i}-1)}\frac{N_A^{II,i}}{n}G_O^{II}(1 - w\, b\, \beta_O^{II}\sin(w\, y)) + \frac{D_A^I}{V^I}G_A^I(1 - w\, b\, \beta_A^I \sin(w y))\right\} \quad [34]$$

Equating coefficients, neglecting terms in b^2 and those not involving w since as indicated earlier $w >> 1$ leads to

$$\frac{N_A^{I*}D_{OO}^I G_O^I}{V^I} = \frac{N_O^{I*}D_A^{II(o)}\gamma^{(N_A^{II,i}-1)}N_A^{II,i}G_O^{II}}{nV^{II}} + \frac{N_O^{I*}D_{AA}^I G_A^I}{V^I} \quad [35]$$

and

$$\frac{N_A^{I*}D_{OO}^I G_O^I \beta_O^I}{V^I} = \frac{N_O^{I*}D_A^{II(o)}\gamma^{(N_A^{II,i}-1)}N_A^{II,i}G_O^{II}\beta_O^{II}}{nV^{II}} + \frac{N_O^{I*}D_{AA}^I G_A^I \beta_A^I}{V^I} \quad [36]$$

Equation [7] giving the concentration of element A and oxygen at the perturbed interface when substituted into expression [24] for the local equilibrium values yields upon noting that $N_A^{I*}N_O^{I*} = K$

$$\frac{1 + \beta_A^I}{1 + \beta_O^I} = -\frac{N_A^{I*}}{N_O^{I*}}\frac{G_O^I}{G_A^I} \quad [37]$$

when terms involving b^2 are ignored. From the equilibrium statement, $N_O^{I,i} \sim a_O^{I,i} = a_O^{II,i}$, and upon equating [7b] and [26] we obtain

$$\frac{1 + \beta_O^I}{1 - \beta_O^{II}} = \frac{G_O^{II}}{G_O^I}\frac{N_O^{I*}}{n(a_O^{II*})^n} \quad [38]$$

Using Eq. [17] to define D_A^{II*} and combining [37], [38] with [35], [36] yields

$$\beta_O^I = \frac{N_A^{I*}D_{OO}^I - N_A^{I*}D_{AA}^I - 2N_O^{I*}D_{AA}^I G_A^I/G_O^I - N_A^{II,i}D_A^{II*}V^I/V^{II}}{N_A^{I*}D_{OO}^I + N_A^{I*}D_{AA}^I + N_A^{II,i}D_A^{II*}V^I/V^{II}} \quad [39]$$

We now consider the second limiting case where diffusional interaction of oxygen with the metal gradient is dominant, $D_{OA}\, \partial N_A/\partial x >> D_{OO}\, |\partial N_O/\partial x|$. Substitution of [12b] and [30] into [1] gives

$$u_x\left[\frac{N_O^{II,i}}{V^{II}} - \frac{N_O^{I,i}}{V^I}\right] = u_x\frac{N_O^{II,i}}{V^{II}} + \frac{D_{OO}^I}{V^I}\epsilon_O^A N_O^{I,i} G_A^I\,(1 - w\, b\, \beta_A^I \sin(w\, y)) \quad [40]$$

Dividing [31] by [40] and substituting [7a] for $N_A^{I,i}$ yields upon rearrangement

$$\{N_A^{I*} + G_A^I b \sin(w\, y)\,(1 + \beta_A^I) - D_A^I/D_O^I\epsilon_O^A\}\left\{\frac{D_{OO}^I}{V^I}\epsilon_O^A G_A^I\,(1 - w\, b\, \beta_A^I \sin(w\, y))\right\} = \frac{D_A^{II(o)}}{V^{II}}\gamma^{(N_A^{II,i}-1)}\frac{N_A^{II,i}}{n}G_O^{II}(1 - w\, b\, \beta_O^{II}\sin(w\, y)) \quad [41]$$

For Eq. [41] to be satisfied, the coefficients of $\sin w\, y$ must be equal as must the constants. If terms involving b^2 are ignored

$$\left\{N_A^{I*} - \frac{D_{AA}^I}{D_{OO}^I\epsilon_O^A}\right\}\frac{D_{OO}^I}{V^I}\epsilon_O^A G_A^I = \frac{D_A^{II(o)}}{V^{II}}\gamma^{(N_A^{II,i}-1)}\frac{N_A^{II,i}}{n}G_O^{II} \quad [42]$$

$$- \left\{ N_A^{I*} - \frac{D_{AA}}{D_{OO}^I \epsilon_O^A} \right\} \frac{D_{OO}^I}{V^I} \epsilon_O^A G_A^I w \beta_A^I + \frac{D_{OO}^I}{V^I} \epsilon_O^A G_A^I G_A^I (1 + \beta_A^I) = \frac{-D_A^{II(o)}}{V^{II}} \gamma^{(N_A^{II,i}-1)} \frac{N_A^{II,i}}{n} G_O^{II} \beta_O^{II} w \quad [43]$$

Recalling that $w >> 1$, the second term on the LHS of [43] is neglected. The comparison of [42] and [43] gives the result

$$\beta_A^I = \beta_O^{II} \quad [44]$$

Substitution of [7a] into the equilibrium statement [24] yields

$$N_O^{I,i} = \frac{K}{N_A^{I*} + G_A^I b \sin(w y)(1 + \beta_A^I)} \quad [45]$$

Since $N_O^{I,i} \simeq a_O^I = a_O^{II}$, substitution of [26] into [45] gives

$$a_O^{II*} \left\{ 1 + \frac{b G_O^{II}}{n (a_O^{II*})^n} (1 - \beta_O^{II}) \sin(w y) \right\} = \frac{K}{N_A^{I*} \left\{ 1 + \frac{G_A^I b}{N_A^{I*}} (1 + \beta_A^I) \sin(w y) \right\}} \quad [46]$$

Since $G_A^I b (1 + \beta_A^I) \sin(w y) / N_A^{I*} << 1$ by definition, the RHS of [46] may be approximated by a truncated binomial expansion and

$$a_O^{II*} \left\{ 1 + \frac{b G_O^{II}}{n (a_O^{II*})^n} (1 - \beta_O^{II}) \sin(w y) \right\} = \frac{K}{N_A^{I*}} \left\{ 1 - \frac{b G_A^I}{N_A^{I*}} (1 + \beta_A^I) \sin(w y) \right\} \quad [47]$$

Since $K/N_A^{I*} = N_O^{I*} = a_O^{I*} = a_O^{II*}$, [47] yields

$$\frac{1 + \beta_A^I}{1 - \beta_O^{II}} = \frac{-G_O^{II} N_A^{I*}}{n G_A^I (a_O^{II*})^n} \quad [48]$$

Substitution of [44] into [48] gives

$$\beta_A^I = - \left\{ 1 + \frac{G_O^{II} N_A^{I*}}{n G_A^I (a_O^{II*})^n} \right\} \Bigg/ \left\{ 1 - \frac{G_O^{II} N_A^{I*}}{n G_A^I (a_O^{II*})^n} \right\} \quad [49]$$

Equations for Planar Interface Stability

We are now in position to consider the stability criterion for a planar interface under the two limiting cases where oxygen migration in the alloy is controlled by: (*i*) oxygen diffusion down its own gradient and (*ii*) oxygen diffusion by its interaction with the metal gradient. The interface stability criterion is given by Eq. [3] using Eq. [1] to define the interface velocity.

Stability criterion: oxygen diffusion down its own gradient.—We have shown that

$$u_x = - \frac{D_{OO}^I G_O^I}{N_O^{I,i}} (1 - w\, b\, \beta_O^I \sin(w y)) \quad [33]$$

Substituting from Eq. [7b] for $N_O^{I,i}$, approximating the denominator by the first two terms of a series expansion and neglecting second order terms in b gives

$$u_x = - \frac{D_{OO}^I G_O^I}{N_O^{I*}} \left[1 - \left\{ w \beta_O^I - \frac{G_O^I}{N_O^{I*}} (1 + \beta_O^I) \right\} b \sin(w y) \right] \quad [50a]$$

Clearly at a planar interface $b \sin(w y) = 0$ this result becomes

$$u_x^* = - D_{OO}^I G_O^I / N_O^{I*} \quad [50b]$$

and thus

$$u_x - u_x^* = - u_x^* w\, b\, \beta_O^I \sin(w y) \quad [51]$$

Thus, the criterion for stability is found from [3] to be

$$\beta_O^I > 0 \quad [52]$$

Therefore, using the expression β_O^I from [39] and equating $N_A^{II,i} \simeq N_A^{II*}$, the stability criterion is

$$N_A^{I*} D_{OO}^I - N_A^{I*} D_{AA} - 2 N_O^{I*} D_{AA}^I G_A^I / G_O^I - N_A^{II,i} D_A^{II*} V^I / V^{II} > 0 \quad [53]$$

Approximating

$$G_A^I \simeq (N_A^{Io} - N_A^{I*}) / \sqrt{D_{AA}^I} \quad [54]$$

$$G_O^I \simeq - N_O^{I*} / \sqrt{D_{OO}^I}$$

where N_A^{Io} is the bulk alloy atom fraction of A, we obtain from [53]

$$\frac{N_A^{I*} D_{OO}^I + 2 (N_A^{Io} - N_A^{I*}) \sqrt{D_{AA}^I D_{OO}^I}}{N_A^{I*} D_{AA}^I + N_A^{II*} D_A^{II*} V^I / V^{II}} > 1 \text{ (stable)} \quad [55]$$

Stability criterion: oxygen diffusion on metal gradient.—Equation [40] upon rearrangement gives the interfacial velocity

$$u_x = - D_{OO}^I \epsilon_O^A G_A^I (1 - w\, b\, \beta_A^I \sin(w y)) \quad [56]$$

and for the planar interface

$$u_x^* = - D_{OO}^I \epsilon_O^A G_A^I \quad [57]$$

Thus

$$u_x - u_x^* = - u_x^* w\, b\, \beta_A^I \sin(w y) \quad [58]$$

and the stability criterion is found from [3] to be

$$\beta_A^I > 0 \quad [59]$$

where β_A^I is defined by [49]. Evaluating G_{OO}^{II}/G_A^I from [42] and using [17] to define $D_A^{II} = D_A^{II*}$ at an oxygen activity a_O^*, Eq. [49] becomes

$$\beta_A^I = \frac{q - 1}{q + 1} \quad [60]$$

where

$$q = \frac{N_A^{I*} V^{II} D_{AA}^I}{N_A^{II*} V^I D_A^{II*}} \left\{ 1 - N_A^{I*} \epsilon_O^A \frac{D_{OO}^I}{D_{AA}^I} \right\} > 1 \text{ (stable)} \quad [61]$$

This criterion can be seen to result by comparing [59] and [60] to [61] knowing that the interaction coefficient ϵ_O^A must be of negative magnitude for oxygen diffusion into the alloy on the gradient of element A.

Discussion

The criterion for the stability of the planar alloy-oxide interface is given by Eq. [55] or [61] when oxygen diffusion into the alloy is taken into account according to ternary diffusion theory. These equations can be compared to the expression developed for the pseudobinary limit—no oxygen solution in the alloy and an oxide consisting entirely of the selectively oxidized metallic component. We then consider the validity of the limiting equations used in the present analysis to describe the oxygen flux in the alloy. Finally, some remarks are directed to the applicability of the stability criterion to the oxidation properties of transition metal alloys.

The expression derived by Wagner (1) under the pseudobinary limit using the present nomenclature reads

$$\frac{N_A^{I*} D_A^I V^{II}}{(1 - N_A^{I*}) D_A^{II} V^I} > 1 \text{ (stable)} \quad [62]$$

It is clear, however, that [62] represents an extreme case: a planar interface is not stable if $N_A^{I*} \rightarrow 0$. In this case, Eq. [55], describing oxygen diffusion down its own gradient leads to

$$\frac{2N_A^{Io}\sqrt{D_A^I D_{OO}^I} V^{II}}{N_A^{II*} D_A^{II} V^I} > 1 \text{ (stable)} \qquad [63]$$

For $D_A^I/D_A^{II} << 1$, $N_A^{I*} \rightarrow 0$. However, in [63] the relevant ratio of diffusion coefficients is $\sqrt{D_A^I D_{OO}^I}/D_A^{II}$ which is not necessarily less than unity because $D_{OO}^I >> D_{AA}^I$. Hence the diffusion of oxygen into the alloy reduces the stability criterion. A similar effect is apparent when oxygen diffuses via interaction with the metal gradient as seen in Eq. [61] since $\epsilon_O^A << 0$ is often found (Table I). Under this restriction, Eq. [61] can lead to

$$-\frac{(N_A^{I*})^2 V^{II} \epsilon_O^A D_{OO}^I}{N_A^{II*} V^I D_A^{II*}} > 1 \text{ (stable)} \qquad [64]$$

which is a less stringent criterion insofar as $D_{OO}^I >> D_A^{II}$. It is also interesting to note that [61] under the pseudobinary approximation of no oxygen diffusion into the alloy, $\epsilon_O^A = 0$, becomes

$$\frac{N_A^{I*} D_{AA}^I V^{II}}{N_A^{II*} D_A^{II*} V^I} > 1 \text{ (stable)} \qquad [65]$$

in close similarity to the Wagner expression. The mole fraction N_A^{II*} rather than $1 - N_A^{I*}$ has arisen due to the present analysis incorporating ternary properties of the oxide phase.

The validity of the limiting approximations for oxygen flux in the alloy is now examined. For ideal or Henrian solution of oxygen in the alloy, $\epsilon_O^A = 0$ and oxygen diffusion is to be regarded as occurring solely on its own gradient (Eq. [4]). In the case of more complicated oxygen solution behavior in the alloy, the limiting ratio of the oxygen flux for diffusion on its gradient (Eq. [4] and [54]) to that for diffusion dependent upon oxygen interaction with the metal gradient (Eq. [10] and [54]) is

$$\frac{j_O \text{ (oxygen gradient)}}{j_O \text{ (metal gradient)}} = -\frac{D_{OO}^I N_O^{I*}/\sqrt{D_{OO}^I}}{D_{OO}^I \epsilon_O^A N_O^{I*}(N_A^{Io} - N_A^{I*})/\sqrt{D_{AA}^I}} = -\frac{1}{\epsilon_O^A \Delta N_A^I}\sqrt{\frac{D_{AA}^I}{D_{OO}^I}} \qquad [66]$$

Although it was necessary to assume in our analysis that the alloy was a relatively dilute solution of oxygen and the second metallic component, the paramount importance of oxygen diffusion by interaction with the metal gradient in transition metal alloys resulting from selective oxidation of a metal component can be qualitatively assessed. At 1000°C, the diffusivities of oxygen and metal in the fcc transition metals are of the order 10^{-7} and 10^{-12} cm²/sec, respectively. Thus the ratio in [66] becomes $-3 \times 10^{-2}/\epsilon_O^A$ for an alloy depletion of A of 0.1 atom fraction at the interface. Hence for $\epsilon_O^A = -1$, a very small interaction coefficient, the oxygen flux results predominately from the presence of the metal gradient. Interaction coefficients for oxygen with alloying elements which are selectively oxidized from transition metal alloys are in the range -5 to -50 and as high as $\sim -10^3$ (Table I). It is thus seen that the oxygen flux being considered in the criterion for planar interface stability can readily arise from either the oxygen or metal gradients dependent upon the thermodynamic properties of the alloy solid solution.

These qualitative remarks aptly demonstrate that an oxygen flux relaxes the interface stability criterion based simply on the pseudobinary model of metal diffusion in the oxide and alloy phases. This magnitude of the oxygen flux is dependent upon the thermodynamic properties of the alloy, a large interaction of oxygen with the metallic element which is selectively oxidized greatly increasing the magnitude of oxygen diffusion. Unfortunately, we cannot give a more quantitative analysis directed to specific cases since oxygen interaction parameters are known only for molten alloys and mainly at the very high temperatures in the range of 1600°C for molten steel. Extrapolation of the known values demonstrate that they increase with decreasing temperature (9). Accordingly one expects that oxygen diffusion, which leads to a less stringent condition for interface stability in comparison to the pseudobinary model, occurs predominantly by interaction with the transient metal gradient set up in the alloy during the very early intervals of oxidation (Eq. [61]).

Equations [55] and [61] must be regarded as necessary but not a sufficient condition for describing the stability of a planar alloy-oxide interface. When $D_A^{II} \simeq D_B^{II} \leqq D_{AA}^I$, these equations describe planar stability when a compact scale grows under the influence of chemical diffusion insofar as structural imperfections such as line defects do not influence the nucleation of oxide and the subsequent atomistics of diffusion. However, an essentially planar interface can occur even when $D_A^{II} \simeq D_B^{II} >> D_{AA}^I$ under two commonly observed situations. In the first case, the solubility of B in $(AB)_rO$ can be of sufficient magnitude to invalidate an approximation of this analysis, $N_B^{II} << N_A^{II}$, which will cause only a very small gradient of A in the alloy beneath the scale. In this situation a model for growth of a ternary oxide scale with a planar interface at the A-B alloy surface is applicable (5). In the second case, the inward flux of oxygen described by [55] and [61] may lead to internal oxidation and subsequent relaxation of gradients which is not taken into account in the present model. Thus oxide precipitation internally would give only a small transient period for interface instability which would be of little ultimate dimensional consequence.

These above considerations can be exemplified by referring to the oxidation properties of binary alloys composed of metals in the first transition series ranging from chromium to nickel. The stabilities of the isotypic oxides decrease from chromium to nickel: a metal on the left (A) tends to be selectively oxidized from an alloy matrix of the metal to the right (B). On the binary alloys where a rhombohedral oxide $(AB)_2O_3$ is formed, e.g., Cr_2O_3 on Fe-Cr and Co-Cr alloys, $D_{Cr}^{II} < D_{CrCr}^I$ and a stable interface results. Likewise a planar interface is found upon formation of spinel oxide scales $(AB)_3O_4$ as a consequence of two properties: first, $D_A^{II} \simeq D_B^{II} \simeq D_{AA}^I$ and, second, these oxides exhibit a relatively large solubility of B which minimizes metal gradients in the alloy ($N_A^{I*} >> 0$). Conversely, several of the rock-salt structured divalent MO oxides show large metal diffusivi-

Table I. Values of the Wagner first-order oxygen interaction coefficient with several alloying elements, $\epsilon_O^A = \left(\frac{\partial \ln \gamma_O}{\partial N_A}\right)_{N_B \rightarrow 1}$, in molten dilute iron and copper alloys at 1600°C (9, 10).

Base alloy	Element	ϵ_O^A	Base alloy	Element	ϵ_O^A
Iron	Al	-3.3×10^3	Copper	Co	-1.3×10^1
Iron	La	-4.2×10^3	Copper	Fe	-4.4×10^1
Iron	Cr	-3.4×10^1	Copper	Ni	-5.2
Iron	Ni	-1.9×10^1	Copper	Ag	-3.1
Iron	Ti	-5.1×10^2			
Iron	V	-2.5×10^2			

ties. As examples, the ratio D_A^{II}/D_{AA}^{I} is of the order 10^6 and 10^3 for the FeO-Fe and CoO-Co systems, respectively. However, a planar alloy interface is maintained upon oxidation of Co-Ni, Co-Fe, and Fe-Mn alloys. In these cases the oxides form a complete homogeneous (AB)O solid solution negating the interface stability criterion. Consequently a diffusional analysis based on growth of uniformly thick ternary oxide scales has been found to describe the oxidation properties of these alloys (11-13). FeO exhibits a negligible solubility for nickel (14). Nevertheless, a planar interface results upon formation of an (FeNi)O scale on Fe-Ni alloys due to the removal of the stability restraint as a consequence of inward diffusion of oxygen and copious internal oxidation resulting in formation of a distinct subscale (15).

Codeposition of Glassy Silica and Germania Inside a Tube by Plasma-Activated CVD

D. Küppers, J. Koenings, and H. Wilson

Philips GmbH Forschungslaboratorium Aachen, 5100 Aachen, West Germany

ABSTRACT

Codeposition of glassy silica and germania inside a tube reactor has been studied with the aid of a microwave discharge. The plasma enhances the reaction rate of the reactions $SiCl_4 + O_2 \rightarrow SiO_2 + 2Cl_2$ and $GeCl_4 + O_2 \rightarrow GeO_2 + 2Cl_2$ which are negligibly small at the applied wall temperature of $\sim$1000°C. With an excess of oxygen, both reactions result in complete conversion to SiO_2 and GeO_2, respectively. A SEM analysis of the codeposit of both oxides shows that their deposition kinetics are different. This has a marked effect on the distribution of the refractive index within a single layer. However, when the layer is formed by building up some thousands of individual layers, on an average scale the deposit no longer reflects the deposition kinetics but only the gas phase composition.

In the development of glass fibers for optical communication, methods of producing fibers with well-defined index profiles are of interest. At present, the best results are obtained by successive deposition of layers with differing refractive index onto the inner wall of a quartz tube reactor.

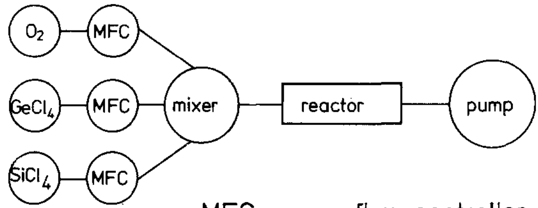
In the flame hydrolysis process (1), silicon dioxide soot doped with other oxides is formed inside the quartz tube by gas phase reactions and is deposited onto the walls. In the modified chemical vapor deposition process the soot is simultaneously deposited and fused (2-3). Here, normally about 50 layers with varying dope concentrations are deposited to approach a given index profile. In both processes the tube is subsequently collapsed to a rod and a fiber is drawn.

In this paper we present the results of a method where the hot zone is replaced by a nonisothermal plasma zone. In this plasma-activated CVD process, soot is avoided and thin film growth is obtained by surface reactions. Normally between 500 and 2000 layers are deposited without increase of the total deposition time.

Key words: optical fiber communication, microwave discharge, chemical reactions.

Experimental

The experimental setup is shown in Fig. 1. The gases $SiCl_4$, $GeCl_4$, and O_2 are metered from a typical supply system using mass flow controllers for regulation of the gas flow Q. In the experiments which are reported here, typical values are 30 sccm $\leq Q_{O_2} \leq$ 50 sccm, 2 sccm $\leq Q_{SiCl_4} \leq$ 3.2 sccm, and 0.2 sccm $\leq Q_{GeCl_4} \leq$ 0.3 sccm. The reaction zone is a short section of an approximately 1m long quartz glass tube of 8 mm outer diameter and 1 mm wall thickness surrounded by a microwave cavity connected to a 2.450 GHz generator with a maximum power, E, of 200W. The temperature, T_f, of the substrate tube can



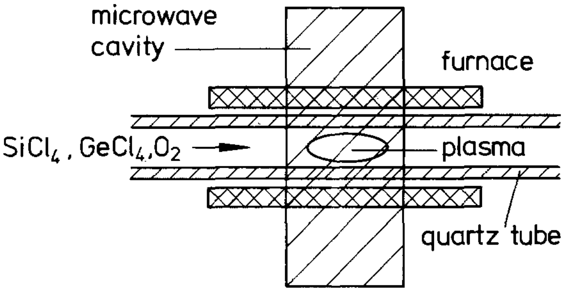


Fig. 1. Experimental setup

be controlled with an additional furnace between room temperature and 1100°C. A sorption pump is used to maintain an oil-free and water-free atmosphere. The pressure, p, inside the tube is selected between 1 and 20 Torr.

Results and Discussion

Local deposition of pure quartz glass.—The reaction $SiCl_4 + O_2 \rightarrow SiO_2 + 2Cl_2$ when initiated by a non-isothermal plasma proceeds with the substrate at room temperature. However, the layers are found to be of high chlorine content and to peel off if the thickness is greater than about 1000Å. When substrate temperatures of 800°-1000°C are used, the chlorine content in the deposited layer is reduced to 0.1% and no cracks appear within the layers (4). The plasma-aided deposition always takes place by surface reaction. Under the applied experimental conditions, soot particles, which might originate from gas phase reactions, are not observed under the microscope.

In order to analyze the deposition profile, the cavity was held in a fixed position and the deposition process was followed over a length of time. A typical result is shown in Fig. 2 for three different deposition periods up to 35 min. The photographs show a section along the tube axis in which the maximum thickness of the deposit is 2 mm. Nearly all $SiCl_4$ fed into the tube reacts to SiO_2 and is deposited onto the walls. In these and the following experiments the gas flow enters from the left. The evaluation of these deposition profiles gives that the time-dependence of the deposited mass can be written (5)

$$m_L(z,t) = m_L{}^o(z) \cdot t \qquad [1]$$

where $m_L(z, t)$ is the total deposited mass per unit length after time, t, and where z is the length coordinate in the direction of the tube axis.

Equation [1] means that the mass deposited per unit length and unit time, $m_L{}^o(z)$, is not affected by the narrowing of the tube. For convenience, $m_L{}^o(z)$ will be called the deposition profile. The deposition kinetics are consistent with a diffusion model where it is assumed that on entering the plasma region the $SiCl_4$ and O_2 molecules are dissociated and SiO_2 deposition occurs on striking of the tube walls by Si species (5).

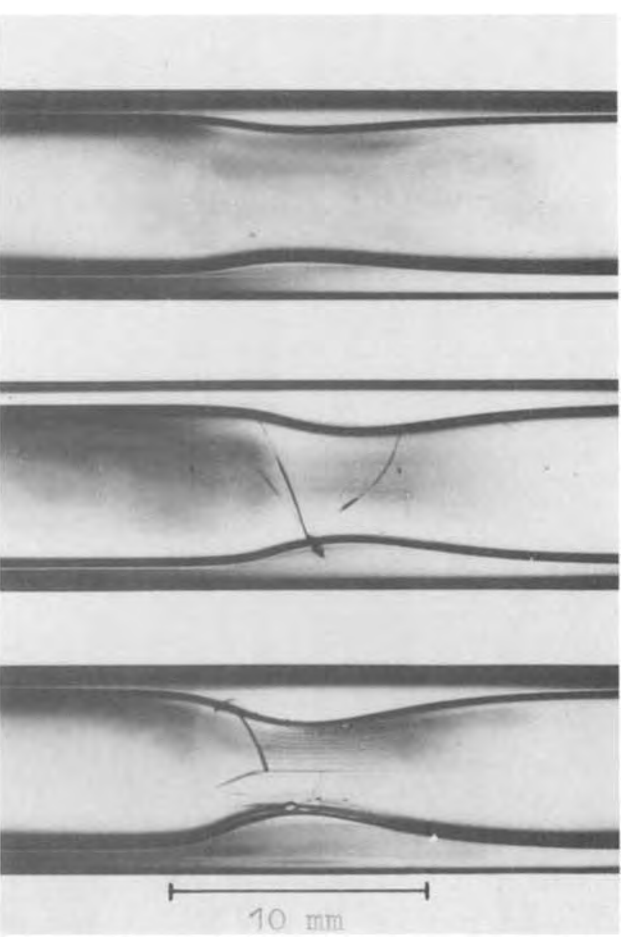

Fig. 2. Deposition of pure quartz glass with stationary plasma (top, 15 min; middle, 25 min; bottom, 35 min). T_f = 970°C, Q_{O_2} = 30 sccm, Q_{SiCl_4} = 3.2 sccm, p = 8 Torr, E = 75W.

Local deposition of doped quartz glass.—In the experiments described in this section, the cavity was at a fixed position. A constant ratio of $SiCl_4$ and $GeCl_4$ flow, normally between 10 and 100, is maintained for codeposition of SiO_2 and GeO_2. A deposition profile similar to that shown in Fig. 2 is obtained and is given in the lower curve of Fig. 3, where $\ln(m_L(z, t)/R_T{}^2\pi\rho)$ is plotted as a function of the length coordinate z. R_T is the starting inner radius of the tube, ρ the density of the deposit. By definition $0 \leq m_L(z, t)/R_T{}^2\pi\rho \leq 1$.

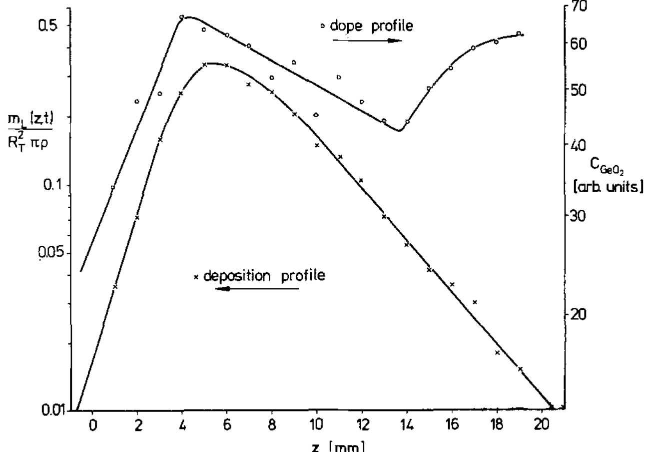

Fig. 3. Simultaneous deposition of SiO_2 and GeO_2. T_f = 900°C, Q_{O_2} = 50 sccm, Q_{SiCl_4} = 2.7 sccm, Q_{GeCl_4} = 0.14 sccm, p = 6 Torr, E = 65W.

Microprobe analysis of the deposited profile revealed a constant value for the concentration, C_{GeO_2} of GeO_2 normal to the tube axis and a change in concentration parallel to the tube axis. In the upper curve of Fig. 3, C_{GeO_2} (in arbitrary units) is given as a function of z. From Fig. 3 it is obvious that the deposition profiles ${}^{S}m_L{}^{o}(z)$ and ${}^{G}m_L{}^{o}(z)$ where S and G stand for SiO_2 and GeO_2, respectively, are different. This result is to be expected since each reaction gives its own deposition profile, $m_L{}^{o}(z)$.

Interestingly, one observes an increase of the dope concentration at the tail end of the deposit. Though the measurements become difficult when the layer is thinner than $\sim 10\ \mu m$, there is evidence that we have a further large increase in germanium concentration beyond the region given in Fig. 3. This reflects the fact that the GeO_2 deposition profile is more elongated than the SiO_2 profile. The larger deposition area has been confirmed in separate experiments where only GeO_2 was deposited.

Deposition of a single quartz layer doped with GeO_2.—When the plasma reactor is moved with constant velocity in one direction a layer of uniform thickness is deposited.

Moving the reactor in the direction of the gas flow.—If the plasma, and therefore the dope profile of Fig. 3, is moved with constant velocity, v, in the same direction as the gas flows through the tube, the consequence is a radial variation of the germanium dioxide concentration in the deposit as illustrated in Fig. 4a. D is the inner diameter of the starting tube, Δd the thickness of the layer, and r is the radial coordinate within the core of the collapsed preform. The resulting germanium distribution in the preform core of Fig. 4a can of course be calculated exactly if ${}^{S}m_L{}^{o}(z)$ and ${}^{G}m_L{}^{o}(z)$ are known.

For this purpose, one considers that the mass which is deposited between z and $z + \Delta z$ in the stationary case corresponds to the mass between r and $r + \Delta r$ in the case where a layer is deposited by the moving reactor and a preform produced. Therefore the problem is to find the relationship between r and z.

If z' gives the coordinate of the microwave resonator, then the generalization of Eq. [1] for a moving resonator leads to

$$m'_L(z, t) = \int_{t_o}^{t} m_L{}^{o}(z, z'(t))\, dt \qquad [2]$$

In the case of constant velocity we have $z' = v \cdot t$ and therefore

$$m'_L(z, t) = \frac{1}{v} \int_{v \cdot t_o}^{v \cdot t} m_L{}^{o}(z, z')\, dz' \qquad [3]$$

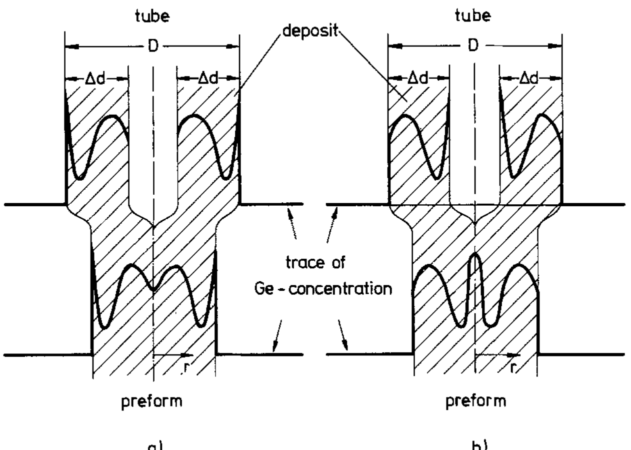

Fig. 4. Variation of dope concentration over layer thickness in single layer deposition (schematic): a. moving the reactor with the gas flow, b. moving the reactor toward the gas flow.

If t_e determines the end of the deposition, we get

$$r^2\pi = \frac{1}{v} \int_{vt}^{vt_e} \frac{m_L{}^{o}(z, z')}{\rho}\, dz' \quad t_o \leq t \leq t_e \qquad [4]$$

By assuming $m_L{}^{o}(z, z') = m_L{}^{o}(z - z')$, which means that the deposition profile does not depend on the position z' of the resonator, we obtain

$$r^2\pi = \frac{1}{v} \int_{vt-z}^{vt_e-z} \frac{m_L{}^{o}(-\omega)}{\rho}\, d\omega \qquad [5]$$

with the abbreviation $\omega = z' - z$. Because the deposition profile has a width of about 10 mm and because the length of the total deposition layer is about 200 mm we can neglect the end effects and can replace t_e by $-\infty$. Thus we get

$$r^2\pi = \frac{1}{v} \int_{-\infty}^{-vt+z} \frac{m_L{}^{o}(\omega)}{\rho}\, d\omega \qquad [6]$$

Dividing by $R_c{}^2\pi$ where R_c is the radius of the core and by inserting Eq. [1] we find

$$\left(\frac{r}{R_c}\right)^2 = \left(\frac{R_T}{R_c}\right)^2 \frac{1}{v \cdot \tau} \int_{-\infty}^{-\omega_t} \frac{m_L(\omega, \tau)}{R_T{}^2\pi\rho}\, d\omega \qquad [7]$$

with the abbreviation $\omega_t = v \cdot t - z$. In our case $m_L(\omega, \tau)/R_T{}^2\pi\rho$ is given by Fig. 3. If N is the normalization constant

$$\left(\frac{R_c}{R_T}\right)^2 \cdot v \cdot \tau = \int_{-\infty}^{+\infty} \frac{m_L(\omega, \tau)}{R_T{}^2\pi\rho}\, d\omega = N \qquad [8]$$

must obviously hold. Therefore we obtain as the final result

$$\frac{r}{R_c} = \left[\frac{1}{N} \int_{-\infty}^{-\omega_t} \frac{m_L(\omega, t)}{R_T{}^2\pi\rho}\, d\omega\right]^{1/2} \qquad [9]$$

Equation [9] gives r/R_c as a function of ω_t or vice

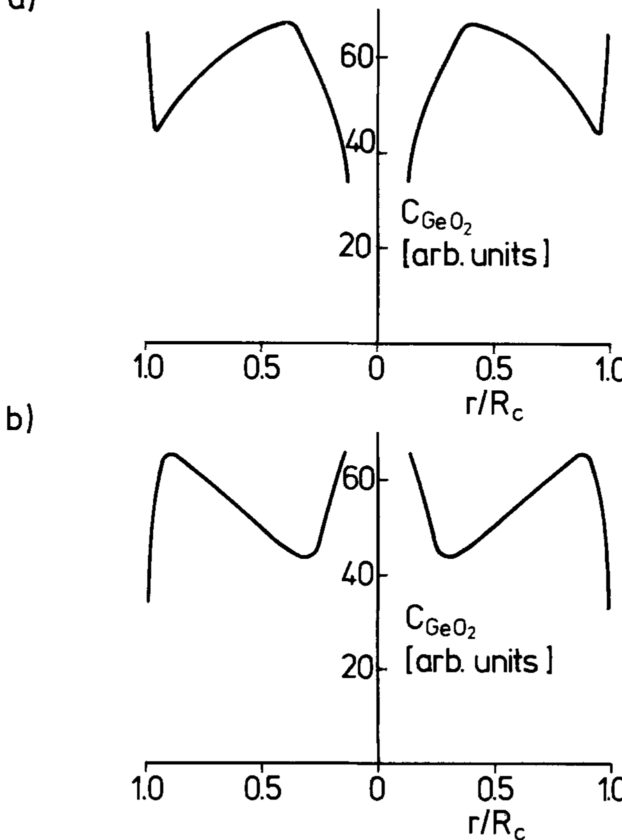

Fig. 5. Variation of the dope concentration over the layer thickness (calculated from Fig. 3): a. moving the reactor with the gas flow, b. moving the reactor toward the gas flow.

versa. Thus from the knowledge of C_{GeO_2} as a function of z in the stationary case, we now find C_{GeO_2} as a function of r/R_c in the case where a layer is deposited. The integral of Eq. [9] has been computed and the resulting C_{GeO_2} (r/R_c) is plotted in Fig. 5a.

We have confirmed these conclusions experimentally by depositing a layer with the reactor moving in the gas flow direction. Figure 6a shows a SEM picture of the collapsed preform core together with the germanium microprobe analysis signal. The bright base line gives the position of the microprobe trace. The form of the signal agrees qualitatively with the calculated concentration shown in Fig. 5a. Regions of higher germanium concentration appear brighter in the picture because of the greater secondary electron emission of germanium compared to that of silicon.

Moving the reactor against the gas flow direction.—If the reactor is moved in the opposite direction to the gas flow, then a dope variation as illustrated in Fig. 4b must result. We have confirmed this by calculation and by experiment. Because of the change in the direction of the reactor movement, Eq. [9] is changed to

$$\frac{r}{R_c} = \left[\frac{1}{N} \int_{\omega_t}^{\infty} \frac{m_L(\omega, \tau)\, d\omega}{R_T^2 \pi \rho} \right]^{1/2} \quad [10]$$

The results are given in Fig. 5b and 6b, respectively. In contrast to predictions based on Fig. 5b, a deep dip in the germanium concentration occurs in the center of Fig. 6b. This is due to the depletion of germanium dioxide by evaporation from the inner surface of the tube during the collapsing process. This effect also occurs in Fig. 6a of course, but coincides with the dip expected from Fig. 5a.

Though the general features are predicted very well by Fig. 5a and 5b, respectively, one fails to get quantitative agreement between Fig. 5 and 6. The reason may be that the experimental conditions are different in different experiments. It turns out that ${}^{S}m_L{}^{o}$ and ${}^{G}m_L{}^{o}$ depend very strongly on the plasma energy, the furnace temperature, and the total gas flow.

Deposition of doped multilayer structure.—The above-described variation of GeO_2 content and thus of refractive index in radial direction is undesirable if well-defined index profiles are wanted, as in the case of optical fibers with low pulse dispersion. Therefore, we have made preforms in which the core was built up of many layers. After deposition of 46 layers, the variation in the dope concentration still could clearly be detected. Figure 7a shows a double beam interference picture of the corresponding preform. Because the core was made by passes both from right to left and from left to right, the periodicity of Fig. 7a is only 23-fold. In another experiment, about 2000 layers were deposited with linearly increasing GeO_2 concentration, each layer with a thickness of about 1100Å. In Fig. 7b these layers can no longer be individually detected because of their thinness. Though in both examples the deposited layers were of nearly equal thickness inside the tube for each pass, this is not true at all for the rod as a consequence of geometrical considerations of the collapsing process.

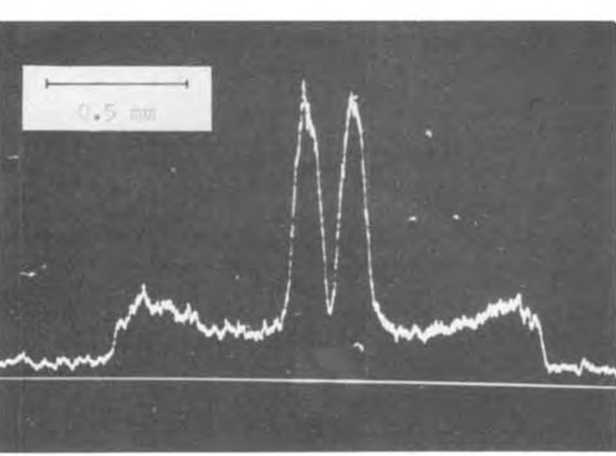

Fig. 6. Microprobe analysis of preform cores. a (top): T_f = 800°C, Q_{O_2} = 50 sccm, Q_{SiCl_4} = 2.8 sccm, Q_{GeCl_4} = 0.3 sccm, p = 8 Torr, E = 150W. b (bottom): T_f = 1040°C, Q_{O_2} = 55 sccm, Q_{SiCl_4} = 2 sccm, Q_{GeCl_4} = 0.2 sccm, p = 7 Torr, E = 90W.

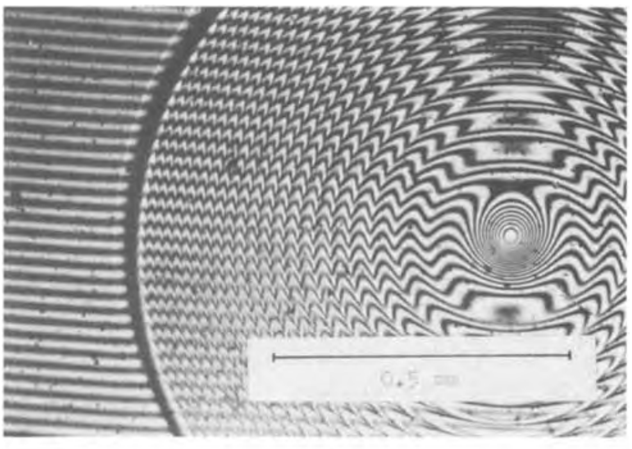

Fig. 7. Interference micrograph of the core of a preform with a (top): 45 successive layers, T_f = 900°C, Q_{O_2} = 50 sccm, Q_{SiCl_4} = 2.8 sccm, Q_{GeCl_4} = 0.3 sccm, p = 10 Torr, E = 100W. b (bottom): 2000 successive layers, T_f = 1000°C, Q_{O_2} = 50 sccm, Q_{SiCl_4} = 2.5 sccm, Q_{GeCl_4} = 0.3 sccm, p = 15 Torr, E = 100W.

This, in particular, leads to the quadratic index profile of Fig. 7b.

Other arbitrary dope profiles can obviously be obtained by proper variation of the dopant concentration in the reacting gases. Fibers drawn from preforms produced by the process described above give minimum attenuation of 1.4 dB/km at 1.05μ (6).

Summary

SiO_2 and GeO_2 were deposited simultaneously onto the inner wall of a quartz tube reactor with the aid of a nonisothermal plasma. It was found that the deposition profiles of the two oxides do not coincide. This has a marked effect on the radial dope concentration in multilayer structures with a single layer thickness of some micrometers. If the layer thickness gets very small, however, the short range variations are smeared out during collapsing and the radial dope profile is no longer influenced by deposition kinetics but solely by the gas phase composition.

The Solid Solubility of Bi in GaP

A. S. Jordan,* F. A. Trumbore,* D. L. Nash, and M. Kowalchik

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The solid solubility of Bi (an isoelectronic center) in GaP crystals, grown by a thermal gradient transport technique from Bi-Ga alloys at ~1050°C, has been determined by emission spectroscopic analysis. These results, together with earlier data on solution-grown platelets, are thermodynamically analyzed by means of liquidus isotherms and activities calculated from a recent theory of regular associated liquid solutions applicable to the Ga-P-Bi system, permitting the evaluation of the equilibrium constant for Bi incorporation according to $Bi(l) + Ga(l) = Bi_P + Ga_{Ga}$. This leads to the calculation of the solid solubility isotherms for Bi in GaP over a wide temperature range. It is shown that in equilibrium Bi is incorporated on phosphorus sites. Furthermore, the GaP-Bi pseudo-binary solidus curve is retrograde and compares favorably with the results of an estimate based on the solubility of Bi in Ge and Si. The solubility of Bi in GaP increases with increasing temperature. Although the measured values at ~1050°C are low (~10^{17} atoms cm^{-3}), it is predicted that doping levels as high as ~10^{19} atoms cm^{-3} should be possible by a suitable high temperature crystal growth technique.

The technologically important ternary solid solutions obtained by the addition of a third element from Group III or V of the periodic system to binary III-V semiconducting compounds occur as both continuous series and terminal (primary) solid solutions. For example, the red and infrared light-emitting materials $GaAs_uP_{1-u}$ and $Ga_uAl_{1-u}As$ both form continuous series of solid solutions since the differences in the tetrahedral covalent radii of As and P and of Ga and Al are small (1). In contrast, when either N or Bi substitutes for P in GaP, terminal solid solution behavior is exhibited because of the large size difference between N and P or Bi and P.[1] The properties of the isoelectronic impurity N occupying P-sites have been thoroughly investigated and this center is responsible for efficient room temperature green luminescence in commercially available GaP light-emitting diodes (2). The isoelectronic impurity Bi in GaP also produces a deep trap which is a very efficient emitter of yellow-orange light at low temperatures (20°K) (3). There is recent evidence that the addition of Bi to N-doped GaP leads to yellow instead of green light emission at room temperature (4). However, the doping levels of Bi in GaP achieved in all those studies were only in the low 10^{17} atoms/cm^3 range whereas, depending on the growth technique, N-doping levels one to two orders of magnitude higher have been attained.

Future crystal growth experiments directed toward exploiting light generation of a desirable wavelength by increasing the contribution of the Bi center require a detailed knowledge of solid-liquid equilibria in the Ga-P-Bi ternary system. Therefore, the major goal of this study is to construct the solid solubility isotherms for Bi in GaP over a wide range of compositions and temperatures. First, we present the solid solubility of Bi in GaP as determined by emission

* Electrochemical Society Active Member.

Key words: crystal growth, semiconductors, impurity incorporation, phase diagrams, thermodynamics.

[1] The tetrahedral covalent radii of Ga and Al are 1.26A for both atoms, while the radii of N, P, As, Sb, and Bi are 0.70, 1.10, 1.18, 1.36, and 1.46A, respectively (1).

spectroscopic analysis on crystals grown from Bi-Ga solutions at ~1050°C by means of thermal gradient transport (TGT) over a very small temperature difference. Second, these results, together with previously reported Bi solubility data on solution-grown GaP platelets (3), are treated thermodynamically in order to evaluate the temperature dependence of the equilibrium constant for Bi incorporation. The Ga-P-Bi ternary liquidus isotherms and activities needed to perform a self-consistent analysis are obtained from a recent study based on a regular associated solution model (5). Third, it is shown that the calculations are consistent with the expected preference of Bi for P-sites and the findings are discussed in relation to the major modes of substitutional impurity incorporation (equilibrium and surface controlled) in GaP. Finally, in view of the retrograde nature of the GaP-Bi pseudo-binary solidus curve, the results are compared with the similarly retrograde solubility of Bi in the elemental semiconductors Ge and Si.

Experimental Procedure

Bi-doped GaP crystals were grown by a thermal gradient transport technique (TGT) used previously for solid solubility studies in GaP (6). Excess GaP (Monsanto boat-grown ingot material), together with known amounts of Ga and Bi (both of 99.9999% nominal purity) were sealed under vacuum in a tapered vitreous silica tube. Several such tubes, containing varying amounts of Ga and Bi, were placed in a furnace for 45 days in a thermal gradient of ~12°C/cm at ~1050°C. The resulting Bi-doped GaP crystals were separated from the Ga-Bi solutions by digesting in HNO_3.

The procedure used to prepare the crystals for emission spectroscopic analysis is described here in some detail to emphasize the care needed to obtain consistent results for doping levels of $\lesssim 5 \times 10^{17}$ atoms/cm³. The critical requirement is that all occluded bismuth must be eliminated prior to analysis. In fact, in a number of crystals inclusions were visible to the naked eye. The samples were crushed and powdered using a boron carbide mortar and pestle, yielding a brownish powder. After digesting for about 1 min in conc HNO_3 to which a few drops of conc HCl were added, the powder turned a bright yellow or orange color characteristic of GaP. This color change apparently results from solution of the "damaged" GaP, discussed by Rubenstein (7). It should be noted that if the few drops of HCl were not added to the HNO_3 the damaged material was not dissolved and, although HNO_3 dissolves bismuth, higher and more erratic values of the bismuth concentration were obtained spectroscopically. In addition, it was found that the analytical results were erratic if the HNO_3-HCl solution (containing any dissolved bismuth) was separated simply by washing in deionized water. These erratic results are thought to have been caused by hydrolysis of the soluble bismuth salt to form an insoluble compound. When portions of the same GaP powder sample were treated the same way but were washed with dilute HNO_3 prior to the final washing with deionized water, the bismuth concentrations obtained were lower and more consistent. In Table I we list the Bi concentrations, C^s_{Bi} (atoms/cm³), determined in a number of GaP crystals grown by TGT as a function of initial Bi atom fraction in the Ga-Bi alloy.

Analysis of the Data

Substitutional isoelectronic impurities such as N or Bi in GaP are considered to be electrically neutral. Therefore, assuming that at the crystal growth temperature equilibrium between the solid and liquid phases prevails, the incorporation of Bi in GaP can be represented by the following defect chemical reactions

Table I. Emission spectroscopic analysis of Bi-doped GaP crystals grown by thermal gradient transport at ~1050°C

Sample number	Atom fraction Bi in Ga-Bi alloy prior to dissolution of GaP	Atom fraction Bi (In Ga-P-Bi ternary solution)	Atom fraction Ga (In Ga-P-Bi ternary solution)	Atoms/cm³ Bi in GaP × 10¹⁷

$$\mathrm{Bi}(l) = \mathrm{Bi_P} + V_{\mathrm{Ga}} \quad [1a]$$

$$\mathrm{Ga}(l) = \mathrm{Ga_{Ga}} + V_{\mathrm{P}} \quad [1b]$$

$$V_{\mathrm{Ga}} + V_{\mathrm{P}} = 0 \quad [1c]$$

where Eq. [1c] is the reaction of the Schottky pair. The sum of these three reactions yields the over-all incorporation of Bi in GaP according to

$$\mathrm{Ga}(l) + \mathrm{Bi}(l) = \mathrm{Ga_{Ga}} + \mathrm{Bi_P} \quad [2]$$

At any growth temperature, T, the equilibrium constant, K, for reaction [2] can be written as

$$K = \frac{x^s_{\mathrm{Bi}}}{a_{\mathrm{Ga}} a_{\mathrm{Bi}}} \quad [3]$$

where a_{Ga} and a_{Bi} are the thermodynamic activities of Ga and Bi, respectively, at some composition along the ternary liquidus isotherm of the Ga-P-Bi system, and x^s_{Bi} is the corresponding equilibrium Bi concentration in the solid in site fraction units. In Eq. [3], it is assumed that the site fraction of Ga atoms on their own sites is unity and that Henry's law applies for Bi in the dilute solid solutions. Thus, the activity coefficient of Bi in GaP (*i.e.*, Henry's law constant) has been absorbed in K.

To evaluate K at ~1050°C from the solubility data in Table I (listed as $2.47 \times 10^{22}\, x^s_{Bi}$), the activities a_{Ga} and a_{Bi} along the liquidus isotherm, as well as the actual ternary liquid compositions, corresponding to the initial binary Ga-Bi alloy compositions were taken from Ref. (5). In Ref. (5) a new theory of regular associated solutions was formulated to provide a consistent representation of the ternary liquidus surface and the participating binaries in the Ga-P-Bi system. It was assumed that the ternary liquid solution is comprised of Ga, P, and Bi atoms and Bi_2 dimeric molecules. The activities derived for a ternary system are given by

$$RT \ln a_{\mathrm{Ga}} = RT \ln x_{\mathrm{Ga}} + \alpha_{\mathrm{Ga-Bi}} x^2_{\mathrm{Bi}} + \alpha_{\mathrm{Ga-P}} x^2_{\mathrm{P}} + x_{\mathrm{Bi}} x_{\mathrm{P}} (\alpha_{\mathrm{Ga-Bi}} + \alpha_{\mathrm{Ga-P}} - \alpha_{\mathrm{Bi-P}}) + RT \ln \frac{2(x_s + Q_s)}{(1 + x_s)(1 + Q_s)} \quad [4a]$$

$$RT \ln a_{\mathrm{Bi}} = RT \ln x_{\mathrm{Bi}} + \alpha_{\mathrm{Ga-Bi}} x^2_{\mathrm{Ga}} + \alpha_{\mathrm{Bi-P}} x^2_{\mathrm{P}} + x_{\mathrm{Ga}} x_{\mathrm{P}} (\alpha_{\mathrm{Ga-Bi}} + \alpha_{\mathrm{Bi-P}} - \alpha_{\mathrm{Ga-P}}) + RT \ln \frac{1 + Q^o}{1 + Q_s} \quad [4b]$$

$$RT \ln a_{\mathrm{P}} = RT \ln x_{\mathrm{P}} + \alpha_{\mathrm{Ga-P}} x^2_{\mathrm{Ga}} + \alpha_{\mathrm{Bi-P}} x^2_{\mathrm{Bi}} + x_{\mathrm{Ga}} x_{\mathrm{Bi}} (\alpha_{\mathrm{Ga-P}} + \alpha_{\mathrm{Bi-P}} - \alpha_{\mathrm{Ga-Bi}}) + RT \ln \frac{2(x_s + Q_s)}{(1 + x_s)(1 + Q_s)} \quad [4c]$$

where

$$x_s = x_{\mathrm{Ga}} + x_{\mathrm{P}}, \quad Q_s = \sqrt{1 + \frac{4}{K_d}(1 - x^2_s)}$$

$$\text{and} \quad Q^o = \sqrt{1 + \frac{4}{K_d}}$$

The quantities x_{Ga}, x_{Bi}, and x_P are the atom fractions of the designated components in the liquid solution. The quantities α_{Ga-P}, α_{Ga-Bi}, and α_{Bi-P} are ternary interchange energies and K_d is the equilibrium constant for the dissociation reaction $[Bi_2(l) = 2Bi(l)]$. Substituting Eq. [4a] and [4c] into the general thermodynamic equation for the liquidus surface of a binary compound containing a small amount of an impurity yields

$$\Delta H^F_{GaP} - T\Delta S^F_{GaP} + RT \ln 4x_{Ga}x_P = \alpha_{Ga-P}[0.5 - x_P(1 - x_{Ga}) - x_{Ga}(1 - x_P)] + \alpha_{Ga-Bi}x_{Bi}(2x_{Ga} - 1) + \alpha_{Bi-P}x_{Bi}(2x_P - 1) - 2RT \ln \frac{2(x_s + Q_s)}{(1 + x_s)(1 + Q_s)} \quad [5]$$

where ΔH^F_{GaP} and ΔS^F_{GaP} are the molar enthalpy and entropy of fusion of GaP, respectively. In Ref. (5) α_{Ga-Bi} and the enthalpy and entropy changes related to K_d, ΔH_d, and ΔS_d, were evaluated from binary activity data for the Ga-Bi system. In addition, the interchange energy, α_{Bi-P}, was estimated by fitting the pseudo-binary liquidus data to a simplified form of Eq. [5] valid along the pseudo-binary ($x_{Ga} = x_P$). All the relevant parameters required to calculate the activities and liquidus isotherms for the Ga-P-Bi system are summarized in Table II.

Once the liquidus isotherm at 1050°C is known, the determination of the actual ternary liquid composition corresponding to the initial binary (Ga-Bi) alloy composition is quite simple. From stoichiometric relationships and the properties of an equilateral composition triangle, routinely used to represent ternary isothermal data, it can be proven that the final equilibrium concentration attained when an excess of an AC compound (*e.g.*, GaP) is heated in contact with a binary liquid alloy (*e.g.*, Ga-Bi) lies on a straight line connecting the initial binary composition on the A-B axis with the compound composition on the A-C axis. The ternary liquid compositions obtained by intersecting the straight lines with the 1050°C liquidus isotherm are also listed in Table I. It can be seen that the difference between the binary and ternary compositions is quite small since the ternary liquid solution is very dilute in P.

Substituting the ternary compositions into Eq. [4a] and [4c] yields the Ga and Bi activities for the liquid phase which are necessary to calculate K according to Eq. [3]. Excluding from the analysis the two samples grown from alloys with extremely high Bi concentration ($x_{Bi} = 0.94$ and 0.96) because the measured impurity levels may reflect some inadvertently present occluded Bi, the logarithmic least square (8) value of K at ~1050°C becomes $K = 5.51 \pm 0.40 \times 10^{-5}$. In Fig. 1 the solid solubility of Bi in GaP in equilibrium with solutions along the 1050°C Ga-P-Bi ternary liquidus isotherm, calculated from Eq. [3], [4], and [5], is superimposed on the experimental data. Apart from the previously mentioned high Bi concentrations, the theoretical and experimental values are in good agreement.

Table II. Interchange energies*

Interaction	a (cal)	b (cal °K^{-1})

	Reaction
ΔH_d = 8,180 cal/mole ΔS_d = 1.06 cal/mole °K	$Bi_2(l) = 2Bi(l)$
ΔH^F_{GaP} = 27,600 cal/mole	
ΔS^F_{GaP} = 15.9 cal/mole °K	
ΔH = 48,100 cal/ mole ΔS = 16.9 cal/mole °K	$Ga(l) + Bi(l) = Bi_P + Ga_{Ga}$

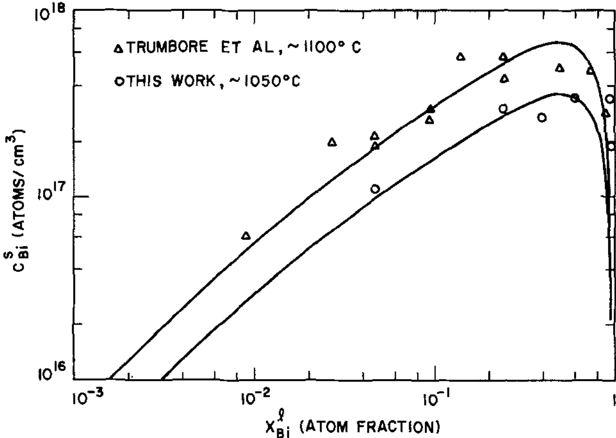

Fig. 1. Solubility data for Bi in GaP as a function of Bi concentrations along the 1050° and 1100°C ternary liquidus isotherms in the Ga-P-Bi system. The lines ——— were calculated from Eq. [3], [4], and [5] in combination with the parameters listed in Table II.

To evaluate the temperature dependence of K, we must use solubility data obtained at a different crystal growth temperature in the analysis. Previously, Trumbore *et al.* (3) determined the solubility of Bi in GaP platelets by emission spectroscopic analysis. The crystals were prepared by the slow cooling of saturated unseeded solutions of GaP in Ga-Bi alloys (SG) from an initial growth temperature of ~1160° to ~900°C.[2] The average growth temperature is estimated to be ~1100°C since the platelets grown by SG are nearly fully developed upon reaching this temperature. The approximate temperature assignment is also supported by the fact that the Zn solubility in GaP crystals grown from solutions with a wide range of Zn additions (a factor of 40) is well represented by the theoretical 1100°C solid solubility isotherm (9).

After deleting the two measurements with erratically high Bi solubility at $x_{Bi} > 0.9$, we reproduce the solubility data on SG platelets from Ref. (3) in Fig. 1. Following the procedure discussed with respect to the TGT crystals, the ternary compositions have been located along the 1100°C liquidus isotherm. A combination of the ternary compositions and appropriate values of a_{Ga} and a_{Bi} with x^s_{Bi} via Eq. [3] leads to a set of discrete K values which when treated by the logarithmic least square technique yield $K = 10.70 \pm 0.60 \times 10^{-5}$. In Fig. 1 we further present the solid solubility of Bi in GaP in equilibrium with ternary solutions along the 1100°C Ga-P-Bi liquidus isotherm, calculated from Eq. [3], [4], and [5] and the constants in Table II. The theoretical curve provides a reasonably good over-all representation of the experimental results.

Having evaluated the equilibrium constant for Bi incorporation in GaP according to Eq. [3] at two temperatures, we can derive the temperature dependence of K by applying to the data the thermodynamic relation

$$-RT \ln K = \Delta H - T\Delta S \quad [6]$$

where ΔH and ΔS are the enthalpy and entropy change associated with reaction [2]. From the K values at 1050° and 1100°C, the two constants are determined to be

$$\Delta H = 48.1 \text{ kcal/mole}, \quad \Delta S = 16.9 \text{ cal/mole°K}$$

[2] The subtleties involved in Bi analysis, as given in the section on experimental procedure, were not fully appreciated in Ref. (3). Hence, the effect of occluded Bi on the analysis cannot be completely ruled out.

The knowledge of the liquidus isotherms, activities (Eq. [4]), and the temperature dependence of the incorporation equilibrium constant permits the calculation of the solid solubility isotherms of Bi in GaP over a wide range of compositions and temperatures. In Fig. 2 the solid solubility isotherms are shown between 900° and 1400°C in 100°C intervals. The 1100°, 1200°, and 1300°C isotherms are terminated on the P-rich side at compositions where phase separation occurs in the liquid (5) (Bi-doped GaP and two immiscible liquid solutions). In Fig. 3 we present the pseudo-binary liquidus curve together with the published data (10, 11) and the corresponding pseudo-binary solidus curve in temperature *vs.* x_{Bi} and temperature *vs.* log x_{Bi} projections, respectively. Note that the calculated pseudo-binary solidus curve exhibits retrograde behavior.

Discussion

Modes of incorporation and site preference for Bi in GaP.—Two major modes of impurity incorporation have been observed in III-V compounds. Rapidly diffusing ionized impurities (*e.g.*, Zn-acceptors in GaP and GaAs) follow defect chemical relations appropriate for bulk equilibrium (6, 8, 12). In contrast, slowly diffusing ionized impurities [*e.g.*, Te-donors in GaAs (15) and Te (13) and O-donors (13, 14) in GaP] exhibit surface-controlled incorporation behavior.[3] Furthermore, it appears that the incorporation of isoelectronic impurities such N or Bi in GaP is also a bulk equilibrium process. For a liquid solution dilute in Bi ($a_{Ga} \approx 1$), Eq. [3] immediately suggests a linear relation between Bi concentration in the solid and in the liquid as long as this solute obeys Henry's law in both phases. In Fig. 1 and 2, C^s_{Bi} is linear in x_{Bi} up to $x_{Bi} \approx 0.01$; above this value departure from linearity is observed because of the deviation of a_{Ga} from unity and a_{Bi} from Henry's law. The good agreement seen in Fig. 1 between the thermodynamically calculated solid solubility isotherms and the experimental data at ~1050° and ~1100°C may be taken as evidence that the incorporation of Bi in GaP follows a bulk equilibrium process. It is very likely that the incorporation of N is also an equilibrium process, at least when crystals are grown by liquid-phase epitaxy, on account of the linear variation of N solubility on the partial pressure of NH_3 up to the pressure corresponding to the formation of GaN (16).

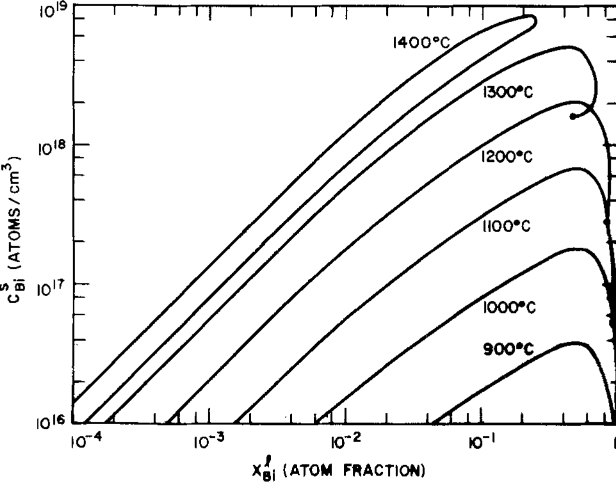

Fig. 2. Calculated solid solubility isotherms for Bi in GaP along the 900°, 1000°, 1100°, 1200°, 1300°, and 1400°C liquidus isotherms in the Ga-P-Bi system. The 1100°, 1200°, and 1300°C isotherms are terminated by solid dots at the liquid compositions where phase separation occurs in the liquid phase.

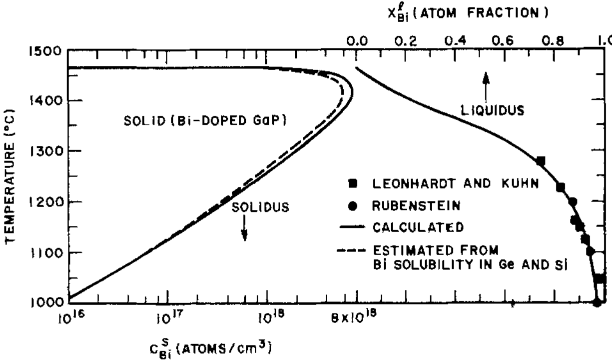

Fig. 3. Solid-liquid equilibria along the pseudo-binary liquidus curve ($x_{Ga} = x_P$) of the Ga-P-Bi ternary system. The liquidus and solidus curves (solid lines) are based on Eq. [3] and Eq. [3], [4], and [5], respectively, in combination with the parameters listed in Table II. The solidus curve (dashed line) is estimated from the average enthalpy and entropy of Bi incorporation in Si and Ge (see text).

The maximum followed by a downturn exhibited by the experimental data[4] and the calculated solubility curves are consistent with the expectation that Bi occupies P-sites (3). If Bi were incorporated on Ga-sites, then at a fixed T C^s_{Bi} would be proportional to the product $a_{Bi}a_P$ and not to $a_{Bi}a_{Ga}$. But both a_{Bi} and a_P increase along the Ga-rich branch of the ternary liquidus isotherm. Hence, unlike the product $a_{Bi}a_{Ga}$ that shows a maximum before the downturn, $a_{Bi}a_P$ governing the supposed incorporation on Ga-sites increases continuously along the Ga-rich isotherm followed by a rapid upturn as the P-rich side is reached, which is contradicted by the experimental information. Of course, the calculated maximum would occur even if the liquid solution were ideal, as assumed in Ref. (3). However, the solubility isotherms calculated on the basis of the ideal solution model would be located about a factor of two below the data for low Bi levels, both at 1050° and 1100°C. In contrast, in the same region, the solubility isotherms based on the regular associated liquid solution model agree well with the data. It was pointed out earlier that for ternary solution compositions containing $x_{Bi} \gtrsim 0.90$, the measured Bi concentrations are above the predicted values. It is reasonable to assume that entrapped Bi is responsible for the large apparent Bi levels. However, this explanation is complicated by the emergence of a ternary miscibility gap near these liquid solution compositions (5).

A key feature of the complete solubility isotherms in Fig. 2 is the increase in Bi-doping levels with increasing T at a constant Bi concentration in the liquid solution. It appears that at elevated temperatures Bi additions between 10^{18} and 10^{19} atoms/cm³ in GaP are feasible. Therefore, if it is assumed that when GaP is simultaneously doped with Bi and N (4), the yellow light generation is limited by the relatively small Bi solubility set by the conventional liquid-phase epitaxial and SG techniques, the efficiency might be increased by high temperature growth [*e.g.*, the liquid-encapsulation Czochralski method from nonstoichiometric melts at, say, ~1400°C (17)].

Relation between terminal and continuous series solid solutions.—The solid solubility isotherms for Bi in GaP calculated from the combination of the defect chemical equilibrium constant (Eq. [3] and [6]) and the Ga-P-Bi liquidus isotherms (Eq. [15]) and illustrated in Fig. 2 show terminal solid solution behavior.

[3] If, at the growth rates employed, equilibrium can be reached between an impurity in the external phase and the bulk of the crystal, we refer to bulk equilibrium incorporation. If, however, equilibrium is established only between the external phase and the semiconductor surface but not between this surface and the bulk, we speak of surface-controlled incorporation.

[4] Even at the highest Bi concentration in the liquid where occlusions of Bi would be expected to give high values of C^s_{Bi} the data indicate a maximum in the solid solubility.

It is of course well known that replacing P with As in GaP leads to a continuous series of solid solutions $GaAs_uP_{1-u}$. For such solid solutions the thermodynamic description of solid-liquid equilibria is well established. Accordingly, at any T the solid-liquid phase relations are given by the roots of a pair of transcendental "heat of fusion" equations of the form (18, 19)

$$\Delta H^F_{GaZ} - T\Delta S^F_{GaZ} = RT \ln \frac{a^{GaZ}_{Ga}(0.5)\, a^{GaZ}_{Z}(0.5)}{a_{Ga}a_Z} + RT \ln a^s_{GaZ} \quad [7]$$

where Z = P and, say, As; a^s_{GaZ} is the activity of GaZ in the solid solution, and a^{GaZ}_{Ga} (0.5) and a^{GaZ}_{Z} (0.5) are the Ga and Z activities in the liquid solution at T and at the compound composition $x_{Ga} = x_Z = 0.5$. A question of importance is whether Eq. [3] and [5] for terminal solid solutions are related in any manner to Eq. [7] for a continuous series of solid solutions.

In the particular case of Bi dissolved in GaP, we have $a^s_{GaP} = 1$ (GaP is almost pure) and in the dilute (henrian) limit of the regular solution approximation $RT \ln a^s_{GaBi} = RT \ln u + \alpha^s_{Bi-P}$. In this relation $u (<< 1)$ is the site-fraction of Bi atoms on P-sites and α^s_{Bi-P} is the Bi-P interchange energy in the crystal. Under these conditions Eq. [7] reduce to

$$\Delta H^F_{GaP} - T\Delta S^F_{GaP} = RT \ln \frac{a^{GaP}_{Ga}(0.5)\, a^{GaP}_{P}(0.5)}{a_{Ga}a_P} \quad [8a]$$

and

$$\Delta H^F_{GaBi} - T\Delta S^F_{GaBi} = RT \ln \frac{a^{GaBi}_{Ga}(0.5)\, a^{GaBi}_{Bi}(0.5)\, u}{a_{Ga}a_{Bi}} + \alpha^s_{Bi-P} \quad [8b]$$

where ΔH^F_{GaBi} refers to the hypothetical III-V compound "GaBi." Equation [8a] is identical with the thermodynamic liquidus equation from which the Ga-P-Bi liquidus surface was derived (Eq. [5]). A simple thermodynamic identity[5] transforms Eq. [8b] into

$$- RT \ln \frac{u}{a_{Ga}a_{Bi}} = \Delta H^o_{GaBi} - T\Delta S^o_{GaBi} + \alpha^s_{Bi-P} \quad [9]$$

where ΔH^o_{GaBi} and ΔS^o_{GaBi} are the enthalpy and entropy of formation of GaBi from pure liquid components.

It can be readily observed that Eq. [9] is identical with Eq. [3] and [6] because $u \equiv x^s_{Bi}$ and $u/a_{Ga}a_{Bi} = K$. Accordingly, the pair of simultaneous equations describing solid-liquid equilibria for a continuous series of solid solutions (Eq [7]) decouple in the limit of $a^s_{GaP} \approx 1$ to the thermodynamic equation of the ternary liquidus surface (Eq. [8a]) and an equation providing the solubility of the isoelectronic impurity in the ternary solid solution in equilibrium with the liquid phase (Eq. [9]).

In order to contrast the behavior of Bi and N in GaP we estimate the free-energy of formation of GaBi. Comparing Eq. [9] and [6] and assuming that α^s_{Bi-P} is as large as α_{Bi-P}, we obtain from the values in Table II +17,400 cal at 1300°K for the free-energy of formation from pure liquid components. Adding the free energy of condensation for 1/2 $Bi_2(g)$ (21) yields 8600 cal at 1300°K for the free-energy of formation of GaBi from Ga(l) + 1/2 $Bi_2(g)$. That this quantity is positive agrees with the fact that no compound exists in the Ga-Bi system.[6] In contrast, the free-energy of formation of GaN from Ga(l) + 1/2 $N_2(g)$ is negative below 1100°K (23). Likewise, the enthalpy of formation of GaN is negative, whereas that of GaBi is positive. This difference in the sign of the enthalpies of formation is consistent with the opposite heat effects accompanying N and Bi incorporation in GaP. Accordingly, the distribution coefficient-related ratio $C^s_N/\sqrt{p_{N_2}}$ increases with decreasing T, while the distribution coefficient C^s_{Bi}/x_{Bi} increases with increasing T.

Comparison with Bi solubility in Si and Ge.—As seen in Fig. 3, Bi-doped GaP crystals in equilibrium with liquid solutions along the GaP-Bi pseudo-binary liquidus curve exhibit retrograde behavior. Retrograde solid solubility is a common occurrence for a variety of impurities, including Bi, in the elemental semiconductors Ge and Si (24). In view of the notable similarities between compound and elemental semiconductors in their thermodynamic properties (25), it would be of interest to estimate the GaP-Bi pseudo-binary solidus on the basis of data for Si and Ge.

To meet this objective, we construct the pseudo-equilibrium constants K_{Ge} and K_{Si}, in analogy with reactions [2] and Eq. [3] for the over-all incorporation reactions[7]

$$Ge(l) + Bi(l) = Ge_{Ge} + Bi_{Ge}, \quad K_{Ge} = \frac{C^s_{Bi}}{a_{Bi}a_{Ge}} \quad [10]$$

and a similar expression for Si and K_{Si}, obtained by replacing the subscript Ge by Si in Eq. [10].

Combining the solubility data of Trumbore (24) and Trumbore *et al.* (26) for the Si-Bi and Ge-Bi systems, respectively, with the activities along the appropriate liquidus curves evaluated from the work of Thurmond and Kowalchik (27), K_{Ge} and K_{Si} were determined as a function of T. Treating the temperature dependences as in Eq. [6], ΔH_{Ge}, ΔS_{Ge}, ΔH_{Si}, and ΔS_{Si} were obtained for the above over-all incorporation reactions. In line with Thurmond's study on the thermodynamic properties of GaP and GaAs (25), we estimate the enthalpy and entropy changes for the over-all incorporation of Bi in GaP (reaction [2]) by forming the average of these quantities in Ge and Si. Then, we find for Bi in GaP $\Delta H = 45.8$ kcal/mole, $\Delta S = 15.1$ cal/mole°K which compare favorably with the values derived from the solubility of Bi in GaP (viz., Table II). In Fig. 3, we show the GaP-Bi pseudo-binary solidus (dashed curve) calculated on the basis of these estimated quantities. It can be seen that the solidus derived from information for the elemental semiconductors closely parallels the actual solidus.

Finally, it is worth mentioning that the GaP-Bi pseudo-binary liquidus curve also possesses some features in common with the Ge-Bi and Si-Bi binary liquidus curves. As seen in Fig. 3, the GaP-Bi pseudo-binary liquidus curve is concave for small values of x_{Bi}. Since ΔS^F_{GaP} is not unduly small, the concavity is a consequence of a strong positive deviation from ideality in the liquid solution which may be a symptom of imminent phase separation in the liquid. Like the GaP-Bi pseudo-binary, the Ge-Bi binary liquidus curve is concave, while a miscibility gap has been observed in the Si-Bi system (22, 27). Considering GaP dissolved in the liquid solution along the GaP-Bi pseudo-binary as an equimolar mixture of Ge and Si, one could argue if no other information were available, that the GaP-Bi system approaches demixing. Extending the reasoning, one would expect that by moving from the pseudo-binary toward more P-rich compositions liquid immiscibility must

[5] The identity (20) is
$$\Delta H^F_{GaBi} - T\Delta S^F_{GaBi} - RT \ln a^{GaBi}_{Ga}(0.5)\, a^{GaBi}_{Bi}(0.5) = -\Delta H^o_{GaBi} + T\Delta S^o_{GaBi}$$

[6] InBi is the only known III-V compound involving Bi (22).

[7] The actual equilibrium constant here would be for the reaction $Bi(l) = Bi^+_{Ge} + e^-$. Since Bi in GaP is neutral, for purposes of comparison, the ionization of Bi in Ge and Si has been ignored.

occur because this corresponds to adding more Si to the solution. In fact, the regular associated solution treatment of the complete Ga-P-Bi liquidus surface leads to a ternary miscibility gap on the P-rich side of the system (5).

Acknowledgments

The authors are grateful to C. D. Thurmond for helpful discussions and critical comments on the manuscript. Useful suggestions on the paper by R. H. Saul are also appreciated.

Manuscript submitted Sept. 26, 1975; revised manuscript received Jan. 26, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were partially assisted by Bell Laboratories.

The Anodization of GaAs and GaP in Aqueous Solutions

B. Schwartz,* F. Ermanis, and M. H. Brastad

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The anodic oxidation of GaAs and GaP in properly conductivity- and/or pH-adjusted water has been successfully demonstrated under both constant voltage and constant current conditions. With H_3PO_4 as the acidic conductivity/pH modifier, uniform, well-controlled oxides have been grown in the pH range 2.5-3.5. The oxide thickness-voltage relationships for both GaAs and GaP are linear, with slopes of approximately 20 and 12 Å/V, respectively. At room temperature, oxides as thick as 3600 and 2000Å can reproducibly be grown on GaAs and GaP, respectively; at 100°C, an oxide as thick as 5000Å has been grown on GaAs. Under basic conditions, with NH_4OH as the conductivity/pH modifier, oxides have been grown in the pH range of 10-11, but dissolution of the oxide in the bath results in much poorer control than in the acidic system; this dissolution effect can be utilized more in the line of electroetching than in simple oxide formation. Anodic oxidation, with relatively little oxide dissolution, has also been accomplished in near neutral-pH water (*i.e.*, ~7) with $(NH_4)_2HPO_4$ as the conductivity/pH modifier. Restricted-area oxidation and/or etching has been demonstrated whereby a prefabricated photoresist pattern is used to define restricted areas for anodization; lines as narrow as 5μ wide are readily delineated. Anodization in aqueous solutions containing either Cl^- or NO_3^- ions is shown to result in simple electroetching, and current densities in the range 10-20 mA/cm² are demonstrated to be most effective for controlled electroetching. The grown oxides are soluble, in HCl, HNO_3, and H_2SO_4, and are affected by prolonged contact with water. If properly baked, however, the oxide grown on GaAs shows no evidence of change in months of storage in laboratory air; the oxide grown on GaP does show evidence of moisture absorption after 1 month of equivalent storage. A preliminary analysis of some of the controlling electrical factors during anodization shows that under constant voltage conditions, the current (I) varies as

$$I = \sqrt{\frac{A}{Bt + C}}$$

and under constant current conditions, the time derivative of the voltage is a constant.

The growth of native oxides on GaAs and GaP by galvanic and anodic techniques (1-4) using 30% aqueous solutions of H_2O_2 as the electrolyte has been shown to be a useful new technology for passivation of semiconductor device surfaces (5, 6), as a diffusion mask (7), and for selective area etching (2). The use of a buffered aqueous solution for the growth of an anodic oxide on GaP has recently been described (8). This paper describes the successful results of growing anodic oxides on GaAs and GaP using water as the electrolyte, under the proper conductivity and/or pH conditions. For both materials, the oxide thicknesses are approximately linear with applied voltage, but the complication of rapid film dissolution at the oxide-electrolyte interface can be an appreciable correction factor to be considered. In fact, it is shown that the entire range, from anodic oxidation with minimal oxide etching to total anodic etching with minimal residual surface oxide, can be controllably achieved by proper choice of anion, pH, and conductivity control.

The choice of anion in the pH/conductivity modifier can be a very important factor, and conditions where simple anodic etching is achieved are described.

Finally, the feasibility of combining photoresist technology and oxidation in water to make restricted area oxide patterns directly on the surface of the semiconductor are shown; under the proper solution conditions, electrolytic etching through these photoresist masks can also be accomplished readily.

Key words: native oxides, compound semiconductors, anodic oxidation.

Experimental Procedure

The electrolytic cell used for this study was almost identical to that previously described (1), except that either a constant voltage or a constant current supply could be used as the power source. Because the reagent was water instead of H_2O_2, the lack of reaction between the platinum cathode and the electrolyte eliminated the need for a baffle in the system, and a simple quartz beaker was, therefore, used as the bath container. The semiconductor samples were either partly or fully immersed in the bath while held in an aluminum clamp since the aluminum also anodized in water (3). The water used in these studies was 15 megohm-cm at the resin bed and 6 megohm-cm at the point of use; the pH of the starting water was approximately 6.5. When anodization was attempted in this water directly, it was found that the conductivity was so low that almost the entire voltage drop occurred across the solution (2) and very little appeared at the semiconductor-electrolyte interface, so that no oxide growth was achieved. The pH of the water was adjusted downward with H_3PO_4 or upward with NH_4OH; in one series of anodizations, the pH was made nearly neutral (*i.e.*, 7.8) with $(NH_4)_2HPO_4$ as the conductivity modifier.

The GaAs slices were all n-type, (100)-oriented, Si- or Te-doped at about $1 \times 10^{18}/cm^3$. Most of the GaP used was n-type, $(\bar{1}\bar{1}\bar{1})$-oriented, Se-doped with $|N_D - N_A|$ between 0.1 and 1×10^{18}. A few experiments were performed on p-type, Zn-doped GaP with $|N_A - N_D| = 0.5$ to 5×10^{18}. All samples were chem-

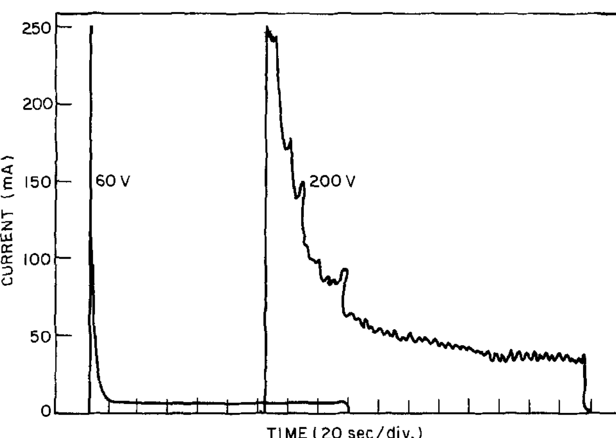

Fig. 1. Current vs. time during anodization of n-type GaAs at constant voltage of 60 and 200V in acidic (pH = 2.5) water.

mechanically polished directly from the saw-cut condition in a 0.075% bromine-in-methanol solution, on a PAN-W polishing cloth. Following this step, the slices were given at least 12 cycles of acetone wash in a Soxhlet extractor, then air dried and stored until used.

After anodization, the samples were either water-rinsed and air-dried, or water-rinsed and bake-dried in a nitrogen-purged oven for 1 hr at 95°C and 2 hr at 250°C; then the thickness and index of refraction were determined on a Rudolph ellipsometer[1] at 6328Å radiation.

Experimental Results

Anodic oxidation in acidic [H_3PO_4] water: GaAs.—A monitoring of the current as a function of time, for constant voltage anodizations and with the room temperature water adjusted to a pH of 2.5, yielded the data presented in Fig. 1. At voltages up to and including 170V, all of the results appeared similar to the 60V curve; the entire surface area of the grown film was uniform in color and specular. However, at biases in the range 180-200V, the data shown as the 200V *I-t* curve resulted. The films were still uniform in color, but were slightly hazy in appearance; above 200V, the samples took on a nonuniform mottled look (1).

A monitoring of the voltage as a function of time, for constant current anodization, with the room temperature water adjusted to a pH of 2.5, yielded the data shown in Fig. 2.[2] The conclusions to be drawn from these data are: (*i*) the apparent critical current density necessary to start the oxide growth, and (*ii*) the apparent linear relationship between voltage and time, which is to be compared with the very nonlinear current-time curve determined for constant voltage anodization (see Fig. 1). In the case of constant voltage, if the anodization is allowed to proceed long enough for the asymptotic current level to be approached, or in the case of constant current a predetermined voltage level is reached,[3] a plot of the resulting oxide thickness against applied voltage yields a straight line, as shown in Fig. 3. Note that this curve extrapolates back through the origin and has a slope of about 20 Å/V.

In order that the influence of temperature on the thickness-voltage curve might be determined, a series of samples were anodized in water at 100°C (*i.e.*, the water was adjusted to a pH of 2.5 at room temperature and then brought to its boiling point). The data obtained are shown in Fig. 4; note that the lower por-

[1] A few measurements were also made on a Gaertner ellipsometer with 5461A light.

[2] Although the area of the exposed surfaces was held relatively constant at about 1 cm², there was enough unmeasured variation to indicate that the currents listed do not necessarily reflect the absolute current densities.

[3] Assuming the time to be long enough for the achievement of a steady-state condition, and the voltage to be near neither the breakdown limit of the oxide nor the saturation limit of the power supply.

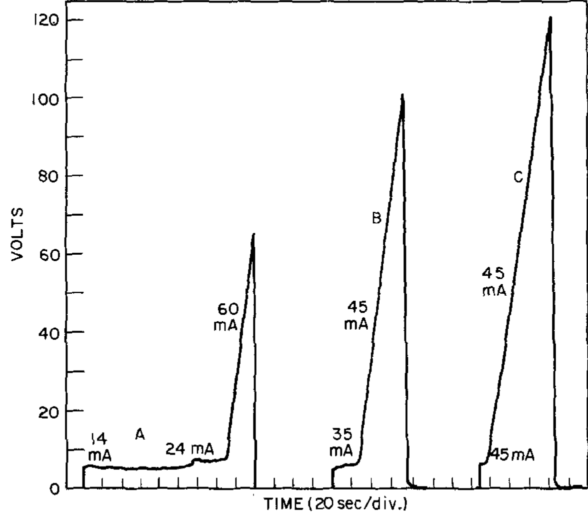

Fig. 2. Voltage vs. time during anodization of n-type GaAs in the constant current mode in acidic (pH = 2.5) water.

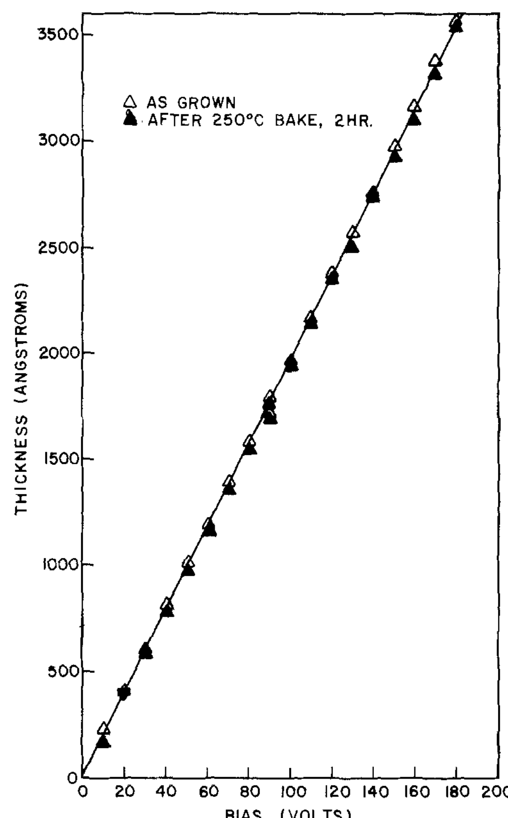

Fig. 3. Oxide thickness vs. bias voltage for n-type GaAs anodized at constant voltage in acidic (pH = 2.6) water.

tion of this curve is linear with a slope of approximately 25 Å/V, but that as the voltage increases the thickness dependence rises superlinearly, approaching almost 50 Å/V at the upper end before the "limiting" voltage is reached. This higher order dependence is similar to that observed in the anodization of GaAs in boiling H_2O_2 (3).

The effect of varying the pH on the growth of an oxide at a fixed bias (*i.e.*, 45V) is shown in Fig. 5; note the falloff in growth rate below a pH of 2.5 and above a pH of 3.5.

As was observed in the anodization of GaAs in H_2O_2 (3), a bake in dry nitrogen at about 250°C has been found suitable for stabilizing the grown oxide. Thickness changes of less than 10% and refractive index shifts (*i.e.*, from n = 1.80) of less than ±0.01 have been observed during this drying procedure. The stabilized oxide has been found to be soluble in

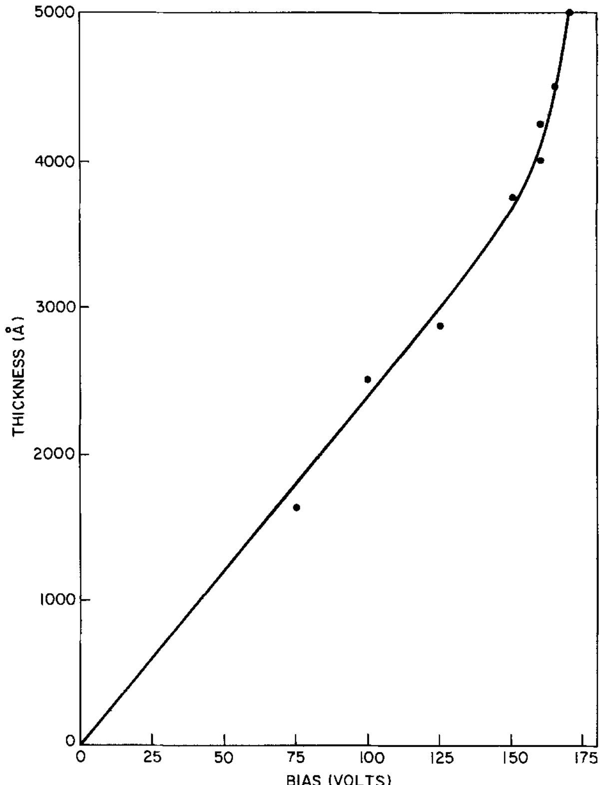

Fig. 4. Oxide thickness vs. bias voltage for n-type GaAs anodized at constant voltage in acidic (pH = 2.6) water at 100°C.

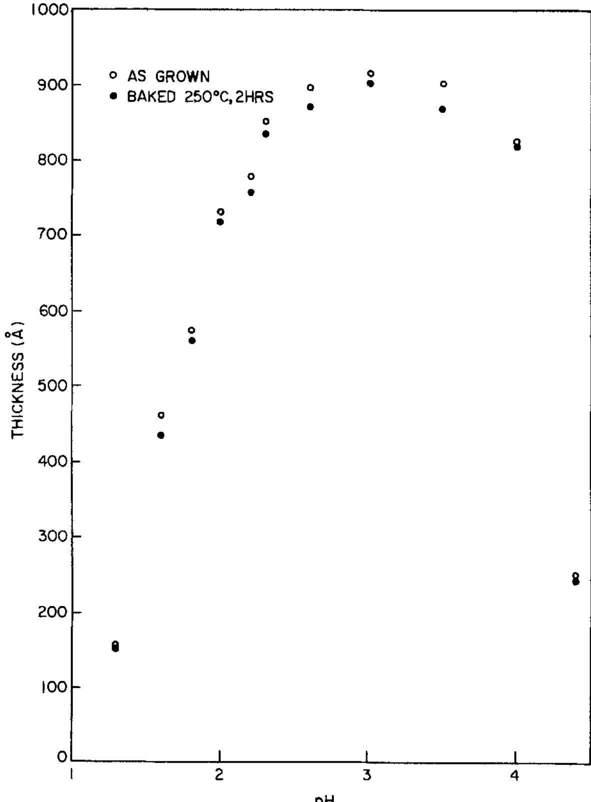

Fig. 5. Variation of oxide thickness as a function of pH for n-type GaAs anodized at constant 45V.

aqueous solutions of NH_4OH and HCl, both in the concentrated forms (15 and 12M, respectively) and diluted 10 parts water to 1 part concentrated base or acid. Again, as was found with the anodic oxide grown in H_2O_2, the oxide grown in water was insoluble in Br_2-CH_3OH whether it was baked or not. Exposed to room air, the baked oxides showed no ob-

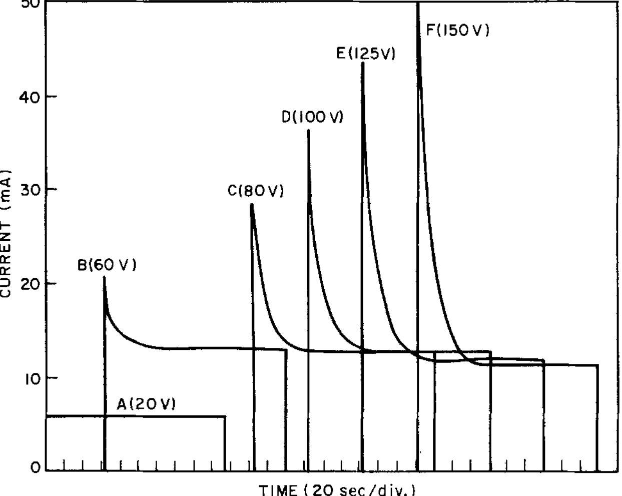

Fig. 6. Current vs. anodization time for n-type GaAs in basic water (pH = 10) at constant voltage.

servable changes over a period of 10 months. In direct contact with deionized water, however, both the as-grown and the baked oxides developed localized pinhole-type defects and nonuniform thickness changes.

Optically levered laser-beam measurements (9) on 10 mil thick GaAs slices anodized in acidic water indicated that there is no measurable stress[4] induced in the samples after anodization, after baking at 250°C, or after annealing at 650°C in dry nitrogen for ½ hr.

Anodic oxidation in basic [NH_4OH] water: GaAs.—Figure 6 shows the results of attempting anodization of GaAs, in room temperature water adjusted to a pH of 10, under various constant voltage conditions. The most obvious result is that at 20V no oxide of any appreciable thickness grew and only etching was achieved. Secondly, even where oxide growth was evident (*i.e.*, by current falloff with time), the ultimate leakage current was relatively high (*i.e.*, 2 to 3 times as high as in the acidic case shown in Fig. 1), again indicating rapid dissolution of the oxide under steady-state conditions. Further evidence for this rapid dissolution of the native oxide in basic water is shown in Fig. 7. In this case, an initial bias of 120V was applied to the sample for 40 sec, after which time the voltage was dropped to only 20V; this lower bias was then maintained for approximately 60 sec. The sequence was then repeated twice before the power supply was turned off. On examination of any complete cycle in Fig. 7, it becomes quite obvious that during the second part of the cycle, where the bias on the sample was maintained at the lower voltage (*i.e.*, 20V), the resistance of the cell was changing with time. This resistance change was the result of a thinning of the oxide layer by dissolution, until the very thin, steady-state oxide thickness for the 20V was achieved.

Anodization under constant current conditions in water at a pH of about 10 also yielded data indicative of excessive etching of the oxide (see Fig. 8). In addition, whereas constant current anodization in acidic water yielded a linear dependence of the voltage on time, there is evidence that deviation from linearity occurred in a number of cases for the basic system.

The nonreproducibility of oxide thickness for basic-water oxidation was also illustrated when a plot of thickness *vs.* voltage was attempted; the scatter of the points was so large as to make this kind of plot essentially meaningless, thus indicating the poor control for growing oxides in high pH solutions. However, the potential for use of this pH range as an electrolytic etching region becomes attractive.

Anodic oxidation in acidic [H_3PO_4] water: GaP.—When GaP was anodized in room temperature water

[4] Minimum measurable stress level in GaAs is 1-2 × 10^8 dynes/cm (2).

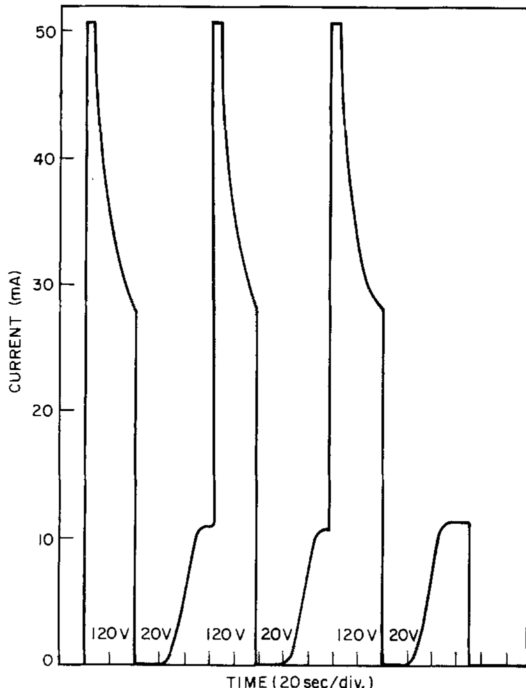

Fig. 7. Behavior of anodization current as a function of time during anodization of n-type GaAs in basic (pH = 11) water at cycled biases of 120 and 20V. The current maximum of 52 mA was due to a current limiter on the powder supply used.

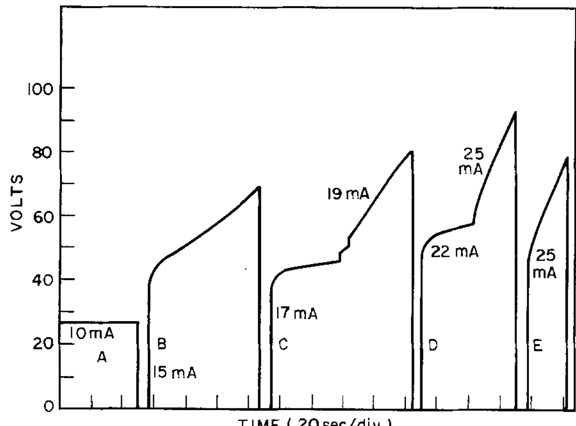

Fig. 8. Voltage vs. time during anodization of n-type GaAs in the constant current mode in basic (pH = 10) water.

adjusted to a pH of 2.8, at either constant voltage or constant current, curves similar to those shown in Fig. 1 and 2 were obtained. Figure 9 is a plot of thickness *vs.* voltage for both p- and n-type GaP anodized at constant voltage. The plot also shows the negligible effect of drying on the film thickness. The slopes of the straight lines through both sets of data are approximately 12 Å/V. The one for n-type GaP, however, is shifted toward higher voltages, thus showing that n-type material anodized at identical voltages grows an oxide approximately 100Å thinner than p-type material. This voltage shift is believed to be due to the different (*i.e.*, lower) doping level of the n-type samples (10). In any case, the ultimate oxide thickness achievable in the anodization of GaP is lower than that for GaAs which can be anodized under similar conditions at about 20 Å/V.

Another effect that is delineated in the data of Fig. 9 is the nonlinearity of the apparent film thickness in both the low and the high voltage ranges. A probable reason for the scatter in the low voltage range is the relatively large uncertainty in the assignment of thickness values from the ellipsometrically measured parameters, Δ and Ψ, in this, the thin film re-

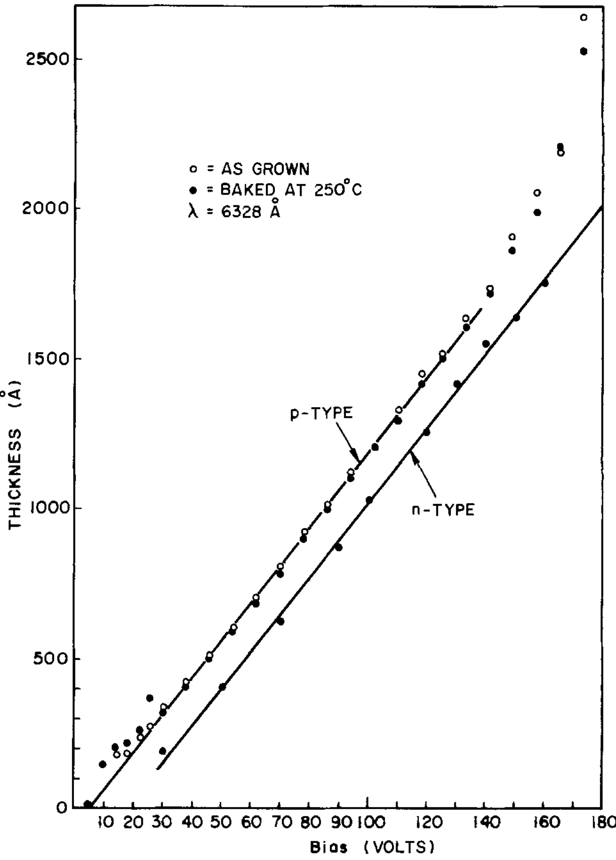

Fig. 9. Ellipsometrically determined oxide thickness vs. applied voltage for p- and n-type GaP anodized in acidic (pH = 2.7) water. The wavelength of the measuring light source was 6328Å.

gion (11). It is believed that in the thick oxide region of the curve, the deviation from linearity is only an artifact of the measurement; evaluation of the film thickness on a rotating-analyzer ellipsometer (12) yields data to indicate that the thickness extrapolates linearly to about 200V. The fact that the refractive index appears to vary as a function of the oxide-forming voltage (see Fig. 10), and that the variation seems to be measurement wavelength dependent are thought to be due to an anomalous reflectivity effect at the oxide-semiconductor interface (4). An attempt is under way at this time to achieve an understanding of this anomaly.

When the effect of pH on the growth of the GaP-oxides in acidic media was examined, the data shown in Fig. 11 were obtained. Again, a falloff in oxide thickness was observed below a pH of about 2 and above about 3.5. As noted in Fig. 9, baking the oxidized samples at 250°C for 2 hr in a nitrogen-purged oven had very little effect on the oxide thickness. However, anodization at a pH less than 2 yielded some very startling results in the aging characteristics of the formed oxide. Whereas an oxide grown on GaP at pH = 2.7 and not stabilized can sit in a flat-pack on the shelf for about 2 weeks with no apparent change in thickness or refractive index, a film grown at a pH of 1.9 or less will show drastic color changes when allowed to sit unstabilized for less than 1 day under identical conditions. The instability of the oxide becomes evident on the baked samples as well after storage of about 1 month, when localized color changes can be observed. The new color spots are those of oxides thicker than those originally grown, thus indicating a swelling of the oxide, possibly due to absorption of moisture from the atmosphere. This relative instability is to be compared to the case of a galvanic oxide grown on GaP which was bake-dried and showed no change in thickness or refractive index after storage in room air for 2.5 years.

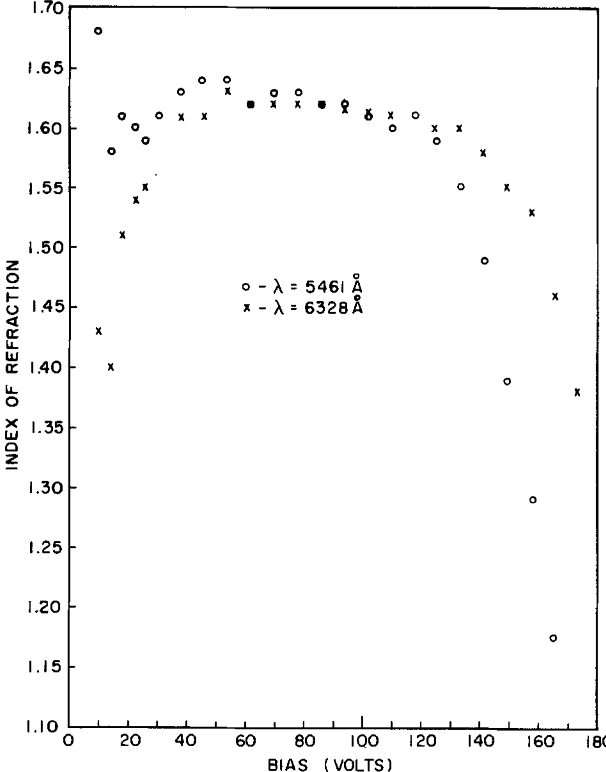

Fig. 10. Index of refraction of GaP-oxide films as a function of anodization voltage, in acidic (pH = 2.8) water determined ellipsometrically on the same sample with 2 different wavelengths of light: 5401Å (○) and 6328Å (×).

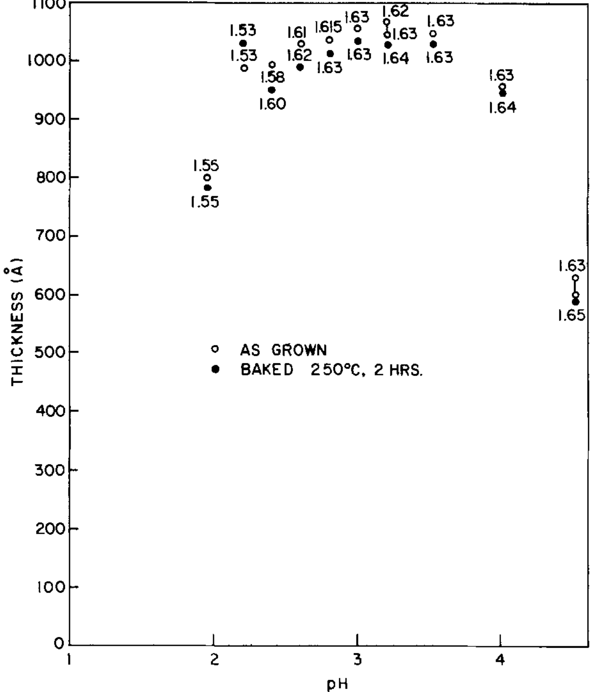

Fig. 11. Thickness of GaP-oxide films grown at a constant bias of 100V, as a function of the pH of the acidified water electrolyte. The figures near the symbols denote the index of refraction before (○) and after (●) a 2 hr, 250°C bake.

In order that the effects of water on anodized and baked GaP might be observed, 2 samples with oxides 750 and 2000Å thick were immersed in deionized water for a period of 4 weeks. After an initial loss of about 20Å during the first 2 or 3 days, the sample remained covered with an oxide which showed a tendency toward increasing thickness. Owing to its nonuniform appearance, however, no exact thickness measurements were obtainable.

Anodic oxidation in basic [NH_4OH] water: GaP.—As was found with GaAs, anodization of GaP in water at pH of 10-11 can yield relatively thick surface oxides as an end product. However, again as with GaAs, the high solubility of the oxide in the high pH electrolyte causes large errors when attempts are made to reproduce an oxide thickness-voltage plot (*i.e.*, very short delays in removing the sample from the solution and rinsing it can introduce large errors due to the severe etching of the formed oxide). It is therefore recommended that this pH range be considered more for its electroetching potential than for its oxide growth capability.

Anodic oxidation in near neutral [$(NH_4)_2HPO_4$] water: GaAs.—Because deionized water (*i.e.*, 16 megohm-cm) has extremely low conductivity, it is very difficult to achieve an anodization of GaAs or GaP at moderate voltages. It was therefore decided to attempt to modify the conductivity of the deionized water without going very far in either the acidic or the basic direction. This is easily accomplished by the use of the ammonium acid phosphate salts, and we chose to examine $(NH_4)_2HPO_4$ as the additive; a 0.1*N* aqueous solution of this reagent will automatically adjust to a pH of 7.8. When a constant voltage anodization at 100V was attempted, the classic rapid current falloff was observed and a gold-colored oxide (*i.e.*, 2000Å) was found on the sample. Adjusting the pH of the solution to 7.15 by the addition of H_3PO_4 also yielded good oxidation. It appeared that some slight etching of the oxide occurred in the original pH 7.8 solution, and less in the 7.15 pH solution. A further discussion of the potential of this system appears in the next section which deals with masked anodization.

Restricted-area anodic oxidation: GaAs and GaP.—All anodizations described thus far were performed by immersing the samples in the electrolyte and anodizing the entire exposed surface area. Subsequent to anodization photolithographic processing has been utilized to define specifically required oxidized and nonoxidized regions of the surface for further device fabrication needs (13). Thus certain implied restrictions were placed on the condition of the sample to allow for this processing approach (*e.g.*, no nonoxidizable ohmic contacts were to be exposed). In addition, it had been noted (13) that in the development of the photoresist (*i.e.*, AZ-111) the developing solution was caustic enough that both the exposed photoresist and the underlying grown oxide were removed simultaneously. Although this single develop-etch process simplifies the operation of oxide pattern generation, it provides for a less controlled geometry in that undercutting of the oxide is a severe problem when one attempts to achieve fine line definition. When a negative resist was used with a nonalkaline developer, the single develop-etch step was eliminated. However, it was difficult to control the amount of oxide undercutting during the oxide etch step.

As an alternative to using oxidation first and then photolithography, an experiment in reversing the order (*i.e.*, first photolithography and then anodization) was attempted. When this was performed in the 30% H_2O_2 electrolytic system, it was found that the photoresist could survive only for seconds because of the strong oxidizing action of the H_2O_2 on the organic polymer. However, when the same experiment was tried on some n-type GaAs in acidic water (pH = 2.05, 55V bias, 60 sec anodization time) with the Ealing test pattern as the geometry system, localized oxidation was observed. The sample was then placed in an acetone-containing Soxhlet extractor (after being blot-dried but not baked) and the photoresist was stripped from the sample. Subsequent baking in a nitrogen-purged oven at 95°C for 1 hr and then at 250°C for 2 hr yielded the sample shown in Fig. 12 (*i.e.*, the dark

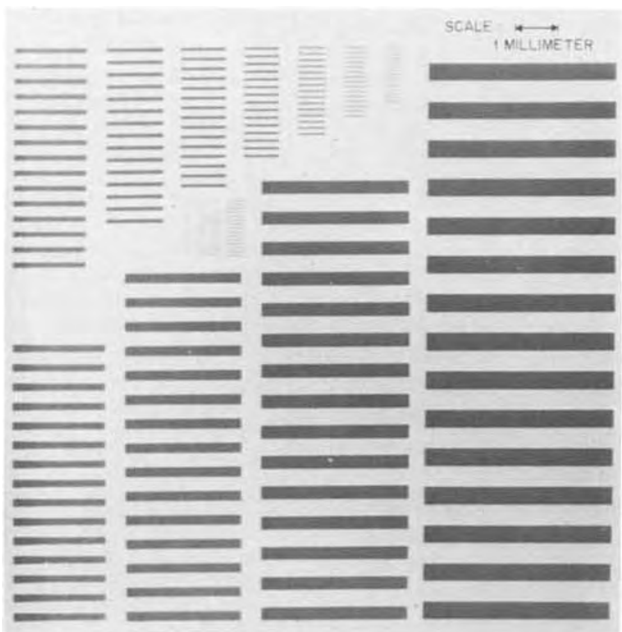

Fig. 12. A GaAs sample with deposited Ealing test pattern after anodization at 55V in water of $pH = 2.5$ and after removal of the photoresist. The oxidized areas are dark; original magnification was approximately 30X.

regions are the oxidized areas). On careful examination of the generated oxide pattern, it was determined that oxide stripes 5μ wide were well delineated on the surface of the GaAs.

When a similar experiment was attempted in basic water (*i.e.*, $pH = 10$, NH_4OH), similar oxidation results were obtained. However, when the sample was allowed to sit in the electrolyte after the voltage was turned off, the oxide redissolved. A restricted-area etching experiment was then performed whereby a photoresisted sample was anodized in basic water under conditions similar to those shown in Fig. 7; 120V for 40 sec and then 20V for 60 sec for a total of 3 complete cycles. Subsequent Talystep scanning of the sample surface (after removal of the AZ-111 with acetone) showed that the 3 cycles of oxidation and dissolution produced steps about 6000Å deep. The delineation of the Ealing pattern was only fair, however, because the AZ-111 had obviously been attacked by the alkaline water.

In either case (*i.e.*, acidic or basic water), after a few minutes exposure of the photoresist to the electrolytic solution, deterioration of the resist was observed. However, when a similar experiment was performed in water with $(NH_4)_2HPO_4$ as the conductivity modifier, oxidation was observed; and negligible attack occurred on the photoresist even after 10 min exposure.

Anodic etching: GaAs and GaP.—Up to this point, the discussion has centered about the anodization of GaAs and GaP in phosphate or hydroxide solutions. Previous observations revealed that a change in the anion used for pH modification to NO_3^- or Cl^- resulted in severe inhibition of oxide growth (2). A more detailed examination of this effect indicates that electrolytic etching takes place in the presence of these two anions (*i.e.*, the oxide never really grows very thick before it is dissolved in the electrolyte). The contamination level required before an anion will cause the system to shift from oxide growth to etching has been determined. The approach used was to take concentrated HCl and HNO_3 and dilute, 1 ml acid to 99 ml water. One drop of this diluted acid[5] was then added each time to about 400 ml of H_3PO_4-acidified water, preset at a pH of 3. An anodization

[5] It was found that 40 drops were equivalent to 1½ ml.

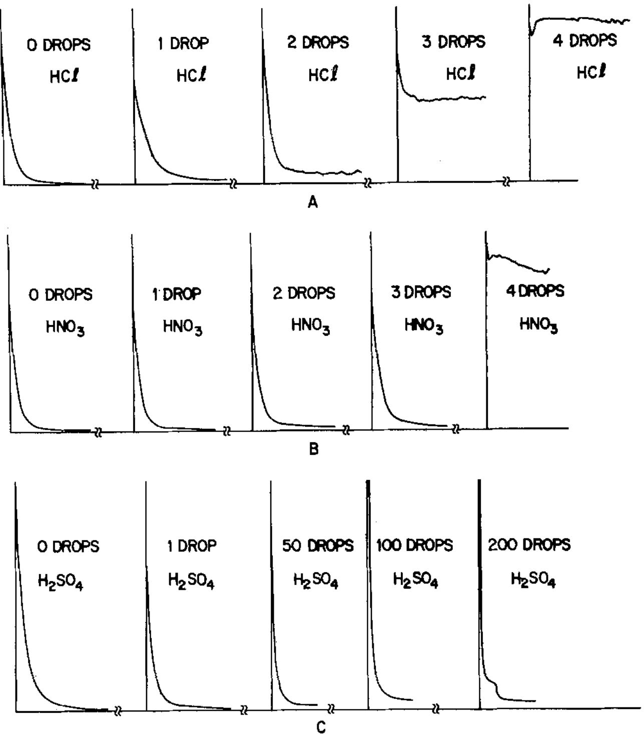

Fig. 13. Current-time curves for a constant voltage (50V) anodization of n-type ($N_D - N_A \approx 1 \times 10^{18}$ cm^{-2}) GaAs in acidic ($pH = 3$) water. (A) Contamination with dilute HCl where each drop of additive provided 4.4×10^{-6} moles of HCl. (B) Contaminated with dilute HNO_3 where each drop of additive provided 6.2×10^{-6} moles of HNO_3. (C) Contaminated with dilute H_2SO_4 where each drop of additive provided 6.8×10^{-6} moles of H_2SO_4.

curve (constant voltage) was then generated using a new piece of standard n-type, silicon-doped GaAs with $|N_D - N_A| \approx 1 \times 10^{18}$, at a fixed 50V bias. Figure 13 A and B are the current-time curves of the samples after zero to four drops of diluted acid were added to the electrolytic solution. Note, in Fig. 13A, that there was a very gradual increase in the saturation current for the HCl-contaminated solution from almost the first drop, but that there was a large shift on the addition of the third and fourth drops of contaminant. The HNO_3-contaminated system did not appear to respond until at least the third drop, but by the fourth drop it reacted severely. Considering that one drop of added dilute solution caused an impurity level of about 0.2-0.3 parts per million, it appears that at approximately one part per million of either NO_3^- or Cl^-, radical effects are observed.

Because not all acidic anions are deleterious to oxide growth (*e.g.*, phosphate, tartrate, citrate), it was decided to examine H_2SO_4 to determine the effect of the sulfate anion. Figure 13C shows that very little effect on the anodization curves was observed up to about 100 drops of diluted H_2SO_4 and that at 200 drops, a moderate effect was beginning to emerge. Clearly, the system can tolerate almost two orders of magnitude more sulfate ion than it can either chloride or nitrate ion.

Going one step further, the conditions for straightforward electrolytic etching of GaAs and GaP in dilute solutions of HCl and HNO_3 have been studied. Table I is a summary of the etching characteristics of both GaAs and GaP in these reagents as a function of acid concentrations and current densities. An analysis of these data combined with impressions obtained on visual examination of the surface after etching can be summarized as follows: (*i*) A current density of 40 mA/cm^2 and above "pulverizes" the surface, leaving a black-appearing residue on the surface. (*ii*) A current density of 2 mA/cm^2 barely attacks the surface, only

Table I.

Run number	Acid	Sample*	Concentration (normality)	Sample surface area (cm^2)	Orientation	Current** (mA)	Voltage (V)	Amount removed (Å)	Electron conversion efficiency (%)
1	HNO_3	GaAs	1	0.5	(100)	5.0	1.6	3,750	12.5

delineating some of the residual polishing scratches. (*iii*) The most efficient current density for good electrolytic etching is between 10 and 20 mA/cm^2.

Discussion

Analysis of electrical control parameters.—Until this point only the phenomenological observations made during the anodization of GaAs and GaP have been described. In this section an attempt is made to obtain better understanding of the anodization processes by developing a set of current-voltage-time equations based on a very simple linearized equivalent circuit, shown in Fig. 14. In this circuit the oxide resistance is represented by a variable resistance, r, which during anodic oxidation varies from essentially zero to extremely large values while during anodic etching remains very small.

From the two basic equations:

Ohm's law

$$V = I(r + R) \quad [1]$$

where r and R are the resistances of the oxide and of the solution, respectively, and

Faraday's law

$$r = K \int_0^t I(t)dt \quad [2]$$

where the constant K includes all parameters assumed to be constant, such as the geometrical factors, the oxide composition, resistivity, and electron-to-oxide conversion efficiency, etc. The time-dependent form of Ohm's law which results is

$$\frac{\partial V}{\partial t} = \left(R + K \int_0^t I(t)\,dt \right) \frac{\partial I}{\partial t} + KI^2 \quad [3]$$

For the case of constant current, $I = I_a$, the solution of

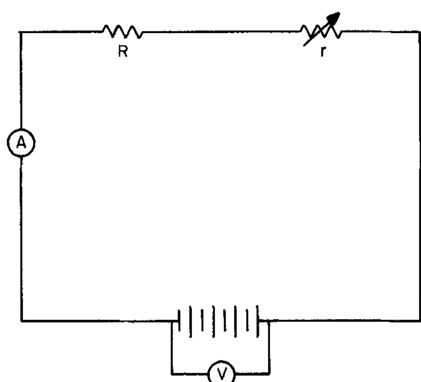

Fig. 14. Simplified circuit diagram of the anodizing system: *R*, resistance of the electrolyte; *r*, resistance of the oxide layer; *V*, applied bias; *A*, current following.

Eq. [3] is

$$V = KI_a^2t + I_aR \quad [4]$$

For the case of constant voltage, $V = V_a$, Eq. [3] reduces to

$$(r + R) \frac{\partial I}{\partial t} + KI^2 = 0 \quad [5]$$

which has a solution

$$I = \sqrt{\frac{V_a^2}{R^2 + 2V_aKt}} \quad [6]$$

or with proper substitutions

$$r = \sqrt{R^2 + 2V_aKt} - R \quad [7]$$

The voltage drop across the oxide, V_o, is then

$$V_o = V_a \left(1 - \frac{R}{r + R}\right) \quad [8]$$

One can now readily see, that by taking the derivative of Eq. [4], the time variation of voltage at constant current is a constant, which is exactly what was observed in the data of Fig. 2. Since in this analysis it was assumed that the resistivity, among other factors, was held constant in order to yield the linear voltage-time dependence, the experimental verification of this linear dependence implies that the resistivity of the growing film is constant under the constant-current anodization conditions studied here.

Also note, from Eq. [6], that the current-time relationship, at constant voltage, is a relatively complicated expression. Whereas previously an exponential dependence of current on time had been assumed (2), one can now see that an inverse square root form of dependence on time could be governing the situation. The extremely rapid current falloff in the initial stages of anodization is now recognized to be due to the operation of the parameter K (which has a value of about 10^5 ohms-coulombs^{-1}) on t in Eq. [6].

In utilizing the equivalent circuit shown in Fig. 14, the situation has been drastically oversimplified. The assumption is made for example, that R is a simple constant, that there is no voltage drop in the semiconductor, and that there is no charge storage in the oxide. These simplifications have allowed a working basis from which to start. These corrections may now be incorporated into the equations just developed.

Since the simple properties of concentrated acids and bases are well known (15), one can easily determine that the reagent concentrations for the anodic oxidation systems under study are approximately 0.002M for H_3PO_4 and 0.02M for NH_4OH. In Tables II and III are listed the resistivity, equivalent conductance, and pH as functions of molarity of H_3PO_4 and NH_4OH solutions, respectively (only values up to about 10M are listed). On the basis of these data, one might

postulate that: (*i*) The simple solution resistance for the caustic system should be about 5 orders of magnitude higher than for the acid system used, and (*ii*) because the minimum in the acid system resistivity is close to the 2×10^{-3}M determined for the electrolyte concentration used, this should be the governing factor in the shape of Fig. 5.

Unfortunately, the data indicate a factor of only about 10 difference in our anode-to-cathode electrical resistance (*i.e.*, approximately 30-3 kohms for base and acid, respectively) and not the factor of 10^5 predicted. This higher resistance in the caustic system could also be involved in the very rapid voltage increases noted in Fig. 8. Note that whereas Table II predicts a factor of 20 increase in resistance between $pH = 2.15$ and 1.5, the data in Fig. 5 show that there is a drop in ultimate thickness of about a factor of 3. Unquestionably, the resistance of the solution is an important factor in the control of oxide formation, but it is not the total answer.

Examining the question of field distribution in going from the solution into the solid anode, one finds that at least five "resistances" must be taken into account: the depletion region at the liquid-oxide interface, the oxide itself, the depletion width in the semiconductor, the resistance in the bulk of the semiconductor, and the contact resistance between the semiconductor and the aluminum-tipped tweezers. One can dispense with the bulk and contact resistances by assuming that they are constant and can be included in R of Fig. 14. It must be kept in mind, however, that a large change in the free carrier concentration in the semiconductor could introduce an appreciable amount of bulk series resistance, thereby altering the field distribution available for oxidation at the surface. For this reason one should expect moderate effects on the position of the thickness-voltage curve (such as that shown in Fig. 9) for samples with lower or higher free carrier density than was used to generate any of the voltage thickness curves in this paper.

The three remaining resistances to be considered are the two depletion regions at the liquid-oxide and oxide-semiconductor interfaces and the oxide resistance itself. It was shown recently (16) that when an n-type electrode is used as the anode in either of these electrolytes, a reverse biased Schottky diode situation is achieved. One can therefore expect that the additional voltage drop across the depletion layer in the semiconductor will also cause variation in the position of voltage *vs.* thickness plots as the doping density of the semiconductor varies. Therefore, in order to be more thorough, one would have to account for this additional voltage drop (V_b) in Eq. [8] by subtracting it from V_a thus

$$V_o(t) = (V_a - V_b)(r(t)) \quad [9]$$

One possible way to minimize this doping level effect is to generate free carriers optically, with high intensity light of the proper energy.

Similarly, if one examines the solutions being used for these oxidations one finds that there are 1.1×10^{18} and 5×10^{17} ionized molecules/cm³ for the H_3PO_4 and NH_4OH solutions, respectively. Again, depletion regions are formed on the solution side of the electrolyte-oxide interface because of the higher dielectric constant of water [80 for pure H_2O as against 11 and 10 for GaAs and GaP, respectively (15, 17)]. Also, the caustic solution will have a larger voltage drop than the acid solution because of the lower free charge density in the former solution. Consideration of the voltage drop, V_s, across the depletion region on the electrolyte side of the solution-oxide interface results in an additional modification to Eq. [8] shown as

$$V_o = (V_a - V_b - V_s)(r(t)) \quad [10]$$

Earlier in this section we concluded that the resistivity of the oxide was a constant because of the linearity of the voltage-time plot of Fig. 2. This does not necessarily mean, however, that the oxide is absolutely uniform in the lack of distributed charge. On the contrary, some recent results (18) concerning the conduction mechanism for oxides indicate the presence of large quantities of trapped charges in the oxide. If this is so, then on the average, the resistivity of the oxide can be a constant, but the local field in the oxide does not necessarily have to be constant. Therefore, as the oxide becomes thicker, the field nonuniformities can become appreciable; and a stage is finally reached where nonuniform oxide growth will occur. The authors realize, however, that this is not the full explanation of the nonuniform coloration on the 200V samples. As was mentioned earlier, films grown at applied biases up to about 180V for GaAs and 125V for GaP in acidic baths had constant refractive indexes (1.81 and 1.60, respectively), but above this voltage range the apparent refractive index began to deviate markedly from these values (see Fig. 10). We believe this deviation is due to the formation of a peculiar interface region, which is neither well defined nor well understood, but which interferes with a good specular reflection from the oxide-semiconductor interface.

In the analysis presented here, all of the charge carriers in the anodization system have been treated identically, and differentiating between electronic and ionic current has been avoided. Obviously, simplification has been employed again in order to make the problem tractable. Because the specific ionic species moving in and through the oxides are not known (from either the semiconductor or the electrolyte side), it would be foolhardy to attempt an in-depth analysis of the drift effects that most assuredly play a role in the anodic oxidation of these materials. However, the following can be done as a first attempt in this direction. The field across the oxide that causes ionic drift of the oxidant is

$$E_o = \frac{V_o}{d} \qquad [11]$$

where d is the thickness of the oxide. Note that the slope of the thickness *vs.* applied bias curves (see Fig. 3 and 9) is d/V_a, the slopes being 20 and 12 Å/V for GaAs and GaP, respectively. In obtaining the data for Fig. 3 and 9, heavily doped material (*i.e.*, $\sim 1 \times 10^{18}$ cm^{-1}) was used and therefore V_B was approximately $\leq$ 10V (17). Because high-conductivity solutions were used, V_s can be expected to be negligibly small. Therefore, at $t = \infty$ under constant voltage conditions

$$V_o = V_A - 10 \qquad [12]$$

but at high applied voltages

$$V_o \approx V_A \qquad [13]$$

and one can therefore write

$$E_o = \frac{\frac{1}{d}}{V_o} \cong (\text{slope})^{-1} \qquad [14]$$

This means, then, that for GaAs and GaP, $E_o \geq 5 \times 10^6$ and 8×10^7 V/cm, respectively, and one might consider these to be the critical fields necessary for oxide growth to take place.

It is hoped that some future studies will help to elaborate the details of the mechanisms interactive in this area.

Conclusions

Information is reported regarding the anodization of GaAs and GaP in aqueous solutions, whereby one can obtain either controlled oxide growth or controlled electrolytic etching. By replacing the older (*i.e.*, aqueous H_2O_2) approach with the simpler, cheaper water system, one eliminates the problems of spontaneous electrolyte decomposition at the platinum cathode. Also, because of the absence of gas generation, the need for the baffle between the anode and the cathode has disappeared and apparatus requirements have been simplified still further. In addition, since one no longer need purchase a commercial product (*i.e.*, H_2O_2) from an outside vendor, it is now possible to have total control of all aspects of the electrolyte preparation.

The influence of a graded region at the semiconductor oxide interface is seen in the anomalous ellipsometry values obtained on samples grown at high voltages. More work will have to be done in order to explain these effects.

Acknowledgments

The authors would like to extend sincere thanks to the many colleagues whose discussions and comments were helpful to us. We especially wish to thank D. L. Rode for his analysis that led to the development of the *I-V-t* equations, D. E. Aspnes for his assistance with ellipsometry problems, E. H. Nicollian for discussions on the charge in the oxide, F. K. Reinhart and W. C. Niehaus for discussions regarding the depletion layers at the two oxide interfaces, D. L. Deppen for his preparation of the photoresist pattern used in restricted-area oxidations, and A. P. Pisarchik for his general help on this project.

Manuscript submitted Sept 29. 1975; revised manuscript received Feb. 9, 1976. This was Paper 282 presented at the Miami Beach, Florida, Meeting of the Society, Oct. 8-13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were partially assisted by Bell Laboratories.

A Mechanism for Generation of Pulsating Growth and Nonrotational Striations during Initial Transient of Solidification

H. U. Walter

Department of Physics, University of Alabama, Huntsville, Alabama 35807

ABSTRACT

A system of on-facet and off-facet striations was observed in selenium-doped ($10^{19}/cm^3$) InSb that was prepared at g-levels of 10^{-4}-10^{-6} during Skylab mission SL-4. The off-facet striations could not be explained in terms of existing theory. A new concept is derived that considers the decrease of liquidus temperature in the initial transient region due to buildup of a diffusion layer. This model not only explains off-facet striations in space-grown InSb, but may also be the basis of certain nonrotational striations that are observed in crystals processed on the ground.

Redistribution of solute resulting from directional solidification of a binary solution under conditions of complete mixing has been treated mathematically by Gulliver (1), Scheuer (2), Hayes and Chipman (3) for normal freezing, and by Pfann (4) for zone melting. Both normal freezing and zone melting have been analyzed by Tiller *et al.* (5) with the assumption that convection in the liquid is negligible. Further treatment of this subject was given by Smith *et al.* (6). Effects of natural and forced convection on macrosegregation have been calculated by Wagner (7) and others.

Constant rate of solidification and/or constant segregation coefficient throughout the process of solidification is assumed with these theories. An additional difficulty associated with their application is due to the fact that both of the extreme cases, complete mixing and solely diffusion-controlled conditions, are difficult to verify in practice. Complete mixing can only be approximated due to the difficulty of effectively stirring the diffusion layer; whereas some convective mixing is observed even with crystal growth under stabilizing thermal gradients, solidification of conductive melts in transverse magnetic fields, and with growth at low Rayleigh numbers. The latter includes the use of baffles and growth in capillaries.

This transient fluid flow, which we are unable to control on earth, is one of the major causes of compositional microinhomogeneities (striations) that we observe in virtually all material prepared by directional solidification of multicomponent systems. Aside from inhomogeneities that are due to constitutional supercooling, grain boundary segregation, solid-liquid interface facet formation, solid-state diffusion of impurities to defect clusters, changes of melt composition, inclusions and cavities, microinhomogeneities are generally attributed to growth rate variations and changes of diffusion layer thickness. Such changes may be caused by the following effects: (*i*) thermal effects such as thermal instabilities, Joule and Peltier heating and Peltier cooling of interfaces, thermal asymmetry in conjunction with crystal rotation (rotational striations), (*ii*) mechanical effects, *e.g.*, vibrations, mechanical instabilities due to imperfect pulling mechanisms, (*iii*) pressure effects due to variations of isostatic pressure in confined geometries and also vibrations, (*iv*) electrical effects such as electromigration, and, most importantly, (*v*) fluid flow effects. Fluid flow may be due to stirring, both thermally and compositionally induced gravity-driven convection, surface tension gradients (Marangoni-flow), volume changes upon solidification, Coriolis forces, instabilities of liquid meniscus both at seed and crucible walls ("meniscus jumps").

Key words: macro- and microsegregation, indium antimonide, nonrotational striations, space processing.

Owing to their transient nature, most of the impurity striations caused by these effects have been described qualitatively only. Quantitative models are available for a few specific cases. For diffusion-controlled conditions step function changes of solidification rate have been treated by Tiller *et al.* (5) and Smith *et al.* (6). Sinusoidal growth rate oscillations have been analyzed by Lewis (8) and Carruthers (9) and the effect of sinusoidal temperature fluctuations by Hurle *et al.* (10, 11). Variations of melt composition and changes of diffusion layer thickness during steady-state crystallization were treated by Prim (12) and Burton, Prim, and Slichter (13), respectively. Reviews are given by Carruthers and Witt (14) and Slichter and Burton (8).

Other theories on impurity striations consider adsorption of dopant impurities at the solid-liquid interface (15); theories by Landau (16) and Milevski (17) postulate periodic buildup and solidification of constitutionally supercooled layers. The latter theories are, however, in disagreement with the experimental finding that interfaces become corrugated as soon as constitutional supercooling develops. In addition, diffusion layer thickness is of the order of microns only, larger spaced striations could not be considered on the basis of this mechanism.

As a result of the space program of the National Aeronautics and Space Administration, theories on solidification of quiescent melts could be tested by performing normal freezing experiments on board of orbiting space stations such as Skylab and ASTP. With the exclusion of gravity-driven convection, it was expected that macrosegregation would closely follow profiles as predicted by Tiller *et al.* (5) and Smith *et al.* (6); microsegregation was expected to be minimal. Ideal, diffusion-controlled, steady-state segregation was indeed observed with InSb doped with tellurium to $10^{18}/cm^3$ (18) whereas considerable microinhomogeneities were present in germanium crystals doped with gallium to $8 \cdot 10^{16}$ atoms/cm^3 (19); both experiments were conducted on board Skylab.

A systematic set of impurity striations was observed in InSb doped with 10^{19} atoms of selenium per cubic centimeter melt. This sample was also prepared on board Skylab during Skylab mission SL-4 at g-levels of 10^{-4}-10^{-6}. Since the observed striations could not be understood in terms of existing theory, an attempt is made in the following to explain these segregation effects in terms of a new model.

Experimental Observations

The selenium-doped InSb crystal described in the following was prepared on board Skylab by seeded, directional solidification of a pendant drop. Experimental details are described elsewhere (20, 21). Growth direction was approximately [110]; length of

space-grown sample was about 2 cm, maximum diameter 1 cm. Interface shape was convex throughout solidification. Average selenium concentration in the starting material (seed) was $10^{19}/cm^3$ as determined by resistivity and Hall measurements.

High resolution differential etching (22) of longitudinal sections reveals a system of very distinct impurity striations in the first half of the crystal as shown in Fig. 1 and 2. Orientation of the section shown in Fig. 1 is (111)A. Usually (211) cuts are investigated, the major reason being that differential etching of (111)A surfaces also reveals crystal defects such as grain and twin boundaries, dislocations, and vacancy clusters. In our case this was not a severe limitation since no grain boundaries were present; dislocation density was of the order of $100/cm^2$ in the first part of the crystal and decreased to virtually zero in the last half of the sample.

Three types of striations can be discerned in the crystal section shown in Fig. 1. Rotational striations in the Czochralski-grown seed in the lower half, and in the space-grown section (upper half) off-facet striations at right and striations associated with the formation of a peripheral (111)B solid-liquid interface facet at left. Etch pits decorating the outcrops of dislocations are also visible. Off-facet striations are again shown at larger magnification in Fig. 2. Only off-facet striations are considered in the following.

Off-facet striations extend 5-7 mm into the crystal. The very first off-facet striations observed within 0.5 mm of regrown material are most distinct. Beginning in the center of the crystal, they become increasingly shallow and degenerate slowly into multiple oscillatory-type impurity bands until they disappear completely. This striated section is followed by a homogeneously doped region of about 5-8 mm after which increasingly sharp striations reappear towards the end of the sample.

Fig. 1. Etched (111)A longitudinal section of InSb(Se) single crystal (sample E3-SL4). Arrow indicates demarcation between Czochralski-grown seed at bottom with rotational striations and space-grown section. (111)B solid-liquid interface facet striations at upper left, off-facet striations at upper right. Etch pits due to In-dislocations. Magnification approximately 17X. Inset (b) Meltback interface, 125X.

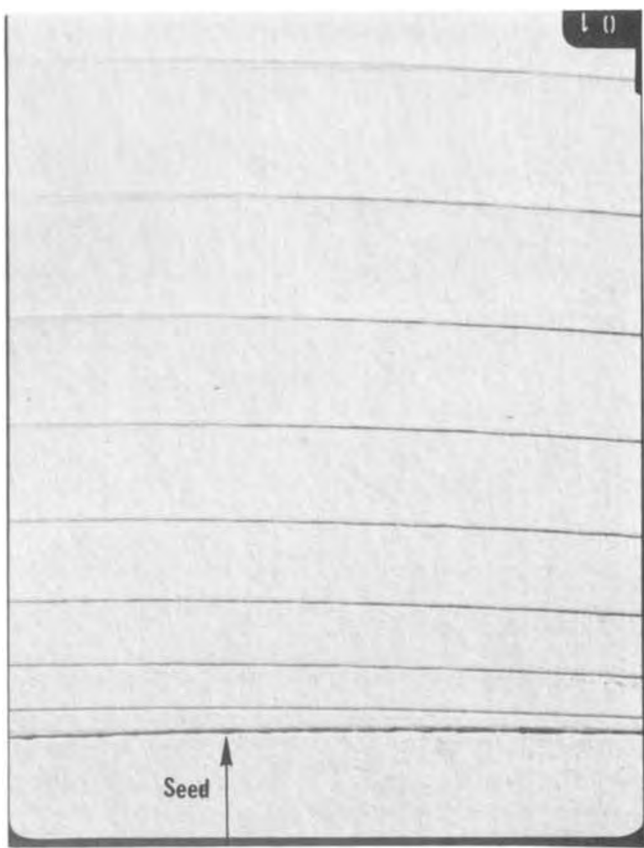

Fig. 2. Striations in off-facet region of space-grown crystal. Multiple striations begin to appear at $N = 4$ on left side toward center of sample, on right side toward periphery at $N = 5$. Magnification 53X.

Tolanski multiple beam microscopy reveals the relief of the surface associated with the first off-facet striations (Fig. 3); 0 denominates the interface between seed and space-grown crystal. Surface depressions that mark striae become increasingly shallow as one proceeds along the direction of growth. A similar area as in Fig. 3 is shown in the dual beam interferogram in Fig. 4. Higher contrast and much more defined interference fringes that are due to reflection from the space-grown material indicate much improved chemical microhomogeneity as compared to the Czochralski-grown seed material. In addition, we observe, especially for the first striations, that the shape of fringes between striae is asymmetrical and S-shaped, rather than U-shaped. Spacing of striations is plotted in Fig. 5; only the very first, singular ones are included.

Since the melt was completely uncontained during solidification, additional information concerning variation of dopant concentration in the bulk could be obtained from surface features. The termination of bulk striations on the surface of the sample is marked by annular grooves for sharp striations and smooth surface undulations for shallow and oscillatory striations as they occur later in the sample. Discontinuous meniscus rearrangements during solidification, meniscus jumps, a possible mechanism for growth discontinuities could be ruled out on the basis of this observation since meniscus jumps would always result in sharp surface grooves and not undulations. In addition, no orientation dependence of surface features could be observed; steps on surface facets and grooves on the cylindrical portions coincide. Wetting instabilities would not occur simultaneously for faceted and cylindrical regions and it can, therefore, be concluded that these features result from discontinuities in bulk solidification and not vice versa.

Fig. 3. Off-facet striations in space-grown InSb(Se); Tolanski multiple beam interferogram of etched, longitudinal section. Note the decreasing fringe deflection-peak sharpness with increasing order number of striations. Dark streak is fault in Fizeau plate. Magnification 100X.

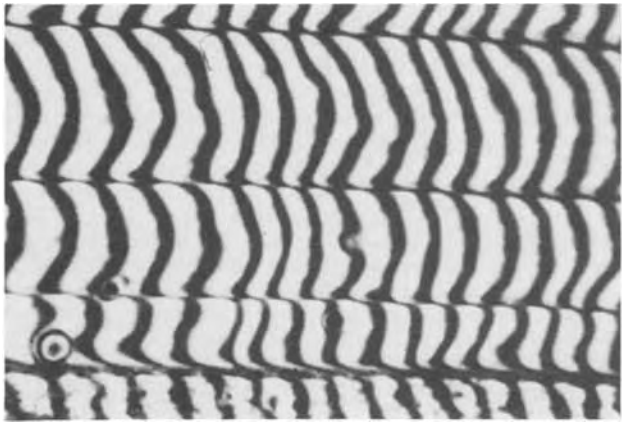

Fig. 4. Off-facet striations in space-grown InSb(Se); dual beam interferogram of etched, longitudinal section. Fringe contrast in space-grown section is much enhanced due to improved microhomogeneity. Magnification 140X.

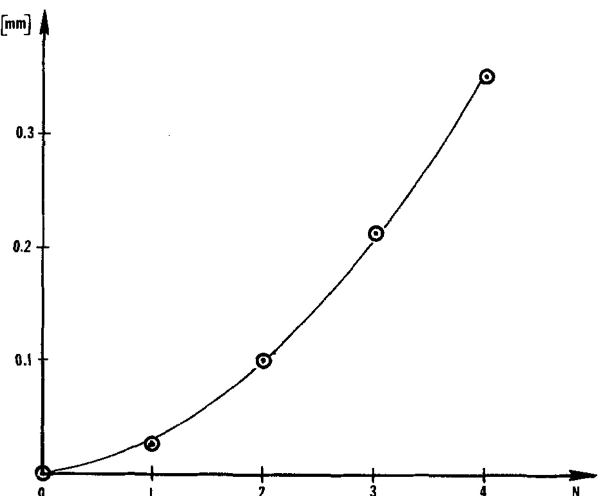

Fig. 5. Distance of singular striations from meltback interface vs. order number *N* (measured at periphery of crystal).

Further causes of off-facet striations to be considered are mechanical instabilities, thermal instabilities, and surface tension gradient-driven convection (Marangoni flow). Both gyro and temperature data that were obtained for the period of solidification were analyzed; no events that could possibly account for the growth discontinuities could be detected. An average solidification rate of 6.9-2.9 μ/sec could be calculated from cooldown rate (0.6°C/min) and gradients in the melt (min, 14.5°C/cm; max, 35°C/cm) that were obtained experimentally and by computer analysis of the system. To account for the first striae, sudden heating or cooling of the interface would have to take place at the following times after solidification is initiated. For $R = 6.9$ μ/sec: 4 sec, 15 sec, 31 sec, 52 sec, 75 sec, 103 sec, 134 sec, etc.; for $R = 2.9$ μ/sec: 10 sec, 35 sec, 73 sec, 124 sec, 179 sec, 245 sec, 1320 sec, etc. Fluid flow cycles that take minutes for each cycle with a distinct thermal discontinuity preserved are very unlikely especially with a melt that is a good thermal conductor. A fluid flow pattern of this type would also be reflected in the interface morphology (depressions where hot melt descends) and in radial intensity variations of striations. Since none of these features is observed, fluid flow, including Marangoni flow, can be ruled out as the cause of striations.

The systematics of the observed striation pattern implies a basic underlying mechanism. It comes to mind that earth-grown samples also exhibit features that we do not thoroughly understand. Dickhoff (23), for example, reports what he terms "fundamental" striations in germanium crystals. Possible known causes, such as pulling, vibrations, rotation, etc., were excluded in this experiment and he concludes that "some striations may be due to some fundamental property of the growth process." A multitude of small amplitude, periodic compositional variations with periodicity of 5 to several hundred microns is always observed in doped crystals grown from the melt. In crystals grown by the Czochralski technique without rotation, they are referred to as "nonrotational" striations (*e.g.*, 24-26). An example of such striations is shown in Fig. 6 for a nonrotated ground-based control sample of InSb(Se). They are presently attributed to convective flow mainly (*e.g.*, 27-31). However, a one

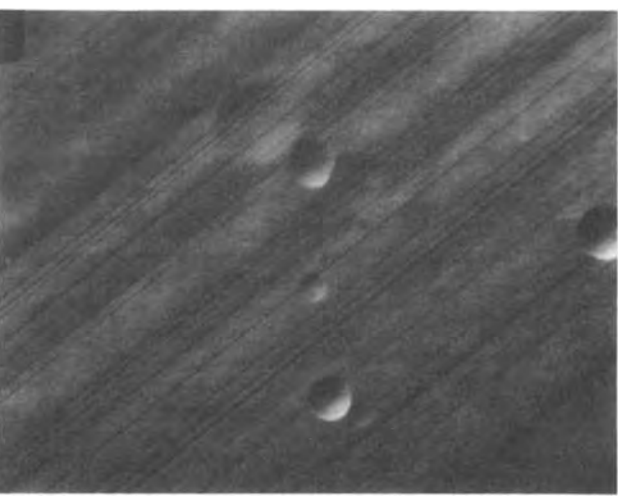

Fig. 6. "Nonrotational striations" in the off-core region of a single crystal of InSb doped with selenium (35 mg Se/85g charge). $(2\bar{1}\bar{1})$ longitudinal section of crystal pulled without rotation, growth axis [111]B. Numarski interference contrast micrograph of polished and etched surface. Magnification 224X.

to one correlation could not always be shown (*e.g.*, 23, 32-36). Additional underlying basic principles cannot be excluded.

Presuming that fluid flow was negligible, meaning that the diffusion layer was undisturbed, the off-facet striations observed in the space-grown InSb(Se) sample cannot be explained in terms of existing theory. A concept is presented in the following that satisfies both the occurrence as well as the sequence and intensity of these striations.

Theory

The effective distribution coefficient k_{eff} is defined as follows

$$k_{eff} = \frac{C_{s(act)}}{C_{l(act)}} \quad [1]$$

where $C_{l(act)}$ is the bulk concentration in the liquid far enough from the growing interface so that concentration gradients are negligible, $C_{s(act)}$ is the concentration in the solid. Values reported for the effective off-facet segregation coefficient for Se in InSb range from 0.17 to 0.35 (37). k_{eff} is affected by experimental conditions such as the rate of stirring, the rate of solidification, crystallographic orientation, and concentration of solute and impurities in the melt.

The equilibrium distribution constant k_o is given by

$$k_o = \frac{a_{s(eq)}}{a_{l(eq)}} \quad [2]$$

where $a_{l(eq)}$ is the equilibrium activity in the liquid and $a_{s(eq)}$ is the equilibrium activity of the solute in the solid. For solidification of dilute solutions at slow rates, k_o may be defined as follows

$$k_o = \frac{C_{s(eq)}}{C_{l(eq)}} = \frac{C_s}{C_T} = k_T \quad [3]$$

C_T is the concentration in the liquid directly at the interface, k_T is the interface segregation coefficient. Since $k_o = k_T \leq k_{eff} \leq 1$, the interface segregation coefficient k_T of Se in InSb may be of the order of 0.2.

During initial transient, the buildup of solute concentration at the interface as a function of interface location x at constant solidification rate R is described by the following equation (5)

$$C_T = \frac{C_s}{k_o} = C_o \left\{ \frac{1-k_o}{k_o} \left[1 - \exp\left(-k_o \frac{R}{D} x \right) \right] + 1 \right\} \quad [4]$$

where C_s is the solute concentration in the solid at the interface, D is the diffusion constant in the liquid. In deriving this equation, the assumptions were made that mass transport in the melt is due to diffusion only and diffusion in the solid is negligible.

After the initial transient, when steady-state solidification has been established, the concentration of solute in the liquid at the interface C_T is equal to C_o/k_T, where C_o is the initial concentration in the liquid. In our case with $C_o = 10^{19}/cm^3$, $k_o = 0.2$, C_T will reach a steady-state value of $5 \cdot 10^{19}/cm^3$. The growth distance x required to reach steady state depends on the growth rate. An estimate can be obtained from $x \approx 2D/(k_oR)$. Initial transient rise of solute as a function of interface location for the system InSb(Se) is shown in Fig. 7 for various growth rates.

This variation of solute concentration corresponds to a variation of liquidus temperature of the liquid adjacent to the interface. According to the equilibrium phase diagram of a binary system A,B, the equilibrium liquidus temperature is given by

$$T_E = T_o - m\,C_T \quad [5]$$

where T_o is the melting temperature of pure phase A and m is the slope of the liquidus curve. As usual, this slope is assumed to be constant.

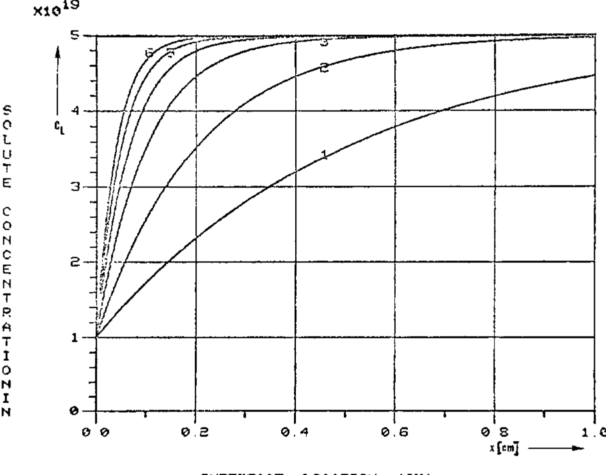

Fig. 7. Dopant concentration in liquid adjacent to solid-liquid interface as a function of interface position. System: InSb(Se); parameters, $C_o = 10^{19}/cm^3$, $D = 10^{-5}$ cm²/sec, $k_o = 0.2$, $R_1 = 1$ μ/sec, $R_2 = 2.5$ μ/sec, $R_3 = 5$ μ/sec, $R_4 = 7.5$ μ/sec, $R_5 = 10$ μ/sec, $R_6 = 12.5$ μ/sec.

The liquidus temperature T_E as a function of x can be described, using Eq. [4] and [5], by the following expression

$$T_E = T_o - m\,C_o \left\{ \frac{1-k_o}{k_o} \left[1 - \exp\left(-k_o \frac{R}{D} x \right) \right] + 1 \right\} \quad [6]$$

Melting and solidification curves (temperature *vs.* time with linear cool down or heating) were determined to estimate liquidus and solidus temperature changes. Excluding supercooling required for nucleation, solidification of InSb doped with selenium to $10^{20}/cm^3$ extends over a temperature range of approximately 20°C. The shape of the curves indicates partial mixing; temperature change associated with the initial period was 5°-10°C. Since the phase diagram InSb-Se is not available, a more conservative value of 0.21°C/(10^{19}Se/cm³) as determined by linear interpolation of melting temperatures is used in the following. Using Eq. [6] and this value, liquidus temperature changes as a function of interface position were computed as shown in Fig. 8. In our experiment, solidification was

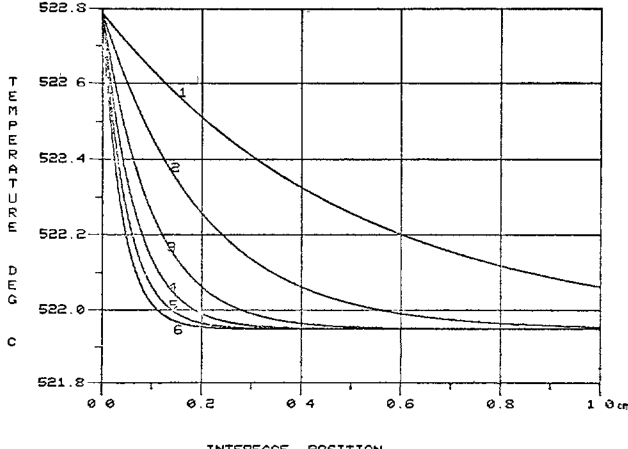

Fig. 8. Decrease of liquidus temperature due to increase of solute concentration in liquid adjacent to advancing solid-liquid interface as a function of interface position. System: InSb(Se); T_m = 523.0°C; $\Delta T/(10^{19}Se/cm^3)$ = 0.21°C. Growth rates and other parameters as listed in Fig. 7.

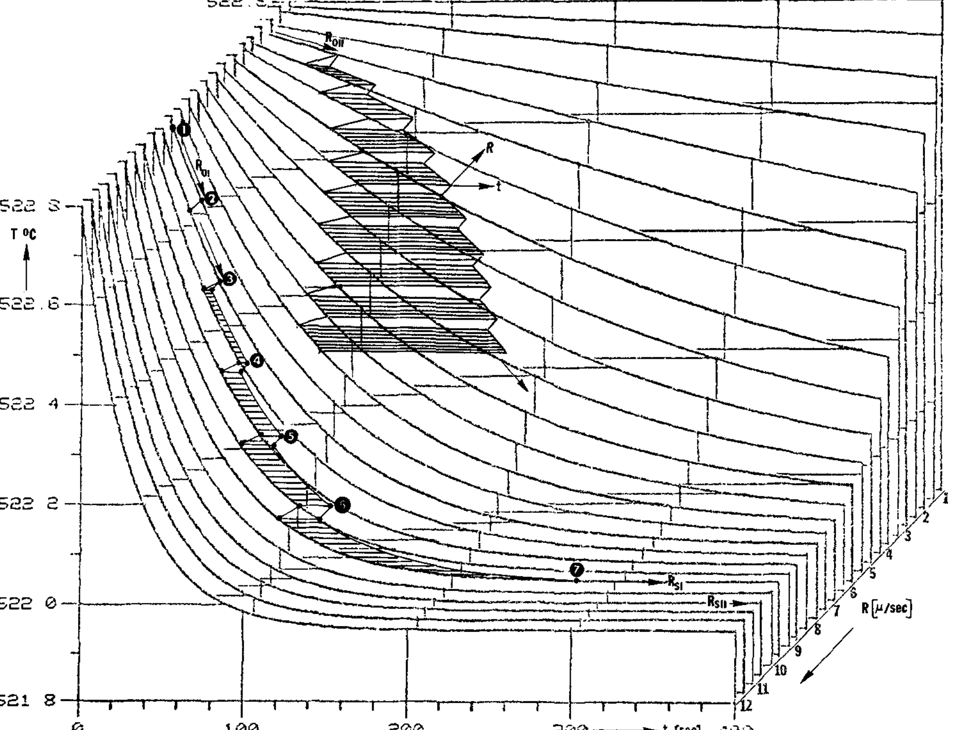

Fig. 9. Decrease of liquidus temperature in the system InSb(Se) as a function of time and growth rate R with each plot computed for constant R (Eq. [6]). Three dimensional step-by-step procedure used to determine T vs. x and R vs. x (see Fig. 10) is indicated for two cases I and II.

initiated by programmed cooldown of 0.6°C/min after a 1 hr soak period. Consequently, the rate of solidification has to be modified during initial transient of solidification owing to a decrease of liquidus temperature of 0.84°C, which corresponds to a time lag of 1.4 min.

In the following, possible cases as to how this can be accomplished are examined. Parameters for InSb(Se) are used. However, the considerations are applicable to multicomponent solidification systems with $k < 1$ in general, and, analogously to systems with $k > 1$.

Aside from shifts of the time axis that need to be considered, solidification has to proceed along the surface shown in the liquidus temperature-time-growth rate diagram in Fig. 9. Steady-state solidification rate R_s is determined by the cooldown rate dT/dt and the gradient in the melt at the interface

$$R_s = \frac{dT/dt}{\text{grad } T} \quad [7]$$

Assuming that virtually no supercooling is required to drive growth and assuming immediate response of the growth rate to alterations of the thermal situation, the growth rate R_s is modified by changes of the liquidus temperature as follows

$$R = R_s - \frac{(dT_E/dt)_R}{\text{grad } T} \quad [8]$$

Neglecting thermal inertia so that dT_{cool}/dt = const throughout solidification, the rate R_o at which growth is initiated at $t = 0$ is determined by

$$\left(\frac{dT_E}{dt}\right)_{R_o} = \frac{dT}{dt} \quad [9]$$

$$R_o \leqq R_s \quad [10]$$

Slower rate would result in increasing supercooling, faster rate is not permissible. With the assumption that virtually no supercooling is required for growth, growth rate will increase from R_o to R_s according to the condition

$$\frac{dT_E}{dR} = \text{const} \quad [11]$$

Using Eq. [6], [7], [9], and [11], variation of R with time or interface position and, consequently, variation of T_{liq}, C_T, and C_s can be determined numerically by a three-dimensional step-by-step procedure. This procedure is indicated in Fig. 9 for two cases, R_I with small $\Delta R = R_{sI} - R_{oI}$ and R_{II} with larger ΔR.

Variation of R_I, T_I, and R_{II}, T_{II} with interface location determined in this manner is shown in Fig. 10. With increasing ΔR, the curves deviate more and more from exponential functions; note the inflection points in the R_{II} and T_{II} curves. Resulting concentration profiles in the solid are given in Fig. 13, for comparison, a profile that would be obtained with R = const is included.

Even though the assumptions made concerning supercooling and response may not be realistic as will be shown in the following, experimental findings may still be in good agreement with data derived by this approach. Best agreement would be expected for dopant levels and systems where the decrease of liquidus temperature is small and the cooldown rapid and where, in addition, growth interfaces are diffuse. These conditions are closely met with the InSb(Te) Skylab experiment mentioned in the introduction (18). Decrease of liquidus temperature due to 10^{18}Se/cm^3 is of the order of 0.05°C only; a relatively

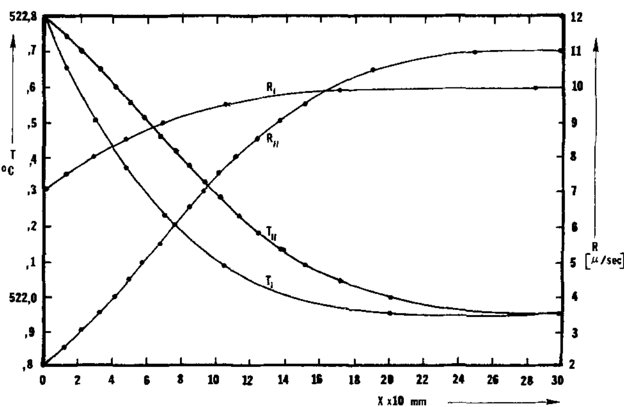

Fig. 10. Liquidus temperature and growth rate R vs. solid-liquid interface location x as determined by step-by-step procedure indicated in Fig. 9 for the system InSb(Se).

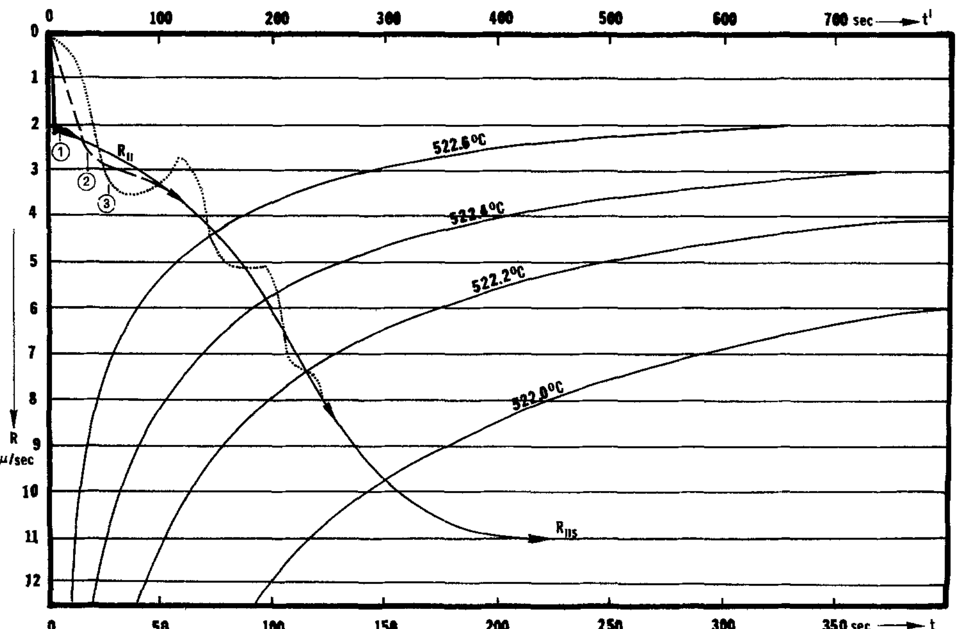

Fig. 11. Top view of T—R—t block diagram shown in Fig. 9 with isotemperature lines indicating times after which the respective liquidus temperatures are established at constant solidification rates. Different cases of growth rate variations with time t' (t' scale compressed to have correct relation with isotherms) are as follows: (A): Curve R_{II}, continuous variation of R due to decrease of liquidus temperature, step function change from $R = 0$ at $t = 0$ to R_{II}. (B): Curve ①, small undercooling required for growth. (C): Curve ②, R proportional to undercooling. (D): Curve ③, growth rate hysteresis. (See also Fig. 12.)

rapid cooldown of 2.4°C/min was employed; growth axis was [111]B; the interface was, however, concave. Details close to the meltback interface could not be resolved and the dopant profile agrees within experimental errors with an exponential profile.

As already mentioned, the assumption of a step-function change from $R = 0$ to R_0 is not realistic. More realistically, this increase will require finite time. Consequently, R will increase from zero to the balance curve (*e.g.*, R_{II}) in a manner indicated in the $R - t$ diagram (top view of Fig. 9) shown in Fig. 11 (curve 1, heavy line). Since growth at $R < R_{II}$ equals increasing supercooling, an overshoot into the region $R > R_{II}$ will result. Due to this overshoot, the thermal imbalance is reversed and one or several high frequency, rapidly decaying growth rate oscillations may result in this region. Finally, growth will proceed according to the R_{II} curve. Even though attributed to drifting of the interface during thermal soak due to thermal instabilities, similar features were observed with antimony ($10^{17}/cm^3$) and gallium ($10^{19}/cm^3$)-doped germanium solidified during ASTP-mission (38).

Considering the various theories describing molecular kinetic mechanisms for solidification, two basic cases can be discerned for our purpose: (*i*) Growth rate R is proportional to the degree of undercooling ΔT. (*ii*) Growth rate R is not proportional to the degree of undercooling ΔT. Proportionality is generally expected for diffuse interfaces, where the interface advances continuously without lateral spreading. The same interdependence is predicted for growth with screw dislocations. Growth of a perfect crystallographic flat is expected to follow an exponential law (nucleation-limited growth), the dislocation law predicts a growth rate that is approximately proportional to $(\Delta T)^2$, whereas BCF theory allows for both linear and parabolic laws. Reviews are, for example, given by Jackson (39), Bennema and Gilmer (40), and Cahn *et al.* (41). Cahn lines out that mock-lateral growth, a continuous mechanism based on lateral growth on interface terrace steps, may be most common especially when growth rate anisotropy is large. Examining both theory and experimental evidence, Cahn concludes that stepwise growth prevails at low undercooling and continuous growth at high undercooling. If different growth mechanisms are operable at different growth rates, growth rate minima and associated striations may be accentuated by enhanced entrapment of solute due to lateral spreading. Information on supercooling required to drive solidification of InSb is available only for {111} facet growth (42). Supercooling up to 6°C has been measured during growth. Systematic changes of interface characteristics with growth rate due to the tendency to approach diffuse interfaces under conditions of rapid growth and singular interfaces at slow growth may, in addition, lead to hysteresis. In this context, growth rate dependent adsorption of impurities that decrease the interfacial free energy may also be of importance.

Growth rate and concomitant liquidus temperature variations resulting from linear interdependence of R and ΔT (Fig. 12b) are indicated in Fig. 11 and 12, dashed curves ②. In analogy to minimal supercooling (Fig. 11, curve ①), one or several lower frequency sinusoidal oscillations of $R_{(2)}$ about R_{II} should be expected (Fig. 11, curve ②). In terms of liquidus temperature (Fig. 12), oscillations will be about $T_{II(2)}$ (dashed curve) and not T_{II} (solid curve) since supercooling is required for growth in this case. So far, this type of behavior has not been observed in space-grown crystals.

Nonlinear interdependence of R and ΔT (Fig. 12c) results in more initial delay (Fig. 11). Consequently, there is more overshoot into the region $R > R_{II}$. The

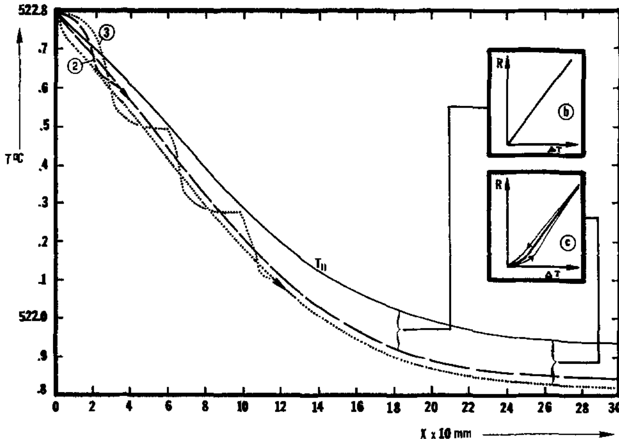

Fig. 12. Decrease of liquidus temperature as a function of interface location. (A), Continuous decrease, T_{II}, as in Fig. 10, zero undercooling. (B), R proportional ΔT as indicated in upper right; dashed curve parallel T_{II} indicates the temperature at which growth would proceed according to R_{II} (Fig. 10). Initial oscillations due to initial time lag, dashed curve ②. (C), Discontinuities (curve ③) due to nonlinear dependence of R and ΔT and eventually hysteresis as indicated in $R - \Delta T$ diagram at lower right. Dotted curve parallel T_{II} shows temperature variation required to grow according to R_{II}.

balance is reversed and the growth rate decreases to $R < R_{II}$. This process again continues until the oscillations are damped out and growth proceeds along R_{II}. Due to the relation of R and ΔT, oscillations are nonsinusoidal as long as R decreases into the nonlinear region of the $R - \Delta T$ curve.

Hysteresis (Fig. 12c), which should be more pronounced in the low growth rate region, results in pronounced growth rate discontinuities for minima of R and eventually discontinuities at maxima. This is shown schematically in Fig. 11 and 12, dotted curve ③.

Figure 1b shows the solid-liquid interface that has developed during soak (1 hr) at large magnification. Clearly this interface is not diffuse but rather composed of a multitude of crystallographic flats. Similar features indicating that interfaces did not simply reflect isotherm shape during solidification are observed with the interfaces marked by the first striae. This observation implies the possibility of growth rate hysteresis that decreases as growth proceeds and overall growth rate increases. Jackson's α-factor predicts diffuse interfaces for $\alpha < 2$ and an increasing tendency for singular interfaces for larger α. It is defined as follows: $\alpha = \xi L/RT$, where $\xi < 1$ is a geometric coefficient equal to the ratio of the nearest neighbor coordination number in the surface to that in the bulk, L is the latent heat of fusion. Not considering ξ, $\alpha = 7.7$ for InSb, which also indicates that growth interfaces tend to be nondiffuse, and, consequently nonlinear growth laws are applicable. Similarly, surface profiles of etched sections as viewed by dual beam interferometry (Fig. 4) indicate nonlinear growth at slow growth rates and growth rate hysteresis. Interference fringes are most asymmetrical and S-shaped close to the meltback interface; minima are increasingly less pronounced, as growth proceeds fringes become less asymmetrical and more and more U-shaped (Fig. 3).

Possible dopant profiles resulting from above mechanisms are shown in Fig. 13. Additional complications would be due to variation of distribution coefficients with melt composition, concentration, and growth rate. The effective off-facet segregation coefficient of selenium and InSb increases from 0.3 to 0.6 as the growth rate increases from 0.8 to 25 μ/sec (43). Also, effects due to evolution of latent heat of fusion ($\approx$ 12 kcal/mol for InSb), which should mostly result in damping of oscillations were not considered.

Conclusions

Experimental evidence has been presented that strongly suggests that growth rate oscillations and growth rate pulsations may result from kinetic supercooling during initial transient. This has been analyzed for quiescent melts and impurities with segregation coefficient $k_o < 1$. According to different models on kinetics of crystal growth, the following cases could be distinguished:

1. Supercooling is neglected; immediate response of growth to the thermal situation is assumed. Growth rate is continuously modified due to decrease of liquidus temperature during initial transient of solidification. Data were obtained for growth rate, liquidus temperature, and concentration of solute in the solid as a function of interface location by three-dimensional step-by-step numerical analysis. These data were used as baseline for the following cases.
2. Growth rate increase from $R = 0$ at $t = 0$ to R_{baseline} is not a step function change. Assuming linear interdependence of growth rate R and supercooling ΔT, sinusoidal oscillations of growth rate (frequency depending on slope of R vs. ΔT) result in the initial region.
3. Nonlinear interdependence of R and ΔT similarly results in oscillations; oscillations are, however, nonsinusoidal.
4. Growth rate hysteresis causes growth rate discontinuities (distinct striations) in the initial transient region of solidification.

To minimize effects of liquidus temperature changes during solidification in practice, rapid cool down (rapid growth) is advantageous.

Similar considerations apply for systems with impurities that have segregation coefficients $k_o > 1$, and also for terminal transient conditions. It has been observed by Bardsley *et al.* (44) for Czochralski-pulling of gallium-doped germanium that "in the later stage of growth, the diameter of the crystal steadily decreases if the power supplied to the melt is held constant." He reasons that "the rejection of gallium into the melt continually lowers the liquidus temperature of the melt, thus making the melt too hot for growth at constant diameter." This observation indicates (continuous) growth rate modulation during terminal transient or throughout solidification under conditions of partial mixing.

Oscillatory or pulsating growth may result during terminal transient as well. Growth rate variations with reversed sequence (oscillatory in the beginning and increasingly distinct towards the end) are observed within the last 2 mm in our crystal. These terminal transient variations may be explained on the basis of the same principles as for initial transient.

Clearly defined growth discontinuities of the kind observed with space-grown crystals could not be observed on earth because of gross convective disturbances. However, the same basic mechanisms are present and, therefore, "nonrotational striations" observed in earth-grown crystals may, in many instances, have to be attributed to kinetic effects.

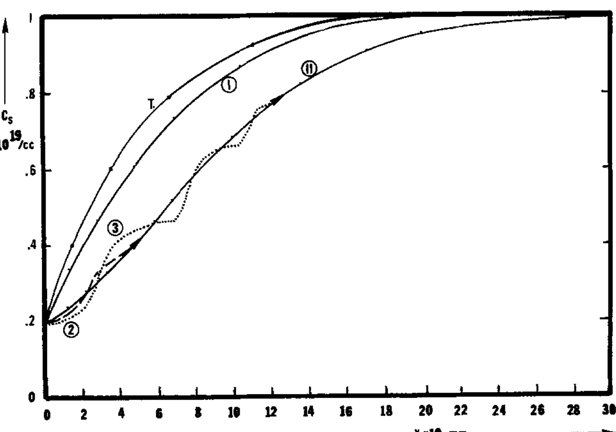

Fig. 13. Possible cases of initial transient dopant profiles when sample is prepared from a quiescent melt. Curve T, R = constant throughout solidification [computed according to Tiller *et al.* (5)], $C_o = 10^{19}/cm^3$, $k_o = 0.2$, $R = 10$ μ/sec. Poly(Methyl Methacrylate-Isobutylene) Copolymers as Highly Sensitive Electron Beam Resists

Edward Gipstein, Wayne Moreau,[1] and Omar Need

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

Methyl methacrylate-isobutylene P(MMA-IB) copolymers have been synthesized and investigated as positive electron beam results. A 75/25 composition P(MMA-IB) copolymer had a sensitivity of 4.5×10^{-6} C/cm^2 at an accelerating voltage of 15 kV. The high sensitivity is attributed to the isobutylene "weak links" in the polymer chain. The incorporation of elastomeric isobutylene groups in the copolymers was also found to improve their adhesion on siloxane substrates. The improvement of the resist performance of PMMA represents an application of polymer tailoring wherein certain deficiencies in one polymer system (PMMA) may be overcome by copolymerization with another monomer (IB) which has good radiation sensitivity, but has limited resist applicability.

The fabrication of very small component circuit elements using current photolithographic technology is limited to linewidths of about 1μ (1). Electron beams, both in theory and practice, have resolution capabilities of the order of 0.1μ or less and are being used increasingly for fabricating microelectronic devices (2-4).

The general use of electron beam fabrication techniques requires polymeric resist materials which have been designed for this process and are optimized with respect to sensitivity, resolution, and processing. While many of the present electron beam systems make use of homopolymers as resists, recent developments suggest that copolymer and terpolymer resists should provide more significant processing advantages because of improved physical and chemical properties (5-6).

Several investigators have used copolymerization and terpolymerization techniques to improve the properties of poly(methyl methacrylate), PMMA, a widely used positive electron beam resist (3, 7). Harris (8) has found that the adhesive properties of PMMA can be improved significantly when it is hydrolyzed with base to form a methyl methacrylate-methacrylic acid copolymer. Roberts (9, 10) has improved the vertical wall profile of PMMA through copolymerization with methacrylic acid and conversion of the acid groups to poly(methacrylic anhydride) sequences by heating at 200°C. Sensitivities comparable to those obtained by

[1] Present address: IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533.

Key words: electron beam lithography, positive resists, methyl methacrylate-isobutylene copolymers, polymer resists, electron resists.

Roberts have been reported for copolymers of methyl methacrylate and methyl isopropenyl ketone (11).

For the PMMA copolymers to meet the engineering requirements for economical processing, minimum sensitivities of 3×10^{-6} C/cm^2 or better would be needed. At the present time, sensitivities of this order of magnitude have been observed only with the poly (olefin sulfones), a new family of positive resists (12-14), and with several copolymers and terpolymers which function as negative resists (15). The lower sensitivities observed for many positive type polymeric resists have been attributed to their low G(scission), which is about 1.7 for PMMA (16).

To obtain the higher sensitivities desired in PMMA, copolymers containing the high radiation susceptible isobutylene group [G(scission) of about 5.4 (17)] were synthesized and evaluated. The maximum isobutylene content in these copolymers was evaluated as a function of resist performance. Additionally, the effect of the elastomeric isobutylene groups on the adhesive properties of the copolymers was evaluated on silanol and siloxane substrates. The sensitivity and etch performance of the copolymers were compared to a polymethylmethacrylate resist of similar molecular weight.

Experimental

The P(MMA/IB) copolymers were prepared in a sealed Parr pressure reactor. Methyl methacrylate was complexed with ethyl aluminum sesquihalide ($AlEt_{1.5}Cl_{1.5}$) (MX) at −20° to −30°C for 30 min inside a helium-purged dry box. Isobutylene and benzoyl peroxide catalyst were introduced, the reactor was sealed, and the polymerization was carried out at 0°C for 24 hr. The polymerization was terminated by adding the reaction mixture slowly to a large excess of cold methyl alcohol containing dilute hydrochloric acid. The copolymer was dissolved in benzene, precipitated in methyl alcohol, and extracted with hexane.

The copolymer structures were confirmed from their NMR spectra (Fig. 1) obtained in o-dichlorobenzene at 148°C with a Varian HA-100 spectrometer using tetramethylsilane as an internal standard. The methyl protons of the MMA units appeared as three peaks centered at 1.10, 1.26, and 1.44δ, assigned to the cotactic configuration. The methylene protons belonging to both MMA and IB appeared together as a broad peak in the range 1.79-2.22δ. The methoxy protons appeared as a single peak at 3.62δ. The gem dimethyl protons of the isobutylene segments appeared as an unresolved single peak centered at 1.00δ. Integration of the peak areas indicated that the ratios of methoxy protons to isobutylene methyl protons were correct for the proposed copolymer structures.

Elemental analyses for these copolymers confirmed the chemical compositions. Analysis calculated for a 90/10 P(MMA/IB) copolymer: C, 62.54; H, 8.69; O, 28.76. Found: C, 62.73; H, 8.59; O, 28.73. Analysis calculated for a 75/25 P(MMA/IB) copolymer: C, 66.40; H, 9.63; O, 23.97. Found: C, 66.76; H, 9.20; O, 24.15.

Molecular weight distribution and molecular weight averages (number and weight averages compared to polystyrene) were obtained with a modified Waters Associates GPC 200 chromatograph in THF solvent. Molecular weight averages ranged from 20,000 to > 100,000 (Table I).

Glass transition temperatures were determined with a du Pont TMA 900 differential thermal analyzer (Table I).

Resist evaluation.—The oxidized silicon surfaces were of two types, siloxane and silanol. The surfaces were prepared by the oxidation method described by Lussow (18). Resist films (1.0μ thick) were spin coated from 7% solutions in chlorobenzene using a Headway Research Model EC-101 spinner. The films were prebaked for 1 hr in air at 145°C. The thickness of the resist and oxide films (0.7μ) was measured on a Rank Talystep instrument. The resist films were exposed to measure doses of 15 kV electrons with a scanning raster type electron beam. The developed films were postbaked at 100°C for 30 min. The oxide films were etched with buffered HF at 22°C. The etch ratio of undercut (19) was measured by scanning electron microscopy.

Results and Discussion

The isobutylene/MMA mole ratio in the monomer feed was an important factor in obtaining an alternating-type copolymer. In the presence of a large excess of isobutylene, an alternating copolymer was formed. When less isobutylene was used, the copolymer was rich in MMA (Table I). Similar results have been observed in the copolymerization of vinyl chloride and MMA (20). When $ZnCl_2$ was used as the metal halide,

[d] MX = $ZnCl_2$.
[e] Workup of polymer was difficut; the polyner was a solid at 0°C, but became a liquid at ambient temperature. The polymer molecular weight must be presumed to be low because of the dilution effect of the large excess of isobutylene.

a block-type copolymer was formed. These polymers were not of high molecular weight and all efforts to increase the molecular weight by changing the IB/MMA ratio and by use of different radical catalysts were unsuccessful.

The use of benzoyl peroxide, a free radical catalyst, in the presence of ethyl aluminum sesquichloride, increased the rate of polymerization with a concurrent decrease in the copolymer molecular weight. It has been demonstrated that the catalyst reacts with the charge transfer complex, that the radical initiated polymerization occurs concurrently with the spontaneous polymerization, and that the propagation reaction is the same irrespective of the initiation mechanism (20, 21), that is

$$CH_2{=}C(CH_3){-}C(OCH_3){=}O \cdot\cdot\cdot AlEt_{1.5}Cl_{1.5} \; + \; CH_2{=}C(CH_3)_2 \xrightarrow[\phi-C(=O)-O-C(=O)-\phi]{0^\circ C} -(-CH_2-C(CH_3)(C(=O)OCH_3)-)_a-(CH_2-C(CH_3)_2-)_b$$

MMA IB

The alternating- and block-type structures of the copolymers were established by pyrolysis studies in a gas chromatograph. The experimental polymers and a PMMA homopolymer were pyrolyzed into a gas chromatograph and the products were fractionated on a 15 ft × 1/8 in. chromosorb G column. PMMA depolymerized 95% to monomer, a portion of the chain undergoing dehydration and decarboxylation to leave a polyene residue. The block copolymer gave polyene fragments and isobutylene indicative of extensive sequences of PMMA uninterrupted by isobutylene sequences. The alternating copolymers gave products characteristic of isobutylene and branched isobutylene structures. Very little of the typical polyene backbone fragments, characteristic of PMMA, were observed, indicating that the PMMA sequences had been extensively interrupted.

The glass transition temperatures (T_g) of the alternating- and block-type copolymers were found to depend on the isobutylene content of the copolymer and on the polymer structure (Table I). Increasing the isobutylene content of the alternating polymers reduced the T_g. The T_g of the block copolymer were higher than those of the alternating polymers. These copolymers and PMMA and PIB homopolymer controls having comparable molecular weights (Table I) were evaluated as electron beam resists.

The copolymers were soluble in many organic solvents and were spin coated from chlorobenzene solutions to thicknesses of several microns. The copolymer films, prebaked at 145°C, were sufficiently melted to allow the casting solvents to evaporate and to provide solid-phase wetting of the oxide substrate. PMMA (8) required a higher prebake of 180°C to remove solvents and to prevent excessive thinning of the unexposed region in the developer. Heating PMMA or the copolymers above 190°C resulted in chain scissioning to lower molecular weights and to the chain unzipping to monomer fragments. Polyisobutylene was a poor resist which had limited resolution because of a low glass transition temperature. Above the glass temperature, this polymer exhibited cold-flow properties and deformed under solvent developer stress (22).

Table II. Sensitivities of P(MMA-IB) copolymers at 15 kV

Polymer	Sensitivity, $\mu C/cm^2$
90/10	7.0
Block	6.0
75/25	4.5
PMMA	28.5

The resist sensitivities were determined by systematic stepped exposures ranging from 1×10^{-6} to 1×10^{-4} C/cm^2 at 15 kV. The choice of developers was evaluated by solubility mapping of the rate of dissolution of the unexposed (S_0) area of copolymer films in various classes of organic solvents such as ketones, esters, alcohols, alkanes, and aromatic hydrocarbons. Xylene was found to be a representative solvent which dissolved the exposed region at rate S. The solubility ratio of S/S_0 was fixed at 5 to 1, and the sensitivity (dose) necessary to achieve the differential dissolution is given in Table II.

Under these conditions, only 20% of a 1μ thick film was dissolved after development. The processed films could be used either in a lift-off scheme of metal patterns, or as an etch resist. The resists are readily stripped in solvents such as benzene or acetone.

The sensitivity of the copolymers increased with isobutylene content (Table II). The 75/25 copolymer required a low dose of 5×10^{-6} C/cm^2 compared to 3×10^{-5} C/cm^2 for the PMMA control. A comparable dose of 4×10^{-5} C/cm^2 has been noted (23) for PMMA when developed in optimum solvents to a S/S_0 of 5.

The incorporation of isobutylene links in the PMMA chain whether in the form of alternating or blocky sequences enhanced the chain scissioning. Since higher initial molecular weights can also enhance the sensitivity of a positive resist (24), we attempted to increase the molecular weight of the copolymers but were not successful with other catalysts or reaction conditions.

The resist exhibited good resolution capable of producing fine dots of 1.25 geometry in 7000Å thick films of oxidized silicon (Fig. 2). Doses as low as 3×10^{-6} C/cm^2 could be used but the unexposed resist thinned about 40%.

The P(MMA-IB) copolymers were unaffected by cold flow because of their higher glass transition tem-

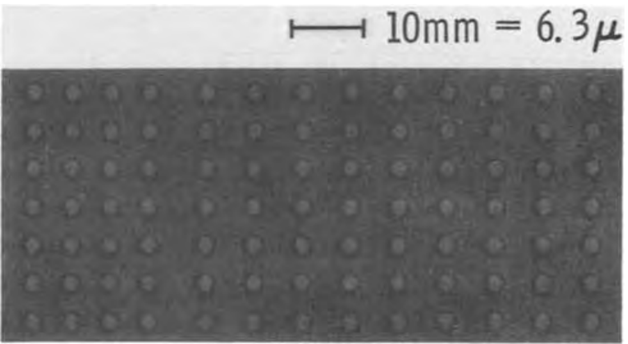

Fig. 2. Images (1.25μ) etched with P(MMA-IB) resist in 7000Å thermal SiO_2.

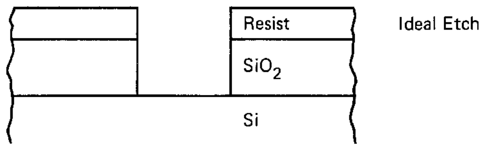
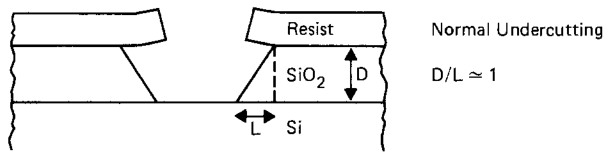
peratures (Table I). However, for optimum processing, the isobutylene content of the copolymer should not exceed 25 mole per cent (m/o) because the glass transition temperature will be significantly lowered. If the glass transition temperature is too low, images in the polymer melt during thermal processing above 100°C. The glass transition of the block copolymer was higher than those of the alternating copolymer. The block form would offer higher processing temperatures.

The adhesion and etch resistance of PMMA and the P(MMA-IB) copolymers on silanol (Si-OH) and siloxane (SiO) surfaces were evaluated by measurement of an undercut factor, D/L. Films of resist (1.0μ thick) were used to etch 7000Å films of silicon dioxide. The undercut factor, D/L, assesses the depth, D, to lateral width, L, of a normalized line at the bottom of the etched substrate (19). A D/L factor less than one implies heavy undercutting (large L) underneath the resist edge (Fig. 3).





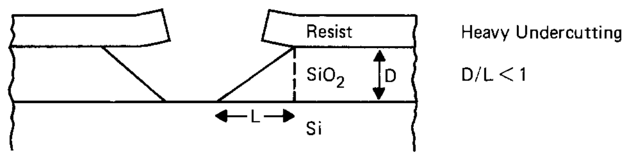


Fig. 3. Resist pattern adhesion and undercutting

Fig. 4. H bonding of PMMA to silanol surface

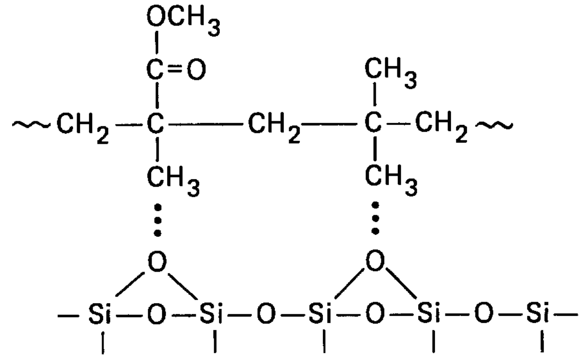

Fig. 5. Van Der Waals bonding of MMA-IB copolymers to siloxane surfaces.

Table III. Adhesion of P(MMA-IB) copolymers on siloxane surfaces

Polymer	Adhesion, D/L
PMMA	0.4 ± 0.1
90/10	0.7 ± 0.1
75/25	0.9 ± 0.1
Block	0.6 ± 0.1

On silanol surfaces, PMMA adhered very well and exhibited a normal undercut of D/L of 0.9 ± 0.1. The adhesion of PMMA and other methacrylate polymers on silica surfaces has also been measured by absorption isotherms and infrared spectroscopy (25, 26). Adhesion was attributed to the hydrogen bonding of the carbonyl group (C=O) (Fig. 4) of the ester to the surface hydroxyl (OH) groups of silanol. The isobutylene segments in the P(MMA-IB) copolymers did not alter the adhesion on the silanol surfaces (D/L = 0.9 ± 0.1) since there are sufficient ester groups remaining for hydrogen bonding.

When PMMA was coated on siloxane surfaces, the etched images were badly undercut with a D/L value of 0.4 ± 0.15. The poor adhesion is attributed to the loss of hydrogen bonding since the silanol groups have been converted to siloxane bridges. However, the adhesion of the P(MMA-IB) copolymers on the siloxane surfaces improved with increasing isobutylene content (Table III). The enhanced adhesion is attributed to the increased Van der Waals type bonding with the increasing number of alkyl groups in the polymer chain (Fig. 5).

Summary

PMMA copolymers containing isobutylene groups are very sensitive to electron beam radiation. The high sensitivities are attributed to the isobutylene "weak links" in the polymer chain.

The adhesion of PMMA type resists can also be improved on siloxane surfaces by incorporation of elastomeric isobutylene groups.

The improvement of the resist performance of PMMA represents an application of polymer tailoring wherein certain deficiencies in one polymer system (PMMA) may be overcome by copolymerization with another monomer (IB) which has good radiation sensitivity, but has limited applicability.

Variation of Solid Composition and Thickness during LPE Growth of $Al_xGa_{1-x}As$

Hachiro Ijuin[1] **and Shun-ichi Gonda**

Electrotechnical Laboratory, Tanashi, Tokyo, Japan

ABSTRACT

The variations of the solid composition and of the layer thickness with the growth time in the LPE $Al_xGa_{1-x}As$ were measured by utilizing luminescence, x-ray analysis, and microscopy by means of an electron microprobe. The variations determined by the experiments are in good agreement with the calculations based on the diffusion-limited growth theory including the effects of nucleation in the ternary solution.

Liquid phase epitaxy (LPE) has been widely used for such applications as electronic and optoelectronic devices which require high quality in crystallographic nature and variety in structure. The LPE layer is normally grown on the substrate from a saturated solution and occasionally from an undersaturated or a supersaturated solution. Variables such as the solid composition and the thickness of the crystal grown by LPE are of great importance in practical application. The variation of the solid composition of $Al_xGa_{1-x}As$ with the growth temperature reflects the growth process and growth conditions. Theoretically, the variation of the solid composition with the growth temperature has been investigated on the basis of the phase diagram for the growth from a saturated solution by Ilegems and Pearson (1) and from a supersaturated solution by Thompson and Kirkby (2). Experimentally, the variation has been investigated by Rado and Crawley (3) and Thompson and Kirkby (2). The results of Rado and Crawley have been compared with the theoretical ones of Ilegems and Pearson. The variation of the solid composition with the growth temperature is regarded as independent of the cooling rate of the growth in the above investigations.

Since LPE growth is not an equilibrium process, the variations of the composition and the thickness of the grown layer are affected by the diffusion rate of the solutes in the solution. Crossley and Small (4) have analyzed the diffusion-limited process by means of a numerical method with which complicated growth conditions are easily taken into account. Nucleation in the solution is considered to affect the process in the LPE growth. We have analyzed the diffusion-limited process taking into account the effects of nucleation in the ternary solution (5, 6). A consistent argument about the experiment and theory has not been made except for the very low cooling-rate process.

In this paper, by the LPE growth of $Al_xGa_{1-x}As$ under different growth conditions, the phase diagram of $Al_xGa_{1-x}As$ generated using the phase data by Ilegems and Panish (7) is discussed. Furthermore, the variations of the solid composition and the thickness of $Al_xGa_{1-x}As$ are measured in detail and the experimental results are compared with the calculations based on the diffusion-limited growth theory including the effects of nucleation in the solution.

Experimental

The $Al_xGa_{1-x}As$ with various solid compositions $x =$ 0.35, 0.40, 0.45, and 0.55 was grown by LPE at 850°C on (100) GaAs substrate using a horizontal sliding-type LPE apparatus. The solution was prepared from 3g of Ga and sufficient amounts of GaAs and Al to produce a LPE layer with appropriate solid composition. Equilibrium liquid compositions were calculated from the phase data reported by Ilegems and Panish (7). The errors in measuring weights of source materials were less than 0.5 mg for GaAs and Al and 5 mg for Ga. The loaded boat was heated in a resistance furnace up to the maximum temperature, 900°C, and was held there for 30 min. Then it was cooled to a growth temperature of 850°C and held again for about 30 min to ensure a uniform temperature profile around the boat. The substrate had been tipped in the solution for 20 min before it was cooled at a rate of 0.5° or 1°C/min. The solution was pushed off after the temperature was lowered to 840° or 830°C. In order to make a consistent argument of the phase diagram and growth mechanisms, the optimum temperature program was used so as to dissolve the source materials completely and to minimize vaporization of the con-

[1] On leave of absence from Waseda University, Shinjuku, Tokyo, Japan.

Key words: compositional variation, nucleation in ternary solution, constitutional supercooling, equilibrium liquidus temperature.

stituents. Clear and flat surfaces from which the growth solutions were wiped off were obtained in a leak-tight system.

After cleaving the crystal, layer thickness was measured using photo and scanning electron microscopy. Solid compositions were measured by electron probe x-ray microanalysis (EPMA) on the cleaved surfaces along the direction of growth in 2 μm steps. Radius of the electron beam was smaller than 200Å. Emission wavelength of cathodoluminescence was measured in order to check the results obtained by EPMA. In this case the solid composition, x, was determined by the empirical formula of Onton *et al.* (8). The errors in these measurements were estimated to be less than 3%.

Experimental Results

The variations of the solid composition in the grown layer determined using EPMA for various LPE $Al_xGa_{1-x}As$ are shown by circles in Fig. 1. Closed and open circles correspond to the results of the growth at 0.5 and 1.0 °C/min, respectively. The solid composition decreases with increasing thickness in the composition range shown here. The variations of the layer thickness with growth time are shown in Fig. 2. As in Fig. 1, closed and open circles indicate the different cooling rates 0.5° and 1.0°C/min, respectively. The measured initial compositions of the layers range from about 0.35 to 0.55. The difference in growth rate of the layers with different initial solid compositions is small.

Once the solid composition, x, and the growth temperature are determined, sufficient amounts of source materials can be calculated by using the phase diagram. The relation between the weights of Al and GaAs for 3g of solvent Ga are shown in Fig. 3 by those contours of equilibrium temperature and solid

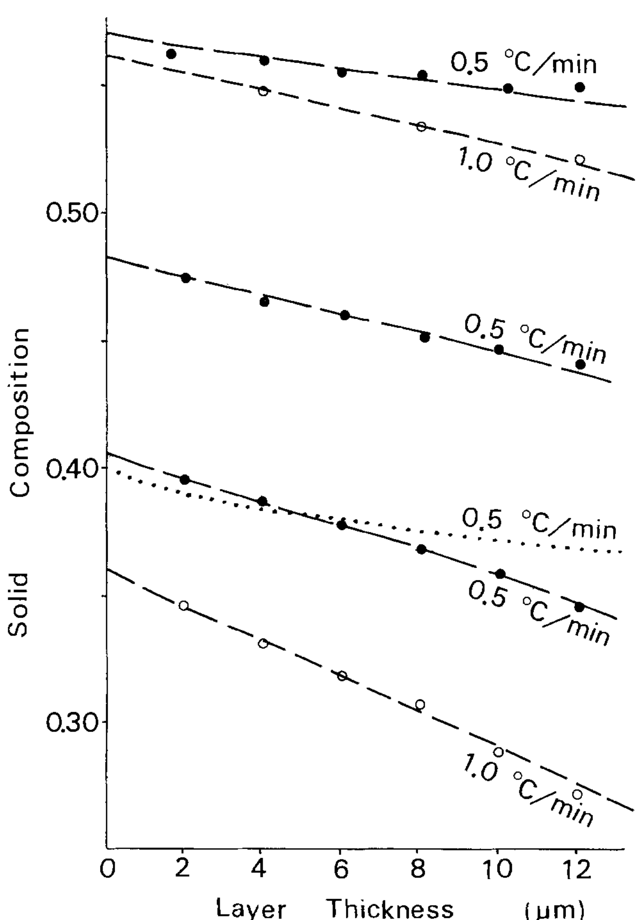

Fig. 1. The variation of the solid composition in the $Al_xGa_{1-x}As$ LPE layers with layer thickness. Dashed and dotted lines are the results calculated using the diffusion-limited growth theory with and without nucleation in the solution.

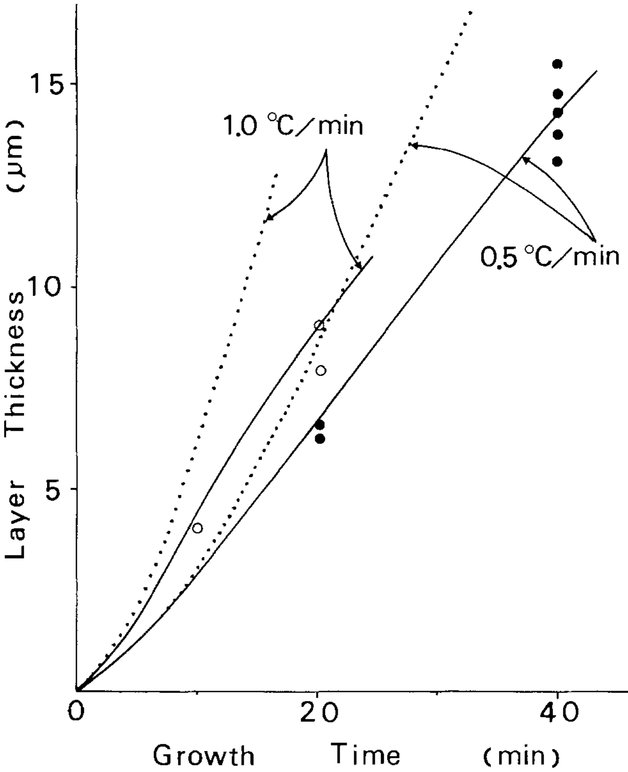

Fig. 2. The variation of the layer thickness with the growth time in LPE $Al_xGa_{1-x}As$. Solid and dotted lines indicate the curves for $x = 0.40$ calculated using the diffusion-limited growth theory with and without nucleation in the solution, respectively.

composition which are calculated by using the phase data of the Al-Ga-As system reported by Ilegems and Panish (7). Circles indicate the measured weights of the source materials, Al and GaAs. Triangles indicate

the starting growth temperature and the initial solid compositions determined from the experiments. Arrows in Fig. 3 show the variation of the solid composition converted from Fig. 1 using the thickness *vs.* temperature relation which can be easily derived from Fig. 2.

Discussion

Compositional profiles in the grown layer are monotonically decreasing ones toward the direction of growth in the composition range concerned, as shown in Fig. 1. This tendency is mainly the result of the large distribution coefficient of solute Al. When nucleation in the liquid cannot be neglected in the LPE growth, the variation of the solid composition tends to be large because the growth rate decreases due to less compositional gradient of solutes in the solution. Since the growth rate of $Al_xGa_{1-x}As$ is limited by an arrival rate of As to the growing interface, the growth rate is expected to be lowered for crystals of larger solid composition (of Al) which grow from solutions with a lesser atomic fraction of As. As shown in Fig. 2, a significant difference in the variation of growth rate for different solid compositions was not recognized by experiments in the presented composition range. If the LPE growth process is analyzed taking into account nucleation in the solution, the experimental results can be well explained.

We have newly introduced the effects of nucleation in the ternary solution into analysis of the growth mechanism (5, 6). As the growth proceeds at higher cooling rate, the compositions of solutes in the liquid decrease more at the growing interface but the composition does not change so much at the solution surface. The equilibrium liquidus temperature of the solution calculated from the phase data and the compositions of solutes are highest at the solution surface because of constitutional supercooling. Effects of nucleation are taken into account by considering that the equilibrium liquidus temperature of the solution cannot be higher than $T + \Delta T_c$, where T is the real temperature of the solution and ΔT_c is a certain critical value of supercooling. The compositional profiles of solutes are flattened at the solution surface at first due to nucleation in the solution when the equilibrium liquidus temperature becomes higher than $T + \Delta T_c$. Therefore, an additional boundary condition to satisfy a criterion of nucleation is applied to the numerical analysis of LPE growth process made by Crossley and Small (4) for the growth of $Al_xGa_{1-x}As$ from a nucleation-free solution. In numerical calculation we assumed solution thickness of 5 mm for Ga solution of 3g in the solution reservoir of the boat with area of 1 $\times$ 1 cm^2. The diffusion coefficient of As was adopted from the data of Rode (9), while the coefficient of Al was adjusted to be 75% of the value in Sn solution reported by Ma and Swalin (10) so as to fit the theoretical curves to the experimental data (6). By adopting 2.5°C as ΔT_c, good agreement between the experimental and theoretical results is obtained, concerning the growth of the LPE layer grown at different cooling rates as shown by solid lines in Fig. 2 as well as dashed lines in Fig. 1 concerning the variation of the solid composition in the grown layer. Theoretical calculations indicate that the growth rate shows almost the same variations in the presented composition range, although the growth rate largely deviates in the smaller composition range. The critical value of supercooling may be thought to be different for different cooling rates, growth temperatures, or solid compositions. However, the difference is hardly recognized in the critical value of supercooling in the ranges concerned. For comparison, the results for $Al_xGa_{1-x}As$ ($x = 0.40$) calculated without taking account of nucleation in the solution are shown by dotted lines in Fig. 1 and 2.

The phase diagram based on the phase data by Ilegems and Panish (7) is experimentally checked, as shown in Fig. 3. The solid compositions of AlAs at the starting growth temperature nearly coincide with the values expected from the contours of constant AlAs in the solid, but these appear to be slightly larger in the large solid composition region. This is presumably due to vaporization of the solute As from the solution.

Conclusions

The variation of solid composition in the grown $Al_xGa_{1-x}As$ layer and the variation of the layer thickness with growth time were investigated experimentally and were compared with the growth theory. Good agreement was obtained when a critical supercooling of the ternary solution is assumed to be 2.5°C. A sort of phase diagram, the relations among the weights of source materials, of the Al-Ga-As system generated by using the reported phase data was checked experimentally. Rather good agreement was obtained, although there was some tendency to deviate in the large solid composition range.

Technical Notes

Particle Growth in Zinc Sulfide Phosphor Containing Halide Fluxes

R. A. Brown*[,1]

RCA Electronic Components, Lancaster, Pennsylvania 17604

The mechanisms by which zinc sulfide powders grow under the action of heat and in the presence of a fluxing agent have been the subject of considerable discussion and speculation (1). Common fluxes employed in ZnS type phosphors include the halogen salts of ammonium and the alkali or alkaline earth metals, although compounds such as barium thiozincate (2) have been recommended also. According to the classical concept of flux action (3), the function of the additive is to provide a liquid phase in which the zinc sulfide is soluble, so that transport of material can occur readily. Apparently, no experimental evidence has been offered in support of this hypothesis. Indeed, the data of Gashurov and Levine (4) show that at 880°C ZnS has a very limited solubility of 0.0152 mole/1000g solvent in the common fluxing agent NaCl. More recent work (5-7) has emphasized the importance of diffusion phenomena in thermal recrystallization and sintering experiments on zinc sulfide powders.

Thus, McQueen and Kuczynski (5) carried out work on the sintering of polycrystalline ZnS as a function of temperature and atmosphere of firing, and interpreted the results obtained in terms of material transport by diffusion mechanisms. Studies on the kinetics of hexagonal-cubic phase transformation in ZnS at 800°-900°C in zinc vapor (6) suggested a diffusion-controlled transition having an activation energy of 67 kcal. Brown (7) investigated the mechanism of flux action in ZnS:Ag phosphors containing either 2 or 10% NaCl. In these systems, and also for zinc sulfide without additives, the rate of increase in particle diameter, D, at a firing time, t, followed the expression $D^3 = kt$, where k is a constant. Two distinct regions of growth were noted. Below about 1000°C an activation energy of 29 kcal was obtained, corresponding to movement of zinc through interstitial channels. At higher temperatures the measured activation energy was 59 kcal, suggesting bulk diffusion of zinc. This change in mechanism corresponded to the onset of the cubic-hexagonal phase transformation.

The objective of the present work was to extend the particle growth experiments reported previously (7) to include other fluxes, with the aim of obtaining a better understanding and control of the particle size characteristics of zinc sulfide phosphors. With this object in mind, measurements were carried out on the rate of increase in particle diameters, as a function of duration and temperature of heating, for the following systems: ZnS:0.015% Ag with either 2% $ZnCl_2$, 2% NH_4Cl, or 2% $CaCl_2$. Note that these values correspond to weight per cent (w/o) compositions. Particle dimensions were obtained by Coulter Counter techniques; the numbers quoted represent median point by weight of particles.

Experimental and Results

Details of the precipitation of zinc sulfide (8) and the preparation and measurement of phosphors (7) have been given previously. A brief account will suffice here.

Batches of about 200g of zinc sulfide were obtained from 2 liters of 1M zinc sulfate solution at 25°C, using a hydrogen sulfide flow of 0.82 liter/min. After filtration through a Buchner funnel and washing with deionized water, the precipitate was subsequently dried for 6 hr at 100°C.

Compositions studied included ZnS:0.015% Ag with 2% $ZnCl_2$, 2% NH_4Cl, or 2% $CaCl_2$. Zinc chloride was added as the hexahydrated salt and calcium chloride as the dihydrate. In order to avoid oxidation of the zinc sulfide and maintain a stoichiometric composition during heating, the following experimental procedure was employed. Test samples of 10g were placed in covered Vitreosil crucibles, located in a larger crucible, surrounded by ZnS powder, and covered with a lid. Kremheller (9) employed a somewhat similar technique during heating of ZnS single crystals and found no sublimation of the crystals, even at 1200°C. Specimens were fired at temperatures in the range 750°-1250°C, for periods of 1-10 hr. Subsequently, the materials were washed with deionized water to remove excess flux, dried at 100°C, and examined by Coulter Counter methods to determine particle sizes.

Figure 1 shows a typical set of curves in which log D is plotted as a function of log t (7) for ZnS:0.015% Ag with 2% zinc chloride. Between 750° and 1100°C the curves are linear with a slope of 0.33. Thus particle growth follows a $D^3 = kt$ dependence. An Arrhenius activation energy was derived from the data of Fig. 1, using a plot of $-\log t'$ against $1/T$ (7) where t' is the time required to reach an arbitrarily chosen particle size of 10 μm. This plot is shown in Fig. 2, which gave an activation energy of 29 ± 2 kcal for the growth processes. Activation energies were calculated by means of a regression and correlation analysis carried out by G. M. Ehemann of this laboratory with the use of an RCA Spectra 70 computer program. At 1200° and 1250°C in this system the relationship between log D and log t was again linear, but in this case with a slope of 0.66 as demonstrated in Fig. 1.

Particle size results for ZnS:Ag containing 2% NH_4Cl are given in Fig. 3. Up to 1000°C there was a gradual, slow rise in particle diameter with increase in the temperature and duration of firing, although no accurate activation energy could be obtained in this range. Between 1100° and 1200°C the relationship between log D and log t was linear with a slope of 0.66, *i.e.*, a $D^{1.5} = kt$ law was followed. Figure 4 gives the

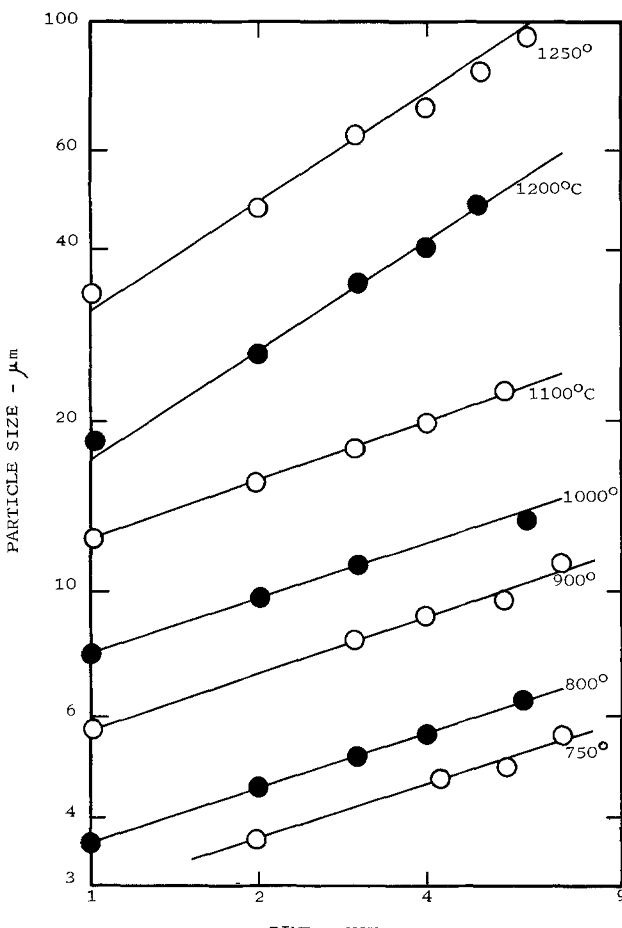

Fig. 1. Rate of particle growth in ZnS:Ag, 2% $ZnCl_2$

corresponding Arrhenius plot, from which the energy of activation was calculated to be 48 ± 3 kcal.

Results obtained in the particle growth experiments for ZnS:Ag, 2% $CaCl_2$ are presented in Fig. 5. At 750° or 800°C the slope of the lines was 0.33, whereas from 850° to 1250°C a slope of 0.5 was obtained. Figure 6 gives the Arrhenius plot for particle growth in ZnS:0.015% Ag with 2% calcium chloride. From this plot an activation energy of 36 ± 2 kcal was calculated for temperatures in the region 850°-1250°C.

Table I summarizes reported work concerning activation energies and particle size dependences obtained for various zinc sulfide systems. Since the results obtained are a function of factors such as sample size, configuration of the firing vessel, duration of heating, rate of cooling, and atmosphere of firing, an exact correspondence is not to be expected. However, the overall time dependence and activation energies obtained should be comparable, provided the experimental conditions are not radically different.

Discussion

On the basis of these results, the following sequences are suggested to occur during thermal recrystallization in zinc sulfide containing the various fluxes.

In the presence of 2% zinc chloride, particle growth at 750°-1000°C followed a $t^{1/3}$ law with an activation energy of 29 kcal. These same results were obtained by Brown (7a) for thermal recrystallization in ZnS containing 2 or 10% NaCl in this temperature range, and these findings are in accord with the value of 29 kcal given by Secco (10) for interstitial zinc diffusion. It is interesting to compare the data obtained in the present study with those given by other authors, as reported in Table I. Thus, Kremheller and Faria (11) fired zinc sulfide, and ZnS with different additives, for 2 hr at 750°-1250°C in open boats using a flowing helium atmosphere, and measured particle sizes by a gas adsorption method. For ZnS without additives these workers (11) derived an activation energy for particle growth of 28 kcal,[2] together with a time dependence of 0.5. This same value of 30 kcal was quoted by Bube (12) on the basis of a diffusion model. Shionoya and Amano (13) obtained a $(\text{time})^{1/3}$ dependence and an activation energy of 30 kcal for thermal recrystallization in zinc sulfide:Cu containing either 4 or 10% NaCl. The data of Leverenz (14) for ZnS, 2% NaCl at 1250°C also follow a $t^{1/3}$ expression. Consequently, the time dependence and activation energy are the same in zinc sulfide without flux as for ZnS containing either NaCl or $ZnCl_2$, which suggests that the same mechanism operates in these systems. In addition, the process does not appear dependent on the activator. These results appear to support the findings of Brown (7a) who proposed material transport by diffusion of zinc through interstitial channels.

At temperatures above about 1050°C, ZnS:Ag containing 2% ammonium chloride followed a $t^{2/3}$ dependence with an activation energy of 48 kcal. Since these results are not in accord with the diffusion mechanism outlined above, an alternative process was sought. A well-known procedure (15, 16) for obtaining single crystals of zinc sulfide involves vapor transport in a closed system under reduced pressure, with NH_4Cl as a transfer agent. The processes occurring may be represented by the reactions

$$NH_4Cl \rightleftharpoons NH_3 + HCl \quad [1]$$

$$ZnS + 2HCl \rightleftharpoons ZnCl_2 + H_2S \quad [2]$$

This sequence seems likely to occur during the growth of polycrystalline ZnS containing NH_4Cl as flux, in keeping with an observation made by Smith (17). Although an evaporation-condensation reaction can take place at least as low as 700°C under appropriate con-

[2] For convenience, results quoted elsewhere in eV are expressed in kcal, on the basis that 1 eV = 23.05 kcal.

ditions, it was observed only at higher firing temperatures in the present work. One possibility is that the experimental procedures employed, and especially protection of the vessel by a stagnant zinc sulfide atmosphere, may delay the onset of the vapor transport process. Note that at 1200° and 1250°C the ZnS-$ZnCl_2$ system also obeyed a $t^{2/3}$ relationship. Zinc chloride has a boiling point of 732°C (18) and should have an appreciable vapor pressure above 1000°C. Consequently, it is possible that at higher temperatures an evaporation-condensation mechanism may operate, according to an exchange reaction of the type

$$ZnS + ZnCl_2 \rightleftharpoons ZnCl_2 + ZnS \quad [3]$$

In ZnS:Ag containing 2% calcium chloride a $t^{1/3}$ relationship was followed at 750° and 800°C, in keeping with the $ZnCl_2$ or NaCl additives, which might indicate a diffusion process, although there is insufficient evidence to make this more than a suggestion. Between 850° and 1250°C a different mode of material transport must be in effect. This change in mechanism became evident at about 800°-850°C, which is close to the normal melting point of 773°C (19) given for the calcium chloride flux. Particle growth in this temperature region was characterized by a time dependence of 0.5 and an activation energy of 36 kcal. Note also that, in contrast to all of the other fluxes examined so far, there was no change in mechanism as the system underwent the cubic-hexagonal phase transition at approximately 1020°C. This point is illustrated in Fig. 6, which demonstrates the Arrhenius curves obtained with ZnS:Ag containing either 2% $CaCl_2$ or 2% NaCl flux. A $t^{1/2}$, parabolic rate law (20) has been observed in many systems involving diffusion-controlled growth processes at an interface. Typical examples include the tarnishing, oxidation, or nitridation of metals (21). The theoretical basis for such processes has been derived by various authors (22). Kremheller and Faria (11) and Gashurov and Banks (23) have applied these concepts to zinc sulfide phosphors, thus it is not proposed to reiterate the discussion here. In the ZnS-$CaCl_2$ system it appears that, at temperatures above the normal melting point of calcium chloride, interaction between host material and flux takes place on the surface of the particles. Subsequently, growth proceeds by a dissolution-reprecipitation process, limited by diffusion of the solute atoms into the moving interface. Such a mechanism would require only a limited solubility of $CaCl_2$ in ZnS.

In summary, these studies have demonstrated that the mechanisms of particle growth in zinc sulfide phosphors are dependent on the nature of the flux used. Thus far, interstitial or bulk diffusion of zinc, diffusion limited dissolution-reprecipitation, and evaporation-condensation means of material transport have been suggested to occur. Sizes obtained have varied from 3-4 to almost 100 μm. A clearer insight has been gained into the understanding and control of the particle size characteristics of this important class of luminescent materials.

Acknowledgments

The author expresses his gratitude to E. W. Bomgardner for assistance with the preparatory work, and thanks Mrs. J. N. Shenk and Mrs. E. M. Rineer for providing the Coulter Counter measurements.

Ion Implantation Gettering of Gold in Silicon

T. W. Sigmon

Hewlett-Packard Laboratories, Palo Alto, California 94304

and L. Csepregi[1] and J. W. Mayer*

California Institute of Technology, Pasadena, California 91125

Numerous studies have demonstrated the feasibility of using ion implantation damage to getter metal impurities in silicon (1-5). Since metallic contaminants are known to degrade the electrical characteristics of a p-n junction, leading to high reverse leakage currents and soft breakdown voltages, this technique is of technological interest (6). The study of Seidel *et al.* (5) showed that the gettering efficiency of the ion-damaged layers is related to the residual disorder present after annealing at elevated temperatures (850°-1150°C). They also show in that work that the amount of residual disorder depends on the implanted ion species. They correlate this effect with the atomic size of the bombarding ion. We note that the implantation doses reported in this work were more than sufficient (10^{16}/cm^2) to form an amorphous layer (except for the B-implanted samples) and that <111> oriented Si wafers were used.

We would like to point out that factors other than ion size can have a comparable or equal influence on the amount of disorder remaining after anneal. Previous studies on the annealing behavior of high dose implants have indicated that the thermal history of the annealing process (7), the orientation of the crystal substrate (8), and the implantation condition (dose, ion energy) (9) can have a pronounced effect. For example, it has been shown that for amorphous layers, formed by either B or As implants on <111> Si, the amount of disorder remaining after anneal is dependent on the procedure used in annealing: samples annealed at 550°C and then at 950°C exhibit significantly less disorder than samples annealed directly to 950°C (7). We show in this note that the orientation of the substrate used for the gettering can have a pronounced influence on the amount of Au that is gettered.

In this work, <100> and <111> oriented 2-10 ohm-cm resistivity, n-type, low dislocation density wafers were equilibrated with Au at 1100°C in N_2 following the procedures given by Seidel and Meek (3). After lapping away the piled-up Au at the surfaces and polishing the samples, Si ions were implanted with the substrate held near LN_2 temperature at energies (dose) of 200 (2×10^{15} cm^{-2}), 150 (10^{15} cm^{-2}), 100 (8×10^{14} cm^{-2}), and 50 (4×10^{14} cm^{-2}) keV to form an approximately 4000Å thick amorphous layer (10). After implantation the samples were annealed together in dry N_2 at 1000°C for 1 hr. Due to a slight amount of oxygen present in the N_2, approximately 50Å of SiO_2 is grown on the surface of the wafer during this anneal. This differs slightly from the procedures used by Seidel and Meek as there was no heat-treatment at 375°C before going to the higher anneal temperature. However, it is known that relatively little or no recrystallization of amorphous layers occurs at this temperature (11). Backscattering and channeling of 2 MeV He ions were used to study the residual disorder and the amount of gettered Au impurities.

The substrate orientation dependence of the amount of residual disorder after anneal can be seen in the random and aligned spectra shown in Fig. 1. Also, the thin oxide layer can be seen in the aligned spectra. For the <100> sample, the aligned spectra are close to that for an unimplanted sample (minimum yield is less than 5%). This low amount of residual disorder was also found in <100> Si implanted to amorphous condition by B and As ions (rather than Si ions) and annealed directly to temperatures of 950°C (7, 8). However, for the <111> samples the spectra show that the amount of residual disorder is quite high. The height of the aligned spectra shown in Fig. 1 over the thickness of 4000Å is about 65% of the random yield. These high levels of disorder were also found in B- and As-implanted <111> samples that were annealed directly to 950°C (7).

The aligned spectra shown for samples used by Seidel *et al.* (3, 12) in their gettering studies also exhibit a high level of disorder. It is to be noted that these wafers were all of <111> orientation. Also, the As spectra show considerably less residual damage than the other atoms used in their experiments. This effect has been reported before (9) and can be partly attributed to substrate temperature rise during implantation.

Since the amount of Au gettered is influenced by the amount of residual disorder, it is much higher (a factor of 10) in the <111> than in the <100> oriented sample. The gettered Au peak in Fig. 1 appearing at energies greater than 1.6 MeV in the spectra for th<111> oriented sample extends over a depth whic correlates well with the thickness of the disorder

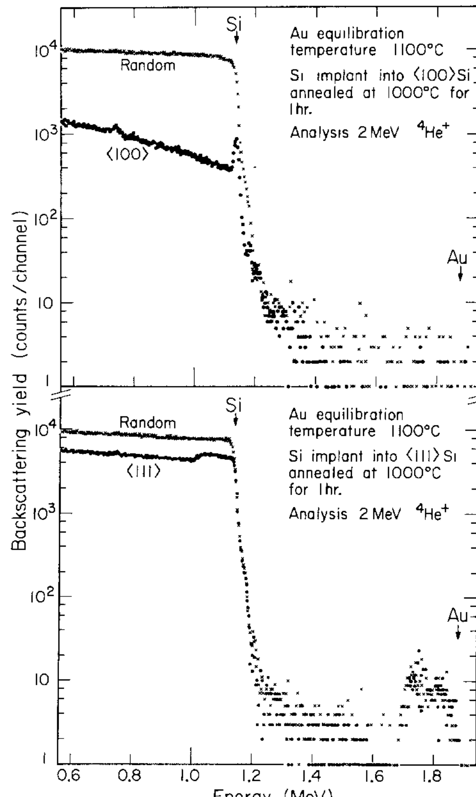

Fig. 1. Random and aligned 2 MeV $^4He^+$ backscattering spectra for <100> and <111> Si equilibrated with Au at 1100°C and implanted with Si at LN_2 temperature. Samples were annealed at 1000°C for 1 hr in N_2. The channeling axis coincides with the surface normal.

Key words: ion implantation, silicon, gettering.

layer; the amount of Au gettered in this layer is about 5×10^{13} atom/cm^2. These observations for the <111> oriented Si are consistent with the results presented in the previous gettering studies referenced.

In conclusion, we point out: (*i*) the results of gettering studies on implant-damaged <111> Si should be applied with caution to Si substrates of other orientations; (*ii*) the residual disorder in <111> oriented Si depends strongly on the thermal history of the sample both during and after the implantation. Hence, the amount of gettered impurities may also depend upon these factors.

Formation of Silicon Nitride at a Si-SiO_2 Interface during Local Oxidation of Silicon and during Heat-Treatment of Oxidized Silicon in NH_3 Gas

E. Kooi,* J. G. van Lierop, and J. A. Appels

Philips Research Laboratories, Eindhoven, The Netherlands

This paper is primarily based on an observation which we made during the preparation of MOS integrated circuits using local oxidation of the silicon (LOCOS) to prepare the thick field oxide. In certain cases the effect may also play a role in the preparation of other LOCOS devices, as has been described in previous publications (1-4).

Preparation of a LOCOS Field Oxide in MOS Circuits

A sketch of part of a possible method of preparing LOCOS MOS devices is given in Fig. 1. A layer of silicon nitride (1500Å in our experiments) is used as the oxidation mask. The silicon nitride is separated from the silicon by a thin layer (500Å) of silicon oxide. The presence of this oxide prevents the formation of dislocations which might be induced in the silicon if the latter were heated in direct contact with the nitride layer (1). The presence of the oxide layer also influences the shape of the sunk-oxide pattern (2, 4). Due to some lateral oxidation effect, the oxide acquires a smooth beak shape at the edges where the nitride mask is lifted up. In our experiments the LOCOS process was carried out by 16 hr oxidation in wet O_2 (dew point 95°C) at 1000°C. The nitride mask and the underlying oxide were then removed and a gate oxide grown (45 min oxidation at 1100°C, yielding 1000Å SiO_2). The further processing of the MOS devices has not been indicated in Fig. 1. If used, a silicon gate process would include the deposition of a polycrystalline silicon film, and definition of gate, source, and drain areas, etc. (4).

A "White Ribbon" Effect in LOCOS Structures

In the final stage indicated in Fig. 1, we observed occasionally a peculiar effect at the LOCOS edges. Through an optical microscope it would look like a "white ribbon" with a width of about 1 μm, following precisely the LOCOS pattern (Fig. 2). The effect was observed for both (111) and (100) oriented substrates, although the photographs presented in this paper all refer to (100) material. A scanning electron microscope picture of a cross section, as indicated in Fig. 3, shows that this ribbon is due to a narrow region of nonoxidized silicon present at a small distance from the beak-shaped LOCOS edge. To explain the effect, we have to assume that the silicon in the ribbon area is covered by a very thin oxidation-masking material. The best oxidation-masking material known is silicon nitride and the most probable assumption is, therefore, that in the ribbon area some silicon nitride is formed at the Si-SiO_2 interface during the local oxidation process. Of course this nitride may not consist of pure Si_3N_4, but for simplicity we will indicate it as such. The question is, of course, how such an effect can occur. The model we propose is indicated in Fig. 4. It is based on the transfer of nitrogen from the nitride oxidation mask to the Si-SiO_2 interface. The figure indicates that during the LOCOS process H_2O diffuses through the growing oxide film. There is also a lateral diffusion and subsequent oxidation of silicon under the edge of the nitride oxidation mask, causing the ultimate beak-shaped pattern to be formed. Some oxidation of the silicon nitride will also occur, not only at the top side but also at the lower side of the nitride edges. In a simple chemical reaction equation as indicated in Fig.

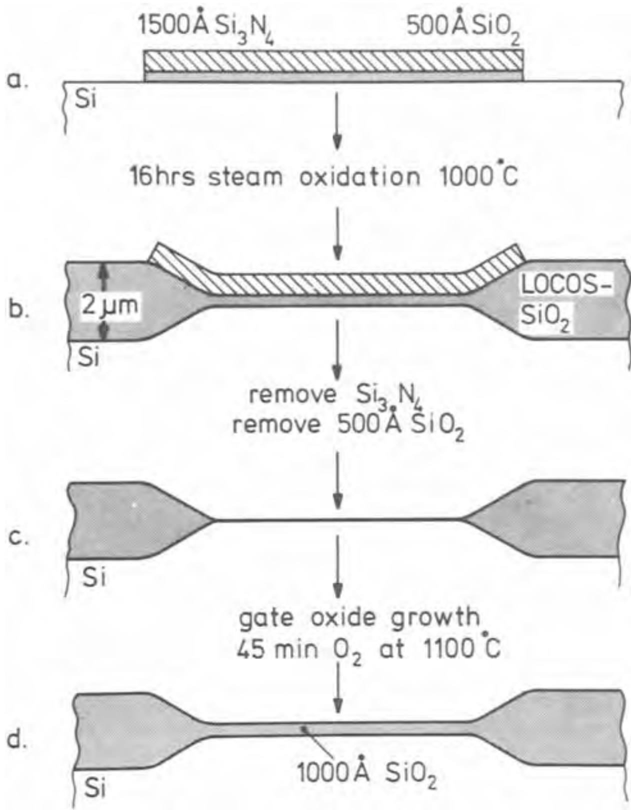

Fig. 1. Part of a LOCOS MOS process. After gate oxide growth (d) the phenomenon indicated in Fig. 2 and 3 may be observed.

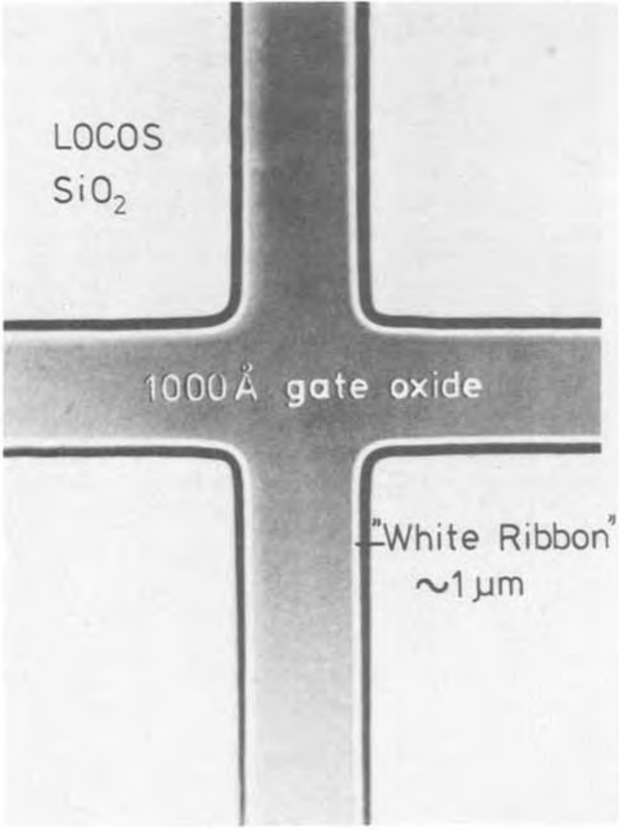

Fig. 2. Top view of a LOCOS structure with a "white ribbon" effect.

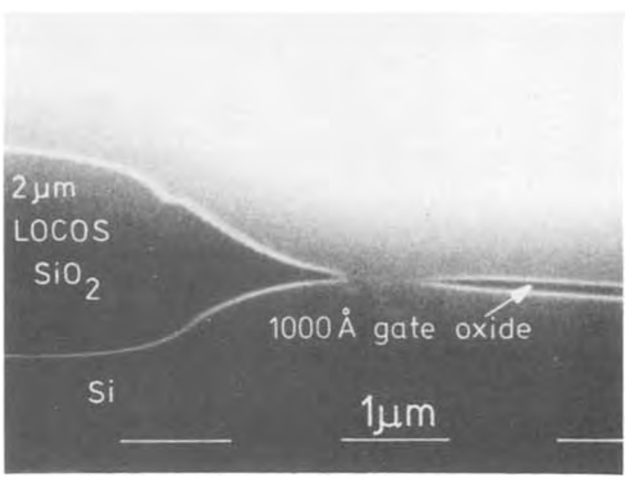

Fig. 3. Scanning electron microscope picture of a cross section of a LOCOS structure with a "white ribbon" effect. (The cross sections shown in this paper were made after a layer of polycrystalline silicon had been deposited on the specimen. This helps to give a good contrast in the SEM picture).

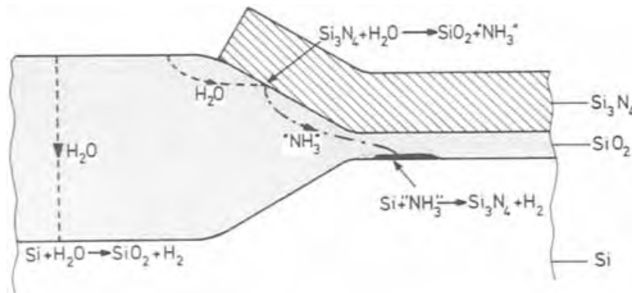

Fig. 4. Proposed model to explain silicon nitride formation at the Si-SiO_2 interface at some distance from the LOCOS edge.

4, one can assume that the oxidation results in the formation of SiO_2 and NH_3. It is more probable that instead of NH_3, the formation of nitrogen atoms or some other NH compound will occur. What has to be assumed is that the reactive nitrogen can diffuse relatively easily through SiO_2. It can reach the Si-SiO_2 interface. But under the LOCOS and also at the beak this does not result in an effective reaction product because of the competition of the oxidation reaction of Si with H_2O. However, at some distance from the LOCOS edge, under the nitride mask, the concentration of H_2O becomes low enough to allow a reaction of silicon with "NH_3" to form Si_3N_4. Again, it is quite possible that stoichiometric Si_3N_4 is not really formed but rather a mixed compound of silicon, nitrogen, oxygen, and, possibly, hydrogen.

When, as in Fig. 1, the nitride oxidation mask and the underlying thin oxide film are removed, the nitride ribbon may remain present. Consequently, the gate oxidation will not be effective in that area and the results shown in Fig. 2 and 3 are to be expected. The fact that this effect is often not observed can be explained by removal of the nitride ribbon due to some overetching applied when the oxide film is removed. Nitridation experiments, to be described later on in this paper, lead us to believe that the nitride formed at the silicon surface is probably not more than 10-20Å thick.

Further Evidence for the Occurrence of the "White Ribbon" Effect

We have argued that, if the given explanation is true, the effect indicated in Fig. 4 will always take place (in the given process conditions). This can readily be checked by doing experiments as indicated in Fig. 5. In this case the nitride oxidation mask is removed after the LOCOS process carried out by oxidation in wet O_2 (water at 95°C through which oxygen is bubbled, the same result is obtained with nitrogen as carrier gas), but the thin oxide film under it is kept

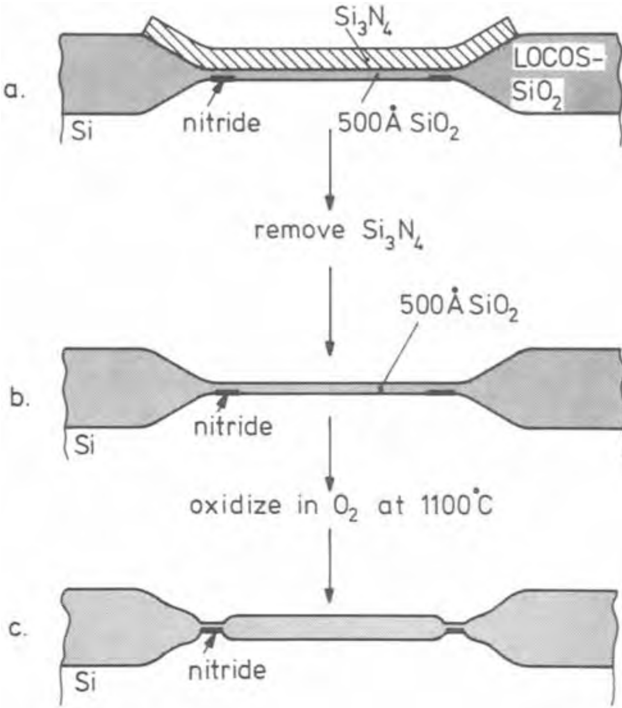

Fig. 5. Experimental procedure to show that the nitride formation along a LOCOS edge always takes place (under the given conditions of local oxidation: 16 hr steam at 1000°C).

in place. This means that any nitride formed under it cannot be attacked either. A subsequent oxidation treatment would then cause no (or retarded) oxide growth in the "ribbon areas." A cross section like that indicated in Fig. 5c would then be the result.

The cross section in Fig. 6 shows that the expected result is obtained. In this case the oxidation after nitride removal was carried out for 2 hr in dry oxygen at 1100°C. The 500Å SiO_2 already present has increased in thickness to 1800Å, but in a ribbon-type region along the LOCOS edge the oxide has remained 500Å thick.

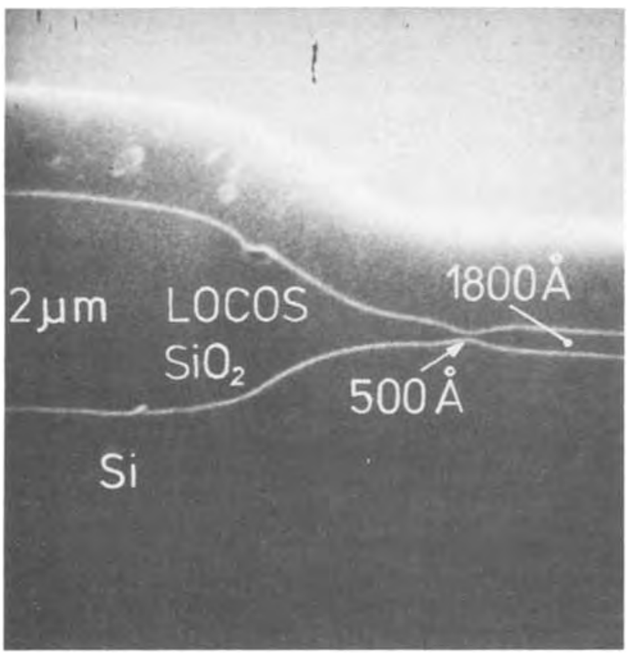

Fig. 6. Cross section of a silicon sample which had been subjected to a procedure as shown in Fig. 5. Experimental conditions: LOCOS by steam oxidation, 16 hr at 1000°C; oxidation after nitride mask removal, 2 hr O_2 at 1100°C.

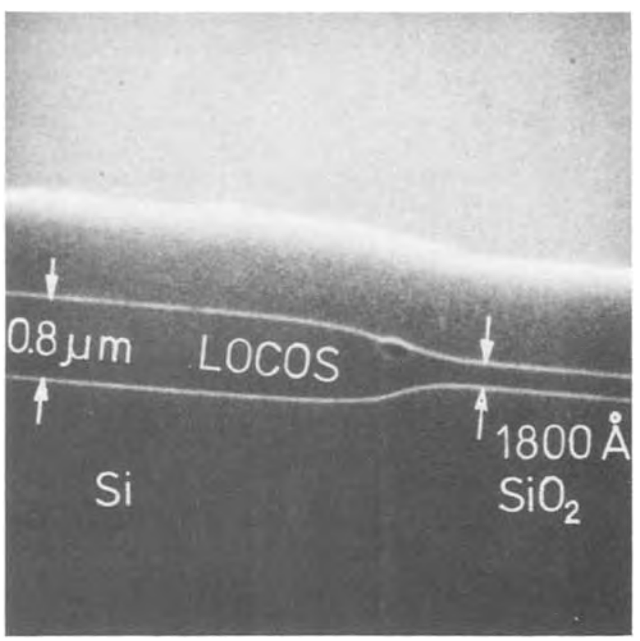

Fig. 7. Cross section of a silicon sample which had been subjected to a procedure as shown in Fig. 5. Experimental conditions: LOCOS by oxidation in dry O_2, 64 hr at 1000°C; oxidation after nitride mask removal, 2 hr at 1100°C. In contrast with Fig. 6, no oxidation retardation along the LOCOS edge is observed.

Figure 7 shows a cross section of a sample subjected to the same reoxidation treatment of 2 hr dry oxygen at 1100°C. In this case, however, the LOCOS pattern was grown in dry O_2 (64 hr at 1000°C, yielding 0.8 µm SiO_2). In contrast with the wet oxidation case, no indication of a ribbon-type oxidation masking effect along the LOCOS edge is observed. This means either that during dry oxidation the formation of nitrogen due to oxidation of silicon nitride is much less effective, or that the nitrogen formed diffuses less rapidly through SiO_2, or that the nitrogen species formed in this case are not very reactive with the silicon surface.

Nitride Formation during Heat-Treatment of Oxidized Silicon in NH_3 Gas

The foregoing results and their probable explanation brought us to the idea that a similar effect might be obtained by heating oxidized silicon in NH_3 gas. NH_3 molecules or reactive dissociation products of it such as nitrogen atoms might be expected to diffuse through SiO_2 and cause nitride formation at the Si-SiO_2 interface. The easiest way to check such nitride formation is to subject the samples afterwards to a thermal oxidation treatment. The oxide will not increase in thickness as long as oxidation-masking silicon nitride has not been converted to silicon oxide.

Table I gives some results for a nitridation treatment at 900°C. One sample had a very thick (20,000Å) ox-

Table I. Oxidation resistance of (111) oriented oxidized silicon slices after nitridation. Nitridation: 16 hr at 900°C in N_2 with 3% NH_3.

First oxidation treatment	Oxide thickness	Oxidation resistance at 900°C in O_2 after nitridation	SiO_2 thickness which can be grown on bare Si during time of oxidation resistance
Boiling nitric acid	20A	10 hr	1300A
15 min dry O_2 at 1100°C	500A	7 hr	1100A
16 hr steam at 1000°C	20,000A the oxide was then thinned by etching to 500A	3 hr	650A

ide. As such a thick oxide increases very slowly in thickness during further oxidation, we etched it down to 500Å after the nitridation cycle and then measured the oxidation resistance. The table shows that even for the thick oxide a considerable oxidation resistance effect is found, although less than for the thinner oxides. This indicates that, although the diffusion of the nitrogen through the SiO_2 has influence on the nitridation, the presence of oxide does not prevent the effect at all. The fact that the sample with the 20,000Å thick oxide shows resistance against oxidation even after the major part of the oxide has been etched off proves that nitridation occurs at or near the Si-SiO_2 interface. This does not exclude, of course, that some nitridation effect may occur throughout the oxide, but we have no indications that this is an appreciable effect. Assuming that the nitridation treatment does not change the SiO_2 properties but rather adds a nitride surface film, some nitride thicknesses were calculated from ellipsometric measurements. Table II presents results as a function of temperature and (at 1000°C) as a function of time. The initial oxide was 20Å in this case and made by oxidation in boiling nitric acid. Using samples with 500Å thermal oxide, we obtained in this manner a nitride thickness of 10Å after nitridation for 16 hr at 1000°C (to be compared with 18Å for a sample with 20Å initial oxide). Material removal by sputtering combined with Auger electron spectroscopy was carried out on samples with 20Å initial oxide, treated with N_2-3% NH_3 for 16 hr at 1000°C. The results revealed the presence of oxygen at the top and nitrogen at the silicon side of the surface film(s).

A few experiments were carried out with hydrogen instead of nitrogen as the carrier gas for the NH_3. Oxidation resistance appeared to be of the same order of magnitude. It has recently been shown by Raider, Gdula, and Petrak (5) that nitrogen gas as such has a nitridation effect, even when a (thin) silicon oxide film is present on the silicon. These authors heated silicon samples for several days at 1000°C in N_2 and found an oxidation resistance time (in O_2 at 1000°C) of the order of a couple of hours. Table III indicates clearly that NH_3 is indeed much more effective than N_2. Although we found oxidation retardation after 16 hr treatment at 1150°C in N_2 of a silicon slice covered with 500Å SiO_2, heating of a similar sample for 16 hr at 1000°C did not result in a measurable effect. For comparison, a result has been given of a treatment for 16 hr at 1000°C in N_2 with 3% NH_3 added. In this case an oxidation resistance time of 10 hr was measured.

Although the nitride films formed in the described manner are rather thin, we think that they may have a number of interesting device applications; for example, as masking layers. In Tables I and III we have indicated how much oxide can be grown on bare silicon during the time that a nitridized surface can withstand oxidation. The figures indicate that employment for local oxidation of silicon (the substrate or, if present, poly-Si lines) is possible, although not when thick LOCOS patterns are desired. For that purpose thicker nitride films would be needed. Table II indicates that the nitride film thickness is limited. Diffusion of either nitrogen or silicon through the film may be the limiting factor for further growth. We would like to emphasize, however, that the present paper presents preliminary results. As long as the nitridation mechanism is not fully clear, one may think, for example, that thicker nitride films may be possible when the NH_3 pressure is increased. Further, it may be that traces of H_2O have an effect on the nitridation and that the results presented need to be reconsidered in the light of more precisely defined experimental conditions.

Table II. Nitride thickness after treatment of Si (with 20Å SiO_2) in N_2 + 3% NH_3. The given values are based on ellipsometric measurements and the assumption that a nitride film with index of refraction $n = 2.0$ is formed in addition to the SiO_2 film ($n = 1.47$) already present.

	900°C	1000°C	1100°C
1 hr	—	15Å	—
4 hr	—	17Å	—
16 hr	11Å	18Å	27Å

Table III. Comparison of nitridation of oxidized silicon with NH_3 and with N_2

Initial oxide	Nitridation treatment	Time of oxidation resistance in O_2 at 1000°C	SiO_2 thickness which can be grown on bare Si during time of oxidation resistance
500Å	16 hr N_2 + 3% NH_3 1000°C	10 hr	2600Å
500Å	16 hr N_2 1000°C	0	0
500Å	16 hr N_2 1150°C	2 hr	1150Å

A very interesting aspect of nitridation is that a new type of silicon surface is formed. Measurements made so far show that the number of fixed oxide charges and fast surface states can be low [$2 \cdot 10^{10}$ per cm^2 for (100) surfaces] and that the nitridation causes an improvement of MOS structures with respect to charge trapping at the silicon surface under negative gate-bias conditions. The behavior of the new interface during annealing in various ambient gases can be different from the usual Si-SiO_2 interface and deserves further study.

Conclusions

The experimental results presented in this paper indicate that at elevated temperatures nitrogen can diffuse relatively easily through SiO_2 films on silicon so that silicon nitride can form at the Si-SiO_2 boundary. Ammonia gas has considerably more effect than molecular nitrogen. A specific case of production and subsequent diffusion of active nitrogen through SiO_2 was found in the case of preparation of LOCOS structures by steam oxidation. This can result in the formation of some nitride at the silicon surface along the LOCOS edge. It has a masking action against oxidation and consequently the gate oxide of MOS structures may become too thin near the LOCOS edge, resulting in low gate-breakdown voltages. In practice the effect can readily be overcome by removal of the nitride ribbon by etching. The nitridation effects may find use in the preparation of stable silicon surfaces and/or the preparation of special device structures.

Acknowledgments

The ellipsometry mentioned in this paper was carried out by A. Kroes and F. Meyer, and the Auger electron spectroscopy by J. J. A. M. Vrakking, to whom we are most grateful. We also wish to thank D. J. Breed for his stimulating interest and for the surface state measurements.

Electromigration in Current-Controlled LPE

L. Jastrzebski, H. C. Gatos,* and A. F. Witt*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

It was shown experimentally that current-controlled LPE (1) of III-V compounds (*e.g.*, GaAs and InSb) is brought about by electromigration of the group III and group V charged atoms in the liquid phase. The mobility of these charged atoms was estimated; the growth rate calculated from the mobility values was found to be in good agreement with measured growth rate. Peltier cooling at the growth interface makes no appreciable contribution to current-controlled LPE.

It has been reported (1) that LPE could be initiated and sustained by passing electric current across the growth interface while the temperature of the over-all growth system is maintained constant; growth has been attributed to Peltier cooling associated with current flow. InSb (1), GaAs (2), and GaAlAs (3) layers have been successfully grown by this method. In the present note experimental results are reported showing that electromigration leads to the observed LPE. Electromigration has been extensively studied in metallic melts (4); its occurrence in semiconductor solutions has also been proposed (3, 5).

Current-controlled LPE layers of GaAs were grown in a commonly employed apparatus described elsewhere (1). Using a 96.3 a/o Ga-3.7 a/o As solution doped with Cd and Sn and a current density of 8 A/cm^2 [with the (100) substrate having a positive polarity], an n-type GaAs layer ($n = 2.5 \times 10^{18}$/cm^3) 1 cm^2 was obtained, in 90 min at 850°C, having a thickness of 60 μm. On the basis of the Ga-As phase diagram, the amount of the epitaxially deposited GaAs would necessitate a temperature decrease of about 20°C, assuming that GaAs was nucleated only on the substrate (nucleation in the melt or elsewhere would necessitate even greater decrease in temperature). Yet, a total temperature decrease of only 0.2°C was measured with a thermocouple at a distance of about 200 μm from the growth interface. In a conventional cooling experiment using the same experimental arrangement (but no electric current), an epitaxial layer of about 0.5 μm was obtained upon a temperature decrease of 0.2°C.

These results indicate that Peltier cooling is not the primary driving force in current-controlled LPE; rather electromigration of As to the growth interface causes supersaturation of the melt and consequently nucleation and growth of GaAs at a virtually constant temperature. Consistent with this conclusion a p-type ($p = 2 \times 10^{19}$/cm^3), Ge-doped layer of GaAs was grown at 800°C at a current density of 7 A/cm^2 (with the substrate having a positive polarity); the rate of growth in this case, as determined by interface demarcation (6), was approximately the same as for n-type material, *i.e.*, 0.35 μm/min. In the case of the p-type GaAs, the sign of the Peltier coefficient (as determined experimentally) was opposite to that of the n-type GaAs and slight heating took place at the growth interface. It should also be pointed out that upon reversing the direction of the current, dissolution of the substrate took place, regardless of the sign of the Peltier coefficient, apparently due to electromigration of Ga to the growth interface and of As away from the interface.

To demonstrate the electromigration of As and Ga, the following experiment was performed. A GaAs wafer was brought into contact with Ga-As melt, in equilibrium at 850°C, contained in two wells as shown schematically in Fig. 1. The system was allowed to equilibrate for 30 min and then current was passed. The result obtained with a p-type (Zn-doped 2×10^{18}/cm^3) GaAs wafer ($1 \times 0.18 \times 0.03$ cm) after passing current (0.5 A/cm^2) for 40 sec in a hydrogen atmosphere is shown in Fig. 2. The solidified melts are attached to the ends of the wafer. It is seen that migration of the solution took place along the surface of the wafer up to regions B and B′ in the figure. Elec-

Key words: electromigration, liquid phase epitaxy, gallium arsenide.

tron microprobe analysis showed that the concentration of As in the solution on the wafer near B′ was more than 50% higher than on the surface near B. Apparently electromigration of charged As and Ga species caused the observed migration of the solution (4); no solution migration was obtained in the absence of an electric current. The distance of migration on the wafer was found to increase linearly with time and with electric field. Accordingly, effective mobilities for Ga (migrating to the negative end of the wafer) and for As (migrating to the positive end) were calculated to be 2×10^{-2} and 7×10^{-3} cm²/V sec, respectively. These mobility values are believed to be smaller than in the LPE process, since surface tension is acting against solution migration in the experimental arrangement of Fig. 1.

On the basis of the Verhoeven (4) analysis for electromigration in metallic melts, the growth rate during current-controlled LPE was estimated. Since the contribution of diffusion and the movement of the growth interface can be neglected, the flux of As toward the interface is (6)

$$J_{As} = C_{As}C_{Ga}\overline{V}_{Ga}U\,E$$

where C_{As} is the concentration of As in the melt (0.0235), C_{Ga} is the concentration of Ga, $\overline{V}_{Ga}$ is the partial molar volume of Ga (in the present case $C_{Ga}\overline{V}_{Ga} \simeq 1$), U is the difference in mobilities $v_{Ga} - v_{As}$ (taken from the present experiments $\approx 2.7 \times 10^{-2}$ cm²/V sec), and E is the electric field (10^{-3} V/cm); E was calculated from the current density (10 A/cm²), the dimensions of the solution, and the resistivity of the solution which was taken as 10^{-4} ohm-cm assuming a linear increase with temperature from its value of 2.6×10^{-5} ohm-cm at 30°C (7). On the basis of the above relationship, and assuming no nucleation of GaAs in the melt, a growth rate of $\sim 8 \times 10^{-1}$ μm/min is obtained; this value is in good agreement with the experimentally determined values of $4\text{-}7 \times 10^{-1}$ μm/min.

The above experiments were also carried out employing In-Sb solutions (25 a/o Sb) and InSb substrates at 450°C. The results were consistent with those obtained for the GaAs system. (The mobilities of In and Sb were estimated to be 3×10^{-3} and 0.6×10^{-3} cm²/V sec, respectively.)

In summary, it was shown that electromigration rather than Peltier cooling is the controlling factor in current-induced LPE. The implications of the present finding to the refinement of the growth and doping of III-V compound liquid-phase epitaxial layers are being pursued.

Cathodic Reduction Mechanisms of Manganese Dioxide from Derivative Discharge Curves

H. E. L. G. Schweigart and C. R. A. Clauss

Chemical Engineering Research Group, Council for Scientific and Industrial Research, Pretoria 0001, South Africa

ABSTRACT

Derivative discharge curves of α-, β-, or γ-MnO_2 can be resolved into a set of six normal distribution functions, designated as peaks O, A, B, C, D, and E, which can each be attributed to a specific reaction. Peak O situated at the highest cell voltages is attributed to the reduction of adsorbed oxygen. The following peak A which is linked to the formation of dissolved Mn^{++}-ions ends when the solubility product of $Mn(OH)_2$ is attained in the electrolyte. For peak B the over-all reaction $MnO_2 + Mn^{++} + 2H_2O + 2e^- \rightarrow 2Mn(OH)_2$ is proposed. In 9M KOH the electrochemical reduction of β-MnO_2 proceeds in one step to $Mn(OH)_2$, α-MnO_2 is at first (peak C) reduced to Mn_3O_4 and then (peak D) to $Mn(OH)_2$, and γ-MnO_2 reduces in three successive steps to an amorphous substance, Mn_3O_4 and $Mn(OH)_2$. As in practically all cases the presence of $Mn(OH)_2$ has been observed, it is proposed that bivalent manganese is the primary reduction product which reacts in alkaline electrolyte with unreduced MnO_2 to give secondary reduction products the kind of which depends on the type of MnO_2 involved, the electrolyte, and time of contact. Mixing MnO_2 with appropriate amounts of $Mn(OH)_2$ gives, under comparable conditions, the same products as obtained in electrochemical reduction.

Following the proposition of Balewski and Brenet (1) the first derivatives of discharge curves obtained during cathodic reduction of manganese dioxides under Leclanché-type dry cell conditions have been examined with a pulse galvanostatic analyzer (2, 3). The derivative discharge curves obtained can be resolved into a set of up to six normal distribution functions: peaks O, A, B, C, D, and E. Their relative importance is mainly governed by the mass ratios of electrolyte to manganese dioxide in the depolarizer mix pills (3). This observation and especially the changes of the peak areas with increasing mass ratios suggest that each peak may be attributable to a specific chemical reaction taking place in the depolarizer mixes during the cathodic reduction.

It is the purpose of the present communication to make proposals for this attribution. In order to obtain further evidence, discharge reactions of α-, β-, and γ-MnO_2 in 9M KOH and in modified Leclanché-type dry cell electrolytes have been investigated and the various reduction products formed in alkaline electrolyte have been examined by x-ray diffraction.

Experimental

Samples and discharge procedure.—The properties of the manganese dioxides used in the experiments are compiled in Table I and the compositions of the depolarizer mixes are presented in Table II. The pulse galvanostatic analyzer, preparation of the depolarizer mixes, and discharge tests together with their evaluation are described in foregoing publications (2, 3).

Key words: reduction, manganese dioxide, Leclanché, dry cell, potassium hydroxide, discharge curves, derivative, mechanism, reaction.

Examination of reduction products.—For the x-ray diffraction analysis of the reduction products, the discharge tests were interrupted at the desired reduction states, the depolarizer mix transferred from the test cells into the sample holder as quickly as possible and analyzed immediately. Part of the mix was washed with distilled water on a filter until the wash water was neutral, dried in a vacuum desiccator, and analyzed soon after. In some cases samples were stored unwashed and washed and investigated after a period of several days to determine the effect of washing.

The x-ray diffraction tests were carried out using a Philips x-ray diffractometer with unfiltered Cu radiation. The diffracted beam was monochromatized by a curved carbon crystal (AMR focusing monochromator E202) and measured with a pulse height discriminator.

Table I. Characterization of manganese dioxide samples used in experiments
