Initial Stages of Oxide Growth and Pore Initiation in the Porous Anodization of Aluminum

C. J. Dell'Oca*[,1] and P. J. Fleming*[,1]

Fairchild Semiconductor, Mountain View, California 94040

ABSTRACT

Ellipsometry studies of evaporated aluminum films anodized in 0.6M H_3PO_4 at constant current indicate that the anodic oxide produced is at first homogeneous with a refractive index of 1.62, as found for barrier anodic oxide of thin film and bulk Al. As the thickness increases, the optical properties change signifying the onset of pore formation. This occurs at increasing thicknesses with increasing current density, however, pore formation always occurs well before the peak in voltage is reached at constant current. Ellipsometry indicates that the mode of development of the oxide prior to pore initiation is similar to that of barrier anodic oxides. However, the efficiency of oxide growth and the electric field required to pass a given ionic current, J, are generally lower and approach values for barrier oxides (of thin film and bulk Al) only at high current densities. The curvature of the log J *vs.* E curve is in the opposite sense to that normally observed for anodic oxides and it is interpreted in terms of cation and anion motion. After pore formation the efficiency of oxide growth increases and becomes near unity when steady-state formation conditions are reached. These results appear consistent with the model that dissolution at the pore bases is an electric field-aided process.

Anodization of evaporated aluminum films is becoming increasingly important in the fabrication of monolithic, large-scale integrated circuits utilizing aluminum metal electrical interconnections where anodization provides both improved processing and reliability (1). In order to arrive at optimum processing, it is necessary to understand the anodization properties of aluminum films. In a previous paper, the barrier anodization properties were studied and found to be essentially the same as those of bulk aluminum (2). The present study is concerned with porous anodization. In particular, the initial stages of oxide growth and the onset of pore formation are quantitatively characterized using ellipsometry. This has not been done previously for porous anodization of aluminum and the results should be valuable in arriving at the mechanism of pore formation.

Of the vast literature on porous anodization of aluminum, very little deals with initial stages of film formation. That which does is mostly qualitative because of the difficulties involved with measuring very thin films. The evidence that is presented indicates that a barrierlike film initially forms, followed by pore initiation and porous oxide growth. For example, the anodization characteristics, such as the time development of current at constant voltage (3) or of voltage at constant current, are at first similar to those observed in barrier anodizations. Also, direct observations of the surface with electron microscopy indicate that surface roughness occurs after some growth has taken place (3, 4). Thus, the oxide formed in the initial stages of porous oxide growth and that which remains interposed between the pore-containing layer and the metal is often referred to as a barrier layer. In this paper, these layers will be respectively referred to as the initial film (or oxide) and the pore-free layer. To avoid ambiguity, the term "barrier" will be reserved to describe oxides formed in a barrier anodization.

The basic difficulty involved with the study of the initial film is the measurement of thickness. Previous methods include reanodization in barrier film forming electrolyte (5) and direct observation of thickness using cross sections and electron microscopy (4). The first method assumes that the ionic conductivity of the initial film is the same as that of barrier oxides. These methods have limited resolution and accuracy and, in addition, are destructive and therefore cumbersome. In the present study these drawbacks are overcome using ellipsometry. This is a nondestructive optical technique that is very sensitive to the presence of and changes in thin surface layers. Thus, it has been widely used to characterize properties of thin films (6) including those of barrier oxides formed on bulk (7, 8) and thin film aluminum (2).

If the initial film growth characteristics are as have been presented, then it should be possible with ellipsometry not only to determine the growth properties but also to determine the onset of pore formation. That is, the optical properties of the initial film should at first be similar to those of barrier oxides which have been found to be optically homogeneous (2, 7). The advent of pore formation causes a change of optical properties which should be detectable by ellipsometry. This turns out to be the case.

Experimental

The investigation was carried out with 2 μm thick aluminum films deposited on thermally oxidized polished silicon wafers by the electron beam evaporation of 99.999% pure aluminum under high vacuum. Films deposited under these conditions have barrier anodization properties which are not detectably different than those of bulk aluminum (2). The thin film is more convenient to use than bulk aluminum because a smooth surface suitable for anodization is obtained directly without polishing and because photolithography and etching can be used to precisely define the anodization area.

Two types of specimens were used and these are shown schematically in Fig. 1. One type had a 3.22 cm^2 anodization area defined using photolithography and etching of a previously formed, 2700Å thick, barrier anodic oxide on the aluminum film. The other type had a circular 10 cm^2 aluminum area defined by photolithography and etching of the deposited aluminum film. An aluminum strip 1 mil wide was left to connect the aluminum in the contact area to the anodization area. The strip is of negligible area but

it is sufficiently long to keep the contact area above the electrolyte during anodization. The first type of specimen was used mostly for kinetic studies while the second type was used for density measurement. No noticeable difference in oxide growth was noted between these two surface preparation methods.

The anodizations were carried out at constant current (regulated to 0.3%) in a stirred 0.6M H_3PO_4 electrolyte held at 25° ± 0.2°C. This electrolyte was chosen because the pore-free portion of the porous oxide can, depending on current density, be varied over a substantial thickness range, leading to a more precise determination of film properties. The anodizations were carried out in a stepwise fashion with ellipsometry measurements made on the surface prior to anodization and after each anodization step. All ellipsometry measurements were made at 70° angle of incidence using a He-Ne laser unpolarized light source of 6328Å wavelength. Other experimental details are as described in a previous paper (2).

Results

Optical properties.—Since the analysis of ellipsometry results from the initial film relies heavily on the ellipsometry characteristics of barrier anodic oxide formed on evaporated aluminum films, the latter results are quoted in Fig. 2 (2). This figure presents the conventional Δ *vs.* ψ plot used in ellipsometry, where Δ and ψ are the quantities determined in ellipsometry and are related to the properties of the film and underlying substrate. The experimental results begin at the point marked "bare" substrate which represents the surface of the aluminum film prior to barrier anodization in a tartrate solution. As the surface is anodized and remeasured at intervals, the experimental points obtained (denoted by crosses) trace out, in a counterclockwise direction, an elliptically shaped curve which eventually recycles on itself as indicated by the circular points. The curve in the figure represents the best fit to the experimental points indicating a uniform oxide with an index of refraction ($N = n - jk$) of 1.62 on aluminum having a refractive index of 1.3-6.5.

As expected, the ellipsometry results characteristic of initial film growth in 0.6M H_3PO_4 are at first similar to those of barrier oxides. Figure 3 shows a superposition of results from various anodization current densities. The dashed curve in this figure is the ellipsometry curve for barrier anodization taken from Fig. 2 and it serves as a reference. The ellipsometry measurements taken at intervals during porous anodization at first are coincident with the reference curve indicating that the initial film has the optical properties of barrier films. For sake of clarity, the experimental points are not shown. Eventually, the experimental curve deviates from the reference curve signifying a change in optical properties, *i.e.*, the presence of pores. The reproducibility of these results is good in the region before deviation and for some time

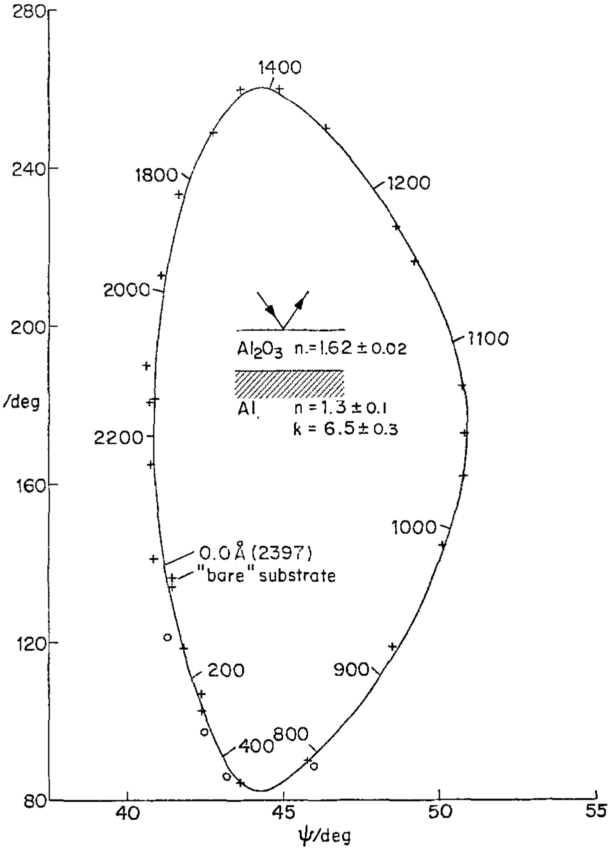

Fig. 2. Ellipsometry results and fitted curve for anodization of aluminum films in 3% tartaric acid (pH of 5.5) at 25°C (2). Numbers along curve indicate film thickness.

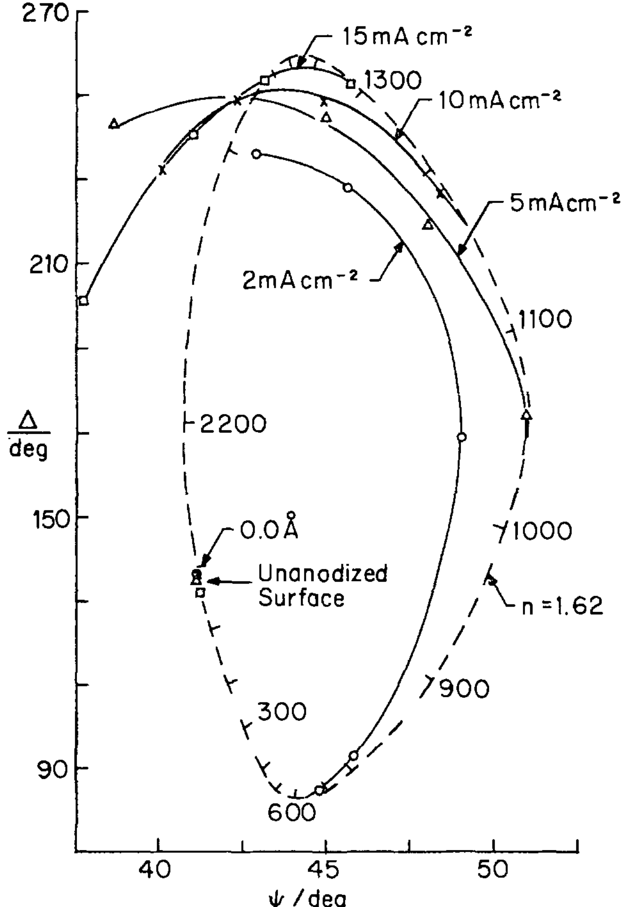

Fig. 3. Departure from dashed curve representing the homogeneous film in Fig. 2 of ellipsometry results from oxides formed at various current densities on Al in 0.6M H_3PO_4.

after deviation from the reference curve. The reproducibility becomes less good at large deviations, *i.e.*, near the ends of the experimental curves.

A quantitative analysis of these results is not feasible because of the complex mode of film growth after pore initiation. That is, the growth rates of the initial and pore containing layers are expected to, respectively, decrease and increase in a complex way. In addition, the size and number of pores is expected to change with voltage until the steady-state voltage is reached in the constant current anodization (4). A further complication to this picture is that in addition to pore formation at the upper surface of the growing film, after a while, roughening of the aluminum also occurs, effectively changing its optical properties.

A qualitative analysis of the experimental results is instructive and can be made using a simplified model of growth. In this model it is assumed that, once the pores begin to form, these pores have a fixed size and they penetrate the growing layer at some fixed rate. Indicative calculated ellipsometry curves are given in Fig. 4 and 5. The respective thicknesses at which pore formation begins are chosen as 500Å (Fig. 4) and 1000Å (Fig. 5) to, respectively, correspond to the 2 and 5 mA/cm² formation currents.

The simplest case is one where the pores grow at a rate equal to film growth. In other words, the initial layer remains fixed at the pore-initiation thickness. Optically, this corresponds to a porous layer growing over a pore-free layer of fixed thickness and refractive index of 1.62. This simple model predicts that the refractive index of the porous layer must be lower than that of the barrier films in order to obtain ellipsometry curves that deviate on the correct side of reference curve (Fig. 4 and 5). This behavior is expected since the presence of pores decreases the density of the oxide.

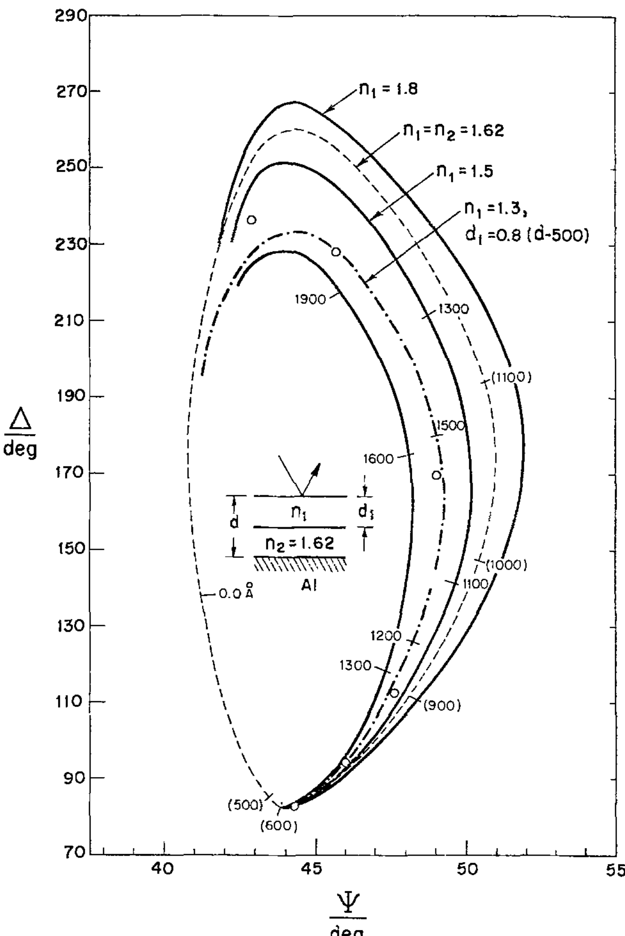

Fig. 4. Calculated ellipsometry curves using a two-layer approximation of film growth after pore initiation occurs at 500Å. ——— Layer 2 fixed at 500Å; — · — · layer 2 contributes 20% of the total film growth; — — — reference curve from Fig. 1; ○ ○ ○ = 2 mA/cm² experimental points from Fig. 3; numbers indicate total film thickness, *d*, and bracketed numbers apply to reference curve.

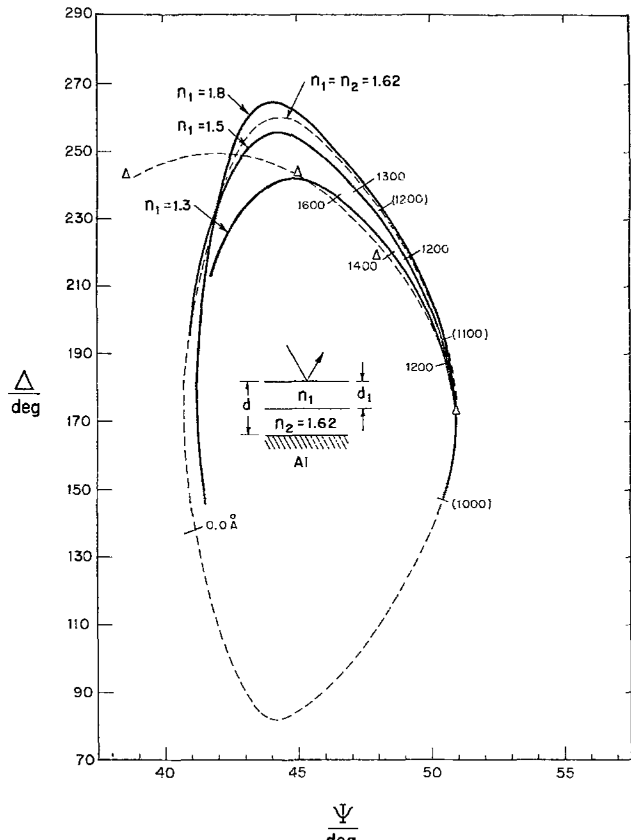

Fig. 5. Same as in Fig. 4 but for the case of pore initiation at 1000Å and layer 2 fixed at 1000Å (—△—△ = 5 mA/cm² experimental points from Fig 3).

A pore growth rate less than that of film growth, *i.e.*, an initial layer that continues to grow at some rate after pore initiation, has the effect of moving the calculated curves in Fig. 4 and 5 closer to the reference curve. In the extreme case where only the initial layer grows (*i.e.*, no pore formation), the reference curve is regained. A calculated curve which comes close to the 2 mA/cm² results is shown in Fig. 4. In this case, after pore initiation at 500Å, a porous layer of refractive index 1.3 contributes 80% of the total increase in film thickness.

One characteristic difference between the calculated and experimental curves is that with increasing thickness the former turn and proceed to pass near the point marked 0.0Å, which represents the original surface. The experimental results do not have this tendency because as the pores grow, a scallop is developed in the aluminum surface under each pore cell (4). The result is a fine grain surface roughness which effectively changes the refractive index of the aluminum and shifts the ellipsometry results.

Pore initiation.—As a first approximation, the onset of pore formation is determined from the point where the ellipsometry curve begins to deviate from the reference curve (Fig. 3). This point occurs approximately at 600, 1050, 1150, and 1275Å, respectively, for formation currents of 2, 5, 10, and 15 mA/cm². The accuracy within which these points can be determined depends on where the deviation occurs on the reference curve. The sensitivity is higher in the 900-1200Å region than at the apex of the reference curve.

The voltage of pore initiation is determined from the above thickness using a graph of voltage *vs.* thickness for the various anodization current densities. (This figure is presented later in the section on growth properties.) The important result here is that pore initiation occurs well before the peak in voltage is reached in the constant current anodizations. Figure 6 shows the voltage-time curves which are characteristic of porous aluminum anodization and typical for the present experiments. The onset of pore formation occurs at about 70% of the steady-state voltage. O'Sullivan and Wood using electron microscopy have reported for anodizations at 5 mA/cm² in 0.4M H_3PO_4 at 25°C that very minor film roughening is noted after 40 sec of growth (4). This is in agreement with the present results at the same current density in a somewhat more concentrated electrolyte.

The thickness at which the onset of pore formation occurs has probably been overestimated to some degree. This is because the deviation from the reference curve occurs slowly with changing film thickness. Some indications of how slowly can be obtained from the calculated curves of Fig. 4 and 5. If a similar estimation of pore initiation is made for these curves, then the onset of pore formation would be thought to occur at about 600Å (Fig. 4) and 1050Å (Fig. 5) when, in actuality, it began at 500 and 1000Å, respectively.

However, it is highly unlikely that pores are present and grow from the outset of the anodization. This would require the pore-containing portion of the film to remain relatively insignificant until near the point of deviation and then almost abruptly become significant. To be insignificant, the pore-containing layer should change the refractive index of the over-all film by less than 1% for the formations above 2 mA/cm². In addition to this argument, the thickness determined by ellipsometry was checked at various points along the 10 mA/cm² anodization by an independent method utilizing the Tolansky interference measurement of the height of a silvered step formed in the anodic oxide. These measurements were found to be in agreement.

Characteristics of initial film growth.—The characteristics of initial film growth at constant current in 0.6M H_3PO_4 at 25°C were found to be similar to those of barrier oxide growth. That is, the thickness increases linearly with time and the voltage increases linearly with thickness. Typical results are given in Fig. 7 and 8. The thickness was determined using ellipsometry and the optical properties of barrier film (reference curve of Fig. 3). In some cases the thickness was checked by the independent method

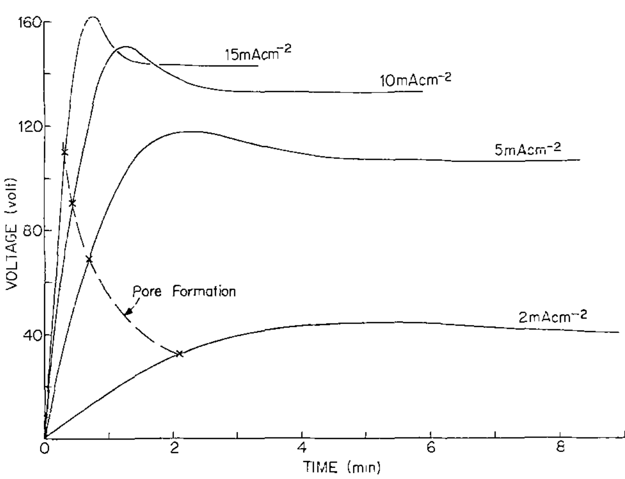

Fig. 6. Time development of voltage for porous anodization at various current densities showing the onset of pore formation.

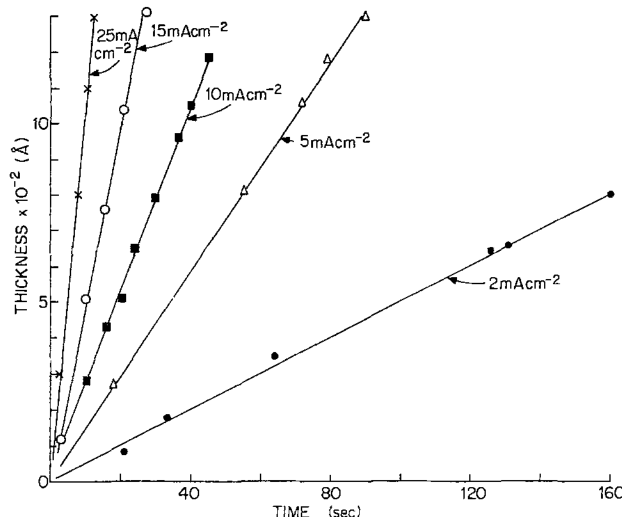

Fig. 7. Typical initial film thickness development with time for various anodization current densities.

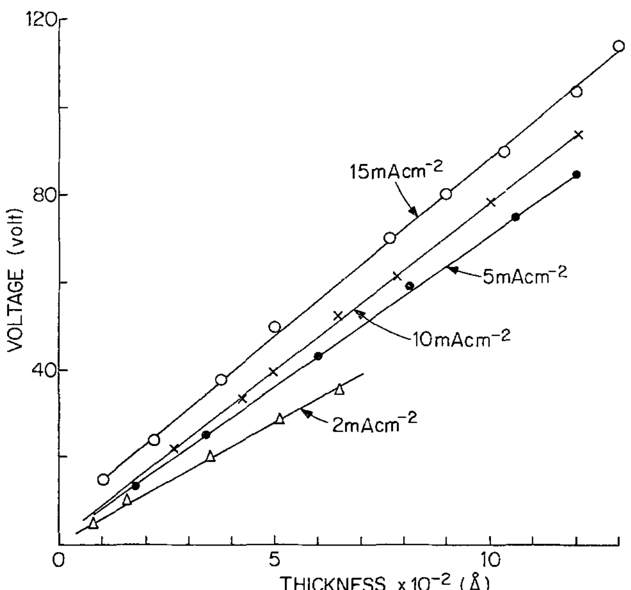

Fig. 8. Typical cell voltage development with initial film thickness for various anodization current densities.

already mentioned. These results were generally quite reproducible.

The efficiency of oxide growth, *i.e.*, oxygen uptake, and the efficiency of aluminum consumed during the anodization were determined and found to be different. The efficiency of oxide growth is low and increases with current density of formation (Table I). The efficiency is calculated using Faraday's law for an oxide of formula Al_2O_3, and the rate of film growth determined from the experimental thickness *vs.* time curves. An oxide density of 3 g/cm³ was used in these calculations. This is within the range of values (2.90-3.2 g/cm³) obtained from our measurements of density and is a value that has been used by others (9). By comparison, barrier films formed in a tartrate

Table I. Efficiency of initial oxide growth in 0.6M H_3PO_4 at 25°C

Applied current (mA/cm²)	Electric field (10^6 V/cm)	Growth rate (Å/sec)	Growth efficiency (%)
2	5.5	5	43
5	6.74	14	47
10	7.66	30	51
15	8.2	51	58
25	8.6	109	74

solution at the same temperature, have efficiencies close to 70 and 80%, respectively, at 2 and 10 mA/cm^2 formation (2). While the efficiency of oxide formation is low, the efficiency of aluminum used in the anodization approaches unity. This was determined from calculations based on the difference in weight from prior to anodization to after anodization and removal of the anodic oxide. That is, the amount of aluminum used in the anodization corresponds to that predicted from Faraday's law for the charge passed. This indicates that, within experimental error, electronic currents are not contributing to current transport through the oxide. Hence, the low efficiencies observed for oxide growth occur from the loss of aluminum to the electrolyte by oxide dissolution.

The open-circuit oxide dissolution rate in the electrolyte was measured and found to be less than 0.2Å/sec which is insignificant when compared to the rates of oxide growth. The effect was further minimized by minimizing the open-circuit exposure of oxide to the electrolyte. Thus, oxide dissolution must be a function of electric field in the oxide in order to cause the observed loss in oxide growth efficiency. This is discussed later.

The growth kinetics of the initial oxide, *i.e.*, the log of ionic current density *vs.* electric field, are given in Fig. 9. The electric field is obtained from the slope of the voltage *vs.* thickness curves. The ionic current density (dashed curve, Fig. 9) is the applied current density (left curve, Fig. 9) corrected for efficiency of growth. The curve on the right in Fig. 9 represents the growth kinetics for barrier oxide formed in a tartrate solution. It is seen that at high current densities the growth kinetics of the initial oxide approach that of barrier oxides. At lower currents, the ionic conductivity of the initial film is significantly higher than that of barrier oxides. Also, note that the electric fields are lower than the 10^7 V/cm which have been reported to occur across the dense oxide after steady-state porous oxide growth is reached in the same electrolyte (4).

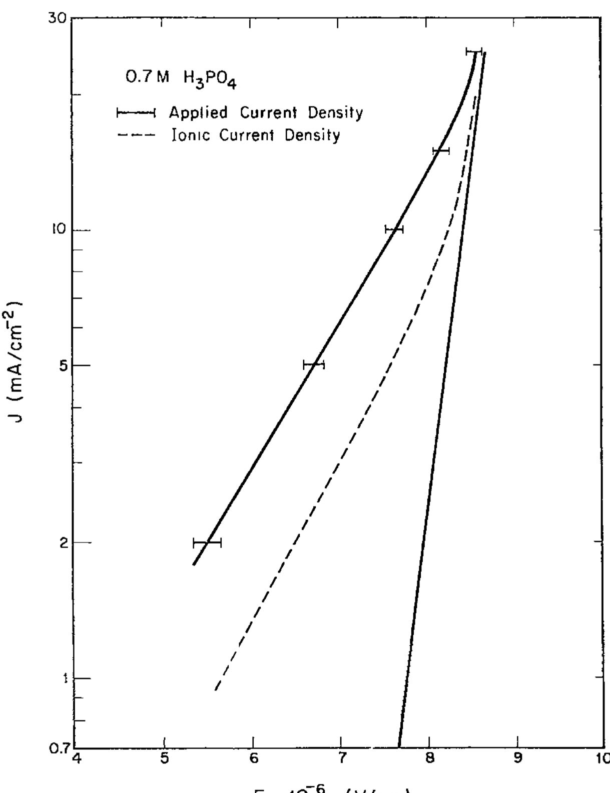

Fig. 9. Constant current kinetics of initial film growth in 0.6M H_3PO_4 at 25°C. Curve to the left represents applied current density. Dashed curve is the ionic current density. The curve on the right gives the kinetics obtained in the barrier anodization of Al films (2).

The higher ionic conductivity of the initial film does not appear to be an artifact of the thickness measurements. Systematic measurement errors in thickness do not enter because rates of change rather than absolute values are used to determine growth efficiency and electric field. In order to observe a lower field, the initial film thickness must be overestimated by a factor that increases with thickness. This is highly unlikely even if it is assumed that pore formation occurs far earlier than estimated. If pore formation occurred much earlier than has been estimated, then it might be expected that the effective film thickness for ionic conduction would be less, hence reducing the required voltage and leading to a lower estimate of electric field. Contrary to this is the fact that the presence of pores effectively decreases the anodization area and hence increases the effective current density and, in turn, the electric field. Thus, the measured electric field across the pore-free layer is far greater than that of the barrier films, being on the order 10^7 V/cm (4). In addition, if pores are present, the qualitative indications (Fig. 4 and 5) are that using the reference curve, ellipsometry would underestimate the thickness of the film and hence the efficiency of oxide growth would also be underestimated. This would have the effect of bringing the ionic current (Fig. 9) closer to the applied current and hence lowering the electric field. Thus, it is not clear that early pore formation would lead to an underestimation of the electric field. In any event, the present evidence and that from direct observation (4) almost exclude early pore formation.

Steady-state porous oxide growth.—Although it is not the intention of this paper to characterize porous film growth, it was found that the growth rate is significantly higher during steady-state porous anodization. That is, after the voltage reaches a more or less constant value under constant applied current. A typical result for the 10 mA/cm^2 anodization is shown in Fig. 10. The thickness of the initial film was determined by ellipsometry and by Tolansky interference measurement of step height. The thickness of the porous film was determined solely by the latter method and also by a mechanical surface profilometer. The results extend out to film thicknesses beyond 3 μm.

Discussion

Kinetics of oxide growth.—The optical properties of the initial oxide formed in a porous anodization of aluminum are similar to those of the barrier anodic oxides. The log J *vs.* E characteristics do appear to be different, but this does not necessarily imply a different mechanism of ionic conduction. In fact, it may be argued that these results are consistent with the high field Frenkel defect theory of ionic conduction in anodic oxides and the mobility of both oxygen (anions) and metal (cations) ions during oxide growth. There is a body of evidence indicating that both ions are mobile and contribute to oxide growth at the oxide-electrolyte and metal-oxide interface, respectively. [For a review of anodic oxides see Ref. (11) and (12).] According to the Frenkel defect theory (10), ionic conduction occurs by a thermally activated electric field-aided process in which ions of charge q overcome energy barriers of height W and have a half-jump (activation) distance of a. The ionic current density then is $J = Ae^{-(W-qaE)/kT}$, with A, W, and qa characteristic of the particular ion species. In a log J *vs.* E plot, each ion current will be represented by a straight line of slope proportional to the product qa. The two lines will intersect at some point. The total current (sum of the ion currents) will be dominated by the ion with the lower qa below this point and by the ion with the higher qa above this point. Thus, the

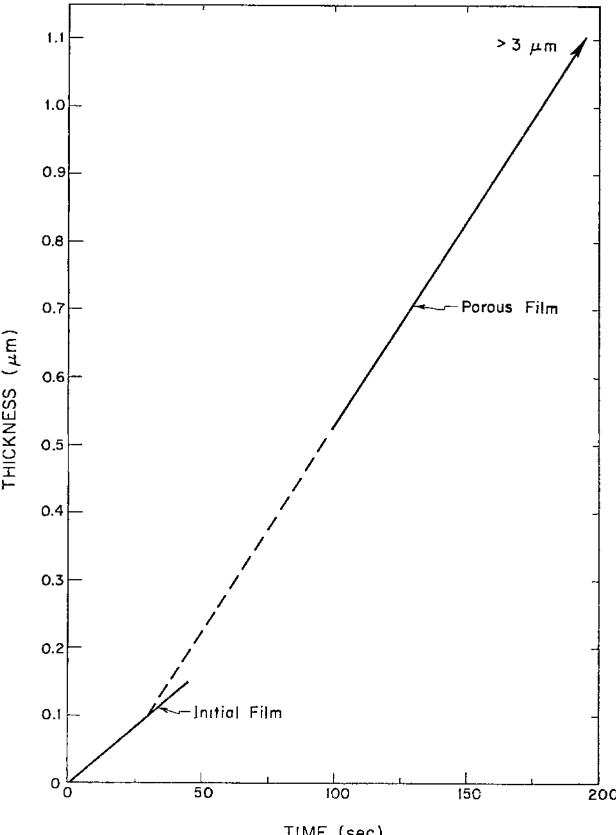

Fig. 10. Development of film thickness with time for a 10 mA/cm² porous anodization in 0.6M H_3PO_4 at 25°C.

total current will have a curve whose slope increases with electric field as is observed in this study.

The foregoing argument was first presented (11) to show the inconsistency of the Frenkel defect theory and the curvature observed for anodic oxides of Ta, Al, and Nb. The curvature for these oxides is in the opposite sense, *i.e.*, the log J *vs.* E curve slowly decreases in slope with increasing electric field, giving a log $J \propto \alpha E - \beta E^2$. While numerous models have been proposed [see Ref. (11) and (12)], it is not known whether the effect is intrinsic to ionic conduction or whether, as has been proposed (13), caused by incorporation of electrolyte impurities into the oxide. It has been found that the curvature is enhanced for Ta anodized in dilute H_3PO_4 or more concentrated H_2SO_4, where impurity incorporation is more pronounced (12).

If impurities cause curvature, why is the curvature not noted for the present anodization in H_3PO_4? Perhaps impurity incorporation is much smaller in Al_2O_3. Or, the effect may simply be overwhelmed by the change from oxygen to metal ion current domination. However, it is certain that the low efficiencies, particularly at low currents, serve to minimize the fraction of oxide-containing impurities. If the incorporated impurities are, as has been indicated (14), immobile with respect to the rate of oxide growth, then incorporation of the impurities into the oxide will only occur if the metal ion transport number, t_m,[2] is greater than the difference between the efficiency of oxide growth and unity. The t_m for Al anodization in H_3PO_4 is not known. However, it is expected to increase with current density of formation. For example, for the anodization of Al in another aqueous electrolyte (ammonium citrate), t_m varied from 0.56 at 1 mA/cm² to 0.72 at 10 mA/cm² (15). Since both the efficiency and t_m increase with current density, the effect of incorporation will become more noticeable at higher currents. In fact, if impurity incorporation occurs with Al_2O_3, it should be expected that at higher currents than those used in this study the log J *vs.* E curve for the initial oxide would tend to curve back in the direction found for oxides of Ta, Al, and Nb.

[2] t_m is the fraction of oxide which grows at the oxide-electrolyte interface from metal ion transport. The remaining oxide grows at the metal-oxide interface from oxygen in transport.

Thus it appears that the kinetics of initial film growth can be analyzed in terms of anion and cation currents. Then, in the linear region, *i.e.*, at low currents, the activation or half-jump distance should be calculated for an anion with a valence charge of $q = -2e$ for O^{--} or $q = -e$ for OH^- as proposed by Hoar and Mott (16). The activation distance found is 1.1 and 2.2Å, respectively, which are not unrealistic values. An activation distance for cation motion cannot be obtained because the present data do not reach high enough currents where presumably the linear region for cation-dominated conduction is found. However, there seems to be a tendency toward a line similar to that of the barrier oxide kinetics. Based on a metal ion with q of $3e$, an activation distance close to 3Å is obtained both for barrier oxides formed on thin film (2) and bulk aluminum (9).

Pore formation.—The two observations important to pore formation and growth are the efficiency of initial film formation and its increase during porous film growth. Both of these observations are in direct support of the model that etching at the pore bases is an electric field-aided process (16). First, although the efficiency of initial film growth increases with current density (and hence electric field), the net dissolution rate (inefficiency) also increases with current density or electric field. In fact, the rate of dissolution increases exponentially with electric field, except at the higher current density where the rate of increase is slower. Secondly, as the porous film grows, the electric field across the porous oxide becomes much less than across the pore-free layer; therefore, the efficiency of growth should become near unity since the surface dissolution is decreasing.

In addition to field-assisted dissolution, it is also claimed that some anion motion is necessary to sustain porous film growth (16). Dissolution requires high fields. Fields corresponding to 10^7 V/cm have been observed across the pore-free layer for anodization in dilute H_3PO_4 (4). However, from the observation of initial film growth, anion-current dominance occurs at lower fields. There are several explanations for this apparent inconsistency. One is that oxide curvature tends to increase the electric field at the surface of the pore base while the bulk of the pore-free oxide experiences lower fields. However, in order to explain this in terms of anion and cation electric field dependent currents, it is necessary to postulate the buildup of space charge in the oxide. A more likely explanation appears to be that of fringing electric fields. That is, ionic conduction takes place not only as postulated through the oxide surrounding the pore base (4) but also for some distance up the pore wall. The idea is not unreasonable, when it is considered that ionic conduction through the initial film is observed to occur at fields that are considerably lower than that effectively across the pore base oxide. Thus, ionic conduction can occur to (or from) points on the pore wall surface which are separated from the metal by distances considerably larger than the thickness of the oxide under the pore base. Proceeding from the pore base up the pore wall, the electric field will decrease in some fashion. The decreasing field is accompanied by decreasing ionic current which, in turn, has an increasing oxygen ion component. Since this current flow is toward the metal under the pore wall, this is exactly what is necessary to build up the pore wall. In addition, since the fringing fields also support dissolution, a variety of pore shapes near the pore base are possible depending on whether the

fringing field causes net growth or dissolution at a point.

Turning to the mechanism of pore initiation, it is difficult to reconcile the present ideas of field-aided ionic conduction and oxide dissolution with an oxide thickness instability resulting in a pore. What is even more perplexing is that at a given current density pore initiation occurs after a certain oxide thickness is reached. Perhaps, at a given current density, a certain thickness must be reached before the allowed local variation in oxide thickness reaches a value where the probability of pore initiation is high. Pore initiation might occur at the edge of such a region where the gradient in electric field gives rise to a varying interplay of dissolution, oxide growth, and perhaps metal and oxygen ion motion.

Conclusions

Ellipsometry has been shown to be a useful technique for studying initial film growth in porous aluminum anodization. It can be used to determine both the growth properties and the onset of pore formation.

The initial films formed in the course of porous anodization resemble ordinary barrier films both optically and in their mode of development. However, the electric field required to grow these films is significantly lower and approaches values for ordinary barrier films only at high current densities.

The observations that film dissolution increases with field, that the efficiency of oxide growth increases after pore initiation, and that the fields causing growth are significantly smaller prior to pore formation appear to be in direct support of the model presented by Hoar and Mott (16), that the dissolution at the pore base is a field-aided process.

Manuscript submitted Jan. 13, 1976; revised manuscript received June 18, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Line Emission Penetration Phosphors: Preparation and Cathodoluminescent Properties

S. Ignasiak*,[1] and H. Veron[2]

Sperry Research Center, Sudbury, Massachusetts 01776

ABSTRACT

The preparation of three rare earth phosphors with onionskin barrier layers is described. The new materials are lanthanum oxysulfides and oxysulfates activated with terbium and in some cases coactivated with europium. When these phosphors with high dead voltage, and green emission are mixed with a commercial phosphor, such as YVO_4: Eu, a penetration phosphor results which has four distinct colors as a function of voltage in CRT displays. The emission from this phosphor system is at all times narrow band.

Several methods have been developed which allow the generation of multicolor displays on cathode-ray tubes (CRT). When the color is determined by the accelerating potential on the electrons from a single electron gun, these devices often use several phosphor layers either as discrete layers on the face of the CRT (1-3) or as layered "onionskin" particles (4). Among the latter group a practical phosphor mixture has been developed using a sulfide phosphor with green emission and an inert onionskin coating or containing a phosphor poison (5, 6). This coated phosphor is mixed with a commercial red-emitting phosphor. When the mixture is excited by an electron beam, the red emission is visible at low energies, but as the energy of the electrons is increased, the barrier of the coated phosphor is penetrated and green light is emitted. The gradual increase in green emission with increasing beam voltage creates orange, yellow, and finally green light. This particular system has a broad wavelength emission in the green portion of the visible spectrum as opposed to the line emission typical of rare earth ions.

Three new onionskin phosphors have been developed. They have a barrier layer and they emit intense narrow wavelength green light only at sufficiently high accelerating voltages. These rare earth barrier phosphors

Key words: lanthanum oxysulfide, lanthanum oxysulfate, barrier layer phosphors, europium, terbium.

operate in the same manner as the sulfide phosphor when mixed with commercial red-emitting phosphors. The purpose of this paper is to describe the synthesis and cathodoluminescent characteristics of these rare earth barrier phosphors and their behavior in penetration phosphor mixtures.

Composition and Mechanism

A method was desired for creating a poisoned surface on rare earth phosphors analogous to the use of cobalt diffusion in zinc sulfide phosphors (6). Possible mechanisms for achieving this effect were examined. Since intense green emission is obtained from terbium ions in a number of host lattices, the immediate problem was to quench the terbium emission in the outer surface of a terbium-activated phosphor. This could be accomplished by concentration quenching (7), energy transfer (8-10), or a change in host lattice in the barrier region (4). All three effects or combinations of them were found to yield barrier layers permitting the adjustment of the threshold voltage to a higher value. Typical values of threshold voltages for rare earth phosphors are approximately 1-2 kV. The dead voltage (defined as the extrapolation to zero intensity of the linear portion of a brightness *vs.* voltage curve) for a typical barrier phosphor is approximately 8-10 kV.

The composition of the three materials is summarized in Table I. Shown in Table I is the composition of the inner core and that of the onionskin portion with respect to host lattice and activators. Mechanisms by which the terbium emission is quenched in the barrier layer are discussed in the following paragraphs, numbered to correspond with the phosphor types listed in Table I.

I. In this case the entire particle has a host lattice of La_2O_2S (hexagonal crystal structure) which is activated by terbium ions homogeneously dispersed throughout. The barrier region is coactivated with europium ions which quench the emission of the terbium ions in their neighborhood. The decrease in terbium emission is attributed to two effects. The first effect is concentration quenching. The additional europium ions increase the total concentration of activator ions so that the optimum brightness is no longer obtained. The brightness of a terbium-doped phosphor is sensitive to the activator concentration (7). Moreover, the effect of coactivation of rare earth lattices has been found to reduce the brightness of a phosphor relative to a phosphor containing only one activator (7). The concentration quenching effect can be obtained by the addition of any of several of the rare earth ions including terbium itself. Europium is chosen for coactivation because the emission from europium ions is red and is generally more intense than that of other red-emitting rare earth ions, also there is energy transfer from Tb to Eu. The second effect, energy transfer, has been demonstrated in several hosts for terbium-europium coactivated materials (8-10).

II. In this case the core material is the same as in case I. The coating material is lanthanum oxysulfate (orthorhombic crystal structure) (11). The terbium activator ions are homogeneously dispersed throughout the phosphor particle but since the coating material is a poor host lattice the emission is weak in the barrier region. This quenching effect is caused by the change in the crystal structure.

III. In the third material the core is again the same. The quenching effect on the terbium ions in the coating is achieved by a combination of the effects described in cases I and II.

In all three materials the core provides intense green emission when excited by high energy electrons, whereas low energy electrons do not penetrate to the core. Any of the above barrier phosphors can be mixed with a red-emitting phosphor. The resulting phosphor mixture emits red at low voltages, then orange, yellow, and green with increasing voltages. In penetration phosphor mixtures using barrier phosphors type I and III it is fortuitous that some additional red emission can be obtained at low voltages from the europium in the barrier coating.

Table I. Barrier layer phosphors

Type	Core: Host lattice	Core: Activator	Onionskin: Host lattice	Onionskin: Activator
I	La_2O_2S	Tb	La_2O_2S	Tb, Eu
II	La_2O_2S	Tb	$La_2O_2SO_4$	Tb
III	La_2O_2S	Tb	$La_2O_2SO_4$	Tb, Eu

Synthesis

The problem in the synthesis of the barrier phosphors, types I and III, is to diffuse europium ions to a specified depth with a reasonable degree of precision. (The thickness of the barrier region is discussed in the Appendix.) For barrier phosphors, types II and III, it is necessary to oxidize the lanthanum oxysulfide to lanthanum oxysulfate to a specified depth on each particle. Both of these problems are related by the fact that europium diffusion in lanthanum oxysulfide is negligible, whereas in lanthanum oxysulfate it is appreciable. In order to diffuse europium into the barrier region it is necessary first to form the oxysulfate structure. This is the main reason that lanthanum was chosen as the host lattice ion, its chemistry differs from that of other rare earths in that the oxysulfate is stable (12).

To demonstrate the diffusion of europium in lanthanum oxysulfate a series of materials was produced starting from La_2O_2S:Tb (a commercial phosphor, JEDEC No. P-44). This commercial phosphor has a dead voltage of approximately 2 kV as shown in Fig. 1. The phosphor was mixed with a chelate of europium and annealed under conditions which excluded excess oxygen at a temperature above 700°C. The decomposition of the chelate released the oxygen which it contained.

Since the amount of oxygen was limited, the phosphor particles were only partially converted to the oxysulfate and europium diffused only in the outer oxysulfate portion of each particle. In this manner a new material (A) was formed with a dead voltage of 5 kV (refer to curve A in Fig. 1). After several cycles of mixing with an oxygen-containing chelate of euro-

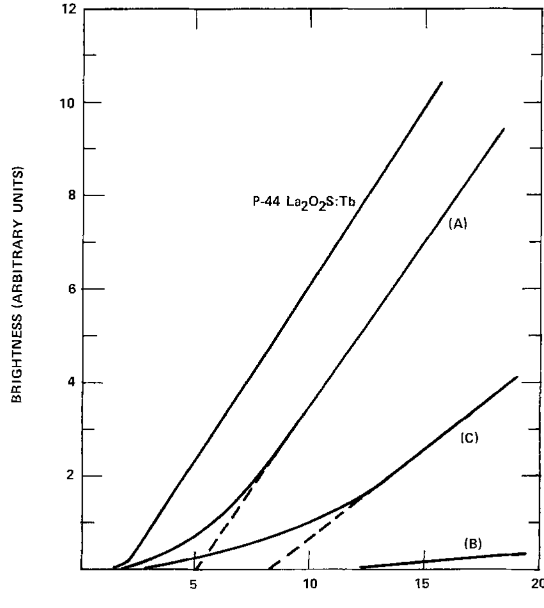

Fig. 1. Brightness vs. beam voltage for commercial P-44 La_2O_2S:Tb and a type I barrier phosphor with a dead voltage of 5 kV (A), a lanthanum oxysulfate phosphor (B), and a type I barrier phosphor with a dead voltage of 8 kV (C).

pium and annealing no increase in dead voltage is obtained. This process will not produce a barrier phosphor with a dead voltage above 5 kV because the oxygen released by the chelate cannot penetrate any further during the short time it is available. The anneal which decomposed the chelate was performed under an atmosphere of argon containing hydrogen sulfide and water vapor (13). Under these conditions the crystal structure was converted to the original oxysulfide form after the chelate was destroyed. Material A is a type I barrier phosphor having a core of La_2O_2S:Tb with an outer surface of La_2O_2S:Tb,Eu.

A sample of the europium-coated La_2O_2S:Tb (material A) was next oxygen annealed to produce phosphor particles which were mainly lanthanum oxysulfate (material B). As expected this material is a poor host because of the change in crystal structure and emission is very weak as is shown by curve B in Fig. 1. Finally, a sample of material B was reconverted to the oxysulfide form (material C). The brightness increased compared to the oxysulfate form (B) and the extrapolated threshold voltage increased (refer to curve C in Fig. 1). The increase in dead voltage indicates that europium diffusion took place in the lanthanum oxysulfate phase during the oxygen anneal.

By controlling the amount of oxygen available or the temperature and time of the oxygen anneal the formation of lanthanum oxysulfate can be limited. When a thin (submicron) onionskin layer of lanthanum oxysulfate is formed on lanthanum oxysulfide, it provides a barrier phosphor of type II. If europium is diffused into the oxysulfate a barrier phosphor of type III is obtained. When a type III phosphor is annealed under an atmosphere containing hydrogen sulfide and water vapor a type I barrier phosphor is obtained.

An important consideration in the synthesis of barrier phosphors is the maintenance of temperature equilibrium over the entire sample during the oxygen anneal. If temperature equilibrium is not maintained, the rate of formation of lanthanum oxysulfate will vary and result in uneven coating thickness. This in turn will increase the nonlinearity of the brightness *vs.* voltage curve for the sample. Also, the slope of the brightness *vs.* voltage curve will be reduced, that is, it will not be parallel to the curve for an untreated phosphor. In order to obtain a wide spread in color coordinates with changing voltage in the final mixture the slope of the brightness *vs.* voltage curve for the barrier phosphor must be steep. In other words, the brightness *vs.* voltage curve should be parallel to the curve for a phosphor without a barrier layer but should have a higher threshold.

The oxygen anneal is most easily carried out in a rotating quartz chamber. This is especially necessary when the bulk of a large sample becomes so great that it is not uniformly in contact with oxygen. Indentations in the chamber insure that the powder is tumbled during the anneal. The dimensions of the chamber should be kept within the constant temperature zone of the oven. Samples were prepared using a quartz reaction chamber attached to a thick-walled quartz tube which extended beyond the horizontal furnace. A controlled atmosphere was obtained by passing gases through the tube. A ball and socket joint allowed the rotation of the reaction chamber in the oven during the anneal (Fig. 2).

In the following syntheses europium-tris-2, 2, 6, 6-tetramethylheptanedionate is used to coat the surface of the phosphor with europium. Many other europium-containing compounds will produce adequate results. However, with some materials there are side reactions as with europium trichloride which yields lanthanum oxychloride. Therefore, satisfactory results are most easily obtained with organic chelates containing only carbon, hydrogen, and oxygen in addition to the rare earth ion. Another suitable chelate can be made with pentanedione (acetyl acetone) and europium (14).

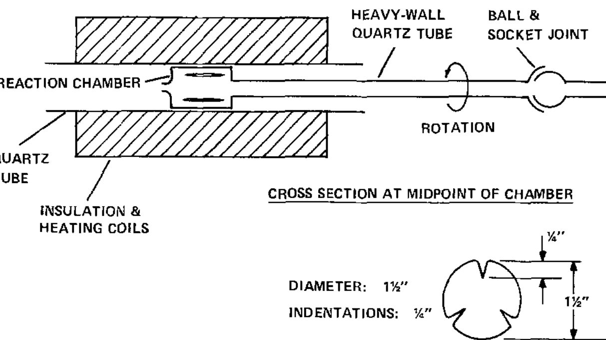

Fig. 2. Rotating quartz reaction chamber

Synthesis of La_2O_2S:Tb-La_2O_2S:Tb,Eu (type I).—In a polyethylene bottle 20.0g La_2O_2S:Tb (General Electric phosphor No. 118-2-35) (5.85×10^{-2} mole) was added to 405 mg Eu(III)-tris-2, 2, 6, 6-tetramethylheptanedionate (5.7×10^{-4} mole). The chelate was presieved through a 53μ mesh. After tumbling the mixture it was fired in a quartz reaction chamber in a horizontal tube furnace. The chamber contents were kept under argon until a temperature of 750°C was reached. At this point oxygen replaced the argon flow and the chamber was rotated for 20 min. The material was air quenched and a sample was removed for analysis. The remaining material was replaced in the furnace under a flow of argon bubbled through water at 25°C and approximately 30% hydrogen sulfide. After 6 hr at a maximum temperature of 1000°C the product was cooled under argon.

X-ray analyses showed the sample that was removed after the oxygen anneal to be approximately 15 mole percent (m/o) lanthanum oxysulfate and the final product was 100% lanthanum oxysulfide. When brightness under cathode-ray excitation was plotted as a function of beam voltage the extrapolated dead voltage was 8.5 kV. The reflected color was white.

Synthesis of La_2O_2S:Tb-$La_2O_2SO_4$:Tb (type II).—A 10g sample of La_2O_2S:Tb (General Electric No. 118-2-35) was oxygen annealed in a rotating quartz chamber for 25 min at 750°C. The material was kept under argon flow until the anneal temperature was reached and at the end of the anneal it was air quenched. X-ray analysis indicated approximately 9 m/o lanthanum oxysulfate. The reflected color was white and the dead voltage was 6.2 kV.

Synthesis of La_2O_2S:Tb-$La_2O_2SO_4$:Tb,Eu (type III).—In a polyethylene bottle 10.0g La_2O_2S:Tb (General Electric No. 118-2-35) (2.9×10^{-2} mole) was combined with 400 mg Eu-tetramethylheptanedionate (5.7×10^{-4} mole). After mixing, the material was oxygen annealed for 30 min at 725°C and air quenched. X-ray analysis indicated 12 m/o lanthanum oxysulfate.

Several more samples of barrier layer phosphors prepared by one of the procedures described above are described in Table II. The anneal time under oxygen atmosphere and anneal temperature are listed. The samples were kept under argon until the anneal temperature was reached and while cooling to room temperature. Different furnaces and controllers were used, so the accuracy of the temperature reading varies. The mole percent lanthanum oxysulfate was determined from x-ray diffraction intensities. The relationship between the amount of oxysulfate formed and the dead voltage is discussed in the Appendix.

Measurements

Apparatus.—In order to measure the cathodoluminescent properties of phosphor samples, a demountable CRT was assembled. The unit was constructed by adapting a standard oil diffusion vacuum coating apparatus. The pumping system provided pressures on the order of 10^{-7} Torr.

Table II. Oxygen anneal conditions for barrier layer formation

Anneal time in oxygen (min)	Anneal temperature (°C)	M/O $La_2O_2SO_4$*	Dead voltage (kV)

30	~725	7	3.5

* Refer to Appendix.

The demountable CRT was assembled using a Pyrex Tee with a 6-in. diameter which served as the test volume. The bottom portion of the Tee was connected to the vacuum pump. The 18 in. horizontal portion of the Tee contained a standard black and white electron gun and yoke on one end and the phosphor target holder on the opposite end. For ease of replacement, the electron gun was inserted into a quick-disconnect mounted on a stainless steel flange. A sample holder was fabricated so that 16 samples could be tested at one time. The phosphors were gravity settled using standard techniques on Nesatron glass and remained unaluminized for the results reported in this paper.

For simplicity of measurement, a pulsed electron beam was used rather than a raster scan. The measurements were made in the unsaturated mode of the cathodoluminescent behavior of the phosphors. The cathodoluminescent spectra and brightness were measured via transmission through the sample. The brightness from the electron beam spot on the phosphor target was measured with a Spectra® Brightness Spot Meter (Model UB½, Photo Research Corporation). Brightness was measured at constant beam current. The spot diameter was focused to 0.20 in. on a removable overlay grid with 0.050 in. divisions for each level of accelerating voltage. The emission spectrum was obtained using a Jarrel-Ash ½ meter Ebert scanning monochromator. The color coordinates were determined from the corrected spectra and the 1931 C.I.E. standard tables. It should be pointed out that the brightness measurements were always compared to a commercial P-44 phosphor sample whose thickness was optimized so as to obtain maximum brightness. All other samples were deposited with the same thickness as the P-44 La_2O_2S:Tb phosphor.

Results.—Samples of penetration phosphor were prepared by mixing green phosphor which had a barrier layer with a commercial red-emitting phosphor. In the two examples given below the commercial phosphor was YVO_4:Eu, approximately 15 weight percent of the total mixture. Barrier phosphors of types II and III were used. Table III gives the color coordinates of these mixtures at various beam voltages. The efficiency in lumens per watt is listed.

Summary

Controlled oxidation of lanthanum oxysulfide yields particles coated with lanthanum oxysulfate. While europium diffuses readily in $La_2O_2SO_4$ at several hundred degrees centigrade, it does not diffuse in La_2O_2S to any appreciable extent under the same conditions.

A barrier layer containing Eu^{+3} ions will quench the emission from La_2O_2S:Tb phosphor particles. An onion-skin barrier layer of lanthanum oxysulfate will also produce this effect.

Table III. Color co-ordinates of penetration phosphors

Beam voltage (kV)	X	Y	Lumens/Watt
Sample 1 Type II La_2O_2S: Tb—$La_2O_2SO_4$: Tb with YVO_4: Eu			
5	0.587	0.395	2.0
7	0.574	0.405	2.1
10	0.538	0.435	3.4
14	0.489	0.479	5.4
18	0.461	0.501	7.6
Sample 2 Type III La_2O_2S: Tb—$La_2O_2SO_4$: Tb, Eu with YVO_4: Eu			
5	0.568	0.413	4.3
12.5	0.514	0.460	7.0
18	0.470	0.494	9.6

Green-emitting phosphors with high dead voltages (8-10 kV) can be obtained using either or both of the quenching effects described above.

Barrier phosphors made from La_2O_2S:Tb can be mixed with commercial red phosphors such as YVO_4:Eu. to produce penetration phosphors with line emission whose color is a function of voltage.

APPENDIX

Analysis of Barrier Thickness

The barrier layer on the lanthanum phosphors is not a "coating" in the sense that additional material is added to each particle. However, since the density of lanthanum oxysulfate (5.52 g/cm³) is less than that for lanthanum oxysulfide (5.73 g/cm³) there is probably a slight but insignificant increase in particle diameter in materials of types II and III (see Table I). The typical median particle diameter for P-44 La_2O_2S:Tb is 10.0μ as determined by Coulter Counter.[3] Scanning electron micrographs indicate the particles to be irregular polyhedra, only roughly spherical. No significant detectable change in particle size or shape after formation of a barrier layer was seen in scanning electron micrographs.

In order to obtain an estimate of the thickness of the barrier layer in the materials described above the following modified model of dead voltage as a function of barrier thickness was used.

A general equation describing electron penetration of solids is

$$d = CV^n \quad [1]$$

where d is the depth of penetration, V is the energy of the electrons and C and n are constants characteristic of the material. Kingsley and Prener (5, 6) have determined experimentally values for C and n in Eq. [1] for zinc sulfide phosphors where $C = 7.3 \times 10^{-7}$ and $n = 1.77$ when V is in kilovolts and d is in centimeters. The coefficient, C was modified by correcting for differences in atomic number, molecular weight, and density between zinc sulfide and lanthanum oxysulfide to obtain

$$d = 5.7 \times 10^{-7} V^{1.77} \quad [2]$$

where d is in centimeters and V is the accelerating potential on the electrons in kilovolts. The correction fac-

[3] General Electric Product Data Sheet for P-44 La_2O_2S:Tb (No. 118-2-35).

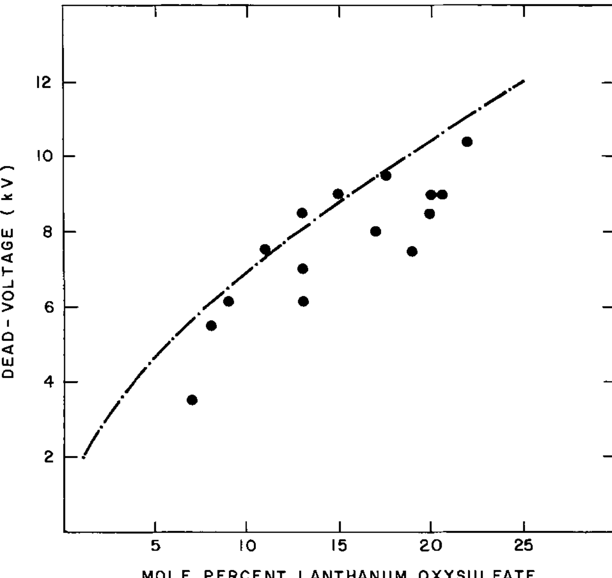

Fig. 3. Dead voltage *vs.* mole per cent lanthanum oxysulfate. The solid line is the expected relationship for 10μ diameter particles using Eq. [2].

tor for the coefficient, 0.776, was obtained by multiplying the ratio of molecular weights by the inverse of the ratios of the densities and number of electrons for La_2O_2S/ZnS. The depth of penetration is proportional to molecular weight and inversely proportional to density and number of electrons (5, 15). The thickness of a barrier layer is represented by d when V is the dead voltage in kilovolts.

For a desired dead voltage the modified equation predicts a barrier thickness. The predicted value for barrier thickness can be used to calculate the amount of lanthanum oxysulfate it will be necessary to form in a 10μ diameter particle. The volume occupied by the onionskin is calculated assuming spherical particles. The percent active phosphor material remaining in the core determines the maximum possible brightness which can be obtained from the resulting barrier phosphor. Using the modified Eq. [2] and assuming that the median particle diameter of the phosphor is 10μ it is calculated that 13-19% of each oxysulfide particle must be converted to oxysulfate in order to obtain a barrier phosphor with a dead voltage of 8-10 kV.

To check these predictions two methods were used for measuring the amount of material in the barrier region. The first method depended on the atomic absorption analysis of the europium and terbium content of dissolved samples of barrier phosphor. When the europium/terbium ratio of a completely dissolved sample was compared to that for a partially dissolved sample it indicated that the europium was contained in a surface layer less than 1μ thick. Because this analysis is destructive and sample preparation is difficult, this method was abandoned in favor of the second.

The second method was based on quantitative x-ray diffraction. Standards of known ratios of lanthanum oxysulfide and lanthanum oxysulfate were prepared. By comparison with the standards the amount of oxysulfate coating in the samples of barrier phosphor was estimated. The results are summarized in Table II. The mole percent lanthanum oxysulfate as determined by comparison of x-ray diffraction patterns has an estimated error of ±2 m/o. The dead voltage is determined from a brightness *vs.* voltage curve for each sample. A graph of dead voltage *vs.* mole percent oxysulfate for several samples annealed under oxygen indicates that the expected trend is followed (Fig. 3). The data points are scattered around the prediction (solid line in Fig. 3) based on the modified equation and 10μ diameter particles. The empirical relationship derived for zinc sulfide was sufficiently accurate when modified to be useful in preparing barrier layers of desired thickness on lanthanum oxysulfide phosphors.

Control of Sulfur Doping for Gallium Arsenide Epitaxial Layers

M. A. Savva

British Post Office, Research Department, London NW2 7DT

ABSTRACT

In growing gallium arsenide epitaxial layers for device manufacture it is necessary to control the dopant (usually n-type) concentration in the gas stream. A novel method is presented for introducing known and controlled concentrations of sulfur compounds based on "the modified entrainment method." The dopant is confined to a small bottle with a capillary, which acts as a resistance, and the rate at which the dopant is transported out of the bottle depends on the vapor pressure, the capillary dimensions, and the diffusion coefficient. Using this method, the rates of weight loss of sulfur, thionyl chloride, and sulfur dichloride were measured in nitrogen over a range of temperatures. From these measurements the diffusion coefficient of the compounds is calculated and it is concluded that the method can be used to give controlled dopant concentrations in the gas stream of an epitaxial reactor. Using these data the dopant concentrations in a typical reactor are calculated as a function of temperature for different size capillaries. The distribution coefficient of sulfur between the epitaxial layer and the gas phase is found to be about 60 for carrier concentrations in the region of high 10^{16} carriers cm^{-3}.

The growth of gallium arsenide epitaxial layers by the $Ga/AsCl_3/H_2$ process (1), for the manufacture of devices such as IMPATT diodes, requires the material to be doped n-type at various controlled levels. Generally, the epitaxial layers are sulfur doped and the mole fractions of hydrogen sulfide required in the gas stream are less than 10^{-6}. In order to grow doped epitaxial layers reproducibly, and indeed to understand the mechanisms of dopant incorporation, it is necessary to control and know the concentration of dopant injected into the gas stream.

Bachem and Bruch (2) have pointed out some of the obvious weaknesses of introducing the dopant, either directly as hydrogen sulfide from a gas cylinder, or indirectly by heating sulfur vapor, from a solid source, in the hydrogen gas stream and converting it to hydrogen sulfide. They have attempted to obtain better control over the direct method by restricting the flow from the reducing valve of the gas cylinder, using a small capillary. Also. they have doped the transporting agent. arsenic trichloride, with sulfur monochloride and deduced the concentration of dopant in the gas stream by assuming that the solution is ideal. Both of their methods seem to be consistent each yielding epitaxial layers at the same carrier concentration for a given concentration in the gas stream. However, the ratio of the carrier concentration to the dopant concentration in the gas stream is much lower than that reported by other workers (3-5) and is lower than we observed in our work. In this paper we present a novel method for introducing known and controlled concentrations of sulfur compounds into the gas stream of an epitaxial reactor. The method is easy to set up and operate and can cope with a wide range of dopant concentrations.

This method is adapted from the modified entrainment method, which has been developed from the early work of Stefan [see Ref. (6)], and used for measuring vapor pressures (7), diffusion coefficients (8), and heterogeneous equilibrium constants (9, 10). The theory is described in detail elsewhere (7) and here we only outline the principles of the modified entrainment method in its application to dopant control. The dopant is placed in a small bottle and is allowed to diffuse along a capillary of known dimensions and at the end of the capillary it is swept away by the gas stream. The capillary acts as a resistance, thus permitting the dopant to reach its equilibrium vapor pressure inside the bottle. Hence, at a given temperature, the rate of transport of the dopant out of the bottle is well defined, and its concentration in the gas stream can be calculated, if the flow rate over the bottle is known.

Key words: gallium arsenide, vapor phase epitaxy, sulfur doping, diffusion coefficient.

So as to validate the method for its application for introducing a sulfur compound into an epitaxial reactor, we have measured the rates of loss of liquid sulfur, thionyl chloride, and sulfur dichloride from such a bottle over a range of temperatures. From these measurements we can be sure that the equilibrium vapor pressures are attained in the bottle, and by using available data for vapor pressures we can determine the diffusion coefficients for the above species. From these data we can then calculate the concentration of the dopant that is injected into the gas stream of an epitaxial reactor.

Theory

For a single species, A, evaporating into a stream of an inert gas the vapor pressure ($p°_A$) of that species is given by

$$p°_A = p[1 - e^{-\xi}] \qquad [1]$$

where p is the total pressure and ξ, the transport function, is

$$\xi = \frac{\dot{W}RTl}{DpM_A\pi r^2} \qquad [2]$$

where $\dot{W}$ is the rate of weight loss of species A through a capillary of length l and radius r, at a temperature T. M_A is the molecular weight of A and D is the diffusion coefficient of A in the inert gas. The temperature dependence of the diffusion coefficient can be expressed as

$$D = \frac{D_o p_o}{p}\left(\frac{T}{T_o}\right)^{1+s} \qquad [3]$$

where D_o is the diffusion coefficient at a reference temperature T_o and a reference pressure p_o, and s has a value between 0.5 and 1, which is usually close to 0.8 (11). The reference pressure is taken as 1 atm

which is also the pressure at which the measurements are made.

From Eq. [1]-[3], the vapor pressure of a species can be calculated by estimating a value for D_0 and s. Therefore, by measuring the rate of weight loss as a function of temperature, the enthalpy (ΔH_v) and the entropy (ΔS_v) of evaporation can be calculated since

$$R \ln p^\circ_A = -\Delta H_v/T + \Delta S_v \quad [4]$$

If the boiling point is known then a value of D_0 can be chosen so that, for the calculated values of ΔH_v and ΔS_v, the vapor pressure is unity at the boiling point. When the vapor pressure of a species is known, then, from Eq. [1] and [2], the diffusion coefficient can be calculated. The values for D_0 and s can be obtained using Eq. [3] by plotting log D *vs.* log T.

In some instances, the vapor may contain polymeric species, for example sulfur exists mainly as S_8, S_6, S_4, and S_2 up to the boiling point with S_8 predominating. In such cases the total rate of weight loss can be related to the individual partial pressures from a series of Eq. [1] and [2]

$$\dot{W} = \frac{pM_A\pi r^2}{RTl} \Sigma n D_{A_n} \ln\left(1 - \frac{p^\circ_{A_n}}{p}\right) \quad [5]$$

where $p^\circ_{A_n}$ is the partial pressure of species A_n with a diffusion coefficient of D_{A_n} in the inert gas. M_A is the molecular weight of the monomer. The diffusion coefficients of each species can be related to the diffusion coefficient of the dominant species by Graham's law

$$\frac{D_{A_n}}{D_{A_m}} = \sqrt{\frac{M_{A_m}}{M_{A_n}}} = \sqrt{\frac{m}{n}} \quad [6]$$

Thus, from measurements of rate of weight loss at different temperatures, values for D_0 and s can be calculated for the dominant species, as described earlier, if the partial pressure of each species is known as a function of temperature.

Experimental

The apparatus is illustrated in Fig. 1 and is similar to that described by Battat *et al.* (7). The effusion bottle was suspended on a silica fiber from a CI Electronics 2CT5 microforce balance. The bottle was hung either inside a tube which was heated with a small furnace up to 400°C to give a flat temperature profile, or else inside a glass condenser which was temperature controlled in the range −5° to 55°C. The temperature was measured either with a Chromel-Alumel thermocouple or with a mercury-in-glass thermometer just beneath the bottle. The gas inlet through the balance was controlled using a mass flow controller.

Results

Evaporation of sulfur in nitrogen.—The sample of crystalline sulfur was 99.999% pure (Koch-Light Limited, England). The experimental rates of weight loss in nitrogen and at various temperatures, using a capillary 1.991 cm in length and 0.201 cm in diameter, are given in Fig. 2. From these results the diffusion coefficient of S_8 in nitrogen was calculated using Eq. [5] and [6], so as to take into account all species of sulfur, and the vapor pressure data of Braune *et al.* (12), which are recommended by Nesmeyanov (13). The calculated values of the diffusion coefficient are plotted out as a function of temperature in Fig. 3 from which we obtain a value of 0.068 cm² sec⁻¹ for the diffusion coefficient at 20°C and a temperature dependence of $T^{1.86}$ (*i.e.*, $s = 0.86$).

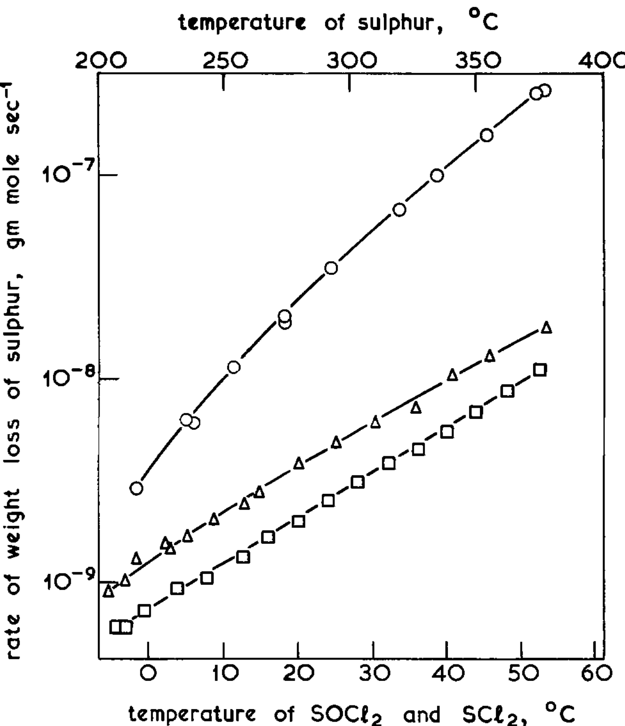

Fig. 2. Rate of weight loss as a function of temperature: ○ = sulfur, □ = thionyl chloride, △ = sulfur dichloride.

Evaporation of thionyl chloride in nitrogen.—The experimental rates of weight loss for thionyl chloride (Hopkin and Williams Limited, England) in nitrogen and at various temperatures, using a capillary 2.000 cm in length and 0.097 cm in diameter, are given in Fig. 2. From these results the diffusion coefficient of thionyl chloride in nitrogen was calculated using Eq. [1] and [2], and the vapor pressure data given

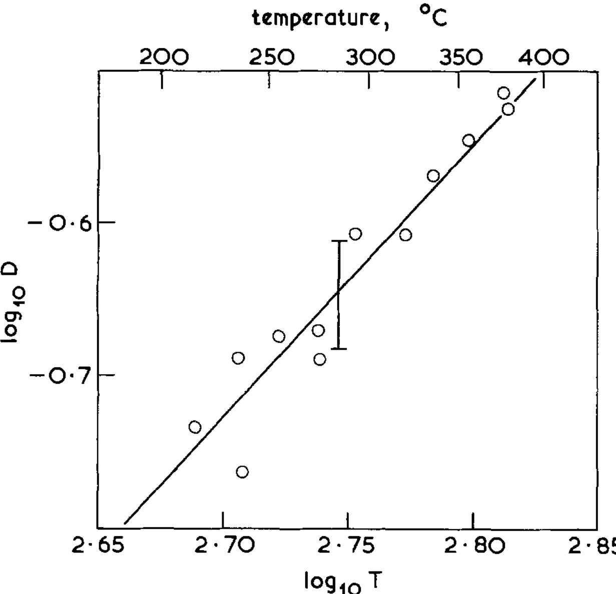

Fig. 3. Diffusion coefficient for S_8-N_2 as a function of temperature: bar ≡ 5% deviation; $D = 0.0688 \left(\frac{T}{293.2}\right)^{1.86}$ $cm^2\ sec^{-1}$.

in the literature (14). The calculated values of the diffusion coefficient are plotted out as a function of temperature in Fig. 4 from which we obtain a value of 0.101 $cm^2\ sec^{-1}$ for the diffusion coefficient at 20°C and a temperature dependence of $T^{1.86}$ (*i.e.*, $s = 0.86$).

Evaporation of sulfur dichloride in nitrogen.—The experimental rates of weight loss of sulfur dichloride (Hopkin and Williams Limited, England) in nitrogen and at various temperatures, using a capillary 2.189 cm in length and 0.103 cm in diameter, are given in Fig. 2. As we do not consider the literature values for the vapor pressure of sulfur dichloride (14) to be reliable (see below), we have chosen D_0 at 20°C to be 0.082 $cm^2\ sec^{-1}$ with $s = 0.8$ and using Eq. [1]-[3] we have calculated the vapor pressure of sulfur dichloride. From the plot of the vapor pressure *vs.* temperature in Fig. 5 we calculate second law values for ΔH_v and ΔS_v as 28.0 kJ $mole^{-1}$ and 84.1 J $mole^{-1}$

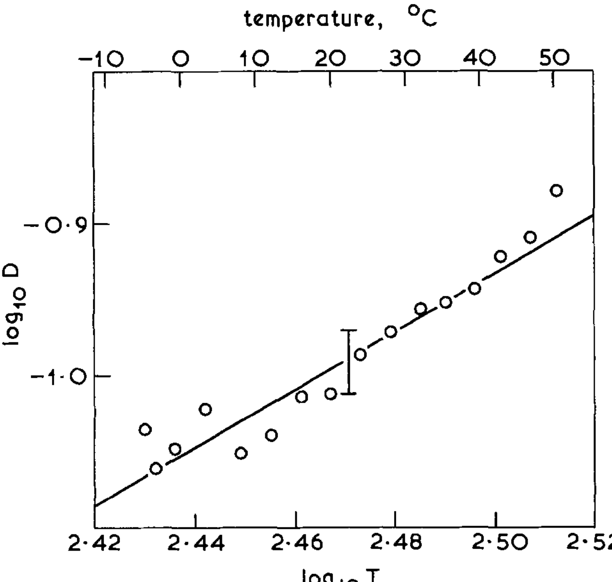

Fig. 4. Diffusion coefficient for $SOCl_2$-N_2 as a function of temperature: bar ≡ 5% deviation; $D = 0.101 \left(\frac{T}{293.2}\right)^{1.86}$ $cm^2\ sec^{-1}$.

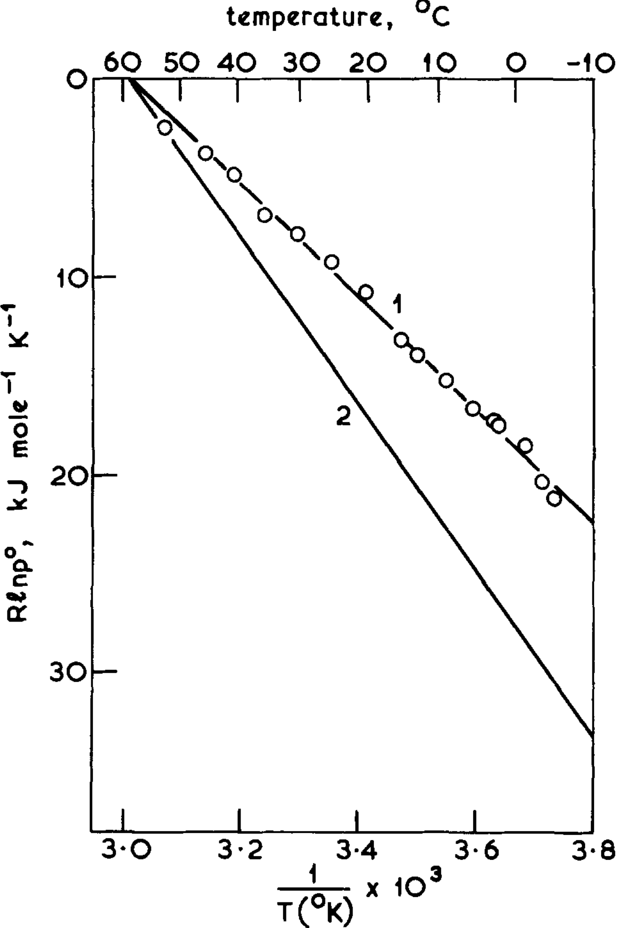

Fig. 5. Vapor pressure of SCl_2 as a function of temperature: 1 = this work $R \ln p^\circ = -\frac{28.0 \times 10^3}{T} + 84.1$ kJ $mole^{-1}\ K^{-1}$; 2 = from Ref. (14).

K^{-1}, respectively, at our mean temperature of 25°C. The value of D_0 was chosen so that the plot in Fig. 5 went through the boiling point of sulfur dichloride (59°C) at a vapor pressure of 1 atm.

Discussion

The diffusion coefficients at 20°C that we have calculated from our experimental results are compared with the listed values of other species in nitrogen (11, 15) in a plot of $1/D$ against $\sqrt{M}$ as shown in Fig. 6. From the plot it is apparent that the relationship is linear for the rare gases, and all other species have a relatively lower diffusion coefficient. Our calculated diffusion coefficients and values for the temperature dependence are consistent with the general trend.

In analyzing the results of sulfur dichloride, we considered the literature values for the vapor pressure dependence on temperature to be unreliable since ΔS_v has a reported value of about 125 J $mole^{-1}\ K^{-1}$, whereas from Trouton's rule it should be nearer 92 J $mole^{-1}\ K^{-1}$ (we calculated 84.1 J $mole^{-1}\ K^{-1}$). Consequently, the literature value of ΔH_v is over 12 kJ $mole^{-1}$ higher than our value of 28 kJ $mole^{-1}$. The issue is complicated further as it is commonly reported (16) that sulfur dichloride is nearly completely dissociated into sulfur monochloride and chlorine at the boiling point. However, Stevenson (17) has looked at the dissociation of sulfur dichloride and sulfur monochloride into sulfur and chlorine at high temperatures, and it is apparent from his data that only about 10% of the dichloride will dissociate into the monochloride and chlorine at 500°C. Therefore, in our analysis we have assumed no dissociation

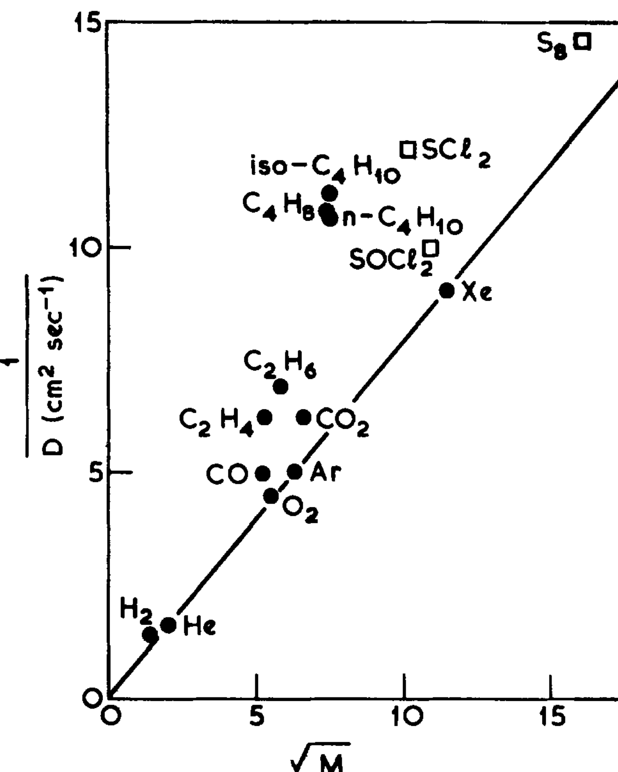

Fig. 6. Diffusion coefficients of various gases in nitrogen at 20°C as a function of molecular weight: ● = values from Ref. (11) and (15), □ = values derived in this work.

and we calculated values for the entropy of evaporation and for the diffusion coefficient in nitrogen.

The modified entrainment method is designed so that equilibrium is attained in the effusion bottle. If equilibrium is not attained, then the rates of weight loss would be low and have a higher dependence on temperature than expected. Consequently, in the case of sulfur and thionyl chloride, the calculated temperature dependence of the diffusion coefficient would be extraordinarily high. In the case of sulfur dichloride, ΔS_v would be high. Our results do not bear this out in the temperature range of our measurements and we are confident that the equilibrium vapor pressures are approached closely in the effusion bottle. Therefore, the modified entrainment method can be used for introducing known and controlled concentrations of dopant into a gas stream.

Rates of weight loss for sulfur below 200°C were made over several hours and during that time the ambient temperature changed, giving fluctuations in the balance output that were comparable with the rates of weight loss ($\sim 5 \times 10^{-8}$ g sec^{-1}). Therefore, the low temperature results were disregarded. In order to make reliable measurements down to the melting point, and indeed for crystalline sulfur, we would need to compensate in some way for changes in ambient temperature. It is desirable to go down to lower temperatures so that we can determine the point at which the vapor pressure in the bottle is dictated by surface kinetic limitations rather than equilibrium conditions. Similarly, it would be useful to investigate the sulfur chlorides at lower temperatures but the balance used cannot measure low rates of evaporation. Furthermore, by using high temperatures there is no need to use solid sulfur. This avoids any irreproducibility of vapor pressures due to the slow transformation from monoclinic to rhombic sulfur, as reported by Kniepkamp *et al.* (18).

Doping in an Epitaxial Reactor

The work described above demonstrates that over the specified temperature ranges it is possible to obtain known dopant concentrations in a gas stream by controlling the temperature of a dopant which is confined to a small bottle with a capillary. The method is simple to set up and use.

Table I. Ratio of diffusion coefficients in H_2 and N_2

Gas	Diffusion coefficient in hydrogen (cm² sec⁻¹) at 20°C (15)	Diffusion coefficient in nitrogen (cm² sec⁻¹) at 20°C (15)	Ratio
Ar	0.77	0.20	3.85
O_2	0 697	0.181	3.85
CO	0.651	0.192	3.39
CO_2	0.550	0.144	3.82
C_2H_4	0.602	0.163	3.69
C_2H_6	0.537	0.148	3.63
cis-butene-2	0.378	0.095	3.98
		Average	3.74 ± 0.15

In applying this method of dopant control to a gallium arsenide epitaxial reactor we need to know the diffusion coefficient in hydrogen rather than in nitrogen. From Graham's law, the diffusion coefficient should be 3.74 times higher (*i.e.*, $\sqrt{28/2}$). In Table I we list the reported diffusion coefficients, at 20°C, of various species in hydrogen and nitrogen (11, 15) and calculate the ratios. The average of these ratios is 3.74 ± 0.15 and it is reasonable, therefore, to use Graham's law in our application.

Now the concentration of dopant used during the growth of gallium arsenide is small and therefore the resistance of the capillary would have to be higher than that used during our measurements. As a guide, we have calculated the concentration of dopant in an epitaxial reactor, which has 200 ml min^{-1} (measured at room temperature) of hydrogen flowing through it, as a function of dopant temperature for capillaries 1 cm in length but with different diameters. Figure 7 shows the concentration of sulfur in the temperature range from the melting point to boiling

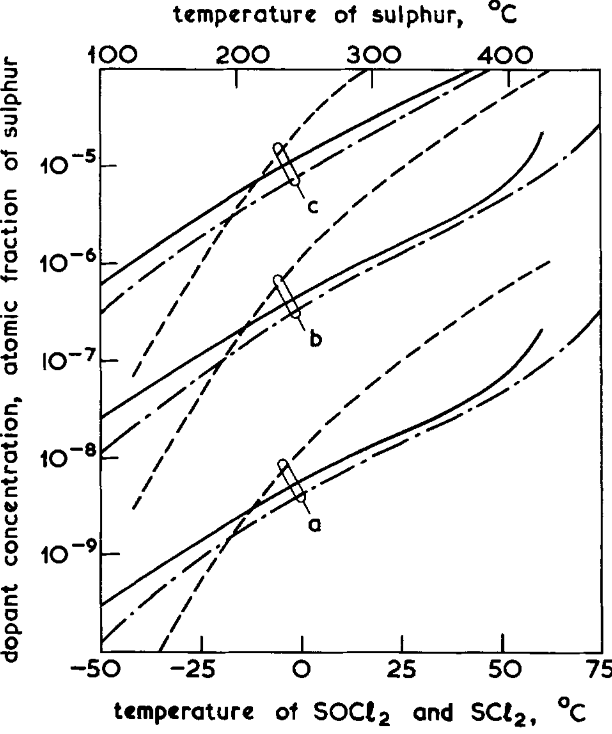

Fig. 7. Dopant concentration in the gas stream as a function of effusion bottle temperature for a hydrogen flow rate of 200 ml min^{-1} and a capillary 1 cm long with a diameter of (a) 0.001 cm, (b) 0.01 cm, (c) 0.05 cm. - - - - Sulfur; — - — - thionyl chloride, ——— sulfur dichloride.

point and the concentration of thionyl chloride and sulfur dichloride from $-50^{\circ}C$ to the boiling point. In these calculations the temperature range has been extended to lower temperatures than those used during our measurements. This is not too unreasonable since for higher resistance capillaries the temperature at which surface kinetics begin to influence the vapor pressure in the bottle will be lower. However, it is better to use high temperatures and high resistance capillaries so as to ensure that equilibrium vapor pressures are attained and thereby yielding reproducible results.

Our epitaxial reactor is based on the $Ga/AsCl_3/H_2$ system and we find that a hydrogen sulfide concentration of 5×10^{-8}, obtained from sulfur by the method described in this paper, in the gas stream yields layers grown on (100) surfaces in the region of high 10^{16} carriers cm^{-3}. If we assume that the concentration of carriers is equivalent to the concentration of sulfur in the layer, then we obtain a distribution coefficient (k) of ~ 60 with

$$k = \frac{\text{atomic fraction of sulfur in the epitaxial layer}}{\text{atomic fraction of sulfur in the gas stream}}$$

We hesitate to be more precise in our value of k since we have found, in common with others (4), that the growth rate can have a dramatic influence on dopant incorporation. This work will be reported in a future communication (19).

Our value of k differs markedly from that of some workers (2, 3) but is consistent with that of other workers (4, 5). Bachem and Bruch (2) obtained a value of ~ 1 for k while from the work of DiLorenzo and Moore (3) we extract a value of ~ 1000. The work of Hollan and Mircea (5) suggests that k has a value of at least ~ 40 while Luther and DiLorenzo (4) have extracted from their results a value of ~ 20 and found that the value depended on the growth rate.

Conclusions

We have presented a method for introducing known and controlled concentrations of sulfur compounds into an epitaxial reactor based on the modified entrainment method. We have shown that over the temperature range studied the method is reproducible as equilibrium vapor pressures are attained in the effusion bottle. The diffusion coefficients of sulfur, thionyl chloride, and sulfur dichloride, which are needed to calculate the dopant concentration introduced into the epitaxial reactor, have been determined.

Thin Film Epitaxial Growth of $In_xGa_{1-x}As$ on GaAs

S. B. Hyder
Varian Associates, Corporate Research Laboratories, Palo Alto, California 94303

ABSTRACT

Thin film, n-type single crystal epitaxial $In_xGa_{1-x}As$ was grown on semi-insulating GaAs substrates using an open-tube $Ga\text{-}In\text{-}AsCl_3/H_2$ CVD system. Electron concentrations of about 10^{17} cm^{-3} were obtained using H_2S doping. Semi-insulating layers were produced using CrO_2Cl_2 as a dopant. InAs concentration of up to 23 mole percent (m/o) was obtained by compositional grading for lattice matching. The active layers were less than a micron thick and growth rates as low as 0.01 μ/min were achieved. The epitaxial layers were evaluated for surface quality, InAs concentration, electron concentration, and electron mobility for use in fabrication of microwave Schottky barrier gate field effect transistors. Good surfaces were obtained with all concentrations of InAs. Electron mobilities generally higher than those so far reported in the literature were obtained when care was taken to optimize the grading layer.

The $In_xGa_{1-x}As$ alloy system has attracted considerable attention recently because of its device application potential. Stillman *et al.* (1) and Nahory, Pollock, and DeWinter (2) have successfully fabricated detectors; and Nuese *et al.* (3) have constructed lasers for the 1.06μ region. Application for use in near-infrared photocathodes has also been shown (4, 5). A preliminary report (6) has been made of the performance of this material in a microwave Schottky barrier field effect transistor application. This paper describes the work undertaken to produce the material for the microwave FET fabrication.

$In_xGa_{1-x}As$ can be grown by liquid phase epitaxy (7-9), but homogeneous FET quality material is difficult to obtain, and uniform compositional grading is also difficult by this method. Growth by chemical vapor deposition (10-12), on the other hand, lends itself easily to preparation of homogeneous material of any desired composition and donor concentration by facilitating lattice matching through compositional grading. Mass spectroscopic studies have been reported recently by Ban and Ettenberg (13) who applied equilibrium thermodynamics to $In_xGa_{1-x}As$ CVD system and found reasonable agreement with experimental data. Mixed sources of In and Ga as well as separate In, Ga, and As sources have been used (10-12) with AsH_4, HCl, and $AsCl_3$ systems.

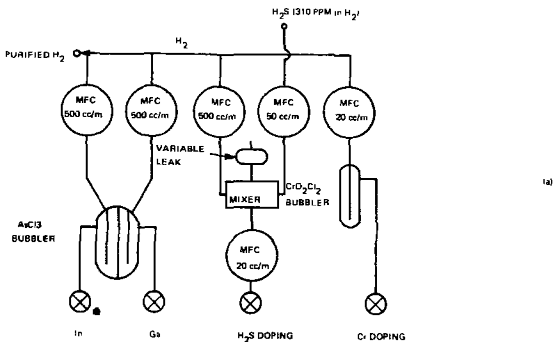
In the present work, separate sources of In and Ga were used to ensure that no change of composition occurs during growth due to depletion of one source. Transport by $AsCl_3/H_2$ was used to achieve the highest attainable purity. The advantage of this method is the use of only two sources with $AsCl_3$ supplying the As as well as HCl that is necessary for transport of In and Ga.

Experimental Procedure

The $In_xGa_{1-x}As$ growth system and reactor are shown schematically in Fig. 1. Tylan Corporation's electronic mass flow controllers control the flow of purified H_2. The $AsCl_3$ bubbler is kept at any desired temperature by a thermal bath and is connected to the In and Ga chambers; the $AsCl_3/H_2$ flow over each element being separately controlled. The flow line to In is also connected through valved bypasses to an etch line entering the reactor chamber, and the flow can be diverted to this line if desired. The H_2S tank gas (310 ppm in H_2) is further diluted with H_2 in a mixing chamber and the diluted gas is fed into the reactor ahead of the substrate position for S doping. Chromium doping is achieved using a CrO_2Cl_2 bubbler and a cracking furnace kept at 500°C. The CrO_3/H_2 mixture enters the reactor between the sources and the substrate, according to the reaction

$$3CrO_2Cl_2 + 3H_2 \rightarrow CrO_3 \cdot Cr_2O_3 + 6HCl$$

The monochloride vapors of Ga and In are mixed in the reactor by means of a baffle placed at the exit of the In/Ga chambers to ensure homogeneous mixing. A 0.4 mm thick substrate of area about 5 cm^2 is placed horizontally in a holder, and a thermocouple inserted into a well incorporated in the holder records



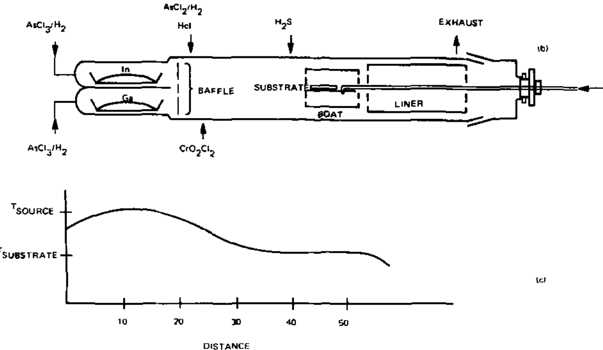


Fig. 1. Deposition reactor and system

Key words: $AsCl_3$ CVD, compositional grading, Schottky barrier gate FET, CrO_2Cl_2 doping.

the temperature. A quartz liner protects the reactor from monochlorides depositing in the cold region. All the glassware in the high temperature region is made from Spectrosil grade quartz. The reactor tube of cross-sectional area 9 cm^2 is held in a horizontal position and the furnace is rolled onto it to start the deposition process. An approximate temperature profile of the furnace when placed over the reactor is shown in Fig. 1(c). The source temperature was about 780°C, and the substrate temperature was usually about 720°C. Temperature variation over the length of the substrate was less than a degree per centimeter and about 5°C over the length of the source boats, which were 8 cm long with the source surface area of about 12 cm^2.

Vapor Phase Deposition

Source preparation and saturation.—50g of elemental In and Ga of minimum purity 99.9999% are used. Gallium is poured into the source boat as received, but indium is baked in H_2 stream at about 900°C for 72 hr before transferring it to the source boat in the reactor. Use of $AsCl_3$ and elemental sources requires that the sources are saturated with As until a crust of InAs and GaAs is formed on the respective sources. Transport and epitaxial growth occurs only after the sources are saturated.

The source temperature during saturation was kept at about 770°C. The $AsCl_3$ vapor pressure was 9.15×10^{-3} atm at 20°C bubbler temperature. Using a H_2 flow rate of 300 cm^3/min, the saturation time of 5.6 hr was calculated using the relation given by Shaw (14) for Ga

$$t_{satu} = \frac{RT_1}{p_{AsCl_3}F_1} \cdot \left[\frac{X_{As}}{1 - X_{As}}\right] \frac{W}{mw}$$

where t_{satu} = saturation time in minutes, p_{AsCl_3} = $AsCl_3$ vapor pressure (atm), T_1 = source temperature, F_1 = flow rate in liters per minute, X_{As} = mole fraction As in saturated source, W = weight of the source, mw = molecular weight of the element, and R = gas constant 0.0821 atm/deg-mole. Arsenic solubility was taken from Hall's (15) data shown in Fig. 2 for Ga and In.

Ban and Ettenberg (13) have calculated that at a deposition temperature of 1000°K, about 10% of InCl is converted into solid from the gas phase as compared to about 60% for GaCl. This also indicates that the In source is depleting faster than the Ga source in the same ratio since depletion of the elemental source occurs according to the relation

$$2M_l + 2HCl_g \rightarrow 2MCl_g + H_2$$

For a source temperature of 780°C it was observed that after a series of test depositions the Ga source depleted about 20% whereas the In source depleted as much as 80%. Considering this faster depletion of In source, the saturation time for the In source was estimated by dividing Shaw's (14) expression by four. Indium saturation time was then calculated to be about 11 hr in reasonable agreement with the experimentally observed time of about 10 hr for In saturation with As.

After temperature equilibration, during which some desaturation occurs, the sources were resaturated initially with 300 cm^3/min of $AsCl_3/H_2$ flow over the In source and 100 cm^3/min over the Ga source After a series of depositions, the In source was found to deplete from the high temperature side of the source boat. This situation does not interfere with normal growth in any way until the source size is depleted about 80% or so after a considerable number of hours of saturations and depositions. The effect on the growth surface is then observed as formation of hillocks running along the (110) direction as shown in Fig. 3.

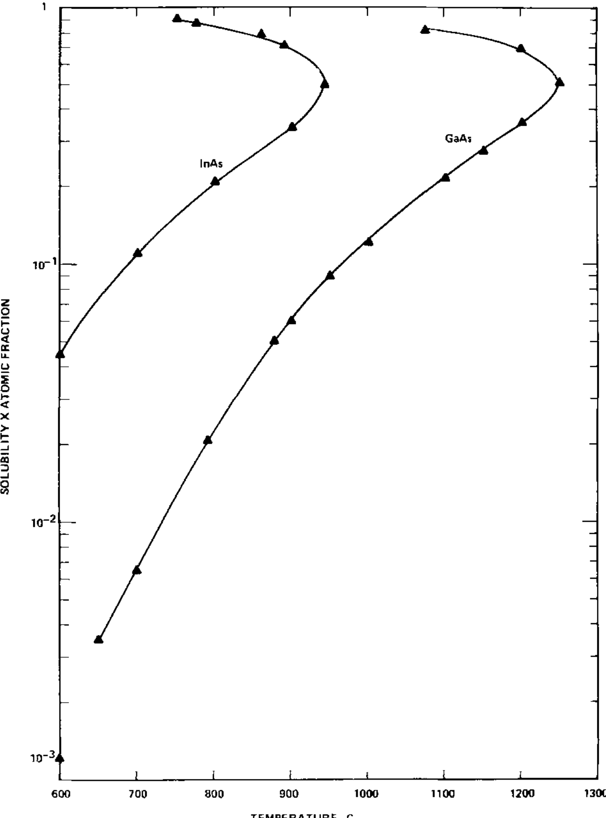

Fig. 2. Solubility curves for As dissolution in In and Ga (after Hall).

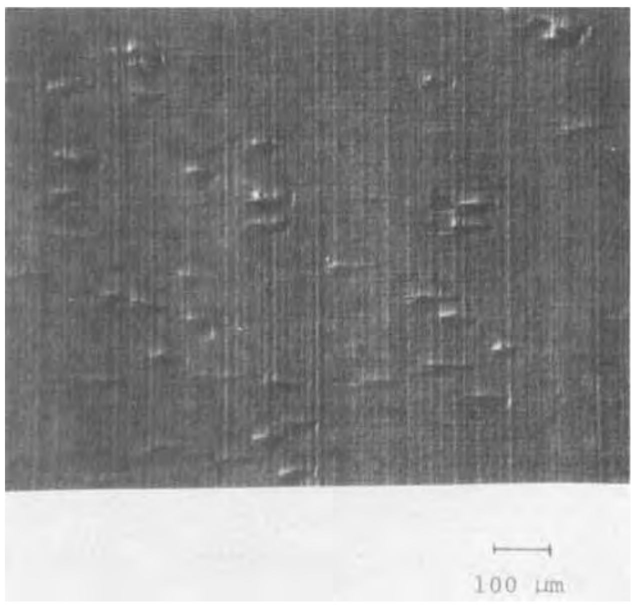

Fig. 3. Hillock formation with high flow rates and small source volume.

Reduction of $AsCl_3/H_2$ flow at this point in the life of the source seems to eliminate hillock formation.

Compositional grading and epitaxial growth.—During grading for lattice matching and epitaxial growth, the substrate was kept at a temperature between 713° and 725°C and the sources were kept at 780°C. The composition of the deposited $In_xGa_{1-x}As$ layers was varied by varying the $AsCl_3/H_2$ flow over the In and Ga sources. Experiments were conducted to determine the composition of epitaxial $In_xGa_{1-x}As$ as a function of fractional $AsCl_3/H_2$ flow ratio over the Ga source. The results are shown in Fig. 4 and com-

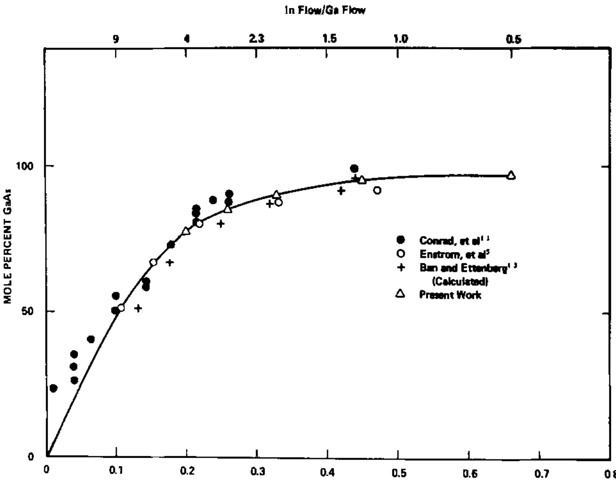

Fig. 4. Variation of epitaxial $In_xGa_{1-x}As$ composition with $AsCl_3/H_2$ flow over Ga and In.

pared with previous experimental data (5, 11) and calculated values of Ban and Ettenberg (13). Compositional grading to the desired composition was accomplished by continuously controlling the input flow ratios to Ga and In (according to the data shown in Fig. 4) by means of a dual-channel electrostatic-curve-following programmer. Both the In and Ga flows were varied to keep the total flow constant. Since the composition of the deposited $In_xGa_{1-x}As$ is governed by equilibrium thermodynamics, letting the flow rate change during compositional grading by keeping flow through one source constant changes the growth rate during grading and results in degradation of surface quality and of electrical properties. Figure 5 shows the surface of epitaxially grown $In_xGa_{1-x}As$ with 14 m/o InAs, with (a) ungraded growth, (b) with 1 μm of graded layer, and (c) with 3.9 μm of graded layer. The better quality of the 3.9 μm layer grown with constant flow rate is immediately obvious. Figure 6 shows the electron mobility at 300°K of some of the films grown with different thickness of graded layers and ungraded growth. The material was doped to about $10^{17}/cm^3$ electron density with H_2S. The graded layer was made semi-insulating with Cr doping using CrO_2Cl_2 as indicated in Fig. 1. The best results were obtained for graded layers of > 3 μm thickness using constant total flow rates, with mobilities of 6920 and 6840 $cm^2/Vsec$, indicated by 4.9 and 4.8, respectively, in Fig. 6. Samples 4.11 and 4.10 were also grown with constant flow rates, but the graded layers were only 2.5 μm and 2.8 μm thick, respectively. Specimen 4.1 has a 2.5 μm graded layer, but the flow rate was not constant throughout the grading. Effect of both variable flow rate and smaller graded thickness is depicted by specimen 4.4 with a room temperature mobility of only 2770 $cm^2/Vsec$. The higher InAs concentration in this specimen with improper grading and gas flow rate also contributes to lower mobility. These can be compared with specimen 6.5, with a mobility of 6360 $cm^2/Vsec$ which had a 2.9 μm graded layer and was grown at a constant gas flow rate. $In_xGa_{1-x}As$ grown directly on the GaAs substrate is exemplified by specimen 3.15. The mobility is 4190 $cm^2/Vsec$ as compared with about 5200 $cm^2/Vsec$ obtained by Glicksman *et al.* (12), but is better than specimens 4.4 and 4.1 only because the InAs mole percent is much smaller, and lattice mismatch is not too large (0.3% as compared to about 1.4%).

CrO_2Cl_2 flow of about 3.4×10^{-7} mole/min was used for doping graded layers which yielded epilayer resistivity of the order of 2×10^8 Ω-cm with a total

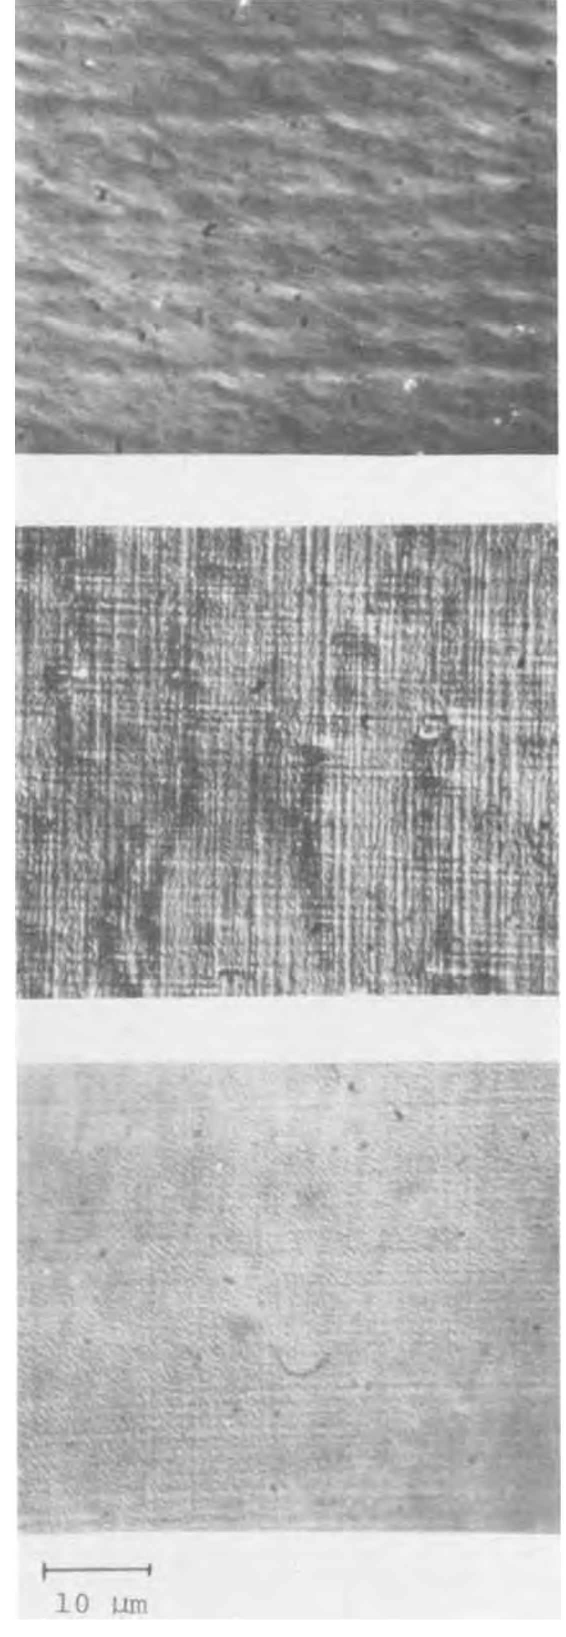

Fig. 5. Surface of epitaxially grown $In_{0.14}Ga_{0.86}As$ grown on ungraded and lattice-matched graded layers: a = ungraded, b = 1 μm graded layer, c = 3.9 μm graded layer.

$AsCl_3/H_2$ flow of 460 cm^3/min. When lower total $AsCl_3$ flows were used, surface imperfections, shown in Fig. 7, were observed running along the (110) direction. These are possibly due to excessive Cr. Similar imperfections have been observed by Mizuno, Kikuchi, and Seki (16) and were attributed to Ga_2O_3 formation when water vapor produced in the reaction

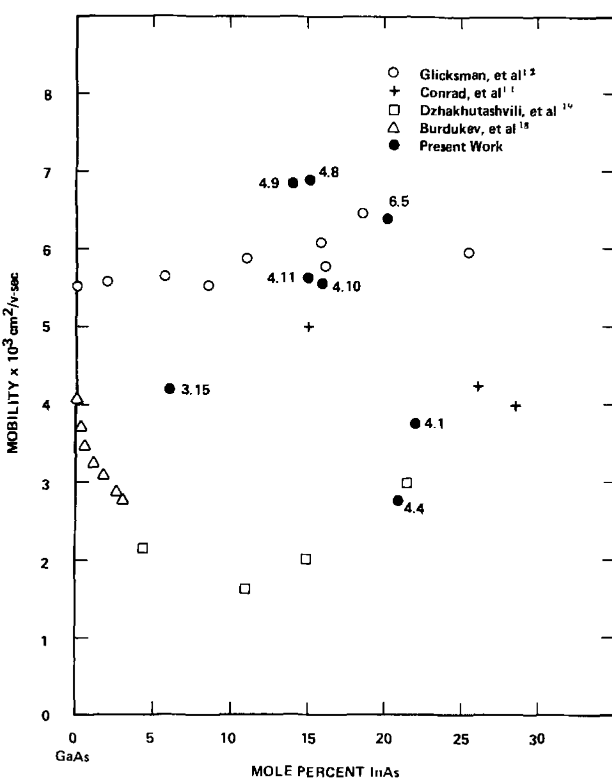

Fig. 6. Hall mobility as a function of mole percent InAs

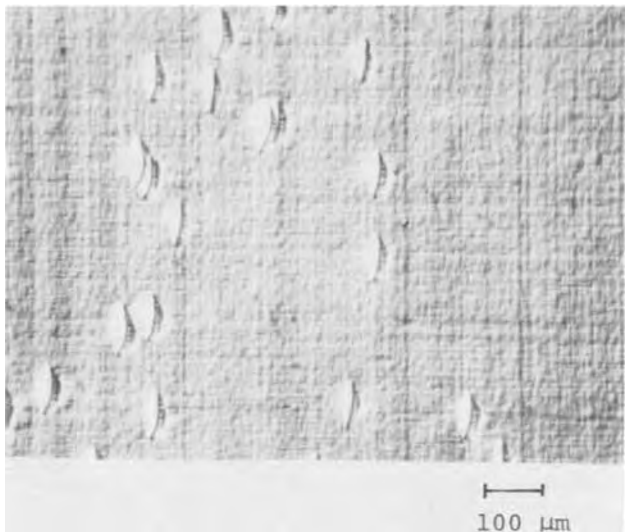

Fig. 7. Surface defects formed at high CrO_2Cl_2 flow

reacted with the Ga source. Since the CrO_2Cl_2 does not pass over the Ga source in our arrangement, the defects observed are tentatively attributed to the formation of stoichiometric CrAs which is found to give needle-shaped precipitates in Czochralski grown GaAs (17). No attempt at compositional analysis, however, was made to confirm this speculation.

To establish desirable equilibrium growth conditions with the InGaAs system described in Fig. 1, the input $AsCl_3$ vapor pressure was adjusted by varying the $AsCl_3$ vaporizer temperature. Complete conversion of HCl to the monochloride of In and Ga was determined by placing a GaAs substrate partially covered with SiO_2 in the high temperature zone and measuring the amount of material etched. Increasing $AsCl_3$ vapor pressure was found to increase etching due to increased HCl production, while at lower $AsCl_3$ vapor pressures growth occurred at the substrate. Figure 8 shows the etch rate as a function of $AsCl_3$ vaporizer temperature. Complete conversion seems to occur at a vaporizer temperature of about 11°C, below which growth occurs in the high temperature region. Since in this series of experiments CrO_2Cl_2 is also used to provide Cr doping, extra HCl enters the reactor through the reaction of CrO_2Cl_2 and H_2. Use of an $AsCl_3$ vaporizer temperature of 11°C can therefore cause severe etching of the substrate. Figure 9 shows the growth surface with $AsCl_3$ vaporizer temperature of 11°C and CrO_2Cl_2 addition. An $AsCl_3$ vaporizer temperature of 7°C was therefore selected for the growth of material reported here, as a compromise among smooth etching, complete conversion, and low growth rates.

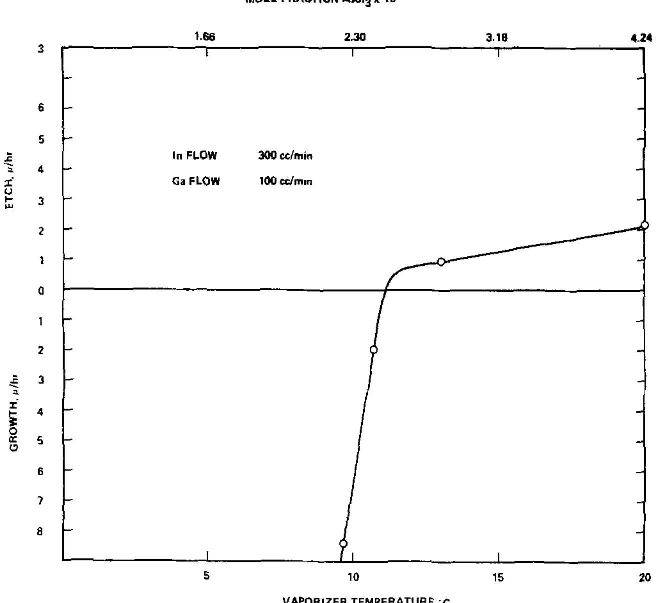

Fig. 8. Etch and growth rate at high temperature as a function of mole fraction $AsCl_3$.

Typically, S-doped $In_xGa_{1-x}As$ epitaxial layers with electron densities of the order of 10^{17} cm^{-3} were grown on semi-insulating GaAs (100) wafers oriented about 2° off axis toward the (110) plane. Graded layers for lattice matching were made semi-insulating with Cr doping. The GaAs substrate was placed in a horizontal position on the substrate holder and

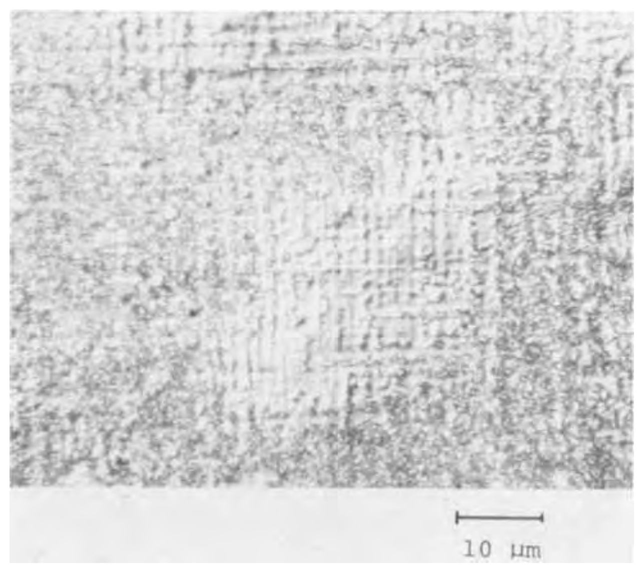

Fig. 9. Growth surface with the $AsCl_3$ bubbler at 11°C in the presence of CrO_2Cl_2.

pushed into the hot zone during temperature equilibration and resaturation of the sources. After HCl etch cleaning, the substrate was pulled back just beyond the S-doping line (Fig. 1), and a graded layer grown on it to the desired InAs composition, as determined from the curve of Fig. 4. After a graded layer of about 3 μm or more was grown, the substrate was pulled further down in the deposition region where S-doped $In_xGa_{1-x}As$ was grown. This growth rate was found to depend on the total flow rate. For a typical flow rate of about 460 cm^3/min $AsCl_3/H_2$, the growth rate was found to be about 0.03 μm/min. A growth rate of 0.01 μm/min was obtained when the total flow rate was reduced to 260 cm^3/min. The growth rate during grading was typically 0.07 μm/min. The effect of flow rate and substrate temperature on composition and growth rates is being investigated and will be the subject of another report.

After the desired epitaxial growth thickness had been obtained, the doping line and $AsCl_3$ flow was shut off and the furnace rolled off from the reactor tube. The substrate was cleaned and stained to delineate the growth layers and the growth thickness was determined optically. Surface structure was observed optically under a Zeiss microscope. The electron density was determined using an impurity profile plotter. The InAs molar concentration was determined by measuring the bandgap (8) by photoluminescence and by x-ray diffraction determination of lattice constants. Hall mobilities were measured by the Van der Pauw method on square samples with alloyed In contacts on the corners. No correction for submicron layer thicknesses was made.

Results and Discussion

Earlier measurements of electron mobility in melt-grown $In_xGa_{1-x}As$ with impurity concentrations of the order of 10^{17} cm^{-3} showed a drastic decrease in mobility with increasing concentration of InAs (18, 19). This decrease in electron mobility was attributed to alloy scattering. A similar effect was observed by Ku (20) in $GaAs_{1-x}P_x$ with a carrier concentration of 1.5×10^{17} cm^{-3}. As opposed to $GaAs_{1-x}P_x$ [where a direct-to-indirect bandgap crossover occurs at $x = 0.44$ (21)], $In_xGa_{1-x}As$ has direct bandgap through all compositions from GaAs to InAs. The expression for the variation of bandgap with InAs concentration is given by Nahory, Pollack, and DeWinter (2). The energy of the Γ conduction band minimum in $In_xGa_{1-x}As$ decreases rapidly with increasing x whereas the energy of the x minimum increases slowly. The electrons are thus characterized by decreasing effective mass. Experimentally determined conduction band effective masses have been found by Fetterman, Waldman, and Wolfe (22) to decrease linearly with increasing InAs concentration. The decrease in electron mobility observed in melt-grown alloys is too large to be explained on the basis of alloy scattering and is probably due to material being inhomogeneous. Purer and more homogeneous material grown from vapor has been shown to have a less marked decrease in mobility [Conrad, Hoyt, and Martin (11) and Fetterman, Waldman, and Wolfe (22)]. Glicksman *et al.* (12), on the other hand, found practically no effect of composition up to a composition of $x = 0.25$ InAs. In Fig. 6, the data points labeled with sample numbers show the mobilities obtained in some good and bad samples of thin film $In_xGa_{1-x}As$, all grown from vapor with a donor concentration of the order of 10^{17} cm^{-3}. Results of other work reported in literature are also shown for comparison. All the alloy layers grown in the present study were of the order of a micron or less in thickness as shown in Table I, and the graded layers for compositional lattice matching were made semi-insulating as indicated earlier. The difference between the $N_D - N_A$ value obtained from d-c Hall data and the charged carrier concentration obtained by differential capacitance measurement is due to the nature of the latter measurement which is carried out at 100 kHz frequency and is less sensitive to carrier trapping at room temperature.

Our data do not confirm the downward trend in mobility with increase of InAs content noted in earlier literature. In this respect, our results agree with those of Glicksman *et al.* (12). On the other hand, quality of the surface and quality and thickness of graded layers seem to affect the electrical properties. For slow growth rates that were used, a thickness of the graded layer of about 3-5 μm seems to be sufficient. Using constant flow rates, as mentioned earlier, also seems to improve the quality of the film. Sample 3.15 was ungraded and seems to have a moderately highly compensating acceptor impurity. Sample 4.1 was grown on an undoped graded layer. It is seen from these results that for a properly grown $In_xGa_{1-x}As$ layer such as 4.8 and 4.9, for example, the room temperature mobility is higher than previously reported for any alloy of comparable composition and carrier density. The degradation in mobility seems to be due only to inhomogeneity and other structural disorders in the epitaxially grown alloys. Effort is under way to increase the InAs concentration up to about 50% and study the effect on mobility of higher InAs concentration in moderately heavily n-doped $In_xGa_{1-x}As$.

Conclusions

Submicron epitaxial layers of $In_xGa_{1-x}As$ were grown successfully on high resistivity graded epilayers to lattice match with GaAs substrates. N-type active layers doped to a carrier concentration of 10^{17} cm^{-3} showed high electron mobilities. It is concluded that alloy scattering as assumed in earlier work does not play any important role in homogeneous $In_xGa_{1-x}As$ alloys grown by chemical vapor deposition. Structural defects, on the other hand, can degrade mobility. The effect of impurity concentration is to reduce mobility in general according to accepted laws, but composition variation alone has minimal or no effect on the electrical properties of the material.

ABSTRACT

Polycrystalline p-type InP films were grown on various insulating and conducting substrates, *e.g.*, glass or carbon, via chemical vapor deposition in an open-tube $In/H_2/PCl_3$ flow system. Zn and Cd were used as dopants. Noticeable differences in growth characteristics are observed as compared to epitaxial layer growth on InP single crystal substrates. Preliminary polycrystalline CdS/InP solar cells have a power conversion efficiency of 2.8%.

Heterodiodes n-CdS/p-InP have potential for solar cell applications since the bandgaps and the excellent lattice match of these materials result in a high solar power conversion efficiency and the stability of the two compounds assures good resistance against degradation. Present state-of-the-art single crystal CdS/InP solar cells have a power conversion efficiency of 14% at air mass 2 (1) and recent accelerated lifetime tests showed that such cells can be heated in air at 485°C for 1 week without significant decay in the device performance (2). InP has a direct bandgap and correspondingly low ($\lesssim 1$ μm) absorption lengths for solar light with 0.50 μm $\lesssim \lambda \lesssim$ 0.96 μm. Over this entire "window" of the InP/CdS cell, InP grain sizes of a few micrometers should thus suffice for efficient collection of photogenerated minority carrier electrons. The cell is therefore an attractive candidate for production in thin film form. At the present stage of development, the preparation of polycrystalline CdS/InP solar cell hinges on the fabrication of p-type films of InP on a suitable substrate material.

In this paper we report on the growth of polycrystalline films of p-type InP on transparent insulators, and on conducting substrates that provide a large area contact to the InP, utilizing the $In/H_2/PCl_3$ growth method (3). In this system, the temperature dependence of the equilibrium constant of the reaction

$$InP(s) + HCl(g) \rightleftarrows InCl(g) + \tfrac{1}{2}H_2(g) + \tfrac{1}{4}P_4(g)$$

regulates transport of InP from an InP crust on an In metal source formed by reaction with PCl_3 to a distant substrate in an open-tube hydrogen flow system. The thermodynamic foundation of the HCl transport of InP has been investigated by Seki and Minagawa (4) and by Shaw (5). Also, there exist several experimental studies of the chemical vapor deposition (CVD) of epitaxial InP layers on single crystal InP substrates (6-11) which were mostly directed towards the fabrication of microwave oscillators.

Key words: thin film solar cells, polycrystalline InP.

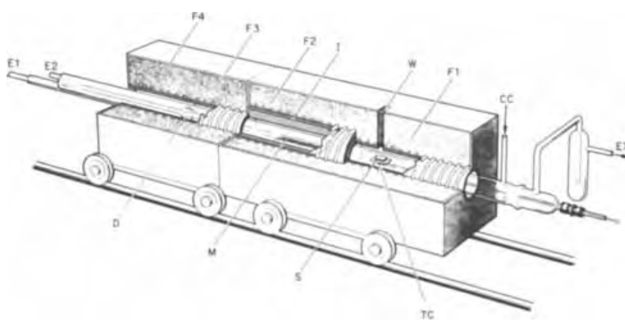

Fig. 1. Open-tube H_2 flow system for chemical vapor deposition of InP. E1 = entrance for the PCl_3/H_2 mixture, E2 = entrance for pure H_2, D = dopant source, M = InP saturated In source, F1-F4 = furnaces, I = isothermal furnace linear, W = window, CC = counter current of pure H_2, S = substrate, TC = thermocouple, EX = exhaust.

Experimental

A drawing of the experimental arrangement is shown in Fig. 1. A stream of Pd-diffused H_2 is passed through a bubbler filled with PCl_3 which is kept at +2.2°C corresponding to a saturation pressure of 40 Torr. The PCl_3-saturated H_2 is diluted by pure H_2 to attain proper molar fractions x_{PCl_3} of PCl_3, typically 2%, and is injected into entrance E2 to the deposition tube. Also, part of the pure H_2 is channeled through a separate entrance on the downstream end of the deposition tube establishing a counter current flow, CC, on the outer side of a quartz liner that surrounds the seed

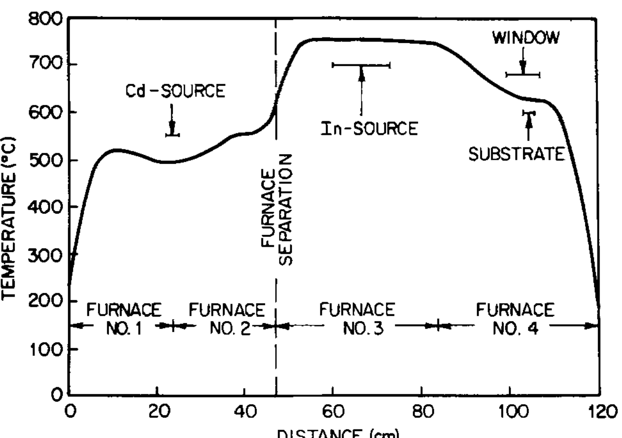

Fig. 2. Temperature profile of F1-F4

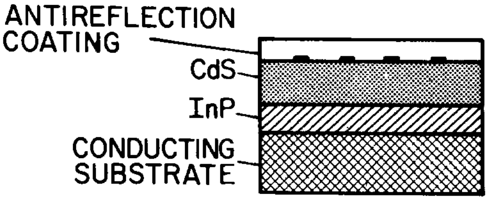

Fig. 3. Schematic cross section of a CdS/InP solar cell

holder so that all reaction products are deposited inside this liner and are removed with the substrate, S, after the experiment is terminated. S can be positioned by means of a quartz push rod for *in situ* visual inspection through window, W, in furnace F1 that controls the deposition temperature. The push rod contains a thermocouple, TC, for monitoring the substrate temperature. The boat, M, contains In-metal that is saturated with InP prior to the CVD experiment as described by Clarke, Joyce, and Wilgoss (8) and is kept by means of furnace F2 at a constant temperature which is typically 750°C. An isothermal furnace liner, I, is inserted into F2 to provide an ~ 20 cm long isothermal section in F2 that warrants equal temperature for all parts of M. The p-type dopant, D, is contained in a separate quartz tube which ends shortly before M and is swept by pure H_2 injected into entrance El. Furnaces F3 and F4 are used to establish a temperature profile that keeps D inside the spherical section shown in Fig. 1. A typical temperature profile for the entire furnace assembly is shown in Fig. 2.

Both pure Cd and Zn have been used as dopant materials yielding net acceptor concentrations of $N_A - N_D \leq 2 \times 10^{18}$ cm^{-3}. The dopant concentration in the vapor phase is typically 10^{-3}-10^{-2}, *e.g.*, a molar fraction of Zn of 1.8×10^{-3} in the vapor phase results in epitaxial InP layers that have a resistivity $\rho = 0.07$ Ω-cm, $N_A - N_D = 9 \times 10^{17}$ cm^{-3}, and $\mu_h = 97$ cm^2/Vsec on Fe-doped semi-insulating (100) InP single crystal substrates. Alternatively, anhydrous $CdCl_2$ or $ZnCl_2$ may be used as dopant materials which eliminates the need for separating D from the HCl-containing vapor atmosphere.

Figure 3 shows a schematic drawing of a cross section through a polycrystalline CdS/InP solar cell consisting of a large area contact to the InP layer, the p-n junction, and a contact grid on top of the CdS which is covered by an antireflection coating. If a suitable conducting substrate is used, the formation of the large area contact to the InP film is included in the CVD step. If an insulating substrate, *e.g.*, glass, is used then the contact to the InP would have to be provided by a contact grid previously deposited on the glass or subsequently attached to a part of the InP layer that is masked from the following CdS deposition.

Figure 4 shows InP coatings produced via CVD on various substrate materials that match the thermal expansion of InP: (A) Corning 7059 glass. (B) molybdenum, (C) carbon, and (D) Fe 30% Ni steel. Note that severe peeling of the InP occurs on the Fe/Ni

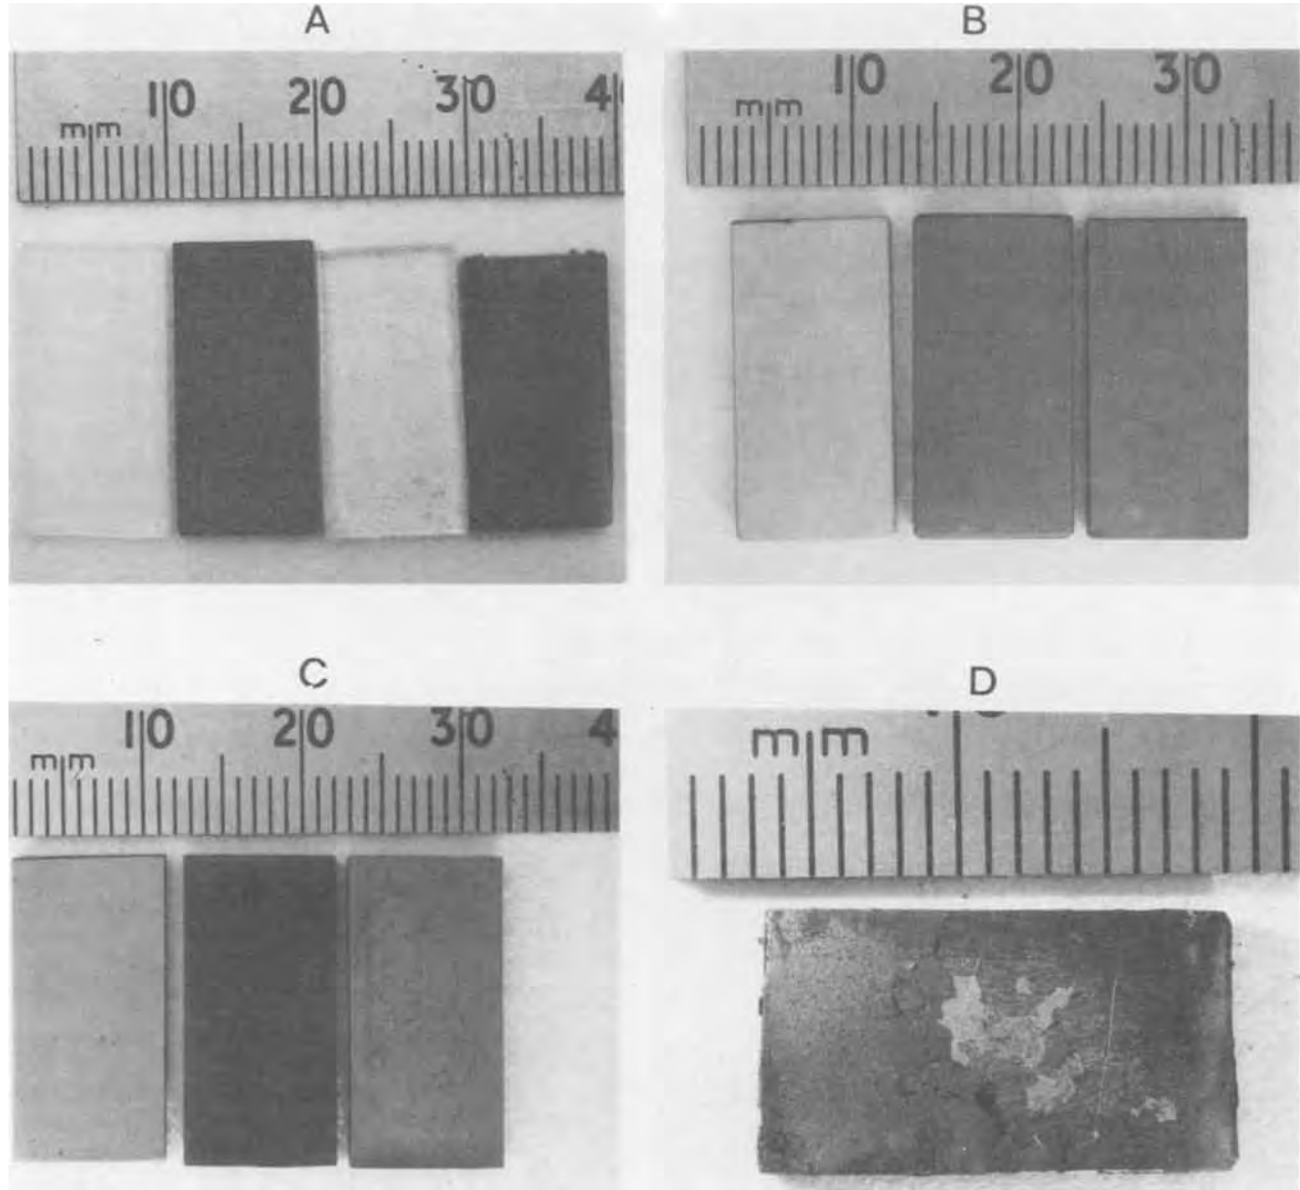

Fig. 4. InP coatings on various substrates: A = glass substrates (left etched, right not etched); B = etched Mo substrate, InP-covered Mo substrates; C = AEC carbon covered with InP, uncovered AEC carbon, InP covered POCO graphite; D = InP on a Fe 30% Ni substrate.

substrate and the reason for this behavior is revealed by Fig. 5 that shows a scanning electron micrograph of a cross section through such a layer, the substrate being on the right-hand side. The top part of Fig. 5 shows x-ray emission analysis traces obtained at various locations marked by arrows on the cross section. The second trace from bottom (No. 4) is an x-ray emission analysis of the original Fe 30% Ni alloy. Clearly In is diffusing into the base alloy (top trace) while Fe and to a lesser extent Ni are reacting with the InP films to form Fe_3P and Ni_3P that do not match the lattice of InP and do not have a similar expansion coefficient as the base alloy. Because of this, the film cracks off at the Fe_3P/alloy interface and Fe/Ni is, therefore, not a suitable substrate material. A similar behavior is observed for Kovar which has both a better match to the expansion characteristics of InP and a somewhat better chemical stability. Therefore, a diffusion barrier layer would have to be used with all Fe-base alloys as substrate materials.

Glass, molybdenum, and carbon are all well suited for coating with InP via HCl transport and no cracking and excellent adhesion of the InP to the substrate is obtained for these substrates. For glass (Corning 7052, Nonex, etc.), more uniform nucleation is obtained on matted surfaces prepared by either mechanical abrasion or by a slight etch in HF. The Mo substrates were etched in a mixture of HNO_3:HF = 30:1 and the carbon substrates (AEC carbon, POCO graphite) where cleaned by heating to ~ 1000°C in vacuum.

Figure 6 shows scanning electron micrographs of p-type InP coatings on molybdenum (A and C) and carbon (B and D) substrates. The grain size is comparable or larger than the absorption length for InP, *i.e.*. $\gtrsim$ 1 μm, and one can, therefore, expect that grain boundaries will not substantially reduce the quantum efficiency of CdS/InP solar cells prepared from such InP films. The morphology of the InP grains on carbon is favorable to that obtained on Mo, and because of its chemical inertness, mechanical stability, abundance, and low cost, we consider graphitized carbon as a possible substrate choice for the preparation of large area solar cells.

The growth rate of the InP films on substrates like carbon or glass is strongly influenced by kinetic factors and, in general, does not follow thermodynamic predictions. Thermodynamic calculations result, at constant input partial pressure p_{PCl_3} of PCl_3 and constant source temperature T_1, in an equilibrium transport rate from the source to the substrate that increases approximately exponentially with decreasing substrate temperature T_2 (5). The actual growth rate *vs.* $\Delta T = T_1 - T_2$ relation on a carbon substrate is shown in Fig. 7 for $x_{PCl_3} = 2.3 \times 10^{-2}$ and $T_1 = 740°C$. Due to hindrances in the formation of three-dimensional nuclei of InP on the carbon, the growth rate remains zero[1] up to a critical temperature difference ΔT_c. At $\Delta T > \Delta T_c$ the growth rate increases steeply within a narrow range of ΔT and changes relatively little for further increases in ΔT.

In contrast to the conditions for CVD of InP on single crystal InP substrates, a foreign substrate does not provide a preferred nucleation site for the InP as compared to fused silica. Therefore, ΔT_c is strongly affected by competitive nucleation and growth of InP on the quartzware in the vicinity of the substrate. That is, due to such competitive deposition, the actual supersaturation at the location of the substrate may be reduced below the value indicated by ΔT and geometric factors. The temperature distribution in the vicinity of the substrate and the flow rate may, therefore, affect the experimentally obtained ΔT_c. Large flow rates tend to reduce these effects. Usually we worked at a linear flow velocity $v_l = 30$ cm/min and $x_{PCl_3} \gtrsim 1.5\%$.

[1] Zero growth rate means that within an incubation time of 3 hr no critical InP nuclei have formed on the carbon.

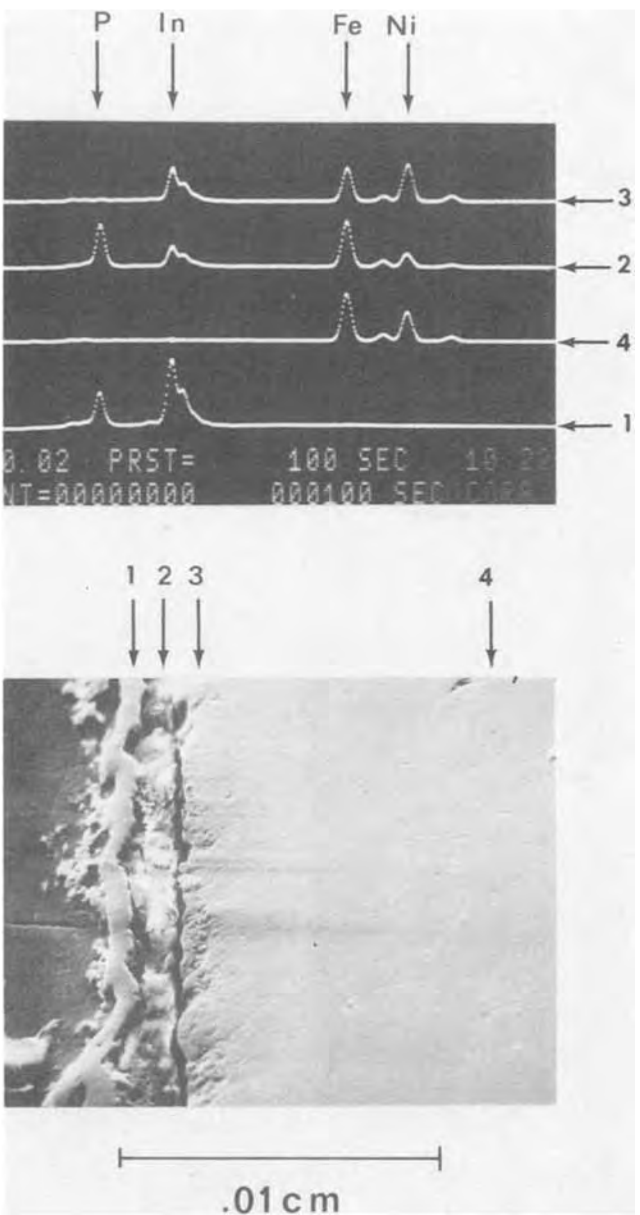

Fig. 5. Scanning electron micrograph of a cross section through InP/Fe 30% Ni (bottom), x-ray emission analysis traces (top).

The kinetics of InP transport in a PCl_3/H_2 flow system to isolated (110), (111), and (100) faces of InP single crystal substrates has been examined recently by Mizuno (12). For deposition on InP single crystals and small ΔT, the growth rate followed qualitatively the ΔT characteristics predicted by thermodynamic calculations. However, depending somewhat on the crystallographic orientation and on the PCl_3 flow rate, the growth rate becomes kinetically limited at $\Delta T \gtrsim$ 100°C. Because of the existence of a nucleation barrier that has to be overcome in polycrystalline film growth on foreign substrates, one is forced to work in the kinetically limited range, at least during the nucleation stage of film growth. Also, in the preparation of p-type InP layers, it is necessary to work at relatively high PCl_3 concentrations, which are usually one order of magnitude larger than those used in Ref. (12), thereby shifting the onset of kinetically limited growth towards lower ΔT_c, to suppress a high background donor concentration that arises when working with $x_{PCl_3} < 1\%$ (10).

X-ray pole figure studies of polycrystalline InP films grown on C, Mo, or glass reveal that the crystallographic orientation of the InP crystallites in such films

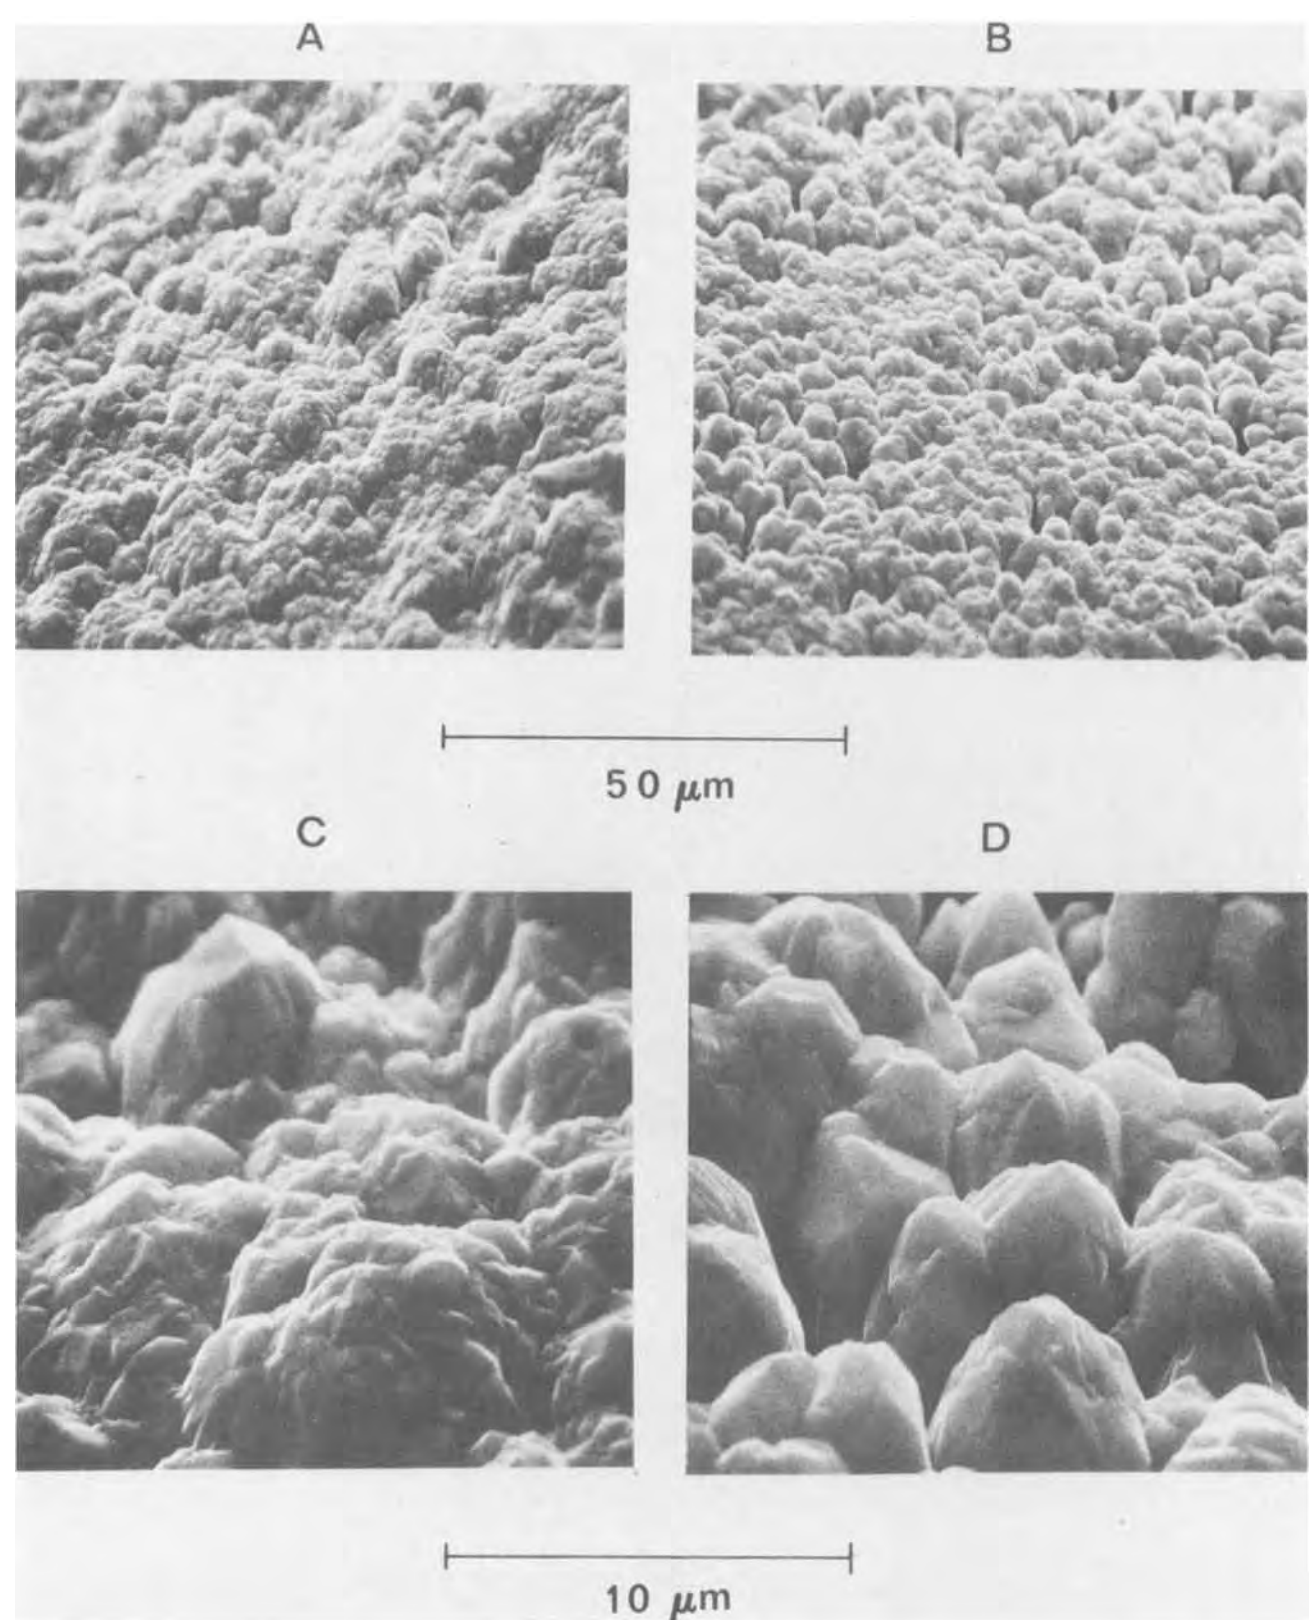

Fig. 6. Scanning electron micrographs of p-type InP layers on molybdenum and carbon substrates

is random. Therefore, effects of the anisotropy in growth rate usually average out in polycrystalline film growth and the grains are more or less equiaxed (compare Fig. 6). However, drastic anisotropies in growth rate and dramatic increases in its magnitude may be induced by the presence of impurities which, in extreme cases, lead to whisker growth that is detrimental to the preparation of solar cells. A study of the conditions and of the morphological characteristics of InP whisker growth will be presented in a separate publication (13).

Preliminary Polycrystalline CdS/InP Solar Cells

Polycrystalline n-CdS/p-InP solar cells were prepared by depositing ~ 10 μm thick layers of CdS onto the above-described InP films utilizing a vacuum deposition technique described previously (14). A comparison between the properties of a representative poly-

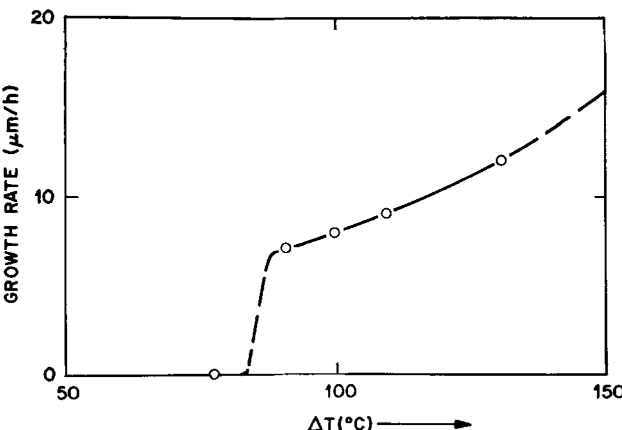

Fig. 7. Growth rate vs. temperature difference between source and substrate, carbon substrate, v_l = 30 cm/min, x_{PCl_3} = 2.3%.

crystalline thin film CdS/InP solar cell grown on a carbon substrate and of a typical single crystal CdS/InP solar cell is made in Table I. The short-circuit current density, I_{SC}, is virtually identical for both types of CdS/InP solar cells. However, the open-circuit voltage. V_{OC}, and the fill factor, F, of the polycrystalline solar cell are considerably smaller than for single crystal devices. Therefore the solar power conversion efficiency, P, of the preliminary polycrystalline cells described above is presently limited to 2.8% as compared to 14% for annealed single crystal devices. For more detailed information on the properties of our present thin film CdS/InP solar cells we refer the reader to a forthcoming publication (15).

Acknowledgments

We would like to thank G. K. Kammlott for providing the scanning electron micrographs of the InP films.

Film-Substrate Interaction in Si/Ta and Si/Ta_2O_5 Structures

A. G. Revesz and T. D. Kirkendall

COMSAT Laboratories, Clarksburg, Maryland 20734

ABSTRACT

Gravimetric and SIMS analyses of vacuum-deposited Ta films on Si substrates as well as Ta_2O_5 films obtained by their thermal oxidation demonstrate a significant interaction in Si/Ta (Ta_2O_5) structures well below the usual temperatures required to form $TaSi_2$ or SiO_2 on silicon. The interaction begins during the deposition of the Ta film, leading to the incorporation of silicon in the film. It is suggested that oxygen gettered by tantalum facilitates this process. During oxidation of the Ta film, the silicon in the film is co-oxidized and oxygen diffusing through the already formed oxide enhances the further entry of silicon into the film. Oxygen diffusing through the completely oxidized Ta film further reacts with the silicon substrate during postoxidation heat-treatment in oxygen. There is no evidence that the interaction during any of these three steps is caused by intermixing elemental tantalum and silicon. The results of gravimetric and SIMS analyses are qualitatively consistent with the measured dielectric parameters of the film and the observed electronic properties of the Si/Ta_2O_5 interface.

Tantalum and niobium oxides have recently been developed as antireflection films in silicon solar cells with increased conversion efficiency (1, 2). These oxide films, obtained by thermal oxidation of vacuum-deposited Ta or Nb film, are noncrystalline with a high degree of short-range order. During the development work, it has been observed that an unexpected interaction between the film and silicon substrate occurs significantly below the temperatures at which silicon is oxidized or Ta silicide is formed. This interaction results in a graded refractive index of the Ta oxide film (3).

Detailed investigations of the optical properties (4) and Rutherford backscattering (RBS) analysis (5) of Ta oxide films on silicon have revealed that these films are, to a first approximation, stoichiometric Ta_2O_5. However, their refractive indexes vary from ~1.9 to ~2.4, the particular value depending on the thickness of the Ta film, oxidation conditions, and postoxidation treatments. This effect has been attributed to the incorporation of varying amounts of silicon into the noncrystalline Ta_2O_5. However, the amount of silicon estimated by RBS analysis appears to be insufficient to explain the observed large variation, indicating that Si-O bonds present in Ta_2O_5 have a profound effect on the polarizability of the Ta-O bonds, and hence on the refractive indexes (4).

The work reported herein is intended to study the film-substrate interaction in Si/Ta (Ta_2O_5) structures by secondary ion mass spectroscopy (SIMS) and gravimetry. It is shown that silicon is already present in the vacuum-deposited Ta film, and that its amount further increases during oxidation. However, the quantitative aspects of the silicon incorporation are not yet fully resolved. This interaction is compared with those observed in other silicon/thin film structures as well as with those occurring during heat-treatment of anodically prepared Ta_2O_5 films on tantalum.

Experimental

Polycrystalline (β-tetragonal) tantalum films about 28 nm thick were deposited on silicon substrates in a vacuum of better than 10^{-6} Torr obtained with a diffusion pump using a liquid N_2 trap. The high purity source was heated with electron beams and a shutter was used. The average area of the substrates was 4.05 cm^2. The substrate temperature during Ta deposition was estimated to be less than ~50°C.[1] In a few cases the films were deposited on previously oxidized (~250 nm thick SiO_2) Si substrates. Oxidation was carried out in oxygen atmosphere at 530°C for 15 min. Under these conditions the tantalum was fully converted into a ~60 nm thick Ta_2O_5 film. More details on preparation conditions are given in Ref. (2), (4), and (5).

Both the Ta and Ta_2O_5 films were analyzed gravimetrically and with SIMS. For the gravimetric analysis, the weights of four samples were determined from five measurements performed with a Cahn microbalance (Model RH 2501 UHV, sensitivity = 2 μg) at each of the following stages: before processing, after metal deposition, after oxidation, and following dissolution of the oxide film in HF. The results were evaluated by statistical methods.

The SIMS analysis was performed with a CAMECA instrument using mainly O_2^+ as the primary beam, although some samples were also analyzed with an Ar^+ beam. (Qualitatively, the results were similar.) In both cases, the profiles of two species were determined simultaneously. The primary ion beam was raster scanned over a large area (~300 μm diameter) while the secondary ion collection was limited to a small central region (~70 μm diameter) in the bottom of the crater to avoid edge effects. Since no standards were used, the results of this analysis were essentially qualitative. At the completion of the crater formation, a spectral analysis over the mass range of 190-270 amu was taken at the crater edge where all species in the exposed film could be measured simultaneously.

The thickness of the oxide films was determined with ellipsometry.

Results

Gravimetric analysis.—The results of the gravimetric analysis are shown in Table I. Several points should be mentioned in connection with this table. The density of the Ta films, as calculated from the average weight and thickness is about 13 gcm^{-3}. This value is less than the bulk density (16.6 gcm^{-3}), indicating that the Ta films are porous. The thickness of the oxide

Key words: solar cells, Ta_2O_5 films, Ta films, SIMS.

[1] This temperature was estimated by considering that the power radiated from tantalum at 3500°K is absorbed in the silicon sample held at 50 cm distance from the Ta source. The absorbed power is then reradiated so that the Si sample is in thermal equilibrium. The following approximate values were used in the calculation: emissivity of Ta = 0.1, absorptivity and emissivity of silicon = 0.8.

Table I. Gravimetric analysis of four samples of thermally oxidized Ta_2O_5 films on silicon (all weights are in μg)

	Weights and probable error of individual samples (5 determinations each)						
	1	2	3	4	Avg	Std dev	Avg prob error*
Deposited Ta	142 ± 2.3	151 ± 2.3	162 ± 1.5	155 ± 1.7	152	7.2	2.0
Oxygen uptake	34 ± 1.9	43 ± 1.7	41 ± 1.4	33 ± 1.6	38	4.3	1.6
Excess oxygen	2.6 ± 2.0	9.6 ± 1.8	5.2 ± 1.4	−1.2 ± 1.7	4.0	4.0	1.7
	2.6 ± 2.0	9.6 ± 1.8	5.2 ± 1.4	—	5.8**	2.9	1.7

* At the usual 50% confidence level.
** This average weight is based on 3 samples, the fourth being excluded because the error exceeds the value itself.

film calculated from the amount of tantalum is 57 nm, assuming that the oxide is Ta_2O_5 with a density of 8.0 gcm^{-3} (the value for noncrystalline anodic Ta_2O_5). However, the experimentally determined thickness is ~60 nm, indicating that the density is less than 8.0 gcm^{-3} and/or the oxide is not pure Ta_2O_5. For each sample the amount of oxygen needed to convert the particular amount of tantalum into Ta_2O_5 (corresponding to the highest oxidation state of tantalum) has been subtracted from the oxygen uptake associated with the oxidation. Since, except for one sample, the difference is positive, this difference is labeled excess oxygen.

Table I shows that the sum of deposited tantalum and oxygen uptake is significantly less than the weight of the oxide film determined by dissolution. The reason for this is that some amount of silicon was lost when the oxide film was dissolved, as shown in the last row. The average value of the silicon loss reported here is less than the result of the preliminary investigation (40 μg) (3), but, statistically, it is still highly significant, as indicated by both the standard deviation and average probable error values. The previous result was obtained without statistical analysis. Even if the unusually strict 95% (rather than the usual 50%) confidence limit is considered, the individual error terms vary from 25 to 52%. Hence, the loss must be due to a real effect. Indeed, no significant change has been observed in the weight of similarly treated silicon control samples without Ta film. Thus, it is concluded that the Ta oxide film on silicon contains a significant amount of silicon. This is the reason why the oxide film is thicker than expected.

The question of how this silicon is incorporated in the oxide cannot be easily answered. If it is assumed that the Si is incorporated in the oxidized Ta film as SiO_2, the amount of excess oxygen taken up (average 5.8 μg) corresponds to 5.1 μg Si, much less than the Si loss (average 20 μg) determined by HF dissolution of the film. On the basis of ellipsometric measurements, the possibility that there is a discrete layer of SiO_2 between the Si substrate and the Ta_2O_5 film has been eliminated (3). This suggests that the silicon atoms in the noncrystalline Ta-O network form bonds with oxygen atoms which are associated with one or more tantalum atoms. Consequently, the O to Si ratio corresponds to 0.5 rather than 2, as it would for SiO_2 (if a uniform distribution of Si atoms in the oxide were assumed).

Another approach to the problem is to consider the density of the oxide film. From the weight of tantalum and the oxygen uptake, the average density is 7.5 gcm^{-3}, whereas its value determined from the weight loss in HF is 8.3. These values can be compared with the reported density of noncrystalline anodic Ta_2O_5 (8.0 gcm^{-3}) and noncrystalline SiO_2 (2.20 gcm^{-3}). A further comparison can be made with the "apparent" density of similarly prepared Ta_2O_5 films on silicon determined by RBS analysis [6.3-6.6 gcm^{-3} for about 60 nm thick oxide films (5)]. These values have been obtained from the areal density of Ta atoms using the ellipsometric thickness value of the oxide, which is assumed to be Ta_2O_5. The unrealistically low apparent density values indicate that a significant amount of foreign constituent in the oxide has not been detected with the RBS technique.

The amount of silicon determined gravimetrically corresponds to 0.85 Si atom/Ta atom in the oxide film. This value is much higher than even the most conservative limit of detection of the RBS technique: 0.16 Si atom/Ta atom (5). This discrepancy is not yet resolved, but does suggest that the majority of the Si atoms incorporated in the film are concentrated near the interface rather than distributed more uniformly in the film. The SIMS results, discussed below, corroborate this hypothesis. On the other hand, the behavior of the refractive index of Ta_2O_5 films on silicon indicates that, in qualitative agreement with gravimetric analysis, a significant amount of Si-O bonds must be present throughout the oxide film. These considerations are based on the assumption that the polarizability of the Si-O and Ta-O bonds in these films is the same as in vitreous silica and anodic Ta_2O_5, respectively, and that the bond polarizability is additive (4).

In conclusion, the results of the gravimetric analysis demonstrate that thermally grown Ta_2O_5 films on silicon contain a significant amount of silicon. This may qualitatively explain the large variation in the refractive index and its gradient within the oxide (decreasing toward the Ta_2O_5/Si interface), but there is an unresolved discrepancy between these results and those obtained with the RBS technique.

SIMS analysis.—The results obtained for an as-deposited Ta film on silicon are shown in Fig. 1, which indicates that all four species, $^{28}Si^+$, $^{56}Si_2^+$, $^{32}O_2^+$, and $^{60}SiO_2^+$, exhibit an apparent gradient at the outer surface. Since this gradient occurs within an estimated thickness less than ~10 nm, it may be due to spurious surface effects; therefore, it is designated as apparent. However, no gradient, not even an apparent one, would have been observed unless these species were present in the Ta film.

In addition, the distribution profiles of both silicon species exhibit a kink on the Ta side of the Ta/Si interface, *i.e.*, the number of counts there is higher than expected from a sharp Ta/Si interface. This also indicates that some silicon is present in the Ta film. Significant impurity effects in Ta films on silicon have also been observed with the RBS technique; they have been attributed mainly to gettering of oxygen, but it is also possible that silicon is present in the Ta film (5).

Although the Ta films are porous, they are not discontinuous in the sense that x-ray surface diffraction analysis showed only the structure of tantalum but not of silicon. Also, very thin (~20 nm) Ta_2O_5 films are very uniform morphologically and optically (4), indicating that even Ta films which are much thinner than ~28 nm are continuous.

Figure 2 shows the results obtained with Ta_2O_5 films on silicon using an Ar^+ ion beam. Qualitatively, the

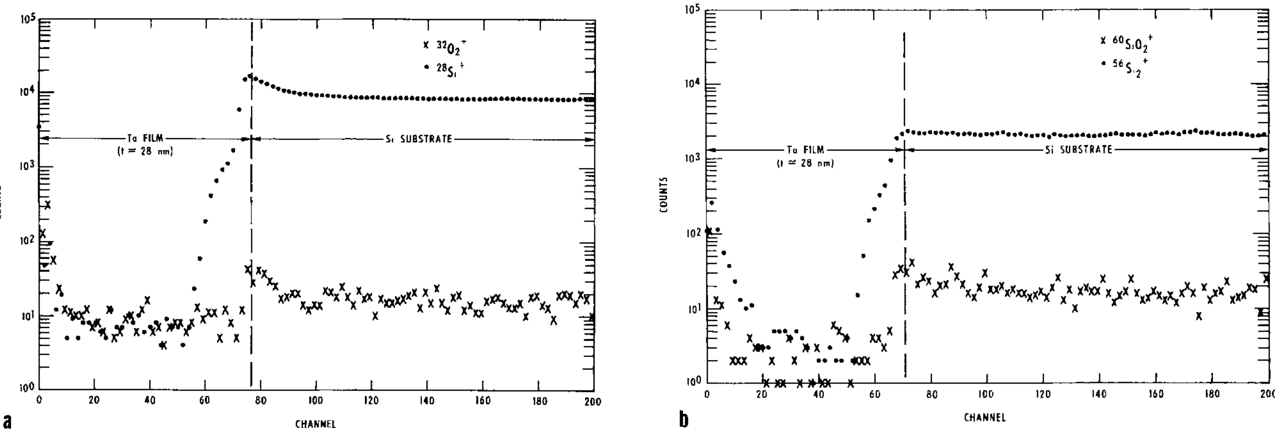

Fig. 1. SIMS analysis of Ta film on silicon. The beam is O_2^+. a and b represent two separate scans on the same sample which has been prepared by electron beam deposition of Ta on Si. The apparent rise in the $^{28}Si^+$ curve at the Ta/Si interface relative to the bulk silicon is probably a chemical enhancement effect.

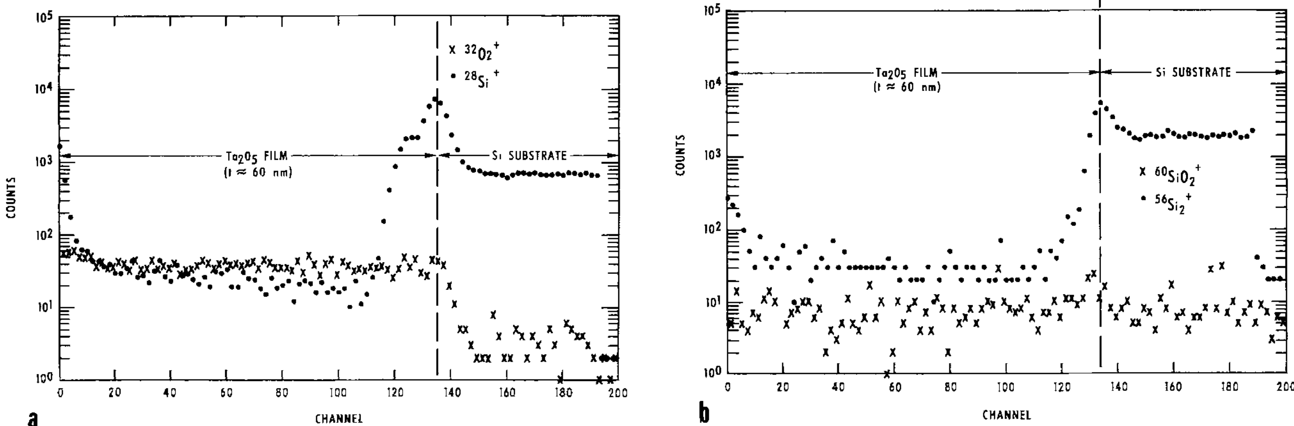

Fig. 2. SIMS analysis of Ta_2O_5 film on silicon. The beam is Ar^+. a and b represent two separate scans on the same sample which has been prepared by thermal oxidation at 530°C of EB-deposited Ta on Si. The location of the Ta_2O_5/Si interface has been estimated from the negligible solubility of oxygen in silicon.

essential features are the same as in Fig. 1; however, the $^{60}SiO_2^+$ level is now uniform across the whole sample and both silicon species exhibit an enhancement effect on the silicon side of the Ta_2O_5/Si interface. Comparison with the $^{56}Si_2^+$ and $^{60}SiO_2^+$ profiles obtained with an O_2^+ beam (see Fig. 3) indicates that the enhancement of $^{56}Si_2^+$ on the silicon side of the Ta_2O_5/Si interface is probably due to the presence of an oxide film [a similar effect has been observed at the SiO_2/Si interface (6)], but the enhancement of $^{60}SiO_2$ at the Si/Ta_2O_5 interface in Fig. 3 is probably an artifact caused by the O_2^+ beam. Obviously there is no SiO_2 in the Si substrate. On the basis of arguments similar to those used above for the Ta films on silicon, and from the qualitative feature of the $^{28}Si^+$ and $^{56}Si_2^+$ profiles, it is concluded that silicon is present in the oxide film.

The mass spectrum taken at the completion of the crater formation (Fig. 4) demonstrates that a large variety of Ta-Si-O complexes were present among the ions detected. It is possible that, due to some reactions with the ion beam, not all the species shown in the spectrum were present as such in the film and/or not in that relative concentration. Nevertheless, it is very unlikely that all the complexes resulted from spurious effects.

Similarly, it was observed that several constituents of a glassy substrate, especially silicon, became incorporated in Ta_2O_5 films obtained by thermal oxidation of sputtered Ta films (7). In this case, the concentration of silicon was estimated as ~0.5 atomic percent (a/o), most of which was in oxidized form. Apparently, some interaction took place between the glass and Ta and/or Ta_2O_5 film. Since silicon is more reactive than glass, it is plausible that the concentration of silicon in the Ta_2O_5 film on silicon would be higher than in the case of a glass substrate.

The possibility of an interaction with a silica substrate has not been investigated in great detail. Nevertheless, it is instructive to compare the profiles shown in Fig. 2 and 3 with those characteristic of a Ta_2O_5 film on an oxidized silicon substrate (see Fig. 5). In this figure, the counts for both $^{60}SiO_2^+$ and $^{56}Si_2^+$ on the Ta_2O_5 side of the Ta_2O_5/SiO_2 interface fall into the noise level, whereas in Fig. 2b and 3 the $^{56}Si_2^+$ counts are higher than the $^{60}SiO_2^+$ counts and their noise

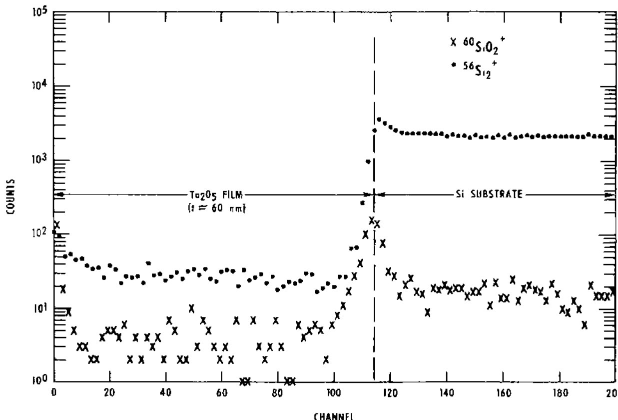

Fig. 3. SIMS analysis of Ta_2O_5 films on silicon. The beam is O_2^+. The inflection of the $^{60}SiO_2$ signal at the Ta_2O_5/Si interface is more pronounced than in the case of Ar^+ (Fig. 2b).

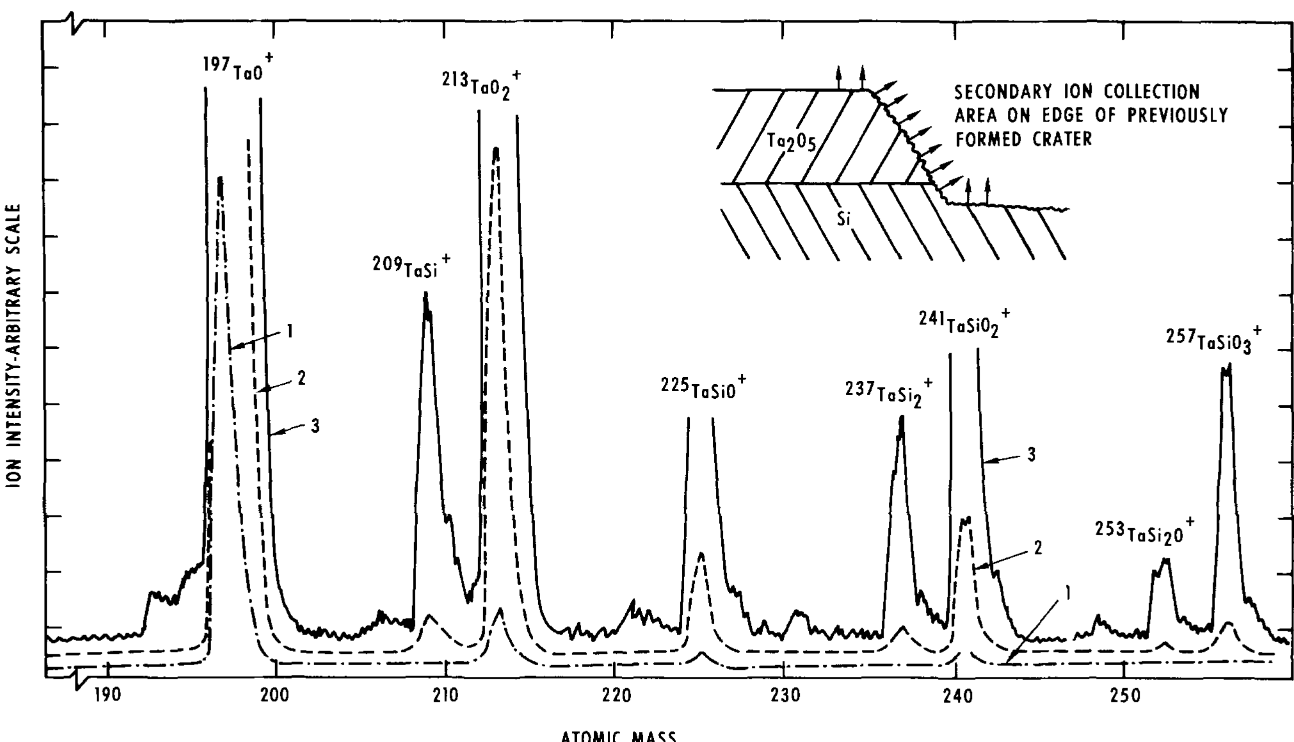

Fig. 4. Mass spectrum taken at the completion of the crater. The beam is O_2^+. The ions shown in the spectrum originate mostly from the edge of the crater to include species in the film and interface region. Each trace has 10 times greater sensitivity than the preceding. The insert is not to scale.

level is much less than that of the $^{60}SiO_2^+$ profile. This may indicate that the extent of the film-substrate interaction is less, if any, for a SiO_2 than for a Si substrate.

Because of the interest in applying Nb_2O_5 as an antireflection film in silicon solar cells (1, 2), thermally grown Nb_2O_5 films on silicon were also analyzed to a limited extent. The SIMS results were essentially the same as those obtained for Ta_2O_5 films. Preliminary Auger analysis indicated that silicon is present at the outer surface of both Ta_2O_5 and Nb_2O_5 films.

The results of the SIMS analysis demonstrate qualitatively that silicon is present in both vacuum-deposited Ta and thermally grown Ta_2O_5 films on silicon substrates. Together with the results of the gravimetric analysis, they indicate a film-substrate interaction in the Si/Ta (Ta_2O_5) structure.

Discussion

The results presented above show that an interaction with the silicon substrate occurs during the vacuum deposition of the tantalum film, leading to the entry of Si atoms into the metal film. The compositionally rather ill-defined thin (~2 nm) oxide film that covers the silicon surface at room ambient is probably destroyed during this process. This interaction must be quite different from that resulting in silicide formation, since the temperature of the substrate (not purposely heated) is far below 650°C, the temperature at which $TaSi_2$ has been reported to form in silicon-Ta film structures (8).[2] However, the observed interaction resembles the diffusion of silicon into a Pt film, which has been reported to proceed to the extent of 20-40 nm during the deposition process, and to be independent of the deposition method. The silicon content of an as-deposited Pt film on Si has been given as 3 a/o (9).

Based on the assumption that oxygen is the only contaminant, it has been inferred from RBS analysis (5) that oxygen is also present in vacuum-deposited Ta films (corresponding to 0.15-0.60 O atom/Ta atom). Hence, the incorporation of silicon, *e.g.*, by grain boundary diffusion, into the Ta film may have been facilitated by oxygen due to the formation of strong Si-O bonds. Consequently, silicon incorporation occurs at a much lower temperature than that needed to form $TaSi_2$.

Following the deposition, the oxygen content of the film rapidly increases during thermal oxidation, resulting in a Ta_2O_5 film. During this process, silicon already present in the film is co-oxidized with tantalum and further interaction with the Si substrate takes place. This process occurs at a temperature at which only an extremely thin SiO_2 film can be obtained when silicon alone is oxidized. To wit, oxidation of bare silicon at 600°C (as opposed to 530°C in these experiments) for 30 min results in only a 2 nm thick SiO_2 film (10). As mentioned above, no oxidation of silicon has been observed at 530°C in addition to the room ambient oxide film.

The interaction in the Si/Ta (Ta_2O_5) structure resembles to some extent the formation of an SiO_2 layer

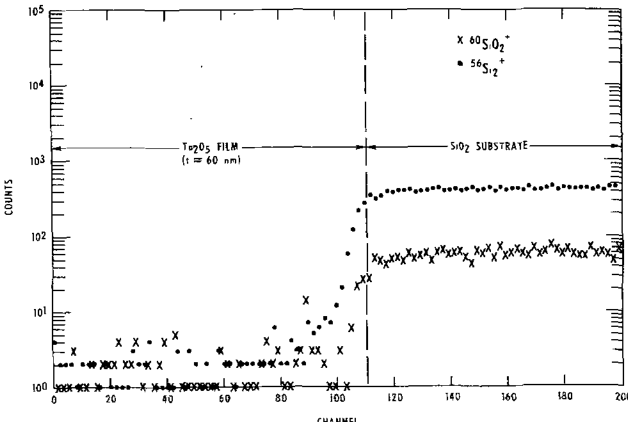

Fig. 5. SIMS analysis of Ta_2O_5 film on SiO_2. The beam is O_2^+. The substrate is ≈ 250 nm of SiO_2 prepared by thermal oxidation of Si. The Ta_2O_5 film has been prepared by EB deposition of Ta with subsequent oxidation at 530°C for 15 min in oxygen.

[2] In accordance with Ref. (8), low angle x-ray diffraction investigation of Ta/Si structure heat-treated at 500°C in neutral ambient did not show the presence of $TaSi_2$.

on the top of vacuum-deposited gold films on silicon substrates (11). That process occurs at 150°-250°C, which is also well below the oxidation temperature of silicon. The significant difference is that gold cannot be oxidized so that a separate SiO_2 film forms, whereas the tantalum is oxidized to Ta_2O_5 film, which contains silicon associated with oxygen (Si-O bonds). However, there is also a strong similarity: in both cases the entry of silicon into the metal film, its migration there, and its oxidation are closely related processes. In the case of gold on silicon, this relationship is manifested in the fact that no intermixing of silicon and gold (as shown by the disappearance of a sharp Si-Au interface in terms of both Si and Au distributions) below the eutectic point (375°C) has been observed when the sample is heated in a nonoxidizing ambient, thus precluding the formation of an SiO_2 film on the gold surface (11). Apparently, a significant intermixing of gold and silicon at low temperatures is possible only when the Si atoms can be tied to oxygen atoms.[3] That is, the Au/SiO_2 interface acts as a sink for the Si atoms migrating from the Si-Au mixed phase through the Au layer to the Au/SiO_2 interface.

According to the model proposed in Ref. (11), the intermixed Si-Au layer plays a key role in the formation of a SiO_2 film on the gold surface. The RBS results have shown that, in terms of tantalum distribution, both the Si/Ta and Si/Ta_2O_5 interfaces are very sharp, indicating that Ta is not present in the Si substrate. Accordingly, the film-substrate interaction in Si/Ta (Ta_2O_5) structures must involve some phenomenon other than the formation of an intermixed layer.

It is interesting to note that the SIMS results indicate the possibility of silicon enhancement at the outer surface of Ta films (see Fig. 1). The reason for this effect may be a similar "sink effect" due to oxygen, since oxygen is also accumulated at the outer surface of Ta films.

It is important to realize that during the thermal oxidation of a Ta film on silicon there is no sharp boundary in the oxygen concentration between Ta_2O_5 on the surface and "unoxidized" tantalum beneath it (5). Therefore, concomitant with the formation of Ta_2O_5 and co-oxidation of silicon already present in the Ta film, the oxygen concentration further increases in that region of the Ta film which has not yet been converted into Ta_2O_5. Thus, the entry of silicon into the Ta film is further enhanced. This model is consistent with the observed decrease in silicon enhancement at the outer surface after the Ta film has been fully oxidized (compare Fig. 1a and 3). It also explains the decrease in the refractive index from the outer surface of the Ta_2O_5 film toward the Si/Ta_2O_5 interface (3, 4); this decrease results from the increased concentration of Si-O bonds toward the Si/Ta_2O_5 interface. This increase may be the reason for the presence of a kink in the silicon distribution profile at the Si/Ta and Si/Ta_2O_5 interfaces.

The film-substrate interaction in Si/Ta (Ta_2O_5) structures does not stop when the Ta film is fully oxidized. It has been observed that the determination of the end point of the oxidation process is somewhat complicated by a continuous increase in the oxide thickness and decrease in the oxide refractive index (3). Similar effects have been observed during post oxidation heat-treatment in an oxidizing ambient (4). These observations demonstrate that the oxidation of silicon and its incorporation into the oxide film proceed even when no more metallic tantalum is present. Furthermore, this process also occurs at temperatures at which bare silicon cannot practicably be oxidized. This observation further emphasizes the role of oxygen in the film-substrate interactions, especially its diffusion through the Ta_2O_5 film and its reaction with silicon. It is important to realize that there are no grain boundaries present in the morphologically and optically very homogeneous noncrystalline Ta_2O_5 film. Hence, the migration of silicon there cannot proceed via grain boundary diffusion.

The Ta_2O_5 films on silicon discussed in this paper are noncrystalline. The properties of noncrystalline Ta_2O_5 films obtained by thermal oxidation of bulk tantalum are not well known, but noncrystalline Ta_2O_5 films prepared by anodic oxidation of tantalum have been studied extensively. For instance, it has been reported that oxygen can easily diffuse through anodic Ta_2O_5 films in the temperature range of 400°-600°C and then gets absorbed in the underlying tantalum (12). Very significantly, the diffusion of oxygen through the anodic Ta_2O_5 film has not resulted in additional oxide growth when the anodic oxidation is reasonably thick (*e.g.*, a 50 nm oxide has remained unchanged for 24 hr at 500°C). Thus, the bulk tantalum acts simply as an oxygen sink. Similarly, in the case of Si/Ta (Ta_2O_5) structures, the silicon substrate may act as an oxygen sink after complete oxidation of the Ta film. It can be estimated from the data in Ref. (12) that the diffusion of oxygen at 530°C through a 60 nm thick Ta_2O_5 film can oxidize about 20 μg of silicon on a 4.05 cm^2 wafer within 20 min. The agreement between this value and the measured silicon loss (Table I) is probably fortuitous, but the important point is that oxygen can be supplied for further oxidation through the already formed Ta_2O_5 film.

It is more difficult to explain why the oxidation of silicon proceeds at a lower temperature at the Si/Ta_2O_5 interface than at the Si/SiO_2 interface (as is the case during the usual thermal oxidation). It may be argued that, before the oxidation of the Ta film is complete, oxidation of silicon already present in the Ta film may occur at a lower temperature than oxidation of bulk silicon because in the former the Si atoms are not bound to other Si atoms. Thus, the situation is somewhat similar to the Si/Au structure, where Si atoms arriving on the gold surface also combine with oxygen at even lower temperatures because they are not part of the silicon crystal. However, this is no longer the case after the Ta film has been fully oxidized. Thus, it is apparently easier to transfer a silicon atom from the silicon crystal into Ta_2O_5 than into SiO_2.

As a result of the incorporation of Si atoms into the Ta_2O_5 film, the Si/Ta_2O_5 interface does not coincide with the original Si surface or Si/Ta interface. In this respect, this process resembles the oxidation of silicon, which, under proper conditions, results in a nearly perfect semiconductor-insulator interface. The perfection of the Si/SiO_2 interface results from two basic features: (*i*) a growth process (*i.e.*, transfer of Si atoms from the silicon crystal into the SiO_2 film) by which the silicon surface is displaced from its original position into a new one which was formerly in the bulk, and (*ii*) the structural flexibility of noncrystalline SiO_2, which is essential for the accommodation of the two solids at the interface with minimum disorder (13). The Si/Ta_2O_5 structures exhibit similar characteristics. Indeed, there are indications that the Si/Ta_2O_5 interface has a perfection that is unexpected for an extrinsic (*i.e.*, non-SiO_2) oxide film on silicon (2, 14).

The nature of the Si/Ta_2O_5 interface is, of course, intimately related to the existence of the Si-O, Si-O-Ta, and the somewhat improbable Si-Ta bonds in the oxide. The mass spectrum in Fig. 4 indicates a large variety of possible combinations of Si, Ta, and O atoms. However, some of these combinations may not occur in the oxide but may be artifacts produced in the course of the analysis. Polarizability considerations have indicated that this oxide somehow lies intermediate between Ta_2O_5 and SiO_2, where the role of Si-O bonds appears to be disproportionally large and may even affect the Ta-O bonds (4). Unfortunately, very little

[3] It should be noted that the model proposed in Ref. (11) does not provide an explanation for the observation that no Si-Au intermixed layer formed below the eutectic point in a nonoxidizing ambient.

is known about the structure of noncrystalline Ta_2O_5 and the relationship with its properties. However, from the above discussion it is clear that a significant interaction occurring in Si/Ta and Si/Ta_2O_5 structures plays a predominant role in obtaining an oxide film with remarkable properties. Some of these properties can be varied in a controlled manner within a very wide range.

Conclusions

According to gravimetric analysis, Ta_2O_5 films on silicon substrates obtained by thermal oxidation of vacuum-deposited tantalum contain a significant amount of silicon. Corroborative secondary ion mass spectroscopy further indicates that silicon is already present in the as-deposited Ta film. These results agree qualitatively with the behavior of the refractive index and dielectric constant of these oxide films described previously, although comparison with former RBS data shows an inconsistency. A model is suggested in which an interaction between silicon and oxygen is responsible for the incorporation of silicon into the Ta and Ta_2O_5 film at temperatures well below the usual temperature for oxidation of silicon.

Gel Formation in Negative Electron Resists

Nobufumi Atoda and Hisazo Kawakatsu

Electrotechnical Laboratory, Tanashi, Tokyo, 188 Japan

ABSTRACT

Exposure characteristics of negative electron resists are described on the basis of Charlesby's theory on gel formation by a chain reaction. By use of the theory, the important resist parameters, contrast and sensitivity, can be related to the chemical properties of the resist materials. Applicability of the theory to exposure curves of Kodak thin film resist (KTFR), polymethylvinylsiloxane (PMVS), and epoxidized polybutadiene (EPB) is experimentally verified. The radiation yield for the reaction initiated directly by the electron irradiation and that for the over-all reaction propagated via radicals is separately estimated. It is found that the sensitivity of styrene-butadiene copolymers (SB) is increased by an introduction of α-phenylmaleimide. This increase in sensitivity is also explained by the theory. The observed lowering in contrast associating the improvement in sensitivity by α-phenylmaleimidation in SB, by epoxidation in polybutadiene, and by introduction of vinyl groups in polysiloxanes is in good agreement with the theoretical results. It is concluded that if a resist with higher contrast than 1.0 is required, the chain reaction must be inhibited so that the inhibition factor is larger than about 0.5.

Electron beam lithography has become important in order to fabricate master masks or direct devices having high resolution structures. If the electron beam parameters and resist properties are properly combined, a minimum linewidth down to 1000Å can be obtained with an electron optical system of the scanning electron microscope type (1). However, for practical processes, further development concerning the pattern-fabricating speed is required. The amount of time for writing a desired pattern is restricted by the electron beam current and the sensitivity of the resist. Since the electron current is limited by the brightness of the electron source and decreases rapidly with the spot diameter (2), resists with high sensitivity are needed for writing the desired pattern with satisfactory resolution in a reasonable amount of time.

Resist materials are classified into two categories: negative resists, which are cross-linked and converted to insoluble gels by electron irradiation, and positive resists, which are degraded and dissolved in the irradiated area. Negative resists are, in general, more sensitive than positive resists, although positive re-

Key words: electron lithography, chain reaction, radiation yield, contrast, sensitivity.

sists are preferable for high resolution applications (3). The comparatively low resolution of negative resists is mainly due to the fact that electrons back scattered from the substrate cause a gradual slope at the edge of the developed pattern (4). The extent of this effect strongly depends on the contrast, Γ, of the resist, which is defined as the slope of the exposure characteristic curve. It is noted that if negative resists with high contrast ($\Gamma > 1.0$) are properly processed, resolutions close to the diameter of the electron beam can be obtained (5). However, negative resists with high sensitivity tend to exhibit comparatively low contrast, especially when the sensitivity is improved by the introduction of a reactive chemical group, such as epoxy or vinyl. Then the contrast is lowered in comparison with that of the original material (6, 7).

In the present work, gel formation in negative resists is studied on the basis of radiation chemistry, with the intention of understanding the dependence of contrast and sensitivity on the chemical properties of resist materials. The study on gel formation by electron irradiation can be reduced into two steps. The first is formation of cross-links by electron irradiation, which is conveniently discussed in terms of radiation yield, independent of any detailed mechanism. In the second, gel fraction is related to the extent of cross-linking. This problem has been theoretically treated in detail by Charlesby (8). A radiation chemical approach to the insolubilization of electron resists has been first reported by Ku and Scala (9). Although their result provides valuable information as to dependence of the critical dose on chemical properties of resists, such as average molecular weight and radiation yield, it cannot offer any information as to the important resist parameter, contrast. Moreover, it is not always applicable to every resist system. In resist materials which contain epoxy or vinyl groups, it is supposed that the insoluble gel is formed through chain reactions of cross-linking. For such a case, a Charlesby theory on random cross-linking (10), which is implicitly postulated in the treatment by Ku and Scala, is no longer valid.

The chain reaction has been used to explain experimental results. Broyde has estimated the radiation yield of Kodak thin film resist (KTFR) assuming the chain reaction (11). Paal *et al.* (12) and Roberts (6) have attributed the high sensitivity of newly developed resists to the chain reaction. However, the applicability of chain process to the resist systems has not been fully verified. The work reported by Nonogaki *et al.* is taken as experimental evidence, in which the dependence of the sensitivity of epoxidized polybutadiene (EPB) (13) on the epoxy content is empirically formulated by assuming chain process (14), while Feit *et al.* have observed little dependence in the same experiments (7). Moreover, theoretical treatments and quantitative descriptions of contrast have not been reported.

The theory on gel formation by the chain mechanism has been given by Charlesby (15). By use of the theory, contrast as well as sensitivity can be related quantitatively to the extent of chain propagation. In the present work, the applicability of the theory to exposure curves of KTFR, EPB, and PMVS (polymethylvinylsiloxane) (16) is examined. Further, the observed tendency that improvement in sensitivity by the introduction of vinyl, epoxy, or α-phenylmaleimide (α-PMI) is accompanied by a lowering in contrast is studied according to the theory.

Theoretical Basis

Gel formation through a chain reaction.—A mathematical analysis applicable to gel formation through a chain reaction has been given by Charlesby (15). It is assumed in the analysis that a double bond on a polyester molecule is converted to two radicals by irradiation, and that the radical reacts with a double bond on a neighboring molecule, forming a cross-link and at the same time producing a radical on the molecule. Another assumption is the inhibition of the reaction, which determines the length of the chain propagation. Thus the important material parameters are ν, the average number of reacting sites per molecule of number average molecular weight, and i, the inhibitor activity defined as the probability that a growing chain is terminated at any one step by cyclization, resonance stabilization, mutual termination of two radicals, or termination by an additive.

Charlesby's result is presented in a form of somewhat complicated simultaneous equations including a parameter which should be eliminated by numerical calculations. On the basis that ν is in general large compared with one in actual resist materials, we can obtain rather simplified formulas approximated from the original equations. The result depends on the initial molecular weight distribution of the polymer. If all molecules are initially of the same size (uniform distribution)

$$g = 1 - \exp\{-\delta g f(g,i)\} \quad [1]$$

and for a random distribution

$$g = 1 - \frac{1}{\{1 + \delta g f(g,i)/2\}^2} \quad [2]$$

where g is the gel fraction and δ the cross-linking coefficient defined as the average number of cross-linked sites per molecule of weight average molecular weight. $f(g, i)$ is a function of g and i, which implies the effect of the chain reaction

$$f(g,i) = \frac{g + \dfrac{2i}{1-i}}{\left(g + \dfrac{i}{1-i}\right)^2} \quad [3]$$

If $f(g, i)$ is equated to 1, Eq. [1] and [2] become the formulas for the case where cross-linking takes place at random without any chain reaction (10).

In Fig. 1, calculated curves of Eq [1] (solid line) and Eq. [2] (broken line) for $i = 0.04$ and 0.25 are shown. Curves for nonchain process are also shown for comparison, where the relationship between g and δ is independent of material, and the gel point where gel formation first starts is $\delta_m = 1$. In the case of the chain reaction, the same value of g as in the nonchain process is obtained at a value of δ lowered by a factor $1/f(g,i)$. Since $f(g,i)$ is nearly equal to $2(1-i)/i$ for small g, the gel point is

$$\delta_m = \frac{i}{2(1-i)} \quad [4]$$

Therefore, as shown in Fig. 1, the smaller the value of i, the smaller the gel point and the slope of the curve. The effect of the molecular weight distribution on the slope of the curve is also seen from the figure, that is, the slope for a random distribution (polydispersity $\overline{M_w}/\overline{M_n} = 2$, where $\overline{M_w}$ is the weight average molecular weight and $\overline{M_n}$ is the number average molecular weight) is more gradual than that for a uniform distribution ($\overline{M_w}/\overline{M_n} = 1$).

In comparison with experimental results, the gel fraction g is equivalent to the normalized film thickness d/d_0, where d is the film thickness after development and d_0 is the initial film thickness. On the other hand, in order to relate the cross-linking coefficient δ with the exposure dose q, the absorption of irradiated energy and subsequent chemical events must be known. These processes are described con-

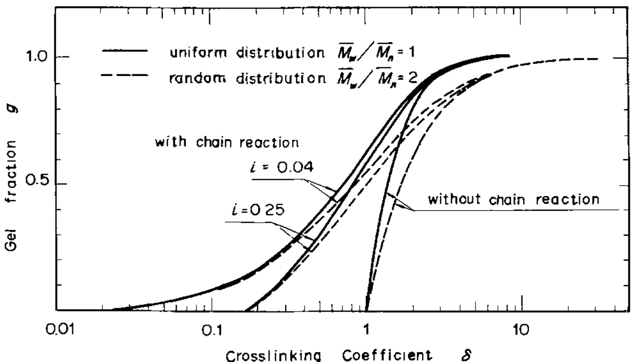

Fig. 1. Theoretical relationships between gel fraction g and cross-linking coefficient δ for the cases without chain reaction and with chain reaction corresponding to an inhibitor activity $i = 0.04$ and 0.25.

veniently by use of the empirical depth-dose function (17) and the radiation yield G defined as the number of cross-links effected per 100 eV of the energy absorbed. For a nonchain process, a relationship between δ and q has been given (18), assuming no chain scission

$$\delta = \delta_0\{1 - \exp(-Kq/\delta_0)\} \qquad [5]$$

with

$$K = \frac{G\overline{M}_w \Delta E}{50 e \rho N_A}$$

where δ_0 is the total number of cross-linkable sites per molecule, ΔE the energy absorbed per unit length, ρ the density, e the electronic charge, and N_A Avogadro's number. In electron resists, δ_0 is in general much larger than 100, whereas gel fraction almost saturates when δ is larger than 10. Therefore, Eq. [5] can be reduced to a linear relationship between δ and q.

In the case of a chain reaction, δ appearing in Eq. [1] and [2] is the over-all cross-linking coefficient, including the effect of chain propagation. Since each radical produced directly by electron irradiation gives rise to a chain reaction linking together $1/i$ molecules on the average (in this sense, $\alpha \equiv 1/i$ may be called the chain reaction coefficient), a linear relationship between δ and q is obtained

$$\delta = Kq/i \qquad [6]$$

The factor K determines the sensitivity and therefore is called the sensitivity factor in this work.

Assuming the critical dose q_m, defined as the minimum dose required for insolubilization, corresponds to the gel point predicted theoretically, Eq. [6] yields

$$G_a = \frac{G_i}{i} = \frac{50 e \rho N_A \delta_m}{\overline{M}_w \Delta E q_m} \qquad [7]$$

Here, G_i is the radiation yield for the reaction initiated directly by the electron irradiation and G_a is the radiation yield for the over-all reaction propagated via radicals. If $i = 1$ and $\delta_m = 1$, Eq. [7] gives the formula derived by Ku and Scala (9).

Contrast and sensitivity.—Contrast is a measure of the gradient of the exposure curve of the resist and is one of the main factors determining the edge acuity of the exposed and developed pattern. A gradual slope at the pattern edge is a reflection, through the shape of the exposure curve of the resist, of the spatial distribution of the exposing beam and the subsequently scattered electrons (19, 20).

The definition of contrast as the slope of the linear portion of the exposure curve does not include the tailing at low dosages as in the EPB results shown later, which effectively affects the cutoff of the edge (21). Moreover, exposure with low dosage is preferable for high resolution work since the effect of scattered electrons becomes significant in the high dosage region. Thus, the slope between the critical dose q_m and the dose required for $d/d_0 = 0.5$, $q_{0.5}$, is employed as the definition of contrast and denoted $\Gamma_{0.5}$

$$\Gamma_{0.5} \equiv \frac{0.5}{\log(q_{0.5}/q_m)} \qquad [8]$$

In many cases, this definition gives a good linear approximation to the lower portion of the exposure curve.

A theoretical value of $\Gamma_{0.5}$ for a uniform distribution is given from the definition and Eq. [1]

$$\Gamma_{0.5} = \frac{0.5}{\log(\delta_{0.5}/\delta_m)} \simeq \frac{0.5}{\log\{1.39(1+i)^2/i(1+3i)\}} \qquad [9]$$

where $\delta_{0.5}$ is the cross-linking coefficient for $g = 0.5$. $q_{0.5}$ is employed as a measure of sensitivity. Using Eq. [6]

$$q_{0.5} = \frac{i\delta_{0.5}}{K} \simeq \frac{0.693 i (1+i)^2}{K(1+3i)(1-i)} \qquad [10]$$

For a random distribution, similar equations can be derived which differ only in factors, that is, 1.39 in Eq. [9] is replaced by 1.66 and 0.693 and in Eq. [10] by 0.828.

Calculated results of $\Gamma_{0.5}$ and $q_{0.5}$ are shown in Fig. 2, where the curves with solid lines are for a uniform distribution, and those with broken lines are for a random one. $q_{0.5}$ is a function of both K and i, while $\Gamma_{0.5}$ is determined only by i. The axes of i for uniform and random distributions are shown on the right side. It is shown in the figure that when the inhibition of chain reaction i decreases, the sensitivity increases, while the contrast decreases. It is also shown that with an increase in i, the contrast approaches saturation values, 3.5 in a uniform distribution and 2.3 in a random distribution, which are the contrast values in the nonchain process. On the other hand, with the increase in the sensitivity factor K as shown in the figure for $K = 10^4$, 10^5, 10^6, and 10^7 (cm²/C), these curves are shifted laterally toward high sensitivity without changing contrast.

Experimental

Experimental procedures.—Resist materials studied were KTFR (Eastman Kodak Company), PMVS (Toray Silicone Company, SH 410), EPB (Tokyo Ohka Kogyo Company), and a styrene-butadiene copolymer with α-PMI (Somar Manufacturing Company). These materials contain a double bond, epoxy,

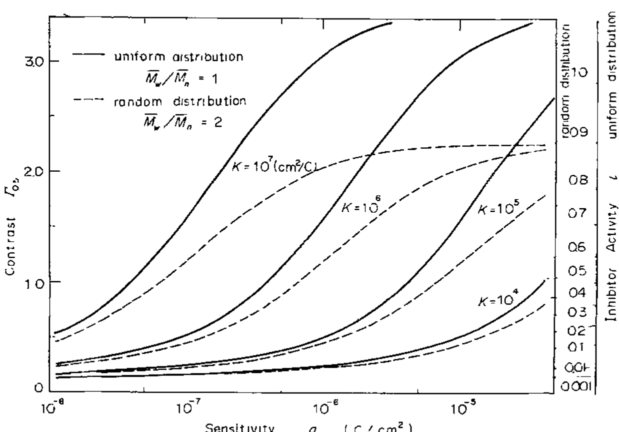

Fig. 2. Theoretical relationships between contrast $\Gamma_{0.5}$ and sensitivity $q_{0.5}$ (C/cm²) for the sensitivity factor $K = 10^4$, 10^5, 10^6, and 10^7 (cm²/C).

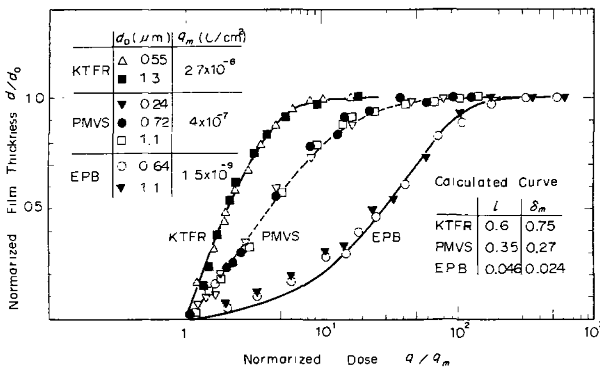

Fig. 3. Comparison of exposure characteristics of KTFR, PMVS, and EPB with the theoretical curves. The curves with solid lines for KTFR and EPB are calculated from the equation for uniform molecular weight distribution, and the curve with the broken line for PMVS is for a random distribution

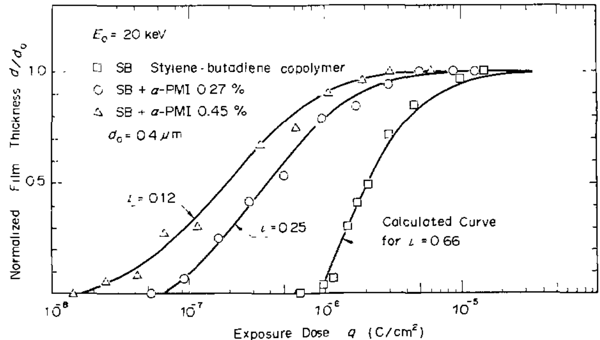

Fig. 4. Variation of the exposure characteristic in SB due to the introduction rate of α-PMI. The curves are calculated from the equation for random molecular weight distribution with the inhibitor activity i = 0.66 for the original SB, and i = 0.25 and 0.12 for SB with 0.27 and 0.45 m/o α-phenylmaleimidized styrenes, respectively.

or α-PMI which can initiate chain reactions, and the critical doses ranged from 1.5×10^{-9} to 2.7×10^{-6} C/cm².

Resist films were prepared by the conventional spin-coating method on aluminum films of about 150Å thickness evaporated on glass plates. In order to prevent spontaneous cross-linking (22) affecting reproducibility, the resist films were coated just before the electron exposure. After exposure to a uniformly diverging electron beam, the resist film was developed with the proper solvent. Then the thickness of the insoluble film left on the substrate d was measured with a Tolansky-type interferometer.

Results and discussions.—Gel-dose relation.—Measured relationships between normalized film thickness after development d/d_0 and normalized exposure charge density q/q_m for EPB and PMVS at the incident electron energy E_0 = 20 keV, and for KTFR at E_0 = 40 keV are shown in Fig. 3. The thickness of the saturation d_0 is found to closely coincide with the initial thickness in PMVS and KTFR. In EPB, deformation of the film during development is significant in the saturating region. Consequently, measurement of the saturation thickness is often affected, and the accuracy of the characteristics for EPB is not as precise as for PMVS and KTFR. The obtained curve, however, is qualitatively similar in shape to that given by Feit *et al.* (7).

By equating the experimental value of $q_{0.5}/q_m$ to the theoretical expression of $\delta_{0.5}/\delta_m$ by Eq. [1] or [2], values of i and consequently of δ_m by Eq. [4] are obtained. The curves in Fig. 3 are the calculated results. It is seen that the experimental points fit fairly well to the calculated curves of Eq. [2] for i = 0.35 in PMVS, and of Eq. [1] for i = 0.6 and 0.046 in KTFR and EPB, respectively.

In order to estimate the radiation yield, ΔE is calculated using the depth-dose function given by Hoff and Everhart (17), and $\overline{M_w}$ is measured with a gel permeation chromatograph (Hitachi GPC-635). In each resist, average values of ΔE and q_m are used for different d_0. In Table I the values obtained for i, δ_m, G_i, and G_a are shown, together with the material and the experimental parameters. G_a = 1.14 in KTFR is comparable to the value 1.20 which has been obtained by assuming that G_i is equal to the G value of KPR (Kodak photo resist) (11). The high sensitivity (small value of q_m) in EPB, in spite of the small value of G_i, is due to the fact that δ_m is much less than one and the multiplication of the reaction by chain propagation amounts to over 20 times.

Radiation-induced scission was proposed as a partial explanation for the slow rate of gel formation in EPB by Feit *et al.* (7). According to the theory of simultaneous cross-linking and main chain scission for a nonchain process (23), the maximum gel fraction attainable, g_0, decreases and the gel point increases with an increase in the ratio of degradation to cross-linking, p_0/q_0. However, it is found that when the calculated relationships between gel fraction and cross-linking coefficient are reduced to a normalized form, g/g_0 *vs.* δ/δ_m, the shapes of the curves are almost independent of the value of p_0/q_0. Another possibility is the scission of cross-links (7). In this case, a term of $-q^2$ will be added to the linear relationship between δ and q, since the increment of scission is proportional to the number of cross-links already formed. Then the gel-dose curve will become more gradual than those shown in Fig. 3 especially in the high dose region.

Contrast and sensitivity.—It was found that the sensitivity of SB (styrene-butadiene copolymer) can be increased by introduction of α-PMI (α-phenylmaleimide) to phenyl groups on the styrene molecules. In Fig. 4, the exposure characteristics of SB's with 0.27 and 0.45 mole percent (m/o) of α-phenylmaleimidized styrenes are shown in comparison with that of the original SB which is a copolymer of 40 m/o styrene and 60 m/o butadiene. It can be seen that a lowering of the critical dose by over one order of magnitude is achieved by a small introduction of α-PMI. This suggests that a chain process must be included in the reaction. Comparison with the theoretical formula of the chain reaction for a random dis-

* Ref. (11).

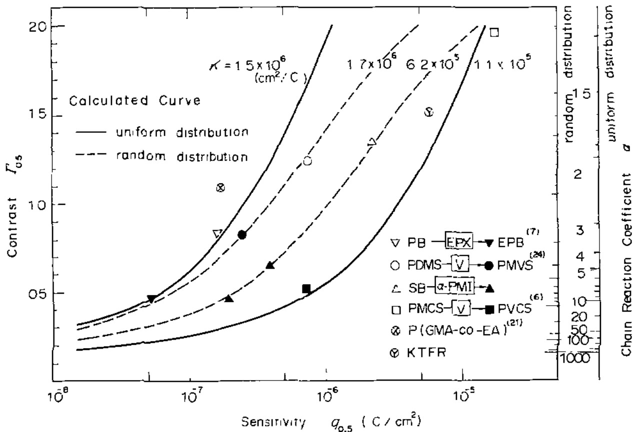

Fig. 5. Comparison of experimental data on contrast $\Gamma_{0.5}$ and sensitivity $q_{0.5}$ with the calculated curves. Abbreviations used in the figure are as follows: EPX = epoxidation, V = introduction of vinyl groups, α-PMI = α-phenylmaleimidation.

tribution, Eq. [2], shows that the best fits are obtained when $i = 0.66$ for the original SB, $i = 0.25$ for SB with 0.27% α-PMI, and $i = 0.12$ for SB with 0.45% α-PMI. In the original SB where $i = 0.66$, the gel point is close to 1 and the chain reaction coefficient α is about 1.5. This means that the chain process is not dominant in the original SB. The curves in Fig. 4 are the calculated results, showing good agreement with the experimental data.

The observed variation of contrast $\Gamma_{0.5}$ and sensitivity $q_{0.5}$ of SB with the introduction rate of α-PMI is shown in comparison with the calculated curve for $K = 6.2 \times 10^5$ (cm²/C) in Fig. 5, where the axis of the chain reaction coefficient $\alpha \equiv 1/i$ corresponding to contrast $\Gamma_{0.5}$ is at the right side. Similar variations can be seen in experimental data previously reported, which are also shown in Fig. 5. EPB is reported to present higher sensitivity and lower contrast than the original PB (1,4-polybutadiene, CB221) (7). The data are compared with the calculated curve for $K = 1.5 \times 10^6$ (cm²/C). It can be seen that, as suggested by Feit *et al.* (7), gel formation in CB221 includes chain processes, and the shift towards high sensitivity and low contrast in EPB coincides with the calculated variation, corresponding to the increase in the chain reaction coefficient α from 3 to 10.

PMVS has a molecular structure in which methyl groups of polydimethylsiloxane (PDMS) are replaced by vinyl groups to more than 1 m/o (16). Experimental data of PMVS and PDMS (24) are shown in Fig. 5, compared with the calculated curve for $K = 1.7 \times 10^6$ (cm²/C). Experimental points of polymethylcyclosiloxane (PMCS) and polyvinylcyclosiloxane (PVCS) obtained from exposure curves by Roberts (6) are also shown in comparison with the calculated curve for $K = 1.1 \times 10^5$ (cm²/C). Although precise measurements on molecular parameters and detailed investigation into the gel formation mechanism in individual resist materials are not carried out, fairly good agreement between the experimental data and the calculated curves supports the applicability of the theory to those materials.

Experimental values of $\Gamma_{0.5}$ and $q_{0.5}$, and estimated values of i, δ_m, α, and K for each resist are listed in Table II. The value of i is obtained by equating $\Gamma_{0.5}$ to the theoretical formula Eq. [9], then δ_m is given by Eq. [4] and K is calculated from Eq. [6] using i, δ_m, and q_m. The estimated values of K in each group of the resist material are not greatly changed by the improvement in sensitivity. This suggests that the change in G is not so significant as to result in an increase in sensitivity by one order or more, since $\overline{M_w}$, the other changeable parameter in K, is probably not changed significantly by the introduction of epoxy, vinyl, or α-PMI. In fact, $G_i = 2.1$ obtained for PMVS is comparable to $G = 2.2$-2.5 in PDMS obtained by irradiation of 800 kV electrons (25, 26). Thus the improvement in sensitivity by the introduction of epoxy, vinyl, or α-PMI is mainly due to the increase in the subsequent multiplication of the reaction by chain propagation, indicated by α, and the decrease in the gel point δ_m.

As a result, it may be concluded that in order to obtain resists with high contrast and high sensitivity, large K and small α are preferable. If a high contrast larger than 1.0 is required, the chain reaction should be restricted so that α is less than about 2, when the chain process becomes no longer dominant, as in P(GMA-co-EA) (21), PDMS (16, 24), SB, and PMCS (6).

Conclusions

Exposure characteristics of negative electron resists are studied on the basis of Charlesby's theory on gel formation through chain reactions. By use of the theory, the important resist parameters, sensitivity and contrast, can be related quantitatively to the chemical properties of the material. Some important aspects are summarized as follows.

1. It is experimentally verified that Charlesby's theory on gel formation by chain reactions is applicable to exposure curves of KTFR, PMVS, and EPB.

2. By use of the theory, the radiation yield for the reaction initiated directly by the electron irradiation G_i and that for the over-all reaction including the effect of chain propagation G_a is separately estimated. G_i is small even in EPB, the resist of the highest sensitivity previously reported. The high sensitivity is mainly due to the decrease in the gel point and to the increase in the chain reaction coefficient.

3. It is found that the sensitivity of styrene-butadiene copolymers is increased by the introduction of α-PMI. This increase in sensitivity is also explained by the theory.

4. Theoretical formulas of contrast and sensitivity are given as functions of the inhibitor activity of the chain reaction i and the sensitivity factor K. Improvement in sensitivity and associated lowering in contrast by epoxidation in polybutadiene, by α-phenyl-

Table II. Parameters related to contrast and sensitivity

Resist material	Contrast, $\Gamma_{0.5}$	Sensitivity, $q_{0.5}$ (C/cm²)	Inhibitor activity, i	Chain reaction coefficient, α	Gel point, δ_m	Sensitivity factor, K (cm²/C)
Polybutadiene

maleimidation in SB, and by introduction of vinyl groups in polysiloxanes are in good agreement with the theoretical results.

5. In order to obtain resists with high sensitivity, large K and small i are preferable. On the other hand, for high contrast, i must be large. If a contrast higher than 1.0 is required, the chain reaction should be inhibited, so that i is larger than about 0.5.

VPE Growth of n-AlAs on GaAs for Heterojunction Devices

W. D. Johnston, Jr. and W. M. Callahan

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

Vapor phase epitaxial growth of AlAs on Zn-doped GaAs substrates by chloride transport in an all-alumina reactor yields useful n-AlAs/p-GaAs heterojunction material. Smooth, planar interfaces and gently hummocked top surfaces have been obtained. The heterojunctions are found to be abrupt, both metallurgically and electrically, and have been used to demonstrate large area, high efficiency solar cells. The utility of Mn and Be as p-type dopants for vapor phase AlAs growth has been explored, without success.

In contrast to the extensive (and highly successful) efforts which have been devoted to the preparation by liquid phase epitaxy (LPE) of heterostructure materials and devices based on the $Al_xGa_{1-x}As$-GaAs system, little interest has been shown in the growth of such material by vapor phase epitaxy (VPE). It is much more difficult to prepare $Al_xGa_{1-x}As$ of high quality by VPE for x appreciably different from 0 or 1. Alloys with $x \sim 1$ are unstable in moist air and are more difficult to contact and process than those with significant Ga content. To date, VPE AlAs has only been obtained as n-type material and no satisfactory way to grow p-type layers of AlAs has been reported. In earlier work by Sigai *et al.* (1), a type-converted interfacial layer was reported at the interface between substrate GaAs and VPE AlAs. Taken together, the device potential of VPE AlAs material appeared discouraging, particularly in contrast to the successes achieved with LPE heterostructure growth (2).

Key words: solar cells, vapor phase epitaxy, III-V compounds.

We have recently reported progress in overcoming some of these difficulties, showing that suitable anodization (3) of AlAs provides adequate protection for standard device processing, and that n-AlAs can be grown by VPE on p-GaAs substrates to provide multi-square-centimeter junctions comparable in quality to LPE material of similar area, and having

similar potential for high performance solar cells (4). This successful initial demonstration of useful AlAs device material makes further study of VPE AlAs worthwhile, and in this paper we describe our growth apparatus and technique, our observations of the relation of surface morphology to growth variables, the bulk layer electrical properties and results of our efforts to grow p-type material, and the interface properties of our n-AlAs/p-GaAs heterojunctions.

Growth Apparatus and Technique

Our growth reactor, shown schematically in Fig. 1, is similar in general design to that described by Ettenberg *et al.* (5). In an effort to minimize problems (1, 5) arising from the reactivity of SiO_2 with Al compounds, we have completely excluded fused quartz components. All components in the heated zone, save for a small quantity of tungsten sheet (0.2 mm × 1.5 cm²) and wire (0.1 mm × 10 cm) used for securing the substrate, are made from 99.8% Al_2O_3 ceramic (6). This material is vacuum tight to at least 1300°C and tubing to 2.5 cm diameter by 1m long has adequate mechanical strength for self-supported design. Our main reactor tubes (2m × 7 cm diameter, 0.4 cm wall) required over-all support to prevent cracking from their own weight under high temperature and high temperature gradient conditions. Provisions also had to be made for the tube to expand freely and move to relieve stress from thermal expansion. These ends were accomplished by mounting the Al_2O_3 tube within a larger mullite tube, leaving an annular space of ~0.5 cm filled loosely with expanded alumina insulating beads. Connections to gas inlet lines were made through flexible stainless steel hose at one end, and via a lightweight neoprene bellows to a gate valve at the substrate insertion (exhaust) end.

Since the growth of AlAs in the 1000°-1100°C range is rather far from equilibrium, *i.e.*, AlAs is formed directly in the mixing region, provision must be made to extend that region to accommodate substrate placement. In the work described in Ref. (1) and (5), restriction of the AlCl-H_2 flow by a perforated plug was used to increase the stream velocity. We use a closed-end, 2.5 cm diameter Al_2O_3 tube to hold the aluminum source (5*N* metal), with several 1 mm holes drilled into the closed end (see Fig. 1b). Since we have noticed no important differences whether one hole or twenty-four are used in deposition geometry with the same total flow conditions, we feel that the stream velocities in our apparatus are all sufficiently low as to be unimportant compared to diffusive gas mixing. Nevertheless, the restrictions tend to prevent growth of AlAs within the Al source tube, and we normally use 20-24 evenly patterned perforations. We have grown layers with less than 10% thickness variation over 4 × 4 cm substrates positioned 2.5 cm from the tube end.

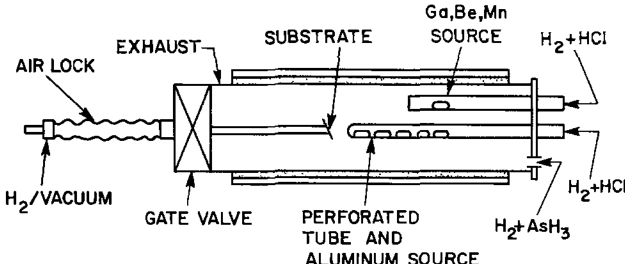
The alumina substrate support tube is closed at the substrate end and contains a Pt-Pt/Rh thermocouple to monitor temperature at the substrate position. The motion required for substrate insertion and withdrawal is accommodated with a 1.2m long flexible "bellows" seal made from thin wall, large diameter rubber tubing. The assembly is leak-free under vacuum or H_2 overpressure to 1400°C. A three-zone furnace with independent temperature controllers provides ±1°C stability in the source and growth regions.

Additional Al_2O_3 ceramic tubes permit other metal species to be introduced into the growth region. Ga, Be, or Mn can be transported as chlorides by introducing gaseous HCl into the H_2 flow through the appropriate tube. In the initial stages of this work, an $AlCl_3$ sublimation source external to the main reactor was used. We were unable to obtain good epilayer growth, which we attribute to the presence of excess HCl [AlCl is the stable species at our growth temperatures (5)]. At the inlet end of the growth apparatus the ceramic tubes are sealed with Viton O-rings and Monel fittings. The Al_2O_3 ceramic is neither particularly round nor smooth compared to fused silica tubing, but vacuum- and pressure-tight demountable static seals can be achieved with care. The inlet gas plumbing utilized standard commercial stainless steel and Monel components and included manual differential pressure-type flow controllers.

The apparently trivial task of devising a substrate holder proved difficult owing to the corrosive HCl/AlCl atmosphere, the large temperature excursion, etc. Commercial "high alumina" ceramic cements disintegrate due to chloride attack on proprietary binder materials, apparently sulfates and silicates or silica. A satisfactory solution was obtained with a small quantity of tungsten wire and sheet and small diameter alumina rod as shown in Fig. 1b. The tungsten suffers typical hydrogen embrittlement and eventual fracture after several dozen growth runs, but is available for inspection and replacement after each run as needed and does not appear to be attacked by the chloride vapors.

In normal operation the furnace is brought to temperature at about 100°K per hour and maintained at growth temperature for many runs. Cooling is accomplished at a similar rate to avoid thermomechanical stresses on the alumina components. Except for modifications, metals reloading, or cleaning, a flow of high purity hydrogen is maintained through the reactor tubing assembly.

The growth sequence is straightforward: commercially obtained GaAs substrates, typically (100) oriented with a Syton-NaOCl polish, were etched for 20 min in 4:1:1 $H_2SO_4/H_2O/H_2O_2$, rinsed in deionized water, 2% Br-methanol, and high purity methanol, and mounted on the substrate holder rod. The air lock chamber is closed, evacuated, and flushed with H_2, the gate valve to the growth reactor opened, the AsH_3 flow initiated, and the substrate inserted, allowing a few minutes to equilibrate at about 500° and 800°C, before insertion to the final position in the 1000°-1100°C range. The quality of the GaAs/AlAs interface depends on the timing of initiation of HCl flow over the Al during this insertion, since thermal etching of the GaAs is rapid at 1000°C and growth must start promptly. The HCl flow must not be initiated too soon, on the other hand, as the downstream HCl leads to chemical vapor etching at temperatures as low as 600°C. Both the high temperature thermal etching and the HCl vapor etching are selective and preferentially



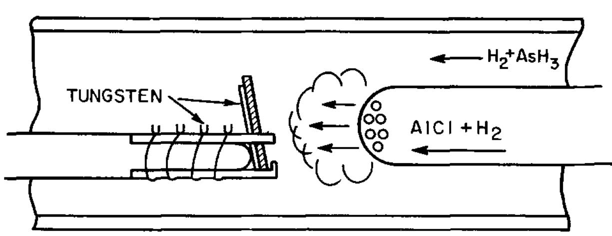


Fig. 1. (a, left) Schematic drawing of growth reactor. (b, right) Detail of substrate holder and aluminum source tube

attack residual work damage, points of dislocation emergence, etc.

The typical flow rates for our reactor are 4 cm^3/min for HCl and AsH_3 and a total of 2 liters/min of H_2. (The HCl and AsH_3 are both obtained as 2% dilutions in H_2, and further diluted in the reactor.) Reactant flow is continued for the desired time (growth may be varied from ~10 to ~60 μm per hour), after which the substrate is withdrawn and reactant flows returned to pure H_2. Growth of alternating layers of GaAs and AlAs is accomplished by partially withdrawing the substrate to an appropriate position in the 600°-800°C range and switching the HCl flow from the Al source to the Ga source, then reversing the procedure to grow another AlAs layer, etc. In this way we have grown alternating layers with good planarity as thin as 0.5 μm.

The primary attractive feature of VPE as compared to LPE or molecular beam epitaxy (7) (MBE) is the potential ease of transfer from research scale to economical production scale growth. The alumina ceramic components of our furnace are presently available commercially (6) in larger sizes which would permit a tenfold increase in production rate, from ~50 cm^2/hr which we have achieved with the apparatus of Fig. 1 (for 20 μm thick epitaxial layers) to at least 600 cm^2/hr. Such a capability is of paramount importance if significant penetration of the space solar cell market [presently 500 m^2 per year (8) for silicon arrays] is seriously contemplated, and absolutely essential for significant terrestrial electric power impact (9), for which a production capacity several orders of magnitude larger must be considered.

Surface Morphology and Reactivity of AlAs Epilayers

The nature of the surface of our VPE AlAs epilayers depends on growth temperature, flow ratio of HCl (over Al) to AsH_3, absolute concentration of HCl and AsH_3, total gas flow rate, substrate orientation and surface treatment, position of substrate relative to the perforated end of the Al source tube, the detailed sequence and timing of substrate insertion and reactant flow initiation, and the long term history of the growth reactor. The last three factors arise from the necessity of growing at a temperature substantially lower than would be desirable from thermodynamic considerations of the As-AlCl reaction kinetics (5). In the 1000°-1100°C range this reaction goes strongly to form AlAs and the deposition range is limited to a few centimeters from the point of AlCl injection into the As atmosphere. Growth occurs in the vicinity of the substrate on the reactor walls, on the perforated tube end, and on the substrate holder as well as on the substrate, and eventually the reactor must be cooled down and cleaned of this deposit. As an alternative, the temperature at the growth region may be raised temporarily above ~1300°C to move the deposit downstream from the substrate position. This permits extension of the time between cleanings, which otherwise are necessary after 30-40 hr of growth operation.

The epitaxial surfaces may be grossly characterized as specular, as having hillocks or hummocks, or as terraced. Misfit dislocation arrays are apparent as (110) directed rectilinear grids, most simply seen in Nomarski interference contrast micrographs, and are a typical feature. The misfit dislocation arrays were observed on all surfaces except those with grossly disturbed topography. Examples of surface appearance are shown in Fig. 2.

Several distinctions may be made with the more familiar VPE growth of GaAs layers. First, terracing is not a typical feature of the AlAs layers, and appears to occur only in conjunction with a characteristic "rectangular etch pit" attack of the substrate prior to

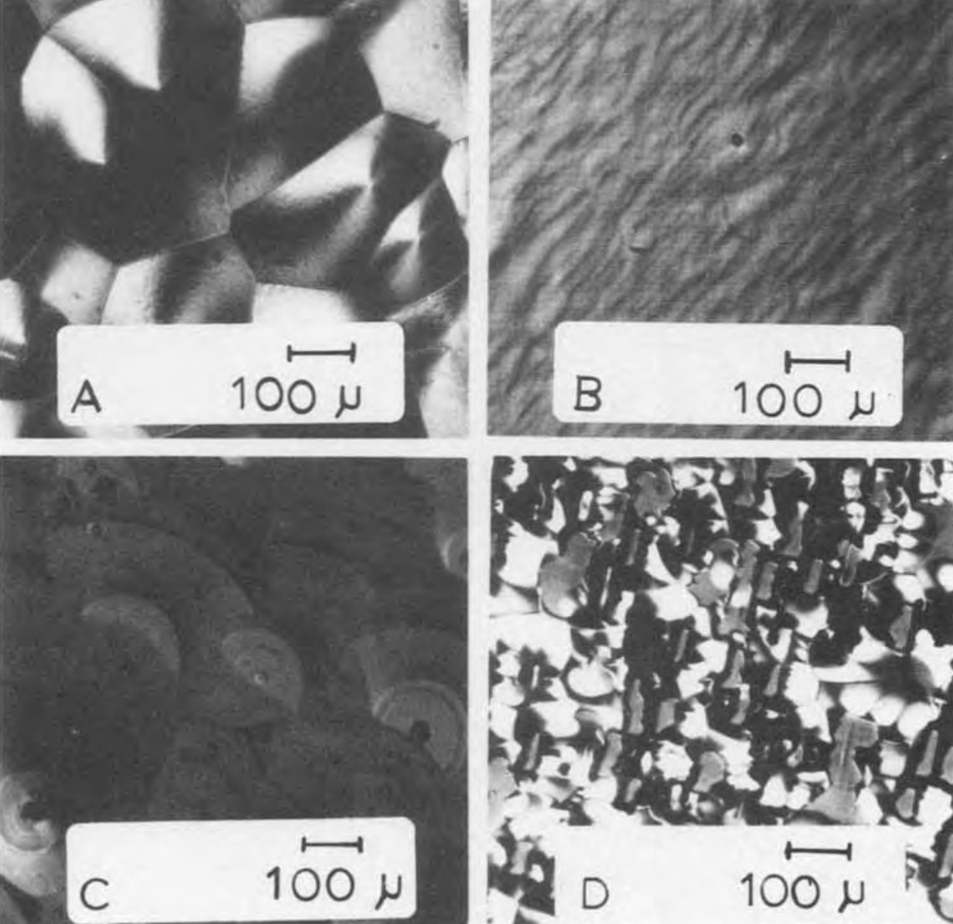

Fig. 2. Differential interference contrast micrographs of surfaces of AlAs VPE layers: A = hillocks, growth at 32 μm/hr; B = "smooth," growth at 12 μm/hr; C = terracing, low As partial pressure; D = rough, disordered surface indicative of severe selective thermal etching of GaAs substrate as in Fig. 5A. Surfaces A and B are more stable and surface D much less stable than surface C in humid air.

growth. This is an effect which may be prevented by ensuring that As vapor is present at the concentration to be used during growth before the substrate is introduced into the high temperature region of the reactor and by proper sequencing of the HCl flow initiation. Terrace planes were observed in the transition region between correct Al/As stoichiometry and the As-rich, Al-poor periphery where spotty, imperfect growth took place, using a single hole Al source tube and low $AlCl/AsH_3$ flow ratios. GaAs layers grown in this apparatus often showed stacking faults, particularly for growth above 800°C, but this behavior was not seen for any AlAs layers grown up to the 1130°C maximum temperature investigated. Substrate orientation is a matter of some importance in obtaining smooth layers for GaAs, but we were unable to observe consistent behavior for AlAs epitaxy, *i.e.*, whether orientation was nominally on <100> or 2°-4° off <100> [toward (110)] did not make much difference. The growth rate and topography were determined by local reactant stoichiometry (mostly reflecting Al source/substrate geometry). In several instances highly specular, featureless layers were grown at about half the usual growth rate on substrates that appeared to be oriented almost exactly to the (100) plane, *i.e.*, much more closely than the nominal ±10′ typical orientation accuracy.

These differences may all be understood qualitatively as reflecting the very substantial departure from equilibrium growth. For near-equilibrium growth relations among growth rate, stacking fault occurrence, terrace formation, and surface energy are beginning to be understood (10), but the relevant approximations do not apply for AlAs growth under our conditions. The typical hummock pattern is also seen for VPE growth of InP, AlP, GaAs, and Si when the substrate temperature is low and reactant supply high. At the highest growth temperatures we investigated, specular surfaces were more often obtained and hummock density was much reduced, but difficulties with evaporation of the GaAs substrate and deterioration of the bulk electrical properties of the AlAs layer became substantial.

The stability of the AlAs layers in air depends on surface quality, relative humidity, and surface post-growth history. Below about 25% relative humidity, surfaces with low hummock density form a protective oxide layer and are stable against further change for several days. The layers may be stored without oxide formation in a low humidity environment (N_2, dry air, or O_2) or under hexane, trichloroethylene, etc. A controlled, stable oxide layer is most easily formed by anodization (3) in highly pure water (resistivity greater than 18 megohm-cm) to which H_3PO_4 has been added to modify the *p*H to the 1.9-2.0 range. This oxide is uniformly formed regardless of surface topography on electrically uniform layers, in contrast to that produced by radio frequency plasma oxidation (11) in oxygen, which produces a uniform oxide only on the smooth surfaces. The rf plasma oxide is also substantially less stable than the anodic oxide in moist air. Both oxides are preferentially attacked at mechanical defects such as scratches, cleaved edges, and at the apexes of topographical features such as hummock peaks where the local surface curvature is a maximum.

Similar surface effects were noted for interaction with evaporated oxides. SiO_x layers were found to react with as-grown AlAs preferentially at regions of high local curvature, followed by rapid deterioration in moist air. SnO_2-evaporated films react with AlAs at 400°C in dry air. Indium-tin-oxide (ITO, 91% In) films (12) did not react on smooth AlAs layers but were reduced on the hillock-covered AlAs surfaces under the same conditions. (A 400°C air bake is used to convert the SnO_2 and ITO films to a high conductivity, high transparency state from the as-evaporated state which is excessively deficient in oxygen.)

The solution to these difficulties is obviously growth at higher temperature. However, as discussed below, this expedient may be undesirable for other reasons, if the ultimate goal is production of heterojunctions to GaAs. With careful control of substrate-Al source geometry, reasonably smooth layers exceeding 15 cm^2 in area may be reproducibly grown as low as 990°C. Such layers are entirely adequate for single heterostructure device applications, but the remaining surface nonplanarity gives rise to problems with multiheterostructure material as would be required, for instance, for continuous wave laser diodes.

Electrical Properties of AlAs Layers

The layers grown in this study were all found to be n-type, with conductivities ranging from 0.02 to 1.0 Ω-cm. Four types of growth were attempted: undoped "high purity" layers (*i.e.*, lowest attainable carrier concentration with highest Hall mobility), undoped layers with reproducible and controlled carrier concentration in the 10^{17}-10^{18} cm^{-3} range, and layers doped with Be or Mn, intended to be p-type. Electrical characterization was made by the Van der Pauw (13) method using spark-formed contacts with 80 μm Au-2% Sn wire. Conductivity type was verified with a thermal probe. The results are summarized in Fig. 3.

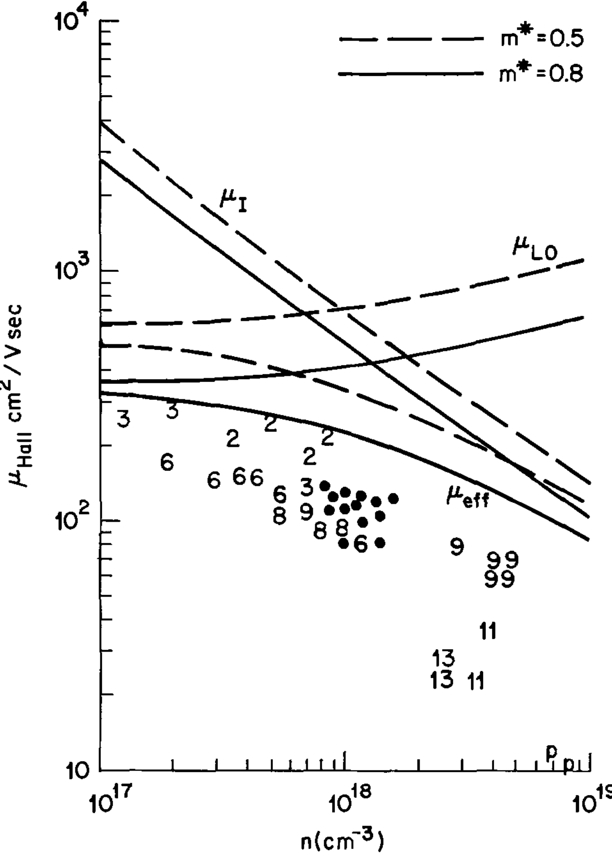

Fig. 3. Mobility and carrier concentration from Hall measurements. The numeric symbols relate to growth temperature as (10 × symbol) + 1000 in °C, and represent runs for which flow rates and geometry were adjusted for maximum mobility. The solid points represent runs at 1000°-1030°C for which growth rates of ~20 μm/hr, good large area uniformity, and fairly smooth surfaces were obtained together with a desired carrier concentration in the 0.7-2.0 × 10^{18} cm^{-3} range. The points marked p represent Be-doped material for which $N_{Be} \sim 4 \times 10^{18}$, $N_{Si} > 10^{19}$, $N_{Mg} \sim 5 \times 10^{17}$ cm^{-3} levels were inferred, and except for addition of $BeCl_2$ were grown identically to the runs shown as points. Theoretical curves represent limiting mobilities predicted: μ_I, from ionized impurity scattering assuming no compensation; μ_{LO}, from optic phonon scattering; and μ_{EFF} ($\mu_{EFF}^{-1} = \mu_{LO}^{-1} + \mu_I^{-1}$).

After a series of growth runs at constant temperature and flow conditions, samples of bulk AlAs (~1g) deposited in the vicinity of the substrate were analyzed qualitatively by emission spectroscopy and quantitatively by atomic absorption spectroscopy. For the undoped runs, particular attention was paid to Mg, Cu, Fe, and Si on the basis of analysis of the Al_2O_3 ceramic material. Of these elements, only Si was detected as a "faint trace," substantially below the quantitative limit of 2 ppm. We can thus state that less than 2 ppm Si was present, with a best estimate of ~0.2 ppm. If fully electrically active, this would provide an estimated donor concentration of $\sim 1.6 \times 10^{16}$ cm^{-3}, nearly two orders of magnitude below that actually observed. Thus we conclude that while Si contamination has not been eliminated in our apparatus, a native defect donor is the more likely cause of the observed n-type conductivity.

The level of conductivity may be reproducibly controlled by fine (*i.e.* millimeter increments) adjustment of the Al source/substrate distance, by modification of the growth rate through the absolute HCl and AsH_3 inlet flows, and to a lesser degree by adjustment of the HCl/AsH_3 inlet ratio or substrate temperature. With increasing growth temperature, the net donor concentration increased, passed through a maximum at about 1090°C, and then decreased again at higher temperatures. Over this range the mobility decreased monotonically. The highest mobility is obtained at low temperatures (~1000°C) and low growth rates (~10 μm/hr), conditions which produce a combination of hillocks and terraces on the surface and a moderately roughened layer-substrate interface. For fixed-growth conditions, the net carrier concentration is one of the most reproducible features of our material, varying less than 20% among repeated runs. This corresponds to the variation from corner to corner over a given substrate and is about the same as the accuracy of our electrical characterization technique.

It would be desirable to be able to prepare p-type AlAs layers without resorting to postgrowth diffusion. Sigai *et al.* (1) have reported a lack of success in growing AlAs with Zn incorporation during growth. We have tried incorporation of Be or Mn, both of which may be readily transported as chlorides at the temperatures in our reactor. With Be, we were able to obtain levels of about 10^{18} cm^{-3} as determined by atomic absorption spectroscopy. At the same time, however, about 2×10^{17} Mg atoms/cm^3 and 8×10^{18} Si atoms/cm^3 were incorporated. The result was compensated n-type conductivity with net donor concentrations in the 7-8 $\times 10^{18}$ range and Hall mobilities of 8-10. This more-than-three order of magnitude increase of Si appears to be due to attack on the Al_2O_3 ceramic by $BeCl_2$ vapor, in which BeO and AlCl are formed. White needles were observed growing from the Al source tube in the vicinity of the substrate as well as on the walls of the Be source. Si is apparently liberated from the 0.1% SiO_2 impurity content of the alumina ceramic as volatile chlorides or oxychlorides and incorporated in the growing AlAs. The greater fraction (~0.8) of the $BeCl_2$ formed must have reacted with the Al_2O_3 ceramic in this way to account for the quantity of Si observed. The Be used contained less than 15 ppm Si and remains in solid form throughout the growth procedure so direct transport of the observed quantity of Si from the Be metal seems unlikely.

The observed Hall mobility and concentrations of Si, Be, and net carriers are consistent with the assumption that all the Be is present as an electrically active acceptor, so it would appear that p-type AlAs could be grown in an apparatus resistant to $BeCl_2$ attack. BeO ceramic tubing is an obvious choice but was not available to us in the required sizes during this work.

In contrast, the results with Mn are less encouraging. We were unable to obtain Mn incorporaiton into the growing epilayer, due to the formation of Mn_2As at the point of injection into the As atmosphere. (A black crystalline mass, $Mn_{2.1}As$ by analysis, was recovered from the region between the Mn source and the substrate.) The conversion of Mn to $MnCl_2$ and transport thereof was quantitative. An arrangement where the Mn and Al chlorides are mixed and injected together into the As ambient at the vicinity of the substrate would be more suitable.

Also shown in Fig. 3 are theoretical curves of limiting mobility due to scattering by polar optical phonons (μ_{LO}) and scattering by ionized impurities (μ_I). The following equations were used

$$\mu_I \simeq \frac{3.2 \times 10^{15}(m_o/m^*)^{1/2}\epsilon^2 T^{3/2}/(N_D + N_A)}{\ln[1.3 \times 10^{14}T^2\epsilon(m^*/m_o)/N_D - N_A} \quad [1]$$

$$\mu_{LO} = 0.199(T/300)^{1/2}(e/e^*)^2(m/m^*)^{3/2}(10^{22}M) \quad [2]$$
$$\times (10^{23}v_a)(10^{-13}\omega)(e^z - 1)(e^{-\xi}G^{(1)})$$

In Eq. [1] [see Ref. (14)] N_D and N_A are the densities of donor and acceptor impurities, ϵ is the (static) dielectric constant (= 10.9 for AlAs) and m^* the electron effective mass. In Eq. [2] [see Ref. (15)] M and v_a are the reduced mass and volume of an Al and As atom pair, $\hbar\omega$ is the LO phonon energy (49 meV), e^* is the screened charge given (15) by $0.0345 (10^{22}M) (10^{-13}\omega)^2 \times (10)^{23}v_a) (\epsilon_\infty^{-1} - \epsilon^{-1})$ with ϵ_∞ the dynamic dielectric constant (= 8.5). Numerical values for AlAs were taken from Ref. (16). The remaining factors are $z = \hbar\omega/kT$ and $e^{-\xi}G^{(1)}$, a function plotted in Ref. (15) which varies from 0.65 to 0.75 for AlAs, 300°K, $n \lesssim 10^{19}$. Equation [2] assumes the validity of Boltzmann statistics and a simple parabolic band. The conduction band minima in AlAs may reasonably be assumed to lie at the X point, giving three equivalent (100) valleys, each presumably ellipsoidal by analogy with GaAs. From symmetry considerations, the ground state of a donor impurity must have a degeneracy factor $g = 2$ or 4 (including spin). Whitaker (17) has measured $m^{*3/2}/g$ and determined $m^* = 0.5$ or 0.8, respectively. The relation for an effective mobility $\mu_{eff}^{-1} = \mu_{LO}^{-1} + \mu_I^{-1}$ is not strictly valid theoretically (18) but is useful within the experimental limits and the theoretical approximation (single effective mass, parabolic band) here.

From Fig. 3 it can be seen that polar optic mode scattering should dominate at room temperature for carrier concentrations below about 10^{18} cm^{-3}. For carrier or ion concentrations above about 2×10^{18}, the scattering should predominantly arise from the impurity ions. Qualitatively at least, the data points are consistent with this picture. If the value of 0.8 is correct for m^*, our highest mobility samples would appear to be relatively uncompensated. The value of m^* for the x_{1c} conduction band minimum in GaAs is known (19) to be 0.85, which lends some plausibility to this argument.

AlAs-GaAs Interface and Junction Properties

The difficulties encountered in growing p-type AlAs by VPE ruled out the study of p-AlAs/n-GaAs heterojunctions at this time. We have, however, investigated VPE grown n-p and n-n heterostructures. The planarity of the AlAs-GaAs transition is a function of the substrate pregrowth treatment and the timing of the thermal etch-growth initiation sequence. In Fig. 4 are shown typical optical micrographs of cleaved sections for layers grown with the empirically determined optimum sequence and with either early or late initiation of AlCl flow. The distribution of interface roughness is easily seen on samples from which the AlAs layer has been stripped with 2% HCl. The examples in Fig. 5 illustrate the selective nature of the thermal etch, since the substrates are introduced into the reactor in an essentially featureless condition. A rough interface is undesirable since it gives rise to a rougher-than-normal top surface and because rough interfaces are as-

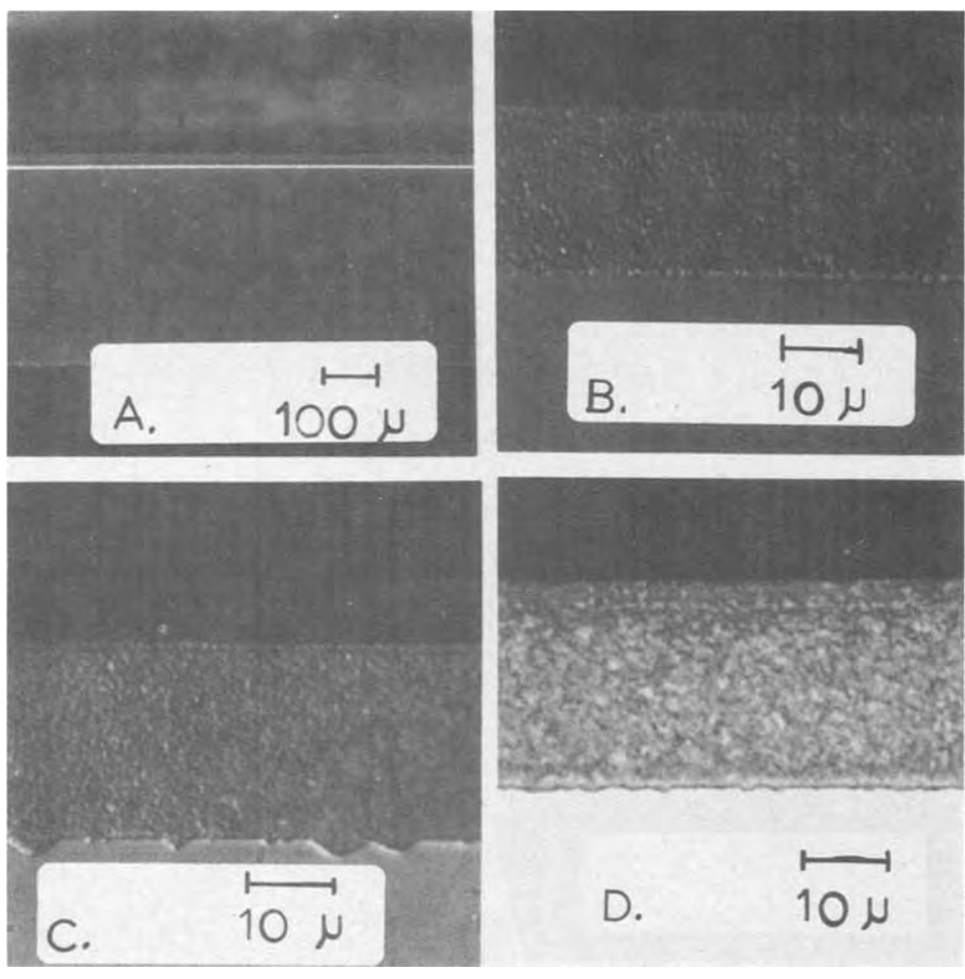

Fig. 4. Optical micrographs of cleaved sections showing AlAs-GaAs interface for optimum sequence of substrate insertion and AlCl flow initiation (A and B) and roughened interfaces for late (C) and early (D) AlCl flow initiation.

sociated with poor heterojunction I-V characteristics. Optical micrographs such as those in Fig. 4 or similar ones taken after use of selective chemical stains (20) show no sign of an interfacial layer nor an extended transition region. This conclusion remains the same under scanning electron microscope examination. We believe that the Al-Ga transition is in fact atomically abrupt, but the precision of our measurements dictates an upper limit of 200Å for metallurgical grading.

The p-n junction for growth on Zn-doped GaAs substrates is located coincidently with the Al-Ga transition. Figure 6 shows an electron beam-induced current trace indicative of this. Additional evidence is that In-Ga slush contacts melted to the substrate surface after removal (with 2% HCl) of the AlAs give a p-type thermal probe result, and the photoresponse (4) extends to 900 nm, completely ruling out the possibility that the junction lies in the AlAs. Results of capacitance-voltage characterization of the junctions (21) are well fit by the abrupt junction Anderson (22) model. The slope of C^{-2} *vs.* voltage plots, and extrapolated voltage intercepts, are in excellent agreement with those calculated from the substrate and epilayer carrier concentrations deduced from Hall data. Apparently Zn diffusion from the substrate during layer growth is not significant, at least over distances on the scale of the 250Å depletion layer width calculated for the $\sim 10^{18}$ cm^{-3} doping in these diodes.

The current-voltage plots for these diodes follow a $J \sim J_s \exp(eV/\eta kT)$ dependence, with η typically 1.95. Values of saturation current density J_s vary over several orders of magnitude. When growth variables were held constant, J_s was found to be determined primarily by choice of substrate, with diodes grown on substrates cut from particular ingots grouping together. The open-circuit voltage measured for solar cells at an illumination intensity yielding J_{ph} short-circuit current density is given by

$$V_{oc} \sim (\eta kT/q)\ln(J_{ph}/J_s + 1)$$

This equation is valid for currents where series resistance may be ignored and where η has a well-defined value. Except for diodes with poor contacts or pathological growth problems, this was found to be the case over several decades of junction current with η for various diodes in the range 2 ± 0.1. This suggests strongly that generation-recombination components dominate the reverse saturation current density, which may then be written (23) as

$$J_s = kT(A + B)/[V_D(V_D - V)]^{1/2}$$

Here, V_D is the "built-in" voltage of the diodes as given by the capacitance-voltage plots and is 1.9-2.0V. A and B are constants depending on the material parameters of the AlAs and GaAs, respectively, and are given, for equal doping, by $A \approx n_i \cdot l/\tau$ with n_i the intrinsic carrier density, l the zero-bias depletion layer width, and τ the minority carrier lifetime in the depletion region of the AlAs. A similar expression for B applies to the GaAs. Thus, at the illumination level producing a particular short-circuit photocurrent density (25 mA/cm^2 is a convenient number corresponding roughly to unfocused terrestrial solar illumination), the open-circuit voltage for a given cell will vary as

$$V_{oc} \sim 0.05 \ln \tau_p + \text{const.}$$

since $n_{iAlAs} << n_{iGaAs}$. We thus can conclude on the basis of this model that the saturation currents and hence open-circuit voltages for our diodes should be determined dominantly by the electron lifetime in the p-GaAs. This has been verified by photoluminescence studies (21) on cells made on substrates cut from different ingots of p-GaAs which were similar in electrical properties but differed widely in photoluminescent efficiency.

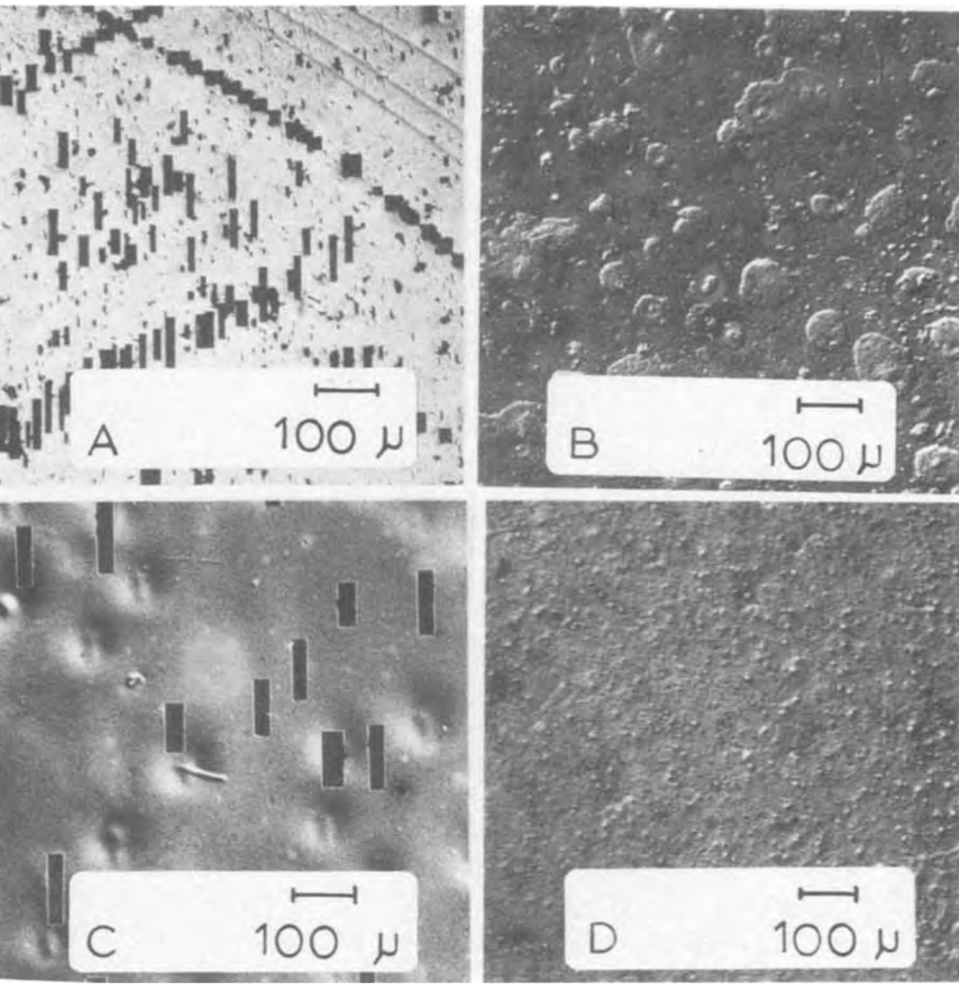

Fig. 5. Differential interference contrast micrographs of top surface of GaAs after growth and removal of AlAs epilayer: A = <110> defined rectangular etch pits, late initiation of AlCl flow; B = early AlCl flow (thermochemical etching in As and HCl atmosphere); C = thermal etching in As deficient atmosphere; D = interfacial surface for near optimum growth initiation. The best interfacial surfaces appear similar to the featureless regions in C.

Conclusions and Discussion

The finding of principal importance in this work is that it is possible, by the use of commercially available high purity Al_2O_3 ceramic furnace components, to grow AlAs by VPE on GaAs substrates without formation of a disturbed interfacial layer. This permits the fabrication of usefully efficient heterojunction solar cells which at present are performance limited by the quality of the substrate material. In several respects, however, the alumina ceramic is less than ideal. Residual Si contamination is still present, although we believe native donor defects to be the more likely cause of the minimum carrier concentration of $\sim 10^{17}$ cm^{-3} in our highest mobility epitaxial AlAs layers. Our results with Be doping indicate that useful, p-type VPE AlAs should be obtainable if the alumina ceramic were replaced by a material not attacked by $BeCl_2$ (or AlCl) vapor in the 1100°C, H_2 ambient.

The interface between the AlAs layer and the GaAs can be reproducibly smooth and planar over the entirety of large area substrates up to 15 cm^2 at least. This requires growth at the lower end of the temperature range for AlAs VPE and careful control of the thermal etch-VPE growth transition. At these temperatures (1000°-1050°C), the AlAs surface morphology consists of hillocks, the density of which depends primarily on substrate-AlCl source spacing. The surface quality is not strongly dependent on the crystallographic orientation of the substrate, growth temperature gradient, or exact Al/As flow ratio, but is moderately dependent on absolute Al and As supply rates.

The heterojunction formed between the n-AlAs and Zn-doped GaAs is well described by an abrupt model. The reverse saturation current of these junctions is determined by the bulk minority carrier lifetime in the GaAs. For many heterojunction device applications,

the low bandgap member is the important one with regard to minority carrier life, and the quality requirements on the wide gap member are relatively much less stringent. Thus, in spite of the fact that all our layers show misfit dislocation arrays of 10^5-10^6 cm^{-2} density, we have no evidence for deleterious effects arising from the interface. We have measured external short-circuit-current quantum efficiencies exceeding 95%, with antireflection coating, and these appear to be limited solely by the electron diffusion length in the p-GaAs bulk.

In spite of eliminating the interfacial layer found by others (1, 5), we have obtained no improvement in mobility or reduction in donor concentration. A calculation of the theoretically expected mobility should properly include (at least) the effects of polar optic mode scattering and ionized impurity scattering which interact in a complex way (18). Approximate calculations indicate that polar phonon scattering limits the mobility in AlAs at 300°K for electron concentrations below 10^{18} in the absence of significant compensation. For total donor and acceptor concentrations above about 2×10^{18} cm^{-3}, ionized impurity or native defect scattering should dominate. Our results are consistent with these expectations.

Studies of the Push-Out Effect in Silicon

II. The Effect of Phosphorus Emitter Diffusion on Gallium-Base Profiles, Determined by Radiotracer Techniques

Christopher L. Jones and Arthur F. W. Willoughby

Engineering Materials Laboratories, The University, Southampton, Hants SO9 5NH, England

ABSTRACT

The push-out of gallium-diffused base layers underneath subsequently diffused phosphorus emitters, has been studied using ^{67}Ga to obtain the complete tracer profiles of the base both within and beyond the emitter. The profiles show two major features which can be treated separately. Firstly, the depression of the base-collector junction in push-out is found to be due entirely to movement of Ga atoms, representing a very large enhancement of diffusion beyond the emitter. For the emitter diffusions used in this work, the magnitude of this enhancement varies from ~8 for a 1050°C emitter diffusion to ~100 for a 900°C emitter diffusion. The mechanism of diffusion enhancement in push-out is discussed in the light of the new data, and is considered to be due to production of an excess of a mobile point defect by high concentration phosphorus diffusion. The nature of the point defect, and the generation mechanism are, however, still to be resolved. Secondly, the tracer profiles also show a pronounced dip in the gallium concentration within the emitter. It is shown that the electric field created during the emitter diffusion could be the cause of such a dip, and the dip position, predicted on such a model, is close to that found experimentally. Similar effects produced by the diffusion of arsenic emitters are compared with these new observations on the effects of phosphorus emitter diffusions.

The push-out or emitter-dip effect is one of the most important anomalous diffusion effects that occur in the manufacture of silicon bipolar transistors (1, 2). The effect can be described as the depression of a base/collector junction beneath a localized emitter diffusion. Figure 1 is a section through a pushed-out structure

Key words: diffusion, enhancement, emitter push, radiotracer, electric field.

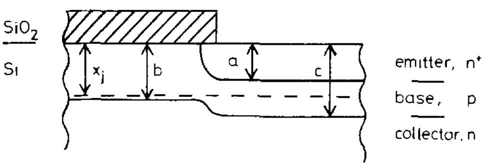

Fig. 1. Section through a transistor structure showing the depths measured: x_j, the initial base depth, is measured before emitter diffusion; a, b, and c after the emitter diffusion.

showing the deeper penetration, c, of the base under the emitter compared with the base depth, b, away from the emitter. The difference between the base depths, $(c - b)$, will be referred to as the amount of push-out.

As discussed in Part I (3) of this work push-out creates particular problems in the fabrication of microwave n-p-n transistors using phosphorus-doped emitters, yet the cause of push-out is still not certain. Although there is a growing body of information concerning the influence of various process parameters on the amount of push-out, as measured by junction depths (3-8), there is still virtually no information about the shape of the pushed-out base doping profile. A certain amount of electrical profiling in the pushed-out base has been carried out (3, 4, 9, 10) but as pointed out in Part I (3) electrical profiling is of very limited value for studying diffusion processes because so little of the base profile can be measured. The purpose of this work was to gain a greater understanding of sequential diffusions involving push-out by the radiotracer profiling of the complete base profile both within and beyond the emitter.

The conventional boron base cannot be profiled by tracer techniques because boron does not have an isotope of sufficiently long half-life (^{8}B and ^{12}B half-lives are < 1 sec) so in this work gallium-base layers have been employed. In Part I (3) the push-out of gallium was compared with boron by junction depth measurements and found to be very similar. It is therefore felt that the results to be described below must be closely related to the usual boron-base, phosphorus-emitter structure.

A preliminary report of the gallium tracer work has already been published (11). In the present paper the experiments are described in detail and the results are analyzed by considering the electric field effect and a general diffusion enhancement caused by the emitter diffusion. The possible reasons for this diffusion enhancement, which produces push-out, are discussed in the light of the new information, and the possibility of predicting the complete base profile shape is also considered.

Experimental Techniques

Material.—The silicon used was n-type, 5-10 Ω-cm, in (111) oriented wafer form, chemically polished on one side. Before diffusion the wafers were thoroughly cleaned as described in Part I (3).

Gallium-base diffusions.—The open-tube system described in Part I was used to form the Ga-base layers. The source was Ga_2O_3 powder containing the radioisotope ^{67}Ga. The use of ^{67}Ga was preferred to the more usual ^{72}Ga because of the former's longer half-life. ^{67}Ga has a half-life of 78 hr and is a γ-emitter, the main γ-energy being 0.092 MeV. The sources were specially prepared from $^{67}GaCl_3$ solution at the Radiochemical Centre, Amersham, and the source mass was made as small as could conveniently be handled ($\sim$ 40 mg) so as to maximize specific activity within the limited total activity allowed for safety reasons (0.5 mCi). During a diffusion the source was at 1050°C and the silicon samples at 1100° ± 2°C while a mixture of H_2 and N_2 gases transferred dopant from the source to the silicon (12).

Phosphorus-emitter diffusions.—These were carried out as described in Part I using a $POCl_3$ liquid source at 0°C and an O_2/N_2 carrier gas mixture. Two experiments used an emitter diffusion temperature of 1050° ± 1°C and one experiment used a temperature of 900° ± 1°C. A light weight furnace boat was used to keep wafer warm-up time to a minimum and all samples were cooled rapidly following the diffusion.

Junction depth measurement.—Junction depths a, b, c, and x_j of Fig. 1 were measured on stained grooves by sodium light interferometry, see Part I. The measurements were made on test pieces processed at the same time as the samples used for profiling.

Profiling.—Analysis of the diffused layers was made by layer removal combined with sheet resistance and radioactivity measurements. The layers were removed by anodizing the silicon and then etching off the anodic oxide in HF solution. The thickness of each layer was determined from the anodic oxide color which had been previously calibrated. The ^{67}Ga activity in each layer of silicon removed was measured using a γ-counting system consisting of a sodium-iodide well-crystal scintillator, photomultiplier, amplifier, pulse height analyzer, ratemeter, and scaler/timer. Profiling was carried out both by counting the activity of the oxide etch only and by counting oxide etch and anodizing electrolyte together and, although some gallium was found in the electrolyte, profiles obtained by the two methods were of closely similar shape. To obtain the "electrical" impurity profile on the same sample as the tracer gallium profile, sheet resistance measurements were made after each HF etch step using a four-point probe. The sheet resistance *vs.* depth data were converted to concentration *vs.* depth profiles by the method of Evans and Donovan (13) and using Irvin's (14) curves to convert resistivity to concentration. The conversion of radioactivity measurements to absolute gallium concentrations was not possible accurately by the normal standardization methods because of uncertainties in stoichiometry, moisture content, etc., of the gallium oxide source. (It must be remembered that the source was prepared from $GaCl_3$ solution, not by irradiation of Ga_2O_3.) In view of this the conversion was made by superimposing the tracer and electrically obtained gallium profiles in the tail region of the profile where concentrations were less than about 10^{18} cm^{-3}. At these concentrations the electrical parameters used are well substantiated and therefore it is a reasonable assumption that the electrical profile is correct. In the following results the term "electrical profile," for both gallium and phosphorus, refers to profiles obtained from electrical measurements and converted to total concentrations via Irvin's curves as detailed above. At high phosphorus concentrations ($>10^{20}$ cm^{-3}) the conversion parameters are not well substantiated and thus the form of the profile in this range is subject to uncertainty.

Results

Experiments were performed to examine the effects of a high concentration phosphorus emitter diffusion on a previously diffused ^{67}Ga base. Two emitter diffusion temperatures were used and in each case the entire pushed-out base profile was determined and compared with the nonpushed-out base.

1050°C emitter diffusion.—Two silicon wafers were diffused simultaneously with ^{67}Ga for 15 min at 1100°C. The oxide was removed from one slice which was then given a 3½ min/1050°C phosphorus diffusion, and finally both samples were profiled. The electrical phosphorus profile and the tracer and electrical gallium profiles are shown in Fig. 2. Conversion of tracer activity to gallium concentration was made by comparing the tracer and electrical profiles of the nonpushed-out base, as described above. The conversion factor is the same for both the pushed-out and nonpushed-out tracer profiles because the initial Ga diffusions were

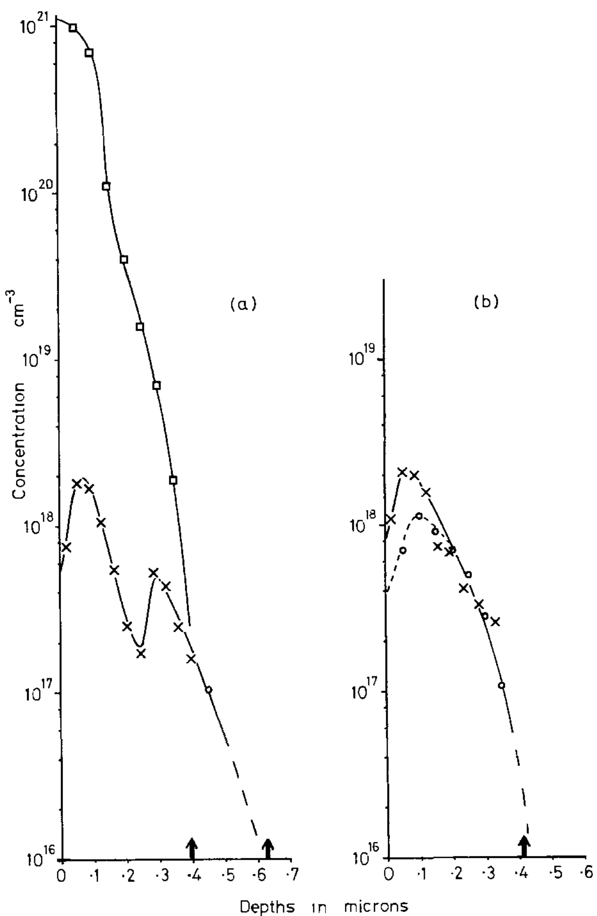

Fig. 3. Repeat experiment using the same conditions as Fig. 2. Symbols same as Fig. 2.

performed simultaneously. Electrical measurements of the pushed-out base (beyond the emitter) proved to be impossible in this experiment because of the low concentration and narrowness of the base.

The junction depths by staining for this experiment were: $a = 0.42$ μm, $b = 0.42$ μm $\approx x_j$, $c = 0.62$ μm, so that the push-out was $(c - b) = 0.20$ μm. These depths are in good agreement with the junction depths inferred from the profiles although close to c tracer measurements were impracticable due to the low activity of the thin layers removed.

The gallium profile in Fig. 2(a) is the first determination of the complete base profile in a pushed-out transistor and it can be seen that the profile is not gaussian or erfc, but has a marked dip within the emitter at about 0.28 μm from the surface.

A repeat experiment was performed, using as near as possible identical conditions, and the results are shown in Fig. 3. The shape of the pushed-out base is very close to that of the previous experiment showing that the profiles are highly reproducible.

900°C emitter diffusion.—Two wafers were diffused with ^{67}Ga for 15 min at 1100°C and the oxide removed from one; both slices were then placed in the phosphorus-diffusion furnace for 30 min (900°C). In this way both slices received the same heat-treatment but phosphorus only diffused into one slice, the other being protected by its oxide. The resultant profiles are shown in Fig. 4. As with the previous experiments (1050°C emitter) a dip in the tracer gallium profile occurs within the emitter but the dip is now shallower, at 0.23 μm, and closer to the emitter/base junction. The wider base width produced in this experiment allowed electrical profiling in the pushed-out base and close agreement is seen between tracer and electrical profiles except near the emitter/base junction where the electrical profile falls more steeply due to compensation by the tail of the phosphorus profile.

The junction depths by staining were: $a = 0.28$ μm, $b = 0.53$ μm,[1] $c = 0.71$ μm, hence the push-out was 0.18 μm.

Some general remarks are appropriate as a result of the above experiments:

(*i*) In both experiments using the 1050°C emitter diffusion the pushed-out base was found, by integrating areas under the profiles, to contain approximately 18% less gallium atoms/cm^2 than the initial base, while in the 900°C emitter experiment the pushed-out base contained 2% more than the nonpushed-out base. The last result is the most significant because here both the pushed-out and nonpushed-out base received exactly the same heat-treatment and the negligible difference at 900°C indicates that the loss of gallium apparent in the 1050°C emitter experiments was simply due to the extra heat-treatment involved in the phosphorus diffusion and not connected with the presence of diffusing phosphorus. It is probable that this loss is an out-diffusion process similar to that thought to contribute to the original profile, see Part I (3).

(*ii*) In Fig. 2(b) and 3(b) there is evidence of non-electrically-active gallium (or compensation) in the high concentration surface regions of the nonpushed-out base whereas this does not apparently happen in Fig. 4(b) where the nonpushed-out base underwent the 900°C/30 min anneal following Ga diffusion.

(*iii*) The phosphorus emitter profiles are characteristic of shallow, high concentration phosphorus diffu-

[1] The deeper base in this experiment compared with the previous experiments was due to the use of a different gas composition during Ga diffusion which gave a higher initial Ga vapor pressure and faster source consumption.

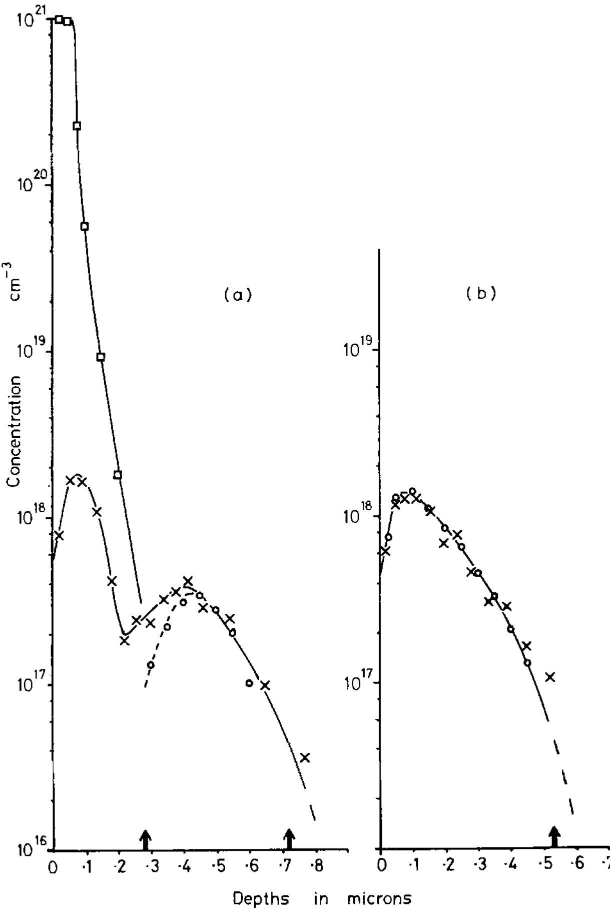

Fig. 4. (a) 15 min/1100°C Ga diffusion followed by 30 min/900°C P diffusion, (b) as (a) but protected from P diffusion by a covering oxide. Symbols same as Fig. 2.

sions below 1100°C (15) having a flat top and a kink. It can be seen that the kink occurs at a lower concentration for the lower diffusion temperature as found by Schwettmann and Kendall (16).

(*iv*) The tracer measurements show that push-out is caused wholly by a real inward movement of gallium atoms during the phosphorus diffusion rather than being partly due to some other process, such as conversion of the collector dopant to an electrically inactive form; a distinction which purely electrical measurements could not recognize.

(*v*) It should be noted that comparison of the pushed-out and nonpushed-out gallium profiles for a particular experiment can be made quite independently of standardization because the samples were diffused simultaneously from one tracer source.

(*vi*) The position of the dip in the pushed-out base relative to the emitter is given increased accuracy in these experiments because the emitter and base profiles were obtained using the same depth data. In other words errors in the depth measurements would not shift the gallium profile relative to the phosphorus profile: this is a considerable advantage over the technique used by Ziegler, Cole, and Baglin (17) to measure boron-base, arsenic emitter profiles.

The results reported above give, for the first time, concentration *vs.* depth distributions of all the impurities in a pushed-out, diffused transistor. Possible reasons for the anomalous shape found in the pushed-out base are discussed in the following section.

Discussion

Enhancement of the tail of the pushed-out base.—The simplest model of push-out assumes that during the emitter diffusion the only effect the emitter has on the base is to enhance the base diffusivity by an amount χ which is constant with time and depth (3, 6, 8). Such a model has been applied to the tracer gallium profiles as follows.

First theoretical curves were fitted to the experimental initial base profiles [*e.g.*, Fig. 2(b) and 4(b), strictly speaking Fig. 4(b) is not an initial base profile but the difference should be negligible for this purpose]. These experimental profiles are not erfc in shape because the very small Ga_2O_3 source used in the tracer experiments could not maintain a constant gallium vapor pressure during the diffusion. It is possible, however, to fit gaussian curves over most of the experimental points and the initial base profile is then described by

$$N = N_o \exp\left(\frac{-x^2}{4D_1t_1}\right) \qquad [1]$$

where N = gallium concentration, N_o is the maximum value of N, x = depth, D_1 = effective base diffusivity, t_1 = effective base diffusion period. Both N_o and the product D_1t_1 are obtained by fitting. The final profile, after emitter diffusion is then given by

$$N = N_o\left[\frac{D_1t_1}{D_1t_1 + \chi D_2t_2}\right]^{1/2} \exp\left\{\frac{-x^2}{4(D_1t_1 + \chi D_2t_2)}\right\} \qquad [2]$$

where χ = diffusion enhancement factor, D_2 = normal gallium diffusivity at emitter diffusion temperature, and t_2 = emitter diffusion period. The pre-exponential term in Eq. [2] arises from the assumption that the total number of gallium atoms is conserved. The only unknown in Eq. [2] is χD_2, the enhanced diffusivity, since t_2 is known and both N_o and D_1t_1 have been fixed by the fit to the initial profile. By adjusting the value of χD_2, Eq. [2] was fitted to the final profile at a concentration of $N \approx 10^{17}$ cm^{-3}. Two examples of this procedure are given in Fig. 5 and it is apparent

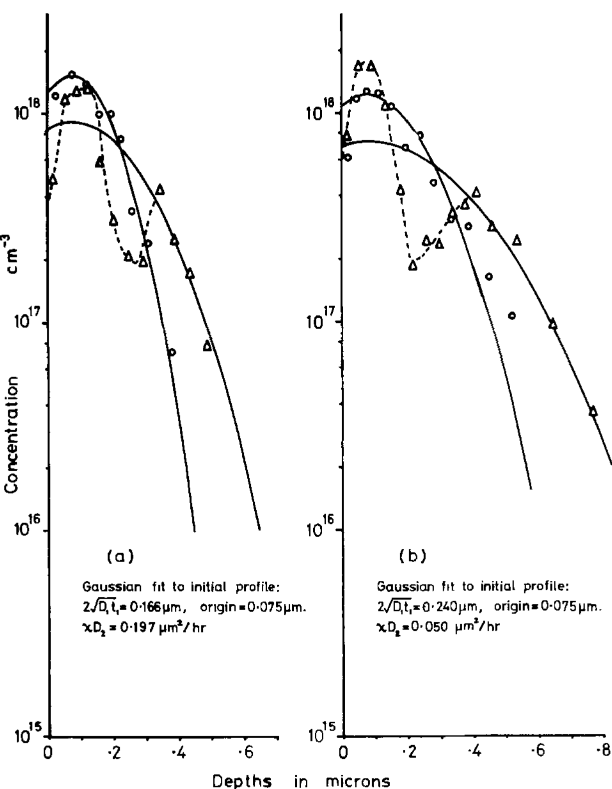

Fig. 5. Curve fitting to initial base, and tail of pushed-out base: (a) 1050°C emitter experiment of Fig. 2, (b) 900°C emitter experiment of Fig. 4. ——— Theory; ○ experiment before emitter; - - -△- - - experiment after emitter.

that a reasonable fit is obtained to the experimental profiles beyond the dip by using χD_2 values of 0.197 μm^2/hr at 1050°C and 0.05 μm^2/hr at 900°C. The corresponding values for χ are: $\chi \approx 8$ at 1050°C and $\chi \approx 100$ at 900°C; these are only approximate since D_2 is not known precisely. The χ(1050°C) value of 8 is the same as that calculated from junction depths (using Eq. [2] in Part I), and assuming gaussian distributions, in the boron push-out work of Part I, thus providing additional evidence that gallium pushes out in the same way as boron.

The assumption, used above, that the base diffusivity is constant with depth during the emitter diffusion is probably incorrect. Experimentally Okamura (18) has found that uniform, heavy n-type doping retards gallium diffusion and the present work shows that there is no extra out-diffusion due to the phosphorus diffusion (see 900°C emitter results) which suggests that the base diffusivity is not enhanced near the surface. In order to estimate the importance of a varying diffusivity the situation was simplified as follows. Suppose $D = D_2$ for $0 < x < x_k$ and $D = \chi D_2$ for $x > x_k$, where x_k defines an imaginary boundary between the two regions of different D. The boundary position was taken as the depth of the kink in the phosphorus profile and it was further assumed that $x_k = ht^{1/2}$, where h is a constant obtained from the final kink depth at time t_2. At the start of the emitter diffusion the whole of the base suffers an enhancement but as the diffusion proceeds the diffusivity in a growing surface region of depth x_k is not enhanced. This procedure has been applied to the experimental results of Fig. 2 and the final profile shape is shown in Fig. 6. A good fit is obtained in the tail region using the same χD_2 product as for the uniform enhancement. The gallium profile has a kink and a higher concentration is retained near the surface than for the uniform enhancement model.

The above analysis demonstrates the point made by Hu and Yeh (6) and discussed fully in Part I (3) that the amount of push-out is determined by the base diffusivity beyond the emitter irrespective of how the diffusivity varies inside the emitter. Consequently, simple models assuming a uniform diffusivity of χD_2 are able to predict amounts of push-out quite well although they are very much in error as regards the over-all profile shape.

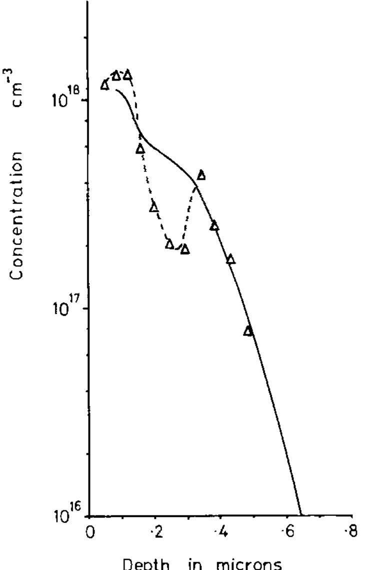

Fig. 6. Calculated profile for a step-function change in D with depth, based on experiment of Fig. 2, and compared with experimental profile. ——— Theory; ---△--- experiment. Gaussian initial profile as in Fig. 5(a). $\chi D_2 = 0.197$ μm^2/hr. Boundary reaching 0.2 μm in 3.5 min.

Formation of a dip in the pushed-out base.—The simple diffusion enhancement theories described above cannot give rise to a dip in the pushed-out base profile but Hu and Schmidt (19) have shown theoretically that the emitter's electric field could cause a dip in the base profile. In 1972 a dip in a boron base following an arsenic emitter diffusion was measured experimentally by Ziegler, Cole, and Baglin (17) but their results did not prove conclusively that the dip was caused by the field effect (20). On the other hand more recent measurements on arsenic emitter/boron-base structures by Blanchard, Boris, De Brebisson, and Monnier (21) using the ion microprobe have tended to support Hu and Schmidt's prediction. The results described in this work show for the first time that a dip is also present when phosphorus is diffused after gallium and it is shown below that these results are consistent with an electric field model. The sequential diffusion equations deduced by Hu and Schmidt cannot be used directly in this case because the equations do not give the correct form for the phosphorus emitter profile.

When the only "driving forces" for diffusion are the concentration gradient and an electric field the flux of ionized base dopant atoms is given by

$$J_x = -D_2\left(\frac{dN}{dx}\right) - s\mu N\mathcal{E} \qquad [3]$$

where J_x = base impurity flux in the $+x$ direction; s = charge state of the impurity; μ = drift mobility of the impurity; and $\mathcal{E}$ = electric field, defined as positive when the force on an electron is in the $+x$ direction. The field term in Eq. [3], $s\mu N\mathcal{E}$, can either assist the concentration gradient or act against it depending on the direction of $\mathcal{E}$, and, if the field is sufficient, diffusion "up" the concentration gradient is possible. The way in which the field could produce a dip can be described qualitatively as follows. Suppose an impurity has been diffused from the surface to give the profile shown in Fig. 7(a) and an electric field is then applied such that the field is constant to a depth A and zero beyond this, see Fig. 7(b). Let the field have the direc-

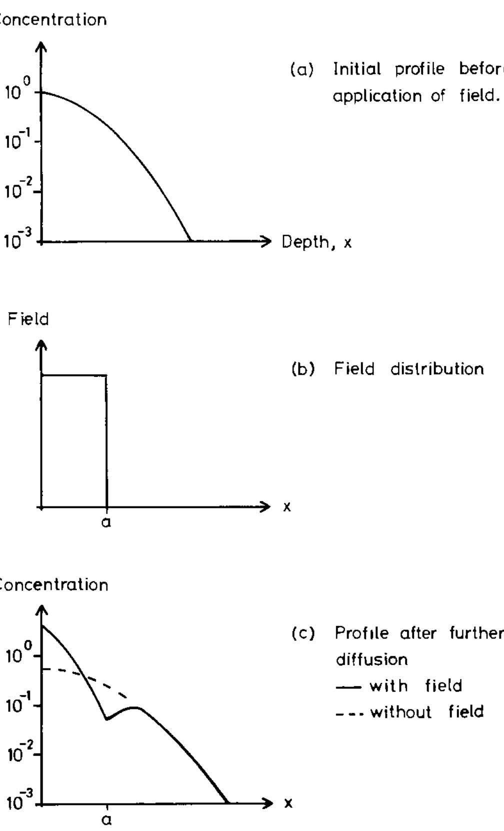

Fig. 7. Simple model of dip production by an electric field

tion and strength to overcome the concentration gradient so that the impurity flux is negative, that is toward the surface, for $0 < x < A$. If diffusion now continues, then as far as the impurities beyond A are concerned, the region $0 < x < A$ appears as a sink since any impurity crossing $x = A$ in the $-x$ direction is swept toward the surface by the field which also prevents impurities crossing in the opposite direction. The profile is then depleted close to A and piled up near the surface. The result is a dip centered on $x = A$ as shown in Fig. 7(c).

In order to see whether a situation such as that described above arises in practice, the magnitude and direction of the electric field created by phosphorus diffusion has to be calculated. Assuming electronic equilibrium is easily maintained during diffusion the Fermi level can be considered constant throughout the diffusing layers so the electric field is given by

$$\mathcal{E} = -\frac{1}{q}\frac{d(E_c - F)}{dx} \qquad [4]$$

where q = electronic charge, E_c = conduction band edge, and F = Fermi level. Equation [4] can be used to calculate the field provided the variation of $(E_c - F)$ with x is known. The dependence of $(E_c - F)$ on donor doping concentration, N_D, at a particular temperature, T, was calculated using Fermi-Dirac statistics and assuming (*i*) that the phosphorus donor level is a discrete level 0.045 eV below E_c and (*ii*) that the bandgap is given by $E_g(T) = [1.21 - 4.1 \times 10^4 T°K]$ eV (22). This information was then used to determine $(E_c - F)$ *vs.* x for the experimental N_D *vs.* x profiles. The method used to calculate Fermi levels is likely to be in error at high concentrations ($>10^{20}$ cm^{-3}) due to heavy doping effects, but this is not significant at the levels important in this analysis. One of the band diagrams obtained is shown in Fig. 8 and beneath this is the field distribution calculated using Eq. [4] on the band diagram.

The field is in the right direction for dip formation, and to test whether it has sufficient strength the flux equation, Eq. [3], has been used with the gaussian fits to both the initial and pushed-out Ga profiles (Fig. 5). The flux equation is first rewritten using the Einstein relation, $\mu = qD_2/kT$ (where k is Boltzmann's constant), and putting $s = -1$ for Ga, and $dN/dx = -xN/2Dt$ for gaussian profiles. Then

$$J_x = D_2 N \left[\frac{x}{2Dt} + \frac{q\mathcal{E}}{kT}\right] \qquad [5]$$

For the 1050°C emitter experiment the gaussian profiles shown in Fig. 5(a) were used together with the field distribution of Fig. 8 to calculate J_x/D_2 at various depths from Eq. [5]. Table I gives the results of these calculations which show that the field overcomes the concentration gradient and the impurity flux is toward the surface over a region with an upper limit 0.25 μm from the surface and a lower limit which is approximately 0.15 μm from the surface; the lower limit is uncertain due to heavy doping effects but it is the upper limit which is closely related to the dip. Using different assumptions the upper limit is calculated (see Table I) as 0.32 μm and the lower limit as approximately 0.1 μm. The position of the bottom of the dip expected on this

basis (and considering Fig. 7) is between 0.25 and 0.32 μm which agrees well with the actual position of 0.28 μm. Similar analysis for the 900°C emitter experiment predicts a dip in the region 0.22-0.25 μm which again agrees well with the measured position of 0.23 μm.

The above calculations can be summarized as follows: (*a*) the emitter's electric field is capable of producing a dip in the base profile, and (*b*) the predicted position of the dip agrees very well with the measured position.

Possibility of predicting the complete base profile.— In principle the above analysis could be developed to predict the entire base profile but before this can be accomplished the variation of the electric field, $\mathcal{E}$, and the base diffusivity, D, with both x and t must be established. As shown above, $\mathcal{E}$ can be obtained from the phosphorus doping profile but the change of this with time is not well characterized because of the anomalous nature of high concentration phosphorus diffusion. For the purpose of calculating the base profile the cause of anomalous phosphorus diffusion need not be known, only the exact shape of the profile at any time, for which the analysis by Tsai (15) applies.

It has been shown above that beyond the emitter the base diffusivity can be considered constant at χD_2 but inside the emitter there are three possible ways in which D could vary. These are:

(*i*) The push-out enhancement factor χ may vary with depth inside the emitter. This will depend on the enhancement mechanism which, of course, is not yet established. Hu and Yeh's (6) vacancy generation by climbing dislocation mechanism leads to a χ which from being unity at the surface increases with depth until it reaches a constant value for $x \gtrsim 2\sqrt{D_3 t_2}$ = the emitter diffusion length. Other models of diffusion enhancement (23, 24) have not been developed sufficiently to indicate how χ varies with x.

(*ii*) The Fermi level may affect D_2 via changes in the charged defect populations; assuming the base impurity diffuses by a defect mechanism. If acceptor impurities diffuse mainly via positively charged vacan-

cies, as suggested by Makris and Masters (25), the base diffusivity would be reduced inside the emitter because fewer vacancies could exist there in the positively charged state. The size of this effect depends on the relative importance of positively charged and neutral vacancies in the diffusion of an acceptor and on the position of the vacancy donor level at diffusion temperatures, both factors are uncertain at present. Hu and Schmidt (19) did not include this effect in their sequential diffusion theory (arsenic emitter) but Hu (26) accepts that it may be important.

(*iii*) Ion-pairing of emitter and base dopants prevents some of the base dopant from diffusing in the normal way. Reiss, Fuller, and Morin (27) have shown that ion pairing can be described in terms of a concentration-dependent diffusivity which is always smaller than the diffusivity in the absence of pairing. The extent to which pairing occurs at diffusion temperatures is not definitely known but Fair (28) has incorporated it into Hu and Schmidt's sequential diffusion theory for the arsenic emitter, boron-base structure and in his treatment it has a small but noticeable effect on the base profile within the emitter.

The combined influence of Fermi-level and ion-pairing effects can be determined experimentally using Okamura's approach (18, 40). He diffused low concentration radiotracer Ga into silicon uniformly doped n-type and found that at 1200°C Ga diffusivity was more than halved when the donor doping level reached 10^{20} cm^{-3}. Experiments at lower temperatures and higher donor concentrations are required to cover more emitter diffusion conditions.

From the foregoing discussion it will be realized that the prediction of a complete pushed-out base profile is not easy. However, now that experimental profiles are available for the first time the correctness of any model used can be checked.

In the absence of a complete mathematical description of base dopant redistribution during phosphorus emitter diffusions a few qualitative comments are worthwhile. Since the position of the dip in the base profile is primarily determined by the emitter's electric field then: (*a*) the steeper the emitter's diffusion front the closer the dip is to the emitter/base junction of the transistor, (*b*) for a very deep phosphorus emitter the field may become so small toward the end of the diffusion that the dip fills up again, and (*c*) lowering the diffusion temperature extends the field to lower doping concentration regions, that is, toward the emitter/base junction, so the dip will move closer to the junction. From the point of view of transistor operation it is probably desirable to have the dip entirely inside the emitter to avoid a retarding field for minority carriers crossing the base, but from the above comments it will be realized that this requirement may be incompatible with the shallow, low temperature diffusions commonly used in high frequency transistors. On the other hand phosphorus could be better than arsenic in this respect since arsenic diffusions apparently never exhibit tails and have very steep diffusion fronts which would always place the dip close to the emitter/base junction (19, 21).

Possible causes of push-out.—In the light of the new results presented here it is appropriate to summarize our present understanding of the push-out effect.

(*i*) The size of the base dopant atoms is not important in push-out, see Part I of this work.

(*ii*) The presence of phosphorus or boron in high concentration is required to produce push-out; oxidation without emitter dopant does not give rise to the large junction movements that occur in push-out [see Hill (30) and Gereth et al. (4)]; arsenic emitters give little or no push-out [see Parekh and Kolmann (39)].

(*iii*) Push-out can be attributed to a diffusion enhancement which is constant with time during the emitter diffusion and with depth below the emitter [see this work, Hu and Yeh (6), and Nakamura *et al.* 8)].

(*iv*) The magnitude of enhancement is dependent on the emitter diffusion temperature varying from 8 times at 1050°C to 100 times at 900°C for the emitter diffusions used in this work (*i.e.*, $POCl_3$ source and surface doped to solid solubility).

(*v*) The diffusion enhancement increases as the phosphorus emitter surface concentration increases [see Lee (7), and Nakamura *et al.* (8)].

(*vi*) The enhancement operates at least 10 μm below the emitter as shown by the buried layer experiments of Lee and Willoughby (29). This suggests that enhanced diffusion could only be due to a point defect generated in the emitter region and capable of migrating considerable distances without being annihilated or trapped.

(*vii*) Diffusion enhancement occurs in all directions which means that a flux of point defects (32) is not primarily responsible [see Lee and Willoughby (29), Hill (30), and Adler (31)].

A mechanism is therefore required whereby a high concentration phosphorus (or boron) diffusion can introduce excess of a mobile point defect which can subsequently enhance the diffusion of any base dopant present. The point defects must be generated throughout the emitter diffusion period. The mechanism should explain the strong dependence on emitter surface concentration, the dependence on emitter diffusion temperature, and why phosphorus and boron produce much more push-out than arsenic.

The most highly developed theory of push-out is the vacancy generation by climbing dislocation model of Hu and Yeh (6). This theory fits the requirements detailed above but there are now several reports of push-out and anomalous phosphorus diffusion in the absence of dislocations (16, 30, 33-36).

Two mechanisms based on the break-up of *E*-centers (phosphorus-vacancy pairs) have been proposed. In both cases the *E*-center can be viewed as a means of transporting vacancies from the surface into the bulk where they are subsequently freed and can enhance the diffusion of any impurities present (provided these impurities diffuse by a vacancy mechanism). Peart and Newman (23) suggested that E-centers break up on changing from the negatively charged state, assumed to be stable, to the neutral state, assumed to be unstable. This change in charge state would occur as the *E*-center migrates out of the high concentration region where the Fermi level is above the *E*-center acceptor level into the lower concentration region where the Fermi level is below the acceptor level. The boundary between these two regions is located, in their model, at a phosphorus concentration equal to the kink concentration, thus vacancies would be released below the kink. Such a mechanism may be able to account for the enhancements observed provided most of the phosphorus flux is in *E*-center form and most of these *E*-centers break up after crossing the kink (37).

More recently Yoshida, Arai, Nakamura, and Terunuma (24) have proposed a mechanism in which *E*-center break-up occurs just beneath the silicon surface. The basis of their model is the assumption that phosphorus can only enter the silicon (at a surface) in the company of a vacancy. Once into the silicon these *E*-centers are in excess of the equilibrium requirement and so most of them immediately break up. Vacancy release would thus occur within a few hundred angstroms of the surface but it is not clear whether sufficient vacancies would diffuse deeper into the bulk to account for the observed enhancements. An important point raised by Yoshida *et al.*'s theory is that vacancy production in their model only occurs while phosphorus is entering the silicon at the surface,

therefore diffusion enhancement should stop on removal of the source At first this prediction appears to be contradicted by an experiment reported by Yoshida *et al.* themselves [see region A of Fig. 6 in Ref. (33)] but it is not clear whether complete removal of the source was achieved in this experiment.

A variation on these *E*-center models is to assume that *E*-centers are breaking up throughout the diffusing phosphorus layer. Such a situation might occur if phosphorus only migrates as *E*-centers and some of these break up in order to try and maintain local equilibrium between *E*-centers and free phosphorus (37). It must be pointed out, however, that any *E*-center theory suffers from its inability to account for the observed difference between phosphorus and arsenic diffusions since an *E*-center type defect is known to exist for arsenic, at least at low temperatures (38).

Conclusions

The first determination of the complete profile of a pushed-out base has been completed by radiotracer techniques. From these experimental results it is possible to conclude that:

(*i*) Push-out is entirely due to movement of the base dopant, and beyond the emitter this movement can be attributed to a simple diffusion enhancement which is constant with time during the emitter diffusion. The magnitude of enhancement is dependent on the emitter diffusion temperature, varying from 8 times at 1050°C to 100 times at 900°C for the emitter diffusions used in this work.

(*ii*) Localized interactions between a phosphorus emitter and a gallium base are complex and give rise to a dip in the gallium profile within the emitter. This dip can be explained by the electric field associated with the phosphorus, causing diffusion of gallium up its own concentration gradient.

It is felt that with the help of these experimental results theoretical prediction of the complete base profile should soon be possible and this would be of considerable assistance in the design and modeling of n-p-n diffused transistors. The cause of push-out is still uncertain but the *E*-center could provide a means of transporting vacancies from the surface into the bulk where they are subsequently freed and can enhance diffusion of the base dopant.

Silicon Nitride Film Thickness Dependence on Bipolar Transistor Characteristics

Hiroaki Mikoshiba

Nippon Electric Company, Limited, IC Division, 1753 Shimonumabe, Kawasaki, Japan

ABSTRACT

The effect on device properties of the Si_3N_4 film deposited on a thermally oxidized silicon wafer has been investigated. Oxide thickness used is mainly about 6000Å. It is shown that bipolar transistor characteristics, *i.e.*, current gain, junction reverse current, and 1/f noise are improved with increasing Si_3N_4 film thickness, except npn transistors at 2500Å of Si_3N_4. The minority carrier lifetime in the bulk silicon is also shown to be increased with increasing film thickness, based upon the fact that surface recombination velocity is not appreciably affected. Lattice strain measurements by Newton ring or x-ray rocking curve show that the lifetime increase is correlative with the reduction in the strain, which is a result of the thermal expansion rates difference. It is proposed that the lifetime be restored by the stress cancellation due to the combination of the Si_3N_4 and the SiO_2 on the silicon wafer. The film thickness dependence is also observed for Al_2O_3 films.

Si_3N_4 films are widely used as an excellent passivation film against ionic contamination in bipolar IC's. However, very few things are known about the influence of these films on device characteristics. The fact that the npn transistor current gain is increased by depositing Si_3N_4 films has only been empirically known among process engineers.

The current gain increase has been assumed to be attributed to surface recombination reduction. This assumption seems plausible, because these films often increase current gain at low collector current. However, it is difficult to believe that vapor-deposited Si_3N_4 film on a relatively thick SiO_2 layer reduces the number of trap centers at the SiO_2-Si interface or that positive charges at the Si_3N_4-SiO_2 interface are of benefit in reducing surface recombination. In addition, surface states are not sufficiently reduced by annealing in a hydrogen ambient at low temperatures, because of the existence of Si_3N_4, which prevents hydrogen from penetrating SiO_2 (1-2).

During the Si_3N_4 film sealed linear IC process development, the author found that the current gain depends on film thickness. This dependence was also found to be closely related to the stress which is induced in a silicon wafer due to mismatched thermal expansion rates (3).

Si and SiO_2 thermal expansion rates are 2.5 and 0.35×10^{-6} deg^{-1}, respectively. Therefore, a silicon wafer thermally oxidized at high temperature is stressed by the large difference in thermal contraction during the cooling period. It is known that stress magnitude is on the order of 10^6-10^7 $dyne/cm^2$ at room temperature (4-5).

The thermal stress can be changed by depositing a dielectric film, such as Si_3N_4 (6) or Al_2O_3, whose thermal expansion rate is larger than that of SiO_2, on the oxide layer under appropriate conditions. As shown in Fig. 1, a silicon wafer thermally oxidized at high temperature has lattice strain at room temperature due to the thermal stress. When the SiO_2 on the back side of the wafer is etched away, the wafer warps, convexing the surface on which the SiO_2 is left. However, when Si_3N_4 film is deposited on SiO_2 at relatively high temperature, the lattice strain, introduced in the course of cooling, is reduced and thus wafer warping is reduced at room temperature due to the large Si_3N_4 thermal expansion rate. If Si_3N_4 film is thin, the stress reduction effect is not conspicuous. If it is too thick, the stress inversely begins to increase, concaving the Si_3N_4 deposited surface.

Key words: silicon nitride, thermal stress, lattice strain, bipolar transistor.

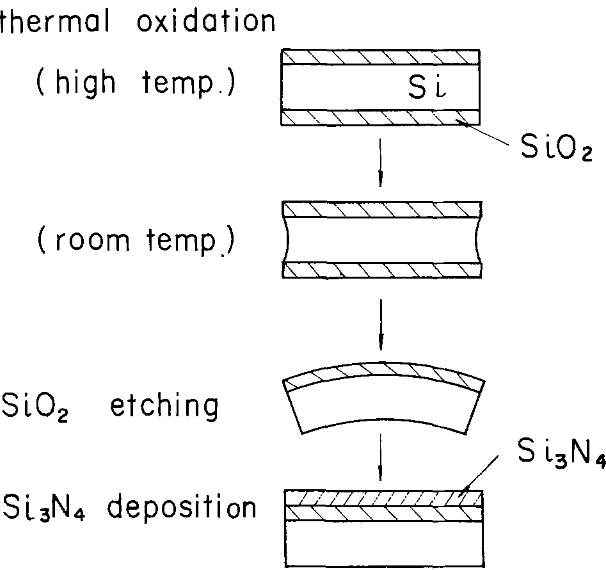

Fig. 1. Thermal stress due to thermal expansion rates difference

Table I lists the curvature radii and the stress in the silicon surface of a thermally oxidized silicon wafer on which Si_3N_4 film was deposited at various thicknesses. The curvature radii were measured using the Newton ring method and stress was calculated from the curvature. These wafers underwent heat-treatments similar to the transistor process adopted in the present work. Oxide thickness was about 6000Å. Table I shows that the stress in silicon can be reduced by a factor of ten by depositing the Si_3N_4 film.

Table I. Stress compensation by depositing Si_3N_4 film. Wafers underwent a heat-treatment similar to that undergone by transistors shown in Fig. 2-9. Total oxide thickness was about 6000Å.

Si_3N_4 film thickness (Å)	Curvature radius ($\times 10^3$ cm)	Stress ($\times 10^6$ $dyne/cm^2$)
0	1.3	17
300	2.1	11
600	2.3	9.8
1000	3.4	6.6
2000	12	2.0

The thermal stress is two or three orders of magnitude smaller than stress magnitude, at which the stress effect can be observed. In general, the stress effect is observed in silicon p-n junction devices under an anisotropic stress of more than 10^9 dyne/cm^2 (7-9). Increase and decrease in junction current and current gain is brought about by the change in carrier concentration due to stress-induced change in the energy gap. Although the thermal stress magnitude is small, it is characterized in that thermal stress rises at high temperature. Since silicon crystal is subjected to all sorts of defects at high temperature, it is expected that the thermal stress could affect the electrical properties of silicon devices (5).

Since the over-all stress is a result of the combination of Si_3N_4 film and SiO_2 on the silicon wafer, oxide thickness and oxidation conditions are also important for the thermal stress. However, the present investigation has been carried out regarding only the effect of Si_3N_4 films. The present work describes in detail the relation between Si_3N_4 film thickness and electrical properties of various transistors, which are commonly used in linear IC's. The influence of stress change on the generation-recombination rates is investigated by separating the bulk from the surface effects. Transistor characteristics improvements, due to the vapor-deposited Si_3N_4 film, are attributed to the increase in minority carrier lifetime in the silicon bulk. The possible mechanism for the generation-recombination centers reduction is discussed.

Experimental

Transistor fabrication.—Si_3N_4 sealed transistors, npn, lateral pnp, and collector-substrate pnp transistors, were fabricated in standard planar transistor process. The dimensions of each transistor are presented in Table II. 8 Ω·cm n-type (111) oriented silicon epitaxial wafers were used. Epitaxial layer and the substrate thickness are about 20 and 400 μm, respectively.

The isolation region was formed by usual boron diffusion. The npn transistor base and the pnp transistor emitter were formed by thermal diffusion of boron. The depth of these layers was about 2 μm. The npn transistor emitter was formed by phosphorus diffusion. In order to minimize thermal stress in a silicon wafer, both oxidation temperature and oxide thickness were reduced as much as possible. However, the oxide should be thick enough to have a masking effect for following diffusion steps. In this experiment, field oxide and oxide on base and emitter were about 6000 and 3000Å thick, respectively.

Si_3N_4 films were deposited at 780°C by SiH_4 and NH_3 decomposition. It is essential for the experiment that the deposition is the final high temperature treatment in wafer processing. In order to derive the full benefit of Si_3N_4 passivation, the oxide section at contact windows was lapped over by Si_3N_4. Si_3N_4 at contact windows was etched by hot phosphoric acid using vapor-deposited SiO_2 at 450°C as a mask.

In the experiment, a PSG layer was formed under Si_3N_4. Though PSG is not necessary, because of the perfection of Si_3N_4 passivation, it was used in order to prevent any surface charge influence.

Similar experiments were carried out by depositing Al_2O_3 instead of Si_3N_4, in order to confirm the same effect for Al_2O_3 and to insure the effect of the thermal stress on transistor characteristics. Al_2O_3 films were deposited at *ca.* 850°C by $AlCl_3$-CO_2-N_2 system hydrolysis.

Table II. Transistors dimensions

	Emitter area (μ)	Base width (μ)
npn	50 × 50	~0.3
Lateral pnp	25 × 25	17.5
Collect.-sub. pnp	70 × 30	~10

Surface recombination velocity.—In order to examine Si_3N_4 film effect on surface properties, surface recombination velocity, S_o, was measured, using the gate-controlled diode. The p^+-n diode was fabricated by boron diffusion into n-type 6 Ω·cm (111) oriented silicon wafers. Diffusions and oxidations conformed to the transistor process adopted in the present experiment. Oxide thicknesses on p^+ and n regions were about 3000 and 6000Å, respectively.

Minority carrier lifetime.—To measure the minority carrier lifetime from the step response of a capacitance, the MNOS capacitor was made on n-type 6 Ω·cm (111) oriented silicon wafers 350 μm in thickness. To add the thermal stress to silicon wafer, thermal oxidation at 1140°C was repeated three times and the oxide on the back of a wafer was etched away every time oxidation was accomplished. Total oxide thickness was 5200Å. The Si_3N_4 film was deposited at 780°C by thermal decomposition of SiH_4 and NH_3, in the same way as before. The gate electrode has a 2 × 2 mm area, so the surface recombination influence in the gate periphery space charge region can be reduced to a negligible amount (10). Capacitance-time response was measured on the wafer. 60V step voltages were applied to the gate to cause deep surface inversion. Capacitance step responses were measured at 1 MHz. Minority carrier lifetime was obtained by making a Zerbst plot from the capacitance-time response (11).

Lattice strain.—After the lifetime measurement, the aluminum gate was etched and lattice strain was measured by recording x-ray rocking curves which were obtained using a double crystal spectrometer. Two crystals were placed in the parallel (1, −1) position and diffraction was accomplished in (511)-(333) arrangement. The x-ray was obtained from the first copper Kα radiation.

Results

Current gain.—Forward voltage *vs.* collector current, I_C, and base current, I_B, characteristics are shown in Fig. 2 for various Si_3N_4 film thicknesses. It is notable that I_C is not changed while I_B is changed. This means that the d-c common emitter current gain, $h_{FE} = I_C/I_B$, is changed. Figure 3 shows the relation between maximum current gain for I_C $h_{FE(max)}$ with its distribution and Si_3N_4 film thickness. $h_{FE(max)}$ is increased with increasing film thickness up to a certain value. However, degradation occurs at 2500Å. As can be seen in Fig. 2, the slope of I_B at low current level approaches q/kT as film thickness increases. The normalized h_{FE} by $h_{FE(max)}$ as a function of I_C is plotted in Fig. 4. It can be seen that the h_{FE} flatness for I_C is greatly improved by the Si_3N_4. Degradation at 2500Å is also observed in the h_{FE} flatness.

Film thickness dependence was also found in pnp transistors. Figures 5 and 6 show h_{FE} *vs.* I_C characteristics of lateral and collector-substrate pnp transistors, respectively. pnp transistor h_{FE} is also increased with increasing Si_3N_4 film thickness. However, degradation at 2500Å does not occur in the case of pnp transistors.

Junction reverse current.—Figures 7 and 8 show the npn transistor emitter-junction and collector-junction reverse current for Si_3N_4 film thickness, respectively. The reverse current properties of each pnp transistor junction were approximately equal to the collector-junction plots shown in Fig. 8. The reverse current is greatly dependent on film thickness, as well. As shown in Fig. 7, reverse current through the emitter-junction is increased at 2500Å. This increase corresponds to the npn transistor h_{FE} degradation. On the other hand, at the collector-junction, which is equivalent to the pnp transistor emitter-junction, the reverse current is not increased at 2500Å. This corresponds

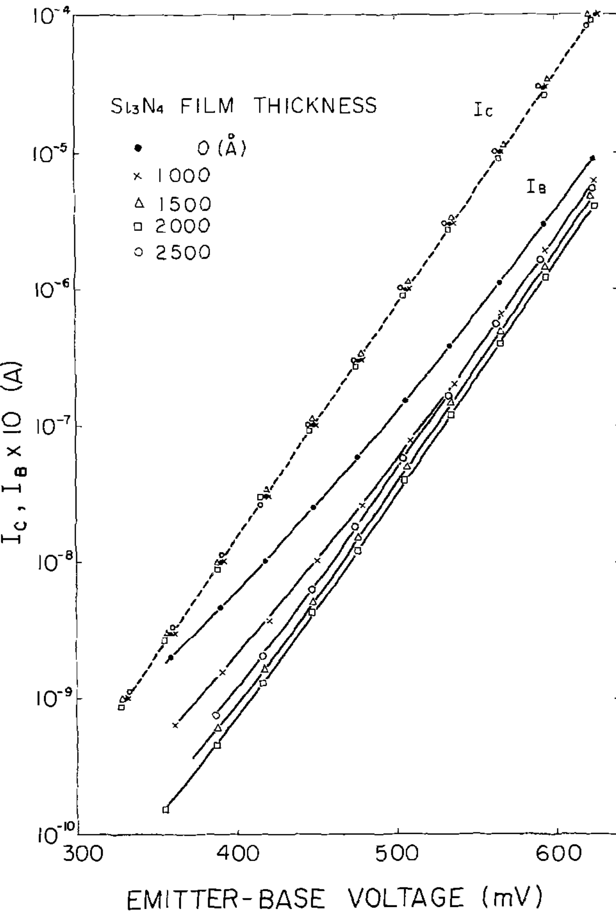

Fig. 2. Collector and base current vs. emitter-base voltage for Si_3N_4 film thickness.

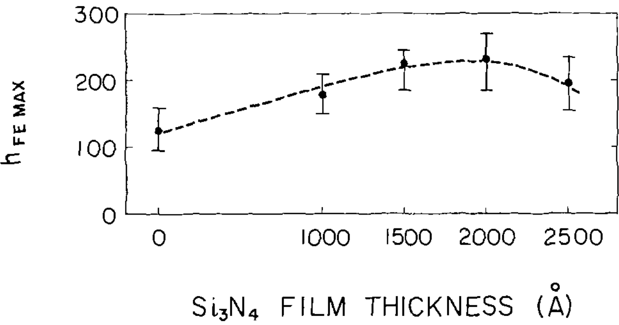

Fig. 3. Relation between $h_{FE(max)}$ and Si_3N_4 film thickness

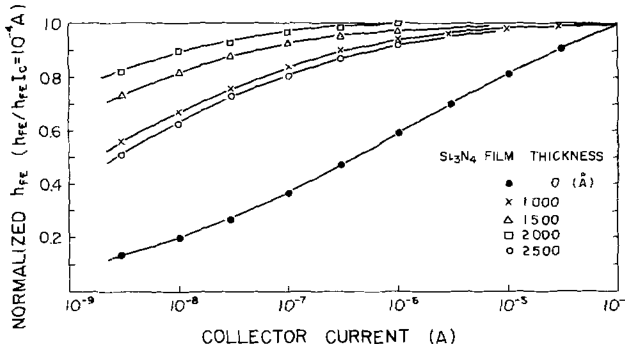

Fig. 4. h_{FE} normalized by $h_{FE(max)}$ vs. collector current with Si_3N_4 film thickness as a parameter.

to the fact that h_{FE} is not decreased at 2500Å in a pnp transistor.

According to the fact that I_C is not affected by the Si_3N_4 film, but both I_B and the reverse current depend on film thickness, it could be considered that the generation-recombination rate in a space charge region is changed, but that carrier concentration is not changed. That is because I_C is primarily determined by the minority carrier concentration in the base region, while I_B and the reverse current result mainly from the carrier recombination and generation, respectively, in space charge regions.

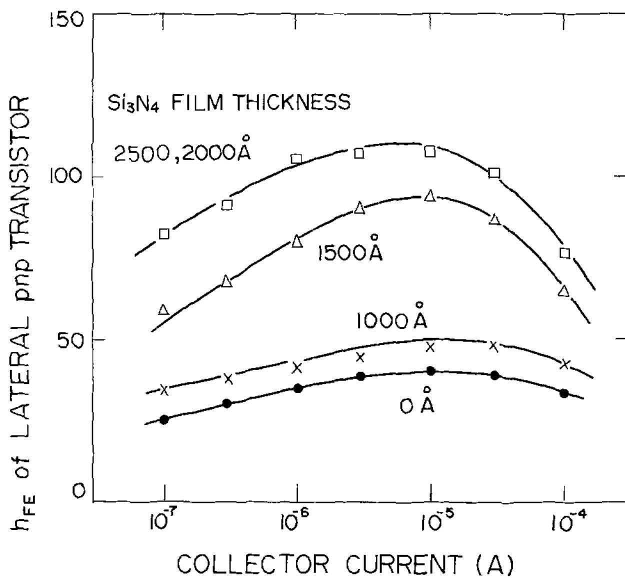

Fig. 5. h_{FE} of lateral pnp transistor vs. collector current with Si_3N_4 film thickness as a parameter.

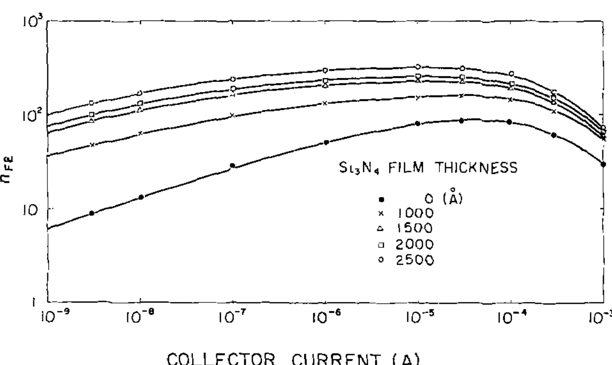

Fig. 6. h_{FE} of collector-substrate pnp transistor vs. collector current with Si_3N_4 film thickness as a parameter.

Noise characteristics.—The npn transistor noise current spectrum is presented in Fig. 9 as a parameter of Si_3N_4 film thickness. The drawing shows that 1/f noise is decreased as film thickness increases. The deterioration at 2500Å is also observed in noise current. It is interesting that noise *vs.* film thickness behavior is quite similar to that of low current h_{FE} and the reverse current. Considering that the 1/f noise results from recombination current fluctuation in emitter-junction space charge region (12), an assumption of a change in the generation-recombination rate seems agreeable. In addition, it is notable that burst noise was scarcely found in Si_3N_4 film sealed transistors. If the burst noise is due to the modulation of carrier flow by trapped charge, as proposed by Hsu and Whittier (13), the burst noise decadence can be explained by the recombination current decrease.

Deposited alumina film effect.—The h_{FE} film thickness dependence was also observed in vapor-deposited Al_2O_3 film. Figure 10 shows change in npn transistor h_{FE} for film thickness. h_{FE} is increased by the Al_2O_3 film. It is significant that the film thickness dependence is not a special effect of Si_3N_4, but a phenomenon

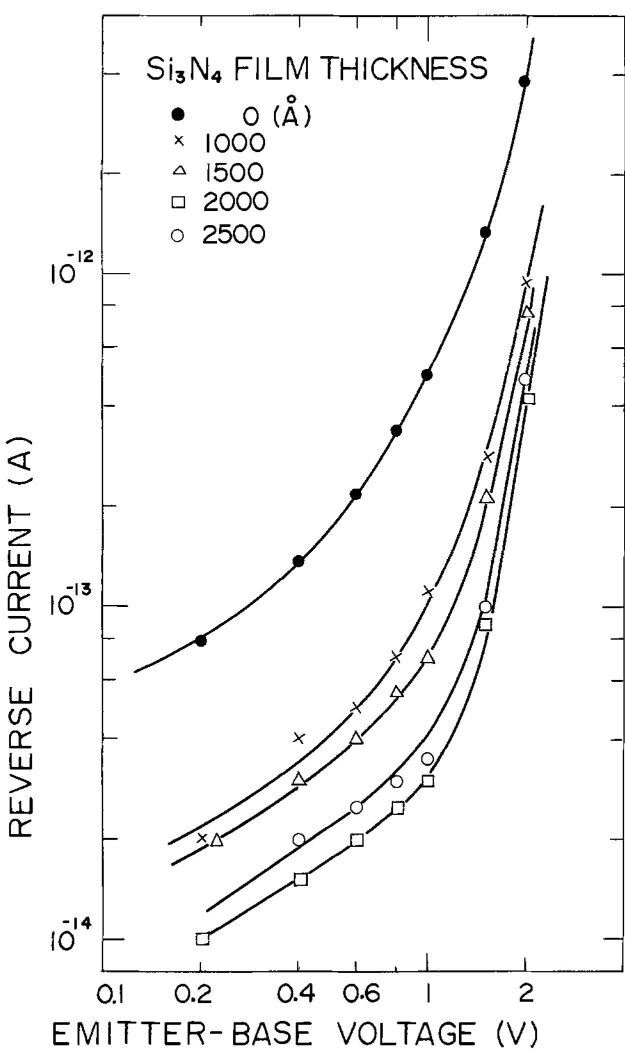

Fig. 7. npn transistor emitter-junction reverse current as a function of emitter-base voltage for Si_3N_4 film thickness.

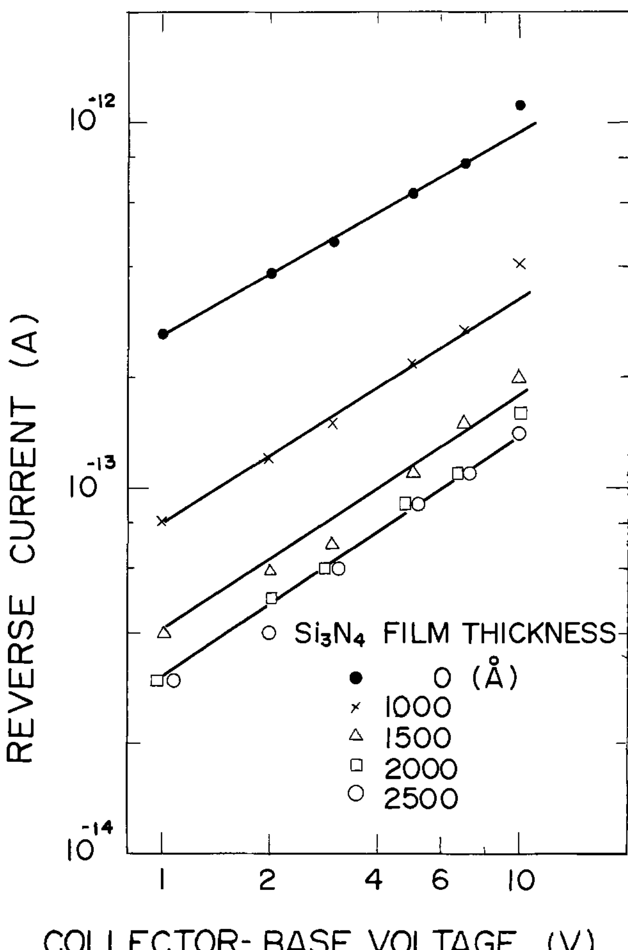

Fig. 8. npn transistor collector-junction reverse current as a function of collector-base voltage for Si_3N_4 film thickness. These characteristics are equivalent to those of each pnp transistor junction.

common to Si_3N_4 and Al_2O_3. This substantiates thermal stress changing transistor characteristics, because the thermal expansion rate of both films is much larger than that of SiO_2.

Surface recombination velocity.—Results obtained from gate-controlled diodes are listed in Table III. Only a slight increase in S_o is shown to result from depositing Si_3N_4 films. This indicates that the surface recombination is not appreciably affected. Therefore, it would be considered that the film thickness dependence is not caused in the silicon surface. This slight increase in S_o seems to arise from the fact that surface state annealing is retarded by the presence of the Si_3N_4 film (1-2).

Minority carrier lifetime.—Zerbst plots for various Si_3N_4 film thicknesses are shown in Fig. 11. Table IV lists the effective lifetime, obtained from the linear portion of the Zerbst plot, the total time of c-t curve t_F, and S_o in the space charge region, calculated from

Table III. Surface recombination velocity obtained from gate-controlled diode. Oxide thicknesses on p^+ and n regions were about 3000 and 6000Å, respectively.

c-t curves (14). The thus obtained S_o value is in good agreement with the value obtained from the gate-controlled diode listed in Table III. Bulk lifetime, τ_g, is related to effective lifetime, τ'_g, by

$$1/\tau'_g = 1/\tau_g + PS_o/A_G$$

where P is gate periphery length and A_G is gate area (10). Since A_G, which is 2 × 2 mm, is large enough, lifetime surface component is only a few percent of τ'_g. Accordingly, τ'_g can be considered as bulk dominated. From the fact that surface recombination is

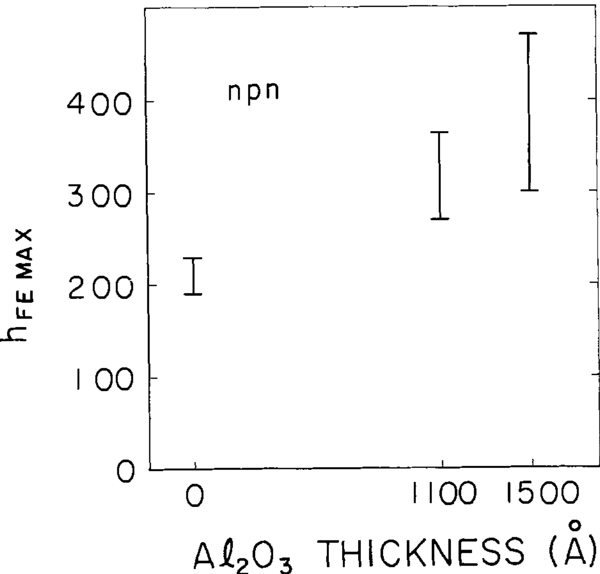

Fig. 10. Al_2O_3 film deposition effect on npn transistor h_{FE}. Film thickness dependence is also observed in Al_2O_3 film deposited transistors.

scarcely affected, it is concluded that the bulk lifetime is increased with increasing Si_3N_4 film thickness.

Lattice strain.—Results of rocking curves, *i.e.*, diffraction intensity and half-width, curvature radii of wafers, and stress in silicon surface calculated from curvature radii are given in Table IV. Curvature radii were obtained from the deviation of the peak of rocking curves at any two points on a wafer. As can be seen in Table IV, as Si_3N_4 film becomes thick, the diffraction intensity increases and the half-width decreases. These values come up to those of a wafer which has had no thermal treatment. This tendency is in good agreement with the stress in silicon surface. These results show clearly that the lifetime increase is correlative with the strain reduction.

Figure 12 shows the transition of the lattice strain at each wafer processing step. When the Si_3N_4 was etched, curvature radius and half-width became the same values as those of a wafer on which Si_3N_4 had not been deposited. Therefore, it is known that the lattice strain due to deposited Si_3N_4 film is within the elastic limit. However, as shown in Fig. 12, the residual strain is observed in a silicon wafer when the SiO_2 is removed. Therefore, it can be considered that the thermal stress exceeds the elastic limit of silicon during the thermal oxidation process because of high temperature.

Discussion

Both $h_{FE(max)}$ and low current h_{FE} improvement, as well as decrease in reverse current, can be attributed to an increase in the bulk lifetime, as follows. h_{FE} of a npn transistor, whose base width, W_B, is much narrower than the electron diffusion length in the base region and whose emitter junction is deeper than the

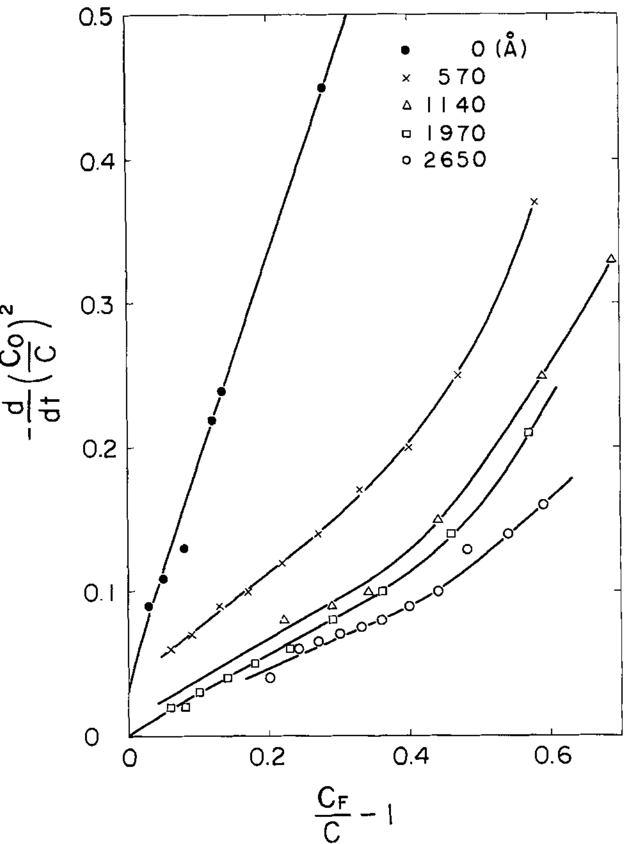

Fig. 11. Zerbst plots for MNOS capacitor c-t characteristics

hole diffusion length in the emitter region, L_{PE}, is described by the following expression (15)

$$\frac{1}{h_{FE}} = \frac{N_{AB}\,W_B\,D_{PE}}{N_{DE}\,L_{PE}\,D_{nB}} + \frac{N_{AB}\,W_B}{D_{nB}}\,\frac{W_{EB}/\tau_o + S_o\,A_s/A_J}{2n_i \exp[qV_{EB}/2kT]} \quad [1]$$

where N_{AB} is the acceptor concentration in the base, N_{DE} is the donor concentration in the emitter, D_{PE} is the diffusivity of holes in the emitter, D_{nB} is the diffusivity of electrons in the base, W_{EB} is the width of the space charge region of the emitter-junction, τ_o is the effective lifetime within the space charge region, A_s is the depleted surface area, and A_J is the emitter-junction area. The first term of Eq. [1] represents $h_{FE(max)}$. The second term becomes dominant at low current level and determines low current h_{FE}. Since diffusion length L_{PE} is related to minority carrier lifetime τ_{PE} in the emitter region by

$$L_{PE} = \sqrt{D_{PE}\,\tau_{PE}}$$

$h_{FE(max)}$ and low current h_{FE} of transistors with the same impurity profile are controlled by the minority carrier lifetime in the emitter neutral region and in the emitter-junction space charge region, respectively. Accordingly, the increment in lifetime results in in-

creasing both $h_{FE(max)}$ and low current h_{FE} at the same time.

As shown in Table III, surface recombination velocity S_o is scarcely changed by Si_3N_4 film, but shows a tendency to slightly increase. This tendency is in an opposite direction for increment in h_{FE}. Consequently, the Si_3N_4 film thickness dependence is not caused by the surface recombination, but is a result of the bulk recombination.

The same explanation is also applicable to a pnp transistor. However, because of relatively wide base, base transport factor

$$\frac{1}{2}\left(\frac{W_B}{L_{PB}}\right)^2$$

should be added to Eq. [1], where L_{PB} denotes the hole diffusion length in the base region. Since the base transport factor is inversely proportional to lifetime in a base neutral region, lifetime increase also produces additional $h_{FE(max)}$ for a pnp transistor.

In the case of a silicon p-n junction, reverse current I_R is due to carrier generation in the space charge region and can be represented by

$$I_R = \frac{1}{2} q n_i A_J \frac{W_s}{\tau_o} \qquad [2]$$

where W_s is the junction space charge region width (15). Reverse current is inversely proportional to the lifetime. As shown in Fig. 7-8, the reverse current is reduced to 1/3-1/8 by the deposited Si_3N_4 film. That is, lifetime increases from 3 to 8 times, according to Eq. [2]. Converting the lifetime increase to change in $h_{FE(max)}$, $h_{FE(max)}$ increases to 1.7-2.8 times, because it is proportional to the square root of the lifetime value. This amount is in good agreement with the results illustrated in Fig. 3, 5, and 6. Thus, the film thickness dependence can consistently be explained by assuming the lifetime increment.

Another possible cause of the present effect is the energy gap change due to lattice strain. Since deviation in energy gap changes minority carrier density, p-n junction and transistor characteristics should be affected. However, the effect of the energy gap cannot be considered, for the following reasons.

(*i*) The thermal stress is on the order of 10^6-10^7 dyne/cm^2. According to the investigation reported by Monteith and Wortman (16), the change in the junction current due to energy gap change is only 0.1% for a stress in the order of 10^8 dyne/cm^2. In order to change the stress magnitude in silicon, the back of the wafer was etched down to about 100 μm in thickness. However, no change in h_{FE} was observed. In addition, when the bending stress, which corresponds to the magnitude of the thermal stress, was applied to the silicon wafer scribed into strips, h_{FE} was not changed. For the stress of about 2×10^9 dyne/cm^2, only 10% increase in h_{FE} under compression stress and 5% decrease in h_{FE} under tension stress were observed. This change in h_{FE} would be due to the energy gap change, because the increase or decrease in h_{FE} is observed according to the direction of the stress.

(*ii*) The intrinsic carrier density is considered to be unchanged, because only reverse current depends on Si_3N_4 film thickness and forward current, such as the collector current, does not.

(*iii*) As pointed out by Buhanan (17), the change of $\Delta h_{FE(max)}$ in the maximum current gain due to the change of ΔEg in the energy gap is given by

$$\Delta h_{FE(max)} \propto \exp\left[-\Delta Eg/kT\right]$$

If $h_{FE(max)}$ was increased by the change in the energy gap, temperature dependence should be affected by Si_3N_4 film thickness. However, as shown in Fig. 13, the temperature coefficient of npn transistor is not appreciably influenced.

As mentioned before, h_{FE} is not affected at room temperature by stress which corresponds to thermal stress magnitude. Namely, lattice strain, which is equivalent to that due to thermal stress, has no effect at room temperature on the generation-recombination rate. Since the Si_3N_4 film is deposited at a relatively high temperature of 780°C, heat-treatments seem to play an important role in addition to the reduction of the lattice strain. As shown in Fig. 12, residual lattice strain is observed in thermally oxidized silicon wafers. The existence of the irreversible lattice strain means that silicon wafers are plastically deformed, therefore lattice defects are introduced. Since no impurities are diffused into silicon, the plastic deformation would be caused by the thermal stress.

Lattice defects due to thermal stress could originate generation-recombination centers. therefore they could decrease the minority carrier lifetime. On the other

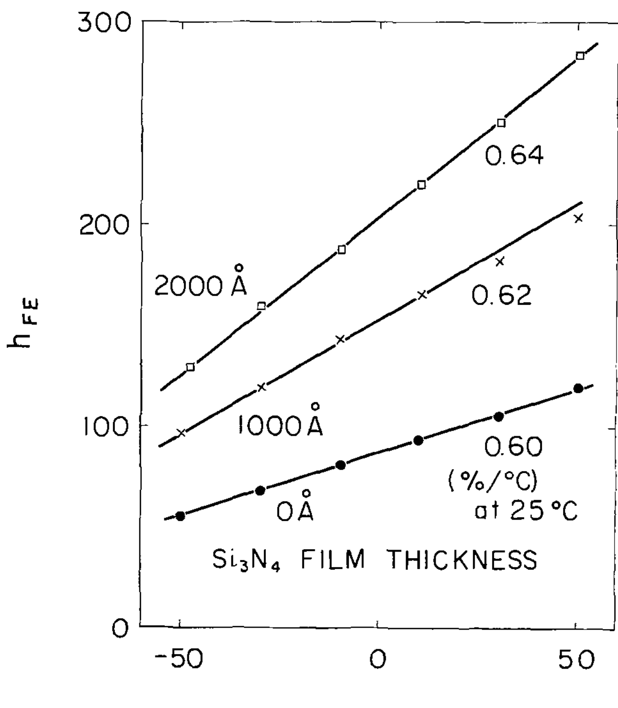

Fig. 13. Temperature dependence of npn transistor $h_{FE(max)}$. Temperature coefficient is not appreciably affected by Si_3N_4 film.

hand, stress compensation by deposited Si_3N_4 film could diminish the defects, because deposition is carried out at a relatively high temperature. As a result, the generation-recombination centers may be decreased and the minority carrier lifetime may be increased. The number of defects reduced by stress compensation would increase as Si_3N_4 film becomes thick and stress in silicon is decreased.

For the degradation of npn transistor characteristics at 2500Å, this seems to result from the heavily doped phosphorus, which forms an emitter region. Because the phosphorus atomic radius is smaller than that of silicon, compressive lattice strain is already induced in the diffused layer (18). Vapor-deposited Si_3N_4 on SiO_2 gives compressive stress to silicon wafers. Therefore, Si_3N_4 tends to increase the strain due to the phosphorus diffusion. As a result, it is considered that the degradation occurs in npn transistors.

Conclusion

It has been found that both $h_{FE(max)}$ and low current h_{FE} increase and 1/f noise and reverse current decrease with increasing film thickness of Si_3N_4 deposited on oxide layer, whose thicknesses are about 6000 and 3000Å on undiffused and diffused regions, respectively. However, these npn transistor characteristics begin to deteriorate when Si_3N_4 film becomes thicker than a certain value, which is *ca.* 2500Å in the present experiment. Film thickness dependence results from lattice strain, which is induced into a silicon wafer by the difference in thermal expansion rates of Si_3N_4, SiO_2, and Si. Lattice strain is reduced as Si_3N_4 film becomes thick. However, it begins to increase in an opposite direction from the thickness which gives zero stress to a silicon wafer. The most improved transistor characteristics are achieved at about this thickness.

It has been verified by the lifetime measurement that transistor characteristics improvements are results of reduction in generation-recombination centers in the bulk due to the relaxation of the lattice strain. The surface recombination is not appreciably affected by deposited Si_3N_4 film.

From the fact that residual lattice strain was observed in thermally oxidized silicon wafers, stress at high temperature seems to easily give rise to lattice defects as well as generation-recombination centers. Moreover, it seems to be essential for reducing generation-recombination centers that silicon lattice not be stressed at high temperature. It has also been found that Al_2O_3 film has a similar effect on transistor characteristics as that of Si_3N_4 film. Therefore, film thickness dependence is not an inherent Si_3N_4 effect, but would be a common effect on films whose thermal expansion rate is larger than that of SiO_2.

Application of the developed process with the optimum Si_3N_4 film thickness to a μA741-type operational amplifier has been proved to be effective in greatly improving d-c and noise properties. That is, input offset voltage and current were successfully reduced down to 328 μV and 1.2 nA in standard deviation, respectively. Input referred noise voltage from d.c. to 10 Hz of 0.25 μVp-p is achieved in typical value.

Process for GaAs Monolithic Integration Applied to Gunn-Effect Logic Circuits

O. Wada, S. Yanagisawa, and H. Takanashi

Fujitsu Laboratories Ltd., 1015 Kamikodanaka, Nakahara-ku, Kawasaki, Japan

ABSTRACT

A new technology based on the orientation dependent chemical etching of GaAs has been developed for simple and reproducible fabrication of monolithically integrated Gunn-effect circuits. By this technology, Schottky barrier gate Gunn-effect devices with fine structures and air-isolated cross-over interconnections can be produced. Using the lateral etching characteristics of H_2SO_4-H_2O_2-H_2O solution, design of the photomasks and the processing conditions are discussed and optimized. Experimental results including the application to a Gunn-effect shift register are demonstrated.

In recent years, several investigators have studied planar Gunn-effect logic devices with Schottky barrier gates to obtain rapid switching speeds (1-4). The AND/OR gates (5) and more complicated functional circuits using these gates have been already proposed (1, 6-8, 13). In order to make these proposals practical, a monolithic integration of Gunn-effect devices on one chip is required. One of the important techniques of fabricating integrated circuits concerns the delineation of fine patterns. The mesa etching technique is used in order to isolate devices. However, this conventional procedure has a disadvantage (9) in the generation of fine contact patterns over mesa steps due to the optical diffraction at the mask edge and its enhancement by the inhomogeneity of photoresist thickness around the mesa step which has a height as large as a few microns. Several remedies (8-12), including the two-plane projection method (8) and the proton bombardment technique (10, 11) have been proposed in order to overcome such a difficulty, but they require special equipment or complicate the whole fabrication process. Another important technique is that for interconnections, especially for cross-over interconnections. These have been achieved so far by the multilayer technique (13) where a dielectric layer such as silicon dioxide is used in order to isolate the upper conductive layer from the lower one, as has been frequently used in silicon technology. However, this technique may cause not only a difficulty in defining a small structure over the mesa step but a large parasitic capacitance between crossing conductive layers.

In this paper, we describe a newly developed technology for GaAs integrated circuits with small geometrical dimensions, which is simpler than those proposed so far and needs no special technique or equipment. In the present method, contacts and interconnections are defined on a flat surface of the substrate as has been done in the completely planar structure (9). The active area is then isolated by chemical etching. Lateral etching under the mask is used in this procedure. This chemical etching technique is also applied to realize a structure of multilevel conductive layers which are air-isolated from each other. In this fabricating method, conventional photolithographic processes can be used and the deposition of intermediate dielectric layers is not necessary. Adding to the simplicity of fabrication, the cross-over structure proposed here has an advantage of small parasitic capacitance between the crossing conductive layers.

In the next section, we describe method to fabricate an integrated circuit. The orientation dependence of chemical etching is described together with the experimental data. The application of this technology to fabricate experimental devices is discussed in the subsequent section.

Key words: Schottky barrier gate, pattern definition, cross-over interconnection, air isolation, parasitic capacitance.

Method

In order to explain the concept of the present integration method, first the process for cross-over interconnections is presented. The process for Gunn-effect devices, which is presented later in this section, can be inserted in this process in the practical fabrication. Figure 1 shows the sequence of process steps for making an air-isolated multilayer structure.

(*i*) First, a metal layer having stripe geometry including windows is formed on a flat surface of GaAs with the (100) plane using conventional photolithographic process.

(*ii*) The epitaxial GaAs layer is removed by chemical etching with the use of the metal layer previously patterned as a protecting mask, thus a few "bridges" are formed. Step (*i*) and (*ii*) can be carried out together with the processes for Gunn-effect devices in the practical fabrication.

(*iii*) A photoresist layer is coated over the metal layer and a stripe window for the crossing metal layer is opened. In this procedure, a positive acting photoresist is used and it is overexposed to be removed under the bridges. Then the evaporation of the metal for the lower conductive layer is carried out using a directional evaporation technique. In this technique the evaporated metal beams are inclined from the substrate surface normal as schematically illustrated in Fig. 2. The angles can be optimized for values of the mesa height and the dimensions of the windows and the bridges of the upper layer.

(*iv*) By lifting off the metal layer deposited on the protecting photoresist layer, the structure of the cross-over interconnection is formed.

As has been suggested above, the lateral etching of GaAs plays an important role in the present technology. In order to use the crystallographic orientation dependence (14-16), the use of an etchant the rate of which is reaction limited is advantageous. Throughout our experiments, $1H_2SO_4$-$8H_2O_2$-$1H_2O$ solution (16) is used at room temperature. This etchant does not attack Al and besides possesses a relatively fast and stable etch rate which is useful for our application where the epitaxial layer has a thickness as large as a few microns. Figure 3 shows the data of the etched distances *vs.* the etching time for various directions of the protecting masks made of SiO_2 stripes. Insets in the figure illustrate the cross sections of the etched holes; the stripe is straight and along (A) the $\langle 011 \rangle$ axis, (B) the $\langle 001 \rangle$ axis and (C) the $\langle 0\bar{1}1 \rangle$ axis, respectively. If the stripe width of the protecting mask is narrow and/or the etching time is long, a tunnel is formed under the stripe, as schematically shown in Fig. 4. In order to obtain appropriate geometries, the mask dimensions and the etching time should be designed using the results of Fig. 3. Examples of parameters for three

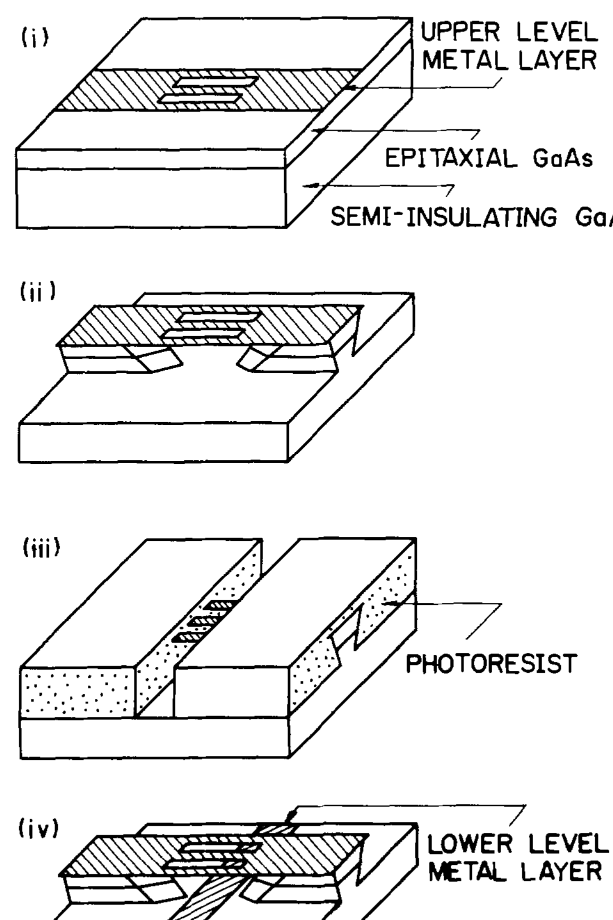

Fig. 1. Schematic illustration showing the process for fabrication of a crossover interconnection: (i) preparation of the upper level metal layer which has a few opening windows; (ii) isolation of the metal layer and formation of a tunnel under the metal layer using the chemical etching technique; (iii) coating of a positive acting photoresist followed by definition of the pattern for the lower level metal layer, and subsequent deposition of the metal using the directional evaporation technique; (iv) removal of the unwanted area of the metal layer by dipping the wafer into acetone. Thus, the structure of an air-isolated cross-over interconnection is formed.

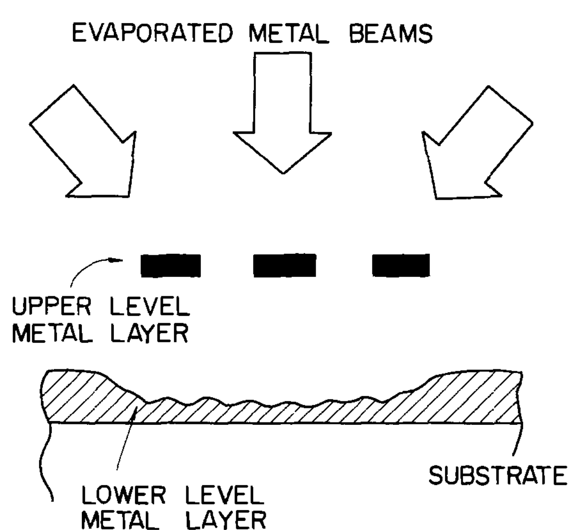

Fig. 2. Schematic representation of the formation of the lower level metal layer for a cross-over interconnection, using the directional evaporation technique. In order to avoid the shadowing effect caused by the upper level metal layer, the evaporated metal beams are inclined.

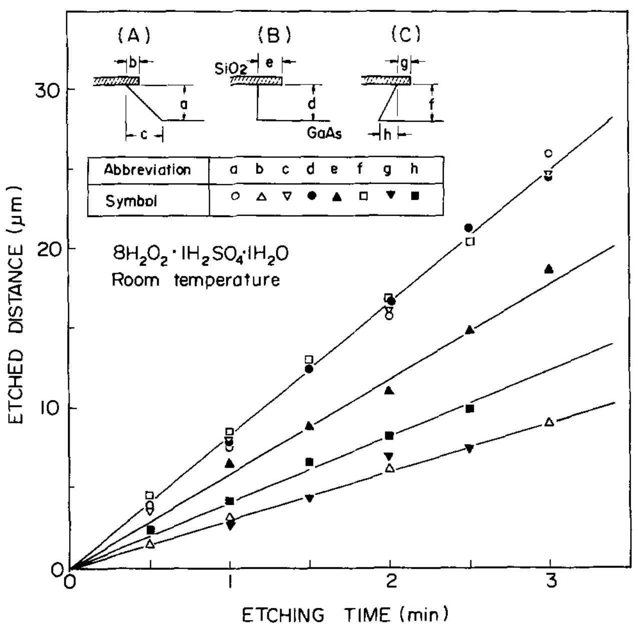

Fig. 3. Dependence of etched distance on the etching time for three directions of the mask edge. The orientation of the initial GaAs is (100). Inset (A) shows the cross section of the etched hole when the mask edge is set along the <011> axis, (B) for the <001>, and (C) for the <01̄1>, respectively.

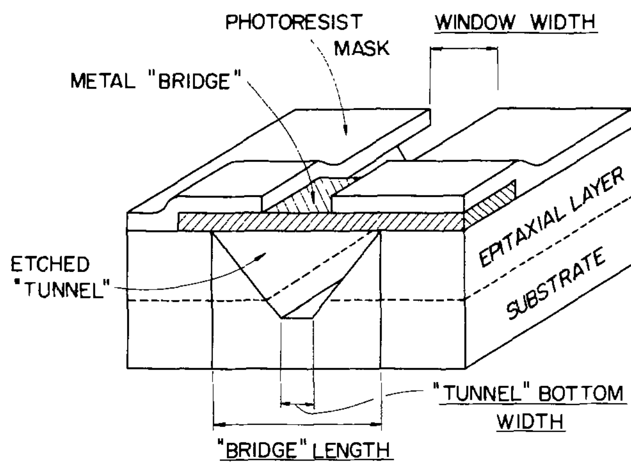

Fig. 4. Diagram showing the bridge structure formed by chemical etching of GaAs. The geometry of the etched tunnel and the bridge length depends on the mask dimensions and the orientation, as discussed in the text.

orientations are listed in Table I. Here, the thickness of the epitaxial layer and the width of the bridge have been assumed to be 5 and 2 μm, respectively. In the Gunn-effect device, as is described in the following, the gate bridge direction is perpendicular to the device current flow. The current flow directions have also been listed in the table for references.

Table I. Effect of crystal orientation on the window width, the etching time needed for the isolation of mesas, and the dimensions of resulted structure. The thickness of the epitaxial layer and the bridge width have been assumed to be 5 and 2 μm, respectively

Current flow direction	Bridge length direction	Min. window width (μm)	Min. etching time (sec)	Min. tunnel bottom width (μm)	Min. bridge length (μm)
<011>	<011>	>0	60	10.6	5.6
<010>	<001>	>0	40	7.2	7.2
<011>	<01̄1>	6.4	40	>0	11

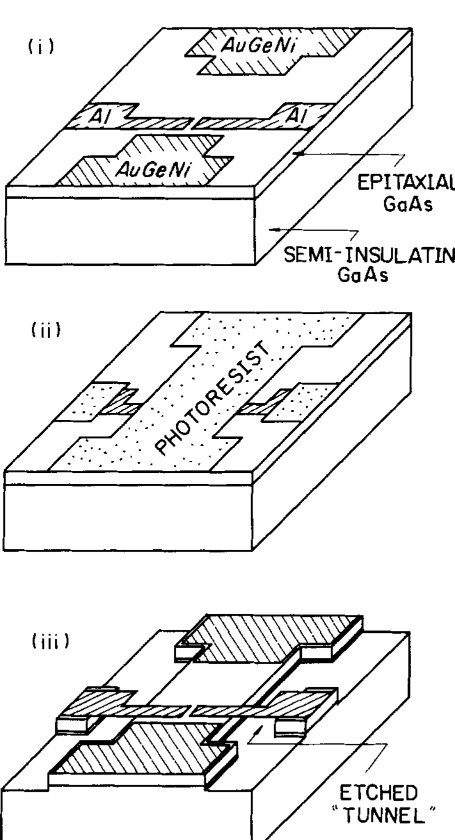

Fig. 5. Schematic illustration showing the process for fabrication of a dual Schottky barrier gate Gunn-effect device: (i) formation of the ohmic and the Schottky barrier contacts on a flat surface of epitaxial GaAs layer; (ii) preparation of the protecting mask for mesa etching using photoresist; (iii) mesa etching of the active area by the chemical etching technique. Thus the active area is isolated by the etched tunnels, and the gate contacts with bridge structures are formed.

Figure 5 separately illustrates the process for a dual-gate Gunn-effect device.

(*i*) The ohmic contacts are prepared by deposition of a 0.2-0.3 μm thick Au-Ge-Ni film followed by delineation and subsequent alloying. The Schottky barrier gate contacts are formed by deposition of 0.4-0.5 μm thick Al film and delineation. Fine patterns can be easily formed because the surface is flat.

(*ii*) The active area and the areas of bonding pads and contact leads excluding small portions of the Al stripes are coated with photoresist.

(*iii*) The uncoated areas of the epitaxial layer are removed by chemical etching. The tunnels produced under the Al bridges isolate the active area from the bonding pads and the contact leads. By removing the photoresist layer, the device structure is produced, in which the gate contacts are connected to the leads through the Al bridges.

These processes can be combined in the procedures (*i*) and (*ii*) of Fig. 1. Subsequent formation of lower conductive layer produces the whole circuit. The present integration technology makes use of the advantage of photolithographic delineation of small patterns on a flat substrate surface. The difficulty caused by the optical diffraction, which is deleterious for a thick photoresist layer particularly around the periphery of step on the substrate, can be avoided in the present method.

Results and Discussion

We have examined fabricated devices using two of the current directions. Figure 6 shows the scanning electron micrographs of the fabricated devices. Figure 6(a) shows the scanning electron micrograph of a device structure the current direction of which is set

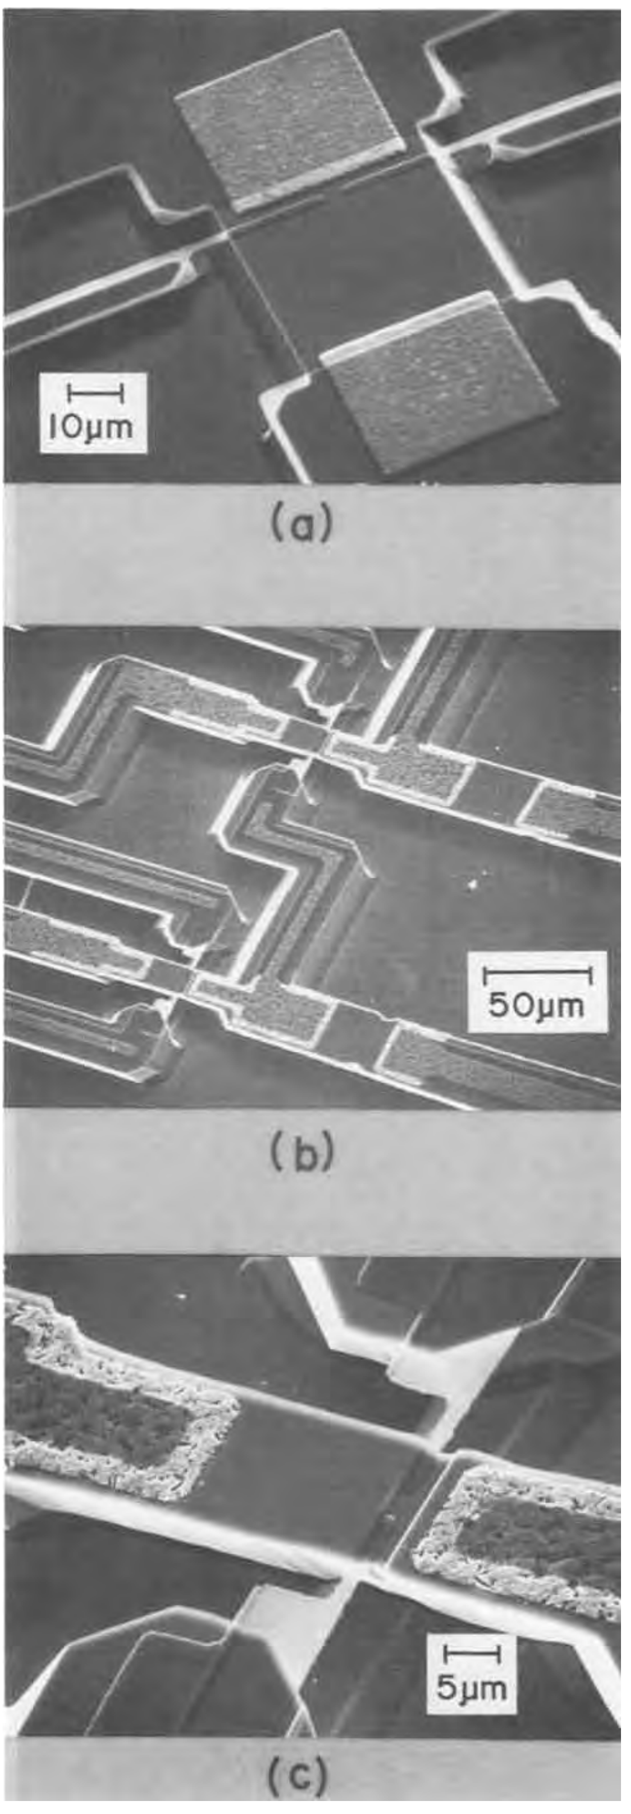

Fig. 6. Scanning electron micrographs showing a Gunn-effect unit device and an integrated circuit: (a) shows a unit device fabricated with the selection of the current flow direction along the <011>; (b) and (c) show a part of a Gunn-effect shift register circuit and a constituent unit device fabricated with the selection of the current flow direction along the <$0\bar{1}1$>.

along the <011> axis. It is worth noticing that a self-stopping effect (17) of etching may occur for this current flow direction. When the window width is excessively small, the appearance of (111) planes on the side walls makes the etched hole structure a V-shaped groove, because of the slowest etch rate of the (111) plane (16). This phenomenon drastically decreases the etch rate in the depth direction, and therefore it is difficult to remove the epitaxial layer completely at the groove bottom. In order to avoid this self-stopping effect, the window width has been designed to be larger than the minimum value as given in Table I. Fine geometry having gate contacts with bridge structures has been formed: the gate length is 2 μm in this case. When the current direction is selected along the <0$\bar{1}$1> axis, there is no restriction for the window width. With this orientation, the etching time should be longer than for other directions. However, the resulting structure has a small bridge length and a large tunnel bottom width. This results in a large mechanical strength and a good electrical isolation. We fabricated a 2 bit Gunn-effect dynamic shift register (18) composed of seven dual gate Gunn-effect devices and seven resistors. Figure 6(b) shows an example of the scanning electron micrograph of the shift register. Figure 6(c) shows the detail of a unit device. The thickness of the epitaxial layer is 3.5 μm, the gate-anode separation is 25 μm. A gate length of only 2 μm has been obtained regardless of the large height of the mesa step.

Another advantage of the present fabrication method is that good electrical characteristics of the contacts can be obtained. It has been reported (19, 20) that a Schottky barrier with the metal deposited at room temperature sometimes shows a poor characteristic. In the case where Al is used, the characteristics can be improved by heating the substrate during or after the metal deposition (20). Taking account of the homogeneity of characteristics of the barriers over the wafer and the reproducibility, the heating during deposition is more useful. This procedure can easily be carried out in the present fabrication method, on the contrary it is prevented from being carried out when the lift off technique (21) is used. By making use of this advantage of the present method, we have made Schottky barrier gate contacts with ideality factors (n-values) better than 1.07. Concerning the dynamic characteristics of the circuits as shown in Fig. 6, we have succeeded in obtaining CW operations of dynamic shift registers with clock rates of 1.6 GHz and 2.7 GHz (18, 22). Figure 7 shows an example of the observed waveforms with the clock rate of 2.7 GHz; a two-bit shift of the signal is shown. The detailed discussions on performances and applications of the shift registers will be given shortly elsewhere.

Although we have not used the cross-over interconnections on the present level of the circuit integration, the integration of higher level inevitably needs these structures. To confirm the usefulness of the present technology, we have carried out experiments to realize cross-overs. The direction of the upper metal stripe is set parallel to <0$\bar{1}$1> axis. With this orientation, a tunnel with a flat bottom surface is obtained by etching of the epitaxial layer as schematically shown in Fig. 1 (*ii*). In the subsequent photolithographic process to make a protecting mask for the deposition of the lower metal layer, the photoresist layer is removed completely even under the bridges, using the overexposure technique. In order to know how long the exposure time should be, measurements were made on the dimensions of the residual region of the photoresist (Shipley 1350J) after development, the data of which are shown in Fig. 8. The overexposure has been carried out with an intimately contacted photomask using a conventional exposure apparatus. As is observed in the figure, if the thickness of the photoresist is 10 μm for example, 30 min exposure is necessary to wash out the photoresist under the bridge

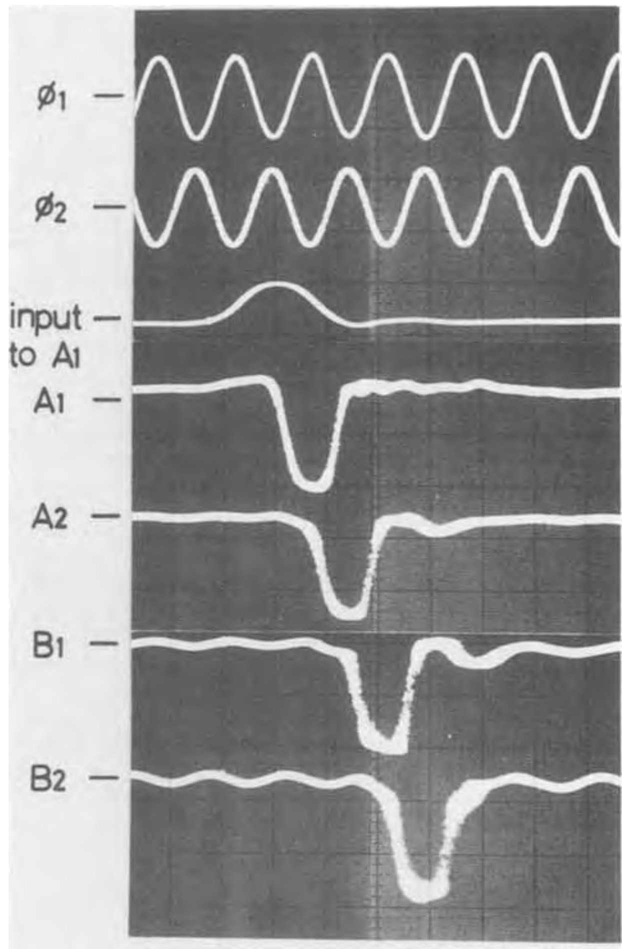

Fig. 7. Waveforms obtained by a shift register. Upper two traces (ϕ1 and ϕ2) are the clock pulses, the middle one is the input to the first device and the lower four (A_1-B_2) are the outputs of the following devices. A two-bit shift of the input signal synchronizing to the clock pulses is shown. The clock rate is 2.7 GHz and the constituent devices are biased by the subthreshold d-c voltages. Vertical scale is 2 mA/div., horizontal scale is 250 ps/div.

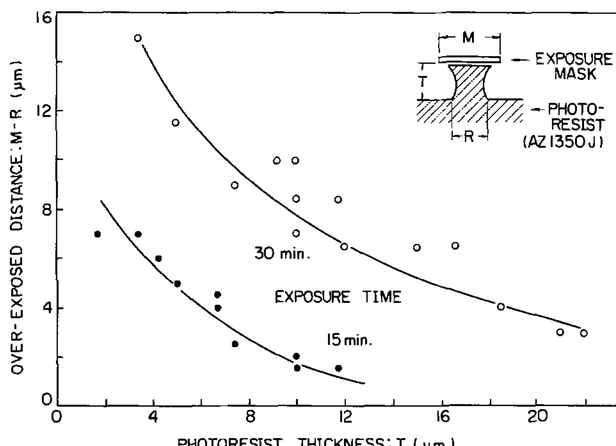

Fig. 8. Reduction of the width of the photoresist pattern after overexposure as a function of the photoresist thickness for two exposure times as parameters.

with 8 μm width. The exposure time can be reduced down to 15 min when the bridge width is decreased down to 2 μm. Relatively small bridge width is advantageous for the continuity of the lower conductive layer, as far as a sufficient mechanical strength is preserved. In our experiment, the bridge width has been fixed to be 5 μm. Figure 9(a) shows an example of the

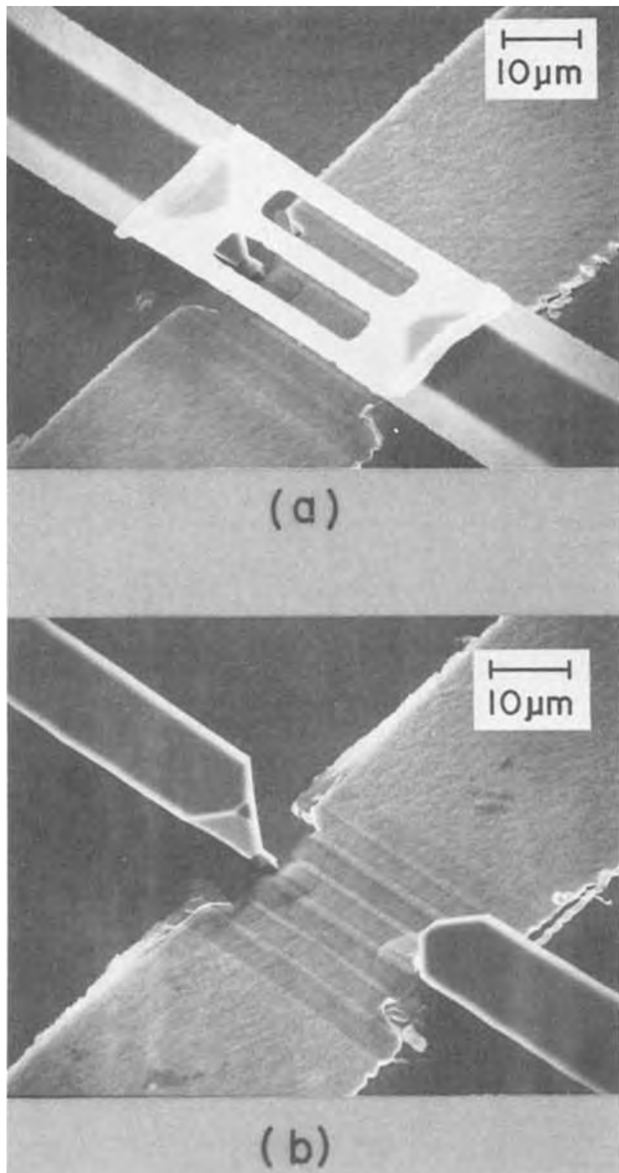

Fig. 9. Scanning electron micrographs showing an air-isolated cross-over interconnection; (a) the view of as-fabricated structure; (b) the view of structure after removal of the upper level metal layer. Note that the lower layer is continuous under the upper layer and isolated from the epitaxial layer.

produced structure. The mesa height is 10 μm and the widths of the upper and the lower conductive layer are 25 and 50 μm, respectively and the thicknesses of layers are about 4000Å. Figure 9(b) shows the structure after only the upper metal layer has been etched away, to demonstrate that the lower layer is continuous along the length and at the same time isolated from epitaxial layers. A complete isolation has also been confirmed by electrical measurement. Concerning the mechanical strength of the bridge structure, it has been observed that no sample having this structure is broken by the usual processing treatment, for example, ultrasonic bonding.

The elimination of depositing insulator films simplifies the process. Moreover, it is worth noticing that the resulting structure has a very small parasitic capacitance compared to the multiple layer structure with an insulator film. Only devices with negligible small parasitic capacitances can take full advantage of the fast response, which is one of the most important characteristics of Gunn-effect devices, and eliminate the possibility of cross-talk or other erroneous operations. For example, the parasitic capacitance of the structure shown in Fig. 9 is only 0.001 pF, which is about a hundred times smaller than that obtained by a multilayer structure having a 5000Å thick SiO_2 layer and conductive layers with dimensions same as those in Fig. 9. This small value can be neglected compared with the gate input capacitance of the usual device of the order of 0.01 pF. The occurrence of resistive/capacitive losses due to the Schottky barrier capacitance between the upper conductive layer and the n-GaAs layer is also avoidable by using an intermediate ohmic contact layer, as has been carried out in Fig. 6(b).

Usually the lower conductive layer is connected at its end to one of the contacts of a unit device each of which lies on the upper level. For this purpose, the lower conductive layer should be transferred to the upper level across the mesa step. However, this procedure is carried out simultaneously in the last process step for the formation of lower conductive layers, and a high yield of the photolithographic process can be obtained due to relatively large widths of lower conductive layers.

Conclusions

We have introduced a new technology of fabricating Schottky barrier gate Gunn-effect device and cross-over interconnection, both of which are important in a monolithically integrated Gunn-effect circuit. We can produce the unit Gunn-effect devices and the upper interconnections by first forming fine contact patterns on a flat surface of epitaxial layer and then isolating the active area by the chemical etching technique. Finally, the lower conductive layer is formed by the directional evaporation technique. The fabrication of monolithically integrated circuits with fine structures and good electrical characteristics can be achieved by the present technology. It has been confirmed experimentally that the present processes can easily be carried out with no sophisticated instrumentation as, for example, required by the proton bombardment technique. In the course of our work, we have succeeded in fabricating a Gunn-effect shift register with a clock rate of 2.7 GHz by applying this technology in forming unit devices. In addition, the small parasitic capacitance obtained by our method is considered to be useful for other semiconductor integrated circuits.

The Nature of Defects in Silicon Dioxide

A. K. Zakzouk,[1] R. A. Stuart, and W. Eccleston

Department of Electrical Engineering and Electronics, University of Liverpool, Liverpool L69 3BX, England

ABSTRACT

Localized conducting regions of silicon dioxide are a major source of failure of integrated circuits. By using liquid crystals in contact with the oxide, and simultaneously applying an electric field across such a sandwich structure, defective regions can be nondestructively identified. By examining the number of defects as a function of the polarity of the applied voltage, and time, it is possible to obtain information on the cause and nature of these localized regions of high conduction. Experiments of this type indicate that defects are frequently caused by imperfections in the silicon substrate and a model is proposed which accounts qualitatively for the results obtained with liquid crystal present.

Thin dielectric films are widely used in the electronics industry. One of the most important applications of such films is in planar technology. Silicon dioxide, silicon nitride, and alumina are the most widely used materials and each has its own set of advantages, particularly when used as an integral part of the gate dielectric of metal oxide semiconductor transistors (MOST). Silicon nitride and alumina are particularly impervious to the migration of sodium and proton ions, unlike silicon dioxide. These ions can give rise to instability in the threshold voltage of MOST devices. Silicon dioxide is still very widely used, however, because thin (1000Å) films can be produced by thermal oxidation of the silicon, providing a semiconductor-insulator interface which is relatively free from surface states. The thin films produced by thermal oxidation are dense and when free from "defects" pass negligibly small currents for the range of electric fields commonly found with MOS transistors. Oxide "defects" do occur in sufficient numbers, however, to cause unreliability in large scale integrated circuits. The failure of circuits may be due to either catastrophic breakdown, or high conduction in the dielectric. The problem is not restricted to conventional MOS circuits, but is also important in both charge coupled devices and bipolar transistor circuits.

Pinholes may be one possible cause of high conduction and are due in many cases to either contamination of the underlying silicon substrate or imperfections in photoengraving masks. High conduction is also found in the absence of pinholes and this is more difficult to explain. The study of defects of this type has been made more difficult, in the past, by the lack of availability of a nondestructive technique for locating them. Kern (1) has reviewed the currently available techniques. Keen (2) has shown that negative nematic crystals provide a good nondestructive method for locating defects in insulating layers. This technique has been studied in more detail by the present authors (3) and is the subject of this publication. DiStefano (4) has used photoemission measurements to show that a highly localized reduction of the silicon-silicon dioxide barrier can occur, particularly after contamination of the oxide by impurity ions such as sodium. The barrier is lower after applying an electric field across the oxide which drives the impurity ions to the silicon surface. Williams *et al.* (5) have suggested that the cause of the localized barrier lowering is a condensation of sodium ions at particular points on the silicon surface. The potential energy of a particular ion is shown to be lower when it is situated near to a metallic-like surface. An accumulated silicon surface approximates such a surface and the positive sodium ions will induce such a surface condition. This effect promotes the condensation and would be expected to produce the highly localized barrier lowering described by DiStefano.

Raider (6) has demonstrated that sodium drift can be responsible for time-dependent breakdowns, presumably due to electron injection into the film at localized regions where the barrier is lowered. Chou and Eldridge (7) have studied the dependence of breakdown on processing parameters and this has been followed by a large amount of work on the effect of sodium on conduction and breakdown (8, 9), all of which must ultimately be fitted into any general theory of oxide conduction and breakdown.

Conduction has been studied in oxides with, presumably, minimal amounts of barrier lowering, by Lenzlinger and Snow (10). Their results, obtained on MOS capacitor structures, indicate that conduction is primarily limited by Fowler-Nordheim tunneling either from the metal or silicon into the oxide. Osburn and Weitzman (11) have arrived at similar conclusions, but also indicate the importance of mobile ions and trapping phenomena in the conduction process.

The Liquid Crystal Technique

With this technique, the thermally oxidized slice is covered by a drop of liquid crystal which is then

Key words: integrated circuit testing, liquid crystals, oxide defects density, field, thickness dependence.

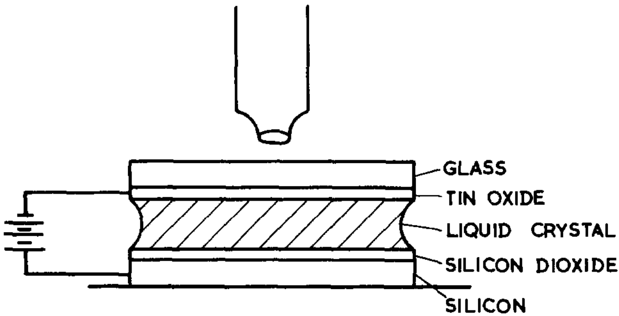

Fig. 1. The apparatus used for the study of oxide defects with liquid crystal. No spacers are necessary since the tin oxide coated glass plate is supported by the liquid crystal film.

placed beneath a tin oxide coated glass slide as shown in Fig. 1. The highly insulating nature of the silicon dioxide prevents the passage of large currents through the liquid crystal. Wherever the silicon dioxide is conducting, however, turbulence is seen in the liquid crystal. The thickness of the liquid crystal layer, under the weight of the glass slide, can be reduced to about 10 μm and this is the diameter of the area of turbulence seen through the microscope. The turbulence effect is known as dynamic scattering and has been discussed by Heilmeier *et al.* (12) and DeGennes (13). The process by which it occurs is by no means certain. The following discussion would appear to represent a consensus view of the process and is the basis of our understanding of the effect when used for locating defects.

We consider an arrangement similar to that shown in Fig. 1, with the oxidized silicon slice replaced by a simple conducting electrode. The liquid crystal molecules, under the action of the applied field, align themselves parallel to the plates. This is due to the presence of a dipole, on each molecule, at right angles to the long axis of the molecule. The molecules, being neutral over-all, cannot provide a d-c current. If they absorb a water molecule, however, they can accept an electron from the negative electrode, move to the positive electrode under the action of the electric field, and there become discharged. A d-c current then passes through the liquid. As the molecule carrying the electron drifts through the liquid medium, molecules on either side rotate because of the electrostatic force on their dipoles. This turbulence causes a change of refractive index and can therefore be clearly seen through the microscope. If the negative electrode is providing electrons to the liquid crystal molecules uniformly over its area, the resultant torque on other molecules is zero and no turbulence is expected. Because of statistical variation in the rate of release of ions, no detailed balance in torque occurs and turbulence is seen.

When one of the electrodes has an insulating layer on its surface, conduction occurs in the liquid crystal in those places where high conduction in the insulating layer due to defects is present. The torque on the liquid crystal molecules in the region of the conducting defect is then particularly strong because of the large variation in the release of charged liquid crystal molecules at the defect compared with those regions of good insulator around it. The effect has been discussed by Keen (2), but has not been the subject of extensive quantitative study.

Fabrication of Samples

All the results described here, unless otherwise stated, were obtained on (111) n-type silicon. The silicon was initially degreased and was then boiled in nitric acid, followed by treatment in hydrofluoric acid, before washing in deionized water. The oxidation was carried out in dry oxygen at 1000°C for sufficient lengths of time to produce 1000 to 5000Å thick films. The furnace was resistance heated and the silicon slices were contained on a quartz boat in a single wall quartz tube. All the oxidations were carried out with the slices horizontal, fully supported by the quartz boat. This minimizes the stress on the silicon during oxidation and cooling.

In many cases this procedure was preceded by steam oxidation of the silicon. Using conventional photolithography, small windows were etched in the "steam" oxide and the thin "dry" oxide was grown in the windows. This procedure was carried out to facilitate precise location of a particular region of oxide during the experiments and to simulate typical processing steps of MOS and charge coupled device oxides. The oxide was removed from the rear of the slice and this was placed in contact with an aluminum plate. A small amount of the nematic liquid crystal (p-methoxybenzylidene-p-n butyl-aniline) was then placed on the top of the oxidized surface of the slice, and the apparatus was set up as shown in Fig. 1.

Initial Experiments

Voltages of both polarity were applied to the tin oxide and the samples were observed for long periods of time. With negative bias on the tin oxide, very few turbulent regions were seen. The oxide itself showed faults in these regions when viewed without liquid crystal, and it is believed that these regions are pinholes presumably caused by contamination during the oxidation process. We shall, henceforth, refer to these as type I defects. Figure 2a shows a type I defect.

With positive bias applied to the tin oxide, many more defects were seen, although type I defects are still present. We shall refer to those defects occurring under positive bias only as type II defects. Figure 2b shows the appearance of a sample after applying positive bias to the tin oxide. Figure 2c shows the same region of oxide sometime later. Both Fig. 2a and b show the type I defect present in Fig. 2a. There is also, clearly, an increase in the number of type II defects with time.

Figure 3 shows the way in which the density of defects increases with time for two films of thickness 0.1 and 0.19 μm. In both cases (curves A and C), the number of defects saturates with time. If negative bias is applied to the top electrode, only type I defects are visible, but on subsequent positive biasing the number of type II defects is initially reduced. However, after a further time has elapsed the defect density rises above its earlier value and ultimately saturates (curves B and D).

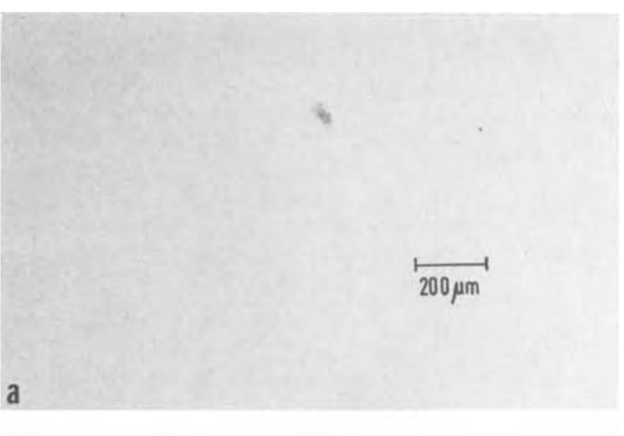
On one sample, which had scratches in the silicon, lines of type II defects were seen along the scratches. In addition, defects occurred preferentially at the points of intersection of thick and thin oxide. At these points there is a ledge in the silicon due to silicon having been removed inside the window during the second oxidation process. This effect is clearly indicated in Fig. 4.

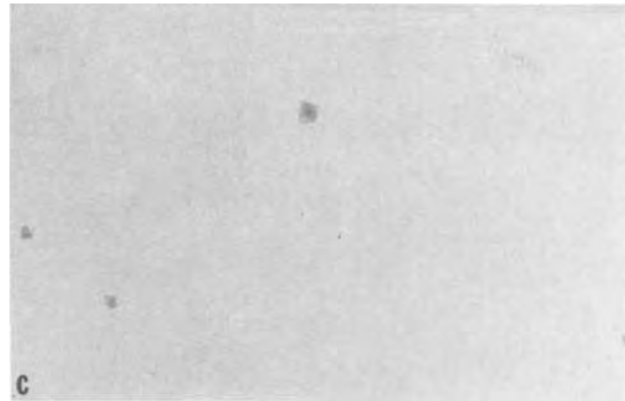
It was found also that the number of type II defects was not significantly affected by the presence of diffused p-type region in the surface of the silicon.

In general, type II defects are not visible as oxide flaws using optical microscopy.

Discussion of Initial Experiments

Three features of the initial results require explanation: the polarity and time dependence of the density of defects and the marked increase in density as a result of negative voltage on the tin oxide. It is conceivable that type II defects are submicroscopic pinholes. Their polarity dependence could then be due to a difference in the heights of the silicon-liquid crystal barrier and the tin oxide-liquid crystal barrier. This would appear not to be the case, however, since larger oxide pinhole defects are visible under both polarities. Measurements have been made on silicon slices of the variation of current with applied voltage, without an





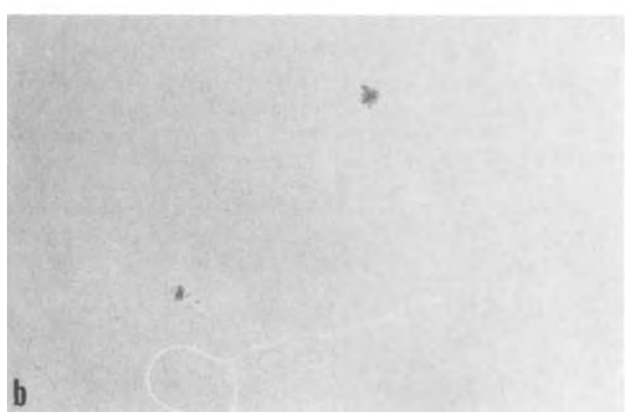


Fig. 2. (a) The appearance of a region of oxide with a negative voltage applied to the tin oxide. A type I defect is present (applied voltage —40V). (b) After reversal of the polarity of the applied voltage, more defects are seen, but type I defects are still present (applied voltage +40V). (c) After 10 min the density of type II defects has increased considerably.

oxide film, and no strong polarity dependence is seen. Figure 5 shows typical curves and can be compared with Fig. 6, for the situation where an oxide film is present, and a strong polarity dependence is present. It seems, therefore, that if type II defects are pinholes, then barrier height differences are not primarily responsible for their polarity dependence. This is in agreement with the earlier work of Heilmeier *et al.* for a wider variety of metal electrodes.

The tendency for type II defects to be distributed along ledges in the silicon indicates the importance of silicon imperfections in these phenomena. We suggest a simple model which would appear to account qualitatively for the initial results. Consider first the processes occurring in a typical oxide film free from defects when placed in the apparatus shown in Fig. 1. The charge motion is shown schematically in Fig. 7a. Electrons tunnel through the barrier from the conduction band of the silicon and then move through the oxide. At the outer surface of the oxide they attach themselves to liquid crystal molecules and are then transported to the positive anode where the molecules are discharged. During the application of the positive voltage any scratches or similar discontinuities act as points of field intensification and positve impurity ions in the film condense at these points. This, together with the field intensification due to the geometry of the irregularities, causes barrier lowering. Since the height of the barrier primarily controls the current, the current increases. Because of the relatively high mobility of electrons in the silicon dioxide, the barrier can be reduced by a large amount before the conduction becomes bulk limited. Presumably, the current ultimately becomes limited by some form of Poole-Frenkel conduction. As positive charge enters the regions of field intensification by diffusion from other parts of the film, one would expect the current and, hence, size of the turbulence to increase. Ultimately the total number of defects seen will saturate, either due to the number of available impurity ions becoming exhausted, or when all the available silicon sites are producing turbulence. Figure 3, curves A and C, would appear to indicate that saturation occurs after approximately 5 and 15 min, respectively. On applying negative voltage to the tin oxide, the positive ions are removed from the region of the silicon surface and geometrical effects cause the positive ions to spread out into the oxide. No turbulence is now present in the liquid crystal indicating that all the voltage is now falling across the oxide. It is well documented that such a high field causes the release, by tunneling, of electrons from traps in the oxide. The tunneling process involves no change of electron energy and the traps must therefore have energies coincident with the conduction band in the presence of the applied field for charge to transfer to the conduction band. Positive charge is created in the oxide. On returning to positive voltage on the tin oxide, the number of turbulences would be expected to be initially small. Impurity ions condense with the lapse of time and gradually the number of defects increases. The total positive charge is now due to not only impurity ions but also the ionized traps obtained through the previous application of negative bias to the tin oxide. It is not surprising that curves B and D of Fig. 3 show an increased number of turbulences since some smaller defects may now have sufficient positive charge surrounding them to produce large enough electron currents for them to become visible.

The model proposed would appear to be the simplest capable of explaining the present observations. If correct, it leads to further deductions about the behavior of oxides when viewed by this method. Since curves A and C show quite definite saturation, we are forced to deduce that we are primarily limited by the concentration of impurity ions in the oxide. Curves B and D indicate that more silicon imperfections are present in the sample than are shown in A and C. In view of the comparatively large amount

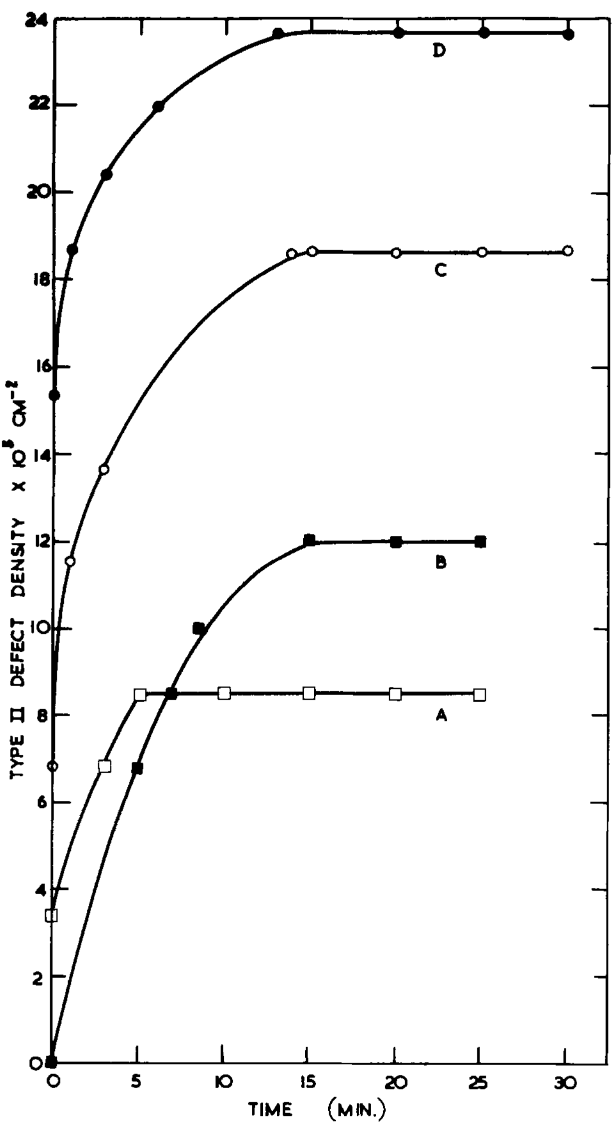

Fig. 3. Curve A shows the density of type II defects as a function of time. The tin oxide is positive and applied field is 1.6 MV cm^{-1}. The silicon oxide thickness is 0.19 μm. Curve B was obtained on the same sample, but after biasing the tin oxide negatively for 35 min with a field of 1.6 MV cm^{-1}. Curve C was obtained in a similar way to Curve A for an oxide of 0.1 μm thickness. Curve D was obtained in a similar way to curve B but is far the thinner oxide of curve C.

of liquid crystal in contact with the slice of silicon, it seems unlikely that the liquid is the source of impurity ions.

It has been suggested by a number of workers that imperfections could be due to crystalline regions of silicon dioxide. While the above model does not require crystallization, it does not preclude this as being a factor.

Further Experiments and Discussions

The above model depends primarily on the occurrence of field intensification at irregularities in the silicon. This is based on the fact that defects have been found to align on scratches on one sample and the higher concentration of turbulences seen at ledges in the silicon. It is clearly necessary to examine the region of a turbulence away from known irregularities in the substrate. Precise location of the center of a turbulent region is difficult, but in every case examined to date a turbulence has coincided with a silicon irregularity on scanning electron microscope pictures. It is not possible at present to give information on the cause of these irregularities since they

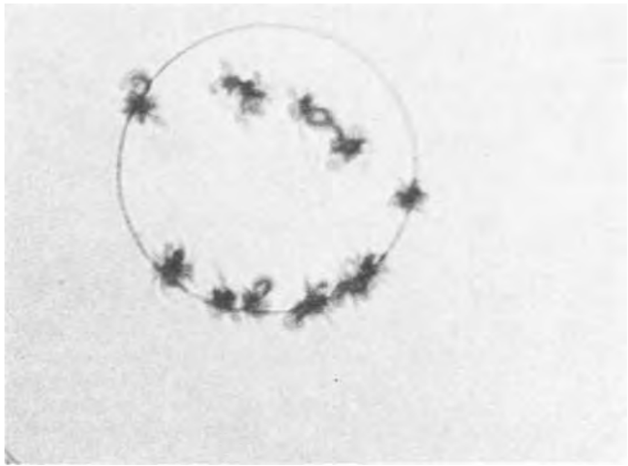

Fig. 4. After opening windows in the thick oxide, the dry oxide was grown. This thin oxide is contained within the circular area. It can be clearly seen that type II defects occur preferentially at the intersection of thin and thick oxides where a ledge in the silicon is situated (circle diameter = 168 μm).

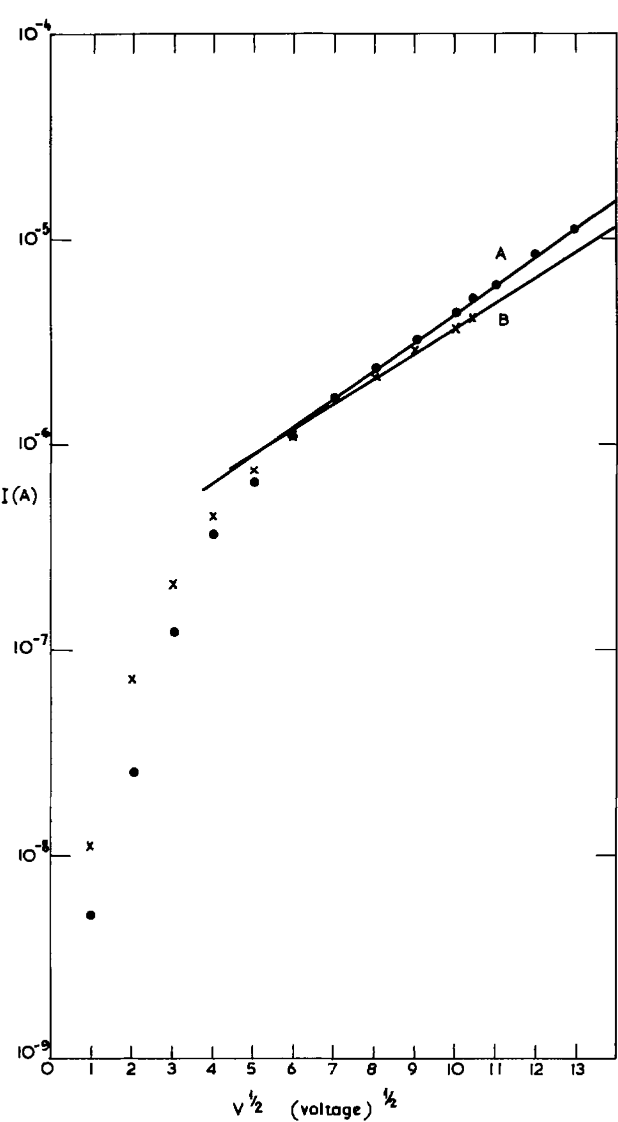

Fig. 5. Current-voltage characteristics of the cell with unoxidized silicon as one of the electrodes. Very little polarity dependence is seen. Curve A corresponds to the tin oxide positive, curve B with its negative. These results are in agreement with those given by Heilmeier *et al.* (12).

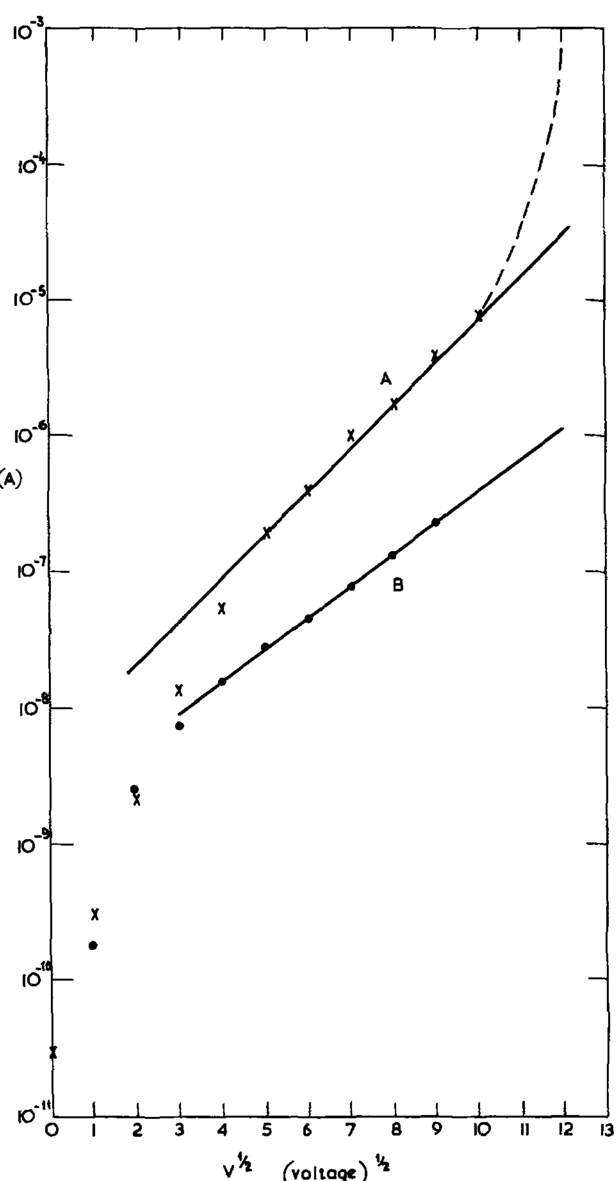

Fig. 6. Current-voltage characteristics of the cell with oxidized silicon and type II turbulences present. Curve A corresponds to the oxide positive, B to its negative. These results correspond to current densities approximately $\times 10^{-3}$ less than those of Fig. 5.

can be of several forms, *e.g.*, hillocks, etch pits, etc. In addition, when turbulence is seen on a silicon ledge as shown in Fig. 4, a very steep portion of the ledge is always present in the region of this turbulence.

A point of practical importance is the variation of defect density with oxide thickness and electric field. Figure 8 shows the variation of defect density as a function of oxide thickness for fields of 2 MV/cm, 3 MV/cm, and 4 MV/cm. Between 0.2 and 0.6 μm the defect density D varies according to the expression

$$D = D_0 \exp\left(\frac{-x_0}{L}\right)$$

where D_0 is a constant which is strongly dependent on the applied field. L is a constant which is field independent and has a value of almost exactly 0.1 μm. At thickness less than 0.2 μm, the defect density increases very rapidly.

We have noted that the current through a defect can depend on either the Fowler-Nordheim tunneling or, when the barrier is significantly reduced, on bulk conduction presumably by some form of Poole-Frenkel conduction. Neither of these phenomena would be expected to give a very strong dependence of density

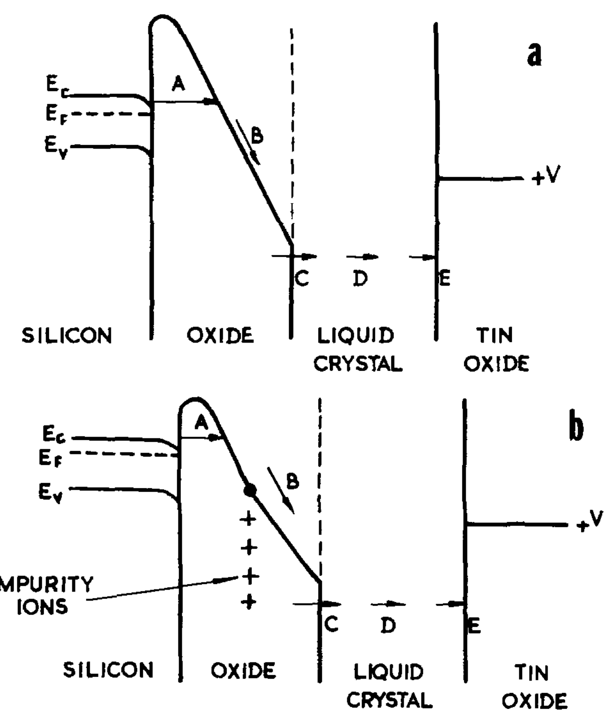

Fig. 7. (a) Diagram of the various conduction processes in the cell without impurities ions present. A is the Fowler-Nordheim process, B is presumed to be Poole-Frenkel bulk conduction, C is the transfer of electrons to liquid crystal molecules, D is the ionic conduction in the liquid crystal, and E the discharge at the positive tin oxide electrode. (b) Shows the same processes as A with additional barrier lowering due to field intensification and mobile impurity ions. In both (a) and (b) the conduction is probably limited by the barrier height (process A).

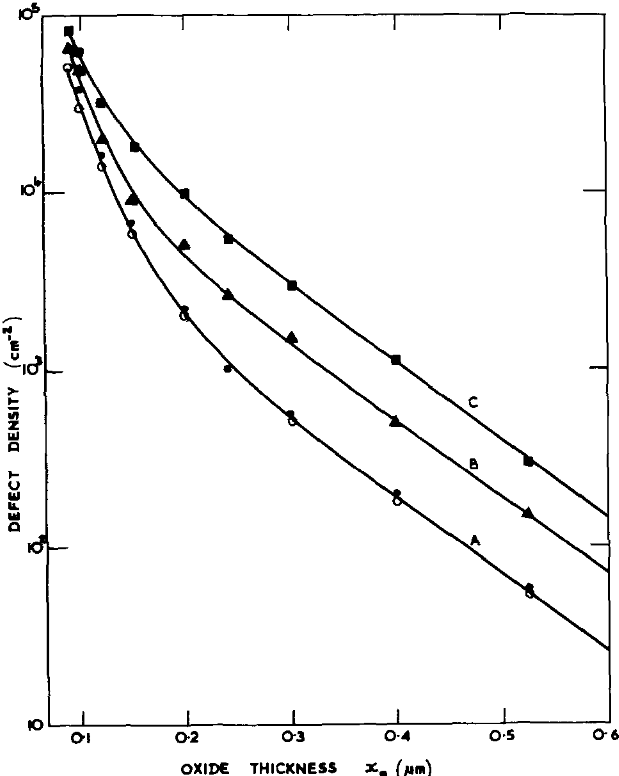

Fig. 8. The density of type II defects a a function of oxide thickness for various field values. Curves A, B, and C were obtained for field values of 2, 3, and 4 MV cm^{-1}, respectively.

of turbulences on thickness for a given value of applied field. The field values quoted do not represent

the actual field experienced by the barrier since superimposed on the applied field is that due to the presence of positive charge in the oxide. This charge is, of course, accumulated very close to the silicon and under steady-state conditions its distribution is determined by the balance between the electric field at any point, which holds the charge near the silicon, and diffusion which counterbalances this effect. Calculations indicate that for a reasonable density of charge all the impurity ions are contained within a distance of a few angstroms from the silicon-silicon dioxide interface so that in the majority of the oxide the field is equal to the applied voltage divided by the oxide thickness. It is not possible without further measurements to explain the thickness dependence of defect density shown in Fig. 8. The result is presented here because of its practical importance in the design of MOS and CCD devices.

Summary

Measurements have been performed on oxide conduction in thin layers of silicon dioxide grown in dry oxygen. The liquid crystal technique has been shown to be a valuable nondestructive technique for studying the behavior of oxide defects as a function of applied voltage and the polarity of this voltage. Two types of defect have been found. Type I defects are probably pinholes and have a very low density. Type II defects occur only under positive bias (on the tin oxide) and show a complex dependence of density on time. By cycling the voltage between positive and negative, it has been possible to suggest a simple qualitative model for the behavior of defects which would seem to be associated with physical irregularities in the silicon.

The model developed depends on the cooperative effects of impurity ions and slow trapping. It suggests that devices will be subject to failure from oxide defects for either type of polarity.

Acknowledgments

We would like to thank Professor J. H. Leck for the provision of facilities and Mr. N. M. St. J. Murphy for useful discussions. Thanks are also due to Mr. J. M. Keen of RRE Malvern for interesting us in the potentialities of the liquid crystal technique and for useful discussions.

ABSTRACT

A new paint-on diffusion source has been developed utilizing chemically stable polymethylsiloxane resins, n-butylacetate as a solvent, and dopant compounds such as carborane polymers for boron, triphenylphosphate for phosphorus, and $As[O\ Si(C_6H_5)_2O]_3As$ for arsenic. These paint-on diffusion sources were spun on silicon wafers by conventional photoresist spinners. Ozone was used at 200°C for the decomposition of paint-on diffusion sources into doped oxide films. Doped oxide densifications or diffusions were performed in the same furnace tube as the decomposition in order to prevent the moisture absorption of the undensified doped oxide. Doped oxide diffusions yielded average sheet resistances with standard deviations of 1.71% for boron and 1.65% for arsenic.

Paint-on diffusion sources offer an economic and simple method of introducing dopants into semiconductors (1-4). Previously, paint-on diffusion sources consisted of acyloxysilanes, monomeric dopant compounds, and solvents. Results of spin-on doped polymers were also reported (5), but composition and processing of such spin-on doped polymers were not disclosed. As acyloxysilanes easily decompose into SiO_2 at low temperatures (3), the change from an organic acyloxysilane into SiO_2 can be achieved by a low temperature heating step. However, the thermal instability of acyloxysilanes causes the difficulty of maintaining a sufficient long shelf-life for paint-on diffusion sources consisting of acyloxysilanes. In the absence of any polymeric compounds, the surface tension of paint-on diffusion sources depends on the weight ratio of solvent, acyloxysilane, and dopant compound. Since the surface tension is low for monomeric solutions in comparison to polymeric solutions, it is difficult to obtain thick paint-on source film layers for monomeric solutions by using a single step spinning process on a conventional photoresist spinner.

In order to develop a paint-on diffusion source that would provide a liquid solution with a high chemical stability and a sufficient surface tension, solutions of silicone polymers such as polydialkylsiloxanes and polyalkyl resins were investigated. The siloxanes are known to be chemically stable and not humidity sensitive at room temperature (6). Only at elevated tem-

peratures above 250°C in the presence of O_2 does a change occur in the chemical composition of silicone polymers (7). Because of the high thermal stability of silicones in comparison to acyloxysilanes, a new processing technique had to be developed for paint-on diffusion sources containing silicones.

Experimental

The complete removal of organic groups attached to silicone polymers can be accomplished by a heat-treatment in O_2 above 600°C (6, 7), by oxidation in ozone above 150°C, or in atomic oxygen at room temperature. After spinning of the paint-on diffusion source on silicon substrates, O_2 decomposition above 600°C caused slight pitting on the silicon surface; whereas during ozone and atomic oxygen decomposition, the silicon surface was not attacked. After ozone and atomic oxygen decomposition, the original paint-on diffusion source film changed from a polysiloxane into a porous SiO_2. This porosity of SiO_2 is advantageous for the complete removal of organic groups. But this porosity imposes a problem because of the humidity sensitivity, unless the porous SiO_2 is immediately densified by a heat-treatment above 700°C (8). Since the atomic oxygen technique utilizes a photoresist ashing system operating only at low pressure conditions (9), the atomic oxygen decomposition technique cannot easily be combined with a high temperature diffusion furnace using diffusion ambients at atmospheric pressure. Therefore the ozone technique was adopted for the decomposition of the polysiloxane polymer into SiO_2.

In order to prevent excessive shrinking of the polysiloxane film during the ozone decomposition, a polymethylsiloxane resin was chosen, which already contains 80 weight percent (w/o) SiO_2. Such a polymethylsiloxane resin is commercially available under the trade name Type 650 Glass Resin of Owens-Illinois (10). The polymethylsiloxane resin was dissolved in an organic solvent together with the dopant compounds. The choice of a suitable solvent is important to obtain a uniform paint-on diffusion source film thickness over the entire wafer surface. The evaporation rate of the paint-on diffusion source solvent during the spinning operation on a photoresist spinner must be in the same order of magnitude as the spreading rate of the paint-on source solution during spinning. Using n-butylacetate as a solvent for polymethysiloxane, a uniform paint-on source film was obtained except for an 8 mil wide rim of paint-on source material at the wafer edge.

Dopant compounds were selected in such a manner that they possessed a high chemical stability, low vapor pressure at room temperature, and low toxicity. Carborane polymers (11) were used as boron dopant compounds, which are produced by Olin Corporation under the trade name of Dexsil 202. Triphenylphosphate, $(C_6H_5O)_3PO$, which has a melting point of 48.5°C (12), served as a phosphorus dopant compound. The arsenosiloxane compound $As[OSi(C_6H_5)_2O]_3As$, which exhibits a melting point of 195°C (13), was chosen as an arsenic dopant compound.

Paint-on diffusion sources were spun at 3000 rpm for 30 sec on a Headway Photoresist Spinner Model 1-EC 101 in a humidity-controlled hood (10% humidity). After spinning, the paint-on diffusion source film was decomposed in O_3 at temperatures between 150° and 250°C for a duration of 30 min. After decomposition in O_3, the paint-on diffusion source was densified or diffused at temperatures above 700°C in oxygen, nitrogen, or argon.

The paint-on diffusion source processing tube is shown in Fig. 1. A rectangular tube (2¼ in. wide, 3½ in. high, and 68 in. long) is inserted into a 25 in. long furnace type Blue M Model OV-480A and into a 30 in. long diffusion furnace of the type Diffusitron Mark II. The ozone-decomposition furnace has an 8 in. long temperature plateau, which deviates less than 2°C from the mean temperature value. The diffusion furnace has a 12 in. long temperature plateau with a 1°C deviation from the mean value. In order to prevent time-consuming temperature profiling of the ozone-decomposition and diffusion furnace, the diffusion furnace was frequently operated as a densification furnace and the diffusion was carried out in a separate diffusion furnace. The gas inlet for ozone, oxygen, nitrogen, and argon is near the tube opening. All gases flow first through the O_3-decomposition furnace and then enter the diffusion furnace before the gases are exhausted at the end of the tube. The ozone is generated by an ozone generator of the type Welsbach Model T-816. This ozone generator produces 16g ozone per hour in oxygen.

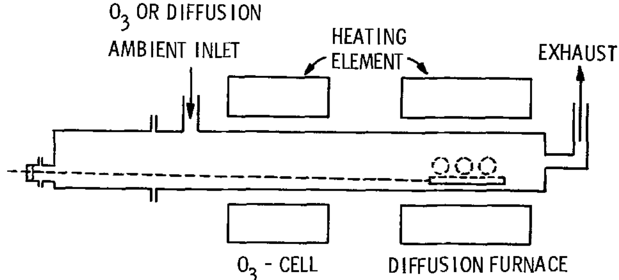

Fig. 1. Paint-on diffusion source processing tube

Results of the Boron Paint-on Diffusion Source

A boron paint-on diffusion source consisting of 8g methylpolysiloxane glass resin, 40.0g n-butylacetate, and 0.8g carborane polymer was spun on an n-type 2¼ in. diam <100> 2 Ω-cm silicon substrate with 3000 rpm for 30 sec. After spinning, a paint-on diffusion source film thickness of 6000Å was measured. Five wafers were standing upright in each of the two rows of the quartz boat. First, the wafers, covered with paint-on source, were decomposed in ozone at 200°C for 30 min in the decomposition zone of the furnace tube. In the same furnace tube, the wafers were then densified at 700°C in N_2 for 30 min by pushing the wafer boat from the decomposition zone into the densification or diffusion zone. After densification, the original film thickness of the paint-on source film was decreased from 6000 to 3000Å. After densification, the wafers were diffused at 1050°C for 30 min in argon in a separate furnace of the type Electroglas Model 35.

In Table I, for five wafers in each row of the wafer boat, the average sheet resistance is given, taken from nine sheet resistance measurements on each wafer. A junction depth of 1.1 μm was observed by using the conventional bevel and stain technique. By applying Irvin's curves (14) to measured sheet resistance and junction depth values, a boron surface concentration of 2.9×10^{20} atom/cm³ in silicon can be calculated. Total variations of less than 7% of the average sheet resistance value were obtained for our boron paint-on diffusion source. These percentile sheet resistance variations are comparable with sheet resistance variations of previous boron paint-on diffusion sources yielding total sheet resistance variations between 5 and 10% (2).

Table I. Sheet resistance uniformity for the boron paint-on diffusion source

	Row		
	1	2	1 and 2
Average sheet resistance (Ω/□) for 5 wafers in each row (9 data per wafer)	19.83	19.39	19.61
Standard deviation (%)	2.01	1.76	1.77

Different boron surface concentrations can be achieved by varying the amount of carborane present as a dopant compound in the boron paint-on diffusion source. In Fig. 2, the boron surface concentration in silicon is shown as a function of the carborane content in the boron paint-on diffusion source for a 1, 1½, and 4 hr diffusion at 1000°C in argon. According to Fig. 2, the boron surface concentration in silicon after diffusion increases with the amount of carborane dopant for all diffusion times. The decrease of boron surface concentration with diffusion time for the same carborane content, as shown in Fig 2, can be attributed to the boron depletion at the interface of the 3000Å borosilicate layer and the silicon surface and to the boron out-diffusion (15).

The infrared absorption spectrum of the boron paint-on diffusion source utilized in the boron paint-on source uniformity study described above is shown in Fig. 3 for three conditions: (*i*) after spinning, (*ii*) after ozone decomposition at 700°C for 30 min, and (*iii*) after densification in N_2 at 200°C for 30 min. As seen from Fig. 3(a), the dominant infrared absorption after spinning of the paint-on source film is the Si-O stretching vibration located between 9 and 10 μm (16). This stretching vibration originates from the siloxane backbone of the polymethylsiloxane resin (16). The other absorptions at 7.8 and 13 μm, present in Fig. 3(a), are caused by the Si-CH_3 group, while the weak absorptions at 3 and 3.4 μm are due to the Si-OH and Si-O-CH_3 group, respectively (16). The weak absorption at 3.9 μm, according to Fig. 3(a) is caused by the stretching of the B-H bond (17). The Si-O, Si-CH_3, and Si-OH groups identified in the infrared spectrum clearly indicate the presence of the methylpolysiloxane resin.

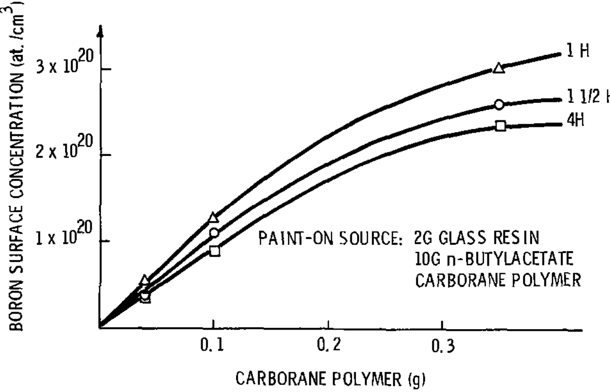

Fig. 2. Dependence of the boron surface concentration in silicon on the amount of carborane present in the boron paint-on diffusion source.

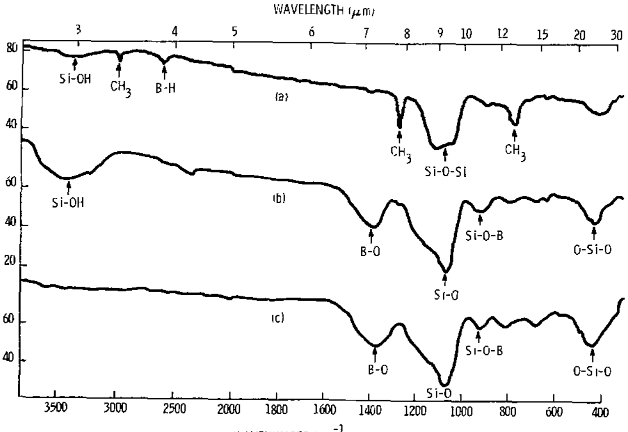

Fig. 3. Infrared spectrum of boron paint-on diffusion source after spinning (a), O_3 decomposition at 200°C for 30 min (b), and densification at 700°C for 30 min in argon (c).

The B-H infrared absorption can only be caused by the carborane polymer (17). Therefore, the infrared absorption spectrum of the paint-on diffusion source after spinning [3(a)] shows the solid components of the paint-on diffusion source.

After O_3 decomposition of the boron paint-on source, absorption bands are observed at 2.95, 7.2, 9.4, 10.8, and 23.5 μm, according to Fig. 3, trace (b). The infrared absorption spectrum of borosilicate glass has Si-O absorption peaks at 9.4 and 23 μm, a B-O absorption peak at 7.2 μm, and a Si-O-B absorption peak at 9.4 μm (8). Therefore except for the 2.95 μm absorption peak, the infrared absorption spectrum of the boron paint-on source after O_3 decomposition is in agreement with the infrared absorption spectrum of borosilicate glass. The absorption peak at 2.95 μm, found in the infrared absorption spectrum of the O_3 decomposed paint-on source, can be attributed to the presence of moisture absorbed from the laboratory environment by the porous borosilicate formed by the O_3 decomposition of the boron paint-on source (8). According to Fig. 3, trace (c), upon densification of the decomposed boron paint-on source film at 700°C, the H_2O absorption peak at 2.95 μm disappears. Therefore the infrared absorption spectrum of the densified boron paint-on diffusion source is identical with the one of the borosilicate glass. In conclusion, the O_3 decomposition and the successive densification of the boron paint-on source transform the original organic polymer mixture into an inorganic borosilicate glass without any organic residues.

Results of the Phosphorus Paint-on Diffusion Source

A phosphorus paint-on diffusion source consisting of 2.0g glass resin, 10.0g n-butylacetate, and 0.16g triphenylphosphate was spun with 3000 rpm for 30 sec on 1¼ in. diameter <100> 10 Ω-cm p-type silicon wafers after 1, 5, 7, and 11 days past the date of the paint-on preparation. All phosphorus paint-on diffusion sources were decomposed in ozone at 225° for 30 min and diffused in argon at 1050°C for 105 min. After the removal of phosphosilicate in HF, sheet resistances and junction depths were measured in five sites of each wafer. Table II shows sheet resistances, sheet resistance variations, and junction depths as a function of the processing time after paint-on diffusion source preparation. According to Table II, the total percentile sheet resistance variations on the same wafer are less than 5%. An average sheet resistance value of 201 Ω/□ with a total variation of 10 Ω/□ can be calculated for all wafers shown in Table II. Therefore, the percentile sheet resistance variation is less than 5% from wafer to wafer for different processing times after source preparation. One may then assert that the phosphorus paint-on diffusion source has a sufficient chemical stability for producing uniform doping levels.

Figure 4 presents the phosphorus surface concentration in silicon as a function of triphenylphosphate dissolved in the paint-on source solution. As evident from Fig. 4, the phosphorus surface concentration increases with the amount of triphenylphosphate in the paint-on solution until a phosphorus surface concentration of approximately 8×10^{19} atom/cm³ in silicon is reached. An explanation for the upper surface concentration limit for the phosphorus paint-on source may

Table II. Reproducibility of a phosphorus paint-on diffusion source as a function of the processing time after source preparation

Processing time after source preparation	Sheet-ρ in Ω/□	Junction depth (in μm)	Surface concentration atom/cm³
After 1 day	198 ± 4Ω	0.553	2.34×10^{19}
After 5 days	207 ± 4Ω	0.633	2.1×10^{19}
After 7 days	201 ± 10Ω	0.649	2.04×10^{19}
After 11 days	198 ± 5Ω	0.574	2.5×10^{19}

be the separation of triphenylphosphate and glass resin during the spinning process. Precipitates of triphenylphosphate were actually observed after spinning on top of the paint-on source film for high triphenylphosphate concentrations.

Results of the Arsenic Paint-on Diffusion Source

An arsenic paint-on diffusion source solution consisting of 12.0g glass resin, 12.0g arsenosiloxane compound, and 100.0g n-butylacetate, designated as solution No. 33, was spun with 3000 rpm for 30 sec on nine <100> 2¼ in. diameter 1-2 Ω-cm p-type silicon wafers. Three wafers were standing upright in each of the three rows of the quartz boat together with 28 wafers covered with an undoped polysiloxane resin film. After ozone decomposition at 181°C for 30 min and a diffusion at 1200°C for 15 min in O_2 followed by a 55 min heat-treatment in N_2, the arsenic-doped oxide was removed by HF in order to measure the sheet resistance on nine sites of each of the nine wafers, which received the arsenic paint-on source diffusion.

The experiment was repeated under identical processing conditions for two different arsenic paint-on solutions containing different polymethylsiloxane resin batches, designated as solutions No. 35 and 38. Solutions No. 35 and 38 were applied for 8 and 2 silicon wafers, respectively. The sheet resistance results (highest, lowest, and mean sheet resistance including standard deviation) are given in Table III for all different paint-on source solutions. The junction depth measured by bevel and stain technique ranged between 2.1 and 2.4 μm for all processed wafers. According to Table III, the

Table III. Sheet resistance uniformity for arsenic paint-on diffusion sources using different batches of polymethylsiloxane resin

	Solution		
	35 (9 samples)	35 (8 samples)	38 (2 samples)
Highest sheet resistance (Ω/□)	9.8	10.1	10.1
Lowest sheet resistance (Ω/□)	9.4	9.6	9.6
Mean sheet resistance	9.6	9.8	9.8
Standard deviation (Ω/□)	0.10	0.14	0.16

Mean sheet resistance averaged over 3 runs: 9.7 ± 0.16 Ω/□

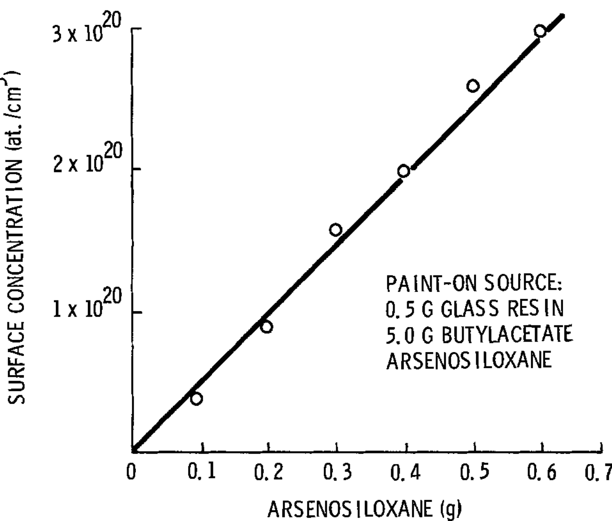

Fig. 5. Arsenic surface concentration in silicon as a function of the arsenosiloxane content in a paint-on diffusion source solution.

total sheet resistance variation from wafer to wafer and from run to run, using different resin batches, is less than 4.2% for a mean sheet resistance value of 9.7 Ω/□. The percentile sheet resistance variations for the arsenic paint-on diffusion source are, therefore, smaller than for the phosphorus and boron paint-on diffusion sources, which have variations of 5 and 7%, respectively. As different batches of polymethylsiloxane resin were used for the solutions No. 33, 35, and 38 in the arsenic paint-on source study, the batch of the polymethylsiloxane resin has a negligible impact on the arsenic doping in silicon after the arsenic paint-on source diffusion because of the small sheet resistance variation of 4.2% for all arsenic paint-on source solutions.

In Fig. 5, the arsenic surface concentration, calculated from sheet resistance and junction depth values by using Irvin's curves (14), is shown as a function of the arsenosiloxane content in a 0.5g glass resin/5.0g n-butylacetate solution for a diffusion at 1150°C for 15 min in oxygen and for 75 min in argon. Figure 5 indicates the arsenic surface concentration in silicon increases linearly with the amount of arsenosiloxane dissolved in the glass resin solution. Therefore, differerent arsenic doping levels in silicon can be easily obtained by varying the amount of arsenosiloxane dissolved in the paint-on diffusion source solution.

Summary

A new paint-on diffusion technology has been developed for boron, phosphorus, and arsenic dopants. The uniformity of the new paint-on diffusion sources is equal to or better than the one of previous paint-on diffusion sources. The new paint-on diffusion source has a long shelf-life and is not humidity sensitive.

ABSTRACT

We have examined the redistribution between oxide, slice, and oxide surface of gold deposited from deliberately contaminated etching solutions onto silicon slices, during subsequent oxidation and phosphosilicate glass deposition. Results presented also show the distribution of gold throughout the oxide. The initial oxidizing or annealing conditions in the furnace are shown to have an important effect on the subsequent gold distribution.

During conventional device processing procedures, a silicon wafer is exposed to various etching, cleaning, and rinsing reagents. While the use of highly pure chemicals and rinse water is usual, it is difficult to completely eliminate the presence of residual heavy metal contaminants. Conventional cleaning procedures are not effective in removing such chemisorbed species from either silicon or SiO_2 (1-4) and, thus, they remain present during subsequent oxidation, diffusion, or other high temperature processes. It is of interest, then, to study the behavior of such surface contaminants during subsequent processing steps. Because we may assume it to be typical of a monovalent heavy metal, and because of its use in the control of lifetime in many devices we have chosen to study the redistribution of gold during the formation of either oxide, oxide-PSG, or PSG layers on silicon. From the latter studies we can also examine the gettering action, if any, of the composite and PSG layers.

Experimental Methods and Results

Gold was deposited onto the freshly cleaned surface of polished silicon wafers by chemideposition from a 10% HF solution containing a carefully standardized concentration of neutron-activated gold. In the subsequent discussion reference to gold concentrations or contamination levels of 10, 1.0, or 0.1 ppm refers to the nominal concentration by weight of gold in the contaminated etch. Where the quoted experimental points do not coincide strictly with these concentrations, it indicates that surface absorption by the container and etching vessel walls has caused a decrease in the gold concentration from the nominal values. The rate of deposition of gold onto silicon or SiO_2 was found to be temperature independent in the range 20°-50°C. Slices were immersed in the etch for ~15 min. For the concentration range 0.1-10 ppm, ancillary experiments showed that this period was sufficient for the surface gold concentration to approach equilibrium.

The oxidation of a contaminated wafer results in the redistribution of the gold between the slice, the oxide, and the oxide surface. The gold concentration in the slice is dependent upon both the conditions of contamination and of oxidation.

By selectively etching off first the gold at the air/oxide surface with hot aqua regia and then removing the oxide using buffered HF, it is possible to determine the net quantities of gold present at the surface of the oxide, dissolved in the oxide, and dissolved in the silicon slice. These observations are hampered by the tendency of the gold already taken into solution in the etch to redeposit upon the freshly exposed oxide or silicon (1-4). To eliminate the effects of such redeposition during the removal of the surface gold or the oxide and during the successive layering of the oxide, the samples were successively etched and rinsed several times in hot aqua regia and deionized water. Control experiments on both contaminated slices and oxides showed that this procedure was successful in removing replated gold, while leaving the oxide unaffected.

The quantities of gold present were determined at each stage by β-particle counting, making a direct comparison with standard samples of a similar counting geometry. The absorption coefficient for the β-particles, λ, was determined from the front-to-back count ratio

* Electrochemical Society Active Member.

Key words: silicon, gold, oxidation.

on a series of slices, between 0.004 and 0.016 in. thick, having gold on one surface only. The ratio was an accurately exponential function of slice thickness corresponding to an absorption coefficient of 50.41 cm^{-1}. Since the absorption of β-particles in this energy range is proportional to the specific gravity of the absorber (5), we can ignore the absorption of oxide layers when present.

If we consider the following counts: X_1 = initial front surface count, Y_1 = initial back surface count, X_2 = front surface after removal of surface gold, Y_2 = back surface after removal of surface gold, X_3 = front surface after removal of oxide, and Y_3 = back surface after removal of oxide, then we can determine the various net gold concentrations from their contribution to the total counts: front surface contribution, $F_s = ((X_1 - X_2) - A(Y_1 - Y_2))/(1 - A^2)$ and back surface contribution, $B_s = ((Y_1 - Y_2) - A(X_1 - X_2))/(1 - A^2)$.

In a similar fashion, the concentration in the oxide is given as: front surface oxide contribution, $F_o = ((X_2 - X_3) - A(Y_2 - Y_3))/(1 - A^2)$ and back surface oxide contribution, $B_o = ((Y_2 - Y_3) - A(X_2 - X_3))/(1 - A^2)$, where $A = \exp(-\lambda t)$, and t is the slice thickness. By comparison of F_s, B_s, F_o, and B_o with known standards, the corresponding net gold concentration was determined.

The determination of the gold concentration in the silicon slice is complicated by the effect of β-absorption. Generally, the profile of the dissolved gold is not known accurately. However, a comparison of the expected counts for a few extreme distributions shows that this is not a serious factor.

Calculation of the front and back counts, C_F and C_B, respectively, for gold distributions that are (*i*) all on one surface, (*ii*) equally divided between the surfaces, and (*iii*) uniform throughout the bulk for a range of slice thicknesses up to 9 mils shows that if we write N for the "correct" count and define the factor F so that $N = F(C_F + C_B)$, then F varies rather little with the gold distribution. Thus, for a slice of 8 mils thickness, $0.736 \leq F \leq 0.799$, a $\pm 4\%$ variation for the three extreme distributions cited. If the profile is known only roughly, a more accurate correction factor can be estimated.

Boron-doped 10 Ω-cm silicon wafers, 0.008 in. thick, <111> orientation, and mirror polished on both faces, were first chemically cleaned and then contaminated using etches containing known gold concentrations. The slices were placed quickly (<30 sec) into the hot zone of the oxidation furnace in an oxygen atmosphere and oxide grown for 60 min (700, 1000 and 1300Å at 1000°, 1050°, and 1100°C, respectively). After oxidation, the quantity of gold present at the surface of the oxide, dissolved in the oxide and dissolved in the slice, was measured.

The results of these studies are shown in Fig. 1-4. Similar experiments were carried out using composite SiO_2-PSG layers and PSG alone. The PSG layers were deposited at 1050°C for times between 20 and 120 min, from a mixture of 1% PH_3 in argon, nitrogen, and oxygen in a ratio 3:50:50. Separate furnaces were used for oxidation and PSG deposition.

In the two-layer structures the slices were brought to the required temperature in a nitrogen atmosphere, oxidized for 1 hr, and then PSG layers of 600, 750, and 900Å were deposited at 1050°C. The experimental results for these samples are shown in Fig. 5 and 6.

The distribution of the gold through the SiO_2 and SiO_2:PSG layers was examined in greater detail. By successive etching steps, using buffered HF and taking care at each step to remove any redeposited gold, a cumulative profile of the gold concentration was obtained. Oxide or oxide:PSG thicknesses were determined at each step by ellipsometer measurement. Etching times were chosen to give approximately 100Å steps. Counting times were selected to provide reasonable accuracy in the final profiles, *e.g.*, the derivative of these results. Examples of such concentration profiles across the SiO_2 and SiO_2-PSG layers are shown in Fig. 7 and 8. The profiles within 100Å of the interface are shown dotted since no measurements could be obtained within 50Å of the silicon surface. The lines drawn correspond to the net gold concentration measured at the penultimate layering operation, assuming a similar profile.

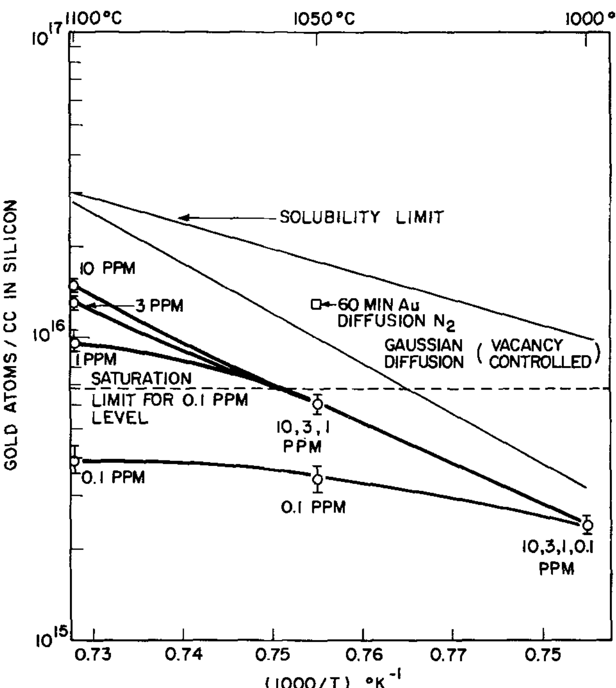

Fig. 1. Variation of the concentration of gold in solution in the silicon slice as a function of initial contamination level and temperature of oxide growth, for a growth time of 60 min.

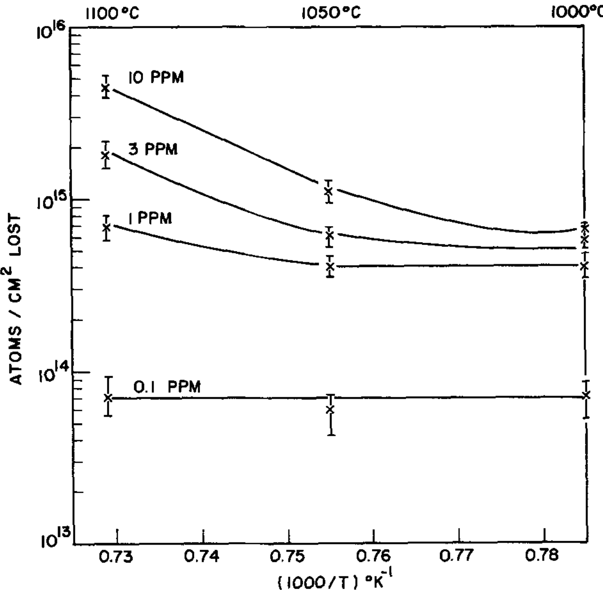

Fig. 2. Variation of the quantity of gold lost in the gas stream, as a function of initial contamination level and oxidation temperature during a 60 min oxidation.

The profiling experiments were repeated using composite layers of 600Å of SiO_2 and 600Å of PSG grown at 1050°C. Initial contamination levels of 10, 1.0 and 0.1 ppm were again employed. The corresponding profiles are shown in Fig. 8.

Discussion of Results

In Fig. 1, in addition to the experimental results, we indicate certain other physical data: (*i*) the solid

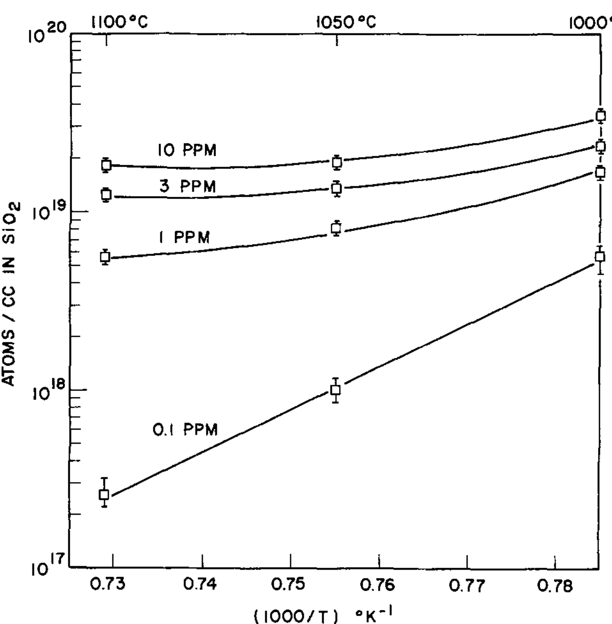

Fig. 4. The variation of net gold concentration in the grown oxide as a function of contamination and oxidation temperature. (See, however, discussion of Fig. 7 and 8.) Growth period 60 min.

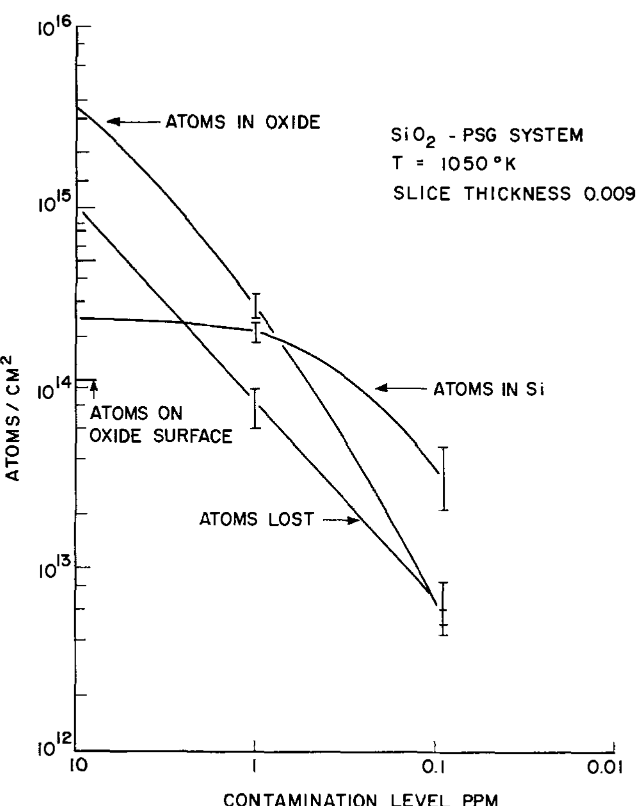

Fig. 5. The concentration of gold in the Si-SiO2-PSG composite system, after growth at 1050°C, as a function of the initial contamination level.

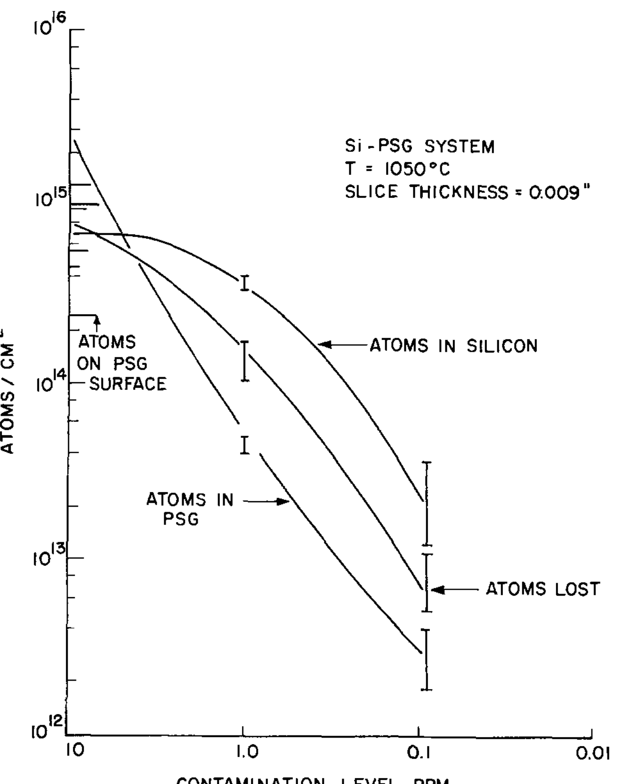

Fig. 6. The concentration of gold in the Si-PSG system, after growth at 1050°C, as a function of the initial contamination level.

solubility limit corresponding to the slice oxidation temperature; (*ii*) the net concentration that would be produced by a vacancy-controlled gaussian diffusion process from a saturated surface layer at that temperature; (*iii*) the gold concentration found after heating the sample in an inert nitrogen atmosphere for 60 min; and (*iv*) the uniform gold concentration that would result if all of the gold deposited onto the slice surface from 0.1 ppm etch were uniformly distributed through the slice.

The annealing experiment (*iii*) yields a concentration that is in reasonable agreement with that predicted from a simple diffusion process (*ii*). The results for the oxidized samples all show a significant decrease in the gold concentration remaining in the slice. At the lowest temperature (1000°C) the results for all contamination levels are approaching the diffusion-limited value.

Reference to Fig. 2 shows that gold is lost during the oxidation process, presumably by the evaporation of gold or of a high temperature oxide. However, in no case is this loss of gold large enough to completely

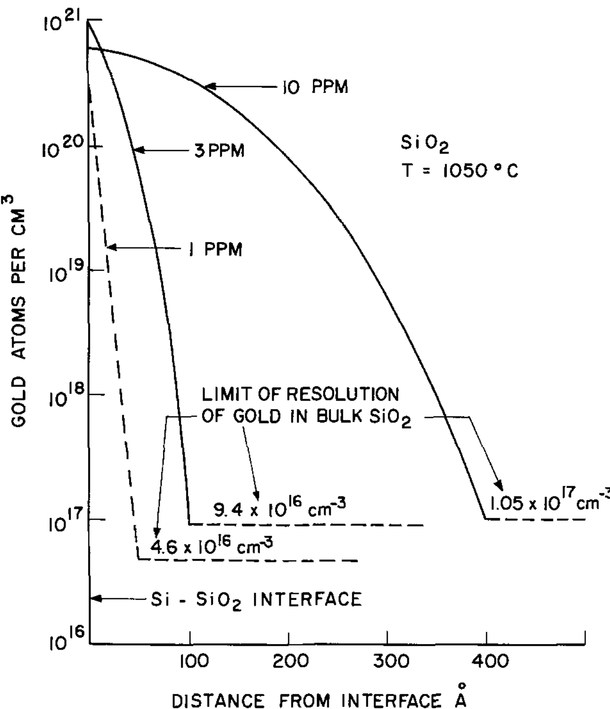

Fig. 7. The distribution of gold adjacent to the Si-SiO_2 interface for a range of initial contamination levels.

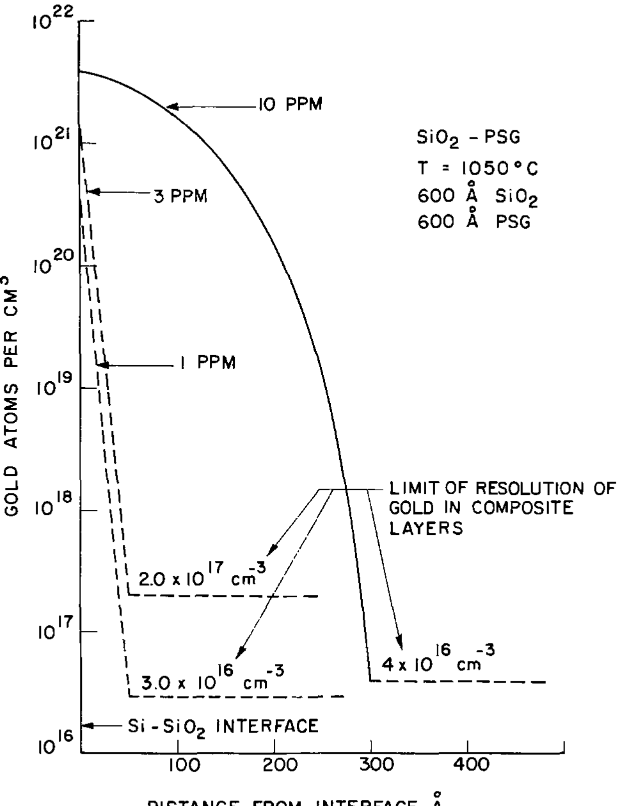

Fig. 8. The distribution of gold adjacent to the Si-SiO_2 interface after the growth of an SiO_2-PSG composite layer.

account for the reduction in the amount of gold present in the silicon. Figure 3 shows that the amount of gold rejected to the surface of the oxide layer decreases with both increasing oxidation temperature and decreasing contamination level. For contamination levels below 3 ppm, no excess gold could be detected at the oxide surface. The very high net concentrations observed in the oxide layers (Fig. 4) will be considered later.

The reduction of the gold concentration in the slice after oxidation indicates that the transfer of gold from the surface of the oxide into the silicon slice is terminated at some point by the formation of the oxide layer. The presence of gold at the oxide/ambient surface indicates that, at some critical thickness, the oxide becomes relatively impermeable to further diffusion of gold. Table I shows, for the range of temperatures studied, the time that would be required for the measured quantity of gold to diffuse into the wafer, and the corresponding oxide thickness that would have formed at that time. It is evident that at all temperatures the formation of approximately 500Å of oxide has prevented the further diffusion of gold into the slice.

The standard deviation for the profiling measurements made on the 10 ppm oxides was 1.05×10^{12} atoms/cm^2. If these atoms were gaussian distributed in the oxide, then using the smallest reported diffusion constant for gold in SiO_2 leads to an estimated surface concentration of 1.5×10^{17} atoms/cm^2. Assuming that this concentration is maintained during the entire growth period, we may calculate the amount of gold that would have reached the slice (6-8). The calculated value is 4.5×10^{11} atoms/cm^2, as compared to a measured value of 2×10^{14} atoms/cm^2. Thus the gold present in the slice must have been incorporated before the growth of a substantial (~500Å) oxide layer.

The results shown in Fig. 1 and 3 may now be interpreted. In an oxidizing atmosphere, the gold initially saturates a very thin surface layer of the silicon, diffusion into the slice commences, and, at the same time oxide starts to form at the silicon surface (6), gold is rejected to the surface of this oxide. When the oxide thickness has reached about 500Å, it is effectively impermeable to further gold diffusion and the supply of gold to the slice is cut off. The gold that has already dissolved into the slice redistributes toward a uniform concentration while the gold at the oxide/ambient surface remains there and may be partially removed by oxidation/evaporation. If the initial surface concentration is low, effectively all of the gold available can diffuse into the slice during the initial oxidation.

Comparison experiments were made in which samples were brought to a temperature of 1050°C in an inert atmosphere and then oxidized for 60 min. At the 10 ppm contamination level the surface (oxide/gas) gold concentration fell to 2×10^{14} cm^{-2} as compared with 5×10^{15} cm^{-2} for a sample brought to temperature in an oxidizing atmosphere. No significant differences in the gold redistribution were found between composite SiO_2-PSG layers and simple SiO_2 for the contamination levels 10, 1.0, and 0.1 ppm, although at the 10 ppm contamination level excess gold would have been rejected from the slice and oxide. There was no evidence of a significantly higher gold solubility either in the PSG layer or at the PSG-SiO_2 interface.

In experiments where PSG was grown directly on a slice, it was found that significantly more gold remained in the slice. Etching away the top 2μ of the slice reduced the amount of gold in the slice by almost 90% (Fig. 9). From this observation one can conclude that the enhanced gold concentration observed was entirely associated with the increased solubility of the gold in the regions of the slice that had been heavily doped n-type by contact with the glass layer. The enhancement shown in Fig. 9 for the

Table I

Temp (°C)	Contamination level (ppm)	Au atoms in Si, 60 min diff. with oxidation	Minutes to diffuse these atoms without oxidation	SiO_2 grown in this time (Å)
1000	10,3,1,0.1	5×10^{13}	33	480
1050	10,3,1	1.25×10^{14}	25	570
1100	10	2.9×10^{14}	12	500

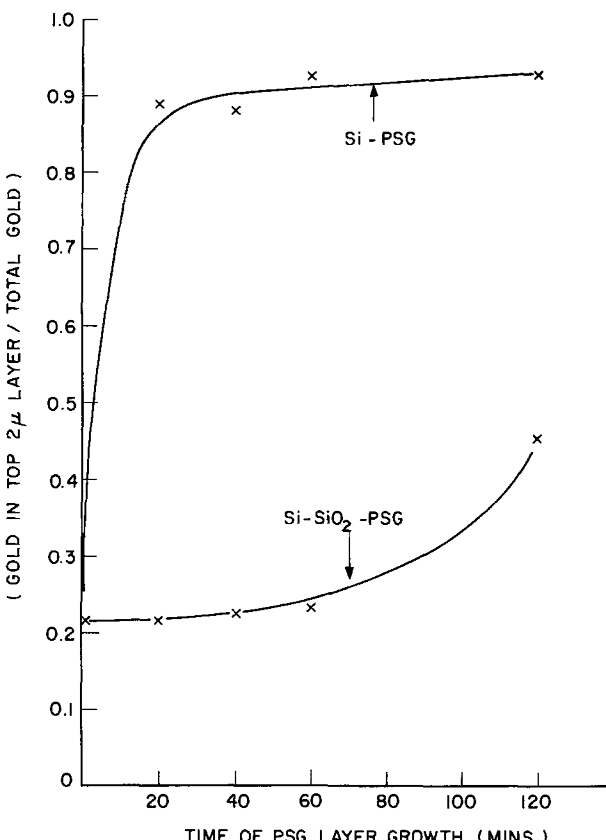

Fig. 9. A comparison of the ratio of the amount of gold in the top 2μ of the silicon slice, to the total amount in the slice after the growth of PSG and SiO_2-PSG composite layers.

composite SiO_2:PSG structures only occurred after prolonged deposition times and corresponded to the penetration of the SiO_2 layer by the PSG.

The gold profile near to the Si-SiO_2 interface is approximately gaussian and for the 10 ppm contamination level the results would correspond to a diffusion constant of 1.4×10^{-16} cm²/sec. Previously reported values of the diffusion constant of gold in SiO_2 range from 9.0×10^{-16} (9) to 9.0×10^{-15} cm²/sec (10) at 1050°C. However, no evidence of a similar profile was found at the SiO_2-ambient surface, even though there would have been a significant concentration of gold present at this surface for the higher contamination levels used.

The growth of SiO_2 is endotaxial, all of the oxide grown has been formed from that region of the parent silicon slice that has the highest gold concentration. Thus the sharp decrease in the gold concentration in the first 50-300Å of oxide adjacent to the silicon implies a rejection process from the bulk oxide (or the failure of the gold to incorporate in the oxide). Otherwise we might expect a gold profile rising toward the oxide/ambient interface. This view is reinforced by the observation that when "excess" gold is rejected to the outer oxide surface, there is no detectable "diffusion" profile into the oxide in this region. Even at the highest temperatures and the lowest contamination levels, it appears (Fig. 4) that a substantial fraction of the chemi-deposited gold is rejected from the region where it could otherwise diffuse into the slice.

The enhanced solubility of impurities in the oxide phase and the corresponding depletion of the bulk dopant is well known. However, in the present case the concentration of the gold just inside the oxide at the oxide-silicon interface exceeds the concentration of gold just on the silicon side of the interface by a factor of more than 10^5.

The implication of these observations is that the gold in the Si/SiO_2 interface region of the oxide is incorporated by some "chemical" bonding process characteristic of the nonstoichiometric nature of the oxide in that region. This gold is not available to participate in the normal diffusion process into either the slice or the oxide. The diffusionlike profile shown by the gold in this region is probably an artifact, associated with the process governing the oxide formation.

Thus the profiles displayed in Fig. 7, 8 should not be attributed to the normal processes of diffusion. It is well known that the growth and etching rates of the first few hundred angstroms of oxide adjacent to the parent slice are anomalous (11-14). This points to a significantly different oxide structure in the SiO_2-Si region from that found in the bulk oxide. The present observations of a substantial amount of dissolved gold close to the slice-oxide interface are further evidence of the different structural nature of the oxide in this region. The observation that the region of anomalously high gold concentration and the oxide thickness required to prevent transport between the gold at the oxide surface and the slice are both of the order 300-500Å further supports the view of a significantly different oxide structure in this region.

The detection limit in these observations was set by the masking effect of the residual β-radiation from the gold in solution in the slice itself. However, it is now possible to note that the net gold concentrations in the oxide observed earlier can be attributed entirely to the gold in the accumulation region occurring at the Si-SiO_2 interface. The interface concentrations of gold are somewhat higher in the PSG-SiO_2 system than in the simple SiO_2 layers. However the composite layers are also thicker and more of the parent slice has been used to form the oxide and glass.

The experiments described could not determine the limiting solid solubility of gold in the SiO_2 layer, since its activity was always masked by the residual activity of the gold piled up at the Si-SiO_2 interface. The lower limit of concentration indicated in Fig. 7 and 8 (9×10^{16} cm^{-3}) is set by the accuracy of the initial counting process (±3%); it does not represent an estimate of the bulk solubility.

Conclusions

The distribution of a model heavy metal contaminant, *i.e.*, gold, during oxidation and/or the growth of PSG layers is dependent upon the previous thermal and ambient history of the slice. Under nonoxidizing conditions, gold will tend to be taken into solution in the silicon and its final concentration will be a function of temperature and initial doping. Excess gold left at the silicon surface will be rejected to the surface of any oxide which is then grown. If equilibrium with the slice is not reached during the initial heating/oxidation period, then further exchange of gold between the oxide/gas surface and the silicon slice will be terminated by the growth of approximately 500Å of oxide. After oxidation gold is found in solution in the slice, at the oxide surface, and dissolved in the oxide region adjacent to the silicon surface. The gold distributions are essentially unchanged by the growth of composite layers of SiO_2 + PSG unless the PSG layer is in contact with the slice itself. In the latter case the enhancement of solubility observed at the slice surface is consistent with the Shockley-Moll model (15, 16) for Fermi level controlled solubility. No additional gettering action is observed either in the PSG layers or at the PSG-SiO_2 interface.

ABSTRACT

The sourcing lifetimes, microstructural stability, and diffusion performance of a new solid planar phosphorus source for silicon doping were investigated in the temperature range 900°-1100°C. The source wafers were highly porous ceramic wafers containing 25 weight percentage (w/o) SiP_2O_7 as the "active" component in an inert refractory binder matrix. The microstructural stability and thermogravimetric analysis (TGA) results indicated the structural integrity and sourcing ability of this material at temperatures of at least 1050°C. Theoretical lifetimes of 260 and 3400 hr at 1000° and 900°C, respectively, have been predicted from the TGA results. Experimental data relating sheet resistance, junction depth, and diffusion coefficient for silicon wafers doped using these source wafers are presented. Special material handling procedures are also described.

The results of previous studies concerning the diffusion performance of boron nitride as a p-type dopant source for silicon technology have shown that planar sources offer several significant advantages over carrier gas diffusion systems using liquids and gases (1, 2). The benefits of planar diffusion sources have been previously reported by Goldsmith *et al.* (3), and it is towards this end that the development and evaluation of the new phosphorus source was aimed. In addition to the benefits presented by Goldsmith *et al.*, there is the added benefit of having a source material which has no toxic or corrosive by-products.

In using boron nitride as a source, the surface is oxidized (activated) to form B_2O_3, and the boron is vaporized and transported as an oxide to the silicon surface. An analogous refractory compound of phosphorus which can be fabricated into a ceramic wafer was not available to emulate the boron nitride technology. However, Murata (4) demonstrated that silicon pyrophosphate, SiP_2O_7, decomposes to SiO_2 and P_2O_5 with the P_2O_5 partial pressure being adequate to effectively dope silicon in the temperature range 850°-1100°C.

In this paper the discussion is confined to a wafer composition of 25 w/o SiP_2O_7 in an inert matrix material as manufactured by The Carborundum Company[1] and designated as Phosphorus Planar Diffusion Source Grade PH-1050.

Experimental

In order to establish that the SiP_2O_7 phase was compatible (chemically inert) with the binder phase, the phases present after long-term annealing at temperatures encompassing the projected use temperatures were determined using standard x-ray diffraction techniques. The stability of the microstructure (retention of the fine grain, porous structure) was evaluated using scanning electron microscopic (SEM) analysis of similar samples.

To establish minimum sourcing lifetimes, the loss of P_2O_5 was monitored as a function of time at projected use temperatures using a semimicro thermogravimetric analysis (TGA) apparatus. The samples were suspended in a fused silica tube in flowing nitrogen (0.21 SLPM) and heated rapidly from 350°C to the desired test temperature. The preheat at 350°C was necessitated by the reversible phase transition in the wafer discussed in more detail below.

All electrical measurements and diffusion experiments were performed with silicon wafers. The silicon wafers were 3.81 × 0.081 cm, boron-doped <111> ori-

ented substrates with resistivities of 0.005-0.010 Ω-cm, and boron-doped epitaxial layers 9.8-14.5μ thick with resistivities of 1.5-4.5 Ω-cm. The phosphorus wafers were 3.81 cm in diameter and 0.089 cm thick. The resistivity data were obtained using a K&S Pacific Model 192 resistivity tester consisting of 0.001-10 mA ± 0.1% of full scale current source and 0-2V ± 0.5% of full scale digital voltmeter with an A&M Fell linear probe with 1.00 mm ± 0.01 spacing. Sheet resistance data, ρ_s, were measured by probing the silicon wafer in four quadrants plus the center and then averaging; ρ_s indicates the average of the five readings. The junction depth was measured using standard angle lapping and staining techniques with a 16 mm interferometer having a half-wavelength light source of 2935A. The surface concentration of electrically active phosphorus was determined by use of incremental sheet resistance technique (5). All the diffusion experiments were done in an N_2 ambient with a spacing of 0.318 cm from source to silicon wafer (Fig. 1).

Results and Discussion

The x-ray diffraction analyses showed that no new major phases were produced during the annealing treatments except for the SiO_2-rich glass which resulted from the decomposition of SiP_2O_7 to yield P_2O_5 vapor. The persistence of a very small amount of the $Si_2P_2O_9$ phase until nearly all of the SiP_2O_7 had decomposed indicates that the $Si_2P_2O_9$ phase is an intermediate reaction product in the decomposition of SiP_2O_7. However, no reactions between these SiO_2-containing phases and the binder phase were observed.

Figure 2 demonstrates that after 48 hr at 1050°C (the maximum recommended use temperature) the fine grain, porous microstructure is retained which accounts for the dimensional stability and continued sourcing ability of these wafers.

The results of isothermal TGA experiments at 900° and 1000°C are presented in Fig. 3. In this figure the weight loss data are also plotted as percentage of available P_2O_5, the P_2O_5 combined with SiO_2 to form SiP_2O_7. After an early nonparabolic period at both temperatures, the weight loss *vs.* $\sqrt{\text{time}}$ curves become linear indicating, to a first approximation, a diffusion-controlled reaction in a stable microstructure.

The main value of these TGA results is in predicting the usefulness of the wafers as sources and, specifically, to predict minimum useful lifetimes. In Fig. 4 the TGA data for a period of 100 hr for the 25 w/o SiP_2O_7 composition are presented. By fitting a straight line to the latter portion of this curve, the weight loss can be expressed as

$$W_D = 0.14t^{1/2}$$

where W_D is the percentage weight decrease in flowing N_2, and t is time in minutes. By substituting the theoretically available P_2O_5 percentage for W_D, one arrives at a minimum lifetime of ~260 hr, assuming no change in the rate constant. Doing the same exercise for the 900°C data yields a minimum lifetime of 3400 hr. It should be pointed out that these are minimum lifetime estimates since they are based on TGA results in flowing nitrogen. They are probably low compared to those experienced in a typical diffusion environment. In a diffusion system the source wafer resides in a relatively stagnant vapor environment which has a P_2O_5 partial pressure near the equilibrium P_2O_5 partial pressure of the wafer, thus reducing the driving force for dissociation. In the TGA environment the evolved P_2O_5 is continuously swept away resulting in a P_2O_5-poor vapor phase and a large driving force for dissociation. This effect has been experimentally verified by monitoring the amount of SiP_2O_7 remaining in wafers subjected to long-term TGA experiments and long-term diffusion heat-treatments at the same temperature.

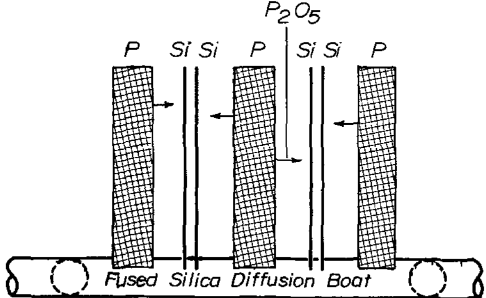

Fig. 1. Diffusion boat schematic with the solid phosphorus source

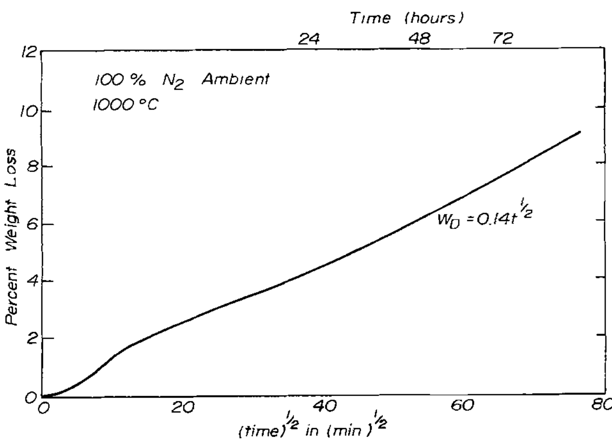

Fig. 4. Weight loss vs. $\sqrt{time}$ for PH-1050 wafers at 1000°C to 100 hr.

The longest experiment to monitor sourcing effectiveness was for the 25 w/o SiP_2O_7 composition at 1000°C which was still sourcing effectively after 216 hr of continuous usage.

The N_2 gas flow rate was found not to be a major factor in diffusion performance. The results of sheet resistance dependence on N_2 flow rate are shown in Fig. 5 for a 30 min diffusion at 1050°C. The sheet resistance tends to increase as flow rate increases which would seem to indicate that the dopant specie, P_2O_5, is being swept out by the N_2. Under conditions of no N_2 flow, the sheet resistance is increased by nearly one order of magnitude. This was accompanied by an increase of phosphorus glass transfer and, consequently, could possibly be due to some Si-P surface phase (6), although no difficulty was experienced in glass removal.

Solmi *et al.* (7) have reported that in a $POCl_3$ system anomalous results have been observed when Si-P or SiO_2-P_2O_5 phases have been formed on or at the silicon interface. The change in sheet resistance accompanied by an increase in dopant glass suggests that Si-P or SiO_2-P_2O_5 phases have formed and are responsible for the observed anomalous behavior.

The sheet resistance data that were obtained for the range 950°-1100°C are shown in Fig. 6. The data compare favorably with other phosphorus sources such as $POCl_3$ (8) and PH_3 (9). Figure 7 shows sheet resistance as a function of $\sqrt{t}$ at 1050°C. The graph is a straight line, as expected, and, hence, $\overline{\rho_s} \propto 1/\sqrt{t}$, except at lower sheet resistance where $\overline{\rho_s}$ increases

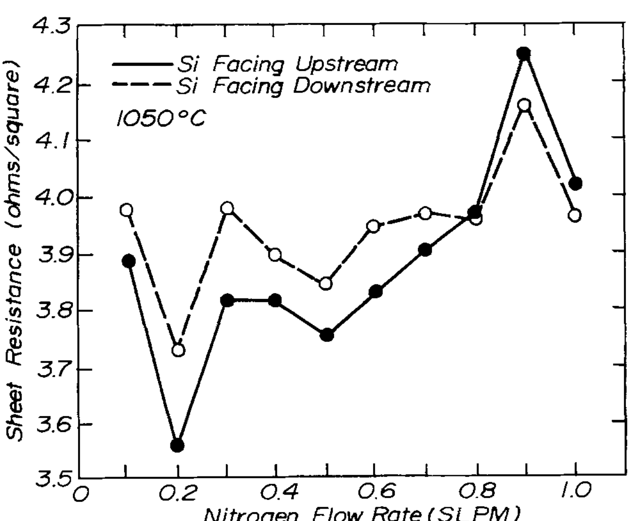

Fig. 5. Sheet resistance vs. flow rate

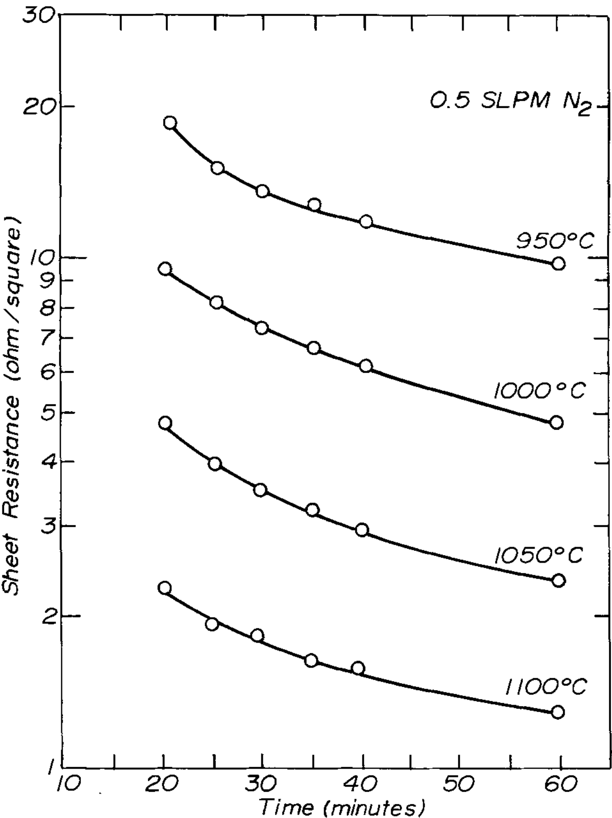

Fig. 6. Sheet resistance vs. time and temperature using 25/75 source.

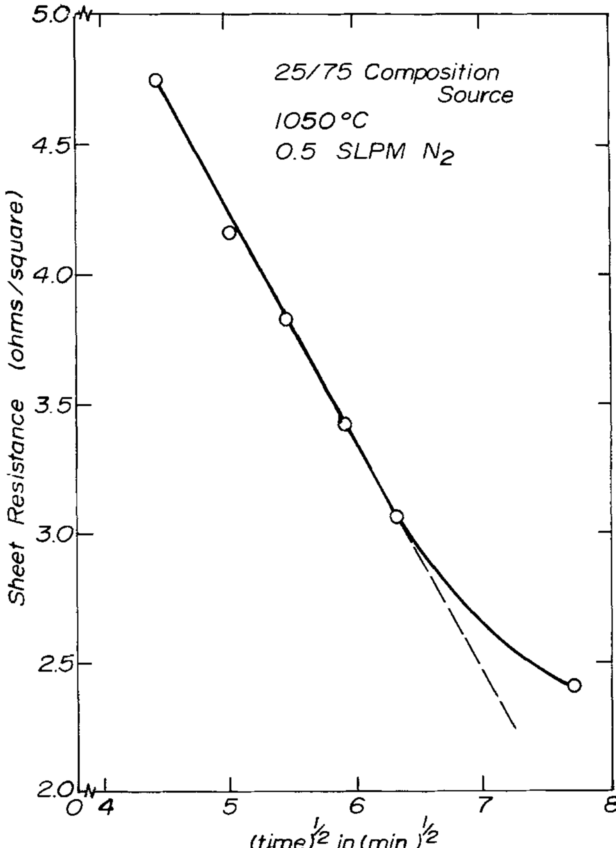

Fig. 7. Sheet resistance vs. $\sqrt{time}$ for constant source diffusion

with $\sqrt{t}$ which might be attributed to the Si-P phase formation. The junction depth, x_j, can be shown to be $\sqrt{t}$ dependent for a one-step process

$$x_j = 2(Dt)^{1/2}\,\text{erfc}^{-1}\left(\frac{C_B}{C_S}\right) \quad [1]$$

where D is the diffusion coefficient (cm²/sec), t is time (seconds), C_B is background concentration (atoms/cm³), and C_S is surface concentration (atoms/cm³). The graph of x_j *vs.* $\sqrt{t}$ for 1000°C is shown in Fig. 8. The straight line relationship indicates that phosphorus obeys the complementary error function distribution. It is also possible to obtain information on the temperature dependence of x_j as well as the diffusion coefficient D. The diffusion coefficient, D, can be expressed in the Arrhenius form (10)

$$D = D_o \exp - \frac{\Delta E_a}{kT} \quad [2]$$

where D_o is diffusion constant ($T = \infty$) (cm²/sec), ΔE_a is the activation energy (eV), k is Boltzmann's constant (eV/°K), and T is absolute temperature (°K). The substitution for D in Eq. [1] results in

$$x_j = 2(D_ot)^{1/2}\,\text{erfc}^{-1}\frac{C_B}{C_S}\exp - \frac{\Delta E_a}{2kT} \quad [3]$$

When D_o, t, C_B, and C_S are constant, Eq. [3] reduces to

$$x_j = K'\exp\frac{\Delta E_a}{2kT} \quad [4]$$

and its logarithm is

$$\log_{10}x_j = \log_{10}K' - \frac{\Delta E_a}{4.606k}\left(\frac{1}{T}\right) \quad [5]$$

Thus the logarithm of x_j is proportional to $1/T$ and Fig. 9 shows log x_j *vs.* 1000/T°K for a 60 min diffusion. It is also possible to obtain the diffusion constant, D_o, and the activation energy ΔE_a. These data are of particular interest because most previous data for phosphorus diffusion were obtained in oxidizing ambients, and in some cases, with halogen vapor present, as is the case with $POCl_3$ and PBr_3 sources. In order to determine an effective diffusion coefficient, it is necessary to know the surface concentration, background concentration, and junction depth for various temperatures. The surface concentration was determined using the technique of incremental sheet resistance. Anodization was used to remove about 525Å. An average lamina resistivity was calculated to be 3.08×10^{-4} Ω-cm which corresponds to a surface concentration of approximately 7.5×10^{20} atoms/cm³. This result is in excellent agreement with the minimum resistivity, 3×10^{-4} Ω-cm, associated with phosphorus-doped silicon reported by Kooi (6).

Using the junction depth data in Fig. 9 and a background concentration of 6.1×10^{15} atoms/cm³, the effective diffusion coefficient for an erfc distribution was calculated for four temperatures and this is shown in the log-linear graph of Fig. 10. From this data the diffusion constant D_o was calculated to be 2.82 cm²/sec and ΔE_a was found to be 3.29 eV. This is in good agreement with values considered to be most accurate by Kendall and DeVries (11), *i.e.*, $\Delta E_a = 3.58$ eV and $D_o = 2.73$ cm²/sec. The uncertainty in values is associated with the uncertainty of junction depth which probably accounts for the many published values. Also, Masetti *et al.* (12) have recently reported that activation energy also depends on diffusion ambient which accounts for the observed differences in inert and oxidizing ambient diffusions.

Special Handling Procedures

One important aspect in the handling of the material is the effect of the reversible thermal expansion of this material, shown in Fig. 11. From this curve it can be seen that as the temperature of the PH-1050 wafers traverses the temperature range 100°-400°C, the material undergoes a rapid phase transition of 300°C which is accompanied by a relatively large linear thermal expansion. If the temperature region from 100° to 400°C is traversed too rapidly, the source wafers break. The effect is more pronounced when

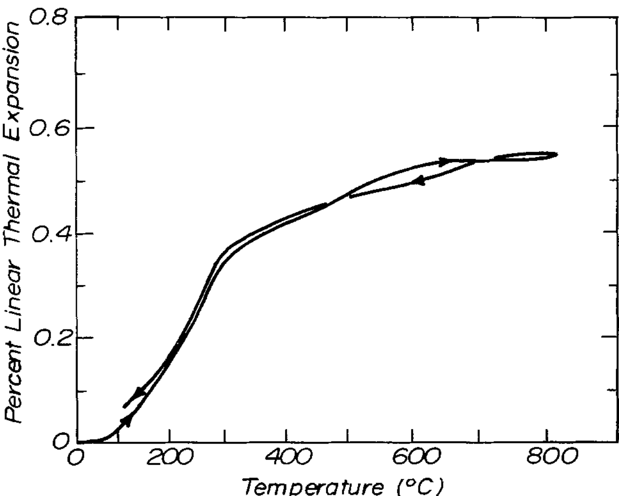

Fig. 11. Percentage linear thermal expansion vs. temperature for PH-1050 wafers.

the source wafers are utilized in the typical format shown in Fig. 1 due to the thermal gradient across the wafers upon insertion into the diffusion furnace. In order to overcome this problem, a preheat cycle has been developed. The function of the preheat cycle is to enable the source and silicon wafers to reach equilibrium at 350°C prior to insertion into the furnace. This can be accomplished by a preheated extension to the diffusion tube. Once the diffusion carrier reaches equilibrium, 350°C, the rate of insertion is not critical, so long as the temperature does not drop below 300°C, because the thermal expansion above 400°C is approximately that of fused silica.

Summary

The evaluation of a new solid planar source for phosphorus diffusion using SiP_2O_7 as the "active" compound in conjunction with an inert matrix phase has been described. From TGA results and assessment of the microstructural stability, the 25 w/o SiP_2O_7 composition appears to fulfill structural and sourcing requirements for use to at least 1050°C. Lifetimes of ~260 and 3400 hr at 1000° and 900°C, respectively, have been predicted from the TGA results assuming all of the P_2O_5 in SiP_2O_7 can be vaporized. Sourcing effectiveness in diffusion runs has been verified for times as long as 216 hr at 1000°C.

The experimental in-service performance of the solid planar phosphorus diffusion source over the temperature range 950°-1100°C has been presented with data for sheet resistance and junction depth. The test results were achieved in a nitrogen ambient. Because the P_2O_5 generated for the diffusion is the result of a solid-state chemical decomposition, there are no unspent gaseous by-products.

Table I. PH-1050 preheat cycle

1. Insert diffusion carrier (boat) with phosphorus and silicon wafers into preheat zone at 350°C.
2. Allow the load to equilibrate at 350°C, time depends on mass and thermal capacity of heating tape.
3. Insert carrier into hot flat zone for desired sheet resistance.
4. Remove carrier from hot zone to preheat zone.
5. Pull carrier from preheat zone into a closed end "white elephant" and allow to cool.
6. Insert next load into preheat zone making sure that the temperature has been stabilized to 350°C.

Chemical Vapor Deposition of Tantalum Pentoxide Films for Metal-Insulator-Semiconductor Devices

E. Kaplan,[1] M. Balog,[2] and D. Frohman-Bentchkowsky

School of Applied Science and Technology, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

Thin amorphous Ta_2O_5 films were deposited by oxygen-assisted pyrolysis of tantalum dichloro-diethoxy-acetylacetonate. Index of refraction and the optical gap measurements of the films were in agreement with previous results. The d-c conduction mechanism appears to be bulk limited following the Poole-Frenkel mechanism with transition towards a space charge limited current at high current densities. The conduction level is high and breakdown voltage is low with respect to SiO_2 or Si_3N_4. The higher dielectric constant of Ta_2O_5 films could make them attractive in double layer insulator MIS devices.

Tantalum pentoxide has been prepared and some of its properties were investigated previously (1-6). This work is concerned with chemical vapor deposition of Ta_2O_5 films in order to investigate their properties with emphasis on their possible usage as part of the gate insulator in MIS devices.

Film Deposition

Chemical vapor deposition (CVD) was used due to its advantage as a method of producing uniform and reproducible films with desired properties at low temperature (7). So far, $TaCl_5$ (3) and Ta alcoholates (4-6), especially $Ta(OC_2H_5)_5$ (4), had been tried as sources for deposition of Ta_2O_5 films. The former requires high temperature (900°C) for the reaction, while the latter are very sensitive to oxygen, hydrolyze easily (8), and thus are inconvenient to work with and require special precautions. The use of organometallic compounds is advantageous since it enables the user to deposit films at lower temperature than others. Tantalum dichloro-diethoxy-acetylacetonate-$TaCl_2(OC_2H_5)_2C_5H_7O_2$, first synthesized by Funk (9), proved to be a better source. It is stable, has a low melting point, and is easy to synthesize (9, 10).

The Ta_2O_5 films were deposited by oxygen-assisted pyrolysis of the source on substrates of silicon and fused silica. The silicon substrates were n- and p-type 5-10 Ω-cm with (100), (110), and (111) orientations. The deposition apparatus is shown in Fig. 1. The source's vapor is carried in nitrogen, argon, or helium from the bubbler (e) through a heated line (o) to the oxygen-rich deposition chamber (f) where reaction yields Ta_2O_5 and other volatile organic derivatives. Deposition conditions were optimized by varying the carrier gas flow rate, the source temperature, the substrate temperature, the geometry of the apparatus, and the diluting gas flow rate. Uniform good quality films are obtained under the following conditions

Carrier gas flow rate	~ 300 cm^3/min
Diluting gas flow rate	~1500 cm^3/min
Oxygen flow rate	~1500 cm^3/min
Source temperature	150°C
Substrate temperature	300°-500°C

Unless otherwise specified, all film properties measurement work was carried out on samples obtained under these conditions.

Film Properties

General.—The Ta_2O_5 films deposited were up to 1 μm thick as evaluated by the Tolansky method (11). The deposition conditions stated above resulted in uniform film deposited at a rate of ~70 Å/min. No dependence on substrate orientation was observed. The films could be easily etched in aqueous HF. In 1.5:1/48% HF:H_2O, the etch rate was ~280 Å/min for films obtained at 500°C. Films deposited at lower temperatures had greater etch rates. The adhesion of the films to the substrates was good showing no evidence of cracking even on abrupt cooling by liquid air. Ta_2O_5 films deposited at 300°C with a thickness greater than 1 μm tend to crack and peel off. Films deposited at 500°C did not show this phenomenon.

Film structure.—Metallurgical microscope and scanning electron microscope micrographs of the samples showed smooth film surfaces comparable with previous results (4). X-ray diffraction patterns showed that the films were amorphous. After annealing in an inert atmosphere at 800°C for 4 hr, the films became polycrystalline hexagonal δ-Ta_2O_5 (12, 13) and not β-Ta_2O_5 (14) as mentioned by Wang *et al.* (4).

Optical properties.—The index of refraction (n) of the films as determined by the Abeles method (15) varied between 1.96 and 2.30 for films obtained at 300° and 500°C, respectively (λ = 6328Å). This is in good agreement with values reported before (3-5).

The optical energy gap was evaluated from the absorption curve of films deposited at 500°C on fused silica disks measured on a Perkin Elmer 450 UV-VIS-NIR spectrophotometer. The absorption spectrum in the 2000-10,000Å region showed only one absorption

peak which was assumed to be due to the fundamental energy gap absorption. Plotting the square of the absorption coefficient as a function of the wavelength or the photon energy gives (16), by extrapolation to zero, the value of 4.38 ± 0.15 eV for the optical bandgap (Fig. 2). This result is in agreement with values reported by Knausenberger *et al.* (3). It also agrees well with values calculated from the heat of formation (17).

Electrical properties.—The electrical properties were evaluated by measurements on MIS structures which were prepared by deposition of 900-2000Å Ta_2O_5 films on 5-10 Ω-cm p- and n-type silicon wafers of (100) and (111) orientations. Aluminum dots of 0.96 × 10^{-3} cm^2 in area and 0.4 μm thick were EB evaporated to form the gate electrode. A film of Al was also evaporated as back contact. The samples were annealed in an inert atmosphere at 500°C for 5 min after evaporation.

C-V measurements.—The dielectric properties of the MIS structure incorporating the Ta_2O_5 films as the gate dielectric were measured by the high frequency *C-V* technique (18). Figure 3 shows the *C-V* curve of a p-type specimen with (111) orientation. There was no difference among the three orientations of (100), (110), and (111). No hysteresis was observed at room temperature with the exception of films deposited at 300°C (Fig. 4) which gave irregular

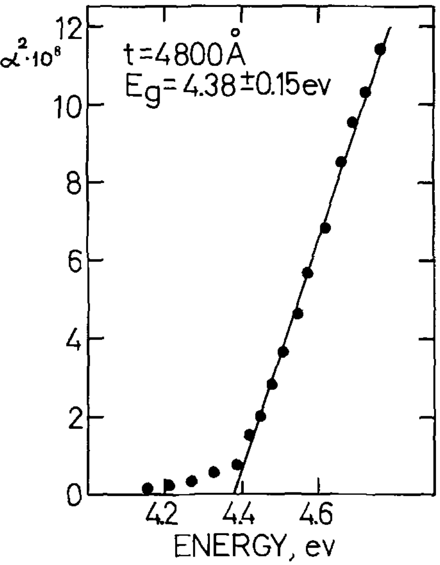

Fig. 2. (Absorption coefficient)^2 as a function of photon energy ($h\nu$) for Ta_2O_5.

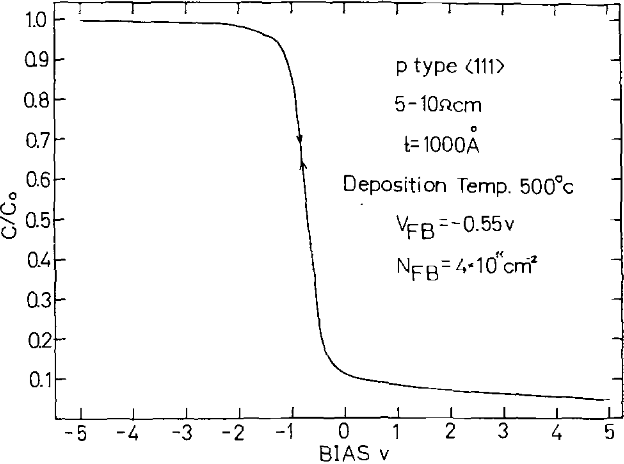

Fig. 3. Normalized *C-V* curve of a MIS structure with Ta_2O_5 at 1 MHz.

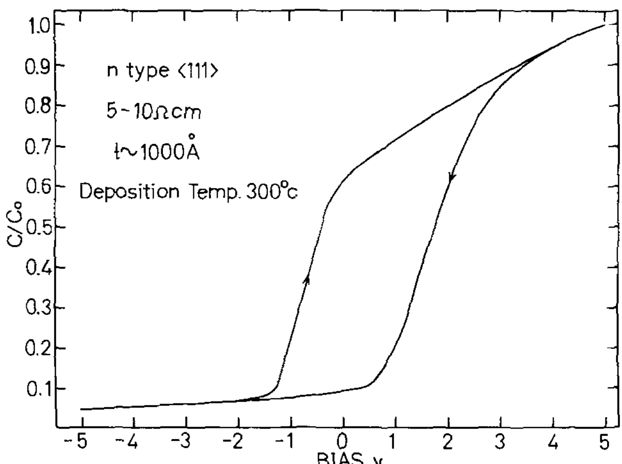

Fig. 4. Normalized *C-V* curve at 1 MHz for Ta_2O_5 film deposited at 300°C.

results and thus were unreliable. Therefore, the rest of the electrical characterization was carried out on films deposited at 500°C. Flatband voltages (V_{FB}) were determined according to Lehovec (19). Their values were 0 to −0.35V and 0 to −0.6V for n- and p-type, respectively, for films in the thickness range of 900-1600Å. The effective surface state charge density (N_{FB}) was calculated from

$$N_{FB} = (\phi_{ms} - V_{FB}) \frac{\epsilon\epsilon_0}{qt} \quad [1]$$

where ϕ_{ms} is the work function difference between Al and Si(20), ϵ is the relative dielectric constant of the Ta_2O_5 films, ϵ_0 is the permittivity of free space, and t is the oxide thickness. N_{FB} values were less than 5 × 10^{11} cm^{-2}. The turn-on voltage varied between 0 and −0.5V for different samples. The relative dielectric constant ϵ was computed from capacitance measurements at 1 MHz and thickness measurements. It varied in the range of 22-25.

Bias-temperature (*B-T*) tests with +10V, −5V at 165°C (Fig. 5) do not indicate any substantial shifts in the *C-V* characteristics due to mobile ions such as sometimes found in SiO_2 (21, 22). The distortion in the *C-V* curve can be attributed to fast surface states (18).

D-C conductivity.—Current-voltage measurements were carried out using the Keithley 602 electrometer. The data are plotted (Fig. 6) in the form of a "Schottky plot" which applies both to the Schottky and to the Poole-Frenkel conduction mechanisms (23, 24).

The current density in the Schottky mechanism is given by

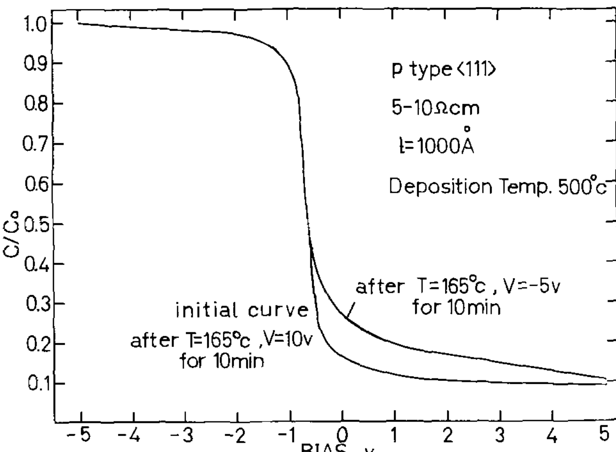

Fig. 5. Normalized *C-V* curve at 1 MHz of a bias-temperature test

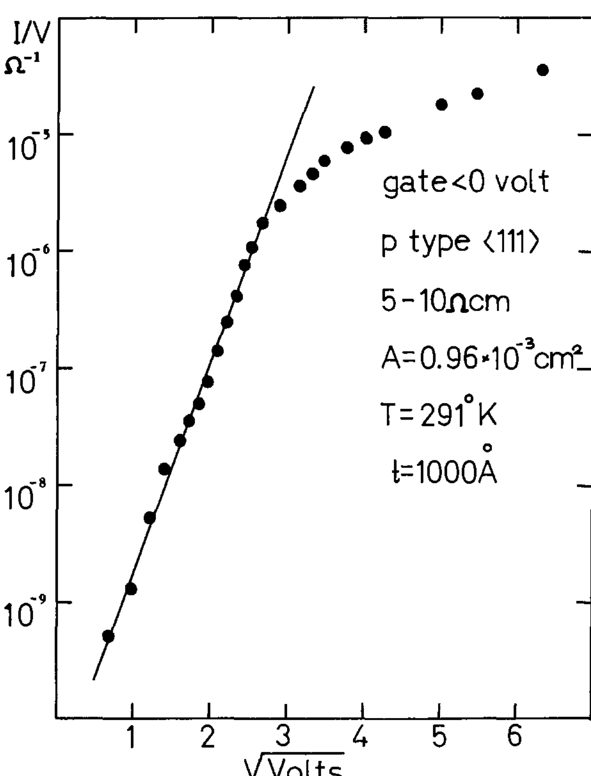

Fig. 6. Log I/V vs. $V^{1/2}$ for Ta_2O_5 film on Si

$$J = AT^2 \exp \left\{ q \left[\left(\frac{q}{4\pi\epsilon\epsilon_0 t} V \right)^{1/2} - \psi_s \right] / kT \right\} \quad [2]$$

where A is the Richardson constant, V is the voltage across the insulator, and ψ_s is the potential barrier between the metal and the insulator. In the Poole-Frenkel mechanism the current density is given by (25)

$$J = G_0 V \exp \{ q[(qv/\pi\epsilon\epsilon_0 t)^{1/2} - \psi_{PF}]/kT \} \quad [3]$$

where G_0 is a constant and ψ_{PF} is the potential barrier of the traps.

The slope of the linear region of Fig. 6 yields (Eq. [3]) a dielectric constant of 5.3 which fits the optical dielectric constant $\epsilon = n^2 = 5.3$ (24). It appears that in the saturation region (Fig. 6 and 7) the current is space charge limited with a current-voltage relationship of $J \alpha V^{2.4}$ (26, 27).

The activation energy as measured from the slope of Fig. 8 is 0.45 eV which gives, after considering the Schottky effect, a barrier height of 0.55 eV. Similar values were found using the zero field current values plotted as a function of temperature (24). These values are in agreement with previous results (28). The low activation energy and the value of the dielectric constant evaluated from Fig. 6 suggest that the conduction in these Ta_2O_5 films is bulk limited with a Poole-Frenkel mechanism at low current densities and a transition towards a space charge limited current at high current densities.

Figure 9 shows results of Ta_2O_5 films in comparison with Si_3N_4 and SiO_2 obtained by Deal *et al.* (29). Note the high conductivity of Ta_2O_5 with respect to the other films. The current saturation can also be noted on the vapor-deposited SiO_2 film. Breakdown field of the Ta_2O_5 films was $\sim 4 \times 10^6$ V/cm.

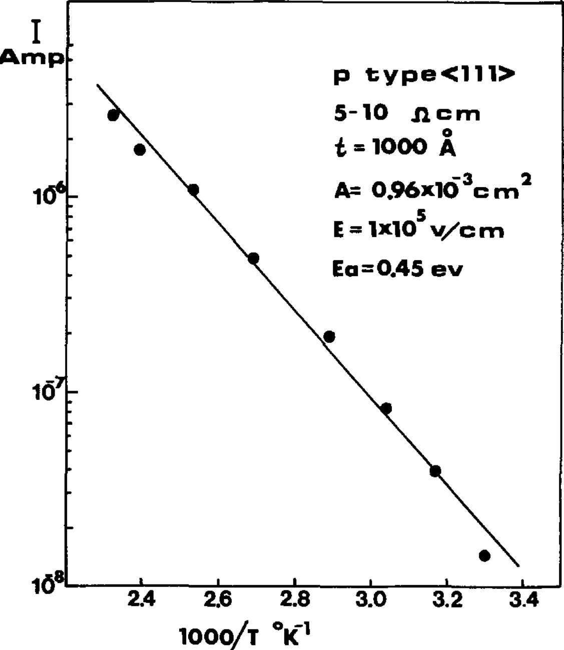

Fig. 8. The current-temperature relationship at a constant electric field.

Conclusions

Properties such as good adhesion, ease of etching, large dielectric constant ($\epsilon = 22$-25), and a possible good barrier against ionic contamination make Ta_2O_5 films prepared by CVD of good potential for usage both as part of passive and active elements in integrated circuits. The high d-c conduction level and the low breakdown voltage relative to SiO_2 and Si_3N_4 make Ta_2O_5 inferior to those films in MIS structures. However, Ta_2O_5's other properties, as mentioned above, could make it useful as a second insulator layer to SiO_2 in multilayer gate MIS devices (30).

Technical Notes

Phosphorous-Doped Polysilicon Growth

Z. Lieblich and A. Bar-Lev

Department of Electrical Engineering, Technion—Israel Institute of Technology, Haifa, Israel

Polysilicon is currently used in various technologies involving semiconductor devices: as mechanical support (3, 4), as resistive or field shaping layers (2, 5, 6), or as gates in MOS or CCD devices (1). These uses exploit its ease of deposition, the fact that it can be deposited over silicon dioxide, and the fact that its deposition at relatively low temperatures does not appreciably affect underlying diffusions. They do not exploit its properties as a semiconductor which are relatively poor. This work is a study of polysilicon grown under conditions most favorable to its use as a semiconductor with the aim of forming a polysilicon

Key words: epitaxy, phosphorous, silane, doping, resistivity, mobility.

to silicon diode (7). The properties of polysilicon grown under these conditions are compared with those obtained by other workers of polysilicon grown under different conditions, generally chosen to emphasize some other properties particular to it.

Experimental Procedure

Gases.—The layers were grown in a horizontal epitaxial reactor consisting of a water-cooled quartz tube through which the gases passed. The gas mixture consisted of 0.07% SiH_4 in H_2. Phosphine was added to the mixture in concentrations varying from 2×10^{-5} to 10^{-1} times that of the silane.

Growth temperature.—A SiC-coated carbon susceptor which supported the substrates was heated by rf induction. Substrate temperature during growth was 800°C, measured by an optical pyrometer and then confirmed by a thermocouple embedded in the susceptor. Silicon grown at less than 600°C is found to be amorphous (8). For increases in growth temperature up to 750°C, there is a progressive drop in resistivity of undoped layers (9), and, if the substrate is single crystalline silicon, the proportion of substrate-oriented grains increases until substrate orientation begins to dominate at 800°C (1). Above 800°C, grain size continues to increase without significant improvement in electrical properties, till above 1050°C when growth becomes epitaxial. Thus it can be seen that a growth temperature of 800°C is a good compromise for obtaining good electrical properties, while retaining the properties of a low temperature process.

Preparation of samples.—The substrates were SiO_2, thermally grown on single crystal silicon. After polysilicon growth, 400 × 400 μm square patterns were etched, and the circuit passivated with an SiO_2 layer grown at 350°C by the Silox process. Windows were etched in the Silox for aluminum contacts. Resistivity (ρ) and Hall mobility (μ) were measured by the Van der Pauw method. Active donor concentration was then obtained from the well-known relationship $\rho = 1/q\mu N_d$.

A separate wafer was grown in each run for measuring the thickness of the grown layers. Part of the polysilicon was etched down to the oxide substrate, and the height of the step measured with a Sloan Dektak surface profile tracer. Growth times were adjusted so that thickness would fall between 1.0 and 1.5 μm.

Results and Discussion

It was established that the growth of the polysilicon in this study is largely mass transfer limited. A check of growth rates at temperatures between 700° and 800°C revealed an activation energy at these temperatures of 0.26 eV. Since it is known (19) that activation energy in the surface reaction rate limited region is about 1.6 eV, it is apparent that we are operating in or near the mass transfer limited region, which is desirable for good thickness uniformity and control. This concurs with Eversteyn and Put (11), who found growth to be temperature independent above 830°C. Variation of thickness over the same wafer was found in our samples to be typically within ±3%.

Figure 1 shows that the growth rate at 800°C is moderately dependent on the phosphine/silane ratio (P/Si) in the gas, and drops from 1.0 μ/min %Si (%Si is the percentage of silane to hydrogen) for (P/Si) = 10^{-5} to 0.6 μ/min %Si for (P/Si) = 10^{-1}. Eversteyn and Put (11) found a stronger dependence for their samples grown at 680°C, where growth rate drops from 0.1 μ/min %Si for (P/Si) = 0 to 0.04 μ/min %Si for (P/Si) = 2.5×10^{-3}. Two samples which they grew at 800°C are also shown in Fig. 1. A similarly strong inhibition of growth at 680°C has been found when doping with arsine (11), while at 1200°C the dependence is weakened (12).

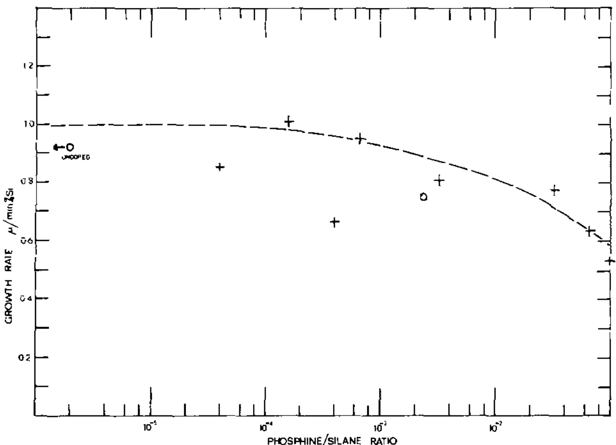

Fig. 1. Growth rate vs. phosphine-silane ratio in the gas phase: + = 800°C, SiH_4-PH_3 at 0.07×10^{-2} atm; ○ = 800°C, SiH_4-PH_3 at 0.35×10^{-2} atm, Ref. (11).

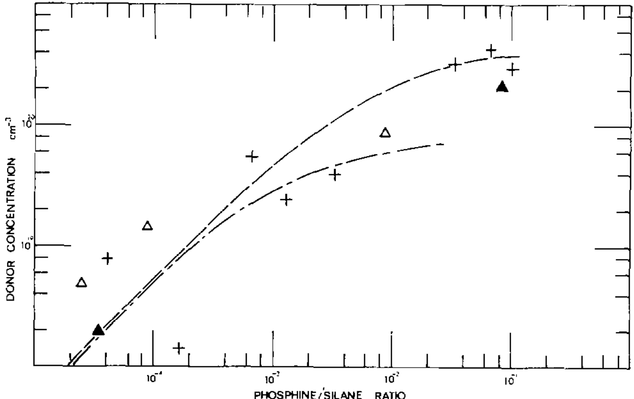

Fig. 2. Active donor concentration vs. phosphine-silane ratio in gas phase: + = 800°C, SiH_4PH_3; ▲ = 840°C. $SiBr_4$-PH_3, Ref. (13); △ = 650°C, SiH_4-PH_3, Ref. (13); ——— phosphorus-doped single crystal silicon, Ref. (16).

In Fig. 2 it can be seen that for (P/Si) ranging from 10^{-5} to 10^{-2} the active donor concentration (N_d) behaves according to the linear relationship

$$N_d \simeq (P/Si) \cdot 5 \times 10^{22}$$

Cowher and Sedgwick (13) found that

$$N_d \simeq (P/Si) \cdot 35 \times 10^{22}$$

for their samples grown at 650°C. Samples which they grew at 840°C from $SiBr_4$ are also shown in Fig. 2. For (P/Si) $\geqq 10^{-2}$, N_d saturates at a value equal to the solid solubility of phosphorus in single crystal silicon at 800°C (14).

In Fig. 3 resistivity is shown as a function of N_d. This is compared with the curve for polysilicon grown at 680°C and doped with arsenic (12). It can be seen that resistivities below 10^{-3} Ω-cm can be attained.

Figure 4 compares mobility measurements of various workers with those obtained in this work. The most important feature seen is an increase in mobility as N_d increases above 10^{18} cm^{-3}. This can be explained by either of two conduction theories:

(*i*) The "carrier trapping model" (15) which assumes that carriers are trapped in deep states at grain boundaries forming potential barriers and associated depletion regions which lower effective mobility. As N_d increases beyond the value at which the deep states are saturated, the height of the barriers, as seen by an electron in the conduction band, decreases and consequently increases mobility.

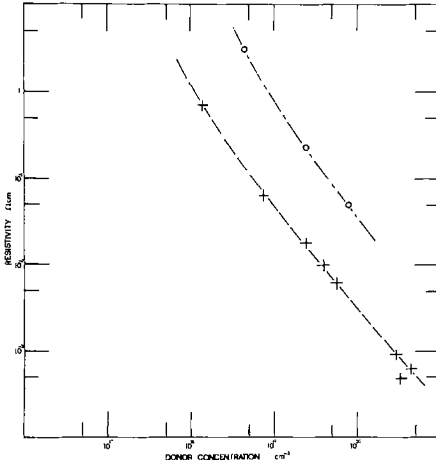

Fig. 3. Resistivity vs. active donor concentration: + = 800°C, SiH_4-PH_3; ○ = 680°C, SiH_4-AsH_3, Ref. (12).

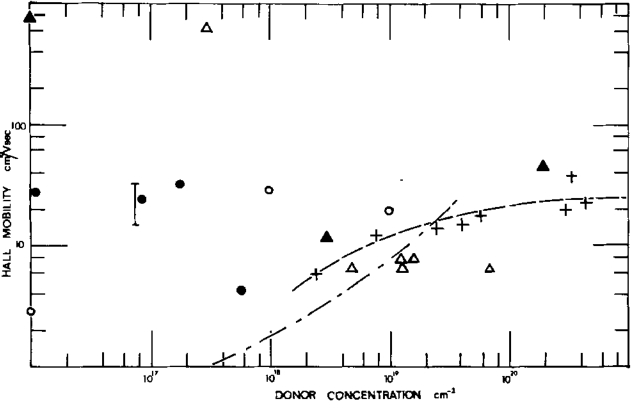

Fig. 4. Hall mobility vs. active donor concentration: + = 800°C, SiH_4-PH_3; ▲ = 840°C, $SiBr_4$-PH_3, Ref. (13); △ = 650°C, SiH_4-PH_3, Ref. (13); ● = 1035°C, SiH_4-PH_3, Ref. (17); ○ = 1035°C, SiH_4-PH_3, Ref. (15); Ɪ = 1100°C, $(CH_3)SiHCl_2$-$SiCl_3$-PCl_3, Ref. (18); — — — 730°C; evaporation; dopant diffused; Ref. (2).

(*ii*) The "dopant segregation model" (13) assumes that at low dopant concentration the dopant atoms tend to segregate at the grain boundaries where they are not ionized and do not contribute free carriers. At concentrations of 10^{18}-10^{19} cm^{-3}, the dopant atoms begin to enter the crystal grains and contribute carriers. The increase in mobility at these concentrations is attributed to the compensation of crystalline defects by the dopant atoms which effectively removes scattering centers.

Summary

Polysilicon was grown in an epitaxial reactor at 800°C and doped during growth by adding phosphine to the gas mixture. It was found that phosphine doping inhibits silicon growth at 800°C to a lesser degree than at lower temperatures, and that resistivities of less than 10^{-3} Ω-cm can be achieved. The donor concentration (N_d) in the layer is given by

$$N_d = (P/Si) \cdot 5 \times 10^{22}$$

where (P/Si) is the phosphine/silane molecular ratio. N_d saturates at a value of 2×10^{20} cm^{-3}. Hall mobility in the polysilicon is 20-30 cm^2/Vsec for N_d above 10^{19} cm^{-3}.

Light Emitting Patterns of Gallium Nitride Electroluminescence

A. Shintani and S. Minagawa*

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

The light production mechanism in GaN MIS light emitting diodes (LED's) is generally considered a radiative recombination of the minor carriers generated in a high electric field at the i-n junction. It has been reported that the lights are emitted in the form of discrete spots around the electrode for a point contact (1) or at crystal subgrain boundaries for In metal contact over the i-layer surface (2, 3). However, the authors found the light occurrence at subgrain centers rather than at subgrain boundaries with respect to the i-n GaN LED's fabricated on

* Electrochemical Society Active Member.
Key words: light spot sites, dislocations, Zn concentration, growth hillocks.

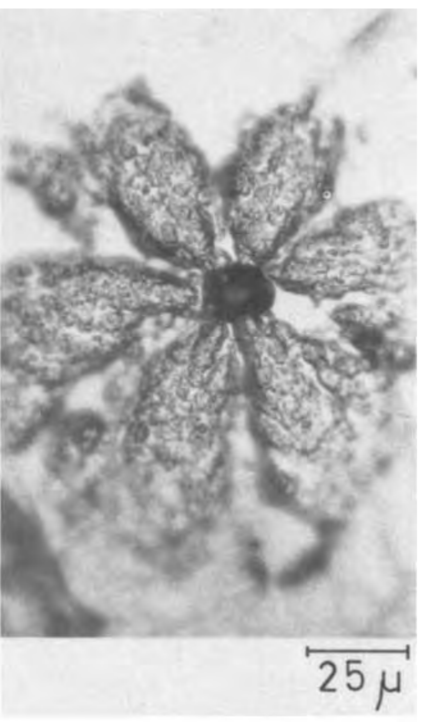

Fig. 2. Etch patterns on a large hillock of the i-layer. A large etch pit develops at the apex.

(0001) oriented sapphires (Fig. 1). In order to investigate the causes of these emissions at the centers, the study was performed by examining the correlation of the light spot sites with crystal growth morphology, Zn concentration, and etch patterns.

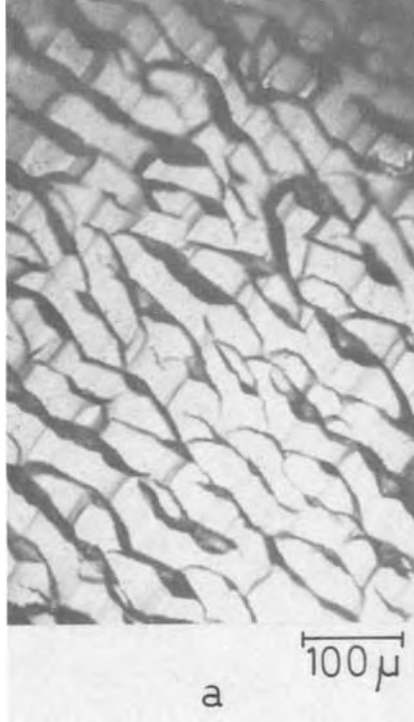
The GaN crystal growth method, phosphoric acid etching technique, and the fabrication process of the GaN:Zn LED's used in the study have been presented in detail elsewhere (4, 6). The Zn concentration distribution on the i-layer surfaces was measured by scanning electron microprobe analysis (EMA). The electron beam irradiated on the crystal surface is several microns in diameter, which is less than one-tenth of the crystal hillock diameter. To reduce measurement error due to surface roughness, the distribution condition of the Zn concentration was expressed by the $K\alpha$-ray intensity ratio of Zn to Ga, in which the Ga $K\alpha$-ray intensity was used as a reference level. Both $K\alpha$-rays were simultaneously measured. Optical microscopic studies on the electroluminescence (EL) and crystal morphology were carried out with an ordinal microscope which allowed focusing magnification up to $400\times$.

The Zn concentration tended to be higher at the peripheries than at the center regions of the growth hillocks by $1 \sim 25\%$. On the other hand, the etch patterns developed first on the peripheries of the growth hillocks and their distribution extended to the hillock faces as etching time increased. Moreover, a large etch pit developed at each apex of the growth hillock (Fig. 2). These etch patterns differ in form, development, and ascription from the hexagonal etch pits on the n-layer (4). The i-layer etch patterns are attributable to crystal defects or precipitates caused by doping with a large amount of Zn.

Thus, phosphoric acid etching of the i-layers indicates that the Zn doping process induces crystal defects including certain dislocations or precipitates within the i-layer growth hillock. The crystal growth mechanism of the i-layer is different from that of the n-layer with no hillock boundaries on both layers being superimposed on one another (4). The etch patterns on the peripheries and faces of the hexagonal hillocks on the i-layer cannot be attributed to dislocations because they are not pitted, but prominent (4). To the contrary, the etch pit development at the apexes suggested that dislocations in the c axis direction can exist in the hillock centers. Therefore, other emission sites should be taken into account in addition to subgrain boundaries. Since the electrical characteristics of the dislocations can cause a channeling of carriers for occurrence of an avalanche breakdown (5), it is reasonable to assume that the light occurs at the hillock central dislocation. However, the etching technique gave no evidence that the dislocations passed through the i-n junction, because the etch pits at the hillock apexes on the lapped i-layer surface were difficult to distinguish from other etch patterns that were present in a high density condition.

The local nonuniformity of the diode internal electrical resistance due to the fluctuation of the Zn concentration distribution provides another reason for the EL occurrence at the growth hillock centers. The yellow LED's made in this work were estimated to have a Zn concentration twice or more that of the blue LED's. The internal resistance of the yellow LED's was found to be ten times or more that of the blue LED's. For example, the yellow LED emits light at 16.8V-1.9 mA and the blue LED at 3.5V-12.9 mA (6). Accordingly, the easier injection of electrons in the hillock center regions follows from the difference in Zn concentration between the two regions described previously. As a result, the light can occur more easily at the centers.

The In metal contact over the surface was employed for the above observations. When a probe was used as the electrode as in the first of Pankove's experiments (1), the lights occurred mostly around the probe without any relation to the growth hillocks. Also, lights sometimes occurred at diverse positions without any relation to the probe position. In the case of this point contact, it is difficult to extend the current over all the i-layer because of its high electrical resistance. This restriction of the current extension causes the light sites to be limited to the region around and under the probe. This light crea-



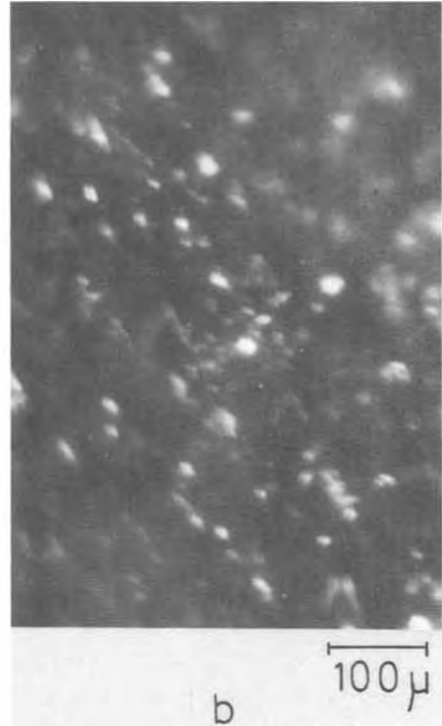


Fig. 3. {11$\bar{2}$0} GaN crystal surface (a) and light spots observed from the substrates (b)

tion does not reflect the nonuniformity of the crystal as well as the lights in the case of the In metal contacts.

The above description is concerned with {0001} crystals. On the other hand, crystals grown on (1$\bar{1}$02) substrates are oriented in {11$\bar{2}$0}, and their surfaces became more wavy [Fig. 3(a)]. The light spots with In metal contact over these surfaces were emitted along the ridges and/or valleys of the wavy surface. These positions disagreed with the observation made on GaN:Mg LED by Maruska *et al.* where the lights were produced with relation to crystal facets (3). The light form on the {11$\bar{2}$0} plane apparently differs from that on the {0001} plane, as seen in Fig. 3(b). Some of the lights seem to be a bar rather than a spot. The light spots on the {11$\bar{2}$0} crystal can be close to each other because there is no development of distinct growth hillocks as large as those on the {0001} crystal. As a result, the lights seem to be in a bar form. It was difficult to find whether or not crystal defects contributing to the emissions exist in the ridges and valleys because the etch patterns developed in a very high density condition on the {11$\bar{2}$0} plane. However, since one of the hexagonal crystal cleavage planes consists of a {0001} plane, it seems plausible that dislocations are formed in a direction perpendicular to the {11$\bar{2}$0} plane.

The lights themselves are actually created inside the devices on the two substrates with the emitting region being precisely at the i-n junction as shown in Fig. 4. This figure gives a more distinct light position than that given before on the GaN:Mg LED (3). The light positions differ from the GaN:Zn antistokes light position which is produced in the i-layer (7). The difference between these light positions in GaN:Zn LED is caused by reversing the electrical bias direction.

In summary, the EL lights in the case of the {0001} GaN crystals occur in the form of discrete spots at the growth hillock centers, but no light is emitted at hillock boundaries. These lights are concerned with certain dislocations at the hillock apexes and/or with Zn concentration nonuniformity within the hillocks. On the other hand, the EL lights in the case of

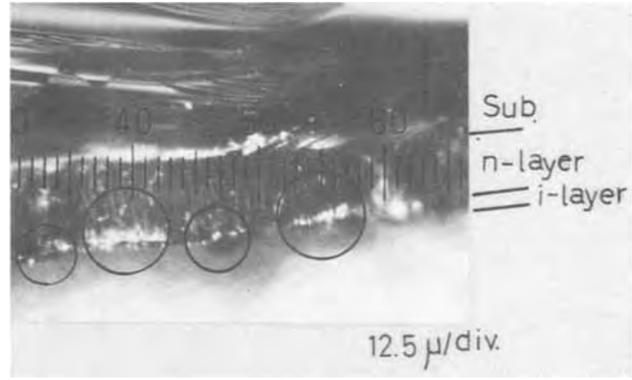

Fig. 4. Observation of the light occurrence (encircled) at the cleavaged surface with a forward bias. The In contact over the i-layer surface is out of focus in the photograph.

the {11$\bar{2}$0} crystals are produced on the ridges or valleys of wavy surface. The lights seem to not always be in the discrete spot form.

Acknowledgments

The authors wish to express their thanks to Minoru Wada for fabricating the LED's used in this work.

Chemical Vapor Deposition of Silicon Nitride

J. J. Gebhardt, R. A. Tanzilli, and T. A. Harris

General Electric Company, Re-Entry & Environmental Systems Division and Space Sciences Laboratory, Space Division, Philadelphia, Pennsylvania 19101

Crystalline α-Si_3N_4 is formed from the gas phase by the reaction of silane with ammonia or, somewhat less expensively and more conveniently, by reaction between a silicon tetrahalide and ammonia. Billy (1) has elucidated the chemistry of the silicon tetrachloride-ammonia and silicon tetrabromide-ammonia systems at lower temperatures (−78°-100°C), and has demonstrated that the silyl imide, $Si(NH)_2$, and possibly polymers based on it are the principal precursors to silicon nitride. The precursors, on thermal decomposition to above *ca.* 1000°C, lead to only one product, identified as amorphous silicon nitride, which on further heat-treatment to about 1450°C yields α-Si_3N_4. Mazdiyasni and Cooke (2) have used the high purity, fine particle size powder obtained by this approach to form high density, fine-grained polycrystalline bodies by hot pressing, with magnesium nitride as a sintering aid. The formation, precipitation, and crystallization of the intermediate imides also appears to be the path by which dense, crystalline layers of α-silicon nitride are formed by chemical vapor deposition under controlled conditions. Galasso, Kuntz, and Croft (3) have demonstrated that above about 1100°C and under suitable flow and concentration conditions, translucent deposits were formed and identified as α-Si_3N_4, of high purity and considerable preferred orientation. Similarly, Airey, Clarke, and Popper (4) deposited amorphous and crystalline silicon nitride from silane-ammonia and silicon tetrachloride-ammonia mixtures.

Experimental Approach

Silicon nitride deposits were formed by reacting both silicon tetrachloride and silicon tetrafluoride with ammonia in a dynamic hot-wall reaction system, at low pressure (less than 5 Torr) and between 1100° and 1550°C. Silicon tetrachloride (Fisher Scientific Company, Technical Grade) was entrained in a nitrogen carrier gas, or alternatively, pumped directly into the furnace from a stainless steel reservoir through a metering valve. In the former case, the amount of tetrachloride fed was determined from the nitrogen flow and assuming liquid vapor equilibrium at the reservoir temperature. In the latter case, the metering valve was calibrated by determining the weight loss of the tetrachloride reservoir. Silicon tetrafluoride (Matheson Gas Products, 99.6% min.), a vapor at room temperature, was metered through a flowmeter, as was anhydrous ammonia gas (Matheson Gas Products 99.99%). All reagents were used as received, without further purification.

Deposits were prepared using a vertical, resistance-heated, graphite element vacuum furnace which contained a graphite reaction tube 1 in. in diameter by 8 in. long and made from Speer 580 graphite. Within this tube was fitted a graphite channel (Union Carbide Corporation, CS Grade), ½ in. square by 8 in. long, the inner surfaces of which were covered with a thin layer of Grafoil®,[1] which served as the actual deposition surface. Reagents were metered to the furnace as vapors through stainless steel lines and mixed within the furnace to prevent clogging of the lines by the solid adduct. Exhaust gases were pumped from the furnace through a liquid nitrogen trap and vented or passed through an alkaline scrubbing solution when silicon tetrafluoride was used. Solid by-products collected in cooler regions of the furnace as well as in the furnace exhaust lines in both the chloride and fluoride reactions, although in the latter case these deposits were slightly less voluminous. Accumulation of these solids constituted the limiting factor in the length of a given experiment due to closing off of the gas passages to the pump. Temperature was determined using a Leeds and Northrup disappearing filament pyrometer and sighting on the deposition surface through a window at the top of the deposition tube until the window became obscured with by-products. From this point, power settings were kept constant and thermal equilibrium was assumed. Prior to starting, the furnace was stabilized at deposition temperature for 30 min with a nitrogen flow equivalent in volume to the experimental flow.

The deposits were freed from the graphite channel by grinding away the bulk of the channel and heating the remainder in air for several hours at about 650°C, leaving the deposit as a free-standing, square cross-section tube. Portions of certain deposits were ground and polished for determination of optical properties; others were used for preliminary oxidation and creep studies. Most of the deposits were less than 0.5 mm (20 mils) thick.

Discussion of Results

Deposition process.—Deposits obtained from the tetrachloride system ranged from white and glassy or vitreous at low temperatures to dark green around 1500°C. Under the conditions used, white or vitreous deposits were again obtained at 1550°C. Typical as-deposited surfaces are shown in Fig. 1. On the other hand, deposits made from the fluoride system were light tan in color at 1500°C. However, conditions leading to vitreous deposits were not used with the fluoride system as will be discussed shortly. The color difference between materials produced from the chloride *vs.* the fluoride system persisted through polishing, with the former yielding transparent yellow brown plates, while the latter materials were almost water white and clear.

Deposition stresses appeared to be greater at long residence times (8 msec) and cylindrical deposits appeared to contain residual compressive stresses around 45-70 MN/m^2, estimated from the change in radius on cutting a ring-shaped piece. At shorter residence times ($\sim$ 1 msec), the materials were of somewhat smaller grain size and presented no difficulty in cutting or machining for polishing. Residence times were estimated from the total gas volume fed, at deposition temperature and pressure, and the total reactor volume. Typical densities of polished specimens were around 3.19 g/cm^3, close to the measured and calculated values of 3.168-3.169 g/cm^3 of Wild *et al.* (5).

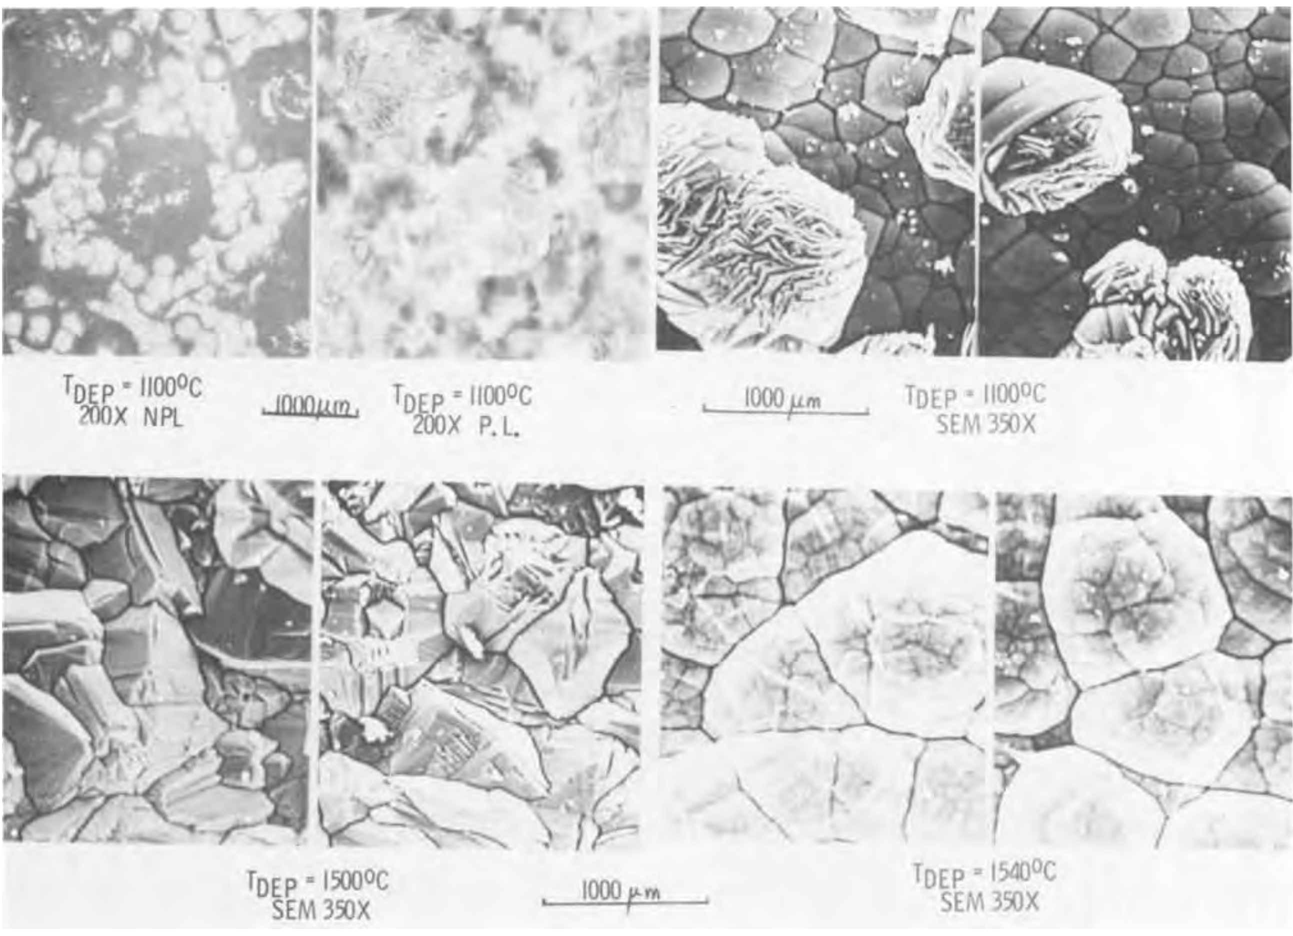

Fig. 1. Optical and scanning electron microscope views of as-deposited silicon nitride obtained from the chloride system. Adhering particles in upper right view appear to be precursors to crystalline material in lower left view.

The deposition of silicon nitride appears to differ in some respects from many other CVD processes in that solid deposition intermediates form immediately on mixing the reagents, rather than as a result of a gas phase reaction or decomposition which is controlled by chemical or diffusional kinetics. The situation is somewhat analogous to the deposition of boron nitride, but in that case, the last identifiable intermediate, B-trichloroborazole, is less stable and more volatile.

From the evidence presented in the literature (1,2), the stability of the silyl imide intermediate, at least up to about 1000°C, appears to be relatively high, while the crystallization rate is low, the formation of α-Si_3N_4 requiring several hours to reach completion. Thus, unlike situations in which the deposition precursors are molecular species or fragments, silicon nitride is formed from precursor particles of considerably greater mass which require more time for complete decomposition and crystal formation. The latter can occur while the particles are still suspended in the gas phase, judging from the partially decomposed appearance of particles adhering to the surfaces of 1100°C deposits shown in Fig. 1. If intermediate concentrations are too high, the frequency with which they collide and grow in the gas phase, as well as the rate at which they strike and adhere to the substrate, may overbalance the rate at which particles attached previously can decompose and form crystalline material. Thus, despite temperature increases which tend to favor decomposition and crystallization, a vitreous material can be formed in the temperature range where crystalline deposits would otherwise be obtained.

Specimens of the by-products of both fluoride and chloride deposition experiments were collected from the furnace exhaust lines and examined briefly by means of infrared spectra, using the KBr pellet technique. In both cases, the specimens were somewhat contaminated with moisture during handling and had hydrolyzed to some extent. The respective ammonium halide salts were also present. The spectra showed the presence of ammonium ions and Si-O bonding as well as the respective ammonium halide ions. A sharp peak at about 480 cm^{-1}, a frequency characteristic of Si-N stretching, may have been due to intermediates carried out of the furnace or to small silicon nitride particles already completely deamminated in the gas phase.

A specimen of the chloride system by-product was heated at 1450°C under flowing nitrogen (10 Torr) for 1 hr. This resulted in formation of elemental silicon, with no traces of α-Si_3N_4. Since traces of elemental silicon were occasionally found in x-ray diffraction patterns of crystalline deposits, it is possible that some disproportionation of the intermediate compound occurs during deposition of the nitride.

X-ray studies.—X-ray diffraction examination was carried out on powder specimens deposited at 1500°C from both chloride and fluoride mixtures. Both reaction systems yielded α-silicon nitride. All experimentally determined d spacings and diffracted intensities compared favorably with the values listed in JCPDA tables (6) for α-silicon nitride. There was no indication of noncrystalline or amorphous constituents in these deposits, in contrast to materials prepared at lower deposition temperatures (*e. g.*,1100°-1300°C).

X-ray diffractometry examination of thin (*e.g.*, 0.8 mm) flat plates of both fluoride and chloride material showed some α-Si_3N_4 reflections to be absent while others exhibited intensities greatly different from those obtained with randomly ordered powders of the same specimens. This is indicative of a degree of preferred orientation with respect to the

deposition surface and has been noted by others (3). Table I lists the experimental relative peak intensities obtained with nickel-filtered copper radiation, for flat plates, parallel to the deposition substrate, and also includes the literature values for comparison. No corrections were made for polarization, absorption, etc. The data indicate that the (110) crystal planes of the fluoride deposits tend to be parallel to the substrate while the basal planes of the hexagonal unit cells (002) of the chloride deposits assume this orientation. It is not clear whether these orientations are the result of differences in the deposition chemistry of the two reaction systems, or if they are typical of all deposits obtained from these two processes.

Optical properties.—The region of transparency of polished crystalline α-Si_3N_4 was found to extend from 0.3 to 5.0 μm, as shown by the transmittance data in Fig. 2 and 3. Other than visible color, little difference in optical transmittance characteristics was observed in deposits prepared using either silicon tetrachloride or tetrafluoride reactants in conjunction with ammonia. The polished deposits were translucent, although good imaging was obtained when the polished deposits were placed in contact with printed matter, as shown in Fig. 4. A quantitative measure of the degree of diffuse infrared scattering for specimens from the two reaction mixtures is given approximately by the differences in transmittance levels between the hemispherical and

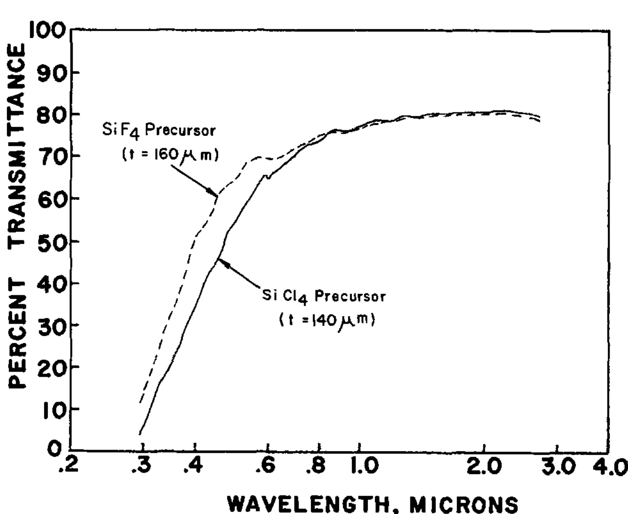

Fig. 2. Visible and near-infrared hemispherical transmission of polished silicon nitride deposits from both chloride and fluoride systems.

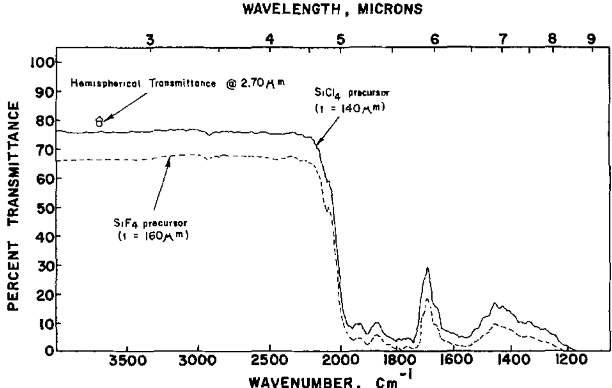

Fig. 3. Near-normal specular transmittance of polished silicon nitride deposits.

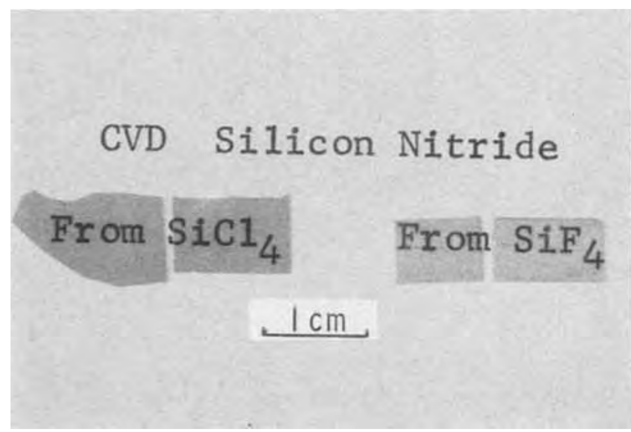

Fig. 4. Optically polished deposits from both fluoride and chloride systems; former is nearly water white transparent, latter is tan.

near normal specular data at 2.7 μm, as shown in Fig. 3. A comparison of the specular reflectance spectra of the polished α-Si_3N_4 deposit (prepared from the chloride precursor) with that obtained from a polished specimen of hot-pressed β-Si_3N_4 prepared by Norton Company (NC-132) is displayed in Fig. 5. Both modifications exhibit similar Reststrahlen peaks in the 9-12 μm range. No attempt was made to analyze the detailed spectra, however; these differences are most likely related to crystallographic variations between the α- and β-modifications of silicon nitride.

Mechanical and oxidation tests.—Preliminary oxidation and creep resistance data were obtained by

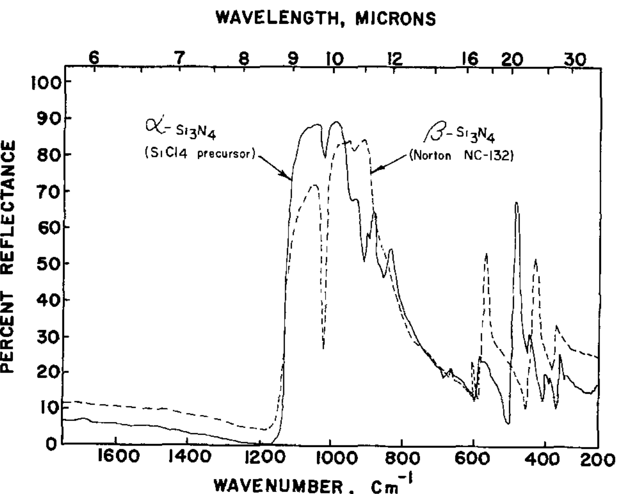

Fig. 5. Near-normal specular reflectance of CVD α-Si_3N_4 compared to hot-pressed β-Si_3N_4.

Rosolowski and Greskovich 7) using crystalline material prepared in this study from the chloride-ammonia system in the as-deposited condition. Creep at elevated temperatures was measured in air in three-point bending by supporting a piece of the silicon nitride, about 2.5 × 0.5 cm, at its ends on silicon carbide knife edges, and suspending a weight across the center of the specimen on another knife edge. This apparatus was located in a furnace equipped with silica windows for temperature measurement as well as for photographic recording of beam deflections with time. Under the most severe conditions used, a 69 MN/m^2 (10,000 psi) load at 1560°C, no measurable creep was observed after 198 hr at temperature. Assuming that a 20 μm deflection had occurred, *i.e.*, close to the minimum detectable movement, it was estimated that the upper limit of creep rate for this material was about 1.6×10^{-7} hr^{-1}.

Preliminary estimates of oxidation resistance were made by maintaining as-deposited specimens at elevated temperatures in air with periodic removal from the furnace for weighing to determine the amount of silica formed (7). The specimens lay on a bed of silicon nitride powder during the experiments. The weight increase in each case was expressed in milligrams per square centimeter and the data plotted as a function of the square root of time in hours. Data obtained at 1550°C are shown in Fig. 6 and indicate a weight change of less than 0.01 mg/cm^2-$hr^{-1/2}$. Other specimens gave slightly higher rates at lower temperatures, probably because of greater surface roughness which made area calculations imprecise.

Thermal stability.—In order to evaluate the thermal stability of crystalline and vitreous deposits of silicon nitride under vacuum, as well as to assess qualitatively the degree of by-product entrapment, specimens were heated in a Knudsen cell between 1400° and 2000°C and the evolving gases analyzed by mass spectrometer. Crystalline materials, deposited from both fluoride and chloride systems at 1500°C, evolved only nitrogen, commencing *ca.* 1450°-1500°C and ending *ca* 1700°C, probably through exhaustion of the specimen. A vitreous deposit prepared at 1350°C from the chloride system behaved similarly, although a much larger sample which evolved too much nitrogen to be measured also gave off relatively small amounts of both chlorine and silicon. By comparison to the latter case, vitreous boron nitride yielded considerably more ammonia, nitrogen, and chlorine as well as boron under similar circumstances (8). The silicon nitride deposits are evidently much "cleaner" than the respective boron nitride deposits despite the greater stability of its intermediate species.

A polished specimen of crystalline silicon nitride deposited at 1500°C showed evidence of intracrystalline residual stresses in transmission micrographs as shown in Fig. 7. This heated specimen was placed on a silicon nitride platform and heated for 1 hr at 1700°C in a hydrogen-nitrogen mixture (1:5) at 1 atm. There was no change in the appearance of the specimen, nor any evidence of crystallographic transformation. A slight reduction in the 1-5 μm region of the infrared transmittance spectrum was the only change produced. This is in agreement with other reports of the stability of very pure α-Si_3N_4 with respect to transformation to the beta-form (9). The vitreous material transformed to the alpha-form on heating at 1600°C and 10 Torr (nitrogen) but also decomposed sufficiently to produce strong β-silicon carbide lines as a result of reaction between the deposit or vaporizing species and the graphite substrate.

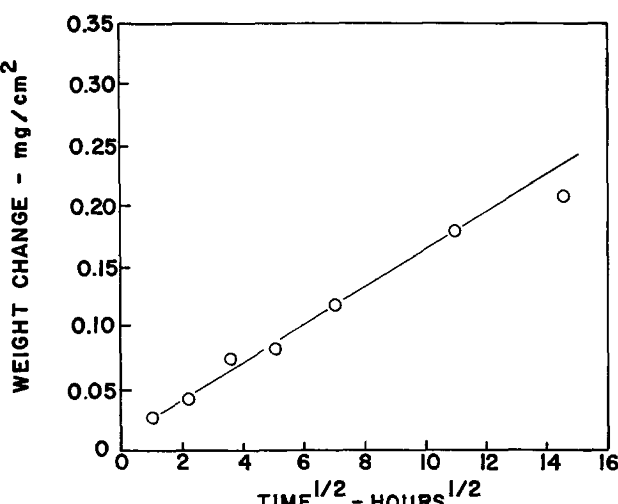

Fig. 6. Oxidization of CVD silicon nitride at 1550°C [Ref. (7)]

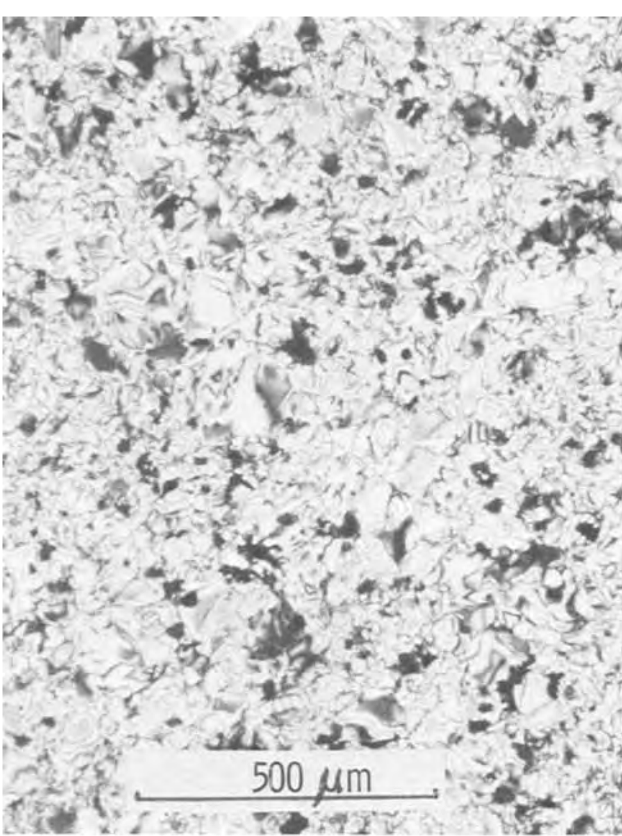

Fig. 7. Transmission microscope view of polished silicon nitride (PL).

Summary

Pure α-Si_3N_4 was deposited from mixtures of ammonia with silicon tetrachloride and tetrafluoride at reduced pressure and temperatures between 1400° and 1500°C. Vitreous or amorphous silicon nitride was obtained from the tetrachloride system below 1400° and above 1500°C, apparently as a result of excessive intermediate species formation and insufficient time for crystal formation.

Crystalline α-Si_3N_4 made by chemical vapor deposition is considerably more resistant to creep and oxidation in air than the hot-pressed materials which contain sintering additives.

Flat specimens from both reaction systems were able to be ground and polished to give transparent plates with relatively low intrinsic scatter. Optical properties were measured by transmission in the visible region and by both specular and hemispherical transmission and reflection in the infrared region. X-ray diffractometer measurements made on polished specimens indicated some degree of preferred orientation in both materials, although they differed regarding the direction of orientation.

Metallurgical Structure of Be-Au and Si-Au Ohmic Contacts to GaP

W. A. Brantley,[1] V. G. Keramidas,* B. Schwartz,* M. H. Read, and P. M. Petroff

Bell Laboratories, Murray Hill, New Jersey 07974

Ohmic contacts to p- and n-type GaP can be obtained with Be-Au and Si-Au metallizations, respectively (1, 2). While satisfactory electrically for use in the fabrication of GaP LED's, little information is available regarding the metallurgical structure of these contacts. Recently, secondary ion mass spectrometry (SIMS) experiments have shown that extensive gallium migration and some phosphorous migration through the contact metallizations occur during the alloying[2] process; in addition, the presence of intermetallic compounds within the alloyed contacts was reported (3). In this note, the identification of these intermetallic compounds by transmission electron microscopy (TEM) and x-ray diffraction (XRD) is discussed in more detail, along with results from other experiments to elucidate the complex metallurgical structure of alloyed Be-Au and Si-Au contacts to GaP.

Specimen Preparation

Metallizations were deposited by electron-gun evaporation over the full surfaces of GaP chips. The p-contact metallization consisted nominally of a 5000Å Be-Au layer evaporated from an alloy source having ~1 w/o Be in Au, followed by a 10,000Å gold film. These films were deposited on {111} P faces of p-type layers of GaP p/n junction material grown by liquid phase epitaxy (LPE) or p-type liquid encapsulated Czochralski (LEC) GaP, both having $N_A - N_D \gtrsim 5 \times 10^{17}$ cm^{-3}. The n-contact metallizations consisted nominally of a 5000Å Si-Au layer evaporated from an alloy source having ~3 w/o Si in Au, followed by a 10,000Å gold film. These latter films were deposited on {111} Ga faces of n-type LEC GaP having $N_D - N_A \gtrsim 3 \times 10^{17}$ cm^{-3}. Ohmic contacts were obtained by heating specimens at 600°C for 5 min in a N_2-H_2 atmosphere.

[2] The term "alloying" is used here to denote any heat-treatment for achieving ohmic contacts.
Key words: compound semiconductors, intermetallic compounds, ohmic contacts.

Chemical Analyses of Film Compositions

The concentrations of beryllium and silicon in the as-deposited Be-Au and Si-Au layers were determined by atomic absorption spectrometry (AAS). For these analyses, Si-Au and Be-Au films, nominally 10,000Å thick, were deposited on sapphire substrates, and subsequently stripped from the substrates by aqua regia for examination. The AAS results indicated that the Be:Au ratio in the deposited film is approximately that of the starting alloy source. However, the Si:Au ratio for the film can be as much as an order of magnitude lower than in the alloy source, as a consequence of the higher vapor pressure of gold compared to silicon (4).

Transmission Electron Microscopy Observations of Metallization-GaP Interfaces

The region near the metallization-GaP interface for the alloyed p- and n-contacts was examined by TEM to search for intermetallic compounds, as well as to investigate the structure of the metallization and the dislocation density in the GaP. For these specimens, the GaP substrates were mechanically polished using 0.3 μm Al_2O_3 particles; subsequent thinning of both the GaP substrates and the alloyed films was accomplished by ion milling with 6 keV Ar^+ ions.

A bright-field electron micrograph for a region near the interface between the alloyed p-contact and GaP is illustrated in Fig. 1(a). Electron diffraction patterns, as shown in Fig. 1(b), indicate the presence of the β (~21 a/o Ga) and/or β' (~23 a/o Ga) phases (5) between gold and gallium, in addition to polycrystalline gold. Although β' is the room temperature equilibrium phase, β' and β have similar diffraction patterns (5) and both phases may be present. The satellite spots around some primary diffraction spots in Fig. 1(b) suggest (6) that the gold-gallium phase(s) initially form(s) an epitaxial layer with GaP, followed by a polycrystalline layer. These gold-gallium crystallites appear as bright spots in the dark-field electron micrograph of Fig. 1(c), corresponding to the indicated diffraction ring in Fig. 1(b). Similar micro-

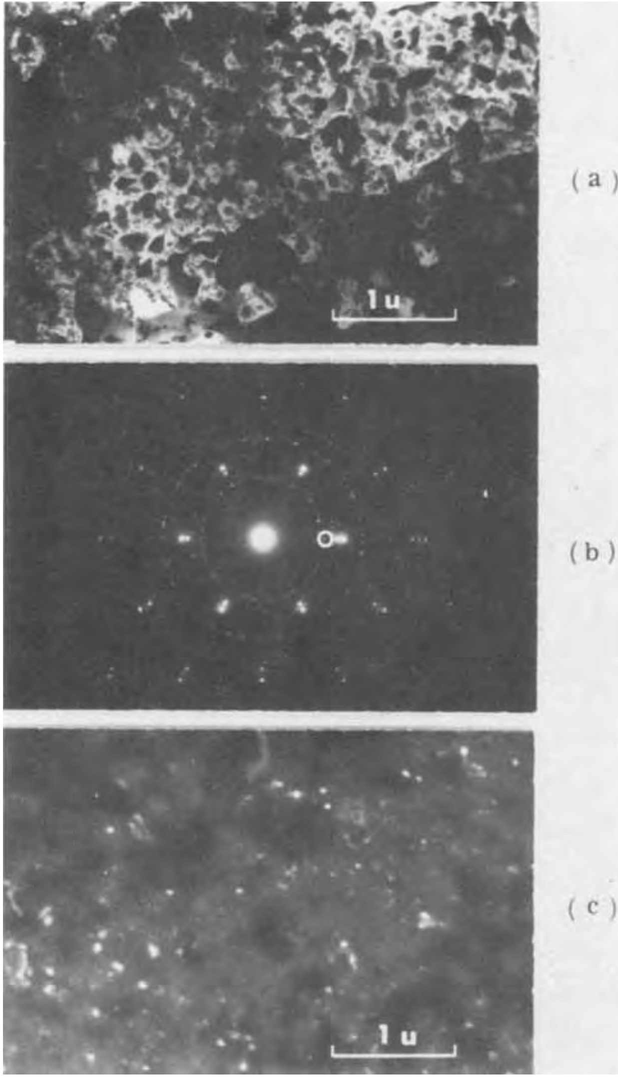

Fig. 1. (a) Bright-field electron micrograph of a region near the interface for the alloyed p-contact on GaP. (b) Electron diffraction pattern from the region of Fig. 1. (c) Dark-field electron micrograph corresponding to the first diffraction ring (indicated by the circle) in (b) for the β phase between gold and gallium.

structural results to those in Fig. 1 were observed by TEM for the alloyed n-contact; gold and the β and/or β' phase in the Au-Ga system again were the only phases near the metallization-GaP interface. The dislocation density detected by TEM in the GaP substrates near the interface was in the low 10^4 cm^{-2} range; thus, no interfacial region of high dislocation density is generated by the contact alloying process.

X-Ray Diffraction Studies

To complement the TEM analyses, alloyed contacts also were examined by XRD for the presence of intermetallic compounds. A wide film Debye-Scherrer technique was employed, utilizing Cu Kα radiation incident on the top surface of the metallization at an angle of $\sim$16° (7). In contrast to the TEM observations, no evidence of intermetallic compounds in the p- and n-contacts was detected by XRD, indicating that intermetallic compounds are not present in large concentrations near the surface. (The strongest lines for the β and β' Au-Ga phases coincide with weak gold diffraction lines from residual Cu Kβ radiation.)

In order to facilitate detection of intermetallic compounds, alloyed 5000Å thick Be-Au and Si-Au films on GaP also were investigated, where the 10,000Å gold overlay was omitted. For these specimens, a profusion of XRD lines due to intermetallic compounds was observed. Some preferred orientation for these phases was evident from the appearance (7) of the diffraction arcs. No significant differences for the XRD lines were noted when these latter films were alloyed for 30 min instead of 5 min. In all cases, the diffraction lines for gold were weak, indicating that the gold had principally formed intermetallic compounds.

For the Si-Au films alloyed with GaP, the strongest lines could generally be assigned to the β and/or β' Au-Ga phases. The positions of other lines suggested that the α' ($\sim$13 a/o Ga) (5), AuGa, and $AuGa_2$ phases also might be present. [The interplanar spacings for the γ phase, which contains $\sim$30 a/o Ga, were not reported in Ref. (5).] No evidence for SiP_2 in these films was found.

The situation for the Be-Au films alloyed with GaP is more complicated than for the Si-Au films because beryllium and gold form a series of intermetallic compounds (8) whereas no intermediate phases exist between gold and silicon. The strongest XRD lines for these specimens could be assigned to Au_3Be, while Au_2Be also may be present; no evidence was found for AuBe and $AuBe_5$. The presence of the Au-Be phases results in less certain identification for Au-Ga intermetallics because of similar line positions; the β and/or β' Au-Ga phases probably were present in these films. In addition, Be_3P_2 also may form during alloying, but identification is difficult because of the very few relatively strong XRD lines for this compound.

SIMS experiments (3) could not provide support in interpreting the XRD results, such as whether or not Be_3P_2 forms during the alloying process for p-contacts. At present, absolute concentrations for the various chemical species within the metallizations cannot be established by SIMS due to the lack of appropriate chemical standards for comparison and possible differential sputtering rates. (For example, beryllium can be in solid solution with gold, in intermetallic compounds, or segregated at grain boundaries in the films.) Attempts to obtain depth profiles for beryllium and silicon through alloyed p- and n-contacts using SIMS were unsuccessful because nonplanar sputtering fronts occur for deep "burns," due to gold globules lying on the film surfaces. Alternatively, accurate depth profiles could not be obtained by sputtering through the unmetallized back side of the GaP, because of uncertainties in the sputtering rate for the long duration burn required.

The formation of intermetallic compounds during alloying provides one potential source of stress in the semiconductor device and may adversely affect reliability. Using an x-ray diffraction lattice curvature measurement technique (9), an approximate value of $\sim 3 \times 10^9$ dyne/cm^2 was determined for the stress in a p-contact which had been alloyed with GaP at 600°C. The maximum value of the stress in the GaP at the interface with the contact (neglecting stress concentrations at the edges of the metallization) was $\sim 7 \times 10^7$ dyne/cm^2 ($\sim 1 \times 10^3$ psi), considerably lower than the stress in the contact because of the ratio of contact thickness to substrate thickness (10). No evidence of freshly generated dislocations in GaP was revealed near the periphery of alloyed p-contact dots by conventional (11) etching solutions. The stresses associated with ohmic n-contacts are expected to be of similar magnitudes.

It has not been possible from scanning electron microscopy and optical microscopy observations on numerous specimens to assess unambiguously the relative contributions of solid-state diffusion and/or formation of a liquid phase during the contact alloying. Efforts to delineate an alloyed region on a GaP cleavage face by

photoetching with $HF:H_2O_2$ or prolonged chemical etching with aqua regia were unsuccessful. However, the absence of detectable (by XRD) amounts of intermetallic compounds in the outer portions of the alloyed n- and p-contacts suggests that dissolution of the metallizations during the alloying process may be principally confined to regions near the interface with GaP.

Acknowledgments

The authors are grateful to T. Y. Kometani for performing the atomic absorption spectrometry measurements, to T. T. Sheng for assistance with the transmission electron microscopy, to G. A. Rozgonyi for performing the x-ray diffraction stress measurement, and to G. W. Kammlott for performing the scanning electron microscopy. Special thanks are extended to C. R. Paola for helpful comments and extensive assistance regarding the deposition procedures.

Brief Communications

Defect Chemistry of $BaTiO_3$

N.-H. Chan and D. M. Smyth*

Materials Research Center, Lehigh University, Bethlehem, Pennsylvania 18015

We have been studying the defect chemistry of $BaTiO_3$ by measurement of the equilibrium electrical conductivity by a four-probe d-c technique as a function of temperature (600°-1000°C), oxygen pressure (10^{-24}-1 atm), Ba/Ti ratio (0.9950-1.0000), and added impurities. The samples are polycrystalline bars, 98% dense, sintered from powders prepared by calcination of a homogeneous glassy solid obtained by polymerization of an organic solution in which the cationic constituents have been dissolved in precisely weighed amounts (1). The oxygen activities were obtained by precision-mixed $Ar\text{-}O_2$ (high pressure range), $CO\text{-}CO_2$ (low pressure range), and by means of an electrochemical oxygen pump and oxygen activity detector based on CaO-doped ZrO_2 for the midrange of pressures (2).

The results shown in Fig. 1 are typical of acceptor-doped and undoped material, and are very similar to previously reported results (3-5). This sample contained 134 ppm (atomic) of added aluminum as a Ti-site acceptor. We believe that all results reported to date have been dominated by acceptor impurities in the near-stoichiometric region, whether deliberately added or not. This reflects the greater natural abundance of acceptor-type impurities, *e.g.*, alkali metals on Ba sites or Al, Mg, Fe on Ti sites, compared with donor-type impurities, *e.g.*, rare earths or Th on Ba sites or Nb, Ta, W on Ti sites; and the very small concentration of intrinsic ionic disorder to be expected because of the highly unfavorable nature of such defects as $Ba_I^{\cdot\cdot}|O_I''$, O_I'', and V_{Ti}''''.

The conductivity minima correspond to the completely compensated state, neglecting mobility differences, and their temperature dependence has been shown to correspond closely to the optical bandgap

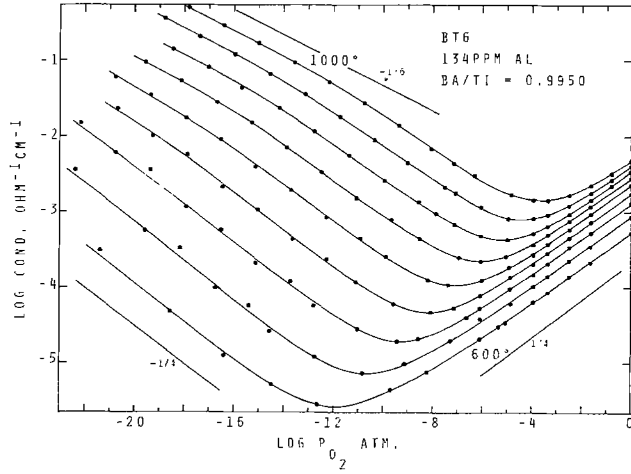

Fig. 1. Equilibrium conductivity of acceptor-doped $BaTiO_3$. Temperatures at 50° intervals. Lines having ideal slopes are indicated for reference.

of $BaTiO_3$ (3-5). The results in the lower pressure range are in close accord with the reduction reaction

$$O_o \rightleftharpoons 1/2\,O_2 + V_o^{\cdot\cdot} + 2e' \quad [1]$$

whose mass-action expression

$$[V_o^{\cdot\cdot}]n^2 = K_1 p_{O_2}^{-1/2} \quad [2]$$

combined with the charge-neutrality condition

$$[A'] \approx 2[V_o^{\cdot\cdot}] \quad [3]$$

leads to $\sigma \propto p_{O_2}^{-1/4}$ below the minima, where A' is an unknown or added acceptor impurity, σ is the electronic conductivity, and p_{O_2} the oxygen pressure. At the lowest p_{O_2} and highest temperature the pressure dependence changes to $\sigma \propto p_{O_2}^{-1/6}$ as Eq. [1] becomes the dominant source of defects and the charge neutrality condition changes to

$$n \approx 2[V_o^{\cdot\cdot}] \quad [4]$$

At pressures above the conductivity minima, oxygen is easily added to the lattice by filling the impurity-related $V_o^{\cdot\cdot}$

$$V_o^{\cdot\cdot} + 1/2\,O_2 \rightleftharpoons O_o + 2h^{\cdot} \quad [5]$$

The mass-action expression for Eq. [5] combined with Eq. [3] gives $\sigma \propto p_{O_2}^{1/4}$ as observed, as long as only a minor fraction of the impurity-related $V_o^{\cdot\cdot}$ is filled. The ready availability of oxygen vacancies explains the unusual ease with which the material accepts a stoichiometric excess of oxygen, as indicated by the anomalously low temperature dependence of conductivity in the oxygen-excess region near 1 atm.

Compared with undoped samples, the acceptor-doped material with Ba/Ti = 0.9950 behaves as predicted by the combination of Eq. [2] and [3]. The conductivity is slightly higher above the conduction minima, and slightly lower below the minima, and the minima occur at lower p_{O_2}. The magnitude of these changes indicates that the net acceptor content of the doped sample is about twice that of the undoped sample. In the region where $\sigma \propto p_{O_2}^{-1/6}$, the conductivity is independent of impurity content, confirming that this region (and only this region) represents the intrinsic behavior of $BaTiO_3$.

Samples prepared with Ba/Ti = 1.0000 rather than 0.9950 behave very similarly. It is concluded that the defects related to BaO deficiency, assumed to be V_{Ba}'' and $V_o^{\cdot\cdot}$, must be almost entirely associated into defect complexes of the type $(V_{Ba}''V_o^{\cdot\cdot})$. Otherwise reaction [1] could not become the dominant source of $V_o^{\cdot\cdot}$ at low pressures and the relationship $\sigma \propto p_{O_2}^{-1/6}$ would not be observed.

The behavior of a donor-doped sample is shown in Fig. 2. Instead of a series of conductivity minima, there is an extensive region where the conductivity is nearly independent of temperature and p_{O_2}. We interpret this as indicating a region of impurity-controlled electron concentration

$$[Nb_{Ti}^{\cdot}] \approx n \quad [6]$$

where $[Nb_{Ti}^{\cdot}]$ represents the excess donor concentration. At very low pressures, the conductivity values and pressure dependence agree well with those of undoped and acceptor-doped samples, indicating a region of impurity-insensitive behavior.

The drop in conductivity as the oxygen pressure approaches 1 atm is attributed to a change from electronic compensation of the excess donor, as in Eq. [6], to compensation by an oxygen-excess ionic defect, most likely V_{Ba}''

$$[Nb_{Ti}^{\cdot}] \approx 2[V_{Ba}''] \quad [7]$$

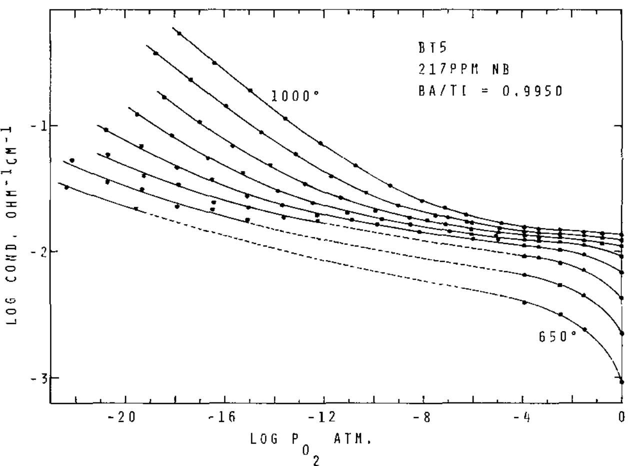

Fig. 2. Equilibrium conductivity of donor-doped $BaTiO_3$. Temperatures at 50° intervals.

These could be generated by the filling of the $V_o^{\cdot\cdot}$ part of the BaO-deficient defect complex

$$(V_{Ba}''V_o^{\cdot\cdot}) + 2e' + 1/2\,O_2 \rightleftharpoons O_o + V_{Ba}'' \quad [8]$$

leading to the mass-action expression

$$\frac{[V_{Ba}'']}{[(V_{Ba}''V_o^{\cdot\cdot})]n^2} = K_8 p_{O_2}^{1/2} \quad [9]$$

As long as [6] is valid, $[V_{Ba}'']$ will increase as $p_{O_2}^{1/2}$; when [7] becomes valid, n will begin to decrease as $p_{O_2}^{-1/4}$, approximately as observed.

Over a considerable range of intermediate p_{O_2}, the donor-doped samples equilibrate with the ambient much more slowly then acceptor-doped or undoped samples, even when BaO deficient. Thus the BaO deficiency does not lead to mobile defects which can contribute to rapid changes in oxygen content. This is in accord with the hypothesis of association of the defects related to BaO deficiency. An association enthalpy of 2 eV would be adequate to provide the degree of defect association required by the above model. This does not seem unreasonable for doubly charged defects such as V_{Ba}'' and $V_o^{\cdot\cdot}$ on adjacent lattice sites, when it is recalled that the association enthalpies for singly charged defects in the alkali halides, such as $(Sr_{Na}^{\cdot}V_{Na}')$ and $(V_{Na}'V_{Cl}^{\cdot})$ are known to be about 0.5 and 1.0 eV, respectively. The latter defect involves adjacent lattice sites and is thus the closer analogue.

Structural Study of the Sunlight Absorber

S. Yamaguchi*

National Institute for Researches in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki-ken 300-31, Japan

A preliminary examination was conducted with a specimen of the sunlight absorber which is in practical use: a copper plate whose surface has been blackened by oxidation. The blackening of the surface was carried out by immersing it in an aqueous solution of sodium chlorite ($NaClO_2$) at 10°C whose concentration was about 10% by weight. The black, mat surface produced in this way was investigated in terms of electron reflection. The diffraction pattern observed from the specimen is shown in Fig. 1. It can be noted in this figure that the reflections appear distinct which correspond to a uniform dispersion of CuO crystallites (see Table I). The mean particle size of the crystallites is estimated to be about 500Å from the half-value width of the reflections. It is of interest that this particle size is smaller than the wavelength of the sunlight. It can also be noticed in Fig. 1 that the (020) reflection from the CuO crystals shows a preferred orientation whose fibrous axis lies nearly perpendicular to the substrate face.

The appearance of the black surface in question was closely akin to that of platinum sponge, so far as the velvetlike matted darkness is concerned. It was, therefore, reasonable to reexamine a typical platinum black in terms of electron diffraction.

A porous spongy layer of platinum was prepared in the following way. The fine particles of platinum were deposited on a smooth metal surface by hydrothermally decomposing at 130°C an aqueous solution of K_2PtCl_4 whose concentration was 0.1 mole/liter (2). The deposit obtained looked quite black and mat, which gave the electron reflection pattern shown in Fig. 2. This pattern corresponds to an evenly dispersed state of the platinum particles whose mean size is about 500Å. In Fig. 2 the reflections are relieved against the low background. This is due to the fact that the crystal particle size is not only uniform, but it is also suitable for a coherent penetration of the electrons applied. These observations are similar to those from the blacked copper specimen.

The black, mat surface of platinum could be distinguished from a lustrous mirror surface in terms of the electron reflection. Figure 3 was observed from the latter surface. In this figure, the reflections are blurred and the background is very high. These findings are characteristic of an amorphous and fluidal Beilby surface layer. Compare Fig. 2 with Fig. 3. From these experimental results one can infer the surface structure of the sunshine absorber as illustrated in Fig. 4.

* Interplanar spacings corresponding to the reflections in Fig. 1.
** Reflection intensities in arbitrary unit.
These values measured agree with the known data of monoclinic CuO whose lattice constants are a_0 = 4.68, b_0 = 3.43, c_0 = 5.13A, β = 99°28′, C2/c (1).

Within the porous sponge there are found labyrinths for the incident sunlight (see Fig. 4). Since each particle situated at the sponge surface is smaller than the wavelength of the light, the incident rays are not reflected at the surface, but diffracted from there into the interior of the sponge.

In the following experiment, it is demonstrated by the aid of a physical specimen that the surface as composed of parts smaller than the wavelength of sunlight appears completely dark, labyrinths for the light being beneath the surface.

About 500 sewing needles, with pointed ends smaller than the light wavelength, were tied up tightly into a bundle. The dimensions of the needles employed are shown in Fig. 5. The surface of the prepared needle bundle is characterized by an extreme roughness. The sunlight falling nearly perpendicular to the surface of the bundle cannot be reflected there, but is diffracted into the interior of the bundle, insofar as the tips of the constituent needles are smaller than the light

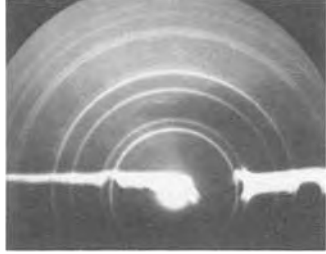

Fig. 2. Diffraction pattern from the platinum sponge. The reflections of Pt appear distinct, and the background is low. Electron wavelength = 0.0380Å.

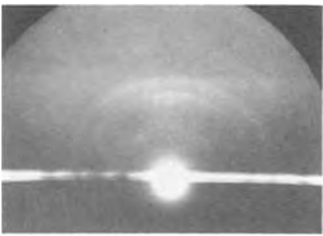

Fig. 3. Reflection pattern from a mirror surface of platinum. Reflections are blurred, and the background is high. Compare this figure with Fig. 2. Electron wavelength = 0.0315Å.

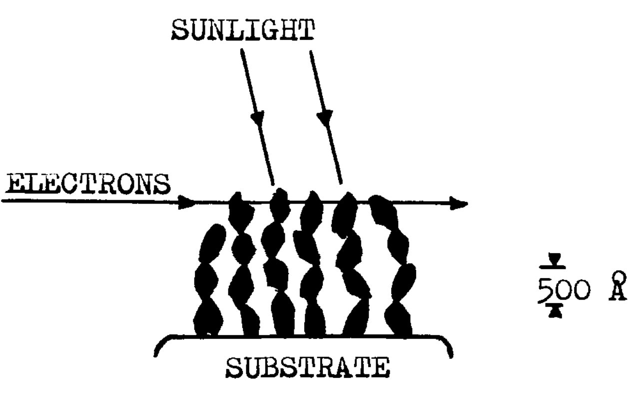

Fig. 4. Spongy state formed on the metal substrate, which serves as a sunlight absorber. The size of the particles constructing the sponge is about 500Å so that it is smaller than the sunlight wavelength. The incident light is not reflected at the sponge face, but is diffracted there and then runs into the sponge interior. The electrons applied are able to coherently penetrate the crystallites of the 500Å size.

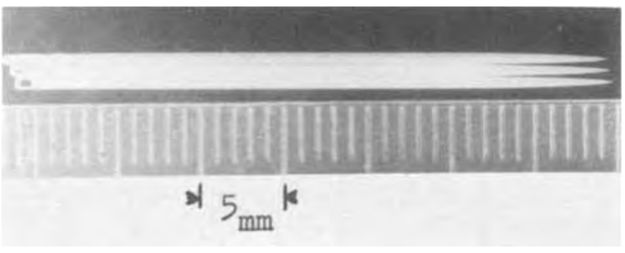

Fig. 5. The dimensions of the sewing needles employed for preparing the Planck's black body are seen here.

wavelength. The diffracted rays are repeatedly reflected at the lateral mirror faces of the needles, and finally they are completely absorbed into the bundle. It is of interest that the lateral faces of the needles are not transparent for the light. The behavior of the needle bundle, when exposed to the direct rays of the sun, is shown in Fig. 6 where it can be noticed that the surface of the bundle looks blacker than its shadow. The passages of the rays in the needle bundle are illustrated in Fig. 7 (3).

With the help of the needle bundle, this experiment amounts to a black-body simulation of the blacked copper plate and of the platinum black in the present study. The blacked copper plate is truly an able sunlight absorber, but it has been proved to weather in wet, polluted air. In fact, it has been found that

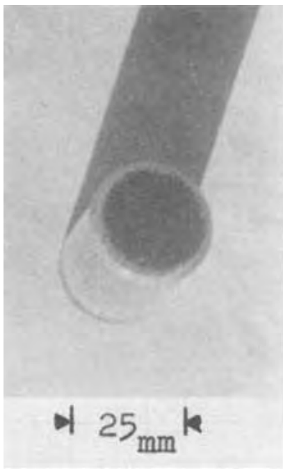

Fig. 6. A bundle of the sewing needles under the sun. The face of the bundle looks blacker than the shadow.

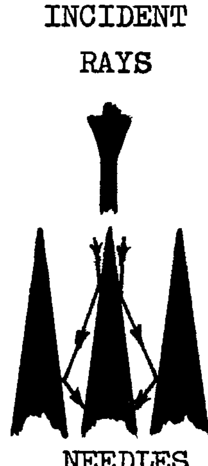

Fig. 7. Illustrating the diffraction of the light rays falling upon the face of the needle bundle.

verdigris is formed on the plate used over one year. In order to overcome this disadvantage, the corrosion-resisting surfaces with the prescribed geometric structure were produced on steel and aluminum plates.

A rolled plate of Cr-Mo-Ti steel (Cr: 18, Mo: 1, Ti: 0.4) was utilized as the material for sunshine absorber. The surface of the plate was oxidized in an acidic sodium dichromate solution ($Na_2Cr_2O_7 \cdot 2H_2O$: 200 g/liter, H_2SO_4: 600 g/liter) at 100°C for 20 min. The surface obtained in this way looked mat as well as black. According to the investigation by means of electron reflection, this surface was composed of the particles of the spinel type iron oxide which were regularly oriented against the substrate face and whose mean size was about 500Å. These circumstances were analogous to those in the case of the blacked copper plate. The thermal efficiency of the blacked steel plate as a sunlight absorber was inferior to that of the copper plate, but the former plate was superior to the latter one in corrosion resistance. The surface of a plate of the eutectic aluminum alloy that contained silicon by 7 weight percent (w/o) was oxidized at 10°C by an anodic process with a current density of 2 A/dm^2. The bath employed for the electrolysis consisted of oxalic acid and sulfuric acid whose concentrations were 2.4 and 0.14 w/o, respectively. After having experienced the anodic oxidation, the anode was treated with a boiling water in order to mask its surface with a stable böhmite film. The surface obtained in this way looked black, mat, and spongelike, similar to the platinum black. This alumilite plate could be utilized as a sunlight absorber, its thermal efficiency approaching that of the blacked copper. It should be underlined that aluminum is not only a cheaper and lighter material than copper, but it is also more plastic than steel.

An Abrupt Dopant Profile in GaAs Produced by Te Implantation

B. K. Shin

Systems Research Laboratories, Incorporated, Dayton, Ohio 45440

and Y. S. Park

Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio 45433

The recent advent of ion implantation technology in GaAs has generated much enthusiasm for the fabrication of optoelectronic and microwave devices as demonstrated by injection lasers (1), FET's (2, 3), TED's (4), and IMPATT diodes (5). Inasmuch as the fabrication of these devices requires a high degree of sophistication, the production of shallow layers having precisely controlled doping concentrations and a well-defined dopant profile is an important goal of ion implantation efforts.

In implantation doping usually a postimplantation heat-treatment at temperatures of 800°-900°C is required to remove radiation damage produced during implantation and to cause a substantial fraction of implanted ions to become electrically active. At these annealing temperatures, diffusion effects play an important role in the determination of the impurity distribution, even though other mechanisms such as enhanced diffusion effects or redistribution effects may also influence the profile. (In addition, decomposition and outdiffusion occur on these samples during annealing at these temperatures, and a careful selection of encapsulants must be made in order to protect the sample surface.) Therefore, knowledge of the diffusion coefficients of each impurity dopant becomes important in predicting implantation profiles.

In the present paper, the use of Te implantation in GaAs to achieve abrupt electrical profiles and the comparison of Te to other impurity dopants are presented and discussed briefly. Diffusion coefficients of Group II (Zn, Cd) p-type dopants and Group IV (Si, Sn) and Group VI (S, Se, Te) n-type dopants are considered at annealing temperatures of 900°C. It was found that the use of pyrolytically prepared Si_3N_4 layer does not alter the electrical profile, predicted by diffusion properties, of either Cd- or Te-implanted GaAs.

Experimental

The substrate material used was Cr-doped semi-insulating ($\sim 10^9$ Ω-cm) GaAs single crystal, oriented in the <100> direction, obtained from the Laser Diode Laboratories. Prior to implantation, each sample was cleaned and etched in a freshly prepared $5H_2SO_4$:$1H_2O_2$:$1H_2O$ solution, and then an ~300Å layer of Si_3N_4 was deposited on the sample at 720°C in a pyrolytic reactor (6). The implantation was carried out at an energy of 120 keV to a dose (ϕ) of 10^{14} Te/cm^2 at an elevated temperature of 250°C. After implantation, each sample was annealed at T_A = 900°C in flowing Ar-gas ambient. van der Pauw measurements, in conjunction with a chemical-etch-thin-layer-removal technique, were made at room temperature on the finished mesa structure. The details of such measurements are described elsewhere (7).

Results and Discussion

Carrier concentration profiles measured on both Te- and Cd-implanted GaAs are displayed in Fig. 1 for T_A = 900°C. The LSS distribution (8) for $\phi \simeq 10^{14}$ ions/cm^2 is also shown in the figure, and it can be seen that the actual profiles for Cd-implanted samples are considerably broadened, closely following the profiles expected from the Cd-diffusion effect (9). In the case of Te implantation, a very abrupt profile similar to the LSS profile was obtained in the region where $x > R_p$ ($x \simeq$ 600Å). The maximum electron concentration of $\sim 2.6 \times 10^{18}$ cm^{-3} was obtained near x = 600Å; the concentration is somewhat lower than the solubility limit of Te in GaAs (10, 11) (C_s = 5-8 $\times 10^{18}$ cm^{-3}).

Table I shows the influence of diffusion effects upon the distribution of implanted impurities for various dopants of Group II, IV, and VI elements (9, 12-15). Here, R_p is the projected range, ΔR_p is the mean range straggling, D is the diffusion coefficient of an impurity at T = 900°C, and t is the diffusion time of 600 sec. An implantation energy of 120 keV is considered since an energy in the range of several hundred kiloelectron volts is required when an LSS profile of <1 μm abrupt dopant distribution is desired for most of the n- and p-type dopants in GaAs. The ratio of the diffusion length to the mean range straggling, $(Dt)^{1/2}/\Delta R_p$, gives the indication of whether the broadening of the profile may be appreciable. The table indicates that the diffusion property affects the Group II p-type dopants sig-

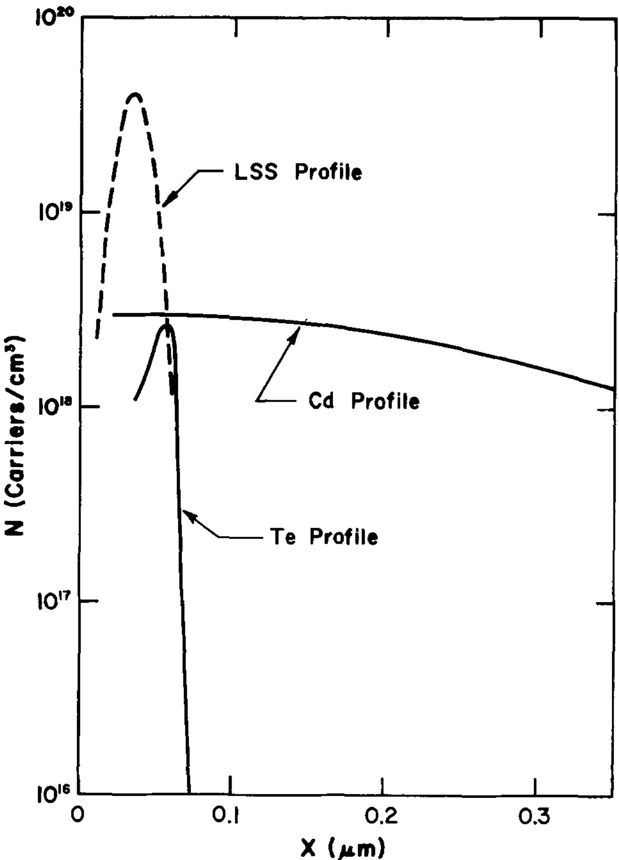

Fig. 1. Electrical profiles of Cd- and Te-implanted GaAs annealed at 900°C. The LSS profile is shown by the broken line for 120 keV, 10^{14} ions/cm^2 implantation. (The LSS profiles for Cd and Te are almost identical.)

Key words: electrical profiles, ion implantation.

nificantly, while it is less significant in the case of the Group IV and VI n-type dopants. In fact, implantation studies of Group II p-type dopants revealed considerable diffusion after annealing at 800°-900°C. Diffusion effects in Group IV and VI impurities are not so clearly defined.

Recently, an abrupt profile was reported in Sn-implanted n-type GaAs (16) at an annealing temperature of 700°C. Implantation of other n-type impurities (17) such as S yielded a much deeper electrical profile than that expected from the diffusion table. In the present investigation, an abrupt profile resembling the LSS profile was obtained with implantation at 120 keV and annealing at 900°C with pyrolytic Si_3N_4 encapsulation, and the diffusion was found to have little affect upon the final impurity distribution, as expected from the diffusion property of Te in GaAs.

In the profiles shown in Fig. 1, the absence of electrical activity in the region $\lesssim$ 300Å represents the etched-away Si_3N_4 layer after annealing. In analyzing the concentration profiles, it should be noted that since the range of Te is approximately equal to the thickness of the Si_3N_4 layer (and the range of ions in GaAs and Si_3N_4 is known to be almost identical), about one-half of the as-implanted Te ions would occupy the GaAs substrate region. (Since the value of range straggling is small and the thickness of the deposited Si_3N_4 layer is not accurately known, it is difficult to predict the exact value of the Te ions implanted into the GaAs.) In the region $300Å < x < 600Å$, the Te concentration profile shows that the electrical activity is roughly one order of magnitude lower than the predicted LSS value. Furthermore, in this region, the electrical activity decreases with increasing Te ion concentration (with decreasing x toward R_p), with the lowest doping efficiency being observed near R_p. Unlike Te implantion, a substantial amount of implanted Cd became electrically active after the 900°C anneal, which is consistent with the diffusion properties of Cd in GaAs shown in Table I. The low electrical activity observed in the Te implantation may arise from the electrical compensation of residual damages in the implanted region. The inverse relation of the LSS profile and the electrical profile near R_p supports the above statement since the damage profile might be expected to be closely related to the LSS profile. Further experiments are required to verify this.

Acknowledgments

The authors wish to thank W. T. Lindley and R. McClelland of M.I.T. Lincoln Laboratory for allowing the pyrolytic Si_3N_4 encapsulations to be performed in their facilities. We are also grateful to D. E. Johnson and J. E. Ehret of the Air Force Avionics Laboratory for technical assistance. Finally, thanks are due M. Whitaker for editorial assistance and preparation of the manuscript. This work was supported under U.S. Air Force Contract No. F33615-72-C-1099.

ABSTRACT

Lithium-aluminum alloy electrodes have shown a great deal of promise for meeting the performance requirements of negative electrodes in batteries for off-peak energy storage in utility networks and for vehicle propulsion. To develop negative electrodes that meet the cell performance goals, the effects of a number of variables on the lithium-aluminum electrode performance were determined. Investigations were conducted to determine the effects of volume fraction electrolyte in the electrode, electrode thickness, fabrication technique, lithium concentration in the Li-Al alloy, and current collector in the electrode. Electrochemically formed Li-Al electrodes that are 0.32 cm thick, have an electrolyte volume fraction of 0.2 in the charged state, and contain about 2 weight percent stainless steel wire current collector have demonstrated the performance goals for the negative electrodes in a Li-Al/FeS_2 electric automobile battery. For electrode thicknesses $\geqq$0.64 cm, vibratorily loaded pyrometallurgical Li-Al electrodes with porous metallic current collectors have demonstrated the highest lithium utilization and capacity density over a wide range of discharge current densities and have met the performance goals for negative electrodes in a Li-Al/FeS_2 off-peak energy storage battery.

A lithium-aluminum alloy of approximately 50 atom percent (a/o) lithium has shown a great deal of promise for meeting the performance requirements of negative electrodes in lithium/metal sulfide batteries being developed at Argonne National Laboratory (ANL) (1-4). These batteries are being developed for use as energy storage devices for load leveling on electric utilities and as power sources for electric automobiles.

Lithium is attractive as a negative electrode material for high performance batteries (5-7) because of its low weight per unit of electricity delivered, low affinity for electrons, and high electrochemical reactivity. However, containment of liquid lithium in the negative electrode over a large number of cycles has proved to be a problem because, in time, uncontained lithium bridges to the positive electrode, forming electrical short circuits. Another problem with liquid lithium has been the high corrosion rates of ceramic separators and electrical feedthroughs. Our studies have indicated that these problems can be avoided by the use of solid Li-Al alloys. In previous work by other investigators, excellent electrochemical performance of electrochemically prepared lithium-aluminum alloy (composition range 17-62 a/o Li) in molten salt systems has been reported (8-10). The emf of a lithium-aluminum alloy electrode is constant, about 0.3V *vs.* Li reference, and independent of lithium concentration up to about 45 a/o Li in the alloy.

This paper describes a study to determine the effects of a number of variables on the performance of lithium-aluminum electrodes so that negative electrodes meeting the cell performance goals can be developed.

* Electrochemical Society Active Member.

Key words: battery, rechargeable, sulfur, negative, electrolyte.

Investigations were conducted on the effects of volume fraction of electrolyte in the electrode, electrode thickness, fabrication technique, lithium concentration in the Li-Al alloy, and type of current collector in the electrode.

Experimental

Li-Al electrode fabrication.—The solid lithium-aluminum electrodes were prepared by four processes:

1. Electrochemical formation in a substrate of compressed aluminum fibers. The initial porosities of the substrates were 40-80%, and the volume fraction electrolyte in the Li-Al electrodes in the fully charged state was 0.20-0.70.
2. Electrochemical preparation of the Li-Al electrode by direct contact with lithium. This was accomplished by placing a compressed aluminum-fiber disk in direct contact with stainless steel Feltmetal containing liquid lithium in electrolyte (LiCl-KCl).
3. Pyrometallurgical preparation of the Li-Al electrodes. In this procedure, the alloy was formed by heating lithium and aluminum to a temperature above the alloy melting point (720°C); the Li-Al alloy was cast and ground; the powder was then mixed with electrolyte; and the mixture was compacted (under pressure and above the melting point of the electrolyte) into disks of the desired thickness and diameter.
4. Vibratory loading of pyrometallurgically prepared Li-Al powder into a porous metallic structure. The structure also serves as the current collector.

A description of several of these electrodes is presented in Table I.

Experimental cells.—The electrodes were tested in cells with an electrolyte of LiCl-KCl eutectic (m.p. 352°C) and a counterelectrode of FeS_2; the operating

temperatures were between 390° and 450°C. An essential feature of the cells used in studying the performance of Li-Al electrodes is that the Li-Al electrode is the limiting electrode. The liquid lithium electrode would be an ideal electrode for the Li-Al characterization studies because of low polarization, even at high current densities, but this electrode has not been successfully operated in compact cell configurations. In order to obtain performance data in a practical cell configuration which could be used in a battery (negative and positive electrodes compressed against an electrode separator), most of the cells were operated with FeS_2 electrodes whose performance was well characterized. Reference electrodes were used in some cells to ensure that the Li-Al electrode was limiting. These results were compared to those of similar studies using liquid lithium counterelectrodes (11).

Two positive FeS_2 electrodes with housings of porous graphite were used to evaluate most of the Li-Al electrodes in this study. Zirconia cloth was attached to the housing for one of these electrodes (cell S-63) to retain the FeS_2 particulates. This electrode had a current collector of corrugated molybdenum mesh and an FeS_2 theoretical capacity density of 1.14 A-hr/cm². The other electrode (cell S-69) utilized carbon fabric as the particulate retainer and vitreous carbon foam as the current collector, and had an FeS_2 theoretical capacity density of 0.92 A-hr/cm². Boron nitride or yttria fabric was used as the electrode separator in both cells. The cell configuration for these electrodes is shown in Fig. 1. For cells that had a liquid lithium electrode, the lithium was contained in a Type 347 stainless steel porous metal structure, 20 cm² electrode area.

Testing procedures.—All of the experimental work that involved assembly of charged Li-Al electrodes, pyrometallurgical preparation of Li-Al alloy, electrochemical formation of Li-Al electrodes, and testing of cells was performed in a glove box containing a high purity (about 2 ppm each of O_2 and N_2 and <1 ppm H_2O) helium atmosphere. Assembled cells were heated in a furnace well which was attached to the floor of the glove box and the temperature was maintained between 390° and 450°C. Current and voltage leads were connected to metering and recording equipment outside the glove box by means of hermetically sealed feedthroughs.

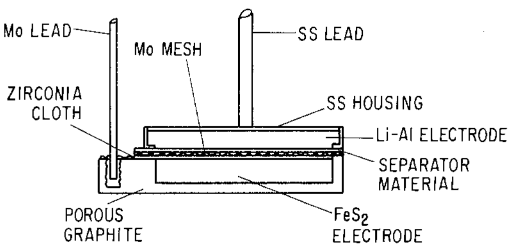

Fig. 1. Lithium-aluminum/iron sulfide cell configuration

Most of the discharge and charge operations were conducted at constant current with the aid of a regulated d-c power supply. The cells were connected to a meter relay that automatically reversed the polarity of the power supply when a cell reached the preset cutoff voltage for either charge or discharge. In this way, the cells could be automatically charged and discharged at selected (and often widely different) current densities. The total capacity (ampere-hour) for the charge and discharge half-cycles was determined electronically and was provided in a printout form. Since many of the cells were cycled for hundreds of cycles and hundreds of hours, variables such as cell voltage, current, charge and discharge time, and temperature were monitored by an automatic data acquisition system. The magnetic tapes could be fed to a computer to perform calculations and to produce performance curves.

Results and Discussion

A summary of the performance of several negative electrodes used in cell S-69 is shown in Fig. 2. Descriptions of these electrodes were given in Table I and the designated symbols for the individual curves in Fig. 2 are keyed to the electrode descriptions in that table.

The ranges of variables in the negative electrodes were as follows: volume fraction electrolyte, 0.2-0.70;

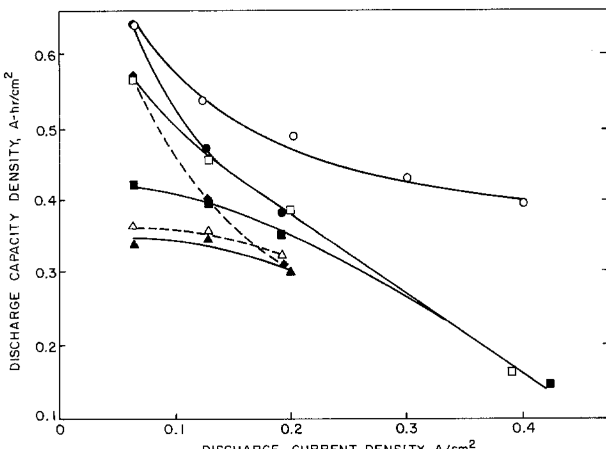

Fig. 2. Capacity density-current density curves for several negative electrodes.

Symbol	Electrode type	Fabrication technique	Volume fraction electrolyte	Thickness, cm

◆	Electrochem.	—	0.40	0.60

and thickness, 0.32-1.62 cm. The range of theoretical capacity density was 0.43-1.55 A-hr/cm^2. Two of the negative electrodes had theoretical capacity densities greater than that of the FeS_2 electrode (0.92 A-hr/cm^2); one was a liquid lithium electrode (1.40 A-hr/cm^2) and the other was a pyrometallurgical Li-Al electrode (1.55 A-hr/cm^2). These were operated primarily to serve as a basis for evaluating the FeS_2 electrode, but the liquid lithium electrode also served as a basis for certain evaluations of the Li-Al electrodes.

It is desirable to develop Li-Al electrodes having a low electrolyte content to increase the theoretical Li-Al capacity per unit electrode volume (ampere-hour/cubic centimeter). However, high utilization of the Li-Al electrode at discharge current densities greater than about 0.2 A/cm^2 is favored by a higher electrolyte content. Lithium-aluminum utilization is also strongly affected by electrode thickness. Therefore, investigations of these variables were necessary in order to optimize the performance for the two applications of interest. Several fabrication techniques were considered for the Li-Al electrodes in an attempt to determine the lowest cost electrode that appeared to be suitable for large quantity manufacture and that met the performance goals. Only the performance results are discussed in this paper.

The data presented in Fig. 2 and Tables I and II show the strong influence of current collector on the utilization of Li-Al electrodes. Significant improvement in Li-Al utilization results from improved current collection, at discharge current densities greater than 0.1 A/cm^2, for vibratorily loaded Li-Al electrodes with porous metal structures and thicknesses greater than 0.6 cm. Electrode A-2 contained porous nickel current collector and showed much better Li-Al utilizations at the higher current densities than the electrochemically formed electrode B-1 which contained much less current collector.

The Li-Al electrode utilization as a function of current density is shown in Fig. 3, where the symbols are also keyed to the descriptions in Table I. The thinner Li-Al electrode designated A-1 (electrochemically formed, 0.32 cm thick) demonstrated the highest Li-Al utilization at high discharge rates.

The much higher performance at 0.4 A/cm^2 with the liquid lithium electrode (A-4) indicated that the best Li-Al electrode described in Fig. 2 and 3 and Table II was limiting at high discharge rates. The positive electrode, however, was capable of higher performance at the high discharge rates. These results were verified in tests in which reference electrodes were used to identify the limiting electrode.

The effects of electrolyte content (20, 46, and 70%) on the performance of thin, electrochemically formed Li-Al electrodes was determined in cell S-63. The Li-Al electrodes were electrochemically formed from aluminum wire disks; the electrodes were 0.32 cm thick and had an area of 15.6 cm^2. The electrodes were charged at 0.064 A/cm^2 to a 2.27V (*IR*-included) cutoff. The cell resistance in each case was about 40 mΩ. The performance results for these electrodes are shown in Fig. 4. As can be seen in the figure, the electrode containing 20 volume percent (v/o) electrolyte showed the best performance (86-83% of Li-Al theoretical capacity density) at current densities ranging from 0.064 to 0.19 A/cm^2. The capacity densities for the electrode containing 46 v/o electrolyte were about 27% lower, and those for the electrode with 70 v/o electrolyte were 66.5% lower than the electrode with 20 v/o electrolyte. Thus, for thin (0.32 cm) electrodes and relatively low charge rates, the best results were obtained with 20 v/o electrolyte in the electrode.

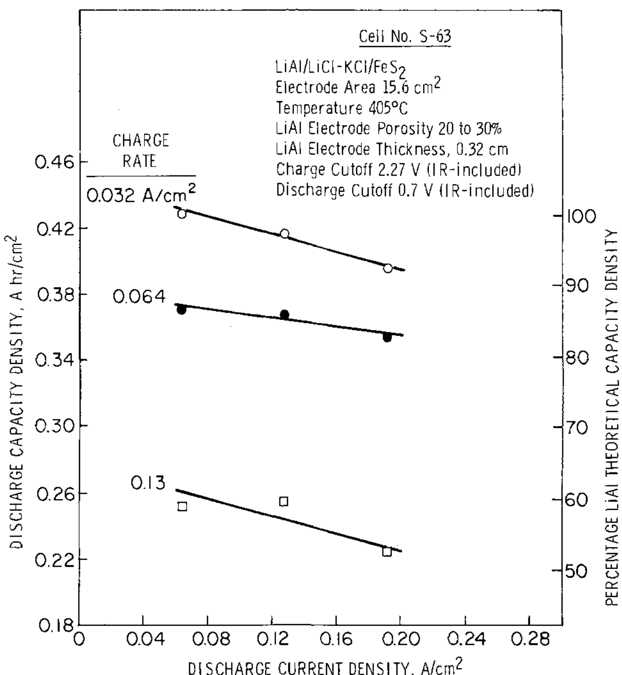

Fig. 6. Discharge capacity density *vs.* current density of cell No. S-63. LiAl/LiCl-KCl/FeS_2; electrode area, 15.6 cm^2; temperature, 405°C; LiAl electrode porosity 20-30%; LiAl electrode thickness, 0.32 cm; charge cutoff (*IR* included), 2.27V; discharge cutoff (*IR* included), 0.7V.

The improvement in performance for the electrode with 20 v/o electrolyte was not nearly as great at high charge rates (see Fig. 5). At a charge current density of 0.128 A/cm^2, the charge capacity densities were 0.234 and 0.228 A-hr/cm^2 (55 and 89% of theoretical) for the electrodes with 20 and 46 v/o electrolyte, respectively. With the charge conditions described above and a discharge rate of 0.192 A/cm^2, discharge capacity densities of 0.223 A-hr/cm^2 (52.0% of the Li-Al theoretical capacity density) and 0.207 A-hr/cm^2 (69.2% theoretical), respectively, were measured for the electrodes with 20 and 46 v/o electrolyte. The capacity densities measured for these electrodes were nearly the same.

A plot of discharge capacity density *vs.* current density for a constant *IR*-included charge cutoff voltage is shown in Fig. 6. These results were obtained for the Li-Al electrode containing 20 v/o electrolyte, which demonstrated the highest performance. The *IR*-included charge cutoff voltage is significant in LiAl/FeS_2 cells because liquid lithium has been formed in some cells at high charge cutoff voltages and has, in some cases, bridged across the BN separator and caused electrical short circuits. The 2.27V charge cutoff used in the cells described in this paper was low enough to prevent liquid lithium formation. However, in attempts to charge the cells at high charge rates (0.13 A/cm^2) to the same *IR*-free charge cutoffs as used at low charge rates (0.032 A/cm^2), some shorting problems have been encountered. No reactions between the active materials or current collectors and the electrolyte have been observed at charge cutoffs below 2.27V. As shown in Fig. 6, over 90% of the Li-Al theoretical capacity density was obtained over a wide range of discharge rates for a charge rate of 0.032 A/cm^2. However, at a charge rate of 0.13 A/cm^2, the capacity density decreased to about 50% of theoretical.

The effects of charge rate and *IR*-free charge cutoff voltage on the performance of Li-Al electrodes were studied by other investigators at ANL in Li/Li-Al type cells (12). The electrical performance characteristics of a 0.32 cm thick Li-Al electrode with 20 v/o electrolyte were evaluated by cycling against a molten lithium electrode. The capacity density was determined at charge rates of 0.05-0.10 A/cm^2 and discharge rates of 0.05-0.20 A/cm^2. An *IR*-free cutoff potential *vs.* lithium of 0.15V was normally used during charge and 0.40V was used during discharge. At the 0.10 A/cm^2 charge rate, a cutoff potential *vs.* lithium of 0.04V was also used. At a charge and discharge rate of 0.05 A/cm^2, greater than 90% of the Li-Al theoretical capacity density was achieved with a charge cutoff potential of 0.15V. At a charge and discharge rate of 0.2 A/cm^2, the capacity density decreased to about 67.5% of the Li-Al theoretical capacity density. At a charge and discharge rate of 0.10 A/cm^2, the lithium utilization is greater than 85% of the theoretical capacity density at the lower charge cutoff potential (0.04V). When the higher charge cutoff potential *vs.* lithium of 0.15V was used, the capacity density decreased to about 70% of theoretical.

The effects on electrode performance of fabrication technique, composition of the Li-Al alloy, and amounts of current collector were determined as follows. Lithium-aluminum alloys of 51 and 55 a/o Li were prepared by the pyrometallurgical process. This material was mixed with electrolyte and about 2 w/o stainless steel current collector and compressed at about 35.2 kg/cm^2 and 400°C to form two disks of approximately 20 v/o electrolyte and 0.32 cm thickness. These disks were placed in a stainless steel housing with a fine mesh screen for particulate retention in the electrode and the electrodes were operated against a FeS_2 electrode. The performance was then compared with that of an electrochemical Li-Al electrode with identical thickness and electrolyte content and which was operated against the same FeS_2 electrode.

A comparison of the capacity density-current density curves for these electrodes is shown in Fig. 7. For the electrochemically formed Li-Al electrode, capacity densities of 0.43-0.40 A-hr/cm^2 (greater than 90% of the Li-Al theoretical) were measured at discharge current densities of 0.05-0.20 A/cm^2. The best performance with the pyrometallurgical Li-Al electrodes was achieved with the 55 a/o Li composition. However, this performance was about 15% lower than that measured for the electrochemical Li-Al electrode. These results

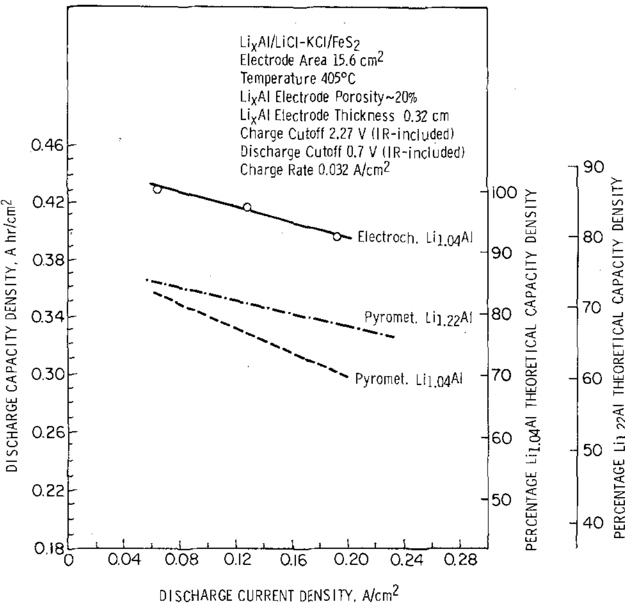

Fig. 7. Performance of thin Li-Al electrodes with small amounts of current collector. $Li_xAl/LiCl-KCl/FeS_2$; electrode area, 15.6 cm²; temperature, 405°C: Li_xAl electrode porosity, ~20%; Li_xAl electrode thickness, 0.32 cm; charge cutoff (*IR* included), 2.27V; discharge cutoff (*IR* included), 0.7V; charge rate, 0.032 A/cm².

indicate that the electrochemical Li-Al electrode has the better performance for electrodes of 20 v/o electrolyte, 0.32 cm thickness, and small amounts of current collector (~2 w/o).

Charge-discharge characteristics of cell S-63 (for the negative electrode A-1 described in Table I) are shown in Fig. 8. At charge and discharge current densities of 0.032 and 0.064 A/cm², respectively, no significant variation in the electrode polarization was observed. The resistance overvoltage on discharge showed little change with a value of 0.01V. Similar observations were made at discharge current densities up to 0.2 A/cm².

Several of the Li-Al electrodes operated in these investigations meet our near-term performance goals for electrodes in the off-peak energy storage battery and the vehicle-propulsion battery. These goals are shown in Table III. Calculations to determine the performance requirements of electrodes for cells in electric vehicle batteries indicate that if the capacity density-current density behavior shown in Fig. 2 for the electrochemically formed Li-Al electrode of 0.32 cm thickness (A-1) can be maintained for larger diameter electrodes (~15 cm diameter), these electrodes would be suitable for this purpose. Similarly, the pyrometallurgical Li-Al

electrodes with the porous metal current collectors appear to be suitable for cells in off-peak energy storage batteries. Further improvements could be gained, however, by developing negative electrodes having higher performance at high current densities and by coupling these electrodes with a high performance positive electrode, such as the FeS_2 electrode used in cell S-69 in these investigations.

Conclusions

The following conclusions can be made from the studies described above:

1. Significant progress has been made in the development of Li-Al electrodes that meet the performance requirements of off-peak energy storage and electric vehicle propulsion batteries.
2. Increase in the $Li-Al/FeS_2$ cell performance at high discharge rates (>0.2 A/cm²) could be realized by the development of Li-Al electrodes with higher utilization under these operating conditions. The FeS_2 electrode has demonstrated much greater utilization at high discharge rates.
3. Electrochemically formed Li-Al electrodes that are 0.32 cm thick, contain 20 v/o electrolyte in the charged state, and contain about 2 w/o stainless steel wire current collector, have demonstrated the performance goals of Table III for the negative electrodes in a $Li-Al/FeS_2$ electric vehicle battery.
4. Capacity density measurements of 0.32 cm thick electrochemically formed Li-Al electrodes with 20, 46, and 70 v/o electrolyte indicated that the highest utilization was achieved with 20 v/o electrolyte.
5. Higher capacity density was achieved with electrochemically formed Li-Al electrodes of 0.32 cm thickness, 20 v/o electrolyte, and 2 w/o current collector, than with hot-pressed Li-Al electrodes fabricated from mixtures of pyrometallurgical Li-Al powder and electrolyte with the same thickness and electrolyte composition.
6. For electrode thicknesses ≥ 0.64 cm, vibratorily loaded, pyrometallurgical Li-Al electrodes with porous metallic current collectors have demonstrated the highest lithium utilization and capacity density over a discharge current densities range of 0.05-0.4 A/cm². These electrodes have demonstrated the performance goals for negative electrodes in a $Li-Al/FeS_2$ off-peak energy storage battery shown in Table III.

Dental Amalgam Stabilization by Selective Interfacial Amalgamation

L. D. Zardiackas,* G. E. Stoner,† and F. K. Smith

Department of Materials Science, University of Virginia, Charlottesville, Virginia 22901

ABSTRACT

The purpose of this investigation was to explore the feasibility of enhancing the electrochemical stability of dental amalgam restorations by a process of "selective interfacial amalgamation." If dental amalgam restorations can be selectively alloyed at the tooth-amalgam interface, to a minor thickness as compared with the dimensions of the bulk amalgam, so as to present a more electrochemically stable phase than γ_2 to the oral environment, corrosion will be reduced and desirable qualities of existing amalgams can be utilized.

Dental amalgam is the most successful of all biomaterials. In the United States alone, there are approximately 1.6×10^8 amalgam restorations placed each year. Of these approximately 40% are for the replacement of amalgam restorations which have failed. Although the role that corrosion plays in this failure is not totally agreed upon, it is generally agreed that corrosion contributes to the failure of the amalgam and recurrent decay.

Dental amalgam is formed during a sintering reaction between an amalgam alloy, whose primary constituents are silver and tin, and mercury to form two new primary phases

$$Ag_3Sn(\gamma) + Hg \rightarrow Ag_2Hg_3(\gamma_1) + Sn_{7\text{-}8}Hg(\gamma_2) + \gamma + Hg$$

These constituents upon trituration give a plastic mass which can be hand condensed into a prepared cavity and react to give a restoration with a tensile strength of the order of 8×10^3 psi.

Corrosion of dental amalgam occurs due to the formation of an oxygen concentration cell. Thus dental amalgam corrodes at the tooth-amalgam interface below the external surface of the restoration. Wagner (1) in 1962 showed that the only phase which corrodes is the $Sn_{7\text{-}8}Hg(\gamma_2)$ phase. Corrosion therefore occurs due to the anodic oxidation of tin and the cathodic reduction of oxygen. In addition, hydroxide precipitation and ingestion of food causes localized pH changes thereby initiating cathodic reduction of hydrogen. Subsequent to the work of Wagner, Jorgensen (2) showed that the γ_2 phase formed a continuous network throughout the amalgam and that excess mercury in the margins caused increased amounts of corrosion. The total reaction for the corrosion of dental amalgam *in vitro* have been suggested by Otani, Jesser, and Wilsdorf (3)

$$Sn \rightarrow Sn^{++} + 2e^-$$

$$Sn^{++} + 2\,OH^- \rightarrow Sn(OH)_2$$

$$Sn(OH)_2 \rightarrow SnO \cdot \tfrac{1}{2}\,H_2O + \tfrac{1}{2}\,H_2O$$

$$SnO \cdot \tfrac{1}{2}\,H_2O \rightarrow SnO + \tfrac{1}{2}\,H_2O$$

Mateer and Reitz (4) have identified the *in vivo* corrosion products as β-SnO_2 SnS_3. There have been a number of attempts to reduce the corrosion of dental amalgam by alloying. Work done by Johnson and co-workers (5) has shown the elimination of the γ_2 phase by the substitution of 10 weight percent (w/o) Au for Ag. This caused the formation of an $AuSn_4$ intermetallic around the original alloy particles. Innes and Youdelis (6), in 1963, developed an alloy having a dispersant Ag_3Cu eutectic. Sarkar and Greener (7) confirmed the work of Duperon, Nevile, and Kesloff (8) as to the superior corrosion resistance of Dispersalloy.[1] Mahler (9) reported the presence of a phase intermediate between the intermetallics of Cu_3Sn and Cu_6Sn_5, however work by Sarkar and Greener (7) has shown the presence of γ_2 in Dispersalloy after 7 days. Work by Waterstratt (10) has shown the elimination of γ_2 by alloying with manganese. Another attempt at reducing marginal corrosion has been through the use of organic cavity sealers. Both of

[1] Trade name manufactured by Johnson and Johnson.

these methods of electrochemical stabilization have shortcomings however.

Because of this, a new method from now on termed "selective interfacial amalgamation" has been developed. This method is diagramatically shown in Fig. 1 and will be subsequently described. First the carious lesion is removed and the cavity prepared by ordinary clinical techniques. A silver suspension, emulsion, or the like, is painted onto the cavity surface using a camel's-hair brush. The suspension is air dried. A conventional dental amalgam is then hand condensed into the cavity using ordinary clinical technique. Mercury expressed from the amalgam bulk during hand condensing reacts with the silver in the suspension. This provides an interfacial region of the highly corrosion resistant γ_1 phase at the tooth-amalgam interface.

Experimental Procedure

Samples for differential aeration studies, scanning electron microscopy, and x-ray energy analysis were prepared using 9 × 5 × 1 mm Plexiglas molds. Lined samples were prepared by painting the mold cavity walls with suspensions ranging in composition from 40 to 92 volume percent (v/o) Ag and a methyl cellulose binder. Spherical amalgam containing a 50 w/o Hg admix was triturated for 20 sec then hand condensed into the mold cavity using conventional amalgam pluggers and a 2 kg balance apparatus to approximate clinical technique. Samples were allowed to react for 2 hr, then removed from the molds. Selectively amalgamated samples were then placed in petri dishes with the selectively alloyed side facing the bottom of the petri dish. The petri dish was then filled with 1.0 w/o NaCl, covered, and placed in an oven at 37°C. Controls were identically prepared and placed in an oven at 37°C. Periodic additions of distilled H_2O was necessary to maintain the 1.0 w/o NaCl concentration. Additional selectively amalgamated samples were prepared in the aforementioned manner for scanning microscopy and x-ray energy analysis. Samples were prepared for time lapse photography to determine reaction rates by hand condensing 9 × 5 × 1 mm amalgam samples onto a glass slide previously painted with silver suspension.

Results

Preliminary screening of several silver suspensions showed that below 80 w/o silver in the suspension, there was insufficient bonding of the selectively amalgamated layer to the amalgam bulk to provide an integrated, electrochemically stable amalgam. Time lapse photography of the reaction as shown in Fig. 2 determined the reaction time of the amalgamated layer to be in the range of 1.5-2.0 hr. Scanning microscopy showed that this reaction was completed in all samples having initial unreacted silver layers ranging from 10 to 500 μm. In addition scanning microscopy and x-ray energy analysis showed integrity of the selectively amalgamated layer, no tin present at the surface, and continuity of the γ_1 phase into the amalgam bulk as shown in Fig. 3.

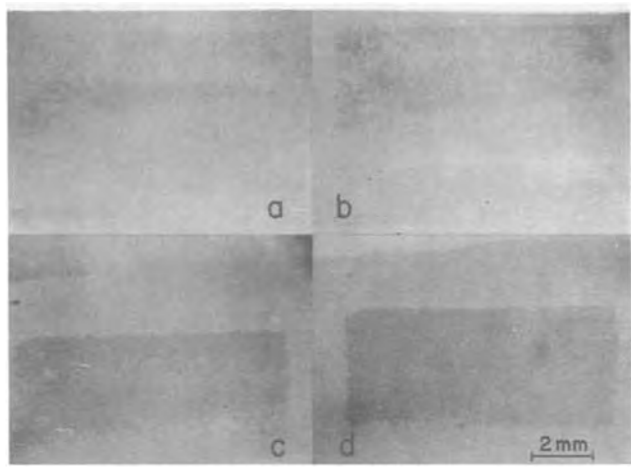

Fig. 2. Selective interfacial amalgamation formation

Corrosion testing results of spherical amalgam controls, high copper amalgam controls, and selectively amalgamated samples at 80 days are shown in Fig. 4. While the high copper alloy shows a significant improvement over the conventional alloy, both show corrosion while the selectively amalgamated sample shows none. The x-ray energy trace shown in Fig. 5 shows an absence of tin from the surface of the selectively amalgamated sample after corroding for 80 days while tin is present at the surface of the conventional alloy. At nine months the conventional alloy is essentially destroyed by the corrosion process while the selectively amalgamated sample shows good integrity. However at 9 months the alloyed layer is beginning to show dissolution not due to corrosion but due to the methyl cellulose binder of the original silver suspension.

Conclusion

These results have shown that the process of selective interfacial amalgamation is indeed feasible. Samples prepared have shown no tin at the surface even though the solubility of tin in mercury is 1.1 w/o. This may be accounted for since up to 7 atoms of tin may be present in the γ_1 lattice. In addition the γ_1 layer becomes an integral part of the total amalgam with a continuity of the γ_1 phase. Finally the amalgam system has been electrochemically stabilized showing a marked improvement of the corrosion characteristics

of this system over both conventional and a high copper amalgam. Further work on this system is now in progress and results will be published in subsequent papers.

Kinetics of the Extended Growth of Anodic Oxide Films at Platinum in H_2SO_4 Solution

A. Ward,* A. Damjanovic,[1] E. Gray, and M. O'Jea[2]

Xerox Corporation, Webster Research Center, Webster, New York 14580

ABSTRACT

The kinetics of growth of anodic oxide films at platinum in $0.1N$ H_2SO_4 solution have been studied by *in situ* chronoellipsometry both under constant potential and under constant current mode of polarization. Two regions of growth can now be distinguished. In the first, the kinetics of growth satisfy the formalism of the Cabrera-Mott model of high field assisted formation and migration of ions in the oxide phase, *i.e.*

$$i = i_o \exp\left[\frac{\alpha \Delta V_f}{d}\right]$$

where ΔV_f is the potential difference across the oxide film and d is the film thickness. In the first region, oxide growth is the only reaction that occurs at the electrode. Following this initial growth, which is already completed at a thickness of 4-6Å depending on the rate of growth, oxygen starts to evolve but the oxide film continues to grow though now with a reduced rate. The kinetics of growth in the second region are described by an equation of the form

$$i = i_o \exp\left[\frac{-d(t)}{d_o} + \frac{\Delta V_f(t)}{V_o}\right]$$

This equation for the extended growth of platinum oxide films is diametrically different from that which describes the initial growth. The complex nature of oxide growth at platinum is discussed in relation to the oxygen evolution reaction.

It has been shown in a previous paper (1) that the frequently observed (2-6) linear charging curves associated with the initial galvanostatic growth of anodic films on Pt in acid solutions satisfy the formalism of the Cabrera-Mott model (7) for high field assisted ionic growth of oxide films. Starting from about 1.0V (*vs.* HE), electrode potential at any constant applied current density (*e.g.*, from 10^{-6} to 10^{-2} $A\text{-}cm^{-2}$) initially increases linearly with time or charge, q (cf., Fig. 1). No oxygen evolves in this linear V-q region, hence q gives a measure of the anodic film thickness. The slopes $(\partial V/\partial q)_i$ in this region are proportional (1) to log i. Chronoellipsometric thickness-potential relationships closely follow the q-V relationships. It follows then that the growth rate is represented by

$$i = i_o \exp\left[\frac{\alpha(V - V_o)}{d}\right] \qquad [1]$$

where i_o is the exchange current density for oxide growth, α is the transfer or field coefficient, d is the film thickness, and V_o ($\approx$0.9V) is the potential at $d = 0$ so that $(V - V_o)/d$ is the field within the oxide film. This equation has the same form as the Cabrera-Mott expression for high field assisted ionic growth of oxide films.

Following the linear V-q or V-d region, which ends at $q = 0.8$ to 1.3 $mC\text{-}cm^{-2}$ depending on current density, oxygen begins to evolve and soon becomes the major reaction. After the knee in the V-T curves (cf., point N, Fig. 1), the electrode potential continues to increase with time but now only very slowly. Early work by Bockris and Huq (8) indicates that the increase in electrode potential is logarithmic. It has since been shown that this increase in potential under galvanostatic conditions is due to the effect of the very slow and extended growth of an insulating anodic oxide film on the catalysis of the oxygen evolution reaction. The relationship between anodic film thickness, electrode potential, and current density for oxygen evolution has been given by (9)

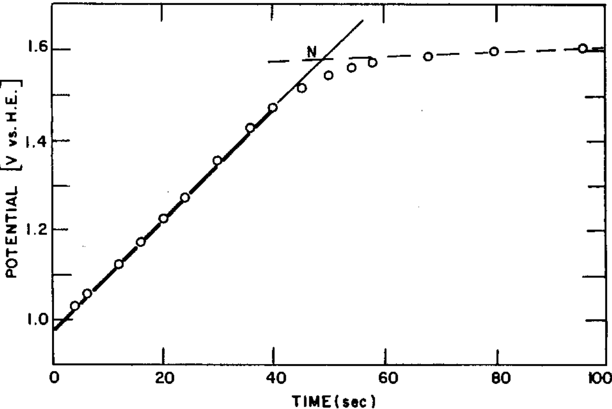

Fig. 1. Change of potential with time of polarization at constant current density $i = 2 \cdot 10^{-5} A \cdot cm^{-2}$.

$$i_{O2} = A \exp\left[\frac{-\delta d}{2}\right] \exp\left[\frac{\alpha \mathbf{F} \Delta V}{RT}\right] \qquad [2]$$

where δ is independent of potential ΔV ($= V - V_{REV}$) or current density; A is a constant at a given pH and temperature; and α is the transfer coefficient equal to about 0.5. Other symbols have their usual significance. Schultze and Vetter (10) have obtained a similar relationship but with δ dependent on V and with $\alpha \approx 0.62$. Now, if potential increases with logarithm of time of polarization, as evident from Bockris and Huq's work, then from Eq. [2] it follows that the thickness, d, of the oxide film should increase logarithmically with time, *i.e.*

$$d(t) = a + b \log(t) \qquad [3]$$

* Electrochemical Society Active Member.

[1] Present address: Allied Chemical Corporation, Morristown, New Jersey 07960.

[2] Present address: Eastman Kodak Company, Rochester, New York 14650.

Key words: ellipsometry, growth mechanism, oxygen.

This dependence, which is known as the "direct logarithmic law of growth," has been observed for anodic film growth at platinum under constant potential conditions (11, 12).

For growth according to the Cabrera-Mott mechanism under conditions of constant potential difference across the oxide film, Eq. [1] can be integrated by parts and the dependence of thickness on time obtained (2). Writing $\alpha V = d_o$ and assuming that all current is used for oxide growth, Eq. [1] reduces to

$$\frac{d_o}{d(t)} = \text{const.} = \log(t) \quad [4]$$

This equation is known as the "inverse logarithmic law of growth." It has recently been shown that under constant potential conditions the first anodic film on Pt grows according to this law (13).

Evidently, the extended growth of anodic oxides on platinum [and on gold (14)] under potentiostatic conditions either does not occur according to the Cabrera-Mott mechanism, or does not occur under conditions of constant potential difference across the oxide film.

In the present study, the long term growth of anodic oxides on platinum has been followed by chronoellipsometry under both galvanostatic and potentiostatic conditions with the objective of clarifying the growth kinetics and mechanism. There does not appear to have been any previous attempt to continuously monitor the time-dependence of oxide film thickness on Pt in the oxygen evolution region.[3]

In addition to this study of long term extended growth of anodic films, the behavior of the system has been examined during stepwise decreases of electrode potential following polarization at different constant potentials for a fixed time. The objective here was to confirm the validity of the oxygen evolution Eq. [2], derived previously on the basis of experiments under galvanostatic conditions, by examining the catalysis of the oxygen evolution reaction under potentiostatic conditions also.

Experimental

An automatic recording ellipsometer was used to follow galvanostatic and potentiostatic anodic film growth on Pt as a function of time. The ellipsometric setup, cell, platinum disk electrode, and solution preparation (0.1*N* H_2SO_4) have been described previously (1). The azimuth, α, and ellipticity, ϵ, of the elliptically polarized light reflected from the Pt disk face were initially measured with the electrode held at +0.5V *vs.* HE (after first subjecting the electrode to several anodic and cathodic pulses, ending cathodic, and exchanging the electrolyte). A constant current density between 10^{-5} and 3.10^{-3} A-cm^{-2} or constant potential between 1.5 and 1.8V was then applied to the disk and the ellipsometric parameters were monitored continuously at frequencies up to 54 sec^{-1} for periods up to 10^4 sec. Potential or current was monitored synchronously.

It was first necessary to assess the effect of oxygen accumulation at the electrode on the ellipsometric parameters. This was done by comparing the azimuth and ellipticity monitored continuously with the same parameters monitored at intervals after vigorous purging of the electrode with a jet of oxygen directed at the reflecting surface. Except at the highest current densities ($i > 10^{-3}$ A-cm^{-2}) the discrepancy was surprisingly small and could be ignored. Upon close inspection the reason for this becomes clearer. Only that light which strikes the surface cleanly and is reflected without being intercepted by a bubble can remain within the acceptance angle of the detection system. Any light which encounters a bubble in its trajectory is scattered out of the regime of acceptance. Accordingly, the detector faithfully records azimuth and ellipticity as long as there is sufficient light to activate the system, *i.e.*, as long as a significant portion of the electrode remains bubble free. Of course, it is no longer possible to monitor the relative intensity of the reflected light under these conditions so that a complete determination of the anodic film optical constants and thickness of the oxide film from ellipsometric parameters alone becomes inaccessible. However, in the case of the Pt/anodic oxide/aq. H_2SO_4 system the optical characteristics have been well documented (16-19) so that a knowledge of the relative intensity variation is not required for an unambiguous determination of film thickness. In the work reported here the optical constants used in the analysis of the ellipsometric data have been taken from Kim, Paik, and Bockris (16) and the thickness calculations have been further simplified by the use of Drude's equations for thin nonabsorbing films. The changes in α and ϵ associated with the changes in the electrode surface from the initial, freshly reduced film-free state (at +0.5V *vs.* HE) to the anodically oxidized state at some later time were used to calculate the change $(\Delta_o - \Delta)$ in the relative phase retardation, Δ, between components of the light polarized perpendicular and parallel to the plane of incidence, respectively. This change was used to calculate the mean film thickness, *d*, using Drude's approximation, *i.e.*

$$\tan \Delta = \frac{\tan 2\epsilon}{\sin 2\alpha} \quad [5]$$

$$(\Delta_o - \Delta) = kd \quad [6]$$

where k depends on the refractive index of the film, $n_1 = 2.80$, the refractive index of the Pt substrate, $n_2 = 1.94$, and the absorption constant of the substrate, $\kappa = 4.36$, at the wavelength of light, $\lambda = 5460$Å, and angle of incidence, $\phi = 75°$, used in the experiments. Constant k is calculated as 0.263 deg·Å^{-1}.

Results

A typical relationship between potential and time (or thickness) for polarization at a constant current density is shown in Fig. 1. At this current density [corrected for roughness factor, see Ref. (1)] each increment of 0.1V in potential in the initial linear region of growth corresponds to an increase in mean thickness of the anodic film equivalent to 150 μC-cm^{-2}. The growth at first is rapid and linear but levels off at a potential between 1.5 and 1.9V depending on applied current density [see Ref. (1)]. The point at which the linearity ceases (N in Fig. 1) is taken as the origin of a new time axis for extended galvanostatic growth. If potential at a constant current density is plotted on this new axis as a logarithmic function of time, a straight line results as shown in Fig. 2. A straight line also results when ellipsometric thickness is plotted in the same way (Fig. 3). Furthermore, the thickness-log·time relationships for different current densities are parallel and equally spaced for equal increments of log·current density.

It may be noted that only a small part of the current is used for oxide formation. For instance, at 10^{-3} A-cm^{-2} during the first 10^3 sec, less than 0.3% of the total charge goes for oxide formation, so oxygen evolution is the major reaction.

From Fig. 3 it is observed that

$$\left[\frac{\partial d(t)}{\partial \ln t}\right]_{i_{O_2}} = \psi = 0.34\text{Å} \quad \text{independent of } i_{O_2} \quad [7]$$

[3] Sirohi and Genshaw (15) have, however, used an intensity transient technique to monitor phase retardation, Δ, on gold after potentiostatic polarization for various fixed times in aq. H_2SO_4. They found a logarithmic relationship between Δ and time of polarization.

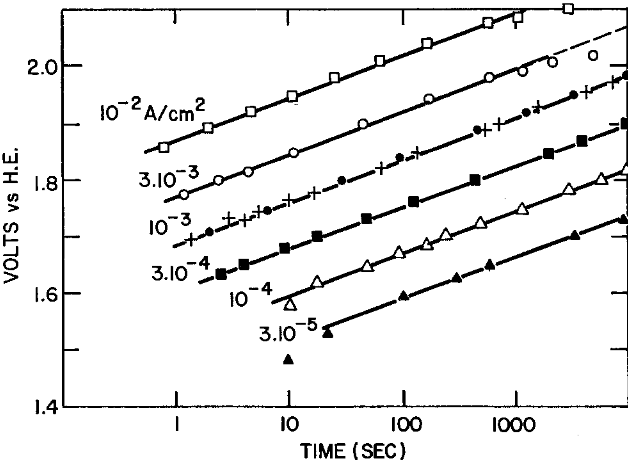

Fig. 2. Change of potential with time at various constant current densities, i_p.

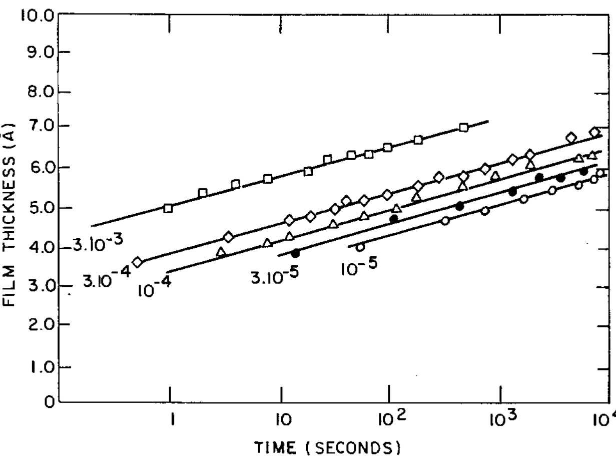

Fig. 3. Change of ellipsometric thickness with time of polarization at various constant current densities. The major reaction is O_2 evolution.

Further, from the separation of the parallel $d(t)$-log t lines one obtains

$$\left[\frac{\partial d(t)}{\partial \ln i_{O_2}}\right]_t = \epsilon = 0.38\text{Å} \quad \text{independent of } (t) \qquad [8]$$

as shown in Fig. 4.

At a constant potential too, the ellipsometric thickness of the oxide film increases logarithmically with time as shown in Fig. 5. Here, the initial growth is

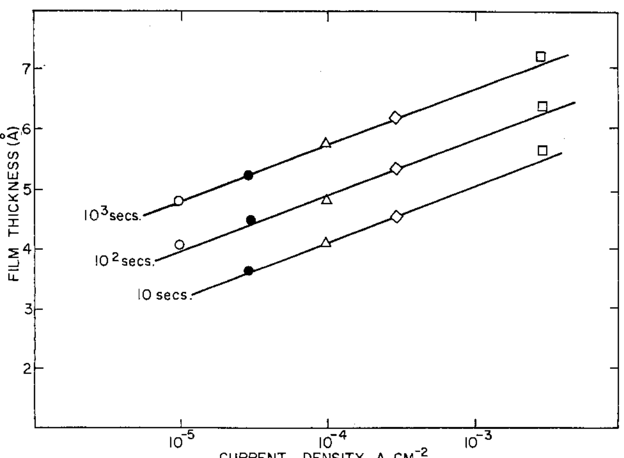

Fig. 4. Dependence of ellipsometric thickness on log · current density of polarization for three fixed times of polarization.

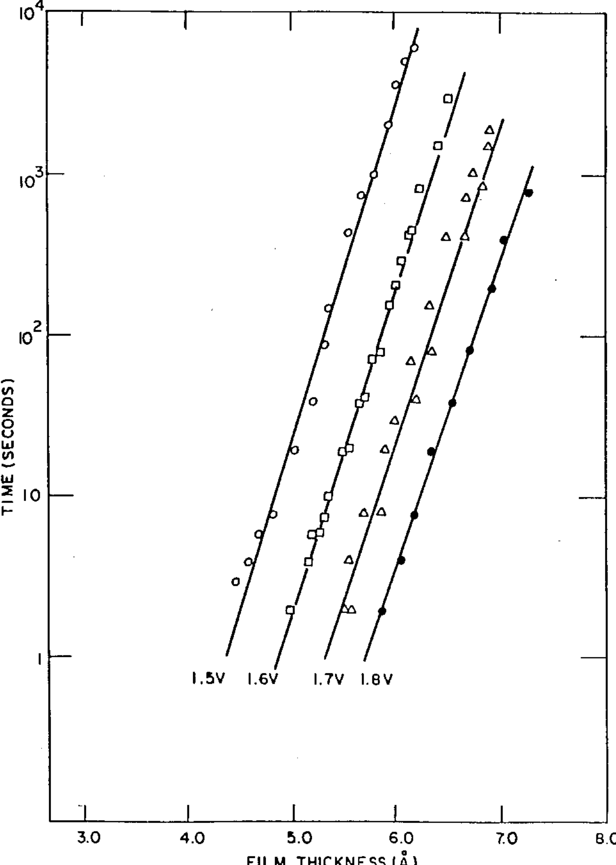

Fig. 5. Change of ellipsometric thickness with time of polarization at various constant potentials, V_p.

virtually instantaneous and the thickness-time relationship is evaluated from the onset of polarization, but see Ref. (13). Again, since the slopes of the lines for the different potentials are independent of other variables it follows that

$$\left[\frac{\partial d(t)}{\partial \ln t}\right]_V = \omega = 0.23\text{Å} \quad \text{independent of } V \qquad [9]$$

Note, however, that $\omega \neq \psi$. Furthermore, the d-log t lines at different potentials are separated in such a way that

$$\left[\frac{\partial d(t)}{\partial V}\right]_t = \sigma = 4.7\text{Å } V^{-1} \quad \text{independent of } (t) \qquad [10]$$

as shown in Fig. 6.

The effect on ellipsometric thickness and current density of polarizing at different constant potentials for fixed times of 10^2 and 10^3 sec is shown in Fig. 7 and 8, respectively. Also shown is the effect of making stepwise decreases of potential starting from the potential of the initial fixed-time polarization. The open circles in the left-hand side of Fig. 7 are the thicknesses obtained at a given potential, V_p, after 100 sec, starting from the initially oxide-free state. The open circles in the right-hand side of the same figure are current densities at various constant V_p for the same time of polarization. A linear dependence of both thickness and log current density on V_p is obtained under these conditions. The slope $(\partial d/\partial V_p)$ is close to 4.7Å V^{-1} and $(\partial V_p/\partial \log i)$ to 170 mV/decade of current density.

After an electrode has been kept at V_p for 10^2 sec and the potential decreased in steps, no change in thickness, d, is observed (open squares in the left-hand side of Fig. 7). In contrast to this, the current density, i, decreases as potential, V, is decreased (open squares in right-hand side of Fig. 7). The same be-

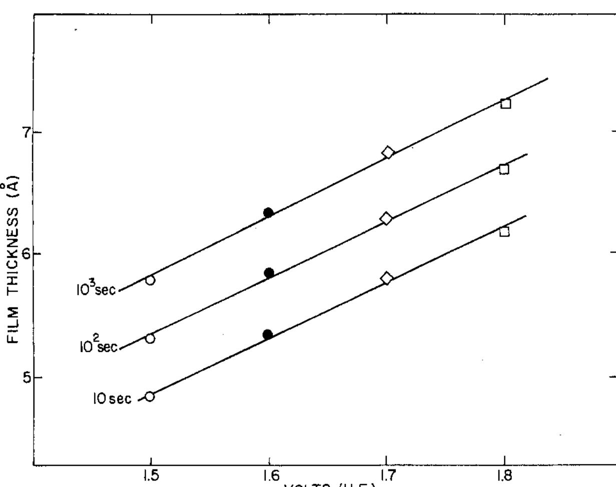

Fig. 6. Dependence of ellipsometric thickness on potential for three fixed times of polarization.

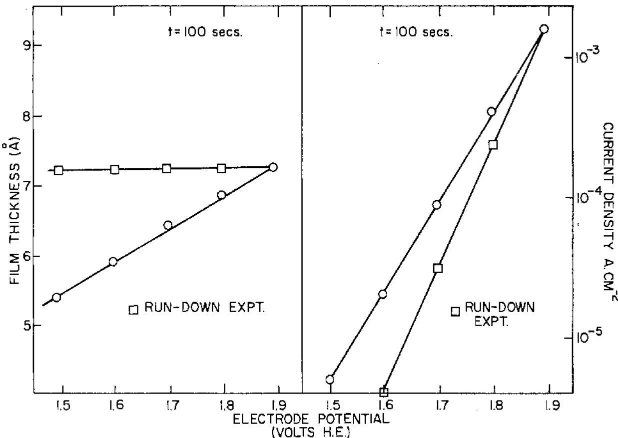

Fig. 7. Dependence of ellipsometric thickness and current density on electrode potential after potentiostatic polarization for 100 sec (open circles), and after subsequent stepwise decreases of potential (open squares).

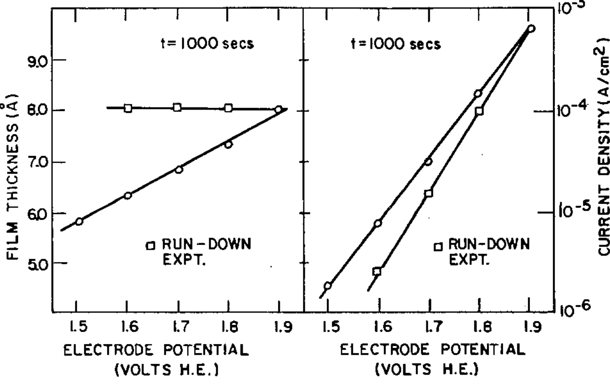

Fig. 8. Dependence of ellipsometric thickness and current density on electrode potential after potentiostatic polarization for 1000 sec (open circles), and after subsequent stepwise decreases of potential (open squares).

havior is observed for an electrode prepolarized at V_p for 10^3 sec as shown in Fig. 8. The slope $(\partial V/\partial \log i)$ is now close to 120 mV/decade of current density, *i.e.*, close to 2·3 $(2RT/\mathbf{F})$. No change is observed in any of the slopes when an electrode is polarized for a longer time. Note however, that for the shorter time of polarization the film thickness at any given potential is smaller and the current density is higher than that observed at longer times of polarization.

Discussion

For any constant time of polarization at a constant potential, V_p, current density increases logarithmically with V_p at a rate close to $(170 \text{ mV/decade})^{-1}$. The same rate is obtained (9) when current density is held constant and potential is recorded after a fixed time of polarization. Film thickness achieved during potentiostatic polarization at V_p remains constant after potential is decreased to lower values. An analogous effect under galvanostatic conditions has already been reported (9). A "hysteresis" in surface coverage has been reported also in coulometric studies though in the potential region lower than that of the present work (20, 21).

A V-log i relationship which is linear over several decades of current density with slope $dV/d \log i$ close to 2.3 $(2RT/\mathbf{F})$ is obtained therefore only under the condition of constant thickness of the oxide film, *i.e.*

$$\left[\frac{\partial V}{\partial \ln i}\right] = \text{const.} = \frac{2RT}{\mathbf{F}} \quad \text{independent of } V, d, i, t \qquad [11]$$

The same result has been obtained in galvanostatic studies (9). It follows, as in the galvanostatic case, that a unique linear relationship exists between V, ln i, and d, *i.e.*

$$f(V, d, \ln i) = \text{const.} \qquad [12]$$

This relationship can be obtained in the following way. First, from Fig. 7 and 8 one evaluates approximately $(\partial \ln i/\partial d)$ at any V_p and then from[4]

$$d \ln i = \left[\frac{\partial \ln i}{\partial V}\right]_d dV + \left[\frac{\partial \ln i}{\partial d}\right]_V dd \qquad [13]$$

obtains

$$\ln i = \frac{\mathbf{F}V}{2RT} - \frac{\delta d}{2} + \text{const.} \qquad [14]$$

Here, $\delta = 2(\partial \ln i/\partial d) \approx 2.8\text{Å}^{-1}$. This equation is identical to Eq. [2]. As expected the same rate equation describes the oxygen evolution reaction regardless of the pretreatment of the electrode or mode of polarization. The observed changes in catalytic activity are due to changes in thickness of the anodic oxide film.[5]

Turning now to the long term growth of oxide films, inspection of Fig. 3 and 5, or integration of Eq. [7]-[10] gives the dependence of thickness on time during the extended growth

$$d(t) = \epsilon \ln i_{02} + \psi \ln \left[\frac{t}{t_0}\right] + C' \qquad [15]$$

for constant current, or

$$d(t) = \sigma V + \omega \ln \left[\frac{t}{t_0}\right] + C'' \qquad [16]$$

for constant potential mode of polarization. As shown above, ϵ, σ, ψ, and ω are constants independent of V_p or i_p. Equations [15] and [16] describe the "direct logarithmic law" of growth. A similar dependence has been deduced from coulometric thickness data by Feldberg, Enke, and Bricker (11) and by Vetter and Schultze (12). According to Vetter and Schultze, however, the $(\partial q/\partial \ln t)_V$ slopes increase with increasing potential[6] so that ω is not independent of V. Equation [16] for the extended growth of oxide films is diametrically different from Eq. [4] which describes the initial stages of growth of anodic films at constant potential.

From Eq. [15] combined with [2], which holds irrespective of the mode of polarization, one obtains

[4] Subscript p can now be dropped because of Eq. [12].

[5] A change in the film properties may also affect the rate at potentials higher than 2.0V as recently shown by Visscher and Blijlevens (22).

[6] However, in the potential range where oxygen evolution is the major reaction, *e.g.*, from 1.6 to 1.9V, the $q - \log t$ lines of Vetter and Schultze appear to be nearly parallel [*cf.* Fig. 5 in Ref. (12)].

$$\frac{2RTd}{\mathbf{F}}\left[\frac{1}{\epsilon}+\frac{\delta}{2}\right]=V+\frac{2RT\psi}{\epsilon\mathbf{F}}\ln\frac{t}{t_0}+C''' \quad [17]$$

This equation can now be compared with [16]. The coefficient $(2RT\psi/\mathbf{F}\epsilon) \approx 0.044$V is numerically nearly equal to $\omega/\sigma(\approx 0.047\text{V})$ of Eq. [16]. Further, with δ evaluated from the constant potential data, the ratio (≈ 1.13) of the coefficients for d in [16] and [17] is fairly close to 1. This comparison of coefficients suggests that these two equations are identical (excluding the constant terms), and that both equations are valid for either mode of polarization (with Eq. [2] providing the link between them). The apparent self-consistency of the experimental parameters leads to the conclusion that the mechanism of the extended growth is independent of the mode of polarization. Now one can obtain an equation for the rate of growth of the anodic oxide film in the extended growth regime. From Eq. [15], [16], and [2], differentiation and elimination yields

$$r\frac{dd}{dt}=i=i_0\exp\left[-\frac{d}{\omega}+\frac{\sigma}{\omega}\Delta V\right] \quad [18]$$

Here, r is a conversion factor $(1\cdot 1.10^{-4}\ \text{CÅ}^{-1}\ \text{cm}^{-2})$ and ΔV refers here to any arbitrary zero. Again, this equation holds both for galvanostatic and for potentiostatic mode of polarization. Evidently, it is different from Eq. [1] which describes the initial stages of growth of anodic oxide films at platinum.

Constant potential mode of growth does not mean that the surface oxide film grows under the condition of constant potential difference across the oxide film itself, ΔV_f. The major ongoing reaction is oxygen evolution and ΔV_f will change with time to accommodate this reaction. It has recently been suggested that the current for oxygen evolution is given by (9)

$$i_{O_2}=X_0\exp(-\delta d)\exp\left[\frac{\mathbf{F}\Delta V_f'}{RT}\right]$$

$$=A\exp\left[-\frac{\delta d}{2}\right]\exp\left[\frac{\mathbf{F}\Delta V}{2RT}\right] \quad [19]$$

$\Delta V_f'$ is the change of potential across the oxide film from that at the reversible oxygen potential. It is taken that $\Delta V_f' = \Delta V_f + \text{const.}$ From [19] ΔV_f is given by

$$\Delta V_f'=\frac{RT}{2\mathbf{F}}\delta d+\frac{\Delta V}{2}+\text{const.} \quad [20]$$

It follows that when V is constant the potential across the oxide film increases logarithmically with time.

The next step is to examine whether the apparent difference in the kinetics of the initial and extended growth is due to this logarithmic change of ΔV_f with time rather than to a change in the mechanism of growth itself. The rate of growth can be obtained by differentiating [15], [16], and [20] with respect to time and eliminating dV/dt and $d\ \ln i/dt$ with the help of [19]

$$i=i_0\exp\left[-\frac{1+\epsilon\delta}{\psi}d(t)+\frac{\mathbf{F}\Delta V_f'}{\psi RT}\right] \quad [21]$$

Equation [21], which holds for growth both under constant potential and constant current conditions, can now be compared with the rate equation [1] which, for a constant $\Delta V_f = V - V_o$, describes growth according to the "indirect logarithmic law". Clearly, the expressions are different. Furthermore, as shown in Fig. 9, plotting the experimental data for the extended growth in the form of $1/d$ *vs.* log t does not lead to the linear relationships predicted by Eq. [4]. The observed change in the kinetics of initial and extended growth is therefore due, not to a particular change in ΔV_f, but rather to a change in the mechanism of growth itself.

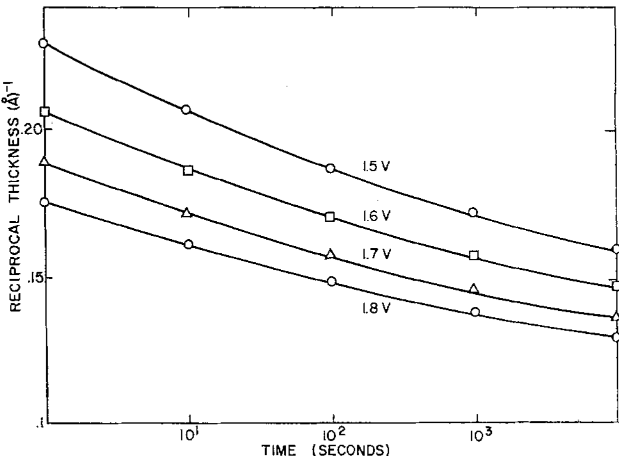

Fig. 9. Plot of the reciprocal of the ellipsometric thickness *vs.* time for polarization at various constant potentials. The plots are not linear.

An equation identical in form to [18] is frequently observed for the growth of anodic oxide films at other metals, *e.g.*, at iron with no evolution of oxygen, *i.e.*, when the major reaction is the growth of the oxide film itself (23). At iron electrodes, the change of potential with time represents the change arising only from the increase in thickness of the oxide film (23-25). In contrast to this, at platinum electrodes, the change of potential with time represents the change due to the major ongoing reaction, the oxygen evolution reaction, and is only indirectly related to the thickness of the oxide film.

The change of growth mechanism from the initial growth that proceeds according to Eq. [1], to the extended growth, that proceeds according to Eq. [18] or [21], occurs after O_2 starts to evolve or becomes the major reaction. It is not clear why the mechanism changes at this point or whether the change is related to the onset of an electronic current through the oxide film which in turn causes redistribution [cf. Ref. (26)] of the anode potential difference V between the potential difference across the oxide film, ΔV_f, and that across the double layer, ΔV_{dl}, in such a way that ΔV_f is significantly reduced. If this were the case the mechanism of high field assisted diffusion and growth would cease to operate and an alternative mechanism, perhaps similar to that described by Sato and Cohen (23) for anodic oxidation of iron, would take over.

Influence of Substrate Structure on Electroless Gold Deposition

R. Sard* and B. C. Wonsiewicz

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The electroless gold process invented by Okinaka is capable of producing high quality gold conductors by direct deposition onto catalytic regions of a substrate. This study shows that the crystallographic orientation of the metal substrates onto which electroless gold is plated may have a profound effect on the process kinetics and the structure of the deposits. On single crystal copper substrates, the initial plating rate can vary by an order of magnitude with {111} >> {100} > {110}. TEM studies show that the initial growth is epitaxial and accompanied by profuse microtwinning. X-ray pole figure results clearly show that the transition from slow initial plating on {100} and {110} to a much faster rate equivalent to that of the {111} surfaces is due to the formation of a <111> preferred orientation which occurs due to complex multiple twinning processes. Experiments with a variety of technologically relevant polycrystalline substrates are in general agreement with the single crystal results. The substrate effects identified in this work as being important for the electroless gold plating process are believed to be applicable to other catalytic systems for metal deposition.

In 1969, Okinaka discovered a plating process capable of autocatalytic gold deposition which is therefore called electroless gold (1, 2). It is suitable for a number of electronic applications and has recently been applied to the formation of beam leads on integrated circuits (3). These applications have utilized the unique attribute of selective gold deposition at catalytic regions of a substrate. Substrates capable of catalyzing the electroless gold reaction include Pd, Pt, Cu, and other noble metals (4). The gold is only applied where needed, therefore, raw materials are saved and gold does not have to be etched away. Moreover, process steps can be eliminated resulting in further economies.

The deposition conditions profoundly influence the structure of the plated film and the plating rate. In a study which examined a wide range of plating variables, Sard identified two distinct growth morphologies, a lateral or layer type and an outward or particle type (5). The more three dimensional morphology, outward growth, is favored by several factors which increase deposition rate; namely, decreasing gold concentration, increasing reducing agent concentration, and increasing temperature. Agitation is an exception; increasing agitation increases the deposition rate but favors lateral growth.

Key words: texture, structure, gold plating, catalysis.

Sard also concluded that the orientation of the substrate was important in determining the orientation of the plated film. The initial stages of growth (~10 nm) on single crystal substrates were epitaxial; that is, the orientation of the film reproduced the orientation of the substrate. Preliminary observations indicated that the plating rate was greatest for {111} surfaces. When polycrystalline substrates were used, the orientation of thicker (1 μm) films was similar to the substrate, as measured by the ratio of peak intensities in an x-ray diffractometer.

Oriented growth has been commonly observed in thin films (6), especially those grown by vacuum deposition or electroplating. Under special conditions epitaxial growth occurs; more generally, the deposit has a low index crystallographic direction (the fiber axis) oriented perpendicular to the plane of the sheet, but is rotationally symmetric in the plane of the sheet. Such textures are called fiber textures, by analogy with a bundle of fibers arranged with their axes all pointing in the same direction. Under certain conditions, the fiber axis in deposited films can be tipped away from the film normal, usually toward the direction of greatest mass flux.

In view of the link between substrate orientation, plating rate, and orientation for the electroless gold system, a more detailed investigation was carried out.

A key improvement over previous studies was the use of x-ray pole figures to characterize the orientation distribution of the deposits. Pole figure determination is normally so tedious and time consuming as to rule it out for studying a large number of samples. However the use of a computer-aided system reduced the labor required to construct a pole figure from about 3 hr to 15 min (7).

The structure of films was studied at several stages of growth on single crystals and on several important polycrystalline substrates using the pole figure method. Additional data on the initial stages of growth were obtained by transmission electron microscopy (TEM), and scanning electron microscopy (SEM) was used to study the morphology of thick deposits. This approach has provided information relevant to some of the practical and fundamental aspects of electroless gold deposition. Some of our findings are undoubtedly applicable to other catalytic processes at solid/liquid interfaces.

Experimental Details

Single crystal substrates.—A copper single crystal 1.5 cm in diameter was grown by the Bridgeman method. Several thin slices 1 mm thick were spark cut parallel to each of the low index planes: {111}, {100}, and {110}. The orientation of the cut surfaces was within about 1° of the true planes.

Surface damage was removed by mechanical polishing followed by a chemical bright dip in an aqueous solution of 40% H_2SO_4, 20% HNO_3, and 0.1% HCl and electropolishing in 50% H_3PO_4 solution. After gold plating and the completion of measurements, the crystals were recycled by dissolving the gold in an iodide solution (8), rinsing in methanol, and water, then repeating the bright dip and electropolish procedures. After about 4 such cycles the crystals showed signs of increased surface roughness and had to be repolished mechanically. This changing surface roughness was probably responsible for some minor variations noted in the plating rate and microstructure on different regions of the samples and from run to run; however these effects were judged to be of second order importance and are not considered further.

Polycrystalline substrates.—A number of experiments were conducted using polycrystalline samples of two different types: (*i*) evaporated noble metal films (Au and Pd) on titanium-coated sapphire and glass, and (*ii*) copper metal sheets. A more detailed description of these materials and their preparation history is given together with the results below.

Electroless deposition.—For most experiments, electroless deposition was carried out using the solution formulation which was previously found to give the layer-type growth: $KAu(CN)_2$, 0.02M; KBH_4, 0.4M; KOH, 0.2M; and KCN, 0.2M. Unless otherwise specified, experiments were performed at 75° ± 0.5°C using a PTFE holder to maintain the substrates in cylindrical geometry. The agitation conditions were changed by introducing a glass stirrer with flattened blade coupled to an external motor rotating at 3000 rpm. A few experiments were also performed using a carousel arrangement in which the substrates rotated at about 150 rpm on a 2 in. diameter PTFE wheel. An alternate solution, formulated with 0.005M $KAu(CN)_2$, was also used for some experiments with forced agitation. This system was known to plate at a faster rate, due to its more negative deposition potential (9).

Film thicknesses were determined by the beta backscatter method using a promethium source and NBS calibration standards for the case of the bulk single crystal and polycrystalline Cu substrates. Although the absolute accuracy of these measurements is approximately ±5%, the results were checked against the weight gain method for sheet substrates and found to agree within 1-2%. The latter method was used for all thin film substrates. The plating rate was calculated by dividing the change in thickness averaged over the sampling area by the plating time, based on the assumption of uniform deposits with the density of bulk gold.

Structure determination.—The crystallographic orientation distribution was determined by the standard pole figure technique (10) using Ni filtered Cu K_α radiation and the (111) Bragg reflection. A block diagram of the system is shown in Fig. 1. An automatic pole figure goniometer (either Siemens or Norelco) was used to rotate the specimen along a predetermined scanning geometry. X-ray intensity was recorded on punched paper tape using an Ortec digital ratemeter and printout control and a Model 35 Teletype. Specimen identification and values for constructing the intensity contours were entered directly on the paper tape. The tape, together with a group of Fortran IV programs served as input to a Honeywell H-6000 computer which generated the final drawings on a Xerox LDX graphics device. The present computer charges are about three dollars for a finished pole figure. The programs are capable of making corrections for background and absorption and will smooth data if necessary. Generally, no corrections were necessary in this study. The experimental techniques used gave good results for gold deposits in excess of 0.2 μm thick.

Microstructure results were obtained using the standard methods of interference contrast (Normarski) optical microscopy and scanning and transmission electron microscopy.

Results and Discussion

Single crystal substrates.—A typical set of results showing the effect of orientation on plating thickness as a function of time is illustrated in Fig. 2. The curves are drawn through averaged experimental points taken by removing the substrates periodically from a solution agitated with strong forced convection. The experimental points shown at the right edge of Fig. 2 were obtained by plating a similar set of substrates without forced convection. These data show clearly that the initial rate of gold plating, *i.e.*, the initial slope, is highly orientation dependent with {111} > {100} > {110}, regardless of the transport conditions. By comparing the slopes over the interval 5-10 min and normalizing to {111}, one obtains relative rates for the three orientations of approximately 1 > 0.25 > 0.10. The interval from 0-5 min is complicated by the galvanic displacement effect which occurs in the first 10 nm of film growth. It is also evident from the curves that after 20 min, the rates are nearly the same

on all three substrates, indicating a transition to steady-state conditions determined by the plating conditions. By following the changes in structure of such deposits, considerable insight was gained as to the physical aspects of the deposition mechanisms which govern this system.

The microstructures formed during the initial portion of the process, *i.e.*, the first 5 min or so, can be studied conveniently by transmission electron microscopy after chemical removal from the substrate (11). Figures 3a, 4a, and 5a illustrate the typical features evident in bright field images of Au deposits stripped from {111}, {100}, and {110} substrates, respectively, and their corresponding selected-area diffraction patterns are given in Fig. 3b, 4b, and 5b.

As the diffraction patterns show, the films at the earliest stages reproduce the substrate orientation, *i.e.*, the growth is epitaxial. This is apparently due to the displacement process as discussed previously (11). Small, parallel-sided features are visible in the micrographs; they are planar defects, small volumes of material which bear a twin orientation relationship with the matrix. In Fig. 3b, the six interior spots in hexagonal array are due to diffraction at the boundaries where twinning occurs. This result is similar to that for electroplated gold on copper (12). Similar microtwins have been observed in epitaxial evaporated films and the resulting twin-matrix structure is often called "double positioning" (13-15). The satellite reflections adjacent to the {100} reflections in Fig. 4b arise from double diffraction at the twin boundaries. This fact was confirmed by TEM dark field studies, *e.g.*, using the matrix and satellite spots encircled. The substructure evident in Fig. 3-5a is due primarily to the high density of twin faults which formed in the gold deposits.

The fact that these twins are due to deposition and not to deformation upon stripping the foils from the substrates was confirmed by the pole figures which were obtained with the deposits in place on the substrates.

Pole figures taken at the initial stages of film growth show quite clearly the epitaxial nature of the orientation as well as a weaker twin orientation. As the plating proceeds, the orientation distribution becomes more complex; the twin orientations with surface normals near <111> grow in volume most quickly.

Pole figures corresponding to a later stage of plating show a very intricate structure. The simplest structure is found on the fast plating {111} substrate. In the pole figure, Fig. 6a, the solid triangles locate the {111} substrate orientation and the open triangles locate the twin orientation. The twinned material has mirror symmetry with the original matrix. This matrix-twin relationship is equivalent to the "double-positioning" structure evident in the early stages of film growth shown in Fig. 3.

The more complex structure evident in Fig. 6b is found in films plated on the {100} substrate. The pseudo-twelvefold symmetry apparent in the pole figure also arises from twinning. In the original epitaxial deposit, there are four <111> poles symmetrically oriented as indicated by the four half-filled squares in Fig. 6b. Twinning on one of the {111} planes will produce the orientation shown as open squares labeled A(1) through A(4). Twinning on the other three original {111} planes produces the rest of the poles shown by open squares. Note that the twinning places four <111> directions within 15.8° of the surface normal. Nevertheless the actual intensity recorded in Fig.

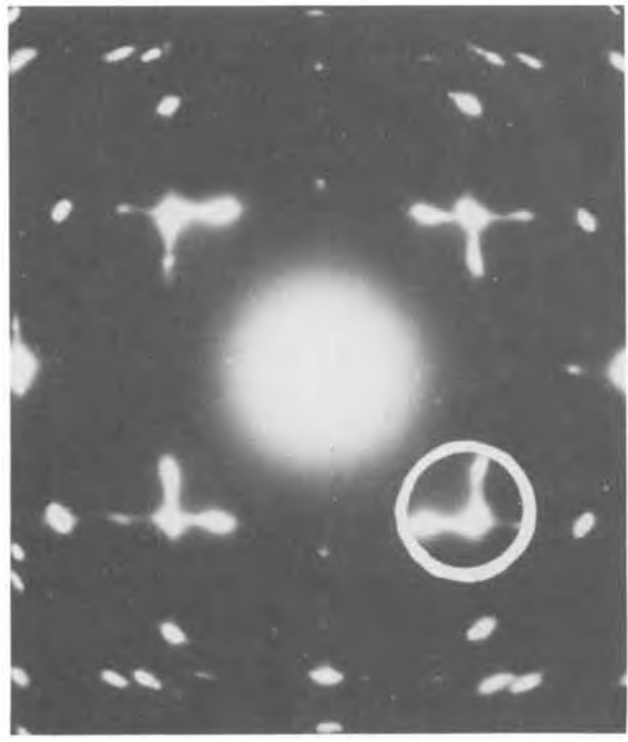

Fig. 4. TEM results for thin gold deposit on {100} substrate. (a, top) Bright-field image, original magnification 110,000×. (b, bottom) Selected-area diffraction pattern.

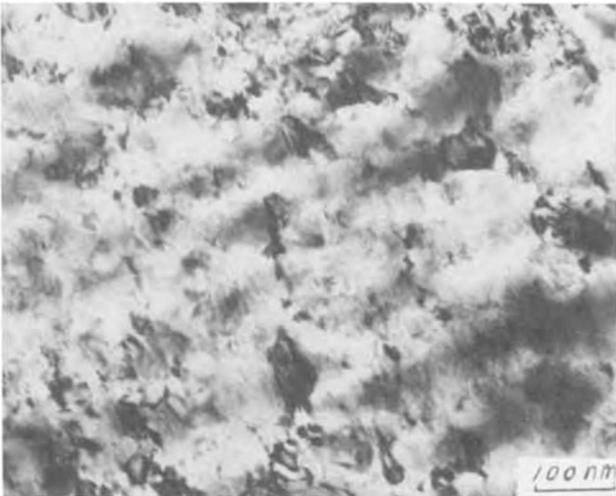
6a is greatest at the surface normal rather than 15.8° away. This indicates a rotation during growth to a final {111} film orientation. As can be seen in Fig. 6b, little intensity remains in the region of the original {100} orientation and the transition to the final {111} orientation is highly developed.

The films plated on the {110} copper substrate have a still more complex orientation. The original epitaxial orientation is indicated on the pole figure shown in Fig. 6c by the lens symbol. Note that there are twenty intensity maxima in addition to the two located by the original epitaxial orientation. All of them can be precisely located by twinning reorientations. The first



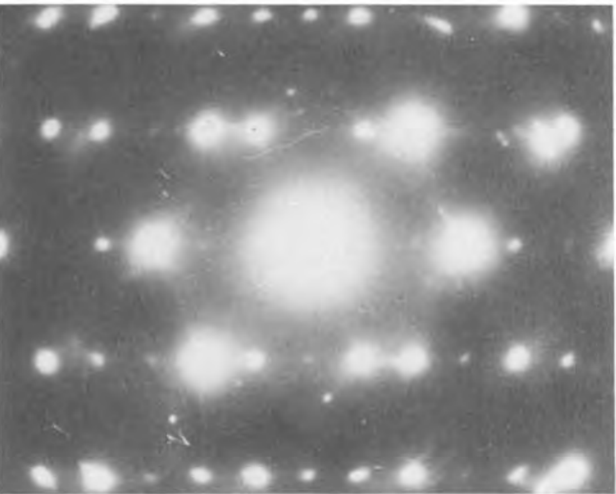


Fig. 5. TEM results for thin gold deposit on {110} substrate. (a, top) Bright-field image, original magnification 120,000×. (b, bottom) Selected-area diffraction pattern.

group of orientations indicated by the squares in Fig. 6c were produced by twinning on the two {111} planes visible in the pole figure; the new orientation locates the film normal about 19.5° away from [001]. The second group of orientations indicated by triangles is obtained by retwinning of the previous orientation, the squares. The twin plane normal is designated by an overlapping square and triangle. After twinning first on the square and then on the triangle, the new orientation of the doubly twinned material is within 5° of the fast growing {111} orientation. The remaining group of orientations designated by the circles can be produced by twinning first on the triangles and then retwinning on the plane indicated by the overlapping circle and triangle. This doubly twinned volume is oriented about 25° from <111>, midway between <112> and <113>. The combination of primary twinning followed by two different types of secondary twinning can explain all the maxima observed in Fig. 6c.

A generalization of the single crystal results is that the substrate orientation is reproduced in the film and that additional orientations are generated by {111} twinning. If the twinning or retwinning process places a <111> direction in the vicinity of the film normal, a transition to a {111} film orientation begins. Agitation did little to modify these observations, except to produce slightly asymmetrical pole figures. When strong convection was present, orientations with <111> directions inclined toward the direction of fluid flow were the most intense. This is in agreement with the observations of film growth from the vapor; namely

that the <111> direction is inclined toward the direction of greatest mass flux (6).

An interesting correlation exists between the change in plating rate, shown in Fig. 2, and the change in film orientation due to twinning. Once the various complex twinning mechanisms operative for the {100} and {110} substrates have taken place, the deposits all tend toward the <111> preferred orientation and the rate of deposition becomes independent of substrate. At this point, the kinetics of the electroless gold reaction have reached steady state and are controlled by the deposition conditions and the mixed-electrode potential (9).

The catalysis literature contains numerous papers dealing with the effect of crystal orientation on the kinetics of gas phase reactions (16, 17), and the role of structural factors in electrocatalysis (18). Crystallographic orientation is the most important structural factor controlling the catalytic activity of platinum surfaces in studies of hydrogen evolution and the anodic oxidation of methanol (18). The rates of these reactions were greatest on the {111} face by up to an order of magnitude, as compared to other crystal faces with lower atomic packing density. Our results for the electroless gold system are in good agreement with these findings, as has been pointed out by Okinaka (9)

who noted that the chemisorption of reacting species is an important feature of catalytic processes. Other results from electrocrystallization studies have shown that exchange current densities for the electrodeposition of copper on copper single crystals increases by a factor of five on going from {111} to {100} to {110}. This means that the rate of deposition at constant overpotential increases in the order {110} > {100} > {111} (19). The electroless gold results (Fig. 2) are exactly opposite. Thus, from the standpoint of the deposition mechanism, the electroless gold has more in common with the electrocatalysis of platinum than the electrocrystallization of copper. One aspect of the electroless gold process not studied in this work but discussed elsewhere (9), is that the anodic reaction may be rate controlling.

Examination of the surfaces of the electroless gold deposits by optical microscopy and SEM also showed that the substrate orientation strongly affects the growth morphology, consistent with the established literature on electrocrystallization studies (20). Normarski optical microscopy revealed that the deposit on the {111} substrate consisted of 200-400 μm features that were similar to previously reported structures for thick copper deposits on {111} (21). The other two substrate orientations yielded surfaces with much finer features that could not be resolved optically. Representative SEM results are shown in Fig. 7a-c for the {111}, {100}, and {110} substrates, respectively. Because of the large features on the {111} surface, there is relatively little structure visible at high magnification unless one looks near the edges of the features as in Fig. 7a. The appearance of the surface on the {100} substrate (Fig. 7b) is quite similar to the smooth faceted structure which is commonly observed for technological deposits on polycrystalline substrates under these plating conditions (4). The deposits on the {110} substrate have an irregular microstructure with numerous fine features ($\sim$0.2 μm) as well as larger ones (>2 μm). These results suggest that the process of lateral growth occurs most readily on {111} substrates which is in agreement with recent findings for gold electrodeposits (22). Consideration of these data together with the plating rates (Fig. 2) and pole figures (Fig. 6) indicates that the twinning processes, the microstructure, and the nonuniform initial plating rates are interrelated.

Polycrystalline substrates.—Evaporated films.—Two sets of experiments were carried out using evaporated film substrates and the standard plating solution. In the first set, either Pd or Au films, 80 nm thick, were evaporated at 1.5 nm/sec using an e-beam system at 2×10^{-7} Torr onto a 30 nm thick layer of Ti which was freshly deposited onto clean, polished sapphire surfaces 9 mm $\times$ 2.0 cm in size. Three samples of each type of film were mounted in a PTFE holder and plated simultaneously either in still solutions or with vigorous stirring using a rod at 3000 rpm. The effects of agitation on plating rate have been discussed in detail elsewhere (4). The rate of deposition was 40% greater on the Au substrate than on the Pd substrate if the solution was agitated. Without agitation the difference was 20%. Since the difference in plating rate was suspected to be due to a difference in the structure of the substrates, the structure of both the substrates and deposits was studied in some detail. Pole figures for the deposits on the gold substrates showed a very strong <111> fiber feature which was also quite strong in the substrate films; whereas, the gold deposits on Pd substrates showed a weaker <111> fiber texture as did the substrates which were much more randomly oriented. Since the <111> orientation is known to plate at a fast rate, Fig. 2, the difference in plating rate is probably due in part to the difference in orientation. Further examination of the substrates by TEM showed that the Pd films were uniformly fine grained ($\sim$10 nm) and the Au films were more heterogeneous with many grains >100 nm in size.

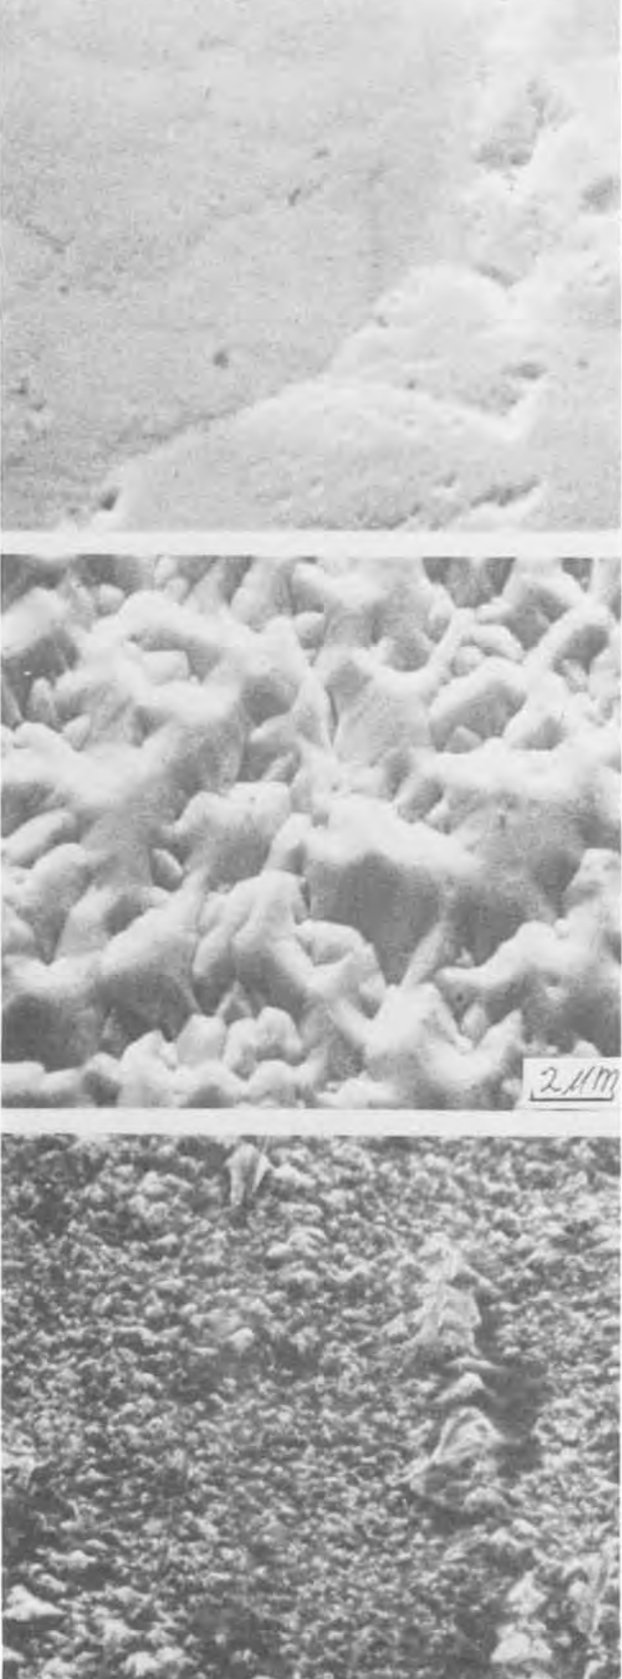

Fig. 7. SEM results showing surfaces of thick gold films on single crystal substrates, original magnification 5000×. (a, top) {111} Substrate. (b, center) {100} Substrate. (c, bottom) {110} Substrate.

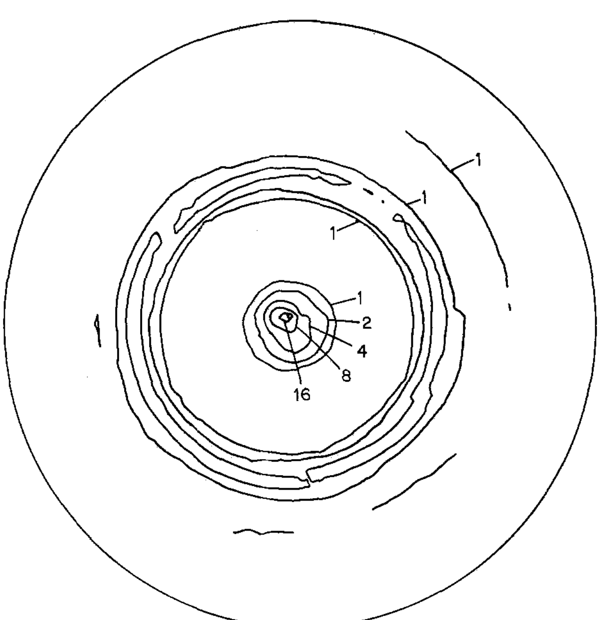
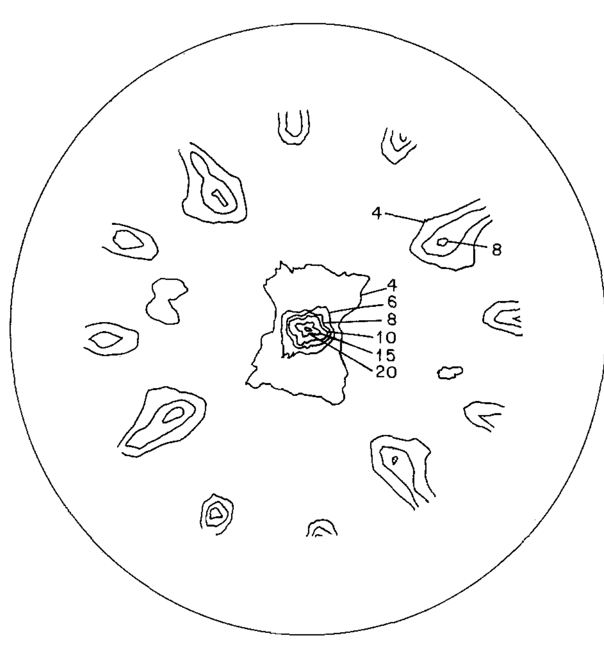
In a second series of experiments Au/Ti/glass substrates were evaporated at higher pressure ($\sim 2 \times 10^{-5}$ Torr). These substrates had a complex texture. The fiber axis was tilted away from the sheet normal toward the direction of mass flux during evaporation. The texture consisted of a strong <111> component combined with a weaker <100> component. The substrates were plated in the standard solution with different amounts of agitation. Figure 8a gives the pole figure for a 2 μm thick deposit plated without agitation at the normal rate of 0.7 μm/hr. The plated film reproduced the orientation of the substrate. The more complex pole figure in Fig. 8b corresponds to a deposit plated in the same bath to the same thickness but with carousel stirring at a velocity of 0.46 m/sec which produces a threefold increase in plating rate (4). These conditions yield a <111> fiber texture with a strong <311> component as seen in Fig. 8b.

In both of these sets of experiments with evaporated noble metal film substrates it was found that the deposits were formed epitaxially and that the <111> orientation of the substrates was maintained for deposits <2 μm in thickness. Subtle but real effects due to substrate grain size and the strength or degree of the <111> texture were observed.

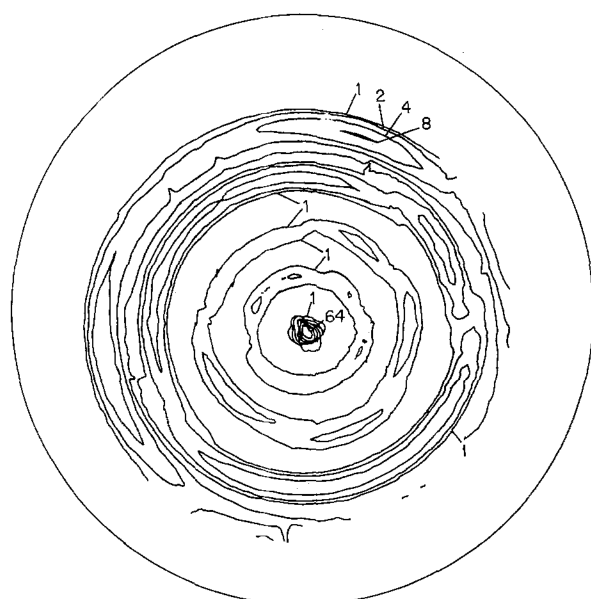
Rolled sheet metal.—In an initial set of experiments, two lots of nominally identical commercial copper foil plated at substantially different rates under the same conditions (23). One batch of material gave the normal plating rate (1.5 μm/hr) and the other showed a surprising twofold increase in rate which was maintained to a thickness of >5 μm. Pole figures for both substrates showed them both to be qualitatively the same, with cube textures as expected. Figure 9a shows the pole figure for the deposit with the normal plating rate. Here we see the characteristic epitaxial growth of the cube texture and the transition to {111} by the multiple twinning mechanism which has already been discussed for the case of the {100} single crystal substrate, Fig. 6b. Figure 9b shows that the anomalously fast plating deposit remained in the cube orientation.



a. No agitation, plating rate 0.7 μm/hr.



a. Normal plating rate 1.5 μm/hr.



b. Agitation at 2750 cm/min, plating rate 2.1 μm/hr.

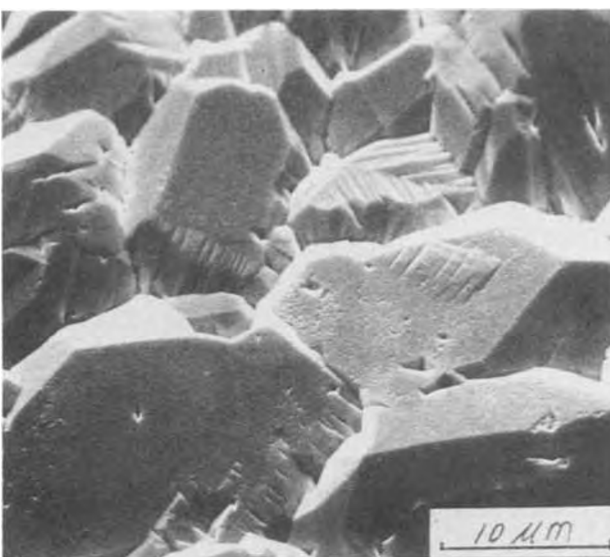

Fig. 10. Surface structure corresponding to Fig. 9b, original magnification 2500×.

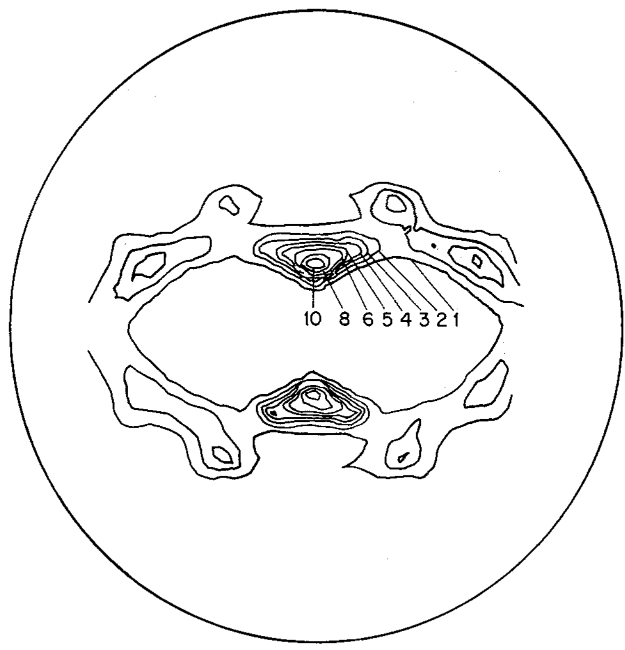

Fig. 11. {111} Pole figure of 1.5 μm thick gold deposit on cold-rolled OFHC copper sheet.

The microstructure of this deposit observed in the SEM was also unusual and is shown in Fig. 10. Here we see a large, faceted grain structure with smooth features ~20 μm across whereas the deposits plated at the normal rate showed a considerably finer microstructure with background features 1-2 μm in size and some larger, nodular features.

A SEM examination of etched samples of the two substrates indicated some qualitative differences such as the grain size and shape but did not permit us to explain the anomalously high plating rate. One possibility is that an impurity species, which may have dissolved from the surface region of the fast copper substrate during the initial displacement process, somehow altered the growth process by preventing the twinning mechanism from occurring. However, in this case we would expect the rate to be slow as one finds with {100} single crystals; but this is not the case for this material by at least an order of magnitude.

Additional experiments were conducted in an attempt to shed some light on the above result and see whether or not it could be reproduced using other copper sheet substrates. To do this, we started with bulk OFHC Cu and prepared sheet samples, 0.010 in. thick, by cold rolling to a 92% reduction. The pole figure in Fig. 11 indicates that this texture is copied by the electroless gold deposit, which in this case was 1.5 μm thick and plated at the normal rate. Deposits plated on annealed substrates from the same material (300°C, 1 hr) showed a similar plating rate and the expected structure for the case of cube-texture substrates, *i.e.*, identical to Fig. 9a. This set of experiments included other sheet substrates (Au and phosphor bronze) and plating runs at temperatures both 10°C above and below nominal. In no case were we able to find any increase in the plating rate, comparable to that observed with the "fast copper."

Summary and Conclusions

The results of this study show that the structure of metal substrates onto which electroless gold deposits are plated may have a profound effect on the process kinetics and the structure of the deposits. On single crystal copper substrates, the initial plating rate can vary by an order of magnitude with {111} >> {100} > {110}. In all three cases twinning is observed during the initial stages of growth (~0.1 μm). The TEM results show twin fault densities > $10^{+11}/cm^2$. X-Ray pole figures for thick deposits provide additional evidence for the importance of twinning in this deposition process. In particular, the pole figure results indicate that multiple twinning processes are responsible for the transition from the slow initial plating rates on the {100} and {110} substrates to the faster rate typical of the <111> preferred orientation.

Electroless gold deposits on evaporated noble metal film substrates exhibit a <111> fiber axis which represents a continuation of the substrate texture. A somewhat lower rate of deposition is observed for Pd substrates relative to that on Au films. The magnitude of this effect is about 20% without forced convection and about 40% when the plating solution is stirred vigorously. The somewhat lower plating rate on Pd is apparently due to the fact that these substrate surfaces are comprised of much smaller grains (~10 nm) that are more randomly oriented than the Au films.

Experiments with polycrystalline Cu sheet substrates are in general agreement with the single crystal results except for one particular batch of commercial material onto which deposits with an unusually large grained microstructure were formed at an anomalously fast plating rate. This result could not be reproduced with laboratory-prepared sheet substrates.

We conclude by noting that the substrate effects identified in this work as being important for the electroless gold plating process are likely to be applicable to other catalytic systems for metal deposition. This would appear therefore to be a fruitful area for further work.

Electrodeposition of Cobalt Using an Insoluble Anode

G. R. Lakshminarayanan, E. S. Chen, J. C. Sadak, and F. K. Sautter

Benet Weapons Laboratory, Watervliet Arsenal, Watervliet, New York 12189

ABSTRACT

A method has been developed which permits the use of an insoluble anode to electrodeposit cobalt by the addition of a sufficient amount of an electrochemically active substance such as vanadium pentoxide to the cobalt sulfate plating solution. In the absence of such additions, formation of Co^{3+} ions and cobalt oxide (Co_2O_3) at the platinum anode results during plating. The effects of the addition of vanadium pentoxide on the electrode process during plating have been investigated through the analyses of various electrolysis products as a function of additive concentration and plating time. The results show that besides cobalt deposition, vanadium ions of lower oxidation state (V^{++}, V^{+++}, VO^{++}) are formed at the cathode and these ions seem to be responsible for the reduction and suppression of Co^{3+} ions and the oxide at the platinum anode. It has also been observed that the concentration of the added electrochemically active substance changed very little, indicating no incorporation of vanadium with the deposit during plating. The mechanical properties of the deposits prepared using an insoluble anode are compared with those obtained using a soluble anode.

The electrodeposition of cobalt, dispersion-hardened cobalt, and cobalt-based alloys has been the subject of investigation (1-6) at this laboratory for many years because of the potential application as protective coatings to improve the wear and erosion characteristics of the substrates. In conventional cobalt plating, soluble anodes are used to replenish the metal deposited at the cathode. In plating the inside of small bore tubes such as small caliber gun tubes, however, it would be necessary and also highly advantageous to use an insoluble anode since the dimensions of the anode would not change. However, the use of an insoluble anode like platinum in cobalt plating solutions leads to the formation of undesirable black cobalt oxide particles at the anode. They appear at the anode as a strongly adherent black coating or remain as suspended particles in the plating solution. The codeposition of these particles with the deposits has a detrimental effect on the structure and properties of the deposits. In order to suppress the undesirable reactions leading to the formation of cobalt oxide, other electrochemically active substances were introduced in the plating solution. It was hypothesized that the oxide formation could be suppressed if other reducible agents were present in the electrolyte. The additive should be such that it does not interfere with the normal plating process and has no detrimental effect on the properties of the deposit. Vanadium pentoxide was found to be a very effective and suitable chemical in this regard. By undergoing reduction at the cathode and oxidation at the anode without being codeposited, this substance provides electrochemically active species during plating which suppress the oxide formation. This investigation deals with a study of the effects of addition of vanadium pentoxide to the cobalt sulfate plating solution on the electrodeposition of cobalt using a soluble or an insoluble (platinum) anode.

Key words: insoluble anode, electrochemically active substances, electrode process.

Experimental

Plating solutions and plating procedure.—All chemicals were of reagent grade quality and were used without further purification. A stock solution of cobalt sulfate (1.0M) was prepared and unless otherwise stated, 150 ml fresh solution was used for each experiment. Vanadium pentoxide (up to about 4.5 g/liter) was added to the plating solution. The dissolution of vanadium pentoxide was slow and it took up to 50-60 hr to dissolve 4.5 g/liter at 40°C and at *p*H 1.0. A regulated power supply was used as a power source. Cobalt or platinum anodes and stainless steel or brass cathodes (substrates) were used for plating. Cobalt plating was generally carried out at a current density of 5 A/dm^2, a temperature of 40°C, and at an initial *p*H 1.00.[1]

[1] The low *p*H was used, in spite of reduced cathode efficiency, in order to obtain increased solubility of V_2O_5 and reduced formation of black oxide particles.

Analysis of solutions.—The oxidation-reduction method of analysis (redox methods) was adopted to determine the concentration of the various electrode reaction products. Cerium (IV) sulfate and ferrous (II) sulfate solutions were prepared, standardized, and used for the analysis of the electrolysis products. A Beckman electroscan was used to monitor the variation of the potential during the titration of solutions. The cobalt oxide particles formed during the electrolysis were quantitatively determined by the gravimetric procedure (7) using millipore filters.

Mechanical properties of the deposits.—Cobalt was deposited on brass shim stock (0.003 in.) substrates from cobalt sulfate and cobalt sulfate-vanadium pentoxide plating solutions (1.8 liter). Both soluble and insoluble anodes were used to prepare the deposits. The brass substrate was anodically dissolved in a $KOH-K_2CO_3$ solution. The deposits were cut into tensile specimens and the room temperature yield strength (0.2% offset), tensile strength, and elongation were obtained using an Instron tensile testing machine.

Results and Discussion

Electrolysis of cobalt sulfate solution.—With a soluble cobalt anode, Co^{++} ions are produced at the anode during plating and are reduced to Co at the cathode. When an anode such as platinum is used, no metal is dissolved at the anode during plating. The reaction which is essential for the passage of current from the anode to the electrolyte is one of oxidation of the components of the electrolyte at the anode-solution interface. Depending on the anode potential, several anode reactions may proceed simultaneously. In an acidic cobalt sulfate electrolyte, oxygen discharge takes place according to the reaction, $2H_2O \rightarrow 4H^+ + O_2 + 4e^-$. Simultaneously, Co^{2+} ions are oxidized to Co^{3+} ions leading to the formation of cobalt oxide (Co_2O_3) at the anode. The presence of Co^{3+} ions in the plating solution can be quantitatively determined with ferrous sulfate solution according to the oxidation-reduction reaction $Co^{3+} + Fe^{2+} \rightleftharpoons Co^{2+} + Fe^{3+}$. The cobalt sulfate solution was electrolyzed for 3.5 hr at 5 A/dm^2 using an insoluble anode and a soluble anode separately and the solutions were analyzed for the Co^{3+} ion content. The results of the analysis are shown in Fig. 1. Curve A shows the variation of potential with respect to saturated calomel electrode of the electrolyzed solution (with an insoluble anode) on titration with ferrous sulfate solution. Curves B and C represent the same data for the electrolyzed solution with a soluble anode and for the unelectrolyzed cobalt sulfate solution, respectively. It can be calculated from curve A that the electrolyzed solution contains Co^{3+} ions corresponding to 4.03×10^{-3} moles/liter. From curves B and C it can be concluded that these solutions contain no Co^{3+} ions. It has been observed that the reaction between Fe^{2+} and Co^{3+} ions is relatively sluggish and attains steady potential values rather slowly. Co^{3+} ions are relatively unstable; the concentration decreased in the above plating solution from 4.03 to 0.45×10^{-3} moles/liter over a period of 21 hr on standing.

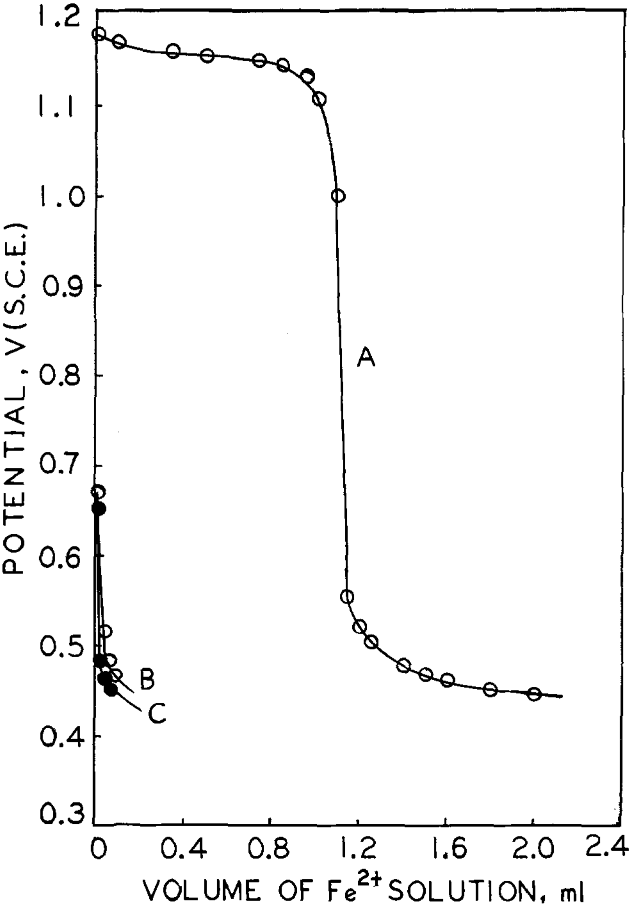

Fig. 1. Variation of potentials during titration of electrolyzed and unelectrolyzed $CoSO_4$ solutions (3.0 ml) with ferrous sulfate solution (0.0108M): A = electrolyzed $CoSO_4$ solution with an insoluble anode, B = electrolyzed $CoSO_4$ solution with a soluble anode, and C = unelectrolyzed $CoSO_4$ solution. Anode:cathode = 1:4, current density = 5 A/dm^2, temperature = 40°C, pH (initial) = 1.00, and plating time = 3.5 hr.

Electrolysis of $CoSO_4$-V_2O_5 solutions.—Vanadium, being a multivalent element, can exist in several oxidation states in solution. The species that form in aqueous solutions are V^{2+}, V^{3+}, VO^{++}, and VO_2^+ ions and their formation depends on the potential and the solution pH. Vanadium pentoxide when added to the cobalt sulfate plating solution at pH 1.0 dissolves in it to form a VO_2^+ ion according to the reaction $V_2O_5 + 2H^+ \rightarrow 2VO_2^+ + H_2O$. When this solution is electrolyzed, besides cobalt deposition at the cathode, other electrolysis products at cathode and anode are formed depending on whether a soluble or an insoluble anode is used.

When a cobalt anode is used, dissolution of the metal to Co^{++} ions takes place and, at the cathode, in addition to cobalt deposition, reduction of VO_2^+ ions occurs according to the reaction.

$$VO_2^+ + 2H^+ + e \rightleftharpoons VO^{++} + H_2O \qquad E^\circ = +0.758V$$

$$VO^{++} + 2H^+ + e \rightleftharpoons V^{+++} + H_2O \qquad E^\circ = 0.119V$$

$$V^{+++} + e \rightleftharpoons V^{++} \qquad E^\circ = -0.497$$

The potentials (E°) noted at which these reactions occur correspond to equilibrium potential values with respect to the saturated calomel electrode (8). A solution of $CoSO_4$-V_2O_5 (4.5 g/liter) was electrolyzed using a cobalt anode and the electrolysis products were analyzed using a standard cerium (IV) sulfate solution. The formation of various electrolysis products is shown as a function of plating time in Fig. 2. Prior to electrolysis vanadium ions exist as VO_2^+. With electrolysis VO_2^+ ions are reduced to VO^{++} and V^{3+} ions initially and with further electrolysis V_2^+ ions are also formed. While all the VO_2^+ ions are reduced to lower oxidation states, the concentration of the lower oxidation species depends on the electrolysis time. These ions are not reoxidized to pentavalent (VO_2^+) state and remain in solution as a mixture of two or three species depending on the length of plating time. This behavior is in contrast to the results obtained with an insoluble anode as is shown below.

When a $CoSO_4$-V_2O_5 solution is electrolyzed with an insoluble anode (platinum), one encounters a new situation. The electrolysis products at the cathode can be expected to be the same as with the soluble anode; however, at the anode, oxygen discharge, Co^{3+} ion formation, and oxidation of vanadium ions (V^{2+}, V^{3+},

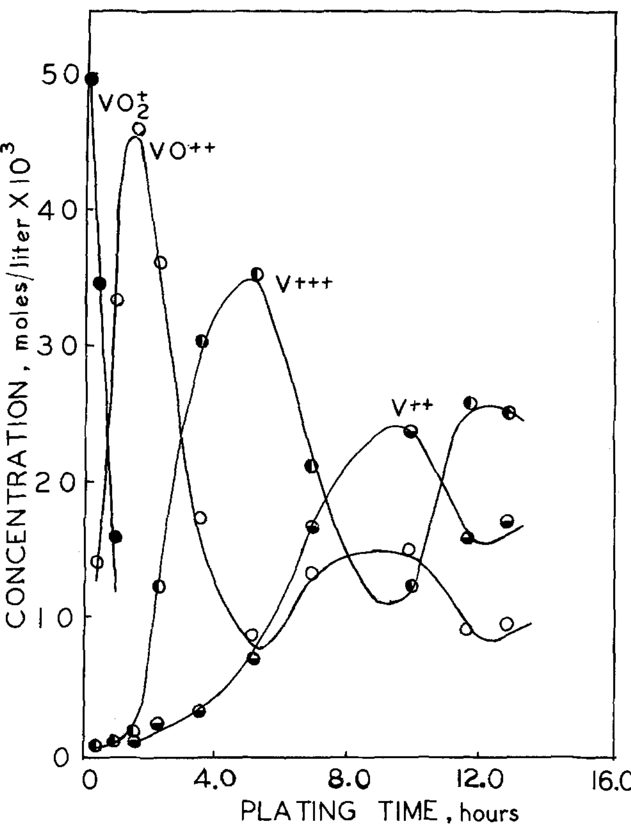

Fig. 2. Formation of vanadium ions of different oxidation state in $CoSO_4$-V_2O_5 (4.5 g/liter) solution as a function of plating time. Soluble anode is used. Current density = 5 A/dm^2, temperature = 40°C, pH = 1.00.

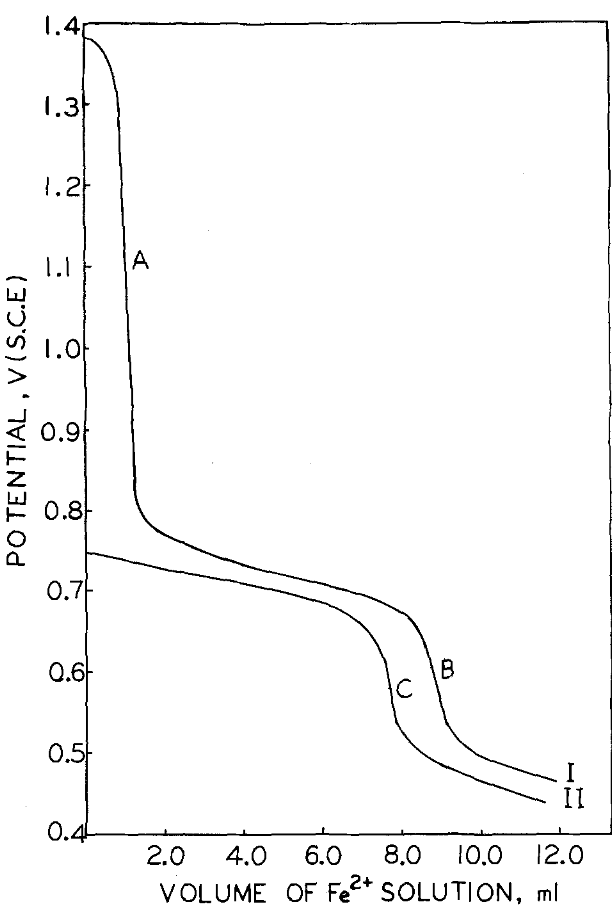

Fig. 3. Variation of potentials during titration of (I) electrolyzed and (II) unelectrolyzed $CoSO_4$-V_2O_5 (1.2 g/liter) solution (3.0 ml) with ferrous sulfate solution (0.0054M). Volume of the solution used for plating = 75 ml, insoluble anode, anode:cathode = 1:4, current density = 5 A/dm^2, temperature = 40°C, pH (initial) = 1.0, plating time = 3.0 hr.

VO^{++}) to VO_2^+ ion would take place. In addition, vanadium ions of a lower oxidation state could interact with Co^{3+} ions.

Figure 3 shows the results of an analysis of the electrolysis products when a cobalt sulfate-V_2O_5 (1.2 g/liter) plating solution is electrolyzed with an insoluble anode. Curves I and II represent the variation of potentials (with respect to saturated calomel electrode) of an electrolyzed and unelectrolyzed solution on titration with ferrous sulfate solution, respectively. The first equivalence point, A (1.67×10^{-3} moles/liter), in curve I corresponds to the reduction of Co^{3+} to Co^{2+} and the second equivalence point, B (1.29×10^{-2} moles/liter), corresponds to the reduction of VO_2^+ to VO^{++}. The equivalence point C (1.28×10^{-2} moles/liter) for the unelectrolyzed solution indicates the reduction of VO_2^+ to VO^{++} only. It is interesting to note that the concentration of VO_2^+ ions in the above plating solution before and after electrolysis changed very little. Similar analyses for various plating solutions were made and the results are summarized in Table I. A close agreement is seen in concentrations of vanadium (represented as VO_2^+ moles/liter) before and after electrolysis, indicating that vanadium is not consumed or codeposited with cobalt during plating.

Table I. Analysis of plating solutions before and after electrolysis*

Run	Before electrolysis VO_2^+ (moles/liter)	After electrolysis VO_2^+ (moles/liter)	After electrolysis Co^{3+} (moles/liter)
1**	1.28×10^{-2}	1.29×10^{-2}	1.67×10^{-3}
2***	2.24×10^{-2}	2.28×10^{-2}	1.26×10^{-3}
3***	3.63×10^{-2}	3.62×10^{-2}	0.74×10^{-3}
4***	4.76×10^{-2}	4.85×10^{-2}	0.59×10^{-3}

* Vanadium concentration is represented as VO_2^+ (moles/liter).
** 3 hr plate, 5A/dm^2, 40°C, volume of plating solution = 75 ml, anode:cathode ratio = 1:4.
*** 3.5 hr plate, 5 A/dm^2, 40°C, volume of plating solution ≈ 150 ml, anode:cathode ratio = 1:1.

Deposits were also analyzed for vanadium using an electron microprobe analyzer (Material Analysis Company). No vanadium was found up to the detection limit (~ 0.05 w/o) of the analyzer.

The effect of the concentration variation of vanadium pentoxide in the plating solution on the formation of Co^{3+} ions and the oxide is shown in Fig. 4. With the addition of vanadium pentoxide, the formation of Co^{3+} ions and the oxide is reduced. For example, in cobalt sulfate solution, after electrolysis with an insoluble anode, the concentration of Co^{3+} ions in solution is 4.03×10^{-3} moles/liter and the concentration of cobalt oxide formed is 0.32 g/liter. In the presence of 2.3 g/liter vanadium pentoxide, the concentration of Co^{3+} ions in solution is reduced to 0.74×10^{-3} moles/liter and the oxide is reduced to 0.025 g/liter. With the addition of 2.8 g/liter or more vanadium pentoxide, no oxide was formed during plating. The effect of electrolysis time on the formation of Co^{3+} ions in different $CoSO_4$-V_2O_5 solutions is shown in Fig. 5. In a pure cobalt sulfate solution, the formation of Co^{3+} ions in solution increases from 1.2 to 5.5×10^{-3} moles/liter over a period of 0.5-5.5 hr and the oxide increases from 0.07 to 0.44 g/liter over the same period. With an addition of 2.3 g/liter vanadium pentoxide, the concentration of Co^{3+} ions is decreased; however, with time there is an increasing trend in the formation of Co^{3+} ions in solution, the concentration increase being 0.56-1.04×10^{-3} moles/liter over a period of 0.5-5.5 hr and the oxide increased from trace amounts to 0.025 g/liter. With 4.3 g/liter vanadium pentoxide in solution, no oxide is formed and a decreasing trend in Co^{3+} ion concentration was observed with an increase in plating time. In fact, when the solution is electrolyzed over

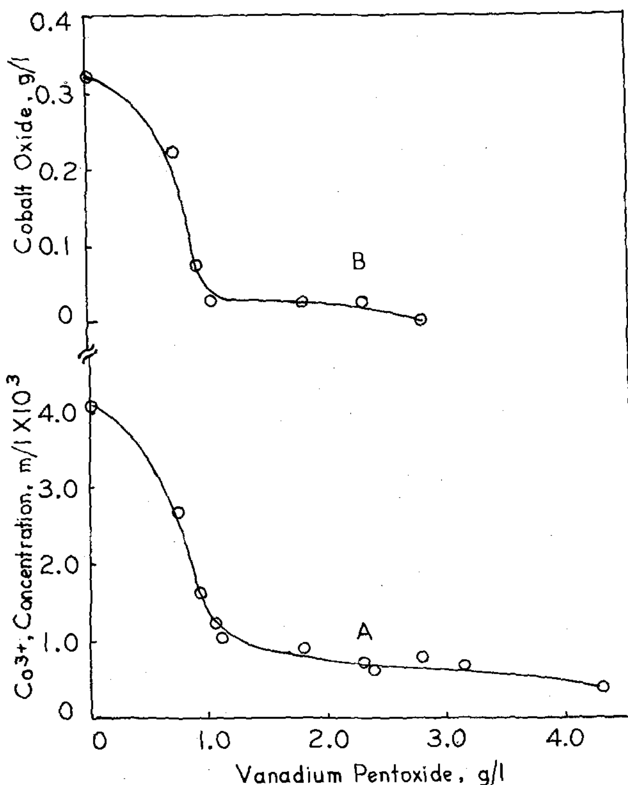

Fig. 4. Effect of V_2O_5 concentration on the formation of (A) Co^{3+} ion in solution and (B) cobalt oxide in solution. Insoluble anode, anode:cathode = 1:4, current density = 5 A/dm^2, temperature = 40°C, pH (initial) = 1.00, plating time = 3.5 hr.

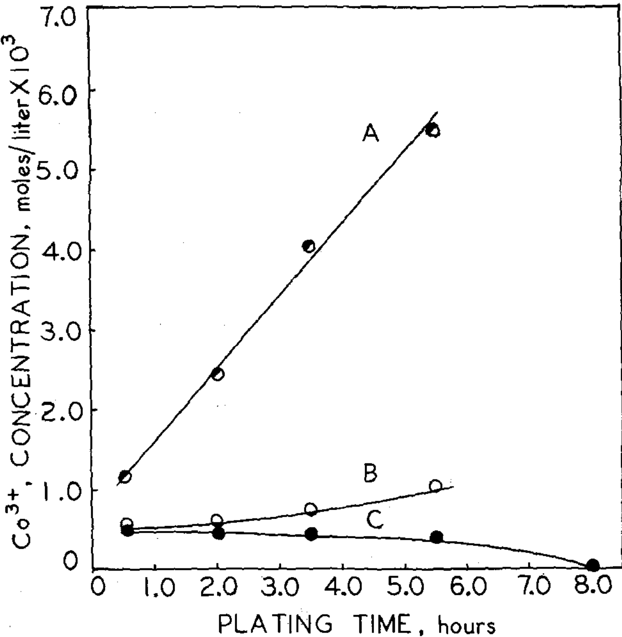

Fig. 5. Variation of Co^{3+} ion concentration with plating time: (A) in $CoSO_4$ solution, (B) in $CoSO_4$-V_2O_5 (2.3 g/liter) solution, (C) in $CoSO_4$-V_2O_5 (4.3 g/liter) solution. Insoluble anode, anode: cathode = 1:4, current density = 5 A/dm^2, temperature = 40°C, pH (initial) = 1.00.

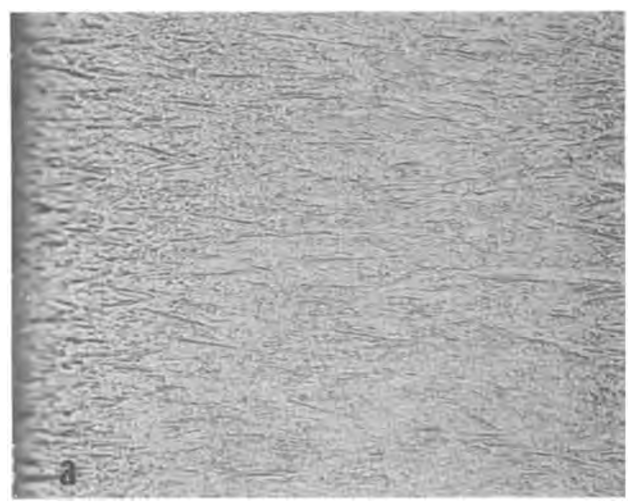
a period of 8 hr, no Co^{3+} ion was found and the solution contained VO^{++} ions (1.9×10^{-3} moles/liter). Another portion (300 ml) of $CoSO_4$-V_2O_5 (4.3 g/liter) solution after 16 hr electrolysis was found to contain VO^{++} (5.6×10^{-3} moles/liter) and no Co^{3+} ions. The results thus suggest that the formation of Co^{3+} ions in the plating solutions is reduced by vanadium ions of a lower oxidation state. The latter are produced at the cathode and are oxidized at the platinum anode.

Mechanical properties of the deposits.—The room temperature yield strength, ultimate tensile strength, and percent elongation of cobalt deposits prepared using both soluble and insoluble anodes are summarized in Table II. With a soluble anode, the pH of the bath increased somewhat (0.88 to 1.10) and with an insoluble anode it decreased (1.04 to 0.90). The relatively low cathode efficiency is due to the lower pH conditions at which these deposits were prepared. With an insoluble anode, the efficiency was only 36% and this is partly due to the decrease in pH during plating. This can be improved and the pH of the bath can be maintained by adopting the method suggested by Sadak *et al.* (9) where a counterplating using a soluble cobalt anode is carried out in the same plating system. The deposits were silvery gray in appearance and relatively ductile. The addition of vanadium pentoxide to the cobalt sulfate bath does not affect the yield strength, ultimate tensile strength, and elongation values of the deposits. The results also show that the yield strength, tensile strength, and elongation for the deposits prepared with an insoluble anode are very similar to those obtained with a soluble anode. An examination of the microstructures (Fig. 6) shows no significant difference between the deposits prepared from cobalt sulfate solutions with and without vanadium pentoxide, respectively. The columnar structure, typical of electrodeposited cobalt, is seen in both cases.



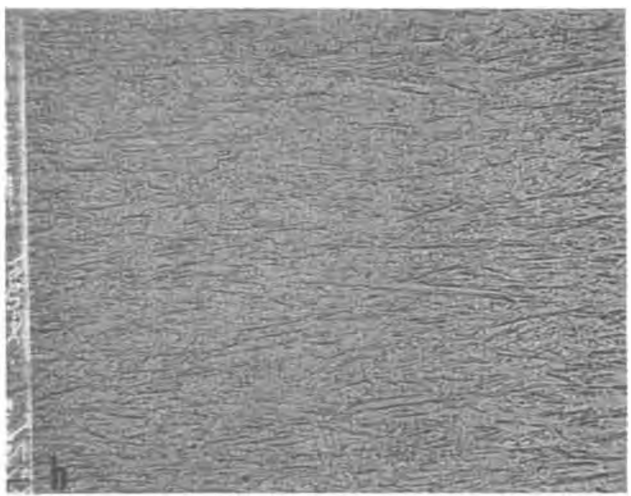


Fig. 6. Microstructures of cobalt deposits prepared from (a) $CoSO_4$-V_2O_5 plating solution, insoluble anode is used and (b) $CoSO_4$ plating solution, soluble anode is used. Plating conditions are reported in Table II. 1000× magnification.

Summary

It has been shown that during plating from a cobalt sulfate solution using an insoluble anode the formation of Co^{3+} ions and cobalt oxide (Co_2O_3) results at the anode. The addition of a sufficient amount of an electrochemically active substance such as vanadium pentoxide to the plating solution has suppressed the formation of Co^{3+} ions and prevented the formation of cobalt oxide at the anode. The electrochemically active substance participates in the electrode reactions both at the cathode and anode but is not consumed or incorporated with the deposit. The mechanical properties of cobalt deposits obtained using an insoluble anode are comparable to those obtained using a soluble anode.

Manuscript submitted April 1, 1976; revised manuscript received May 17, 1976. This was Paper 255 presented at the Las Vegas, Nevada, Meeting of the Society, Oct. 17-22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

ABSTRACT

Shape change, the redistribution of active material over the zinc electrode surface as a result of cell cycling, is hypothesized to be caused by convective flows driven primarily by membrane pumping. A mathematical model is formulated based on the convective flow hypothesis for the zinc-silver oxide secondary cell. The numerical solutions predict redistribution of zinc material over the zinc electrode, fluid flow rates, and variations of current distribution and cell potential with the number of cycles. These calculated results can be compared to experimental results. The results suggest that shape change can be eliminated if the convective flow in the zinc electrode compartment parallel to the electrode surface is stopped.

Zinc electrodes have been used as reducing agents in common primary cells like the Leclanché cell (dry cell) and the alkaline zinc-manganese dioxide cell. They have also been used as negative plates in secondary storage cells such as the zinc-silver oxide cell. The zinc electrode is attractive for use in secondary battery systems because of its low cost, strong reducing potential, and low equivalent weight in comparison with other available negative electrodes. However, secondary cells using zinc negatives have a poor cycle life (100-400 cycles) (1). This is due mainly to the failure of the zinc electrodes (1, 2). If the cycle life of the zinc electrode can be extended, zinc-silver oxide cells would be much more valuable in aerospace and other applications where the high energy density justifies

the costs. Also, an improved zinc electrode might stimulate development of the zinc-nickel oxide cell, which may yield a much lower cost and higher specific energy cell than the popular nickel-cadmium cell.

The failure of the zinc electrodes in zinc-silver oxide cells has been associated with several phenomena. Two causes of failure are migration of colloidal silver from the positive silver electrode to the negative zinc electrode and zinc dendrite growth through the separator causing short-circuiting inside the cell (1). These processes can be controlled successfully by the use of new membrane separator materials (2). It is currently widely believed that a main reason for the failure of zinc electrodes is "shape change." Shape change refers to the redistribution of zinc oxide material over the surface of the zinc electrode. Shape change in the zinc electrode has been demonstrated experimentally; for example, by Lander and Cooper (2), McBreen (3), and Choi *et al.* (4). In their cell designs, zinc oxide material was shown to move from the region near the top toward the center and bottom of the zinc electrode. The accumulation of zinc oxide in one place and depletion in the other is believed to contribute to loss of capacity until the cell potential on discharge falls below acceptable values.

Even though the failure of zinc electrodes due to shape change has been identified, the basic causes of shape change in zinc electrodes have not previously been adequately defined. McBreen (3) has explained shape change in zinc electrodes in terms of nonuniform current distribution. His experimental results demonstrated a correlation between observed shape change in the zinc electrodes and nonuniform current density distribution. However, the contention that shape change is caused by nonuniform current distribution is not proven clearly, and no mechanism for net transport of zinc species is included in the discussion.

An analysis is presented here based on a hypothesis that convective flows driven by membrane separator transport are coupled with changes in the concentration of soluble zinc species to cause the movement of zinc across the electrode.

Hypothesis for the Cause of Shape Change

Several factors contribute to fluid motion within the porous electrodes. In a conventional zinc-silver oxide cell, a membrane[1] between the zinc electrode and the silver electrode separates the cell into two compartments, both of which are filled with concentrated potassium hydroxide solution which is originally saturated with respect to zinc oxide. A volumetric flow across the membrane is directly induced by an electro-osmotic force which arises from the passage of electric current through the membrane. During cycling, a solute concentration difference between the two compartments builds up due to chemical and electrochemical reactions. The resulting osmotic force will also produce a volumetric flow across the membrane. The net flow across the membrane (modified by changes in the porosities of the electrodes due to electrochemical, chemical, and physical phase-change reactions) may be observed as a convective flow in both compartments parallel to the membrane.

The undesirable formation of gas bubbles within the porous electrodes will also influence the fluid motion. Natural convection within porous electrodes is certainly possible (27), but experimental evidence indicates that the direction of the gravitational field does not affect the shape change (2, 4, 26).

The movement of solutes in the direction parallel to the membrane will be determined by the combination of convection, diffusion, and migration transport processes. In this direction, convection is the dominant effect, and migration is assumed to be negligible. As discussed in the preceding paragraphs, the convective flow has a periodic nature due to the cycling process. Simultaneously, the concentration of soluble zinc species varies periodically because the cathodic deposition of zinc depletes the solution and the anodic process temporarily supersaturates the solution before zinc oxide can precipitate. The periodic motion of the fluid, coupled with the periodic concentration of zinc species, will result in a net movement of zinc species parallel to the membrane, in one direction or the other, and extended cycling will eventually produce a significant relocation of zinc. This is zinc shape change.

Let us examine these processes in more detail.

During discharge, as current flows from the zinc electrode to the silver electrode (see Fig. 1), there will be a flow of potassium ions in the same direction through the membrane, since the membrane is a cation exchanger. It is expected that the electro-osmotic force will generate a volumetric flow in the same direction because the cations will tend to entrain water molecules.

At the same time, the KOH concentration will decrease in the zinc electrode compartment and increase in the silver electrode compartment, during discharging, because the anodic process consumes hydroxide, the cathodic process produces hydroxide, and the potassium ions are transported across the cation-exchange membrane. (The use of an anion-exchange membrane would reduce considerably the concentration difference of KOH.) The volumetric flow induced by the osmotic effect due to the KOH concentration difference will be in the same direction as that expected for the electro-osmotic flow, but it will not respond as rapidly to changes in the current because of the time required for the KOH concentration to change.

Also, the concentration of zinc species, assumed to be the zincate ion $Zn(OH)_4^{=}$, will increase in the zinc compartment during discharging due to oxidation and dissolution of zinc. The osmotic flow induced by this concentration change will be in the opposite direction from those enumerated above, but the combination of all the osmotic and electro-osmotic effects is expected to produce a volumetric flow across the membrane from the zinc electrode toward the silver electrode during discharging. The flow would be predominantly in the opposite direction during charging. This means that there will be a downward convective flow in the zinc electrode compartment during discharging (see Fig. 1) and an upward flow during charging.

Now consider the varying zincate concentration and the convective movement of soluble zinc species. During discharging, the solution in the zinc compartment is supersaturated with zincate, and the direction of the volumetric flow is downward. A large amount of zinc is convected downward as soluble zinc species. As the flow is going up in the zinc electrode compartment during charging, the electrolytic solution will be undersaturated with zinc species due to the deposition of

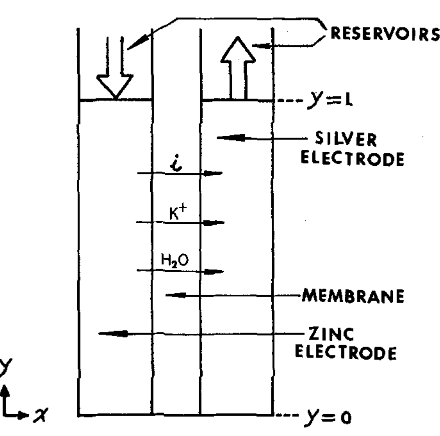

Fig. 1. Schematic cell cross section and flow pattern on discharge

[1] In experimental studies by Lander and Cooper (2) and McBreen (3), RAI-P2291 cation-exchange membranes were used. A similar membrane was used in this study.

zinc. Less zinc moves up on charging than moves down on discharging, and there will be a net movement of zinc downward during a complete cycle. As the cycling process continues, the amount of zinc oxide in the region near the top of the zinc electrode will decrease, and the amount in the region near the center and bottom will increase due to the net transport resulting from low zincate concentration during upflow and high zincate concentration during downflow.

The hypothesis provides a theoretical basis for development of a mathematical model which formulates, with certain approximations, the physical behavior occurring in the cell during cycling into a set of nonlinear, coupled, partial differential equations. These equations are solved by numerical techniques. The primary interest is in shape change in zinc secondary electrodes. A conventional zinc-silver oxide cell is chosen for analysis. As explained above, the convective flow is considered to be the main factor which causes redistribution of zinc oxide material over the zinc electrode. This convective flow is assumed to be driven only by osmotic and electro-osmotic forces, and to a minor extent by changes in the volume fractions of the solids due to chemical reaction. Therefore, shape change in the zinc electrode will be dependent on the resulting hydrodynamic behavior, but not on how the cell is positioned relative to the earth's gravitational field. Figure 1 shows a cross section of the cell. The x direction is parallel to the direction of the electric current, and the y direction is in the direction perpendicular to the electric current. One end of the electrode compartments at $y = 0$ is closed, and the fluxes of species in the y direction are zero there. The other end of the electrodes at $y = L$ is next to the reservoirs which allow fluid to flow into or out of the individual electrode compartments. If the convective flow moves in the positive y direction in the zinc electrode compartment on charge and in the negative y direction on discharge, then according to the hypothesis, the zinc oxide will be expected to move from the region near $y = L$ to the region near $y = 0$.

A Mathematical Model Based on the Convective Flow Hypothesis

Reactions at the electrodes.—The electrochemical reactions which occur at the silver electrode are believed to involve both monovalent and divalent silver oxides. Numerous studies (5-8) have confirmed that monovalent silver oxide forms first on the silver electrode surface in alkaline solution at the beginning of oxidation during charging, and divalent silver oxide forms later. The reverse process occurs during discharge. The process may be summarized as

$$(2Ag + 2\,OH^- \rightleftharpoons Ag_2O + H_2O + 2e)\,\frac{1}{2} \quad [1]$$

$$(Ag_2O + 2\,OH^- \rightleftharpoons 2AgO + H_2O + 2e)\,\frac{1}{2} \quad [2]$$

$$Ag + 2\,OH^- \rightleftharpoons AgO + H_2O + 2e \quad [3]$$

A kinetic mechanism for zinc electrodes in alkaline media has been recently given by Bockris *et al.* (9) and Payne and Bard (10). Evidence shows that the behavior of zinc electrodes in alkaline solution is a dissolution-precipitation process (11, 12). The process occurring in the zinc electrode may be expressed as

$$Zn(OH)_4^{-2} + 2e \rightleftharpoons Zn + 4(OH)^- \quad [4]$$

$$Zn(OH)_4^{-2} \rightleftharpoons ZnO + 2\,OH^- + H_2O \quad [5]$$

Species considered in the electrolytic solutions.—In both the zinc and the silver electrode compartments, the electrolytic solution is initially concentrated KOH solution which is saturated with respect to ZnO. The solution phases contain the species K^+, OH^-, H_2O, and different complex forms of zinc ionic species. Generally, these ionic zinc species include Zn^{+2}, $Zn(OH)^+$, $Zn(OH)_2$, $Zn(OH)_3^-$, and $Zn(OH)_4^{-2}$ which are thermodynamically interrelated by equilibrium constants. Among these zinc ionic species in alkaline solution, the species $Zn(OH)_4^{-2}$ is predominant (13-17). Since charge neutrality must hold in the bulk solution, the concentration of ionic species are not all independent. In the following, K^+ species and zinc ion species are chosen as independent variables. The zinc ionic species are represented by the symbol Zn^{+2}. It is necessary to consider only the three independent fluxes of Zn^{+2}, K^+, and H_2O along with current density in the x direction.

Species transport across the membrane.—If the pressure difference across the membrane is zero, then the fluxes of species Zn^{+2}, K^+, and H_2O across the membrane in the x direction can be written as linear functions of three driving forces: the concentration differences of Zn^{+2} and K^+ across the membrane and the electric current density through the membrane.

For the Zn^{+2} species

$$N_{Zn,x}^m = L_{zz}(c_{Zn}^n - c_{Zn}^p) + L_{zk}(c_K^n - c_K^p) + \frac{t_{Zn}^m i}{2F} \quad [6]$$

For the K^+ species

$$N_{K,x}^m = L_{kk}(c_K^n - c_K^p) + L_{kz}(c_{Zn}^n - c_{Zn}^p) + \frac{t_K^m i}{F} \quad [7]$$

For the H_2O

$$N_{o,x}^m = -L_{oz}(c_{Zn}^n - c_{Zn}^p) - L_{ok}(c_K^n - c_K^p) + \frac{t_o^m i}{F} \quad [8]$$

where $N_{Zn,x}^m$, $N_{K,x}^m$, and $N_{o,x}^m$ represent the fluxes of species Zn^{+2}, K^+, and H_2O, respectively, across the membrane in the x direction, c_{Zn}^p and c_K^p represent the concentrations of Zn^{+2} and K^+ in the silver electrode compartment, respectively, similarly c_{Zn}^n and c_K^n represent the concentrations of Zn^{+2} and K^+ in the zinc electrode compartment. The symbol i represents the current density across the membrane in the x direction.

For the fluxes of species Zn^{+2} and K^+, only the primary concentration driving forces are considered, and the coupling effects are assumed negligible, that is, L_{zk} and L_{kz} are assumed to be zero. Then L_{zz} and L_{kk} can be regarded as equal to the diffusion coefficients of Zn^{+2} and K^+ in the membrane divided by the thickness of the membrane. The symbols t_{Zn}^m and t_K^m represent the transference numbers of Zn^{+2} and K^+ for the membrane, and they are assumed to be constant throughout the membrane. The flux of H_2O is written in terms of osmotic effects and an electro-osmotic effect. Therefore, L_{ok} and L_{oz} are interpreted to be the water transport coefficients across the membrane induced by the concentration differences of species Zn^{+2} and K^+. The symbol t_o^m is a proportionality constant for the water transport induced by the electro-osmotic effect and is called the electro-osmotic coefficient. These transport terms may be concentration dependent, but they are assumed to be constant.

Conservation of species in the porous electrodes.—Inside the porous zinc and silver electrodes, the local transfer current density, species concentration in the solution phase, porosity, conductance of the solid matrix, and the conductivity of the electrolytic solutions may have large ranges of variation. Numerous works have been published during the recent two decades on porous electrodes and their application to batteries. A review of porous electrodes in battery applications has been recently given by Newman and Tiedemann (18). Since the primary interest of this work is to investigate how the zinc oxide redistributes over the zinc electrode in the y direction after a certain number of cycles, it is for simplicity that the local current density, species concentrations, porosity, and conductivity of electrolyte are assumed not to vary in

the x direction inside the porous electrodes. Only the variations in the y direction are considered. This simplification allows the transformation of a two-dimensional problem into a one-dimensional problem which can be solved with much less cost. The transport of species across the membrane from one electrode compartment to the other will be treated as a source term in the species conservation equations in the electrode compartments.

The conservation equation for species in solution within a porous electrode can be written as follows

$$\frac{\partial \epsilon c_i}{\partial t} = -\frac{\partial N_{i,y}}{\partial y} + R_i \quad [9]$$

(Accumulation) = (Net input) + (Source)

where c_i, ϵ, $N_{i,y}$, and R_i represent the concentration of species i, electrode porosity, flux of species i in y direction, and source term of species i respectively. If the dependence of the diffusion coefficient on tortuosity is not considered, then the flux of species i in the y direction can be written in the form

$$N_{i,y} = -D_i\epsilon \frac{\partial c_i}{\partial y} + c_i v_y \quad [10]$$

where D_i is the diffusion coefficient of species i and v_y is the superficial velocity in the y direction. The conservation equations for species Zn^{+2} and K^+ in the electrode compartments can be expressed by substitution of Eq. [10] into Eq. [9]. In the silver electrode compartment

$$\frac{\partial c_{Zn}^p \epsilon^p}{\partial t} = -\frac{\partial}{\partial y}\left(-D_{Zn}^p \epsilon^p \frac{\partial c_{Zn}^p}{\partial y} + c_{Zn}^p v_y^p\right) + R_{Zn}^p \quad [11]$$

$$\frac{\partial c_K^p \epsilon^p}{\partial t} = -\frac{\partial}{\partial y}\left(-D_K^p \epsilon^p \frac{\partial c_K^p}{\partial y} + c_K^p v_y^p\right) + R_K^p \quad [12]$$

In the zinc electrode compartment

$$\frac{\partial c_{Zn}^n \epsilon^n}{\partial t} = -\frac{\partial}{\partial y}\left(-D_{Zn}^n \epsilon^n \frac{\partial c_{Zn}^n}{\partial y} + c_{Zn}^n v_y^n\right) + R_{Zn}^n \quad [13]$$

$$\frac{\partial c_K^n \epsilon^n}{\partial t} = -\frac{\partial}{\partial y}\left(-D_K^n \epsilon^n \frac{\partial c_K^n}{\partial y} + c_K^n v_y^n\right) + R_K^n \quad [14]$$

All the terms have meanings as defined previously. The superscripts p and n designate the quantities in the silver electrode compartment and the zinc electrode compartment, respectively.

Since the K^+ species does not participate in any electrochemical or chemical reactions in both silver and zinc electrode compartments, the source terms of K^+ in both compartments will be equal to the flux of K^+ species across the membrane into the compartments. Then the source terms for K^+ in the silver and the zinc electrode compartments can be expressed as

$$R_K^p = \frac{N_{K,x}^m}{w_p} \quad [15]$$

$$R_K^n = -\frac{N_{K,x}^m}{w_n} \quad [16]$$

where w_p and w_n are the thickness of the silver and the zinc compartments, respectively.

In the zinc electrode compartment, the Zn^{+2} species participates in the electrochemical reaction (oxidation or reduction of Zn) and the phase transformation reaction (dissolution or precipitation of ZnO). Therefore, the source term of Zn^{+2} in the zinc electrode compartment should include all these electrochemical and phase transformation reactions plus the transport of Zn^{+2} species across the membrane into the zinc electrode compartment. It is expressed as

$$R_{Zn}^n = -\frac{N_{Zn,x}^m}{w_n} + \frac{i}{2\mathbf{F}w_n} - ak(c_{Zn}^n - c_{Zn}^{sn}) \quad [17]$$

where the term $i/2\mathbf{F}w_n$ represents the rate of the oxidation (or reduction) reaction of Zn due to the passage of current, $ak(c_{Zn}^n - c_{Zn}^{sn})$ represents the rate of dissolution (or precipitation) reaction determined by the solubility of ZnO in KOH solution, c_{Zn}^s is the saturated concentration of Zn^{+2} species adjacent to the zinc oxide material surface in KOH solution, a is the available surface area for dissolution (or precipitation) of ZnO per unit volume of the electrode compartment, which will be a function of the porous solid matrix structure and the amount of ZnO, and k is the mass transfer coefficient for Zn^{+2} species transfer from the bulk solution to the sites of dissolution or precipitation of ZnO. The magnitude of k is affected by the hydrodynamic behavior occurring in the electrode compartment. It is assumed that the value of k increases with increasing convective flow during ZnO dissolution and decreases with increasing convective flow during ZnO precipitation.[2] The dependence of k on the convective flow is correlated by an empirical exponential term. The product of the two terms a and k can be expressed in an empirical form as follows.

During dissolution of ZnO

$$ak = R_d Q_{ZnO}^{\alpha} e^{\beta_d |v_y^n|} \quad [18]$$

During precipitation of ZnO

$$ak = R_p(1 + \xi Q_{ZnO}^{\alpha}) e^{-\beta_p |v_y^n|} \quad [19]$$

where R_d, R_p, α, ξ, β_d, and β_p are empirical constants, $|v_y^n|$ is the absolute value of the velocity v_y^n, and Q_{ZnO} is the quantity of zinc oxide per unit area.

Equation [18] correlates the rate of dissolution of ZnO into the electrolytic solution with the amount of ZnO in the electrode compartment. As the amount of ZnO in the electrode compartment goes to zero, the dissolution rate of ZnO will go to zero. As the velocity of the convective flow goes to infinity, the rate of dissolution will also go to infinity. Equation [19] correlates the precipitation reaction of ZnO on the solid matrix surface plus the surface of ZnO material in the electrode compartment. As the convective flow goes to zero, the rate of precipitation of ZnO will be equal to the value at a stagnant state.

Similarly, the source term for Zn^{+2} species in the silver electrode compartment can be expressed by summing the net flux of Zn^{+2} species across the membrane and the effect due to precipitation or dissolution of ZnO in the silver electrode as follows

$$R_{Zn}^p = \frac{N_{Zn,x}^m}{w_p} - a^*k^*(c_{Zn}^p - c_{Zn}^{sp}) \quad [20]$$

where the term a^*k^* has the same terms for precipitation and dissolution of ZnO as shown in Eq. [18] and [19]. The empirical constants are specific for the silver electrode compartment.

For dissolution

$$a^*k^* = R_d^p Q_{ZnO^p}^{\alpha^p} e^{\beta_d^p |v_y^p|} \quad [21]$$

For precipitation

$$a^*k^* = R_p^p(1 + \xi^p Q_{ZnO^p}^{\alpha^p}) e^{-\beta_p^p |v_y^p|} \quad [22]$$

In a static solution or in an ideal convective flow (plug flow), the diffusion coefficient of species will be equal to the usual liquid phase diffusion coefficient. But in a more realistic fluid flow behavior in porous media, the diffusion coefficient for species in the solution phase should also include a dispersion contribution due to fingering and backmixing associated with

[2] In retrospect, the reasoning leading to this decreasing mass transfer coefficient on velocity, as manifested by the minus signs in Eq. [19] and [22], is fallacious. The effect on final numerical results is small. The cost of repeating the calculations was too large to justify making the correction.

flow through tortuous pores of varying size and the velocity profiles across the pores. Some correlations of data on dispersion in packed beds have been given recently by Sherwood *et al.* (19). The backmixing dispersion effect in porous electrodes has been discussed by Newman and Tiedemann (18). However, a correlation of data on the dispersion effect has not been obtained directly for porous electrodes. An empirical relationship to account for the dispersion effect in this study is expressed as

$$D_i = D_i^o(1 + \gamma|v_y|) \quad [23]$$

where D_i^o is the effective diffusion coefficient in a static solution within the porous electrode, v_y is the superficial velocity in the y direction, and γ is an empirical constant. As the velocity goes to zero, the dispersion effect will disappear, and the diffusion coefficient D_i becomes equal to D_i^o.

In a dilute electrolytic solution, the solvent concentration can usually be regarded as constant. But in a concentrated electrolytic solution, the solvent concentration will be affected by the change of solute concentration. For simplicity, the solvent (water species) concentration is assumed to be constant. Then the conservation equations for water species in the silver and zinc electrode compartments can be written as follows.

In the silver electrode compartment

$$c_o^p \frac{\partial \epsilon^p}{\partial t} = - c_o^p \frac{\partial v_y^p}{\partial y} + R_{H_2O}^p \quad [24]$$

In the zinc electrode compartment

$$c_o^n \frac{\partial \epsilon^n}{\partial t} = - c_o^n \frac{\partial v_y^n}{\partial y} + R_{H_2O}^n \quad [25]$$

where c_o^p and c_o^n are the water concentrations in the silver and the zinc electrode compartments, and $R_{H_2O}^p$ and $R_{H_2O}^n$ are the source terms for water in the silver and zinc electrode compartments, respectively. By summing the transport of water species across the membrane into the electrode compartment and the effects due to the electrochemical and phase transformation occurring in the electrode compartments, the source terms of water species in the silver and the zinc electrode compartments are expressed as

$$R_{H_2O}^p = \frac{N_{o,x}^m}{w_p} - \frac{i}{2\mathbf{F}w_p} + a^*k^* \ (c_{Zn}^p - c_{Zn}^{sp}) \quad [26]$$

$$R_{H_2O}^n = - \frac{N_{o,x}^m}{w_n} + ak \ (c_{Zn}^n - c_{Zn}^{sn}) \quad [27]$$

where the terms $N_{o,x}^m/w_p$ and $N_{o,x}^m/w_n$ represent the effect due to the transport of water species across the membrane, the term $i/2\mathbf{F}w_p$ represents the effect due to the electrochemical reaction occurring in the silver electrode compartment according to Eq. [3], and the terms $a^*k^* \ (c_{Zn}^p - c_{Zn}^{sp})$ and $ak \ (c_{Zn}^n - c_{Zn}^{sn})$ represent the precipitation (or dissolution) reaction of ZnO in the silver and the zinc electrode compartments, respectively, which are due to the solubility of ZnO in KOH solution represented by Eq. [5].

The conversion of species in the porous electrodes from one solid phase to the other solid phase or from a solid phase to the liquid phase due to phase transition and electrochemical reactions occurring in the porous electrodes may cause changes in the porosities of the electrodes. For example, the transformation of solid silver oxide to solid silver in the silver electrode compartment, deposition of zinc ionic species as metallic zinc, and the dissolution of zinc oxide into the solution or the precipitation of zinc oxides from the solution to the electrode surfaces may change the electrode porosity.[3] Thus, the variations of the porosities with time in the silver electrode compartment and the zinc electrode compartment can be formulated according to Eq. [3], [4], and [5] as follows

$$\frac{\partial \epsilon^p}{\partial t} = (\overline{V}_{AgO} - \overline{V}_{Ag}) \frac{i}{2\mathbf{F}w_p} - \overline{V}_{ZnO} \, a^*k^* \ (c_{Zn}^p - c_{Zn}^{sp}) \quad [28]$$

$$\frac{\partial \epsilon^n}{\partial t} = \frac{\overline{V}_{Zn}}{2\mathbf{F}w_n} i - \overline{V}_{ZnO} \, ak \ (c_{Zn}^n - c_{Zn}^{sn}) \quad [29]$$

where $\overline{V}_{Ag}$, $\overline{V}_{AgO}$, $\overline{V}_{ZnO}$, and $\overline{V}_{Zn}$ are the partial molar volumes of silver, silver oxide, zinc oxide, and zinc. The current density is defined to be positive on discharge and negative on charge. Equation [3] is assumed to be the main reaction in the silver electrode.

Evaluation of the current density across the cell based on Ohm's law.—Assuming the activation overpotential on the electrode surface to be negligible and the cell potential to be governed by the ohmic resistance of the electrolytic solutions in the porous electrodes and membrane, the current density can be written from Ohm's law as

$$i = - \kappa \frac{d\Phi}{dx} \quad [30]$$

where κ is the conductivity of the solution phase, which is a function of the bulk concentration and the porosity of the porous matrix. The over-all ohmic resistance across the cell includes the ohmic resistances of the silver electrode compartment, the membrane, and the zinc electrode compartment. After some algebraic manipulation, and making the approximate but convenient assumption that the transfer current density is constant across the electrodes, Eq. [30] can be rewritten in the form

$$i = - \frac{\Delta\Phi}{\dfrac{w_p}{\kappa_p} + \dfrac{w_n}{\kappa_n} + \displaystyle\int_o^{w_m} \frac{dx}{\kappa_m}} \quad [31]$$

where $\Delta\Phi$ is the total ohmic potential drop across the cell, and κ_p, κ_n, and κ_m are the effective conductivities of the electrolytic solutions in the silver electrode compartment, the zinc electrode compartment, and the membrane, respectively. By regarding the membrane as a porous medium and using a dependence of effective conductivity of solution on porosity suggested by Meredith and Tobias (20), the effective solution conductivities in the silver electrode compartment, the zinc electrode compartment, and the membrane are expressed as

$$\kappa_p = \kappa_p^o \ (\epsilon^p)^{1.5} \quad [32]$$

$$\kappa_n = \kappa_n^o \ (\epsilon^n)^{1.5} \quad [33]$$

$$\kappa_m = \kappa_m^o \ (\epsilon^m)^{1.5} \quad [34]$$

where κ_p^o, κ_n^o, and κ_m^o are the effective bulk solution conductivities in the silver electrode compartment, the zinc electrode compartment, and the membrane, respectively. In the membrane, κ_m^o is dependent on the local solution concentration which is treated as a linear function of the bulk solution concentrations in the silver electrode compartment and the zinc electrode compartment. The integral term in Eq. [31] can be approximated as follows

$$\int_m \frac{dx}{\kappa_m} = \frac{w_m}{M(\epsilon^m)^{1.5}} \sum_i^M \frac{1}{\kappa_{m,i}^o} \quad [35]$$

where w_m is the thickness of the membrane, M is the number of elements into which the membrane is theoretically sectioned, ϵ^m is the membrane porosity, a constant, and $\kappa_{m,i}^o$ is the local solution conductivity of the KOH solution in the ith element of the membrane assuming a linear concentration profile. Since the presence of zinc ions in KOH solution has been found not

[3] The treatment of such porosity changes in porous-electrode modeling occurs first in the work of Alkire *et al.* (28-31). It has subsequently been discussed by Dunning *et al.* (32, 33), Simonsson (34, 35), Micka and Rousar (36), and by Gidaspow and Baker (37, 38).

to affect the conductivity appreciably (21), the conductivity of a pure KOH solution is employed here.

The ohmic potential drop in the collector screens in the y direction has been neglected. The system is designed so that the current density differs from one end of the electrodes to the other by only a few percent due to this effect. The nature of this effect does not change with cycling, and it has no major role in the shape-change process. The integration of current density across the electrode superficial area will be equal to the cell current

$$l \int_0^L i \, dy = I \qquad [36]$$

where l is the width of the electrode, L is the length of the electrode, and I is the cell current. The total cell current is given as part of the problem statement.

Current density distribution when limited by zincate depletion.—As zinc oxide becomes redistributed, there eventually arise regions in which the zincate solution concentration begins to drop during charging due to insufficient solid zinc oxide being available to dissolve. These regions which are depleted in zinc oxide cannot accept the current density evaluated by Ohm's law alone. The current density in these regions becomes limited by the rate of supply of zincate to the reacting surfaces

$$i = \left\{ v_y{}^n \frac{\partial c_{Zn}{}^n}{\partial y} - \frac{\partial}{\partial y}\left(D_{Zn}{}^n \epsilon^n \frac{\partial c_{Zn}{}^n}{\partial y}\right) - \frac{L_{zz}}{w_n} c_{Zn}{}^p - ak\, c_{Zn}{}^{sn} \right\} \frac{w_n \mathbf{F}}{(0.5 - t_{Zn}{}^m)} \qquad [37]$$

Initial and boundary conditions.—Equations [11], [12], [13], [14], [24], [25], [28], [29], and [31] or [37] form a set of nonlinear, coupled differential equations with nine unknowns $c_{Zn}{}^p$, $c_{Zn}{}^n$, $c_K{}^p$, $c_K{}^n$, $v_y{}^n$, $v_y{}^p$, ϵ^n, ϵ^p, and i. These nine variables are functions of time t and position y. Equations [11] through [14] describe the concentrations of the solutes in the two electrode compartments while Eq. [24] and [25] relate how the velocity v_y changes with distance y, on the basis of material balances on the solvent. Equations [28] and [29] formulate the porosity variations of the positive and negative electrodes due to changes in the solid phases during cell operation. The last equation ([31] or [37]) is a description of the current density over the electrode.

The equations can be solved numerically with sufficient initial and boundary conditions. If the solutions can be obtained, then the distribution of ZnO material over the zinc electrode in the y direction may be calculated as

$$Q_{ZnO} = \frac{(1 - \epsilon^n) w_n - Q_{Zn} \overline{V}_{Zn} - \theta_B}{\overline{V}_{ZnO}} \qquad [38]$$

where Q_{ZnO} is the amount of zinc oxide per unit area of the zinc electrode and Q_{Zn} is the amount of metallic zinc per unit area of the zinc electrode

$$Q_{Zn} = \int_0^t \frac{i}{2\mathbf{F}} dt \qquad [39]$$

and θ_B is a constant term which corrects for the amount of inert material[4] in the zinc electrode.

Initially, before passing any current across the cell, the solution concentrations of species in both the silver and the zinc electrode compartments will be the same, the porosities of the silver electrode compartment and the zinc electrode compartment will be equal to their initial values, and both electrode compartments will be in a static situation. Immediately after the current is turned on, the flows begin and the initial conditions for time at zero plus are as follows

[4] The inert material includes expanded silver grid, Teflon binder, and mercuric oxide.

$t = 0+$, all y

$$I = I^o$$
$$c_i{}^p = c_i{}^n = c_{i,o}$$
$$\epsilon^p = \epsilon_o{}^p$$
$$\epsilon^n = \epsilon_o{}^n \qquad [40]$$

At the boundary y = 0 in both electrode compartments, the fluxes of species in the y direction are zero. Then the boundary conditions at y = 0 can be written as follows

y = 0

$$\frac{\partial c_i{}^p}{\partial y} = 0$$
$$\frac{\partial c_i{}^n}{\partial y} = 0$$
$$v_y{}^n = 0$$
$$v_y{}^p = 0 \qquad [41]$$

The subscript i implies either Zn^{+2} or K^+. At the other boundary, y = L, in both electrode compartments, solution may flow into or out of the electrode compartments by utilizing the reservoirs. The direction of flow changes during cycling. If it is assumed that the electrolytic solutions in the reservoirs are completely mixed whenever the fluids are flowing into or out of them, the changes of amount of species with time in the reservoirs will be equal to the fluxes of species across the boundary at y = L in both electrode compartments. Therefore, the boundary conditions at y = L are written as follows

y = L, in the silver electrode compartment

$$\frac{\partial c_i{}^p V_p}{\partial t} = N_{i,y}{}^p w_p l \qquad [42]$$

and in the zinc electrode compartment

$$\frac{\partial c_i{}^n V_n}{\partial t} = N_{i,y}{}^n w_n l \qquad [43]$$

where V_p and V_n are the volumes of the reservoirs next to the silver electrode compartment and the zinc electrode compartment, respectively. The change of volumes of reservoirs with time are expressed as

$$\frac{\partial V_p}{\partial t} = v_y{}^p w_p l \qquad [44]$$

$$\frac{\partial V_n}{\partial t} = v_y{}^n w_n l \qquad [45]$$

where l is the width of the electrode.

The computation procedure.—There are nine principal equations (Eq. [11], [12], [13], [14], [24], [25], [28] [29], and [31] or [37]) to solve for the mathematical model subject to the initial conditions (Eq. [40]) and the boundary conditions (Eq. [41], [42], and [43]). The numerical solutions for the set of equations were carried out on an IBM digital computer 360/91 by use of a finite-difference numerical technique. The Crank-Nicolson implicit method (22) was used for Eq. [11], [12], [13], and [14]. Backward difference expressions were employed for Eq. [24] and [25]. Accuracy to order h^2 was maintained by averaging quantities, other than derivatives with respect to y, between mesh points j and j-1. The time derivatives in Eq. [28] and [29] were expressed by a backward difference in Δt, and the other terms were averaged between the values of the previous and the present time steps. The accuracy of the numerical solutions was of the order h^2 and $(\Delta t)^2$, where h and Δt are the grid sizes of distance and time. The equations were linearized about trial solutions and set in finite-difference forms. The resulting matrix was solved by use of the numerical method described by Newman (23-25). The convergence criterion was that the error of

two successive solutions for all the variables at all the mesh points be less than 0.001%. The details of the numerical calculation and procedure have been described by Choi (26). The values of the parameters for numerical calculations are summarized in the Appendix along with a table of the times for charging and discharging.

Results

The hydrodynamic behavior occurring in the cell compartments during cell cycling is predicted by the model. The convective flow moves upward into the reservoir in the positive y direction in the zinc electrode compartment on charging and downward in the negative y direction on discharging. Since the convective flow is the main cause leading to the zinc material redistribution over the zinc electrode as a result of cycling, a comparison of the zinc movement through the solution phase upward on charging and downward on discharging gives a qualitative measure of how fast the zinc material redistributes over the zinc electrode. Numerical solutions for zinc movement through the solution midway along the zinc electrode for cycles 2, 5, and 8 are shown in Fig. 2, 3, and 4. These results (Fig. 2-4) indicate that the net movement of zinc material is from the upper region of the zinc electrode to the lower region of the zinc electrode as a result of cycling, using the midpoint of the electrode as reference. The net amount of zinc material moving per cycle down through the midpoint of the zinc electrode is initially about 0.21% of the total amount of zinc material in the electrode. It increased to 0.24% for cycle 5, and it remained almost constant (0.24%) for cycle 8. Figure 5 shows the redistribution of zinc material over the zinc electrode after 10, 20, 30, and 35 cycles due to the gradual downward movement of zinc material from the top to the bottom of the zinc electrode.

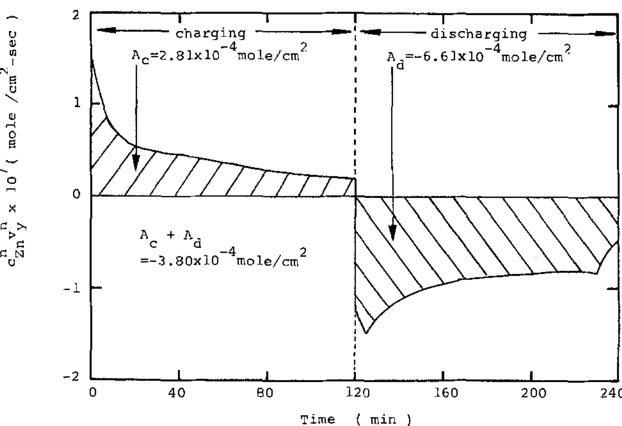

Fig. 2. Zinc movement midway along the zinc electrode during charging and discharging of cycle 2.

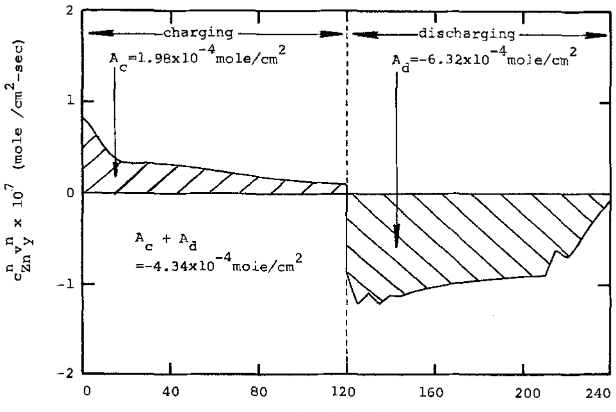

Fig. 3. Zinc movement midway along the zinc electrode during charging and discharging of cycle 5.

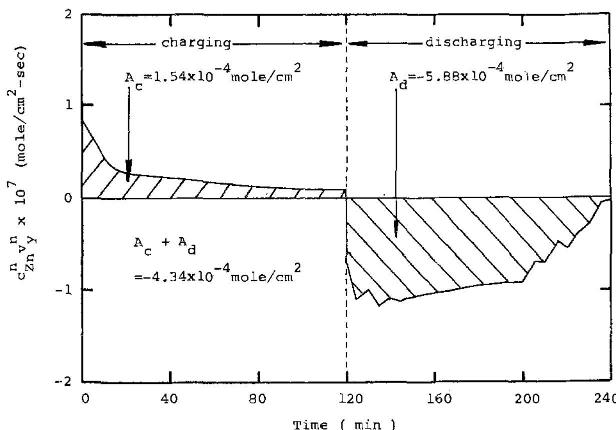

Fig. 4. Zinc movement midway along the zinc electrode during charging and discharging of cycle 8.

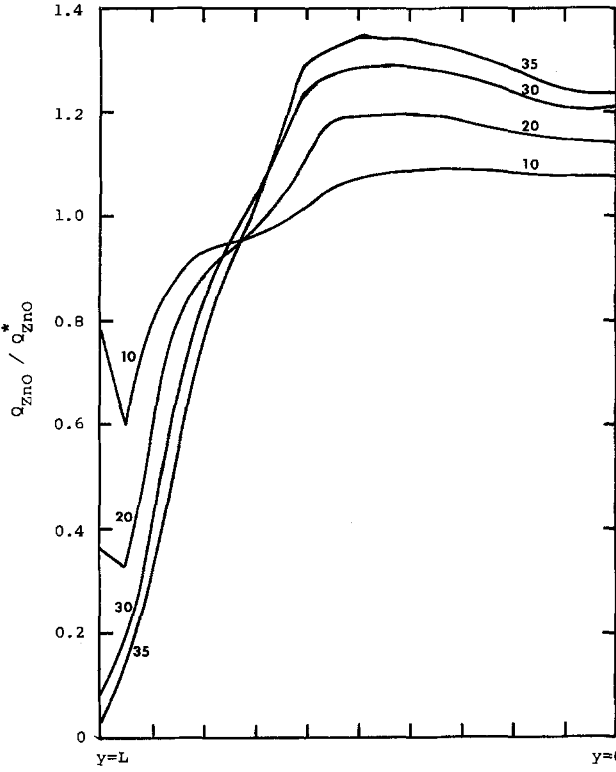

Fig. 5. Distribution of zinc material over the zinc electrode after 10, 20, 30, and 35 cycles. Q_{ZnO}^* is the quantity of ZnO initially present per unit area of the electrode.

The species concentrations in the electrode compartments also varied in the y direction due to the convective flow. Figures 6 and 7 show the variations of K^+ and Zn^{+2} species concentrations at the end of discharge with number of cycles at three different locations of the zinc electrode. After cycles 8, 15, 22, and 28 the cell was allowed to stand for a long period of time until the species concentrations recovered to their initial values. Otherwise the cell was continuously cycled, while allowing only a 3 min rest period between successive half-cycles. These results show that there are large variations of species concentration in the y direction in the zinc electrode. The species concentrations near the bottom of the zinc electrode decreased with the number of cycles. The changes of species concentrations in the y direction and the changes of the porosity of the zinc electrode due to the redistribution of zinc material continuously affect the cell performance as cycling proceeds. Figure 8 shows the variation of cell performance in terms of the change in cell potential with the number of cycles. In

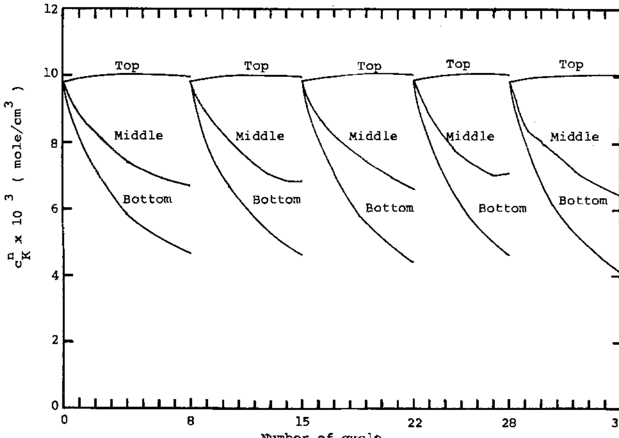

Fig. 6. Concentration profiles of KOH at the top, middle, and bottom of the zinc electrode as a function of the number of cycles. The values correspond to the end of the discharge half-cycle.

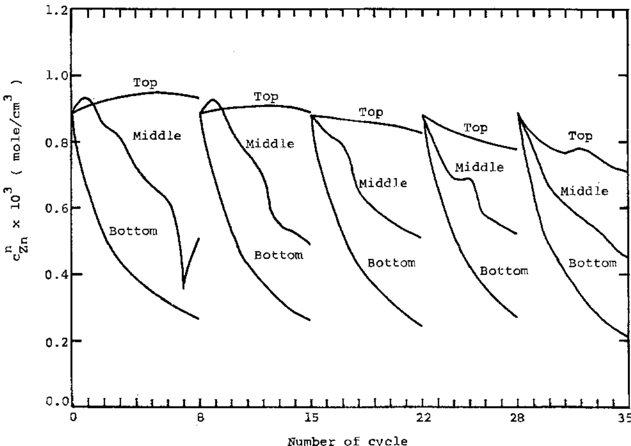

Fig. 7. Concentration profiles of dissolved zincate at the top, middle, and bottom of the zinc electrode as a function of the number of cycles The values correspond to the end of the discharge half-cycle.

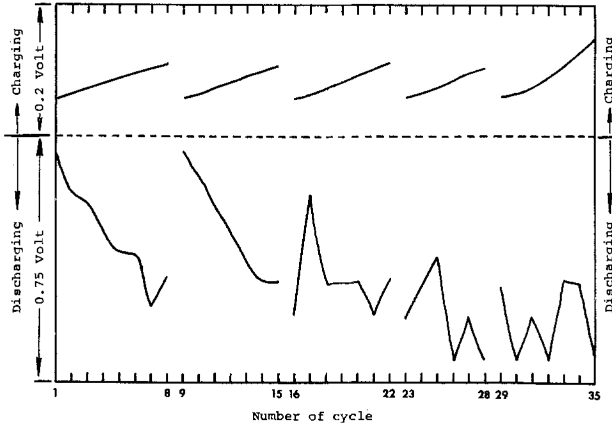

Fig. 8. Variation of cell potential at the end of charge and discharge as a function of the number of cycles

Fig. 8, it is shown that from cycles 1 through 8, the cell potential increases with the number of cycles on charging and decreases rapidly at the end of discharging.

If the cell is allowed to stand for a long period until the concentrations of species recover to their initial values, for example after cycle 8, the cell performance in cycle 9 behaves similarly to cycle 1. As cycling continues from cycle 9 through 15, the cell behavior is very similar to that for cycle 1 through 8 (Fig. 8). However, closer comparison of the cell behavior for cycles 1 through 8 and for cycles 9 to 15 indicates that the cell performance has deteriorated since now a rest period is needed after seven cycles instead of eight. The cell potential at the end of charging and at the end of discharging of cycle 15 is the same as for cycle 8 (Fig. 8). Comparison of the continuous cycling processes for cycles 16 through 22, 23 through 28, and 29 through 35 also shows a steady decrease in cell potential at the end of discharging.

The change of cell performance with the number of cycles may also be reflected by the change in the distribution of metallic zinc and the current density distribution over the zinc electrode as a function of the number of cycles. Figures 9 and 10 show how the metallic zinc distribution varies with number of cycles at the end of charging and discharging. The area under the various curves is not constant because the amount of overcharging varied slightly from cycle to cycle. Zinc does not deposit in as great a quantity near $y = 0$ compared to $y = L/2$ during charging because water is pumped across the membrane, reducing the KOH concentration, increasing the electrical resistance, and decreasing the local current density. As the electrolytic solution flows up in the y direction, KOH is continually added to the solution, the electrical resistance decreases, current density increases, and the amount of zinc deposited increases. At 25°C, the electrical conductivity of KOH goes through a maximum at about 7.3*M*. Above 10*M* the conductivity falls rapidly with increasing concentration. Thus, near $y = L$ the KOH concentration gets high enough during charging that it exceeds the conductivity maximum, the electrical resistance increases, current density decreases, and the amount of zinc deposited becomes less than near $y = L/2$ as is shown in Fig. 9.

Figure 11 shows the variation of current distribution over the zinc electrode at the end of discharging with the number of cycles. These results show that metallic zinc distribution over the zinc electrode at the end of charging becomes more nonuniform as the number of cycles is increased (Fig. 9) which in turn affects the cell performance on discharging. At the end of discharging, Fig. 10 shows that there is no metallic zinc left near the regions close to the top and the bottom of the zinc electrode. Figure 10 also shows that as cycling continues, the area of the zinc electrode where there

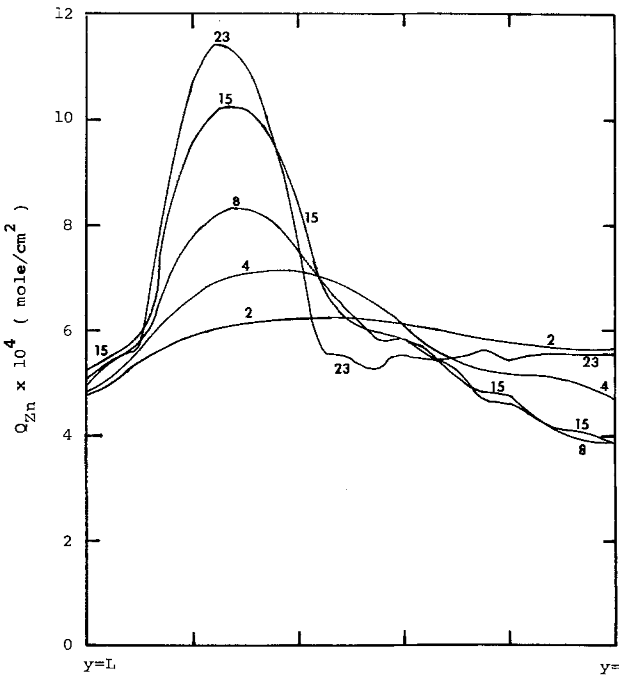

Fig. 9. Distribution of metallic zinc over the zinc electrode at the end of charging for cycles 2, 4, 8, 15, and 23.

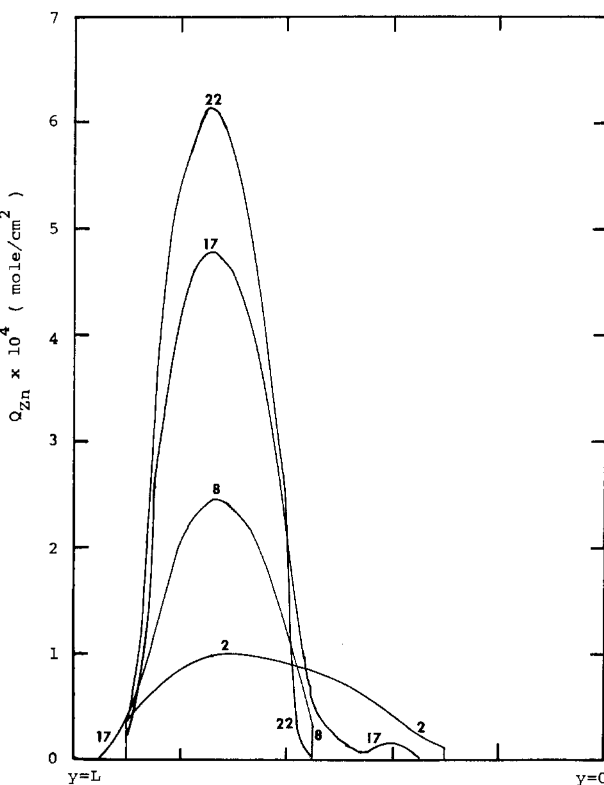

Fig. 10. Distribution of metallic zinc over the zinc electrode at the end of discharge of cycles 2, 8, 17, and 22.

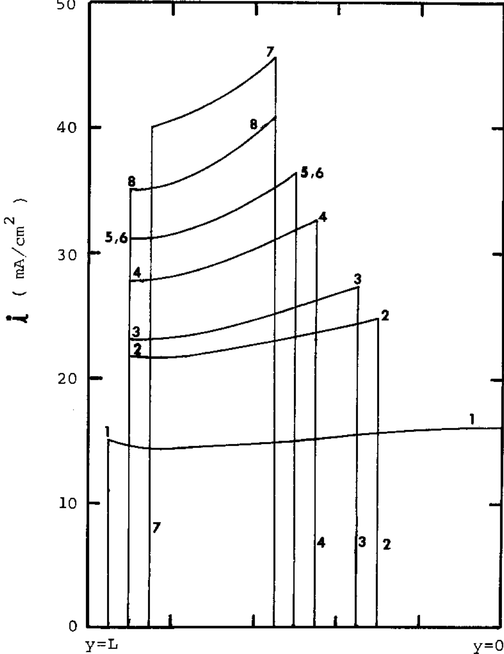

Fig. 11. Current distribution over the zinc electrode at the end of the discharge for cycles 1 to 8.

is metallic zinc left is getting smaller and more concentrated over a small area near the reservoir in the zinc electrode. This behavior can also be reflected by the current distribution over the zinc electrode at the end of discharging (Fig. 11). Figure 11 shows that at the end of discharging, most of the current is concentrated in a small area near the upper center portion of the electrode. This effective area becomes smaller with the number of cycles.

Discussion

Movement of zinc.—The movement of zinc material at the midpoint of the cell during cycles 2, 5, and 8, reported in Fig. 2-4, is from the upper half of the zinc electrode to the lower half. This occurs because the convective flow of solution moving upward in the zinc electrode on charging is undersaturated with zincate because of deposition of zinc, and, as the convective flow of solution moves down in the zinc electrode on discharging, the solution in the zinc electrode is supersaturated with zincate species because of the dissolution of zinc. The amount of zinc material being carried upward in the zinc electrode on charging is less than the amount of zinc material being carried down on discharging because of the difference in zincate concentrations on charging and on discharging. This causes a net amount of zinc material to move downward from the upper region to the lower region in the zinc electrode for each cycle.

The data shown in Fig. 2 and 4 provide a measure of the percentage of the total amount of zinc material moving downward for each cycle. The rate of redistribution of zinc material over the zinc electrode may be estimated by comparison of these figures. Based on these results it can be projected that all of the zinc material in the top half of the cell will be transported to the bottom half after 208 cycles, the maximum possible cycles will, therefore, be less than 208 cycles for the cell being modeled.

Because of the gradual movement of zinc material from the top to the bottom in the zinc electrode, the zinc material near the center and bottom of the zinc electrode increases as cycling proceeds, see Fig. 5. The curves in Fig. 5 also indicate that the location of the maximum amount of zinc material gradually shifts to the center from the lower part of the zinc electrode. This is due to interrelationships between the variation of species concentration (KOH and zincate), convective flow behavior, and the current distribution.

During discharging, when the convective flow is in the downward direction in the zinc electrode, the rate of downward movement of zinc material at the midpoint of the cell slows near the end of the discharge cycle, see Fig. 2-4. At the same time, most of the cell current becomes concentrated near the center of the zinc electrode (Fig. 11) due to zinc metal depletion at the ends. This reduced current near $y = 0$ is one cause of the reduced downward flow rate of solution. The higher current density near $y = L/2$ causes a rapid increase in supersaturation of zinc species there. In addition, the KOH concentration near the middle of the zinc electrode becomes smaller (Fig. 6), decreasing the solubility of zinc oxide. The decreased flushing action of the convection, the increase in local zinc species concentration, and the decreased zinc oxide solubility all combine to increase the rate of zinc oxide precipitation in the upper middle portion of the zinc electrode near the end of a discharge period. As cycling proceeds, these effects are cumulative, and the zinc oxide collects more and more toward the lower middle portion of the zinc electrode.

As the zinc material near the top region of the zinc electrode moves down to the center and bottom of the zinc electrode, the zinc material right on the top boundary of the zinc electrode ($y = L$) does not decrease as rapidly as the region next to it during the first 10 to 20 cycles because there is a large reservoir next to it. The existence of the reservoir, initially assumed to be saturated with zincate, provides a source for zinc and slows down the decrease of zincate concentration at the boundary, which in turn slows down the dissolution of zinc oxide at the boundary. But as cycling proceeds, the zincate concentration of the reservoir in the zinc electrode compartment becomes smaller, and the dissolution rate of the zinc oxide is no longer retarded. The amount of zinc oxide material at the boundary ($y = L$) then shifts down to the minimum (see curve for 30 cycles, Fig. 5).

Since the zinc material movement is due to the convective flow in the zinc electrode, the shape change

behavior may be slowed if the convective flow in the zinc electrode is made smaller. If a neutral membrane (which has negligible electro-osmotic effects and smaller osmotic effects) is used as the separator, shape change behavior in the zinc electrode should not be as severe. It appears possible to eliminate shape change in zinc electrodes if the convective flow in the zinc electrode can be stopped. However there are beneficial effects of the convective flow which would also be eliminated. Some of these tradeoffs are discussed briefly in a later paper (4).

Movement of KOH.—As a result of the convective flow and cell reaction, there is a wide range of KOH concentration in the y direction in the cell. The variation of KOH in the y direction in the zinc electrode with number of cycles is shown in Fig. 6. The variation of KOH concentration directly and indirectly affects the cell performance and the redistribution of the zinc material over the zinc electrode during cycling. As the concentration of KOH is changing in the electrode, the conductivities of the electrolytic solution and the membrane are also changing. This, in turn, affects the current distribution over the zinc electrode. Also, a change of KOH concentration in the zinc electrode causes a change in the solubility of ZnO in KOH solution so that the rate of dissolution and precipitation of ZnO also changes. These interrelated mechanisms may be seen from the variations of KOH concentration (Fig. 6), variation of cell potentials (Fig. 8), distribution of metallic zinc (Fig. 9 and 10), and distribution of current (Fig. 11) with the number of cycles. They are discussed in the following section.

Cell performance.—Generally, the performance of a battery is evaluated from the current-potential behavior on charging and on discharging, the length of charging period, the length of discharging period under a certain load, and variations with number of cycles. A reliable cell should have a long cell cycle life. Under a constant load or a constant cell current, it should be possible to cycle a cell many times without causing a significant increase of the cell potential on charging or a significant decrease of the cell potential on discharging while the duration of charging and of discharging is held constant. The numerical solutions in this study indicate that the performance of the Zn-AgO cell varies with number of cycles because of variations in species concentration in the cell, redistribution of zinc material over the zinc electrode, and variations in the current distribution over the zinc electrode. These interrelated mechanisms may be examined by comparing operation of a cell with relatively uniform zinc distribution to that after the zinc distribution becomes nonuniform.

Before shape change in the zinc electrode became severe, the cell performance was affected by the gradual decrease of species concentrations near the center and bottom of the electrode (Fig. 6 and 7). In the first continuous cycling process (cycles 1 through 8), the cell potential on charging was increasing with number of cycles (Fig. 8). This was due to the gradually created nonuniform distribution of KOH concentration in the cell, which caused the effective cell resistance to increase with the number of cycles. The variation of KOH concentration within the cell also caused a variation of current density over the zinc electrode on charging which was manifested by the metallic zinc distribution after charge for cycles 2, 4, and 8 (Fig. 9). These results indicate that during charging the current density became larger near the center and smaller near the bottom of the electrode. The situation became more pronounced as the number of cycles was increased (compare cycles 2, 4, and 8 in Fig. 9). This decrease in current density was apparently due to the continuous decrease in KOH concentration near the bottom.

Because of the nonuniform distribution of metallic zinc over the zinc electrode after charging and during discharging, part of the electrode area became inactive before the completion of a constant time period of discharging due to depletion of metallic zinc in those areas. Therefore, the cell potential decreased during the rest of the discharging period because most of the cell current was concentrated in a small area, thereby causing an increase in the apparent cell resistance (see Fig. 8). The current distribution and metallic zinc distribution over the zinc electrode at the end of discharge (Fig. 10 and 11) support this hypothesis. The condition became more severe as cycling continued. The potential drop at the end of the discharge portion of the 8th cycle was smaller than that of cycle 7 (see Fig. 8) because the current distribution at the end of discharging during cycle 8 was more uniform than that at the end of cycle 7 (Fig. 11). As cycling continued (from cycle 1 through 8), the numerical solutions indicated that the region near the bottom could not maintain the initial capacity on charging due to the gradual decrease (Fig. 6 and 7) in available zincate in the solution, which was due to reduced solubility of zinc oxide caused by the decreasing KOH concentration and convective removal of zincate.

With only a 3 min rest between half-cycles, the numerical procedures did not allow the cycling process to continue after cycle 8. Allowing the cell to rest for a longer period, for example, until the species concentrations recovered to their initial values, did allow cycling to go on. From cycles 9 through 15, the cell performance was very similar to cycles 1 through 8. After the 15th cycle, the cell was refreshed again by allowing solution concentrations to return to initial values. Comparison of cycles 1 through 8 with cycles 9 through 15 indicates that the cell performance was decreased as the number of cycles increased because within the first cycling period (cycles 1 through 8) 8 continuous cycles were completed before refreshing was necessary, but only 7 continuous cycles were completed for the second cycling period (cycles 9 through 15).

As the loss of zinc oxide material from the region near the top of the zinc electrode become severe, after about 25 cycles, the numerical solution showed that the cause of the failure of the zinc electrode was due to the loss of zinc oxide material near the top of the zinc electrode. In the 28th cycle after 115 min of charging, the numerical solution indicated that the zincate concentration in the zinc electrode near the reservoir became completely depleted due to previous loss of zinc oxide in that region (Fig. 5). The cell was refreshed (all concentrations set at their initial values) and operation continued, as before, for three more cycles of 120 min charging and 120 min discharging with no additional zincate depletion at any point on the zinc electrode.

In the 32nd cycle, after 105 min of charging, the zinc electrode again became depleted of zincate in the region next to the zinc electrode reservoir. In later cycles, zincate depletion began as follows: after 97 min of charging in the 33rd cycle, after 85 min in the 34th cycle, and after 73 min in the 35th cycle. After zincate depletion began, continued charging (in order to maintain a constant charging time at the 1A rate for cycles 32, 33, 34, and 35) caused a significant rise in cell potential at and near the end of charging as shown in Fig. 8. In a real cell, this increased potential would be expected eventually to lead to an increase in hydrogen gas evolution at the zinc electrode (not accounted for in the theoretical model). Practically speaking, it would finally be impossible to continue the 2 hr charging period without reducing the charging current. The model indicates that this situation would become worse if cycling proceeded. A very uneven metallic zinc distribution over the zinc electrode would also result, causing a premature decrease in the cell potential dur-

ing discharge. Eventually, these combined effects would lead to unacceptable cell performance, and the cell would fail.

The region next to the reservoir in the zinc electrode would lose all of the zinc oxide material that was originally there if the cycling process proceeded far enough, as one can infer from the trend of shape change behavior which occurred in the zinc electrode as a result of cycling (see Fig. 5). When that occurs, the region next to the reservoir in the zinc electrode would lose all charge storage capacity. Then the current densities over that region would go to zero during continued cycling. Zero current densities over the region on the top of the zinc electrode have been observed experimentally by McBreen (3) in the later stage of cycling.

ABSTRACT

Experimental data on zinc-silver oxide secondary cells were used to evaluate the convective flow hypothesis on the cause of shape change of zinc electrodes. A cell with flooded, vented electrodes designed to allow "normal" convective flow was studied. Zinc electrodes cycled in this cell showed extensive material redistribution in accord with predictions based on the hypothesis. Measured volume average fluid flow rates for this cell were also in agreement with predicted values. Zinc electrodes cycled in a second cell, designed to minimize convective flow in the zinc electrode compartment, showed virtually no active material redistribution.

Shape change of the zinc electrode is commonly accepted as a primary limiting factor in the life of zinc-silver oxide secondary cells which utilize grafted polyethylene films as separator materials. The phenomenon develops progressively during cell cycling and involves gross redistribution and densification of active material over the surface of the electrode and loss of cell capacity (1). Suggested causes of and methods for alleviation of shape change have been discussed by Oswin and Blurton (2) and by Dalin (3). Lander and Cooper provide a series of photographs which illustrate the progressive development of shape change in their report on active material migration in zinc electrodes (4). McBreen has summarized correlations between shape change and operating and construction parameters of cells and has published extensive data on the distribution of current and potential over the surface of a sectioned zinc electrode during cycling (5). He has offered a theory of shape change based on nonuniform current distribution as a cause.

Recently, a model has been developed for the zinc-silver oxide cell based on the hypothesis that the principal cause of active material redistribution over the zinc electrode is zincate concentration changes coupled with convective flow, parallel to the apparent electrode surface, driven primarily by membrane pumping effects (6, 7). When flow is toward the vent or reservoir location, the electrolytic solution within the porous zinc electrode is undersaturated with zincate. When flow is away from the vent location, the electrolytic solution is supersaturated with zincate. The net effect is a pumping of zinc away from the vent toward the center of the electrode. The model has been used to predict a number of measurable physical quantities as functions of time, including volume average fluid flow rates in the cell and zinc oxide distribution over the zinc electrode. The model has also provided a basis for the discussion of how changes in these and other quantities affect cell performance. The results suggest that material redistribution can be controlled by controlling convective flow in the zinc electrode compartment.

Experiments to test the validity of the basic hypothesis as well as predictions based on the model have been carried out. Fluid flow rates were measured in a flooded, vented zinc-silver oxide cell with "normal" convection.[2] These rates are compared with those predicted from the model. The discharged zinc electrodes from these experiments were sectioned and analyzed, and the ZnO distributions are compared to that on unused zinc electrodes to determine the extent of ZnO redistribution as a result of cell cycling. The observed redistribution of material is also compared with predictions based on the model. In a second cell, flooded, nonvented zinc electrodes have been cycled under conditions intended to minimize convective flow. Discharged electrodes from this cell have also been sectioned and analyzed. ZnO distributions are compared both with that on unused electrodes and those on electrodes cycled in the cell with normal convective flow. The variation of pressure in the zinc electrode compartment as a function of time has also been measured in a modified version of the second cell.

Equipment and Procedures

Electrical equipment.—All cell cycling experiments were carried out at constant current. Power sources were commercially available galvanostats. Potential differences across the cell terminals were recorded continuously to ±0.025V with a recording voltmeter. A second recording voltmeter was used in conjunction with a power resistor in series with the cell to monitor cell current to ±25 mA. A Flexopulse HG 108A6, repeat cycle timer[3] was used as a reversing switch which allowed continuous variation in cell charge and discharge times. The switch also allowed for brief intervals of a few minutes duration with no cell current between half-cycles.

Signal output from the pressure transducer was measured to ±0.01 mV with a Hewlett Packard, Model 3440 A, digital voltmeter with digital print out. Sensitivity of the transducer was determined to be 3.6 mV/bar.

Electrodes.—All electrodes used in this work were furnished by AFAPL (Air Force Aero Propulsion

[2] Convection similar to that in commercial cells.
[3] Eagle Signal, 736 Federal Street, Davenport, Iowa 52803.

Laboratory, Wright Patterson Air Force Base, Ohio). The zinc electrodes came in the discharged state wrapped in Viskon (cellulose rayon) paper and consisted of pressed, blended ZnO, HgO, and Teflon binder on expanded silver screen (3.23×10^{-2}g of Ag/cm^2). These electrodes were prepared according to the procedure described by Keralla (8). They were 10.3 cm long, 6.4 cm wide, and 0.2 cm thick. Different batches of electrodes were found to vary slightly in composition, and different electrodes with the same batch differed in total weight by as much as 8%. During the analysis of both used and unused electrodes, a layered structure in the active material was observed. By color, it appeared that the layer near the collector screen was rich in HgO. This layer also appeared finer grained, more coherent, and more firmly bound together than the material which covered it. The quantity of ZnO present on each electrode was adequate to yield a theoretical capacity, at 100% utilization, of approximately 12 A-hr. HgO content in the electrodes was 33 mg HgO/g ZnO as determined using an atomic absorption spectrophotometer in this laboratory. The silver electrodes also came in the discharged state. They had approximately the same apparent surface area, 66 cm^2, were 0.4 mm thick, and consisted of porous sintered silver (1% palladium) on expanded silver screen. They were prepared according to the procedure of Falk and Fleischer (9). Estimated theoretical capacity of these electrodes at 100% utilization is 6.5 A-hr.

Cell designs.—Two cells were used in the experiments; they are designated cell A and cell B.

Design and operating parameters for cell A (Fig. 1) were chosen to test directly the basic hypothesis that material redistribution over the zinc electrode is caused by convective flows driven by membrane pumping effects. Thus, the cell was designed to minimize convective flow in the zinc electrode compartment during cell operation. The zinc and silver oxide electrodes faced each other across a separator which consisted of three layers of 0.001 in. thick RAI P2291 (40/20) membrane[4] and one layer of 0.005 in. thick Dynel[5] (Webril nonwoven fabric, 1418) which was placed on the silver electrode side of the separator. The RAI material is a beta radiation cross-linked low density polyethylene film which has been gamma radiation grafted with methacrylic acid. The Dynel is a porous, nonwoven acrylonitrile which is resistant to oxidation in the cell environment. The electrodes were recessed in rectangular chambers machined in flat, 3/4 in. thick, acrylic sheets. The zinc electrode chamber was just large enough to contain the electrode. No space was allowed, within machining tolerances, to provide reservoir space outside the porous electrode structure. The silver electrode chamber was deeper than necessary to contain the electrode. The additional space was filled with either an inert, nonabsorbent material, latex sheet, or an absorbent material, for example, Dynel sheet, to provide additional electrolytic solution storage volume. A large O ring, laid in a rectangular groove surrounding the electrodes, sealed the cell when the acrylic sheets were bolted together with six 1/4 in. bolts. Sealed electrical contacts were made to the electrodes through the cell walls. Provision was made for evacuation of the electrode chambers through four ports which were subsequently used for filling the entire free cell volume with solution. The two evacuation and filling ports on the zinc side were normally sealed after the filling operation was complete. The silver electrode compartment could be sealed and the whole cell operated flooded and nonvented without head space, or the compartment ports could be left unsealed allowing the silver electrode to be operated flooded but vented as shown in Fig. 1. Under these circumstances, convection parallel to the long axis of the silver electrode occurred as fluid exchanged convectively between the silver compartment and the reservoirs above the filling ports during cell operation. Some fluid flow in the zinc electrode chamber parallel to the electrical current flux across the membrane was expected due to changes in volume of solids associated with the electrode reactions and straining of the container wall. This latter flow should not, according to the basic hypothesis, cause material redistribution as long as the effects are uniform over the whole electrode. All final seals were O ring seals.

[4] RAI Corporation, 225 Marcus Boulevard, Hauppauge, New York 11787.

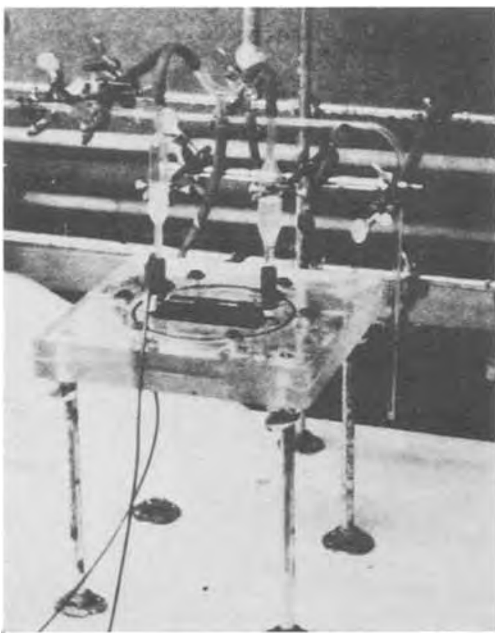

Fig. 1. Photograph of cell A. The cell is operated horizontally as shown with the zinc electrode located below the silver electrode. The silver electrode is flooded and vented.

In a modified version of cell A, designated cell AP, provision was made for sealing a Model 2201, pressure transducer[6] to the cell near the center of the zinc test electrode. Communication between the electrolytic solution filled stainless steel chamber of the transducer and the zinc test electrode compartment was through a 1/8 in. hole in the acrylic wall. The volume of the pressure chamber of the transducer was approximately 3.3 cm^3. In cell AP, the silver electrode was replaced with a second zinc electrode which was precharged to 7.5 A-hr against silver electrodes at approximately 4 mA/cm^2. The zinc counterelectrode was operated flooded and vented with the cell positioned horizontally, as in Fig. 1, with the test electrode below the counterelectrode.

The design and operating parameters for cell B were chosen to allow normal convective flow along the long axis of the electrodes. Experiments with this cell were carried out to collect data on flow rates and material redistributions which could be quantitatively compared with predictions based on the mathematical model. Thus, the design of cell B, shown schematically in Fig. 2, was similar to that of cell A, but it had some additional features. The separator system used with this cell consisted of two layers of RAI P2291 (40/20) with a 0.001 in. Dynel sheet between the silver electrode and the RAI material. The silver compartment was just deep enough to house the elec-

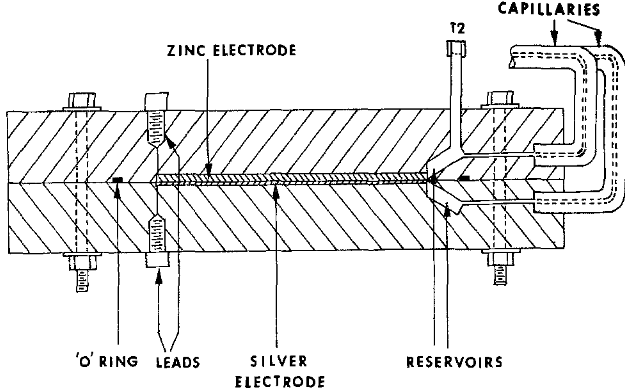

Fig. 2. Schematic drawing of cell B

trode, 0.46 mm. Small reservoirs were machined in the cell walls at one end of each electrode compartment. The two reservoirs were separated by solid, nonconducting acrylic walls. Glass capillaries (0.1 in. diameter), used to monitor fluid flows, exited the cell at the reservoir end. They were bent in such a manner that the flows in the capillaries were horizontal, that is parallel with the earth's surface and, consequently, hydrostatic pressure differences did not arise between the compartments. The cell could be operated with the electrodes oriented horizontally, as shown in Fig. 2, or vertically with respect to the earth's surface; these two configurations will be distinguished below by referring to cell BH and cell BV, respectively. Thus, cell B was operated in all cases with both electrodes flooded and vented, the reservoirs were always filled completely, and fluid partially filled the available lengths of the capillaries.

An additional feature of cell B was the second exit tube from the zinc compartment reservoir, labeled T2 in Fig. 2. This exit tube is used to determine the gas evolution rate from the zinc electrode as explained below.

Electrolytic solution.—The solution used for filling the cells was prepared from doubly distilled water and reagent grade chemicals. KOH was first dissolved in water to prepare a concentrated solution. This solution was diluted to a specific gravity of 1.40 at 20°C. Fine grained ZnO was then added in excess of the amount required to saturate the solution, and magnetic stirring continued for several hours. The solution with excess crystalline ZnO was stored in tightly capped polyethylene bottles.

Cell filling.—Filling of the cell was carried out with the electrodes positioned vertically with respect to the earth's surface. The filling procedure in all cases involved evacuation of the cell and rubber filling lines by mechanical pumping followed by slow, simultaneous vacuum filling of the compartments with solution from a common reservoir. Following return of pressure in the filled cell to atmospheric, the cell was normally left to soak for at least 24 hr before the appropriate ports were plugged and cycling was begun.

Flow rate measurements.—During selected periods of operation of cells BV and BH, the positions of the fluid menisci in the capillaries were observed with a precision cathetometer (± 0.005 cm) to establish fluid flow rates in the cells. Average flow rates were calculated by dividing the volume of fluid flowing into or away from the reservoir by the time interval between observations. The uncertainty in the reported values is estimated to be $\pm 10\%$ based on dimensional tolerance of the capillary, precision capability of the cathetometer, and uncertainty in the time interval measurements. Greater error could have been incurred by undetected gassing or dimensional changes in the compartments, for example, membrane movement. The convention was adopted that positive flow rates indicated that fluid was flowing from the electrode compartment into the reservoir and hence into the capillary; a negative flow rate corresponded to fluid flowing from the reservoir into the compartment, that is, emptying the capillary.

Gas evolution.—During preliminary tests with cell BV, gas evolution at both electrodes was found to interfere with the fluid flow measurements. It was learned that little or no gassing at the positive electrode was detected as long as the charging rate was small (for example, 1.0A), and charging time was 2 hr or less. It was later learned that oxygen evolution at the silver electrode at higher rates of charge could be adequately suppressed by properly preforming the electrode at low current density (10). Hydrogen evolution was found to occur at the zinc electrode throughout a charge-discharge cycle including the no current rest period.

In order to correct observed flow rate data, the rates of hydrogen evolution were measured. The following procedure was used. A tube, T2 (see Fig. 2), which extends vertically upward from the zinc electrode reservoir was added to the cell. After filling the cell, the liquid level in tube T2 was initially the same as the liquid level in the capillary which extends from the zinc electrode reservoir. While current was passed through the cell at 1.0A, the top of tube T2 was closed. After a measured quantity of charge had passed through the circuit, gas bubbles in the zinc compartment were maneuvered into the tube T2. The position of the fluid in the capillary was then noted, the current terminated, and tube T2 opened to allow accumulated gas to escape. From the distance of movement of the meniscus in the capillary, the rate of hydrogen evolution was computed. The average volume rates of H_2 evolution, calculated for room temperature (22°C) and 1 atm pressure, were 0.17×10^{-4} cm^3/sec during charge, 0.15×10^{-4} cm^3/sec during discharge, and 0.09×10^{-4} cm^3/sec during rest periods of no current flow. The volumetric data presented below have been corrected for the effects of H_2 evolution.

Analytical procedures.—Analytical procedures were required to obtain data which would allow quantitative comparisons of material distributions on used and unused zinc electrodes. The unused electrodes consisted of mixtures of ZnO, HgO, and inert binder on expanded silver screen. It was anticipated that used electrodes might contain, in addition to the substances listed above, metallic zinc and mercury and possibly various amalgams of zinc and silver.

In preliminary experiments with bulk reagents, it was found that ZnO could be separated from zinc and HgO by dissolution in concentrated aqueous KOH solution. Therefore, in later experiments ZnO was determined gravimetrically with adequate precision by treatment with concentrated KOH solution, with a specific gravity of 1.40. The fractions of HgO and granular metallic zinc which were lost during dissolution of the ZnO were less than 2%, which was considered negligible. A mixture 1M in NH_4OH and 1M in NH_4Cl was found to be equally effective in separating ZnO and Zn, and, from the standpoint of avoiding gravimetric errors, offered advantages over concentrated KOH as a separating agent; however, it was also found to dissolve HgO at an undesirably high rate. Therefore, in initial experiments the KOH solution was used. It was subsequently found that after 30 to 40 cycles of operation there was no detectable HgO (that is, less than 1 mg of HgO per sample for a sample size of approximately one gram) in the zinc electrode, and, therefore, the NH_4OH-NH_4Cl mixture could be used for ZnO dissolution without difficulty.

A Perkin Elmer Model 303 atomic absorption spectrophotometer was calibrated with standards prepared in this laboratory for determination of potassium, mercury, and zinc. This instrument was used in several cases to check the results of gravimetric measurements.

The procedures used in electrode analyses may be summarized as follows: The electrodes were sectioned into samples with scissors, and each sample was placed in a clean, preweighed and labeled 30 ml medium frit filtering crucible. Care was taken to record the position which the sample occupied on the electrode with respect to the electrode lead. Each sample was thoroughly rinsed with distilled water and then oven dried at approximately 120°C for at least 2 hr (11). After cooling in a desiccator, the samples were weighed. The samples were then repetitively treated with 20 ml portions of concentrated aqueous KOH, specific gravity 1.40, or the NH_4OH-NH_4Cl mixture followed by thorough rinsing with distilled water, drying, and weighing until weight losses caused by the last treatment were judged to be negligible (that is, less than 0.2% of accumulated weight loss). The sample weight losses from this treatment were attributed to ZnO dissolution.

Subsequently, the samples were similarly treated with 6*N* HCl. In the case of used electrodes this was done to determine the quantity of metallic zinc present; in the case of unused electrodes, to determine HgO. In selected cases, the HCl wash and rinse liquids were collected, made up with water to known volume, and tested for zinc, potassium, and mercury by atomic absorption spectrophotometry (AA). Also, in selected cases the metallic screens were separated from the residues after HCl treatment, and the residues and screens were subjected separately to treatment with warm concentrated HNO_3. These liquids were then tested with AA for mercury.

In one case a used silver electrode (from cell A) was repetitively leached in 6*N* HCl, and the leach liquid made to volume and tested with AA for zinc.

Treatment of data.—In these experiments, emphasis was placed on the determination of the distribution of total zinc as ZnO over the used and unused electrodes. The used electrodes were, therefore, completely discharged before removal from the cell, and only residual quantities of metallic zinc were found; in no case more than 3% of the active material reported. In treating the analytical data, these small quantities of metallic zinc found on the used electrodes have been reported as ZnO. Because it was difficult to measure accurately the dimensions of the samples and because of total weight differences between different electrodes, the collector screen material was used to normalize the data. The normalization ratio used for each sample is

$$\frac{Q_{ZnO}}{Q_{ZnO}^*} = \left[W_{ZnO}^i / \left(W_{cs}^i \cdot 66.0 \text{ cm}^2 \Big/ \sum_i W_{cs}^i \right) \right] \Big/ \left[\sum W_{ZnO}^i / 66.0 \text{ cm}^2 \right] \quad [1]$$

where W_{ZnO}^i = weight of ZnO, sample i, and W_{cs}^i = weight of collector screen, sample i. Assuming that the weight per unit area of the collector was uniform, the numerator of the normalization ratio, Q_{ZnO}, is the weight of ZnO per unit area of sample. Similarly, the denominator, Q_{ZnO}^*, is the average weight of ZnO per unit area for the whole electrode. The ratio, Q_{ZnO}/Q_{ZnO}^*, compares the ZnO per unit area at a particular position on the electrode with the average value for the electrode as a whole.

Uncertainty in the reported values of W_{ZnO}^i is estimated to be no greater than ±3%. Comparisons of samples from used electrodes with samples from unused electrodes on the basis of the normalized data involves the assumption of uniformity of weight/area for the used collector screens.

Preliminary experiment.—Several preliminary experiments were carried out with cell A and cell AP to determine the most appropriate modes of cell operation in later tests. Certain interesting observations were made, especially with respect to the ability of the cells to accept charge under different conditions, which should be relevant to suggestions for improving the performance of zinc-silver oxide cells.

In one preliminary experiment, cell A was cycled with both electrodes flooded and neither electrode vented. With no preforming of the electrodes, the freshly filled cell would accept approximately 0.8 A-hr of charge at 2.0A before the terminal potential difference (TPD) rose rapidly above 2.3V. It was established that cells of this type would accept a greater initial charge to the 2.3V cutoff when charged at a lower rate, for example, 1.0 A-hr at 0.5A. However, it became apparent that cell behavior was strongly dependent on cell history since filling. Continued charging beyond the onset of rapid increase in polarization led to drastic initial polarization on discharge and to large decreases in charge acceptance on subsequent cycles, for example, from 0.8 to 0.2 A-hr at 2.0A.

It was found that cell capacity at the 2.0A rate, Q_2,[7] based on a 2.3V cutoff, could, in the initial stages of operation, be increased to approximately 1.6 A-hr by operating the cell with the silver electrode flooded and vented as shown in Fig. 1. Further increase in Q_2, to approximately 2.0 A-hr, was achieved by providing some reservoir space in the silver electrode compartment by replacement of a 0.010 in. latex filler sheet with Dynel. Additional increase in the chamber size produced no significant increase in capacity. With the cell operated with the silver electrode flooded but vented, it was found that volumetric flows between the silver electrode compartment and the reservoirs above the compartment could be correlated with both the onset of rapid gas evolution at the positive and with the rapid increase in TPD near the end of charging. Fluid flows to and from the reservoirs above the silver electrode were observed to be reversible provided charging did not extend into the region of heavy gassing at the positive. A reversible flexing of the acrylic cell wall on the zinc side of the cell was also observed during these experiments. A mechanical strain gauge (least count = 0.001 in.) was used to measure deflections, and values as large as 0.0015 in. were observed during cycling. If copious gassing was allowed to occur at the positive, solution was driven into the reservoirs, and the silver electrode chamber would not refill spontaneously; apparent capacity, Q_2, dropped. Capacity could be partially regained by injecting electrolytic solution into the silver compartment by syringe; however, better results were achieved by vacuum refilling the cell.

To provide a clear test of the convective flow hypothesis, it was deemed desirable to cycle a zinc electrode to as great a depth as possible under conditions of minimized convective flow parallel to the membrane surface. Since operation of cell A with the silver vented allowed deeper cycling while maintaining the limited convection condition on the zinc side, this mode of operation was adopted for subsequent experiments.

During a preliminary experiment with cell AP, it was found that this cell also was subject to severe increases in rate of change of TPD after charging

[7]
$$Q_2 = 2.0 \int_{t_i}^{t_f} dt \quad [2]$$

where t_i = time at which charging begins with the cell initially in the completely discharged state, and t_f = time at which TPD reaches 2.3V at the 2.0A charging rate.

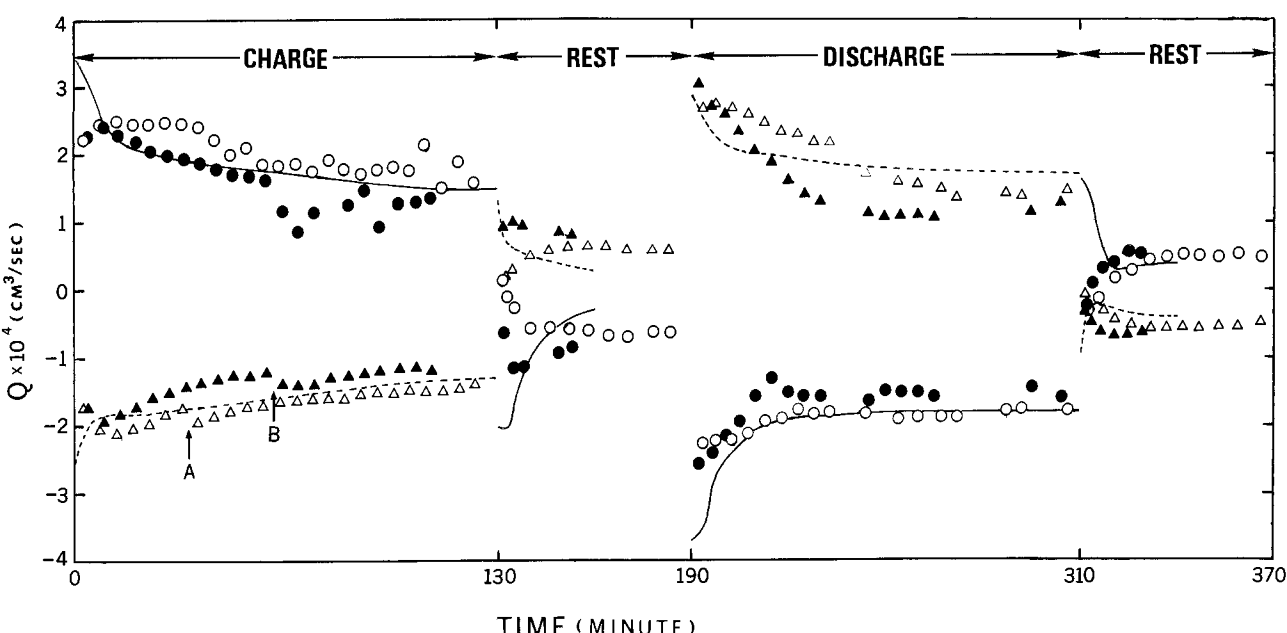

Fig. 3. Volumetric flow rate data for cells BV (cycle 6) and BH (cycle 2). ○, Cell BV, zinc compartment; ●, cell BH, zinc compartment; △, cell BV, silver compartment; ▲, cell BH, silver compartment. ———, Predicted flow rate, zinc compartment; - - - - - -, predicted flow rate silver compartment. Each cycle consisted of 2 hr of charge and 2 hr of discharge at 1.0A. A and B show points where cell potential indicated change from monovalent to divalent silver electrode reaction. A positive flow rate corresponds to flow of liquid out of that compartment through the vent, due to combined effect of an increase in the volume of solid and a flow of liquid through the separator into the compartment.

or discharging the test electrode in excess of 1 hr at 2.0A. Decreasing the cell current to 1.0A allowed several cycles to 2.5 A-hr without onset of severe polarization; however, after a few cycles at this rate a severe increase in rate of polarization again was observed to set in at about 2.0 A-hr.

Results

Cell BV.—The electrodes were subjected to 36 cycles, 2 hr charge and 2 hr discharge, at a constant current of 1.0A, that is, an apparent current density of 15 mA/cm². There was no preforming of either electrode. Irregular time gaps, varying from several minutes to several hours, occurred between half-cycles. TPD of the cell during charging rose gradually as cycling continued but did not reach a level at which noticeable gassing occurred. During the first six cycles, flow rate data were recorded. In Fig. 3, volumetric flow rate data, corrected for H_2 evolution at the zinc electrode, are shown for cycle 6. The data for the other cycles are similar in essential features and are presented elsewhere (7).

After 36 cycles, the zinc electrode was removed from the cell in the completely discharged state (the electrodes were discharged at the normal rate and then shorted for several hours). It was then cut perpendicular to the long axis of the electrode into ten sections of approximately equal area and analyzed for ZnO and Zn as described above. The results are shown in Fig. 4. Also shown in Fig. 4 for comparison are analytical data presented in the same manner for an unused electrode.

Cell BH.—The electrodes of the cell were subjected initially to three low current density forming cycles (2 A-hr at 0.01-0.10A cell current) and then to 43 cycles, 2 hr charge and 2 hr discharge, at 1.0A. Irregular time intervals occurred between half-cycles as with cell BV. Again, TPD on charge gradually increased with cycling. Flow rate data were taken during cycles 2, 23, and 38. Data for cycle 2 are included in Fig. 3. The data for cycles 23 and 38 are similar in essential features and are presented elsewhere (7). After the 43rd cycle, the zinc electrode was removed from the cell in the completely discharged state and treated in the same manner as the zinc electrode from cell BV. Analytical data for the electrode are included in Fig. 4.

Cell A.—Cell A was cycled with the silver electrode flooded and vented as shown in Fig. 1. Initial cycling was at the 2.0A rate; there was no preforming of either electrode. Table I summarizes the types, numbers, and duration of all cycles. Irregular time intervals occurred between half-cycles as with cell BV. As operation proceeded, current densities and cycle

depths were altered as cell capacity changed. Capacity, Q_2, was measured initially and at selected times as shown in Fig. 5. After accumulating about 125 A-hr of charging, the cell was vacuum refilled, resulting in a substantial recovery of capacity; however, continued cycling resulted in rapid loss of capacity as shown. In total, the electrodes of this cell were subjected to over 200 constant current cycles of operation. Total charge delivered to the cell was approximately 219 A-hr.

The zinc electrode was removed from the cell in the completely discharged state. A photograph of the electrode is shown in Fig. 6. The electrode was then cut into 15 sections of approximately equal area for analysis (4 cuts perpendicular to the long axis and 2 cuts perpendicular to the short axis). A summary of the analytical results is shown in Fig. 7. Also shown in Fig. 7 are data for an unused zinc electrode. These data may also be stated in terms of average deviations and outlying results (furthest from the average) for the 15 samples. For the unused electrode the result is 1.00 ± 0.04 with an outlying result of 1.07. For the used electrode the result is 1.00 ± 0.12 with an outlying result of 0.78.

The HCl wash and rinse liquids from the analyses were tested by AA for mercury. No mercury was detected, indicating that negligible quantities of HgO were present at the end of cycling. Residues and collector screens of 5 samples were leached and dissolved, respectively, with warm concentrated nitric acid, and these fluids were tested for mercury. Mercury as determined by AA was found in approximately equal quantities in the collector screens and residues. However, total mercury found by AA in the 5 samples tested was only about 60% of that anticipated on the basis of analysis of unused zinc electrodes.

The silver electrode from the cell was leached with stirring with two portions of 6N HCl for a total of

Fig. 6. Photograph of used zinc electrode from cell A. The electrode was discharged before removal from the cell. Total charge delivered to the electrode during cell operation was approximately 219 A-hr. The distribution of unconsumed, metallic zinc appears as dark, rough appearing areas.

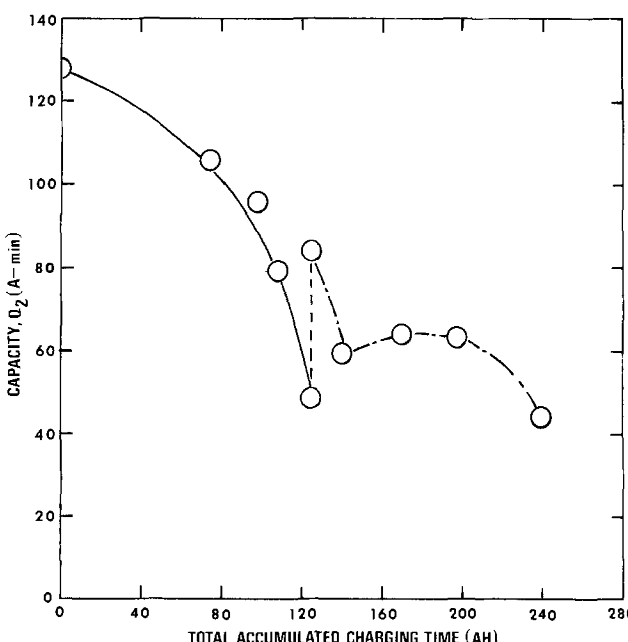

Fig. 5. Capacity, Q_2, for cell A as a function of accumulated charging time. The vertical dashed line denotes the improvement of capacity when the cell was vacuum refilled.

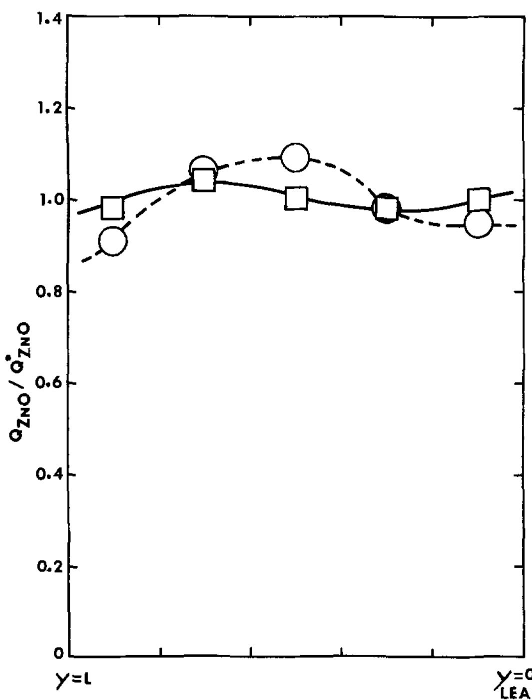

Fig. 7. Normalized ZnO distribution. □, Unused electrode; ○, used electrode from cell A. Each point is an average over three sections taken at the indicated value of y.

approximately 48 hr. The leach liquid was made to volume, and zinc determined by AA. The quantity 0.45g of zinc was found, or, reported as ZnO, 0.56g.

The data reported above for cell A are the results from the second experiment of this type which was carried out. In the first experiment the electrode arrangement differed only in that a single 0.001 in. Dynel interseparator was used rather than the 0.005 in. material. Approximately half as much total cell operating time was accumulated, 110 A-hr of charging at approximately 30 mA/cm^2. Very similar ZnO distribution results were obtained. Problems with the first experiment, involving minor leakage around seals and greater uncertainty in analytical results, dictated that the work be repeated.

Cell AP.—The cell was cycled at 1.0A, 2 hr charge and 2 hr discharge. Observed values of TPD and pressure changes as functions of time are shown for three cycles of operation in Fig. 8.

Membrane evaluation.—Hundreds of hours of operation of several different cells produced only one case of shorting of a cell by zinc dendrites. It was determined that this case involved a prior mechanical puncture of the membrane incurred during cell assembly. Membranes were commonly darkened in color (dark brown to black) in the cell environment; the membrane layers nearest the silver electrode showed the greatest coloration.

Discussion

Basic hypothesis.—According to the basic hypothesis, the principal cause of material redistribution over the zinc electrode is convective flow parallel to the apparent electrode surface. The direction of the flow alternates on cycling and couples with changes in the concentration of soluble zinc species (due also to cycling) to produce a net movement of zinc. After enough cycles, even a small movement of zinc per cycle will lead to a gross redistribution and battery failure. Practitioners of the art have observed convective flows in these cells, but little significance was attached to them.

In the present case, in cells BV and BH, one oriented vertically and one oriented horizontally, the convective flow patterns (Fig. 3) simulate those in commercial silver-zinc storage batteries, and a drastic redistribution of ZnO is observed after 36 or 43 cycles, 72 and 86 A-hr of charging, respectively (see Fig. 4).

In a different experiment in cell A designed to minimize convection parallel to the electrode, substantially less redistribution of ZnO was observed after a total charging of 219 A-hr. The data support the basic hypothesis and also rule out gravity as an influence of redistribution.

Convective flow.—Several observations can be made with respect to the experimental volumetric flow rate curves, shown in Fig. 3: (*a*) The abruptness with which the flows are established initially, the rapid changes in the direction of the flows at the end of charge and discharge, and the abrupt increases in the flow rates at the beginning of discharge suggest that electro-osmotic pumping by the membrane is the main driving force for convective flow during charge and discharge. (*b*) When the cell current is terminated, the electro-osmotic effect is expected to decrease rapidly. Osmotic driving forces, if present, should also relax, but less rapidly. At the end of charge, the flow rates are observed to drop rapidly to zero, change sign, and then increase again to maximum values before beginning a very gradual relaxation to equilibrium. Consideration of the electrode reactions suggest that the osmotic force which tends to drive water from the zinc compartment into the silver compartment during this period of time is caused by a difference in zincate concentration across the membrane. The time necessary for the complete relaxation of this latter effect is approximately 16 hr, indicating a relatively low diffusion coefficient for zincate in this membrane. (*c*) An osmotic effect due to differences in potassium concentration across the membrane should also be expected. During and after charge this effect should tend to drive solvent across the membrane in the same direction as the electro-osmotic effect. The experimental flow rate data for the period after charge suggests that the difference in potassium ion concentration relaxes within minutes, much more rapidly than the difference in zincate concentration. These considerations are also reflected in the initial stages of charging. The flow into the zinc compartment builds up rapidly under the electro-osmotic force and an osmotic force due to a combination of potassium ion and zincate concentration differences. As charging continues, a maximum is observed because of the differences in transport rates of potassium and zincate ions across the membrane.

The membrane used in these studies is a weak cation exchange membrane characterized by particular values of transport coefficients. Evidently, the coefficient for electro-osmotic transport is large and leads to large convective flows in the electrode compartments of the cell with normal convection and, therefore, to rapid material redistribution. The desirability of being able to optimize membrane properties, including transport parameters, seems apparent.

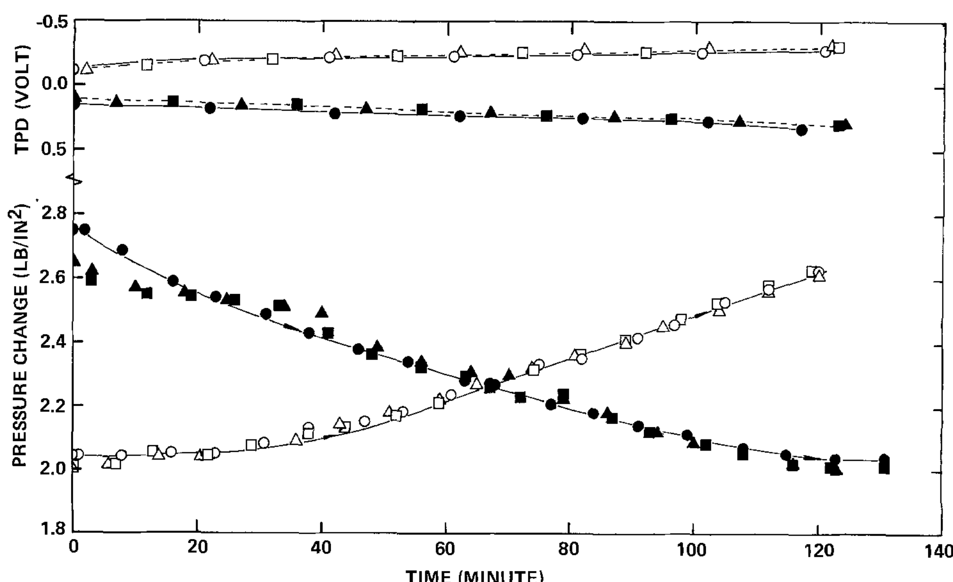

Fig. 8. Cell terminal potential difference (TPD), test electrode, counterelectrode, and pressure corresponding in the zinc test electrode compartment for cell AP as functions of time. ●, Cycle 6, discharge; ○, cycle 6, charge; ■, cycle 7, discharge; □, cycle 7, charge; ▲, cycle 8, discharge; △, cycle 8, charge.

Cell capacity.—During preliminary experiments with cell A when the cell was operated with both electrodes flooded and neither electrode vented, it was established that the freshly filled cell had a reproducible capacity, Q_2. The capacity was found to increase slightly when charging was carried out at a lower rate. Venting of the positive electrode compartment, which allowed both the escape of gas when generated and convective flow between the silver compartment and the reservoirs, led to a significant increase in Q_2. In addition, a correlation was noted between the rates of convective flow and both the onset of gassing and the rapid increase in TPD. Provision of additional reservoir space in the silver compartment also increased Q_2 slightly. These observations indicated that Q_2 was primarily limited by the development of concentration polarization at the positive electrode (hydroxyl ion starved) which led to gas evolution if charging was carried too far. Improvement in capacity through venting could be attributed to enhanced stirring due to the convective action or simply to maintenance of adequate solution volume in the electrode, that is, solution tended to flow from the positive to the negative electrode on charge due to osmotic and electro-osmotic effects, and the positive can be left in a "fluid starved" condition if fluid is not replaced. It is possible that the main effect of increased storage volume in the positive compartment was simply to facilitate convective flow into and through the compartment. In any event, observed capacity, Q_2, was at best only about 30% of the theoretical limiting value of 6.5 A-hr. One other possibility which has been suggested by other studies is a "choking" of the porous silver electrode, that is, the pores of the electrode are choked with product near the surface and only a small fraction of the total porous mass is utilized (12). Some experimental evidence has been presented in the results section which indicates an irreversible accumulation of precipitated ZnO in the positive electrode, which might also contribute to such an effect.

When cell A was repetitively cycled over a long period of time, capacity, Q_2, was observed to decrease with time as shown in Fig. 5. Only partial recovery of cell capacity, to 65% of initial, was achieved by vacuum refilling the cell, indicating that simple accumulation of gas in the electrode chambers was not the only reason for capacity decrease. Subsequent analysis of the zinc electrode revealed only slight material redistribution over the surface of the electrode.

Cell AP was operated with a zinc test electrode and a second zinc electrode replacing the silver electrode. It was initially hoped that greater depth of charge and discharge of the test electrode would be possible with this arrangement. In initial experiments, however, it was determined that this cell also was subject to similar severe increases in polarization after charging or discharging the test electrode in excess of 2 A-hr at the 2.0A rate. Decreasing the cell current again led to increased capacity, but with continued cycling the capacity decreased. Since no reference electrodes were utilized in this experiment, a determination of the distribution of the observed total polarization between the electrodes is impossible. It is clear, however, that polarization effects in cell A are not necessarily linked exclusively to the silver electrode.

Pressure variations, cell AP.—No theoretical analysis of pressure variations in the zinc electrode compartment of cell AP during operation was attempted. Reproducible values of pressure changes have been measured and presented in Fig. 8. One might have expected to observe more rapid changes in pressure reflecting the abrupt changes in electro-osmotic flow rate discussed above. In addition, based on simple thermodynamic osmotic pressure calculations, much larger pressure differences would be expected. Several possible reasons why the observed changes are small and gradual rather than large and abrupt are offered: (*a*) The design of the cell and placement of the pressure sensing chamber may be a factor, that is, the electrodes are tightly packed in the cell, and the mouth to the pressure chamber is effectively plugged by the porous electrode; (*b*) flexing of the acrylic wall (which was actually observed); (*c*) gas bubbles in the electrode; (*d*) delayed changes in volumes of solids and liquids in the chamber due to the cell reaction, for example, such as might occur due to conversion of zincate to zinc followed by slow dissolution of ZnO; (*e*) movement of the membrane during cell operation.

Model.—The mathematical model for a cell with normal convection has been developed on the basis of the convective flow hypothesis. It is a one dimensional model which consists of a set of nonlinear, coupled differential equations with time and position parallel to the membrane surface as independent variables. Those factors have been included which are believed to be significant in governing the redistribution of material over the surface of the electrode. Such factors include: osmotic and electro-osmotic transport of ions and water across the membrane separator, transport of dissolved ions and water in the y direction (parallel to the electrode face) due to convection and diffusion, chemical species source and sink terms due to chemical reactions and precipitation-dissolution phase changes including the dependence of zincate solubility on KOH concentration, and provisions for quantitatively determining changing electrode porosity and local concentration changes with time and position y. Explicit details concerning the model and solution of the differential equations are presented elsewhere (6, 7).

In Fig. 4, experimental ZnO distribution data are presented for the used electrodes from cells BV and BH and for an unused electrode. Also shown in the figure is a predicted ZnO distribution for an electrode which has been operated through 35 cycles at 1.0A for 2 hr charge and 2 hr discharge. Intervals between half-cycles were set at 3 min for the simulation. The computation was interrupted after the 8th, 15th, 22nd, and 28th cycles, and concentration differences which had developed were relaxed to their initial values before continued cycling. The reason for the interruption and relaxation may be explained briefly as follows: Numerical calculations indicated that at the 1.0A rate the normal cell reaction could not be sustained after seven or eight cycles because of variations in KOH and zincate concentrations in the cell, nonuniform distribution of zinc over the zinc electrode, and associated changes in current distribution. Redistributing the KOH and zincate (equivalent to a long rest period) allowed the cell to operate normally again and the theoretical cycling to continue. Experimentally this effect was manifested by increased cell polarization with cycling.

It was originally intended to carry the theoretical cycling to 40 cycles to produce a better comparison to experiment. However, in the 32nd charge cycle of the theoretical calculations, the zinc oxide became completely depleted for the first time near the reservoir end of the electrode. The computer program could handle this situation, but convergence became slow and computer calculation costs went up. Because of the increased cost, theoretical cycling was stopped after 35 cycles. Only one predicted ZnO distribution is shown in Fig. 4 for comparison with the two sets of experimental data because orientation of the cell with respect to the earth's gravitational field is neglected in the model. The agreement between the predicted and observed distributions is excellent

considering the variation of bases, 35 theoretical cycles, and 36 and 43 cycles for the two experimental runs.

In addition to redistribution of total zinc, the model can be used to predict a number of other cell variables as functions of position and time, for example, zinc metal, electrode porosities, ion concentrations. current densities, and volumetric flow rates, as well as their relevance to cell performance. In the experiments being described, only total zinc as ZnO redistributions and volumetric flow rates were measured quantitatively for comparison with predictions based on the model. In Fig. 3 one complete cycle of experimental volumetric flow rate data is plotted for cell BV and one complete cycle for cell BH. Also included in Fig. 3 are lines which represent the predicted flow rates. It is apparent that the model as it is currently constituted can yield flow rate curves which reproduce some of the main features of the experimentally determined curves and are in reasonable quantitative agreement with the observed rates over most of the complete cycle. There are interesting features of the experimental curves which are not reflected by the predicted curves, for example: (*a*) The result of the transition from production of monovalent to divalent silver oxide, marked A and B in Fig. 3, is clearly discernible in the flow rate data for the silver compartment during charging of both cells. This minor effect is not included in the model, that is, the cell charging reaction is modeled in terms of silver going to divalent silver oxide. It is interesting to note that the observed change in flow rate is in reasonable agreement with a change calculated on the basis of the two half-reactions

$$2Ag + 2\,OH^- \rightarrow 2e + Ag_2O + H_2O$$

$$Ag + 2\,OH^- \rightarrow 2e + AgO + H_2O$$

The difference involved in volume changes is 5.5 cm^3 per two Faradays of charge; at 1.0A this volume change should produce a difference in flow rates of 0.29×10^{-4} cm^3/sec. (*b*) During the adjustment times after abrupt changes in cell current, the experimental data reflect the relationships between the electro-osmotic and osmotic effects, for example, at the beginning of the charging period, the flow rate into the zinc compartment rises abruptly due to the electro-osmotic effect, continues to rise because of a rapidly developing osmotic effect due to potassium ion imbalance, and then drops slowly because of a developing opposite osmotic effect due to imbalance of zincate. Although the predicted curves do not currently reflect these changes, it is believed that they could be made to do so by proper adjustment of the appropriate membrane transport parameters.

There are several physical constants involved in the model, and definite values of these constants must be used in order to obtain numerical predictions from the model. In all cases where reliable data were available from the literature, these values were used in calculations. In other cases data simply were not available, and estimates have been made by the authors. The values used in calculations are presented elsewhere (6, 7). No systematic parametric study of the effects of the values of the constants on the predicted ZnO distribution or flow rates has been carried out at this time.

The one dimensional analysis is demonstrably successful in that one can use it to predict correctly ZnO redistribution at the zinc electrode in a cell with normal convection. It is probable that there are other physical processes which take place within the porous zinc electrode which are not adequately treated by the current model. These processes may take on greater importance under other circumstances. For instance, in cells such as cell A in which the zinc electrode is operated with limited convection, the data presented above indicate that mass transport in the zinc electrode in the direction perpendicular to the membrane may be rate limiting.

Conclusions

1. The data in Fig. 4 and 7 demonstrate that material redistribution over the zinc electrode in zinc-silver oxide cells is governed primarily by convective flow through the zinc electrode parallel to the apparent surface of the electrode. Furthermore, the data indicate that orientation of the electrode with respect to the earth's gravitational field has little impact on the material redistribution. Limitation of such parallel convective flow through the zinc electrode significantly decreases the rate of material redistribution.

2. The fluid flow rate data, samples of which are illustrated in Fig. 3, demonstrate that the average volumetric flows are in the directions which one would predict on the basis of osmotic and electro-osmotic pressure considerations. The data indicate that with the separator being used in this case, the primary driving force for convective flow during charge or discharge is electro-osmotic. The choice of the membrane material is important in the regulation of convective flow. Membranes with large electro-osmotic coefficients can be expected to yield large material redistribution effects in cells which allow normal convection; however, such membranes may be required to prevent zinc dendrites from reaching the positive electrode.

3. The one dimensional model for the cell with normal convection, based on the convective flow hypothesis, has been used successfully to predict ZnO redistributions and fluid flow rates. Good agreement between experimental observations and predicted values for these variables is strong evidence that the physically important phenomena in redistribution on the zinc electrode have been properly incorporated into the model.

4. The work done to date and reported above is strongly supportive of the basic convective flow hypothesis; however, much remains to be done in determining how this new knowledge might be used in the design of improved secondary cells. For instance, it appears that one can control the rate of development of shape change by controlling convective flow; however, evidence has also been obtained which indicates that the convective flow is important in determining utilization or capacity of the cell and, furthermore, it is believed that the convective flow also is important in determining the high rate capability of the cell. Gas evolution is frequently a problem in secondary cells; in a porous zinc electrode designed to minimize convection, the control of gas evolution will be critical to its successful operation. Membrane transport as well as chemical properties play important roles in determining cell performance. Continuing improvements in membrane science and technology which will permit detailed specification of membrane properties to optimize battery performance should be sought.

Anodic Oxidation of DDT, Methoxychlor, and Related Compounds

Richard R. Keenan[1] and James D. Stuart*

Department of Chemistry, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

DDT, DDE, methoxychlor, and the ethylene of methoxychlor (MeCe) were oxidized in a 5% aqueous acetonitrile solution at a platinum electrode containing tetraethylammonium perchlorate or tetraethylammonium perfluoroborate as supporting electrolytes. The major electrolysis products were those which resulted from the hydrolysis of the electron-deficient intermediates and included alcohols, ketones, benzoquinones, and acids. 1,1-*Bis*-(*p*-methoxyphenyl) 2,2,2-trichloroethanol, not previously reported as a metabolic degradation product of methoxychlor, was readily isolated as a major electrochemical oxidation product of both methoxychlor and MeCe.

No other man-made chemical has had more impact on the health of the human race or on the environment as has DDT. More than two million metric tons of DDT have been used for insect control since 1940. It has been estimated that DDT has saved fifty million human lives and spared one billion humans from such plagues as malaria, typhus, and yellow fever (1). DDT is considered to be the single major controllable factor that has led to the population explosion in underdeveloped nations of the world. Yet, due to its persistence in the environment, its ability to be "biologically magnified," and its ability to be rendered harmless by many strains of DDT-resistant insects, DDT has become the symbol of man's reckless environmental pollution (1). DDT or DDE, its more persistent degradation product, is found in virtually every environmental sample. DDT levels of from 1 to 10 ppm are generally observed in man. DDE has recently been recognized as the most abundant organochlorine pollutant in the environment.

In preliminary findings cited by Maugh (2), Moilanen and Crosby have shown that DDT undergoes rapid, vapor phase, sunlight degradation in air to DDE. DDE is in turn photodegraded much more slowly to at least eight other products, among them 4,4′-dichlorobenzophenone (DBP) and possibly to polychlorinated biphenyls (PCB's). Figure 1 shows the metabolic and photochemical degradation pathways of DDT involving oxidations. [A paper on the anodic oxidations of PCB's follows this paper (3)].

Effective on January 1, 1973, all use of DDT in the United States has been banned by the Environmental Protection Agency. Yet many agree that no single DDT substitute will be as inexpensive and as universally effective as was DDT. Methoxychlor, the methoxy analogue of DDT, has replaced DDT in certain commercial preparations as it has been found to be a persistent yet biodegradable insecticide. Metcalf has claimed that methoxychlor is one of the safest of all

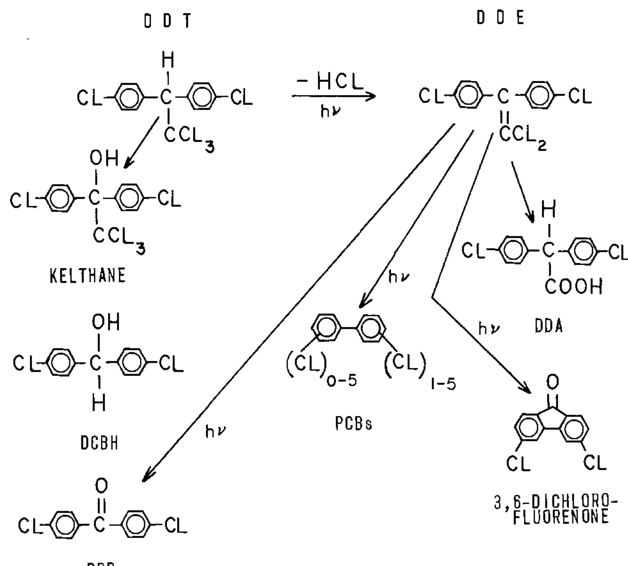

Fig. 1. Natural degradation pathways of DDT involving oxidations. hν denotes the proposed photochemical pathways in sunlight.

insecticides to higher animals (1). Figure 2 shows the known metabolic degradation pathways of methoxychlor (MeC) involving oxidations. Methoxychlor is metabolized through O-dealkylation to *mono*- and *bis*-phenols, which are rapidly conjugated and excreted in higher animals or dehydrochlorinated to the corresponding ethylene (MeCe). Methoxychlor is more effective against DDT-resistant insects, such as the housefly, as the enzymatic-induced rate of dehydrochlorination of methoxychlor to the ethylene of methoxychlor (MeCe) is substantially reduced by the electron-donating properties of the *p*-methoxy groups in comparison to the over-all electron-withdrawing properties of the *p*-chloro groups of DDT.

It must be emphasized that the oxidative pathways occurring in this present report on the electrochemical

Fig. 2. Degradation pathways of methoxychlor involving oxidations.

oxidation of DDT, methoxychlor, and related compounds are no doubt different than the enzyme-assisted, natural degradation routes of these same chemicals. It is interesting that 1.1-*bis*-(*p*-methoxyphenyl-2,2,2-trichloroethanol, never before reported as a metabolic product of methoxychlor, is readily isolated as a major electrolysis product from the electrochemical oxidation of methoxychlor (MeC). All previous electrochemical studies of DDT and related compounds have been concerned with their electrochemical reduction (4-7). Lund has reported the electrochemical oxidation of 4,4'-dichlorobenzhydrol (DCBH) at +2.07V *vs.* SCE in acetonitrile solvent to the ketone, 4,4'-dichlorobenzophenone (DBP) (8).

Experimental

Chemicals.—The following chemicals were used as received after their purity had been checked by thin-layer or gas-liquid chromatography: 1,1,1-trichloro-2,2-*bis*-(*p*-chlorophenyl)ethane (DDT); 1,1-dichloro-2,2-*bis*-(*p*-chlorophenyl)ethylene (DDE); 1,1-*bis*-(*p*-chlorophenyl)-2,2,2-trichloroethanol (Kelthane); 4,4'-dichlorobenzophenone (DBP); 4,4'-dimethoxybenzophenone (DMBP); 1,1-dichloro-2,2-*bis*-(*p*-methoxyphenyl)ethylene (MeCe). 1,1,1-Trichloro-2,2-*bis*-(*p*-methoxyphenyl)ethane or methoxychlor (MeC) both purified and technical grade was kindly provided by the Biochemicals Department, E. I. du Pont de Nemours & Company, Wilmington, Delaware. The technical grade was easily purified by recrystallization from ethanol. The following compounds were chemically prepared following published procedures: 4,4'-dichlorobenzilic acid (DBA) (9); 4,4'-dimethoxybenzilic acid or anisilic acid (DMBA) (10).

The following three compounds were isolated as major electrolysis products: 1,1-*bis*-(*p*-methoxyphenyl)-2,2,2-trichloroethanol or dimethoxykelthane (DMK) was isolated from the large-scale electrolyses of methoxychlor (MeC) and the ethylene of methoxychlor (MeCe); 1,1,1-trichloro-2-(*p*-methoxyphenyl)-2-(3-chloro-4-methoxyphenyl)ethane (3-Cl-MeC) was isolated from the electrolysis of methoxychlor only in anhydrous MeCN (0.1F $LiClO_4$) saturated with Na_2CO_3; 1,1,1-trichloro-2-(*p*-chlorophenyl)-2-(4-chloro-2,5-benzoquinone)ethane (DDT-Q) was isolated from the electrolysis of DDT, being the major product of the electrolysis of DDT in the flow-through cell. The physical as well as the spectroscopic data of these three new compounds have been reported elsewhere (11).

The acetonitrile solvent (MeCN) was purified by distillation from P_2O_5 and then CaH_2, the middle 80% fraction being retained. Tetraethylammonium perchlorate (Et_4NClO_4), used as the supporting electrolyte, was recrystallized twice from distilled water, dried on top of an oven and in an evacuated drying pistol at 100°C with P_2O_5 as dessicant. Tetraethylammonium fluoroborate (Et_4NBF_4) was prepared by reacting Et_4NBr with HBF_4, followed by a washing with ether, two recrystallizations with ethanol and then one with distilled water. This supporting electrolyte was also dried on top of an oven and in an evacuated drying pistol. Due to the hazards of working with perchlorates, especially in the presence of heavy metals, the use of fluoroborate salts as supporting electrolytes was preferred in the latter portions of this work. Perhaps because all work was done in 5% aqueous acetonitrile there appeared to be little difference in the types or amounts of the products when Et_4NBF_4 was used instead of Et_4NClO_4.

Conventional electrochemical equipment was used for the cyclic voltammetry (12, 13) and for the controlled potential electrolyses (Amel Model 557 potentiostat-galvanostat). Controlled potential coulometry was accomplished either by the deposit of silver onto a silver wire cathode (auxiliary electrode) or through a graphic integration of the current-time curve. For cyclic voltammetry, the electrolysis cell was a 4 oz glass jar; the working electrode was a stationary platinum disk (Beckman 39273); the auxiliary electrode was a platinum electrode placed coaxially around the working electrode; the reference electrode was an aqueous SCE isolated from the electrolysis by a two-compartment salt bridge to prevent contamination of the electrolysis cell by chloride. For controlled potential electrolyses, the electrolysis cell was a 250 ml beaker or a glass flow-through cell. With the beaker, the working electrode was a cylindrical platinum mesh electrode; the auxiliary electrode, isolated by a medium porosity glass frit, was either a coiled silver wire in a solution of 0.1F $AgClO_4$-0.1F Et_4NClO_4 or Et_4NBF_4 in MeCN or a cylindrical platinum mesh electrode in 0.1F of the same supporting electrolyte as the working compartment; the reference electrode was a Ag/0.1F $AgClO_4$ in MeCN electrode. All potentials are given *vs.* the aqueous saturated calomel electrode (SCE); those measured against the Ag/$AgClO_4$ reference electrode were converted to the SCE reference electrode by adding +0.30V to the measured value (14).

In order to isolate a greater proportion of the primary hydroxylated product before it could be further oxidized at the electrode, a single-pass flow-through electrolysis cell was used; its construction out of glass being diagramed in Fig. 3. While the over-all product yield was between 10 to 30%, there were significantly fewer products with this flow-through cell. In addition, the unreacted 70-90% of the starting material was used over again in subsequent single-pass electrolyses. In general, while there might be ten or more products detected by thin-layer or high pressure liquid chromatography from a conventional electrolysis, usually only one to three products were observed when the same compound was electrolyzed in the single-pass flow-through cell. It was not possible to make an exact mass balance as it was impossible to isolate in pure form nor to make satisfactory structure assignments to the many minor electrolysis products. As will be noted later, the product yields are low as they are based on the amount of pure isolated product after separation and purification. In most cases the electrolyses were run, exposed to the air, at the lowest controlled potential which produced significant current. The electrolysis was terminated when the current had reached a constant minimum value or when thin-layer chromatography indicated that all of the starting material had been consumed or interesting products were present. The solvent was removed by a rotary evaporator at temperatures below 50°C to minimize thermal degradation of unstable products. Procedures used for the isolation of various oxidation products were as follows: several extractions to isolate the neutral organic mate-

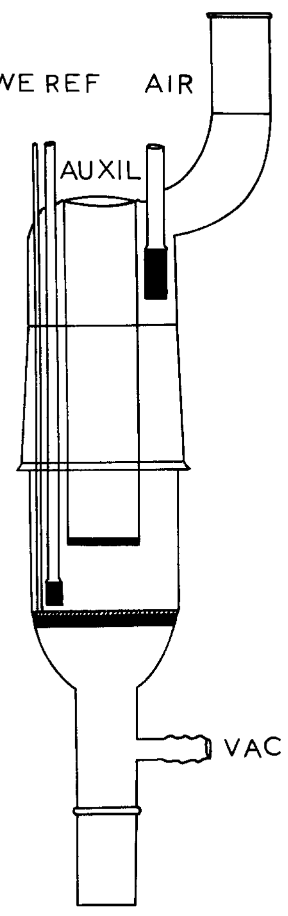

Fig. 3. Single-pass, flow-through electrolysis cell. Of all glass construction, cell height 40 cm by 7.0 cm in maximum diameter. Made out of a 150 ml Filter funnel having a medium porosity glass frit, 5.5 cm in diameter (Corning 36060). WE, PT = working electrode, 100 mesh platinum, 5.5 cm in diameter, wire diameter 0.0076 cm; REF, SCE = reference electrode probe, ultra fine porosity, 0.5 cm in diameter located 1 cm above the working electrode; AUXIL = auxiliary compartment made of a medium porosity glass frit, 3.0 cm in diameter; CE, Pt = counterelectrode, 52 mesh platinum, 4.0 cm in height by 1.5 cm in diameter (not shown in the figure); AIR = coarse glass sparger to create a positive air pressure at the top of the cell, 1.5 cm in diameter; Dropping Funnel = dropping funnel, 100 ml graduated, ending in a 24/40 joint; VAC = provision to attach vacuum if needed to increase the flow rate.

rials from the acidic or phenol products, initial screening by thin-layer chromatography, open column chromatography to remove unwanted or long-eluting products, followed by either preparative thick-layer chromatography or semipreparative, high pressure, liquid chromatography. All of the chromatography was performed on the appropriate type of silica while the high pressure liquid chromatography was performed on 6-12 ft by 7 mm ID packed columns of 37-75μ porous silica using a Waters ALC-201 chromatograph in the recycle mode with an all purpose refractive index detector. Visualization of products on TLC plates was accomplished by ultraviolet radiation or by one of the following spray reagents: concentrated sulfuric acid for DBA and many of the analogües of methoxychlor; diphenylamine-zinc chloride for Kelthane and dimethoxykelthane, 2,4-dinitrophenylhydrazine for the ketones and benzoquinones.

Product identifications were based on melting points compared to authentic samples, elemental analysis, infrared, nuclear magnetic resonance, and mass spectral data (11). Mass spectra were obtained on an AEI MS-902 mass spectrometer with a resolution of 100,000.

Results and Discussion

Cyclic voltammetry was initially used to determine the approximate potential at which to run the ensuing controlled potential electrolyses. Table I shows the anodic peak potentials for DDT, methoxychlor, and their related compounds. The diagnostic criteria of Nicholson and Shain (15, 16) were used to aid in suggesting the over-all major voltammetric anodic pathway of DDT, DDE, methoxychlor, and the ethylene of methoxychlor.

No signs of an electrochemical reversible couple (up to scan rates of 200 V/sec) were evident for any of the compounds listed in Table I except for a quasi-reversible peak for the ethylene of methoxychlor (MeCE) at scan rates greater than 1.0 V/sec. In general, the primary oxidation peak for DDT, DDE, MeC, and MeCE tended to shift to higher anodic potentials and the current function tended to decrease as the sweep rate was increased over four decades (0.01-100 V/sec). These behavior patterns are suggestive of an electron transfer followed by a fast irreversible chemical reaction [case VI of Ref. (15)] or an ECE pathway [either case I-I or I-R of Ref. (16)] with the second electron transfer being at the same or lower potential than the first electron transfer.

Referring to Table I, the presence of additional peaks at higher anodic potentials were due to the subsequent oxidation of the major electrolysis product, the corresponding benzophenone. Thus, the anodic peak at +2.65V for dichlorobenzophenone (DBP) is readily apparent in the anodic voltammograms of DDT, DDE, Kelthane, and DBA. Similarly the two anodic peaks of DMBP at +1.94 and +2.60V are observed in the anodic voltammograms of MeCE and DMBA and partially in the voltammograms of MeC and DMK.

As the controlled potential electrolyses of DDT and its related compounds proceeded very slowly in anhydrous MeCN, and in an effort to more nearly match natural oxidative degradation conditions, all electrolyses were run with water added to the acetonitrile solvent in an atmosphere of air. The weight of the AgCl precipitated in the anode compartment during the course of an oxidation indicated that an irreproducible amount of chloride was being lost from the α-chloromethyl group of each compound. Chromatographies indicated a multitude of electrolysis products, often between ten to twenty; some of them being heat or light sensitive. Hence the isolation and characterization of only the more abundant electrolysis products was possible. The reported product yields are low as they are based on the amount of pure isolated product obtained after separation and purification remembering in certain cases that incomplete controlled potential electrolyses were carried out in the single-pass flow-through cell or in order to isolate the initial electrolysis product.

Electrochemical oxidation of DDE.—When DDE was electrochemically oxidized in 5% aqueous acetonitrile

Table I. Summary of anodic peak potentials of DDT, methoxychlor, and related compounds at 100 mV/sec *vs.* aqueous SCE

Compound	E_p, V *vs.* SCE
DBP	+2.65
DMBP	+1.94, +2.60
DBA	+2.21, +2.6
DMBA	+1.57, +1.94, +2.60
Kelthane	+2.34, +2.66
DMK	+1.72, +1.88
DDE	+1.98, +2.75, (+2.15 to +2.30)*
MeCE	+1.54, +1.92, +2.60, (+1.57)*
DDT	+2.32, +2.6
MeC	+1.73, +2.6

* An additional wave appearing only at scan rates of 2.5 V/sec or higher.

at +1.74V on a platinum electrode, the major products isolated were DBA in 10-60% yield and DBP in 30-80% yield. The variable yield of DBA can, in part, be explained by the fact that DBA itself is slowly oxidized at +1.74V to DBP. At +2.00V in 5% aqueous MeCN, DDE, in about 10^{-2} F, is electrochemically oxidized to DBP in greater than 95% yield in 3-5 hr as opposed to an average electrolysis time of 20 hr at +1.74V. At the higher controlled voltage of 2.00V, any DBA that may have been initially formed upon electrolysis of DDE, is itself quantitatively oxidized to DBP.

The isolation of DBA from the electrolysis of DDE, along with the cyclic voltammetric data, suggests that DDE may be electrochemically oxidized in an ECE pathway proceeding through an unstable vicinal-glycol (I); this very unstable intermediate would undergo rapid hydrolysis and dehydrochlorination to DBA, or could undergo the loss of the good leaving group, dichloromethylene (CCl_2), to produce the benzophenone DBP. This oxidation of the vicinal-glycol (I) is analogous to the oxidation of benzopinacol to benzophenone (17).

The fact that DBA at 1.74V is oxidized after 20 hr to DBP in only 20% yield (the remaining 80% being the starting material) and the highly irreproducible yields of DBP obtained in the oxidation of DDE at +1.74V, yet the consistent controlled potential coulometry indicating an over-all two-electron oxidation of DDE, suggest a branching pathway to the formation of DBP. Figure 4 depicts such a branching mechanism whereby the hydroxylated cationic species (II) or the vicinal-glycol (I) undergo a purely chemical breakdown to DBP. Such a purely chemical pathway must be a significant alternative, as the oxidation of DDE through DBA to DBP requires the loss of four electrons, not the two that is consistently observed in the coulometry.

An additional anodic voltammetric wave for DDE at approximately +2.2V is apparent at scan rates of 2.5 V/sec or higher. This suggests that a branching reactions sequence occurs that is dependent on the rate of the voltage scan. At slow voltammetric scan rates, an initial over-all two-electron oxidation occurs as depicted by the top line of Fig. 4, while at faster scan rates a stepwise EEC sequence occurs as shown on the left-hand part of Fig. 4. This branching sequence is suggested by a significant increase (within bounds) of the current for the new peak at +2.15V with increasing scan rate.

Electrochemical oxidation of 1,1-dichloro-2,2-bis-(p-methoxyphenyl)-ethylene.—When MeCe was electrochemically oxidized in 5% aqueous MeCN at +1.40V on a platinum electrode, the major products were DMBP in 32-43% yield and the unexpected DMK in 25% yield. While DBA was a major product of the electrochemical oxidation of DDE at lower controlled potential, thin-layer chromatography indicated that no 4,4-dimethoxybenzilic acid (DMBA) was obtained in the electrochemical oxidation of MeCE. The closeness in the anodic peak potentials between MeCE and DMBA, within 0.03V (Table I), indicates that a significant accumulation of DMBA is not to be expected in the controlled potential electrolysis of MeCE. This is in sharp contrast to the 0.23V difference in anodic peak potentials between DDE and DBA, which permitted DBA to be isolated in significant amounts from the large-scale controlled potential electrolysis of DDE.

The isolation of DMK in 25% yield from the electrolysis of MeCE indicated that free chloride in the solution is capable of nucleophilic attack on the deficient intermediates to yield a tri-chloromethyl moiety. As MeCE exhibited cyclic voltammetric behavior similar to DDE, including the appearance of an additional anodic wave at +1.57V at faster scan rates, a branching mechanism similar to that proposed for DDE is proposed for MeCE and is depicted in Fig. 5.

Electrochemical oxidation of DDT.—When DDT was electrochemically oxidized in 5% aqueous MeCN at +2.10V on a platinum electrode, the products identified were DBP in an approximate yield of 25% and and 1,1,1-trichloro-2-(p-chlorophenyl)-2-(4-chloro-2,5-benzoquinone)ethane (DDT-Q) in 10% yield and Kelthane (indicated by thin-layer chromatography and spray tests); however the isolation of the Kelthane was not possible due to the extremely small amount present. The isolation of a significant amount of Kelthane from the large-scale, conventional anodic oxidation of DDT was not expected as the oxidation peak of Kelthane occurs within 0.02V of the one for DDT (Table I). The use of a flow-through cell designed to enable the initial hydroxylated product to be swept away from the electrode before it could suffer further oxidation failed to produce Kelthane. Instead the sole product isolated from the flow-through electrolysis of DDT was DDT-Q.

Cyclic voltammetric data at all scan rates indicated that DDT is oxidized irreversibly followed at higher anodic potential by the prominent oxidation peak for DBP. While a stepwise ECE reaction sequences could be written, a more general over-all two-electron branching scheme is depicted in Fig. 6 to account for the formation of the major products. Thus a nucleophilic attack by water on the dicarbonium ion (III) at the central α-carbon would result in the formation of Kelthane and DBP while a nucleophilic attack by water on the electron-deficient aromatic ring would lead to DDT-Q.

Fig. 4. Electrochemical oxidation of DDE in 5% aqueous acetonitrile at +1.74V vs. SCE on a platinum electrode.

Fig. 5. Electrochemical oxidation of 1,1-dichloro-2,2-*bis*-(*p*-methoxyphenyl)-ethylene (MeCe) in 5% aqueous acetonitrile at +1.40V *vs.* SCE on a platinum electrode.

Fig. 6. Electrochemical oxidation of DDT in 5% aqueous acetonitrile at +2.10V *vs.* SCE on a platinum electrode.

Electrochemical oxidation of methoxychlor.—When methoxychlor (MeC) was electrochemically oxidized in 5% aqueous MeCN at +1.50V on a platinum electrode, the products identified were DMBP in an approximate yield of 35% and dimethoxykelthane (DMK) in 5-30% yield. This is the first report of the isolation and identification of DMK as a degradation product of MeC.

In dry MeCN (0.1F $LiClO_4$ as supporting electrolyte) saturated with Na_2CO_3, the major electrolysis product of MeC was found to be 1,1,1-trichloro-2-(*p*-methoxyphenyl)-2-(3-chloro-4-methoxyphenyl)ethane (3-Cl-MeC) in 20% yield. The production of this chloro-adduct must occur as a result of the nucleophilic attack by chloride ion which is produced by the previous degradation of a trichloromethyl group of another methoxychlor molecule. 3-Cl-MeC was not observed by thin-layer chromatography if the electrochemical oxidation of methoxychlor was carried out in 5% aqueous acetonitrile.

The cyclic voltammetric data and product isolation suggest that methoxychlor is oxidized in a general over-all two-electron scheme in aqueous MeCN as shown in Fig. 7. There was no significant evidence for the production of phenols or of their subsequent oxidation products, the benzoquinones. These products would indicate that a nucleophilic attack by water on the electron-deficient aromatic rings does not significantly occur in electrochemical oxidation. O-dealkylation of the methoxy groups to yield *mono-* or *bis*-phenols are the major, known natural degradation pathways of methoxychlor (Fig. 2). Electrochemical oxidation of either 2- or 4-methoxyphenol involving the hydrolysis of the carbonium ion and the loss of methanol to yield the benzoquinone has been reported (18, 19). Apparently, ring hydrolysis to form a phenol or a benzo-

Fig. 7. Electrochemical oxidation of methoxychlor in 5% aqueous acetonitrile at +1.50V vs. SCE on a platinum electrode.

quinone with dealkylation is not a significant electrochemical oxidation pathway for methoxychlor in 5% aqueous acetonitrile at +1.50V.

Summary

The major electrolysis products identified from the controlled potential electrolyses of DDT, DDE, methoxychlor, and the ethylene of methoxychlor in 5% aqueous acetonitrile solution were hydrolysis products. These products were either alcohols, ketones, benzoquinones, or acids that suggested that nucleophilic attack by water occurred mostly at the electron-deficient carbon located at the central α-carbon of each compound studied. The appearance at higher oxidation potential of a voltammetric wave of the benzophenone for each compound studied attests to this fact. DBA is obtained in good yield from the electrochemical oxidation of DDE, and the never-before reported DMK is obtained in good yield from the electrochemical oxidation of methoxychlor and the ethylene of methoxychlor, MeCe. However, nucleophilic attack by water on the electron-deficient aromatic ring did occur in certain cases as a significant amount of DDT-Q was isolated from the electrochemical oxidation of DDT. In an anhydrous media, a nucleophilic attack by chloride ion onto the electron deficient aromatic ring of methoxychlor was evident.

Anodic Oxidation of Two Polychlorinated Biphenyls

Robert J. Fenn,[1] Karl W. Krantz,[2] and James D. Stuart*

Department of Chemistry, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Although very resistant to environmental oxidative degradation reactions, two specific polychlorinated biphenyls (PCB's) and typical commercial mixtures of PCB's are oxidized at very high anodic potentials at a platinum electrode in a medium of aqueous acetonitrile and tetraethylammonium fluoborate. Isolation of the chlorobiphenylols (or hydroxychlorobiphenyls) formed by initial oxidative hydroxylation reactions and the corresponding benzoquinones, in addition to cyclic voltammetric data, indicate an over-all ECE reaction scheme. Certain of the identified oxidation products of the PCB's studied have never been reported, while others are similar to their known metabolic or photochemical degradation products. This indicates that electrochemistry is a convenient method to study the degradation of these very persistent environmental pollutants, as well as a convenient synthetic route for certain of their key degradation products.

Mixtures of polychlorinated biphenyls (PCB's) have been commercially available since 1929, yet their first identification in environmental samples occurred in 1966. Only in the past few years have their long term persistence and wide dispersal in the environment been recognized. An informative text on the analysis, chemistry, and occurrence of PCB's is now available (1).

PCB's are a class of chemically inert, chlorinated hydrocarbons. PCB mixtures have had widespread commercial use as a result of their following favorable properties: high dielectric constant, high thermal and chemical stability, low vapor pressure, low water solubility, low flammability, and high miscibility with most organic solvents, polymers, and paints (2, 3). Different PCB mixtures, with varying degrees of viscosity and density, have been available in many industrial countries of the world. In the United States, PCB mixtures have been manufactured exclusively by the Monsanto Company and sold under the trade name Aroclor®. Their manufacture involves the large scale chlorination of biphenyl with chlorine gas using Fe or $FeCl_3$ as catalyst. The commercial products are a complex mixture of a large number of PCB isomers. While 209 isomers are theoretically possible, 102 isomers have been separated by gas-liquid chromatography in an Aroclor® mixture (1, 2). In September of 1970, Monsanto placed a voluntary reduction of sales on Aroclors®, and on July 6, 1973 the United States government restricted the use of PCB mixtures in commercial products to only those products that could eventually be disposed of in an efficient manner that would not contribute to the environmental contamination (4). No cheap, practical, safe, or as efficient substitute has been found for PCB mixtures in many commercial applications (5).

In the United States, in the record high year of 1970 in which 43 thousand metric tons of Aroclor® were produced, the most important use of PCB mixtures was as capacitor dielectric materials, commonly called Askarel®. It had been estimated that in past years more than 90% of all capacitors sold (80 million annually) contained Aroclor® mixtures. In addition, PCB mixtures had been widely used as insulation and heat transfer fluids, as hydraulic fluids and lubricants, and as components in plasticizers of paints, sealants, and varnish. Their high thermal stability allows them to be vaporized into the atmosphere in inefficient incinerators thus facilitating their global distribution. It has been estimated that at least one million metric tons of PCB materials have reached the world environment from all sources, domestic and foreign (2).

PCB's had attracted little environmental concern, having often been detected but not identified as extraneous gas chromatographic peaks amongst chloroorganic pesticides, until a series of incidents drew attention to their chronic toxic effects in birds, fish, poultry, mammals, and man (1, 3, 6). In comparison to DDT and its principal degradation product DDE, PCB's are believed to be more resistant to enzymatic and photochemical degradation. This, along with their high lipid solubility, accounts for the "biological magnification," of PCB levels in going up the food chain (2).

Toxicological evidence has suggested that certain of the deleterious effects of foreign commercial PCB mixtures (I) may be due to the presence, in part per millions, of chlorodibenzofurans (III) and chlorodibenzo-*p*-dioxins V (7). The origin of (III) and (V), not only in foreign PCB mixtures but also in domestic commercial chlorophenol mixtures (IV), may be due to poorly developed, commercial purification procedures. For example, it had been reported that certain foreign PCB mixtures had been purified by the addition of lime or potassium hydroxide to neutralize the hydrochloric acid byproduct, or by blowing air over the heated crude, commercial mixture followed by distillation under reduced pressure (7, 8). Figure 1 shows PCB's (I), chlorobiphenylols or hydroxychlorobiphenyls (II), chlorophenols (IV) with their postulated alteration routes to the very toxic chlorodibenzofurans (III) and chlorodibenzo-*p*-dioxins (V).

Fig. 1. PCB's, hydroxychlorobiphenyls, and possible transformation routes to chlorinated dibenzofurans and chlorinated dibenzo-*p*-dioxins.

Key words: chlorobiphenylol, hydroxychlorobiphenyl, hydroxylation, PCB's.

Recent efforts have focused on identifying the principal metabolites of PCB's. It has been shown that hydroxychlorobiphenyls (II) are the most prominent metabolites in animals, microorganisms, and plants (1). Thus from rabbits, the principal urinary metabolites of 2,5,2′,5′-tetrachlorobiphenyl, a predominant compound in a commercial PCB mixture, is the 3-OH and the 4-OH isomer as well as a 3,4-dihydroxy-3,4-dihydro-compound, suggesting that enzymatic hydroxylation occurs through an arene oxide intermediate with an oxygen attachment at both the open 3- and 4-positions (9).

It is the 3-hydroxy-2,5,2′,5′-tetrachlorobiphenyl that is isolated as the major hydroxychlorobiphenyl product from the electrochemical oxidation of 2,5,2′,5′-tetrachlorobiphenyl. Thus electrochemistry is a convenient method for the synthesis of the hydroxychlorobiphenyls, as few of these metabolic products are available. In addition, there are few good, organic synthetic methods available that lead to a single hydroxy-isomer in good yield (10). But it must be emphasized that our synthetic method is far different than the enzyme-assisted, natural alteration of the same PCB starting material.

Beland *et al.* have recently reported that a stepwise loss of chloride from a specific PCB by reductive voltammetry is characteristic enough to provide analytical identification of a specific pure PCB isomer (11, 12).

Experimental

Chemicals.—The following chemicals were used as received after their purity had been checked by thin-layer or gas-liquid chromatography or they were purified as described below. 4,4′-Dichlorobiphenyl (DCB) from Aldrich Chemical Company, about 97% pure, was purified by vacuum sublimation, m.p. 146°-148°C [Lit. 146°, 148° (1)]; 2,5,2′,5′-tetrachlorobiphenyl (TCB) was prepared in very high yield through the highly toxic 2,5,2′,5′-tetrachlorobenzidine (11) and in much lower yield by the Ullman coupling reaction (13), m.p. 84.5°-85.5°C [Lit. 86°-87°C (1)]; decachlorobiphenyl, 99%, commercially available from Analabs Incorporated, North Haven, Connecticut; 2,3,7,8-tetrachlorodibenzo-*p*-dioxin kindly provided by E. H. Blair, Dow Chemical U.S.A., Midland, Michigan; perchlorination kit (Analabs PCR-A) used to fully chlorinate biphenyl, dibenzofuran, and dibenzo-*p*-dioxin; commercial Aroclor® mixtures were kindly provided by W. B. Papageorge, Monsanto Company, St. Louis Missouri.

The following compounds were prepared by organic synthetic methods as authentic samples to which the electrolysis products were compared. 4,4′-dichloro-2-biphenylol (or 2-hydroxy-4,4′-dichlorobiphenyl) prepared by making the diazonium salt of 2-methoxy-4-chloroaniline with isoamyl nitrite followed by a free radical coupling reaction with chlorobenzene (10). After washing and a vacuum distillation, the fraction containing the chloromethoxybiphenyls was demethylated with boron tribromide (13). The various hydroxychlorobiphenyl isomers were isolated first by open column chromatography from silica with toluene as eluent then by semipreparative, high pressure liquid chromatography on porous silica 37-75μ, in columns 10 ft by 7 mm ID, with toluene as solvent in certain cases using the Waters 201 liquid chromatograph in the recycle mode. Careful evaluation of their infrared spectra (Perkin Elmer 337) using 0.2 mm thick NaCl liquid cells with carbon tetrachloride and carbon disulfide as solvents showed the first eluted isomer to be the 2,4′-dichloro-4-biphenylol, then the 2′,4-dichloro-2-biphenylol, followed by the desired 4,4′-dichloro-2-biphenylol.

As 2,5,2′,5′-tetrachlorobiphenyl is a more symmetrical compound, a similar organic synthesis reaction of 2,5-dichloroaniline with 2,5-dichloroanisole yielded after demethylation (13) and similar chromatographic separation by semipreparative liquid chromatography, then infrared spectroscopy for structure elucidation, in order of elution with toluene, 2,5,2′,5′-tetrachloro-6-biphenylol, followed by 2,5,2′,5′-tetrachloro-3-biphenylol, then 2,5,2′,5′-tetrachloro-4-biphenylol. In addition, the structure of the major hydroxylated product from the electrochemical oxidation of 2,5,2′,5′-tetrachlorobiphenyl was confirmed by comparing its chromatographic and infrared absorption spectra to that of an authentic sample of 3-hydroxy-2,5,2′,5′-tetrachlorobiphenyl kindly provided by Gardner (9). He has identified the 3- and the 4-isomers as those being eluted in the urine of rabbits, as well as performing the organic synthesis and structure elucidation of each of the isomers. He has reported a convenient thin-layer chromatographic separation of the three isomers compared to 2,5-dichlorophenol as an internal standard (9).

The following compounds were isolated as major electrolysis products from the large-scale controlled potential electrolyses of pure PCB isomers. Those marked by an asterisk have previously not been reported in the available literature. Each compound had infrared, nuclear magnetic resonance and mass spectral data consistent with the assigned structure (14). 2-Chloro-5-(*p*-chlorophenyl)-1,4-benzoquinone (VI) (15, 16); 2-(*p*-chlorophenyl)-1,4-benzoquinone (VII) (16, 17). Both (VI) and (VII) were compared to authentic samples kindly provided by Bagli (16); 2,5-dichloro-3-(2,5-dichlorophenyl)-1,4-benzoquinone (IX)*; *bis*-2,5-dichloro-1,4-benzoquinone (X)*; 2-chloro-3-(2,5-dichlorophenyl)-1,4-benzoquinone (XI)*; 2-chloro-6-(2,5-dichlorophenyl)-1,4-benzoquinone (XII)*.

Tetraethylammonium fluoborate, Et_4NBF_4, was prepared by reacting Et_4NBr and HBF_4 in distilled water (18) followed by washings with ether, two recrystallizations with ethanol and one with distilled water, and drying on top of an oven and in an evacuated drying pistol at 100° with P_2O_5 as dessicant for 24 hr. This supporting electrolyte gave a low residual current to at least +3.5V *vs.* SCE. Upon the addition of progressive amounts of water to 0.1F Et_4NBF_4 in MeCN solvent, an irreversible wave first appeared with a peak at +2.6V followed by an electrolyte breakdown at around + 2.9V; the breakdown progressively shifted to lower anodic potentials as additional amounts of water were added (19).

All instrumentation, procedures, and reagents including the use of the single-pass, flow-through electrolysis cell were as described in the previous paper (20) except for what follows. Because of the high anodic potentials required to cause the electrochemical oxidation of PCB's, tetraethylammonium fluoroborate, Et_4NBF_4, was used as the supporting electrolyte in the MeCN solution for the cyclic voltammetric studies. The use of dual cells and potentiostats were required to electronically subtract the appreciable residual current from the compound's faradaic current (21). All controlled potential electrolyses were carried out in a medium of 2-5% aqueous MeCN, with 0.1F Et_4NBF_4 and 1-2% in 0.2F $AgClO_4$. The $AgClO_4$ was added to remove the irreproducible amount of chloride ions eliminated during the electrolysis of each PCB isomer and made the formation of more highly chlorinated biphenyls less likely, thereby reducing the number of electrolysis products. Visualization of the products separated by thin-layer chromatography was accomplished by ultraviolet light for the PCB's, by 2,4,7-trinitro-9-fluorenone for the chlorobiphenylols (22), and by 2,4-dinitrophenylhydrazine for the benzoquinones. To determine whether oxidative electrochemical conditions used in this study converted the PCB isomers (DCB, TCB and decachlorobiphenyl) to the very highly toxic chlorodibenzofurans (III) or chlorodibenzo-*p*-dioxins (V), a gas-liquid chromatographic analysis was performed. Following the method of Williams and Blanchfield (23), the impure mixture

of an electrolysis product was fully chlorinated using the chlorination kit (Analabs); the relative retention times of the separated perchlorinated products were then compared with authentic retention times of octachlorodibenzofuran or octachlorodibenzo-*p*-dioxin. No conversion of the three PCB isomers studied to the more toxic compounds was evident by gas-liquid chromatography. It is estimated that as little as 0.1% conversion would have been detected.

Results

Cyclic voltammetry was initially used to determine the approximate potential at which to run the ensuing controlled potential electrolyses. Table I shows the anodic half-peak potentials for several of the commercial Aroclor® mixtures. (The last two digits in the Aroclor® number indicates the average chlorine percentage by weight.) A general trend toward higher anodic potential with increasing percentage of chlorine is evident. This trend is to be expected, based on the electron-withdrawing effect of the chlorine substituents. The significant prewaves observed in the voltammograms are thought to be due to the oxidation of the lower chlorinated PCB fractions in the mixture; each mixture has been reported to contain between 40 to 80 different isomers (1).

Table II lists the half-peak potentials of those pure PCB isomers studied, along with those of benzene, biphenyl, and 4,4'-dimethoxybiphenyl for comparison. For the pure chlorinated biphenyl isomers. a similar trend toward higher oxidation potentials with increasing chlorine content is evident. Table III shows the relatively low oxidation potential of several commercially available chlorophenols and hydroxybiphenyls; this table illustrates that any hydroxychlorobiphenyl (II) formed in the large-scale electrolysis of PCB isomers would be further oxidized at the controlled potentials used for the oxidation of the PCB.

The diagnostic criteria of Nicholson and Shain were used to aid in suggesting the over-all major electrochemical pathway of the three pure PCB isomers in

Table I. Voltammetry of Aroclors®*

Arochlor®	$E_{pk_{a/2}}$
1232	2.23 (prewave)
1242	2.39 (prewave)
1254	2.42 (prewave)
1260	2.43 (no prewave)

* All are anodic potentials measured *vs.* aqueous SCE

Table II. Voltammetry of biphenyls*

Biphenyls	$E_{pk_{a/2}}$

3-Hydroxybiphenyl	1.47
4-Hydroxybiphenyl	1.24
3-Chloro,4-hydroxybiphenyl	1.30

* All are anodic potentials measured *vs.* aqueous SCE

Table II. For each PCB isomer only one irreversible anodic wave is evident; its location tended to shift to higher anodic potentials, while its current function tended to decrease, as the sweep rate was increased over three decades of sweep rate (0.1-100 V/sec). These behavior patterns are suggestive of an electron transfer followed by a fast, irreversible chemical reaction [case VI of Ref. (24)] or an ECE pathway [either case I-I or I-R of Ref. (25)]. Adding increasing amounts of water to the solution caused the half-peak potentials at a scan rate of 0.1 V/sec to shift to a less anodic potential and the current function to double. This behavior is in agreement with a proposed ECE mechanism whereby the increasing amounts of water, acting as a nucleophile, caused the rate of the intervening chemical reaction to be significantly increased, and increased the likelihood of the second charge transfer occurring at lower anodic potential.

As expected, the fully chlorinated decachlorobiphenyl showed the appearance of a chlorine/trichloride redox system at +1.1 and +1.7V *vs.* SCE on the second and third cyclic voltammetric scans (26). The final electrolysis solution smelled strongly of HCl, and the thin-layer chromatography and infrared spectroscopy indicated the presence of several benzoquinones; all indicating that a significant loss of chloride ion from the decachlorobiphenyl had occurred. No attempt was made to further identify the electrolysis products due to the small amount of decachlorobiphenyl that was available for electrolysis.

In an effort to more nearly match natural oxidative degradation conditions, all electrolyses were run with water added to the acetonitrile solvent. The weight of the AgCl precipitated in the anode compartment during the course of an oxidation indicated that an irreproducible amount of chloride was being lost from the PCB compound. The reported product yields are low as they are based on the amount of pure isolated product obtained after separation and purification from incomplete controlled potential electrolyses.

Electrochemical oxidation of 4,4'-dichlorobiphenyl.—When 4,4'-dichlorobiphenyl (DCB) was electrochemically oxidized in 2.5% aqueous MeCN between +1.9 to +2.1V *vs.* SCE on a platinum electrode, with Et_4NBF_4 and $AgClO_4$ added, the major electrolysis products isolated were: 2-chloro-5-(*p*-chlorophenyl)-1,4-benzoquinone (VI) in 25-30% yield; 2-(*p*-chlorophenyl)-1,4-benzoquinone (VII) in 4-6% yield; a 4,4'-dichloro-2-biphenylol (VIII) in 4-6% yield; and a trichlorobiphenyl in 2% yield. Figure 2 shows the general electrochemical oxidation scheme of 4,4'-dichlorobiphenyl. [Hutzinger has shown that 4,4'-dichloro-3-biphenylol is the metabolic product of 4,4'-dichlorobiphenyl in rats and goats (1, 10, 27).]

Electrochemical oxidation of 2,5,2',5'-tetrachlorobiphenyl.—When 2,5,2',5'-tetrachlorobiphenyl(TCB) was electrochemically oxidized in 2.5% aqueous MeCN be-

Fig. 2. General electrochemical oxidation scheme of 4,4'-dichlorobiphenyl in 2.5% acetonitrile at +1.9 to +2.1V *vs.* SCE on a platinum electrode.

tween +2.0 to +2.7V *vs.* SCE on a platinum electrode with Et_4NBF_4 and $AgClO_4$ added, the major electrolysis products isolated were: 2,5-dichloro-3-(2,5-dichlorophenyl)-1,4-benzoquinone (IX) in 13-17% yield, *bis*-2,5-dichloro-1,4-benzoquinone (X) in 4% yield, 2-chloro-3-(2,5-dichlorophenyl)-1,4-benzoquinone (XI) in 2% yield, 2-chloro-6-(2,5-dichlorophenyl)-1,4-benzoquinone (XII) in 2% yield, and 3-hydroxy-2,5,2',5'-tetrachlorobiphenyl (XIII) in from 1 to 6% yield. Figure 3 shows the general electrochemical oxidation scheme of 2,5,2',5'-tetrachlorobiphenyl. [Gardner has shown that the 3-hydroxy- and the 4-hydroxy-2,5,2',5'-tetrachlorobiphenyl are the metabolic products from the rabbits (9).]

Discussion

The formation of *p*-quinones as the major electrolysis products from the electrolytic oxidation of aromatic hydrocarbons is well known. The quinones can be shown to be formed by further oxidation of their hydroxy intermediates. Several studies on the oxidation of phenols confirm this pathway (28-31). In this present study, the isolation of the hydroxychlorobiphenyls (VIII) and (XIII) constitute strong evidence for the general electrochemical oxidation schemes of 4,4'-dichlorobiphenyl and 2,5,2',5'-tetrachlorobiphenyl shown in Fig. 2 and 3. As seen by the voltammetric half-peak potentials in Table III, hydroxychlorobiphenyls are oxidized about 1.0V less anodic than the chlorobiphenyls and would be further electrochemically oxidized at the controlled potentials employed to oxidize the PCB's. Thus the isolation of hydroxychlorobiphenyls in exhaustive electrolyses is quite fortuitous.

In the single-pass flow-through cell, wherein the initial hydroxylated product is more effectively flushed-and kept-away from the working electrode, higher yields (up to 10%) of the hydroxychlorobiphenyl was obtained. In the case of the 2,5,2',5'-tetrachlorobiphenyl about 80% of this PCB was recovered and could be recycled through the flow cell. Although the yields may not appear to be impressive, the ability to be able to prepare in a short time the hydroxy-adducts of such slow-to-degrade chemicals warrants more use of flow-through cells in small scale electroorganic synthesis.

As a result of product isolation and the cyclic voltammetric data, a general ECE oxidation scheme appears most reasonable for the electrochemical oxidation of 4,4'-dichlorobiphenyl and 2,5,2',5'-tetrachlorobiphenyl in aqueous MeCN solution. Thus an initial two-electron oxidation followed by hydrolysis would result in the formation of a hydroxychlorobiphenyl (a chlorophenyl phenol). At the controlled working electrode potential, the hydroxychlorobiphenyl would be rapidly further oxidized to the corresponding *p*-benzoquinone. The identification of various benzoquinones and the appearance of numerous minor electrolysis products, seen on the thin-layer chromatographic plate, attest to the complexity of the electrochemical oxidation processes. Elimination of the chloro group, as measured by the weight of AgCl precipitate collected from the anode compartment, occurred to a variable extent.

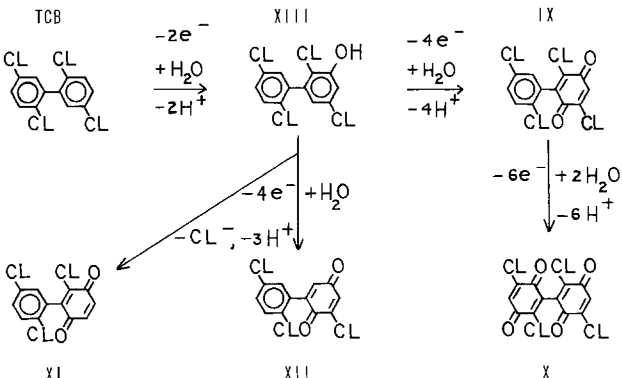

Fig. 3. General electrochemical oxidation scheme of 2,5,2',5'-tetrachlorobiphenyl in 2.5% aqueous acetonitrile at +2.0 to +2.7V *vs.* SCE on a platinum electrode.

While most biologically significant hydroxylations involve the reaction with molecular oxygen (32), with oxygen-transition metal complexes (33), or with hydroxyl or perhydroxyl radicals (34), nucleophilic addition of water to electron deficient centers cannot be excluded and, in fact, has been proven by showing that the O^{18} labeled water is added in an enzyme hydroxylation reaction to nicotinic acid (35). The "awkward hydroxylation of aromatic rings" (34) induced by enzymatic, photochemical, and now electrochemical methods is an important oxidative degradation route of environmentally persistent chemicals. But, it must be emphasized that the high anodic pathways used in this present study of the electrochemical oxidation of PCB isomers, are no doubt different than the enzyme-assisted, natural degradation route of these same chemicals.

Chronoamperometric Studies of Flash Photoemission at a Mercury Electrode

R. P. Baldwin[1] and S. P. Perone

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

ABSTRACT

Flash irradiation and high speed potentiostatic monitoring have been utilized to study the electrochemical processes associated with the photoemission of electrons from a mercury electrode into various electrolyte solutions. Conditions in which no efficient hydrated electron scavenging species was present, as well as conditions employing $10^{-3}M$ concentrations of NO_2^-, H_3O^+, NO_3^-, and acetophenone, were examined. The magnitudes of the resulting flash photocurrents and their variation with electrode potential agreed qualitatively with results obtained previously using continuous radiation or coulostatic monitoring techniques. The temporal behavior of the currents showed that they were capacitive in nature, resulting from double layer recharging in response to the electron pulse caused by the extremely rapid electron emission and scavenging reactions. The charging current model appears valid for the wide variety of scavenging situations considered in this work.

The photoemission of electrons from a mercury electrode into a concentrated electrolyte solution, and the subsequent chemical and physical processes that accompany it, have in recent years been the subject of extensive experimental and theoretical investigations (1-6). The detailed succession of events which occurs upon electron emission has now been determined for a large number of chemical systems by means of a variety of experimental techniques. Specifically, the photoemission phenomenon has been shown to entail, sequentially, electron emission, thermalization, and hydration, followed by the competing processes of chemical scavenging and electrochemical oxidation.

In general, the instrumental approaches employed to generate large-scale photoemission and monitor the resulting events can be placed into one of two classifications. In the first, continuous or long-term electrode illumination is utilized to produce steady-state photocurrents (1, 7-13). Measurements are made by mechanically chopping or electrically modulating the light source to provide both a photoemission and a reference signal, and monitoring the corresponding currents with a potentiostatic or polarographic system. Such methods are well suited for the observation of the net currents associated with continuous electron emission, but are of little use for the direct study of transient photoemission processes.

The alternate experimental approach entails the use of a very short duration flash, or pulsed light, source to generate transient electron emission which can be followed directly to provide kinetic and mechanistic information (3, 14-17). Because of the large amount of noise pickup resulting from the flash discharge and the concomitant difficulties in maintaining adequate potential control at short times, potentiostatic chronoamperometric measurements have not been very useful previously. Rather, the monitoring of subsequent potential changes induced at the emitting electrode under coulostatic conditions has been employed (3, 17). The difficulties inherent in the coulostatic approach include the extremely low signal levels and the sometimes indirect nature of the measurements involved.

Thus, the development of high speed potentiostatic techniques suitable for the investigation of the photoemission process, and subsequent hydrated electron (e_{aq}^-) chemistry, is certainly desirable. Furthermore, previous work in this laboratory has involved the photoelectrochemical study of rapid photolytic processes initiated by flash irradiation (18-21). Since these studies have entailed the potentiostatic monitoring of faradaic currents occurring at short times following the flash, an understanding of the direct effects of

[1] Present address: Department of Chemistry, University of Louisville, Louisville, Kentucky 40208.
Key words: photoelectrochemistry, photoemission, photopolarography.

photoemission in a potentiostatic system is imperative. Accordingly, the objectives of the work reported here were to develop flash photoelectrochemical instrumentation capable of observing photoemission currents potentiostatically, and to construct a working model capable of accounting for these observations in terms of the specific chemical and physical processes known to occur during and after the photoemission event. This required the optimization of the flash irradiation and potentiostatic monitoring systems and the analysis of photoemission results obtained experimentally under a wide range of chemical and electrochemical conditions.

Experimental

Flash radiation.—The flash system employed was essentially the same as has been previously reported (21). The principal difference was that a spherical mirror was used in place of the linear parabolic reflector to permit more efficient collection and transmission of the flash irradiation to the hanging mercury drop electrode, as is shown in Fig. 1. Additional electromagnetic shielding was provided by enclosing the flash lamp, trigger circuit, and all the associated electronics in a separate, grounded faraday cage constructed from copper screening.

The lamp used was a Suntron-6C xenon flash lamp (Xenon Corporation, Medford, Massachusetts). It is a high intensity, fast-extinguishing micropulse flashtube capable of dissipating a maximum energy of 100j with a pulse duration of approximately 10 μsec. The capacitor bank discharged during the flash consisted of a total of 4 μf charged to a limit of 7000V (LK100-405YND, Plastic Capacitors, Incorporated, Chicago). Since it was especially important to know with certainty the precise flash shape and duration associated with this specific setup, the flash output was monitored directly with a Raytheon 929 vacuum photodiode; the results indicated that the flash possessed a width at half-maximum of 8 μsec and exhibited no significant tailing effects.

A further factor often complicating the study of faradaic photocurrents due to electron emission is the occurrence of nonfaradaic currents caused by the irradiation of the electrode/solution interface and related to changes in interfacial temperature and consequent structural changes of the electrical double layer (22). Therefore, it was normally found useful to remove all high wavelength radiation from the flash output and allow only the lower wavelength components to reach the electrochemical cell. Accordingly, a u.v.-transmitting, visible-absorbing Corning 7-54 glass filter was routinely inserted into the flash path to prevent transmission of light of wavelengths longer than 410 nm. This precaution served to attenuate the so-called "thermal" photocurrents (22) to a degree, but did not eliminate them entirely.

Instrumentation.—The cell, electrodes, potentiostat, and general operating procedures were all similar to those described earlier (21). All experimental current-time measurements were made using a Hewlett-Packard (Palo Alto, California) Model 141A oscilloscope with a Model 1421A time-base generator and a Model 1402 dual-trace amplifier. Oscilloscope traces were recorded on a Hewlett-Packard Model 197A Polaroid camera. Oscilloscope triggering was synchronized with the initiation of the flash by means of a phototransistor (PT-100, Fairchild Semiconductor, Mountain View, California) to ensure that the initial times for all measurements corresponded to the beginning of the flash itself.

A typical example of a constant potential chronoamperometric photoemission experiment is shown in Fig. 2. Each experiment consisted of two separate runs: a "blank" or noise run generated by placing an opaque shutter between the flash lamp and the emitting electrode, and a "flash" trace generated by removing the shutter and allowing photoemission to occur. Any current present in the blank trace corresponded only to flash-induced noise, while the flash signal contained the same noise effects superimposed on the photoemission-related currents. Consequently, it was the difference between the flash and blank traces that was used as a measure of the photoemission current of interest. Because of the finite width of the flash and the substantial amount of rf noise pickup still present upon flash discharge, transient current measurements were never considered at times earlier than 15 μsec after the start of the flash.

Reagents.—All chemicals used were reagent grade. Water was deionized by passage through a mixed-bed ion-exchange column and doubly distilled. Solvent-saturated, deoxygenated high purity nitrogen was used to deaerate all solutions prior to irradiation and was allowed to flow continuously over the solution surface during all experimentation.

Results and Discussion

General.—The over-all sequence of events known to occur upon electron photoemission is summarized in Fig. 3. When light of sufficiently low wavelength is incident on a mercury surface that is held at a suitably cathodic potential, electrons are emitted and undergo very rapid thermalization and hydration.[2] Once hydrated, the electrons are free either to react chemically with any electron-accepting scavenger (S) present in

[2] The occurrence of "dry" (nonhydrated) electron reactions is a possibility which may be significant at high scavenger concentrations (>1 mole/liter). In the experiments described here, the scavenger concentration never exceeded $10^{-3}M$; hence all electrons are considered to undergo hydration prior to any scavenging or return to the electrode.

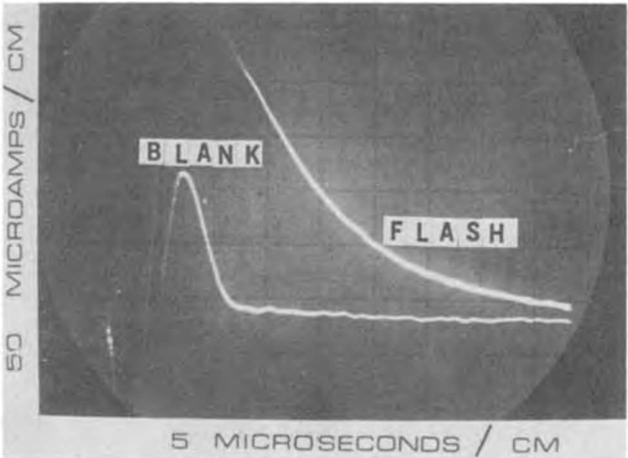

Fig. 2. Continuous potentiostatic analysis following flash irradiation. Analysis of $NaNO_2$ solution ($1.0 \times 10^{-3}M$, 1.0M KCl) at $-1.700V$ vs. SCE. Upper trace corresponds to flash current observed with irradiation, and the lower trace illustrates the blank signal with flash, shutter closed.

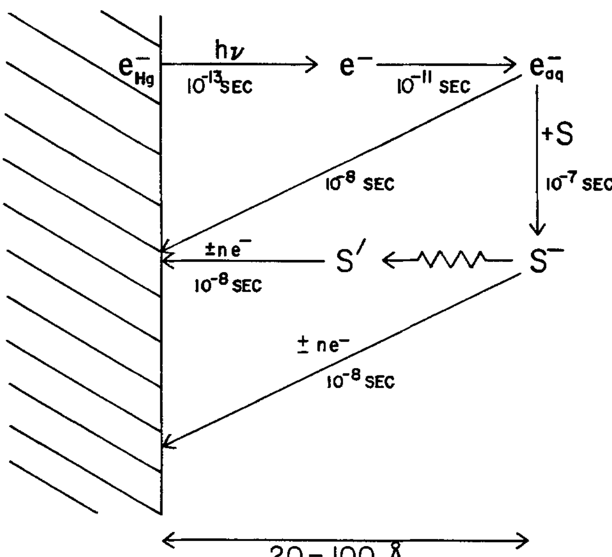

Fig. 3. Processes occurring upon electron photoemission

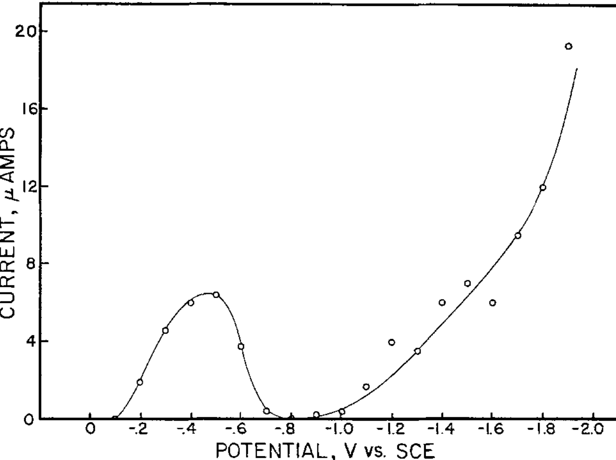

Fig. 4. Current-voltage profile from continuous potentiostatic analysis. 1.0M KCl solution. Currents represent values measured at 15 μsec after initiation of the flash.

solution near the electrode surface or to diffuse back to the electrode surface and return through an electrochemical oxidation process. Similarly, the primary scavenging product (S^-) may undergo further chemical reaction or may participate, along with any secondary scavenging products (S'), in possible redox processes at the electrode. All of these phenomena take place in solution either at or very near the mercury surface and occur at relatively rapid rates compared to the time scale of the flash and the time-constant of the electrochemical cell.

The net effect of all of these phenomena depends heavily on the presence or absence of an efficient scavenging species in solution, its scavenging rate constant, its concentration, and the identity and stability of its primary and secondary scavenging products. When no adequate hydrated electron-accepting species is present, or when the scavenging products are themselves oxidizable, nearly all of the photoemitted electrons ultimately return to the electrode; and there is very little net electron loss. But when scavengers which form products that can be electrochemically reduced are present, there is a net loss of at least two electrons for every one that is emitted and scavenged. Furthermore, the temporal characteristics observed for the photoemission processes are directly dependent on the rates of formation and decay of the scavenging products involved. Accordingly, the experimental approach taken in this work consisted principally of observing and interpreting the photoemission currents resulting from the presence of a number of different scavengers and scavenging conditions.

Fortunately, the products and mechanisms of several scavenging species have previously been determined (23). A list of the scavengers employed in this work and some of their relevant characteristics is provided in Table I. Each scavenger and the flash photocurrents observed with each will be discussed in turn.

Table I. Characteristics of important hydrated electron scavengers

Scavenger	$k_{e^-_{aq}}$ (M^{-1} sec^{-1})	Products	Product electroactive?
Electrolyte	$< 10^{+6}$		
NO_2^-	4.6×10^9	NO	Yes; reducible (n = 1)
H_3O^+	2.2×10^{10}	H	Yes; reducible (n = 1)
NO_3^-	8.5×10^9	NO_2, OH	Yes; reducible (n = 1)
Acetophenone	$10^9 - 10^{10}$	$CH_3—C(O^-)—C_6H_5$	Yes; oxidizable (n = 1)

No scavenger.—The simplest and most straightforward photoemission scheme occurs, of course, when no efficient hydrated electron scavenger is present and the solution contains only "inert" electrolyte (such as KCl, NaCl, or Na_2SO_4). In such situations, no scavenging should take place; and all or most of the electrons emitted should return to the electrode via an electrochemical oxidation step.

When such solutions were flashed, only very small photocurrents were observed experimentally. These currents were cathodic in direction, indicating a net loss of electrons from the hanging mercury drop electrode. Furthermore, their magnitude was found to be dependent on the electrode potential, with the observed currents becoming gradually larger at increasingly cathodic potentials.[3] A corresponding current-voltage profile is shown in Fig. 4.

This behavior is all well accounted for on the basis of the photoemission model described thus far. Since most of the electrons, once photoemitted, are thought to return immediately to the electrode, the net currents expected should be relatively small in magnitude. The fact that even a small number of electrons do indeed fail to return can be explained by the possible slow reaction of e_{aq}^- with a trace electron-scavenging impurity, with the electrolyte species, with water molecules, or perhaps with another e_{aq}^- (1, 17). In addition, the observed potential dependence is analogous to that previously noted for photoemission phenomena in both flash and continous radiation experiments (4, 5), and is due to the lowered work function and, therefore, higher probability for electron emission at higher cathodic potentials.

Scavengers present.—Nitrite and hydrogen ions.—Both NO_2^- and H_3O^+ have two important scavenging properties that allow them to be grouped together: They both react with e_{aq}^- at nearly diffusion-controlled rates, and on reaction they both rapidly form products that undergo a diffusion-controlled one-electron reduction process within the relevant potential range. Upon scavenging, NO_2^- rapidly decomposes ($t_{1/2} < 2$ μsec) to yield NO, which is known to be reduced at potentials more cathodic than −1.1V *vs.* SCE (24). Similarly, the immediate scavenging product of H_3O^+ is thought to be the hydrogen atom which itself is reduced more cathodic than −0.8V *vs.* SCE (11).

When solutions containing these ions were flashed, extremely large cathodic currents were observed (as shown in Fig. 2). The potential dependences, however, were approximately the same as that previously ob-

[3] The photocurrents referred to here are those occurring at potentials more negative than −0.8V. The small cathodic currents occurring between −0.1 and −0.7V correspond to the "thermal" currents referred to earlier. They do not appear to be related to photoemission at all (22).

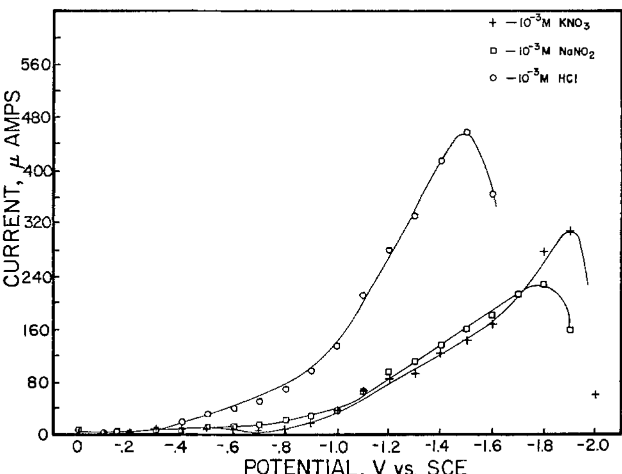

Fig. 5. Current-voltage profiles from continuous potentiostatic analysis. 1.0 × 10^{-3}M solutions of various scavengers (1.0M KCl). Currents represent values measured at 15 μsec after initiation of the flash.

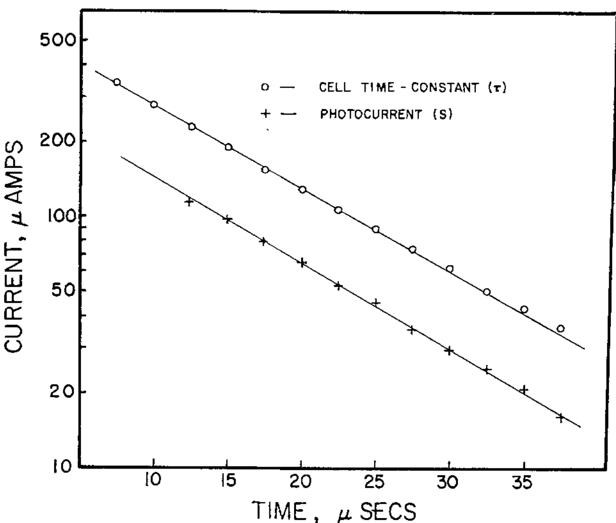

Fig. 6. Log current vs. time plots for both potential step and photoemission currents. 1.0 × 10^{-3}M $NaNO_2$ solution (1.0M KCl) at −1.700V vs. SCE. The upper trace represents the charging current resulting from a 20 mV potential step input, and the lower trace corresponds to the flash photocurrent resulting under constant potential conditions.

served with no scavenger in solution, as can be seen from the current-voltage profiles represented in Fig. 5.

The most interesting and unexpected property of the NO_2^- and H_3O^+ photocurrents was their similar time dependence. Upon observing lifetimes and decay rates of the currents generated for both scavengers under a wide range of solution conditions, it became apparent that their temporal behavior was determined directly by the magnitude of the electrochemical cell time-constant (τ) prevailing for the particular experimental conditions. At low cell time-constant values, the photocurrents were short-lived; but as τ was lengthened, the photocurrent lifetimes increased accordingly. Similar results were obtained independently of the method used to control the value of τ. It was of no consequence whether τ was manipulated chemically, by changing the electrolyte concentration, or electronically, by externally increasing the magnitude of the uncompensated resistance.

Such cell time-constant time dependence represents behavior that is typically characteristic of the charging current generated in routine potential-step experiments. In fact, the customary method employed in the determination of τ values consists of applying a small amplitude potential step to the potentiostat input, measuring the subsequent charging current that flows, and plotting the logarithm of that current as a function of time. The resulting plot should be linear, and the reciprocal of its slope is related to the value of the cell time-constant. Such a cell time-constant plot of current resulting from the input of a 20 mV potential step to a nitrite-containing solution is shown in Fig. 6. When the same log plot was made of the photoemission current that occurred upon flashing an identical NO_2^- solution under constant potential conditions, a nearly identical graph was obtained. The plot was linear; and, when a "photocurrent time-constant" (S) was calculated from the reciprocal of its slope, a value extremely close to τ was obtained. Such a plot is also shown in Fig. 6.

Similar plots were made at several potentials for NO_2^- and H_3O^+ solutions containing electrolyte concentrations ranging from 1.0M to 0.01M and proved to be linear in every case. Further, the S values, reflecting the photocurrent lifetime calculated from log plots, without exception conformed closely to the τ values measured for the identical solution under identical instrumental conditions. These results are summarized in Table II. Furthermore, linear log plots and clear correlation of S and τ values were also found when the uncompensated resistance, and hence the cell time-constant, was artificially increased by inserting an external resistance between the working electrode and ground. For example, when an external resistance of 66.5Ω was employed, values of 39.9 and 40.2 μsec were determined for τ and S, respectively.

To all outward appearances, then, the photoemission currents monitored at constant potential following flash irradiation behaved as the classical charging currents that are generated routinely in potential-step experiments. The most convenient explanation is that the observed "photocurrents" themselves are primarily charging currents. There is no other apparent reason for them to decay according to an exponential time dependence in such close conformity to the prevailing cell time-constants. The key to explaining how the sequence of photoemission processes, known to occur as described in Fig. 3, is translated into charging current lies in the rapid rates at which the processes take place. When NO_2^- or H_3O^+ solutions are flashed, electron emission, scavenging, and scavenging product reduction all occur within a time span of less than 2 μsec, certainly at a much faster rate than the instrument can respond, even with a cell time-constant of 10 μsec. As a result, all the photoemission and subsequent events are virtually coincident with the flash

τ and S values are in units of microseconds.

and have the net effect of depositing a large number of electrons into solution at the electrode surface. The immediate effect on the cell of such an "instantaneous" charge pulse is a rapid discharge of the double layer. The subsequent double layer recharging, provided by the potentiostat and limited by the cell time-constant, actually constitutes the long term "photocurrent" observed experimentally.

According to this model, the currents that we have termed photoemission currents (since they have their origin in actual photoemission processes) are capacitive in nature; and the time dependence that such photoemission currents are expected to exhibit should be close to that determined by the cell time-constant. Thus, the fact that several S values listed in Table II, especially those for H_3O^+ and those measured at the lower electrolyte concentrations, are somewhat faster than the corresponding values of τ calls for explanation. A possible rationalization is that the τ values measured under nonflash conditions (as explained earlier) may not accurately reflect the actual cell time-constant that exists during and shortly after the flash, while photoemission and scavenging are taking place. Conceivably, the deposition of a large number of electrons near the electrode surface and the subsequent processes that occur cause a temporary variation in either the uncompensated solution resistance or in the capacitance of the double layer. Such an explanation is supported, qualitatively at least, by the following experimental observations: the discrepancies between S and τ seem to be less significant at higher electrolyte concentrations, where the scavenging species itself plays only a minor role in determining τ; the discrepancies are more significant for H_3O^+, where its special mobility and conductivity allow it to play a larger role in determining τ; and there are no discrepancies in cases where an external resistance is employed to fix τ artificially.

Nitrate ion.—The NO_3^- ion is similar to NO_2^- and H_3O^+ in that it too is a nearly diffusion-controlled hydrated electron scavenger and that the final product of its scavenging also can undergo reduction throughout the appropriate potential range. The specific mechanism by which NO_3^- scavenging takes place has been clarified recently by Grätzel *et al.* (25) using pulse radiolytic techniques, and is summarized by the following series of reactions

$$NO_3^- + e_{aq}^- \rightarrow NO_3^{2-} \qquad [1]$$

In acidic solution

$$NO_3^{2-} \overset{H^+}{\rightleftharpoons} HNO_3^- \overset{H^+}{\rightleftharpoons} H_2NO_3 \qquad [2]$$

$$HNO_3^- \xrightarrow{t_{1/2} = 3\ \mu\text{sec}} NO_2 + OH^- \qquad [3]$$

$$NO_2 \rightarrow \text{Reduced at electrode} \qquad [4]$$

In basic solution

$$NO_3^{2-} + H_2O \xrightarrow{t_{1/2} = 12.5\ \mu\text{sec}} NO_2 + 2\,OH^- \qquad [5]$$

$$NO_2 \rightarrow \text{Reduced at electrode} \qquad [6]$$

The most interesting features of this mechanism are its pH dependence and the differing time dependences of its two possible pathways. In acidic solution, the rapid protonation reaction [2] allows the final reducible scavenging product NO_2 to be formed at a rate ($t_{1/2} = 3\ \mu$sec) that is relatively fast compared to the prevailing flash width and cell time-constant of 10-15 μsec. As a result, the photoemission currents and their lifetimes observed for an acidic NO_3^- solution should be completely analogous to those previously observed with NO_2^- and H_3O^+. However, under alkaline conditions where reaction [2] is inhibited, NO_2 can only be formed directly from the unprotonated NO_3^{2-} species at a slower rate ($t_{1/2} = 12.5\ \mu$sec) that is comparable to a cell time-constant of 10 μsec. Accordingly, by utilizing basic conditions, the rate of NO_2 formation, and hence of electron discharge into the double layer, should be decreased, perhaps sufficiently to affect directly the time dependence of the observed photoemission current.

Table III. NO_3^- pH dependence

pH	τ	S	$S - \tau$
4.40	12.3	12.1	−0.2
6.09	11.1	10.8	−0.3
6.62	12.7	11.8	−0.9
7.11	11.9	12.0	+0.1
7.80	11.8	12.6	+0.8
8.72	11.4	13.0	+1.6
9.58	11.5	15.3	+3.8

τ and S values are in units of microseconds. Solution contained $10^{-3}M$ KNO_3, 7 × $10^{-3}M$ KH_2PO_4, 1.0M KCl, and NaOH.

When solutions containing NO_3^- were flashed, large cathodic currents possessing the expected photoemission potential dependence were obtained regardless of solution pH. A current-voltage profile so obtained is shown in Fig. 5.

In order to observe the temporal behavior of the nitrate photocurrents as a function of pH and duplicate Grätzel's experiments (25) as faithfully as possible, solutions containing $10^{-3}M$ KNO_3, 1.0M KCl, and 7 × $10^{-3}M$ KH_2PO_4 were adjusted to the desired pH by the addition of NaOH. The photoemission currents generated upon flashing were analyzed by means of log current *vs.* time plots, and the corresponding S and τ values were calculated. Table III shows the results obtained for a series of solutions ranging in pH from 4.40 to 9.58.

At low pH values, there was excellent agreement between the cell time-constants and photocurrent time-constants measured for each solution. As the pH was gradually increased and made alkaline, however, the time dependence of the photoemission currents, as reflected in the S values, increased correspondingly and no longer seemed to be governed solely by the cell time-constant. This behavior is exactly as should be predicted on the basis of the NO_3^- scavenging mechanism: Under acidic conditions, where the scavenging products are formed rapidly, the photoemission currents are fundamentally charging currents and are entirely dependent on the cell time-constant, while in basic solution, where the secondary scavenging reactions are slower, the photoemission currents decay more slowly than would be predicted by the cell time-constant alone.

The same data is illustrated graphically in Fig. 7 along with Grätzel's estimates for the $t_{1/2}$ of the NO_3^{2-}

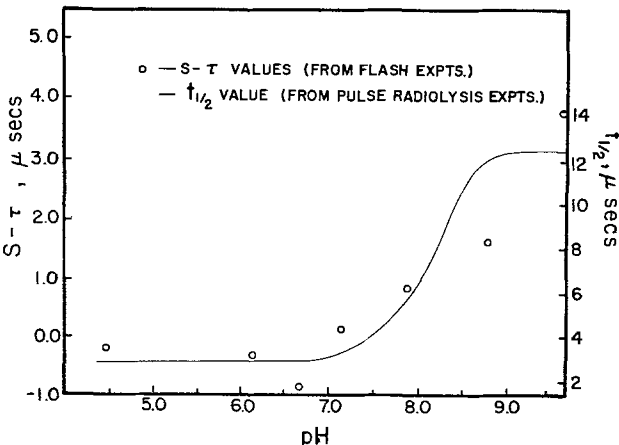

Fig. 7. Temporal behavior of NO_3^- photocurrent as a function of pH at E = −1.4V *vs.* SCE. The solid line represents the pH dependence of $t_{1/2}$ for the decay of NO_3^{2-} as determined by Grätzel *et al.* (25). The circles correspond to (S-τ) values calculated directly from flash experiments (Table III).

species. The quantity used as indication of the photoemission current lifetime is the difference ($S - \tau$) between the measured photocurrent and cell time-constant. This quantity should reflect, qualitatively at least, the increasing half-life for the production of NO_2 at higher pH values. The general agreement between the two methods is evident.

Acetophenone.—In general, the aromatic ketones represent a class of compounds that are known to be nearly diffusion-controlled e_{aq}^- scavengers (23). Their immediate scavenging product is a ketyl radical anion which, depending on the pH, may be in equilibrium with the corresponding ketyl radical (23, 26-28). Furthermore, the radicals and radical anions so produced are usually subject to a rapid one-electron oxidation throughout a wide potential range (29).

For acetophenone in particular, the scavenging mechanism can be summarized as follows

$$CH_3-\overset{O}{\overset{\|}{C}}-C_6H_5 + e_{aq}^- \rightarrow CH_3-\overset{O^-}{\overset{|}{\dot{C}}}-C_6H_5 \quad [7]$$

$$CH_3-\overset{O^-}{\overset{|}{\dot{C}}}-C_6H_5 \overset{H^+}{\rightleftharpoons} CH_3-\overset{OH}{\overset{|}{\dot{C}}}-C_6H_5 \quad [8]$$

$$CH_3-\overset{O^-}{\overset{|}{\dot{C}}}-C_6H_5 \text{ or } CH_3-\overset{OH}{\overset{|}{\dot{C}}}-C_6H_5 \rightarrow \text{Oxidized at electrode} \quad [9]$$

The most important feature of this sequence consists of the fact that every electron that is emitted and scavenged by acetophenone is ultimately returned to the electrode by means of the oxidation of the scavenging product. Hence, even though large-scale photoemission and scavenging should occur, there will be no net electron loss by the electrode.

Experimental observations made of the photoemission currents associated with acetophenone scavenging were complicated by two unavoidable factors. First of all, acetophenone (similarly to other aromatic ketones) absorbs ultraviolet and visible radiation of wavelengths less than 360 nm and undergoes photolysis (30). The products of the photolysis are the same ketyl radicals and radical anions produced by e_{aq}^- scavenging and are likewise readily oxidized electrochemically. Thus, any photoemission currents present are bound to be superimposed on a background of anodic photolysis current. Secondly, in the ethanol-water solvent system chosen for use with acetophenone, the value of the cell time-constant was found to be extremely potential dependent, increasing rapidly in magnitude in the range from -1.0 to -1.6V *vs.* SCE as is shown in Fig. 8. For the interpretation of current-time and current-voltage information, such changes must certainly be taken into consideration.

The current-voltage profiles obtained when 1.0*M* KCl ethanol-water solutions, with and without $10^{-3}M$ acetophenone, were flashed are shown in Fig. 9. For the background solution containing no e_{aq}^- scavenger, the behavior was similar to that observed earlier in non-ethanolic solutions containing no scavenging species (Fig. 4). The apparently distorted potential dependence exhibited between -1.2 and -1.6V occurs in the same region where the cell time-constant most rapidly changes value. Because each point on the current-voltage profile corresponds to measurements made at the same point in time, and because the drastically slower cell response at more negative potentials results in a more drawn-out current-time curve, the measured currents are larger at the less negative potentials.

The current-voltage profile that was obtained when acetophenone was present differed from the background profile by the addition of anodic photolysis current due to the oxidation of acetophenone ketyl radical species formed photochemically. The photolysis current gradually declined at the more negative potentials where acetophenone itself is reduced, and the profile resembled the background. When the variation of cell time-constant with potential was taken into account, the only major discrepancy between the photocurrents observed with and without acetophenone was the presence of the expected photolysis currents.

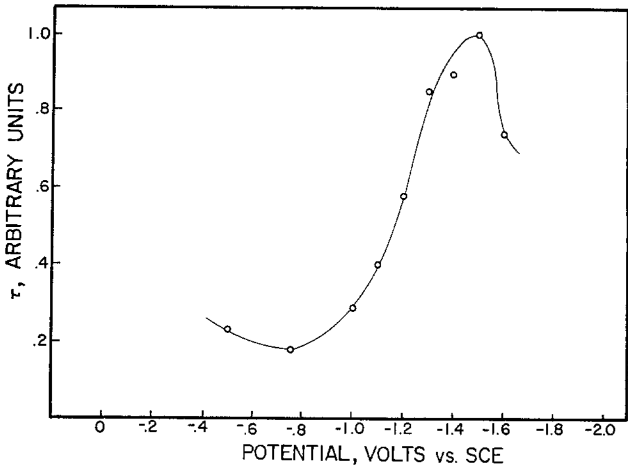

Fig. 8. Cell time-constant variation with potential for 1.0*M* KCl, 30% ethanol-water solution. Absolute τ values measured for this system typically range from approximately 5 μsec ($E = -0.75$V) to 30 μsec ($E = -1.5$V).

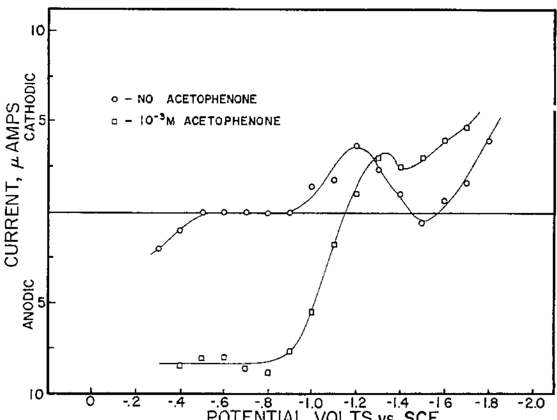

Fig. 9. Current-voltage profile from continuous potentiostatic analysis. With and without acetophenone in 1.0*M* KCl, 30% ethanol-water solution. Currents represent values measured at 15 μsec after initiation of the flash.

Thus, no noticeable contribution to the measured currents due to the photoemission process was detected, despite the presence of an excellent e_{aq}^- scavenger. In fact, no photocurrents even remotely comparable in magnitude to those seen with the previously studied scavengers were in evidence with acetophenone at any potential. (In contrast, the photoemission current observed, under identical conditions, for the analogous NO_2^--containing ethanol-water solution was in excess of 30 μA at $E = -1.4$V.) The absence of any comparable currents with acetophenone can only be due to the fact that, even though a large number of electrons are still photoemitted and scavenged, they are all returned to the elecrode by the virtually instantaneous oxidation of the scavenger product; otherwise, the occurrence of some large-scale current (either anodic, cathodic, or mixed) would *a priori* be required. This fact allows meaningful electrochemical measurement of acetophenone photolysis occurring in solution and supports the validity of previous flash photoelectro-

chemical studies of aromatic ketones (18, 19, 21, 31, 32).

Conclusions

Through the use of flash irradiation and high speed potentiostatic monitoring, currents clearly related to electron photoemission have been observed. Although the expected dependences on electrode potential and scavenger presence were obtained, the time dependence of the observed flash photocurrents was found to be governed primarily by the prevailing electrochemical cell time-constant to such a large degree that they can only be explained as capacitive charging currents in response to a virtually instantaneous flash-induced electron injection into the double layer.

The charging current model for the photoemission-initiated currents, and the experimental results on which it is based, are consistent with the known chemical and physical processes that actually occur for a wide range of scavenging situations. Furthermore, for certain specialized cases (*e.g.*, NO_3^-) in which the secondary scavenging reactions proceed sufficiently slowly, the time dependence of flash photocurrents can be related directly to the reaction rates of scavenging intermediates. In these cases, useful chemical information concerning e_{aq}^- chemistry and scavenging reactions can be obtained.

Hemoglobin Reactions as Interfacial Phenomena

Martin Blank*

Department of Physiology, Columbia University, New York, New York 10032

ABSTRACT

The reactions of hemoglobin with various ligands lead to conformational changes in the macromolecule. The free energy of these changes can be estimated in terms of the surface free energy of a microemulsion droplet of the same size and surface charge as the hemoglobin molecule. Calculations on the basis of this model yield an equilibrium constant that varies with pH, as in the acid and alkaline Bohr effects, and with the ionic strength. The model also provides a physical meaning for the empirical constant in the oxygen binding equation, as well as some insight into the dissociation equilibrium of the hemoglobin tetramers. This approach to equilibria involving globular proteins should be useful for estimating the effects of conformational changes and subunit interactions in other systems.

The study of macromolecules as interfacial systems, *i.e.*, the chemistry of hydrophilic colloids, was the first approach used to characterize the properties of globular proteins. This study was followed by the development of the physical chemistry of macromolecules or polymers, including polyelectrolytes, which then merged into molecular biology. The techniques of mo-

* Electrochemical Society Active Member.
Key words: hemoglobin, ligands, macromolecule, globular protein.

lecular biology, especially those of the subfield x-ray crystallography, have given and continue to give a great amount of structural detail about proteins and other macromolecules.

With each new development for studying proteins, there has been a tendency to overlook the approach that was used during the earlier stage. Perhaps this is inevitable, since change has generally been accompanied by progress. But the recent increase in detailed geometric information is not without its drawbacks. Despite the wealth of structural data, it is difficult to calculate the interaction energies between the parts of a macromolecule, even with the aid of computers. In addition, one cannot perform the reverse calculation, *i.e.*, to define a structure in terms of the energy, because of the large number of conformations with approximately equal energies. It is in the realm of energy calculations that the older approaches to the study of proteins may be useful.

In this paper we shall consider the energy changes in hemoglobin using concepts that were developed for dealing with the electrochemistry of surfaces. We shall smooth out the structure of hemoglobin into a hydrophilic sphere of the same size and charge as the macromolecule, and assume that the known changes in the molecular shape and charge upon interaction can be calculated as changes in surface free energy. This will allow us to estimate the variation of the equilibrium constant as a function of pH and ionic strength in a relatively simple way. We shall also consider other consequences of this model such as a description of the empirical constant in the oxygen equilibrium equation in terms of a surface excess, and an analysis of the energetics of dissociation reactions.

Estimating Changes in Conformational Energy Using Surface Electrochemistry

Hemoglobin, a macromolecule containing four protein chains with attached heme groups, can bind four oxygens (or several other ligands) per molecule (1). The oxygen binding curve is sigmoid in shape, indicating a change in the affinity with the degree of oxygenation. The curve also shifts with pH (the Bohr effect) and ionic strength, indicating a variation of the affinity with pH and salt concentration. These unusual aspects of hemoglobin reactions are generally assumed to be due to the conformational changes in the macromolecule, but the quantitative relation between the conformational changes and the change of affinity has been difficult to establish.

The hemoglobin molecule is approximately spherical and has a diameter of about 60Å, which is in the size range of colloidal systems. If hemoglobin is considered a colloid, the conformational changes that accompany a reaction can be estimated in terms of the surface free energy (2). Using a model system, a protein monolayer stabilizing a spherical hydrophobic droplet, it is possible to derive expressions for the changes in the surface free energy (ΔG_s) as a result of changes in the interfacial area (ΔA) at constant volume, and in the number of surface charges (ΔN)

$$\Delta G_s = f(\Delta A, \Delta N) \quad [1]$$

Assuming changes in the model surface similar to those that accompany the oxygenation reaction, we can estimate ΔG_s from the x-ray data showing conformational changes (3) and the differential titration data showing changes in surface charge (4). The variation of the equilibrium constant, K_e, can then be evaluated in terms of the change in surface free energy in units of k'

$$\Delta \ln K_e = \frac{\Delta G_s}{RT} = \frac{k'}{2} \quad [2]$$

The results of the calculation are shown in Fig. 1 for the variation of K_e with pH, and similar agreement can

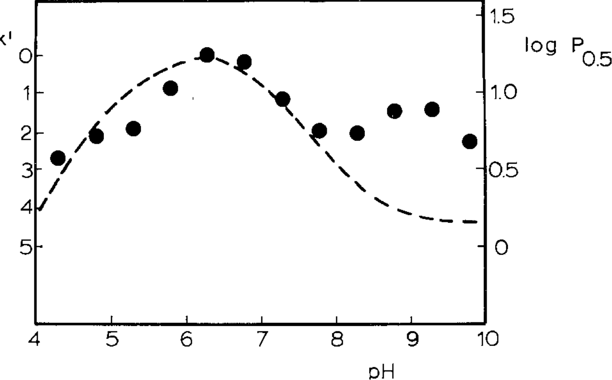

Fig. 1. Calculated values of K_e (●) in units of k', superimposed on the dashed curve of observed values in units of log $p_{1/2}$ (the oxygen pressure for the half-saturation of hemoglobin).

be obtained for the variation of K_e with the ionic strength of the medium (5).

The model is able to account for basic aspects of the hemoglobin reactions with various ligands: (*i*) The sigmoid shape of the binding curve, which is characteristic of cooperative reactions, is present at all pH's as a result of the negative ΔA during the conformational change. (*ii*) K_e shifts with pH even when $\Delta N = 0$ due to the presence of a surface charge on the molecule. (*iii*) The calculated shift of K_e with pH and ionic strength can be of the right order of magnitude. (*iv*) The pH where the maximum in K_e occurs is below the IEP (the isoelectric point). (*v*) The Bohr effect should occur with all ligands that cause comparable changes in ΔA and ΔN upon interaction with hemoglobin.

The agreement of the calculations with the observations on the hemoglobin-oxygen system, suggests that changes in surface free energy can be used to evaluate the cooperative nature of the interaction and the variation of the equilibrium constant with pH and ionic strength. There are other aspects of the equilibrium which are not explained, since the system is more complicated than the model used and additional information is required (2). However, the approach outlined in this paper suggests a relatively simple way of relating the effects of conformational changes and cooperative interactions in globular proteins to changes in affinity.

The Surface Excess and the Hill Coefficient

The interfacial model suggests a simple physical meaning for the Hill coefficient, the empirical constant used in equations governing binding equilibria that are cooperative. The usual binding equation considers that a concentration, C, of ligand reacts with a fraction, y, of available binding sites, and the equilibrium constant or affinity can be described as follows

$$K = \left(\frac{y}{1-y}\right)\frac{1}{C} \quad [3]$$

where $y/(1-y)$ is the ratio of reacted to unreacted sites. A plot of $y(C)$ gives the familiar rectangular hyperbola that is characteristic of the Langmuir adsorption equation, and that is observed when oxygen reacts with one of the monomers of hemoglobin. The affinity is related to $\Delta G°$, the free energy change per mole when all substances are present at unit activity

$$K = \exp\left(-\frac{\Delta G°}{RT}\right) \quad [4]$$

$\Delta G°$ is due to the bonding reaction, but additional changes in free energy (ΔG_s) occur as a result of the conformational changes of hemoglobin.

The additional free energy change results in the displacement of the affinity to a new value

$$K' = \exp\left[-\frac{\Delta G^\circ - \Delta G_S(y)}{RT} \right] = K \exp\left[-\frac{\Delta G_S(y)}{RT} \right] \quad [5]$$

From Eq. [5] it appears that when $\Delta G_s < 0$, the affinity increases, and since ΔG_S varies with y there should be a gradual change in the equilibrium constant during a reaction. In practice, the affinity is assumed to remain constant at a new value, K_e, and the change in binding is usually considered in terms of a change in the dependence of y on C. This is done by raising the concentration to a power, n, as in the Hill equation for the combination of oxygen with hemoglobin

$$K_e = \left(\frac{y}{1-y} \right) \frac{1}{C^n} \quad [6]$$

where $n > 1$ for $\Delta G_s < 0$. When $n > 1$ the interaction is termed cooperative.

Using Eq. [3], [5], and [6], we can write two equivalent expressions for the effect of an additional free energy term on the fraction of sites bound

$$\Delta G^\circ + RT \ln \left(\frac{y}{1-y} \right) - nRT \ln C = 0 \quad [7]$$

$$\Delta G^\circ + \Delta G_S(y) + RT \ln \left(\frac{y}{1-y} \right) - RT \ln C = 0 \quad [8]$$

If we differentiate the two equations and subtract one from the other we see that

$$n - 1 = -\frac{d\Delta G_S(y)}{RT\, d \ln C} \quad [9]$$

Therefore $(n - 1)$ has the form of the surface excess, Γ, in the Gibbs equation

$$\Gamma = -\frac{dG_S}{RT\, d \ln C} \quad [10]$$

where Γ is in mol/cm^2 if RT is in erg/mol and G_S is a surface free energy in erg/cm^2. The empirical exponent n of Eq. [6] can therefore be interpreted rather simply in terms of surface excess. A plot of $(n - 1)$ *vs.* C has the same form as graphs of surface excess in a classical interfacial system (6). (It should be noted that n is not constant, but varies with y and is equal to unity at the extremes of the range, $y = 0$ and $y = 1$.)

Subunit Dissociation Reactions as Colloidal Phenomena

The micro-emulsion droplet model of hemoglobin (where the relatively hydrophobic interior of the molecule is stabilized by a hydrophilic protein monolayer on the surface) suggests a simple qualitative explanation for the association-dissociation equilibria of hemoglobin solutions. We can describe the energetics of these equilibria in terms of the total surface free energy for the idealized model system

$$G = (\gamma_0 - \pi)A \quad [11]$$

where γ_0 = the interfacial free energy of the hydrophobic phase/water interface, π = the surface pressure of the hydrophilic film, and A = the total area. For example, with Eq. [11] we see that the unliganded form of hemoglobin has a lower tendency to dissociate than the various liganded forms. The decrease in A on oxygenation means that the surface free energy of the liganded form is lower than that of the free form. Therefore, the molecule is more stable with regard to dissociation into subunits.

Using the same qualitative reasoning we can describe the variation of the association-dissociation equilibria of hemoglobin with pH and ionic strength. The usual explanation for changes in the subunit interactions in proteins involves electrostatic factors. Thus an increase in charge on either side of the IEP is believed to increase the electrostatic repulsion between the subunits and lead to dissociation. However, an increase in the ionic strength, which decreases the electrostatic interactions, also leads to dissociation. One can invoke the same explanation for the two observations only if one considers that at low net charge the electrostatic factors stabilize, but at higher charge they lead to dissociation. However, the logical inconsistency is reinforced by the knowledge that the tetramer is quite stable when the net charge is zero.

In the surface chemical model, electrostatic factors also come into play in the dissociation reactions, but not in the same way. On increasing the surface charge or decreasing the ionic strength there is an increase in π of Eq. [11], which leads to a lower G. However, as π approaches γ_0, the system becomes unstable and there is a tendency toward "phase inversion" or major conformational change. An "inversion" of the molecule requires a higher cost in free energy than the process of dissociation, which is therefore the preferred path.

If this is so, why do high salt concentrations (which decrease π) also lead to dissociation of the hemoglobin tetramer into smaller subunits (*i.e.*, dimers and monomers)? The answer to this lies in another property of colloidal solutions, the large effect of ionic strength on the activity coefficient of a charged polymer. Consider the hemoglobin dissociation equilibria in terms of the following equation

$$\underset{\text{tetramer}}{\alpha_2\beta_2} \rightleftharpoons \underset{\text{dimers}}{2\alpha\beta} \rightleftharpoons \underset{\text{monomers}}{2\alpha + 2\beta} \quad [12]$$

For any set of conditions (*i.e.*, temperature, concentration, pH, ionic strength), there will be a distribution of the various forms in solution. If we add salt to the solution the activity coefficients of the different protein forms will change, *i.e.*, their solubilities will change. The effects of ionic strength on activity are generally larger for larger molecules (7), so at higher salt concentrations the large proteins will tend to be salted out of solution. Under these circumstances one would expect the equilibrium to shift in the direction of the smaller molecular weight forms. Thus one observes greater dissociation with an increase in the salt concentration, even though the smaller effect on π tends to stabilize association. (The variation of the activity coefficients with concentration of the protein molecules should also cause the dissociation reaction to vary.)

The dissociation reaction in an ideal constant volume system (going from a spherical tetramer to two spherical dimers) leads to an increase of 26% in the total A. If the number of charges remains constant but is spread over the larger area, there is a decrease in the surface charge density, and therefore in π. It is apparent that the A and π changes on dissociation both lead to a $\Delta G_s > 0$, and that under ordinary circumstances all of the factors oppose dissociation.

In making these qualitative statements we have considered that γ_0 is constant upon dissociation. However, for droplets in the size range of hemoglobin, Gibbs (8) pointed out that there is a significant variation of the interfacial free energy with the curvature. The free energy increases with concavity and decreases with convexity when the droplet radii are smaller than 10^{-6} cm (100Å). The variation of interfacial free energy, γ, with the radius, r is (9)

$$\frac{\gamma}{\gamma_\infty} = \left[1 + \frac{2\delta}{r} \right]^{-1} \quad [13]$$

where γ_∞ is the interfacial free energy when $r = \infty$, and δ is a length on the order of the molecular diameter of the molecules in the liquid droplet. (It is difficult to estimate the characteristic length of a macromolecule like hemoglobin but one can probably consider it to be on the order of the diameter of the α helix.) Therefore, there should be a decrease in the

value of γ_0 as a result of dissociation, and the magnitude of the effect should be significant (on the order of 5-10%) in this size range. This would mean that the free energy change upon dissociation is not quite as large as expected.

The above qualitative discussion suggests that some of the ideas of colloid and surface chemistry are apt to be useful in understanding the energetics of globular proteins that are composed of several subunits. Recently, a related approach to the general problem of protein structure, which considers such factors as accessible surface areas, hydrogen bonds, and residue volumes, has apparently been successful in describing the structures of 15 proteins (10).

Conclusion

By considering the hemoglobin molecule as a colloidal particle, it has been possible to obtain a number of insights into the energetics of reactions involving changes in conformation, surface area, and surface charge. Colloid chemistry has proved quite useful in the past in explaining phenomena where the dispersed phase was of the size of many globular proteins, and the ideas should continue to help us deal with the physical properties of protein solutions. Traditionally colloid chemistry has been devoted to the study of phenomena where the properties of interfaces play an essential role in determining the behavior of the system. It is therefore appropriate for this subject to serve as an interface between the detailed structural information that has become available from molecular biology and the physical chemistry of the same substances in solution.

A Thin Layer Spectroelectrochemical Study of Cob(I)alamin to Cob(III)alamin Oxidation Processes

Thomas M. Kenyhercz*,[1] and Harry B. Mark, Jr.**

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT

The air, electrochemical, and autooxidation of cob(I)alamin and also cob(I)inimide under various conditions have been studied. The time-resolved and potential-resolved spectra indicate that in the absence of cyanide ion or cyanide present in equivalent concentrations the reoxidation to aquocob(III)-alamin (vitamin B_{12a}) and cyanocob(III)alamin (vitamin B_{12}) exhibits two cob(II)alamin intermediates. It is speculated that the two intermediates represent "base-on" and "base-off" forms with respect to the coordination of the side chain benzimidazole group in the Y axial position. Experiments on the reoxidation of cob(I)alamin in presence of excess cyanide and on cob(I)-inimide support this conclusion.

A recent cyclic voltammetric study of vitamin B_{12} type compounds has suggested that electrochemical and spectroscopic techniques be combined to elucidate the redox behavior of cobalamin compounds (1). The resultant spectropotentiostatic studies (2, 3) of cobalamins have revealed a previously unobserved sequence of intermediates and steps are involved in the reoxidation mechanism of the cob(I)alamins in this biologically significant reaction (4-10). Optically transparent thin layer electrode (OTTLE) cells (11, 12) have been used in conjunction with a Harrick rapid scanning spectrophotometer to study the reoxidation mechanism of cob(I)alamins (2). The reoxidation sequence of cob(I)alamins investigated by spectropotentiostatic and autooxidation techniques has yielded consistent results. The results apparently indicate the formation of two cob(II)alamin reoxidation intermediates which have been interpreted as corresponding to "base-on" and "base-off" forms with respect to the coordination of the 5,6-dimethylbenzimidazole group at the Y axial site. Furthermore, attempts have been made to correlate cobalamin cyclic voltammetric behavior at a mercury-coated nickel minigrid electrode (Hg-Ni OTTLE) with the spectroelectrochemical evidence.

Key words: cobalamin, spectroelectrochemistry, optically transparent thin layer electrode (OTTLE), oxidation.

Experimental

The recently developed mercury-coated nickel minigrid electrode (11) was used in a thin layer configuration during cyclic voltammetric experiments and as a thin layer electrolysis cell for spectroelectrochemical studies (2, 3, 13). The OTTLE which served as the working electrode was constructed according to established procedures (2, 11). There was some concern that diffusion of unreacted material from the reservoir cup and the edges of the OTTLE cell could affect the mechanism and kinetics of the reoxidation. To check this, an OTTLE cell, in which the minigrid was in contact with the total solution volume (mini-

grid area was exactly equal to that of the solution area) and had no reservoir cup, was constructed. We did not note any measurable difference in experimental results for either OTTLE cell design. The minigrid thin layer cell was assembled using a nickel minigrid (333 lines/in., 60% transmittance, Buckbee Mears Company, St. Paul, Minnesota), microscope slides (1 × 3 in.) and 2 mil Fluorofilm DF-1200 tape (Dilectrix Corporation, Farmingdale, New York). The preparation of Hg-Ni OTTLE used in this investigation has been described elsewhere (11). The exact thickness of the OTTLE cell was determined spectrophotometrically using a standard solution of dicyanocobalamin. The three-electrode system also employed a platinum wire as the auxiliary electrode while a miniature saturated calomel electrode (SCE) served as the reference electrode. The Hg-Ni OTTLE cell was mounted in a computerized Harrick rapid scanning dual beam spectrophotometer (RSS) (2, 14). Experimental procedures interface design, electrochemical instrumentation, computer programming including data acquisition, processing, and reduction has been described previously (15). Crystalline cyanocobalamin, vitamin B_{12} (Sigma Chemical Company, St. Louis, Missouri) was used without further purification and was also employed in the synthesis of aquocobalamin (B_{12a}) (16) and dicyanocobalamin (B_{12}-CN). All solutions (except that noted in Fig. 3) were 1 mM in cobalamin and 1.0M in Na_2SO_4 as the supporting electrolyte (1); the solutions for the B_{12}-CN experiments were also 0.1M in KCN. All cobalamin solutions were deaerated with high purity argon. Unless noted an inert atmosphere of argon was maintained in the RSS. The deaerated cobalamin solutions were introduced into the OTTLE cell with the cobalt of the cobalamin in the +3 valence state. The 1 mM cobalamin solutions were then potentiostated at −1.0V *vs.* SCE until the spectra changed completely to that of the cob(I)alamin (see the first spectrum of Fig. 9) and remained constant for approximately one-half hour. The cob(I)alamin solutions were reoxidized by electrochemical means or by autooxidation in either the presence of air diffusing into the OTTLE cell or under an inert argon atmosphere. The potentiostat was disconnected from the OTTLE cell assembly during the autocatalysis experiments (2). The electrochemical electroreoxidation process involved a stepwise (25 mV increment) potentiostatic polarization (potentiostated at each potential value until the spectra ceased changing, approximately 2 min) under an inert argon atmosphere (2).

Results and Discussion

Thin layer cell cyclic voltammograms.—Typical cyclic voltammograms for cyano- and dicyanocobalamin at a Hg-Ni OTTLE are shown in curves A and B, respectively, of Fig. 1 (3). These cyclic voltammograms appear quite complex and nonideal with respect to peak shape. The irreversibility appears to arise from a combination of slow electron transfer, associated chemical steps in the redox process, and strong adsorption of both reactants and products. Based on a previous study it is possible to at least quantitatively assign peaks to certain redox processes (3, 10, 17, 18). In curve A of Fig. 1 (B_{12} at a Hg-Ni OTTLE), the reduction process occurring in the region of −0.95V *vs.* SCE represents a two-electron reduction corresponding to $B_{12} + 2e \rightarrow B_{12s}$ [Co(III) + $2e \rightarrow$ Co(I)] (1, 3, 10, 17, 18). The reoxidation occurring at −0.85V *vs.* SCE is attributable to the process $B_{12s} - 1e \rightarrow B_{12r}$ [Co(I) − $1e \rightarrow$ Co(II)] (1, 10, 17, 18). A cyclic voltammetric study of the supporting electrolyte (1.0M Na_2SO_4) containing millimolar amounts of cyanide has shown that anodic peaks in the region of −0.3 to 0.0V *vs.* SCE correspond to formation of mercury cyanide complexes (19, 20). The prominence of the mercury cyanide peaks is particularly evident in the B_{12}-CN cyclic voltammo-

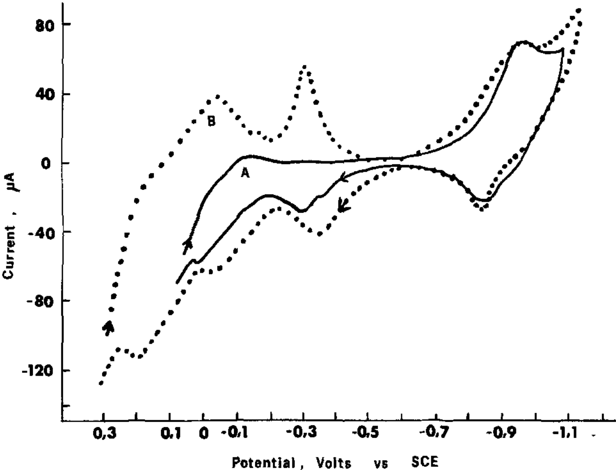

Fig. 1. Thin layer cyclic voltammograms of 1 mM solutions of cyanocobalamin, B_{12} (curve A) and dicyanocobalamin (curve B) at a Hg-Ni minigrid electrode. Scan rate = 2 mV-sec^{-1}. Initial scan cathodic. Curve A, B_{12}: 1.0M Na_2SO_4, 0.1M $NaNO_3$, pH = 7.0. Curve B, B_{23}-CN: 1.0M Na_2SO_4, 0.1M KCN, pH = 10.4.

grams (Fig. 1, curve B). Though not shown in curve A of Fig. 1, a small peak does occur in the region of 0.2V *vs.* SCE which appears to correspond to the reaction $B_{12r} - 1e \rightarrow B_{12}$ [Co(II) − $1e \rightarrow$ Co(III)] (1, 3). All successive cathodic scans of B_{12} show the presence of a cathodic peak around −0.3V similar to those exhibited by B_{12}-CN which correspond to the reduction of mercury cyanide complexes. The cyclic voltammetric behavior of dicyanocobalamin is illustrated in curve B of Fig. 1 (3). Thus, a comparison of curves A and B shows that electron transfer characteristics for B_{12}-CN (curve B) are essentially the same as that of B_{12} (curve A). The additional peaks in the B_{12}-CN cyclic voltammogram are the same as those observed for supporting electrolyte solutions containing 1.0M Na_2SO_4 supporting electrolyte and 2 mM KCN. The cyclic voltammetric behavior of aquocobalamin, vitamin B_{12a} at a Hg-Ni OTTLE is given in Fig. 2 (3). Again, it is possible to assign the reduction peak occurring at about −0.95V *vs.* SCE to the process $B_{12a} + 2e \rightarrow B_{12s}$ or [Co(III) + $2e \rightarrow$ Co(I)]. The reoxidation peak occurring in the region of −0.8V appears to correspond to the reaction of $B_{12s} - 1e \rightarrow B_{12r}$ while the peak in the region of 0.15V corresponds to the reaction $B_{12r} - 1e \rightarrow B_{12a}$. The reduction peak at 0.2V is characteristic of the supporting electrolyte (1.0M Na_2SO_4) at the

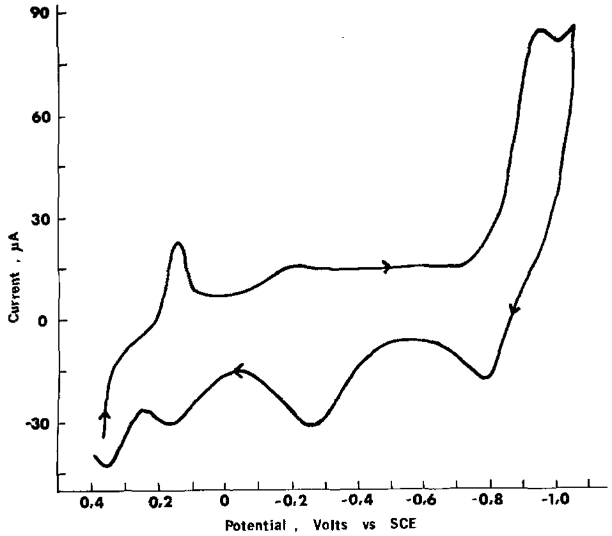

Fig. 2. Thin layer cyclic voltammogram of 0.9 mM solution of aquocobalamin, B_{12a}, at a Hg-Ni minigrid electrode. Scan rate = 2 mV-sec^{-1}. Initial scan cathodic 1.0M Na_2SO_4, 0.1M $NaNO_3$, pH = 7.0.

Hg-Ni OTTLE, though the identity of the −0.25V anodic peak is uncertain. The potential range of this anodic peak is similar to the mercury cyanide anodic peak observed for B_{12}. As the B_{12a} was synthesized from B_{12} (6), one might suspect that some B_{12} remains as an impurity. However, no cyanide is thought to be present in the B_{12a} for several reasons. First of all, the second cathodic of the B_{12a} solution failed to produce the mercury (II) cyanide reduction peak observed for B_{12} and B_{12}-CN. Also the occurrence of this −0.25V reduction peak was investigated at a Hg-Ni OTTLE for B_{12a} samples that had been prepared under diverse conditions (3) (chemically, electrochemically synthesis from B_{12} or biological by microbial action). In all cases the B_{12a} solutions produced a −0.25V reoxidation peak at the mercury-coated nickel minigrid. Thus, it seems unlikely that a "common" cyanide impurity could exist for such diversified batch preparations of aquocobalamin. A further cyclic voltammetric examination of the B_{12a} at a hanging mercury drop electrode (HMDE, surface area = 0.0293 cm^2) was carried out (1, 3) which showed that this aquocobalamin did not exhibit a reoxidation peak in the region of −0.25V (±50 mV) (1). This leads one to speculate that some unique redox process may be occurring between a base-off cob(II)alamin and the Hg-Ni surface. Such an interaction for base-off forms with transition metals and transition metal complexes is not new and is well documented in the literature (21, 22). In general, with the exception given above, it appears as though the cobalamins exhibit the same electrochemical behavior at a Hg-Ni minigrid that they do at a HMDE. Thus, the mercury-coated nickel minigrid in an optically transparent thin layer electrode configuration has been used to study the spectroelectrochemical reoxidation mechanism (2, 3).

Cob(I)alamin reoxidation studies.—Curve A of Fig. 3 represents a typical spectrum of a partially air reoxidized solution of the cob(I)alamin, B_{12s}. The peaks occurring in the region of 380 and 560 nm are characteristic of a cob(I)alamin (23). The peaks at 475 and 410 nm have been previously observed in the spectrum of the cob(II)alamin, B_{12r} (23). The peak at 525 nm is assigned the final oxidation product B_{12a} (28) (see curve B, Fig. 3). Thus, the spectrum of curve A, Fig. 3, is that of a mixture of cob(I)-, cob(II)-, and cob(III)-alamins and the peaks of interest here, which we suggest correspond to cob(II)alamin intermediates in the oxidation sequence, occur at 410 and 475 nm. During the large scale preparations of B_{12a} (16), it was previously observed that the relative ratio of the 410 and 475 nm peaks varied markedly, depending on the rate at which oxygen was introduced into the cob(I)alamin, B_{12s}, solution. This is illustrated by comparing curve A of Fig. 6 to the first curve of Fig. 8. Curve A of Fig. 3 was obtained on bubbling oxygen through a rapidly stirred solution of B_{12s}. Under these conditions the 410 nm peak is much larger than the 475 nm peak. In the curves shown in Fig. 4-11 the 475 nm peak is always much larger than the 410 nm peak. In the latter cases, oxygen was admitted to the system slowly (Fig. 4-8) (by diffusion into the B_{12s} solution from the edges of the OTTLE cell), or was excluded from the system by employing an argon atmosphere in the RSS, Fig. 9-11. Based on these results it is felt that the 410 and 475 nm peaks represent two different cob(II)alamin species, though past investigations have reported both of these peaks as being characteristic of a single species. B_{12r}.

The spectra obtained following the exhaustive reduction of B_{12}, B_{12a}, and B_{12}-CN at −1.0V *vs.* SCE were characteristic of an identical cob(I)alamin species, as can be seen by comparing the initial curves in Fig. 9-11. This is the cob(I)alamin species designated as B_{12s}. Though the exact coordination geometry for the cob(I)alamin is unknown (27), it has been suggested that the coordinated axial benzimidazole is protonated in a base-off configuration with water molecules occupying each of the axial positions (24).

It was found that the time-resolved cobalamin spectral sequences and rates of peak changes were virtually the same in the absence of air and when air was allowed to diffuse into the OTTLE cell from the edges. This indicates that the mechanism for reoxidation under these conditions involves the reaction of cob(I)-alamin with some other oxidant is faster than the rate of diffusion of oxygen into the OTTLE cell. The time-resolved spectra for the "autooxidation" of a cob(I)-alamin solution (OTTLE cell in an argon atmosphere) obtained by the exhaustive reduction of cyanocob(III)-alamin at −1.0V is shown in Fig. 4 and 5. Figure 4 shows that the cob(I)alamin, as monitored by the 385 nm peak is completely reoxidized to a cob(II)alamin (as seen by the development of the 475 nm peak) in the first 100 sec. The peak which develops at 475 nm corresponding to a cob(II)alamin species, grows to a maximum in the first 400 sec. The 475 nm peak then slowly decreases, finally vanishing at about 5 × 10^4 sec. The cyanocob(III)alamin peak at 360 nm begins to develop at 10^4 sec and the B_{12} is completely regenerated by 10^5 sec. The time-resolved spectra for this regeneration of B_{12} can be seen in Fig. 5. The identical reoxidation experiment was performed using aquocob-(III)alamin (B_{12a}) following potentiostating at −1.0V *vs.* SCE to produce the cob(I)alamin. The time-resolved oxidation spectra for B_{12a} are shown in Fig. 6 and 7. The reoxidation sequence of a cob(I)alamin to B_{12a} is very similar to the cob(I)alamin autooxidation

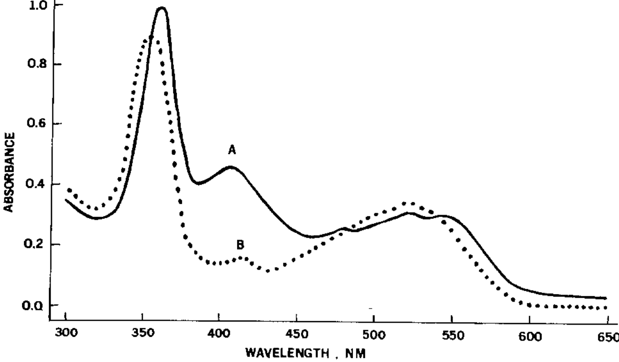

Fig. 3. Spectra of air reoxidized products formed following the exhaustive reduction of cyanocob(III)alamin in 0.1M $NaNO_3$. Curve A represents a partially reoxidized solution of cob(I) alamin. Curve B represents the totally reoxidized cob(III)alamin, aquocobalamin.

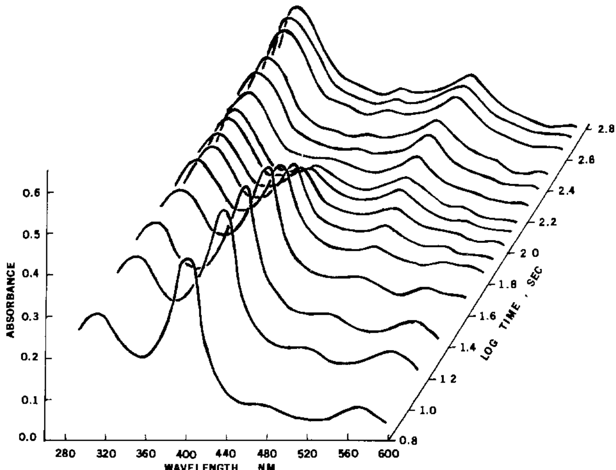

Fig. 4. Time-resolved spectra for the reoxidation of cob(I)alamin (from 1.0 mM cyanocobalamin) to cob(II)alamin, in a 1.0M Na_2SO_4, 0.1M $NaNO_3$ solution; pH = 7.0 initially. Time span = 0-630 sec, at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

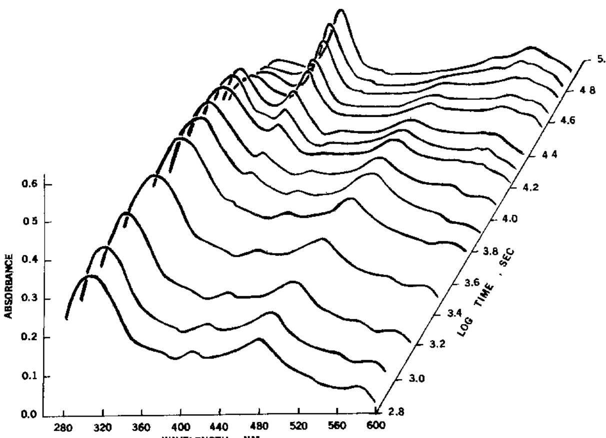

Fig. 5. Time-resolved spectra for the reoxidation of cob(II)alamin to a cob(III)alamin, B_{12}, in a 1.0M Na_2SO_4, 0.1M $NaNO_3$ solution. Time span = 630-70,000 sec at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

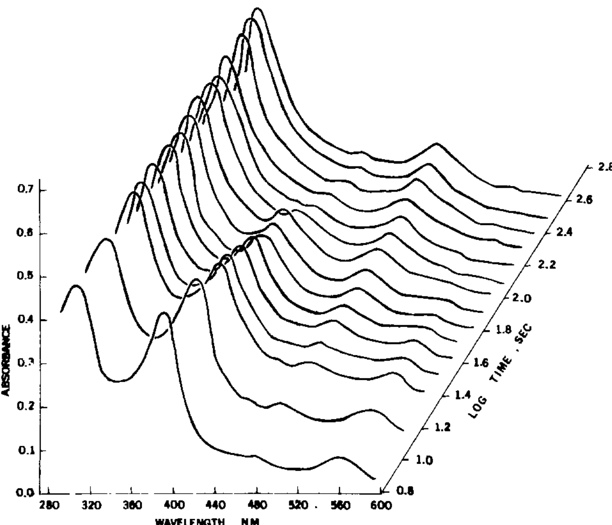

Fig. 6. Time-resolved spectra for the reoxidation of cob(I)alamin (from 0.9 mM aquocobalamin) to a cob(II)alamin, in a 1.0M Na_2SO_4, 0.1M $NaNO_3$ solution; pH = 7.0 initially. Time span = 0-400 sec, at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

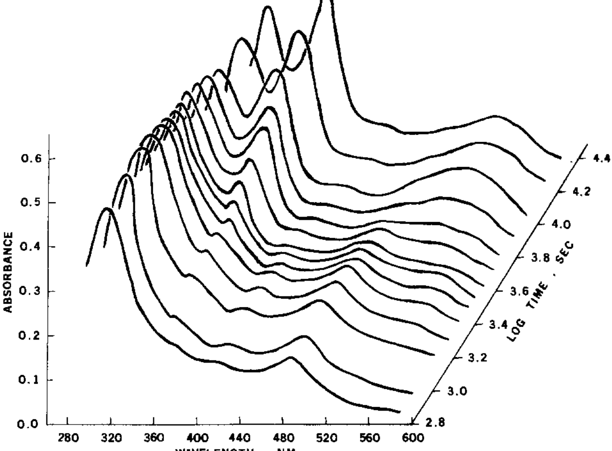

Fig. 7. Time-resolved spectra for the reoxidation of cob(II)alamin to a cob(III)alamin, B_{12a}, in a 1.0M Na_2SO_4, 0.1M $NaNO_3$ solution. Time span = 630-25,000 sec at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

in the presence of equimolar CN^- to B_{12}. For all autooxidation studies involving both B_{12} and B_{12a}, the spectra exhibits a 410 nm peak, which occurs in the same qualitative time period but not necessarily coincident with the absorbance-time values of the characteristic 475 nm cob(II)alamin peak. It appears within 200 sec, has reached a maximum by 5×10^3 sec, and has disappeared by about 2×10^4 sec. Furthermore, there are no peaks in the region of 370 nm which could identify either a Co(I) or Co(III) species during the time interval from 200 to 5000 sec. It is, therefore, felt that the 410 nm peak indicates a second different cob(II)-alamin intermediate which will be identified as B_{12r}'. These two cob(II)alamin species could correspond to base-on and base-off benzimidazole forms, although the possibility exists that some reversible alteration of the corrin ring could also be responsible for this behavior. It is felt that, as the peaks in this region have previously been associated with changes in the axial ligand configuration, this postulation that the two species are base-on and base-off forms is reasonable (25). From the spectra presented in Fig. 4 through 7 it is seen that the B_{12} and B_{12a} formation appears more concomitant with the disappearance of B_{12r}' than B_{12r}. The studies described below with B_{12}-CN and cob(III)inimide have been employed to test this base-on and base-off theory.

The time-resolved spectra for the autooxidation of cob(I)alamin, B_{12s}, obtained by the exhaustive reduction of dicyanocob(III)alamin (formed by adding a 100-fold excess of cyanide to B_{12}) as shown in Fig. 8 is found to be quite different from those obtained of B_{12} and B_{12a}. From Fig. 8 it can be seen that dicyanocob(III)alamin is totally regenerated in less than 400 sec. The time dependency of the increase/decrease in the 290 nm band, the rise and fall of the 475 nm cob(II)alamin peak, the final development of the 368 nm peak plus the total absence of a 410 nm peak all strongly suggest that the reoxidation of B_{12s} in the presence of excess cyanide goes through only a B_{12r} type intermediate. The lack of a 410 nm intermediate in this case is consistent with the suggestion that this intermediate is a different axial ligand configuration rather than a ring alteration which would be consistent for the three cobalamins which were investigated. It is also reasonable that both the X and Y axial positions are occupied by CN^- in the case of a 100-fold excess CN^- in the solution and the base-on B_{12r}' does not form.

The electrochemical reoxidation sequence of the cob(I)alamins formed by the exhaustive reduction of B_{12}, B_{12a}, and B_{12}-CN are shown in Fig. 9 through 11,

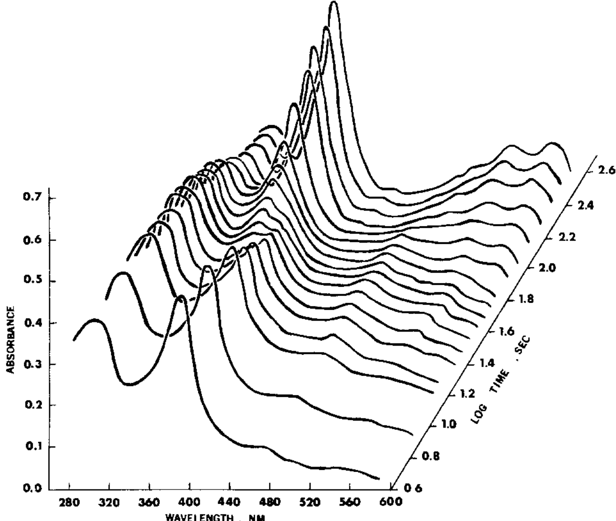

Fig. 8. Time-resolved spectra for the reoxidation of cob(I)alamin (from 1 mM dicyanocobalamin) to dicyanocob(III)alamin, in a 1.0M Na_2SO_4, 0.1M KCN solution; pH = 11.0. Time span = 0-410 sec at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

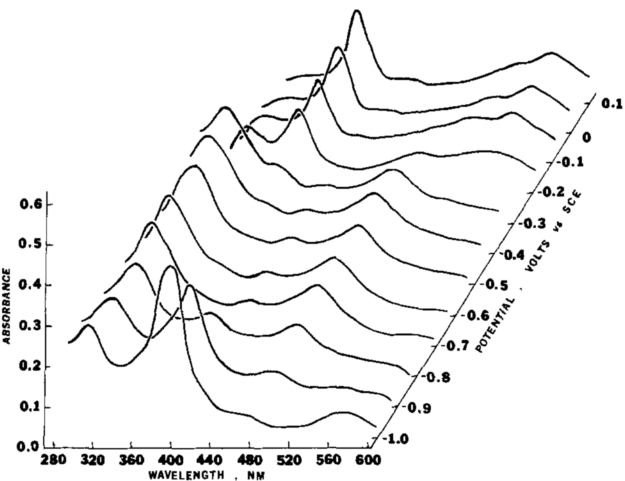

Fig. 9. Spectropotentiostatic curves for the reoxidation of cob(I)alamin (from 1 mM cyanocobalamin) to cyanocob(III)alamin, B_{12}, in 1.0M Na_2SO_4, 0.1M $NaNO_3$; pH = 7.0 initially. Potential range = −1.0 to +0.1V vs. SCE at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

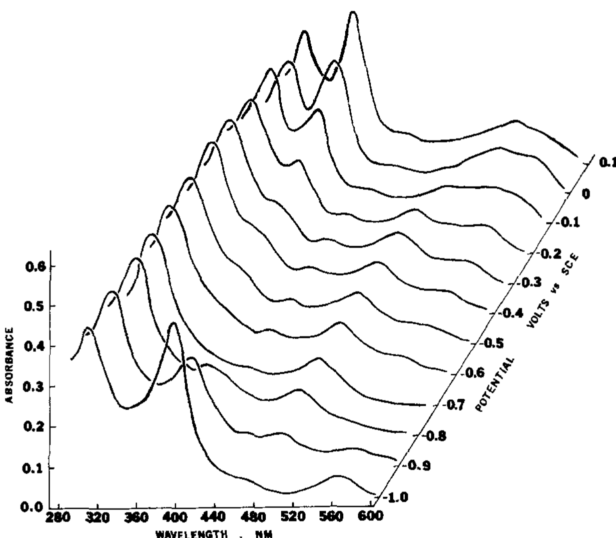

Fig. 10. Spectropotentiostatic curves for the reoxidation of cob(I)alamin (from 0.9 mM aquocobalamin) to aquocob(III)alamin, B_{12a}, in 1.0M $NaSO_4$, 0.1M $NaNO_3$; pH = 7.0 initially. Potential range = −1.0 to +0.1V vs. SCE at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

respectively. The spectroelectrochemical reoxidation sequence for cob(I)alamin prepared from electroreduced cyanocobalamin is illustrated in Fig. 9. The formation of the 475 nm cob(II)alamin peak becomes markedly evident as the potential is decreased below −0.9V *vs.* SCE (3). The 475 nm peak appears to reach a maximum in absorbance between −0.8 and −0.7V SCE. A previous spectroelectrochemical study of B_{12} at 475 nm has shown that the reoxidation plateau region extends from −0.30 to −0.77V *vs.* SCE (3). This fact is well substantiated by the spectropotentiostatic curves of Fig. 9. It can be seen from Fig. 9 that the development of the 410 nm peak is not coincident with the 475 nm peak, but appears to reach a maximum in the region of −0.5V *vs.* SCE, and then decreases. The development of the 360 nm peak characteristic of B_{12} begins in the potential region where the 475 nm peak begins to decline. The cyanocob(III)alamin species appear to have been regenerated in the potential region between 0.00 and 0.10V *vs.* SCE, which again agrees with the previous spectropotentiostatic investigation. The spectropotentiostatic reoxidation of aquocob(III)-alamin (B_{12a}) from cob(I)alamin (B_{12s}) is shown in Fig. 10. In general the spectropotentiostatic reoxidation

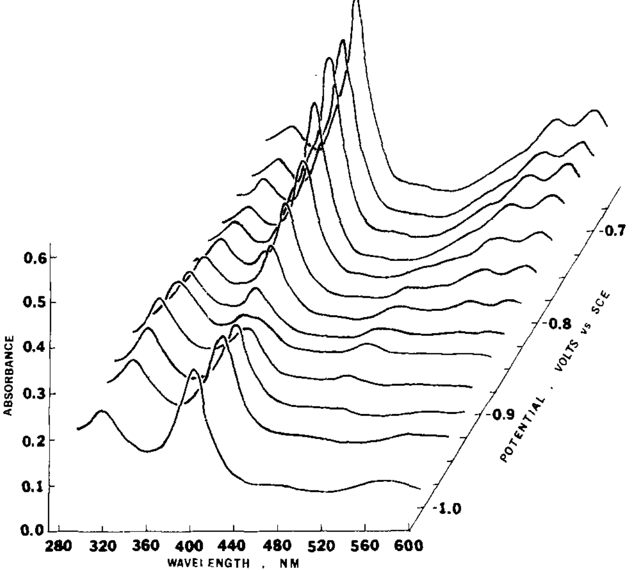

Fig. 11. Spectropotentiostatic curves for the reoxidation of cob(I)alamin (from 1 mM dicyanocobalamin) to dicyanocob(III)alamin, B_{12}-CN, in 1.0M Na_2SO_4, 0.1M $NaNO_3$; pH = 11.0 initially. Potential range = −1.0 to −0.675V vs. SCE at a Hg-Ni OTTLE. Cell thickness = 0.017 cm.

of B_{12a} corresponds almost identically with that of B_{12}. It should however be restated that the development of the 475 nm peak is noncoincident with that of the 410 nm peak. Figure 11 illustrates the spectropotentiostatic reoxidation curves for cob(I)alamin formed by the exhaustive reduction of dicyanocob-(III)alamin (B_{12}-CN). Several features of Fig. 11 are worth noting: (*a*) the potential region over which B_{12}-CN is reoxidized is drastically reduced when compared to B_{12} and B_{12a}, and (*b*) the total absence of a 410 nm absorbance peak during the electrochemical reoxidation sequence. The fact that the dicyanocobalamin reoxidation potential region is much narrower than that of either cyano- or aquocobalamin indicates much more reversible heterogeneous electron transfer kinetics which correlates with the homogeneous autooxidation rate curves shown in Fig. 4 through 8. The total absence of the 410 nm peak in the B_{12}-CN electrochemical reoxidation sequence is consistent also with the homogeneous autooxidation results.

In order to further examine the postulation that the 410 nm peak corresponds to a base-on cob(II)alamin, B_{12r}', the time-resolved autooxidation spectra of a cob(I)inimide (29) (no benzimidazole moiety on the corrin ring system) was examined. The absorbance-potential reduction characteristics of the cyanoaquo-cob(III)inimide (30) starting material and the rate of autooxidation parallel to those of vitamin B_{12} itself indicating that the lack of the benzimidazole moiety has not appreciably altered the redox properties of the central cobalt ion. However, the time-resolved autooxidation spectra of the cob(I)inimide do not exhibit a 410 nm peak as can be seen in Fig. 12 and 13. Thus, the B_{12}-CN and cob(I)inimide autooxidation spectra are consistent with the suggestion that the B_{12r}' (410 nm peak) is a base-on intermediate in the B_{12} and B_{12a} mechanism.

Electrochemical reoxidation of cob(I)alamin, obtained by the electroreduction of B_{12} under an argon atmosphere, goes through both the B_{12r} (475 nm) and B_{12r}' (410 nm) intermediates in the potential region from −0.60 to −0.01V *vs.* SCE yielding B_{12} at +0.10V *vs.* SCE. The conditions of the electrochemical reoxidation experiments indicate that the 410 nm peak is not indicative of an oxygen adduct type of cobalamin species.

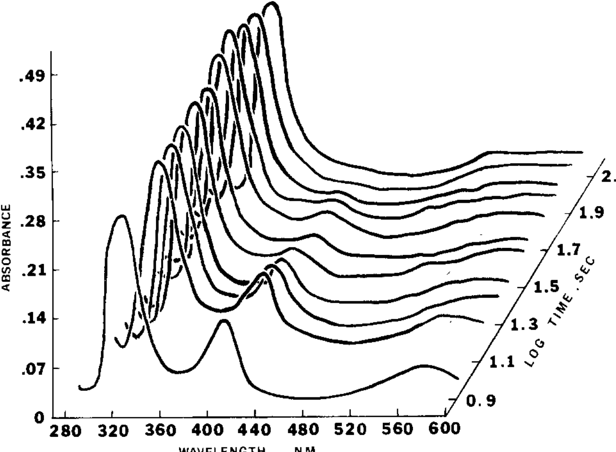

Fig. 12. Time-resolved spectra for the reoxidation of cob(I)inimide (from 1.0 mM aquocyanocob(III)inimide) to a cob(II)inimide in a 1.0M Na_2SO_4 solution; pH = 7 initially. Time span = 0-400 sec at a Hg-Ni OTTLE. Cell thicknesss = 0.017 cm.

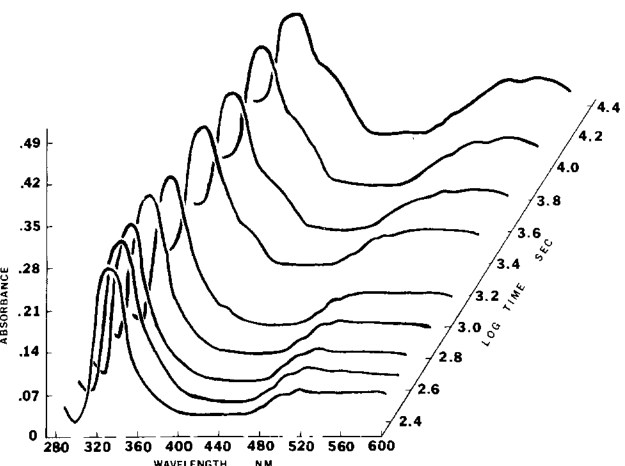

Fig. 13. Time-resolved spectra for the reoxidation of a cob(II)inimide to a cob (III)inimide in a 1.0M Na_2SO_4 solution; pH = 7 initially. Time span = 630-70,000 sec at an Hg-Ni OTTLE. Cell thickness = 0.017 cm.

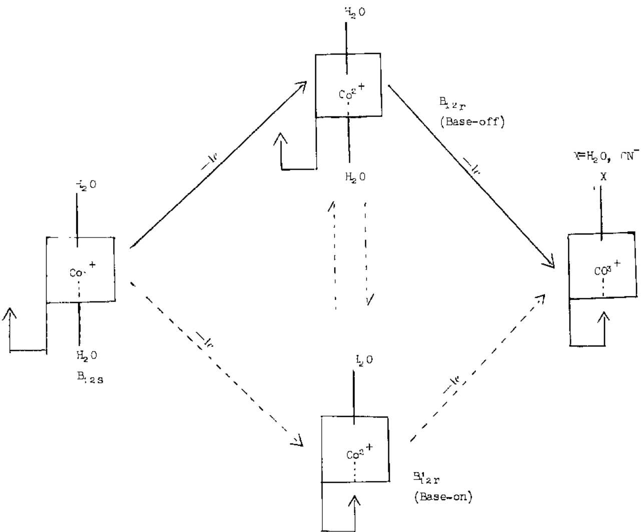
Qualitatively, the time-resolved spectra indicate that the reoxidation of cob(I)alamin in the presence of stoichiometric or less amounts of CN^- follows the reaction scheme illustrated below.



As previously mentioned, the presence of excess cyanide ion affects the reoxidation scheme such that either the B_{12r}' (base-on) species is not formed or that the oxidation of the B_{12r} (base-off) species is kinetically favored. It has been postulated by others (5-10) that cob(I)alamin autooxidizes to a cob(II)alamin with the evolution of hydrogen. This process would certainly explain the reoxidation of B_{12s} to B_{12r} where under existing conditions the hydrogen would be soluble in solution and bubbles not observed in the OTTLE cell. Furthermore, the postulation that the cob(II)-alamin can disproportionate to form a cob(I) and a cob(III)alamin species (5-10) cannot be directly observed by this study. The identical time-resolved spectral data would be observed for either (*i*) a direct sequential two-step oxidation where the first step is fast and the second is slow or (*ii*) a fast initial one-electron transfer to B_{12r} followed by a slow disproportionation to B_{12s} and B_{12}. The work of Birke *et al.* (10) estimated that the thermodynamic and kinetic parameters for such a disproportionation are very unfavorable. It has not been possible to calculate meaningful kinetic parameters from the time and potential resolved spectra as no quantitative diffusion model has been postulated. Moreover, we cannot really tell if the B_{12s} oxidizes directly to both B_{12r} and B_{12r}' at different rates or that if B_{12r}' results simply from a rapid equilibrium with B_{12r} as shown in the proposed mechanism. [Cobalt (II) complexes of this type are generally labile (26).] This same argument applies to the interpretation of B_{12r} and B_{12r}' oxidizing to cob(III)alamin(s). However, it does appear that the reoxidation of B_{12r} to dicyanocob(III)alamin occurs much more rapidly than the reoxidation of either B_{12r} or B_{12r}'. This can be seen by comparing the time scale of Fig. 5 and 7 to that of Fig. 8. Quantitative kinetic studies will be carried out in the near future.

ABSTRACT

In vitro methods have been developed over the last several years to predict the implantation behavior of cardiovascular prostheses. With metals and alloys, their spontaneous potentials in blood or physiological saline, the corrosion behavior in sodium chloride, and surface cleanliness are factors that determine the *in vivo* patency in animals and humans. The materials used for cardiac valves have a wide passivation region. *In vivo* monitoring of cardiac prostheses indicates an anodic shift of their rest potentials. Surface contamination appears to cause premature thrombosis and occlusion of cardiac valves.

Blood and Biocompatibility of Prosthetic Materials

Substitution or replacement of living tissues by artificial materials brings in its wake the problem of biocompatibility. Biocompatibility comprises a broad area covering a number of different types of prosthetic materials; dental, orthopedic, and cardiovascular (Table I). The mechanical, biochemical, and physicochemical requirements of prosthetic materials differ widely for these applications. While noninteraction with the surrounding tissue or body fluids is a primary condition for any implant, the requirements become far more stringent when it comes to cardiovascular prostheses. In this review we plan to cover the problems met with, and progress made in, the use of metallic prosthetic materials in the cardiovascular systems of animals and man.

Cardiovascular applications are varied and cover a very wide range, from *in vitro* and *ex vivo* devices such as cardiopulmonary bypasses and dializers, to *in vivo* prosthetic shunts, bypass grafts, and cardiac valves (Table I). Prosthetic materials that are used in any of these applications must satisfy some basic criteria of blood compatibility (Table II) (1). The material foreign to the body must have minimal effects on (*i*) denaturation of plasma proteins, (*ii*) red cell destruction due to toxicity of the material, (*iii*) platelet adhesion, release, and aggregation, and (*iv*) destruction or activation of blood coagulation factors resulting in thrombogenesis. If the prosthetic material is of biologic origin, such as porcine or bovine heterografts, the antigenic property also becomes an important parameter in determining its acceptance.

flexibility are very important for *in vivo* patency. Dacron velours, expanded polytetrafluoethylene, knitted dacron tubes and heterografts are normally used extensively for these applications.

Because of the various uses for polymers as blood compatible materials in the cardiovascular system, extensive studies have been carried out on (*i*) interactions of polymer surfaces with blood cells (2) and blood proteins (3), (*ii*) modification of surfaces of polymers by chemically binding with anticoagulants (4) and fibrinolytic agents (5), (*iii*) alteration of the constituent ionic groups (6) or use of chemical building blocks of desired structures (7) to synthesize suitable polymers, (*iv*) devising methods to increase the distribution of pores and regulation of pore size (8), (*v*) increasing the hydrophilic character (9), and (*vi*) modification of surfaces using the electret effect (10). These studies have led to the development of blood compatible polymers of better durability.

A few theoretical criteria have been developed to predict the *in vivo* patency of a polymeric material. As animal experimentations are expensive, a preliminary screening by *in vitro* techniques such as adsorption of platelets from whole blood (11), critical surface tension (12), and net surface charge (13) have been helpful in selection of materials. A number of basic studies concerning interactions of blood proteins at the molecular level have been carried out. As the purpose of this communication is to describe the work relating to the use of metals and alloys as cardiovascular prostheses, these aspects are not elaborated.

Metallic Prostheses

Metals and alloys are mainly used in cardiac valves, as, the positioning of the valve in the heart, ease of implantation, and flow conditions require sufficient mechanical strength of the material. The *in vitro* and *in vivo* methods of evaluation of a metallic prosthesis are described in Table III. Very low corrosion, low toxicity and blood destruction, nondenatured adsorption of blood proteins, low degree of platelet aggregation or adhesion are all necessary conditions for satisfactory function of a prosthesis in the vascular tree. However, factors like flow through the valve, stasis, turbulence pockets, and contamination can lead to premature failure of an otherwise satisfactory material or device. In the subsequent sections are described: (*a*) the *in vitro* tests, (*b*) an analysis of the factors contributory to thrombogenesis of metallic prostheses, (c) *in vivo* dysfunction, and (*d*) a few typical results of implantation of materials to illustrate how these factors contribute to proper function of the valves.

In Vitro Methods of Evaluation

Corrosion studies.—Determination of open-circuit potentials.—It has long been recognized that thrombosis is an interfacial reaction. In metals and alloys, their spontaneous potentials in blood or physiologic saline (0.9% NaCl) give an indication of thrombogenicity (14). It was observed that noble metals developing highly positive spontaneous potentials *vs.* NHE in blood or physiologic saline are invariably thrombogenic. Base metals like aluminum, on the other hand, tend to be nonthrombogenic (14). With metals and alloys, it is felt that a factor that determines interactions with blood is the point of zero charge (pzc)

of the component metals (15) and how anodic the rest potential of the alloy is to the pzc of these component metals. It has been generally observed that *in vivo* implantation of the material results in a progressive anodic shift in rest potentials (16). Prosthetic cardiac valves and experimental tubes of the same material have been known to show wide variation in their rest potentials due to storage and accumulation of corrosion products (17). It has been recently observed that commercially available cardiac valves that have welded portions show different potentials at different points of the strut (17). An inhomogeneous potential difference between parts of the same valve can be contributory to thrombosis. Thus the determination of rest potential of the metallic prosthesis gives a first indication of its prospective use in the cardiovascular system.

An extensive electrochemical study of materials for surgical implants in chloride media has been carried out (18). Iron, nickel, cobalt, and titanium based alloys were used for the investigation. Current-potential and potential-time curves were determined in NaCl and Hank's solution. The schematic of open-circuit potential-time curves (E-t) is shown in Fig. 1. Alloys which are potentially useful as implantable materials should have an intact passive film as shown by the E-t curve in Fig. 1(curve c). Vitallium, titanium, and some of its alloys, exhibit this type of potential-time behavior (18). Open-circuit potential-time studies were carried out in Hank's solution using mechanical and electropolished titanium alloys (19). The effects of including amino acids such as tryptophan, cysteine, glycine, cystine, and uric acid (the building blocks of most physiological proteins) on the E-t curves were also studied (19). It is observed that addition of these acids to the solution brings about an anodic shift in open-circuit potentials. These findings are similar to our observation of anodic shift in rest potential of implanted materials *in vivo* (16).

Polarization studies.—In vitro and *in vivo* galvanostatic, potentiostatic, and linear polarization studies have been carried out for a number of metals and alloys used as surgical implants over the last several years (18-28).

The effects of aeration of solution, cold-working, and annealing of some stainless steels have been studied using steady-state potentiostatic current-potential (i-E) determinations (20). Aeration has a marked effect on the shape of i-E curves of stainless steel 316 in Ringer's solution. Saturation of solution with oxygen shifts the passive breakdown potential relative to the deaerated solution by +350 mV *vs.* NHE. The oxygen capacity of human blood is reported to be 20 ml oxygen/100 ml (29) and plasma oxygen pressure in the human artery is 85 mm Hg (30). Thus it is very important to know the alteration in corrosion behavior of metals and al-

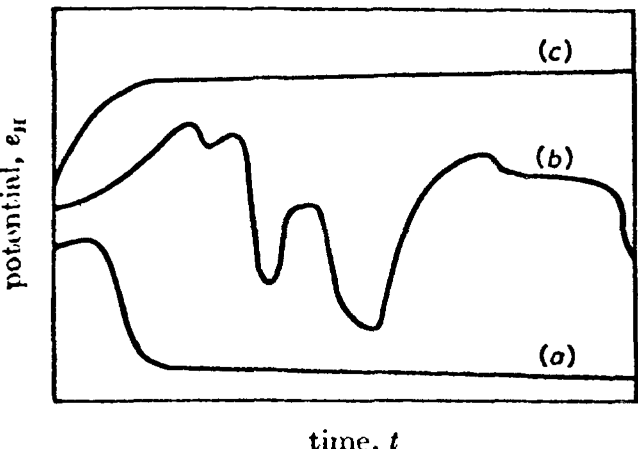

Fig. 1. Schematic potential-time curves (a) general corrosion, (b) pitting corrosion, and (c) film remains intact.

loys due to oxygenation. Metallurgical processes like cold-working and annealing have distinct effects on passivation region, transpassive current-potential behavior, and breakdown potential for stainless steel 316. A comparative evaluation of titanium, Vitallium, and stainless steel clearly shows the remarkable passivity of titanium. Polarization studies show that pure titanium remains passive in the potential range −0.05 to +1.15V *vs.* NHE (20). Figure 2 shows the striking passivity of titanium compared to annealed 316 stainless steel and cast Vitallium. Even Vitallium, which shows marked resistance to pitting attack, does not exhibit the polarization characteristics and passivity of pure titanium (20).

This group has done some studies with Haynes-25 to determine the polarization behavior of the alloy in deaerated physiologic saline. (21). Figure 3 shows the steady-state potentiostatic current-potential curve

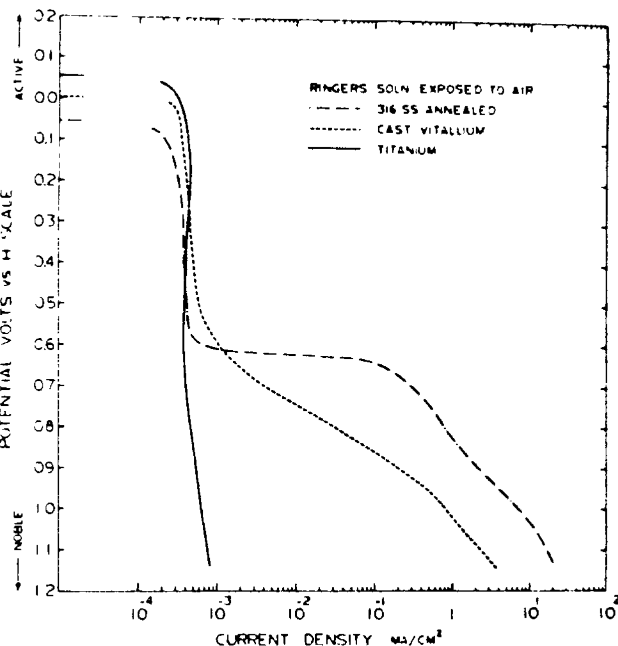

Fig. 2. Polarization behavior of annealed 316 stainless steel, cast Vitallium, and titanium in Ringer's solution.

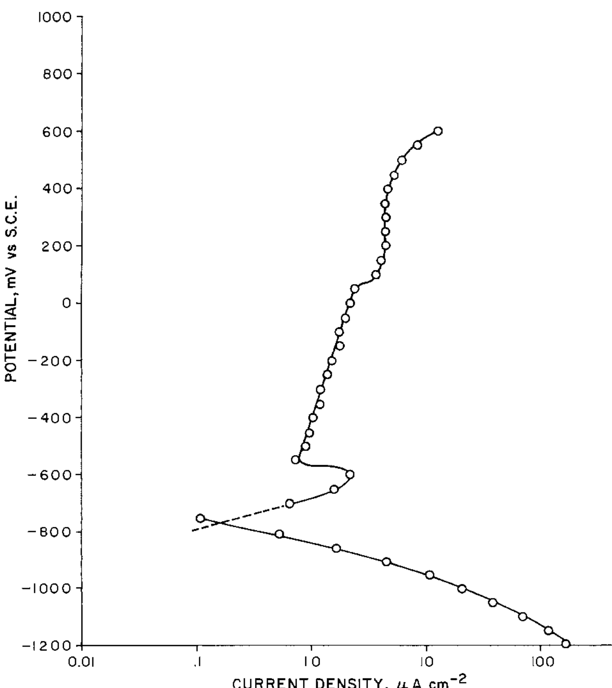

Fig. 3. Polarization behavior of Haynes-25 alloy in 0.9% NaCl

(log i-E) for Haynes-25 alloy in normal saline. The alloy has an extensive passive region (−600 to +400 mV SCE) and low corrosion (0.1 μA cm^{-2}) and passivation (1.2 μA cm^{-2}) current densities. These characteristics make the alloy relatively passive in a chloride ion environment.

Corrosion characteristics of various anode materials used in implantable power sources were determined using *in vitro* and *in vivo* polarization studies (22). *In vitro* anodic linear polarization studies in 0.9% NaCl showed corrosion rates of zinc and magnesium alloy AZ31B to be two to three orders of magnitude greater than that of aluminum under no load conditions. A significant decrease in corrosion currents for each of the metals following autoclave sterilization was observed. Loading of the anode at 25 μA cm^{-2} (equivalent to that used for powering presently available commercial pacemakers) increases the corrosion current for both zinc and aluminum metals, although, more so for the latter (22). These *in vitro* and *in vivo* corrosion studies showed the desirability of aluminum as an implantable anode to power pacemakers.

Effect of surface treatment on corrosion and passivity.—Aside from the base material used, surface preparation is of great importance in the incidence and rate of corrosion. This broad heading includes electrochemical and mechanical cleaning and polishing as well as sterilization techniques. The effect of chemical cleaning of Ti-6Al-4V with conc HCl on current-potential curve is seen in Fig. 4 (23). Since the HCl-treated sample has slightly higher passivation and corrosion currents, it is possible that the HCl treatment depassivates the surface.

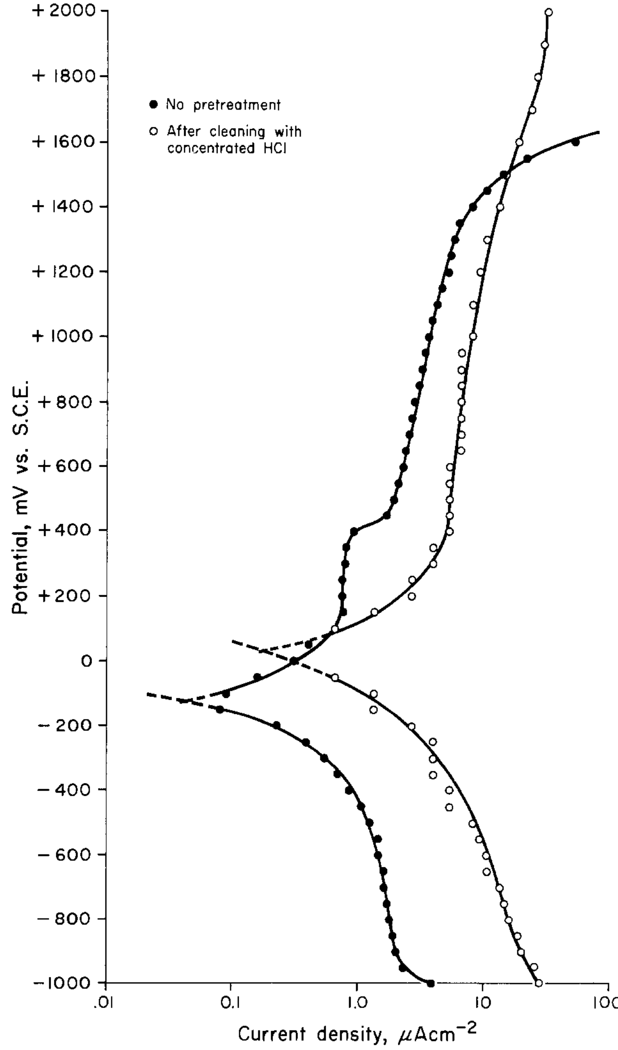

Fig. 4. Polarization behavior of Ti-6Al-4V alloy in 0.9% NaCl

The effects of surface roughness, prepassivation, and sterilization on the corrosion behavior of titanium, Vitallium, and stainless steel 304 and 316 were determined (24, 25). As could be expected, surfaces which were sandblasted, rough and fine mechanically polished and electrochemically polished (stainless steel 316 samples) showed a wide variation in passivation currents (i_{pass}). There was a difference of an order of magnitude in i_{pass} between sandblasted and electropolished samples. Prepassivation of surfaces tends to reduce the i_{pass} of stainless steel and Vitallium though the effects on titanium are less marked (24). Our implantation studies with aluminum and Stellite surfaces show that proper surface treatment has a definite effect in prolonging the patency of the material in the animal (26, 27).

The effect of sterilization, a procedure carried out prior to implantation, on subsequent corrosion behavior has also been studied (19, 25, 28). Electron diffraction studies of surfaces of some titanium alloys which were steam sterilized after electropolishing show the presence of oxides of titanium on the surface formed due to sterilization (19). It is believed that these can provide better initial protection for the implant. Steam sterilization has only minimal effect on i_{pass} of titanium, but leads to a marked reduction in i_{pass} of stainless steel (25). The *in vivo* i_{pass} is also reported to be decreased due to sterilization of some stainless steels (28).

As a final note, it should be pointed out that although sterilization tends to decrease corrosion, it appears to enhance surface thrombogenecity due to extraneous contamination. This effect of sterilization is dealt with later in the section on contamination and valvular dysfunction.

Platelet Adhesion and Release Reaction

A thrombus is formed *in vivo* by the following stages. Platelets from circulating blood stream adhere to a foreign surface or to the site of vascular injury. The adhesion of platelets leads to platelet release reaction, a process in which they exude a number of biochemical agents including adenosine tri, di, and monophosphates (ATP, ADP, and AMP) and glucose-6-phosphate (G-6-P) (31). Release of ADP in turn leads to sticking together of more platelets. This process is called platelet aggregation. The aggregated platelet plug is the first line of defense in preventing excessive blood loss due to injury. After this primary hemostasis, a permanent process of activation of blood coagulation proteins takes place resulting in polymerization of fibrinogen to fibrin (31). The fibrin strands trap further cellular elements to form a firm clot called a thrombus. This necessary defense reaction of the body, when triggered on a prosthetic material, leads to thrombosis and obstruction of function of the prosthesis.

From the foregoing, it is clear that the study of platelet adhesion and release reaction *in vitro* provides a valuable method in predicting the *in vivo* interactions. Platelet adsorption from whole blood has been used in the evaluation of blood compatibility of polymeric materials (11).

Cell precipitation or potential dependent adhesion of red cells and platelets has been studied using platinum electrode (32). It is observed that at potentials more anodic than +200 mV NHE, there is increased cell adhesion. Drugs that are well-known anticoagulants, those that affect platelet aggregation, and membrane poisons reduce the cell adhesion to platinum at all potentials (33), (Fig. 5). Metals and alloys that are presently used as prosthetic materials are now being studied using this test system to determine the extent of platelet adhesion.

Effect of some metals and alloys on platelet release reaction was investigated using rat platelets (34). Platinum, silver, copper, nickel, zinc, aluminum, and stainless steel powders were incubated with washed rat platelets and the release of adenine nucleotides

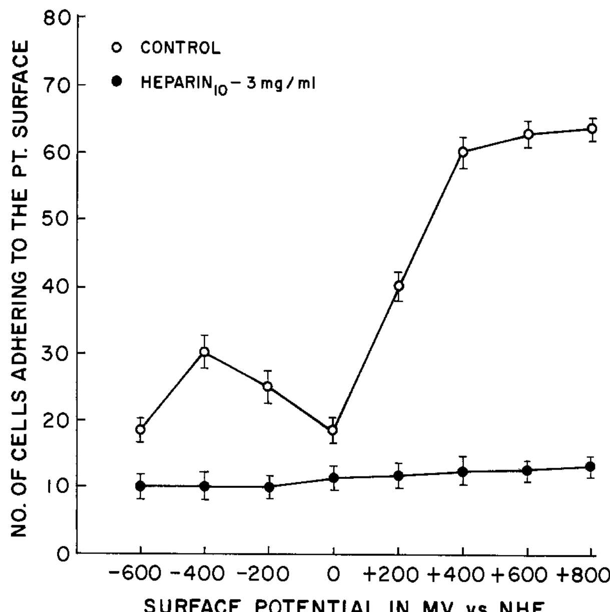

Fig. 5. Effect of heparin on potential dependent adhesion of platelets to platinum.

ATP, ADP, and AMP and G-6-P were determined. The results show (Fig. 6) that the highly corrodible metals like Mg, Zn, and Fe and readily complexed Cu cause extensive cellular destruction. Aluminum, nickel, and stainless steel do not cause either destruction of platelets or significant release of adenine nucleotides. Metals like Ag and Pt cause release of adenine nucleotides from platelets. As the release reaction results in platelet aggregation, it appears that those noble metals that show positive potentials in blood can cause platelet aggregation and subsequent thrombosis. These findings essentially agree with the earlier observations relating rest potentials of metals to thrombogenesis (14).

Interaction with Blood Elements

Circulating blood contains, in addition to platelets, red cells, leukocytes, lymphocytes, and blood coagulation proteins. Destruction of platelets leading to the release reaction has been discussed. Recent studies have shown that leukocytes are possibly involved in occlusion of prosthetic devices used *in vitro* and *in vivo*. The evidence is essentially circumstantial and one of the initial events taking place when a foreign surface, (*e.g.*, kidney dialyzer) comes in contact with blood is entrapment of leukocytes (35). Some animal studies also have shown that leukocytes are implicated in the pathogenesis of thrombosis (36). But detailed investigation as to interactions of foreign surfaces with leukocytes is lacking.

Red cell destruction is another important parameter. This is otherwise called hemolysis. A few tests reveal the occurrence of hemolysis due to implanted materials (37). A lowering of hematocrit is a direct indication of hemolysis. A few other indicators are plasma hemo-

globin, serum iron, red cell survival, serum hepatoglobin, urine hemoglobin, and urine iron.

The *in vitro* cell destruction has been determined for many metals and alloys. Using canine erythrocytes (red cells) and metal powders (Mg, Al, Zn, Cu, Ag, and Pt) the red cell destruction has been determined (38). The results show that metals like copper, platinum, zinc, and magnesium are highly toxic and lead to significant red and white cell destruction (Table IV). The importance of minimal red cell destruction can be understood from the fact that even a very mild red cell destruction of 0.08% in 24 hr due to a practical cardiac valve results in an increased production load on the bone marrow of 10% to prevent occurrence of hemolytic anemia (39).

Interaction with Blood Coagulation Factors

The interfacial reactions of blood coagulation proteins at metallic surfaces have been investigated extensively at the basic level using many electrochemical techniques (40-46). The adsorption and charge transfer reactions of purified blood proteins have been studied at platinum, mercury, and gold-solution interfaces (40-45). In general, highly cathodic potentials lead to desorption of blood proteins at the interface while anodic potentials show an increase in adsorption. Fibrinogen seems to be "electropolymerized" to fibrin-like material at anodic potentials (45). Fibrinogen is readily adsorbed on to the metallic surfaces. The strong adsorption of fibrinogen may be due to the number of tryptophan residues in the molecules (44).

The effect of certain metal powders on whole blood clotting times (38), fibrinogen polymerization time, and thrombin recalcification time for plasma were determined (47). Some of the typical results are shown in Tables IV-VI. It is observed that copper is readily complexed by blood proteins and hence results in abnormally long clotting times. The effects of aluminum, gold, and platinum on plasma and fibrinogen clotting times appear to be minimal, especially if fibrinogen solutions are well buffered. Copper is complexed by blood proteins as can be seen by the development of blue color and incoagulability of fibrinogen and plasma.

The importance of extension of such studies to practical prosthetic materials that are presently used in cardiac valves need not be overemphasized. Adsorption and activation of blood proteins at surfaces can serve as a trigger mechanism for the blood coagulation cascade resulting in conversion of fibrinogen to fibrin (48). Fibrin is the essential constituent of all formed thrombi *in vivo*. A basic understanding of adsorption of blood coagulation proteins at these metal (alloy)-solution interfaces is necessary for proper choice of blood compatible materials. The studies carried out using Pt, Hg, and Au show that anodic potentials favor adsorption (40-45). An *in vivo* follow up of potentials of implanted prostheses show an anodic shift with time (16). Thus the study of potential dependent adsorption of proteins and consequent transformation or denaturation will be highly fruitful. With practical prostheses, however, such studies have not been reported.

Recently adsorption of fibrinogen on Stellite-21 has been studied using radioactively labeled fibrinogen (49). The results are of particular relevance in the design and manufacture of cardiac valves. It was observed that adsorption of fibrinogen is (*i*) less on polished glass compared to polished Stellite-21, (*ii*) the amount of fibrinogen adsorbed on to polished Stellite-21 is dependent on polishing characteristics of the surfaces, and (*iii*) Teflon-coated Stellite-21 surfaces adsorb more fibrinogen (Fig. 7) (49).

In Vivo Evaluation

The *in vivo* evaluation of a material which has satisfactory *in vitro* interactions could be carried out in a number of ways. Polymeric tubes and materials have been tested on an *ex vivo* system by extra-corporeal shunting of the artery of experimental animals through the prostheses (50). This is a fast and inexpensive short-term study where one can examine the thrombi deposited in short periods of time. A more stringent preliminary method of evaluation is to implant the prosthesis in the form of a Gott ring (51) or Sawyer tube (52) in the thoracic inferior vena cava or descending thoracic aorta of an experimental animal for varying periods of time. On removal, the implant is visually examined for junctional thrombus and the nature of thrombus deposited is studied by histologic and electron microscopic techniques.

Thrombogenic Propensity of Metallic Prostheses: Alteration by Artificial Means

A potentially highly thrombogenic metallic prosthesis can be made virtually thrombus-free *in vivo* by artificial means. As described earlier, metals and alloys that show highly negative spontaneous potentials in blood or physiologic saline are nonthrombogenic (14). If materials that develop positive spontaneous potentials are maintained at cathodic potentials by passing a cathodic current (53) or galvanic coupling (54), the *in vivo* patency can be radically improved. The re-

Table VI. Effect of metal powders on coagulation of plasma

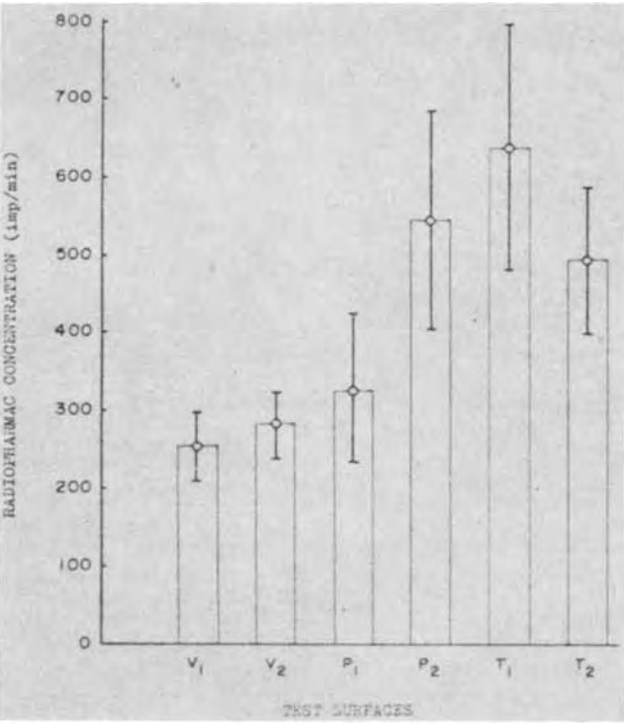

Fig. 7. Adsorption of ^{125}I labeled fibrinogen to (a) polished glass (V_1 and V_2); (b) polished Stellite-21 (P_1 and P_2); and (c) Teflon-coated Stellite-21 (T_1 and T_2) surfaces.

sults of such studies clearly show the importance of negative potentials in maintaining *in vivo* patency of a metallic implant in the cardiovascular system. Two typical examples of prosthetic materials illustrate this point.

Copper is highly thrombogenic, toxic to blood, complexed by body proteins, and occludes completely in a few hours when implanted as a cardiac valve or as a tube (in canine thoracic inferior vena cava) (53). A thrombosed copper prosthesis is shown in Fig. 8. When the copper tube is maintained at a negative potential either by passing a cathodic current (Fig. 9) (53), or high frequency (100 Hz) alternating current (Fig. 10) (55), no thrombus is deposited in the tube for as long as the circuits are operational. It is clear from Table VII that both the techniques result in development and maintenance of a negative potential on the prostheses in the blood stream. Histologic evaluation of the thin deposit on the tubes that have been polarized by a.c. reveals randomly scattered green, brown, and red specks throughout the protenacious matter indicating leaching of Cu as Cu(II) that gets later precipitated

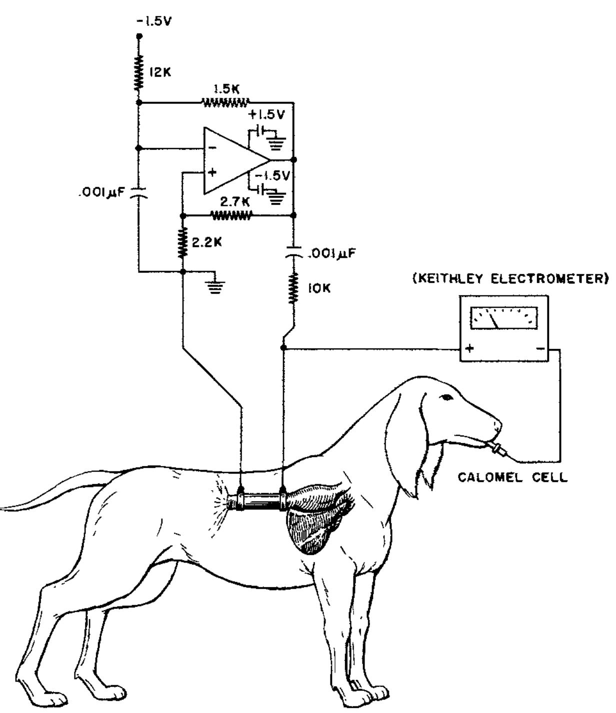

Fig. 10. Copper tube with 100 kHz a-c polarization, schematic

probably as basic copper oxides (55). Thus the inherent reactivity of copper is still observable though the thrombotic problems are virtually eliminated.

Another equally interesting case investigated is a titanium alloy (Ti-6Al-4V). Corrosion studies with this alloy have been carried out (Fig. 4) (23). The *i-E* curve shows a large passive region with low corrosion and passivation currents. But the rest potentials are positive *vs.* NHE (Table VIII). Tubes of the alloy, irrespective of the mode of pretreatment, occlude completely in the animal and the longest survivor lasted only for 135 min (Table VIII). The same material was galvanically coupled with aluminum and one could see from Table IX the improvement in *in vivo* patency. As could be expected, wrapping aluminum foil on the outside of the tube shifts the rest potential to highly cathodic values and tubes are thrombus-free.

Factors Resulting in Dysfunction of Cardiac Valves

Choice of material and design of the valve.—Metallic heart valves in major use today, are the Starr-Ed-

wards, Lillehei-Kaster, Bjork-Shiley and Smelloff-Cutter valves. Only titanium and cobalt base alloys are used for the manufacture of these valves; Stellite-21 (Starr-Edwards series), titanium (Smelloff-Cutter, Lillehei-Kaster), and Haynes-25 (Bjork-Shiley). The compositions of the two alloys are given in Table X (56, 57). Based on open-circuit potential-time measurements, and *in vitro* and *in vivo* corrosion studies, it was felt that the best materials for surgical implants are titanium and cobalt based alloys (18). All these metals are passive in chloride medium, take a good mechanical polish, are mechanically strong, and have minimal blood cell and blood protein interactions. The disk or ball used in these valves are made of either Stellite, silastic or pyrolytic graphite. These are also nontoxic and nonreactive. A successful cardiac valve must be designed in such a way as to lower blood trauma, possess long durability, develop low pressure gradient, and result in minimal regurgitation (39). These additional problems, caused by blood flowing through a valve that has impaired flow characteristics, and imperfect closing, can lead to serious valvular dysfunction.

Despite proper choice of materials, design and standardized methods of manufacture, packing and storage, varying degrees of success in long-term function of the valve have been achieved at different centers. The factors that are contributory to this unpredictable dysfunction are indicated in Table XI. The problems related to stasis of blood and hemolysis are tackled purely by better designs which result in (*i*) exposure of minimal areas for blood stasis, and (*ii*) reduced areas of overlap between the disk or ball and the seat, which lessens trauma to cellular elements in blood and hence lowers hemolysis. Another clinically relevant factor, though of not much interest from the electrochemical standpoint, is poor healing of the sutured valve, resulting in fibroblastic invasion, proliferation of collagen, total trapping of the disk or ball, and consequent failure. This problem has been virtually eliminated in our laboratory animal implantations by the autogenous venous ring technique (58).

Contamination.—This is one of the factors contributory to serious thrombosis and embolization. Only recently this aspect of valvular dysfunction has been recognized and studied in detail (26, 27, 59). Sources of surface contamination can occur (*i*) during manufacture, (*e.g.*, polishing waxes), (*ii*) during storage, due to accumulation of corrosion products, (*iii*) during autoclaving prior to implantation, and (*iv*) during actual

implantation as a result of talc and foreign materials from gloves.

A systematic study of the influence of these factors has been made in our laboratories during the last five years. Scanning electron microscopy coupled with x-ray spectroscopy is a highly useful technique for "screening" and identification of surface contamination on cardiac valves. Figures 11 and 12 show the surface of a Starr-Edwards Stellite-21 valve subjected to different types of pretreatment and autoclaving. The incorporation of extraneous ions due to steam autoclaving could be seen clearly in the x-ray spectroscopic photographs (Fig. 12). In some of the cardiac valves removed due to failure, one could see fingerprints on the valve "preserved" by thrombi formed on these sites.

It thus appears extremely important to maintain care during pretreatment and implantation of these valves if reproducible long-term patency is to be achieved.

The contamination problem raises the question of the best method of pretreatment. We have obtained excellent results in animal implantation studies using electropolished or electrocleaned valves (26, 27). Figure 13 shows an electropolished aluminum valve implanted for 82 days. It is clear that even the striations on the strut surface, formed due to gas evolution during electropolishing, do not serve as foci for thrombus deposit.

The effect of the factors described above on the long-term survival of cardiac valves and tubes in experimental animals is seen clearly in Fig. 14 and 15. The function of aluminum and one of the commercially used cardiac valves are compared. One can see that thrombogenesis and long-term survival are critically dependent on type of surface treatment employed, the care with which implant was handled during surgery, and proper healing of the valve seat in the heart.

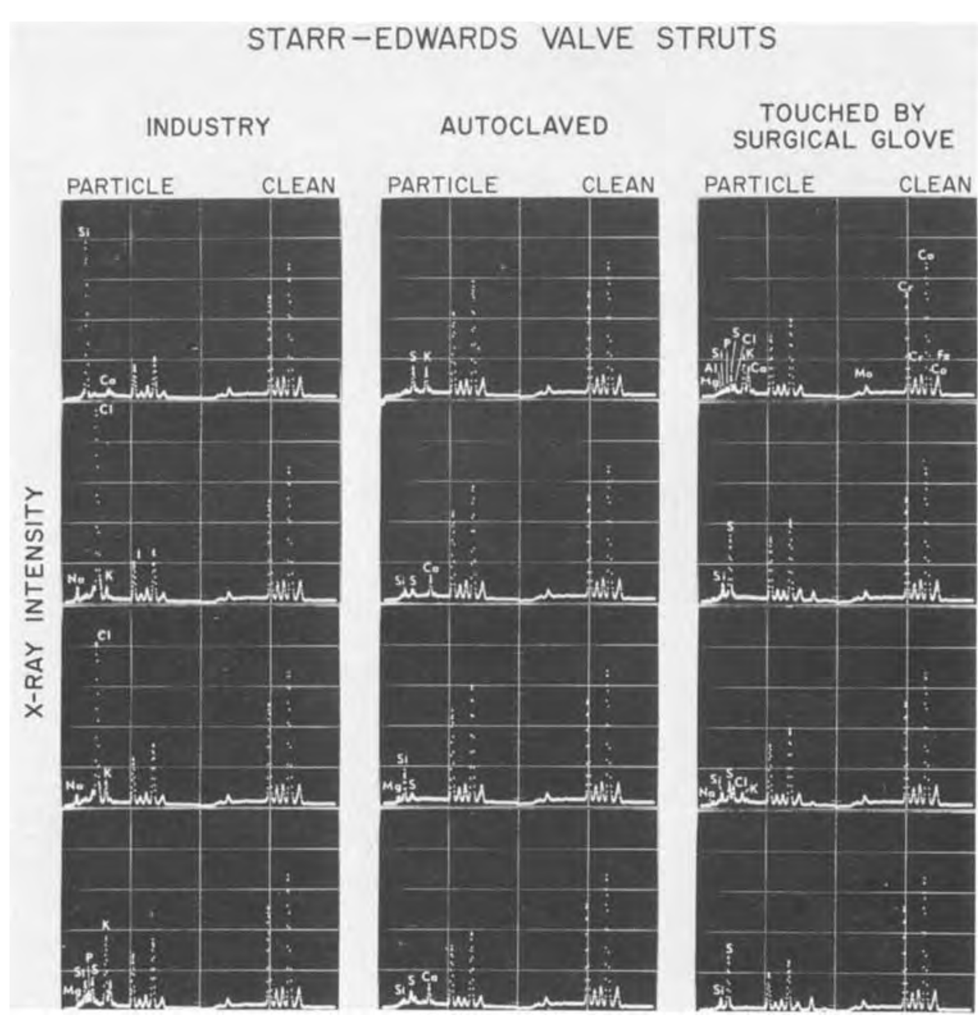

Fig. 12. Characterization of surface contamination using x-ray spectroscopy. The peaks on the left side marked "particle" of the three columns represent areas on Fig. 11 where one could see particulate matter. X-ray peaks on the right side of the three columns, marked "clean" represent the particle free areas of Fig. 11.

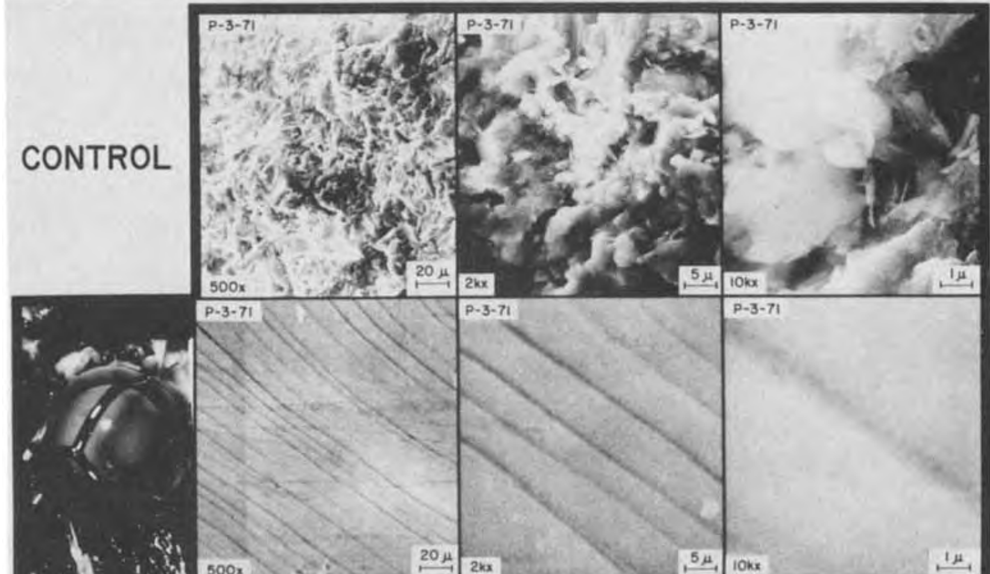

Fig. 13. Electropolished aluminum valve implanted for 82 days, an SEM study.

Embolization.—Despite the precautions taken during implantation, embolization is still a problem in humans. When a formed thrombus breaks loose and is carried away by the blood stream, the small thrombi, called emboli can cause death if they manage to occlude blood vessels in the brain or lung. Thus most humans with prosthetic heart valves are on some form of anticoagulant therapy for the rest of their lives. Cases of fatality are reported due to insufficient anticoagulation (39).

Conclusion

A metal or an alloy that could be used as a cardiovascular prosthesis has to satisfy the following criteria: (*a*) the material must be passive or have very low corrosion rate in physiologic medium, (*b*) it should have low toxicity to blood cells, (*c*) the platelet adhesion and release must be minimal, and (*d*) it must not react or activate the blood coagulation proteins.

The spontaneous potential of the material appears to predict the *in vivo* function if it is clean. Thus metals showing high negative potentials (*vs.* NHE) are nonthrombogenic. In practical prostheses, additional factors, including design of the valve, contamination, and poor healing, can contribute to valvular dysfunction. *In vitro* corrosion studies and measurement of rest potentials give an indication of the suitability of a metal as a candidate for cardiovascular prosthesis. Electrochemical cleaning and polishing techniques appear to be effective in improving the long-term patency of many metallic cardiac implants.

Manuscript received June 30, 1975. This was Paper 370 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Studies in Photoelectrochemistry

III. Theory for Induced Charging Currents in Potentiostatic Chronoamperometry Involving Competing Chemical Reactions

S. S. Fratoni, Jr.[1] and S. P. Perone

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

ABSTRACT

The first paper in this series (1) developed a theoretical model for characterizing the charging currents induced by changing faradaic currents measured under potentiostatic conditions. This paper describes application of the theoretical model to measurements involving electrolysis mechanisms complicated by competing reactions. The model is particularly relevant for flash photoelectrochemical studies. The mechanisms considered here include first order and second order decay of electroactive photoproducts. The dependence of measured currents on various experimental and chemical parameters—including the cell time-constant, photoproduct concentrations, and rate constants—is described for a wide range of conditions. Theoretical relationships can be used to predict total measured currents, or to tabulate correction factors to extract purely faradaic currents from measured currents. In addition, an alternative derivative-correction method for extracting faradaic signals from combined currents is described.

The concept of "induced" charging currents in potentiostatic chronoamperometric experiments has been described previously (1). Even under applied potentiostatic conditions, such as in flash photoelectrochemical studies (2, 3), changing faradaic current causes a change in potential across the double layer and consequently induces charging current to flow. Because these induced currents depend on the nature of the faradaic current time dependence, an experimental "blank" cannot be obtained. Thus, a theoretical model was developed (1) to characterize this effect. The model was then applied to the specific case involving diffusion-limited faradaic current (1), and the predicted relationships were verified experimentally (4).

This paper considers the extension of the theoretical model to potentiostatic chronoamperometric measurements of systems involving chemical complications. Specifically, the induced charging current effects are characterized for systems in which the electroactive species is also involved in a chemical reaction. First and second order competing reactions are considered, assuming instantaneous generations of transient electroactive species, such as in flash photolysis experiments.

Theory

The same model and method of analysis as presented previously (1) is used here. The basic procedure consists first of defining an electrical equivalent representation of the electrochemical cell and potentiostat (Fig. 1). Standard electrical circuit analysis (5) is then performed to determine the relationships between the current terms. The first step in this analysis involves transformation of the equivalent circuit into its Laplace domain representation (Fig. 2). This allows analysis of the circuit based on fundamental electrical laws to find the Laplacian expression for the total current. The time domain function can then be obtained by taking the inverse transform. Following this procedure, as demonstrated in (1), the following Laplace domain expression is obtained

$$I_T(s) = \frac{1}{R} \cdot \left\{ \frac{E_f}{s} - \frac{\dfrac{E_f}{sR} + E_iC - I_F(s)}{\dfrac{1}{R} + sC} \right\} \quad [1]$$

where $I_T(s)$ = Laplace transform of total current, R = effective uncompensated resistance (assumed to be constant), s = Laplace variable, E_f = reference electrode potential during experiment, E_i = reference electrode potential immediately before experiment, C = double layer capacitance (assumed to be constant), $I_F(s)$ = Laplace transform of faradaic current. This general expression is next modified to represent the specific conditions present during the measurement. For this work, potentiostatic conditions are assumed. This is accomplished by letting $E_f = E_i = E$, where E is the applied potential. Substituting into Eq. [1] and rearranging gives

$$I_T(s) = \frac{1}{RC} \left\{ \frac{I_F(s)}{s + \dfrac{1}{RC}} \right\} \quad [2]$$

This expression will hold for any electrolysis mechanism under potentiostatic conditions.

Key words: photoelectrochemistry, photopolarography, chronoamperometry.

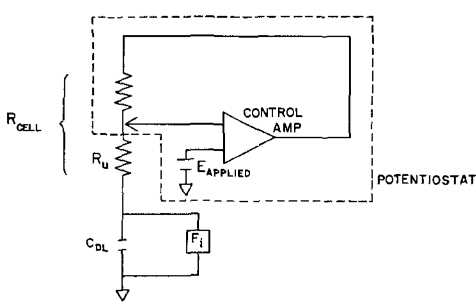

Fig. 1. Simplified model of electrochemical cell

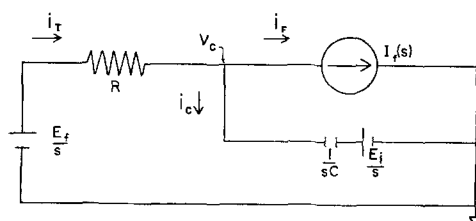

Fig. 2. Laplace domain equivalent circuit representation of electrochemical cell (arrows indicate direction of anodic current).

For this work, flash-initiated electrolysis currents will be assumed, with a typical example of the electrode process

$$O \xrightarrow{h\nu} R \quad [3]$$

$$R \rightarrow O + ne^- \quad [4]$$

Previously (1, 4), the specific case where R was a stable species, and reaction [4] produced diffusion-limited faradaic currents described by the Cottrell equation, was considered. The results indicated that, rather than following the expected Cottrell behavior, the measured current should reflect both charging and faradaic contributions, as described by Eq. [5]

$$i_T(t) = \frac{2K}{\sqrt{\pi RC}} e^{-t/RC} \int_0^{\sqrt{t/RC}} e^{\lambda^2} d\lambda \quad [5]$$

Here, t = time after the flash and $K = n\mathbf{F}AD^{1/2}C^o$, with the various symbols having their usual electrochemical meaning.

This paper is concerned with the case where the electrode process involves a chemical reaction, parallel to [4] above, involving species R. The nature of this competing reaction must be considered in order to determine $I_F(s)$. The specific cases of a first and second order competing reaction will be given below.

It is important to note here that the only assumptions made thus far specify potentiostatic conditions, constant electrolysis mechanism, and constant R_u and C_{DL}. Therefore, the derivation is not limited to photolysis-initiated processes. The expressions are equally valid for other electrochemical experiments, such as potential step, with the addition of the standard charging current term to compensate for the applied potential change (1). However, regardless of how the chemical process is initiated, such as with a potential step, the form of the faradaic current expression, $I_F(s)$, must be known to derive the total current. The derivations below are, for convenience, described in photopolarographic terms.

First order case.—If the photolyzed species produced by the flash decays by a first order process in addition to being oxidized at the monitoring electrode, the reactions involved would be

$$O \xrightarrow{h\nu} R \quad [6]$$

$$R \rightarrow O + ne^- \quad [7]$$

$$R \xrightarrow{k_1} Z \quad [8]$$

Assuming an infinitesimally short flash, homogeneous production of R around the electrode, Z is not electrochemically active, and the electrode potential is always on the diffusion plateau, then the faradaic current measured should be described by (2)

$$i_F(t) = \frac{K}{\sqrt{\pi t}} e^{-k_1 t} \quad [9]$$

where $K = n\mathbf{F}AD^{1/2}C^o$, k_1 = first order rate constant, t = time after flash, C^o is the initial concentration of species R, and the other terms have their usual meaning. $I_F(s)$ is then found simply by taking the Laplace transform of Eq. [9]

$$I_F(s) = \frac{K}{\sqrt{s + k_1}} \quad [10]$$

Substituting this into Eq. [2] above gives

$$I_T(s) = \frac{K}{RC} \cdot \left[\frac{1}{\sqrt{s + k_1}\,(s + 1/RC)} \right] \quad [11]$$

The inverse transform of Eq. [11] will then give the time domain expression for the total current

$$i_T(t) = \frac{K}{RC\sqrt{k_1 - 1/RC}} e^{-t/RC} \operatorname{erf}\left[\sqrt{(k_1 - 1/RC)t}\right] \quad [12]$$

This expression can be simplified by making the following substitutions

$$\tau = t/RC \quad [13]$$

$$\beta = \frac{k_1}{1/RC} = k_1 RC \quad [14]$$

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-u^2} du \quad [15]$$

$$K' = \frac{K}{\sqrt{\pi RC}} \quad [16]$$

The resulting equation is

$$i_T(\tau) = \frac{2K' e^{-\tau}}{\sqrt{\beta - 1}} \int_0^{\sqrt{(\beta-1)\tau}} e^{-u^2} du \quad [17]$$

This expression can only be evaluated for $\beta > 1$, ($k_1 > 1/RC$). Equivalent expressions can be derived in order to determine the magnitude of the total current for the case of $\beta = 1$ (by taking the limit of Eq. [17] as $\beta \rightarrow 1$), and $\beta < 1$ (by factoring out a $\sqrt{-1}$ from ($\beta - 1$) terms in Eq. [17]). The resulting expressions are: for $\beta = 1$, (or $k_1 = 1/RC$)

$$i_T(\tau) = 2K' \sqrt{\tau}\, e^{-\tau} \quad [18]$$

for $\beta < 1$, (or $k_1 < 1/RC$)

$$i_T(\tau) = \frac{2K'}{\sqrt{1-\beta}} e^{-\tau} \int_0^{\sqrt{(1-\beta)\tau}} e^{u^2} du \quad [19]$$

Figure 3 gives plots of total current as a function of time (in terms of τ) and β. From these curves, it is evident that as β increases, the peak maximum is less, it occurs at shorter times, and the current decays to zero faster. Interpretation of these observations is simplified by referring to Eq. [14]. β is a dimensionless parameter that represents the ratio of the "time constants" of the chemical and capacitive process. Increasing β corresponds to increasing the rate of reaction [8] compared to the electrolysis reaction [7]. A composite plot of the total, faradaic, and charging currents *vs.* time for $\beta = 1$ is given in Fig. 4. Because the ratio between i_F and i_T is dependent on both RC and k_1, the time at which the induced charging current can be considered negligible cannot be described

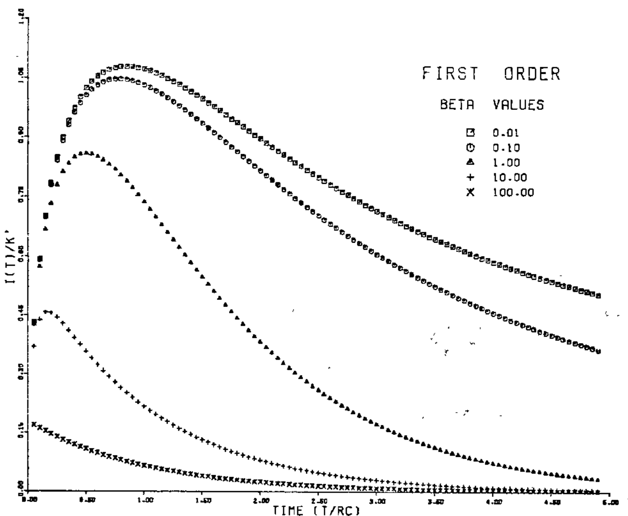

Fig. 3. Total current *vs.* τ with β = 0.01, 0.1, 1.0, 10.0, and 100.0, for potentiostatic/first order case (τ = 0.0-5.0).

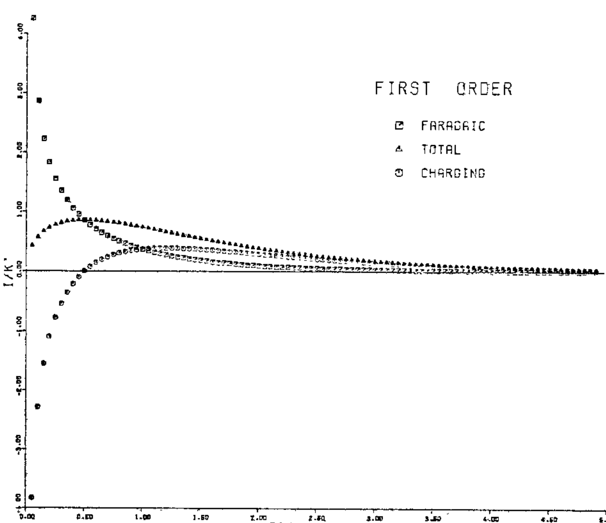

Fig. 4. Composite plot of predicted $I(T)/K'$, $I(C)/K'$, and $I(F)/K'$ vs. τ with $\beta = 1.0$ for potentiostatic/first order case ($\tau = 0.0$-5.0).

solely in terms of the cell time-constant as was the case for diffusion-controlled faradaic currents (1).

Second order case.—A more common occurrence in photopolarographic experiments involves a second-order competing reaction and a corresponding mechanism as given below.

$$O \xrightarrow{h\nu} R \qquad [20]$$

$$R \rightarrow O + ne^- \qquad [21]$$

$$2R \xrightarrow{k_2} Z \qquad [22]$$

Again it is assumed that R is produced homogeneously around the electrode by an instantaneous flash, that Z is electrochemically inactive, and that the electrode potential is always on the diffusion plateau. The faradaic current expected in this case would be (2, 6)

$$i_F(t) = \frac{K}{0.73k_2C^o\sqrt{\pi}} \cdot \left[\frac{1}{\sqrt{t}(t + 1/0.73k_2C^o)} \right] \qquad [23]$$

where k_2 = second order rate constant, C^o = initial concentration of electroactive species, and other terms as defined previously. Transforming this into the Laplace domain gives

$$I_F(s) = \frac{K\sqrt{\pi}}{\sqrt{0.73k_2C^o}} e^{s/0.73k_2C^o} \operatorname{erfc} [\sqrt{s/0.73k_2C^o}] \qquad [24]$$

In order to find the total current expression, Eq. [24] is substituted into Eq. [2]

$$I_T(s) = \frac{K\sqrt{\pi}}{RC\sqrt{0.73k_2C^o}} \left[\frac{e^{s/0.73k_2C^o} \operatorname{erfc} \sqrt{s/0.73k_2C^o}}{s + 1/RC} \right] \qquad [25]$$

The time domain expression for the total current is found next by taking the inverse transform of Eq. [25]. However, in this case the inverse transform cannot be taken directly by reference to available tables. In this case, the convolution integral (7) was used

$$\mathcal{L}^{-1} F_1(s) F_2(s) = \int_0^t f_1(\lambda) f_2(t - \lambda) d\lambda \qquad [26]$$

where $\mathcal{L}$ is the Laplacian operator, $\mathcal{L}^{-1}$ is the inverse operation, and $F_x = \mathcal{L}(f_x)$. Equation [25] can be broken down by letting

$$F_1(s) = e^{s/0.73k_2C^o} \operatorname{erfc}\sqrt{s/0.73k_2C^o} \qquad [27]$$

$$\text{and } f_1(\lambda) = \frac{\sqrt{1/0.73k_2C^o}}{\pi\sqrt{\lambda}(\lambda + 1/0.73k_2C^o)} \qquad [28]$$

$$F_2(s) = \frac{1}{s + 1/RC} \qquad [29]$$

$$\text{and } f_2(t - \lambda) = e^{-(t-\lambda)/RC} \qquad [30]$$

Substituting these expressions into Eq. [25] results in

$$i_T(t) = \frac{K}{RC\sqrt{\pi}} e^{-t/RC} \int_0^t \frac{e^{\lambda/RC}}{\sqrt{\lambda}(0.73k_2C^o\lambda + 1)} d\lambda \qquad [31]$$

This integral cannot be evaluated in its present form because the integrand is undefined at $\lambda = 0$, even though the over-all integral should be continuous. This problem is resolved by defining a new variable z such that

$$z = \sqrt{\lambda/RC} \qquad [32]$$

In addition, the equation can be generalized by defining a dimensionless parameter α such that

$$\alpha = \frac{0.73k_2C^o}{1/RC} = 0.73k_2C^oRC \qquad [33]$$

α is the ratio of the time constants for the chemical and capacitive processes. The final expression for the total or measured current, after making the above substitution in addition to those given in Eq. [13] and [16] gives

$$i_T(\tau) = 2K'e^{-\tau} \int_0^{\sqrt{\tau}} \frac{e^{z^2}}{1 + \alpha z^2} dz \qquad [34]$$

A plot of the resulting current terms (total, faradaic, and charging) *vs.* time for $\alpha = 1$ is given in Fig. 5. The effect of α on the total current is shown in Fig. 6. The change in the total current with increasing α is very similar to the first order case where β is varied. Obviously, the significance of the induced charging current at any time will be dependent on the values of the second order rate constant (k_2) and initial concentration of electroactive species (C^o), as well as the cell time-constant (RC).

Discussion

Known electrolysis mechanism.—The two expressions for the total current derived above for the first and second order cases (Eq. [17] and [34]) should approach the diffusion-limited case as α or β go to zero. This would correspond to the competing reactions, [8]

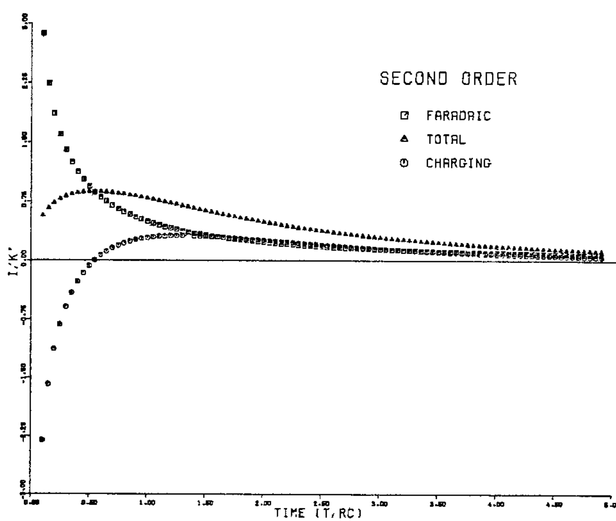

Fig. 5. Composite plot of predicted $I(T)/K'$, $I(C)/K'$, and $I(F)/K'$ vs. τ with $\alpha = 1.0$ for potentiostatic/second order case ($\tau = 0.0$-5.0).

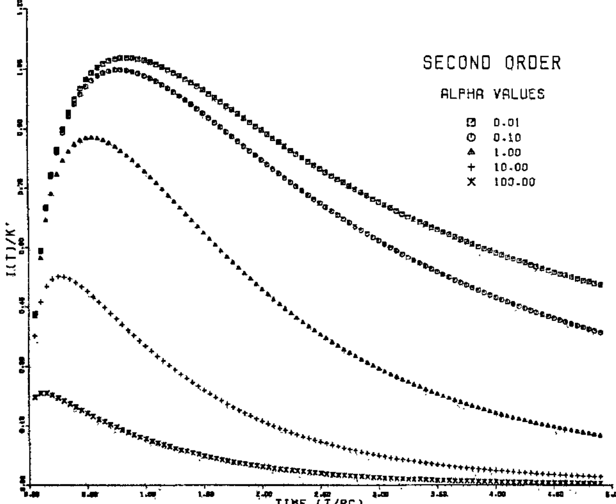

Fig. 6. Total current vs. τ with α = 0.01, 0.1, 1.0, 10.0, and 100.0, for potentiostatic/second order case (τ = 0.0-5.0).

or [22], becoming negligible. It is obvious for the first order case (Eq. [19]), as $\beta \to 0$, and for the second order case (Eq. [34]) as $\alpha \to 0$, that the diffusion-limited expression (Eq. [5]) is obtained. As a further indication that both Eq. [34] and [19] do approach the diffusion-limited case, the value of τ at which the maximum total current occurs was calculated *vs.* β (Table I) and α (Table II). As is evident from these tables, the peak maximum for both the first and second order total currents approach, with decreased α or β, the diffusion-limited value (1) of $\tau_{I_T(\max)} = 0.85$. These results support the validity of the derivations given here.

Application of these expressions for experimental correction should follow the approach used previously. A correction factor composed of the predicted ratio $i_F(\tau)/i_T(\tau)$ based on the measured time is first calculated. The measured current at each point is then multiplied by its corresponding factor. For these cases, however, the value of α or β must be known in addition to the cell time-constant (RC). For the diffusion-limited case, only the cell time-constant had to be known, in addition to the measured time, to evaluate the correction factor. The time constant can be measured in a separate experiment, or, as was demonstrated for the diffusion-limited cases (4), found directly from the measured current-time curves (for longer cell time constants). For the two cases presented here, the time constant does not appear to be directly determinable from the total current. Tables I and II,

Table I. Dependence of τ at I_T(max) on β for first order case

β	$\tau I_{T(\max)}$
0.001	0.85
0.05	0.81
0.10	0.78
0.5	0.61
1.0	0.50
10.0	0.16
100.0	0.04

Table II. Dependence of τ at I_T(max) on α for second order case

α	$\tau I_{T(\max)}$
0.001	0.85
0.05	0.81
0.10	0.78
0.5	0.63
1.0	0.54
10.0	0.26
100.0	0.12

however, indicate that the peak current time ($\tau_{I_T(\max)}$) may be indicative of the value of α or β.

As is evident from the two cases presented above, the theoretical model (1) is adaptable to any form of electrolysis mechanism. The procedure demonstrated above should be the general approach used to find the explicit mathematical expression for the total current when the time dependence of the faradaic current is mathematically defined.

Derivation of the time domain representation of the total current can be shortened in future work, however, by application of the convolution integral directly to Eq. [2]. This eliminates determination of the Laplace transform of the faradaic time function (which may be extremely difficult for complex electrolysis mechanisms), as in Eq. [24], and inverse transformation of the Laplace expression for the total current, as in Eq. [25].

Equation [2], which will hold for any electrolysis mechanism under applied potentiostatic conditions, can be rewritten as the product of two terms

$$I_T(s) = [I_F(s)] \cdot \left[\frac{1}{RC} \cdot \frac{1}{s + 1/RC} \right] \qquad [2]$$

The convolution integral (refer to Eq. [26]) can be applied directly to this product to obtain a time domain expression of the total current without first obtaining a Laplace domain expression for i_F. The first term (f_1) will be the time-dependent expression for the faradaic current with the t's replaced by λ's. The second term (f_2) of the resulting integral will be

$$\frac{1}{RC} e^{-(t-\lambda)/RC} \qquad [35]$$

as given above. By this method, true Laplace domain analysis can be accomplished without requiring intermediate transformations.

Unknown electrolysis mechanism.—The work presented here and previously (1) has employed a theoretical model based on prior knowledge of the electrolysis mechanism. This knowledge is necessary if the total current expression is to be derived. However, many instances may occur when the mechanism is not known. Under these conditions it is possible to correct observed currents for induced charging current by following an alternative procedure described below.

The induced charging current can be computed directly from observed total currents, under potentiostatic conditions, as long as RC is known. The general relationship is given by (1)

$$i_T = i_F + i_{ch} \qquad [36]$$

Assuming constant double layer capacitance

$$i_{ch} = C \frac{dE_{DL}}{dt} \qquad [37]$$

where E_{DL} is the potential across the double layer, $R = R_u$, and $C = C_{DL}$. Also

$$E_{DL} = E_p - i_T R \qquad [38]$$

where E_p is the applied cell potential. Combining these and rearranging, Eq. [39] is obtained, which allows for direct calculation of corrected faradaic current

$$i_F = i_T + RC \frac{di_T}{dt} \qquad [39]$$

Although experimental difficulties exist in obtaining the necessary derivative in Eq. [39], principally due to noisy signals, the corrected currents should be much closer to the "true" value than the measured total current. Subsequent evaluation of the faradaic current behavior should lead to a possible mechanism for the chemical system. Once this preliminary analysis is per-

formed, it is still advantageous to use the method demonstrated above to obtain a rigorous mathematical expression for the total current. Such an expression will indicate the effect of all experimental factors on the signal being measured in order to optimize the measured current for the data acquisition system. Experimental information may also be directly obtainable from the total current, *e.g.*, RC in the diffusion-limited case (1) and α or β as shown above, which cannot be determined directly from the faradaic current. The explicit expression for i_T also allows for inclusion of current terms other than just the faradaic and induced charging currents as was assumed in Eq. [36].

Conclusion

The implications of this work are twofold. The specific expressions derived for reactions involving first and second order competing steps are directly applicable to chronoamperometric measurements in general, and specifically to photoelectrochemistry. Application of correction factors obtainable from these expressions allows for meaningful faradaic current measurements at times short compared with the cell time constant. The magnitude of this improvement is expected to be comparable to that reported previously (4) for diffusion-controlled currents. The explicit expressions obtained from this model also allow for more comprehensive characterization of the total currents involved; consequently additional information (*e.g.*, determination of α or β directly from the measured current) may be obtained.

Another important aspect of this work is the development of a general procedure for applying the theoretical model to other systems. The procedures and suggestions presented here should allow for application of this model to more complicated electrolysis mechanisms and photoelectrochemical processes. Experimental studies have been completed which provide a verification of the expressions derived above. These data are presented elsewhere (8).

An important extension of the concepts discussed here and earlier (1) is the compounding effect of induced potential change. The induced charging current described above arises from a potential change across the double layer as the result of changing faradaic current and a finite, uncompensated resistance. This potential shift was briefly noted by Booman and Holbrook (9), in a derivation similar to ours (1), in their description of various sources of inaccuracy in controlled potential electrolysis. Our studies [including, Ref. (1), (4), and (8)], have been limited to faradaic processes that are potential independent, and therefore involve a constant electrolysis mechanism even with changing potential (*e.g.*, where the double layer potential remains on the redox plateau). Although the effect of induced charging current is significant under these limited conditions (4), it is expected to be a much more important factor when potential-dependent faradaic currents are involved. Work is presently underway in this laboratory to employ this model under these conditions and characterize the effect on relevant controlled-potential, electrochemical methods.

Studies in Photoelectrochemistry

IV. Flash Photolysis Studies of *p*H Dependence of Benzophenone Photodimerization

K. F. Dahnke[1] and S. P. Perone

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

ABSTRACT

A chronoamperometric study of the *p*H dependence of flash photodimerization of benzophenone in H_2O/ethanol solution is presented. Measured potentiostatic currents have been corrected for induced charging currents prior to kinetic analysis. Either a curve-fitting technique or a derivative correction method was used to obtain purely faradaic currents. Rate constants for the photodimerization reaction in acidic solution are reported here for the first time. Three methods were used for the extraction of kinetic information from current-time data: (*i*) approximate chronoamperometric theory, (*ii*) rigorous chronoamperometric theory, and (*iii*) digital simulation. The latter two techniques produce nearly identical rate constants for a given data set. This suggests that both are valid; also, it demonstrates that the digital simulation approach may be applied successfully to other coupled kinetic-diffusion problems where rigorous mathematical solutions do not exist. The *p*H study presented here was used to obtain individual rate constants for the radical-radical, radical-radical anion, and radical anion-radical anion reactions. The values reported are 2.5×10^8 M^{-1} sec^{-1}, 1.1×10^9 M^{-1} sec^{-1}, and $\leq 7.8 \times 10^4$ M^{-1} sec^{-1}, respectively.

Flash photoelectrochemistry has been used with varying degrees of success to study photochemical reactions (1-9). The electrochemical methods, while inherently sensitive and specific, have suffered because they perturb the measured system due to electrolysis. As a result, the interpretation of chronoamperometric signals is not always straightforward. For example, in previous photoelectrochemical studies, measured potentiostatic currents were considered to be totally faradaic in nature, ignoring any charging current contribution that may have been present. Also, rigorous solutions of kinetic-diffusion equations, allowing useful kinetic data to be extracted, did not exist for other than the first order case (10).

An approximate solution to the second order case was reported by Birk and Perone (2), and has been used in several kinetic studies, including flash photoelectrochemistry (2-4) and pulse radiolytic polarography (11). However, a more rigorous, generally useful theoretical approach is needed to allow the study of a wide variety of photoelectrochemical processes. A digital simulation technique, developed by Feldberg (12) for complex kinetic-diffusion equations, has been applied here to the second order kinetic case in flash photoelectrochemistry.

Britz and Kastening (13) have recently reported a rigorous mathematical solution to the coupled second order kinetic-diffusion problem for flash photopolarography at stationary planar or spherical electrodes. Their results indicate that the second order rate constant obtained using the Birk-Perone approximation (2) is about 27% too low, although the initial intermediate concentration obtained from their expression is correct.

In this paper, results have been compared for the Britz-Kastening (13), Birk-Perone (2), and digital simulation data interpretation methods for the benzophenone photodimerization reaction (2, 14). Also, the measured currents have been corrected for induced charging currents, using the approaches described by Fratoni and Perone (15, 16), prior to kinetic analysis by any of the above methods. Because of the theoretical refinements mentioned above, it was possible to conduct a study of the *p*H dependence of the second order photodimerization reaction of the benzophenone ketyl radical and/or radical anion (2, 14) over a wider range than had previously been attainable (2). Rate constants obtained using each of the above three methods have been compared. Also, rate constants for the three individual reactions (radical-radical, radical-radical anion, radical anion-radical anion) have been calculated from the *p*H study.

Experimental

Instrumentation.—All of the instrumentation used in this work has been extensively reported elsewhere (16). No modifications of the electrode and cell design, potentiostat, flash, or measurement devices have been made. The system utilizes a 200J 15 μsec xenon flash; the monitoring electrode is a hanging mercury drop (HMDE); the potentiostat has a 0.16 μsec transient response time; and the minicomputer data acquisition system uses a 50 kHz maximum data rate. Cell time constant measurements were made as described previously (16).

Data handling.—Second order curve-fitting method.—A computer program was used to extract second order rate constants and initial radical concentrations from the measured chronoamperometric data using the Fratoni-Perone curve-fitting method (15). A second order data handling program (SODH) allowed for correction of current-time data for induced charging current, while calculating values for k_d and C^o using the Birk-Perone second order plot technique (2). The program carries out an iterative calculation starting with an initial estimate of α, ($k_d C^o R_u C_{DL}$), from the raw data and the measured cell time constant (15); finding the appropriate i_F/i_T values; multiplying the measured currents (i_T) by these factors to obtain i_F; calculating $1/i\sqrt{t}$ *vs.* time; and calculating a new $k_2 C^o$ for the corrected data. The whole procedure is repeated until α converges to within preset limits. Final values of k_d, C^o, i, and $1/i\sqrt{t}$ are printed out. (R_u is the uncompensated cell resistance and C_{DL} is the double layer capacitance. Their product is the cell time constant.)

Derivative correction method.—Another computer program was written to extract purely faradaic currents based on the following method. If the electrochemical cell is represented schematically as shown in Fig. 1,

[1] Present address: Phillips Petroleum Company, Phillips Research Center, 238RB-1, Bartlesville, Oklahoma 74004.

Key words: photoelectrochemistry, photopolarography, flash photolysis.

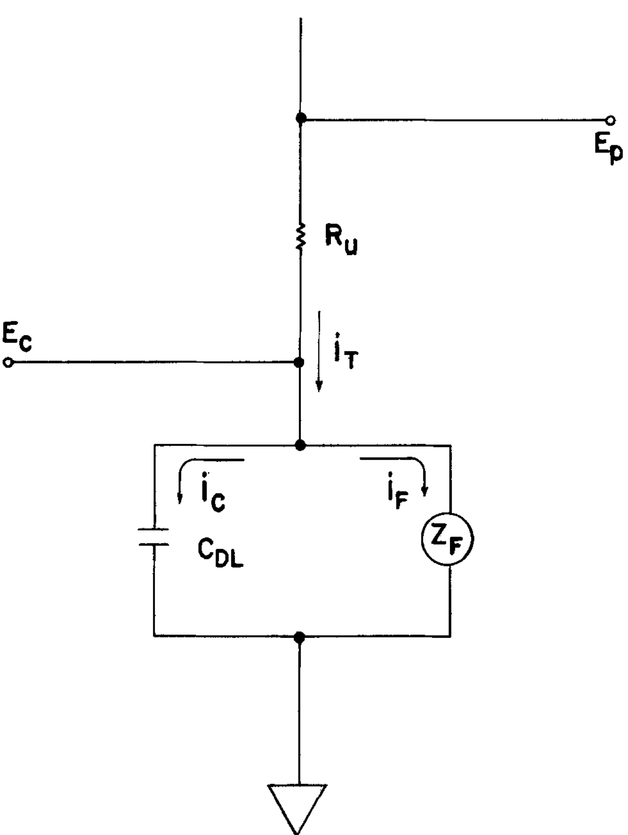

Fig. 1. Electrochemical cell model, induced charging currents: E_P = applied potential from potentiostat, E_C = actual working electrode potential, R_U = uncompensated resistance, C_{DL} = capacitance of electrode double layer, Z_F = faradaic resistive element, i_T = total current, i_F = faradaic current, i_C = faradaic-induced charging current.

the total current, i_T, flowing through the cell at any time may be expressed as

$$i_T = i_F + i_C \quad [1]$$

where i_F = the faradaic current and i_C = charging current. But, the charging current is defined as follows

$$i_C = C_{DL}\left(\frac{dE_C}{dt}\right) \quad [2]$$

Since

$$E_C = E_P - i_T R_u \quad [3]$$

and

$$\frac{dE_C}{dt} = -R_u \frac{di_T}{dt} \quad [4]$$

Under potentiostatic conditions, the applied potential E_P is constant; therefore the following expression should be valid

$$i_F = i_T + R_u C_{DL}\left(\frac{di_T}{dt}\right) \quad [5]$$

Hence, if di_T/dt, the derivative of the measured current-time curve, is obtained, and if the cell time constant is known, purely faradaic current values may be extracted. The computer program calculates the derivative of a current-time curve at each point as $(i_2 - i_1)/(t_2 - t_1)$ and calculates i_F. A smoothing routine using the Savitsky-Golay seven-point or nine-point method (17) may be elected to reduce the noise introduced to the i_F-t curve due to the derivative processing technique. k_d and C^o values are then calculated using the Birk-Perone second order plot method (2) from the i_F-time values. Figure 2 shows a comparison of a typical current-time curve that was uncorrected corrected using the curve-fitting SODH program, and corrected by the derivative technique.

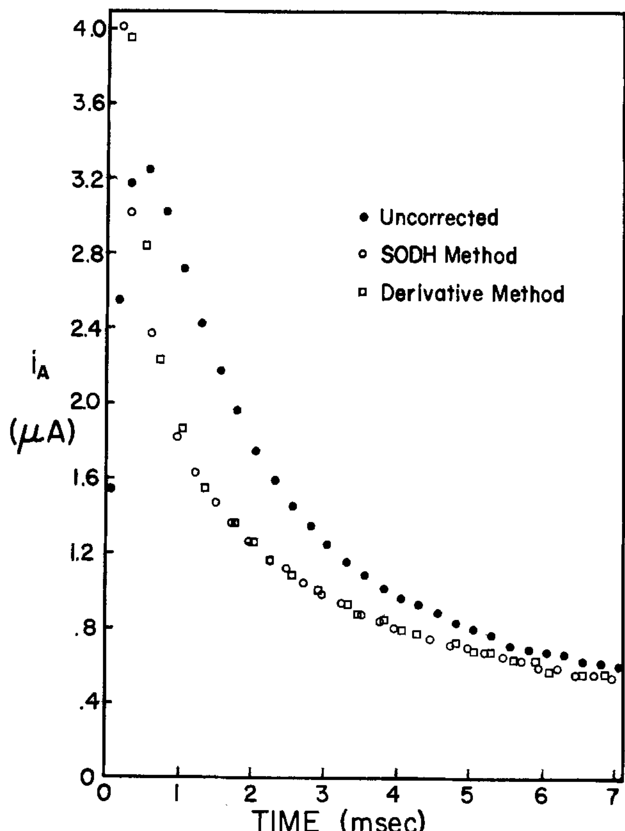

Fig. 2. Current-time curves, correction method comparison: $5 \times 10^{-4}M$ benzophenone, 0.01M NaOH, 0.25M KCl, 50% ethanol/H_2O, RC = 568 μsec.

Other computer programs.—A program was written to provide calculation of the digital simulation (12) working curve for the coupled second order kinetic-diffusion problem. Calculation of k_d from corrected experimental data was done manually from this curve.

Other programs allow calculation of charging-current-free current-voltage profiles by either of the above techniques. All programs were written in Hewlett-Packard BASIC with BASIO subroutine overlay (16), modified to allow 50 kHz data acquisition.

Experimental procedures.—The following procedures were used to obtain current-voltage profiles. At all potentials positive of the start of the benzophenone reduction wave, potentiostatic current measurements were made. For potentials more negative than the foot of the wave, a potential step was applied, simultaneously with the flash, to the monitoring potential of interest, from a potential where benzophenone is not reduced.

There are two kinds of background signals for which various chronoamperometric experiments must be corrected. One of these pertains only to potential-step experiments, and this is due to potential-step charging current. This background was measured as described above for potential-step experiments, except the solution contained only the background electrolyte. This blank was then subtracted off-line from the potential-step currents measured with benzophenone present.

The other type of background signal pertains to all chronoamperometric experiments, including the potential-step blank runs. This is the combined background due to electronic disturbances related to the flash discharge and any amplifier drift or offset. A measure of this background is obtained prior to every flash experiment by initiating the flash discharge and measuring the resulting current-time curve while preventing the light from reaching the cell with a movable shutter. This background signal is then subtracted on-line from a subsequent current-time curve, obtained

either potentiostatically or with potential step, with the shutter open or closed. Further off-line data processing (extraction of faradaic currents and kinetic plots) proceeded only on data corrected for background signals. At least two experimental curves were averaged at each potential.

Electrode positioning and optical alignment were maintained throughout the entire current-voltage profile and blank measurement processes. At least 1 ml of solution was removed from the immediate vicinity of the mercury drop after every flash, and nitrogen was bubbled throughout for 10-15 sec to insure homogeneity in solution for the next flash experiment. No noticeable change in the total concentration of benzophenone present was observed after many flashes of the same solution, as long as the minimum volume was not allowed to fall below 20 ml from the initial 90 ml.

Individual current-time curves used for the kinetic study were obtained potentiostatically using the above procedures. At least 10 *i-t* curves were averaged together, however, for these data sets.

Reagents.—All studies were conducted in 50% ethanol/water solutions. Buffers down to *p*H 9 were prepared using CO_2-free water from KCl-NaOH-$NaHCO_3$ solutions. For kinetic studies the ionic strength was maintained at 0.25, except for the 0.5*M* NaOH solution. The *p*H 5.5 solution was prepared using an 0.25*M* acetate buffer. The *p*H 7 solution was prepared from a 0.01*M* phosphate buffer, adjusted to *p*H 7.0 with NaOH; because of the limited solubility of this buffer in the ethanol/water solvent, the ionic strength was adjusted to 0.25 with KCl. *p*H measurements were made with a Corning Model 110 expanded scale *p*H meter (Corning Laboratory Products, Corning New York). All chemicals were analytical reagent grade.

Results and Discussion

Benzophenone in 50% ethanol/H_2O was studied at various *p*H values. The mechanism for the photochemical reduction of benzophenone in solvents like ethanol has been reported elsewhere (2, 14, 18). Benzophenone absorbs radiant energy below about 390 nm and undergoes efficient intersystem crossing to form its excited triplet state, which then can abstract an α-hydrogen from a solvent like ethanol. This produces a ketyl radical plus a very short-lived ethanol radical (11)

$$\left|\phi-\overset{O^*}{\overset{\|}{C}}-\phi\right| + CH_3CH_2OH \rightarrow \phi-\underset{\cdot}{\overset{OH}{\overset{|}{C}}}-\phi + CH_3\underset{\cdot}{C}HOH \quad [6]$$

The ketyl radical is in rapid equilibrium with its radical anion

$$\phi-\underset{\cdot}{\overset{OH}{\overset{|}{C}}}-\phi \rightleftharpoons \phi-\underset{\cdot}{\overset{O^-}{\overset{|}{C}}}-\phi + H^+ \quad [7]$$

The ketyl radical or radical anion species can then react by three possible paths, all second order

$$\underset{(R\cdot)}{\phi-\underset{\cdot}{\overset{OH}{\overset{|}{C}}}-\phi} + \phi-\underset{\cdot}{\overset{OH}{\overset{|}{C}}}-\phi \xrightarrow{k_1} \underset{(P)}{\phi-\underset{\phi}{\underset{|}{\overset{OH}{\overset{|}{C}}}}-\underset{\phi}{\underset{|}{\overset{OH}{\overset{|}{C}}}}-\phi} \quad [8]$$

$$\underset{(R\cdot^-)}{\phi-\underset{\cdot}{\overset{O^-}{\overset{|}{C}}}-\phi} + \phi-\underset{\cdot}{\overset{OH}{\overset{|}{C}}}-\phi \xrightarrow{k_2} \underset{(P^-)}{\phi-\underset{\phi}{\underset{|}{\overset{OH}{\overset{|}{C}}}}-\underset{\phi}{\underset{|}{\overset{O^-}{\overset{|}{C}}}}-\phi} \quad [9]$$

$$\phi-\underset{\cdot}{\overset{O^-}{\overset{|}{C}}}-\phi + \phi-\underset{\cdot}{\overset{O^-}{\overset{|}{C}}}-\phi \xrightarrow{k_3} \underset{(P^=)}{\phi-\underset{\phi}{\underset{|}{\overset{O^-}{\overset{|}{C}}}}-\underset{\phi}{\underset{|}{\overset{O^-}{\overset{|}{C}}}}-\phi} \quad [10]$$

Each reaction forms the benzopinacol product. In basic solution, the pinacol dissociates slowly to benzhydrol and benzophenone. The over-all second order rate process has been studied electrochemically (1-4, 19-21). The total amount of ketyl radical plus ketyl radical anion can be monitored electrochemically, since both species are oxidized at any potential positive of the benzophenone reduction potential. However, if the reaction is studied over a *p*H range where all three reactions occur significantly, the second order rate constant for each of the three above reactions may be obtained.

The flash photoelectrochemical behavior of benzophenone in very alkaline solution is shown in the charging-current-free current-voltage profiles in Fig. 3 and 4. Region I represents current due to a 2-electron reduction of benzophenone (20) before and after the flash. Region II shows current due to a 1-electron oxidation of the ketyl radical/radical-anion intermediate. Region III shows current due to the 2-electron oxidation of the benzopinacol product. No benzopinacol oxidation is noted in Fig. 3 because of the very "slow" kinetics relative to 2 msec after the flash. Except for changes in half-wave potentials, similar profiles for the benzophenone system are obtained at every *p*H studied here. However, the time scale must be modified to accommodate kinetic changes with *p*H.

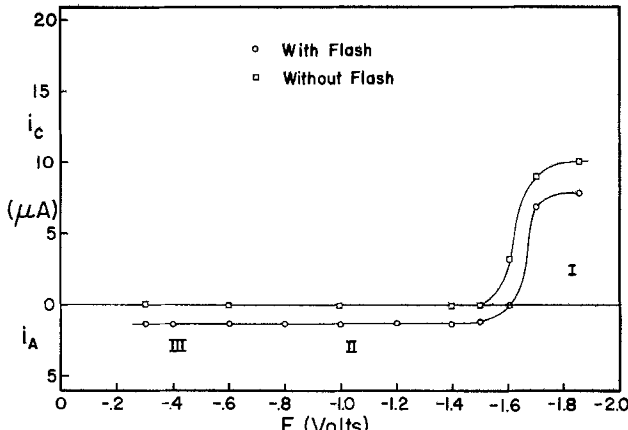

Fig. 3. Current-voltage profile: $5 \times 10^{-4}M$ benzophenone, 0.25*M* NaOH, 50% ethanol/H_2O, $t = 2$ msec after start of experiment (with or without flash).

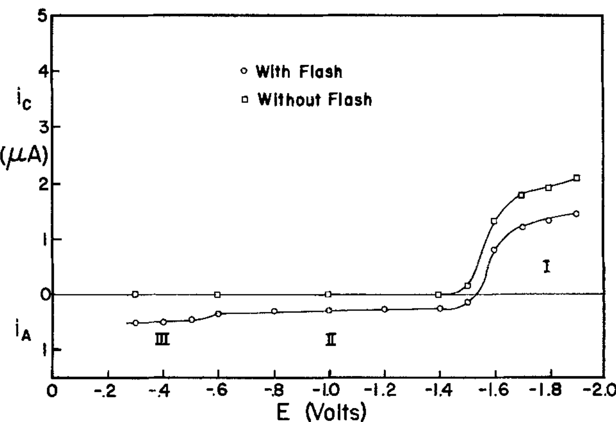

Fig. 4. Current-voltage profile: $5 \times 10^{-4}M$ benzophenone, 0.25*M* NaOH, 50% ethanol/H_2O, $t = 50$ msec after start of experiment (with or without flash).

If a potential on the oxidation plateau of the radical species is applied, one can monitor currents related to the total concentration of the ketyl radical/radical anion present at any time after the flash. Only currents corrected for faradaic-induced charging current have been used in the kinetic studies reported below; no previously reported photoelectrochemical studies of this reaction (1-4, 8-9) have considered the significance of the induced charging current, and the comparison between results reported here and previously will be discussed.

Theory.—Assuming the following photodimerization-electrochemical model

$$O \xrightarrow{h\nu} R\cdot \xrightarrow{k_d} \tfrac{1}{2}P \quad (R\cdot \xrightarrow{-e^-} O) \qquad [11]$$

Birk and Perone (2) applied Eq. [12] to the analysis of chronoamperometric data for the oxidation of the radical intermediate

$$\frac{1}{it^{1/2}} = \left[\frac{\pi^{1/2}}{nFAD^{1/2}}\right]\left[\frac{1}{C^o} + k_d t\right] \qquad [12]$$

C^o is the initial concentration of the radical plus radical anion, k_d is the second order rate constant for the disappearance of total R, and the other symbols have the usual electrochemical meanings (22). Thus, a plot of $1/it^{1/2}$ *vs.* time should be linear, having a slope proportional to k_d and intercept related to C^o. However, because Eq. [12] represents only an approximate solution to the kinetic-diffusion equation (2), it was felt that a more generally applicable method would be desirable.

A digital simulation of the coupled second order kinetic-diffusion process defined in Eq. [11] was formulated here, using the method of Feldberg (12), which is an explicit approach to the solution of partial differential equations by finite differences. The fundamental expression which relates the change of concentration of species R (ΔC_R, change in total ketyl radical plus radical anion) in discrete volume elements X units away from a planar electrode, as a function of time, is as follows

$$\Delta C_R = \frac{(\Delta t)D_R}{(\Delta X)^2} \cdot (C_{RX-1} - 2C_{RX} + C_{RX+1}) - k_d C_{RX}^2(\Delta t) \qquad [13]$$

This expression is a restatement of Fick's second law of diffusion for the second order kinetic case, defined in Eq. [11], in terms of discrete values for distance, X, time, t, and concentration, C_R. The term D_R is analogous to the diffusion coefficient of the intermediate. A computer program was written to calculate ΔC_R in Eq. [13] for up to 1000 volume and time elements. The program calculates the change of concentration of the intermediate at the electrode surface for a given time element and then calculates the flux, or current per unit electrode area, as a function of time. This information is most appropriately represented as a plot of two dimensionless parameters, $[(\text{flux})t^{1/2}]/(C^oD^{1/2})$ and k_dC^ot. Such a plot is shown in Fig. 5 for the second order kinetic-diffusion case, and, since it is independent of the k_d, C^o, or D_R values, it can be used as a working curve for kinetic studies. From experimental flash chronoamperometric data, the value of the function $(it^{1/2})/(nFAD^{1/2}C^o)$ can be determined, assuming all of the denominator terms are known. This expression corresponds to the Y-axis parameter for the simulator plot. Thus, the second order rate constant, k_d, can be found from the corresponding value of the X parameter on the simulator working curve. The k_d values obtained for different times from a single current-time curve should be the same within experimental error (± 10-15%). If this is not the case, the kinetic model is probably not correct for the real data. A serious complication, of course, is that the initial concentration, C^o, must be known from independent data.

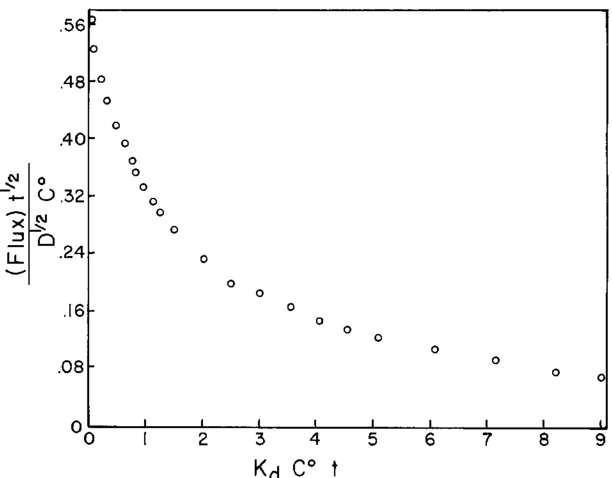

Fig. 5. Digital simulator working curve, coupled second order kinetic-diffusion problem.

Very recently, a rigorous mathematical solution to the coupled second order kinetic-diffusion problem has been presented by Britz and Kastening (13), without any experimental verification. Their results for a planar electrode were as follows

$$\frac{1}{it^{1/2}} = \frac{\pi^{1/2}}{nFAD^{1/2}} \cdot (1/C^o + 0.7268k_d t) \qquad [14]$$

This expression is totally analogous to the Birk-Perone approximation (2) (Eq. [12]), except for the factor 0.7268, which indicates that the k_d value obtained from the slope of the Birk-Perone second order plot will be less than the "true" k_d by about 27%. This difference is attributed to the fact that the Birk-Perone derivation neglects the nonhomogeneous decay rate profile in the diffusion layer for the second order process. The intercept for either expression gives the same initial intermediate concentration. Britz and Kastening (13) extended their derivation to the spherical electrode case. That expression reduces to the form of Eq. [14], however, on the time scales used to make the measurements reported in this work. All three methods require that the diffusion coefficient, D, either be known from independent measurements or be estimated accurately (20). Also, as mentioned previously, regardless of the theoretical treatment, purely faradaic currents are assumed. Thus, experimental data must be corrected for induced charging currents, as pointed out by Fratoni and Perone (15). Figure 6 demonstrates the results obtained for kinetic analysis of ketyl intermediate oxidation currents for flash photolysis of benzophenone at pH 12. The SODH program described earlier was used, and the improvement is obvious. The derivative method gives very similar results. The initial intermediate concentration calculated from the intercept of the corrected data second order plot agrees very well with that obtained by performing the same experiment at higher pH (13.5) where the dimerization reaction is slow, and making measurements at very short times where diffusion-limited currents are obtained.

Faradaic current extraction methods comparison.—Both methods used here to extract faradaic current from the total measured current have inherent advantages and disadvantages. The curve-fitting method, based on the technique proposed by Fratoni and Perone (15), uses the SODH program which was discussed earlier. Faradaic currents will be extracted correctly only if the proper kinetic mechanism is known beforehand for the given data set. Also, the alpha value which is used (k_dC^oRC) must be such that the limits of the

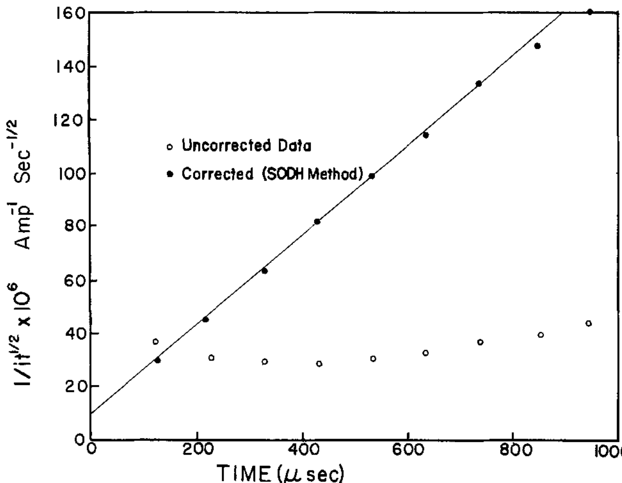

Fig. 6. Second order kinetic plot (Birk-Perone method): $5 \times 10^{-4}M$ benzophenone, $0.1M$ NaOH, $0.15M$ KCl, 50% ethanol/H_2O.

computer's accuracy are not exceeded. Thus, for our computer system, α must be $>10^{-2}$. For example, if $t_{1/2} = 100$ msec, the cell time constant must be > 1 msec or convergence will not occur. (If necessary, an external resistance may be inserted between the working electrode and ground to attain a longer cell time constant and an appropriate value for α. This does not diminish the effectiveness of data interpretation so long as the cell time constant is not too long compared to the reaction half-life.) The SODH program can be rather time consuming, however, depending upon how many points are used and how long it takes the curve-fitting program to converge to the desired accuracy in α.

The derivative approach is a much more general method which can be used for any data set. No experimental limitations need be imposed during data acquisition. Any data may be used, even if the mechanism of the kinetic process is not known beforehand. However, considerable noise can be injected into the data by the derivative procedure, and even the digital smoothing methods used (17) usually cannot diminish noise to the level of the SODH results. In addition, these smoothing and derivative methods cause data points to be lost at the beginning and end of the data set. It has been found also that it is far better to take the derivative of the raw data first, correct the data to get i_F, and then apply digital smoothing, rather than in the inverse order.

In this work, current-time data at each pH were processed using both correction methods, and the kinetic data obtained agreed within the experimental precision ($\pm$ 10-15%). Data reported in Tables I and II reflect average values for at least 10 runs processed both ways.

pH dependence of photodimerization rate constant.—Alkaline solution.—A kinetic study of the radical dimerization reaction was carried out by a series of flash photolysis experiments at various pH's. The current-time data were corrected as described above.

In Table I our results are used to compare the kinetic data obtained with the three different data handling techniques. Using our experimental data, the Birk-Perone approximate theory results are in column 1 (2), the digital simulation results in column 2, and the Britz-Kastening rigorous theory results (column 1 plus 27%) in column 3. [As discussed previously (2) the experimental limitation on kinetic accuracy is about ±25%. Experimental precision, however, is about ±10%.] The significant point is that the results in columns 2 and 3 agree very closely at all pH values. This indicates that the digital simulation and the rigorous theory expression both provide valid solutions to the same kinetic-diffusion problem. All subsequent kinetic studies reported here use one of these methods of analysis.

Table I. Comparison of kinetic data for benzophenone photodimerization using three different data processing methods*

pH	1 Approximate theory (2)	2 Digital simulation	3 Rigorous theory (13)
0.5M NaOH	5.4×10^4 M^{-1} sec^{-1}	7.8×10^4 M^{-1} sec^{-1}	7.6×10^4 M^{-1} sec^{-1}

*** Data obtained in this work using digital simulation method; currents corrected for induced charging current. All values ±20-25%.
† Because of limited buffer capacity at this pH (see experimental section) this value of k_d may be in error.

Table II compares previous and current electrochemical results with each other and with Beckett and Porter's (14) spectroscopic results. Our results agree quite well with the others at the very highest (>13) and very lowest (<11) pH values, but the intermediate results vary. The discrepancy in the electrochemical kinetic results is not surprising, as the earlier work (2) utilized approximate theory and also neglected effects of induced charging currents. Thus, at high pH, where the reaction half-life ($t_{1/2} = 1/k_d C^o$) is long compared to the cell time-constant, the effect of induced charging current is small and the kinetic data disagree only slightly. At lower pH, these effects cannot be ignored and large errors in the earlier kinetic data are obvious. The disagreement with Beckett and Porter's results (14) is probably because, spectroscopically, they were monitoring the rate of disappearance of the radical anion, whereas electrochemically we cannot differentiate the two radical species and are always monitoring the sum of the two. Hence, in the pH range where the radical-radical anion reaction predominates (pH 11-13), it is not surprising that our results disagree significantly with Beckett and Porter's.

Acid solution.—At pH <10, the benzophenone photodimerization reaction becomes very rapid, approaching the diffusion-controlled rate. Because the reaction is so fast, it has not been studied previously in this pH region. To apply either the SODH or derivative correction methods, the value of the cell time-constant must be known very accurately, as it is close to $t_{1/2}$ of the reaction. When an external resistance is added between the working electrode and ground, the effective cell time-constant is much less dependent upon variations in the electrochemical cell conditions, and hence it may be measured more accurately. Experimental data at pH 9, 7, and 5.5 were obtained with a 1 kohm resistance between the working electrode and ground. The kinetic results are given in Tables I and II, and show that the reaction rate constant levels off below pH 10, indicating that radical dimerization is probably the dominant reaction. A current-voltage profile of the system obtain at pH 5.5, 490 μsec after the flash, appears in Fig. 7. These corrected faradaic currents were obtained using the derivative program method, with a Savitsky-Golay nine-point smooth (17) applied to each corrected current-time curve. The profile is qualitatively similar to those at higher pH, except that the oxidation $E_{1/2}$ of benzopinacol is about −0.15V, and the reduction $E_{1/2}$ of benzophenone is about −1.20V *vs.* SCE. The lack of any additional oxidation or reduction waves suggests that other short-lived oxidizable or reducible species are not present on this time scale.

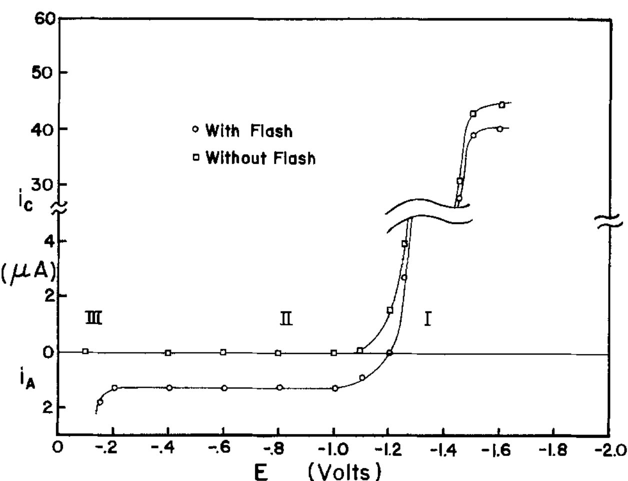

Fig. 7. Current-voltage profile: $5 \times 10^{-4}M$ benzophenone, 0.50*M* acetate buffer, 50% ethanol/H_2O, pH = 5.5, *t* = 490 μsec after flash.

Calculation of individual rate constants.—The pH study allows calculation of the three second-order rate constants for Eq. [8]-[10]. Because R· and R·⁻ are indistinguishable electrochemically, an over-all rate expression may be written

$$\frac{dP}{dt} = \frac{1}{2}\left[\frac{dC_T}{dt}\right] \quad [15]$$

where P = product benzopinacol, and $C_T = C_{R\cdot} + C_{R\cdot^-}$. From this and Eq. [8]-[10] it follows

$$\frac{dC_T}{dt} = \frac{dC_{R\cdot}}{dt} + \frac{dC_{R\cdot^-}}{dt} \quad [16]$$

$$\frac{dC_{R\cdot}}{dt} = -\left[k_1(C_{R\cdot})^2 + k_2 C_{R\cdot} C_{R\cdot^-}\right] \quad [17]$$

$$\frac{dC_{R\cdot^-}}{dt} = -\left[k_3(C_{R\cdot^-})^2 + k_2 C_{R\cdot} C_{R\cdot^-}\right] \quad [18]$$

$$\frac{dC_T}{dt} = -\left[k_1(C_{R\cdot})^2 + 2k_2 C_{R\cdot} C_{R\cdot^-} + k_3(C_{R\cdot^-})^2\right] \quad [19]$$

$$\frac{dC_T}{dt} = -k_d(C_T)^2 \quad [20]$$

Where k_d = second order rate constant measured electrochemically. Rearranging this expression in terms of the equilibrium constant (23) between ketyl radical and radical anion ($K_{eq} = 10^{9.2} = 1/K_A$)

$$k_d = \frac{k_1 K_{eq}^2 (H^+)^2 + 2k_2 K_{eq}(H^+) + k_3}{[1 + K_{eq}(H^+)]^2} \quad [21]$$

Inserting the values for k_d (digital simulation method) and (H^+) from Table I into Eq. [21], one obtains 10 equations with 3 unknowns. When these are solved as discussed below, one obtains the results in Table III for k_1, k_2, and k_3. Hence, these three rate constants can be measured even though the individual processes cannot be monitored directly. Values which were measured spectroscopically for disappearance of the radical anion in isopropanol/water solution by Beckett and Porter (14) are also shown in Table III for comparison.

The values obtained for these rate constants are subject to experimental limitations. For example, at no pH does the R·⁻ dimerization reaction (Eq. [10]) dominate. Even at pH 13.6, the radical-radical anion reaction still is significant because it is so fast. Hence, the value given for k_3 in Table III is the upper limit for that process; k_3 cannot be faster than 7.8×10^4 M^{-1} sec^{-1}. On the other end of the pH scale however, this problem does not exist. At pH 5.5, the reaction which is measured is due almost completely to the radical dimerization. Hence, the k_d value measured is k_1 directly. The value of k_2 given is the average value calculated from Eq. [21] with the intermediate pH data, using the above values for k_1 and k_3.

Conclusions

The studies reported here have served several purposes. One of these was to demonstrate the validity of the theoretical expressions for combined faradaic and induced charging currents presented previously (15). The evaluation of two approaches for extracting faradaic currents from experimental measurements showed that the derivative method is more generally useful, but suffers from some practical limitations in implementation. The experimental verification of the

Table III. Individual radical reaction rate constants

Reaction	k	Beckett-Porter (14)
(k_1) R· + R·	2.5×10^8 M^{-1} sec^{-1}	5.9×10^7 M^{-1} sec^{-1}
(k_2) R· + R·⁻	1.1×10^9	1.1×10^9
(k_3) R·⁻ + R·⁻	$\leq 7.8 \times 10^4$	$\leq 1.8 \times 10^5$

Britz-Kastening (13) and digital simulation theoretical expressions for photodimerization kinetic studies resolves a long-standing question in photoelectrochemistry. The availability of valid kinetic-diffusion theory and accurate corrections for induced charging currents has allowed the extension of benzophenone photoreduction studies into the acid pH range for the first time. Finally, it has been shown here that the quantitative interpretation of current-voltage-time relationships is now possible because of more accurate extraction of faradaic currents.

Acknowledgments

The authors wish to thank Sam Fratoni, Jr. for help with the SODH program and second order faradaic current extraction method, Nancy Stanford Davis for her digital simulation programming, Betty Hall for obtaining some of the kinetic data, and S. W. Feldberg for his helpful comments about the derivative I_F extraction technique. This work was supported by Public Health Service Grant No. CA-07773 from the National Cancer Institute and by a grant from the National Science Foundation.

Photo-oxidation of Water at Barium Titanate Electrodes

John H. Kennedy* and Karl W. Frese, Jr.

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Photoeffects at polycrystalline, semiconducting barium titanate were investigated. Photocurrent efficiencies were related to solid-state properties and agreement was found between donor densities calculated from efficiency-potential plots and those calculated from Mott-Schottky plots. The existence of a significant temperature effect on the photocurrent efficiency was demonstrated. The influence of pH on the flatband potential was also determined.

A number of studies (1-8) of photoeffects at polycrystalline semiconductor electrodes in electrochemical cells have been reported in the recent literature. However, measurement of photocurrent efficiencies and the distribution of potential in semiconducting $BaTiO_3$ have not been investigated. Also the effect of temperature on efficiency has been largely ignored for TiO_2 and titanates although Wrighton *et al.* (9) reported on temperature effects at SnO_2 electrodes.

In this study we have applied the standard techniques for studying single crystal electrodes to polycrystalline sintered $BaTiO_3$ and have demonstrated a temperature effect of the photocurrent efficiency. Our use of well-known semiconductor depletion layer theory allows a useful interpretation of our efficiency data in terms of solid-state properties.

Key words: barium titanate, photo-assisted electrolysis of water, photo-oxidation, semiconductor electrodes.

Experimental

Electrode preparation.—Barium titanate was prepared from $Ba(NO_3)_2$ (reagent grade) and TiO_2 (99.9%). The materials were dry mixed for 24 hr in an alumina ball mill and then heated at 1000°C for 12 hr. After further grinding, the mixture was pressed into disks at 4000 psi and sintered in air at 1350°C for at least 2 hr. The conductivity of the $BaTiO_3$ was increased by heating the sintered material in a stream of H_2 at temperatures up to 1300°C for several hours. Resistivities were 10^3 Ω-cm and final densities were 5.2-5.5 g/cm³. The samples were cooled in N_2 from about 800°C and were found to have a black insulating layer presumably due to some reoxidation by O_2 in the N_2 stream. This layer was removed by light mechanical polishing with SiC paper and thorough ultrasonic washing in deionized water. The resulting material was dark blue, characteristic of Ti^{3+} ions. Contact to the

electrode was made by applying Ag epoxy (Epoxy Technology) to which a copper wire was soldered. The electrode was then mounted in a glass tube and sealed with epoxy resin. Current-voltage curves for reduced $BaTiO_3$ with Ag epoxy electrodes were found to follow Ohm's law.

Illumination.—The $BaTiO_3$ electrodes were illuminated (quartz window) with a 150W Xe lamp using a Bausch and Lomb visible grating monochromator and collimating lens. The photon flux at 360 nm was determined using 0.006*M* ferrioxalate actinometry (10). The flux at 350 and 360 nm was determined from relative power density measurements using a YSI Model 65A radiometer. These intensities agreed well with those obtained from Reinecke actinometry (11) at 504 nm and radiometric measurements. Reflection losses from the cell window were accounted for by the actinometry procedures, however the light reflected from the electrode surface was ignored in the calculations.

Electrochemical measurements.—The cell arrangement consisted of a $BaTiO_3$ working electrode, platinized Pt counterelectrode and a SCE reference electrode. Buffer solutions were NBS standard buffers in 0.5M KCl or Mallinckrodt Standard "Buffar" solutions. Current-potential curves were obtained with a PAR Model 174 polarographic analyzer at a scan rate of 2 mV/sec. Solutions were deoxygenated with N_2 gas before all measurements and a N_2 atmosphere was maintained during the measurements.

Capacitance measurements.—Capacitance measurements of the cell $BaTiO_3$/buffer solution/Pt were made with a General Radio Model 1650-A impedance bridge operating at 1000 Hz. The bridge was biased using a Harrison 6112A power supply. The $BaTiO_3$ electrode potential was measured *vs.* SCE with a Hewlett Packard Model 412 A VTVM.

Results

Flatband potentials.—The flatband potential of sintered $BaTiO_3$ electrode was measured in the dark as a function of *p*H. The determination of the flatband potential, V_{FB}, for a wide gap semiconductor is based on the Mott-Schottky relation (12)

$$1/C_{sc}^2 = \frac{2}{q\epsilon\epsilon_o N_D} (V - V_{FB} - kT/q) \qquad [1]$$

where C_{sc} is the space charge capacitance per unit area, q is the electronic charge, ϵ is the dielectric constant of the space charge layer [1500 for polycrystalline $BaTiO_3$ (13)], ϵ_o is the permittivity of vacuum, N_D is the donor density, and V is the $BaTiO_3$ electrode potential *vs.* a reference electrode. Typical Mott-Schottky plots are shown in Fig. 1. The donor concentration

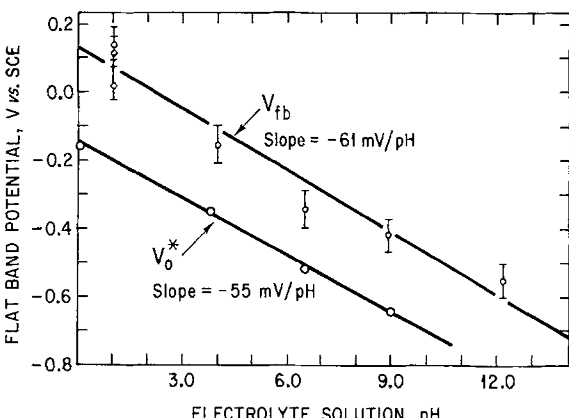

Fig. 2. Flatband potential and zero-efficiency potential of barium titanate vs. pH, $t = 23°C$.

calculated from these slopes is $\sim 3 \times 10^{19}$ cm^{-3}. Similar linear plots were obtained for electrodes with donor densities as low as 10^{16} cm^{-3}. Figure 2 shows the effect of solution *p*H on the flatband potential. The slope of the V_{FB} *vs.* *p*H plot was found to be -61 mV/*p*H. The usual interpretation (12) for this value is that a dissociative equilibrium exists between a protonated oxide ion on the surface of the lattice and the solvent. Thus the change of the Fermi level with *p*H at the electrode surface is determined by the free energy change for the reaction

$$\text{Ti-OH}^+_{surf} \rightleftharpoons \text{Ti-O}_{surf} + H^+$$

It should be noted that these flatband potentials found for $BaTiO_3$ are approximately 0.75 and 0.35V more anodic than for single crystal $SrTiO_3$ (14, 15) and TiO_2 (16), respectively.

Photocurrent efficiencies.—Figure 3 shows typical photocurrent *vs.* electrode potential curves at 360 nm for various *p*H values. The equivalent photon current was 48 μA. The photocurrent efficiency, η_p, was calculated from

$$\eta_p = \frac{i(\text{light}) - i(\text{dark})}{i(\text{photon})} \qquad [2]$$

It can be seen that for a given overvoltage the efficiency was practically independent of *p*H. This result suggests that the rate-limiting step depends on processes occurring within the semiconductor. This point will be further discussed below. The effect of *p*H on the potential of zero efficiency V_o^* is shown in Fig. 2. The slope dV_o^*/dpH was found to be -55 mV/*p*H.

The open-circuit voltage, V_{oc}, at *p*H 3.8 in 0.5M KCl was found to be -0.054V *vs.* SCE in the dark and -0.32V *vs.* SCE under illumination at 360 nm. The corresponding flatband potential in the dark was -0.10V

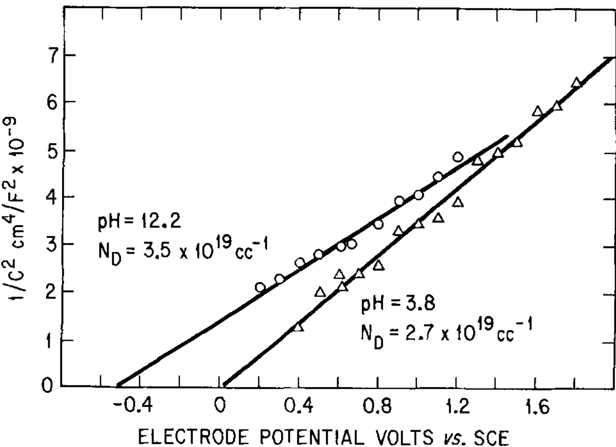

Fig. 1. Mott-Schottky plots for polycrystalline barium titanate. In dark, $t = 23°C$.

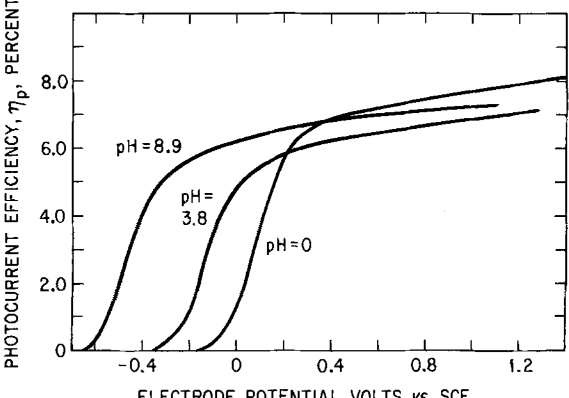

Fig. 3. Photocurrent efficiency of polycrystalline barium titanate. $\lambda = 360$ nm, $t = 23°C$.

from Fig. 2. This result indicates that the bands were bent slightly upward in the dark at open circuit and that in the dark the open-circuit voltage and flatband potential are approximately equal. It follows from the agreement between V_{oc} and V_{FB} in the dark and V_{oc}^* and V_o^* (−0.32V *vs.* −0.35) that V_o^* would measure approximately the flatband potential under illumination.

Temperature effect.—Figure 4 shows the effect of solution temperature on the photocurrent efficiency. At the two wavelengths shown, the rate of increase of η_p with temperature is almost identical at ~0.11%/°C. For $BaTiO_3$ the efficiency can be doubled for a 60°C increase in temperature. Although the high temperature efficiencies are still low compared to TiO_2, the existence of a temperature effect could have important consequences for other higher efficiency semiconductors allowing some use of longer wavelength solar radiation. Similar increases of efficiency with temperature were found for polycrystalline TiO_2 and $SrTiO_3$. In each case rate of increase was ~0.1%/°C at 1.0V *vs.* SCE. Typical values of η_p at room temperature and 340 nm were 37 and 19% at 1.0V *vs.* SCE for TiO_2 and $SrTiO_3$, respectively. At elevated temperatures, typical values of η_p for TiO_2 and $SrTiO_3$ were 40% at 55°C and 21% at 50°C, respectively. It should be noted that efficiencies for polycrystalline $SrTiO_3$ reported here are nearly the same as those reported by Watanabe *et al.* (14) for single crystal $SrTiO_3$. Although it is anticipated that single crystals may exhibit highest efficiencies, especially for anisotropic material which could be oriented for maximum efficiency, it is clear from these results that polycrystalline material can produce photocurrents comparable to single crystals.

Discussion

A reasonable interpretation of our efficiency results for $BaTiO_3$ can be made by use of the theory of depletion-layer photoeffects as given by Gärtner (17) and discussed by Myamlin and Pleskov (18). The photocurrent efficiency η_p under anodic bias (bands bent up) for negligible recombination is given by

$$\eta_p = 1 - \frac{e^{-aL}}{1 + aL_p} \qquad [3]$$

where a is the absorption coefficient, L is the effective width of the space charge region, and L_p is the mean diffusion length for holes outside the space charge region. The width of the space charge region is related to solid-state properties of the semiconductor and the overvoltage in the space charge region, $\Delta\phi_s$, by the relation (18)

$$L = \left(\frac{\epsilon\epsilon_0}{2qN_D}\right)^{1/2} \Delta\phi_s^{1/2} \qquad [4]$$

Algebraic manipulation of Eq. [3] and [4] leads to

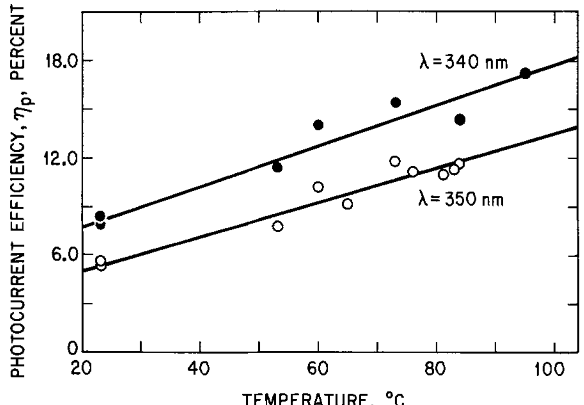

Fig. 4. Effect of temperature on photocurrent efficiency for polycrystalline barium titanate, pH = 7.0.

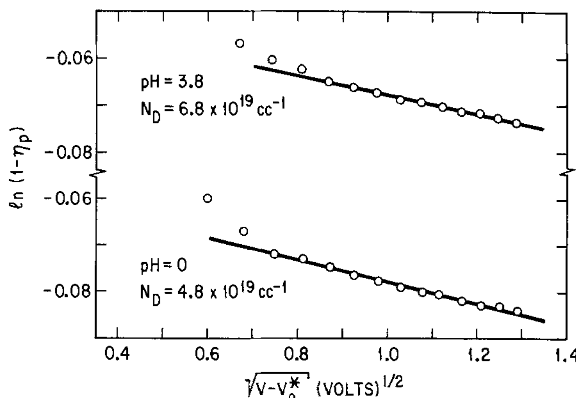

Fig. 5. Determination of N_D and L_p from photocurrent vs. potential for polycrystalline barium titanate. λ = 360 nm.

Eq. [5]

$$\ln(1 - \eta_p) = -a\left(\frac{\epsilon\epsilon_0}{2qN_D}\right)^{1/2} \Delta\phi_s^{1/2} - \ln(1 + aL_p) \qquad [5]$$

which shows that a plot of ln $(1 - \eta_p)$ *vs.* $\Delta\phi_s^{1/2}$ should be linear with a slope of $-a(\epsilon\epsilon_0/2qN_D)^{1/2}$ and an intercept of $-\ln(1 + aL_p)$. This relation is expected to hold for sufficiently large overvoltages so that recombination of holes and electrons generated by illumination in the space charge region is negligible. Thus Eq. [3] and [5] provide a basis for photocurrent potential curves under anodic bias. In addition to the linearity discussed above, a further test of the validity of Eq. [5] can be made by comparing values of N_D obtained from the efficiency-potential plots using known ϵ and a with those obtained from Mott-Schottky slopes. Figure 5 shows some of our results for $BaTiO_3$ at various values of pH where we have assumed that $\Delta\phi_s$ can be approximated by $V - V_o^*$, *i.e.*, V_o^* measures the flatband potential under illumination and all the potential drop occurs across the space charge layer. Table I summarizes the results for $BaTiO_3$ at room temperature and 360 nm where $a \cong 8 \times 10^3$ cm^{-1} (19-21). It can be seen that the two methods give fair agreement between N_D values and the diffusion lengths of about 700Å are independent of pH as expected.

Our data on the temperature effect of the photocurrent efficiency can be understood with the help of Eq. [3] and absorption coefficient data for $BaTiO_3$ at various temperatures and energies. The absorption coefficient *vs.* temperature and photon energy has been studied by Wemple (19) in the wavelength region where ln a is a linear function of energy at constant temperature. These data were used to calculate η_p at 23° and 50°C using Eq. [3]. Over this temperature range the dielectric constant is reasonably constant at 1500. The only assumptions made were the validity of Eq. [3] and that L_p was independent of temperature. The values of N_D and L_p were averages of those given in Table I, and $\Delta\phi_s$ was taken to be 1.5V which corresponds to an electrode potential of 1.0V *vs.* SCE at pH 7. The ratio, η_p^{50}/η_p^{23} was calculated to be 3.0, 2.5, and 1.8 at 3.0, 3.1, and 3.3 eV, respectively. The decrease in relative efficiency is due to the smaller effect of tem-

Table I. Comparison of N_D obtained from Mott-Schottky plots with N_D obtained from photocurrent efficiency (λ = 360 nm, $a \cong 8.0 \times 10^3$ cm^{-1})

pH	Mott-Schottky calc. N_D, cm^{-3}	Photocurrent efficiency calc. N_D, cm^{-3}	Photocurrent efficiency calc. L_p, cm
0	—	4.8×10^{19}	7.0×10^{-6}
3.8	2.7×10^{19}	6.8×10^{19}	6.1×10^{-6}
6.5	2.2×10^{19}	7.0×10^{19}	6.9×10^{-6}
8.4	2.1×10^{19}	6.6×10^{19}	6.4×10^{-6}
12.2	3.5×10^{19}	—	—

perature on the absorption coefficient as higher energies are approached. Therefore, we would expect the ratio to be <1.8 at 3.6 eV, the photon energy used for the data given in Fig. 4. The experimental value was 1.4 which is quite reasonable, and thus we conclude that temperature effects primarily reflect changes in absorption coefficient as the simple theory of depletion layer photoeffects predicts. It cannot be overlooked, however, that over large temperature ranges other factors such as L, L_p, and ϵ may also play an important role.

We are currently extending our measurements to higher temperatures with the aim of investigating the effect of the tetragonal $\rightarrow$ cubic phase change at the ferroelectric Curie point ($\sim$120°C). It is well established that an anomalous shift in the bandgap to lower energy occurs in the region of the phase transition. The bandgap values for ferroelectric materials such as $BaTiO_3$, $SrTiO_3$, and $KTaO_3$ must be defined at an arbitrary value of absorption coefficient because of the exponential decay of a *vs.* photon energy (Urbach edge). Therefore the quoted shifts in bandgap probably reflect changes in a.

Measurements of η_p in the wavelength region where η_p is small (≤ 0.10) and $aL_p \leq 0.10$ at constant electrode potential and temperature can provide an additional test for the applicability of the theory. Under the above conditions, Eq. [3] may be written after expansion of the logarithms as

$$\eta_p \cong a(L + L_p)$$

It can be seen that plotting η_p *vs.* absorption coefficient should be linear with a slope $(L + L_p)$. We have measured η_p at 10 nm intervals from 400 to 360 nm at 1.0V *vs.* SCE, *p*H 3.8, 23°C in 0.5M KCl. The slope, $d\eta_p/da$, was found to be 8.6×10^{-6} cm. From the value $N_D = 6.3 \times 10^{19}$ cm^{-3} given in Table I, and $\Delta\phi_s = 1.35$V, L can be calculated from Eq. [4] giving 3×10^{-6} cm. Combining this result with $d\eta_p/da$, we calculate L_p to be 5.6×10^{-6} cm, in good agreement with 6.6×10^{-6} cm obtained from intercepts of plots using Eq. [5]. It can be concluded that our data and the theory of depletion layer photoeffects are consistent with respect to changes in η_p arising from changes in electrode potential, temperature, and absorption coefficient.

Mass Transfer to a Rotating Disk in Transition Flow

Charles M. Mohr, Jr.* **and John Newman****

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

An experimental study of mass transfer to a rotating disk electrode has been employed to determine an empirical correlation for the mass transfer rate in the Reynolds number regime lying between simple laminar and turbulent flows. This domain, apparently characterized by a regular vortex pattern, was found to extend from a Reynolds number of 2.0×10^5 to approximately 3.0×10^5. The resultant correlation for the average tranfser rate, in terms of dimensionless Nusselt, Reynolds, and Schmidt numbers, is

$$\overline{\mathrm{Nu}} = 0.89 \times 10^5\,\mathrm{Re_o}^{-1/2}\mathrm{Sc}^{1/3} + 9.7 \times 10^{-15}\,\mathrm{Re_o}^3\mathrm{Sc}^{1/3}$$

The result is strictly applicable to the case of a uniform surface concentration; that is, to the limiting-current condition.

The mass transfer behavior of the rotating disk electrode is of continuing interest. While the bulk of its uses are based upon the uniform-accessibility property described by Levich (1) for disks upon which simple laminar flow (2) prevails, for sufficiently high rotation speeds turbulence may be reached near the edge of the disk. The nonuniform (enhanced) mass transfer rate resulting from this turbulence may be a desirable feature for some studies. In particular, this behavior has been found useful for studies of corrosion, when the effect of a varying local rate of oxygen transport to the surface of the corroding metal is of interest (3-6).

An accurate description of the behavior of such an electrode requires knowledge of the local transfer rate for the full range of Reynolds numbers involved. The Reynolds number found appropriate for the disk is $\mathrm{Re} = r^2\Omega/\nu$, where r is the radial distance from the center of rotation, Ω the angular rotation speed, and ν the kinematic viscosity of the fluid in which the disk rotates. This behavior for simple laminar flow, as described by von Kármán (2), is well known, having been first described by Levich (1), who gave the mass transfer rate as

$$\overline{\mathrm{Nu}}_{\mathrm{lam}} = 0.6205\,\mathrm{Re_o}^{1/2}\mathrm{Sc}^{1/3} \quad [1]$$

where the Nusselt number $\overline{\mathrm{Nu}} = \bar{i}r_o/n\mathbf{F}D\Delta c$, the Schmidt number $\mathrm{Sc} = \nu/D$, and $\mathrm{Re_o}$ is the Reynolds number based upon the electrode radius r_o. $\bar{i}$ is the average current density on the electrode, n the number of electrons transferred per ion reacting, $\mathbf{F}$ Faraday's constant, D the diffusion coefficient of the active species, and Δc is the concentration driving force for diffusion, bulk concentration minus concentration at the electrode surface.

The transfer rate for well-developed turbulent flow has been the subject of several studies (7-12), and accurate correlations have been proposed for its dependence upon the Reynolds number. The two most useful of these correlations are due to Ellison and Cornet (7) and Daguenet (9), since both of these also include the Schmidt number influence upon the Nusselt number. Ellison and Cornet report that the mass transfer may be described as

$$\overline{\mathrm{Nu}}_{\mathrm{turb}} = 0.0117\,\mathrm{Re_o}^{0.896}\mathrm{Sc}^{0.249} \quad [2]$$

while the result of Daguenet is

$$\overline{\mathrm{Nu}}_{\mathrm{turb}} = 0.00725\,\mathrm{Re_o}^{0.9}\mathrm{Sc}^{0.33} \quad [3]$$

We have chosen to use Daguenet's equation for two reasons. First, the bulk of the data gathered by Ellison was for larger Reynolds numbers than are of interest here ($\mathrm{Re_o} > 10^6$), while Daguenet thoroughly investigated the flow regime immediately adjacent to the transition region ($3 \times 10^5 < \mathrm{Re_o} < 10^6$). Second, in light of the many studies of turbulent transfer in different geometries, it seems that the exponent 1/3 is more realistic than 1/4 for the Schmidt number dependence. This conclusion is supported by the investigations of Donovan *et al.* for turbulent boundary layers (13), Hubbard and Lightfoot (14, 15), and Vielstich *et al.* (16). The influence of the structure of the turbulent flow upon this exponent is discussed by Levich (17). Also, Ellison and Cornet's data for $\mathrm{Re_o} < 10^6$ are quite scattered and may possibly be better fit by a $\mathrm{Sc}^{1/3}$ dependence.

However, we have refit Daguenet's data, as shown in Fig. 1, according to the correlation

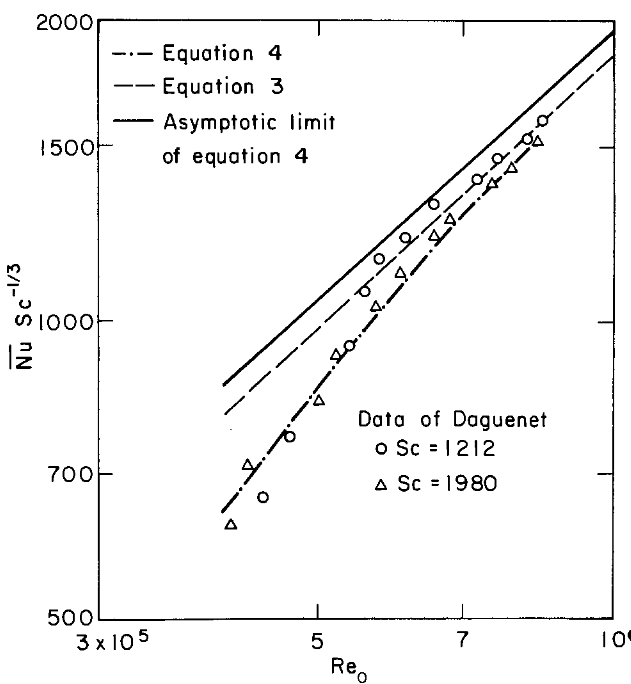

Fig. 1. Correlation of Daguenet's data for turbulent mass transfer to a rotating disk.

Key words: limiting current, turbulence, fluid flow.

$$\overline{Nu}\,Sc^{-1/3} = 0.0078\,Re_o^{0.9} - 1.38 \times 10^5\,Re_o^{-1/2} \quad [4]$$

This form is based on the supposition that the local asymptotic transfer rate is proportional to $Re_o^{0.9}$, although over-all Nusselt numbers for $Re_o < 10^6$ are still significantly dependent upon transfer in the laminar and transition zones. The coefficient of the last term in Eq. [4] will thus be adjusted subsequently by integration of local rates in the laminar and transition zones, while the first term should depend only on the asymptotic behavior in the turbulent regime. This leads to the following correlation for the large Reynolds number asymptotic mass transfer behavior

$$\overline{Nu}_{turb} = 0.0078\,Re_o^{0.9}Sc^{1/3} \quad [5]$$

The problem remains to describe the mass transfer behavior as a function of Reynolds number for the region in which the simple laminar flow becomes unstable and yields to turbulence. The range of Reynolds numbers over which this change takes place has been termed the "transition region," and the experimental determination of its mass transfer behavior is the purpose of this investigation.

The nature of this transition region was first described by Gregory, Stuart, and Walker (18) who demonstrated that the simple laminar flow found near the center of the disk becomes unstable at a Reynolds number equal to approximately 1.8×10^5, and that fully developed turbulence was not reached until $Re \sim 3 \times 10^5$. Stuart (18) also developed a nonlinear stability analysis which showed that stable periodic solutions to the Navier-Stokes equation could be expected for this range of Reynolds numbers. The experimental and theoretical results both point to the presence of a stable vortex pattern, rather than a predominantly random flow, in the transition region.

Subsequent work by others has served to reinforce the conclusions of Gregory *et al.* In particular, the work of Chin and Litt (19) has provided perhaps the most accurate determination of the critical Reynolds numbers bounding the transition region. These investigators embedded a small electrode in a disk at some distance from the center of rotation. By varying the rotation speed, the electrode was subjected to a range of Reynolds numbers. A spectral analysis of the current signal to the electrode was used to determine if a regularly varying mass transfer mode was present, indicating vortices moving across the electrode. Their results agreed well with Gregory *et al.* (18) for the lower bound of the transition region, their value being $Re = 1.7 \times 10^5$, but they found evidence that the vortices persist to a Reynolds number of about 3.5×10^5, well beyond the value reported by Gregory.

Various studies of mass transfer in the turbulent flow regime also include some data in the transition region. Kreith, Taylor, and Chong (11) report significant deviation from values predicted by the Levich analysis for laminar flow beginning at a Reynolds number of about 2×10^5. The rather scattered data of Cobb and Saunders (12) tend to agree with this. Daguenet (9) reported a lower bound of the transition region of approximately 2.6×10^5, but this value varied with the Schmidt number of the solution. An experimental study performed by Tien and Campbell (10) agreed more closely with Chin and Litt in that they reported enhanced mass transfer beginning at $Re = 1.8 \times 10^5$. Ellison and Cornet (7) have also performed an experimental (and theoretical) investigation of mas transfer in the turbulent regime. While their data for low ($<3 \times 10^5$) Reynolds numbers are somewhat scattered, they state that significant deviation from the Levich theory does not begin until $Re = 3 \times 10^5$ is reached.

In view of the lack of agreement about the value of the Reynolds number at which the Levich theory becomes inappropriate and the lack of a correlation for mass transfer in the transition region, an experimental study of this problem was performed. It is hoped that a more exact treatment of the dependence of the local transfer rate upon the Reynolds number, particularly in the transition region, will be found useful for such studies in which variation of the local mass transfer rate (as a function of position) is desired.

Experimental Work

Electrochemical systems of interest.—Two reactions were chosen for study: the electrodeposition of copper from a cupric sulfate-sulfuric acid solution onto a rotating copper disk, and cathodic reduction of ferricyanide ions to ferrocyanide ions, also on a copper disk, from a potassium ferricyanide-potassium ferrocyanide-potassium hydroxide solution. Concentrations of the active species were approximately 0.005M, while 1.5M sulfuric acid and 0.85M potassium hydroxide were used as supporting electrolytes. For the ferricyanide reduction, an excess of ferrocyanide was used (conc $\sim$ 0.007M) to help insure that the limiting current was achieved on the cathode (disk) before excessive oxygen evolution occurred at the anode. Oxygen evolution at the anode of the ferricyanide system is not desirable since it reduces the amount of ferrocyanide oxidized, thus depleting the solution of ferricyanide. A counterelectrode of copper was used for the cupric acid system to provide the atomic copper for the anodic reaction. A nickel counterelectrode was used for the ferricyanide system anode.

Experimental apparatus.—A series of three PTFE slinger rings on the rotating shaft, each in its own compartment, was used to prevent loss of the solution at high rates of revolution and minimize aeration of the solution during the trials. The electrode consisted of a copper disk approximately 2¼ in. in diameter soldered to a ¼ in.-20 machine screw which provided electrical continuity to the shaft. The back and edge of the electrode were insulated with Shell epoxy casting resin which was extended ¼ in. beyond the edge of the electrode to reduce the effect of the hydrodynamic disturbance due to the edge of the disk upon the flow field over the conducting area. A series of six baffles around the perimeter of the cell was used to minimize bulk rotation of the fluid.

The peripheral electronic equipment consisted of a galvanostat (with a built-in current ramp generator) which was built to order for high current applications. Continuous polarograms were recorded on a Hewlett-Packard Model 7044A X-Y plotter. Current measurements were made by placing a precision resistor (0.1495Ω, 25W maximum power dissipation) in the lead to the counterelectrode, and the voltage drop across it measured directly using the X-Y plotter. The rotation speed of the electrode was determined with a "Strobotac" stroboscopic tachometer.

Electrode preparation.—The electrode was polished prior to each series of runs with 4/0 grit emery paper followed by buffing on a canvas polishing wheel coated with 6 μm diamond paste to a mirror finish. Following both the polishing and buffing, the electrode was washed with Amway L.O.C. cleaning solution followed by rinsing with distilled water and ethanol and drying in a stream of hot air. Due to the low concentrations of Cu^{++} in the cupric sulfate solutions (approximately 0.005M) and the short duration of the trials, the surface remained quite smooth and mirrorlike even after a series of 15-20 trials. The trials involving the ferricyanide solutions were observed not to alter the surface detectably during the experiments, although the copper would apparently corrode if allowed to remain in contact with the KOH solution.

Experimental procedure.—For each series of trials, the cell was disassembled and cleaned, and the proper counter and reference electrodes were installed and polished with emery paper. Freshly prepared solution was introduced into the cell, with care being taken to exclude air bubbles. The solution level found to mini-

mize apparent aeration at high rotation speeds was reached when the surface was approximately at the same level as the middle slinger ring, which required about 1.6 liter of solution. The polarograms were recorded at various rotation speeds, noting the temperature of the solution at each trial. A series of 15 trials was found to increase the temperature about 1°C. Typical polarograms for a series of measurements are shown on Fig. 2. Viscosities of the solutions were determined for the range of temperatures encountered using a capillary viscometer. Diffusion coefficients were measured with the experimental electrode system operated at low revolution speeds using the Levich formula (1) for laminar flow to a rotating disk. For slight temperature variations, the Stokes-Einstein equation $D\mu = CT$, where T is degrees Kelvin and μ = absolute viscosity, was used. During the run, measurements were made at low rotation speeds to monitor possible concentration variation, a problem which occurred in the ferricyanide system due to oxygen evolution at the anode.

Results

The inflection point on the plateau of a polarogram in Fig. 2 corresponds, in essence, to the limiting current. The shape of the curve thus introduces some uncertainty into the values so obtained. The experimental results are presented on Fig. 3 as a graph of $\overline{Nu}\ Sc^{-1/3}$ *vs.* Re_o. The data gathered for $Re_o < 1.4 \times 10^5$, used to determine the diffusivity of the reacting species and monitor concentration changes, are not shown on this figure. The departure from the predictions of the Levich formula, Eq. [1], are observed to begin at approximately $Re_o = 2 \times 10^5$, in agreement with previous studies. The approach to the values predicted by Eq. [5] is also shown.

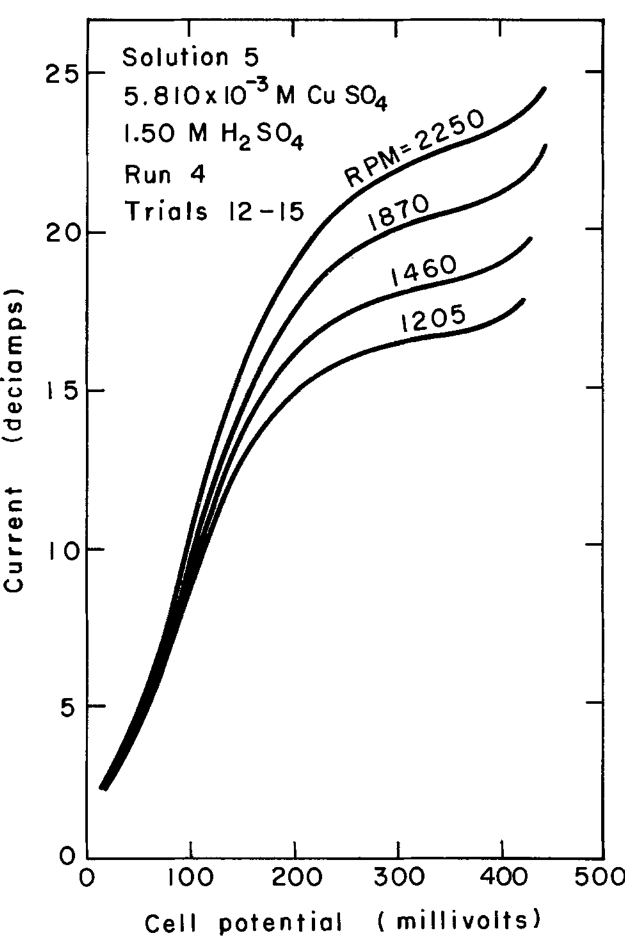

Fig. 2. Typical polarograms for mass transfer to a rotating disk

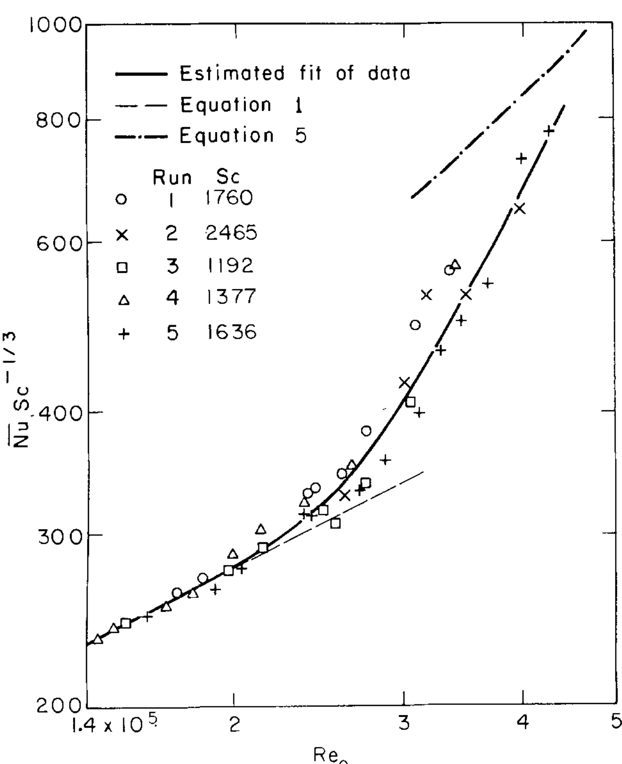

Fig. 3. Over-all mass transfer rate ($\overline{Nu}Sc^{-1/3}$) vs. Reynolds number for laminar, transition, and turbulent regimes. Standard deviations for the Schmidt numbers are 31, 41, 26, 38, and 57 for runs 1 to 5. Runs 3 and 4 involve deposition of copper; the others are reduction of ferricyanide.

To determine the local mass transfer rate as a function of Reynolds number from the experimental data and Eq. [1]-[5], one may use the expression (4, 5)[1]

$$Nu_{loc} = \frac{i_{loc}r}{nFD\Delta c} = \frac{1}{2}\frac{d}{d(Re_o^{1/2})}[\overline{Nu}\,Re_o^{1/2}] \quad [6]$$

$\overline{Nu}\ Sc^{-1/3}Re_o^{1/2}$ is shown on Fig. 4 as a function of the square root of the Reynolds number. While the scatter in the data detracts from the accuracy of the derivatives determined from the curve fit, the results should still be useful in providing an estimate of the local transfer rates which lie within the data scatter. It should provide an improvement over previous work (4, 5) in which the local transfer rate for the laminar region was spliced (with considerable discontinuity) directly to the local transfer rate predicted from the work of Ellison and Cornet, Eq. [2].

The local Nusselt number derived from Eq. [1] (using Eq. [6]) is

$$Nu_{lam} = 0.6205\,Re^{1/2}Sc^{1/3} \quad [7]$$

In a similar manner, Eq. [4] or [5] yields

$$Nu_{turb} = 0.01092\,Re^{0.9}Sc^{1/3} \quad [8]$$

These equations, along with the local Nusselt numbers for the transition region determined by differentiation of the curve fit given in Fig. 4, are given in Fig. 5. A straight-line fit of the data for the transition region seems reasonable; the one shown dotted in Fig. 5 leads to a correlation for the local Nusselt number

[1] This equation may be derived by transforming the variable r to $\sqrt{\frac{\nu}{\Omega}Re}$ in the integral identity defining the average current density

$$\pi r_o^2 \bar{i} = \int_0^{r_o} 2\pi r i dr$$

and differentiating with respect to $Re_o^{1/2}$, recalling that r and i are both independent of Re_o.

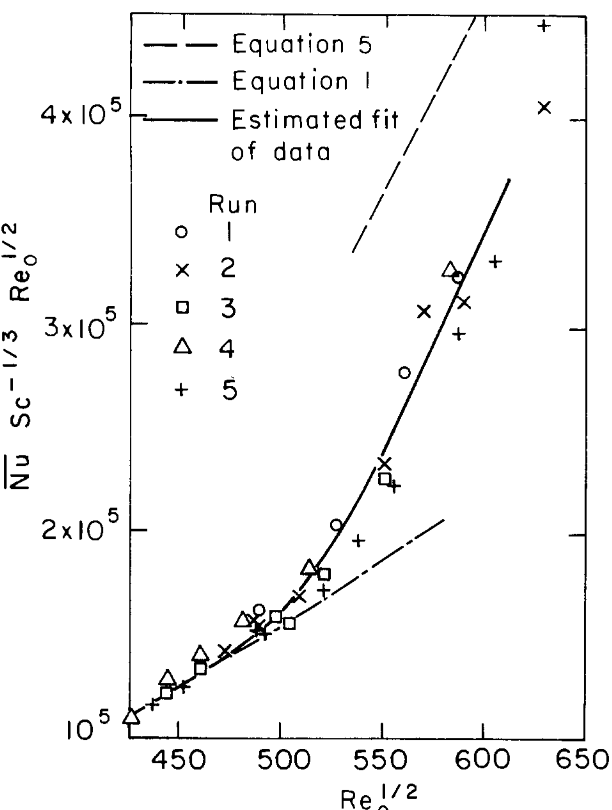

Fig. 4. Over-all mass transfer rate vs. square root of the Reynolds number.

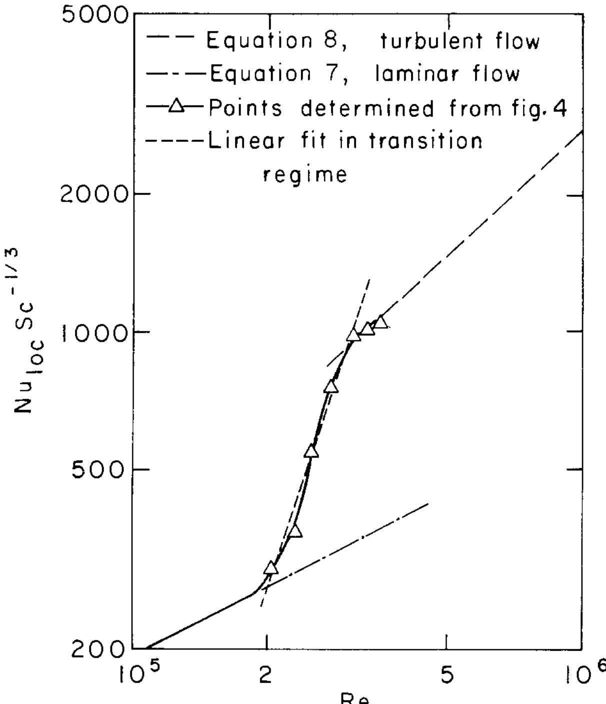

Fig. 5. Local mass transfer rate vs. Reynolds number for transition, laminar, and turbulent regimes.

$$\mathrm{Nu_{trans}} = 3.4 \times 10^{-14}\mathrm{Re}^3 \qquad [9]$$

for Reynolds numbers between 2.0×10^5 and 3.0×10^5 and is continuous with the laminar and turbulent Eq. [7] and [8] at these values of Re. A rigorous statistical curve fit of the data was not attempted, since a preferred form for the curve was not determined. While this could have been done once the linear approximation was adopted for the local transfer rate (Eq. [9]), the readily apparent limits of the transition region forced the straight-line fit through these points, with reasonable agreement in the intervening region.

Given these results for the local transfer rate in the three regions, we can reconstruct the over-all transfer rate behavior by integrating Eq. [6]. For the laminar region, Eq. [1] is unchanged. In the transition region, $2 \times 10^5 < \mathrm{Re_o} < 3 \times 10^5$, integration of Eq. [9] leads to

$$\overline{\mathrm{Nu}}_{\mathrm{trans}}\mathrm{Re_o}^{1/2} = 2\int_0^{\sqrt{2\times 10^5}} \mathrm{Nu_{lam}}d(\mathrm{Re}^{1/2}) + 2\int_{\sqrt{2\times 10^5}}^{\sqrt{\mathrm{Re_o}}} \mathrm{Nu_{trans}}d(\mathrm{Re}^{1/2}) = (0.89 \times 10^5 + 9.7 \times 10^{-15}\,\mathrm{Re_o}^{3.5})\mathrm{Sc}^{1/3} \qquad [10]$$

For the turbulent region, $\mathrm{Re_o} > 3 \times 10^5$

$$\overline{\mathrm{Nu}}_{\mathrm{turb}}\mathrm{Re_o}^{1/2} = 2\int_0^{\sqrt{2\times 10^5}} \mathrm{Nu_{lam}}d(\mathrm{Re}^{1/2}) + 2\int_{\sqrt{2\times 10^5}}^{\sqrt{3\times 10^5}} \mathrm{Nu_{trans}}d(\mathrm{Re}^{1/2}) + 2\int_{\sqrt{3\times 10^5}}^{\sqrt{\mathrm{Re_o}}} \mathrm{Nu_{turb}}d(\mathrm{Re}^{1/2}) = (0.0078\,\mathrm{Re_o}^{1.4} - 1.30 \times 10^5)\mathrm{Sc}^{1/3} \qquad [11]$$

when the appropriate expressions are substituted for $\mathrm{Nu_{lam}}$, $\mathrm{N_{trans}}$, and $\mathrm{Nu_{turb}}$.

The over-all Nusselt numbers given by Eq. [1], [10], and [11] are shown on Fig. 6 as a function of Reynolds number. The curve representing the fitted experimental data is also shown, along with the modified correlation of Daguenet for the turbulent region. The graph supports the statement by Ellison and Cornet (7) that for $\mathrm{Re} > 10^6$ only the contribution to the over-all mass transfer due to the turbulent region is of consequence. At $\mathrm{Re} = 10^6$, the difference between the correlation of Daguenet, Eq. [5], and the results which include the contribution of the laminar and transition regions, Eq. [11], is less than 7%. This is within the range of the maximum deviation of the data from the fitting curve. The estimated local Nusselt numbers in the transition region differ from the experimentally determined val-

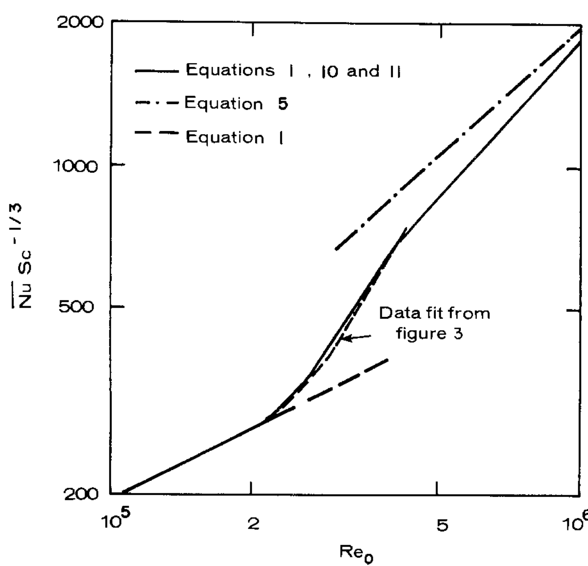

Fig. 6. Over-all mass transfer rate as predicted by correlations for the transition and turbulent flow regimes.

ues, shown on Fig. 5 by at most 10% near Re = 3.5×10^5; the fit is improved for larger Reynolds numbers.

SEM Studies of Discharge Products from Alkaline Iron Electrodes

Lars Öjefors[1]

Department of Chemical Technology, Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

ABSTRACT

Anodic oxidation products in 5*N* KOH of both planar and porous iron electrodes have been investigated with SEM techniques. On the first discharge level well-defined crystallites of $Fe(OH)_2$ are formed, while on continued discharge the products become sludge formed, probably consisting of hydrated FeOOH. The morphologies support the dissolution-precipitation mechanism during the first discharge step. The second anodic level proceeds probably via migration of ions and electrons in the solid phase. The crystallite size increases with temperature which depends on that the relative supersaturation decreases.

The anodic discharge process of a charged iron electrode occurs at two distinct voltage levels −0.85 and −0.65V *vs.* Hg/HgO in alkaline media. The reaction mechanisms and the nature of the products formed during these steps have been investigated by several workers (1-19) with various results.

Foerster (1) found that metallic iron was converted to $Fe(OH)_2$ during the first and to $Fe(OH)_3$ during the second discharge level. Faust (2) was of the opinion that at discharge a Fe-H compound was formed which during the second step was converted to metallic iron. In (3) Foerster and Herold explain the second step as mainly representing the conversion of $Fe(OH)_2$ to Fe(III) oxide, which runs parallel to the oxidation of metallic iron. The latter process is supposed to depend on uncovering of Fe by a break up of the $Fe(OH)_2$ layer. Kabanov and Leikis (4) found from theoretical considerations a topochemical reaction to be impossible because of the thick oxide layer produced. They proposed a dissolution-precipitation process where $HFeO_2^-$ and FeO_2^- are intermediate species during the first and second steps, respectively.

By studying the increase in weight of an iron electrode during discharge Winkler found FeO to be the product of the first level instead of $Fe(OH)_2$. He also found that the length of the first discharge step increased with cycling at the expense of the second. Addition of HgO or S^{2-} to the electrodes had a stabilizing effect on the processes.

[1] Present address: Swedish National Development Company, Fack, S-103 40 Stockholm 40, Sweden.

Key words: iron anode, discharge products, scanning electron microscopy.

Schwarz and Simon (7) studied the behavior of carbonyl and ingot iron in 4*N* KOH at 90°C. During anodic polarization they found that iron dissolves into FeO_2^{2-} which due to its low solubility precipitates to a layer of $Fe(OH)_2$. They also determined the corrosion current in this media to $2 \cdot 10^{-6}$ A/cm² at 90°C which is a low value when compared to self-discharge measurements.

Salkind, Venuto, and Falk (8) studied the discharge products for iron active material from ESB Incorporated and NIFE Jungner with x-ray diffraction techniques. The patterns were obtained by *in situ* measurements on electrodes cycled in sealed polyethylene bags, as well as with washed and dried active materials. From the first plateau only patterns of $Fe(OH)_2$ and α-Fe were observed with the *in situ* technique. On continuation of discharge patterns of α-Fe, $Fe(OH)_2$, and Fe_3O_4 were observed although very weak for the latter two products. For the material washed with distilled water and dried, Fe_3O_4 was also found during the first discharge step.

Flerov *et al.* (9) studied iron powder electrodes in order to determine the reaction mechanism for the second anodic step. They found that temperature is a very important factor for this discharge level, since this is at 20°C of 50% extent of the first anodic phase, while the two potential steps are of similar extension at 60°C. Changes in electrolyte concentration and addition of LiOH had no noticeable effect on the second step. The investigators propose that this potential step occurs without intermediate ionization and the process continues into the active particles by migration of electrons and ions in the solid phase. FeOOH is found to be the most probable product. A voltammetric study by Flerov and Pavlova (10) shows that the discharge reactions go over the dissolved forms of the divalent and three-valent hydroxides ($HFeO_2^-$ and FeO_2^-) which are supposed to be responsible for the slow rate of the electrochemical processes. This study by Flerov consequently contradicts his former study on iron powder electrodes.

From potential-time studies on planar electrodes at constant currents Sherstobikova *et al.* (11) verified Flerov's theory that FeOOH was the product of the second discharge plateau. The same authors have studied (12) the mechanism of solution and passivation of iron in alkali as well as the velocity ratio of these two processes by an impedance measurement method. They found that the solution process of the first stage is divided into two steps where the first is the transition $Fe \rightarrow Fe(I)$ with the loss of one electron, which leads to the intermediate complex $Fe(OH)_{ads}$. The second step is represented by the conversion of $Fe(OH)_{ads}$ to $HFeO_2^-$, which is rate determining. Parallel to this step oxides with valencies exceeding two are formed which are supposed to have a passivating effect.

Silver and Lekas (13) identified the following phases in a porous carbonyl iron electrode at different discharge states with x-ray diffraction. At the end of the first plateau they found α-Fe and $Fe(OH)_2$, and at the end of the second plateau α-Fe and FeOOH after the first cycle. On subsequent cycling a gradual conversion to Fe_3O_4 was observed at the end of the second anodic potential step. For an electrode cycled in 30% KOH saturated with LiOH only α-Fe and Fe_3O_4 were detected at this plateau. These results were confirmed by Labat, Jarrousseau, and Laurent who quantitatively studied the discharge products of industrial iron electrodes from SAFT with x-ray diffraction. They found, apart from α-Fe, mainly $Fe(OH)_2$ formed during the first discharge level with some traces of FeOOH at the end of it. The discharge products of the second plateau after three cycles consisted mainly of FeOOH with less than 5% Fe_3O_4.

Armstrong and Baurhoo (15, 16) studied the discharge and charge reactions of the alkaline iron electrode by using a ring-disk system in order to get information on the soluble intermediates. The results clearly indicate that, above room temperature and in more concentrated KOH solutions, Fe(II) species, probably $HFeO_2^-$ or $Fe(OH)_3^-$, are produced as intermediates. At moderate overpotentials, -0.86V *vs.* Hg/HgO, the intermediate precipitates to $Fe(OH)_2$ while at higher potentials Fe(II) is easily oxidized to Fe(III) which precipitates to FeOOH or Fe_3O_4.

Chnobloch *et al.* (19) studied the different reactions of iron powder on a magnetic electrode by scanning it slowly (2 V/min) in the region -1.1 to -0.4V *vs.* Hg/HgO in 6*N* KOH. In full agreement with (14) three separate peaks appeared apart from the one representing oxidation of hydrogen produced during the charge process. During anodic scan (from -1.1 to -0.4V) the peaks were found to represent the following reactions

$$Fe \rightarrow HFeO_2^- \rightarrow Fe(OH)_2 \quad [1]$$

$$Fe \rightarrow HFeO_2^- \rightarrow FeO_2^- \rightarrow Fe_3O_4 \quad [2]$$

$$Fe(OH)_2 \rightarrow Fe_3O_4 \quad [3]$$

When scanning the electrode back in the same interval identical reactions appear but naturally in opposite order and direction. The investigators opinion that Fe_3O_4 is the product of second discharge level is based on (8, 13), and not on the result of any qualitative analysis.

The behavior of iron in LiOH solutions has been studied by (16, 17) and seems not to differ considerably from that in KOH. The reaction products from the second anodic potential level were found to be Fe_2O_3 or $Fe(OH)_3$.

The present study has been undertaken to define the discharge products for both planar and porous iron electrodes with scanning electron microscope (SEM) technique. This method is also of interest to study the decrease in porosity during discharge which depends on the high volume of the oxidation products.

Experimental

Planar and porous iron electrodes were discharged galvanostatically in 5*N* KOH solution at room temperature and at 50°C. The morphology of the discharge products were examined with scanning electron microscope (JSM-U2, JEOLCO, Japan). The basic concept of the test cell and other equipment used is presented in (20) where also the manufacturing process of the porous electrodes is described.

For the planar electrode, a piece ($10 \times 10 \times 3$ mm) of highly pure electrolytic iron was used on which all sides but one was covered with polymer material. The open face (10×10 mm) was before insertation in the cell mechanically polished with silicon carbide paper, then with powder of the same material. After assembling the cell it was deaerated with nitrogen. A constant current (1 mA/cm² calculated on the geometrical area) was applied and the electrode cycled twice down to -0.5V *vs.* Hg/HgO. Thereafter the electrode was discharged down to the potential to be studied with the same current density. It is notable that capacity increased during these three cycles.

The porous electrodes studied were 1.2 mm thick, 9.5 mm in diameter, and weighing 0.2g. Average pore diameter was 7 μm and Hg-porosimetry curve is given in Fig. 1. No nets were incorporated in order to increase mechanical stability. After assembling and deaerating the cell, the electrode was cycled twice with 20 mA.

After galvanostatic discharge down to the potential level to be studied, the electrodes were immediately taken out of the cell, washed with distilled water, and dried under nitrogen atmosphere. The top surface of the planar electrode and the interior of the porous plaques after breaking them along their diameters were studied. No gold or other current-conducting material was vaporized on the specimen.

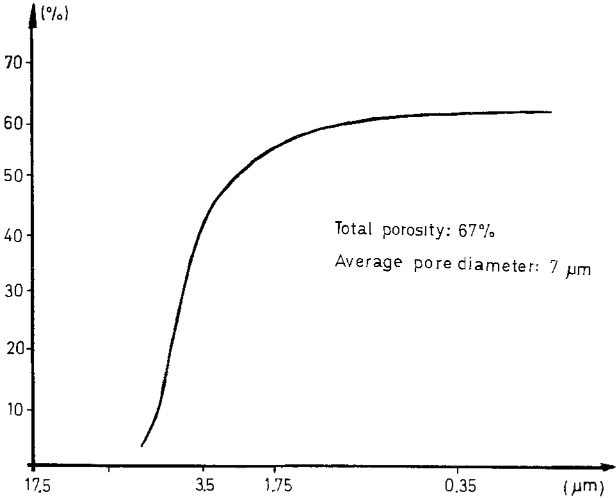

Fig. 1. Hg-porosimetry curve of the electrodes tested

Results

Figure 2 shows the variation in potential at room temperature for the planar electrode and also the potential levels for Fig. 3.1 and 3.2. At the end of first plateau the $Fe(OH)_2$ crystallites appear distinctly. On continuation of discharge (Fig. 3.2) the structure becomes covered with a gelatinous precipitation, probably hydrated FeOOH, which can be written $Fe_2O_3 \cdot nH_2O$, in accordance with Table I which gives crystal structures of possible oxidation products. The distinct morphological features of the first anodic step, together with the observed looseness of the crystallites on the surface, give support to the dissolution-precipitation mechanism during discharge.

Figure 5 shows a micrograph of a porous iron electrode before any electrochemical treatment and in Fig. 6 and 7 the same structure in discharged state. A similar pattern to the planar electrodes is shown for both levels. The micrographs show that nucleation and growth of $Fe(OH)_2$ play the dominant role at the early part of the first discharge step. During the later part crystal growth predominates with a possible secondary growth due to dissolution of smaller crystallites and increase of larger ones. Also these facts support the precipitation-dissolution mechanism.

On continuation of discharge the same sludge-formed precipitation as on planar electrodes appears. The form of the oxidation products indicates that this process goes over migration of ions and electrons in the solid phase. No opening up process can be noted when comparing Fig. 6.2 and 6.3. This means that the volume density of the oxidation products of both levels must be of the same magnitude and that hydrated FeOOH is the product of the second anodic step.

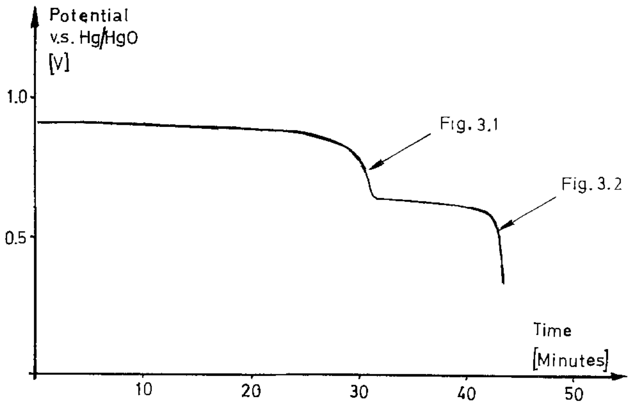

Fig. 2. Potential of planar electrodes during discharge (1 mA/cm^2, 25°C).

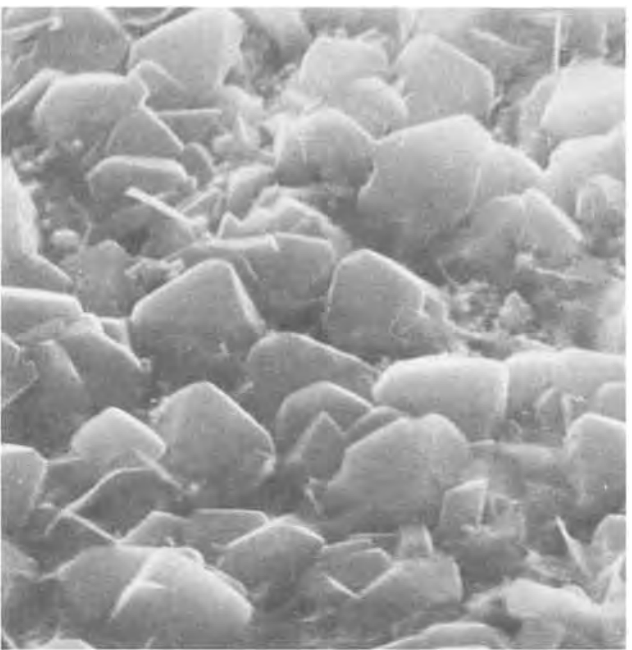
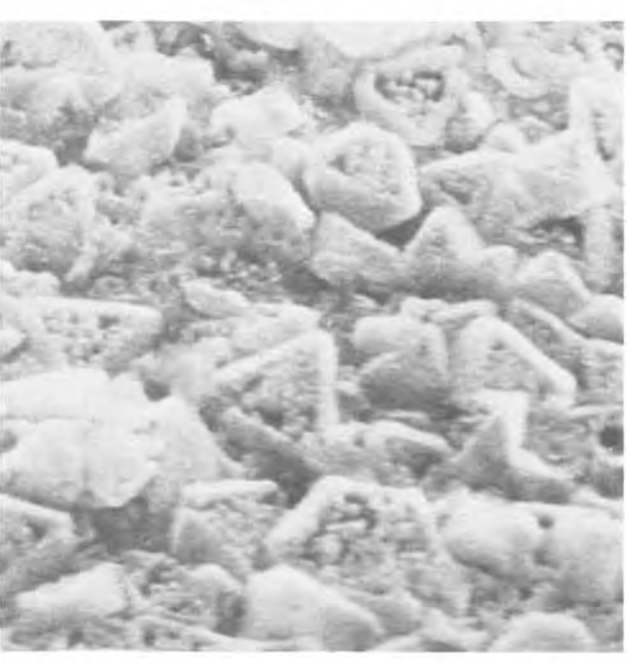


3.1



3.2

Fig. 3. Micrographs of planar electrode at two different discharge states.

The micrographs shown in Fig. 7.1 to 7.4, from 50°C, show crystallite size 2-3 times larger compared to room temperature, even at beginning of discharge. The nucleation process seems not that important at this temperature level and current density. This depends on that the relative supersaturation is lower since the solubility of the intermediate $HFeO_2^-$ increases with

temperature (21, 22). Also the diffusion rate increases naturally with temperature. When increasing the current density the morphology of the products become similar to those of lower temperature. At continuation of discharge at 50°C the same sludge-formed precipitation appears as in Fig. 3 and 5. Toward the end of the second anodic plateau small crystallites of prob-

ably Fe_3O_4 appear, the formation of which is favored by higher temperatures in accordance with the Schikorr reaction.

Discussion

The results obtained support the dissolution-precipitation theory presented by Flerov and Pavlova (10), which also has been suggested by Armstrong and Baurhoo (16, 17) from experimental data obtained with ring-disk technique. The products found on second discharge level are in full accordance with the results of (13) and (14) where FeOOH was found during the first cycles.

It is quite evident that a possible change in composition of the discharge products may occur during the washing procedure. This treatment is however more lenient to the products than the cleaning and milling procedure preceding most x-ray studies here discussed.

Technical Notes

Aluminum Perchlorate in Aluminum-MnO_2 Dry Cells

Brooke Schumm, Jr.*

Union Carbide Corporation, Battery Products Division, Cleveland, Ohio 44101

Aluminum appears to be an attractive substitute for zinc in dry cells. It is higher than zinc in the electromotive series, higher in coulombic yield per unit weight, is more abundant in nature, and inexpensive (see Table I). As a possible anode material, however, it does not behave as well as zinc (1). In neutral *p*H solutions passive surface oxide layers tend to form creating an ineffective electrode surface. In common acid or alkaline salt solutions aluminum is an active anode (2-4), but when not on load corrodes rapidly with evolution of hydrogen. These difficulties must be overcome for aluminum to be commercially useful in dry cells.

The success of aqueous perchlorate electrolyte in magnesium or zinc cells (5, 6) suggests that similar opportunities exist in other metal anode-manganese dioxide systems. Aluminum perchlorate was studied to find if alone in aqueous solution or in combination with other agents in aluminum-manganese dioxide "dry" cells it would allow the following characteristics: (*i*) a balance between anode activity and passivity during cell storage, (*ii*) low internal cell resistance, and (*iii*) adequate chemical activity and ion diffusion in the electrolyte during discharge.

Observation of the corrosion rate and manner of corrosion attack of aluminum perchlorate solutions on aluminum metal could be expected to guide the choice of concentration of salt and any addition agents which would be needed. For the best electrochemical performance, the anode surface should be corroding very slowly without the formation of pits in the anode metal (7). This state allows cell current generation on demand without undesirable waiting periods for electrodes to reach full activity. Experience with corrosion rates in commercial Leclanché cells indicates that up to 0.05 mg/cm^2/day of aluminum could be lost in storage and be acceptable. Usually a small amount of inhibitors and carefully chosen salt concentrations give the necessary balance of anode activity and corrosion resistance (8, 9).

For the cathode mix, the proper percentages of conductive phase (usually carbon) manganese dioxide and of salt and solution are necessary to have low internal cell resistance. The choice of separator material is also important. The optimized combination of materials

also allows the necessary chemical activity and diffusion in the electrolyte during discharge. Often less than optimum composition for one aspect is more than compensated by improvement in other factors.

If the aluminum alloy (10-13), separator, and cathode mixture combination is found which will fulfill the stated objectives, then performance matching that of other commercial dry cells should be achieved.

Experimental

The solution *p*H was expected to have a major effect since aluminum corrodes rapidly in extremely acid solutions which are typical of aluminum salts such as aluminum chloride. The results of measurement of the *p*H of aluminum perchlorate solutions are given in Table II.

Aluminum coupons prepared from commercially (99.5%) pure aluminum were cut, 2.54 × 10.16 cm, and immersed 2.54 cm into the test solution. Since the *p*H is so low at even small salt concentrations and the observed corrosion rates so high (Table III), the effect of the addition of small amounts of sodium hydroxide on the *p*H of the solutions was studied. The corrosion rate tests were repeated for solutions which might be sufficiently buffered to be less corrosive yet low enough in *p*H to be an active electrolyte. In the encouraging

70				0.032 (0.13)

results three of the values observed of corrosion loss (in Table III) were better than the maximum acceptable rate of 0.05 mg/cm²/day. In a nearly sealed cell the corrosion could be expected to be even lower.

Cell Assembly

Aluminum perchlorate and sodium hydroxide concentrations were chosen for cell cathode mix from the lower ranges of the region which showed acceptable rates of attack on aluminum. This was to allow for the addition of aluminum and hydroxyl ions to the solution of the cells during discharge which would move the anolyte composition to the higher buffered aluminum concentrations of Table III. The chosen electrolyte mixture (Table IV) was added to a dry blend of seven parts of natural African manganese dioxide (79% MnO_2) and one part acetylene black. 60g of this cathode mix were packed into D-size aluminum (0.6% zinc) alloy cans (12) with an alpha-cellulose uncoated paper liner and a Kraft bottom cup. The usual porous, wet-proofed carbon electrode was driven into the mix as a collector. The cell was sealed with a poured asphalt layer on a cardboard washer as shown in Fig. 1.

Cell Test Results

Initial cell properties and fresh tests.—The cells exhibited an open-circuit voltage of 1.52-1.55V and a short-circuit current of 3-4A which the cells could support for several minutes. On 2¼Ω continuous drain three cells averaged an excellent voltage *vs.* time discharge for a paper-lined cell (Fig. 2). Similarly, attractive performance was found on 2¼Ω LIF test (4 min/hr, 8 hr/day) both on cells tested after 1 month of aging at room temperature and on other cells tested after an additional month at 45°C (Fig. 3). Cell to cell variation was high, however, and discharge voltage readings less predictable after the elevated temperature storage.

The cells had a slight starting delay, as magnesium cells do (5), but the shape of the initial voltage curve was interesting (Fig. 4). The sample voltage delay shown occurred at the start of the sixth 4 min test cycle on the second day (fourteenth cycle after 52 min on load). Note that the voltage never went more than 0.30V below the final closed-circuit value and recovered to within 0.05V of the final value in 0.45 sec. A magnesium cell often would drop much farther below the final loaded voltage level.

Cell efficiency and effects on continuous load.—The cells achieved an average anode efficiency of 70% and a cathode efficiency of 40% to 0.65V on 2¼Ω continous drain. The rest of the anode consumption represented

corrosion loss accompanied by generation of substantial amounts of hydrogen gas. This gas forced open the seals and contributed to the advent of cell leakage shortly after the end of useful cell life.

Cell leakage.—These aluminum cells exhibited electrolyte movement similar to that seen in paper separator Leclanché cells. Electrolyte movement on heavy loads such as 2¼Ω continuous associated with hydrogen generation makes containment of the electrolyte very difficult. Special constructions and gas-venting mechanisms would be necessary to achieve reasonable cell leakage resistance.

Discussion of Results

The open-circuit and initial closed-circuit voltage of these aluminum-perchlorate electrolyte-manganese dioxide cells was much lower than expected considering the place of aluminum in the electromotive series. A cell could have shown as high as 2.59V (open circuit) if the theoretical half-cell voltage of aluminum were exhibited when the manganese dioxide contributes approximately 0.92V (*vs.* hydrogen) as in a Leclanché cell. The actual half-cell manganese dioxide contribution is more nearly 1.03V (14) considering the electrolyte *p*H. Thus the aluminum is not operating at full theoretical voltage. A complete study and discussion of this phenomenon is beyond the scope of this paper.

If the cell electrolyte *p*H rises on discharge as observed in Leclanché cells, hydrated aluminum hydroxide will precipitate (15). This rapid removal of water from the system by the precipitation of hydrated aluminum hydroxide should eventually severely limit necessary diffusion in the cathode because of loss of the ion carrier medium. Nonetheless the performance on heavy service tests was good when compared to commercial Leclanché cells with similar natural manganese dioxide.

Of particular interest was the surprisingly good service maintenance after 1 month at 45°C even though no strong inhibitors were included in the cell chemicals. With the small initial delay it can be concluded that the desirable balance between a tendency for the aluminum anode to corrode and to passivate on-shelf had been achieved. The irregular form of the curve, however, indicates probable anode surface change from partially passivated (due to oxide film and possibly being too dry) to moist with the oxide film dissolved during discharge.

The cell initial internal resistance was rather high. At the same manganese ore to carbon ratio a Leclanché D cell would exhibit 7-10A short-circuit current as compared to the 3-4A found with these aluminum cells. Although short-circuit current is only an approximate measure, the internal resistance of the experimental cells is thus at least twice that of similar Leclanché cells.

With such a high internal resistance the encouraging performance on heavy drains indicates that the concentration polarization and activation polarization of the Al-aluminum perchlorate-MnO_2 cell must be low. These latter factors are evidently sufficient to override the resistance losses and water consumption and allow adequate cell service.

Other systems such as in magnesium-manganese dioxide cells and zinc-manganese dioxide cells with zinc chloride electrolyte usually show little or no electrolyte movement on abusive discharge. The different action here observed probably is caused by precipitation of aluminum hydroxide which interferes with the diffusion of ions near the separator. Ion concentration imbalances then build up in the aluminum cell. Water moves in the cell to bring about concentration equilibrium causing the appearance of exudate and cell leakage next to the aluminum anode. This action is aggravated by the pumping action of the hydrogen gas released during rapid discharge.

Conclusions

Attractive service performance can be obtained from aluminum manganese dioxide cells with an aqueous aluminum perchlorate electrolyte. Corrosion resistance of aluminum has been good in the presence of a cell electrolyte buffered to a *p*H of 0-4 with sodium hydroxide. Internal resistance of such cells is higher than that of Leclanché cells, but the low concentration polarization and activation polarization in the over-all system appear to compensate for the internal resistance losses. The amount of gaseous corrosion by-product observed on discharge combined with undesirable electrolyte movements makes the cells difficult to seal and be simultaneously safe against leakage or swelling.

Effect of Surface Dissolution on Plastic Deformation of Iron and Steel

Herbert H. Uhlig*

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

The slow plastic deformation of a metal subject to an applied stress, usually at a value below the elastic limit, is called creep. Our previous results on the mechanism of corrosion fatigue (1, 2) suggested that a metal deforms plastically much more readily when it is actively corroding. According to this viewpoint a corroding metal should also exhibit accelerated creep. This expectation was confirmed for brass and for pure copper by Revie and Uhlig (3, 4). The effect was large: A corrosion rate for 0.027 cm diam Cu wire corresponding to 0.9 mA/cm² accounted for a 600% increase in extension over its corresponding extension in air, independent of any thinning caused by the corrosion process. A characteristic delay in change of creep rate was observed on either starting or stopping corrosion. Reversed polarity (cathodic protection) had little or no effect on the creep rate of fine grained copper, but did accelerate creep of large grained copper. It was proposed that the latter effect was caused by reduction of surface energy and consequent ease of slip step formation occurring in the large outer grains that influence the creep rate. On the other hand, it was suggested that anodic dissolution generates surface divacancies which readily diffuse into the metal, whether small or large grained, to interact with piled-up dislocations below the surface causing dislocation climb followed by increased plastic deformation. Accordingly the time for divacancies to reach the dislocation arrays is equated to the observed delay in creep response with change in corrosion rate. The effect of corrosion to similarly accelerate plastic deformation of iron and steel is presently reported.

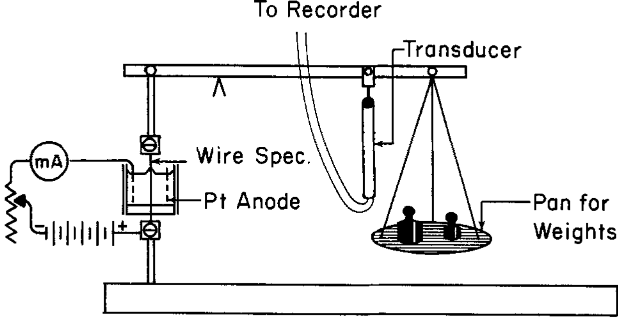

Fig. 1. Schematic sketch of creep apparatus

Experimental

Experiments were carried out on cold-rolled Armco iron strip, 1.6 mm wide, 0.065 mm thick, and on high strength 0.77% C steel wire 0.71 mm (28 mils) diam. The latter was supplied courtesy of The United States Steel Corporation and was used in the heat-treated and cold-drawn state as received. For some tests, the cold-rolled strip was annealed in a N_2 atmosphere; this was accomplished by passing an electric current through the strip to red heat and gradually reducing the current over a period of ½ min. Stress was applied by weighting a pan attached by a lever arm to the chuck holding the wire or strip. Displacement of the lever arm was measured by a Sanborn DC LVDT transducer connected to a chart recorder. Linear sensitivity of the transducer as measured at the chuck holding the iron specimen was 1.42×10^{-4} cm/mV. A glass cylinder 3½ cm diam fitted with a cylindrical Pt electrode surrounded the lower portion of the test specimen. The specimen made a water-tight seal when pressed between a Teflon insert in a rubber stopper at the bottom opening of the glass cylinder (Fig. 1). The electrolyte was either 3% NaCl or 3% NaCl + 3% Na acetate solution.

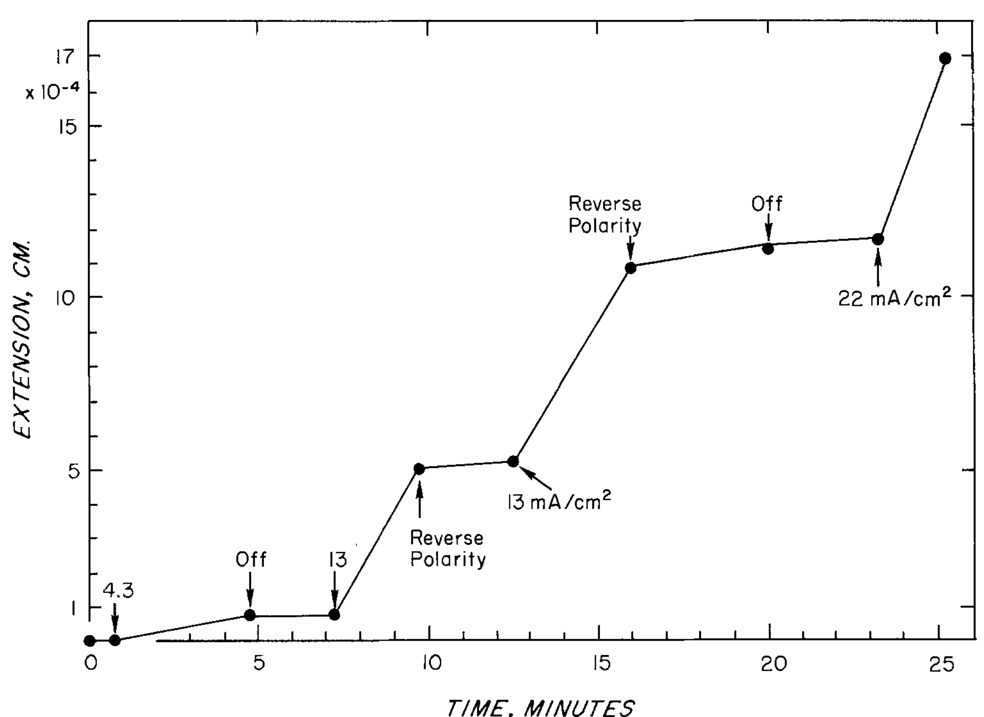

Fig. 2. Effect of anodic dissolution and cathodic protection on creep extension of cold-rolled Armco iron strip in 3% NaCl, 3% Na acetate solution, 55.5 kg/mm² (79,000 psi), room temp.

The effect of applied anodic polarization current densities, on creep extension of the cold-rolled Armco iron strip is illustrated in Fig. 2. This is measured in correspondence to a variety of controlled corrosion rates. The indicated points are arbitrary references taken directly from the continuous chart record. It is observed that accelerated creep or extension of the strip increases with current density, and that reversed polarity (cathodic protection) in common with no current at all has no effect. Since the iron strip (as well as the steel wire) is fine grained, no effect of cathodic protection is expected. Accelerated creep also occurs when corrosion is caused by a corrosive solution, such as $FeCl_3 + HCl$, in absence of anodic polarization. On the other hand, anodic polarization of the strip in dilute Na_2SO_4 solution to within the passive region fails to accelerate creep because the anodic corrosion rate is negligible. In contrast to the effects for copper, the response of the cold-rolled strip to changes in corrosion rate show no appreciable delay time. The annealed strip, as described later, behaves differently.

Taking slopes of extension *vs.* time for a given applied anodic current density, the effect of current density on creep rate is shown in Fig. 3. These results, as well as those presented later, are for short-time tests in the order of 3-10 min at each current density. The increase in creep rate at 10 mA/cm², corresponding to a corrosion rate of 25,000 mg/dm²/day, over that in air is approximately 650%. Thinning of the strip by corrosion is not a factor, as is shown by the low observed creep rate at zero current measured at the termination of all the runs. Calculation applying Faraday's law confirms that the total corrosion during any series of tests does not significantly reduce cross-sectional area of the strip.

The effect of applied stress on the creep rate of cold-drawn Armco iron strip at various current densities is shown in Fig. 4. The usual semilogarithmic relation between stress and creep rate holds at each current density. This relation does not hold at low applied stresses in view of extrapolated positive creep rates at zero stress. Data of Fig. 3 and 4 are consistent within the presently observed experimental variations of creep rate for different strip specimens.

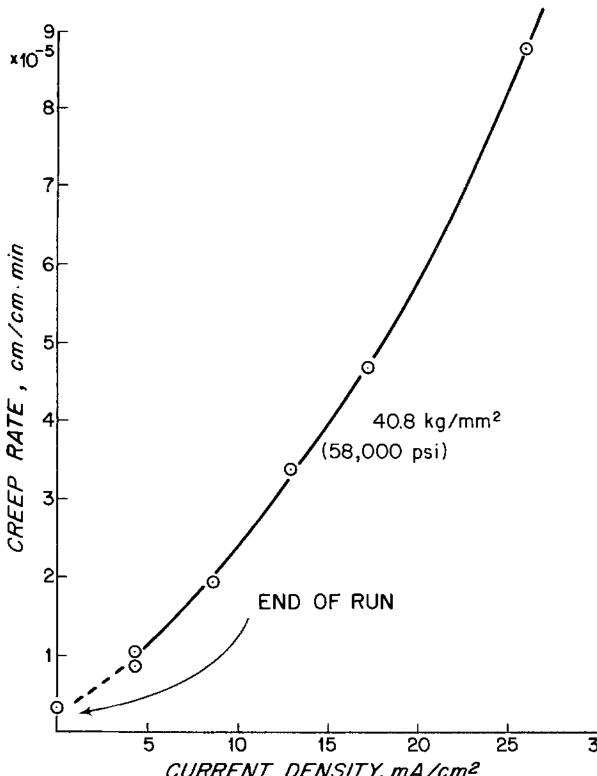

Fig. 3. Effect of anodic current density on creep rate of cold-rolled Armco iron strip in 3% NaCl, 3% Na acetate solution, room temp.

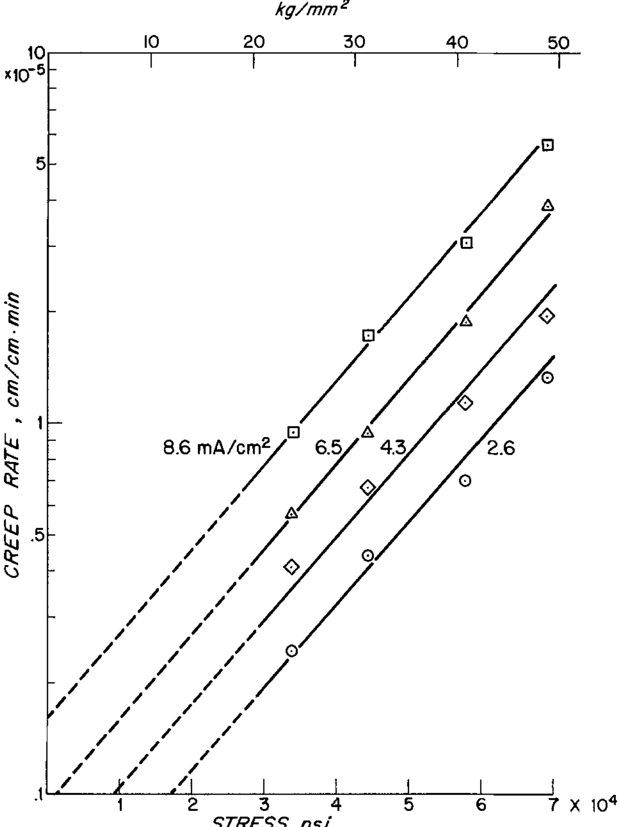

Fig. 4. Effect of applied stress on creep rate of cold-rolled Armco iron strip at various anodic current densities in 3% NaCl, 3% Na acetate solution, room temp.

The effect of annealing the strip is shown in Fig. 5. The creep rate at a given applied stress is much larger than for cold-rolled material (Fig. 2) and anodic corrosion again exerts a large accelerating effect. The accelerating effect at low current densities, or low corrosion rates, is more pronounced at an applied stress of 11.7 kg/mm² (16,600 psi) compared to 10.3 kg/mm² (14,700 psi). Another characteristic is a longer time required to achieve a linear extension *vs.* time compared to that for cold-rolled strip, and also a longer time to regain the normal creep rate upon shutting off the current or reversing polarity.

The effect of anodic current density on the creep rate of high strength carbon steel wire is shown in Fig. 6. The creep rate at a given applied stress is considerably less than for the cold-rolled strip but the percentage acceleration induced by a given corrosion rate is comparable. Again, there is no effect on creep for reversed polarity corresponding to cathodic protection of the wire. The shape of the creep *vs.* current density for this high strength differs from that for the lower strength wires, but the reasons are unknown.

As previously suggested for copper (4), the cause of accelerated creep is plausibly related to the formation of divacancies generated by the corrosion reaction. The divacancies, in turn, diffuse into the metal at room temperature across grain boundaries to interact with dislocations piled up below the metal surface. The diminished delay time or its absence for cold-rolled strip and high strength wire indicates that either piled-up dislocations are located nearer the surface compared to the situation for copper, or that divacancies diffuse at a higher rate in the present ferrous materials. Similar to copper, there is no evidence that a hard debris layer forms at the surface of a plastically deformed iron, the dissolution of which supposedly accounts for increased creep. This was demonstrated by corroding a previously loaded cold-rolled strip for sev-

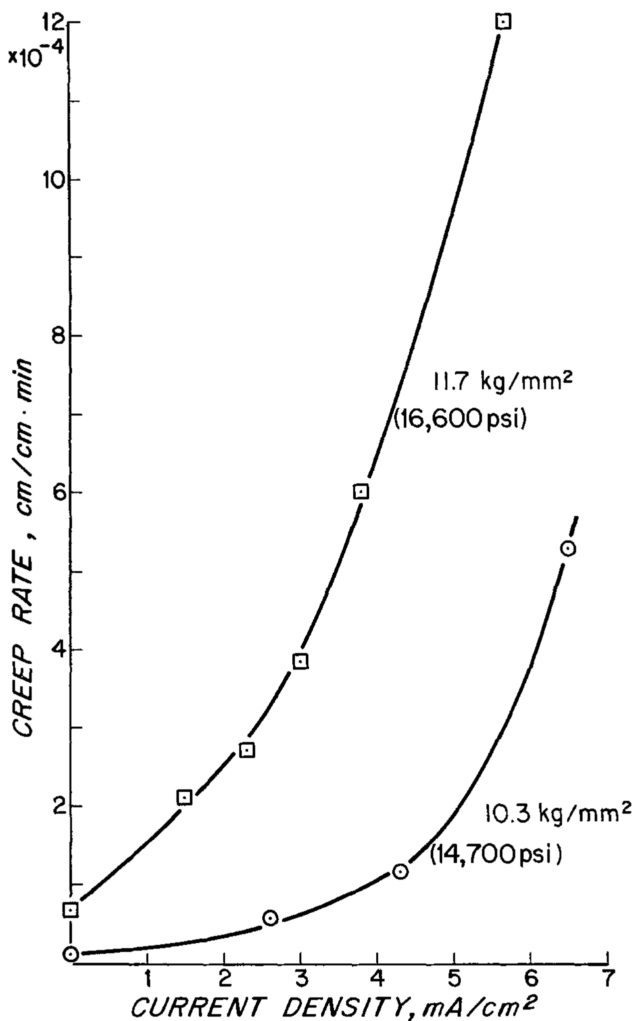

Fig. 5. Effect of anodic current density on creep rate of annealed Armco iron strip in 3% NaCl solution, room temp.

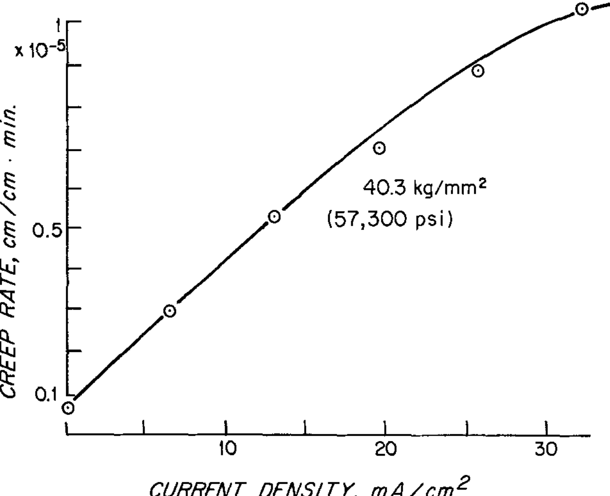

Fig. 6. Effect of anodic current density on creep rate of high strength 0.77%C steel wire, 0.71 mm diam, in 3% NaCl, 3% Na acetate solution, room temp.

eral minutes at zero stress, then applying the normal stress at zero current and noting no change of creep rate. Had the debris layer been present, an increased creep rate would be expected. Further arguments on this matter by Kramer (5) and by Revie and Uhlig (6) have been published.

The effect of corrosion on creep acceleration probably applies generally to all metals, not only to copper and iron. This is in view of the fact that corrosion usually reduces observed fatigue life of metals.

However, the effect of corrosion on creep acceleration, unlike its effect on fatigue, is limited to shapes corresponding to a large surface to volume ratio, *i.e.*, wire or strip. The large effect of the present high strength steel wire (0.71 mm in diameter) on creep brings current observations into the area of relevancy since many present practical applications for wire include this diameter. These results also lend additional support to the previously proposed mechanism of corrosion fatigue based on the effect of corrosion to accelerate plastic deformation of stressed metals.

Conclusions

1. Creep of stressed Armco iron strip or high strength 0.77%C steel wire is appreciably accelerated by surface dissolution, independent of any thinning caused by the corrosion process.
2. The results lend additional support to the previously proposed mechanism of corrosion fatigue based on the effect of corrosion to accelerate plastic deformation of stressed metals.

Holographic Study of Electropolishing

R. J. Schaefer and J. A. Blodgett

Naval Research Laboratory, Washington, D.C. 20375

Electropolishing can produce bright, specular surfaces on metals, but these surfaces often have poor flatness because the local rate of dissolution of the metal is influenced by convection or other inhomogeneous processes. Although these effects can often be mitigated, for example by careful selection of an electrolyte or by controlled flow patterns, they usually cannot be entirely eliminated, especially if the object being polished is large or complex in shape. Therefore it is important to understand the effects which lead to locally inhomogeneous rates of dissolution.

Key words: interferometry, convection, copper.

We have previously reported on the use of holography to study crystal growth of transparent materials, using transmitted light (1, 2). We describe here a holographic study of the electropolishing of copper, using light reflected from the surface of copper specimens. Double-exposure and real-time holography (3) have

enabled us to measure interferometrically the development of convection-related inhomogeneities in the polishing rate.

Experimental

Flat copper specimens were illuminated at normal incidence by a collimated beam of light from an argon or krypton ion laser. The reflected light was directed by a beam-splitter to a film or plate which was simultaneously illuminated by a coherent reference beam to form the hologram. All components of the apparatus were rigidly mounted on a vibration isolation table.

The electropolishing specimens were prepared as strips of annealed copper sheet 1.5 cm wide which were first polished mechanically to 3/0 grade polishing paper and then electropolished to give a uniform bright surface. This surface was then masked by a transparent insulating lacquer everywhere except for a small "window" where the metal was left bare for the subsequent electropolishing experiments. The polishing windows had several different shapes with typical over-all dimensions of 5-10 mm. The strips were mounted vertically in a glass polishing chamber with two copper cathodes. The electrolyte was 70% H_3PO_4 and polishing was carried out at a constant applied voltage of 1.5V. The current density at the anode polishing window reached a steady-state value of approximately 35 mA/cm^2 within 90 sec of the start of polishing, after the decay of an initial transient pulse of about ten times the steady-state current density.

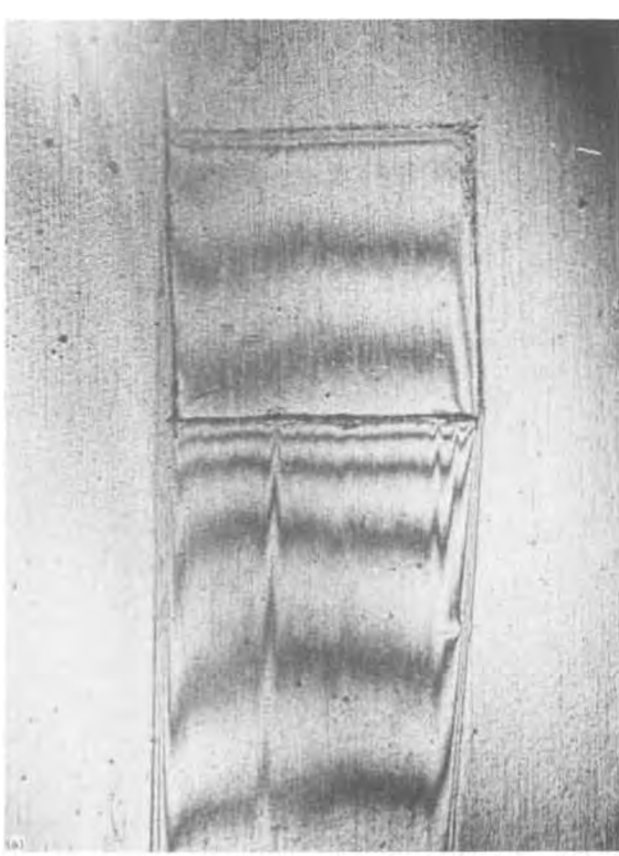
Double-exposure holograms were made by recording two exposures in sequence without moving either the specimen or the photographic plate. The reconstructed double-exposure holograms showed interference fringes indicating changes in the specimen in the time interval between the two exposures. Real-time holography was accomplished by recording a single-exposure hologram of the copper anode in position in the polishing cell before the start of polishing. This hologram was then removed from its holder, processed, and replaced exactly in its original position. The virtual image reconstructed by the hologram was thus superimposed on the specimen itself, and changes in the specimen, in the form of moving fringes, could be seen as they occurred.

Holographic interferometry was found to work well only on specimens which already had smooth, bright surfaces; hence the initial polishing of the copper strips before coating with the insulating lacquer. However, the quality of the initial surface required was much less than the fraction of a wavelength surface which would be required if performing the experiment by means of conventional interferometry. An etching or microscopic roughening of the specimen surface, in either its initial or final state, caused an unresolvable jumble of contorted fringes which obliterated the fringes due to larger scale events.

The fringes in the reconstructed holograms are due to changes in the optical path length of the laser light. These changes are caused both by changes in the geometrical path length, as metal is removed from the copper surface, and by changes in refractive index of the electrolyte, as its composition changes during polishing. These two effects cannot in general be separated, except that it can be shown that the electrolyte composition eventually reaches a quasi-steady state so that further optical path length changes are due entirely to increases in the geometrical path length.

Results

Figure 1(a) shows an image reconstructed from a double-exposure hologram of an electropolishing specimen. The first exposure was recorded before the start of polishing and the second exposure was recorded after 2 min of polishing. The fringes visible within the square polishing area result from the combined effects of the geometrical path length increase due to metal removal, and the refractive index change due to compositional variation of the electrolyte. The fringes visible in the masked area below the polishing window are due entirely to the downward convection of the dense,



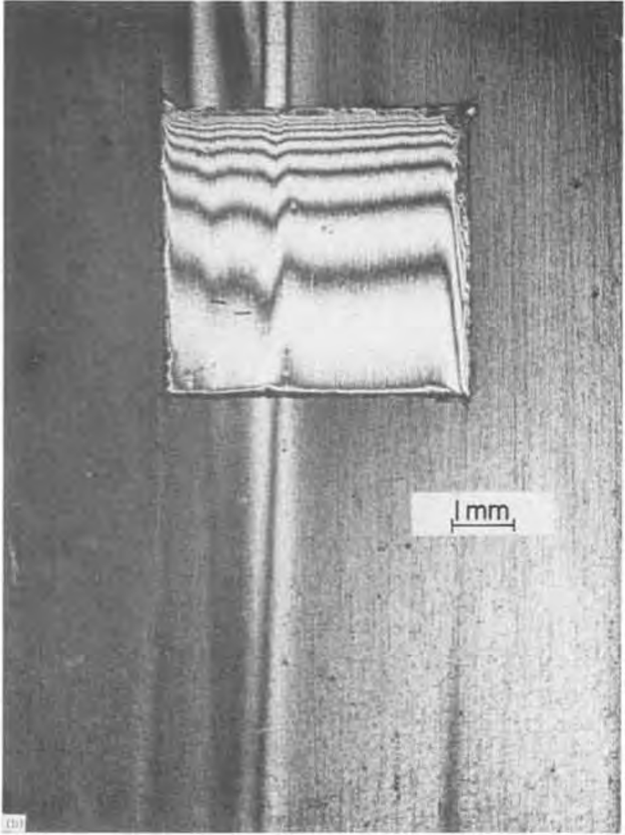


Fig. 1. Double-exposure holograms of copper specimen electropolishing in H_3PO_4 solution: (a) exposures at $t = 0$ and $t = 2$ min, (b) exposures at $t = 8$ min and $t = 10$ min.

copper-rich electrolyte. Figure 1(b) shows a reconstructed double-exposure hologram of the same specimen, the two exposures in this case having been recorded 8 and 10 min after the start of polishing. No fringes are now seen in the masked region below the polishing window, indicating that the downward-streaming electrolyte has reached a steady-state condition. It is reasonable to assume that the electrolyte composition in the region of the polishing window has also reached a steady-state condition and that the fringes in the polishing region are thus due solely to the geometrical path length increase resulting from metal removal. The fringes indicate that the metal removal rate changes rapidly as the top edge of the polishing window is approached.

Each fringe in this case corresponds to a change in surface elevation of $\lambda/2n$, where λ is the wavelength in air (514.5 nm) and n is the refractive index of the electrolyte (1.424). In this system the fringe interval is thus 0.18 μm. Analysis of the fringes of Fig. 1(b) indicates that over most of the specimen area the inhomogeneous part of the metal removal rate can be described by the equation

$$\frac{dh}{dt} = \frac{0.66}{z^{0.34}} - 0.3 \qquad 0.2\,\text{mm} < z < 5\,\text{mm} \qquad [1]$$

where dh/dt is the rate of metal removal in micrometers per minute, and z is the distance in millimeters from the top edge of the polishing window. One can of course expect this equation to apply only under the specific conditions of electrolyte composition and applied voltage that were used in these experiments.

To determine whether the fringes near the top of the polishing window represent increasing or decreasing metal removal rate, a small angular offset of the beam illuminating the specimen was introduced between the two exposures of the hologram. A series of vertical fringes was thereby produced in the reconstructed hologram, and the direction of fringe displacement corresponding to increasing path length was known. The fringes within the polishing area then showed clearly that the polishing rate decreases as one moves downward from the top of the polishing window. This decrease can be attributed to the buildup of the downward-streaming, copper-rich laminar layer adjacent to the metal surface.

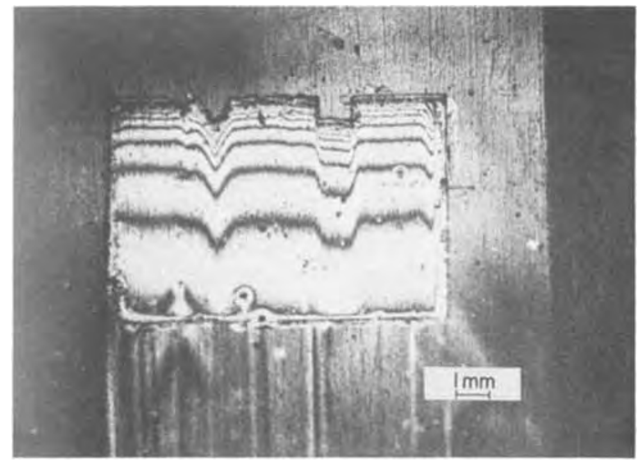

Fig. 3. Double-exposure hologram of a copper specimen with irregularities in the top edge of the polishing window. The fringes show the inhomogeneous rate of metal removal under steady-state polishing conditions.

Confirmation of the interpretation of the fringes was obtained by electropoishing an initially flat specimen for 10 min and then measuring the depth of metal removed from the surface by means of a Dektak profilometer. Figure 2 shows the specimen profile with the much greater depth of metal removed near the top edge of the polishing window. Using Eq. [1] to subtract out the inhomogeneous part of the metal removal rate from the profile of Fig. 2, we obtain the dotted line, closely paralleling the original specimen surface and thus confirming the validity of Eq. [1].

The sensitivity of the local polishing rate to the proximity of the top edge of the polishing area can be dramatically shown by introducing irregularities in the shape of the top edge. Figure 3 shows a specimen in which small triangular and rectangular irregulari-

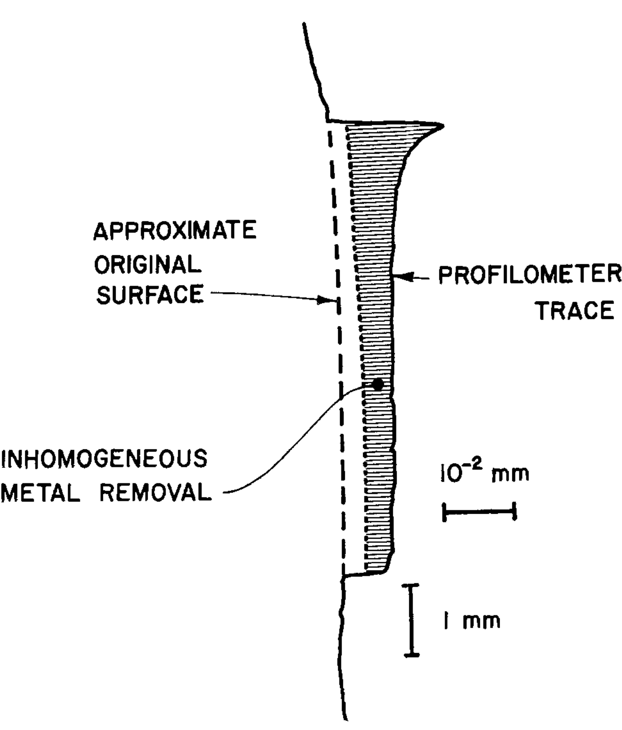

Fig. 2. Surface relief of electropolished copper specimen as measured by profilometer. The shaded region represents the inhomogeneity in metal removal rate associated with the top edge of the polishing window, as given by Eq. [1].

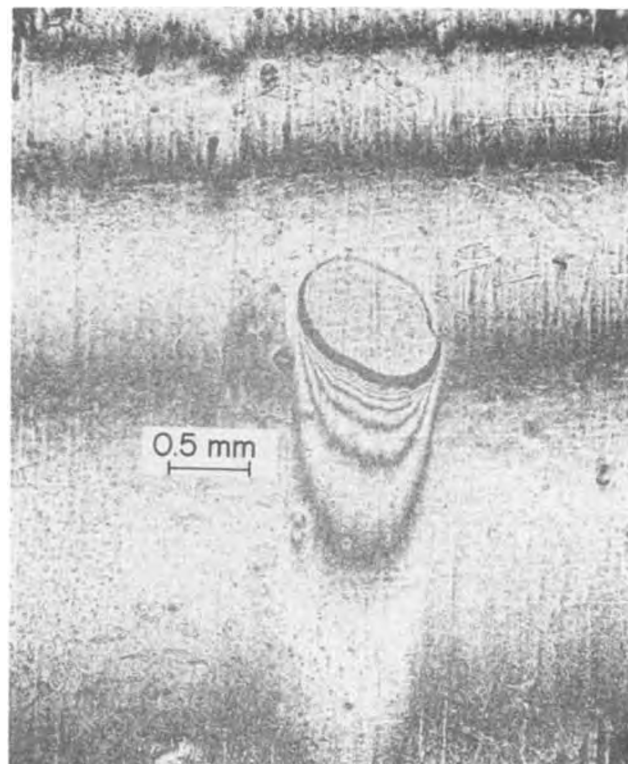

Fig. 4. Inhomogeneous metal removal rate in the vicinity of a small spot of insulating lacquer on the copper surface.

ties have thus been introduced. The shape of the irregularities is faithfully reproduced in each of the fringes in this reconstructed double-exposure hologram, indicating that there is little lateral spreading of the downward-flowing electrolyte.

When a small spot of insulating lacquer is placed in the middle of the polishing window (Fig. 4), it is seen that the metal removal rate is considerably greater immediately below the spot than at the sides or top of the spot. This experiment demonstrates that the metal removal rate at a point on the surface is not simply a function of the total amount of copper per unit area in the laminar layer covering that point, which may be expressed as

$$C(y,z) = \int_0^\infty c(x,y,z)\,dx \qquad [2]$$

where $c(x,y,z)$ is the local concentration of copper, x is the distance from the copper surface, and y and z are the other two Cartesian coordinates. Because of the laminar nature of the surface layer, $C(y,z)$ below the insulated spot cannot be significantly less than $C(y,z)$ immediately above the spot, yet the metal removal rate is much greater below the spot than above it. We can therefore conclude that the metal removal rate is not a function of $C(y,z)$ but rather is related to the concentration $c(x=0,y,z)$ directly at the metal surface, which could differ significantly above and below the insulated spot. Unfortunately, while $C(y,z)$ can be measured holographically through its influence on the optical path length, $c(x=0,y,z)$ cannot be measured holographically.

The double-exposure technique suffers from the disadvantage that it is not possible to measure the absolute local rates of metal removal, but only the inhomogeneities in the rate. An absolute measurement would require an enumeration of the order of the individual fringes since it is impossible to trace the individual fringes across the sharp step at the edges of the polishing area.

With real-time holography one can measure the rate at which fringes sweep across the surface of the specimen and thereby determine the absolute rate of metal removal, once the electrolyte has reached its steady-state composition distribution. One can also observe transient phenomena during the initial stages of polishing. The moving fringes in our real-time holograms were recorded on motion picture film for later analysis. Real-time holography is much more demanding than double-exposure holography with respect to experimental requirements such as vibration isolation and equality of object and reference path length, and the fringes in real-time holograms were often faint and difficult to follow.

The real-time holograms compare the specimen's current condition to its condition before the start of polishing. Thus, within the polishing area, the change in path length is due to both electrolyte composition changes and metal removal. The holograms show, however, that convection of the electrolyte does not become

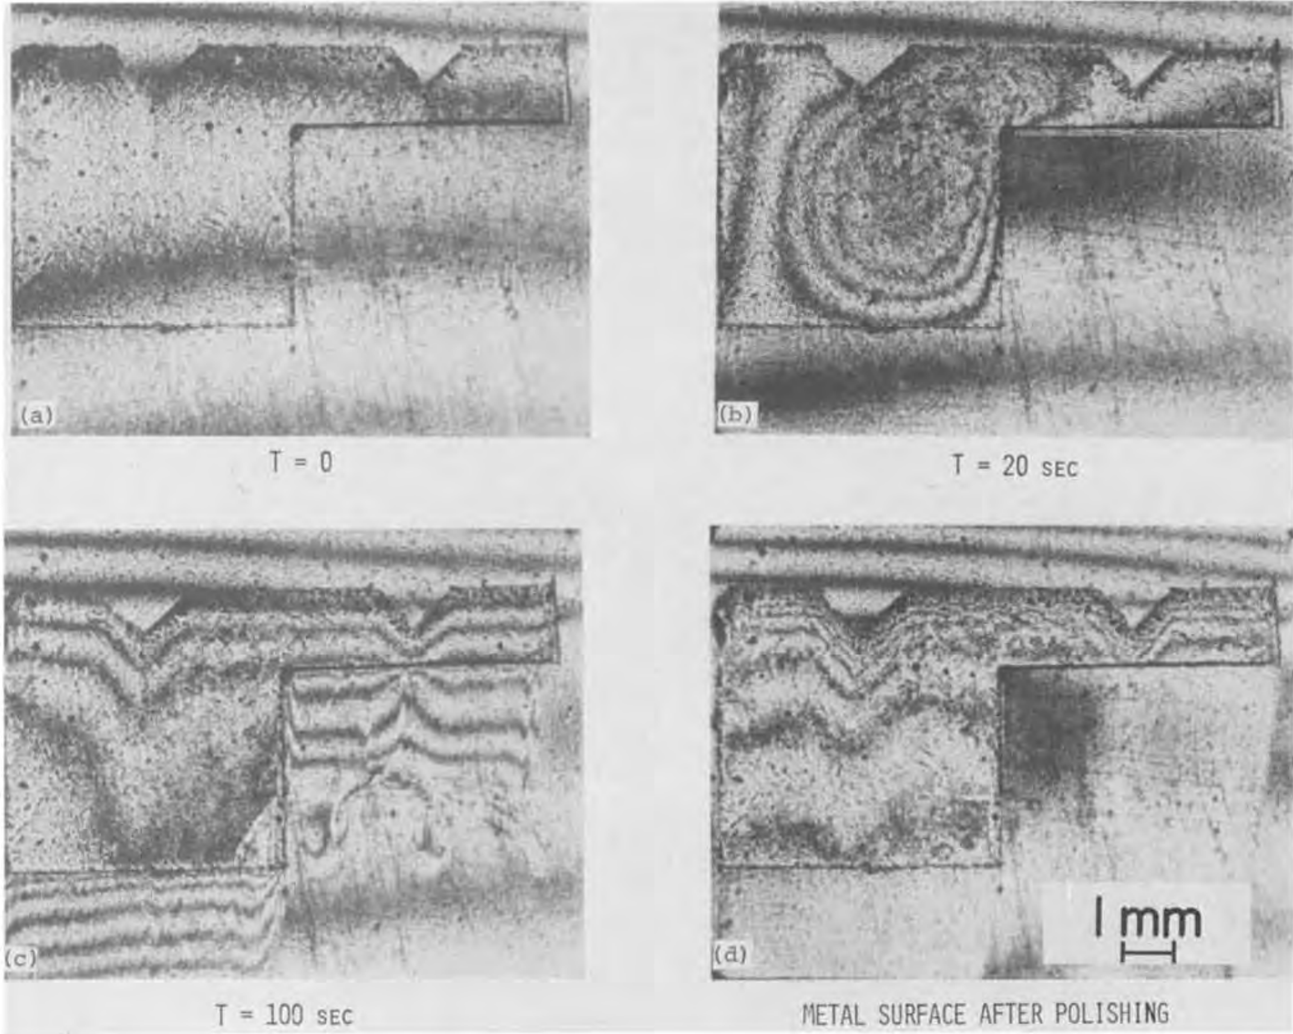

Fig. 5. Real time holography showing: (a) the initial appearance of the specimen with the superimposed holographic reconstruction, (b) the appearance during the initial transient period of polishing with current highest at the corners and edges, (c) the appearance after the start of convective flow, and, (d) the appearance after polishing is stopped and the copper-enriched electrolyte has been allowed to dissipate.

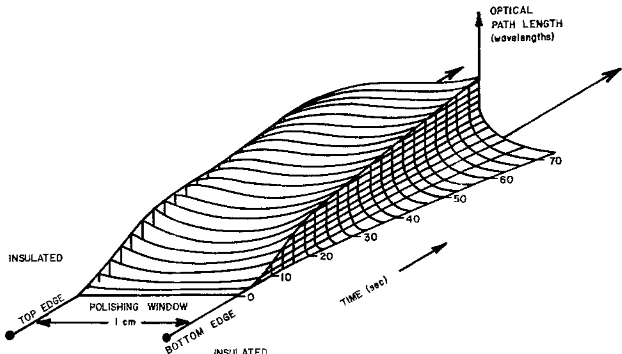

Fig. 6. Optical path length increase as a function of time, along a vertical line through the center of a 1 cm square polishing window.

significant until about 25 sec after the start of polishing. Therefore we can expect that during the first 25 sec the electrolyte composition change at any point is proportional to the metal removed from the surface at that point, and the increase in optical path length at that point is thus related in a linear manner to the amount of metal removed.

The real-time holograms in Fig. 5 show that initially the rate of removal is highest at the edges and corners of the polishing window [Fig. 5(b)], *i.e.*, in those areas where the current would be largest if the current is limited by the ohmic resistance of the electrolyte. As the electrolyte composition at the interface changes, however, the flow of current is retarded locally, thus tending to make the current distribution more uniform. Later, as convection sweeps the copper-rich electrolyte downward, the current density and metal removal rate are highest near the top edge of the polishing area, where fresh electrolyte is sweeping in [Fig. 5(c)].

The inhomogeneities in the total amount of metal removed during an electropolishing experiment were revealed by observing the specimen a few minutes after the applied voltage had been removed. This time interval allowed dissipation of the inhomogeneous boundary layer and the fringes then revealed the shape of the metal surface [Fig. 5(d)].

Figure 6 shows the increase in optical path length, as a function of time, along a vertical line through the center of a 1 cm square polishing area. Initially, metal removal is fastest at the top and bottom edges. After convection starts, copper-rich electrolyte spills over the bottom edge of the polishing area, and the optical path length within the polishing area can no longer be interpreted as the sum of two terms which are directly proportional to one another.

During the first few seconds of electropolishing, the polishing rate showed a small sensitivity to crystallographic orientation, and the corresponding offset of the fringe pattern produced optical contrast, rendering the grain structure of the copper visible. The difference in the amount of metal removed from adjacent grains corresponded to no more than about one-half of a fringe (roughly 0.1 μm), and at later times the contrast between grains disappeared, indicating that the effects of the nonuniform removal rate had been eliminated.

Summary

Holographic interferometry can be used to observe changes occurring at a metal surface during electropolishing. When it can be demonstrated that the refractive index of the electrolyte is in a steady-state condition, variations in the local rate of metal removal can be measured.

During the electropolishing of small vertical areas of copper in a quiescent phosphoric acid electrolyte, the current is initially greatest near the edges and corners of the polishing area. Later, the layer of copper-rich electrolyte accumulating adjacent to the metal surface flows downward in a laminar manner, and the local metal removal rate is greatest near the top edge, where the copper-rich layer is thinnest. Irregularities in the upper perimeter of the polishing area result in grooves or ridges in the metal surface, extending downward from the irregularities.

A Multilayer Iron-Thionine Photogalvanic Cell

D. E. Hall and J. A. Eckert

Exxon Research and Engineering Company, Solar Energy Conversion Unit, Linden, New Jersey 07036

and N. N. Lichtin and P. D. Wildes

Department of Chemistry, Boston University, Boston, Massachusetts 02215

Recent interest in the conversion of solar energy directly to electricity has resulted in several publications concerning the iron-thionine photogalvanic system (1-5). This communication reports our most recent progress in this area. A novel photogalvanic cell, with two transparent semiconductor electrodes, has been designed and evaluated. The use of two transparent electrodes has made possible the construction of multilayer photogalvanic devices, in which there are several layers of photogalvanically active iron-thionine solution. An increased efficiency has been obtained with these devices.

Key words: photogalvanic, solar, thionine.

A multilayer photogalvanic device is shown in Fig. 1. Each layer is an individual photogalvanic cell, containing a tin oxide anode and an indium tin oxide cathode. Tin oxide was obtained from Corning Glass Works as thin films on low alkali glass substrates. Cathodes were prepared by sputtering indium tin oxide on glass, or were obtained from PPG. Sheet resistances, measured with a four-point probe, were about 30 Ω/sq for SnO_2 and about 10 Ω/sq for sputtered indium tin oxide. Both electrodes were quite transparent (80-90%T) at 600 nm. Sputtered platinum films were used as cathodes in single layer cells, and as the rear element in some multilayer cells.

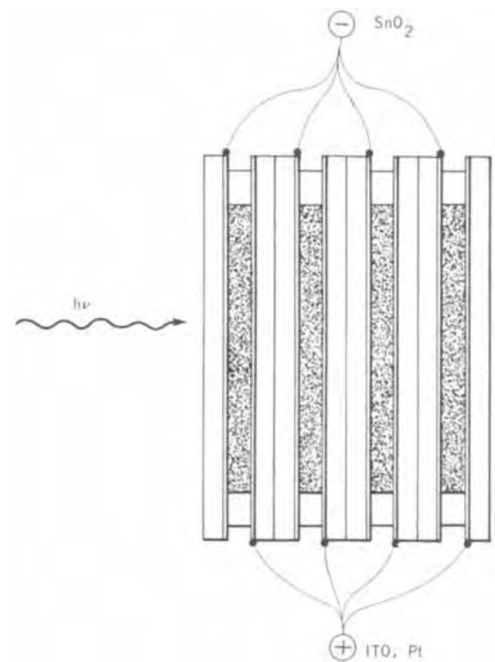

Fig. 1. Four-layer cell, top view

Electrodes making up each element were separated by strips of inert spacing material, usually 80 μm thick Teflon. Spacers used in some single layer cells were made of 25 μm thick Celgard 2400. Cell elements were filled with solution by capillarity.

Photogalvanic solutions typically contained $10^{-2}M$ H_2SO_4 in acetonitrile/water (50/50, v/v) as solvent, $10^{-2}M$ $FeSO_4$, and saturated (~1 mM) thionine, added as the free base. Ferric ion was present as impurity from ferrous sulfate, at $\sim 5 \times 10^{-4}M$.

Cells were illuminated by light from a 650W tungsten spot heater. The light was focused into a 2-in. beam and passed through a water tank and infrared filter. The resultant light incident on the cell produced the same power output as 35 mW-cm^{-2} sunlight. This value was used in calculating efficiencies.

Table I shows the output measured from a four-layer cell, wired in parallel. The outputs for each separate layer are also shown. These outputs were measured in the assembled multilayer device. The drop in short-circuit current (I_{sc}) from the front to the rear element is caused by the increased screening experienced by a given element as the number of layers of dye solution between it and the light source increases. Open-circuit voltages (V_{oc}) show the same behavior, but also reflect variations due to slight differences in the electrode materials.

The efficiency of the multilayer device is estimated in the following way. The effective illuminated area of individual layers varied, and could not be determined exactly. Therefore, an opaque mask with a 1 × 2 cm slit was inserted between the light source and cell to provide a common area of illumination. The power output of the device per square centimeter is

$$\text{Power} = \frac{V_{oc} \times I_{sc} \times ff}{\text{Area}} = \frac{0.134\text{V} \times 1.0 \times 10^{-3}\text{A} \times 0.33}{2\ \text{cm}^2} = 2.2 \times 10^{-5}\ \text{W-cm}^{-2}$$

The fill factor, ff, is the ratio of the product of current and voltage at maximum power to the product of $I_{sc} \times V_{oc}$. The value 0.33 was found to be representative for the photogalvanic device in several determinations. Using the value of 35 mW-cm^{-2} for incident light intensity gives

Table I. Output of four-layer cell

Layer	V_{oc}, V	I_{sc}, mA*
1-4	0.134	1.60
1 (Front)	0.137	0.55
2	0.142	0.47
3	0.132	0.35
4 (Rear)	0.128	0.23

* I_{sc} from 2.0 cm² area = 1.0 mA.

$$\text{Efficiency} = \frac{2.2 \times 10^{-5}\text{W}}{3.5 \times 10^{-2}\text{W}} = 0.063\%$$

This represents the efficiency of converting incident light directly to electrical power and has been termed the sunlight engineering efficiency (SEE) (1).

A totally illuminated cell is possible because the SnO_2 electrode exhibits selectivity in its response. In the dark, both electrodes are governed at equilibrium by the Fe^{+2}/Fe^{+3} couple. The dye is essentially all in the oxidized form. Under illumination, photoreduction of thionine to leucothionine causes a substantial amount of each form to exist at steady state. The dye couple reacts readily at SnO_2 (5). However, the reactions of the Fe^{+2}/Fe^{+3} couple at SnO_2 are suppressed through a large potential range (5). The redox potential of Fe^{+2}/Fe^{+3} is considerably more anodic than the flat-band potential (E_{fb}) of SnO_2 in the photogalvanic cell. This, together with the large rearrangement energy (6) of Fe^{+2}/Fe^{+3}, makes it difficult for Fe^{+2} oxidation to occur even though the SnO_2 is anodically polarized with respect to E_{fb}. The reduction of Fe^{+3} is also suppressed due to the lack of electrons available in the depletion region and the relatively high energy levels of Fe^{+3} in solution resulting from the large rearrangement energy. The behavior of Fe^{+2}/Fe^{+3} at SnO_2 electrodes is discussed in more detail elsewhere (6, 7).

Under illumination, the potential of the SnO_2 electrode is thus determined mainly by the thionine/leucothionine couple (Table II). Its redox potential is closer to E_{fb}, and in addition, the lower rearrangement energy characteristic of quinone-type system (8) is probably effective in creating a much greater degree of overlap of redox energy levels with the lower edge of the conduction band. The platinum electrode shows only a slight potential shift under illumination thus responding primarily to the Fe^{+2}/Fe^{+3} couple. The dye couple does have some effect on the potential of the platinum electrode, however. Upon illumination, the concentration ratio of Fe^{+3} to Fe^{+2} increases. Thus, the potential of the platinum electrode would shift anodically in the absence of any dye couple effects. The observed slight cathodic shift represents an efficiency loss. A selective electrode, at which only the iron couple could react (*i.e.*, at which the dye couple has a very low i_o), would be desirable as a cathode.

The degenerate indium tin oxide (ITO) electrode used as a cathode material in the multilayer cell exhibits nearly metallic behavior toward the Fe^{+2}/Fe^{+3} couple, as shown in Fig. 2. The redox reactions are slightly less reversible at ITO than at platinum. Short-circuit currents from single layer cells containing ITO rather than Pt are about 30% lower, while open-circuit voltages are about the same or slightly lower.

Monochromatic quantum efficiencies (MQE) for single layer photogalvanic cells were measured using a

Table II. Photogalvanic electrode potentials (vs. SCE)

	Dark	0.385
Pt	Light	0.385
	Dark	0.395

V_{oc} measured in the light = 0.175V.

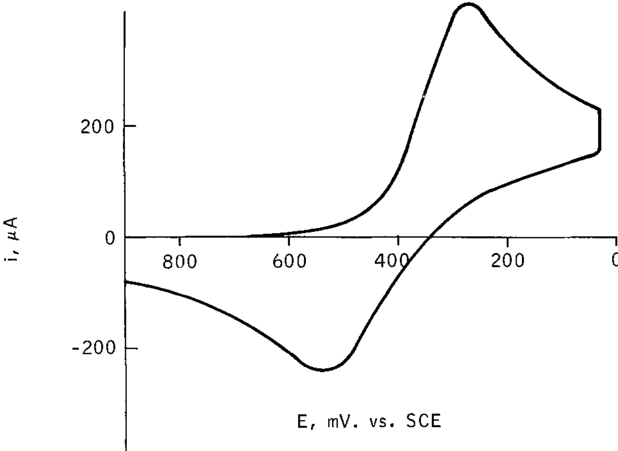

Fig. 2. Cyclic voltammetry of $10^{-3}M$ Fe^{+2} and $10^{-3}M$ Fe^{+3} in 0.12M H_2SO_4 at an indium tin oxide thin film electrode. Scan rate = 100 mV-sec^{-1}.

semitransparent (135Å thick) platinum cathode, so that light absorption could be measured by an Eppley thermopile placed directly behind the cell. Band pass filters of 578, 589, and 620 nm were placed in the incident light beam to provide monochromatic illumination. Results of MQE measurements of 80 μm thick cells are shown in Table IIIA. The quantity calculated is defined as the short-circuit current flow in electrons sec^{-1} divided by the absorbed light in photons sec^{-1}. There is some scatter in the data, but there appears to be no significant dependence of quantum efficiency on the wavelength of incident light.

MQE was also measured as a function of the solution thickness. As shown in Table IIIB, decreasing the cell thickness by a factor of 3 causes only about a 10% drop in short-circuit current, using the tungsten light source. Correspondingly, MQE is about twice as high for 25 μm thick cells as for 80 μm thick cells. These results indicate that the collection of electroactive species from the first 25 μm of solution occurs more efficiently than from the extra volume contained in the 80 μm cell.

Kinetic data make the above interpretation reasonable. An analysis of reaction rates in solution gives an estimated lifetime for leucothionine of ~1.1 sec. If one assumes that the movement of electroactive leucothionine in the solution is solely due to diffusion, the average distance traveled by a leucothionine molecule during its lifetime can be estimated by the relation $l = (2Dt)^{1/2}$, which applies to one-dimensional motion between two planes. Taking D as 7.6×10^{-6} cm^{-2}-sec^{-1}, the value reported (9) for methylene blue, a similar molecule, in water solution, the calculated value of l is 41 μm, indicating that the collection of leucothionine generated in the 25 μm of solution nearest the anode should proceed quite efficiently. The fraction of leucothionine reaching the anode from the remaining 55 μm of solution in the 80 μm cell would be substantially lower.

Table IIIA. Monochromatic quantum efficiency at selected wavelengths of incident light

λ, μm	Intensity, mW-cm^{-2}	MQE, %
578	0.61	7
589	0.53	5-9
620	0.77	8

Table IIIB. Monochromatic quantum efficiency vs. cell thickness (intensities as in Table IIIA)

Thickness, μm	λ, μm	MQE, %
25	578	13
80		7
25	589	18
80		5-9

Table IIIC. V_{oc} and I_{sc} vs. cell thickness (tungsten illumination, 35 mW-cm^{-2})

Thickness, μm	V_{oc}, V	I_{sc}, mA
25	0.135	0.60
80	0.143	0.64

Cell area ~ 6 cm².

Table IV. Two-layer two-dye cell (tungsten illumination, 35 mW-cm^{-2})

Layer 1: SnO_2 anode, ITO cathode, ~1 mM thionine.
Layer 2: SnO_2 anode, Pt cathode, ~4 mM methylene blue.

Layer	V_{oc}, V	I_{sc}, mA
1 + 2	0.135	0.82
1	0.155	0.64
2	0.115	0.27

Cell area ~ 5.5 cm².

The monochromatic quantum efficiency results, together with the above calculation, indicate that a multilayer cell with 25 μm solution layers rather than 80 μm layers should be more efficient in converting absorbed light to electricity.

Several thiazine dyes other than thionine show substantial photogalvanic activity. These include methylene blue, Azure A, Azure B, and Toluidine Blue O. Combinations of photogalvanically active thiazines have been used in the multilayer device to broaden the spectral response of the photogalvanic cell. This approach was suggested in a recent publication (3). Results obtained with a two-layer cell containing one layer of thionine solution and one layer of methylene blue solution are shown in Table IV.

The development of a photogalvanic device using two transparent thin film electrodes has permitted the contruction of multilayer devices. These devices can be used to increase the conversion efficiency of light at a given wavelength by increasing the number of active solution layers. In addition, the spectral response of the photogalvanic device can be broadened by using successive solution layers of photogalvanically active dyes which absorb light at different wavelengths.

A Kinetic Model for the Reduction of Transiently Formed Oxide Film on Smooth Platinum Electrodes with Hydrogen under Open-Circuit Conditions

C. G. Rader and B. V. Tilak

Hooker Chemicals & Plastics Corporation, Research Center, Grand Island, New York 14072

It has been well established (1)[1] that the rate at which PtO is reduced by H_2 under open-circuit conditions increases with time. Shibata and Sumino (1) carried out thorough investigations on the kinetics of reduction of thin films of PtO formed on smooth Pt electrodes by hydrogen, in an attempt to elucidate the nature of oxide films deposited under steady-state and transient conditions, and made the suggestion, following Breiter (2), that the observed variation in the reduction rate with surface coverage could be explained by considering the following reaction scheme

scheme A (chemical reaction)

$$\begin{matrix} \text{Pt—O} \\ | \\ \text{Pt—O} \end{matrix} + H_2 \xrightarrow{k_1} \begin{matrix} \text{Pt—OH} \\ | \\ \text{Pt—OH} \end{matrix} \qquad [1A]$$

$$\begin{matrix} \text{Pt—OH} \\ | \\ \text{Pt—OH} \end{matrix} \xrightarrow{\text{fast}} \begin{matrix} \text{Pt} \\ | \\ \text{Pt—O} \end{matrix} + H_2O \qquad [2A]$$

scheme B (electrochemical sequence)

$$\begin{matrix} \text{Pt} \\ | \\ \text{Pt} \end{matrix} + H_2 \xrightarrow{k_2} \begin{matrix} \text{Pt—H} \\ | \\ \text{Pt—H} \end{matrix} \qquad [1B]$$

$$\begin{matrix} \text{Pt—H} \\ | \\ \text{Pt—H} \end{matrix} \xrightarrow{\text{fast}} \begin{matrix} \text{Pt} \\ | \\ \text{Pt} \end{matrix} + 2H^+ + 2e \qquad [2B]$$

$$PtO + 2H^+ + 2e \rightarrow Pt + H_2O \qquad [3B]$$

At high surface coverages, step [1A] was assumed to be rate determining; in the low coverage region, dissociation of molecular H_2 on the "free" Pt sites (step [1B]) was considered to be the rate-controlling step. [See Ref. (11) for a discussion of the kinetics of the oxidation of H_2 on the Pt electrodes in aqueous H_2SO_4.]

In the present communication, the kinetics of transiently formed platinum oxide (TFO) reduction are reexamined in an attempt to provide a unified theory for the mechanism of TFO reduction over the entire coverage range, and evaluate the kinetic parameters which are consistent with the data reported by Shibata and Sumino (1). Shibata and Sumino's reaction scheme and alternate reaction sequences are considered. Kinetic behavior of the reduction of platinum oxide films formed under steady-state conditions was not dealt with here because of the ambiguity regarding the formation of more than a monolayer of PtO, and the likelihood of further oxidation of PtO to PtO_2, especially when polarized beyond ~1.5V (4, 9).

Shibata and Sumino's Model

One possible reaction scheme for the reduction of transiently formed oxide layers by hydrogen under open-circuit conditions is the one considered by Shibata and Sumino which assumes parallel rate-controlling pathways involving steps [1A] and [1B].

The variation of the fractional coverage of the electrode surface by Pt-O, θ, with time, t, may be expressed, taking into account the interaction effects between the adsorbed species, as

$$-\frac{d\theta}{dt} = k_1 p_{H_2}\theta^2 \exp(2g_1\theta) + k_2 p_{H_2}(1-\theta)^2 \exp(2g_2\theta) \qquad [1]$$

where k_1 and k_2, respectively, refer to the rate constants of steps [1A] and [1B], and g_1 and g_2 to the change in the free energy of adsorption (in units of RT) with coverage under Temkin conditions of nonactivated adsorption (3).

The first term on the right-hand side of Eq. [1][2] represents the contribution from the initial step of the chemical reaction (scheme A) and the second term arises from the slow dissociative chemisorption of H_2 on Pt (step [1B]). Induced heterogeneity factors are invoked in the present treatment since we are dealing with a highly interacting system: a surface covered with several chemical and/or structurally dissimilar adsorbed species, *viz.*, PtOH, PtO, H^+, PtH, H_2.

An analytical solution for the coverage-time relationship may be found by neglecting the interaction parameters in Eq. [1], *i.e.*, $g_1 = g_2 = 0$, and integrating between the limits θ_i, at time 0, and θ, at time t; the resulting expression appears as

$$t = -\frac{1}{k_1 p_{H_2}\sqrt{A}}\left\{\tan^{-1}\left[\frac{(1+A)\theta - A}{\sqrt{A}}\right] - \tan^{-1}\left[\frac{(1+A)\theta_i - A}{\sqrt{A}}\right]\right\} \qquad [2]$$

where $A = k_2/k_1$.

The time dependence of surface coverage when $g_1 \neq g_2 \neq 0$ can readily be solved by numerical integration of Eq. [1] between the limits of θ_i and θ. It is instructive at this point to examine the influence of the rate constants k_1 and k_2 and the interaction parameters g_1 and g_2 on the surface coverage-time relationship which is shown in Fig. 1 for some values of k_1 and k_2. In the absence of the electrochemical step, *i.e.*, when $k_2 = 0$, the time required for complete reduction of the surface oxide decreases as the chemical reaction rate constant k_1 is increased (*cf.* curve 2 *vs.* curve 1 in Fig. 1). On the other hand, when $k_1 = 0$ and the electrochemical rate is the rate-controlling step, the θ-log t curve is characterized by a long induction period followed by an abrupt decrease in the surface coverage (curve 4 of Fig. 1). If repulsive interactions were to prevail, inclusion of the g term in the expression for $d\theta/dt$ would lead to a profound influence on the rate at which PtO reduction takes place, as it tends to accelerate the overall process (see curve 3 in Fig. 1). It should be noted that in all the above analyses the hydrogen partial pressure (p_{H_2}) was taken to be constant, at a value of 1 atm.

Figure 2 illustrates the effect of the interaction term for constant (and arbitrary) values of the chemical re-

[1] A review of the pertinent literature is also given in Ref. (1).
Key words: chemical reduction, hydrogen ionization, coupled reactions.

[2] A detailed discussion of the second order dependence on surface coverage of the chemical reaction rate and the "electrochemical reaction" rate may be found in Ref. (1).

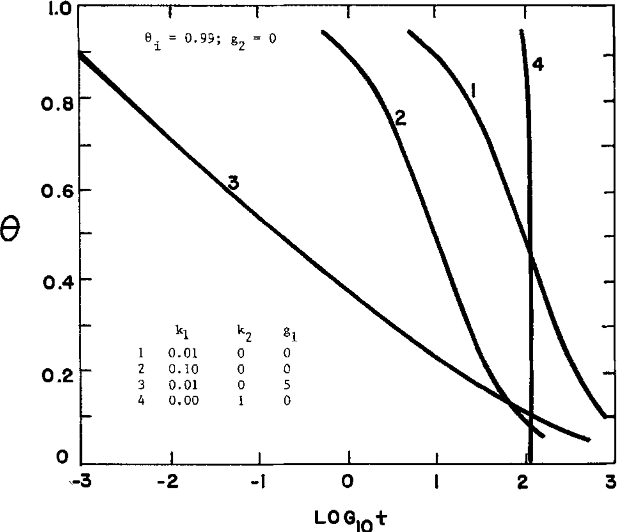

Fig. 1. Coverage variation with $\log_{10}$ [t (in sec)] calculated using Eq. [1] for various values of k_1, k_2, and g_1, when $\theta_i = 0.99$ and $g_2 = 0$.

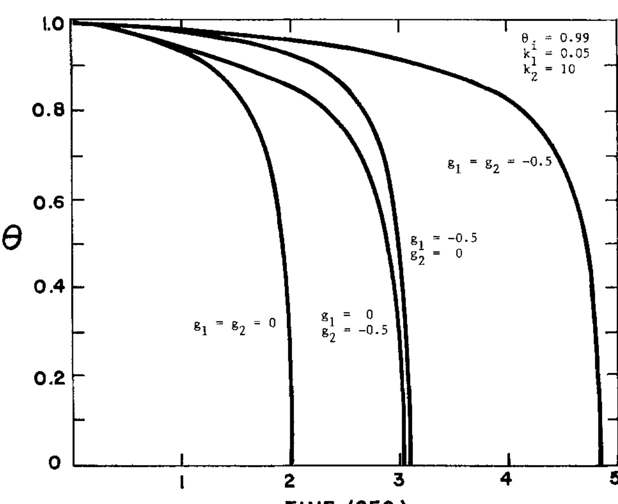

Fig. 2. Coverage variation with time (in sec) calculated using Eq. [1] for various values of g_1 and g_2, shown in the figure, when $\theta_i = 0.99$, $k_1 = 0.05$ sec^{-1}, and $k_2 = 10$ sec^{-1}.

action rate constant ($k_1 = 0.05$ sec^{-1}) and electrochemical reaction rate constant ($k_2 = 10$ sec^{-1}). Negative g values (representing attractive forces between the oxide species on the surface) tend to increase the time required for complete reduction of the surface oxide. On the other hand, when g is positive, the reduction process is accelerated, since increasing g would indirectly imply an increase in the rate constants k_1 and k_2.

The analytical solution for the combined chemical/electrochemical reduction of TFO may now be used to determine the time required for complete reduction of the surface oxide. Thus for $\theta = 0$, the total reduction time (τ) may be expressed

$$\tau = -\frac{1}{k_1 p_{H_2}\sqrt{A}}\left\{\tan^{-1}(-\sqrt{A}) - \tan^{-1}\left(\frac{(1+A)\theta_i - A}{\sqrt{A}}\right)\right\} \quad [3]$$

From Eq. [3] it can be seen that if the reaction rate constants k_1 and k_2 are known, the time required for reduction of a transiently formed platinum oxide surface covered by any site fraction of PtO (up to $\theta_i = 1$) can be computed.

The initial premise in the present treatment stated that pure chemical reaction is rate controlling at high surface coverage (*i.e.*, $\theta_i \rightarrow 1$) and that electrochemical PtO reduction is rate controlling at lower surface oxide fractions. It is proposed to utilize these physical arguments to provide first order estimates of the reaction rate constants from the kinetic rate data reported by Shibata and Sumino (1).

Equation [3] may be rewritten in the following form

$$\frac{\tau + D}{C} = \tan^{-1}\chi \quad [4]$$

where

$$C \equiv \frac{1}{k_1 p_{H_2}\sqrt{A}}$$

$$D \equiv C[\tan^{-1}(-\sqrt{A})]$$

and

$$\chi \equiv \frac{(1+A)}{\sqrt{A}}\theta_i - \sqrt{A}$$

Limiting case I ($\chi^2 < 1$).— For $\chi^2 < 1$, $\tan^{-1}\chi \approx \chi$. Under this restriction, Eq. [4] becomes

$$\tau \approx \frac{(1+A)}{k_1 p_{H_2} A}\theta_i - \left[\frac{1}{k_1 p_{H_2}} + \frac{\tan^{-1}(-\sqrt{A})}{k_1 p_{H_2}\sqrt{A}}\right] \quad [5]$$

When $A >> 1$, Eq. [5] further reduces to the following

$$\tau \approx \frac{1}{k_1 p_{H_2}}\theta_i - \left[\frac{1}{k_1 p_{H_2}} + \frac{\tan^{-1}(-\sqrt{A})}{k_1 p_{H_2}\sqrt{A}}\right] \quad [6]$$

Thus, for $\chi^2 < 1$ (corresponding to $\theta_i \approx 1$) a plot of τ *vs.* θ_i should yield a straight line of slope $1/k_1 p_{H_2}$. This limiting case provides a means for estimating the chemical reaction rate constant k_1. Figure 3 illustrates this analysis applied to the Shibata and Sumino data. From Fig. 3 the chemical reaction rate constant is estimated to be 0.41 sec^{-1}.

Limiting case II, ($\chi^2 > 1$).—For $\chi^2 > 1$, $\tan^{-1}\chi \approx \pi/2 - 1/\chi$. For these conditions Eq. [4] yields the following expression for τ

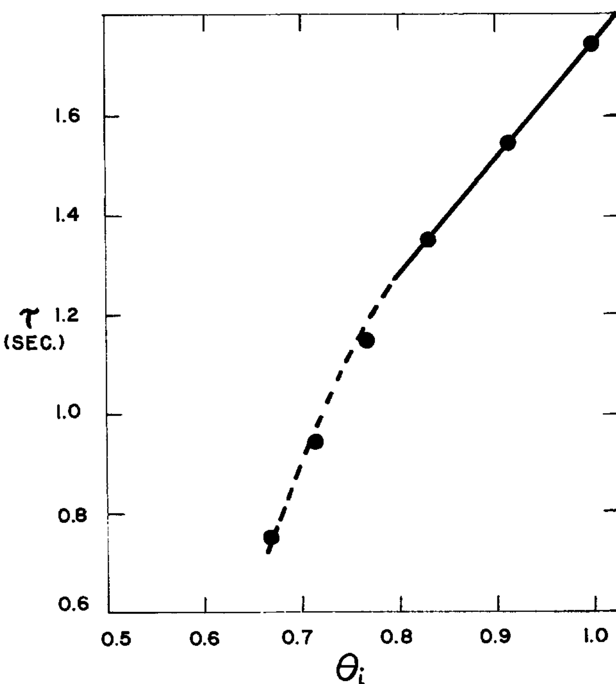

Fig. 3. Dependence of τ (in sec) on the initial value of surface coverage using the data from Ref. (1).

$$\tau \approx \left[\frac{C\pi}{2} - D\right] - \frac{1}{k_1 p_{H_2}(1+A)} \left\{\frac{1}{\theta_i - \dfrac{A}{(1+A)}}\right\} \quad [7]$$

Again for the case where $A >> 1$

$$\tau \approx \left[\frac{C\pi}{2} - D\right] + \frac{1}{k_2 p_{H_2}} \left[\frac{1}{1-\theta_i}\right] \quad [8]$$

From Eq. [8] it is apparent that a plot of τ *vs.* $1/1 - \theta_i$ should yield a straight line of slope $1/k_2 p_{H_2}$. Figure 4 again depicts the data of Shibata and Sumino (1) subjected to the present analysis. From the data presented in Fig. 4, the electrochemical reaction rate constant is estimated to be 2.47 $sec.^{-1}$.

The reaction rate constants for the reduction by hydrogen of transiently formed PtO were estimated to be $k_1 = 0.41$ sec^{-1} and $k_2 = 2.47$ sec^{-1}. Using these values of k_1 and k_2, the total reduction time τ can be directly computed as a function of initial surface coverage θ_i according to Eq. [3]. This τ *vs.* θ_i function is plotted in Fig. 5, along with the experimental data reported by Shibata and Sumino (1). Also included in Fig. 5 is the complete numerical solution of Eq. [1] for total reduction time τ, for $k_1 = 0.41$ sec^{-1}, $k_2 = 2.47$ sec^{-1}, $g_1 = -0.25$, and $g_2 = 0$. The inclusion of the interaction parameter g_1 tends to provide slightly better agreement between theory and experiment. It is important to note that the choice of $g_1 = -0.25$ is completely empirical and inclusion of this factor is difficult to justify solely on the basis of improved correlation between theory and experiment. The present results may be compared with Shibata and Sumino's estimates of $k_1 = 0.49$ sec^{-1}, $k_2 = 7.2$ sec^{-1}, and τ (for $\theta_i = 1$) = 0.7 sec, deduced from an alternate solution of Eq. [1].

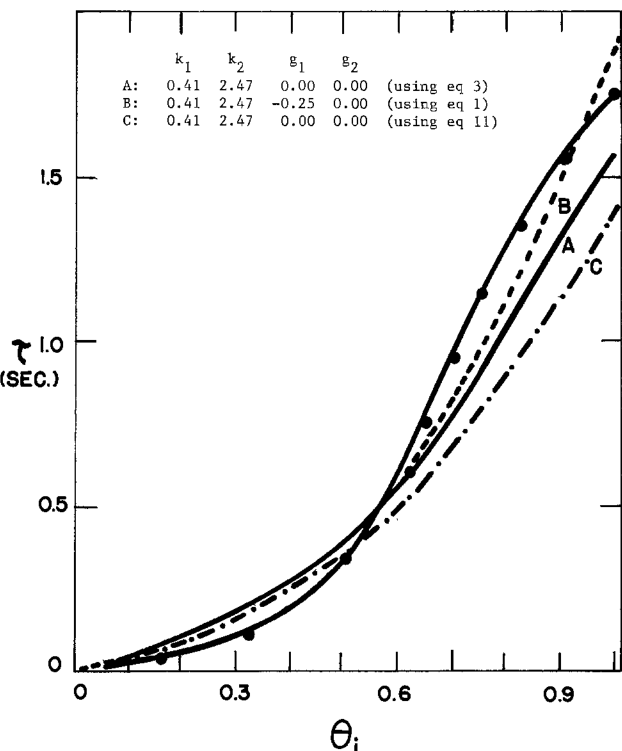

Fig. 5. Comparison of the experimental values of τ (in sec) [from the data in Fig. 5 and 12 of Ref. (1)] with the calculated values for $k_1 = 0.41$ sec^{-1} and $k_2 = 2.47$ sec^{-1}, using Eq. [3] when $g_1 = g_2 = 0$ (curve A); $g_1 = -0.25$, $g_2 = 0$ (curve B). Line C refers to values calculated using Eq. [10] with $k_1 = 0.41$ sec^{-1}, $k_2 = 2.47$ sec^{-1}, and $g_1 = g_2 = 0$.

Modified Reaction Scheme for the Reduction of TFO by H_2

Thermodynamic considerations suggest that the corrosion mechanism represented by the electrochemical route (scheme B) will be operative under the conditions where PtO is reduced by H_2 on open circuit. However, it is difficult to rationalize (4) the chemical reaction sequence (scheme A), especially the dehydration step [1B] which implies generation of "free Pt" sites at potentials where the oxidation of Pt readily takes place (4, 9). This dilemma may be resolved by considering two alternate reaction sequences instead of reaction scheme A. In the first instance, the following steps for the chemical reduction of PtO by H_2 may be considered

scheme A1

$$\begin{matrix} Pt{-}O \\ | \\ Pt{-}O \end{matrix} + H_2 \xrightarrow{k_1} \begin{matrix} Pt{-}OH \\ | \\ Pt{-}OH \end{matrix} \quad [1C]$$

$$\begin{matrix} Pt{-}OH \\ | \\ Pt{-}OH \end{matrix} + H_2 \xrightarrow{fast} \begin{matrix} Pt \\ | \\ Pt \end{matrix} + 2H_2O \quad [2C]$$

For this reaction scheme, the expression for the reduction of PtO would be identical to that proposed by Shibata and Sumino, and the treatment presented in the previous section (along with the k_1 and k_2 values) would describe the kinetics of TFO reduction by hydrogen.

Instead of postulating the various elementary steps for the chemical reduction schemes A and A1, the over-all chemical reaction may be regarded as one of the rate-controlling steps in the coupled chemical-electrochemical route

scheme A2

$$PtO + H_2 \xrightarrow{k_3} Pt + H_2O \quad [1D]$$

when the over-all process of TFO reduction by H_2 proceeds via schemes A2 and B, the coverage variation can be expressed as

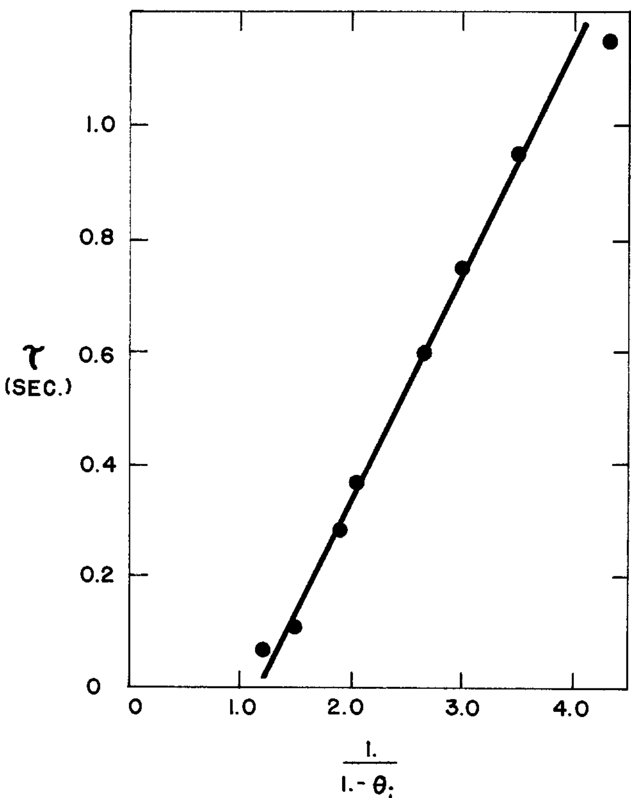

Fig. 4. Variation of τ (in sec) with $1/1 - \theta_i$ employing the data from Ref. (1).

$$\frac{d\theta}{dt} = -k_3 p_{H_2} \theta \exp(g_3\theta) - k_2 p_{H_2}(1-\theta)^2 \exp(2g_2\theta) \quad [9]$$

where g_3 refers to the interaction parameter described earlier. Setting $g_3 = g_2 = 0$, Eq. [9] may be integrated between the limits θ_i (at time = 0) and θ, at time t. The coverage variation with time appears as

$$t = -\frac{2}{k_3 p_{H_2}\sqrt{4a-1}} \left\{ \tan^{-1}\left(\frac{(2a(\theta-1)+1)}{\sqrt{4a-1}}\right) - \tan^{-1}\left(\frac{(2a(\theta_i-1)+1)}{\sqrt{4a-1}}\right)\right\} \quad [10]$$

where $a \equiv k_2/k_3$. The time for the complete reduction of the oxide, τ, corresponding to $\theta = 0$, would then be equal to

$$\tau = -\frac{2}{k_3 p_{H_2}\sqrt{4a-1}} \left\{ \tan^{-1}\left(\frac{1-2a}{\sqrt{4a-1}}\right) - \tan^{-1}\left(\frac{(2a(\theta_i-1)+1)}{\sqrt{4a-1}}\right)\right\} \quad [11]$$

Denoting $\delta = \frac{(2a(\theta_i-1)+1)}{(\sqrt{4a-1})}$, one may examine the limiting conditions when $\theta_i \to 0$ or 1, following the procedure in the previous section.

Limiting case I ($\delta^2 < 1$).—When $\delta^2 < 1$, $\tan^{-1}\delta \approx \delta$ and Eq. [11] becomes

$$\tau \approx \left\{\frac{(4a(\theta_i-1)+2)}{k_3 p_{H_2}(4a-1)}\right\} - \frac{2}{k_3 p_{H_2}\sqrt{4a-1}} \tan^{-1}\left(\frac{1-2a}{\sqrt{4a-1}}\right) \quad [12]$$

For $4a >> 1$, Eq. [12] further reduces to

$$\tau \approx \frac{1}{k_3 p_{H_2}} \left\{ \theta_i + \left(\frac{1-2a}{2a}\right) - \frac{2}{\sqrt{4a-1}} \tan^{-1}\left(\frac{1-2a}{\sqrt{4a-1}}\right)\right\} \quad [13]$$

Thus, for $\delta^2 < 1$ (when $\theta_i \sim 1$), a plot of τ *vs.* θ_i should again result in a straight line with a slope equal to $1/k_3 p_{H_2}$. This is illustrated in Fig. 3, from which k_3 is estimated to be 0.41 sec^{-1}.

Limiting case II ($\delta^2 > 1$).—When $\delta^2 > 1$, $\tan^{-1}\delta \approx \pi/2 - 1/\delta$ and

$$\tau \approx \frac{1}{k_3 p_{H_2}} \left\{ \frac{1}{\sqrt{4a-1}} \left(\pi - 2\tan^{-1}\left(\frac{1-2a}{\sqrt{4a-1}}\right)\right) - \left(\frac{2}{(2a(\theta_i-1)+1)}\right)\right\} \quad [14]$$

For $2a(\theta_i - 1) >> 1$

$$\tau \approx \left\{\frac{1}{k_3 p_{H_2}\sqrt{4a-1}} \left[\pi - 2\tan^{-1}\left(\frac{1-2a}{\sqrt{4a-1}}\right)\right]\right\} + \left(\frac{1}{k_2 p_{H_2}(1-\theta_i)}\right) \quad [15]$$

It is seen from Eq. [15] that k_2 can again be estimated from a plot of τ *vs.* $1/1 - \theta_i$ as depicted in Fig. 4.

Conclusions

The present work has illustrated, for the three reaction schemes presented for PtO reduction by hydrogen, that the calculation procedure for estimating the reaction rate constants is the same. The final equations representing the total oxide reduction time as a function of initial surface coverage are identical for reaction scheme A and scheme A1; the analogous expression for reaction scheme A2 is similar in form to the other solutions.

Figure 5 depicts all of the τ *vs.* θ_i functions derived in the present note, along with the data reported by Shibata and Sumino. It is interesting to note that all of the proposed mechanisms for the coupled chemical-electrochemical reduction of transiently formed PtO provide reasonable agreement with Shibata and Sumino's experimental data. For reasons already discussed, it is unlikely that scheme A is a realistic representation of the chemical reduction of PtO at high surface coverage. The most reasonable mechanism for the purely chemical PtO reduction appears to be scheme A1, in which the rate-determining step is taken to be the chemical reaction of H_2 with two PtO surface sites. The concept of an over-all rate-determining chemical reaction (*i.e.*, scheme A2) does not seem likely, in view of the work reported earlier [*cf.*, Ref. (5-11)] regarding the existence of PtOH as an intermediate in the surface oxidation of platinum.

Following the suggestion of Shibata and Sumino that the reduction by hydrogen of transiently formed PtO proceeds via a coupled chemical-electrochemical reaction mechanism, the present communication has extended the previous analysis theoretically, by accounting for molecular interaction, and procedurally, by providing an internally consistent means for estimating the kinetic rate constants of the coupled process. Assuming that reaction scheme A1 is operative at high surface coverages, and that the dissociation of H_2 to form H on Pt applies at lower coverages, the present analysis provides good agreement with the experimental data reported by Shibata and Sumino over the entire range of θ_i. In view of these encouraging results, despite the approximations involved in the estimation of the kinetic rate constants, a finer distinction of PtO and PtOH in normal and rearranged states as proposed (4, 9) during the reduction of surface oxides on platinum under potentiodynamic conditions was not made in this communication.

The work reported by Shibata and Sumino also involved application of the coupled chemical-electrochemical theory to the seemingly more complex case of steady-state formed oxides of platinum. However, the present analysis was not extended to this situation, in view of the physical complexities stated earlier.

Acknowledgments

The authors wish to thank Professor B. E. Conway and Dr. H. Angerstein-Kozlowska for helpful discussions and useful suggestions during the course of this work. We also wish to thank Hooker Chemicals & Plastics Corporation for permission to publish this note.

Manuscript submitted May 24, 1976; revised manuscript received Aug. 5, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by Hooker Chemicals & Plastics Corporation.

Electrical Conduction in CaO-Doped Thoria Electrolytes

H. S. Maiti[1] and E. C. Subbarao

Department of Metallurgical Engineering, Indian Institute of Technology, Kanpur 208016, India

ABSTRACT

The electrical conductivity of sintered specimens of nominally pure thoria and thoria doped with 1-15 mole percent (m/o) CaO was measured between 600° and 1400°C in the p_{O_2} range of 1-10^{-25} atm. The measured conductivity decreases initially with decreasing p_{O_2} (mixed conduction region where electron holes and oxygen ions contribute), until it becomes independent of p_{O_2} (ionic conduction region). The p_{O_2} corresponding to the transition between these regions is a function of temperature and composition. The variation of conductivity with temperature gives rise to three regions: the high temperature region where the conductivity is attributed to dissociated vacancies, an intermediate temperature range where associated vacancy-impurity complexes dominate, and a low temperature region where grain boundary effects appear to become significant. The activation energy for electrical conduction is a function of composition and p_{O_2}.

Zirconia-based electrolytes are useful in high temperature galvanic cells, fuel cells, oxygen gauges, oxygen pumps, etc. Detailed investigations (1-4) on the defect structure and the electrolytic properties of "pure" and yttria-doped thoria electrolytes have demonstrated that these electrolytes behave as mixed conductors with a predominant electron hole conduction near 1 atm of oxygen pressure and become exclusively oxygen ion conductors in the lower partial pressure range, down to a much lower oxygen partial pressure than zirconia-base electrolytes.

When thoria is doped with CaO, it has been suggested that the electrical neutrality is maintained by the introduction of oxygen vacancies. The observed internal friction and dielectric loss peaks in ThO_2-1.5 o/o CaO have been explained with a model where Ca^{2+} ions are associated with oxygen vacancies (5). Kiukola and Wagner (6) in their pioneering work on solid-state galvanic cell measurements did not use ThO_2-CaO electrolytes since they were found to be less conductive than either ZrO_2-CaO or ThO_2-Y_2O_3 electrolytes. Based on their limited conductivity measurements, Steele and Alcock (7) also concluded that the conductivity of ThO_2-CaO electrolytes was lower than that of the corresponding ThO_2-Y_2O_3 compositions and the hole contribution is higher at a given oxygen partial pressure in the mixed conduction region. On the other hand, a preliminary investigation on ThO_2-CaO solid solutions made earlier by the present investigators (8) showed that the conductivity values in air are not too low compared to those of ThO_2-$YO_{1.5}$ solid solutions measured by Lasker and Rapp. A detailed measurement of electrical conductivity under various experimenal conditions of temperature, oxygen partial pressure, and composition was, therefore, undertaken in order to ascertain the electrolytic behavior as well as the defect structure of CaO-doped ThO_2 electrolytes.

Key words: electrical conduction, ionic conductivity, defect structure, thoria, doped thoria, solid electrolytes.

Experimental Procedure

CaO-doped ThO_2 specimens were prepared from reactor grade thorium oxide (impurities in excess of 10 ppm are Ca 2000, sulfate 120, Fe 90, phosphate 25, Cr 10) and analytical grade anhydrous calcium carbonate, as per procedures described earlier (8). The sintered pellets were about 10 mm in diameter and 2-3 mm thick and possessed more than 95% of the theoretical density except that "pure" ThO_2 had only 89% of the theoretical density. For electrical measurements, the flat surfaces of the specimens were painted with unfluxed platinum paste (Engelhard No. 6926) and were heated to around 900°C. The a-c electrical conductivity at a frequency of 1000 Hz was measured over a temperature range of 600°-1400°C and oxygen partial pressure range of 1-10^{-25} atm. The desired oxygen partial pressures were generated by using an electrochemical oxygen pump, similar to that of Kröger *et al.* (9-11) and Agrawal *et al.* (12) and is described elsewhere (13). The oxygen partial pressure of the gas was measured through a zirconia tube oxygen probe. It was difficult to control the p_{O_2} in the range of 10^{-8}-10^{-18} atm with the help of oxygen pump and therefore the ionic conductivity of a few of the samples was checked by using metal-metal oxide pellets. The temperature of the specimens was measured with a Pt-Pt 10% Rh thermocouple, the tip of which was placed within 2-3 mm of the specimens. The a-c conductance of the specimens was measured either with a two-probe bridge method (in lower temperature range) or by a four-lead *I-V* technique which has been described earlier (8). At each temperature and oxygen partial pressure, sufficient time was allowed for equilibration. Equilibrium was assumed to have been attained when two conductance readings at an interval of 1 hr remained unchanged.

Results

The a-c total conductivity of "pure" ThO_2 and ThO_2-CaO solid solutions with CaO contents ranging from 1 to 15 m/o was measured initially in air in the tempera-

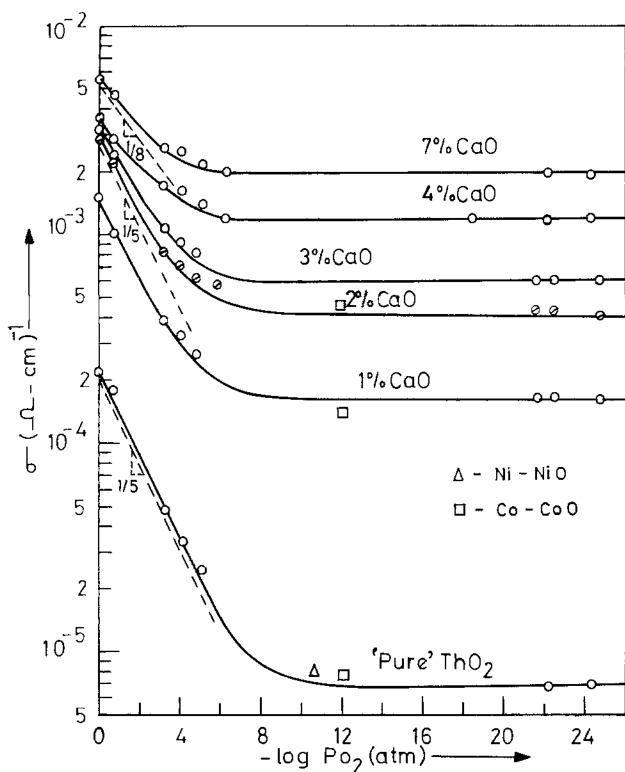

Fig. 1. Electrical conductivity of ThO_2-CaO solid solutions as a function of oxygen partial pressure at 1000°C.

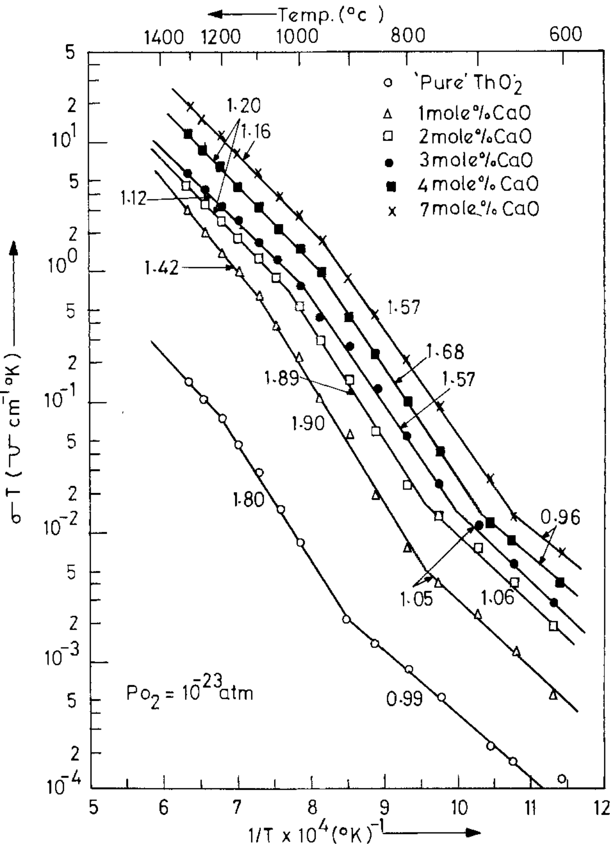

Fig. 2. Electrical conductivity of ThO_2-CaO solid solutions as a function of temperature at an oxygen partial pressure of 10^{-23} atm.

ture range of 600°-1400°C. At each temperature, the conductivity increases sharply for small additions of CaO (< 2 m/o CaO) and goes through a flat maximum around 10 m/o CaO. It should be mentioned here that the conductivity values reported earlier [Ref. (8)] for 8 m/o specimen were later found to be for 4 m/o specimen. Samples containing more than 7 m/o CaO were excluded from the rest of the present measurements because the effect of dopant on conductivity in this range is rather insignificant and also due to possible existence of a second phase. The conductivities of "pure" and CaO-doped thoria specimens were also measured in the p_{O_2} range of 1-10^{-25} atm and at temperatures between 600° and 1200°C. Figure 1 shows the typical plots of conductivity *vs.* log p_{O_2} for "pure" and CaO-doped ThO_2 specimens at 1000°C. There are clearly two regions: (*i*) the conductivity decreases with decreasing p_{O_2} with a slope of 1/5 for "pure" and slightly doped samples, the slope decreasing to 1/8 for more impure ones and (*ii*) the conductivity is independent of p_{O_2} at low values of p_{O_2}. The p_{O_2} value corresponding to the onset of region (*ii*) is a function of impurity content and temperature. For example, for "pure" ThO_2 the plateau is reached at 10^{-8} atm at 800°C and the value decreases to 10^{-10} atm at 1200°C, while in a 7 m/o CaO specimen the corresponding values are 10^{-7} and 10^{-5} atm, respectively. The conductivity value at any p_{O_2} increases steadily with temperature as well as with impurity content.

The conductivity of "pure" and CaO-doped thoria specimens has been measured as a function of temperature between 600° and 1400°C under fixed oxygen partial pressures of 10^{-23}, 10^{-5}, $10^{-0.7}$ (air), and 10^0 atm (oxygen). Typical results at $p_{O_2} = 10^{-23}$ atm and in oxygen atmosphere are shown in Fig. 2 and 3, respectively. In the plots of log σT *vs.* $1/T$, straight lines with different slopes are obtained in the different temperature regions. In each region, the activation energy was calculated from the slope of the straight line which has been fitted to the experimental points by a least squares method. Table I gives the complete list of observed activation energies under different experimental conditions.

At a very low oxygen partial pressure (10^{-23} atm) where all the specimens may be considered as exclusive ionic conductors, three distinctly different temperature ranges having different activation energies are evident (Fig. 2). The activation energy is highest in the intermediate temperature range while it is lower both in the low and high temperature regions. The activation energy in the low temperature range is of the order of 1.0 eV and does not change significantly with the CaO content. However, in the intermediate temperature range, the activation energies for highly doped

** Data from Ref. (8) at temperatures above 1100°C in air.

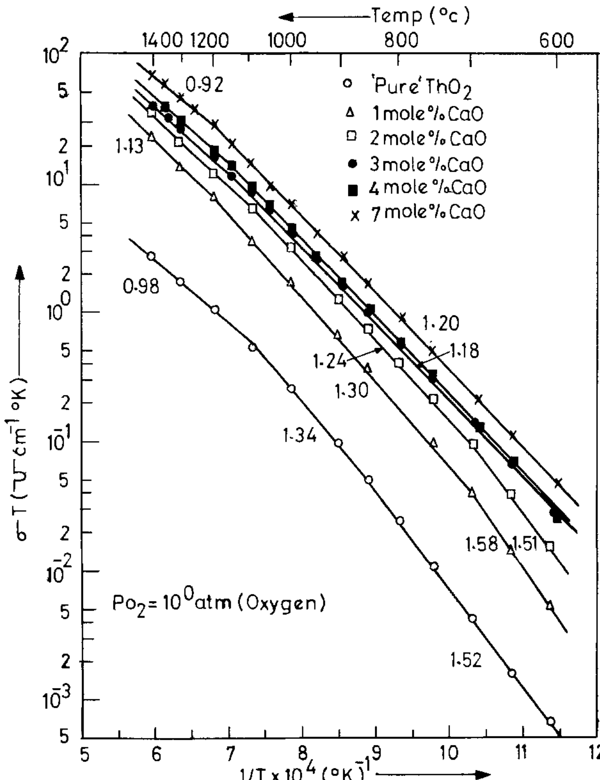

Fig. 3. Electrical conductivity of ThO_2-CaO solid solutions as a function of temperature in oxygen atmosphere.

specimens (3-7 m/o CaO) are lower ($\sim$ 1.60 eV) than that of "pure" ThO_2 (1.80 eV) as well as those with lower dopant concentration (1-2 m/o CaO). The activation energy in the high temperature region varies between 1.12 and 1.42 eV but does not follow any definite trend with the variation of CaO.

The transition temperatures corresponding to the breaks in the conductivity curve (Fig. 2) in the low-intermediate-high temperature ranges decreases with increasing CaO content. For example, in "pure" ThO_2 the breaks occur at 900° and 1200°C whereas in a specimen containing 7 m/o CaO the corresponding temperatures are 650° and 950°C.

It may be noted that the activation energy in the different temperature ranges varies in different ways with oxygen partial pressure and, therefore, the overall shape of the log σT *vs.* $1/T$ plots also changes with oxygen partial pressure. The activation energy increases with decreasing p_{O_2} in the intermediate temperature range whereas it decreases markedly with decreasing p_{O_2} in the low temperature range. As a consequence, at low oxygen partial pressures (Fig. 2), the low temperature activation energy is lower than that in the intermediate temperature range but with increasing oxygen partial pressure (Fig. 3), the trend is reversed especially in specimens having a lower percentage of CaO. The high temperature activation energy, on the other hand, is always lower than that in the intermediate temperature range.

Discussion

Defect structure.—In a ThO_2-CaO solid solution, substitution of Th^{4+} ions by Ca^{2+} ions results in an overall charge of -2 per each impurity cation site (Ca_{Th}'') and therefore the neutrality condition may be written using Kröger-Vink type notations as

$$[h^\cdot] + 2[V_O^{\cdot\cdot}] = [e'] + 2[O_i''] + 2[Ca_{Th}''] \quad [1]$$

Even with a small amount of impurities, the concentration of oxygen vacancies in a CaO-doped ThO_2 lattice will far exceed that of oxygen interstitials *i.e.*

$$[V_O^{\cdot\cdot}] >> [O_i'']$$

and therefore the defect concentration will be chiefly determined by the concentration of the impurity ions. In the intermediate p_{O_2} range where ionic defect compensation takes place

$$[V_O^{\cdot\cdot}] = [Ca_{Th}''] = [CaO] \quad [2]$$

and

$$[h^\cdot] = \left\{ \frac{K_2[CaO]}{K_1} \right\}^{1/2} p_{O_2}^{1/4} \quad [3]$$

where K_1 and K_2 are the equilibrium constants for the anti-Frenkel and oxygen interstitial defect formation reactions, respectively.

It may be noted that in the mixed conduction region the hole concentration in a doped oxide is proportional to $p_{O_2}^{1/4}$. Therefore, it is expected that a plot of log σ_h *vs.* log p_{O_2} will yield a slope of ¼. This becomes evident when one plots log $(\sigma_T - \sigma_{ion})$ *vs.* log p_{O_2} (Fig. 4), assuming σ_{ion} to be independent of p_{O_2} even in the mixed conduction region and the value equals that obtained at lower partial pressures (1). However, in Fig. 1 the plots of σ_T *vs.* log p_{O_2} indicate lower slopes (1/5 to 1/8) since the oxygen partial pressures in this range are very much within the transition zone between p_{O_2} independent ionic conduction and characteristic mixed conduction regions. In this connection, Bransky and Tallan (2) have earlier pointed out that the predicted ¼ pressure dependence in the impurity-controlled mixed conduction region may not be observed in plots of log σ_T *vs.* log p_{O_2} unless $\sigma_T/\sigma_{ion} \geqq 10$.

Transference number.—The ionic transference number of ThO_2-CaO electrolytes in the mixed conduction region may be expressed as

$$t_{ion} = \frac{1}{1 + \frac{1}{2}\beta_h (K_2/K_1)^{1/2} p_{O_2}^{1/4} [CaO]^{-1/2}} \quad [4]$$

in which β_h is the ratio of mobilities of electron hole (μ_h) and that of oxygen vacancy (μ_v). Ionic transference numbers for "pure" and doped specimens have been calculated from the conductivity isotherms (Fig. 1) at different oxygen partial pressures following the procedure adopted by Lasker and Rapp (1) in which it is assumed that the ionic contribution remains constant in the mixed conduction region and is given by the pressure independent conductivity value in the lower partial pressure range. The results of the calculation are shown in Fig. 5 for two different temperatures (800° and 1000°C). As predicted from the con-

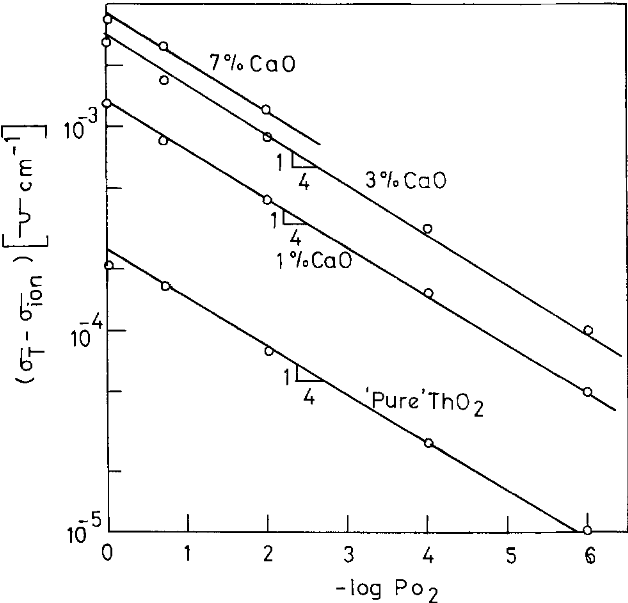

Fig. 4. Plots of $(\sigma_T - \sigma_{ion})$ vs. log p_{O_2} for ThO_2-CaO electrolytes at 1000°C.

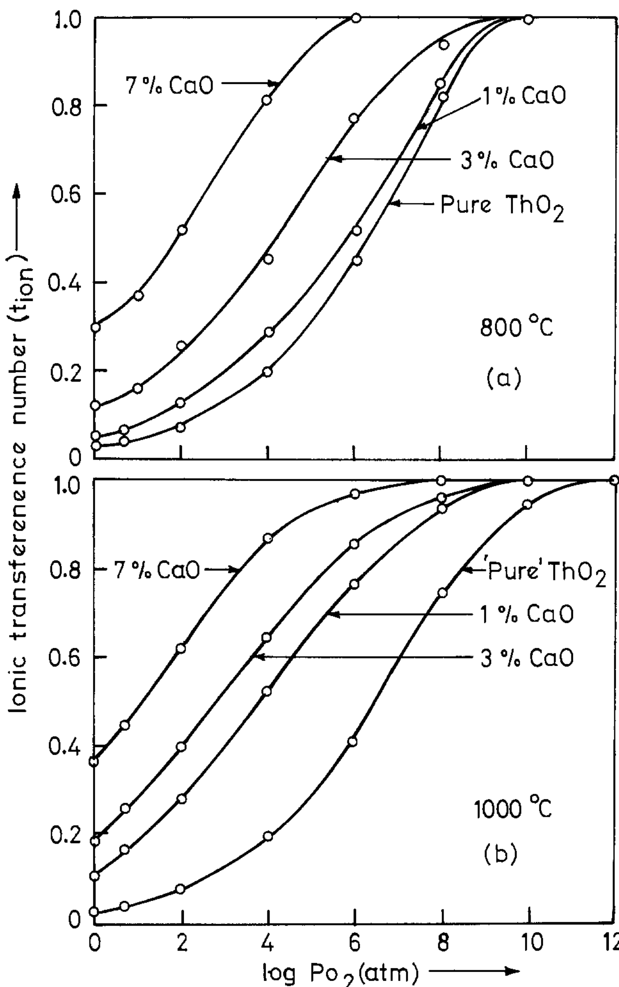

Fig. 5. Ionic transference numbers of ThO_2-CaO solid solutions as a function of oxygen partial pressure at 800°C (a) and 1000°C (b).

ductivity curves, the value of t_{ion} increases with decreasing p_{O_2} and it becomes unity when the conductivity becomes independent of p_{O_2}.

As expected from Eq. [4], addition of CaO increases the ionic transference number at each p_{O_2} and therefore improves the electrolytic behavior of the solid solution. By addition of 7 m/o CaO, the conductivity of the solid solution becomes fully ionic below about 10^{-6}-10^{-8} atm, depending on temperature, and may be considered as a useful solid electrolyte below this partial pressure range. It may be pointed out that yttria-doped thoria electrolytes are also useful in the same partial pressure range.

Ionic conductivity.—Assuming that the mobility is independent of the defect concentration, the ionic conductivity of ThO_2-CaO solid solution is expressed as

$$\sigma_{ion} = 2\,|e|\,\mu_v\,[V_O^{\cdot\cdot}]$$
$$= 2\,|e|\,\mu_v\,[\text{CaO}] \quad [5]$$

which shows that σ_{ion} is proportional to [CaO]. In Fig. 6, log ionic conductivity of ThO_2-CaO electrolytes has been plotted *vs.* percent anion vacancy as well as mole percent impurity concentration, along with that of ThO_2-$YO_{1.5}$ electrolytes obtained by different investigators (1, 3, 7). As expected the conductivity increases with increasing CaO content. The ionic conductivity of pure thoria obtained in the present investigation is lower than that obtained by the earlier investigators. A lower conductivity may be expected in a purer sample, but it is not the case in the present study. The variation is, however, within the scatter in conductivity values measured by various investigators. On the other hand,

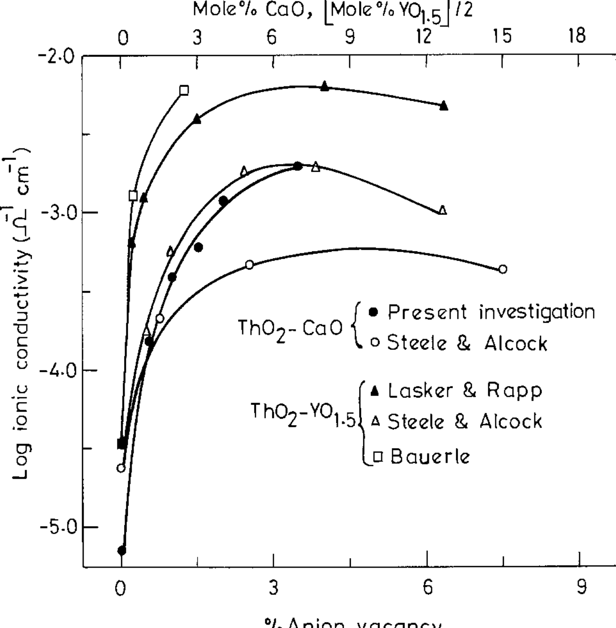

Fig. 6. Ionic conductivity of ThO_2-base electrolytes as a function of mole percent anion vacancy at 1000°C.

the conductivities of the ThO_2-CaO solid solutions are higher than the corresponding values obtained by Steele and Alcock (7) and are very close to those of ThO_2-$YO_{1.5}$ electrolytes measured by the same investigators. However, the conductivity values of ThO_2-$YO_{1.5}$ electrolytes measured by Bauerle (3) are much higher than those measured by either Lasker and Rapp (1) or Steele and Alcock (7). In the present investigation, the ionic conductivities were not determined beyond 7 m/o CaO content. However, from the conductivity values obtained in air, it is expected that a slightly higher ionic conductivity may be obtained at around 10 m/o CaO. At higher concentrations the lowering of conductivity in both the systems may be attributed to the decreased mobility of the defects mainly due to impurity defect interactions.

Activation energy in the low temperature region.—It has been observed in the present investigation that the activation energy for ionic conduction in both "pure" and CaO-doped thoria specimens decreases in the low temperature region relative to that in the intermediate temperature region (Fig. 2 and Table I). A plausible explanation for this may be advanced on the basis of the effect of grain boundaries at low temperatures. However, this explanation needs verification by varying grain size systematically.

In a polycrystalline material, grain boundaries are crystallographically disordered regions. Further, the grain boundaries contain a larger concentration of solute atoms (15), giving rise to a higher defect concentration. These factors lead to enhanced diffusion and ionic conductivity in the grain boundaries relative to the bulk. Enhanced oxygen diffusion along grain boundaries or dislocations has been observed in a number of oxide systems such as Al_2O_3 (16), MgO (17, 18), Fe_2O_3 (19), CoO (20), $SrTiO_3$ (21), etc. The activation energy for diffusion through the grain boundaries is lower compared to that for bulk diffusion. However, since the volume of the grain boundary region is much smaller than the bulk volume, the grain boundary contribution becomes significant only at lower temperatures where the bulk diffusion is not large. Similarly, higher electrical conductivity along the grain boundaries has been observed in ionic conductors like alkali halides (22) and CaO-stabilized zirconia specimens (23). The observed activation energy for grain boundary conduction of 1.0 ± 0.05 eV in the present investi-

gation is very close to that of 0.96 eV obtained in calcia-stabilized zirconia specimens (23). It may be noticed in Fig. 2 that the effect of grain boundaries becomes observable at lower temperatures as the CaO content of the specimen is increased. The addition of CaO increases the defect concentration (and consequently the ionic conductivity) of the bulk more sharply than that of the grain boundaries which are already grossly defective and disordered to start with. Therefore, the transition from the low temperature region where the grain boundary effects are predominant to the intermediate temperature range where the bulk diffusion is more important should occur at lower temperatures as the CaO content increases, which in fact was observed (Fig. 2).

While the activation energy for ionic conduction is less in the low temperature range due to the effect of grain boundaries, it is not so at higher oxygen pressures where the samples are predominantly electron hole conductors. Between $p_{O_2} = 1$ and 10^{-5} atm, samples with lower dopant concentration show larger activation energies at low temperatures compared to those in the intermediate temperature range. The difference in activation energies becomes distinct when log σ_h instead of log σ_T is plotted against $1/T$ (Fig. 7). A similar behavior has been observed in pure ZrO_2 by Kumar *et al.* (24) who plotted electronic conductivity against $1/T$ and obtained an activation energy of 3.74 eV below 700°C compared to 1.33 eV above this temperature. The reason for such a break is not very clear. However a possible explanation may be that the activation energy for movement of electrons or electron holes through the grain boundaries is expected to be higher than that through the bulk because the grain boundaries can act as effective scattering centers for the free electrons, due to their highly disordered nature. The effect of grain boundaries is predominant at low temperatures and, therefore, it increases the activation energy for conduction in this temperature

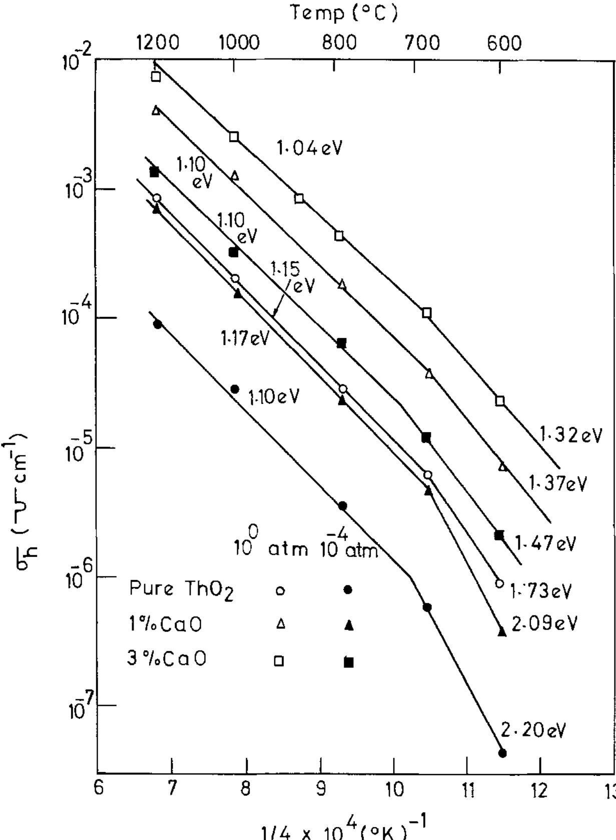

Fig. 7. Plots of electron hole conductivity vs. inverse of temperature for ThO_2-CaO electrolytes.

range. On the other hand, no difference in the activation energy could be detected between the intermediate and low temperature regions in case of samples having higher percentages of CaO (Table I). This may be due to the higher total conductivity and the larger ionic transference number for these samples. The activation energy for hole conduction above 700°C is found to be of the order of 1.10 eV and is nearly independent of either p_{O_2} or composition compared to a value of 0.85 eV measured by Hammou and Deportes (4) in "pure" ThO_2.

Activation energy in the high and intermediate temperature regions.—The activation energy in the high temperature region is observed to be lower than that in the intermediate temperature range for each of the oxygen partial pressures and compositions studied (Fig. 2 and 3 and Table I). [Data from Ref. (8) is also included in Table I and is seen to compare well.] The change in activation energy is comparatively more distinct at the lowest p_{O_2} value where the samples may be considered as exclusive ionic conductors. Earlier studies on "pure" ThO_2 (2), pure HfO_2 (25), and yttria-doped thoria (26) showed similar behavior at high oxygen partial pressures. However, Ullmann (27) has observed a higher activation energy at temperatures greater than 1100°C than that at lower temperatures for ThO_2 and CaO-ThO_2 samples measured in air. Further, Bransky and Tallan (2) have observed that at low p_{O_2} (ionic conduction region) the activation energy in the high temperature range is higher than that at intermediate temperatures.

The activation energy for ionic conduction in "pure" ThO_2 obtained in the intermediate temperature range in the present study (1.80 eV) compares well with the most recent data of Choudhury and Patterson (28), *viz.*, 1.93 and 1.81 eV for two different samples for ThO_2. However, these values are considerably higher than the activation energy of about 1.5 eV of Bransky and Tallan (2). While it is tempting to associate the higher activation energies with the intrinsic behavior and higher purity of the samples, it is not considered a plausible explanation, at least in the case of the present samples. Alternately, the larger activation energy may include migration energy and dissociation energy for defect complexes. The latter explanation appears more appropriate for ThO_2 samples of the present study, since the activation energy for ionic conduction in the high temperature range is lower (1.28 eV) compared to that in the intermediate temperature range. This value is in reasonable agreement with the 1.17 eV obtained by Bransky and Tallan (2) in the same temperature region.

In the ThO_2-CaO specimens, the activation energies in air for different compositions are 0.97-1.20 eV at high temperatures and 1.20-1.38 eV in the intermediate temperature range (Table I). For the same system the activation energy values of 1.1 and 0.9 eV were obtained in air by Valchenkova and Palguev (29) and Ullmann (27), respectively. The results of the present investigation are thus in reasonable agreement with the published results in air atmosphere. No earlier results, however, are available at lower partial pressures to compare with the present data on these solid solutions.

The activation energies observed for the ThO_2-CaO compositions may also be compared with those reported in the ThO_2-$YO_{1.5}$ system for which the observed activation energies are 1.12-1.38 (30) in air, 1.2 (1), 1.09 (7), and 0.85-1.1 eV (26) for ionic transport. These values are close to those observed on CaO-doped ThO_2 specimens measured in air over a wide temperature range, but are lower than the values observed in the ionic conduction region at intermediate temperatures.

The high values of activation energy in the intermediate temperature region compared to those at high temperatures may be explained if one considers that

the oxygen vacancies are associated with the impurity cations in this temperature range. The formation of such defect complexes is favored in a ThO_2-CaO lattice due to a favorable charge distribution between the oxygen vacancies and the Ca^{2+} ions. Dielectric and mechanical relaxation experiments have earlier indicated the presence of such defect complexes in CaO-doped ThO_2 specimens (5). The high value of activation energy (1.80 eV) in the intermediate temperature range in pure thoria of the present investigation compared to that of other investigators (1, 2) may be attributed to the presence of a significant quantity ($<$ 2000 ppm) of Ca in the starting material compared to total impurity content of $<$ 90 ppm in their samples.

It may also be noticed in Table I that the activation energy for ionic conduction (*i.e.*, at $p_{O_2} = 10^{-23}$ atm) remains high and nearly constant (1.80-1.90 eV) in the intermediate temperature region up to 2 m/o CaO and decreases thereafter (Fig. 2). These results may be interpreted as follows: The introduction of increasing amounts of CaO in ThO_2 lattice tends to increase the concentration of defect complexes referred to above which in turn leads to an increase in activation energy for defect migration. However, at higher CaO contents the lattice becomes more open with a larger number of vacancies and consequently the activation energy for conduction is reduced.

By increasing oxygen partial pressure, the contribution from the hole conductivity is increased and therefore the observed activation energy is less representative of the motion of defect complexes.

In the high temperature region, the activation energies are much closer to those observed earlier in pure ThO_2 and ThO_2-$YO_{1.5}$ solid solutions and it may be expected that the defects are in the dissociated state at these high temperatures. The difference between the activation energies in the high and intermediate temperature ranges, in that case, gives the binding energy for the defect complex and is found to vary between 0.4 and 0.7 eV for different CaO-doped ThO_2 specimens. The dissociation energy of the vacancy defect has been observed to be 0.22 eV in the internal friction and dielectric loss measurements (5), compared to a calculated value of 0.71 eV. The present values are closer to the theoretical value. Possible existence of impurity cation-oxygen vacancy interaction in "pure" ThO_2 has also been pointed out by Hammou and Deportes (4). These values may be compared with those of 0.3-0.4 eV (31) obtained for alkali halides with divalent impurities. For oxide systems, a higher binding energy is expected due to the higher charges associated with the defects.

Conclusions

Like all other ThO_2-base electrolytes, ThO_2-CaO solid solutions are predominantly electron hole conductors in the high oxygen partial pressure range and become fully ionic below 10^{-6}-10^{-10} atm, the exact value being dependent upon the composition and temperature. The ionic conductivities of these solid solutions are quite comparable to those of ThO_2-Y_2O_3 electrolytes and may be considered useful in the same p_{O_2} range as that of the latter. Both ionic conductivity and the transference number increase with increasing CaO content at least up to 10 m/o of CaO.

The variation of conductivity with reciprocal temperature led to three temperature regions with different activation energies. The activation energy for ionic conduction in the low temperature range is lower while that of hole conduction is higher than that in the intermediate temperature range and appears to be the effect of grain boundaries. The activation energy for ionic conduction is higher than that for hole conduction and is a function of composition. A defect complex formation appears to be operative in the intermediate temperature range while the conductivity at the highest temperatures represents the behavior due to dissociated defects.

The Crystallographic Site of Cosputtered Eu in RF-Sputtered SnO_2 Films

Takao Tohda, Kiyotaka Wasa, and Shigeru Hayakawa

Matsushita Electric Industrial Company, Limited, Materials Research Laboratories, Kadoma, Osaka, 571 Japan

ABSTRACT

Polycrystalline SnO_2 films doped with various amounts of Eu were prepared on glass substrates by a cosputtering process in an rf-sputtering system. The site of the cosputtered Eu in the SnO_2 films was investigated by cathodoluminescence studies. It has been found that the films with a 1 atomic percent (a/o) Eu concentration show sharp emission lines due to a magnetic dipole transition $^5D_0$-$^7F_1$, while the films with a 14 a/o Eu concentration show strong emission lines due to an electric dipole transition $^5D_0$-$^7F_2$. In the former the films have a good crystallinity and the cosputtered Eu has been substituted for Sn in the SnO_2 crystal matrix, while in the latter the cosputtered Eu inhibits the SnO_2 crystal grain growth and is possibly incorporated into regions with large disorder near the grain boundaries.

A cosputtering process using a multicomponent target or multitargets is available for controlling the structural and electrical properties of resultant sputtered films. In an earlier paper (1) dealing with the influence of cosputtered Al and Cu on the structural and electrical properties of sputtered ZnO films, it has been shown that, as one would expect, the addition of Al lowers the resistivity of the ZnO films, whereas the addition of Cu increases it. Furthermore, the addition of Al inhibits the growth of the c-axis orientation, whereas Cu favors it. Very few studies of the location of cosputtered minor constituents in the host crystal films have been reported. Recently we have made Eu-doped SnO_2 films on glass substrates by cosputtering Eu with SnO_2 in an rf-sputtering system. In SnO_2 single crystals, Crabtree (2) suggested that Eu could be doped as much as 8 mole percent (m/o) by heating the crystals with $EuCl_3$. This paper describes a cathodoluminescence study of the cosputtered Eu in the SnO_2 films.

Experimental

A planar electrode rf-sputtering system with an ultrahigh-vacuum diffusion pump was used for the cosputtering process. The background pressure before sputtering was 2×10^{-5} Torr. Electrode construction is shown in Fig. 1. The distances from the target to the anode and substrates were 13 and 18 mm, respectively. The anode was perforated and the substrates were placed behind it. Cosputtering of Eu with SnO_2 was achieved by using sintered SnO_2 disk targets with various amounts of Eu. The diameter and thickness of the targets were 20 and 3 mm, respectively. They were prepared by pressing 99.9% pure SnO_2 powder mixed with 99.9% pure Eu_2O_3 powder at 1000 kg/cm^2 and successively firing at 1000°C for 5 hr in air. The concentration of Eu was varied from 1 to 14 a/o. Corning 7059 glass plates were used as the substrates, since their thermal expansion coefficient was close to that of SnO_2. The substrates were cleaned in boiling trichloroethylene.

The sputtering was carried out at 2×10^{-2} Torr of Ar and O_2 with an oxygen concentration of 50%. The cathode current density and potential were 2 mA/cm^2 and -1100V, respectively. The substrate temperature was 70°C. Before the deposition of SnO_2, presputtering was done for 30 min. Films of 1 ~ 2 μm thickness were deposited on the substrates in 1 hr. These sputtered films were annealed at 500°C for 1 hr in air.

The cathodoluminescent properties of the SnO_2 films were examined by bombarding them with 2 keV electrons at a current density of 50 μA/cm^2. The emitted light was focused on the entrance slit of an Ebert grating monochrometer (Nippon Jarrell-Ash) and detected by a photomultiplier (HTV. R446). The resolution of the monochrometer during these experiments was 5Å.

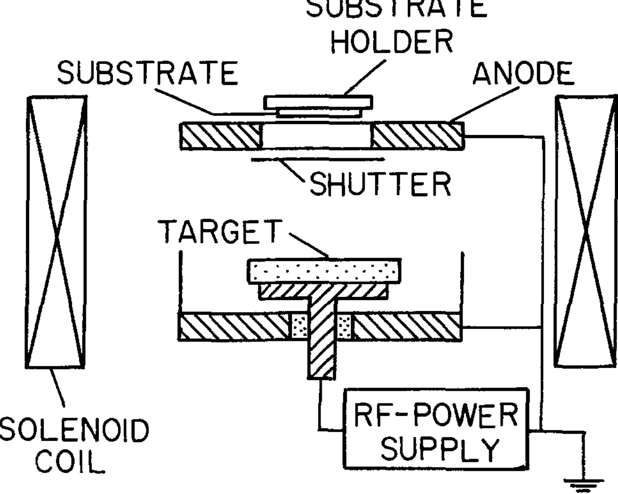

Fig. 1. Electrode construction of an rf-sputtering system

Results and Discussion

Figure 2 shows the emission spectrum obtained from the SnO_2 target with an Eu concentration of 5 a/o. The spectrum is quite similar to that of the single crystal SnO_2 doped with Eu (2); a strong magnetic dipole emission $^5D_0$-$^7F_1$ and weak electric dipole emissions

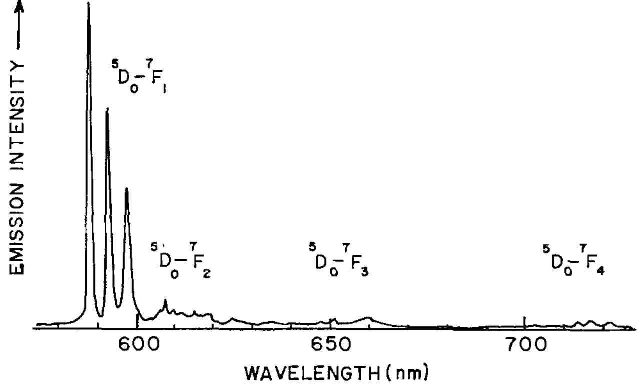

Fig. 2. Emission spectrum from SnO_2:Eu (5 a/o) target

Key words: cathodoluminescence, thin films, rf sputtering.

$^5D_0$-$^7F_{2,3,4}$ suggest that most of the Eu^{3+} ions are incorporated into the Sn site of the SnO_2 crystal matrix. Similar emission spectra were also observed from the targets with Eu concentrations of 1 and 14 a/o. The annealed SnO_2 films exhibited, however, different emission spectra. They vary with the amount of Eu, as shown in Fig. 3. Spectrum (a) was measured from 1 a/o Eu-doped films. The spectrum is similar to that of the single crystal SnO_2. This indicates that the crystal field around the Eu^{3+} ions in the films is similar to that in the single crystal. Spectrum (b) was measured from 5 a/o Eu-doped films. A broad electric dipole emission $^5D_0$-$^7F_2$ is superposed on the magnetic dipole emission $^5D_0$-$^7F_1$. This indicates that some of the Eu^{3+} ions stay at the center of symmetry of the SnO_2 crystal, while the rest stays at a site with no inversion symmetry (3). In 14 a/o Eu-doped films, the electric dipole emission is strongly enhanced and the magnetic dipole emission is reduced, as seen in spectrum (c). This indicates that most of the Eu^{3+} ions stay at sites with no inversion symmetry. The crystal field around the Eu^{3+} ions which emanate the electric dipole emission varies from ion to ion, since the spectrum shows broad emission bands.

X-ray diffraction measurements showed that the films crystallized to a rutilelike polycrystalline structure with the (110) plane parallel to the substrate surface. Table I compares the (110) diffraction line half-widths of the annealed SnO_2 films with that of an undoped SnO_2 crystal. It is seen that in the annealed films with a low Eu concentration, the half-width is nearly equal to that of the undoped SnO_2 crystal. This indicates that the films have good crystallinity and that Eu is quite possibly substituted for Sn. At high Eu concentration, the cosputtered Eu inhibits SnO_2 crystal grain growth and reduces the grain size. This consideration is supported by the fact that the highly Eu-doped films show a broad x-ray diffraction line. The grain size calculated from the half-width of the (110) diffraction line is found to be as small as 50Å. It is speculated that the Eu may be incorporated mostly into regions with large disorder near the grain boundaries. This may cause the enhanced electric dipole emission. These crystal structures in the highly Eu-doped films are unusual ones in thermally Eu-doped SnO_2 crystals in which the enhanced electric dipole emission is scarcely observed. In the sputtering process, the films grow under nonthermal equilibrium conditions. The cosputtered Eu may strongly affect the film growth process and the unusual crystal structures may easily be quenched, as is observed in Ge-doped Bi_2O_3 prepared by the cosputtering process (4).

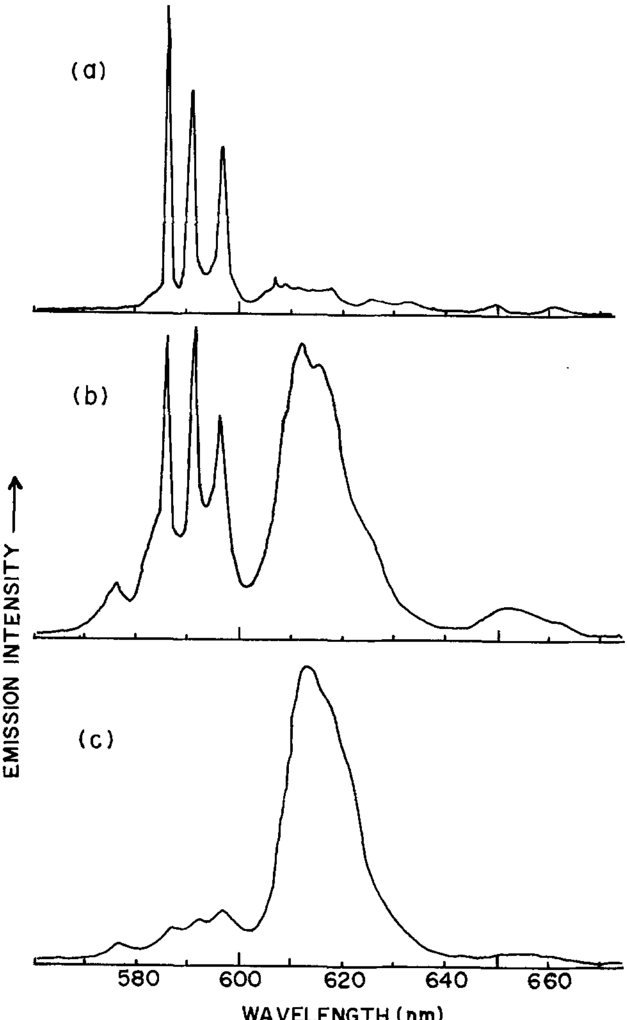

Fig. 3. Emission spectra from annealed SnO_2 films of 4000Å thickness doped with 1 a/o Eu (a), 5 a/o Eu (b), and 14 a/o Eu (c).

Table I. (110) line half-widths of undoped SnO_2 crystal and annealed films (x-ray diffraction measurements)

Sample	Line half-width (2θ deg)
Undoped SnO_2 crystal	0.2
1 a/o Eu-doped film	0.3
5 a/o Eu-doped film	0.4
14 a/o Eu-doped film	1.5

The present annealing process may not essentially affect the crystallographic site of the cosputtered Eu since the cathodoluminescent spectra from as-sputtered Eu-doped SnO_2 films are similar to those of the annealed ones, although they are much less intense.

Conclusion

The crystallographic site of cosputtered Eu in SnO_2 films can be determined by studying their cathodoluminescent spectra. The results are as follows.

(*i*) The sputtered films with a low Eu concentration show a sharp magnetic dipole emission. This indicates that the cosputtered Eu is substituted for Sn in the SnO_2 crystal matrix.

(*ii*) The sputtered films with a high Eu concentration show a strong electric dipole emission. In this case, the cosputtered Eu inhibits SnO_2 crystal grain growth and reduces the grain size. It is speculated that the Eu may mostly be incorporated into regions with large disorder near the grain boundaries.

Structure and Properties of Boron Nitride Films Grown by High Temperature Reactive Plasma Deposition

S. B. Hyder* and T. O. Yep

Varian Associates, Corporate Solid State Laboratory, Palo Alto, California 94303

ABSTRACT

Thin films of boron nitride were grown by reactive plasma deposition using the ammonia-diborane reaction. The crystalline growth on substrates of silicon, compression-annealed pyrolytic graphite, and compression-annealed pyrolytic BN was investigated by electron microscopy, and composition of the deposited material was determined by electron microprobe analysis. The effect of gas ratio and substrate temperature on growth rate was also investigated. Some crystalline order was observed; the largest single crystal BN grains were obtained on compression-annealed pyrolytic graphite. Resistivities of the order of 2×10^9 Ω-cm were measured with dielectric constant varying from 2.7 to 7.7 for growth with different gas ratios. Efforts to determine the drift velocity of carriers in thin films of BN were not successful.

The interest in BN stems from the fact that it is a high resistivity III-V compound with a large bandgap (3.8 to 7.58 eV) (1, 2) and if crystalline thin films could be obtained with large carrier drift velocity, it could be a promising material for certain microwave devices. This communication describes the results of the study undertaken to obtain crystalline thin films of BN by reactive plasma deposition (RPD) using the reaction of NH_3 with B_2H_6.

Experimental

Thin films of BN were grown on Si substrates by chemical vapor deposition (CVD) by Rand and Roberts (1) using the reaction between NH_3 and B_2H_6 in hydrogen. The reaction proceeded as follows

$$B_2H_6 + 2NH_3 \rightarrow (NH_3)_2BH_2 + BH_4 \text{ (low temperature)}$$

$$\rightarrow 2BN + 6H_2 \text{ (high temperature)}$$

with the free energy equal to −165 and −177 kcal/mole at 900° and 1100°K, respectively. Alexander, Joyce, and Sterling (3) have also grown BN by reactive plasma deposition at room temperature.

The present work describes the results of the growth of BN using the reaction of NH_3 with B_2H_6 in H_2 at a high substrate temperature (> 1000°K) together with an rf plasma on graphite, Si, and BN substrates. The deposited material was smooth and transparent and was found to have better crystalline quality than the material obtained by NH_3:B_2H_6 CVD at high temperature alone.

Figure 1 shows a schematic of the reactive plasma deposition system. The NH_3 and 1.96% B_2H_6 diluted in H_2 gases are metered by their respective Tylan mass flow controllers and are mixed in the heated mixing chamber. The 13.5 MHz rf excitation is coupled into the plasma within the radiant furnace hot zone by a capacitive coupler consisting of a platinum grid electrode placed outside a 3 in. diameter furnace tube and the grounded graphite susceptor inside the furnace tube. The input and reflected rf power were measured by a Thruline wattmeter manufactured by Bird Electronic Corporation. Typically 4W of rf power was absorbed by the plasma. The substrates and graphite susceptor are heated to the deposition temperatures by a 14 kW parabolic clamshell radiant heater furnace manufactured by Research, Incorporated. The temperature is monitored by a Chromel-Alumel thermocouple imbedded in the graphite susceptor close to the substrate. Six 40 liter Varian Vacsorb pumps are used to maintain the plasma at a pressure of 39-133 Pa (300-1000 μm).

In a typical run, the reactor tube is evacuated to *ca.* 0.66-1.33 Pa (5-10 μm) pressure using the Vacsorb pumps. The substrates are then heated until a steady temperature is recorded by the thermocouple. After the desired substrate temperature is reached, NH_3 and B_2H_6 are let into the mixing chamber at the desired ratio, but with a flow rate about a tenth of the normal flow rate during deposition. The slow initial growth rate promotes better nucleation and consequently a better crystalline structure. The plasma is ignited with a Tesla coil as the gases enter the hot zone. The pressure in the reactor tube stabilizes to *ca.* 39-66.5 Pa (300-500 μm). After the nucleation period, the reactive gases are introduced at full flow which ranges from 26 to 120 cm³/min for NH_3 and 480 to 575 cm³/min for B_2H_6, depending upon the gas ratio being used. The pressure in the reactor tube increases with deposition duration and is adjusted by increasing the pumping rate to sustain a vacuum less than 133 Pa (1000 μm) in order to maintain the plasma.

Different gas ratios and substrate temperatures were examined. Substrates used were: (111)Si, compression-annealed graphite (CAPG) from Union Carbide and Pfizer, and compression-annealed pyrolytic BN (CAPB) from Union Carbide. The growth rate generally increased with increasing temperature and decreased with increasing NH_3:B_2H_6 ratio but was practically independent of the substrate and its orientation. The growth rate was also highest upstream where the gases enter the hot zone. Table I shows the growth rate for different substrate temperatures and gas ratios for some of the reactive plasma chemical vapor depositions made.

Results

Material.—The RPD material deposited at high temperatures had better crystalline quality than the material deposited by high temperature NH_3:B_2H_6 CVD

5-16	4.5	1000	0.82
6-5	2.2	750	0.72

alone. A typical example of the improvement in grain size with high temperature RPD over CVD is observed in the electron diffraction patterns shown in Fig. 2 (a) and (b) for material grown by CVD and RPD, respectively. In both cases the material was grown under the same conditions of gas ratio (NH_3:B_2H_6 8:1) and substrate temperature (770°C) on graphite substrates obtained from the Supertemp Corporation.

Compression-annealed pyrolytic graphite (CAPG) from Pfizer and Union Carbide was examined with the 100 keV electron microscope for the degree of single crystallinity. The reflection electron diffraction patterns of the CAPG material from Pfizer and Union Carbide are shown in Fig. 3(a) and 4(a), respectively. Diffraction patterns from the Union Carbide CAPG substrate indicates coarse grained crystalline material. The Pfizer graphite on the other hand consists of fine grain randomly oriented polycrystalline material, as evidence by the series of sharp circular rings in the diffraction pattern. Figures 3(b) and 4(b) are transmission electron diffraction micrographs of BN films on

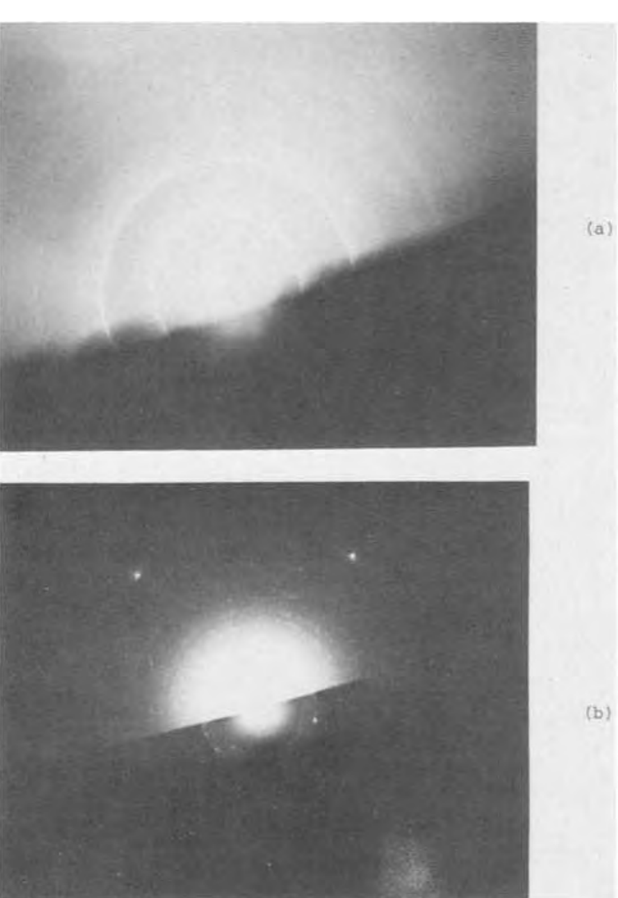

Fig. 2. (a) Reflection electron diffraction pattern of CVD BN deposited on Supertemp graphite substrate. (b) Reflection electron diffraction pattern of high temperature reactive plasma BN deposited on Supertemp graphite substrate.

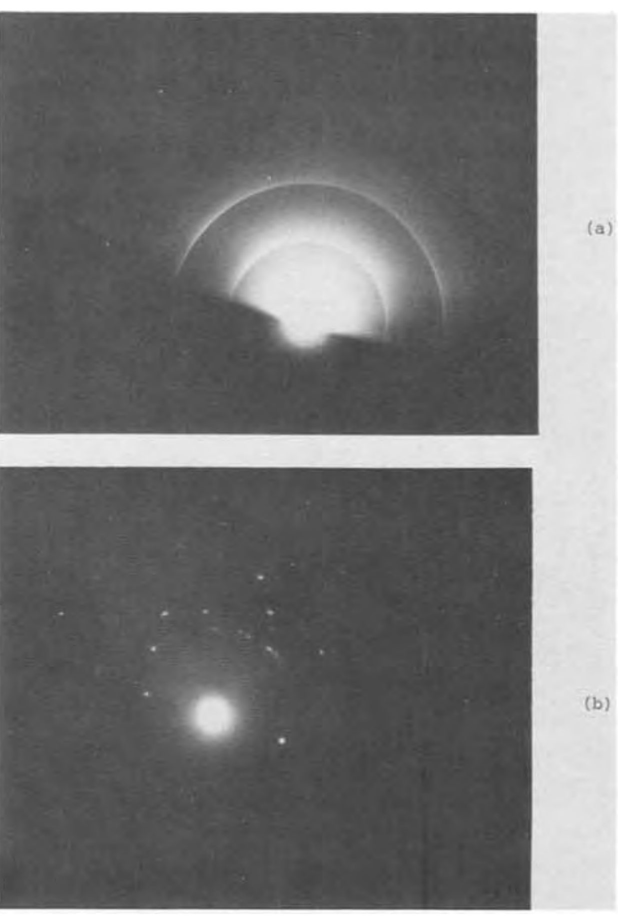

Fig. 3. (a) Reflection electron diffraction pattern of Pfizer compression-annealed pyrolytic graphite. (b) Transmission electron diffraction pattern of reactive plasma BN deposited on Pfizer compression-annealed pyrolytic graphite.

graphite substrates from Pfizer and Union Carbide, respectively. The BN layers that separated from the substrate due to differences in thermal expansion were thinned in hot phosphoric acid for the transmission microscopy. The diffraction micrograph for the BN layer deposited at 770°C with a NH_3:B_2H_6 gas ratio of 8:1 on the Union Carbide CAPG shows rather markedly that this BN layer has larger single crystallites than the BN films deposited on the other substrate, and the single crystals are large enough so that there are but a few single crystal grains within the 50 μm objective aperture of the microscope.

A comparison of the electron diffraction patterns of the RPD BN layers in Fig. 3(b) and 4(b) with their respective CAPG substrates in Fig. 3(a) and 4(a) show that the single grain size in the deposited BN is larger than that in the substrate.

Figure 5 shows the diffraction pattern that is typically obtained in BN deposited on CAPG material from Union Carbide. After indexing the diffraction spots, two grains with zone axes along $(01\bar{1}0)$ and $(\bar{1}5\bar{4}1)$ could be identified in the multigrain structure.

BN films were also deposited on (111) Si substrates with some degree of single crystallinity. Figure 6 is a transmission electron diffraction pattern of a BN film grown again with a gas ratio of 8:1 at a temperature of 770°C on a (111) Si substrate. The Si substrate was etched off the BN for the transmission electron microscopy. In addition to the diffraction spots, Kikuchi lines were also observed, indicating fairly large grain crystalline material.

Chemically vapor deposited hexagonal BN from Union Carbide that had been compression annealed for improved ordering of the crystalline structure was also

used as substrate material. Figure 7(a) is a transmission electron diffraction micrograph of some of this substrate material, which indicates that the material consists of preferentially oriented crystallites. Figure 7(b) shows a transmission electron diffraction of the BN film grown by reactive plasma that peeled away from the substrate. The hexagonal symmetry of the multiple grain is evident from the diffraction pattern.

Table II. B-N composition EMP analysis

Specimen	B (%)	N (%)	NH_3:B_2H_6 ratio	Temp (°C)
4-14	49.25	50.75	4.5:1	1000
4-8	55.40	44.60	4.5:1	930
5-15	41.67	58.33	8.1:1	1000
Allied Chemical	46.32	53.68	—	—
Boralloy (U.C.)	45.29	54.71	—	—
Theoretical	43.56	56.44	—	—

The effect of varying the NH_3:B_2H_6 ratio from 4.5:1 to 19.2:1 was also examined, and the substrate growth temperature was varied from 750° to 1000°C. The most ordered single crystals of deposited BN were obtained for a NH_3:B_2H_6 ratio of 8:1 with a growth temperature range of 770°-1000°C.

A Kevex energy-dispersive electron microprobe analysis was made on some compression-annealed BN "Boralloy" from Union Carbide, a vapor-liquid solution-grown BN specimen obtained from R. Kirk of Allied Chemical, and our reactive plasma BN films. Table II contains a summary of the compositional analysis. When compared to the theoretical composition for stoichiometric BN, all of the BN specimens tested were B rich except sample No. 5-15, which was N rich and had been deposited with the largest NH_3:B_2H_6 ratio. This would indicate that a stoichiometric BN composition could be obtained from a reactive plasma BN deposition at 1000°C using a NH_3:B_2H_6 gas ratio of 7.1:1.

Measurements.—Infrared absorption measurements were made on our reactive plasma BN films with a Model 457 Perkin-Elmer infrared spectrometer over the wavelength range of 2.5-40 μm. The typical spectrum observed on our depositions is shown in Fig. 8. The BN optical phonon absorption peak occurs at 7.1 μm and a possible B-N-B resonance is at 12.5 μm. This is the standard spectrum also observed in commercially available BN.

A four-point probe measurement utilizing a Tektronix 576 curve tracer as the constant current source and a Keithley 602 electrometer to measure the voltage determined that the room temperature electrical resistivity of our BN films was typically 2×10^9 Ω-cm.

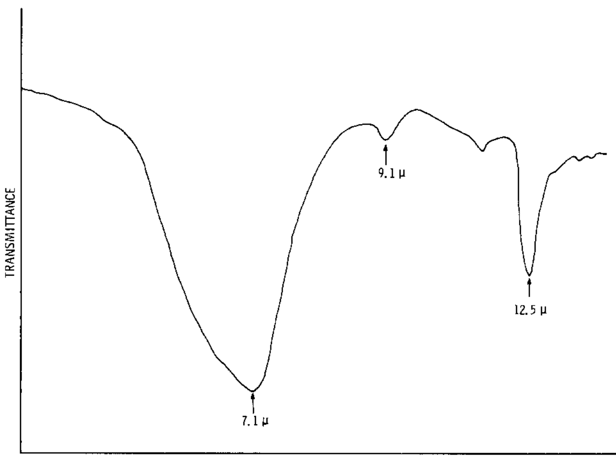

Fig. 8. Typical infrared absorption spectrum of reactive plasma BN.

The *I-V* characteristics were essentially linear to a field of 10^4 V/cm at which the resistivity was measured.

A General Radio 1615A capacitance bridge was used to determine the dielectric constants at 100 kHz of BN films deposited with different NH_3:B_2H_6 ratios by measuring the capacitance of BN capacitors of known area and thickness. Evaporated Al electrodes 3 mm in diameter were used. For a ratio of NH_3:B_2H_6 of 4.5:1 and substrate temperature of 1000°C, the dielectric constant was 2.7. For a ratio of NH_3:B_2H_6 of 11.6:1 and substrate temperature of 800°C, the dielectric constant varied from 5.3 to 7.7 from sample to sample.

An attempt was made to measure the carrier drift velocity by the method of Ruch and Kino (3), but no meaningful electrical response on the sampling scope could be detected from the incident 15 keV electron beam current on all our BN material. BN thicknesses from 10 to 75 μm were used. Electric fields up to 10^6 V/cm were applied across the BN specimens. Evidently the density of recombination centers is too high to permit any measurable carrier transit current to be observed.

Conclusions

Thin films of BN were grown by high temperature reactive plasma deposition using the reaction of ammonia and diborane. The crystalline growth on substrates of Si, pyrolytic graphite, and compression-annealed pyrolytic BN was investigated by transmission and reflection electron microscopy. The highest crystalline order with the largest single crystal grains was observed to occur for deposits on Union Carbide compression-annealed pyrolytic graphite grown with an ammonia/diborane ratio of 8:1 at temperatures between 770° and 1000°C. Energy dispersive electron microprobe analysis of the BN films indicated that stoichiometric BN should be obtained by growths at 1000°C with an ammonia/diborane ratio of 7.1:1. The electrical measurements indicated the BN films had room temperature resistivities of 2×10^9 Ω-cm and 100 kHz dielectric constants of 2.7-7.7 depending on the growth conditions. No drift velocity values for carriers in BN could be obtained.

ABSTRACT

Gallium nitride light emitting diodes (LED's) fabricated on {1$\bar{1}$02} oriented sapphire substrates are found to emit only green light independent of Zn concentration during the i-layer growth of i-n structures, while LED's on {0001} substrates are found to be able to emit blue to yellow light by controlling the Zn concentration. In investigating the temperature dependence of electroluminescence and photoluminescence spectra, it was found that the spectra consist of two components: blue emission and yellow or green emission. The relative intensity of the blue emission increased with the decrease in temperature. On the other hand, the yellow and green emissions were found to increase in their relative intensities when the temperature was raised to room temperature. These results imply that two kinds of acceptors are formed by doping with Zn into a GaN crystal. The acceptor contributing to the blue emission is located at 0.4 eV above the valence band. The other acceptor responsible for the yellow and green emissions is an impurity band situated at a position higher than 0.8 eV above the valence band.

Since gallium nitride light emitting diodes (LED's) composed of the i (Zn- or Mg-doped layer)-n (undoped layer) junction were reported by Pankove and his coworkers (1, 2), various GaN LED's with blue (3), yellow (4), red (5), and violet color emission (6, 7) have been fabricated. However, the mechanism by which GaN LED's emit at various wavelengths throughout the visible spectrum has remained unclear, though luminescence centers contributing to the various emissions have been found to extend from 0.6 to 1.1 eV above the valence band (4).

This paper reports that there are some differences in the color of the emission between the LED's fabricated on {0001} and {1$\bar{1}$02} oriented sapphire substrates. The LED fabricated on {1$\bar{1}$02} substrate was found to emit green light almost independent of the Zn concentration during the i-layer growth, though the emission from the LED on {0001} substrate was found to vary in color by controlling the Zn concentration. The LED's on {0001} substrates produced blue to yellow color emissions. In this work, it was also found that there is a different temperature dependence in the relative intensity and spectrum shift between the blue emission and the other emissions. A peak energy difference between the spectra of photoluminescence (PL) and electroluminescence (EL) was observed at room temperature for the blue LED, but not for the yellow and green LED's.

Experimental

Crystal growth and LED fabrication.—The GaN crystals used in this work were grown according to the Maruska and Tietjen method (8). Substrates used were {0001} and {1$\bar{1}$02} oriented sapphires grown by the Czochralski method. These substrates were annealed in air at 1000°C for 5 hr in order to reduce any strain in the crystals. The surfaces were etched off in H_3PO_4 at 320°C to remove lapping scratches. First an undoped n-type conducting layer was grown on these substrates and then a Zn-doped layer was grown. Thus, an i-n junction was formed during crystal growth. The reactor employed had three horizontal inlet nozzles, which were used to introduce HCl, NH_3, and Zn vapor. The quartz boat for Zn was movable by magnet from up to down stream in the gas flow. This boat permitted evaporation of Zn at high temperatures during the i-layer growth time after the n-layer deposition. A Zn source temperature of about 600°C was required to compensate native donors. The n-layers obtained were $3 \times 10^{18} \sim 7 \times 10^{19}$ cm^{-3} in carrier concentration by the van der Pauw method and were 50 $\sim$ 80 μm thick. The i-layers were about 10 μm thick. Their carrier concentrations were unknown because of their semi-insulating characteristics.

The wafers were cut into 3 to 5 mm square disks. An indium contact was soldered onto the whole surface of the i-layer, while the other contact was attached to the n-layer exposed on the chip side. Electroluminescence could be obtained with a forward bias of 3.5-20V (9) with respect to the i-layer surface. Emission was observed through the substrate at the back. The reverse bias generated almost no light. This phenomenon is contrary to what has already been reported (4).

Zinc concentration distribution in the i-layer.—The Zn concentration distribution in the i-layer surface was semiquantitatively analyzed by scanning electron microprobe analysis (EMA). The electron beam incident on the crystal surface was several microns in diameter. This is less than one-tenth the crystal growth hillock diameter. To reduce the error in the measurement due to surface roughness, the relative Zn concentration was expressed by the K_α-ray intensity ratio of Zn to Ga, $(Zn/Ga)_i$, in which the Ga K_α-ray intensity was used as an internal criterion. The Zn and Ga K_α-rays were simultaneously measured. The ratios, $(Zn/Ga)_i$, were also employed to compare the Zn concentration between samples.

EL and PL measurements.—The devices fabricated in this way were mounted on the cold finger of a liquid nitrogen cryostat. Then, their EL spectra at room (RT) and liquid nitrogen temperatures (LNT) were measured by a Spex-II spectrometer and an RCA 7625 photomultiplier.

The specimens used for the PL measurements were prepared from the same sample used for the EL measurements. For these measurements, Kr laser light (3509A) was irradiated on the i-layer surface through a lens system. The measurements were carried out at RT and liquid helium temperature (LHeT) using a Perkin Elmer El spectrometer and an HTV-592 photomultiplier.

Results

Case of {0001} substrates.—In this case, the crystals in the {0001} orientation are grown. The EL color of a diode fabricated on {0001} substrate (hereafter referred to as {0001} diode) depended on the Zn concentration in the i-layer, *i.e.*, the color of the emission shifted to the longer wavelengths with the increase in

* Electrochemical Society Active Member.
Key words: substrate orientation, electroluminescence photoluminescence temperature dependence, luminescence centers.

Zn concentration. This result agrees qualitatively with Pankove's experiment (3). However, there has been no report clarifying the quantitative correlation of Zn concentration during i-layer growth [supplied amount ratio of Zn to Ga, $(Zn/Ga)_g$] with that in the i-layer [$(Zn/Ga)_i$] and the color of the emission. Investigating the relationship between the two kinds of Zn concentrations, *i.e.*, $(Zn/Ga)_g$ and $(Zn/Ga)_i$, $(Zn/Ga)_i$ was found to increase steeply with $(Zn/Ga)_g$ when $(Zn/Ga)_g$ was in the narrow range below 0.1 (Fig. 1). The $(Zn/Ga)_i$ increased gradually with $(Zn/Ga)_g$ in the range above 0.1. When $(Zn/Ga)_g$ was above 0.5, *i.e.*, i-layer Zn concentration was high, yellow LED's were usually obtained. Orange to red lights were sometimes produced; when $(Zn/Ga)_g$ was below 0.2, blue light emission was apt to occur. Then Zn concentration in the i-layer of the yellow LED was two or more times that of the blue one (Fig. 1). The steep increase of $(Zn/Ga)_i$ in the near zero range of $(Zn/Ga)_g$ may be caused by complete incorporation of the Zn supplied into the GaN crystal. As a result, $(Zn/Ga)_i$ fluctuated widely with small fluctuations in the amount of Zn supplied when the $(Zn/Ga)_g$ was below 0.2. For this reason, blue LED's are difficult to obtain with good reproducibility. On the contrary, yellow LED's doped with a high concentration of Zn could be fabricated with good reproducibility.

The EL spectra of the blue LED and yellow LED measured at RT [Fig. 2(a)] consisted of a single band peaking at 450 nm (2.76 eV) and 585 nm (2.12 eV), respectively. The EL spectrum of the blue LED at RT is analogous in the peak position and half-width to that reported already (3). On the other hand, the EL spectrum of the yellow LED fabricated in this work differs from the EL spectrum observed by Pankove *et al.* (4) in a broad orange contribution peaking at 1.7 eV. No shoulder band is observed in Fig. 2(a). When the yellow LED made in this work was cooled to LNT, a subband corresponding to the emission peak of the blue LED was apparent [Fig. 2(b)]. No side band developed in the EL spectrum of the blue LED at LNT, although the peak position was found to shift to higher energy, *i.e.*, blue shift. However, in the EL spectrum of the yellow LED no shift of the main band peak position occurred. The blue shift of the GaN EL is known to

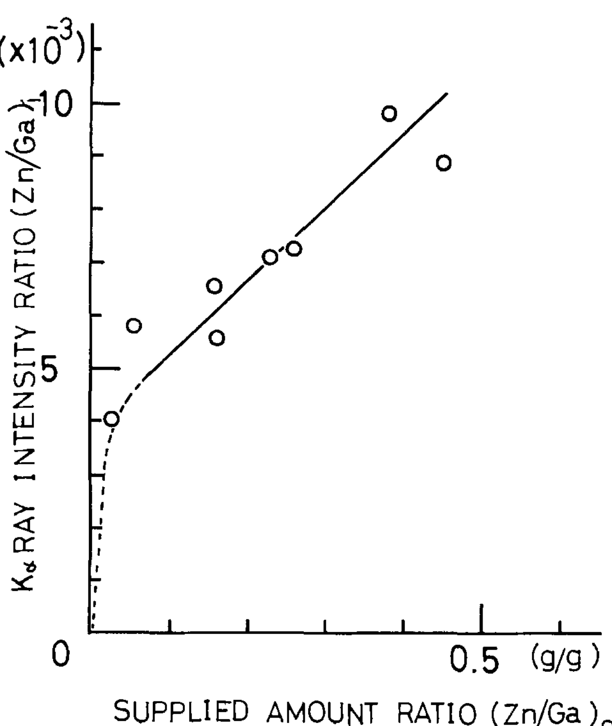

Fig. 1. The relationship between relative Zn concentrations in the i-layers, $(Zn/Ga)_i$, and the supplied $(Zn/Ga)_g$ ratio.

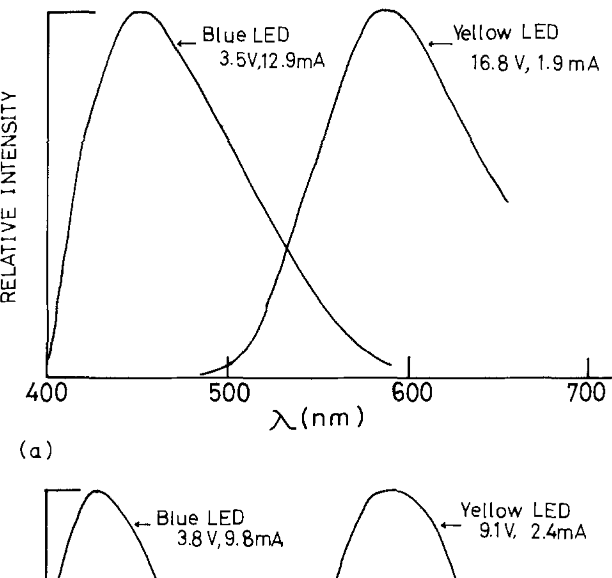

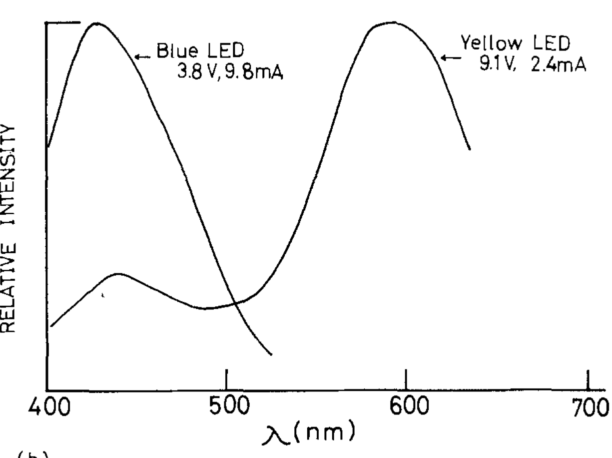

Fig. 2. Electroluminescence spectra of blue and yellow LED's at RT (a) and at LNT (b). The values in the spectra show the applied voltages and current through the diodes.

occur with the increase in current through the diode (7, 9). The peak shift observed here was not caused by the current increase, since the current through the blue LED in Fig. 2 was less at LNT than at RT.

As opposed to the EL spectrum differences between the blue and yellow LED's mentioned above, no large peak energy difference was observed in the PL spectra between the blue and yellow LED's [Fig. 3(a)]; the peak energies were located around 560 ~ 580 nm (2.12 ~ 2.14 eV). In comparing the spectrum peak energy difference between the PL and EL at RT, however, there was some difference between the blue LED and yellow LED. The peak energy of the EL spectrum was found to be higher than that of the PL spectrum by 0.5 eV in the blue LED, whereas no peak energy difference was found in the yellow LED. When temperature was decreased to LHeT, the PL spectrum of the yellow LED occurred at the same peak position as that of the blue one [Fig. 3(b)]. The peak was located at 445 nm (2.79 eV), and this peak position is nearly in agreement with that of the blue component of the EL spectra at LNT [see Fig. 2(b)]. The spectrum shown in Fig. 3(b) was almost entirely in agreement with the low temperature PL spectra reported already.

Case of $\{1\bar{1}02\}$ substrates.—The epitaxial layers of GaN crystals of $\{11\bar{2}0\}$ oriented surface were grown on $\{1\bar{1}02\}$ surfaces of sapphire substrates. The LED's made on $\{1\bar{1}02\}$ sapphires (hereafter referred to as $\{11\bar{2}0\}$ LED) differed from $\{0001\}$ LED's in the Zn concentration dependence of the EL. That is, the peak energy for the EL spectrum of the $\{11\bar{2}0\}$ LED was almost independent of $(Zn/Ga)_g$. Even when $(Zn/Ga)_g$ values were varied in the range from 0.4 to 1.1, $\{11\bar{2}0\}$ LED's generated only green light, although $\{0001\}$ LED's

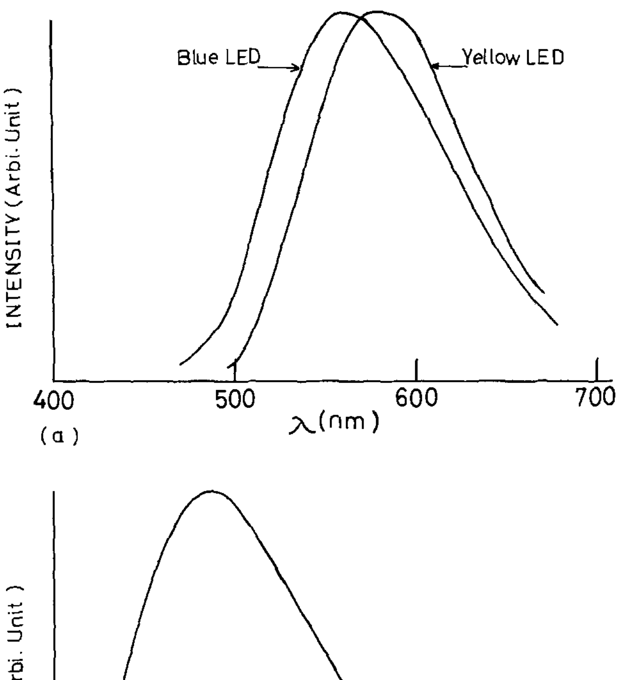

Fig. 3. Photoluminescence spectra of the i-layers of blue and yellow LED's at RT (a) and at LHeT (b). At LHeT, the two spectra are completely superimposed on one another.

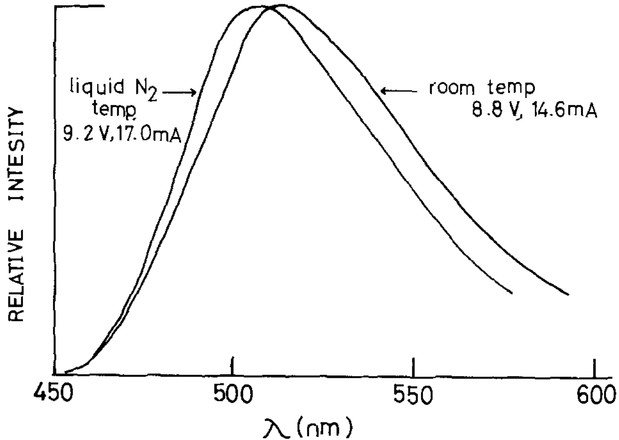

Fig. 4. Electroluminescence spectra of green LED at RT and at LNT.

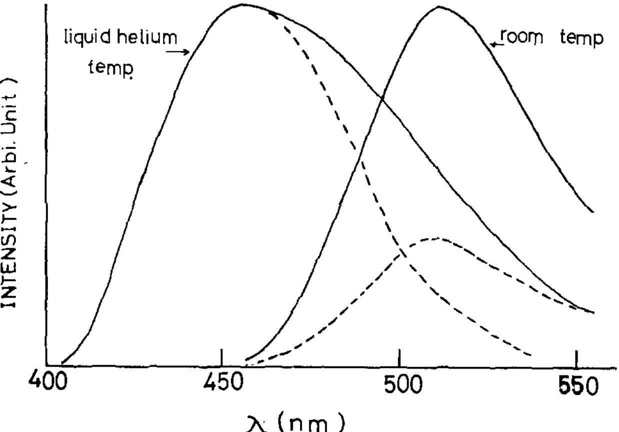

Fig. 5. Photoluminescence spectra of green LED's i-layer at RT and at LHeT. The PL spectrum at LHeT consists of two components (broken lines).

under similar conditions produced yellow to red light. The {11$\bar{2}$0} green LED's were apt to be lower in $(Zn/Ga)_i$, measured in EMA, than the {0001} yellow LED's, though there were some exceptions. The {11$\bar{2}$0} green LED's were midway between blue and yellow {0001} LED's with regard to electric resistance. These results imply that the Zn concentration in the green LED is intermediate between the blue and yellow LED's. In the case of Zn supplying conditions such as used when fabricating the blue LED on {0001} substrate, the GaN crystals grown on {1$\bar{1}$02} substrate did not become a semi-insulator. It was therefore found that there is a limit to the amount of Zn incorporated into {11$\bar{2}$0} oriented GaN crystal.

The EL spectrum of the {11$\bar{2}$0} green LED consisted of a single band peaking at 520 nm (2.38 eV) (Fig. 4). No large peak position difference was observed between the spectra at RT and LNT, similarly to the case of the yellow LED. However, no blue side band such as seen in the EL spectrum of the yellow LED was observed even at low temperature.

With regard to the peak position correspondence between the PL and EL spectra, the green LED resembled the yellow one. That is, the PL spectrum at RT of the {11$\bar{2}$0} green LED agreed in its peak energy (515 nm, 2.14 eV) with the EL spectrum as seen in Fig. 4 and 5. When temperature was decreased, the peak position of the PL spectrum of the green LED shifted to 450 nm (2.76 eV) (LHeT) which is nearly in agreement in peak energy with those of the blue and yellow {0001} LED's. The PL spectrum of the green LED at LHeT was broader than the others (Fig. 3 and 5).

Discussion

Luminescence of {0001} LED's.—The luminescence center responsible for the blue and yellow emissions from GaN:Zn, such as shown in Fig. 2, has been generally considered to be one kind of energy band in the forbidden gap described previously (4). This model cannot interpret the fact that the side band contributing to a blue emission develops in the EL spectrum of the yellow LED at low temperature [Fig. 2(b)]. It is also incapable of interpreting that there is a peak position shift (0.5 eV) over the bandgap reduction [0.07 eV (11)] with the temperature difference, which was observed in the PL spectra of the blue LED in the temperature range RT-LHeT [Fig. 3(a) and (b)]. Furthermore, a subband sometimes accompanied the main yellow band at 580 nm (2.14 eV) in the PL spectra at RT of i-layers used for fabricating yellow LED's. The intensity of this blue side band increased relative to the yellow band as temperature was lowered, so that the spectrum changed into a single blue band at LHeT. Thus, there exist two emission components in the spectra of both EL from the i-n junction and PL from the i-layer. These two components are different in their temperature dependence; the temperature dependence of each component does not change in PL and EL. These facts do not indicate that the color variation of the emission light described above is caused by a broad luminescence center such as explained previously. They clearly imply that two kinds of luminescence centers generated by doping with Zn atoms into GaN crystal are responsible for the emission color variation. It was already reported that the blue PL increases in intensity as temperature is lowered (10,

12). However, there has been no report on the observation of the two bands in the EL spectrum from one GaN LED or in the PL spectrum from one GaN semi-insulating layer. In addition, no study on temperature dependences of the two bands has been carried out. The reason that these two components have not been observed is that the samples used for that observation may be lower in Zn concentration than the samples used in this work. A model of the two luminescence centers is presented below.

The large difference between the EL and PL spectra of the blue LED at RT in the spectrum peak energy is presumed to be caused by the Zn concentration gradient near the i-n junction along the crystal growth direction. The electric potential distributions across the junction measured by Pankove (13) and Maruska *et al.* (14) change near the i-n junction, but not abruptly. This potential distribution indicates that the Zn concentration near the junction increases along the crystal growth direction. The EL occurs precisely at the junction (14, 15), *i.e.*, at the interface of the n- and i-layers. Accordingly, these facts suggest that the EL is generated at the lowest Zn concentration region of the i-layer. On the other hand, the PL emissions reflect properties of the i-layer near the surface where the Zn concentration is high. The reason that no peak energy difference between the EL and PL of the yellow LED's is observed is assumed to be that the $(Zn/Ga)_g$ is so high that the yellow luminescence center formed exists at the junction.

Luminescence of {11$\bar{2}$0} LED's.—The broader PL spectrum of the green LED, as opposed to those of the blue and yellow LED's, can be divided into two components. One of these is responsible for the blue emission, while the other contributes to the green emission (Fig. 5). At LHeT this blue component is higher in emission intensity than the green component. At RT the blue component vanished, while the other component survived. The green emission is analogous in the temperature variation of its intensity to the yellow emission; the green emission intensity is higher at RT than at lower temperatures. At lower temperatures the blue component intensity increases. Accordingly, there exist two kinds of luminescence centers, the properties of which differ, as in the case of the yellow LED.

Easier fabrication of the green LED on {1$\bar{1}$02} than {0001} substrate is assumed to be related to dependence of the Zn incorporation on the crystal surface orientation.

Luminescence center model.—There have been some discussions on blue emission peaking at 2.8 eV, *i.e.*, whether this emission is based on a conduction-band-to-acceptor transition (10) or a complex center (12). As previously described, the emission bands located in the range 445 nm (2.79 eV) to 580 nm (2.14 eV) (Fig. 2, 3, 4, and 5) are clearly influenced by Zn dopant; and it is generally thought that Zn atoms incorporated in a GaN crystal compensate native donors and form acceptors because the crystal becomes semi-insulating. Accordingly, the two luminescence centers mentioned previously are assumed to be two kinds of acceptors formed by Zn doping. One of these acceptors contributing to blue emission (acceptor I) is situated at 0.4 eV above the valence band. The other, responsible for green and yellow emissions (acceptor II), is located at a position higher than 0.8 eV above the valence band. This energy estimation is based on the bandgap (3.22 eV) of Zn-doped GaN at RT (17). The electrons at these acceptors are raised to the conduction band by photoexcitation or collisions with hot electrons (18). As a result, the holes arise at the acceptors. The radiative recombinations of these holes occur with electrons at donors or the conduction band. The holes at the acceptors are thermally excited to the valence band with increasing temperature. The density of the hole excited from acceptor I, which has an energy level lower than acceptor II with respect to the valance band, increases relatively with the decrease in temperature. Thus, the hole density at the acceptors varies according to temperature, thereby causing the electron transition probabilities from the conduction band or the donor states to the acceptors to vary. Because of this probability variation, the blue emission as a result of the transition to acceptor I is relatively higher at LNT or LHeT than RT.

The acceptors are formed in the following way. Zinc atoms in GaN crystals are first substituted for Ga, thus forming acceptor I. If the number of Zn atoms introduced to the crystal is increased, Zn atoms can occupy N-vacancy sites (16). They can also be incorporated into interstitial sites because of the crystal lattice expansion due to the large atomic radii of Zn at N-vacancies and Ga sites. Therefore, these Zn dopants are assumed to form a broad impurity band (acceptor II) in the forbidden gap. The impurity levels may be associated with other impurities, such as Cu and Fe. In our samples, Al and Si of concentrations less than 0.005 w/o were detected by spectrochemical analysis. Lower concentrations of Mg, Cu and Fe were also detected.

It is known that the EL emission peak shifts to the short wavelength side with the increase in current through the diode (7, 9). The increase in the current density induces enhancement of electron density excited from the acceptors by impact ionization. The excited electrons fill up energy states of the conduction band tail. Consequently, if all the blue, green, and yellow EL emissions are generated by electron transitions from the conduction band to acceptors I and II, the blue shift of the EL emission with the current can be explained.

Summary

In summary, the wavelength of the light emitted from the GaN LED can be controlled by varying the Zn dopant density. In the case of {0001} GaN crystals, the Zn concentration is two or more times higher for yellow LED's than for blue LED's. On the other hand, green LED's are easier to fabricate for {11$\bar{2}$0} GaN crystals than for {0001} GaN crystals. The blue emission, when compared with the green and yellow emissions, is found to be higher in relative intensity at lower temperatures than RT. All these emissions are produced by electron transitions from the conduction band to the two kinds of acceptors; one responsible for the blue emission is located 0.4 eV above the valance band, while the other contributing to the green to yellow emissions is situated at positions higher than 0.8 eV above the valence band.

Topology of Silicon Structures with Recessed SiO_2

E. Bassous,* H. N. Yu, and V. Maniscalco

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The performance and packing density of silicon integrated circuits can be increased by the use of thermally grown silicon dioxide for the dielectric isolation of the active components of the circuit and by employing fabrication procedures which yield devices with flat surfaces. Using Si_3N_4 masking, anisotropic etching of the silicon substrate, and thermal oxidation, structures were fabricated in which the SiO_2 was recessed below the original surface. Because of the lateral oxidation under the edge of the Si_3N_4 mask, a so-called bird's beak shaped structure is formed at the Si-SiO_2 and SiO_2-Si_3N_4 interfaces. Factors which influence the surface planarity due to the bird's beak formation have been studied experimentally. This investigation studies the minimization of the bird's beak by using a combination of a thick Si_3N_4 film, a thin SiO_2 pad, and a suitable thickness of recessed oxide (ROX). Uniform anisotropic etching and parallel alignment to <110> are also required to maintain dimensional control.

The use of silicon dioxide for the isolation of the active components of silicon integrated circuits offers the potential for the fabrication of circuits with increased performance and high packing density (1). The enhanced performance can be achieved by reducing the capacitance between the active regions of the circuit, while the increased packing density can be obtained by the use of high resolution lithography to reduce the spacing between circuit elements. To define patterns in the micrometer or submicrometer range, it is preferred to have the oxide used for isolation recessed into the silicon substrate to form a recessed oxide (ROX) structure whose surface is substantially coplanar with the silicon surface.

In the fabrication of MOS and bipolar devices with thermally grown recessed SiO_2 (2-10), Si_3N_4 is commonly used as the oxidation barrier. The surface of a wafer is protected in selected regions with a thin film of Si_3N_4 and the recessed oxide layer is thermally grown in the exposed areas. The volume of the thermally grown SiO_2 is about twice the volume of silicon consumed in forming the oxide. The SiO_2 film thickness is thus divided approximately equally above and below the original silicon surface, more exactly 55.7 and 44.3%, respectively, to yield a semirecessed oxide (SEMIROX) structure. To obtain a planar surface with a fully recessed oxide, part of the exposed silicon is removed prior to thermal oxidation as shown in Fig. 1.

The ideal profiles shown in Fig. 1 are not obtained in practice due to the diffusion of oxygen and the growth of SiO_2 under the edge of the Si_3N_4 film during thermal oxidation. A ridge of thermal oxide which protrudes above the ROX surface is formed around the perimeter of the Si_3N_4 mask. The profile of the oxide ridge in cross section appears as a bird's head with a prominent crest and "beak" as shown in Fig. 2. Such ridges or bumps on an otherwise planar surface which result from this dielectric isolation process are undesirable. They create abrupt topographic features on the surface

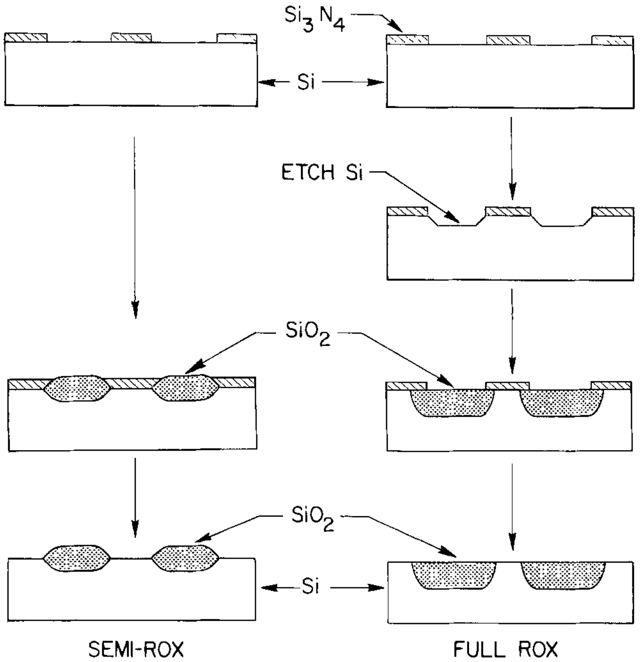

Fig. 1. Formation of semirecessed oxide (SEMIROX) and fully recessed oxide (FULL ROX) silicon structures using Si_3N_4 as an oxidation mask. Ideal profiles are shown.

which can cause breaks or discontinuities in thin films covering the steps. The bird's beak is also undesirable because it reduces the available active surface area and thus detracts from the packing density of the integrated circuit. This experimental study was therefore undertaken to determine the conditions required to fabricate fully recessed oxide structures with a high degree of surface planarity suitable for the fabrication of very high density n-channel FET memory circuits.

Experimental

For convenience of fabrication and examination of the bird's beak, silicon test structures were fabricated consisting of sets of parallel lines of thermal SiO_2 recessed into the silicon substrate. The width of the oxide lines and silicon mesa lines varied between 2 and 30 μm. The sequence of steps in the fabrication process is shown in Fig. 3 and involves a single masking step using processing conditions which are compatible with the fabrication of high density FET circuits.

Fabrication steps.—As shown in Fig. 3(a), an oxidation mask consisting of a thin film of thermal SiO_2 and a film of CVD Si_3N_4 is deposited on the surface of a (100) oriented silicon wafer, 2 Ω-cm p-type, 1.25 in. diameter. A third layer of CVD SiO_2 is also deposited to serve as an etching mask for the underlying Si_3N_4 film.

After the wafer is coated with photoresist, sets of parallel lines oriented along the <110> direction are defined and etched in the CVD SiO_2 film using buffered HF. The photoresist is removed and the Si_3N_4 film is now etched in boiling H_3PO_4 at 180°C. The oxide pad between Si_3N_4 and the Si substrate is dip etched in buffered HF to yield a structure as shown in Fig. 3(b).

The exposed silicon substrate is etched to a predetermined depth in an anisotropic etching solution containing KOH, water, and isopropanol to form sets of parallel trenches of varying width. A cross section of a single silicon mesa line is shown in Fig. 3(c).

The silicon wafer is then thermally oxidized in steam at 1000°C to form the recessed oxide (ROX) in the etched trenches as shown in Fig. 3(d).

The wafer is scribed and cleaved across the sets of parallel lines and examined by SEM.

Processing conditions.—Oxidation mask.—A single layer of Si_3N_4 deposited directly on silicon serves as an excellent oxidation mask. If the Si_3N_4 film is sufficiently thick, it gives rise to only a small bird's beak. It was experimentally determined, however, that the silicon surface becomes heavily doped with n-type impurities due to the etching of the Si_3N_4 film in H_3PO_4 at 180°C. Furthermore, oxides grown on a silicon surface which had been coated with Si_3N_4 and subjected to annealing in steam exhibited poor dielectric breakdown characteristics. Figure 4 shows *C-V* curves of MOS capacitors fabricated on Si wafers 10 Ω-cm, n-type, which were immersed in H_3PO_4 at 180°C prior to oxidation. From the change in capacitance under strong inversion, it appears that the average surface doping caused by H_3PO_4 is about 1×10^{18} cm^{-3}. The doping layer introduced by H_3PO_4 can be substantially eliminated by etching in buffered HF prior to oxidation. The doping and degradation of the silicon surface can be minimized if a thin layer of SiO_2 (oxide pad) is introduced between the Si_3N_4 film and the silicon surface.

TEM examination of silicon surfaces as shown in Fig. 5(a) and (b) clearly shows damage caused by Si_3N_4 deposition which increases with the thickness of the film. The damage is reduced significantly if a thin SiO_2 layer is introduced at the Si_3N_4-Si interface.

The SiO_2 pad is thermally grown in dry oxygen at temperatures varying between 700° and 1000°C, depending on the thickness required. The Si_3N_4 film is deposited at 800°C using a ratio of NH_3:SiH_4 of 150:1 by volume, with N_2 as a carrier gas. The deposition rate is 180 Å/min, the refractive index of the Si_3N_4 film is 2.0, and the etch rate in H_3PO_4 at 180°C is about

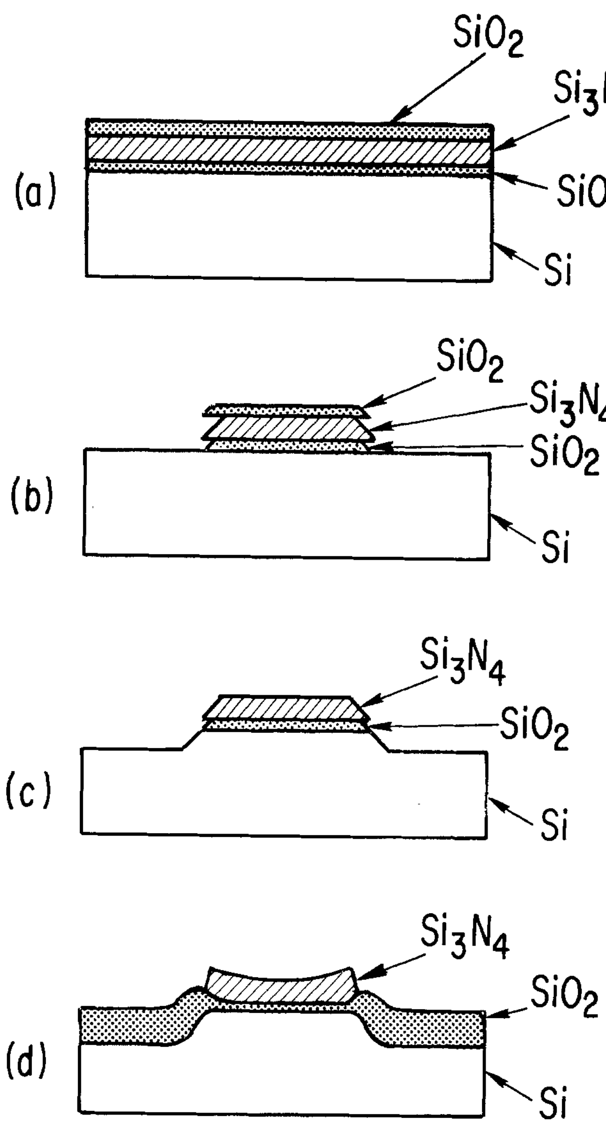

Fig. 3. Sequence of steps in the fabrication of experimental silicon recessed oxide structures.

100 Å/min. The CVD SiO_2 which serves as an etching mask for Si_3N_4 is deposited *in situ* immediately following the nitride deposition. The deposition rate is 160 Å/min at 800°C using SiH_4 and N_2O with N_2 carrier gas.

Anisotropic etching.—Anisotropic etching of (100) oriented silicon wafers followed by thermal oxidation has been proposed (11) as a method to fabricate densely packed and dielectrically isolated silicon integrated circuits. The characteristic feature of anisotropic etchants such as KOH and other strongly alkaline solutions (12-20) is that the etch rate varies widely depending on the crystallographic orientation of the silicon substrate. For the three low index crystal planes of silicon, the etch rate decreases in the order (100), (110), and (111). If holes are etched in (100) silicon with an anisotropic etching solution, the cavities formed are pyramidal in shape, bounded on four sides by the slowest etching (111) crystal planes which form an angle of 54.7° with the (100) surface plane. Rectangular openings whose sides are aligned parallel to the <110> direction, *i.e.*, parallel or perpendicular to the (110) flat of a (100) wafer, yield trenches with (111) sloping side walls and no significant undercutting. Because the profile of the cavities is highly predictable and the depth can be accurately controlled, the ROX line density can be greatly increased. Isotropic etchants, on the other hand, are not crystallographically preferential, cause excessive undercutting,

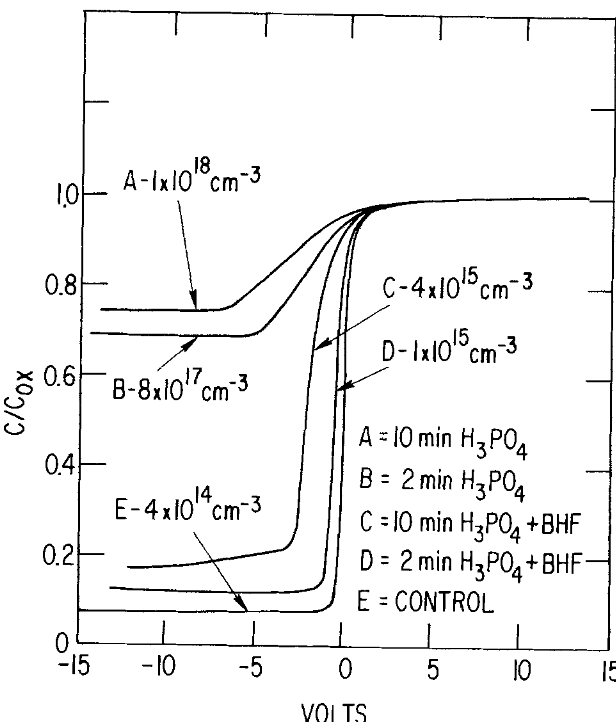

Fig. 4. Normalized capacitance-voltage characteristics of SiO_2 grown on 10-20 Ω-cm n-type Si. Wafers A and B were subjected to boiling H_3PO_4 at 180°C prior to oxidation, wafers C and D were also etched in buffered HF for 15 sec prior to oxidation. The average donor concentration at the surface shown for each curve is calculated from the ideal MOS minimum capacitance curves of A. [Ref. (23).]

and thus are not as useful in the fabrication of high density circuits using ROX technology.

The etching solution used in these experiments is a mixture of 100 ml 2M aqueous KOH and 25 ml isopropanol at 44°-45°C. The etch rate of (100) oriented silicon is about 10 Å/sec and is uniform over extended etching times.

Results and Discussion

The shape of the bird's beak and crest at the transition between the Si_3N_4 masked area and the recessed oxide region depends on the following factors: (*i*) the thickness of the SiO_2 pad between the Si_3N_4 film and the Si surface; (*ii*) the thickness of the Si_3N_4 film used as the oxidation mask; (*iii*) the thickness of silicon etched from the substrate to form the trench and the extent of the undercutting of the oxide pad which tends to decrease the width of the silicon mesa lines; (*iv*) the uniformity of the etching of the Si substrate, the profile of the etched trench, and the degree of misalignment of line patterns relative to the <110> direction of a (100) oriented wafer; and (*v*) the thickness of the thermally grown recessed oxide.

The relative size of the bird's beak and the prominence of the bird's crest are illustrated in Fig. 6. As silicon is removed by etching to enable the oxide to be recessed deeper into the substrate, the beak tends to increase in length and the crest tends to be more pronounced. In SEMIROX structures, which are formed without etching the silicon substrate, the oxide thickness is approximately equally divided above and below the original silicon surface. A step appears at the ROX-Si boundary but no crest is apparent. The absence of a protruding crest is a distinguishing feature of a SEMIROX structure as compared to a full ROX structure.

The thicknesses of the nitride layer and of the oxide pad have opposing effects on the size of the bird's beak and crest. As the nitride thickness is increased, the growth of bird's beak and crest are more effectively suppressed due to the increasing rigidity of the nitride

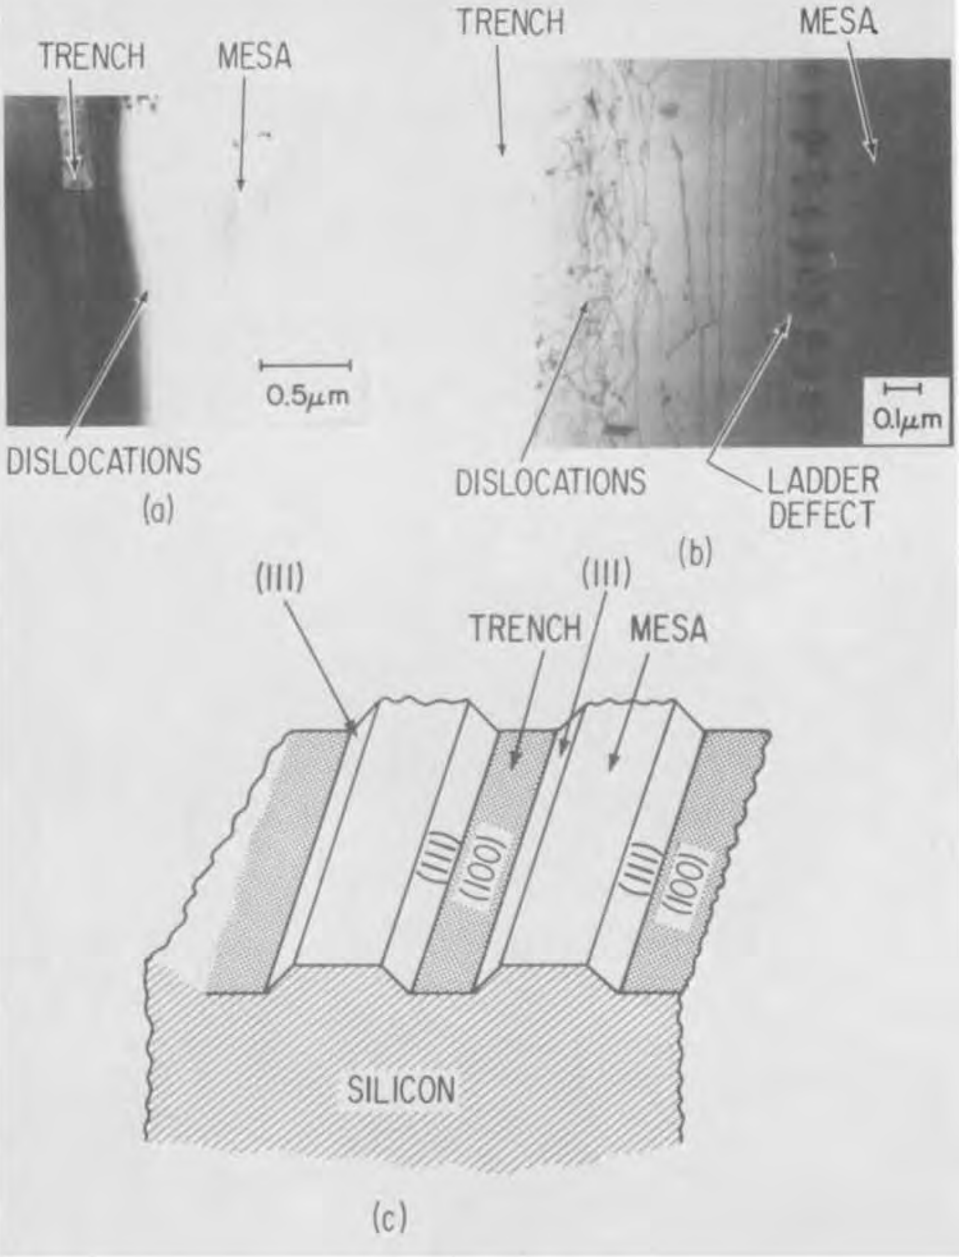

Fig. 5. Transmission electron micrographs of ROX structures showing dislocations and damage in the silicon mesa lines and (111) sidewalls. The trenches etched in silicon are 2000Å deep, and the ROX grown is 4500Å thick, SiO_2 pad 50Å under Si_3N_4. (a) Si_3N_4 2000Å, (b) Si_3N_4 4500Å.

film. Figure 7 shows SEM photomicrographs of ROX structures prepared under similar conditions with nitride films ranging between 300 and 4500Å in thickness. After the growth of the recessed oxide, the nitride film is strained and tends to bend. The curvature of the strained nitride film is apparent for thicknesses less than 2000Å. With a nitride film 300Å in thickness, it shows considerable curvature as evident in the semicylindrical shape of the 2 μm wide line in sample 3H of Fig. 7.

Although suppression of the bird's beak and crest is desirable for device fabrication, thick nitride films tend to damage the silicon and to degrade the dielectric properties of the oxide subsequently grown on it. A film of Si_3N_4 4500Å in thickness suppresses the bird's beak; however, the stress in the film is so large that it causes a visible distortion of a 0.2 mm thick wafer. Thin nitride films, on the other hand, tend to curl, giving rise to a large beak and crest after the ROX growth. Selection of parameters for a trade-off between a complete suppression of the bird's beak and the avoidance of damage to the silicon surface is necessary in the fabrication of ROX device structures.

The oxide pad thickness determines the ease of oxidation between the nitride film and the silicon substrate. As expected, the bird's beak tends to increase as the pad thickness increases, as is evident in Fig. 8 which shows SEM photomicrographs of cross sections of SEMIROX structures prepared without anisotropic etching of the silicon substrate. A similar but more pronounced increase in the bird's beak is also observed as the thickness of the recessed oxide is increased as shown in the SEM photomicrographs of Fig. 9.

Quantitative measurements of the bird's beak and crest were made from SEM photomicrographs of cross sections of ROX device samples. The results are plotted as a function of various film thicknesses in Fig. 10, 11, and 12.

In Fig. 10 the magnitude of the bird's beak and crest are plotted as a function of the thickness of silicon which is anisotropically etched from the substrate to form the recessed oxide structures. All the data points

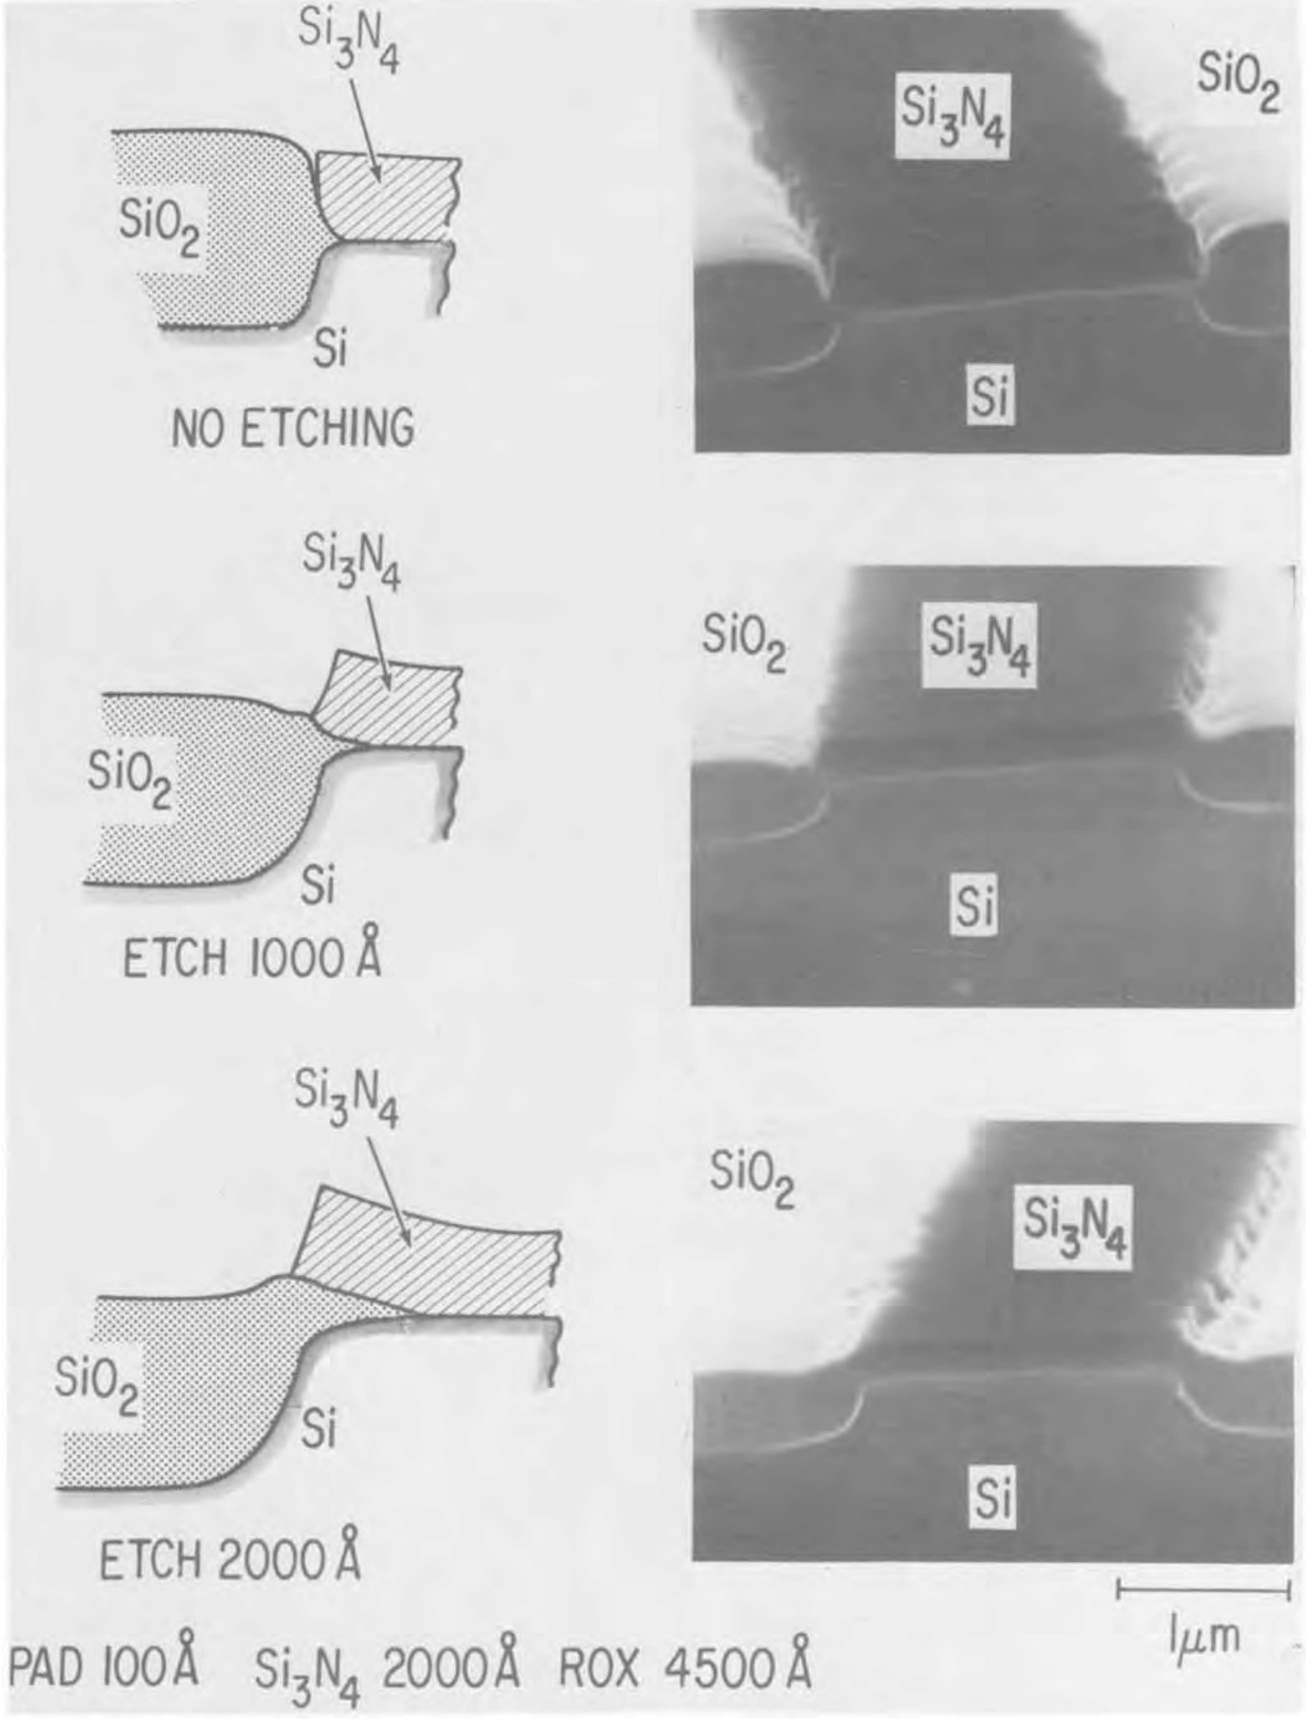

Fig. 6. Cross sections of recessed oxide structures showing the change in the shape of the bird's crest and beak as silicon is anisotropically etched from the substrate. Top: no etching of Si substrate prior to thermal oxidation to form the SEMIROX structure. Note absence of crest. Middle: 1000Å of Si etched from the substrate prior to growing the recessed oxide. shown in Fig. 10 are for samples prepared with 50Å SiO_2 pad, 1000Å Si_3N_4, and 4500Å of recessed oxide. The beak appears to be relatively insensitive to the thickness of silicon etched from the substrate in the range 0-2000Å provided there is no undercutting. The crest, however, is initially unaffected but then shows a

Fig. 7. SEM photomicrographs of ROX structures fabricated with different thicknesses of Si_3N_4. Si_3N_4 4500Å thick is rigid and gives rise to a minimum crest and no beak, whereas a film 300Å thick shows a large curvature, with a pronounced crest and a long beak (sample 3H).

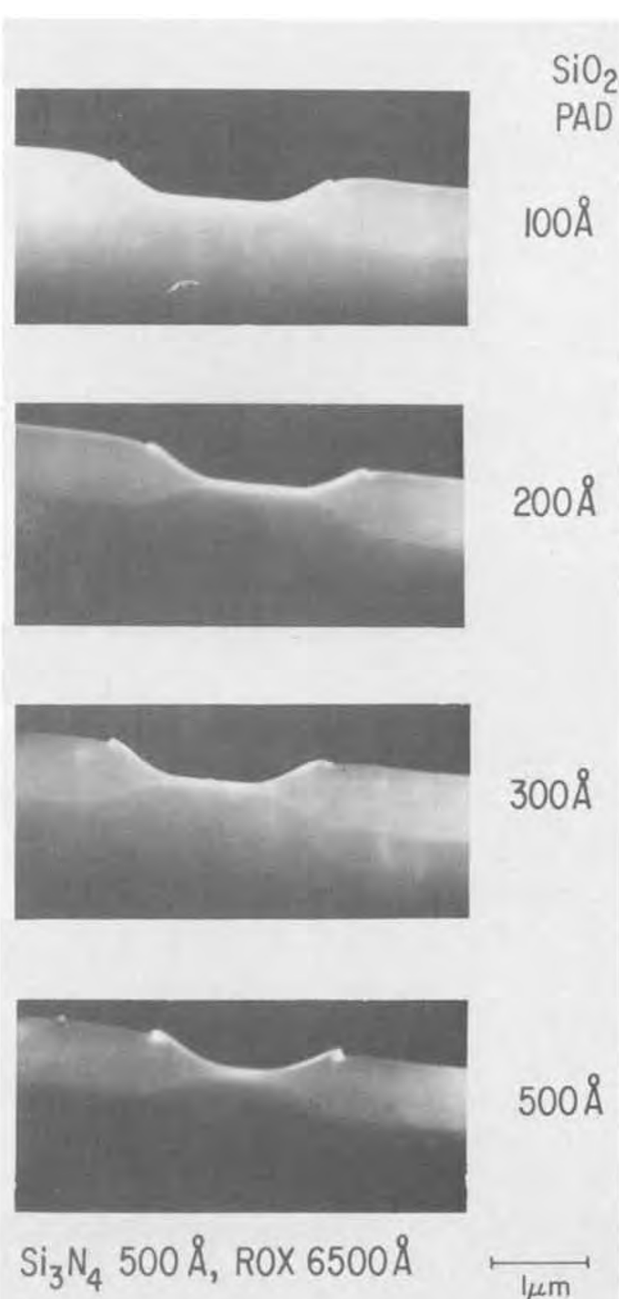

Fig. 8. SEM photomicrographs of cross sections of SEMIROX structures showing the increase in the bird's beak as the SiO_2 pad thickness is increased. The SiO_2 pad is between the Si substrate and the Si_3N_4 oxidation mask.

sharp increase between 1000 and 2000Å of etched silicon. The sample formed by etching 2000Å of Si is a fully recessed oxide structure whose surface is essentially coplanar with the surface of the substrate with the crest appearing as a raised ridge above the wafer surface. The samples prepared with less than 2000Å of etched silicon have partially recessed oxides showing little or no protruding ridges but exhibit a step with a gradual sloping sidewall where the ROX surface is raised relative to the surface of the Si substrate. Surface ridges or steps exist in both fully recessed and partially recessed oxide structures, but they differ in geometry and magnitude depending on processing conditions.

The effect of the thickness of the Si_3N_4 film on fully recessed oxide structures prepared by anisotropic etching of 2000Å of silicon followed by growing 4500Å of ROX to form a quasi-planar surface is shown in Fig. 11. The bird's head is diminished in proportion to the thickness of Si_3N_4 film used, whereas the opposite result is observed if the oxide pad is increased from 50 to 100Å. The bird's beak and crest are also equally sensitive to processing conditions particularly in regard to the extent of undercutting of the oxide pad during the fabrication of ROX structures. As shown in Fig. 4, the CVD SiO_2 used as an etching mask for Si_3N_4 is etched off prior to anisotropic etching, causing undercutting of the oxide pad by 50-100% of the thickness of the CVD SiO_2 film. To minimize the bird's beak, the CVD SiO_2 film should either be as thin as possible or be removed after the recessed oxide is formed to avoid any undercutting. Undercutting will also take place in the anisotropic etching of silicon if the line pattern is misaligned relative to the <110> directions which are parallel to and perpendicular to the (110) "flat" on a (100) oriented silicon wafer. The

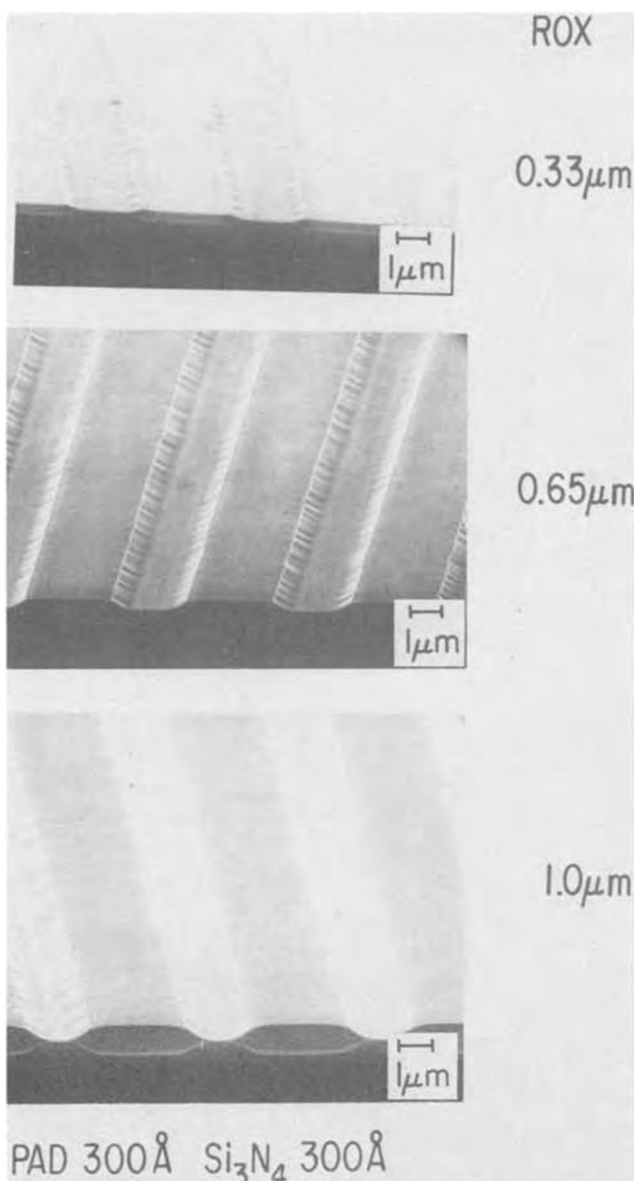

Fig. 9. SEM photomicrographs of SEMIROX structures showing the increase in the bird's beak as the thickness of the recessed oxide in the field is increased.

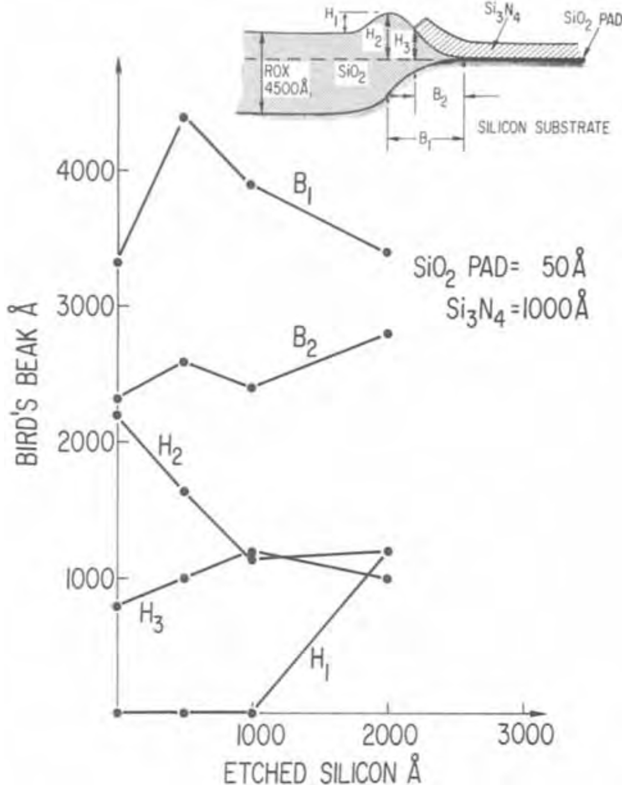

Fig. 10. Selected features of the bird's beak and crest plotted as the ordinate *vs.* the thickness of silicon removed from the substrate by anisotropic etching prior to thermally growing 4500Å of recessed oxide.

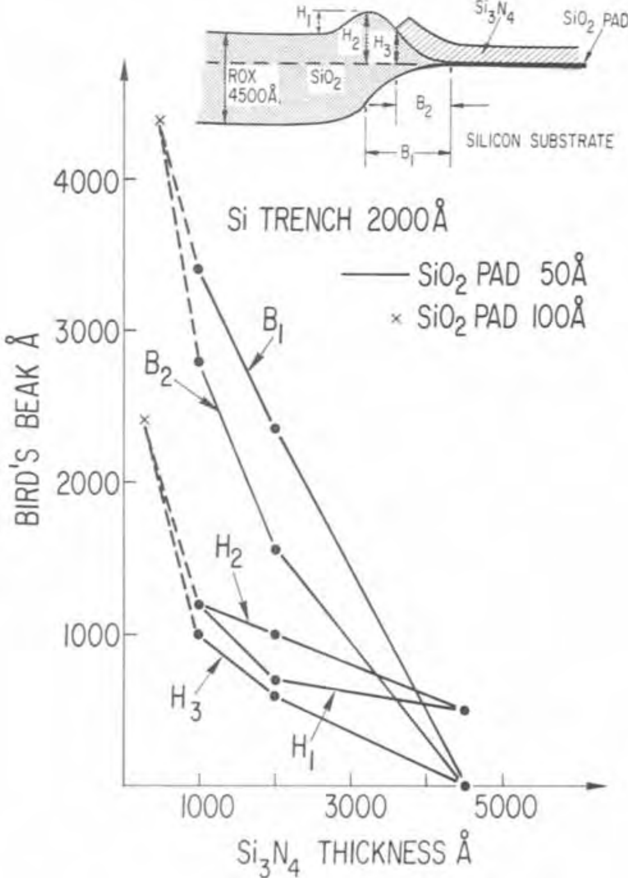

Fig. 11. Selected features of the bird's beak and crest of full ROX structures plotted as the ordinate *vs.* the thickness of Si_3N_4 used as the oxidation mask. The thickness of silicon etched anisotropically from the substrate was 2000Å prior to thermally growing 4500Å of recessed oxide.

degree of undercutting is a maximum when the line pattern makes an angle of 45° with the <110> direction and is a minimum when this angle is 0°.

The corresponding curves for semirecessed oxide structures prepared with no anisotropic etching of the substrate are shown in Fig. 12. The oxide pad thickness has little effect on the curvature of the Si_3N_4 film after growing the recessed oxide, but has some influence on the bird's beak. The data points in Fig. 12 for samples prepared with 500Å Si_3N_4 were measured from the SEM photomicrographs shown in Fig. 8. The 500Å CVD SiO_2 film used as an etch mask for the Si_3N_4 film was etched off prior to the oxidation of these samples.

Most of the experimental ROX structures were fabricated on (100) oriented silicon with trenches etched anisotropically to form a profile with (111) sidewalls slanting at an angle of 55° with the horizontal. In order to find out how a trench with vertical sidewalls affects the geometry of ROX structures (21), trenches in (110) oriented wafers were etched by aligning them parallel to one set of the (111) planes which intersect the (110) surface plane vertically. As shown in Fig. 13, properly aligned and etched trenches can be obtained with vertical sidewalls and no observable undercutting. They yield a recessed oxide whose topography displays

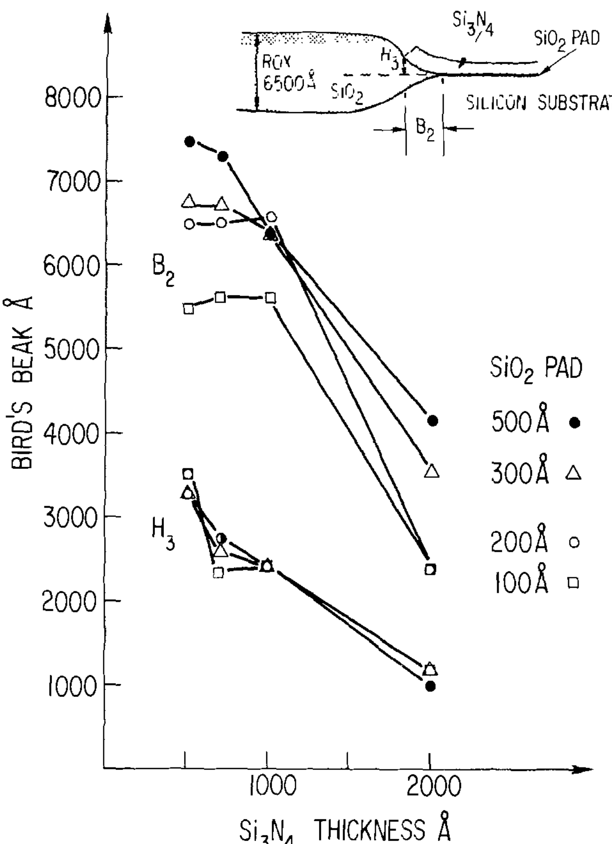

Fig. 12. Selected features of the bird's beak of SEMIROX structures plotted as the ordinate vs. the thickness of Si_3N_4 used as the oxidation mask, for different thicknesses of SiO_2 pad. The semirecessed oxide 6500Å thick is the same for all the samples.

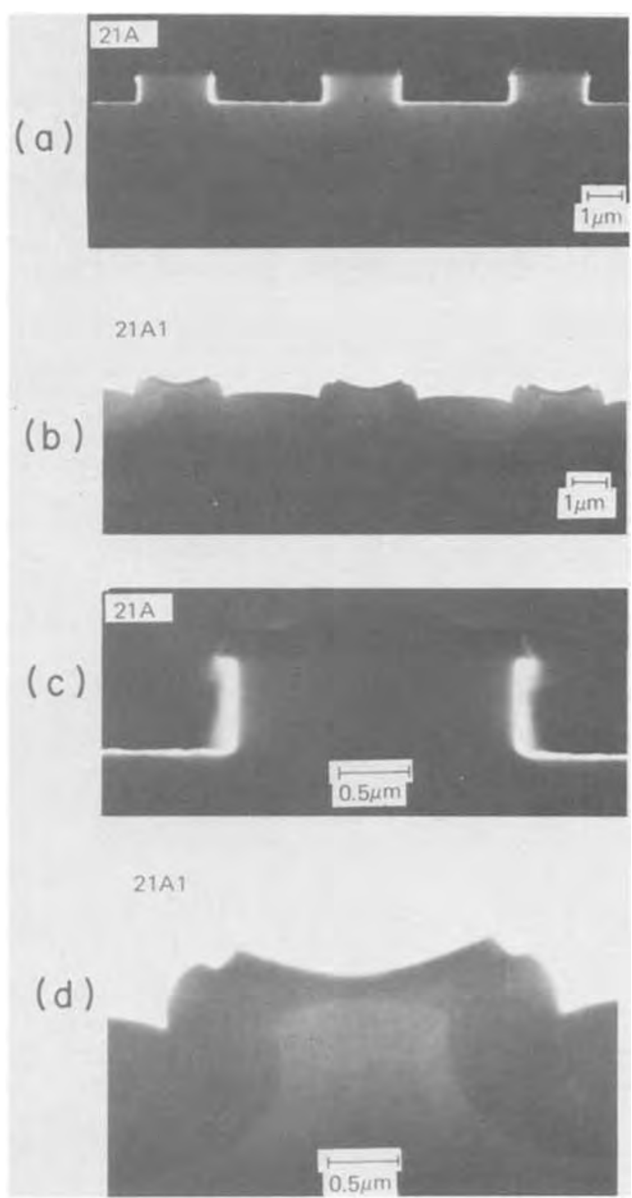

Fig. 13. SEM photomicrographs of cross sections through silicon mesa lines and ROX structures fabricated by anisotropic etching of (110) oriented Si wafers: (a) 3 mesa lines with vertical sidewalls; (b) ROX structures formed after thermal oxidation of sample (a); (c) single mesa line, showing minimum undercutting; (d) ROX structure formed after thermal oxidation of sample (c).

a prominent crest and beak conforming with the profile of the etched trench configuration. The surface planarity in this case shows no improvement over the ROX structures formed in (100) wafers.

An optimum surface planarity with minimum bird's beak was obtained using 50Å SiO_2 pad, an oxidation mask of Si_3N_4 2000Å thick, anisotropic etching of the silicon substrate to form trenches 2000Å deep, and a fully recessed field oxide 4500Å thick. These processing conditions have been successfully applied to the fabrication of an experimental 8K bit MOSFET memory chip 1.1 × 1.6 mm^2 with 1.25 μm minimum linewidth with a fully recessed field oxide (22).

Conclusions

Silicon structures with recessed oxide which are fabricated using Si_3N_4 as the oxidation mask, anisotropic etching of the silicon, and thermal oxidation deviate from surface planarity due to lateral oxidation at the edge of the Si_3N_4-masked region. The protruded structure on the surface of the wafer appears as a bird's head whose size can be predicted from the processing conditions used to fabricate the structures. The suppression of the bird's beak and crest which is highly desirable for IC fabrication can be achieved by increasing the thickness of the Si_3N_4 oxidation mask, decreasing the thickness of the SiO_2 pad between the Si substrate and the Si_3N_4 layer, and by minimizing the ROX thickness. Too thick a layer of Si_3N_4 will degrade or damage the Si surface. A compromise of 50Å SiO_2, 2000Å Si_3N_4, and ROX 4500Å grown in an anisotropically etched substrate 2000Å deep was found to be satisfactory in the fabrication of a high density 8K bit MOSFET memory chip with 1.25 μm minimum linewidth.

High Surface Concentration Zn Diffusion in GaAs

K. K. Shih*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A high surface concentration layer is essential for obtaining good ohmic contact on GaAs devices. Zn diffusion in GaAs using Zn_3As_2, $ZnAs_2$, Zn_3As_2 + $ZnAs_2$, and $ZnAs_2$ + As as diffusion sources at low temperatures (600°-730°C) has been studied. The resulting surfaces were reproducible and undamaged, and the surface concentrations were in the 10^{20} cm^{-3} range.

The use of Zn as a diffusion source to obtain a high surface concentration layer for the purpose of reducing the contact resistance of p-type GaAs has been applied to many devices, especially the GaAs-$Al_xGa_{1-x}As$ double heterojunction lasers. Most of the Zn diffusions were carried out under excess As pressure, using Zn and As compounds as diffusion sources at low temperatures to obtain thin, high surface concentration layers (1-3). In this paper, a systematic study of the diffusion processes using Zn_3As_2, $ZnAs_2$, Zn_3As_2 + $ZnAs_2$, and $ZnAs_2$ + As as diffusion sources at low temperatures (600°-730°C) was made. The resulting diffused layers had high surface concentrations ($\sim 10^{20}$ cm^{-3}) with undamaged surfaces, and reproducible results were obtained.

Phase Diagram Consideration

The diffusion of Zn in GaAs is affected by the Ga vacancy concentration, which in turn is governed by the As pressure. Hence, in order to understand the diffusion results, it is necessary to determine the phase relationship between the constituents. Under the conditions of our experiments, it is expected that the gaseous and liquid phases and the surface of the GaAs will be in mutual equilibrium. It is therefore permissible to use the equilibrium phase diagram in discussing these parts of the system (4, 5).

From a study of the Ga-As-Zn phase diagram, it was found that at low temperatures, say between 600° and 730°C, all the liquid and solid phases in the phase diagram have nearly the same boundaries at all temperatures within this range. Figure 1 is a 700°C isothermal section of the ternary phase diagram using the data of Panish (6). At this temperature there is a large region where no liquid phase exists.

* Electrochemical Society Active Member.

Key words: Zn diffusion, $ZnAs_2$, Zn_3As_2, GaAs.

Diffusion of Zn in GaAs is limited to regions that have solid GaAs in equilibrium with other phases. These are regions I-VI in Fig. 1 where regions III and V are grossly exaggerated. Since region I contains a series of liquid phases and II contains liquid phase A, the surface of GaAs may deteriorate if diffusion is held in one of these two regions. Hence, only regions III-VI where there are no liquid phases in these regions are to be considered.

The consequences for diffusion in regions III-VI can be best understood in terms of the number of degrees of freedom *F*. For an isothermal ternary system in

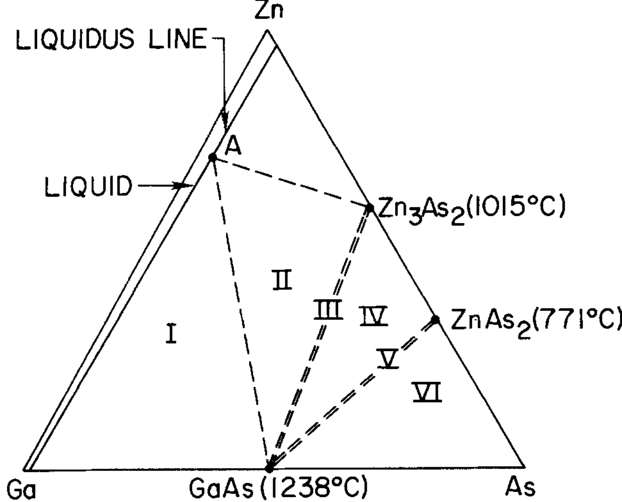

Fig. 1. The 700°C Ga-As-Zn ternary isotherm. Regions I-VI have solid GaAs in equilibrium with other phases.

contact with the vapor, the phase rule (7) specifies that $F = 3 - P$ where P is the number of condensed phases.

(*i*) Region III is a narrow region separating regions II and IV. There is no liquid phase, but there are two solid phases, GaAs and Zn_3As_2, so that $F = 1$. Hence one parameter such as the As pressure can specify the system. This is the region to be considered when Zn_3As_2 is used as a diffusion source for Zn diffusion in GaAs. The As pressure in this region can vary from the As pressure in region II to that in region IV depending on the weights of source and GaAs samples and the volume of the diffusion ampul. Therefore the control of weight and volume is required for a reproducible junction depth.

(*ii*) In region IV, there are three solid phases, GaAs, Zn_3As_2, and $ZnAs_2$, so that $F = 0$. This means that everything is fixed in this region, including the As pressure. There is a large area where there is no liquid phase. This is the region of interest when Zn_3As_2 + $ZnAs_2$ is used as a diffusion source. In this region, the result of Zn diffusion is independent of the weights of the source and GaAs samples and volume of the ampul and depends only on temperature, because a small change in the amount of material placed in the ampul will have no effect on the Zn and As vapor pressure if diffusion is done in this region. It is in this region where reproducible results with undamaged surfaces can be obtained.

(*iii*) Region V is also a narrow region similar to region III. This is the region to be considered when $ZnAs_2$ is used as a diffusion source. The As pressure can be varied from that in region IV to that in region VI, depending on the weights of the source and GaAs samples and the volume of the ampul. Therefore the control of weight and volume is also required for a reproducible junction depth.

(*iv*) Region VI can be discussed in the same manner as that of region IV. Same as region IV, reproducible results with undamaged surface can be obtained if diffusion is held in this region. This is the region of interest when $ZnAs_2$ + As is used as a diffusion source. The As pressure in this region is not only fixed but it is also the highest among all the regions.

Experimental

The diffusion sources Zn_3As_2 and $ZnAs_2$ of 6-9's quality were obtained from the Cerac Company. Three (100) oriented GaAs single crystals, which, respectively, were Sn-doped with electron concentration about 2×10^{17} cm^{-3}, Si-doped with electron concentration about 2×10^{18} cm^{-3}, and Zn-doped with hole concentration about 3×10^{18} cm^{-3}, were used as samples in each diffusion experiment. The surfaces were chemically polished to provide a damage-free surface. Cleaning prior to sealing consisted of degreasing and washing in solvents and deionized water. All three GaAs samples, each approximately ¼ in. square and about 25 mil thick, were sealed in a fused-silica ampul along with 1-4 mg of the source materials. This amount of source is in excess in order to maintain a solid phase during the diffusion. Source and samples were separated by slightly necking down the 10 mm ID silica tubing near the end to form a bubble shape. The ampul was evacuated to a pressure of about 10^{-7} Torr and sealed at a length of 3 in. Numerous diffusions were made between 600° and 730°C for times ranging from 10 min to 4 hr. After diffusion, the source end of the tube was withdrawn first and cooled rapidly to prevent deposition of the vapor on sample surfaces.

The sheet resistance of each sample was then measured using the four-point probe method. The junction depth was measured after the samples were cleaved and stained in 1:1:10 HF:H_2O_2:H_2O solution under illumination.

Results and Discussion

The smooth and shiny appearance of the wafer surfaces was retained after three diffusions. After examining the junction depth, x_j, of all three samples from the same diffusion, it was found that the values were very close to each other, indicating that the diffusion profiles are very steep. These results are consistent with that reported previously for the diffusion of Zn into GaAs under excess As pressure (4, 5). In order to demonstrate the reproducibility of these diffusion processes, some of the diffusions have been repeated several times and the same junction depth has been obtained. The junction depth *vs.* the square root of time for various diffusions using Zn_3As_2, $ZnAs_2$ or Zn_3As_2 + $ZnAs_2$, and $ZnAs_2$ + As as diffusion sources is plotted in Fig. 2, 3, and 4, respectively. The straight line relationship indicates that Fick's law (8) is obeyed.

By comparing Fig. 2, 3, and 4, it was found that at the same temperature, the junction depth was the greatest when Zn_3As_2 was used as a diffusion while the junction depth was the smallest when $ZnAs_2$ + As was used as a diffusion source. These results were expected because the As pressure was the lowest when Zn_3As_2 was used as a diffusion source and the highest when $ZnAs_2$ + As was used as a diffusion source. These results are consistent with that reported in Ref. (4) where the junction depth decreases with increasing As pressure.

It was also noted that at a given temperature the junction depth for diffusions using either $ZnAs_2$ or Zn_3As_2 + $ZnAs_2$ as diffusion sources was exactly the same. This suggests that the As pressure in the ampul for both sources was the same during our diffusion studies. From the discussion of the phase diagram in Fig. 1, it was concluded that the As pressure in the region containing Zn_3As_2 + $ZnAs_2$ is fixed at a given

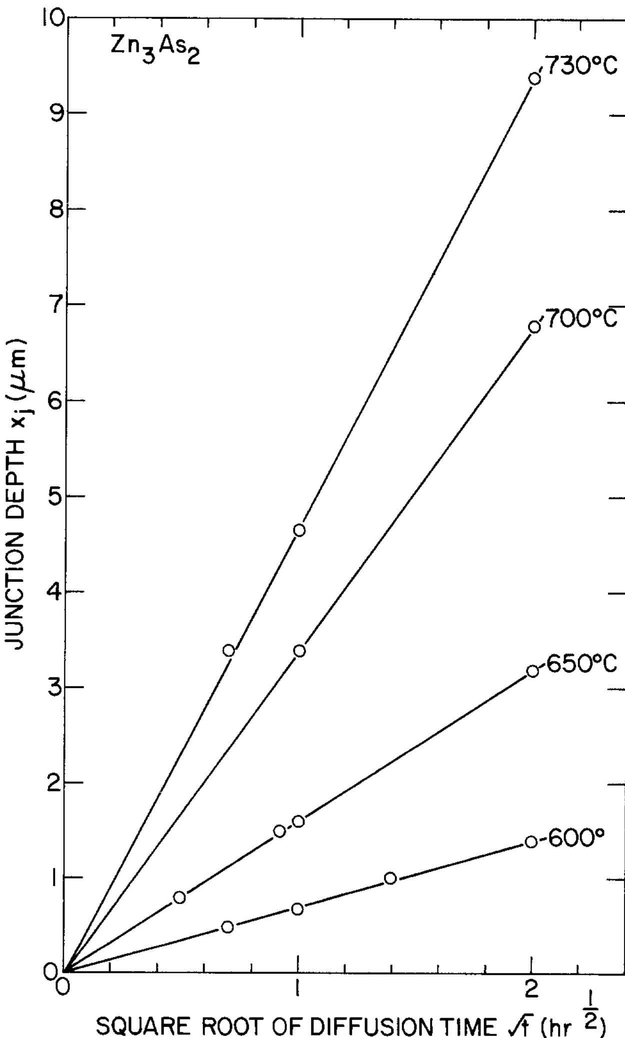

Fig. 2. The junction depth *vs.* square root of time at different temperatures (diffusion source Zn_3As_2).

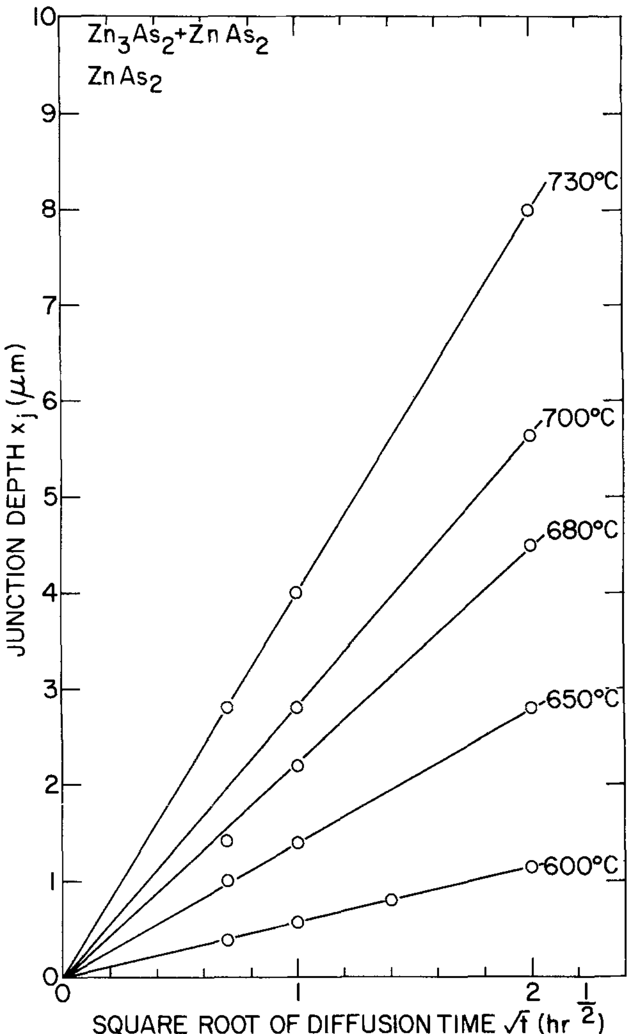

Fig. 3. The junction depth vs. square root of time at different temperatures (diffusion source $ZnAs_2$ or Zn_3As_2 + $ZnAs_2$).

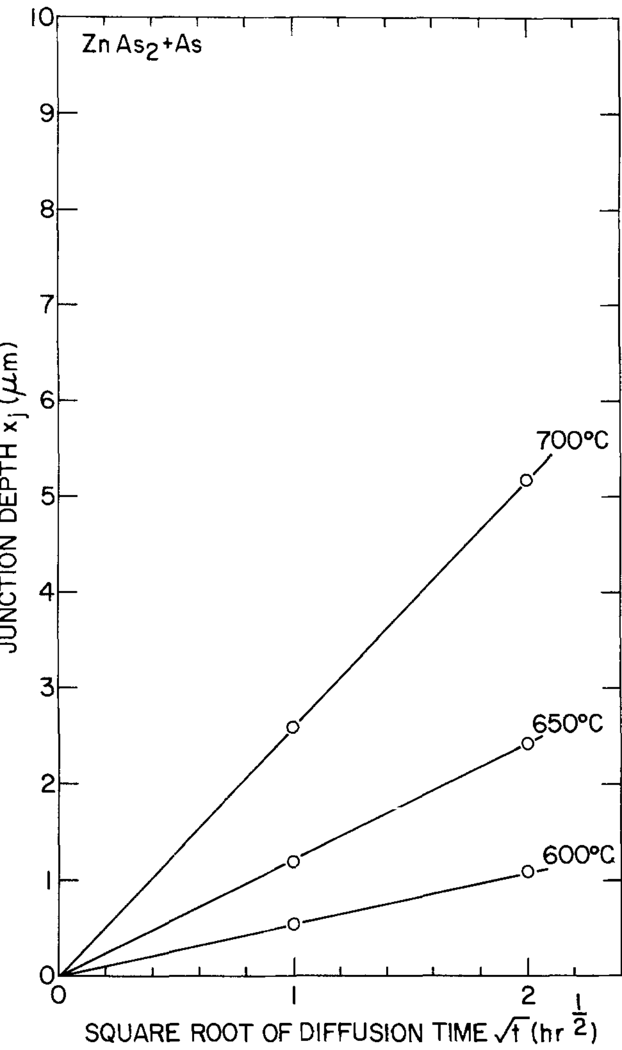

Fig. 4. The junction depth vs. square root of time at different temperatures (diffusion source $ZnAs_2$ + As).

temperature, while the As pressure in the region containing $ZnAs_2$ can be varied from that in the region containing Zn_3As_2 + $ZnAs_2$ to higher values. Since the weight of the $ZnAs_2$ source, which was about 1 mg in our diffusion case, was small in comparison with the weight of the GaAs samples, which was over 100 mg, with no extra As added in the system, the As pressure using $ZnAs_2$ as a diffusion source in our studies was always on the low side and therefore closer to the As pressure using Zn_3As_2 + $ZnAs_2$ as a diffusion source. This also applies to the Zn_3As_2 case, where the As pressure using Zn_3As_2 as a source in our diffusion studies was also on the low side and closer to the As pressure in region II.

The variation of junction depth *vs.* temperature at a given time using $ZnAs_2$ or Zn_3As_2 + $ZnAs_2$ as diffusion sources was deduced from Fig. 3 and the results are plotted in Fig. 5. The information presented in Fig. 5 is useful in predetermining the junction depth at various temperatures. The same kind of information can be deduced from Fig. 2 and 4 for the other two sources.

The sheet resistance, ρ_s, of the diffusion layers has been measured by the four-point probe method. In Fig. 6, the resistivity ρ which is the product of sheet resistance ρ_s and junction depth x_j is plotted as a function of temperature for different diffusion sources. The average conductivity $\bar{\sigma}$ of a diffused layer can be expressed as (9)

$$\bar{\sigma} = \frac{1}{\rho} = \frac{1}{\rho_s x_j} = q\mu N \quad [1]$$

where q is the electron charge, μ is the average carrier

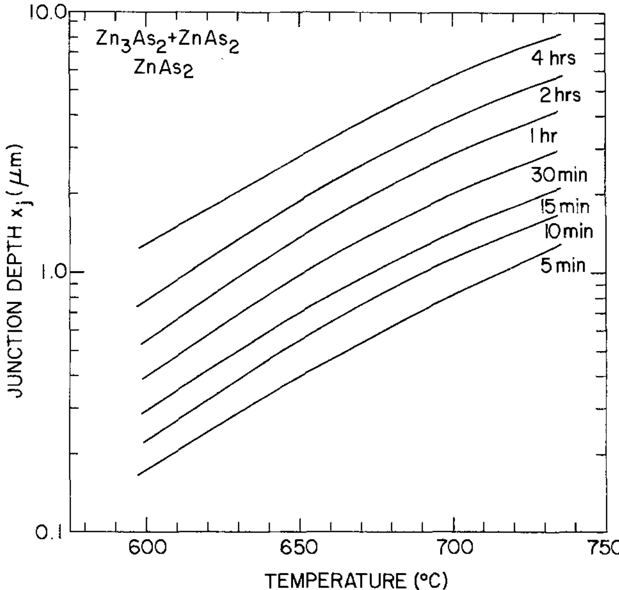

Fig. 5. The variation of junction depth with temperature at different time (diffusion source $ZnAs_2$ or Zn_3As_2 + $ZnAs_2$).

mobility, and N is the density of carriers. For high Zn diffusion with excess As pressure, the diffusion profiles are very steep so that we can assume that $N \cong \bar{C} \cong C_o$ where $\bar{C}$ is the average concentration of the diffused

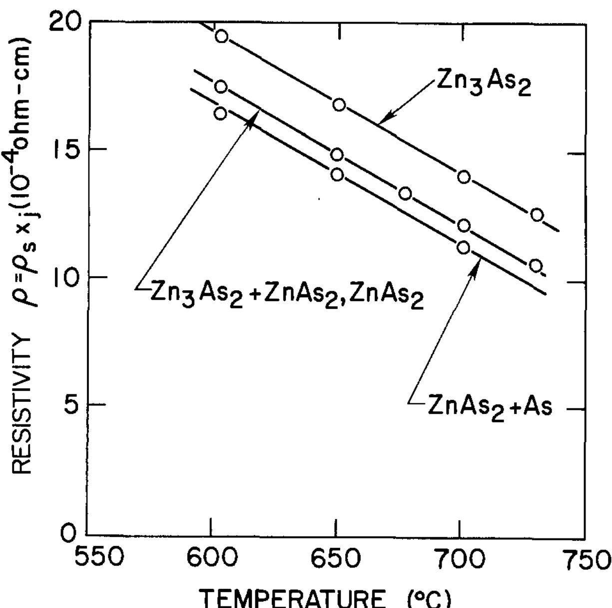

Fig. 6. Resistivity *vs.* temperature for different diffusion sources

layer and C_o is the surface carrier concentration. From Eq. [1], C_o can be approximately expressed as

$$C_o \cong \frac{1}{q\mu\rho} \quad [2]$$

For example, at 700°C with Zn_3As_2 + $ZnAs_2$ source, $\rho = 12 \times 10^{-4}$ Ω-cm (from Fig. 6), $q = 1.6 \times 10^{-19}$C, and if μ is assumed to be 25 cm^2/Vsec from Ref (10), then $C_o \cong 2.1 \times 10^{20}$ cm^{-3} which is close to the experimental value of 2.5×10^{20} cm^{-3} from Ref. (5).

The results in Fig. 6 also indicate that slightly higher surface concentrations can be obtained using $ZnAs_2$ + As as the diffusion source because of the lower resistivity values that can be obtained. At temperatures as low as 600°C, C_o in the 10^{20} cm^{-3} range can be easily obtained using any one of the four sources. Since the doping level for most devices is in the range between 10^{17} and 10^{18} cm^{-3}, the contact resistance can be reduced by orders of magnitude using these diffusions (11).

In summary, Zn diffusion in GaAs between 600° and 730°C to obtain high surface concentrations has been studied using different diffusion sources. The junction depth at different temperature and time has been determined and the surface carrier concentration can be approximately determined. This information is valuable for choosing optimum diffusion conditions not only for making good contact but also for making devices with diffusion techniques.

ABSTRACT

Cadmium stannate (Cd_2SnO_4) films of 1Ω per square sheet resistance and 85% average transmissivity (500-650 nm) have been grown by means of rf sputtering onto silica substrates. CdS-Cu_2S thin film solar cells with conversion efficiencies greater than 5% for front and rear illumination have been fabricated. The reflection of transmitted light back through the cell has increased the light generated current. Fabrication techniques are described and current-voltage and spectral response measurements are presented for frontwall and backwall modes of operation.

Solar cells fabricated on transparent substrates allow the backwall mode of operation to be utilized, whereby light is incident on the p-n junction interface through the wide gap material and absorbed in the narrow gap layer (see Fig. 1). In this investigation, the wide gap material is CdS (n-type, 2.4 eV bandgap) and the narrow gap material is Cu_2S (p-type, 1.2 eV gap). For the CdS-Cu_2S cell, a possible advantage of the backwall mode of operation is that more light is absorbed near the heterojunction than near the Cu_2S surface. If the Cu_2S layer is on the order of a minority carrier diffusion length thick, one anticipates that the backwall collection efficiency would exceed that of the frontwall mode since a larger fraction of the minority carriers are created near the junction (of course, absorption of light in the back electrode and the CdS must also be taken into account). In addition, the backwall mode could be less dependent upon the thickness and other physical characteristics of the Cu_2S layer. Instead of applying a grid pattern to the Cu_2S surface to act as the anode, as must be done for the frontwall cell, a continuous metallic layer could be used. This would have practical advantages, as well as providing a reflecting surface on the front of the cell which would increase the backwall response.

We would like to describe the fabrication of CdS-Cu_2S cells on Cd_2SnO_4-silica substrates, and measurements of the front and rear modes of operation. The major phases of research that we report here deal with the following:

(*i*) Construction of a transparent, conducting, and stable film of Cd_2SnO_4 (cadmium stannate) on a transparent substrate (silica).

(*ii*) Deposition of an adherent and pinhole-free film of CdS onto the Cd_2SnO_4.

(*iii*) Formation of a CdS-Cu_2S heterojunction resulting in a photovoltaic cell.

(*iv*) Cell electrical characterization, including diode analysis and spectral response in frontwall and backwall modes of operation

A general diagram of the cell that is to be discussed is shown in Fig. 1. The items outlined above are described below.

The Cd_2SnO_4-Silica Substrate

The transparent cadmium stannate electrodes were coated onto silica substrates (1 × 1 in. or 1 × ½ in.) by rf sputtering from a hot-pressed Cd_2SnO_4 target. During deposition the substrate surface temperature should exceed 400°C to achieve film crystallization. Polycrystalline films have the required high electrical conductivities (1); the conductivities of amorphous cadmium stannate (2) are too low for solar cell applications. Heating of the substrate surface is conveniently done by utilizing the energy of the rf plasma so that an auxiliary heater is not required.

Sputtering can be carried out either in an oxygen or argon/oxygen plasma. Best results are obtained with pure oxygen. The sputtered films are n-type semiconductors with an apparent energy gap of 2 eV. Their free electron concentration is of the order of 10^{19} cm^{-3} and the Hall mobilities reach 10 cm^2/Vsec. The x-ray spectra of these films indicate the presence of a small concentration of cadmium oxide.

The transparent electrode properties of the sputtered cadmium stannate films improve substantially if they are subjected to a short heat-treatment. After a 10 min exposure to an argon/cadmium sulfide atmosphere at 600°-700°C, the optical absorption edge shifts to 2.9 eV and the cadmium oxide phase disappears from the x-ray spectra. Simultaneously, the free electron concentrations increase to 10^{21} cm^{-3} and the Hall mobilities to approximately 30 cm^2/Vsec resulting in electrical conductivities of 6000 Ω^{-1} cm^{-1} and higher.

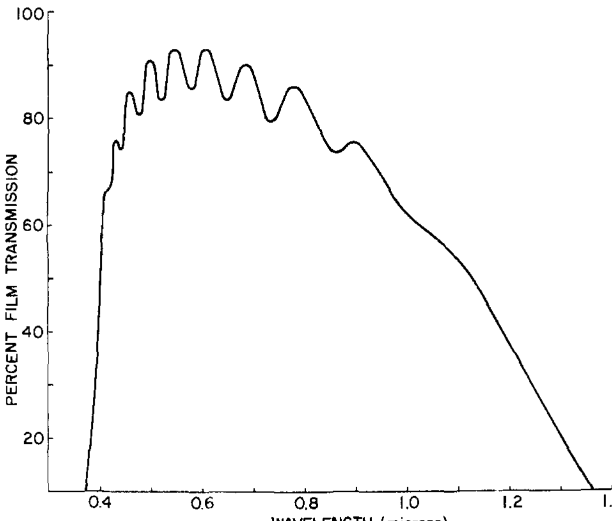

Fig. 2. Optical transmission of a sputter-coated cadmium stannate film with 1.4 Ω/square sheet resistance.

A typical example of the transparent electrode properties, which can be achieved with cadmium stannate films, is given in Fig. 2. This figure shows the optical transmission as a function of wavelength for a coating with approximately 1 Ω/square sheet resistance. Maximum film transmission occurs in a wavelength range in which the solar spectrum also has its highest intensity. The short wavelength cutoff at 350 nm is considerably below that of CdS. The backwall response of the CdS/Cu_2S cell, therefore, is not limited by the short-wavelength transmission characteristics of the cadmium stannate electrode.

Cell Fabrication

Cadmium sulfide layers (n-type, ~ 1 Ω-cm resistivity) of 20-30 μm thickness are deposited onto the Cd_2SnO_4-silica substrates using conventional thermal evaporation techniques. A graphite crucible for the CdS is used, and the deposition rate is about 2 μm/min. The substrate temperature is maintained nominally at 160°C during the deposition by means of a radiation heater, the temperature being monitored by means of a thermocouple placed against the Cd_2SnO_4 surface.

Adherence of the CdS to the Cd_2SnO_4 has proven to be excellent, with no cracking or peeling evident. The ohmic nature of the CdS-Cd_2SnO_4 contact and the bulk resistivity of CdS layers have been determined using the technique illustrated in Fig. 3. The central part of the Cd_2SnO_4 is etched away, providing a space for the CdS "resistor" deposited onto the substrate. The current-voltage characteristics are linear, with bulk resistivities of about 1 Ω-cm. In addition, bulk resistivity measurements were made using indium as the contact to the CdS (3). The bulk resistivity values found using these two techniques agree to within experimental error. The ohmic nature of the CdS-Cd_2SnO_4 contact is also verified by examination of the resulting cell current-voltage characteristics.

CdS films were examined by means of optical and scanning electron microscopes. SEM pictures of the CdS surface are shown in Fig. 4 (magnification = 3000). A grain size of about 5-10 μm is evident for the as-deposited CdS.

X-ray diffraction scans verify that the CdS film is highly ordered in the c-direction in comparison to CdS films deposited under similar conditions onto metal substrates. It is not evident that this order has any major effect on the quality of the resulting cell.

The CdS is typically etched in HCl (55%, 40°C, 3 sec) prior to formation of the Cu_2S layer. As shown in Fig. 4, the etched surface is extremely rough, due in part to preferential etching along grain boundaries. It has been found that the etch substantially reduces the

average reflectivity of the cell surface, with the resulting light generated current being increased by about 15% due to this effect.

The copper sulfide (Cu_2S) layer is formed by means of a well-known ion exchange reaction (4)

$$CdS + Cu_2Cl_2 \rightarrow Cu_2S + CdCl_2$$

resulting from immersion of the CdS and substrate in a hot (95°C) cuprous chloride solution for several seconds.

The Cu_2S thickness is 0.2-0.3 μm (depending on reaction time) as measured by Auger spectrometry accompanied by argon ion milling, by Rutherford backscattering and electrolytically. The stoichiometry factor x (in Cu_xS) has been electrolytically measured to be 1.997 ± 0.002. This is consistent with the Cu_2S resistivity values of about 0.1 Ω-cm measured on these samples (5, 6).

After formation of the Cu_2S layer, a gold-plated copper contact grid (10 × 60 lines per inch) is laminated onto the Cu_2S surface by means of epoxy under a 0.0005 in. Mylar cover. Lamination conditions are: temperature = 190°C, pressure = 100 lb/in.², time = 20 min.

Cell Electrical Characteristics

Immediately following the attachment of the grid onto the Cu_2S surface, cell current-voltage characteristics are measured. The solar simulator supplies tungsten illumination filtered by a 0.12% Cu_2SO_4 solution, and is calibrated to AM1 equivalent illumination by adjusting the short-circuit current of a CdS standard cell supplied by NASA. [Due to the fact that the filtered tungsten radiation has a larger fraction of its total power in the most spectrally sensitive region of the cell than does natural insulation, AM1 equivalent conditions correspond to an incident power density of about 58 mW/cm² (7).]

As is the case for CdS-Cu_2S cells made on metal substrates (4-8), the current-voltage characteristics significantly improve after a 16 hr heat-treatment at 130°C, at a pressure of about 400 μm. Current-voltage characteristics for a heat-treated cell are shown in Fig. 5.

Due to partial transparency of the Cu_2S layer, light can be reflected back through the cell for a second pass by means of a front surface mirror, thus enhancing response in both the front and rear modes of operation. A detailed analysis of this effect as applied to this type of cell was reported elsewhere (9). Short-circuit current values have been improved by up to 35% for some cells, although 10-15% is more typical.

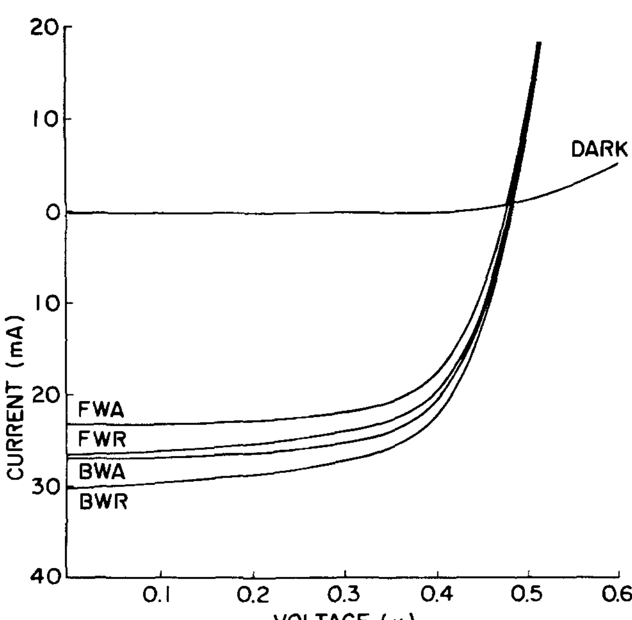

Fig. 5. Current-voltage characteristics for the four modes of cell operation.

The characteristics seen in Fig. 5 thus represent the four possible modes of operation in the light: frontwall and backwall with the cell located either on an absorbing or reflecting surface. The current density dependence on voltage under illumination can be approximated by the diode relation (for unit area)

$$J = -J_L + J_0 \left[\exp \frac{q}{nkT} (V - JR_s) - 1 \right] - \frac{V - JR_s}{R_{sh}}$$

where J_L is the light generated current density, R_s and R_{sh} are the series and shunt resistances, and n is a diode parameter. The preexponential factor J_0 is described by

$$J_0 = J_{00} \exp \left[\frac{-\phi_B}{kT} \right]$$

where J_{00} is the available reverse saturation current density. Salient parameters for a 5% efficient cell are listed in Table I.

The cell series resistance, for the current densities presently obtainable (14-18 mA/cm²), is not a serious problem. The rather low fill factors of 60-65% are due to a rounding of the I-V characteristic in the fourth quadrant believed to be due to a nonohmic grid contact resistance and not to high series or low shunt resistance values. From geometrical considerations, the 1.0Ω series resistance measured in far forward bias can be attributed to the Cd_2SnO_4 (about 0.3Ω for 1 Ω/square sheet resistance) and the CdS (the remaining 0.7Ω). A detailed analysis has been performed of the dependence of cell efficiency upon Cd_2SnO_4 thickness, for parameters pertaining to the CdS-Cu_2S cell (10). In this regard, a tradeoff must be made between series resistance (thick Cd_2SnO_4 layer desirable) and light absorption in the backwall and backwall reflection modes (thin Cd_2SnO_4 film desirable). It was found in this analysis that for cell parameters such as those listed in Table I an optimum Cd_2SnO_4 thickness is 1.0-1.3 μm, depending on exact cell parameters used, and on the Cd_2SnO_4 absorption coefficient and sheet resistance. Cd_2SnO_4 thicknesses in this range were used for the cells herein reported.

CdS-Cu_2S cells on metal substrates, made under otherwise identical conditions, exhibited efficiencies in the 5.5-6.0% range when measured under tungsten illumination (8). This was due mainly to larger fill factors (68-71%) for those cells. V_{oc} and J_{sc} values typically measured for metal and glass substrate cells are not significantly different. It should also be noted that for the 10 × 60 lpi contact grids, roughly 17% of the incident light is lost due to shading.

Spectral Response Measurements

Collection efficiencies were computed over the spectrally sensitive region of a given cell from measurements of short-circuit current and incident light flux. Samples were illuminated with wide band (~ 40 nm) light from a Bausch and Lomb monochromator, with the beam collimated to an area of approximately 0.5

Table I. Summary of key cell parameters (cell 132A)*

Mode**	V_{oc}	J_{sc}	η	FF
FWA	0.475V	14.2 mA/cm²	4.40%	65.2%
FWR	0.485	16.6	5.17	64.0
BWA	0.475	15.4	4.66	63.6
BWR	0.480	17.1	5.20	63.4

* R_s = 1.0Ω, R_{sh} = 1500Ω, ϕ = 0.88 eV, n = 1.0, J_0 (25°C) = 4.20 × 10^{-8} mA/cm², J_{00} = 8.15 × 10^7 mA/cm², cell area = 1.7 cm².

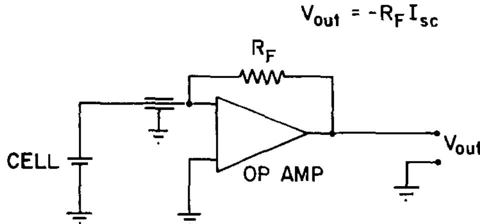

Fig. 6. Electrical circuit used for spectral response measurements

cm². The current-measuring circuit is shown in Fig. 6. Light intensity was measured by means of a Tektronix Model J16 digital photometer. The cell holder had provisions for sliding an absorbing or reflecting surface immediately behind the sample.

Figure 7 shows the spectral dependence of collection efficiency for cell 132A in the four modes of operation. Salient features of the curves are (*i*) the significant response for $\lambda \leq 500$ nm in the FW modes, (*ii*) the cutoff at $\lambda \sim 500$ nm for BW modes, and (*iii*) the sharp decrease in response beyond $\lambda = 650$ nm for all modes. Similar results were obtained for a number of cells prepared as described above.

In the FW modes, light response for $\lambda \leq 500$ nm results from minority carrier generation in and collection from both the Cu_2S and the CdS. [This is in contrast to the behavior seen in this spectral region for other thin film CdS cells. For example, Brandhorst *et al.* (11) report little spectral sensitivity for $\lambda \leq 500$ nm. These differences will be the subject of a separate communication.]

No response is detected for $\lambda \leq 500$ nm in the BW modes because of the complete absorption of light in the CdS. The decrease in response for $\lambda \geq 650$ nm is due to a quenching phenomenon that has been previously reported (11-14), whereby illumination of the CdS space charge region decreases the current collected from the Cu_2S. These effects can be removed by simultaneous illumination with shorter wavelength light, or by white light (11-14). Consequently, the collection efficiency improves considerably.

The maximum collection efficiency measured was about 0.52 at 625 nm. There are several sources of current loss that may result in this value. These include interface reflections, absorption in the Cd_2SnO_4 and CdS, and losses due to electronic processes in the cell. Examples of the latter include surface and interface recombination, and bulk recombination in the Cu_2S.

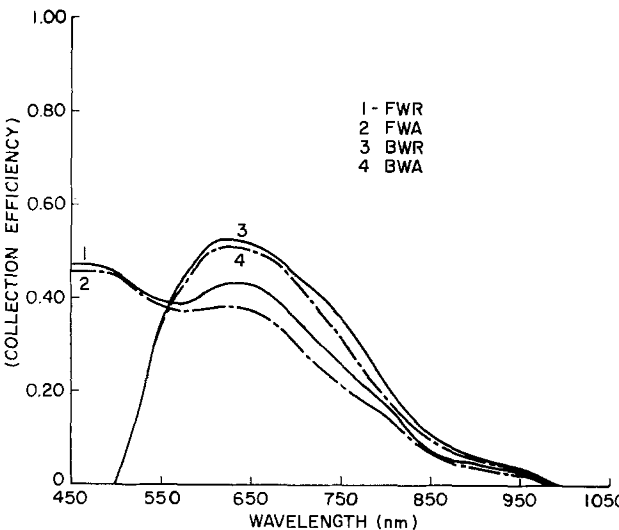

Fig. 7. Spectral dependence of collection efficiency for the four modes of cell operation.

Conclusions

We have verified that Cd_2SnO_4 films are suitable from a performance standpoint for CdS-Cu_2S solar cells operating in the backwall mode. Even though this mode does show a higher collection efficiency than the frontwall, total response is somewhat reduced due to absorption in the CdS. On the other hand, a reflecting surface was used to increase the response, due to incomplete light absorption in the Cu_2S. The use of Cd_2SnO_4 films as solar cell electrodes, and of a reflecting surface to pass transmitted light back through the cell, should also be applicable to other types of photovoltaic devices.

Four-Point Probe Correction Factors for Use in Measuring Large Diameter Doped Semiconductor Wafers

David S. Perloff

Signetics Corporation, Research and Development Laboratory, Sunnyvale, California 94086

ABSTRACT

Conformal mapping techniques are employed to determine geometrical correction factors for the general case of an in-line four-point probe positioned on a thin circular sample. Simplified expressions are also obtained which relate the correction factor to a single dimensionless quantity when the probe separation distance is a small fraction ($\lesssim$ 10%) of the wafer radius. Experimental results are presented which confirm the validity of the theoretical correction factors and demonstrate the importance of accounting for geometric effects when presenting data in the form of iso-sheet resistance contour maps.

The homogeneity of doped semiconductor wafers is commonly determined by measuring the sheet resistance ρ_s at a number of points on the wafer using the in-line four-point probe (FPP) described by Valdes (1). If the probe separation is at least twice the thickness of the doped layer, ρ_s will be given by the expression

$$\rho_s = k\frac{\Delta V}{I} = kR \ (\Omega/\square) \qquad [1]$$

where k is a correction factor which in general depends on the location of the FPP and the shape of the sample, I is a current through two of the probes, ΔV is the potential difference measured between the remaining two probes, and the resistance R is defined as $\Delta V/I$ (2). Ordinarily, the outer probes are chosen to carry current and the inner probes to measure voltage since, for an FPP having equal separations between the probe needles, this assignment results in the largest value of ΔV (3).

Logan (4) has shown that a circular sample doped on both sides should behave as if its front surface were part of a continuous infinite sheet for which the correction factor is a constant value, independent of the location of the FPP. (For an in-line FPP having equal separations between the probe needles, $k = \pi/\ln 2 = 4.532$.) If however, the sample is doped on one side only, as for example in the case of ion implanted wafers, one must take into account the orientation and position of the probe array when employing Eq. [1] (5, 6).

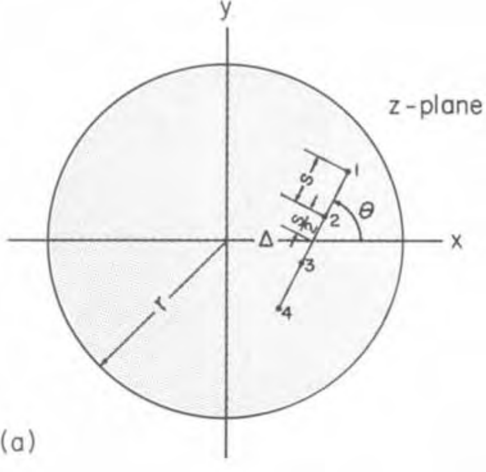
The most common orientation of the probe array on a circular sample is either perpendicular to or along the wafer radius. Correction factors for these particular cases were derived by Swartzendruber (7) and Logan (4) and tabulated by the National Bureau of Standards (8). In recent years, wafer probing equipment has become available which makes it possible to automate sheet resistance measurements, as described by Crossley and Ham (9). In order, however, to employ such equipment for FPP sheet resistance measurements, it is necessary to account for the varying orientation of the FPP with respect to the wafer radius. This paper provides a general solution for the in-line FPP on a thin circular sample and supplies experimental data which confirm its validity. Examples of iso-sheet resistance topographs are presented which illustrate the importance of accounting for geometric effects. For the case of manual wafer probing, in which the positioning of the FPP is generally imprecise, simplified expressions are derived which may be used to estimate correction factors when the probe separation is a small fraction ($\lesssim$ 10%) of the wafer radius.

Key words: contour map, silicon, sheet resistance, wafer probing.

Correction Factors for Thin Circular Samples

General case.—The general case of an in-line FPP oriented arbitrarily with respect to the radius of a thin circular sample [Fig. 1(a)] is treated in Appendix A using conformal mapping techniques. The cases dealt with by Logan (4) and Swartzendruber (7) correspond, respectively, to setting $\theta = 0$ and $\pi/2$.

Frequently, one is concerned with the relative variation of ρ_s over the semiconductor wafer. For a uniformly doped wafer, k is a maximum (since ΔV is a minimum) when the FPP is located at the center of the wafer. It is thus convenient to employ this location as a reference point. Smits (2) has shown that the correction factor for an FPP (probe separation s) located



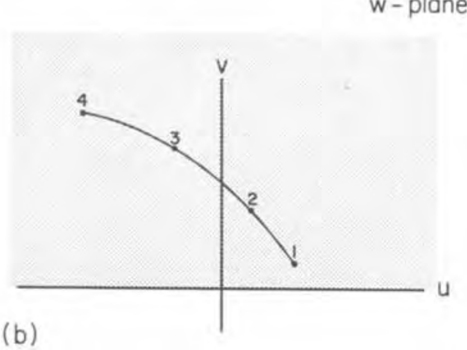


Fig. 1. Coordinate system for an in-line four-point probe array on a circular sample (a). The interior of the circle in the z-plane is conformally mapped into the upper half of the w-plane (b) to facilitate determination of the potential distribution.

at the center of a wafer of radius r is given by the expression

$$k^* = \frac{\pi}{\ln 2} \cdot \frac{1}{1 + \eta} \qquad [2]$$

where

$$\eta = \frac{\ln \left[\dfrac{1 + 3\left(\dfrac{s}{2r}\right)^2}{1 - 3\left(\dfrac{s}{2r}\right)^2} \right]}{\ln 2} \qquad [3]$$

When the FPP is displaced a distance Δ from the center of the wafer (or, equivalently, a distance $a = r - \Delta$ from the edge of the wafer), the value of k will decrease by the fractional amount

$$\delta_k = \frac{k - k^*}{k^*} \qquad [4]$$

The relationship between the dimensionless parameters a/r and s/r as a function of $|\delta_k|$ is shown in Fig. 2 for the FPP positioned perpendicular to the wafer radius and in Fig. 3 for the FPP positioned along the wafer radius. The solid lines represent the exact solution, obtained by iteration of the general expressions of Appendix A. The broken lines represent the approximate solution for k discussed in the following section.

Figures 2 and 3 enable one to determine, for $\theta = \pi/2$ and $\theta = 0$, the location of the FPP at which the measured resistance $R(\pi/2)$ or $R(0)$ exceeds the resistance at the center of the wafer R^* by some fixed percentage. As an example, consider the case of a 62.5 mil FPP used to measure the sheet resistance of a 3 in. diameter wafer ($s/r = 0.0625/1.500 = 0.0417$) and suppose one wishes to determine the value of a for which $R(\pi/2)/R^* = k^*/k(\pi/2) = 1.01$. According to Fig. 2, $k(\pi/2)$ is 1% lower in value than k^* (or, equivalently, $R(\pi/2)$ is 1% greater in value than R^*) when $a/r \simeq 0.3$, *i.e.*, when $a \simeq 0.45$ in. Examination of Fig. 2 and 3 shows that k decreases dramatically as the FPP approaches the edge of the wafer ($a/r \rightarrow 0$), and that the magnitude of $k(0)$ is always smaller than that of $k(\pi/2)$.

Large wafer approximation.—In the majority of practical applications involving silicon wafers, $s/r \leq$

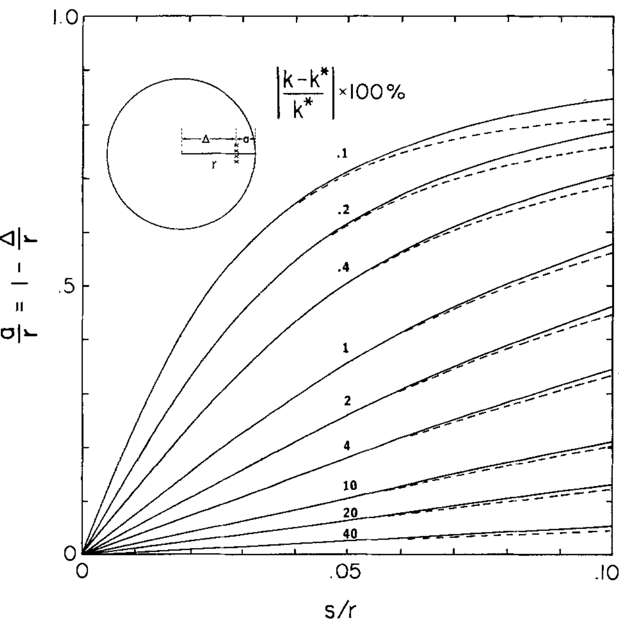

Fig. 2. Plot of a/r vs. s/r for an in-line four-point probe oriented perpendicular to the radius of a thin circular sample, for various values of the parameter $|\delta_k|$. The solid lines represent a solution of the exact equations of Appendix A, while the broken lines represent the approximate solution given in Eq. [7].

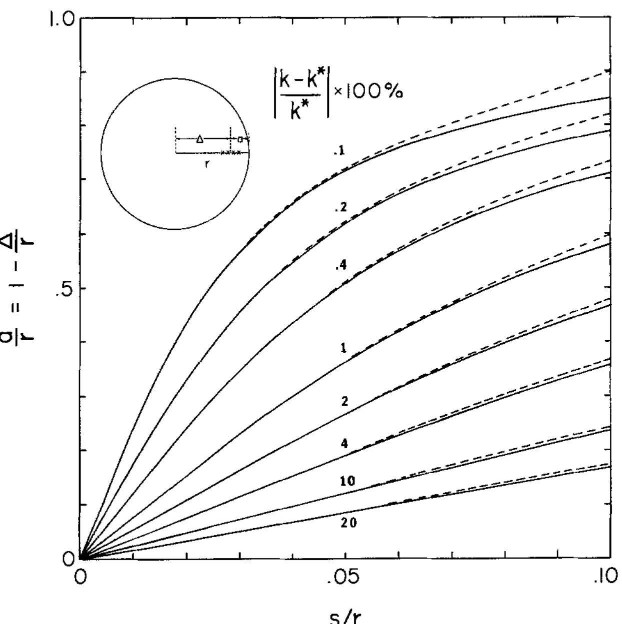

Fig. 3. Plot of a/r vs. s/r for an in-line four-point probe oriented along the radius of a thin circular sample, for various values of the parameter $|\delta_k|$. The solid lines represent a solution of the exact equations of Appendix A, while the broken lines represent the approximate solution given in Equation [8].

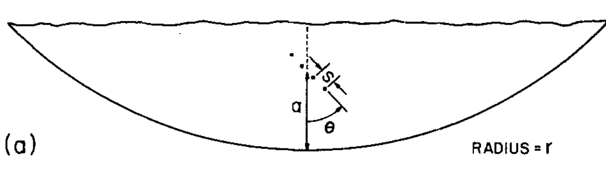
0.0625 (assuming $s \leq 62.5$ mil and $r \geq 1.0$ in.). When the probe separation is small compared to the radius of the sample, the expressions derived in Appendix A may be simplified considerably. The analysis of Appendix B shows that, for $s/r << 1$, an arbitrarily oriented FPP (probe separation s) located a distance a from the nonconducting edge of a thin circular sample [Fig. 4(a)] will have the same correction factor as a similarly oriented FPP (probe separation $s' = s/(1 - a/2r)$) located a distance a from the nonconducting edge of a thin semi-infinite sample [Fig. 4(b)]. When the FPP is oriented perpendicular to the wafer radius Eq. [B-11] reduces to the expression

$$k\left(\frac{\pi}{2}\right) \approx \frac{\pi}{\ln 2 + \dfrac{1}{2} \ln \left[\dfrac{(a/s')^2 + 1}{(a/s')^2 + \dfrac{1}{4}} \right]} \qquad [5]$$

Similarly, when the FPP is positioned along the wafer radius



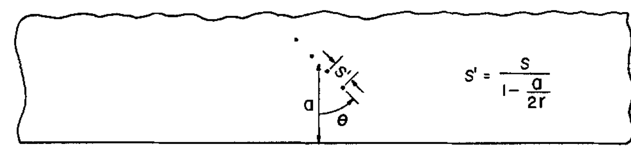


Fig. 4. An arbitrarily oriented four-point probe (probe separation s) located at a distance a from the nonconducting edge of a thin circular sample of radius r (a) is equivalent, in the limit $s << r$, to a similarly oriented four-point probe (probe separation s') located a distance a from the nonconducting edge of a thin semi-infinite sample (b).

$$k(0) \approx \frac{\pi}{\ln 2 + \frac{1}{2} \ln \left[\frac{(a/s')^2 - \frac{1}{4}}{(a/s')^2 - 1} \right]} \qquad [6]$$

Eq. [5] and [6] may be rearranged to yield closed expressions relating a/r and s/r when $s << r$

$$\frac{a}{r} \approx 1 - \sqrt{1 - 2\frac{s}{r}\sqrt{\frac{4^{\lambda-1} - 1}{1 - 4^{\lambda}}}} \left(\theta = \frac{\pi}{2} \right) \qquad [7]$$

and

$$\frac{a}{r} \approx 1 - \sqrt{1 - \frac{s}{r}\sqrt{\frac{1 - 4^{\lambda+1}}{1 - 4^{\lambda}}}} \quad (\theta = 0) \qquad [8]$$

where

$$\lambda = \frac{\eta + |\delta_k|}{1 - |\delta_k|} \qquad [9]$$

Equations [7] and [8] are represented by the broken lines in Fig. 2 and 3, respectively. The agreement with the exact solution (solid lines) is seen to be excellent for $s/r \sim 0.05$ but still satisfactory for $s/r \sim 0.10$. As an example, again consider the case of a 62.5 mil FPP used to measure the sheet resistance of a 3 in. diameter wafer. Substituting $s/r = 0.0417$ in Eq. [3], one has that $\eta = 3.757 \times 10^{-3}$. Taking $|\delta_k(\pi/2)| = 0.01$, one finds using Eq. [9] that $\lambda = 0.01390$. For these values of λ and s/r, Eq. [7] yields the result that $a/r \approx 0.3041$. This value compares favorably with the actual value of 0.3047, obtained by iterative solution of the expressions in Appendix A, and the value of 0.3 graphically determined in the preceding section from Fig. 2.

Geometry independent case.—Rymaszewski (3) has shown that the method employed by van der Pauw (10) for determining the sheet resistance of peripherally contacted, arbitrarily shaped laminar samples may be applied, under certain circumstances, to FPP measurements on the interior of such samples. For a circular geometry, the requirements specified by Rymaszewski are satisfied only for the case of an in-line FPP oriented along a sample radius. As in the case of van der Pauw patterns, ρ_s is determined by measuring the resistance associated with each of two independent current/voltage configurations. Employing the configurations defined in Table I, one has that

$$k'(0) = \frac{\rho_s}{R_a(0)} = \frac{\pi}{\ln 2} g(\xi) \qquad [10]$$

where

$$\xi = R_a(0)/R_c(0) \qquad [11]$$

$$g(\xi) = (1 + 1/\xi) f(\xi) \qquad [12]$$

and the function $f(\xi)$ satisfies the transcendental relation derived by van der Pauw

$$\frac{\xi - 1}{\xi + 1} = \frac{\cosh^{-1}\left\{ \frac{1}{2} \exp(\ln 2/f) \right\}}{\ln 2/f} \qquad [13]$$

The symbol $k'(0)$ has been introduced in Eq. [10] to identify the geometry- and sheet resistance-independent correction factor empirically determined by the method of Rymaszewski. The symbol k will continue to be used to identify the correction factor calculated in terms of the geometric parameters r, θ, and Δ.

Table I. Possible current/voltage configurations for an in-line four-point probe array. The probe numbering convention is shown in Fig. 1(a)

Configuration	Current (or voltage)	Voltage (or current)
A	(1,4)	(2,3)
B	(1,3)	(2,4)
C	(1,2)	(4,3)

Configurations A, B, and C are related through the expression

$$R_c = R_a - R_b \qquad [14]$$

It may be shown that $0.977 \leq R_a/R_b \leq 1.262$ for $0 \leq s/r \leq 3/2$, so that the resistances measured in configurations A and B are comparable in magnitude. In contrast, $4.819 \leq R_a/R_c \leq 42.96$ for $0 \leq s/r \leq 3/2$. It may thus be convenient, when carrying out actual measurements, to determine R_c by measuring R_a and R_b and employ Eq. [14]. This approach is utilized in the example given in the following section.

Experimental Results

Position dependence.—In order to verify the derivation of Appendix A, FPP measurements were carried out at a number of locations along the radius of a 3-in. diam boron-implanted (5×10^{14} cm^{-2}, 70 keV) 10 Ω-cm n-type silicon wafer annealed to full electrical activity (950°C, 30 min, dry N_2). The measurement current I was provided by a Keithley 225 constant (±0.005% stability) current supply; the potential ΔV was measured with a resolution of 10 μV by a Nonlinear Systems Corporation Model MX-1 digital voltmeter. The polarity of the current supply was reversed and readings of ΔV averaged to eliminate small offset voltages associated with thermoelectric effects. Table II shows results of measurements made along a radius of this wafer using a precision FPP (11) ($s = 25$ mil) in conjunction with a conventional x-y wafer probing apparatus capable of stepping in 1-mil increments. With the FPP oriented along the wafer radius, the resistance was measured in configurations A and B (Table I) in order to obtain the values identified by $R_a(0)$ and $R_b(0)$ in Table II. Equations [10]-[14] were then employed to compute the geometry-independent correction factor $k'(0)$. After rotating the wafer 90° to orient the FPP perpendicular to the wafer radius, values of $R_a(\pi/2)$ were measured and used to compute the correction factor from the formula

$$k''(\pi/2) = \frac{\rho_s}{R_a(\pi/2)} = k'(0) \frac{R_a(0)}{R_a(\pi/2)} \qquad [15]$$

[The symbol $k''(\pi/2)$ is intended to indicate that this correction factor is computed using results for $\theta = 0$.]

According to Table II, the values of $k(0)$ and $k(\pi/2)$ obtained from the expressions given in Appendix A are in excellent agreement with the empirically determined values $k'(0)$ and $k''(\pi/2)$. Because the minimum practical distance of approach to the edge of the wafer was 0.04 in. for $\theta = 0$, the values of $k''(\pi/2)$ for $a \leq$ 0.03-in. are based on an estimate of ρ_s obtained from the average of the values measured at $a = 0.04$ and 0.05 in. For this reason, and the fact that there may

Table II. Results of four-point probe measurements made along the radius of a 3 in. diameter doped silicon wafer. The correction factors k' and k'' are determined empirically; the correction factor k is computed using the expressions derived in Appendix A ($s = 0.025$ in, $r = 1.50$ in.).

* Assuming $\rho_s = 207.4$ Ω/□.

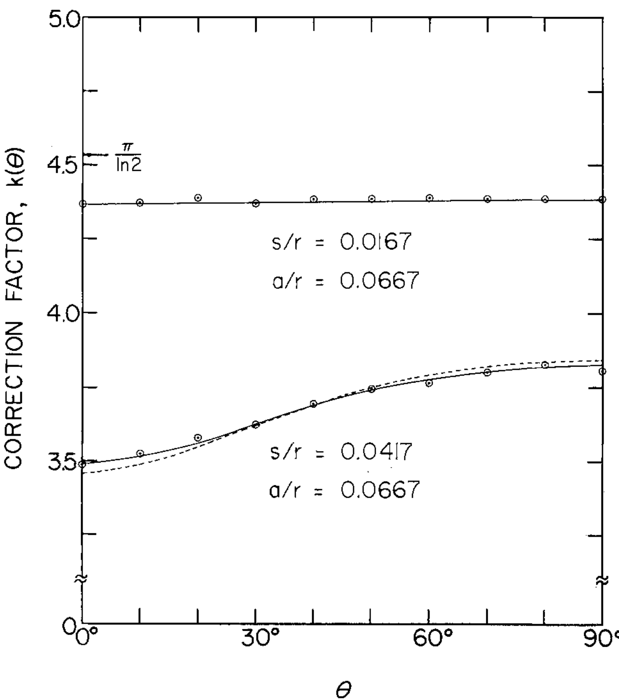

Fig. 5. Calculated (solid lines) and experimental values (open circles) for k as a function of angle of orientation with respect to the radius of a 3 in. diameter doped circular sample. The broken line represents an approximate solution which is appropriate in the limit $s/r << 1$.

have been small errors in specifying the location of the FPP, the agreement between $k''(\pi/2)$ and $k(\pi/2)$ is somewhat poorer for $a \leq 0.02$ in. than for the larger values of a in Table II.

Orientation dependence.—The orientation dependence of the correction factor was examined with the FPP oriented at angles between 0 and 90°, in 10° increments, at a distance $a = 0.100$ in. from the edge of the implanted wafer described in the previous section. Data are shown in Fig. 5 for $s/r = 0.0167$ ($s = 25$ mil) and $s/r = 0.0417$ ($s = 62.5$ mil). The experimental points were computed in the manner described above, according to the more general formula

$$k''(\theta) = \frac{\rho_s}{R_a(\theta)} = k'(0)\frac{R_a(0)}{R_a(\theta)} \quad [16]$$

In this case, a group of values $R_a(0)$, $R_b(0)$, and $R_a(\theta)$ was obtained at each of 10 different locations on the wafer, since the equipment employed permitted rotational movement of the wafer but not of the FPP assembly. The solid curves of Fig. 5 represent the exact solution for $k(\theta)$, using the expressions derived in Appendix A. The broken line for $s/r = 0.0417$ represents the approximate solution of Eq. [B-11]. (For $s/r = 0.0167$, the exact and approximate solutions are essentially identical.)

These results show the $s = 25$ mil FPP is almost completely insensitive ($k(\pi/2)/k(0) = 4.3794/4.3683 = 1.0025$) to angular variations within 0.1 in. of the edge of a 3 in. diameter wafer. In contrast, the correction factor for the 62.5 mil FPP is much more sensitive to angular variations ($k(\pi/2)/k(0) = 3.8241/3.4948 = 1.0942$) at the same distance from the edge of the wafer.

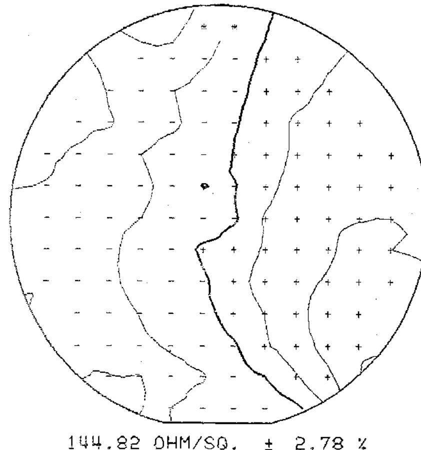
The angular independence of the 25 mil FPP is an example of a limiting case for which the parameter $(a/s')^2 >> 1$. Under these circumstances, it is easily shown that Eq. [B-11] reduces to

$$k \rightarrow \frac{\pi}{\ln 2 + \frac{1}{2}\ln\left\{1 + \frac{3}{4}\left(\frac{s'}{a}\right)^2\right\}} \quad [17]$$

a result which is independent of θ. For $a = 0.100$ in., $s = 0.025$ in., and $r = 1.5$ in., $a/s' = 4.14$ and hence $(a/s')^2 = 17.1$. From Eq. [17], $k \rightarrow 4.3778$, a value which is bracketed by the exact values $k(\pi/2) = 4.3794$ and $k(0) = 4.3683$.

Wafer mapping.—Results are presented in this section for a boron-implanted (5×10^{14} cm^{-2}, 155 keV) 3 in. diameter n-type silicon wafer annealed to full electrical activity (950°C, 30 min, dry N_2) which demonstrates the importance of correction factors when using the FPP for automated wafer testing. Resistance measurements were carried out at 118 uniformly distributed test sites using the equipment and procedure described above. Data were automatically recorded and subsequently analyzed by means of a Digital Equipment Corporation PDP 11 computing system equipped with program and disk drives, tape reader, and terminal. An iso-sheet resistance contour map was generated for each of the conditions to be described below. This method of presenting data has been found to be a highly effective means of exhibiting the spatial homogeneity not only of impurity distributions but, for example, of the thickness of the various insulating layers used to fabricate devices in silicon wafers (12).

Figure 6 and 7 are computer-drawn iso-sheet resistance topographs for, respectively, $s = 25$ mil and $s = 62.5$ mil FPP assemblies (11). The heavy contour line represents the mean sheet resistance $\bar{\rho}_s$. The lighter contour lines represent values of ρ_s which differ from $\bar{\rho}_s$ in increments of 1%. The symbol $+(-)$ identifies the location of an experimental point whose value is



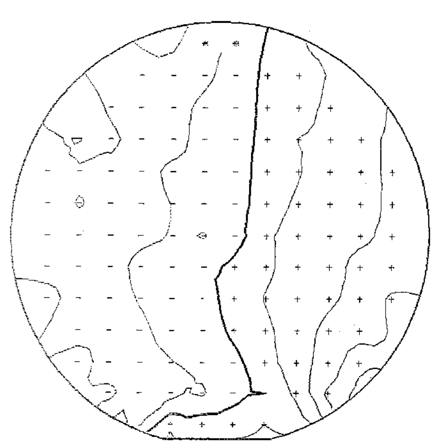


Fig. 6. Iso-sheet resistance topographs for a p-type implanted layer. In (a) k is computed as a function of position and orientation of the probe array, whereas in (b) k is assumed constant and equal to 4.532 over the entire wafer. ($r = 1.5$ in., $s = 25$ mil)

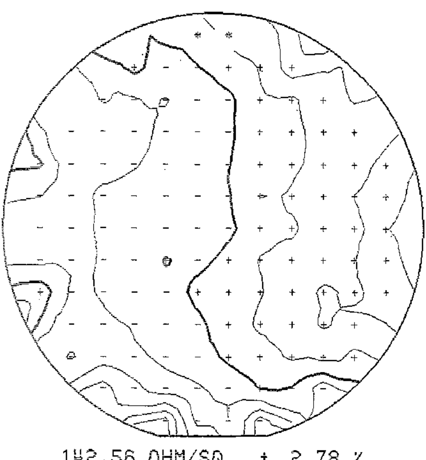
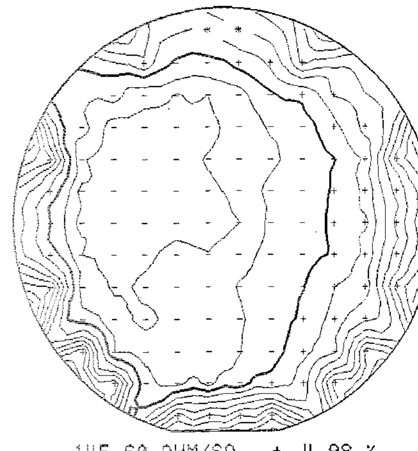


(a)



(b)

Fig. 7. Iso-sheet resistance topographs for the p-type implanted layer of Fig. 6, with $s = 62.5$ mil. As in Fig. 6, k is computed as a function of the position and orientation of the probe array in (a), but assumed constant and equal to 4.532 in. (b).

greater (less) than $\bar{\rho}_s$. The uniformity is expressed as $\pm 2\sigma/\bar{\rho}_s \times 100\%$, where σ is the standard deviation. The symbol * denotes an experimental point which falls beyond preassigned sorting limits.

Figure 6 represents data obtained using the $s = 25$ mil probe assembly. In Fig. 6 (a) the data have been corrected for geometric effects using the results of Appendix A, whereas in (b) they have not. Both topographs reveal the presence of a distinctive left-to-right doping gradient which is characteristic of a wafer which has been tilted (about an axis perpendicular to the flat) relative to the ion beam in an electrostatically scanning implantation system (6). The corrected data are found to have a slightly smaller standard deviation and mean sheet resistance than the uncorrected data.

Figure 7 represents data obtained by probing the same wafer with an $s = 62.5$ mil probe assembly. Again Fig. 7 (a) represents the data which have been corrected for geometric effects, whereas (b) represents data to which the appropriate correction factors have not been applied. In this case, the doping gradient cannot be identified in topograph (b), since the geometrical effects of the wafer boundary completely overwhelm the underlying pattern of doping. This behavior is a consequence of the greater sensitivity of the 62.5 mil probe array to the wafer edge, as may be ascertained by reference to Fig. 2 and 3.

The corrected data presented in Fig. 6 (a) and 7 (a), while in satisfactory quantitative and qualitative agreement, indicate that small errors in specifying the position of the FPP become significant when $a \sim s$. In particular, the topograph of Fig. 7 (a) exhibits various features along the wafer edge which are not present in Fig. 6 (a). This is especially evident near the wafer flat, where the assumption of a circular boundary is no longer valid. [Perloff *et al.* (6) have described an alternative approach which involves the use of photolithographically defined test patterns to maintain a constant value of k. This method, however, requires additional processing steps.]

Conclusion

The homogeneity of doped semiconductor wafers may be determined by measuring the sheet resistance at a number of points using a conventional in-line four-point probe. Correction factors have been derived which take into account varying orientation of the probe array with respect to the wafer radius, making it possible to automate such measurements using standard x-y wafer probing equipment. Simplified expressions have also been obtained which relate the correction factor to a single dimensionless quantity for the case of the probe separation small ($\lesssim 10\%$) in comparison with the wafer radius.

APPENDIX A

Figure 1(a) illustrates the case of an in-line FPP oriented at an arbitrary angle with respect to the radius of a circular pattern. The coordinates of the probes are given by

$$x_1 = \Delta + \frac{3}{2} s \cos\theta$$

$$x_2 = \Delta + \frac{1}{2} s \cos\theta$$

$$x_3 = \Delta - \frac{1}{2} s \cos\theta$$

$$x_4 = \Delta - \frac{3}{2} s \cos\theta$$

$$y_1 = \frac{3}{2} s \sin\theta = -y_4$$

$$y_2 = \frac{1}{2} s \sin\theta = -y_3 \qquad [A-1]$$

where Δ is the distance of the center of the probe array from the center of the circle, θ is the angle of inclination of the probe with respect to the radius, and s is the probe separation distance.

According to conformal mapping theory, a circle in the z-plane can be mapped into the upper half of the w-plane [Fig. 1(b)] using the transformation

$$w = i\frac{r - z}{r + z} \qquad [A-2]$$

where $i = \sqrt{-1}$, $z = x + iy$, and $w = u + iv$. Thus

$$u(x,y) = \frac{2ry}{(r+x)^2+y^2}, \quad v(x,y) = \frac{r^2-x^2-y^2}{(r+x)^2+y^2} \quad \text{[A-3]}$$

describes the location of points 1, 2, 3, and 4 in the w-plane. By introducing images of the current sources at $(u_1, -v_1)$ and $(u_4, -v_4)$ the problem reduces to that of determining the potential difference between points 2 and 3 due to the four current sources in the w-plane. Since a current source in an infinite sheet results in a logarithmic potential (2), the potential difference is

$$\Delta V = \frac{I\rho_s}{4\pi}\left[\ln\frac{\alpha_1\alpha_2}{\alpha_3\alpha_4} + \ln\frac{\beta_1\beta_2}{\beta_3\beta_4}\right] \quad \text{[A-4]}$$

where

$$\alpha_1 = (v_2 - v_4)^2 + (u_2 - u_4)^2$$
$$\alpha_2 = (v_2 + v_4)^2 + (u_2 - u_4)^2$$
$$\alpha_3 = (v_2 - v_1)^2 + (u_2 - u_1)^2$$
$$\alpha_4 = (v_2 + v_1)^2 + (u_2 - u_1)^2$$

and

$$\beta_1 = (v_3 - v_1)^2 + (u_3 - u_1)^2$$
$$\beta_2 = (v_3 + v_1)^2 + (u_3 - u_1)^2$$
$$\beta_3 = (v_3 - v_4)^2 + (u_3 - u_4)^2$$
$$\beta_4 = (v_3 + v_4)^2 + (u_3 - u_4)^2 \quad \text{[A-5]}$$

The correction factor defined by Eq. [1] is thus

$$k = 4\pi \cdot \left[\ln\frac{\alpha_1\alpha_2}{\alpha_3\alpha_4} + \ln\frac{\beta_1\beta_2}{\beta_3\beta_4}\right]^{-1} \quad \text{[A-6]}$$

for an FPP oriented at an arbitrary angle with respect to the radius of a thin circular pattern.

APPENDIX B

According to Eq. [A-1] and [A-3]

$$u(x,y) = \frac{2ry}{(r+x)^2}\cdot\left[1+\frac{y^2}{(r+x)^2}\right]^{-1} \approx \frac{2ry}{(r+x)^2} \quad \text{[B-1]}$$

and

$$v(x,y) = \left[\frac{r-x}{r+x} - \frac{y^2}{(r+x)^2}\right]\cdot\left[1+\frac{y^2}{(r+x)^2}\right]^{-1} \approx \frac{r-x}{r+x} \quad \text{[B-2]}$$

since $y^2/(r+x)^2 << 1$ when $s << r$. Using Eq. [A-1], and defining $u' = u \cdot (r+\Delta)$ and $v' = v \cdot (r+\Delta)$, the coordinates of probe location 1 may be written (again assuming $s << r$)

$$u_1' = u_1 \cdot (r+\Delta)$$
$$= \frac{2r}{r+\Delta}\cdot\frac{3}{2}s\sin\theta\left\{1+\frac{\frac{3}{2}s\cos\theta}{r+\Delta}\right\}^{-2}$$
$$\approx \frac{2r}{r+\Delta}\cdot\frac{3}{2}s\sin\theta \quad \text{[B-3]}$$

and

$$v_1' = v_1 \cdot (r+\Delta)$$
$$= \left(r-\Delta-\frac{3}{2}s\cos\theta\right)\left\{1+\frac{\frac{3}{2}s\cos\theta}{r+\Delta}\right\}^{-1}$$
$$\approx r-\Delta-\frac{2r}{r+\Delta}\cdot\frac{3}{2}s\cos\theta \quad \text{[B-4]}$$

Introducing the effective probe separation distance

$$s' = \frac{2r}{r+\Delta}s = \frac{s}{1-\frac{a}{2r}} \quad \text{[B-5]}$$

where

$$a = r - \Delta \quad \text{[B-6]}$$

is the distance to the edge of the wafer, one has that

$$u_1' \approx \frac{3}{2}s'\sin\theta, \qquad v_1' \approx a - \frac{3}{2}s'\cos\theta \quad \text{[B-7]}$$

A similar treatment for the coordinates of probe locations 2, 3, and 4 leads to the expressions

$$u_2' \approx \frac{1}{2}s'\sin\theta, \qquad v_2' \approx a - \frac{1}{2}s'\cos\theta \quad \text{[B-8]}$$

$$u_3' \approx -\frac{1}{2}s'\sin\theta, \qquad v_3' \approx a + \frac{1}{2}s'\cos\theta \quad \text{[B-9]}$$

$$u_4' \approx -\frac{3}{2}s'\sin\theta, \qquad v_4' \approx a + \frac{3}{2}s'\cos\theta \quad \text{[B-10]}$$

Equations [B-7]-[B-10] describe a probe array of separation s' oriented at an angle θ with respect to a line drawn normal to the nonconducting edge of a semi-infinite sample [Fig. 4(b)]. Images of the current sources may be located at $(u_1', -v_1')$ and $(u_4', -v_4')$ and Eq. [A-5] and [A-6] used to compute the correction factor as was done for the general case described in Appendix A. The result is

$$k(\theta) \approx \frac{\pi}{\ln 2 + \frac{1}{4}\ln\left\{\frac{\left[(a/s')^2+\sin^2\theta-\frac{1}{4}\cos^2\theta\right]^2+\cos^2\theta\sin^2\theta}{\left[(a/s')^2+\frac{1}{4}\sin^2\theta-\cos^2\theta\right]^2+\cos^2\theta\sin^2\theta}\right\}} \quad \text{[B-11]}$$

subject to the requirement that

$$\left(1-\frac{a}{r}+\frac{3}{2}\frac{s}{r}\cos\theta\right)^2 + \left(\frac{3}{2}\frac{s}{r}\sin\theta\right)^2 \leq 1 \quad \text{[B-12]}$$

Equation [B-12] is a statement of the condition that all four probes must lie within the boundary of the circular sample. Uhlir (13) has previously treated the case of an FPP near the edge of a semi-infinite sample of finite thickness. The solution, however, was obtained in terms of functions related to the potential of a line of point charges.

Impurity Profiles within a Shallow p-n Junction by a New Differential Spreading Resistance Method

O. Kudoh, K. Uda, Y. Ikushima, and M. Kamoshida

Nippon Electric Company, Limited, IC Division, Kawasaki, 211 Japan

ABSTRACT

A new simple model for profiling the impurities within a shallow p-n junction from spreading resistance data is proposed. Dickey's capacitance analogue method is extended to a "multilayer" geometry. Direct translation of the differential sheet conductance method to the spreading resistance method is performed. As examples of this approach, the cases of shallow boron ($^{11}B^+$)-, phosphorus ($^{31}P^+$)-, and arsenic (As)-doped layers in silicon are discussed.

Mechanical or technical problems involved in obtaining reliable spreading resistance data have been almost completely settled and automatic measuring equipment is commercially available.[1] However, the procedure for determining impurity profiles from spreading resistance data is still worthy of improvement. Many attempts have been made to determine accurate correction factors, which must be applied to the measured spreading resistance values in order to get the corrected resistivities (1-4). The simplest formula is the "unilayer" theory, which sometimes gives inaccurate information concerning impurity profiles, especially in the cases of profiles within shallow p-n junctions (1). As the correction factors of the "unilayer" theory depend only upon the distance between the probe tip and the p-n junction, only the concentrations averaged between the probe tip and the junction can be attainable from this theory.

The "multilayer" theory has been successfully adopted to determine accurate correction factors, by solving $(2N + 2)$ matrix determinants, where N is the layer number (4). However, this procedure could not be employed without utilizing a computer on a large scale.

In this report, a new simple model for profiling impurities within a shallow p-n junction from spreading resistance data is proposed which does not require a direct determination of correction factors. Only hand calculation or, at most, calculation by a minicomputer is required with this new approach. As examples of this method, boron ($^{11}B^+$) and phosphorus ($^{31}P^+$) ion-implanted layers and arsenic (As)-diffused layers are considered.

Analysis Procedure

In a shallow p-n junction, where the junction depth is smaller than the effective radius of the probe tip, current is forced to flow parallel to the surface, and the equipotential of the probe can be approximated as reaching the junction edge. Dickey calculated correction factors of the uniformly doped layer of this two-point geometry by using a capacitance analogue of the two-parallel-wire transmission line (5). Dickey's formula can be extended to the layer consisting of N thin layers of resistivity $\rho_1, \rho_2, \ldots, \rho_{N-1}, \rho_N$, as shown in Fig. 1.

The spreading resistance, R_N is defined as

$$\frac{1}{R_N} = \sum_{I=1}^{N} \frac{\pi d}{2\rho_I \cdot \ln(D/a)} \qquad [1]$$

where D is the probe spacing, a is the effective probe tip radius, d is the thickness of each thin layer, and ρ_I is the resistivity of the I-th thin layer (6).

Key words: profile measurement, spreading resistance calculation, ion implantation profile, arsenic diffusion profile.

[1] The ASR-100 automatic spreading resistance probe, Solid State Measurements Incorporated, was used in this work.

Equation [1] permits the differential sheet conductance method to be applied to spreading resistance data taken along a beveled edge. Setting R_{N-1} as the spreading resistance of the layer, after removing the uppermost N-th thin layer from the layer shown in Fig. 1, ρ_N is given as

$$\rho_N = \frac{\pi d}{2\ln(D/a)} \cdot \frac{R_{N-1} \cdot R_N}{R_{N-1} - R_N} \qquad [2]$$

Accordingly, determining only two adjacent data values from among the measured spreading resistance data sequence is sufficient to determine accurate resistivity of each thin layer. The resistivity can be converted to net impurity concentration according to Irvin's curve (7).

However, in contrast to the differential sheet conductance method, the measured spreading resistance R_m contains a contribution R_B, the barrier resistance between the probe and the sample surface, in addition to the true spreading resistance R

$$R_m = R_B + R \qquad [3]$$

The barrier resistance R_B depends strongly upon surface layer resistivity and other complex factors (8). With the present state of knowledge, R_B can be best estimated for arbitrary resistivity ρ by using several uniformly doped wafers of known resistivity, as calibration specimens and employing the interpolation procedure, described by Mazur and Dickey (1). This estimate assumes that barrier resistance and contact potential are independent of current and voltage distribution under the probe tip.

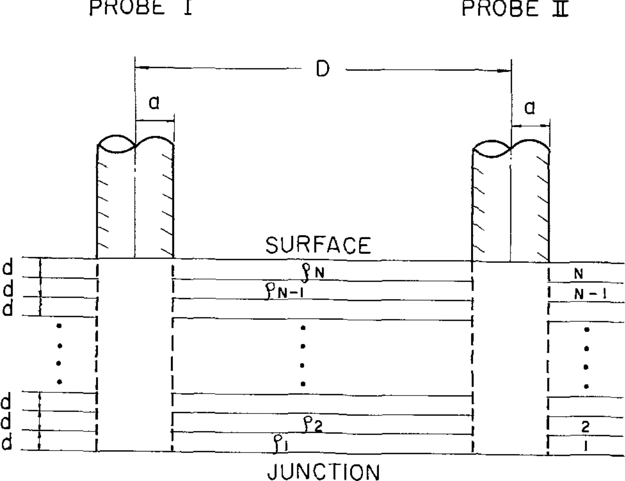

Fig. 1. Two point geometry for multilayer case between surface and junction.

To determine the impurity profile from measured spreading resistance data, R_{m1}, R_{m2}, ..., R_{mN}, the following iteration procedure is necessary.

1. Set $\rho'_I = 2a\,R_{mI}$
2. Compute $R_B\,(\rho'_I)$
3. Set $R_I = R_{mI} - R_B\,(\rho'_I)$
4. Compute $\rho_I = \dfrac{\pi d}{2\ln(D/a)} \cdot \dfrac{R_{I-1} \cdot R_I}{R_{I-1} - R_I}$

(R_{I-1}; known)

5. If $|\rho'_I - \rho_I| > \rho'_I \cdot \epsilon$, set $\rho'_I = \rho_I$ and repeat step 2.
6. If $|\rho'_I - \rho_I| < \rho'_I \cdot \epsilon$, record R_I and set $\rho_{I\,true} = \rho_I$.

Knowing ρ_1, resistivities of the whole layer can be subsequently obtained, beginning from the junction edge and continuing toward the surface, in the following sequence

$$\begin{array}{cccccccc} \rho_1 & \rho_2 & \cdots \rho_{I-1} & \rho_I & \cdots \rho_{N-1} & \rho_N \\ \downarrow \nearrow & \downarrow \nearrow & \downarrow & \nearrow \downarrow & \downarrow & \nearrow \\ R_1 & R_2 & \ldots R_{I-1} & R_I \ldots & R_N \end{array}$$

For fast convergence of this calculation, the "skip" procedure is sometimes convenient for a small difference of R_{I-1} and R_I.

Experimental Results and Discussions

Figure 2 shows profiles of a $^{11}B^+$-implanted layer, determined by the three different methods. The implant was performed at an energy of 150 keV and dose of 4×10^{14} cm^{-2}. The sample was annealed at 900°C for 30 min in dry N_2. The squares and the triangles were obtained by the "no correction" method, which contains no geometrical correction, and the "unilayer" method of Dickey (5), respectively. These results are far from the profile predicted by the LSS theory (9) and empirical reports (10). The circles were obtained by the present method. The resultant profile seems to be reliable, considering the profile of the LSS theory (9) which is shown as the dashed-line curve in Fig. 2.

Figure 3 shows the same profiles as presented in Fig. 2, obtained by the present method, as a function of implant dose (4×10^{13}-2×10^{15} cm^{-2}). Observed profiles are similar to a gaussian distribution, especially on the p-n junction side. However, they are not symmetrical and are widely spread on the surface side. Their peak concentration positions are slightly shallower than the projected range R_p of the LSS theory (9). Recently, $^{11}B^+$ profiles in silicon shallower than those of Ref. (9) were published accounting for the new data on electronic cross sections (11). The LSS theory predicts an asymmetrical $^{11}B^+$ profile in silicon, skewed toward the surface (12). Theoretical profiles incorporating these effects would be expected to explain the results shown in Fig. 2 and 3. As the integrated sum of each profile in Fig. 3 closely fits each implant dose, implanted $^{11}B^+$ ions are fully electrically activated over the whole dose range considered here (13).

The measured peak concentrations shown in Fig. 3 are plotted *vs.* the implant dose in Fig. 4. Considering the redistribution during annealing, coincidences of measured values with LSS theoretical values are sufficient except for the low dose region. As the impurity concentration becomes lower, the difference between adjacent values of measured spreading resistance data becomes smaller. In these cases, the present method is not applicable. This situation is quite similar to the differential sheet conductance method.

Comparison between the differential sheet conductance method and the present method is shown in Fig. 5 for the case of $^{11}B^+$ implanted layer at an energy of 50 keV and dose of 1×10^{14} cm^{-2}. The open and closed

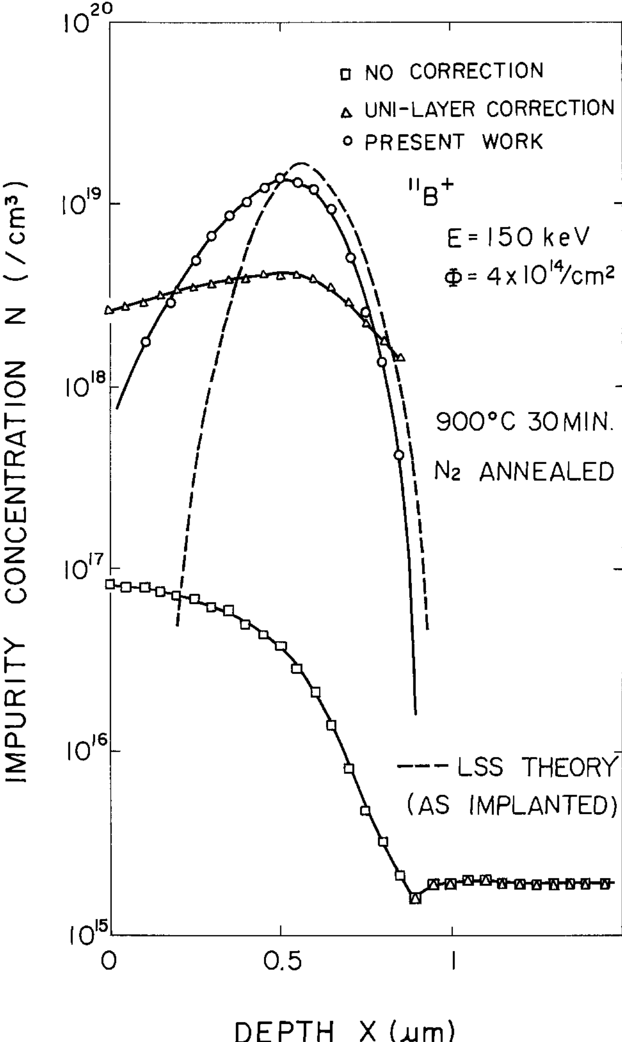

Fig. 2. Comparison of profiles obtained by three different methods for the case of a $^{11}B^+$ layer implanted at an energy of 150 keV and dose of 4×10^{14} cm^{-2}. Dashed-line curve shows LSS theoretical values.

circles were obtained by the four-point differential conductance method, employing a layer removal technique, and the present spreading resistance method, respectively. They coincide well within measuring error limits. This result confirms the reliability of the present method.

The second example of this method is the measurement of a $^{31}P^+$ layer implanted at an energy of 100 keV and dose of 1×10^{16} cm^{-2} into a bare silicon surface. Figure 6 shows annealing time dependences of $^{31}P^+$ ion profiles for activation at 900°C in dry N_2. Measured profiles have much deeper junction depths than those of the LSS theory and have a "kink" at a concentration of nearly 2×10^{19} cm^{-3}. One of the reasons for these results would be the ion-channeling effect during implantation (14). As the "kink" was also observed in the thermally diffused phosphorus case (15, 16), there remains some possibility that the inherent property of phosphorus in silicon is playing a role in determining the profiles shown in Fig. 6.

The third example is the arsenic profile shown in Fig. 7. Arsenic was diffused for 60 min at 1000°C from an As-doped polysilicon film, which was chemically deposited at 750°C in a mixed flow of SiH_4 and $AsCl_3$. Again, good agreement is obtained for the two resultant As profiles, measured by the four-point differential sheet conductance method (○) and the present spreading resistance method (●). Note that the data spacing of the spreading resistance method is 125Å and that the deviations of the measured concentrations are still

small. The sample was lapped at an angle of 17 min. If the sample preparation is good enough, the present method yields quite accurate information for impurity

profiles in semiconductor devices, even for such a short data spacing.

Conclusion

The present new approach to the spreading resistance method has proved to be a reliable means of profiling impurities within shallow p-n junctions in silicon. Obtained profiles of implanted $^{11}B^+$ and $^{31}P^+$ ions and As diffused from a doped polysilicon film are consistent with those of LSS theory, the differential sheet conductance method, and the work performed previously by other authors.

Technical Notes

Silicon Monoxide Thin Films

S. I. Raider*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

and R. Flitsch

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

The composition of thin, solid, silicon monoxide (SiO) films remains controversial despite numerous investigations (1-7). Structural studies of deposited films have led to conjecture as to whether SiO exists as a unique species in the solid state. Brewer and Greene (8) observed that an SiO condensate is metastable and

* Electrochemical Society Active Member.

Key words: silicon oxide, dielectric, x-ray photoelectron spectroscopy, ESCA.

has no temperature range of thermodynamic stability. Evaporated SiO films have been described in terms of unique species, such as SiO, Si_2O_3, Si, and SiO_2, and also as a continuous distribution of suboxide species, SiO_x, centered about $SiO_{1.0}$. In the gas phase, spectroscopic evidence (9, 10) indicates that a monomeric species, SiO, does exist and is similar in electronic structure to gaseous carbon monoxide (11). The variability in SiO thin film composition is determined by film deposition parameters which include the evaporation rate, the source temperature, the substrate temperature, and the pressure in the evaporating system (1, 4). SiO vapor condenses to form a solid product with an O: Si composition ratio equal to 1:1.

We have examined deposited SiO films using x-ray photoelectron spectroscopy, or ESCA (electron spectroscopy for chemical analysis), as part of a study of silicon-oxygen bonding in thin films. The O 1s and Si 2p photoelectron binding energies and the O 1s: Si 2p intensity ratio in SiO were compared with similar data from spectra of SiO_2 and Si. A model of chemical bonding near an SiO surface is described based on observed differences in Si 2p photoelectron binding energies, O 1s: Si 2p intensity ratios, and variations in photoelectron line half-widths (FWHM)[1] from SiO deposited at 24°C and from similar samples subsequently heated to 400°C.

Experimental

SiO films, 800-4000Å thick, were prepared by SiO (Cerac/Pure Incorporated, 99.99% pure) evaporation at pressures of 6-8 $\times$ 10^{-6} Torr, and by deposition onto cleaned Si substrates, at a substrate temperature of 24°C, at source temperatures of 1300°-1450°C, and at deposition rates of 7.5-30 Å/sec. An AEI-ES 100 electrostatic analyzer was used to measure the Si 2p, O 1s, C 1s, and Au $4f_{7/2}$ photoelectron lines. Binding energy data were referenced to Si 2p lines in Si (99.3 eV) and in SiO_2 (103.7 eV) (12), Au $4f_{7/2}$ (83.8 eV), and C 1s (284.9 eV). The binding energy of a reference gold film was measured. Binding energies were corrected for charging effects which increased with film thickness and varied between 0.1 and 0.6 eV. Distinct Si and SiO_2 impurity Si 2p lines with binding energies at 99.3 and 103.7 eV, respectively, and characteristic linewidths, were sometimes observed in SiO spectra and used as reference lines. Spectra were generally obtained with the sample at room temperature, although measurements were also made with the sample at 400°C in order to desorb surface impurities. Variations in spectrometer stability were less than $\pm$0.1 eV. ESCA measurements were made after exposure of deposited SiO samples to air for periods of less than 1 hr to several days.

Results

In Fig. 1, O 1s and Si 2p photoelectron spectra of a 1000Å SiO film are plotted as a function of binding energies corrected for charging effects. The initial spectra were obtained at 23°C about 1 hr after SiO deposition. The O 1s line has a binding energy of 532.5 $\pm$ 0.4 eV and a linewidth (FWHM) of 1.8 eV. The Si 2p line consists primarily of a single line at a binding energy of 101.5 $\pm 0.1_5$ eV with a width (FWHM) of 2.4 eV. The Si 2p linewidth is sensitive to small changes in SiO deposition parameters and was generally found to be greater than 2.4 eV. A shoulder with a binding energy similar to that of free silicon (99.3 eV) is superimposed on the Si 2p line and comprises 2-4% of the total Si 2p intensity. On heating the SiO sample to 400°C for ½ hr in vacuum, the major Si 2p line shifts to a binding energy of 101.6 eV and increases in width to 2.5_5 eV. The intensity of the shoulder doubles in intensity but remains at a binding energy of 99.3 eV. The O 1s binding energy and linewidth remain constant after heating to 400°C. Photoelectron line intensity ratios, I(O 1s): I(Si 2p), for SiO were 1.3-1.45. No changes in ESCA spectra were observed after exposing a similar sample

[1] FWHM: full width at half maximum.

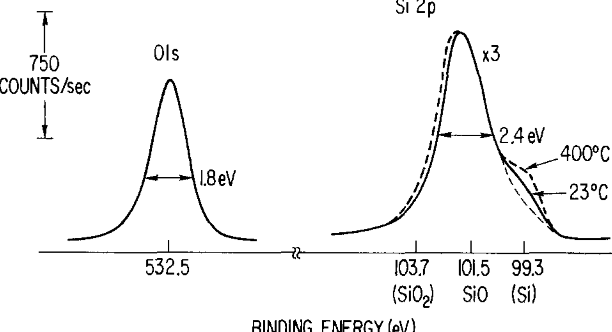

Fig. 1. ESCA O 1s and Si 2p spectra of a deposited SiO film

to air for one week at 23°C. ESCA data of Si, evaporated SiO, and SiO_2 are compared in Table I.

SiO films were also deposited at lower deposition rates and with higher evaporator background pressures. A broad Si 2p line with a binding energy characteristic of SiO was observed in all ESCA spectra. However, distinct additional Si 2p lines, asymmetric broadening of the SiO Si 2p spectrum, and consistent changes in the I(O 1s):I(Si 2p) ratio indicated that excess oxygen, excess silicon, or silicon dioxide and silicon were present as impurities in these SiO samples. Oxygen-rich components of an SiO film, present as impurities, were preferentially removed by chemical etching with diluted HF (1:10). Silicon and silicon-rich components, which increased in concentration with decreasing deposition rates, were often detected as the major impurity lines in spectra of SiO films. This may account for the detection of Si in deposited SiO films by diffraction techniques.

Discussion

A photoelectron line intensity is proportional to the total number of emitting atoms in a homogeneous sample if the surface is representative of the bulk (13). With a noncontaminated surface, the O: Si composition ratio in SiO can be estimated by comparing ESCA intensity ratio data, *i.e.*, I(O 1s):I(Si 2p), with intensity data from a reference compound such as SiO_2 (12). The presence of excess nonoxidized Si atoms located at the film surface, rather than excess oxidized Si atoms, indicates that oxygenated species adsorbed at an SiO surface have not altered the chemical composition of the film. Comparison of intensity ratios of SiO and SiO_2 samples exposed for several days to air leads to an SiO stoichiometry of $SiO_{1.0 \pm 0.1}$. These results for SiO are surprisingly good if we consider that, besides possible changes in surface chemistry, differences in adsorbed contaminants present on both surfaces will further modify an intensity ratio for elements with different mean escape depths.

The O 1s binding energy in SiO and SiO_2 (12) films is 532.5, which suggests that a similar chemical environment for oxygen exists in both materials. The siloxane linkage is characteristic of SiO_2, of silicones, and is expected of other polymeric silicon-oxygen species (14). A high melting point and low vapor pressure of solid SiO indicate that SiO is not molecular but has a cross-linked polymeric structure (14). Furthermore, in infrared spectra of gaseous SiO isolated in Ar or N_2

Table I. Relative photoelectron intensities, binding energies, and linewidths (FWHM) for Si, SiO, and SiO_2

	I(O 1s): I(Si 2p)	O 1s (eV)	FWHM (eV)	Si 2p (eV)	FWHM (eV)
Si				99.3	1.3
SiO	1.3-1.45	532.5 $\pm$ 0.4	1.8	101.5 $\pm$ 0.1_5*	2.3*
SiO_2	2.7	532.5	1.7	103.7	1.7

* Extrapolated value (see text).

matrixes at 20°K (15, 16) dimeric and trimeric units, Si_2O_2 and Si_3O_3 were observed together with monomer units of SiO. These polymeric species formed ring structures with siloxane bridges as the probable first step in the formation of condensed solid polymeric SiO.

The O 1s linewidth of 1.8 eV in SiO is greater than the O 1s linewidth in SiO_2 (1.5 eV). No increase in O 1s linewidth was detected for SiO or SiO_2 upon exposure to air for several days or after heating SiO at 400°C. SiO and SiO_2 films are amorphous and have oxygen atoms in similar chemical environments. Second-order bonding about oxygen in SiO with distributions of species changing from O_3-Si-O-Si-O_3 to Si_3-Si-O-Si-Si_3 is a likely cause of this broadened line.

A change in binding energy of an element has been associated with first-order changes in bonding in a series of similar materials (13). The Si 2p binding energy in SiO is located at about half the binding energy difference between Si (99.3 eV) and SiO_2 (103.7 eV), as is indicated in Fig. 2. A linear, or nearly linear, empirical relationship exists between changes in binding energy and changes in oxygen content of silicon oxide films. The tetrahedral configurations shown in Fig. 2 represent examples of the change in average composition about photoexcited Si atoms with change in binding energy, and provide a basis for determining oxide film composition (12, 17). During SiO evaporation, some SiO is dissociated and then deposited as nonoxidized Si atoms and O atoms. The O atoms presumably oxidize the partially oxidized Si atoms. This results in a small increase in the Si 2p binding energy and linewidth. Depositing the SiO onto a heated substrate may enhance this dissociation (1, 4). Heating the SiO sample, which was deposited at 24°C, to 400°C does not alter the O:Si ratio but does cause internal chemical changes in the film. More nonoxidized silicon is formed; the remainder of the film is more highly oxidized, which causes the Si 2p binding energy and linewidth to increase. An estimated SiO binding energy and linewidth of 101.5 and 2.3 eV, respectively, are obtained by extrapolation to form a Si 2p line free of nonoxidized Si atoms.

ESCA spectra of Si 2p photoelectron lines in SiO evaporated film (7) and SiO powders (18) have recently been described and may be compared with our results. The binding energy separation between the Si 2p lines in SiO and in Si (2.2 eV) obtained by Hollinger *et al.* (7) is in agreement with our data (2.2 eV). For the SiO powder (18), this separation in Si 2p binding energies (estimated from a published spectrum) is about 3.3 eV and suggests that the oxidized Si in the powder possesses an O:Si ratio significantly greater than 1:1. From analysis of Auger spectra of SiO evaporated onto substrates held at 200°C and ion sputtered for a short time, Johannessen *et al.* (19) proposed that

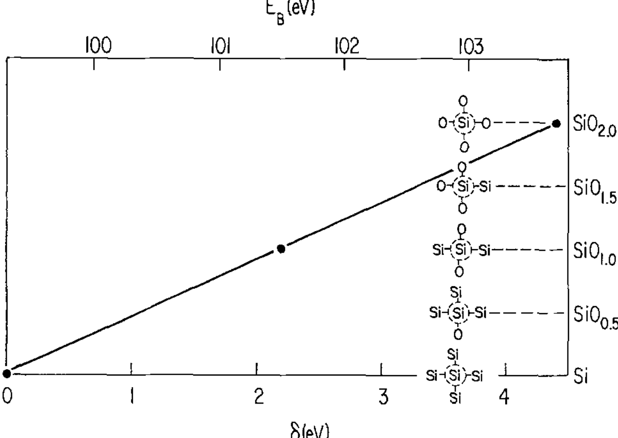

Fig. 2. Variation of Si 2p binding energy with average oxide film composition. Encircled Si atoms in tetrahedral configurations represent photoexcited atoms.

SiO is a mixture of Si and SiO_2. However, both deposition onto a heated substrate and ion sputtering of the SiO surface may alter the SiO composition by enhancing decomposition to Si and SiO_x.

Si atoms are generally tetravalently bonded, and multiple bonds involving Si atoms are unknown. Si atoms in SiO possess, on the average, tetrahedral Si atoms bonded to two oxygens and two silicons, *i.e.*, Si-$(O)_2(Si)_2$, a configuration intermediate between tetrahedra in silicon, Si-$(Si)_4$, and in silicon dioxide, Si-$(O)_4$. The larger Si 2p linewidth value in SiO (2.3 eV) relative to the linewidth in a Si single crystal (1.3 eV) or in an amorphous SiO_2 film (1.8 eV) is also consistent with the presence of a continuous distribution of oxidized tetrahedral Si species contributing to a Si 2p line in SiO. Furthermore, the decomposition of SiO at 400°C does not cause unique oxide compounds, such as SiO_2, to form, but rather extends the distribution of Si atoms already oxidized to include a greater number of more completely oxidized Si atoms (Fig. 1). A unique SiO species does not exist in the solid state. Rather, SiO has a composition Si-$(O)_x(Si)_y$, where $x + y = 4$, with the most probable composition being $x = y = 2$. The absence of two distinct Si 2p lines at 99.3 and 103.7 eV, and the presence of a single line at 101.5 eV, is a direct indication that a properly evaporated SiO film is not composed of a mixture of Si and SiO_2. Similarly, no single unique Si_2O_3 species was identified from ESCA SiO spectra. Properly prepared SiO contains Si, SiO, Si_2O_3, SiO_2, etc., only as components of a normal distribution of silicon oxide species whose average composition is $SiO_{1.0}$ This model of an SiO surface derived from ESCA data is in agreement with the previously reported conclusions of Philipp (6) for thick SiO films.

Acknowledgments

We thank T. Hickmott and B. H. Vromen for their helpful criticisms of this manuscript. In addition, we are grateful to J. M. Brown, M. J. Palmer, and B. H. Vromen for providing SiO films.

Electrophotographic Characteristics of (HgI_2:CdS) Binder Layers

P. K. C. Pillai, S. K. Agarwal, and R. C. Ahuja

Department of Physics, Indian Institute of Technology, New Delhi 110029, India

The combination of a photoconductor and insulating resin provides a photoconductive insulator capable of retaining a surface charge in dark and discharging in light. These combinations have some unique aspects: (*i*) The photoconductive material need not have high dark resistivity (which is required to retain charge) and this allows for a wide choice of materials. (*ii*) The independent characteristics of several photoconductors can be incorporated in one layer by dispersing these as powders in the resin binder. Several studies have been reported on the binder-type plates of Se (1), ZnO (2), anthracene (3), CdS (4), and their combinations (5-6).

The present investigations deal with the surface charge characteristics of HgI_2:CdS mixed system in polystyrene. Our earlier photoconductivity studies (6) have shown that the binder layers of CdS dispersed in polystyrene have $I_{photo}/I_{dark} = 100$ and a low speed of response, while the binder layers of HgI_2 have $I_{photo}/I_{dark} = 150$ and a fast speed of response. This suggested that the binder layers of HgI_2:CdS mixed system might possess some characteristics more desirable for use in electrophotography. The experiments have shown that the layer containing HgI_2 and CdS in the 60:40 ratio exhibits the maximum value of I_{photo}/I_{dark} (5×10^3 at 1750 lx). It was then felt worthwhile to study the surface charge characteristics.

The surface charge studies were made as follows: The photoconducting layers backed by NESA coated glass plates were charged by using a scorotron unit and the resulting surface charge was measured in terms of surface potential by a vibrating condenser unit. A 100W tungsten filament lamp was used to discharge the layers.

Figure 1 shows typical dark and light decay curves of the HgI_2, CdS, and HgI_2:CdS layers. It is seen that (*i*) maximum surface potential is retained by the HgI_2 layers, (*ii*) dark and light decay are fastest in HgI_2 layers, and (*iii*) HgI_2:CdS layers show slow dark and fast light decay rates.

The effect of binder percentage on the dark and light decay rates of the HgI_2:CdS layers is shown in Fig. 2. It is seen that as the percentage of binder is increased, the dark and light decay rates slow down, and that the surface potential retained by the layer increases. From these characteristics it is evident that the binder layers containing HgI_2:CdS in the 60:40 composition dispersed in 60% by weight of polystyrene show the optimum characteristics for use in electrophotography. For this layer, the surface potential decays only by 5% in a period of 5 sec in dark, while during the same period the light decay is about 70% for 100 lx white illumination. These values indicate that a good image contrast can be obtained, which could be further improved by exposing the layer to higher intensities of light.

Key words: xerography, surface charge, photoconductor.

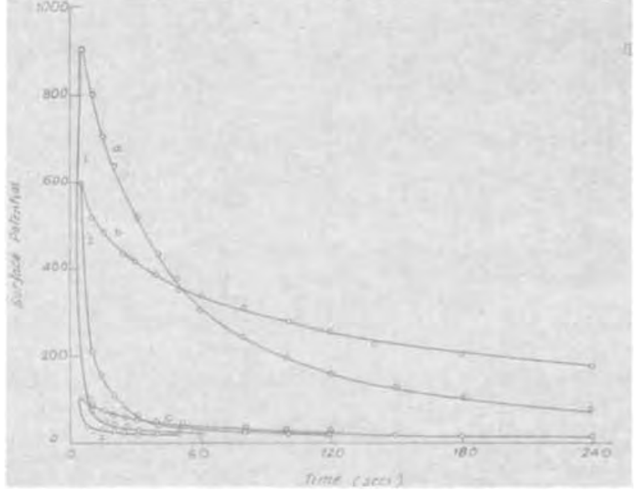

Fig. 1. Dark and light decay curves. Dark decay: (a) 100% HgI_2, (b) 60:40 HgI_2:CdS, (c) 100% CdS. Light decay: (1) 100% HgI_2, (2) 60:40 HgI_2:CdS, (3) 100% CdS. Binder percentage is 40 in all the samples.

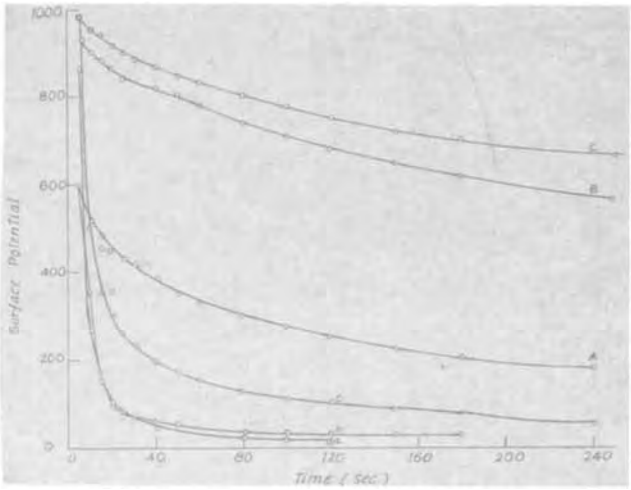

Fig. 2. Effect of binder percentage on the dark and light decay rates of the HgI_2:CdS layers. Dark decay: (A) binder percentage = 40, (B) binder percentage = 60, (C) binder percentage = 80. Light decay: (a) binder percentage = 40, (b) binder percentage = 60, (c) binder percentage = 80. Corona voltage = 5.5 kV, grid voltage = 1100V, charging time = 1 min.

Thus, (HgI_2:CdS) in polystyrene binder seems to offer good promise for use as a master plate in charge transfer electrophotography. The image contrast ob-

tainable with this plate appears to be comparable to that of commercially available plates.

Discontinuous Precipitation as a Mode of Internal Oxidation

D. J. Young,*,[1] J. S. Kirkaldy, and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S/M1

Discontinuous precipitation is the process whereby a supersaturated phase decomposes to a solute-depleted but structurally identical product and a precipitate phase ($\alpha \rightarrow \alpha' + \beta$) by growth of parallel α' and β lamellae into the parent α phase (1, 2). It is emphasized that α' and α denote different compositions of the same phase. This mechanism often substitutes for or competes with the more common phenomenon of general precipitation, when reaction temperatures lead to very low volume diffusion rates. Discontinuous precipitation should be distinguished from a eutectoid reaction in which one phase decomposes into two new phases ($\gamma \rightarrow \alpha + \beta$), although both reactions are controlled by segregation of alloy constituents at or near the interface between the parent phase and the products. Under usual conditions where the supersaturated phase (α) is produced by quenching to a fixed reaction temperature, the velocity, v, at which the interface advances is approximately constant. This does not imply that all discontinuous precipitation reactions proceed at a constant velocity. Indeed, approximately parabolic cellular reactions in multicomponent systems have been observed (3).

It was recently reported by the present authors (4) that a Ni-20 weight percent (w/o) Mo alloy exposed at 700°C to H_2S/H_2 atmospheres adjusted to yield $1 \times 10^{-10} \leq p_{S_2} \leq 4 \times 10^{-10}$ atm underwent internal sulfidation in such a way as to yield this cellular morphology. The purpose of the present communication is to present chemical and microstructural evidence that the mechanism of this internal sulfidation reaction is in fact that of discontinuous precipitation as defined above.

The general appearance of the reaction product is illustrated in Fig. 1. Phases were identified by energy dispersion analysis of the x-rays excited in a scanning electron microscope. The outer scale was found to be Ni sulfide plus Mo sulfide; the inner layer was Mo sulfide (dark region) plus nearly pure Ni metal (white region). The sulfide particles were too small to yield reliable analyses and so their stoichiometries were not established. The formation of the inner layer is described in chemical terms as internal sulfidation. As the equilibrium sulfur partial pressures at 700°C for the reactions $4/3\ Mo + S_2 = 2/3\ Mo_2S_3$, $2Mo_2S_3 + S_2 = 4\ MoS_2$, and $(3 - x)Ni + S_2 = Ni_{3-x}S_2(l)$ are respectively (5, 6), 6.3×10^{-12}, 3.1×10^{-11}, and 3.4×10^{-10} atm, selective sulfidation is thermodynamically expected. In the present nomenclature, the reaction may be written as

$$\text{Alloy} + S \rightarrow \alpha \qquad [1]$$

$$\alpha \rightarrow \alpha' + \beta \qquad [2]$$

Internal oxidation (or sulfidation) has long been known (7) and the kinetics have been described in detail by Wagner (8) on the supposition that step [1] is rate controlling. In step [2] the internally produced reaction product is assumed to nucleate and precipitate at random sites (*i.e.*, general precipitation) and thereafter play no role in the reaction. Wagner's theory supposes that step [1] is controlled by inward diffusion of the oxidizing species through the depleted matrix, α', to reach the as yet unreacted alloy and, therefore, that both the penetration depth of the precipitation zone and the weight gain follow parabolic kinetics. The situation where external scale growth is combined with internal oxidation is rather more complex and has been reviewed by Rapp (9). Under these circumstances a variety of reaction rate laws is possible, depending on the precise nature of the rate-controlling process.

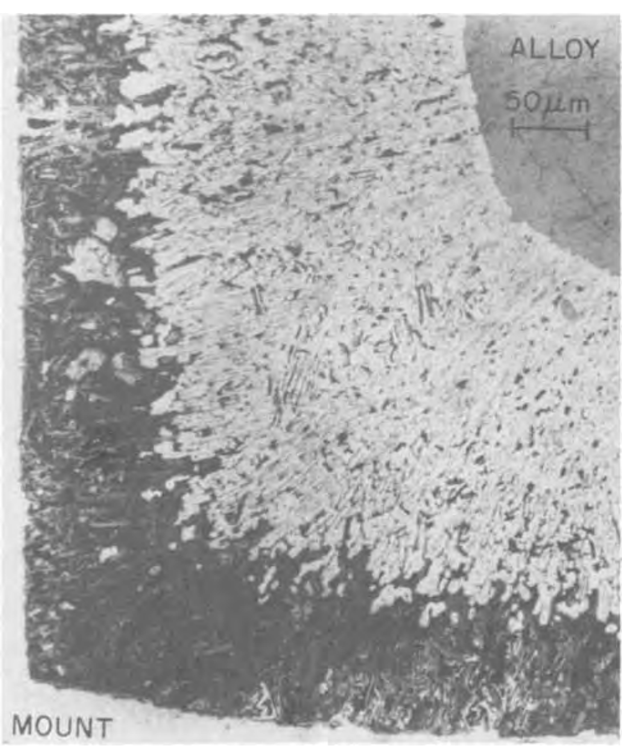

Fig. 1. Cross section of corner of Ni-20Mo sulfidized at $p_{S_2} = 3.5 \times 10^{-10}$ atm for ~ 10 hr. Etched in HNO_3-50 v/o CH_3COOH. Phases are identified in text.

Key words: Ni-Mo-S system, internal oxidation, discontinuous precipitation.

In the present case the observed weight change kinetics are approximately linear (4). Results of metallographic studies of the precipitation zone penetration and the corresponding interlamellar spacing, δ, are summarized in Fig. 2. Penetration has been measured as the distance between the precipitation front and the precipitation zone, external scale interface. The error involved in approximating the position of this latter interface to that of the original alloy surface is less than the experimental error of the measurement. It is seen that the data, with the exception of one deviant point of unknown origin, are described by linear kinetics ($v \simeq 5.5 \times 10^{-7}$ cm sec^{-1}) and constant lamellar spacing. It is therefore concluded that step [1] is not rate controlling in the present case.

To rationalize these results we note that data are available for the diffusion coefficient of S in Ni (10) and in the sulfides. At 700°C, $D_S^{Ni} \simeq 10^{-11}$ cm^2 sec^{-1}, and for the diffusion of S through the Mo sulfides (11), $D_S \simeq 10^{-13}$ cm^2 sec^{-1}. Clearly, neither of these processes can possibly supply S to the reaction front at a rate sufficient to support the observed velocity of that front, so the classical model of internal sulfidation via lattice diffusion of the sulfur is inapplicable. This point is further discussed below.

Morphologically, the present reaction has all the characteristics of discontinuous precipitation. Here it is found that the internal precipitates form as platelets approximately normal to the original alloy surface and to the reaction front (Fig. 1, 3), that these plates are arranged at a regular uniform spacing (Fig. 2, 4), that the orientation of the platelets is independent of the prior grain structure of the alloy (Fig. 1, 3), that the penetration depth of the platelets is uniform (Fig. 3), and that a sharply defined interface exists between the alloy, α, and the depleted matrix, α'. This last feature is seen in an optical micrograph (Fig. 1, 3) as a difference in etching characteristic, and in the scanning electron micrograph (Fig. 5) as a difference in backscattered electron intensity. It was verified by x-ray energy dispersive analysis as being due to a compositional change: within the spatial resolution of this technique (± 1 μm) it was found that a discontinuous change occurs from nearly pure Ni as depleted matrix to Ni-20 w/o Mo in the as yet unaffected alloy.

Lamellar precipitates have occasionally been noted in other internal oxidation reactions. As examples, internal oxidation of several copper alloys containing In, Zn, Al, or Si (7), and of Nb-Zr (12, 13) and U-Nb (14) alloys results in the formation of lamellar precipitates from oxygen diffusion as a rate-determining step. Also, cycling the reaction temperature (15) or oxidant pressure (16) can lead to platelike morphologies. In all of these examples oxygen diffusion is rate controlling and

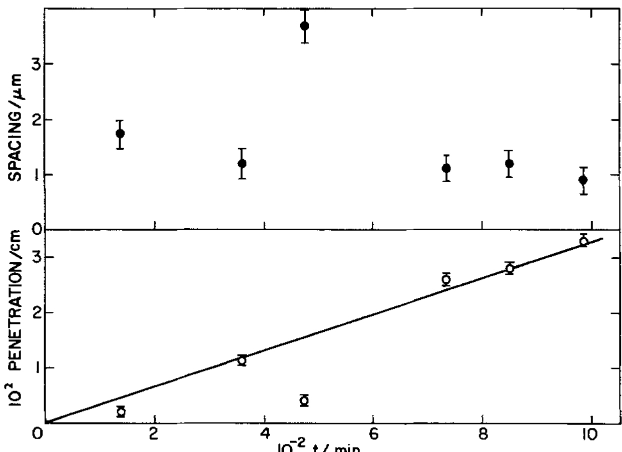

Fig. 2. Penetration depth of precipitate zone and lamellar spacing as a function of time for samples sulfidized at $1 \times 10^{-10} \leq p_{S_2} \leq 4 \times 10^{-10}$ atm.

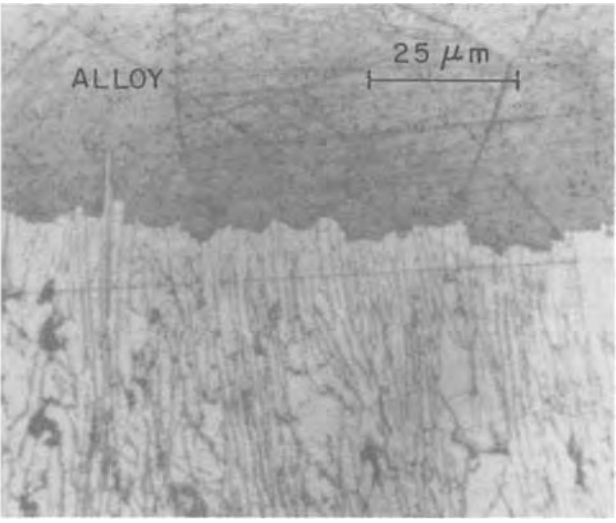

Fig. 3. Optical micrograph of etched cross section showing the precipitation front. Sulfide precipitates have etched black, the Ni matrix appears white, and the unreacted alloy is medium gray with grain boundaries revealed.

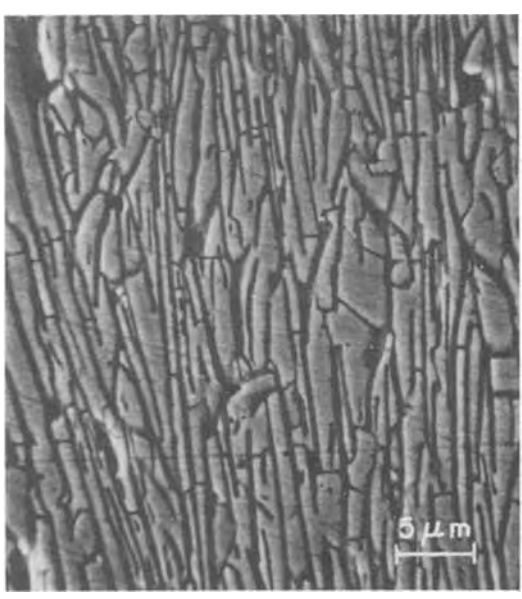

Fig. 4. Scanning electron micrograph of region in precipitation zone. Sulfide precipitate lamellae appear black.

parabolic kinetics are observed. The presently considered internal sulfidation reaction differs from the above examples in two key ways. Firstly, the kinetics are not parabolic. Secondly, a discontinuous change in concentration is found between the alloy, α, and its solute-depleted form, α', the distance over which this change occurs being much less than the distance between precipitates. This novel pattern of behavior is rationalized in the following.

The existence of fine, closely spaced, lamellar precipitates running all the way from the outer metal surface to the reaction front provides a very large α'/β interfacial area connecting the outer metal surface, the source of sulfur, to the reaction front. We therefore conjecture that S is delivered to the precipitation front by rapid diffusion along these precipitate-matrix boundaries, and that little over-all resistance to the reaction is thereby offered.

Both the morphology and kinetics can be accounted for by a mechanism involving alloy component segregation. If segregation is achieved by volume diffusion within α, then the mechanism is morphologically ana-

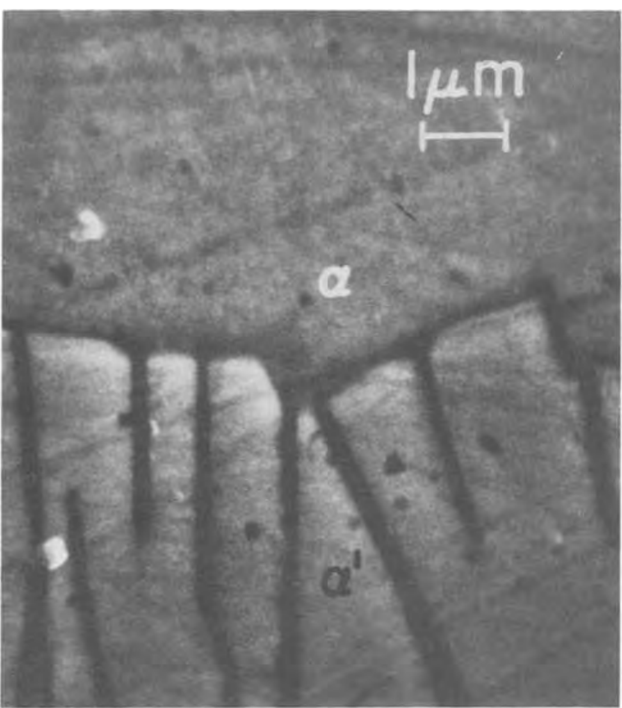

Fig. 5. Scanning electron micrograph of precipitation front. Back-scattered electron image of alloy is darker than that of Ni matrix lamellae.

logous to an isothermal eutectoid transformation in a homogeneous solid and v is related to the lamellar spacing, δ, by

$$v \simeq \frac{D^A}{\delta} f \qquad [3]$$

where D^A is the alloy diffusion coefficient and f is the relative supersaturation (1), which will be here estimated as 0.1. If segregation is achieved by boundary diffusion along the α/α' interface, then an approximate growth equation analogous to [3] is obtained by substituting $D^B\, b/\delta$ for D^A, where D^B is the diffusion constant within the boundary of width b. To a first approximation then

$$v = 0.1\, D^A/\delta \qquad \text{volume diffusion} \qquad [4]$$

$$v = 0.1\, D^B b/\delta^2 \qquad \text{boundary diffusion} \qquad [5]$$

Substitution of the values of v and δ reported in Fig. 2 into [4] and [5] assuming $b = 10\text{Å}$ yields $D^A \sim 10^{-9}$ cm^2 sec^{-1} or $D^B \sim 10^{-6}$ cm^2 sec^{-1}. Extrapolation of high temperature results (17) for volume interdiffusion in the Ni-Mo solid solution yields, at 700°C, $D^A \sim 10^{-15}$ cm^2 sec^{-1}, indicating that segregation must be achieved by the second mechanism of diffusion along the advancing interface. This is almost universally the case with discontinuous precipitation.

It is concluded from the simultaneous observations of linear kinetics, uniform lamellar morphology, and a discontinuous change in concentration at the reaction front that the mechanism of internal sulfidation of Ni-20Mo is that of discontinuous precipitation. It is not possible, however, to conclude that the reaction rate is controlled entirely at the precipitation front. Since the kinetics of the over-all reaction are approximately linear, so too are those of external scale growth. Such behavior in an alloy exposed to H_2S/H_2 atmospheres has frequently been ascribed to rate control by a process occurring at the solid-gas interface. If this is the case in the present instance, then the penetration velocity and interlamellar spacing of the internal precipitation zone may be partially determined by this external constraint.

Growth Texture of Polycrystalline Silicon Prepared by Chemical Vapor Deposition

Baruch Pratt,[1] Subhash Kulkarni, D. P. Pope, and C. D. Graham, Jr.

Departments of Electrical Engineering and Science, and Metallurgy and Materials Science, University of Pennsylvania, Philadelphia, Pennsylvania 19174

We are undertaking a study of the high temperature deformation of polycrystalline silicon as part of a program to find low cost methods of manufacturing silicon solar cells. The material used as samples in these deformation experiments was commercially available, high purity semiconductor grade silicon. This is a polycrystalline material grown by chemical vapor deposition at about 1150°C by the decomposition of trichlorosilane. The silicon rod samples were prepared by Dow-Corning Company, and had a diameter of about 15 cm. Figure 1 shows the grain structure of a cross section of the silicon rod. Growth begins on a single crystal core,

[1] Permanent address: The Technion, Haifa, Israel.

Key words: silicon, polycrystalline silicon, grain structure, texture, chemical vapor deposition, crystallographic orientation.

Fig. 1. Etched surface of 15 cm diameter silicon rod. Surface is perpendicular to log axis. Radial grains emanate from the slim rod.

the slim rod. Columnar grains elongated in the growth direction are clearly visible; many of the grains show a substructure of straight, parallel needles aligned with the growth direction. The appearance of these needles suggests the possibility of growth twins, but they have not been studied in detail. The over-all structure strongly suggests a preferred crystallographic texture in the as-deposited rod. Such a texture is of obvious importance in measurements of the mechanical properties, and since we were unable to find in the literature any determination of the texture, we undertook the study described here.

Experimental Procedure

A 2.5 cm thick slab was cut from the 15 cm diameter rod, perpendicular to the log axis. Samples for x-ray diffraction, each 2.5 × 2.5 × 0.2 cm, were cut in various orientations and from various parts of the rod, as shown in Fig. 2. The samples were cut with a diamond saw, mechanically polished, and finally etched heavily in a solution of $5HNO_3$:3HF:$3CH_3COOH$. Samples denoted ⊥ were cut with their large faces perpendicular to the rod axis. Samples denoted || were cut with faces parallel to the log axis and perpendicular to a diameter. Those denoted || || were cut with faces parallel to the log axis and parallel to a diameter. Sample sets 1

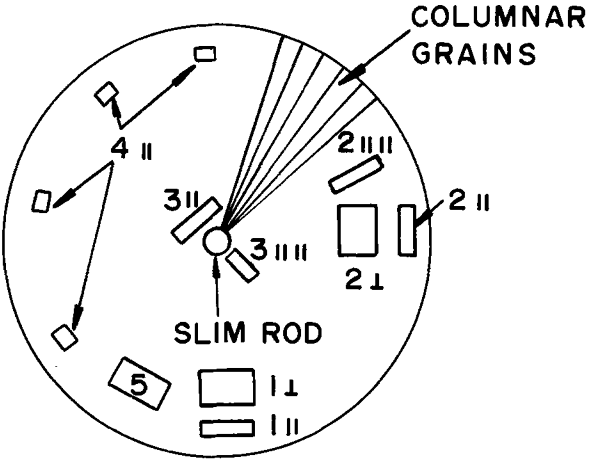

Fig. 2. Identification of samples cut from silicon rod. For explanation, see text.

and 2 were taken near the log surface, at two points 90° apart. Sample set 3 was taken as near the slim-rod core as possible, and sample set 4 consisted of four pieces, each 0.6 × 2.5 × 0.2 cm, and each cut with the 0.6 × 2.5 cm surface perpendicular to a log diameter. These four pieces were assembled to make one x-ray sample; this was done to minimize the spread in orientation resulting from the fanlike growth of the columnar crystals. Sample 5 was cut with faces inclined at 45° to the log axis; it has an orientation halfway between the ⊥ and the || samples, related to them by rotation of 45° about an axis parallel to a log diameter. A small sample was also cut from the slim rod itself. Textures were determined by the Schultz reflection method (1, 2).

Samples were mounted in a Siemens texture diffractometer and irradiated with Cu K_α radiation at 30 kV and 20 mA. Reflections from (111), (220), and (400) planes were recorded, and pole figures were plotted from the resulting strip charts. Diffracted intensities were recorded for a full $\Psi = 360°$ rotation about the normal to the surface of the samples in steps of $\alpha = 2.5°$ away from this normal out to 80°. The resolution of the technique was $d\Psi = \pm 4°$ and $d\alpha = \pm 0.05°$. Intensities were compared to those of a random sample prepared from silicon powder held on a glass slide with petroleum jelly. The samples were aligned by eye so that the diameter of the log appeared as the vertical axis of the pole figures of the ⊥ and || || samples, and the log axis as the vertical axis of the pole figures in || samples.

Results

The recorder chart traces of all samples with faces parallel to a log diameter (types ⊥ and || ||) consisted of a series of very narrow peaks of high intensity. The small width of the peaks, plus the irregularities in their outlines caused by the relatively large grain size of the samples, made the plotting of conventional contour lines on the pole figures impossible. Instead, the height of each peak was read and plotted as a corresponding point on the pole figure. Examples are shown in Fig. 3.

All the pole figures from samples of type ⊥ and || || were in agreement, and indicated clearly that the crystallographic texture of the silicon rod is a very sharp <110> fiber texture with the <110> axis parallel to the growth direction, and with no preferential orientation about this axis. Pole figures of samples of type || unexpectedly showed almost random intensity instead of the circular symmetry about the midpoint expected for a fiber texture examined parallel to the fiber axis. Suspecting that this phenomenon might be associated with the spread in orientation of the fiber axis caused by the cylindrical growth geometry, we prepared the composite sample 4 as explained above; its (220) pole figure showed the expected form (Fig. 4) although with lower intensity than predicted.

As a final check, sample 5 was cut at 45° to the rod axis. The resulting (111) pole figure is shown in Fig. 5; it has the expected form of the (111) pole figure of Fig. 3a, rotated 45° about the equator.

The pole figures of sample set 3, cut near the central slim rod, were closely similar to those of sets 1 and 2. The slim rod itself was found to have a <100> direction parallel to the rod axis.

Conclusions

The crystallographic texture of CVD polycrystalline silicon is found to be a very sharp <110> fiber texture, with the <110> direction parallel to the direction of growth, and with no preferred orientation about this axis. The texture does not appear to be influenced by the orientation of the rod from which growth starts. This <110> growth texture has also been found in silicon films grown by similar methods on various substrates (3).

Thermodynamic Properties of the Lithium-Silicon System

Ram A. Sharma* and Randall N. Seefurth*

General Motors Corporation, Electrochemistry Department, Research Laboratories, Warren, Michigan 48090

ABSTRACT

The feasibility of using silicon as an alloying agent for the negative electrode in Li/FeS_2 cells was determined by studying cells of the type

Li (liq) or 40 a/o Li-Al alloy (sol)	LiCl-KCl eutectic or LiF-LiCl-LiBr melts	Li {in solid Li-Si alloys at equilibrium}

The Li-Si electrode was found reversible with respect to lithium between 650° and 725°K. The nonstoichiometry ranges of the respective Li-Si compounds and electromotive forces (emf's) in the two-phase regions of the Li-Si phase diagram between 650° and 750°K were measured. These studies indicated a new compound, $Li_{21}Si_8$, which was confirmed by x-ray diffraction, scanning electron microscope, and differential thermal analysis. The activities and relative partial molar properties of lithium and silicon in the two-phase regions of the phase diagram were calculated from the emf's in the temperature range 650°-750°K, and the standard free energy of formation for the compounds Li_2Si, $Li_{21}Si_8$, $Li_{15}Si_4$, and $Li_{22}Si_5$, were also determined.

At present, two types of negative electrodes are used for developing Li/FeS_2 cells for secondary batteries of high specific energy and high specific power. One type is pure lithium entrapped in a metallic matrix (1, 2) generally made of stainless steel or nickel. This electrode has a problem retaining lithium for a prolonged period of time during repeated charge-discharge cycles. Lithium also severely attacks the ceramic insulator and separator of the cell.

The second type of negative electrode is made of solid Li-Al alloy (3, 4). In this case, the lithium retention problem is solved, but the theoretical specific energy is reduced because of the additional inert weight of aluminum and decreased cell voltage compared to a cell using a pure lithium electrode. Current densities are also limited because of the difficulty of transport of active material in the solid alloy. However, the reduced activity of lithium decreases its tendency to corrode the ceramic parts.

Silicon, which is next to aluminum in the Periodic Table and forms a few compounds with lithium (5-8), appears to be a suitable alloying agent for the negative electrode. Like Li-Al alloy, Li-Si alloys will probably not have the problems of lithium retention and corrosion and, because of the higher lithium content of solid Li-Si alloys, the specific capacity of the electrode would be higher than that of the Li-Al alloy electrode.

The Li-Si phase diagram (5-8) indicates only two compounds, Li_2Si and Li_4Si, but compounds such as $Li_{13}Si_7$, Li_7Si_2, and $Li_{22}Si_5$ are also reported in the literature (9-11). Therefore, this investigation was conducted to determine the feasibility of using Li-Si alloys as negative electrodes in Li/FeS_2 cells, to determine the various phases of the Li-Si system, and to obtain the relevant thermodynamic data for the phases by emf measurements.

Experimental

All preparatory procedures and cell studies were carried out in a helium atmosphere dry box. The cells used were of the type

Li (liq) or 40 a/o Li-Al alloy (sol)	LiCl-KCl eutectic or LiF-LiCl-LiBr melts	Li {in solid Li-Si alloys at equilibrium}

Schematic diagrams of the cells are shown in Fig. 1. The typical cell assembly consisted of a quartz enclosure (70 mm diameter, 300 mm high) fitted with a cap which served to position the electrodes and thermocouple, and a stainless steel cup (50 mm diameter, 100 mm deep) to hold the electrolyte. All of the metallic parts were hydrogen-fired at 1375°K for 7.5 ksec before use.

Fig. 1. Schematic representations of the lithium-silicon alloy test cells.

* Electrochemical Society Active Member.
Key words: Li-Si phase diagram, emf's, thermodynamic properties.

Negative or reference electrode.—For the lithium electrode, a fibrous nickel block (80% porous), 12 mm diameter and 12 mm high, was attached to a nickel rod voltage lead, 3 mm diameter and 450 mm long. The block was loaded by immersing it in a pool of molten lithium (99.97% pure) at 975°K for 120 sec.

For the Li-Al alloy electrode, a chamber was made by heliarc-welding a 304 stainless steel nut onto the side of a 5 mm long piece of 304 stainless steel tubing (12 mm ID, 16 mm OD). A 304 stainless steel rod (3 mm diameter, 450 mm long) was threaded into the nut to serve as a voltage lead. After hydrogen-firing this compartment, the electrode was completed by inserting a few pieces of 40 atom percent (a/o) Li-Al alloy (4/20 mesh) and spot-welding two 150 mesh 304 stainless steel screen disks over the open sides.

Lithium-silicon alloy positive electrodes.—For the preparation of the alloys, a preweighed amount of clean lithium was placed in a nickel crucible and its temperature was raised to about 600°K. Powdered silicon (99.999% pure) was slowly added to the lithium, avoiding any violent reaction. After adding the calculated amount of silicon, the temperature was raised to 1025°K and maintained there until the melt became homogeneous. The melt was then cooled slowly to room temperature. A few pieces of solidified alloy were then used to prepare a positive electrode, using the method described for the Li-Al alloy electrode. Powdered silicon instead of Li-Si alloy was used for preparation of the pure silicon electrodes.

Electrolyte.—Two types of electrolyte, 57 mole percent (m/o) LiCl-43 m/o KCl eutectic (12) and 22 m/o LiF-31 m/o LiCl-47 m/o LiBr, were used. The LiCl-KCl electrolyte was prepared using LiCl of 99.6% purity and KCl of 99.9% purity. It was purified by bubbling chlorine through it at 725°K for 7 ksec, and subsequently scavenging the chlorine by bubbling helium for about 3.5 ksec (13). The reaction of KCl in the electrolyte with lithium in the electrodes (13) should not influence the emf measurements, as they were carried out in only the two-phase regions of the Li-Si system, where composition change should not have any effect. The rate of the reaction was further suppressed by the reduced activity of lithium in the Li-Al alloys used. In addition, any possible uncertainty in the measurements was removed by using LiF-LiCl-LiBr electrolyte. Lithium bromide of 99.0% purity and high purity optical grade LiF were used for the ternary electrolyte. Prior to adding the LiF, the LiCl-LiBr melt was also purified by bubbling chorine through it at 850°K for 3.5 ksec subsequently removing the resultant bromine by bubbling helium for an additional 3.5 ksec.

Apparatus.—A tubular furnace (150 mm high, 75 mm diameter) was used in conjunction with a proportional band temperature controller to heat the cell. Chromel-Alumel thermocouples and a millivolt potentiometer were used for temperature measurements and another millivolt potentiometer for the emf measurement. The other electrical instruments included a d-c power supply, together with the necessary logic and switching circuitry to cycle the cell automatically according to a preset charge-discharge program, and a dual-channel recorder for measuring cell potential and current.

Procedure.—About 0.1 liter of the electrolyte was placed in the stainless steel container which, in turn, was placed inside the quartz enclosure in the furnace. The electrolyte was heated to a particular temperature and the electrodes were positioned in the melt.

After thermal equilibrium was attained, the emf measurement was carried out. Measurements were continued until the value became constant (less than ±0.1 mV) at that temperature. The equilibrium period was observed to be about 1.8 ksec, but 110 ksec were given for some measurements to see if any fluctuation in the emf value would occur. The emf measurements were made at several temperatures (by alternately raising and lowering the temperature) in each of the two-phase regions of the Li-Si system.

Preparation of samples for analyses.—A mixture of 72.4 a/o lithium and 27.6 a/o silicon was melted in a nickel container, cooled to room temperature, and ground to a fine powder. It was then annealed at 775°K for 600 ksec, cooled slowly to room temperature, and reground. A small portion of this powder was sealed in a fine silica capillary for x-ray diffraction analysis. Another portion (0.3g) for differential thermal analysis (DTA) was sealed in a small, specially designed nickel container which could be closed nearly gas-tight with a threaded cap. A second DTA run was carried out using a 60 a/o Li-Si mixture which was prepared in the same manner.

The sample for the scanning electron microscope was prepared by melting a 72.4 a/o Li-Si mixture in a nickel container, holding it at 925°K for 15 ksec, and then cooling slowly to room temperature.

Results and Discussion

A series of charge-discharge cycles was carried out between a silicon electrode (0.5g/5 cm^2) and a lithium electrode starting from a very low current density (2 mA/cm^2) and increasing gradually. The silicon electrode was charged only to a composition of 80 a/o lithium. The charge-discharge cycles (a plot of a typical cycle at 40 mA/cm^2 and 680°K is shown in Fig. 2) proved that the Li-Si electrode is reversible with respect to lithium, and exhibits current efficiencies greater than 95%. The cycles also indicated three well-defined voltage plateaus up to 80% lithium composition. This type of observation was also made by other workers (14-17), but is in conflict with the Li-Si phase diagram (5-8), according to which two plateaus should appear; one from pure silicon to 66.66 a/o lithium, and the other between 66.66 and 80 a/o lithium.

The three voltage plateaus appearing before 80 a/o lithium were confirmed by an experiment in which a pure silicon electrode (0.2g/10 cm^2) was charged at a very low current density (1 mA/cm^2) using a lithium counterelectrode. The results presented in Fig. 3 as cell voltage *vs.* capacity, show three well-defined plateaus before 80 a/o lithium and two more plateaus

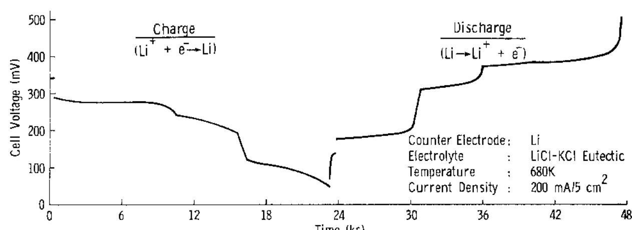

Fig. 2. Discharge-charge cycle for a Li/LiCl-KCl/Li-Si cell

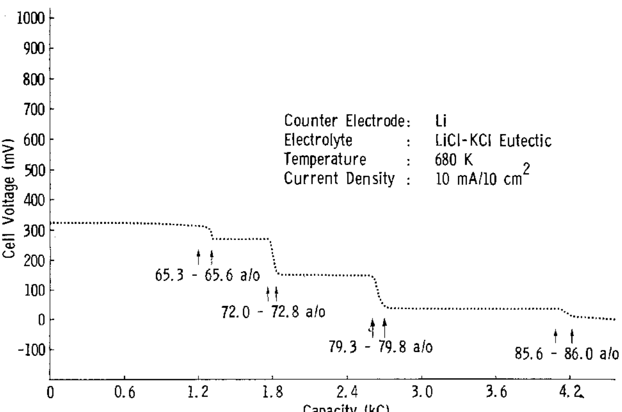

Fig. 3. Slow-rate charge of a silicon electrode

beyond 80 a/o lithium. The same number of plateaus at less than 80 a/o lithium were also observed when a counterelectrode of 40 a/o Li-Al alloy was used (Fig. 4), and when the experiment was repeated using LiF-LiCl-LiBr electrolyte and a 40 a/o Li-Al alloy counterelectrode, the results again showed five voltage plateaus (Fig. 5).

It was previously observed that lithium at its higher activities reacts with KCl in the LiCl-KCl electrolyte and produces volatile potassium which is lost from the cell (13). As a result of this reaction, the lithium concentration of a Li-Si compound calculated from coulometric data can be in error. This is indeed observed in the present case when the results presented in Fig. 5 are compared with those presented in Fig. 3 and 4. They show that the exchange reaction between lithium from the Li-Si alloy and KCl in the electrolyte caused a shift in composition at which the voltage moves to a new plateau value above 80 a/o lithium. This is clearly indicated in Fig. 3 by the transition in the voltage plateau at an approximate composition corresponding to the compound Li_6Si instead of $Li_{22}Si_5$. Evidently a certain amount of the lithium calculated from the coulometric data was lost by reacting with KCl and thus contributed an error in the composition of the compound. The exchange reaction apparently has no effect on the composition ranges covered by the plateaus before 80 a/o lithium, presumably due to lower lithium activity in the alloy.

These studies indicate four compounds are present in the Li-Si system: Li_2Si, $Li_{21}Si_8$, $Li_{15}Si_4$, and $Li_{22}Si_5$. The compounds Li_2Si and Li_4Si (in place of the $Li_{15}Si_4$ found in this investigation) are reported by the Li-Si phase diagram (5-8). The compound $Li_{15}Si_4$ has been reported by Böhm (5) and Klemm and Struck (18). The compound $Li_{22}Si_5$ has also been reported in the literature (11) and its melting point was determined to be 891° ± 3°K in the present investigation. However, no information has been found about the compound $Li_{21}Si_8$, except the probability of its existence, which was reported in recent studies (14, 15, 17). The existence of this compound was confirmed by x-ray diffraction analysis. The data are given in Table I. In addition, its melting point was determined by DTA with heating and cooling rates from 3° to 10°K/min. The compound was observed to melt incongruently at 976° ± 8°K. However, it was also observed that once the compound had melted, it did not reform on cooling because of the probable slow peritectic reaction or supercooling of the melt. The scanning electron microscope photograph (Fig. 6) also indicates a single phase for this compound.

The maximum nonstoichiometric ranges of the Li-Si compounds were clearly indicated by plots such as one in Fig. 7, where a typical profile of voltage *vs.* time during a transition from one voltage plateau to another is shown. As observed in this figure, the voltage profile is curved at each end of the transition. The length of the transition may be influenced by the presence of a composition nonuniformity, giving rise to a mixed potential. The maximum range of nonstoichiometry for each compound was determined from the compositions given by the intersections of the extrapolated straight sections of the curves (Fig. 7). The nonstoichiometric ranges determined in this way are

Fig. 6. Scanning electron microscope photograph of the solidified melt of 72.4 m/o Li-Si alloy after annealing at 925°K for 14.5 ksec showing a single phase of the compound $Li_{21}Si_8$.

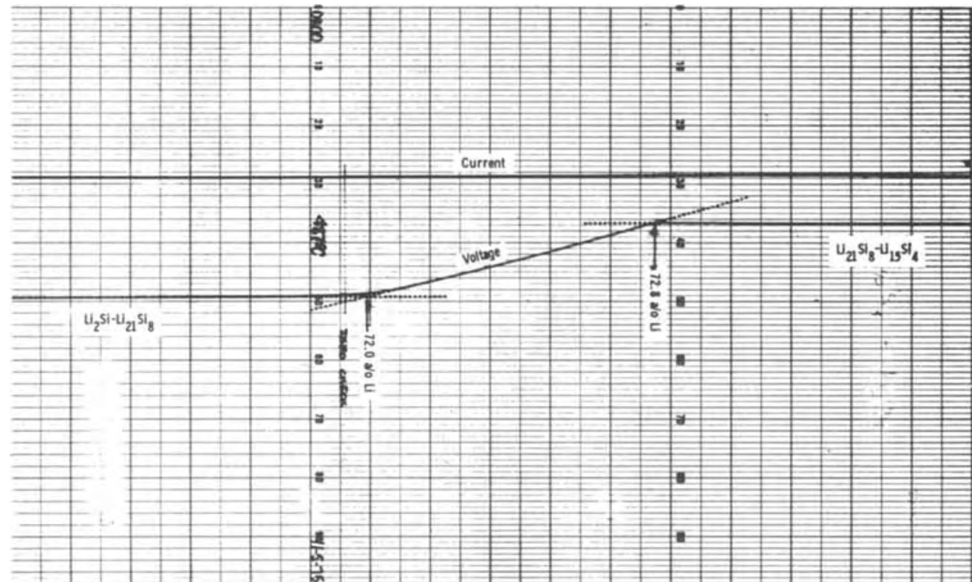

Fig. 7. Typical profile of voltage vs. time through the composition range $Li_{21}Si_8$. (Electrolyte: LiF-LiCl-LiBr and counterelectrode: 40 a/o Li-Al alloy.)

shown by arrows in Fig. 3, 4, and 5. The stoichiometric lithium percentage was found to vary within 0.15 a/o for Li_2Si, within 0.4 a/o for $Li_{21}Si_8$, within 0.15 a/o for $Li_{15}Si_4$, and within 0.1 a/o for $Li_{22}Si_5$. Fedorov and Ioffe (6) reported the stoichiometric lithium percentage to vary within 0.475 a/o for Li_4Si. If this nonstoichiometry is taken for the compound $Li_{15}Si_4$, then it is higher than that of this investigation.

The revised Li-Si phase diagram, after incorporating the results of the present investigation and including the experimental literature data, is presented in Fig. 8. The eutectic temperature, 908° ± 5°K, reported by Böhm (5) appears to be correct as it was confirmed by a DTA run on a 60 a/o Li-Si mixture in this investigation. The melting point of the compound Li_4Si ($Li_{15}Si_4$ observed in this investigation) was also found to be in agreement with that reported in the literature (5, 6). On the silicon side of the phase diagram, the liquidus reported by Böhm (5) appears to be correct as the reported melting point of pure silicon (1685°K) is in agreement with the literature value (1685° ± 3°K) (20), and the liquidus curve is of the pattern generated by using the heat of fusion of silicon and heat capacity data (20).

Further work was directed to emf measurements on compositions in the various two-phase regions of the Li-Si system at selected temperatures. These measurements were made against a 40 a/o Li-Al alloy electrode and are presented in Fig. 9.[1] In the temperature range of 650°-725°K, they are also represented by the relations

$E = -34.525 + 0.1056T$	(0-66.3 a/o Li)	[1]
$E = -88.097 + 0.1122T$	(66.6-72 a/o Li)	[2]
$E = -187.529 + 0.0731T$	(72.8-78.8 a/o Li)	[3]
$E = -311.452 + 0.0954T$	(79.1-81.4 a/o Li)	[4]
$E = -473.856 + 0.2632T$	(81.6 a/o Li to Li [liq] equilibrium)	[5]
$E = -464.438 + 0.2488T$	(9-47 a/o Li in Li-Al alloy *vs.* Li [liq])	[6]

where E = emf (mV) and T = temperature (°K).

The lithium activities with reference to pure liquid lithium as the standard state were calculated by con-

[1] The curves in these figures are least squares fits to the data points.

sidering the following cell reactions

$$\text{Li (liq.)} = [\text{Li}]_{\text{Al}} \text{ (solid 40 a/o Li-Al alloy)} \quad [7]$$

for which

$$-n\mathbf{F}E_{[7]} = \overline{\Delta G'}_{\text{Li}} = RT \ln a'_{\text{Li}} \quad [7\text{A}]$$

$$\text{Li (liq.)} = [\text{Li}]_{\text{Si}} \text{ (solid, two-phase Li-Si alloys at equilibrium)} \quad [8]$$

for which

$$-n\mathbf{F}E_{[8]} = \overline{\Delta G}_{\text{Li}} = RT \ln a_{\text{Li}} \quad [8\text{A}]$$

and

$$[\text{Li}]_{\text{Al}} \text{ (solid 40 a/o Li-Al alloy)} = [\text{Li}]_{\text{Si}} \text{ (solid, two-phase Li-Si alloys at equilibrium)} \quad [9]$$

for which

$$-n\mathbf{F}E_{[9]} = \overline{\Delta G}_{\text{Li}} - \overline{\Delta G'}_{\text{Li}} = RT \ln \frac{a_{\text{Li}}}{a'_{\text{Li}}} \quad [9\text{A}]$$

where R = gas constant, T = temperature °K, $\mathbf{F}$ = Faraday constant, n = number of electrons, a'_{Li} and a_{Li} = lithium activities in the Li-Al alloy and the Li-Si alloys, respectively, and $\overline{\Delta G'}_{\text{Li}}$ and $\overline{\Delta G}_{\text{Li}}$ = the relative partial molar free energies of Li in the Li-Al alloy and the Li-Si alloy, respectively.

Since reaction [8] is the sum of reactions [7] and [9] ($E_{[8]} = E_{[7]} + E_{[9]}$), the relative partial molar-free energies $\overline{\Delta G}_{\text{Li}}$, and activities, a_{Li}, of lithium were calculated from the measured values of $E_{[7]}$ and $E_{[9]}$ using relation [8A]. The results are given at various temperatures in Table II.

The relative partial molar entropies of lithium, $\overline{\Delta S}_{\text{Li}}$, were calculated from the relation

$$\overline{\Delta S}_{\text{Li}} = n\mathbf{F}\, dE/dT \quad [10]$$

using the experimental values of dE/dT reported earlier in Eq. [1]-[6]. These results are reported in Table III.

The relative partial molar enthalpies of lithium, $\overline{\Delta H}_{\text{Li}}$, were calculated from the relation

$$\overline{\Delta H}_{\text{Li}} = -n\mathbf{F}E + n\mathbf{F}T\, dE/dT \quad [11]$$

and are also given in Table III. In addition, $\overline{\Delta H}_{\text{Li}}$, in the composition range 81.6 a/o Li to liquid lithium, was calculated using the equilibrium lithium mole fractions, $X^{\text{Sat}}_{\text{Li}}$, at various temperatures (given in the phase diagram) and assuming a lithium activity coefficient of unity. This assumption is not unreasonable at these high concentrations of lithium ($X_{\text{Li}} > 0.95$) when the activity coefficient of lithium in Li-Al alloys at concentrations of greater than 80 a/o Li is observed to be unity (21). The value of $\overline{\Delta H}_{\text{Li}}$ calculated by the relation

$$\overline{\Delta H}_{\text{Li}} = R \left[\frac{\partial \ln X^{\text{Sat}}_{\text{Li}}}{\partial\, 1/T} \right] \quad [12]$$

was found to be 196.7 cal/g-atom, which was in good agreement with the value of 215.3 cal/g-atom determined from the emf data.

The silicon activities with reference to pure solid silicon as the standard state were calculated using a Gibbs-Duhem relation (22) of the type

$$\log \gamma_{\text{Si}} = -\left[\frac{\log \gamma_{\text{Li}}}{(1 - X_{\text{Li}})^2} \right] X_{\text{Li}} X_{\text{Si}} - \int_{X'_{\text{Si}}}^{X_{\text{Si}}} \left[\frac{\log \gamma_{\text{Li}}}{(1 - X_{\text{Li}})^2} \right] dX_{\text{Si}} - \int_{X_{\text{Si}}=1}^{X'_{\text{Si}}} \left[\frac{\log \gamma_{\text{Li}}}{(1 - X_{\text{Li}})^2} \right] dX_{\text{Si}} \quad [13]$$

where γ = the activity coefficient of the designated component ($\gamma = a/X$), X = the mole fraction of the

designated component, and X'_{Si} = the mole fraction of silicon with a known activity.

The calculated silicon activities, a_{Si}, and the relative partial molar free energies of silicon, $\overline{\Delta G}_{Si}$, obtained using the relation

$$\overline{\Delta G}_{Si} = RT \ln a_{Si} \quad [14]$$

are given at various temperatures in Table II.

The relative partial molar enthalpies of silicon, $\overline{\Delta H}_{Si}$, were calculated from plots of log γ_{Si} *vs.* $1/T$ and the relative partial molar entropies of silicon, $\overline{\Delta S}_{Si}$, were calculated from the relation

$$\overline{\Delta G}_{Si} = \overline{\Delta H}_{Si} - T\,\overline{\Delta S}_{Si} \quad [15]$$

The calculated values of $\overline{\Delta H}_{Si}$ and $\overline{\Delta S}_{Si}$ are given in Table III.

In addition the standard free energies of formation, $\Delta G°_f$, for the compounds Li_2Si, $Li_{21}Si_8$, $Li_{15}Si_4$, and $Li_{22}Si_5$ per gram atom of lithium at 650°, 700°, 725°, and 750°K were obtained from the relation

$$\Delta G°_f = \overline{\Delta G}_{Li} + \frac{X_{Si}}{X_{Li}} \overline{\Delta G}_{Si} \quad [16]$$

and are given in Table IV.

Summary

A series of charge-discharge cycles were carried out between silicon and lithium electrodes at various current densities at 680°K. These measurements indicated: (*i*) the Li-Si alloy electrode is reversible with respect to lithium and exhibits current efficiencies of greater than 95%, (*ii*) the existence of a new compound, $Li_{21}Si_8$ in the Li-Si system, and (*iii*) the range of nonstoichiometry of the various Li-Si compounds.

The electromotive forces in the two-phase regions of the Li-Si system were measured in the temperature range of 650°-750°K and these values were used to calculate the activities and relative partial molar properties of lithium and silicon. In addition, the standard free energy of formation for Li_2Si, $Li_{21}Si_8$, $Li_{15}Si_4$, and $Li_{22}Si_5$ were also determined over the specified temperature range.

Acknowledgments

The authors are thankful to Messrs. David W. Buttram, Ernest J. Verrier, and Walter J. Wright for assistance in the experimental work; Dr. Jack Johnson and Mr. A. C. Ottolini of the Analytical Chemistry Department for the x-ray diffraction and SEM analyses; Dr. Seymour Katz of the Metallurgy Department for the DTA; and Drs. Elton J. Cairns and John S. Dunning of the Electrochemistry Department for useful suggestions and discussions.

ABSTRACT

The effects on battery life of lead-calcium-tin grids (Pb + 0.07%Ca + 0.7%Sn) with bismuth content in the range 7-420 ppm have been studied. Full-sized batteries were cycled to failure using either modified SAE J240 or J537 procedures. The results showed that in the test designed to cause failure by corrosion (SAE J537), no ill effects due to bismuth were noted. In the tests designed to model automotive service (J240), cycle life tended to increase with increasing bismuth content of the grids.

The growing production of maintenance-free, lead-acid, SLI batteries has focused attention on the impurity elements in the lead used in alloying of the lead-calcium-tin grid metal. Bismuth is one of the most common impurities in both refined primary and secondary lead, and, because of its chemical similarity, it is excessively expensive to remove below 200 ppm. Some manufacturers imply that bismuth even at the 200 ppm level is deleterious to the performance of the grid alloy by specifying as little as 10 ppm maximum while others allow as much as 500 ppm.

The chemistry of the primary and secondary available lead is such that a bismuth content requirement for this application below 200 ppm would eliminate major sources of lead from use in lead-calcium-tin grid alloys. The importance of establishing the effects of bismuth at levels at or above 200 ppm is therefore obvious. Toward this end, research has been carried out by both primary and secondary producers. Sokolov and co-workers (3) have reported that bismuth up to 180 ppm has no effect on casting or mechanical properties of lead-calcium-tin grids or the gassing properties of the grids.

The investigation reported herein studied the effect on battery life of lead-calcium-tin grids with bismuth contents in the range 5-500 ppm using full-size batteries tested by modified SAE life cycle testing requirements.

These batteries were cycled to failure in two modes: one designed to cause failure by corrosion (Cycle A) and the other to closely model service in an automobile (Cycle B). It was intended to determine the influence of bismuth, if any, on battery cell overcharge current, gassing, grid corrosion, and active-material stability. Also, valuable insight into the characteristics of lead-calcium-tin MF batteries would be obtained.

Experimental Procedures

Battery construction.—Twenty batteries were constructed in all, eighteen with lead-calcium-tin grids and two with antimonial grids. All of the lead-calcium-tin were of nominal composition Pb-0.07%Ca-0.7%Sn. Nominal bismuth contents were 5, 20, 200, and 500 ppm by weight. The actual composition of these alloys and of the standard antimonial lead composition employed are presented in Table I.

The lead-calcium-tin grids were cast in 600# lots at Wirtz Manufacturing Company, Port Huron, Michigan, on a commercial grid casting machine. In size they were nominally 4-7/8 in. × 5-11/16 in. × 0.062 in.

The only intentional variation in the batteries was in the bismuth content of their grids. A standard 12V, Group 24 design was used employing polypropylene containers with over-the-wall interconnections. All batteries were handmade and had the following features in common:

Nominal capacity: 50 A-hr, equivalent to approximately 70 min reserve capacity rating.

Plates per cell: Four positive, five negative.

Active material: Conventional formula employing commercially available lead oxide. Cube weight (density) of the pastes was controlled to 67-68 g/in^3 (Approx. 4.1 g/cm^3).

Separators: Standard automotive Daramic, 0.065 in. over-all and 0.20 in. web. Separators were folded around each positive plate with ribs inward and the fold at the bottom.

Vent plugs: Standard Richardson gang-vent plugs.

Formation: In 1.120 sp gr acid. Four hours at 2A followed by 44 hr at 3.5A. At the latter rate battery voltage was limited to 16V maximum.

One important difference between these batteries and mass-produced batteries is that the thicknesses of the pasted positive and negative plates were approximately equal. In commercial batteries the amount of positive material is usually greater than the amount stoichiometrically needed for reaction with the negative plates, in order to prolong the life of the battery as the positive plates wear out. The test batteries, however, had approximately 25% less positive material than negative material, assuring capacity limiting by the positive plates throughout the duration of the test. Further, the use of only 9 plates per cell (as compared to at least 13 for commercial maintenance-free batteries) increased current density per plate, again reducing battery life. These design variations changed the rate of failure but not the mode.

Test Cycle A.—This test is based upon the overcharge-life test of SAE Standard J537. Each cycle has

Table I. Analysis of battery grids

Alloy No.	% Ca	% Sn	ppm Bi	Battery No.
1	0.055	0.77	7	1, 2, 9, 13, 14
2	0.071	0.66	25	3, 4, 10
3	0.072	0.76	190	5, 6, 11, 15, 16
4	0.055	0.68	420	7, 8, 12, 17, 18
Antimonials: Sb-4.80%, As-0.38% Sn-0.37%, Bi-200 ppm				19, 20

* Electrochemical Society Active Member.
Key words: batteries, bismuth, cycling, grids, lead.

a duration of exactly one week, and is described as follows:

Overcharge: Place battery on constant current charge at 2A for a total of 110 hr.

Stand: Let battery rest on open circuit for 48 hr.

Test discharge: Apply 150A load to battery for 30 sec, or to a battery end-point voltage of 7.2V, whichever occurs first. Then return battery to overcharge step.

Water: Top up battery as required, weekly.

Temperature: All of the above steps are conducted at 75° or 120°F. At 75°F the battery is kept in controlled room ambient, to within 2°F. At 120°F the battery is in a water bath constructed per SAE J537 and controlled to within 1°F.

Failure: The battery is considered failed the first time it fails to remain above 7.2V for at least 30 sec in the test discharge step above.

The Cycle A current at 2A was selected by subjecting cells of the same design and materials used in the subsequent test to various constant overcharge currents (Table II), ranging from 0.3 to 4.5A (SAE standard current). At 2A (and 75°F) the battery voltage was 17.0V (2.83V/cell) with a positive plate potential of 1.42V *vs.* $Hg/HgSO_4$ reference. These conditions were sufficiently severe to produce a significant rate of corrosion without a totally unrealistic (regarding automotive service) battery voltage.

Results Cycle A.—Twelve batteries were subjected to Cycle A, two of each alloy at 75°F and one of each at 120°F. The batteries were cycled to failure as defined above. Battery lifetimes (cycles to failure) are listed in Table III. There is no trend, positive or negative, on cycle life due to bismuth.

While Test Cycle A was in progress, separate tests were run on the batteries to determine the characteristic overcharge current *vs.* battery voltage curves for each of the batteries. These curves were obtained as follows: After the weekly 110 hr overcharge period, the batteries were left on charge at 2A and voltage measurements were made. Voltages of 3 cells per battery were measured, as were voltages from the positive plates to a PbO_2 reference electrode inserted into the electrolyte through the cell vent opening. These two sets of voltage readings represent very stable values because of the 110 hr period of constant current which had preceded the measurements. Then voltage measurements were taken, at lower constant-current settings. All potential measurements were made after waiting enough hours, per data point, for equilibrium to be reached. While the data are shown as being taken at the end of 11 weeks of cycling, similar runs were made at 8 and 15 weeks with essentially identical results.

The resulting curves are presented in Fig. 1 and 2. The significance of these curves is that the overcharge current at a given battery voltage does not vary with bismuth content of the grid. This means that bismuth, up to 420 ppm does not affect the gassing or corrosion rate of the batteries. This supports the data of Table III in that, although all batteries failed by corrosion, the time to failure was not a function of the bismuth content.

The appearance of the dismantled batteries showed that the principal mode of failure was certainly grid corrosion. The grids had corroded to such an extent that meaningful weight and dimensional measurements could not be obtained. The positive active material on the remaining portions of the grids appeared to be in good condition. Shedding losses of active material were estimated to be less than 10%.

During the course of Cycle A, no variation in the amount or rate of water loss was noted among the alloys.

Test Cycle B.—This test is based upon the life test described in SAE J240. Each cycle has a duration of exactly 1 week and is described as follows:

Shallow cycles: Each cycle consists of a discharge of 25A for 3.5 min, followed immediately (switching time allowed) by a charge at a voltage limited to 14.8V and a current limited to 25A. Charging time is 10 min. In practice the first portion of charge is current limited

Table II. Cell and positive-plate voltages vs. overcharge current-test cells

Over charge amperes	Avg. cell V (room temp.)	Reference electrode (room temp.)	Avg cell V (120°F)	Reference electrode
0.3	2.70	1.37	2.62	1.32
1.0	2.80	1.41	2.73	1.37
2.0	2.83	1.42	2.78	1.40
4.5	2.90	1.44	2.85	1.42

Note: Reference electrode measurements were made with a stabilized PbO_2 electrode, but expressed here *vs.* an Hg/Hg_2SO_4 electrode for direct comparison to the literature.

Table III. Data from Test Cycle A

Battery No.	Alloy No.	Bismuth ppm	Test temperature	Weekly cycles to failure	Average life in alloy group
1	1	7	75°F (24°C)	28	27.0
2	1	7	75°F (24°C)	26	
3	2	25	75°F (24°C)	28	26.5
4	2	25	75°F (24°C)	25	
5	3	190	75°F (24°C)	29	28.5
6	3	190	75°F (24°C)	28	
7	4	420	75°F (24°C)	23	24.5
8	4	420	75°F (24°C)	26	
9	1	7	120°F (49°C)	20	
10	2	25	120°F (49°C)	19	
11	3	190	120°F (49°C)	19	
12	4	420	120°F (49°C)	19	

Additional data: There was no consistently observed difference in the water consumption patterns between any of the batteries. Toward the end of life there were sporadic reductions in water consumption owing to short circuits in the cells in the high temperature batteries. No shorting was observed in the lower temperature units.

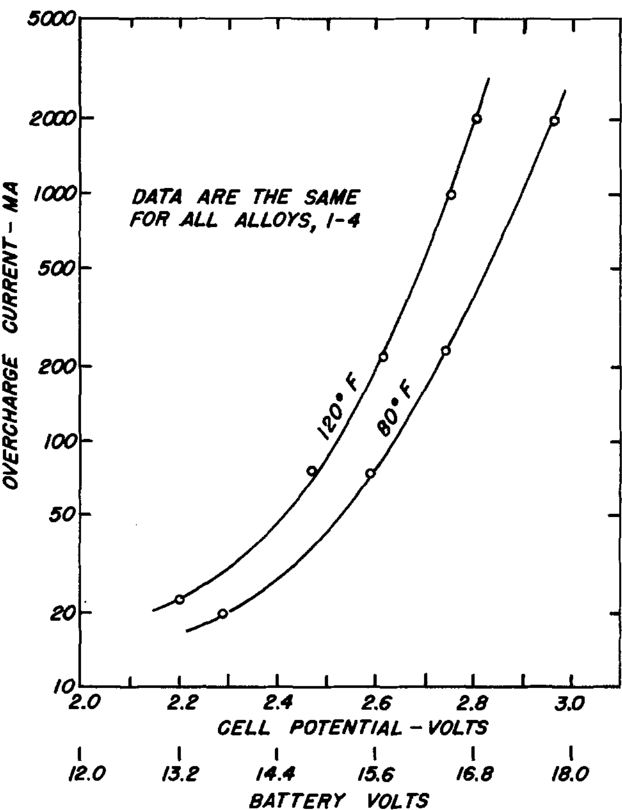

Fig. 1. Overcharge currents vs. cell potential

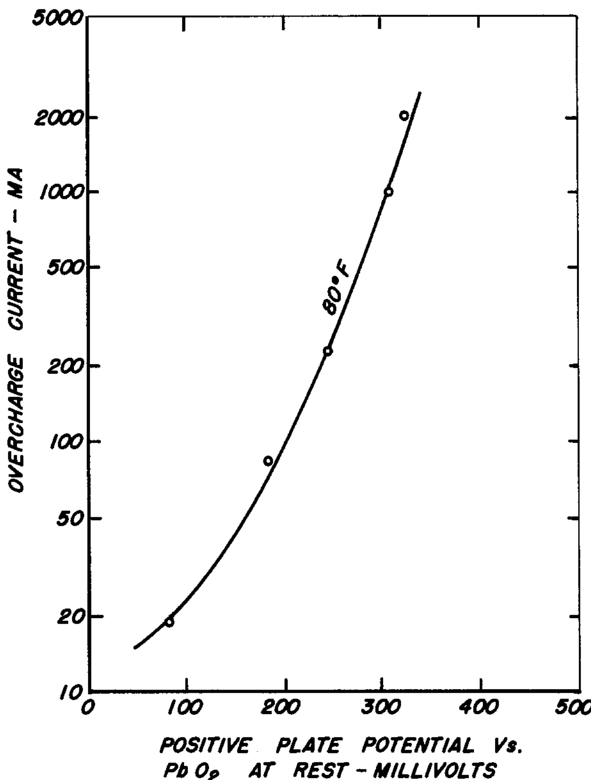

Fig. 2. Overcharge gassing currents, alloys 1 thru 4 (vs. positive plate potential).

and the latter portion is voltage limited. Following the charging period the battery is given a 30 sec rest on open circuit. This shallow cycling is repeated 429 times per week, for a total of 100 hr.

Stand: The battery is given a 60 hr rest on open circuit.

Test discharge: Same as in Test Cycle A except load current is 300A. This is equivalent to 1.48 A/in.^{2} or 0.229 A/cm^2 of apparent total positive plate surface area. The battery is then returned to the shallow cycles without a separate charge.

Water: As in Test Cycle A.

Temperature: Maintained at 105°F.

Failure: Defined as in Test Cycle A.

Instead of the SAE J240 2 min shallow cycle discharge, a 3.5 min discharge time was used for Test Cycle B. It has been found that the mild 2 min discharge lengthens the test time to an unreasonable degree (years) if the test is applied to batteries made of lead-calcium-tin grids. This is because of the very low end-of-charge current and consequent low amount of grid corrosion as compared to standard antimonial grid batteries. There is also much less gassing to disrupt the active material in MF batteries. Therefore, a discharge time which nearly doubles the SAE recommended depth of discharge was used. The shallow cycle portion of this test cycle was automatically controlled by apparatus constructed expressly for this experiment.

Results Cycle B.—Eight batteries in all were subjected to Test Cycle B: six lead-calcium-tin and two antimonial. The results (cycles to failure) are presented in Table V. As in Cycle A there was no deleterious effect with increasing bismuth. On the contrary, cycle life increased as bismuth content increased.

Following failure, the positive grids from Cycle B batteries were removed from the cases, dried, and weighed with the active material intact. The active material was then removed in a solution of sodium hydroxide, mannitol, and hydrazine hydrochloride. The bare grids were reweighed. The resultant weight losses of active material and grid metal are included in Table IV. Corrosion of the antimonial grids was so severe that meaningful measurement could not be made.

Table IV. Data from Test Cycle B

Battery No.	Alloy No.	Bismuth ppm	No. of 14 min cycles to failure	Avg. percent loss in positive grid weight	Avg. percent loss in positive act. material weight
13	1	7	6006	—	—
14	1	7	6435	22%	13%
15	3	190	6435	25%	10%
16	3	190	7722	25%	13%
17	4	420	8151	22%	20%
18	4	420	8580	21%	20%
19	Sb	200	4290	—	—
20	Sb	200	4290	—	—

1. Battery 13 failed because of an apparent short circuit in a cell. The problem has not been located visually. Therefore, it was felt that its grid corrosion and active material loss data were not meaningful.
2. As noted in the test, the two antimonial batteries, at failure, contained such badly disintegrated positive grids that removal from the container was difficult and further weighing and other analysis was essentially impossible.

The mechanism of failure in Cycle B in the lead-calcium-tin batteries is not clear. Failure seems to have occurred due to a combination of factors: (*i*) surface shedding of positive-active material; (*ii*) loosening positive pellets of PbO_2 by a combination of grid corrosion and overcharge gassing, possibly concentrated at the grid-active material interface; and (*iii*) piling up of shedded PbO_2 within the lower portion of the folded separators which tended to "block off" a significant part of the positive plate. Grid growth was not noticeable in any of these batteries and definitely was not a cause of failure.

In the case of the antimonial batteries the failure mode was primarily severe grid corrosion. During the conduct of the test it was noted that the end-of-charge current, at 14.8V, ranged from 0.2-0.4A for lead-calcium-tin grid batteries, and 4-6A for the antimonial batteries. For the lead-calcium-tin batteries this current decreased as a function of life presumably because of the progressive drop in available capacity. In the antimonial batteries the end-of-charge current increased during life, owing to the familiar antimony poisoning phenomenon at the sponge lead surface. Thus, the current at end of life was 30 times higher for the antimonial type than the other. Therefore, one would expect the antimonial batteries to fail more by grid corrosion, and they did. Even in this case, however, no grid growth could be found.

Summary

In an overcharge life test (based on SAE J537) designed to cause battery failure by grid corrosion, no ill effects due to bismuth were noted. Characteristic curves of overcharge amperage *vs.* battery voltage were virtually identical for lead-calcium-tin batteries containing 7-420 ppm bismuth.

In a cycle life test (based on SAE J240) designed to model automotive service, lead-calcium-tin batteries containing 7-420 ppm bismuth failed to show any ill effect due to bismuth. In fact, there was an unmistakable trend to increased cycle life with increasing bismuth.

Acknowledgments

A Solid-State Galvanic Cell with Fluoride-Conducting Electrolytes

J. Schoonman*

Solid State Department, Physical Laboratory, State University of Utrecht, Sorbonnelaan 4, Utrecht-De Uithof, The Netherlands

ABSTRACT

$BiO_{0.09}F_{2.82}$ and β-PbF_2:AgF are suitable fluoride conducting electrolytes for application in galvanic cells. A simple fabrication method for the cell Pb/β-PbF_2:AgF/$BiO_{0.09}F_{2.82}$/Bi is described. Open-circuit voltages are in accord with a theoretical value of 0.33V based on the cell reaction $3Pb + 2BiF_3 \rightarrow 3PbF_2 + 2Bi$. Cells were discharged in the temperature region 298°-375°K with current densities of 12-63 mA/m^2. Short-circuit currents range from 15.7 to 386 mA/m^2. Relatively constant load-circuit voltages were attained over periods of days.

The electrical properties of fluoride conductors with fluorite or tysonite structure have received considerable interest in the recent literature (1-8). Some of these materials are presently used as solid electrolytes.

PbF_2 has been applied successfully as a solid electrolyte in a thin film galvanic cell (5). Thin film galvanic cells Pb/PbF_2/CuF_2(PbF_2)/Cu have been fabricated by vacuum evaporation (5). CuF_2 is, however, a highly resistive material at room temperature. In order to improve the conductivity CuF_2 was codeposited with PbF_2. This in turn leads to an open-circuit voltage (OCV) lower than the theoretical OCV of 0.70V. Both CuF_2, and especially AgF are reactive toward moisture in air. Special precautions are, therefore, needed to avoid blistering of thin films (5).

Kennedy and Miles (6) have tested potassium fluoride-doped β-PbF_2 as an electrolyte in galvanic cells with CuF_2 or AgF as cathode materials. Open-circuit voltages of 0.70 and 1.30V, respectively, were achieved, but the cell potentials fell rapidly when placed under load and current drawn. This poor performance could be due to the formation of an anode passivation layer consisting of low conductivity pure α-PbF_2 (6).

Recently, we have reported on solid electrolyte properties of tysonite-related BiO_xF_{3-2x} ($x = 0.09 \sim 0.1$) (9). The conductivity is ionic and exceeds at ambient temperatures the conductivity of undoped β-PbF_2. When β-PbF_2 is doped with monovalent cations the conductivity substantially increases. Mass transport then occurs via fluoride ion vacancies as in BiO_xF_{3-2x} · BiO_xF_{3-2x}, as well as β-PbF_2 doped with monovalent cations exhibit such conductivity values that extremely thin films are not required. Fabrication of galvanic cells by tedious vacuum evaporation techniques can therefore be avoided. Moreover, both fluorides are quite stable in air.

Solid-state galvanic cells Pb/β-PbF_2:AgF/BiO_xF_{3-2x}/Bi were fabricated using a very simple technique. Their discharge characteristics were studied in the temperature region 290°-375°K.

The cathode-electrolyte BiO_xF_{3-2x} ($x = 0.09 \sim 0.1$) can be considered as oxide-doped bismuth fluoride (9). The following cell reaction

$$3Pb + 2BiF_3 \rightarrow 3PbF_2 + 2Bi \quad [1]$$

should then lead to an OCV of 0.33V.

Experimental Aspects

BiO_xF_{3-2x} phases were obtained by heating mixtures of Bi_2O_3 (Merck, p.a.) and excess NH_4F (Baker, AR). A heat-treatment at 575°K for a period of 2 hr yielded a phase, of which powder diffraction data revealed good agreement with data reported for the phase $BiO_{0.09}F_{2.82}$ (10). Upon heating this phase in air for periods shorter than 1 hr at 925°K we obtained the approximate composition $BiO_{0.1}F_{2.8}$ without the reported (11) fcc β-phase.

β-PbF_2:AgF [0.5 mole percent (m/o)] was prepared by melting zone-refined lead fluoride (Merck, Optipur) with AgF (Merck). The melting procedure was carried out under dried, oxygen-free nitrogen in graphite crucibles (12). The solid electrolytes were ground in a ball mill. The resulting powders were wetted with the volatile ethyl acetate. Thin disks of Pb and Bi (thickness $\sim 1 \times 10^{-3}$m, area 2.83×10^{-5} or 1.77×10^{-4}m^2) were painted with the β-PbF_2:AgF-ethyl acetate and BiO_xF_{3-2x}-ethyl acetate mixtures, respectively. After evaporation of the ethyl acetate each disk was covered with about 1×10^{-5} kg solid electrolyte. Galvanic cells Pb/β-PbF_2:AgF/BiO_xF_{3-2x}/Bi were then obtained by spring-loading the disks in the appropriate sequence between two flat platinum electrodes of a conventional conductivity cell. This cell was equipped with a furnace. The total thickness of the solid electrolytes was about 1×10^{-4}m.

OCV measurements were recorded from a Keithley Model 616 digital electrometer. Short-circuit currents were measured with a Keithley Model 445 digital picoammeter. Polarization currents through the cell (−)Bi/BiO_xF_{3-2x}/Pt(+) were measured with a Keithley Model 153 microvolt-ammeter, whereas applied potential differences across the cell were made using a Keithley Model 610 BR electrometer.

Alternating-current conductivities here referred to were measured with impedance bridges, details of which have been published before (4).

Experimental Results

The galvanic cells exhibited room temperature OCV's of 0.330-0.335V. These values are in good agreement

* Cathode material: $BiO_{0.09}F_{2.82}$.

with the theoretical OCV. These OCV's remain constant over periods of weeks. After such storage periods these cells and freshly prepared cells were used in discharge experiments. These were all performed in air.

Upon application of a constant load (R_L) the load-circuit voltage (LCV) dropped within 5 min to a stable value. LCV's then remained nearly constant during discharge: at room temperature the LCV dropped from 0.15 to 0.13V over a period of 14 days, the load being 1 MΩ. At 363°K and a load of 0.2 MΩ the LCV decreased from 0.23 to 0.22V in 2 days. After these periods discharges were terminated. After disconnecting a load theoretical OCV's were reached within 30 min.

The d-c resistances of cells were calculated using the usual expression

$$R_{dc} = \frac{\text{OCV} - \text{LCV}}{\text{LCV}} R_L \qquad [2]$$

Discharge under a 1 MΩ and a 0.1 MΩ load revealed at room temperature d-c resistances in the range 1.1 × 10^5-5.5 × 10^5 and 0.58 × 10^6-1.23 × 10^6Ω for 1.77 × 10^{-4} and 2.83 × 10^{-5}m² area cells, respectively. These resistances were obtained regardless of whether $BiO_{0.09}F_{2.82}$ or $BiO_{0.1}F_{2.8}$ was used as cathode material. For two galvanic cells (2.83 × 10^{-5}m² area) frequency independent electrolyte resistances R_e and R_{dc} values are summarized in Table I. In addition to these data short-circuit currents are included.

These data are to be compared with a room temperature value of about 1.8 × 10^6Ω, which can be inferred for the d-c resistance of a 1 × 10^{-5}m² area thin film galvanic cell $Pb/PbF_2/CuF_2(PbF_2)/Cu$ from the discharge curve under a 3.3 MΩ load. Discharge under a 0.3 MΩ load revealed for this type of cell for R_{dc} the value 3.36 × 10^5Ω (5).

Performance characteristics improved substantially at elevated temperatures. Figure 1 presents normalized

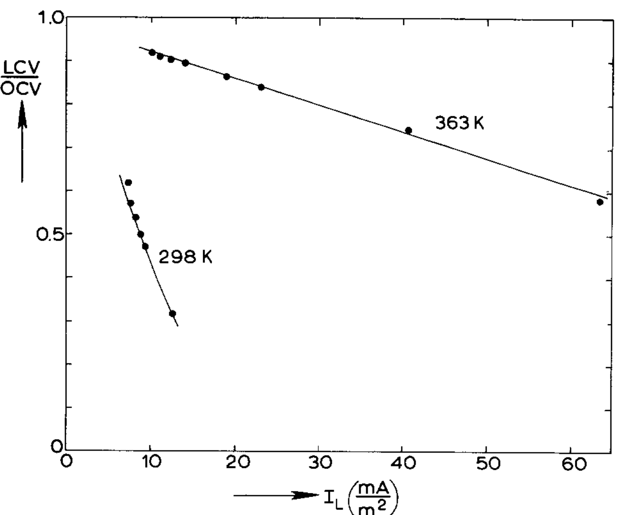

Fig. 1. Normalized load-circuit voltages (LCV/OCV) *vs.* load current densities for 2.83 × 10^{-5} m² area cells with $BiO_{0.09}F_{2.82}$ as cathode material. T = 298°K, R_L = 0.3-1.0 MΩ; T = 363°K, R_L = 0.1-0.9 MΩ.

load-circuit voltages (LCV/OCV) *vs.* current densities at 298° and 363°K. Data on the performance of two galvanic cells at different temperatures are summarized in Table II.

In Fig. 2 the temperature dependence of R_{dc} is plotted *vs.* reciprocal temperature. An activation enthalpy of 0.30 eV was obtained for a freshly prepared cell, and a value of 0.41 eV for a cell which had been discharged for 2 weeks under a 1 MΩ load (cf. Table II).

Cells of the type $Pt/Bi/BiO_{0.09}F_{2.82}/Pt$ were prepared by spring loading a Bi disk, which had been covered with a thin layer of $BiO_{0.09}F_{2.82}$ between two Pt electrodes of a conductivity cell. Cells were polarized with the Bi electrode negative. Steady-state currents exponentially increased on applied potential difference E (Fig. 3). The currents can be expressed by (1)

$$I = \frac{RT}{LF} \sigma^o_h \left[\exp(EF/RT) - 1\right] \qquad [3]$$

where L denotes the cell constant (ratio of electrolyte thickness to electrode area), and σ^o_h the specific electron hole conductivity for $BiO_{0.09}F_{2.82}$ in contact with Bi. Frequency independent conductances showed the electrolyte conductivity to be 6.47 × 10^{-4} Sm^{-1}, (Siemens/m) while the polarization currents lead to the value 1.24 × 10^{-8} Sm^{-1} for σ^o_h.

Discussion

The experimental OCV's confirm the cell reaction to be reaction [1]. The electrode reactions may be considered in terms of the mobile majority ionic point defects

$$\text{anode, } Pb(s) \rightarrow Pb^x_{Pb} + 2V^{\cdot}_F + 2e' \qquad [4]$$

$$\text{cathode, } Bi^x_{Bi} + 3V^{\cdot}_F + 3e' \rightarrow Bi(s) \qquad [5]$$

Polarization studies of the cell $(-)Pb/\beta\text{-}PbF_2/C(+)$ revealed (6, 13) that the interface $Pb/\beta\text{-}PbF_2$ behaves reversibly to both ionic and electronic species. Electrode reaction [4] was used to derive the quantitative

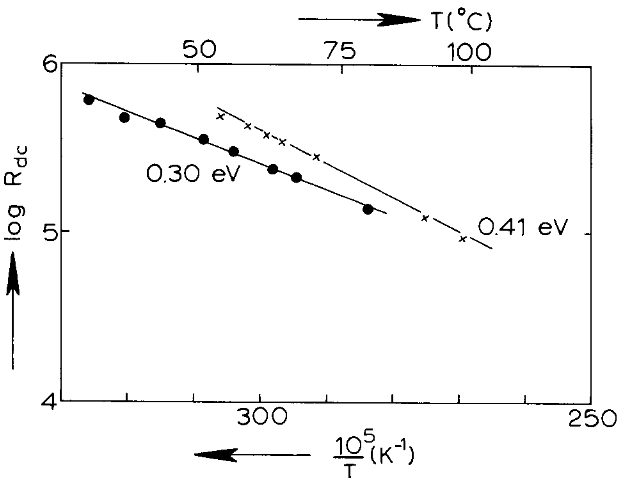

Fig. 2. Temperature dependence of R_{dc} plotted as log R_{dc} *vs.* $10^5/T$. ●, Freshly prepared cell; ×, discharged under a 1 MΩ load for 2 weeks.

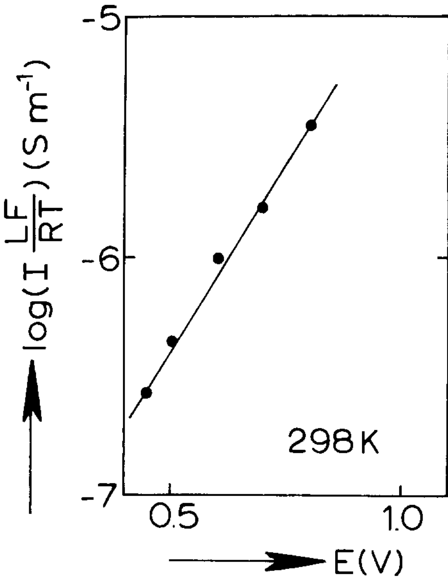

Fig. 3. Electronic conductivity in the cell (−)Bi/$BiO_{0.09}F_{2.82}$/Pt(+). Cell constant 10.6 m^{-1}. $\sigma^{\circ}_{h} = 1.24 \times 10^{-8} Sm^{-1}$.

relations between the concentrations of electrons and ionic point defects F'_i and $V^{\cdot}_F$ in nominally pure and doped β-PbF_2 (13). These expressions reveal that electron currents decrease upon increasing MF-concentrations. This has been confirmed by experimental observation (6). Electron currents will, therefore, be negligibly small in β-PbF_2:AgF.

A study of the frequency dispersion in the conductivity of BiO_xF_{3-2x} between ionically blocking electrodes already revealed negligible electronic conductivity (9). The data in Fig. 3 indicate that $BiO_{0.09}F_{2.82}$ in contact with negatively polarized Bi exhibit very small electron hole currents. The slope of the log $[I(LF/RT)]$ *vs.* E curve is, however, smaller than the theoretical slope, a feature frequently observed for lead halides in contact with lead (1, 14, 15). Whether this behavior is caused by an inefficient blocking of the faradaic processes at the Pt/$BiO_{0.09}F_{2.82}$ interface or a nonreversible behavior at the Bi/$BiO_{0.09}F_{2.82}$ interface cannot be established from the present data.

Since both solid electrolytes exhibit negligible electronic conductivity, electronic leakage will not occur in the galvanic cells.

Plots of the normalized load-circuit voltages (LCV/OCV) *vs.* load current densities (Fig. 1) and data on R_e and R_{dc} (Table I) show that polarization occurs in the galvanic cells. The temperature dependence of R_{dc} revealed activation enthalpies of 0.30 eV for a freshly prepared cell, and 0.41 eV for a cell which has been discharged under a 1 MΩ load for 2 weeks. Both electrolytes have comparable conductivities at room temperature, the values being about 6×10^{-4} Sm^{-1} and about 5×10^{-4} Sm^{-1} for $BiO_{0.09}F_{2.82}$ and β-PbF_2:AgF (0.5 m/o) (12), respectively. Conduction activation enthalpies of several relevant fluorides are summarized in Table III.

These activation enthalpies and the temperature dependence of R_{dc} indicate that the rate-determining step in the cell reaction involves the cathode electrolyte. In regard to the polarization studies on the electrolytes composing the galvanic cell it is also likely that cell polarization partly originates at the Bi/$Bi_{0.09}F_{2.82}$ interface.

Table III. Activation enthalpies for conduction in the temperature region 300°-375°K

Electrolyte	ΔH (eV)	Reference
$BiO_{0.09}F_{2.82}$	0.39	(9)
β-PbF_2:AgF	0.20	(12)
α-PbF_2	0.50, 0.51	(16)

The use of Pb/β-PbF_2:AgF could be limited by the formation of an anode passivation layer of α-PbF_2. Kennedy and Miles (6) detected α-PbF_2 deposits at the anode interface Pb/β-PbF_2:KF after passage of 2 and 9C of charge through a cell Pb/β-PbF_2:KF/Pb. Such deposits were never higher than 4×10^{-5}m. At room temperature the measured discharge of a $2.83 \times 10^{-5}m^2$ area cell was 0.16C (Table II). This could lead to a layer of α-PbF_2 of the order of 10^{-6}m. The room temperature conductivity of α-PbF_2 is about 4×10^{-6} Sm^{-1} (1, 8). Such layers would then exhibit conductances of about 1.1×10^{-4}S. The conductance of the β-PbF_2:AgF layer having a thickness of about 0.5×10^{-4}m amounts to 2.8×10^{-4}S. At 363°K α-PbF_2 exhibits a specific conductivity which is lower than that of $BiO_{0.09}F_{2.82}$ by about factor of 30, the difference with β-PbF_2:AgF being even smaller. The larger conduction activation enthalpy for α-PbF_2 (Table III) accounts for the reduction in the differences in the conductivities at increased temperatures. The thin film geometry is at this temperature again more in favor of α-PbF_2. This in turn strongly supports the interpretation of the temperature dependence of R_{dc} and especially of the partly discharged cell.

Thin film cells of Kennedy and Hunter (5) with the $CuF_2(PbF_2)$ cathode lead to maximum capacities of 1×10^{-2}C at 298°K ($R_L = 3.3 \times 10^6 \Omega$, discharge time 22 hr), and 1.5×10^{-2}C at 348°K (R_L = 0.3 MΩ, discharge time 2 hr). At room temperature discharge times up to 30 hr were attained under a 4 MΩ load. In comparison with the thin film galvanic cells larger capacities are attained with the present cells (cf. Table II). These larger capacities are a direct consequence of the solid electrolyte properties of especially the cathode electrolyte $BiO_{0.09}F_{2.82}$. Extremely thin films are not required, which means that more cathode electrolyte is available in the present cells.

Conclusions

The present study reveals that the solid electrolytes β-PbF_2:AgF and $BiO_{0.09}F_{2.82}$ can be successfully used in a galvanic cell. Powders of these electrolytes are, when dispersed in ethyl acetate, particularly suitable for the fabrication of galvanic cells. The ethyl acetate quickly evaporates at room temperature. The solid electrolytes are stable in air. Their electronic conduction is practically negligible. Electronic leakage will, therefore, not occur in the galvanic cell.

Passivation of the anodes by α-PbF_2 will be a minor importance in the temperature region 298°-375°K and for capacities of 0.1-0.2C. In regard to the conductivity of α-PbF_2 at elevated temperatures the upper limit of the capacities to be attained can be set at ~1C, before anode passivation would seriously affect the operation of the cells.

Acknowledgments

The author is indebted to Mr. G. J. Dirksen for the preparation of the electrolytes, and to Prof. Dr. G. Blasse for critically reading the manuscript.

Mechanism of Pit Initiation on Aluminum Alloy Type 7075

Steven Dallek* and R. T. Foley**

Chemistry Department, The American University, Washington, D. C. 20016

ABSTRACT

The influence of anions on the initiation of pitting and the kinetics of pit growth on aluminum alloy Type 7075 has been investigated. The order of reaction (*i.e.*, the number of anions per Al surface reaction site) and the energy of activation for pitting initiation have been measured in F^-, Cl^-, Br^-, and I^- solutions. The technique involved potentiostating the alloy in the range of anodic passivity, injecting a solution of halide ion, and recording the time, τ, at which an exponential increase in corrosion current occurs. The slope of the plot of the logarithm of $1/\tau$ *vs.* the logarithm of the concentration gives, n, the number of anions associated with an Al surface reaction site in the primary pitting initiation step. The value of n in $1N$ H_2SO_4 varies with the anion as: for Cl^-, $n = 8$; for Br^-, $n = 4$; and for I^-, $n = 2$. In an electrolyte of pH 5.8 the n value for Cl^- is 2; for Br^-, 2; and for F^-, 3. The activation energies measured over the temperature range 5°-60°C in $1N$ H_2SO_4 were: for Cl^-, $E_a = 18$ kcal mole^{-1}; for Br^-, 26 kcal mole^{-1}; and for I^-, 6.6 kcal mole^{-1}. In an electrolyte of pH 5.8, the E_a is 12 kcal mole^{-1} for Cl^-; 10 kcal mole^{-1} for Br^-; and 4.6 kcal mole^{-1} for F^-. These results are interpreted in terms of the formation of transitory species akin to activated complexes, of specific composition, such as $AlBr_4^-$.

The mechanism of the initiation of pitting of aluminum alloys is little understood but of vital concern, not only with respect to the corrosion of aluminum in various natural environments, but also in relation to special problems such as the stress corrosion cracking of high strength aluminum alloys. In the investigation reported here the influence of Cl^-, Br^-, I^-, and F^- ions on the initiation and kinetics of pitting of aluminum alloy Type 7075 is studied over a wide range of temperature and concentration.

Engell and Stolica (1), and later Hoar and Jacob (2), devised a technique to measure the kinetics of breakdown of passivity of iron and stainless steel by halide ions. This technique was applied to aluminum alloys by Bogar and Foley (3), and Foroulis and Thubrikar (4). In this technique the metal electrode is held potentiostatically in the passive range in an appropriate electrolyte, a specific concentration of chloride is injected, and the induction time, τ, for a sharp rise in current is recorded. In the previous investigations the rise in current is correlated with the breakdown of passivity and initiation of pitting. Further, from this induction time it is possible to arrive at the order of reaction, n, the number of chloride ions associated with the dissolution of a single aluminum atom, and the energy of activation, E_a. The reasoning proceeds as follows. The reciprocal of the induction time, $1/\tau$, is taken as the rate of pit initiation, *i.e.*, the number of events per unit time. The rate equation is then

$$\left(\frac{1}{\tau}\right) = k[\text{Al}]^m[\text{X}^-]^n \quad [1]$$

wherein k is the rate constant, [Al] is the aluminum atom concentration, $[X^-]$ is the halide ion concentration, and m and n are the respective orders of reaction. The activity coefficients are included in k. The logarithm form of [1] is

$$\log\left(\frac{1}{\tau}\right) = \log k + m \log[\text{Al}] + n \log[\text{X}^-] \quad [2]$$

Thus, if k and [Al] are taken as constant, then the plot of log $(1/\tau)$ *vs.* log $[X^-]$ will give n, the order of reaction with respect to X^- ions. We now have reason to think that the term m log [Al] is only constant for a specific halide reaction and that m is equivalent to the number of atoms involved in a surface reaction site, *i.e.*, the coordination number of the surface in the sense used by Laidler and others in their development of the theory of absolute rate of surface reactions (5). At constant halide concentration, $(1/\tau)$ will be proportional to the rate constant and

$$\left(\frac{1}{\tau}\right) = Ae^{-E_a/RT} \quad [3]$$

Thus a conventional Arrhenius plot of log $(1/\tau)$ *vs.* the reciprocal of the temperature will yield the apparent activation energy for the initiation process.

These studies have been made within the broad context of examination of the complex ion theory of cor-

Key words: corrosion pitting, aluminum, passivity, chlorides, bromides.

rosion (6). This theory postulates that the role of an anion in a corrosion process may be explained by the direct participation of the anion in the elemental process of metal dissolution. The anion reacts with the metallic ion and the chemical nature of the resultant complex dictates whether the metal will dissolve or achieve a passive state.

Experimental

The experiments were conducted in an electrolytic cell containing a specially designed Teflon electrode holder, a Hg/Hg_2SO_4 reference electrode, a Luggin capillary, and a counterelectrode which was separated from the rest of the cell by a fine porosity glass frit. Stirring was provided by a submersible water-powered magnetic stirrer. The cell was thermostated to $\pm 0.1°C$ with a refrigerated and heated water bath. Experiments were conducted over the range of 5°-60°C.

The potential of the working electrode was controlled by an Anotrol Model 4100 research potential controller; a Keithley Model 600A electrometer was used for an accurate measurement of the potential of the working electrode. The current was recorded on a Sargent Model SRL recorder.

Samples of aluminum alloy Type 7075-T6 were cut into circular samples for electrodes with an area of 0.637 cm^2 when mounted in a special Teflon electrode mount (7). The samples were cleaned by conventional procedures and, following cleaning, were allowed to stand for 24 hr in a desiccator.

In a typical experiment, the sample was allowed to come to equilibrium at a preset temperature. The potential of the working electrode was then set at a value (usually +0.18V) in the passive anodic range as determined by a polarization study of the sample. From the polarization curve run on the alloy prior to the experiment, a point was taken midway in the flat portion (steady-state current) of the curve. Thus, the starting point of the pitting experiment was always the same distance from the open-circuit potential but well above the critical potential. After the resulting passive anodic dissolution current (usually in the microampere range) was recorded for a specific duration (6 min), a solution containing the aggressive anion of known concentration was rapidly injected into the cell with an all-glass syringe. The time required for a sharp continuous rise in current above the steady-state dissolution current was recorded as the induction time, τ, for pit initiation.

Most workers in the field recognize the statistical nature of pitting initiation and agree that impurities, flaws, or defects in the oxide film may play a role in pit initiation. Videm (8), in his aluminum pitting studies, concluded that differences from specimen to specimen usually make it difficult to obtain satisfactory reproducibility of pit initiation studies. In order to improve the reproducibility, a technique similar to that used by Videm (8) was used for screening "unsuitable" samples. Thus, following a uniform surface treatment, the sample was held at the predetermined anodic potential, and the resulting passive anodic dissolution current was recorded for a specific duration of time. An unstable current was observed with those samples which possessed certain surface abnormalities and these samples were thus discarded. An abnormal "leakage" current, usually characterized by the generation of current pulses, a form of oscillatory behavior connected with pitting corrosion, was thus used to sort out abnormal samples.

Results

Following the initiation of the pit, the current rises rapidly and the current is a measure of the faradaic reactions associated with pit growth. Three types of current-time curves have been observed. The first is a smooth curve wherein the current increases exponentially, illustrated in Fig. 1[1] by the reaction of Br^- ion in 1N H_2SO_4 at 50°C. The second type of behavior is illustrated in Fig. 2 by the reaction of Br^- ion in 0.1M Na_2SO_4 (pH 5.80) at 45°C. This "ragged" curve is favored by the neutral solution and lower temperature, *e.g.*, below 35°C. It is interpreted as resulting from a dynamic dissolution-repassivation process. The third type of behavior was shown by F^- ion in 0.1M Na_2SO_4 at 40°C (Fig. 3). The current instead of increasing ex-

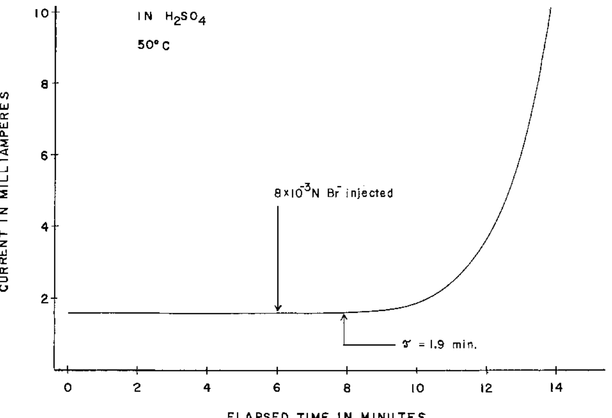

Fig. 1. Pitting initiation curve. Electrolyte, 1*N* H_2SO_4, 50°C, 8 × 10^{-3}*N* Br^- injected after 6 min.

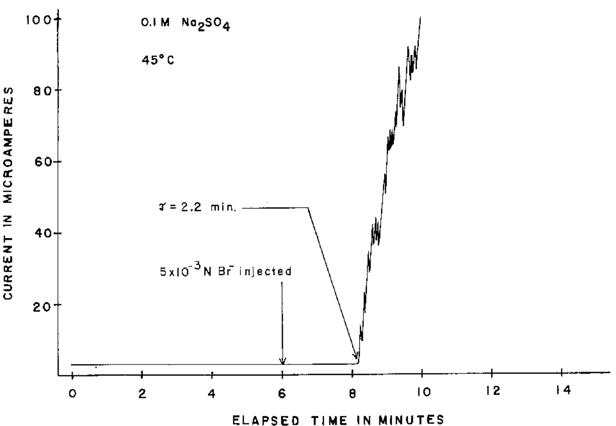

Fig. 2. Pitting initiation curve. Electrolyte, 0.1*M* Na_2SO_4, 45°C, 5 × 10^{-3}*N* Br^- injected after 6 min.

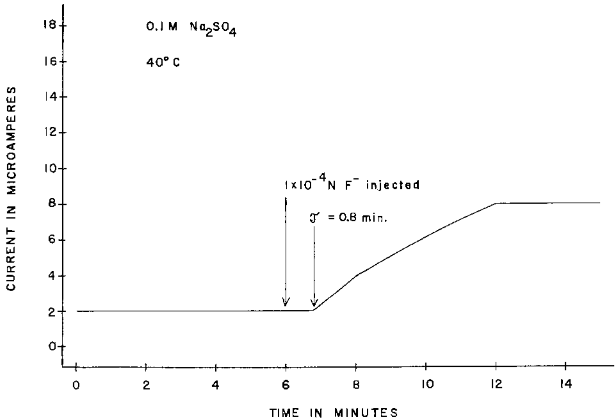

Fig. 3. Pitting initiation curve. Electrolyte, 0.1*M* Na_2SO_4, 40°C, 1 × 10^{-4}*N* F^- injected after 6 min.

[1] In this and similar figures, it is difficult to see the time at which the sharp rise in current occurs. However, on the original lined chart paper, it is quite obvious. Between 6 and 8 on the abscissa there are 20 divisions so that the rise in current can be set within a few seconds.

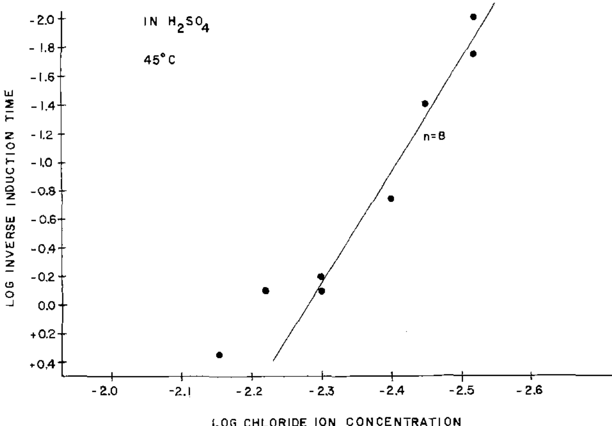

Fig. 4. Order of reaction plot. Electrolyte, 1*N* H_2SO_4, 45°C, $n = 8$.

ponentially reaches a plateau, and this is associated with the formation of a compound on the aluminum surface. It appears reasonable that the shape of the curve and the mathematical equation describing the current-time behavior is related to the geometric shape of the pits and this is now being pursued.

The slope of a plot of log $(1/\tau)$ *vs.* log of the halide concentration yields n, the order of the reaction with respect to the halide ion concentration. In Fig. 4, a plot of the log of the inverse of the induction time in 1*N* H_2SO_4 (*p*H 0.3) at 45°C *vs.* log $[Cl^-]$ yields an n value of 8. This approximates the value reported previously (3) for aluminum alloy Type 2024 in a 1.0*N* H_2SO_4 electrolyte. A similar plot for the results in 0.1M Na_2SO_4 (*p*H 5.80) yields an n value of 2, much lower than that observed in acid solution. This agrees reasonably well with the results reported by Foroulis and Thubrikar (4) who measured the induction time of a 99.99% aluminum sample at a *p*H of 5.9-6.1 and obtained an n of approximately 1.

A similar trend in reaction order was observed with Br^- ion. In 1*N* H_2SO_4 at 50°C, $n = 4$; in 0.1M Na_2SO_4 (*p*H 5.80) at 45°C, $n = 2$.

The reaction order for fluoride ion was only measured in 0.1M Na_2SO_4. From the plot at 50°C shown in Fig. 5, a value of $n = 3$ was obtained, the reaction differing stoichiometrically from that of the Cl^- and Br^- ion.

The reaction order for I^- is lower than that of the other halides. A plot from data at 23°C in 1*N* H_2SO_4 yields an n value of about 2. These results coupled with the low activation energy, suggest a weaker type of binding.

The reaction orders are summarized for the different halides in Table I.

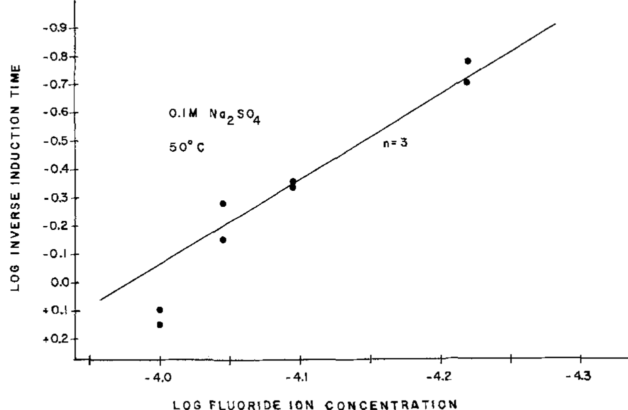

Fig. 5. Order of reaction plot. Electrolyte, 0.1M Na_2SO_4, 50°C, $n = 3$.

I-	2	—

The apparent energy of activation, E_a, may be calculated from the slope of the log $(1/\tau)$ *vs.* $1/T$ plot if the halide concentration is held constant. Such Arrhenius-type plots are shown in Fig. 6 and 7 for constant $[Cl^-]$ in 1*N* H_2SO_4 and 0.1M $NaSO_4$, respectively. The apparent energy of activation goes from 18 to 12 kcal in going from an acid to neutral solution. A similar trend was observed with Br^- ion. The reaction in acid solution had a high E_a, 26 kcal, as compared with 10 kcal in the neutral solution. The activation energy for the I^- ion reaction was low, 6.6 kcal, and the temperature-dependence plot showed considerable scatter. The temperature dependence of the F^- ion reaction calculated from the corresponding Arrhenius-type plot contrasted with the other halides with a low activation energy, $E_a = 4.6$ kcal.

The activation energies for the halide reactions are summarized in Table II.

A comparison of the induction times with the four halides allows for qualitative measure of the "aggressive" character of the halide. Thus the concentration of Br^- required for a comparable induction time is about 2 times the Cl^- concentration; the I^-, 10 times; and the F^- about 0.01 times.

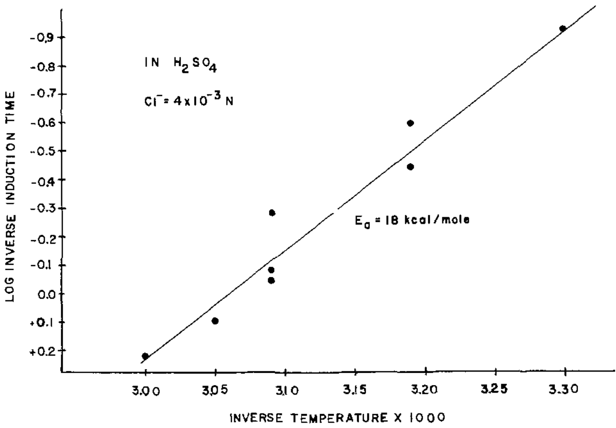

Fig. 6. Energy of activation plot. Electrolyte, 1*N* H_2SO_4, $[Cl^-] = 4 \times 10^{-3}N$; $E_a = 18$ kcal.

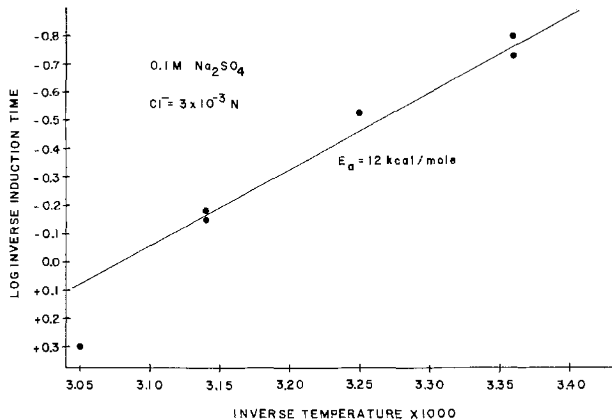

Fig. 7. Energy of activation plot. Electrolyte, 0.1M Na_2SO_4, $[Cl^-] = 3 \times 10^{-3}N$; $E_a = 12$ kcal.

Table II. Activation energies for pitting initiation reaction of aluminum alloy Type 7075 with halides

Anion	E_a (kcal mole^{-1})	
	pH 0.3	pH 5.8
F^-	—	4.6
Cl^-	18	12
Br^-	26	10
I^-	6.6	—

Following the pit initiation experiment, the specimens were examined microscopically. In general, the predominant shape of the pits was hemispherical. For aluminum alloy Type 7075, the pits produced in Cl^- solutions were almost perfectly hemispherical, while those formed in Br^- and I^- solutions were more irregularly shaped. Pits produced in acid solution were more nearly hemispherical than those formed in near-neutral solution. For aluminum alloy Type 1199, on the other hand, both Cl^- and Br^- solutions produced perfectly hemispherical pits.

Discussion

The contemporary thinking regarding the mechanism by which chloride ions break down passivity and initiate pitting has been recently summarized by Foroulis and Thubrikar (4). The prevalent explanations include the following: (*i*) penetration of the oxide film by Cl^- ion; (*ii*) competitive adsorption of Cl^- rather than OH^- or O_2 on metal surface; (*iii*) migration of Cl^- ions inward through the (passive) oxide lattice; (*iv*) peptization of the oxide film by adsorbed anions; (*v*) a dynamic breakdown-repair mechanism.

These authors pointed out that these concepts are inconsistent with their results on the kinetics of breakdown of passivity of preanodized aluminum by chloride ions and proposed the following two-step process. *Step 1.* Adsorption of Cl^- on the oxide-solution interface under the influence of the electric field; the surface sites available for adsorption existing on the hydrated oxide surface rather than on the base metal surface. *Step 2.* Formation of a basic hydroxy chloride aluminum salt which is readily soluble.

The results of the present study reaffirm the stoichiometric and chemical nature of the pitting initiation process as distinguished from continuous adsorption and oxide penetration processes traditionally associated with the breakdown of passivity. The technique used in the present investigation does not give information regarding the surface site at which pitting could be initiated, that is, the Al in Eq. [1] above could be in the aluminum alloy metallic lattice, or it could be an Al ion in the hydrated oxide lattice. Foroulis and Thubrikar (4) with their experiments with varying oxide thicknesses offer convincing evidence that the particular Al ion exists in the oxide lattice at the oxide-electrolyte interface.

The technique used here, on the other hand, does give definite information on the number of halide ions associated with the surface site and the energy of this reaction.

It is postulated that the initial step in the pitting of the Al alloy by Cl^- ion in acid solution is the formation of the complex, $Al_2Cl_8^{=}$. Thus the reaction site involves two Al ions, and an activation energy of 18 kcal is commensurate with chemisorption or chemical reaction. In a similar fashion, a complex of $AlBr_4^-$ forms with Br^- ion, also with a high activation energy. The large iodide ion is involved in a low energy process (6.6 kcal), very likely the physical adsorption of one or two I^- ions per surface site. A consistent picture is drawn for the results in neutral solution wherein reaction orders of two were observed for the Br^- ion and the Cl^- ion. Complexes of the type $Al(OH)_2(Cl)_2^-$ and $Al(OH)_2(Br)_2^-$ are postulated, and, for such complexes, the activation energy is appreciably lower, in agreement with previous reports wherein values of 12 kcal (3) and 6.7 kcal (4) were reported for pure Al at a pH of 6 in Cl^- electrolytes. In nearly neutral solution, fluoride ion exhibits a reaction order of three, consistent with the formation of AlF_3 which has been reported as a stable species in aqueous solutions (9).

These results are consistent with observations on the complexing behavior of aluminum previously reported. The halides of aluminum (except F^-) are dimeric in organic solvents such as benzene. Structures for the dimeric forms of Al_2Cl_6 and Al_2Br_6 are given by Durrant and Durrant (9). This dimeric formation has been attributed to the tendency of the aluminum atoms to complete their octets. Recently, Peled and Gileadi (10) reported the presence of the anions, $Al_2Br_7^-$ and $AlBr_4^-$, by measuring transference numbers of species formed by dissolving $AlBr_3$ and MBr (M = alkali metal or ammonium ion) in hydrocarbons. Morrey and Moore (11) reported the presence of the complex ions, $AlCl_4^-$ and $Al_2Cl_7^-$, in a $KCl\text{-}AlCl_3$ solvent (fused salt). All six fluoride species, *i.e.*, AlF^{++}, AlF_2^+, AlF_3, AlF_4^-, $AlF_5^{=}$, $AlF_6^{\equiv}$, have been reported to exist and their stability constants are given by Bjerrum (12). AlF_3 is reported as a stable species in aqueous solution (13). Katoh (14) has identified the products, $AlF_3 \cdot 3H_2O$ and $AlF_3 \cdot H_2O$, by x-ray analysis of a sample corroded in NaF solution. Zotikov *et al.* (15) studied the corrosion of aluminum in hydrofluoric acid with varying water content and reported the formation of AlF_3 according to the reaction

$$2Al + 6HF \rightleftarrows 2AlF_3 + 3H_2$$

The AlF_3 formed various hydrates such as $AlF_3 \cdot 3H_2O$.

Considering the relative concentrations of the ions, it would be expected that, except for the fluoride compound which forms an insoluble compound on the electrode, these complexes will be intermediates in a stepwise process that terminates eventually with the formation of the hydrated oxide film of aluminum. Thus, the halide ions operate as catalysts being regenerated by the hydrolysis of the hydroxy halide or halide complex. This accounts for the considerable pitting that occurs in dilute solutions, *e.g.*, $10^{-3}N$.

These findings are consistent with the complex ion theory of corrosion (6). The anions function in a specific manner forming chemical species whose stabilities determine the subsequent behavior of the metal, be it accelerated dissolution or repassivation.

Periodic Phenomena during Anodic Dissolution of Mo_4O_{11} Single Crystals

R. M. Peekema* and M. W. Shafer

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The electrochemical behavior of Mo_4O_{11} single crystals has been studied and periodic phenomena were observed during anodic dissolution in 1*M* H_2SO_4. These periodic effects were observed only on the (100) face, and are associated with a 12.3Å periodicity in the crystal structure along the [100] direction, where alternating layers of Mo(IV) and Mo(VI) species are found. A mechanism involving the slow chemical dissolution of Mo(VI) species and the rapid electrochemical dissolution of Mo(IV) species is offered, and is consistent with the experimental data. To the best of our knowledge, this is the first reported correlation of a periodic electrochemical effect with a periodicity in the crystal structure.

Periodic effects in electrochemical systems are not uncommon (1, 2) and usually are a result of a relaxation of a disturbed system toward an equilibrium or steady-state condition. While studying the electrochemical behavior of the molybdenum oxides, we observed periodic fluctuations in the dissolution current when the (100) face of a single crystal of Mo_4O_{11} was made anodic in acid solution. We have studied these oscillations in detail and in this paper we show that they are related to a periodicity in the crystal structure rather than to a relaxation phenomena.

Experimental

The Mo_4O_{11} crystals were prepared at 800°C in sealed evacuated quartz tubes containing stoichiometric amounts of Mo and MoO_3 powders, using small amounts of iodine as the transporting agent. Crystals with faces of 1-2 cm^2 have been grown by this method. A more detailed discussion of the preparative conditions and of the crystal properties is given elsewhere (3).

The electrochemical measurements were carried out using a Wenking potentiostat with a Wavetek function generator to obtain cyclic voltage sweeps, and an X-Y recorder to record the voltammograms. A Keithley digital electrometer was used to isolate the reference electrode from any voltage measuring or plotting circuitry, and a Keithley Picoammeter was placed in series with the working electrode to measure the currents. A Fluke constant current supply replaced the potentiostat when galvanostatic measurements were desired.

A three-compartment cell was used, with the working electrode, the reference electrode, and the counterelectrode each in a separate compartment. Most of the work was carried out in a cell where the three compartments were separated by 10 mm fine porosity (10F) fritted Pyrex disks. The working electrode compartment usually contained 5-15 ml of electrolyte, which was deaerated or agitated as necessary by admitting helium gas (without any pretreatment) through a 10F fritted Pyrex disk in the cell bottom. The crystal surface was mounted in a vertical position.

Reference electrodes were either mercury-mercurous sulfate in 1M H_2SO_4 (MSE) or mercury-mercuric oxide in 1M KOH (MOE). All voltages are referenced to the normal hydrogen electrode (NHE). Solutions were made from reagent grade chemicals and deionized water, and were used without further purification or preelectrolysis. Crystal samples were usually mounted on gold disks, sometimes using indium solder to improve the electrical contact. Some samples were connected to gold wires by a silver-filled epoxy. The unwanted crystal faces and sample supporting areas were masked off with MICCROSTOP.[1] Specimen areas were measured graphically from a photomicrograph taken normal to the surface of a masked-off crystal face, using calibration factors obtained by photographing a rule at the same magnification.

Results and Discussion

Periodic fluctuations in the anodic dissolution current for an Mo_4O_{11} crystal are shown in Fig. 1. This is a trace of a linear voltage sweep on the (100) face of a single crystal Mo_4O_{11} specimen in 1M H_2SO_4. Similar fluctuations occur in the voltage after a galvanostatic step, as shown in Fig. 2. A similar effect (not shown) is noted in the current after a potentiostatic step. The periodic effect in the voltammetry curve was observed to be dependent on scan rate and this is summarized in Table I.

The values for the period in Table I are given at a specified voltage (0.70V *vs.* NHE) because during the linear voltage sweep both the current and period change with potential. However, it is apparent from Table I that the period for the current fluctuations in the region of 0.7V is essentially constant at approximately 1 sec, over nearly an order of magnitude change in sweep rate. At higher sweep rates, one sees fewer peaks in the current over the same region of poten-

tial, and in general the peaks are not as sharply defined. The conditions selected for Fig. 1, namely 12 mV/sec, were chosen because the magnitude of the current fluctuations is most effectively displayed and measured under those conditions. The constant current conditions in Fig. 2 show clearly that the period is nearly constant at a given current. Table II shows that Q, the charge density per period (the product of the current density and the period), is reasonably constant.

The magnitude of the periodic effects in general decreased with time and with cycling of the samples through the potential region of anodic dissolution. Table III summarizes the influence of other electrolytes on the periodic phenomena. As noted, the periodic effects in 1M perchloric acid disappeared after three scans. The periodic effects did return on that same sample after it was returned to sulfuric acid and cycled several times. Further, no periodic effects were observed in 1M KOH solution.

In order to explain the origin of these fluctuations it is necessary to consider the crystal structure of Mo_4O_{11}. This molybdenum oxide is one of five distinct oxide phases between MoO_2 and MoO_3 whose crystal structures have been determined by Magneli (4) and Kihlborg (5). They describe the structure of Mo_4O_{11} as being similar to the ReO_3-type structure. In this structure, shown in Fig. 3A, the MoO_6 octahedra are linked exclusively at the corners. However, Mo_4O_{11} is oxygen deficient when compared to the pure ReO_3-type, and to allow for this deficiency a certain fraction of the molybdenums is tetrahedrally coordinated (MoO_4). The arrangement of the MoO_6 and MoO_4 polyhedra is shown in Fig. 3B. It is seen that this structure is basically comprised of ReO_3-type slabs (the lightly shaded diamond-shaped polyhedra), which represent the MoO_6 octahedra, joined together by black and heavily hatched triangles, representing the MoO_4 tetrahedra at two levels. Since the slabs extend infinitely in the vertical direction and perpendicular to the plane of the

paper, there is a distinct periodicity of the ReO_3 slabs normal to the [100]. The periodicity, *i.e.*, the distance between the interconnecting MoO_4 tetrahedra, is about 12.3Å, which is half of the a_o dimension of the orthorhombic cell ($a_o = 24.49$, $b = 5.45$, and $c = 6.95$). We have measured the electrical resistivity of Mo_4O_{11} by the four-probe method and find it to be 2×10^{-4} Ω-cm at room temperature (3, 6). There was no evidence of anisotropy in the resistivity.

The observed current oscillations correlate well with the structural periodicity. Table IV shows the integrated charge associated with each of the current peaks shown in Fig. 1. A correction for charging current was made by extrapolating the base current in the region of 0.45-0.55V. As can be seen from Table IV, the charge associated with each peak is relatively constant, and amounts to some 260 $\mu C/cm^2$. In addition, Table II shows a fairly constant charge per fluctuation, under constant current conditions, of approximately 230 $\mu C/cm^2$. The charge per period of approximately 230 $\mu C/cm^2$ on that particular crystal is similar to the value shown in Table IV, obtained under potentiostatic conditions.

Based on the crystal density of 4.12 g/cm^3, and complete oxidation of the oxide to Mo(VI) as given in Eq. [1]

$$Mo_4O_{11} + 5H_2O \rightarrow 4H_2MoO_4 + 2H^+ + 2e^- \quad [1]$$

we calculate the amount of charge consumed in oxidizing a 12.3Å layer to be 174 $\mu C/cm^2$. This is some 50% less than the experimental values. To test the validity of Eq. [1] we measured the equivalent weight by observing the weight lost from a crystal during the passage of a known charge. Table V shows the observed equivalent weights for several different experiments, which are in excellent agreement with the expected value of 280 g/equiv.

These equivalent weight results establish that the anodic dissolution of Mo_4O_{11} takes place according to Eq. [1], and that the charge associated with each 12.3Å layer is 174 $\mu C/cm^2$. Observed values of charge per period range from 217 to 280 $\mu C/cm^2$. We feel that this excess of charge is accounted for by undercutting of the mask-off and by nonuniform dissolution of the crystal face; both are effects which would increase the charge observed per period. Undercutting of the mask-off has been confirmed by surface profile measurements after mask-off removal, where observed surface discontinuities were less than one-third those expected from coulometric and weight loss calculations. Further, subsequent microscopic examinations and surface profile measurements of crystal surfaces that had been covered by mask-off during the dissolution showed definite evidence of attack. One would expect relatively less undercutting at higher current densities, and the Q values in Table II are consistent with this view. Nonuniform dissolution was apparent in scanning electron microscope examination of surfaces exposed to anodic treatment, and by visual observation the smooth crystal facet was converted to a matte finish by extended dissolution.

The above evidence shows that the observed oscillations can be correlated with the periodic nature of the crystal structure. Further support of this conclusion is obtained by looking at the anodic dissolution of other crystal orientations of Mo_4O_{11} where there is no structural periodicity normal to the face being dissolved. The (111) is such a face and it is seen in Fig. 4 that there is no evidence of the oscillations seen in Fig. 1. We have examined a number of different crystals, looking at the (100) and (111) faces, and in all cases the oscillations are seen on the former and not the latter.

There is some evidence that not all the current need follow the reaction of Eq. [1]. We have observed the appearance of a deep blue solution and an EPR signal when Mo_4O_{11} is anodically dissolved at high current densities. Both these observations suggest the presence of some Mo(V) species, which is probably in solution. Since both EPR and colorimetric methods are highly sensitive for detecting the Mo(V) species it is likely that only a small fraction of the dissolution occurs via a reaction where the $Mo(IV)_{crystal} \rightarrow Mo(V)_{solution}$.

Let us now consider a dissolution mechanism which satisfactorily explains the above data. Assume that Mo_4O_{11} is a mixed oxide containing Mo(IV) and Mo(VI) in the ratio of 1:3.[2] We expect that all tetrahedral sites are occupied by Mo(VI) since it is a smaller ion than Mo(IV). Further, there is good evidence, from the Mo-O bond distances of the MoO_6 octahedra, that the Mo^{+4} ions are found in the centers of the "ReO_3-type" slabs rather than in those octahedra which connect to the tetrahedra. If the Mo-O distances (5) of the various types of octahedra are examined, it is seen that those octahedra which are on the "outer surfaces of the slabs" (Fig. 3B) are badly distorted, *i.e.*, their Mo-O distances vary by 0.45Å, while those in the center are more regular with variations of only 0.2Å. A comparison of the radius ratios, $r_{Mo(IV)}/r_O$ and $r_{Mo(VI)}/r_O$, shows that the former (0.5) is more favor-

[2] Even though metallic type conductivity is seen in Mo_4O_{11} from which it could be inferred that the molybdenums would be completely nonlocalized, our ESCA measurements show very clearly that both Mo(IV) and Mo(VI) species are present, and in the 1:3 ratio.

able for perfect octahedral coordination and should result in a less distorted octahedra. Since Mo(VI) is smaller, the $r_{Mo(VI)}/r_O$ ratio (0.44) barely falls within the range defining octahedral coordination (0.44-0.732) and a more distorted octahedron is expected. From these data, it appears that the Mo(IV) ions are predominately concentrated in the centers of the ReO_3-type slabs which run perpendicular to the [100] direction.[3] Thus if one looked at the (100) face of a Mo_4O_{11} crystal, one might expect to see predominantly one type of Mo species, either Mo(IV) or Mo(VI), depending on which layer of the crystal is exposed. Since the +4 state is thermodynamically unstable in aqueous solution (7), it is likely that only Mo(VI) species would be exposed on surfaces in contact with an aqueous solution, or even on a crystal exposed to normal atmospheric moisture and oxygen.

Using this model of the Mo ion distribution in the Mo_4O_{11} crystals, we propose the following mechanism, which offers a good explanation of the observed facts: (*i*) Mo(VI) type surfaces are slowly dissolved by the solution in chemical attack whose rate is governed by the pH, temperature, solution composition, etc.; (*ii*) Mo(IV) type surfaces are chemically insoluble, but are rapidly dissolved when made anodic. On Mo_4O_{11}, an Mo(VI) type surface could be considered equivalent to an MoO_3 surface in terms of stoichiometry but not in terms of structure. These surfaces with the "MoO_3-type" stoichiometry are more soluble than bulk crystalline MoO_3, which is relatively insoluble in acid solution. We feel that the reason for this increased solubility of the "MoO_3" surface layer[4] is that it is less stable structurally than bulk MoO_3. This is because it represents either the exposed Mo(VI) plane perpendicular to the [100] or the oxidized Mo(IV) plane, which in both cases are likely to have their octahedra joined in a highly strained unstable arrangement which is likely to be more soluble.

An Mo(IV) type surface on Mo_4O_{11} is stoichiometrically equivalent to an MoO_2 surface, and is chemically insoluble because of the instability of Mo^{+4} in aqueous solution. In order to dissolve chemically, Mo(IV) species would have to undergo disproportionation, which appears to be kinetically hindered. However, this kinetic limitation is avoided if the exposed Mo(IV) species are anodically oxidized to Mo(VI). Once the Mo(IV) species have been oxidized and dissolved, the surface is again comprised of Mo(VI) species which inhibit the further passage of current until that Mo(VI) layer chemically dissolves. This explains the periodic rise and fall of current as one anodically dissolves the (100) face. The absence of periodic effects in basic solution can be explained by the high solubility of Mo(VI) species in that medium (8).

Another observed phenomenon in need of explanation is the damping of the voltage fluctuations shown in Fig. 2. When the experiment is repeated after a brief period (seconds to minutes) at no current or very low currents, the fluctuations return almost identically. Why do these periodic oscillations damp out, only to return after a brief rest? Our explanation is that the dissolution processes, both chemical and anodic, do not proceed at exactly the same rate on all areas of the (100) surface, due to local inhomogeneities, proximity to other faces, concentrations of dislocations, etc. As one area gets out of step with another, *i.e.*, one in chemical dissolution, another anodic, the over-all result is a continuous process with all the local periodic fluctuations averaged out. However, if one removes the applied current and allows a rest period, the chemical dissolution will then proceed on all exposed (100) faces until a layer of Mo(IV) species is uncovered. In other words, the chemical dissolution proceeds on each plateau of the (100) face to essentially an equivalent point in the structure, and terminates there because of the blocking effect of Mo(IV) species. Then, when anodic dissolution is once again resumed, all the different plateaus of the (100) face begin their dissolution in phase, and the periodic phenomena appear with almost the same magnitude as before.

[3] It can also be concluded that there is a higher concentration of semilocalized electrons associated with the Mo(IV) so there is in fact a periodicity in the charge density along the [100].

[4] We assume a thickness of this layer to be approximately 8-15Å.

Finally, we believe that surface roughening accounts for the diminution of the periodic phenomena as a crystal is cycled many times in a potential region of anodic dissolution. Microscopic and scanning electron microscopic examination of such crystal surfaces confirms the etching and roughening effect of anodic dissolution. Since only (100) faces show periodic effects, a roughening of the (100) face would expose other crystal planes to anodic attack and thus diminish the periodic effect. This loss of the effect (not to be confused with the damping in Fig. 2) is generally not reversible, except possibly in the case of the perchloric acid medium.

Summary and Conclusions

Mo_4O_{11}, which exhibits metallic conduction, will dissolve anodically with periodic fluctuations in the dissolution currents.

Periodic effects are noted during the anodic dissolution of the (100) face of Mo_4O_{11} single crystals in acid solution, and occur under potentiostatic, galvanostatic, and voltage sweep conditions.

These effects are absent on other faces, and are related to a 12.3Å periodicity in the crystal structure along the [100] direction, where alternating layers of Mo(IV) and Mo(VI) species are found.

The slow chemical dissolution of Mo(VI) species and the rapid electrochemical dissolution of Mo(IV) species provide a mechanism to explain the observed results.

To the best of our knowledge, this is the first demonstration of a periodic electrochemical effect related to a periodicity in the crystal structure.

Mechanism of the Anodic Oxidation of Nickel

B. MacDougall* and M. Cohen*

National Research Council of Canada, Ottawa, Ontario, Canada

ABSTRACT

The electrochemical oxidation and subsequent reduction of nickel electrodes in acid sulfate solutions was studied with potentiodynamic and galvanostatic techniques in conjunction with potential step polarization. Surface activity measurements gave a relative measure of the extent of surface oxidation and stability of the oxide toward reduction and dissolution, but did not give independently the oxygen coverage. Cathodic galvanostatic charging curves of previously anodized nickel electrodes displayed an arrest structure which was dependent on the extent of anodization. While the arrest charge was related to the cathodic reduction of some oxygen species on nickel, parallel side reactions such as nonelectrochemical dissolution and hydrogen evolution affected substantially the reduction current efficiency. Under certain conditions, the arrest charge component arising from cathodic reduction of the oxygen species on nickel could be resolved and an attempt made at identifying the nature of this species. Initially, anodization resulted in oxygen chemisorption which reached a maximum coverage corresponding to one oxygen atom per surface nickel. Conversion to nickel oxide occurred very rapidly at the active surface sites but more slowly over the rest of the surface.

In a previous paper (1), the oxide film formed by steady-state anodization of nickel in the *p*H range 2.0-8.4 was studied. The film was composed of 9-12Å of nearly stoichiometric NiO (2, 3), its physical and chemical properties being independent of solution *p*H. The steady-state films were stable upon exposure to the atmosphere, allowing x-ray emission and electron diffraction techniques to be used for the oxide analysis. The present work extends the investigation at *p*H 2.8 to the initial stages of nickel oxidation. Electron-optical techniques could not be used to study these oxides since their thicknesses were less than that of the air-formed film (*i.e.*, 6-8Å) and the surfaces were therefore unstable to air exposure. *In situ* cathodic reduction techniques with monitoring of surface activity could, however, be used to study early oxide growth and the results may be interpreted in terms of an initial chemisorption of oxygen followed by conversion to NiO as the oxidation proceeds.

Experimental

Specimen preparation.—Polycrystalline specimens, 1 × 2.5 cm, were prepared from zone-refined nickel sheet of 99.996% purity as described elsewhere (2). They were degreased with benzene, chemically polished (2), electropolished for 2 min at 23°C in a 57% sulfuric acid solution at 0.5 A-cm^{-2}, and then annealed at 800°C in a vacuum of 10^{-8} Torr. The specimens were electropolished again immediately before use in an experiment.

Reference electrode.—Potentials quoted in this paper are referred to the Hg_2SO_4 electrode (+0.665V with respect to the standard reversible hydrogen electrode).

Solution.—Deaerated solutions of 0.15*N* Na_2SO_4 had their *p*H adjusted to 2.8 (1). Experiments were conducted at 25°C.

Apparatus.—A Princeton Applied Research Model 175 universal programmer was used in conjunction with a Wenking fast-rise potentiostat to obtain potentiodynamic sweep profiles. These profiles and galvanostatic cathodic charging curves were recorded on a Hewlett-Packard Model 7004B X-Y recorder. A high speed Brush recorder was used to follow the initial rapid decrease of current after an anodic potential step treatment. Two types of electrochemical cell were used, one having the counter and recording electrodes in the same compartment and the other having them in different compartments separated by a glass frit and stopcock. The former cell was used for potential step experiments since large, initial current surges were involved. Both cells contained 50 ml of electrolyte and gave similar potentiodynamic sweep and galvanostatic charging results.

Electrochemical procedure.—After electropolishing, the electrodes were immersed in a deaerated *p*H 2.8 Na_2SO_4 solution under cathodic polarization sufficient to reduce the prior 6-8Å film of NiO. The procedures for subsequently anodizing and reducing the nickel electrodes were as described elsewhere (1).

With potentiodynamic sweep experiments, anodic cycling of the freshly reduced electropolished nickel initially resulted in a slight increase of the electrode surface area. Consequently, the multisweeps recorded in this paper are those which were obtained after the attainment of reproducibility, generally after 5 sweeps at 10 mV sec^{-1}. Single sweeps were also recorded, especially when the effect of a specific cathodic treatment on a previously anodized electrode was under study.

Electrode surface activities were determined by either the potentiodynamic sweep or anodic potential step techniques. With the former, the surface activity of an electrode is given by the ratio of the charge under its anodic current peak (Fig. 1) to the corresponding (maximum) charge obtained when the electrode has an oxide-free starting surface. With the latter, surface activities were similarly obtained from the ratio of anodic charges passed during the first 2 sec after the potential was stepped to its anodization value, during which time the anodic current fell by about three orders of magnitude. Both techniques gave similar results. At *p*H 2.8, most of the measured anodic charge is due to nickel dissolution; therefore, the surface activity is a measure of the electrode's reactivity toward nickel dissolution. The surface activity of oxide-free nickel is by definition 100%.

Results

Kinetics of oxide formation and reduction.—Figure 1 shows the potentiodynamic sweep profiles at 10 mV sec^{-1} for a nickel electrode in an unstirred *p*H 2.8 Na_2SO_4 solution. Along with the main anodic peak for nickel dissolution, two distinct cathodic peaks were observed with cycling in the range −1.5 to 0.0V. The cathodic peak at −1.4V was due to the deposition of nickel ions, Ni^{2+}, from solution. The main cathodic

Sweep (———) was identical to that obtained on an oxide-free surface, *i.e.*, cathodically reduced electropolished nickel.

peak at −1.2V was associated with oxide reduction and increased substantially with potential and time of anodization in the passive region. However, the charge under this peak gave anomalously high oxide thickness values, the calculated NiO thickness being 40-50Å after cycling to 0.0V at 10 mV sec^{-1} (Fig. 1).

Figure 1 also shows the effect of cycling to different cathodic potentials (after a constant anodic treatment) on the nickel dissolution peak. The anodic treatment consisted of sweeping an oxide-free nickel surface to 0.0V. The anodic current peak, and thus the surface activity, increased with increasing cathodic reversal potential until −1.1V with no further change upon cycling to more cathodic potentials. Similar results were obtained by reversing the direction of the anodic sweep at different potentials. Figure 2 shows the dependence of surface activity on anodic reversal potential with a constant cathodic reversal potential of −0.9V. The oxide formed by sweeping to more anodic potentials was increasingly difficult to remove.

Figure 3 shows the dependence of surface activity on cathodic reversal potential after prior cycling to 0.0V (cf. Fig. 1) along with the effect of cathodic holding at −0.9V for the extra time spent in the region of potentials more cathodic than −0.9V. The time in cycling to various potentials at the same sweep rate is seen to be important, and in order to study separately the role of time and potential, a potential step technique was used.

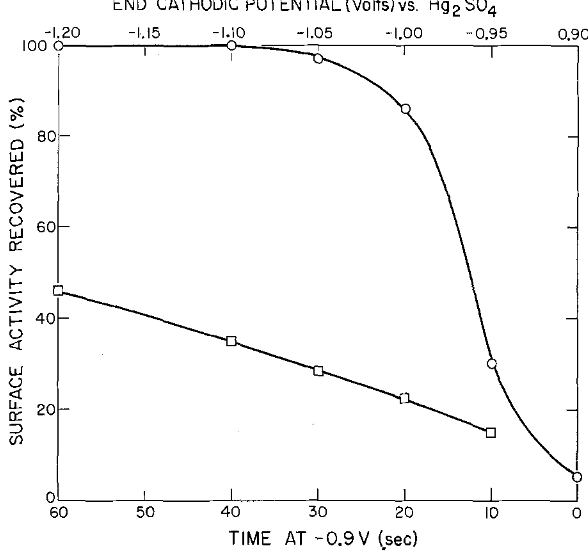

Fig. 3. (—○—) Variation of surface activity with cathodic reversal potential after prior cycling to 0.0V at 10 mV sec^{-1}. (—□—) Effect of time of cathodic holding at −0.9V on surface activity of electrode previously cycled to 0.0V. The holding period at each potential corresponds to the additional time spent in cycling to that potential from −0.9V. Sweep rate was 10 mV sec^{-1}.

Figure 4 shows the effect of time at various cathodic step potentials on the activation of a surface which was initially anodized at 0.0V for 90 sec. To obtain each data point the nickel surface was first given a complete reactivation followed by a potential step to 0.0V for 90 sec, after which the potential was stepped to the cathodic value of interest for a certain period of time. The resulting activity of the surface was determined by stepping the potential back to 0.0V and measuring the anodic charge transient.

The role of potential and time in the anodization of nickel was studied in relation to the cathodic reducibil-

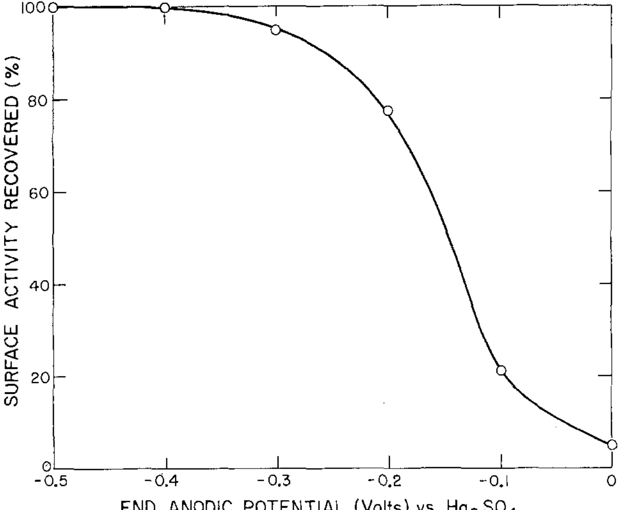

Fig. 2. Dependence of percentage surface activity, obtained during an anodic sweep, on the anodic reversal potential of the previous sweep. After cycling to the various anodic potentials shown, an intervening sweep to −0.9V provided the standard cathodic treatment. Sweep rate was 10 mV sec^{-1}.

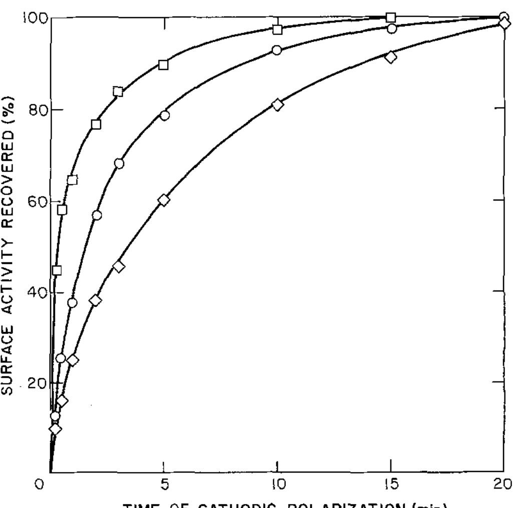

Fig. 4. Variation of surface activity with potential and time of cathodic treatment after anodization at 0.0V for 90 sec. The potential step technique was used for both anodization and reduction, the cathodic potential of reduction being: (—□—) −0.95V; (—○—) −0.9V; (—◇—) −0.85V. To determine the surface activity, a potential step treatment back to 0.0V was employed.

ity of the oxide formed. The change in surface activity recovered, using a constant cathodic treatment, was followed as a function of the condition of anodization. Figure 5 shows the decrease in surface activity with increasing extent of oxidation using a standard cathodic treatment of 30 sec at —0.85V. The differences in oxide reducibility for the different oxidation treatments may be due to changes in the amount and/or the type of oxide. Since an accurate measure of the oxide coverage was not possible with the sweep method, another electrochemical technique (galvanostatic charging) was used in an attempt to determine the oxide reduction charge component.

Galvanostatic reduction of nickel oxide.—Figure 6 shows the cathodic charging curves obtained with nickel electrodes which had previously been anodized at potentials in the range —0.75 to —0.3V for 90 sec. After the milder anodic treatments, two distinct arrests were resolved and labeled arrest 1 and arrest 2. The shape and size of the arrests were independent of solution agitation by N_2 bubbling during the cathodic treatment. Also the arrest structures did not significantly change on going from a solution Ni^{2+} content of 0.2-100 $\mu g\ ml^{-1}$. With increasing anodic treatment the two arrests were replaced by a single arrest, and the time required to attain the potential corresponding to hydrogen evolution from an oxide-free surface increased. The development of the cathodic charging profile with time of anodization at —0.6V is given in Fig. 7.

Some general observations were made regarding the early stages of nickel oxidation at different anodic potentials. Anodization for a time period of < 5 sec at —0.3V gave a cathodic charging profile similar to that obtained at less anodic potentials such as —0.6V for 90 sec (Fig. 6). In both cases, arrests 1 and 2 were initially well resolved with arrest 1 developing before 2. Also, the potential of the plateau associated with arrest 1 for short times at —0.3V corresponded with that for longer anodizations at —0.6V. Indeed, the whole spectrum of cathodic charging profiles associated with, *e.g.*, 90 sec at —0.75 to —0.3V, could be obtained with various times at —0.3V.

The dependence of the arrest charges on cathodic current was next investigated. After mild anodizations, *e.g.*, 90 sec at —0.55V, the charge associated with both arrest 1 and 2 increased with increasing cathodic current density (Fig. 8). The measured arrest time decreased by less than one-half in going from a cathodic current of 4 to 40 $\mu A\ cm^{-2}$ rather than the expected factor of ≥ 10. The fact that the duration of the arrest

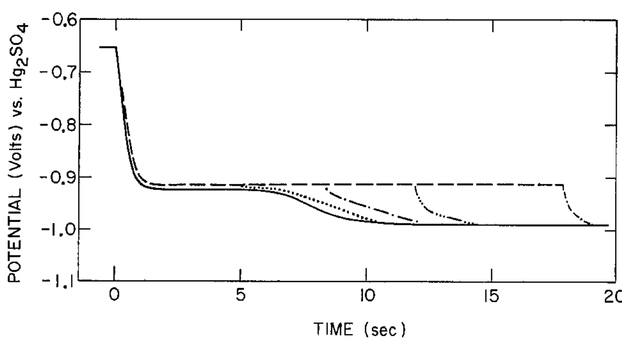

Fig. 9. Cathodic charging curves, at 20 μA cm^{-2}, for electrodes anodized at −0.65V for 90 sec, with an intervening open-circuit treatment for various times: (——) 0 sec; (···) 5 sec; (–·–·) 8 sec; (–···–) 12 sec; (– –·– –) 18 sec. The open-circuit decay curve obtained after the anodic treatment and before initiation of the cathodic pulses is also shown (– – –).

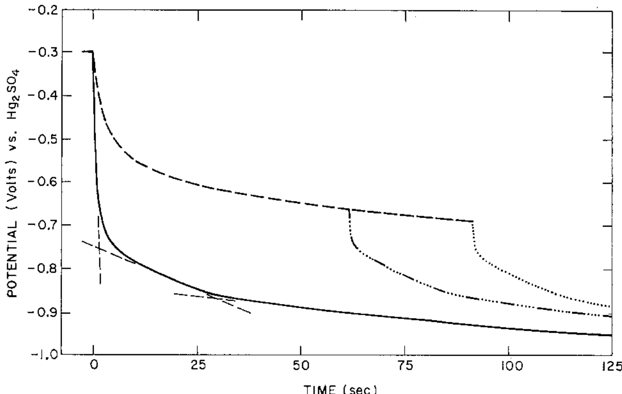

Fig. 10. As in Fig. 9 but with an anodization at −0.3V for 90 sec and with open-circuit times of 0 sec (——); 60 sec (–··–); and 90 sec (···). The open-circuit decay curve is given as (– – –). The standard method was used for determining the transition time of the cathodic arrest and is illustrated for the first charging profile. The points of intersection of the extrapolated lines for the various charging processes are taken as defining the beginning and end of the oxide reduction arrest.

was almost independent of the cathodic charging rate indicates that a nonelectrochemical process, probably oxide dissolution,[1] was playing a significant role. The cathodic faradaic reaction of hydrogen evolution from the oxidized nickel surface was responsible for charge consumption.

Role of nonelectrochemical dissolution.—Open-circuit experiments were performed to determine the stability of the initial oxide toward dissolution. With a previous mild anodization treatment, *e.g.*, $V \leq -0.55$V for 90 sec, a time-dependent fraction of the charge for arrests 1 and 2 disappeared on open circuit (Fig. 9). Indeed, with very thin films the initial portion of the open-circuit decay curve was almost coincident with the cathodic charging profile and the time on open circuit required to dissolve the oxide corresponded approximately with the time of arrest 1 and 2. The rate of open-circuit dissolution was found to decrease with increasing anodization treatment. With a previous anodization of 90 sec at −0.3V, the oxide arrest charge decreased by only 15% after 60 sec on open circuit (Fig. 10). (The points of intersection of the extrapolated lines for the various charging processes were taken as defining the beginning and the end of the oxide reduction arrest.) During cathodic charging at 20 μA cm^{-2}, this 60 sec encompassed all the cathodic arrest. Figure 11 shows the decrease of arrest charge

[1] The term oxide dissolution as used here includes both physical undermining (1) and chemical dissolution (*i.e.*, $NiO + 2H^+ = Ni^{2+} + H_2O$).

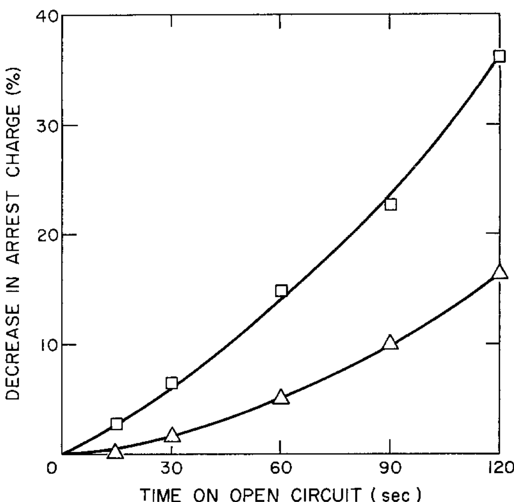

Fig. 11. Decrease of the oxide arrest charge with time on open circuit after previous anodizations at −0.3V (—□—) and −0.2V (—△—) for 90 sec. Cathodic charging current was 20 μA cm^{-2}.

with time on open circuit after anodizations at −0.3 and −0.2V.

Determination of oxygen coverages.—Figure 12 shows the dependence of the reduction arrest charge on the cathodic charging rate for 90 sec oxidations at −0.3 and −0.2V. A linear dependence of arrest charge on cathodic current was obtained with all but the lowest charging rates. For those, the longer arrest times increased the probability that nonelectrochemical oxide dissolution was playing a role. The apparent contribution from oxide dissolution during cathodic charging was somewhat less than that predicted by open-circuit experiment (Fig. 11). This was probably due to cathodic protection of the underlying metal during charging and the subsequently diminished role of oxide undermining.

Extrapolation of the linear portion of the arrest charge profiles in Fig. 12 to $i_{cath} = 0$ gives oxygen coverage values of 0.55 and 0.46 mC cm^{-2}. A surface roughness factor of 1.15 converts the former value to 0.48 mC cm^{-2}, which corresponds to one oxygen atom per surface nickel. To check on the extent of completion of cathodic reduction during the time of the arrest, the activity of the surface was determined at the end of the arrest. This was accomplished (1) by instantaneously stepping the potential back to either −0.3 or −0.2V, after cathodic charging to the end of the arrest, measuring the resulting anodic charge and comparing it with that obtained on a previously oxide-

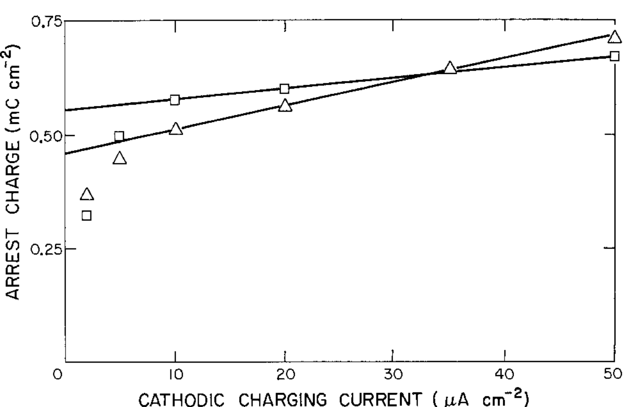

Fig. 12. Dependence of the observed oxide reduction arrest charge on cathodic charging current after prior 90 sec anodizations at −0.3V (—□—) and −0.2V (—△—).

Table I. Dependence of measured and corrected oxide reduction arrest charges and surface activity at end of arrest on previous anodization treatment

−0.5	10 min	0.47			

* Measured at a cathodic charging current of 20 μA cm^{-2}.
** Measured at the end of the arrest.

free nickel surface. With the 90 sec anodization at −0.3V, the activity at the end of the cathodic arrest was 39%, *i.e.*, the other 61% of activity would be recovered during the slow shift of cathodic potential to the value associated with hydrogen evolution on oxide-free nickel. For 90 sec at −0.2V, the activity at the end of the arrest had decreased to 27%. The 39 and 27% activity values were independent of cathodic charging rate, indicating that the linear increase in the arrest charge with i_c (Fig. 12) was not due to cathodic reduction of more of the oxygen on the surface. Table I gives the surface activity at the end of the arrest for oxidations in the range −0.5 to 0V. As may be observed, there was a substantial decrease in the percentage surface activity recovered at the end of the arrest with increasing potential and time of anodization. Also included in Table I are the arrest charges measured at a cathodic current of 20 μA cm^{-2} (Fig. 6). The arrest charge reached a maximum after 90 sec at −0.3V and then began to decrease. Corrected arrest charge values, obtained by extrapolation to $i_c = 0$ (as in Fig. 12), are given in the table and the current efficiency is the ratio of the corrected charge to the total arrest charge measured at 20 μA cm^{-2}.

Figure 13 shows the change in surface activity as a function of cathodic charge passed during galvanostatic charging after previous 90 sec anodizations at −0.4, −0.3, and −0.2V. It is to be noted that the surface activity values, within the time of the charge arrest, fall on fairly good straight lines. The deviation from linearity occurs at those points which mark the end of

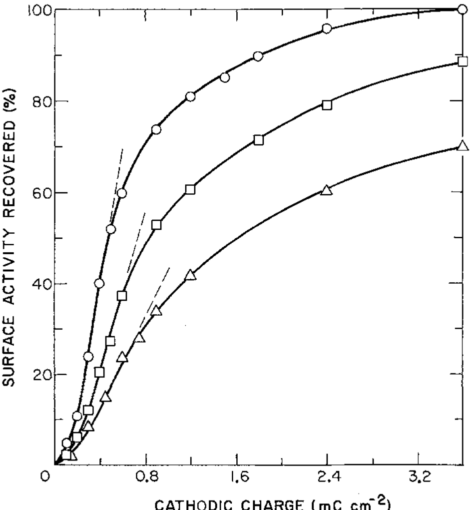

Fig. 13. Increase in surface activity with cathodic charge passed (i_c = 20 μA cm^{-2}) after prior 90 sec anodizations at −0.4V (—○—); −0.3V (—□—); and −0.2V (—△—). The initial linear increase of activity with charge passed is extended (- - -) to give an indication of the cutoff points.

the arrest, and the surface activity subsequently increases more slowly.

Discussion

It has previously been shown that the steady-state oxide on anodized nickel (9-12Å of almost stoichiometric NiO) could be reduced with a moderate cathodic treatment at pH 2.8. The present results indicate that this is also true for the thinner, nonsteady-state films formed by transient anodization in pH 2.8 *In situ* cathodic reduction techniques, together with surface activity measurements, were consequently used to gain an understanding of the initial oxidation processes.

The potentiodynamic sweep experiments showed that the electrode activity is highly dependent on the anodic and cathodic reversal potentials (Fig. 1-3). However, the surface activity data provide only a qualitative measure of the degree of oxidation of the nickel surface, and independent oxide thickness determinations are required. The potentiodynamic sweep technique is not quantitative since the calculated NiO thicknesses, from the oxide reduction peak charge, are anomalously high (*e.g.*, 40-50Å from Fig. 1). This result can be explained in terms of another cathodic reaction, most probably hydrogen evolution on NiO (1, 2), contributing to the charge under the current peak and thereby decreasing the current efficiency for oxide removal.

The effect of potential and time can be separated by using the potential step technique (Fig. 4 and 5). The surface activity recovered after cathodic polarization is decreased by increasing either the time or potential of previous anodic polarization and increased by increasing the time and potential of cathodic polarization.

Galvanostatic charging techniques were also used to reduce the film on anodized nickel. The cathodic charging curves of previously oxidized electrodes display a definite arrest structure, not associated with Ni^{2+} reduction, which varies with potential and time of anodization (Fig. 6 and 7). Other workers have observed a less well defined arrest (4-6); however, little useful information was obtained. In the present work, the very initial oxygen coverages cannot be determined by cathodic charging techniques because of dissolution (Fig. 8 and 9). The significance of oxide dissolution decreases with increasing extent of oxidation (Fig. 10 and 11), but continues to play an important role at the lowest cathodic charging rates, *i.e.*, < 10 μA cm^{-2} (Fig. 12). At the higher charging currents the contribution of dissolution becomes negligible, probably because of increased cathodic protection of the nickel surface and/or shorter times for oxide reduction, and oxygen coverage determinations are possible. The observed linear increase in apparent oxide reduction arrest charge with i_c above 5 μA cm^{-2} (Fig. 12) is due to parallel evolution of molecular hydrogen. The contribution from hydrogen evolution increases with cathodic charging rate since reduction of the oxygen species on nickel is a slow surface process. Extrapolation to $i_c = 0$ therefore gives corrected arrest charges, *i.e.*, without the hydrogen evolution contribution.

The corrected arrest charges do not represent reduction of all of the oxide formed during anodization because the surface activities at the end of the arrests are less than 100%. A certain proportion of oxide is removed after the distinct arrest, and this proportion increases with extent of oxidation. Figure 13 shows that during the time of the arrest, there is a direct proportionality between cathodic charge passed and surface activity recovered. Since the current efficiency for removal of the oxygen species is very high during the arrest (Table I), a direct relationship exists between the oxygen coverage and recovered surface activity over a wide coverage range. The surface activity increases more slowly with cathodic charge passed in the region after the arrest, indicating a fundamental change in the type of oxygen species undergoing reduction.

From the above results it would appear that the anodic formation of an oxide film on nickel takes place in a sequence of steps which depends on both the anodic formation potential and time of polarization. At the very lowest coverages, the oxygen species are unstable with respect to nonelectrochemical dissolution (Fig. 8 and 9) and, although an arrest structure is evident, oxygen coverages cannot be accurately determined. With further anodization, the stability of the oxygen species increases and permits the detection of both chemisorbed oxygen and nucleated oxide at less than one monolayer coverage of the former, *i.e.*, still in the early stages of oxidation. Reduction of the chemisorbed oxygen gives the single, distinct cathodic arrest with the current efficiency for its removal approaching 100%. However, some oxygen remains on the surface even after removal of the chemisorbed oxygen as indicated by the less than 100% recovery of surface activity after the arrest. This oxygen is probably present as nucleated oxide on active sites. Further oxidation gives a maximum corrected arrest charge corresponding to a monolayer of chemisorbed oxygen. At the same time, there is enough nickel oxide on the surface to lower the activity by 60%, *i.e.*, this oxide must have formed on active surface sites since a very small amount has a large effect on activity. Reduction of the nickel oxide after the arrest is an inefficient process and a prolonged cathodic reduction is required to restore complete surface activity.

On anodic polarization for longer times and at higher potentials the chemisorbed monolayer is converted to bulk NiO. This oxide probably grows from the nuclei already present on the active sites. As the oxide thickens the cathodic wave associated with the reduction of chemisorbed oxygen decreases and disappears and the current efficiency for cathodic reduction of the oxide gradually decreases due to the simultaneous production of hydrogen. The oxide is also much more stable on open circuit than either the full or partial monolayer of chemisorbed oxygen.

This sequence of steps for the formation of oxide is quite similar to that proposed for the uptake of oxygen on nickel under ultra-high vacuum conditions (7-9). In this case the oxygen uptake can be measured by x-ray emission or Auger electron spectroscopy and structure changes followed by electron diffraction. The major change from a chemisorbed oxygen structure to an oxide structure takes place at about one monolayer coverage, but some nuclei of nickel oxide are present on the surface before this. The growth rate of the film is consistent with the concept of expanding circles of oxide from a constant number of nuclei present from the beginning.

The cathodic behavior of the oxide with regard to the character of the cathodic waves, the potentials of the waves, and the final reduction potential is also consistent with the proposed mechanism for the formation of the oxide. The initial chemisorbed layer cathodically reduces at a less negative potential than the final bulk oxide. Because the potential for reduction is less negative there is less contribution from hydrogen evolution as a secondary cathodic reaction and, as indicated in Fig. 12 and 13, it is possible to reduce the chemisorbed layer with close to 100% current efficiency. A second factor affecting the reducibility of the layer is the difference in hydrogen overvoltage on the oxide and the metal. In previous work it was shown that hydrogen overvoltage on clean nickel is much higher than on the anodically formed oxide. Hence the contribution of hydrogen evolution to the cathodic current is much less on a partially bare surface, such as one having less than a monolayer of adsorbed oxygen plus some oxide nuclei, than on a surface fully covered with nickel oxide.

The early presence of nucleated oxide is also indicated by the cathodic reduction curves. After oxidation at anodic potentials and times which give only partial monolayer oxygen coverage (*e.g.*, $-0.5V$ and 90 sec) the potential after cathodic reduction of the chemisorbed oxide layer corresponds to the hydrogen overpotential on oxide. The presence of oxide is confirmed by the less than 100% surface activity after reduction of chemisorbed oxygen. The involvement of active sites as nucleation centers for nickel oxide follows from its coexistence with a monolayer of chemisorbed oxygen. The active sites could be surface defects, previously reported to be preferential centers for oxide nucleation (10-12).

The partial monolayers formed at short times and low anodic potentials are easily removed by either chemical dissolution or cathodic reduction. At close to the monolayer coverage observed at higher potentials the adsorbed film is more stable toward chemical dissolution. This may be due to either a decrease in free nickel surface area leading to a decrease in undermining of the oxygen-containing film or a change in the character of the layer. The latter could result from a place exchange transformation (13-15) with alternate oxygen atoms exchanging with the nickel atoms.

Little information can be obtained by cathodic reduction about the thickness and/or coverage of the initially formed oxide due to the significant contribution of parallel oxide dissolution and hydrogen evolution. With further oxidation the amount and stability of the nickel oxide increased. After the corrected arrest charge had reached a maximum value corresponding to approximately a monolayer of NiO_{ads}, the increase in area of oxide coverage should be obtainable from the decrease in the arrest change. However, caution must be used since the thickness of the oxide nuclei may be changing during oxidation (*i.e.*, 9-12Å oxide nuclei may not be present from the beginning). Also, the slow increase in cathodic potential observed after fairly strong anodic treatments will give distinct cathodic arrest structures if the time scale is sufficienly insensitive. Such a situation arose in a previous paper (1) after both 15 and 60 sec at 0.0V. However, the arrest charges corresponded to more than ten times the maximum measured coverage with nickel oxide (1-3), *i.e.*, the current efficiency for cathodic reduction was very low during the so-called arrest. Under such circumstances, the observed cathodic arrest will have little significance with regard to oxygen coverages and the nature of oxygen species on the anodized surface. It is therefore important to have information about the current efficiency for oxygen reduction during the arrest before drawing conclusions about the significance of the arrest.

The present results allow nickel oxidation to be roughly divided into three regions according to oxygen coverage: (*i*) very thin, *i.e.*, substantially less than one oxygen atom per surface nickel; (*ii*) intermediate, *i.e.*, *ca.* one oxygen atom per surface nickel; and (*iii*) thick, *i.e.*, up to the 3 to 4 oxygen atoms per surface nickel found in the steady state. Initially, both chemisorbed oxygen and oxide are formed on the surface but the amount of oxide is only substantial after a monolayer of NiO_{ads} has formed. With continued oxidation, the NiO_{ads} is converted to NiO with the eventual formation of the 9-12Å oxide film. As indicated by the structure in the cathodic charging curves, this general mechanism of oxidation is the same over the wide range of anodic potentials studied.

Summary

1. Surface activity measurements can give a relative measure of the degree of oxidation and/or reduction of nickel and the stability of the oxygen species present toward either reduction or dissolution, but not the amount of oxygen on the surface.

2. The course of oxidation of a nickel electrode can be followed with cathodic charging techniques, the oxide arrest structure varying with the extent of prior anodization.

3. The cathodic charging technique indicates that two distinct oxygen species, most probably chemisorbed oxygen and nickel oxide, are formed on the surface.
4. Chemisorbed oxygen is reduced with a current efficiency close to 100% and gives a distinct arrest structure. Oxygen coverages can be determined since the roles of nonelectrochemical dissolution and parallel hydrogen evolution can be separated out from the cathodic reduction reaction.
5. The current efficiency for reduction of nickel oxide is poor and oxide coverages cannot be determined directly.
6. Oxidation initially gives nickel oxide at the active sites with simultaneous formation of NiO_{ads}, over the rest of the surface, up to a monolayer coverage. Further oxidation converts the NiO_{ads} to nickel oxide.

Charge Transfer Processes during Anodic Polarization of Aluminum

K. Y. Kim,* R. D. Smith, and O. F. Devereux**

Institute of Materials Science and Department of Metallurgy, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

During prolonged anodizing of aluminum in aqueous 3 weight percent ammonium tartrate, ionic current components representing porous oxide development and aluminum dissolution were evaluated by gravimetry and optical absorbance, respectively, and compared to the total flow of charge measured in the external circuit. Electrolytes of pH 6.1 and 7 were studied. The dissolution of aluminum was markedly higher at pH 7, whereas the rate of porous oxide development was only slightly increased. In both cases an electronic current, obtained by difference, was evaluated, but it was very small at pH 7. At pH 7 a large nonelectrodic dissolution of aluminum was seen at the onset of anodizing. These observations are discussed in terms of steady-state processes in the barrier oxide layer involving both ionic transport and oxide dissolution.

Recent work has shown that a steady-state current develops during prolonged anodizing of aluminum in aqueous solutions of ammonium tartrate that is characteristic of the applied potential difference (1). It has been further shown that anodic films formed in this electrolyte, although traditionally regarded as "barrier-type," are, in fact, analogous to films formed in the traditionally "pore-forming" electrolytes (*e.g.*, sulfuric acid), both with respect to structure development and transient behavior of the anodic current at constant applied potential difference (2, 3). In attempting to understand both steady-state and transient aspects of the anodic current it is pertinent to know the nature of the charge transfer processes that occur at the anode. During development of a barrier oxide layer and, in pore-forming electrolytes, subsequent growth of a porous layer, the mode of charge transfer through the anodic oxide has been tacitly regarded as ionic for good and obvious reason. O'Sullivan and Wood, in their excellent treatise, discuss possible ionic processes in detail (4). The actual mechanism of ionic charge transfer is not certain, however, relatively recent tracer studies having supported cationic flow (5), anionic flow (6), and migration by both anions and cations (7, 8). While cationic current must be primarily due to aluminic ion, there may be a small protonic contribution (9, 10), and anionic current may be attributed to hydroxyl ions (9-12), oxide ions (8, 12), and acid anions (13, 14). In contrast, interest in anodic aluminum oxide films formed in "barrier-forming" electrolytes has stemmed largely from their ability to rectify alternating current. Again for obvious reason, the charge transfer mechanism in this case has been tacitly regarded as electronic, prompting considerable study of the role of both electronic and structural defects (11, 15-24). Electronic defects may arise either by hole injection at the metal/oxide interface, or electron injection at the oxide/electrolyte interface occasioned by oxygen liberation from water,

hydroxyl ion, or other oxyanions. Diggle *et al.* (25) have suggested that the charge transfer mechanism in barrier-type films is field dependent; at high fields, the film is growing and both electronic and ionic flow occur, whereas at low fields this is not the case, only electronic flow being seen. Clearly the growth of a porous oxide layer on prolonged anodizing even in barrier-forming electrolytes, cited above (2, 3) and previously noted by others (26-28), is indicative of ionic flow under steady-state conditions.

The present study was performed to distinguish between ionic and electronic currents passed during prolonged anodizing of aluminum in a barrier-forming electrolyte. This was accomplished by measuring (*i*) the total current, and (*ii*) the ionic current, the latter being represented by the appearance of aluminum in the oxide film and also dissolved in the electrolyte. The electronic current (*iii*) was then established as the difference between (*i*) and (*ii*) above.

Experimental Procedures

Anodic oxide films were formed on cylindrical specimens, approximately 1 cm long and 1/2 cm in diameter, prepared from 1/4 in. diameter rod of 99.9995% or 99.999% purity (obtained from Materials Research Company and Leico Industries, Incorporated, respectively). The specimens were center drilled and tapped on one end for incorporation into a specimen assembly described by Greene (29), mechanically polished to 600 grit SiC paper, degreased with benzene followed by methanol, and finally rinsed with doubly distilled water. Some specimens were annealed at this stage of preparation for 1 hr at 80°C, but this was found to have no effect on the experimental results. Subsequently the specimens were chemically polished for 20 min in a solution of 3 parts nitric acid, 80 parts phosphoric acid, and 17 parts distilled water, rinsed with doubly distilled water, and dried with warm air.

Anodizing was conducted in a standard six hole Corning polarization cell, described by Greene (29). This incorporated two platinum counterelectrodes as well as the aluminum working electrode, a thermometer, and a gas inlet tube by which the electrolyte was continuously purged with nitrogen. Before each experiment all assemblies were meticulously cleaned with detergent, followed by concentrated hydrochloric acid, and thoroughly rinsed with doubly distilled water. All experiments were conducted at 30° ± 0.5°C. The anodizing electrolyte was a solution of 3 weight percent (w/o) reagent grade ammonium tartrate in doubly distilled water. In one portion of the work this solution was used as-prepared, having a *p*H value of 6.1; in other experiments it was titrated with dilute ammonium hydroxide to *p*H 7. The cases have been distinguished in reporting the results. In all experiments the anodic current was initially controlled at 1 mA/cm^2 until the anodizing potential reached 50V. This required approximately 5 min. Subsequent to this point in each experiment the potential was controlled at 50V. Experiments were terminated after intervals ranging from the point at which constant potential was imposed to 64 hr.

Several experiments were run for each anodizing time; except as noted all results are reported as averages determined from actual experimental values, with the data spread indicated where possible. For each experiment the following measurements were made:

(*a*) Total charge passed. Total charge passed after a given anodizing time was determined by integrating the as-recorded anodic current over time, using Simpson's rule. Values were normalized by division by individual, as-measured specimen areas.

(*b*) Oxide film weight. Two methods were used to determine the weight of oxide film formed during anodizing. In one technique the anodized specimens were carefully washed with doubly distilled water, then with methanol, and dried in a dessicator. The films were then removed by immersion of the specimens in a saturated aqueous mercuric chloride solution. The films were rinsed in doubly distilled water and again in methanol. The lower surface tension of methanol as compared to that of water reduced the degree of distortion seen in the films on drying. The dried films were weighed with a Cahn RG electrobalance; repetitive measurements showed a reproducibility of 1 μg. The films were not removed intact; in order to obtain the area represented by each weight measurement the films were photographed together with a scale and the areas of the resulting images were determined with a planimeter.

The other technique involved making three weight determinations for each specimen: (*i*) weight before anodizing, (*ii*) weight after anodizing, and (*iii*) weight after removal of the anodic film. Weight (*ii*) minus weight (*iii*) constituted the weight of the oxide film, while weight (*i*) minus weight (*iii*) represented the total aluminum reacted. Oxide film removal was accomplished by repeated brief immersions in a hot phosphoric-chromic acid solution (30), with degree of film removal being monitored by weight measurement.

The second of these methods provided an additional evaluation of the total amount of aluminum reacted, providing an internal check for each experiment, but was less sensitive than the first method due to the greater mass being weighed. Results using the two methods were in agreement.

(*c*) Aluminum dissolved in the electrolyte. Although this could be determined indirectly by the second gravimetric technique described above, it was measured directly for each experiment using an optical absorbance technique, ASTM Standard D857-69, Method C (31). This method was modified by omission of correction procedures for iron and fluoride, and by preparing standard solutions for calibration with fresh anodizing solution rather than with distilled water. A Cary spectrophotometer Model 14R was used.

In addition to the measurements described above selected films and substrates were examined using a Phillips EM300 transmission electron microscope and a Cambridge scanning electron microscope, respectively.

Results

Typical anodic current *vs.* time curves are shown in Fig. 1 for *p*H 6.1 and 7. The behavior of anodizing current over extended periods of time is analogous to that previously reported (1, 2). A dependence of current on *p*H is evidenced, with current values being higher for *p*H 7 than for *p*H 6.1. The total charge passed is shown as a function of time in Fig. 2. Since the anodizing current is virtually constant after the first few hours, the charge passed is linear with time, with a nonzero intercept indicative of the relatively high current passed during the initial constant current region of anodizing. The slopes for *p*H 6.1 and 7 are 21.44 and 28.14 $\mu A/cm^2$, respectively. The oxide film weight, shown *vs.* anodizing time in Fig. 3, exhibits a

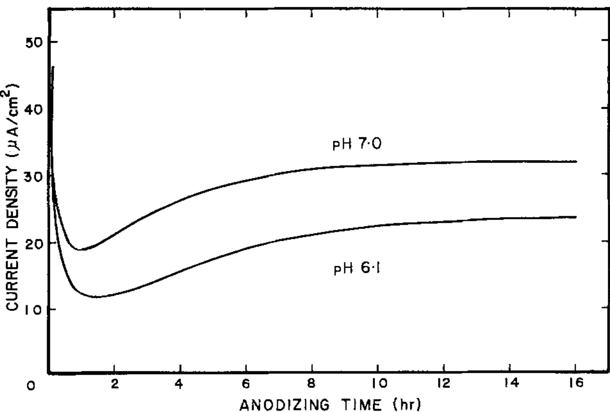

Fig. 1. Anodizing current *vs.* time

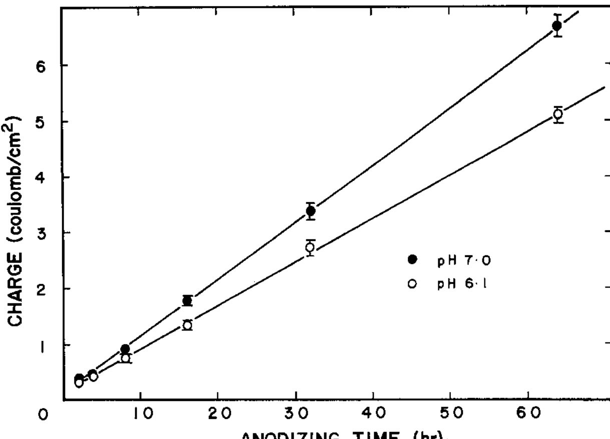

Fig. 2. Total charge passed per unit area vs. time

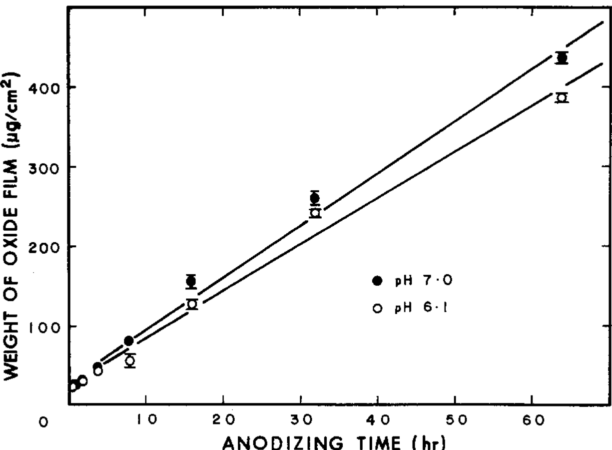

Fig. 3. Weight of anodic oxide per unit area vs. time

similar behavior, being approximately linear[1] with slopes of 5.84 and 6.57 $\mu g/cm^2hr$ at pH 6.1 and 7, respectively. Again, a nonzero intercept is seen, representative of rapid film formation under constant anodic current. The amount of aluminum dissolved in the anodizing electrolyte is shown in Fig. 4. Again, the behavior is approximately linear,[1] with a substantial dependence on pH, the slopes being 2.84 and 5.75 $\mu g/cm^2hr$ for pH 6.1 and 7, respectively. A near zero intercept and small experimental scatter are seen at pH 6.1, while at pH 7 the intercept is approximately 90 $\mu g/cm^2$ and the scatter in analyses is substantial.

[1] Were the error brackets extended to the 95% confidence limits on the mean of each data set, the relationship would be linear. For convenience in the ensuing discussion, linearity is assumed.

Transmission electron microscopy revealed pore development similar to that previously described (2), with pore initiation approximately coincident with the minimum in anodizing current shown in Fig. 1. With the use of stereo pairs (2), it was possible to directly measure the barrier layer thickness to be 625 ± 15Å, corresponding to an anodizing constant of 12.5 ± 0.3 Å/V. SEM examination of the substrates revealed a substantial surface roughness, characteristic of chemical polishing.

Discussion

As noted in the preceding, a basic premise of this study was that the ionic current passed through the oxide could be accounted for by the appearance of aluminum as oxide and as aluminate ion dissolved in the electrolyte. It was further presumed that the difference between this value and the total current passed must represent electronic current. To facilitate comparison data from Fig. 3 and 4 were converted to equivalent charge, assuming that the oxide was stoichiometric Al_2O_3 and that three equivalents of charge were passed for every gram atomic weight of aluminum oxidized. Figures 5 and 6 depict these comparisons for pH 6.1 and 7, respectively. The comparison for pH 6.1 is straightforward; the sum of the two ionic components of the charge passed, subtracted from the total charge passed, yields a net charge flow which must be attributable to electronic flow. This is not true at pH 7, where the sum of the ionic components is more than can be accounted for by the observed flow of charge through the external circuit.

This apparent discrepancy may be explained as follows. At pH 6.1 the charge representing dissolved aluminum has a zero intercept, indicating that the rate of dissolution essentially is constant in time. The total charge and the charge representing the oxide film have essentially identical positive intercepts, representing the initial high current period of anodizing. At pH 7, on the other hand, the charge flow due to dissolved aluminum, although linear, has a large positive intercept, representing a high dissolution rate at the onset of anodizing. This high rate is effective only for a brief period (results not shown in Fig. 6 suggest a period of less than 30 min of anodizing), beyond which the dissolution rate diminishes to a relatively small, constant value. The initial rapid dissolution of aluminum is clearly a nonelectrodic process, inasmuch as there is insufficient charge flow in the external circuit to account for the oxidation of all of the aluminum by electrodic processes. (As an example of such a nonelectrodic process, we suggest reduction of one or both

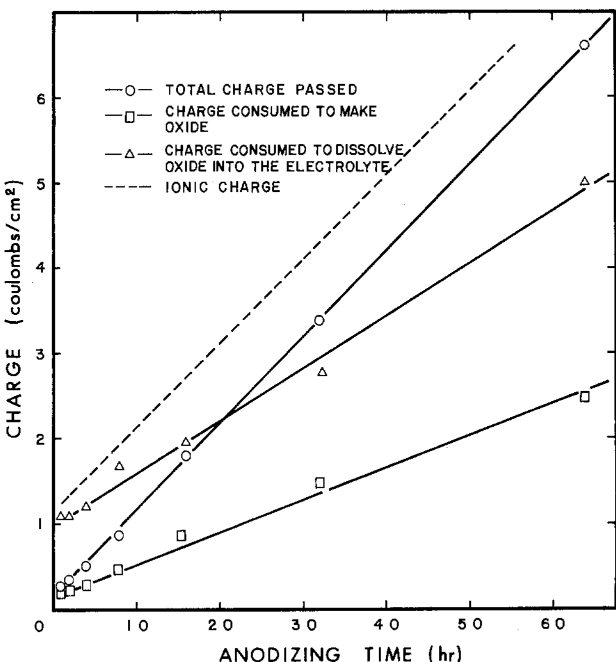

Fig. 6. Ionic contributions to total charge flow, pH 7

carboxyl groups on the tartrate ion by aluminum as more likely than evolution of hydrogen from hydroxyl ion or water due to the overwhelming tartrate concentration and the weaker nature of the carbon-oxygen bond as compared to the hydrogen-oxygen bond. These postulated reactions may be written, respectively

$$3C_4H_4O_6^{=} + 4Al + 3H_2O \rightarrow (C_4H_6O_5^{=})_3Al^{3+} + 3AlO_2^- \quad [1]$$

$$3C_4H_4O_6^{=} + 8Al + 6H_2O \rightarrow (C_4H_8O_4^{=})_3(Al^{3+})_2 + 6AlO_2^- \quad [2]$$

The reaction products are alcohols in which an ionic aluminum-oxygen bond has replaced a covalent hydrogen-oxygen bond.) Such a reaction will diminish markedly in rate as the anodic oxide develops; consequently, the nonelectrodic dissolution is expected to be least significant in environments in which the anodic oxide is least soluble and therefore, develops most rapidly. In this regard it may be shown that anhydrous α-Al_2O_3 exhibits minimum solubility in the vicinity of pH 5 (32). At higher pH, therefore, the solid oxide experiences a greater frequency of interaction with solvating hydroxyl ions via the reaction

$$Al_2O_3 + 2\,OH^- \rightarrow 2AlO_2^- + H_2O \quad [3]$$

so that the rate of dissolution as well as the equilibrium solubility must increase with increasing pH. Clearly, initial formation of the barrier oxide must progress more slowly at higher pH, allowing more time for nonelectrodic dissolution in agreement with observation. (Although we recognize that there is considerable variation in the solubility data pertaining to the various morphological forms of aluminum oxide, and that the anodic oxide may be more properly regarded as a pseudo-amorphous γ-Al_2O_3 rather than α-Al_2O_3 (33), we believe this argument to be qualitatively correct.)

Although the occurrence of a nonelectrodic process precludes meaningful comparison of the components of the total charge passed at pH 7, it is clearly a discrete event pertaining only to the onset of anodizing and does not preclude comparison of components of the steady-state current developed after several hours of anodizing. Such currents, *i.e.*, the slopes of the curves in Fig. 5 and 6, are listed in Table I. These values clearly indicate that the steady-state anodic current can be fully explained by electrodic reactions involving both ionic and electronic currents.

Table I. Steady-state anodic current components

pH	Net current	Al as oxide	Dissolved Al	Total ionic current	Electronic current*
6.1	21.44**	9.21	8.46	17.67	3.77
7	28.14	10.64	17.13	27.77	0.37

* By difference.
** Current reported in $\mu A/cm^2$.

In discussing the values reported in Table I it is instructive to make use of the oxide growth/field-assisted dissolution model for porous oxide development (4, 9) depicted in Fig. 7. In this model a stable barrier oxide layer is presumed to exist, representing a steady-state balance of oxide growth due to field-assisted ionic transport on the one hand, and field-assisted dissolution of the oxide by the electrolyte on the other. A portion of the oxide dissolved by the electrolyte is presumed to precipitate to form a growing porous structure whose presence does not significantly affect the steady-state processes in the barrier layer. Recent dielectric studies have shown that the resistance of the film is dominated by the barrier layer even in the presence of a porous oxide layer orders of magnitude thicker (34). Components pertaining to barrier oxide development are plotted *vs.* field strength in the barrier oxide. To a first approximation, the rate of transport of ions through the oxide can be regarded as exponential with respect to the field (15), while a linear dependence of oxide dissolution on field has been previously assumed and found to be valid in describing the increase of pore diameter and depth with time (2). It is useful, but not essential, to regard the field strength as inversely proportional to barrier layer thickness, although it is clear that this represents an oversimplification (35). No significant dependence of ionic transport on pH is expected; however, as discussed above it may be assumed that the oxide dissolution rate will be higher at pH 7 than at pH 6.1, as illustrated. The dashed curves in Fig. 7 represent the net growth rate of the barrier layer, with the terminal or steady-state barrier layer being represented by zero growth rate.

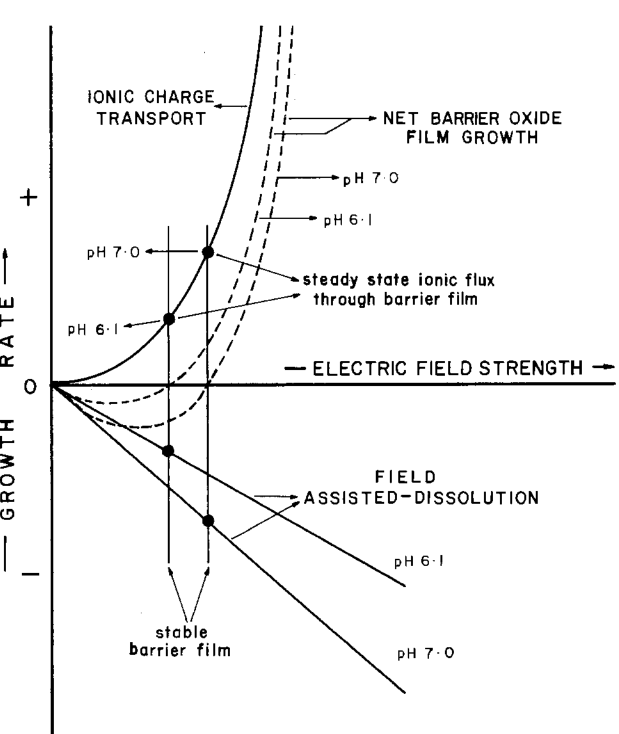

Fig. 7. Schematic representation of steady-state processes in the barrier layer.

The steady-state flux of ions through the oxide is clearly greater at pH 7 than at pH 6.1, reflecting the greater value of the field at steady state. This is in agreement with the values of total ionic flux reported in Table I. This model provides, however, no basis upon which to separate the total ionic flux into components representing growth of porous oxide and dissolution. Empirically, the growth rate is relatively insensitive to pH while, in agreement with the foregoing discussion, the dissolution rate is markedly enhanced by increase in pH in this range.

The observed dependence of electronic current on pH must be associated with a pH dependence of reducing agents at the oxide/electrolyte interface. Smith (22) has suggested electron injection by hydroxyl ions as the origin of the electronic current, although he and others later espoused a "weak spot" theory for conduction in anodic films (23, 15, 24). If electron injection by hydroxyl ion oxidation, in fact, occurs, the increased availability of hydroxyl ion at higher pH would suggest an increased electronic current. On the other hand, the data indicate a marked increase in the dissolution of oxide with increase in pH, effectively consuming near-surface hydroxyl ions by means of reaction (3). In other words, the higher flux of aluminum through the oxide/electrolyte interface may reduce the residence time of hydroxyl ions at the surface, thereby reducing the probability of an oxidation event. It is also possible to postulate oxidation of the tartrate hydroxyl groups as the electron injection mechanism, again with the increased instability of the surface oxide as the reason for reduced levels of injection at higher pH. Clearly further work involving other pH values is necessary in order to be definitive about this point.

In accord with the model of pore development, oxide film weights obtained prior to the appearance of the current minimum in Fig. 1 are representative of the barrier layer which, during the period of rapid current decay prior to the minimum, is growing only very slowly. Weights of films grown for 30 min in both pH 6.1 and 7 electrolytes are approximately equal, 27 $\mu g/cm^2$. Using an oxide density of 3.2 g/cm^3 (36, 37) this observation corresponds to an anodizing constant of 16.9 Å/V in contrast to the directly observed value of 12.5 Å/V. Similarly, the steady-state current value of 28.14 $\mu A/cm^2$ measured at pH 7 is in contrast to the value of 17 $\mu A/cm^2$ obtained in the same environment on electropolished specimens (2). Both of these apparent discrepancies may be attributed to the significant surface roughness derived from the chemical polishing technique. Defining a surface roughness factor as the ratio of the true surface area to the macroscopic surface area, values of 1.35 and 1.65 are derived for the two observations, respectively, in qualitative agreement with SEM observations of the substrate.

Conclusion

The steady-state leakage current observed on anodizing aluminum in a barrier-forming electrolyte, 3 w/o ammonium tartrate, may be regarded as the sum of three components: ionic currents leading to porous oxide formation and to dissolution of aluminum, and an electronic current observed as the difference between the net current and the ionic currents. The net current increases from pH 6.1 to 7, largely due to a doubling in the rate of aluminum dissolution, while the rate of porous oxide formation is relatively pH insensitive. The electronic current decreases with increase in pH, representing 17% of the total current at pH 6.1, but only 1.3% at pH 7. These observations are consistent with an established model of steady state in the barrier oxide layer with an increase in the rate of field-assisted dissolution at the higher pH. The decrease in electronic current with pH is attributed to instability of the oxide surface with a consequent decrease in the residence time of reducible species. A marked nonelectrodic dissolution of aluminum is seen at pH 7, attributed to tartrate ion reduction.

ABSTRACT

Vapor deposition, thin film fabrication techniques have been applied to the preparation of Pt electrodes of various topographies. Large variations were observed in the electrical resistivities of these electrodes as a function of porosities. The effect of these film preparation techniques on Ag electrodeposition from solutions of $AgClO_4$ in sulfolane was examined. Roughness factors, obtained from differential capacitance measurements, varied from 1.0 to 32.8 over the range from bulk Pt to the most porous films. Analysis of cyclic voltammetric data and double potential step chronocoulometric results indicate silver deposition occurs without underpotential deposition in sulfolane in contrast to behavior found in aqueous medium. Little difference is noted in the diffusion-controlled Ag deposition currents as a function of active electrode surface area except at the shortest electrolysis times, ≤ 5 msec. Auger electron spectroscopy and argon ion sputter etching were used to examine the surface and depth profile of controlled potential-deposited thin layers of Ag. Porous films showed deep penetration of all monitored species (Ag, Pt, S, Cl). Detectable amounts of solvent and Ag are found throughout the film electrode. The degree of penetration decreases rapidly with increasing film density. The surface analysis results have been correlated to the electrochemical behavior and interpreted in terms of the extent of solvent, solute interaction prior to electrodeposition.

In recent years, the interest in using thin metal films for basic electrochemical studies has increased. High purity surfaces of various stoichiometries and topographies are routinely prepared using a variety of high vacuum techniques (1-7). Highly reproducible surfaces can be produced which need no additional pretreatment and are thus not subject to possible artifacts caused by polishing or other chemical treatment.

We have previously studied the variation in heterogeneous charge transfer rate of the ferrocene oxidation in the aprotic solvent sulfolane, at a variety of vapor deposited metal films (7). This present work describes the electrochemical deposition of silver using this solvent system. Studies in sulfolane are free from complicating electrode reactions, especially oxidation and reduction of the metallic surface (1, 7). In addition, it is possible to measure the solvent interaction with the electrode using surface analysis techniques such as Auger electron spectroscopy (AES). This interaction may explain the abnormally low rates of heterogeneous charge transfer determined in this solvent (7).

Extensive studies of silver deposition in protic solvents have been reported for bulk metal, single crystal and vapor-deposited thin film electrodes (3, 6, 8-10). These data have led to the conclusion that the diffusion-controlled electrodeposition process is preceded by one or more monolayer depositions of the metal at potentials positive to the formal reduction potential (8). Direct plating then proceeds on this underpotential deposited layer.

This electrodeposition reaction represents the most direct type of electrode interaction. The deposition of silver was selected to demonstrate the extent of solvent and depolarizer interactions with several platinum film types. These processes were studied by comparing electrochemical behavior of thin films in the absence and presence of silver ion followed by surface analysis.

Key words: thin film electrodes, surface capacitance, chronocoulometry, Auger electron spectroscopy, ion sputter etching.

Surface analysis techniques have been employed increasingly to study electrode surfaces in attempts to determine the type and extent of interaction with solution components (1, 11) or to deduce stoichiometric changes where mixed metal or metal oxide electrodes are employed (12-15). The electrodeposition of silver from solution has served as a model for these studies, especially the Auger analysis of thin metallic films (1,16). Results reported here pertain to the study of the silver-platinum electrode system. Complete details of the surface analysis techniques and examination of possible experimental artifacts will be described elsewhere (16).

Experimental

Chemical purification procedures for sulfolane (Shell Chemical) have been previously described (17). Tetrabutylammonium perchlorate (TBAP) and silver perchlorate, both obtained from Eastman Chemicals, were recrystallized from ethanol.

Platinum film electrodes, 20-30 nm thick, were prepared by vapor deposition sputtering. The details of this technique and a description of the resultant films can be found in Ref. (1) and (2). The density of the deposited metal was controlled by varying the argon pressure (20-80 μm) and by controlling the platinum target bias potential (1-4 kV). The highest density films were fabricated using electron beam evaporation of platinum under ultrahigh vacuum ($\leq 10^{-9}$ Torr) conditions (16). These thin films were deposited onto either quartz (Esco Products) or sapphire (Adolph Mueller Company) substrates. Both surfaces were of good optical quality ($\approx$25Å rms roughness). The substrates were cleaned by (*i*) boiling in trichloroethylene, (*ii*) boiling in methanol, (*iii*) boiling in an Alconox solution, (*iv*) scrubbing with cotton using a hot Alconox solution, (*v*) boiling in distilled water, (*vi*) drying with a stream of dry nitrogen or argon, and (*vii*) repeating steps (*iii*)-(*vi*). The substrates were then clamped to a copper block secured on a flange to be mounted in the top of an ultrahigh vacuum system. The copper block had both

heaters and thermocouples affixed to it. A shutter mounted between the samples and the evaporator exposed one of three sample positions at a time so that three different types of films (*e.g.*, thickness, substrate temperatures, evaporation rate, etc.) could be made on a given cycle of the vacuum system. The Pt metal (this technique is applicable to almost any material) was evaporated from a nickel-plated, water-cooled copper e-gun hearth (Varian Model 980-0001). The platinum used was at least 0.9999 pure and was formed into a button to fit into the hearth by arc melting high purity Pt wire in a He atmosphere. The thickness of the film was monitored using a Kronos FTT-300 quartz oscillator thickness monitor which was water cooled. The evaporation rate was less than 1 Å/sec for the films reported here. Before evaporation the substrates were heat cleaned at $\approx$300°C for 2-8 hr in ultrahigh vacuum (the entire vacuum system was prebaked at $\approx$150°C). The substrates were held at $\approx$250°C during evaporation. The resulting films were of extremely high optical quality.

The Teflon electrochemical cell has been previously described (1, 7). The design is similar to that used for spectroelectrochemistry. Solution volume of this cell was approximately 2 cm^3; an electrode of 0.108 cm^2 geometric area was used. The Ag reference electrode (AgRE) for this work was a silver wire previously anodized in a 0.1M TBAP solution. This electrode was positioned within 0.1 cm of the working electrode to minimize solution resistance. A large platinum flag positioned along the wall of the solution chamber served as the counterelectrode.

All solutions were deaerated with a purified argon stream for 1 hr immediately prior to use. Solutions were transferred to the electrochemical cell under an argon atmosphere and the electrochemical cell was sealed prior to measurement. Temperature was controlled at 50.0° $\pm$ 0.3°C by means of an oil circulation system which flowed through the cell body; temperature could be varied from 20° to 80°C. Temperature was monitored using a thermistor probe which protruded directly into the solution. The thermistor was part of a bridge circuit which has been previously described (17).

Electrochemical measurements were made with techniques described previously (7, 17). The potentiostat was equipped with positive feedback compensation. Differential capacitances were determined using previously described methods (18). Usual cyclic voltammetric and double potential step experiments are described in the text. In certain experiments, the charge-time rather than current-time relationships were determined. Plating experiments were also conducted under conditions of diffusion control. Plating times ranged from 50 msec to 120 sec. After cathodic deposition, the potential on the electrode was stepped to a point where silver oxidation occurred.

Auger analysis of several electrodes was conducted following the electrochemical experiments. Small quantities of silver were deposited onto the electrodes. This was done either by controlled potential coulometry or by simply immersing the electrodes into a silver-containing solution. In some cases the silver was removed by anodic stripping. Following each electrode preparation, the materials were thoroughly washed with triply distilled ethanol, dried with high purity argon, and then introduced into the Auger spectrometer.

Auger measurements were made on an instrument constructed in these laboratories (19). This consisted of an all-metal, baked, ultrahigh vacuum system using an Auger spectrometer similar to that described by Gerlach and Tipping (20). The electron beam was controlled at 2 keV during an experiment and maintained a beam current of 10-20 μA. The diameter of the incident electron beam was varied to control power density. The electron gun was coaxial to the analyzer. After each Auger analysis, fractions of the electrode surface were removed by means of argon ion sputtering. The resulting surface was then reanalyzed. The ion beam was controlled at 1-2 keV with an argon background pressure of 4×10^{-5} Torr. This resulted in sputtering rates of 1.5-3.0 nm/min. Details of the calibration of sputtering rates are described elsewhere (16). This calibration was done by sputtering through measured thicknesses of platinum and silver films deposited on quartz substrates. Sputtering rates were the same for all types of platinum films.

Results and Discussion

Electrode fabrication techniques resulted in four different types of electrode surfaces for study. Ion sputter deposition resulted in two quite different surfaces. Under conditions of relatively low target bias (2 keV) and high argon background pressure (80 μm Hg), a highly porous electrode was produced. Scanning electron microscopy (SEM) analysis indicated surface defects as large as $\sim$100 nm in width and 3000 nm in length for the 5000 nm thick films (1). High target bias voltages (4 keV) and low argon pressures (25 μm Hg) resulted in denser platinum films. This second type of film is subsequently referred to as medium porosity. SEM photographs at up to 10,000$\times$ magnification showed little defect structure in these films. Conditions of high target bias and low background pressure allow appreciable surface diffusion before immobilization occurs. Alternate conditions of low target bias and high argon pressure cause immobilization of platinum into a dendritic type of film which leads to a porous structure (21). The densest film electrodes were prepared by electron beam evaporation onto heated substrates under ultrahigh vacuum (UHV). These UHV conditions permit maximum surface diffusion and result in the closest packed metal film (21). No surface structure could be observed by SEM at the highest possible magnification in this third thin film electrode type. The fourth electrode type (bulk Pt) was prepared by abrasively cleaning 10 mil Pt metal foil.

Film resistivities were determined using a four-probe technique that corrects for contact resistance (22). Measured values are listed in Table I. Increases in resistivity were observed as the porosity of the film increased. Resistivities for each film type also increased as the thickness of the deposit was decreased. These data are consistent with previously reported thin film resistance values (5, 21). Since the film thicknesses and the surface defect sizes approach the mean free path of the conduction electrons, these results seem reasonable (21).

Solution capacitance measurements (18) were made with each of these electrode types; results are also included in Table I. Measured capacitance-potential relationships for the different films are qualitatively similar although shifted in magnitude. Substantial increases in capacitance shown in Fig. 1, are observed for the porous electrodes. At 0.0V *vs.* the AgRE, the differential capacitance increased from 8.2 to 68 $\mu F/cm^2$ for the bulk platinum and porous films, respectively.

Table I. Physical and electrical properties of Pt bulk and film electrodes

Electrode	Thickness	ρ ($\mu\Omega$-cm)	C_{dl} at 0.0V* ($\mu F/cm^2$)	Relative roughness factor**
Pt foil	0.13 mm	10	8.2	1.0
Pt (dense) on Al_2O_3	40 nm	20	9.9	1.45
Pt (med) on SiO_2	45 nm	23	11.4	1.87
Pt (porous) on SiO_2	50 nm	35	68	32.8

* *E* (volts *vs.* AgRE).

** Roughness factors were determined from slope of electrode charge *vs.* applied potential, ($\Delta q/\Delta V$), at + 0.5V, cf. Fig. 2.

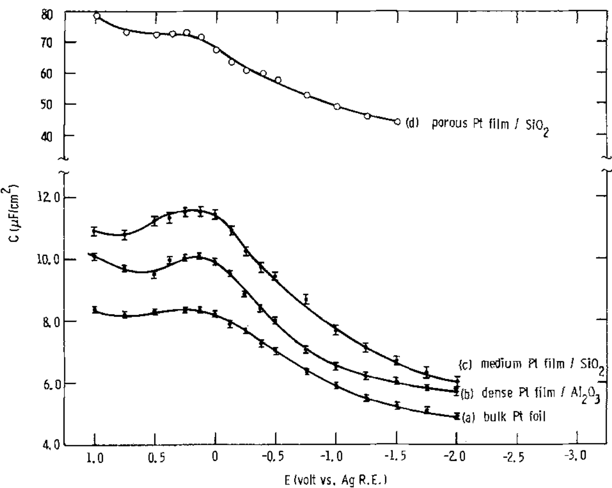

Fig. 1. Capacitance of four Pt electrode types measured as a function of applied potential (E) vs. an Ag reference electrode. Measurements were made in 0.1M TBAP in sulfolane.

The charge-potential relationship was derived from the capacitance-potential plots and is shown graphically in Fig. 2. An electrode potential near the minima in the capacitance plot was arbitrarily chosen as the zero limit of electrode surface charge and electrode charges were computed from this point. From the slope of the charge-potential curves at the zero charge potential, relative roughness factors were evaluated for each electrode compared to the bulk metal (Table I). These slopes should be directly proportional to the electrochemically wettable electrode area (23). As expected, the relative roughness factor for the most porous film suggests appreciable void structure in this material.

Silver deposition from sulfolane solutions was measured on each electrode type. Figure 3 shows a cyclic voltammogram for this process from a 1 *mm* $AgClO_4$/0.1M TBAP solution using a platinum film electrode. Analysis of the current-voltage characteristics on the cathodic branch shows the log $(i_p - i)$ *vs.* E relationship is linear at the onset of the reduction. The silver reduction is slow in this medium. Separations in peak potentials exceeded 200 mV at scan rates greater than 20 mV/sec. For sweep rates of less than 20 mV sec, integration of current as a function of time (for potential limits +0.325 to −0.350V *vs.* AgRE) indicates that the

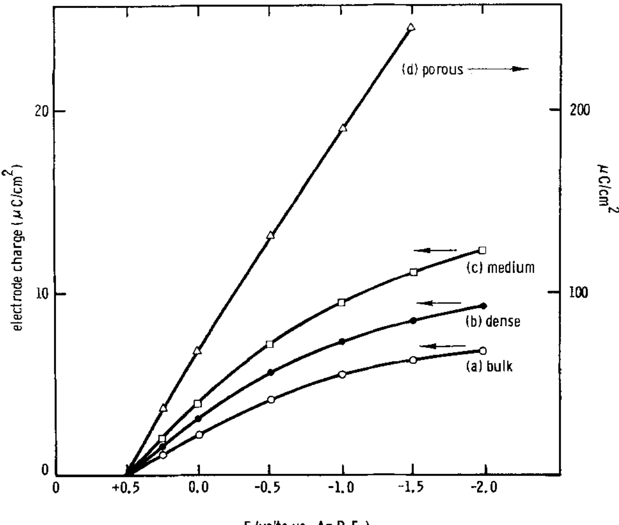

Fig. 2. The charge-potential relationship for each electrode type shown in Fig. 1. Results were derived from the capacitance-potential curves.

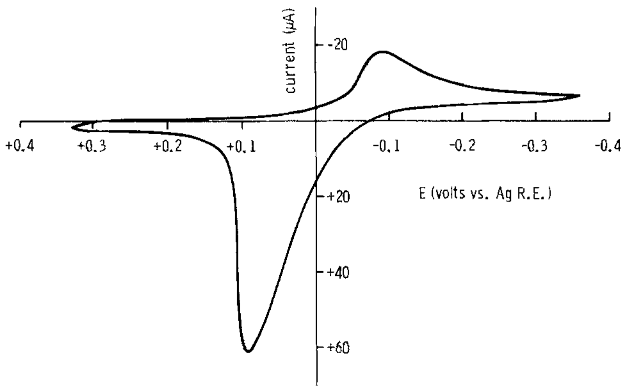

Fig. 3. Cyclic voltammetric scan of Ag plate and strip at a 20 nm Pt film of medium porosity on SiO_2. The electrolyte was 0.1 *mm* $AgClO_4$/0.1M TBAP/sulfolane solution. The scan rate was 20 mV/sec with a measured electrode area of 0.1 cm^2.

charge passed on the reduction step, Q_f, is equal to that passed during the oxidation process, Q_b, *i.e.*, that $Q_f/Q_b = 1.00$. There is no electrochemical evidence that residual silver is retained on the surface. Also, no underpotential deposition of silver was observed even when the silver concentration was increased by over an order of magnitude from that shown in Fig. 2. Potential scans were initiated at potentials more anodic than Fig. 3, yet no predeposition of silver was observed. This suggests that the solvation of silver ion by sulfolane competes favorably with solvation or neutralization of the ion by the metal surface. Silver deposition appears more straightforward in this solvent system compared to that found in aqueous media. Previous aqueous studies showed the necessity for the deposition of up to 2 monolayers of silver on the platinum surface prior to bulk deposition (6, 8, 10). The requirement for a reduced platinum surface for aqueous silver deposition has also been demonstrated (8). No oxidation or reduction of the platinum surface was observed electrochemically in these sulfolane experiments and surface oxides were not observed in the subsequent surface analysis experiments.

Double potential step chronocoulometric experiments were also made using these metallic films. Here the working electrode was stepped to a potential where diffusion-controlled reduction occurred and after a time, τ, back to a potential corresponding to the oxidation of the deposited silver. Figure 4 shows a charge *vs.* $(\text{time})^{1/2}$ plot for a $\tau = 50$ msec experiment. The linear relationship suggests a diffusion-controlled reduction step. This result was found for all the electrodes investigated. This implies that the active electrochemical area of each electrode is approximately equal during this time frame. Similar current distributions should result if the size of the average surface defect is less than the diffusion layer thickness, $2(Dt)^{1/2}$ (24). For electrolysis times of 5 msec and assuming a diffusion coefficient of 10^{-6} cm^2/sec (7, 17), this thickness is 44 μm, or more than an order of magnitude larger than the largest defect size measured by SEM. Variations in active electrode area at shorter electrolysis times were difficult to ascertain since the finite surface resistance of the platinum films caused a negative deviation in the charge *vs.* $(\text{time})^{1/2}$ traces. At 5 msec and using a silver concentration of 1 millimolal, approximately 5% of an equivalent monolayer of silver was deposited.

The ratio of charge transferred on the oxidation step, $Q_{b,2\tau}$ (at time $= 2\tau$), to charge measured on the reduction step, $Q_{f,2\tau}$ (at time $= \tau$), was computed. For every electrode, the ratio $Q_{b,2\tau}/Q_{f,\tau}$ was determined as 0.5-0.6 at $\tau = 50$ msec, 0.6-0.7 at $\tau = 100$ msec, and increased to one as τ approached 500 msec. The shape of the current-time traces for the reduction step is con-

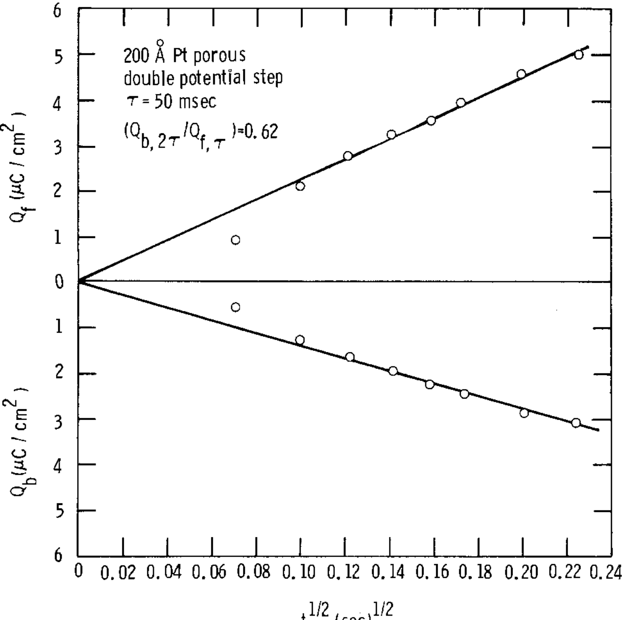

Fig. 4. Double potential step chronocoulometric results for a 50 msec plating (Q_f) and stripping (Q_b) experiment at a 20 nm porous Pt film. The plating solution was 0.1 mm $AgClO_4$/0.1M TBAP/sulfolane.

sistent with the type proposed by Thirsk and Harrison for progressive nucleation of silver on the electrode surface (25).

Experiments were conducted at much longer electrolysis times depositing larger amounts of silver (several hundred equivalent monolayers) followed by electrochemical stripping. The charge-time behavior was again observed. Specular reflectance studies show differences in the deposition reaction of silver between the first equivalent monolayer and subsequent reactions of silver deposition upon silver (6). Similar differences might be expected for the reactions reported here. Figure 5 shows a discontinuity in the normalized charge-time relationship when greater than 95% of the total silver has been removed from the electrode surface. This break may represent a change in the stripping mechanism from stripping of silver from silver to the removal of the last equivalent monolayers of silver from the platinum film. Slight differences were noted between the several electrode studies. The position of this break in the charge-time plots always occurs at earlier dimensionless times for the more porous electrodes. The data suggest that these films expose a larger area of platinum available for deposition than does bulk metal.

The results of these stripping experiments can be compared with results obtained from Auger analysis of electrodes treated in a similar manner. Figure 6 shows several Auger spectra taken on a medium porosity, 20 nm Pt film, which had been previously electrodeposited with 50 μC (approximately 14 equivalent monolayers) of silver from a 1 mm $AgClO_4$/0.1M TBAP/sulfolane solution. This amount of silver corresponds to a 2 nm thickness on the planar surface. The Auger energies are displayed from 0 to 500 eV. Auger analysis shows appreciable quantities of sulfur, chlorine, carbon, and silver. No signals are seen for the platinum substrate. Figures 6b, c, and d show spectra for the same electrode after various argon ion sputtering times. Sputtering rates (16) were 3 nm/min; thus these traces were run at depths of 3, 7.5, and 17.5 nm. Depth profiles for the elements of interest were constructed from these Auger spectra by measuring the peak-to-peak amplitude of each Auger transition at each sputtering depth. Typical results for two electrodes are shown in Fig. 7. The silver peak amplitude was computed using the 356 eV, MNN transition. The platinum peak was measured using the 237.5 eV signal, MMN transition, which did not interfere with other significant Auger signals. The sulfur and carbon levels were estimated from Auger transitions which overlapped slightly with signals from platinum and silver.

From these data it is apparent that silver is found well into the platinum matrix and this penetration is far greater than that of the solvent, represented by the carbon and sulfur signals. Data in Fig. 7 sug-

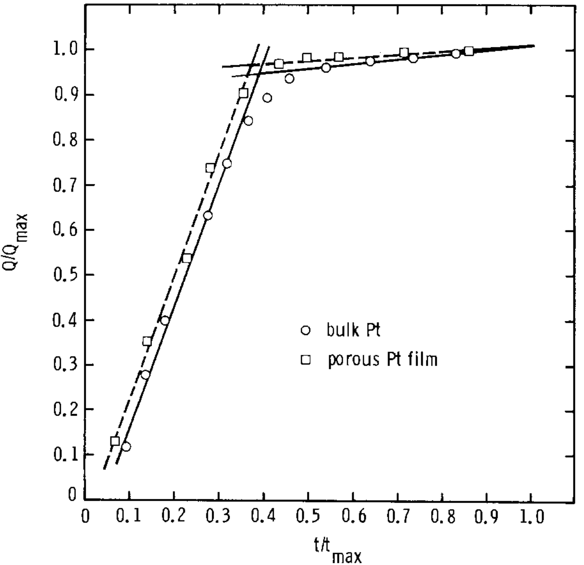

Fig. 5. Normalized charge-time relationship for anodic stripping of electrodeposited Ag at bulk Pt (○) and 20 nm porous Pt film (□) electrodes.

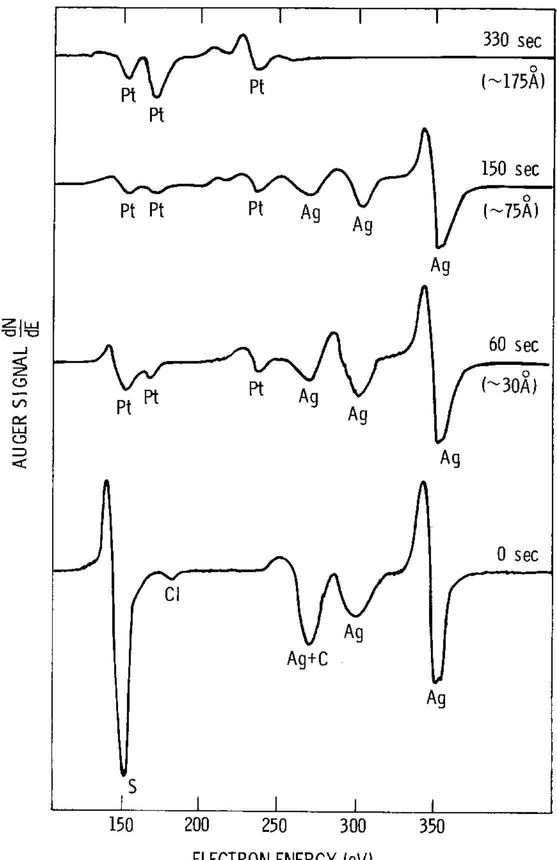

Fig. 6. Auger electron spectra over a limited energy range for a 20 nm, medium porosity Pt film with 500 μC of electrodeposited Ag from 1 mm $AgClO_4$/0.1M TBAP/sulfolane. The times denote sputtering times with approximate depth after sputter in parentheses.

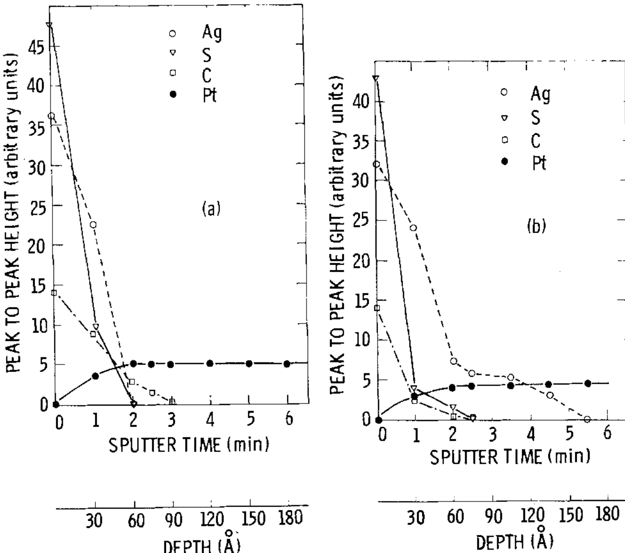

Fig. 7. Depth profiles for (a) medium dense and (b) porous Pt film electrodes plotted in peak-to-peak ratios of principal Auger electron peaks for Pt, Ag, C, and S. The depth is expressed both in sputter time and depth as estimated from the sputtering rate (17). In these experiments 500 μC of Ag was electrodeposited from $AgClO_4$/TBAP/sulfolane solution onto 20 nm Pt film electrodes.

gest that extent of silver penetration correlates well with measured electrode porosities. Experiments done on the highest density platinum films as well as bulk metals show only a slight penetration of silver, *i.e.*, the Auger depth profiles show a sharp silver-platinum boundary. Figure 7a shows this boundary is broad for the medium dense platinum film while Fig. 7b shows silver may be in appreciable concentration throughout the entire porous platinum film thickness (20 nm). We assume our depth resolution for these experiments is sufficient to distinguish between cases Fig. 7a and 7b (16). We also assume that the escape depths of the Auger electrons from these films are approximately equal and that differential sputtering of individual atoms did not occur. This has shown to be the case in other experiments (16). No evidence for selective penetration or "knock on" of silver by the argon beam has been observed.

Figure 8 further emphasizes the extent of silver penetration during electrodeposition. The Auger signals from three platinum electrodes, normalized to the measured surface signal, are shown *vs.* sputtering depth. The extent of penetration of silver in a dense

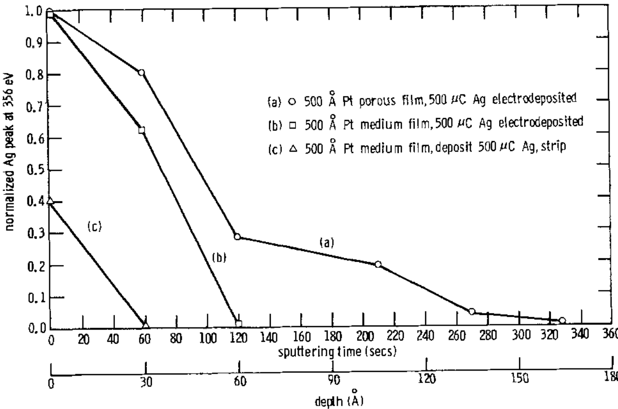

Fig. 8. Silver Auger electron peak at 356 eV (normalized to the measured surface signal) as a function of electrode depth for three platinum electrodes. All were treated in 0.1 *mm* $AgClO_4$/0.1M TBAP/sulfolane solutions: (c) was plated with 5 nm of Ag then electrochemically stripped for a time equal to the plating time.

film which had been plated with approximately 5 nm of silver was studied in the following manner.

The electrode was electrochemically oxidized for a time sufficient to remove that same amount of silver. The absolute magnitude of the silver is lower and the penetration depth is appreciably less than that found for the fully deposited electrode. It is clear that the stripping step did not completely remove the silver deposit. We cannot rule out the possibility that this represents underpotential deposited silver, even though electrochemical experiments did not indicate its presence. Experiments where the electrodes were immersed in silver-containing solution with no electrolysis showed only minor levels of silver which were completely removed with less than 10 sec of argon sputtering, corresponding to a depth of less than 0.5 nm.

These sets of experiments provide interesting comparisons of the electrochemical behavior on several types of platinum surfaces. Vapor deposition techniques provide methods for producing high quality, reproducible surfaces not obtainable by chemical deposition or by polishing. Characterization of these materials both by resistivity and by capacitance measurements shows variations in active surface area and in defect structure. However, the differences in faradaic currents are not observed by usual measurements since the difference would be apparent only at short electrolysis times where defect structures are comparable in magnitude to the diffusion layer thickness (25). The similarity in faradaic response has been seen before with electrolysis data taken at similar electrodes studying the oxidation of ferrocene (1,7). As with the silver reduction, diffusion-controlled ferrocene oxidation appears independent of electrode type at electrolysis times greater than 5 msec.

This similarity in the faradaic silver deposition is contrasted by the differences in the charge-potential behavior and by the Auger analysis found for the various films. The Auger depth profiles suggest significant silver penetration well beyond that found for the solvent in the more porous materials. In fact electrochemical stripping does not completely remove silver deposited within the more porous electrodes. More dense electrodes showed that silver and solvent penetrate to smaller depths.

The absence of evidence for underpotential silver deposition prior to electrolysis in this system contrasts to aqueous systems where this process has been demonstrated (6, 8-10). Competition of the solvent for deposition sites may explain this observation. Appreciable energy would be necessary to overcome this solvent interaction which may contribute to the irreversible behavior of the silver reduction. Once electrodeposition begins silver appears to show appreciable mobility within the film. The solvent-platinum interactions may block surface sites forcing deeper penetration of the silver into the film.

Auger analyses of more porous films show deposition occurring deep in the metallic matrix. Moreover, silver levels are detected considerably deeper than those shown for the solvent. A specific chemical interaction, *e.g.*, alloying, between platinum and silver might contribute to the driving force for this penetration. That this penetration is a result of solvent interaction has been supported by other high vacuum experiments (16). Neutral and ionic silver were deposited onto similar platinum electrodes, within the vacuum apparatus. Auger analysis showed much sharper boundaries between the evaporated silver and the platinum substrates. Significantly less penetration of vacuum-deposited silver was noted on the porous electrodes compared to electrodes with electrochemically deposited silver.

In conclusion, good correlation has been observed between the wettable area of these electrodes, as measured by computing the surface charge, and the extent of penetration of an electrodeposited material such as

silver. Analysis, above, of faradaic currents does not indicate the defect structure of these electrodes. Surface analysis techniques are currently being applied to further study this type of interaction in other electrolyte-electrode systems.

Electrodeposition of Gold

Depolarization Effects Induced by Heavy Metal Ions

J. D. E. McIntyre* and W. F. Peck, Jr.

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Addition of trace quantities (ppm) of heavy metal ions such as Pb(II) or Tl(I) to soft gold electroplating baths induces a marked cathode depolarization that extends the current density range in which bright, fine-grained deposits can be obtained and produces uniform coverage of irregularly shaped substrates. In this study it is shown that the trace foreign metal additives which are most effective as depolarizers are those which tend to deposit uniformly on a gold surface to form an adsorbed monolayer at electrode potentials positive to those where their cathodic deposition as bulk metals begins, *i.e.*, at underpotentials. Of the series of Group B elements (As, Bi, Cd, Cu, Ga, Hg, Pb, Sb, Sn, Tl, and Zn) investigated for depolarization action in alkaline phosphate solutions (pH 8, 70°C), only Pb, Tl, Bi, and Hg were found to induce significant effects. The latter two metals have not previously been reported to act as depolarizers in gold electrodeposition processes. The kinetics of the potential relaxation effects induced by these species under galvanostatic conditions were found to be strongly dependent on mass transport rate, gold deposition rate (*i.e.*, plating current density), and temperature. In addition, it was found that Pb, Bi, Hg, and particularly Tl enhance the anodic dissolution of gold in cyanide-containing solutions. The ranges of underpotential deposition of the metals Pb, Tl, Bi, and Hg from very dilute ($\sim$5 μM) solutions of their ions in pure phosphate supporting electrolyte at 70°C were determined under steady-state mass transport conditions at a rotating gold disk electrode. By varying the disk rotational speed and the potential scan rate, it was shown that a significant amount of Pb(II) [the equivalent of $\sim$20% of a close-packed monolayer of Pb(0)] is specifically adsorbed in the ionic double layer at the gold surface and is not desorbed even at high anodic potentials. A similar phenomenon was observed for the Bi(III) species. The depolarization induced by the trace heavy metal ions is examined in terms of electrocrystallization and electrocatalytic mechanisms. From the magnitude of the potential relaxation ($\sim$0.2V), its temperature dependence, and the ability of Hg to alloy with Au, it is concluded that screw dislocation generation is not responsible for this effect. Failure of Cs^+ ions to enhance the rate of electroreduction of $Au(CN)_2^-$ anions and also the ability of Pb(II) to catalyze the electroreduction of O_2 indicates that electrostatic repulsion effects are of minor importance. It is concluded that the depolarization phenomenon is caused by an enhancement of nucleation rate produced by the strongly adsorbed foreign metal atoms. In addition, catalytic electrochemical displacement reactions are made possible by the fact that the exchange current densities of the various M^{z+}/M depolarizer couples are much greater than that of the $Au(CN)_2^-/Au$ couple and by the specific adsorption of the M^{z+} species. In the case of Hg, displacement is made thermodynamically possible by the complexation of Hg^{2+} by CN^- ions released during the electroreduction of $Au(CN)_2^-$.

In electronic device manufacturing, soft gold coatings are extensively applied for corrosion protection, for conduction of electrical current, and to provide surfaces suitable for bonding (1). The addition of trace quantities (at the part per million level) of heavy metal ions such as thallium or lead to gold-plating baths has been found to yield consistently bright gold electrodeposits of suitable morphology, purity, and hardness, as well as uniform coverage of irregular pieces (2-8). Further, higher plating rates can be employed, underplating is reduced in integrated circuit fabrication, and the life of the bath before restoration becomes necessary is markedly extended.

As yet the mechanism of the marked cathode depolarization induced by these trace metal additives during the electrodeposition of gold has not been well understood. It was the purpose of the present study to examine kinetic and mechanistic aspects of the deposition process in order to reveal the origin of this electrocatalytic effect. It was also desired to determine whether species other than Tl(I) and Pb(II) additives could be used as depolarizers in gold-plating baths. For this purpose, we have focused our attention on alkaline phosphate solutions (pH $\sim$ 8) where well-defined limiting currents for the reduction of potassium dicyanoaurate (I) [$KAu(CN)_2$] are observed and where the free cyanide concentration is very low. In contrast, no limiting current region is observed in citrate gold baths (pH 5) owing to the fact that hydrogen gas is evolved electrochemically in the same potential range where gold electrodeposition occurs (9).

This study revealed that the trace foreign metal additives which are most effective as depolarizers are those which tend to deposit uniformly on a gold surface to form an adsorbed monolayer at electrode potentials positive to those where their bulk metal deposition begins, *i.e.*, at "underpotentials." [For a recent review of underpotential deposition phenomena, see Lorenz *et al.* (10).] Of the series of Group B elements (As, Bi, Cd, Cu, Ga, Hg, Pb, Sb, Sn, Tl, and Zn) investigated for possible depolarization action, only Hg, Tl, Pb, and Bi were found to induce significant effects. These four "super-B" metals follow Au in the third transition series and have atomic diameters from 9 to 22% greater than that of Au (2.88Å). Under galvanostatic conditions, the kinetics of the potential relaxation effects

* Electrochemical Society Active Member.

Key words: gold electrodeposition, depolarization, underpotential adsorption, electrocrystallization, electrocatalysis.

were found to be a function of mass transport rate, plaing current density, and temperature.

It was also found that a high concentration of Cs^+ ions (>0.1M) in solution produced a slow depolarization effect. These large positive ions are only weakly hydrated and are able to contact adsorb on negatively charged metal electrodes such as mercury (11). Owing to a decrease in electrostatic repulsion at the electrode surface, the rate of electroreduction of a number of negatively charged anions, *e.g.*, NO_3^-, $Fe(CN)_6^{3-}$, IO_4^-, and $S_2O_8^{2-}$ is accelerated [*cf.* Parsons (12), Frumkin *et al.* (13), Fawcett *et al.* (14), and references cited therein]. In the present case, however, the depolarization effect was found to be due to residual impurities in the electrolyte. Complementary oxygen reduction studies were also carried out in order to investigate the influence of electrostatic repulsion effects.

The results of these studies are examined in terms of the roles played by dislocation generation, nucleation, and electrocatalytic phenomena. It is shown that the depolarization effect can result from an enhancement of nucleation and crystal growth rate produced by foreign metal adatoms. In addition, electrochemical displacement reactions can occur in which trace heavy metals deposited on the surface in a zero-valent state reduce $Au(CN)_2^-$ anions at an enhanced rate. The oxidized depolarizer species do not leave the surface but remain adsorbed in the electrical double layer, where they can rapidly be reduced again electrochemically; the metal catalyst is thus regenerated. Finally, the physical and chemical characteristics of these "super-B" metals are examined in order to determine why these species are active as electrocatalysts not only for the reduction of $Au(CN)_2^-$ but also for other slow electrochemical reactions.

Thermodynamics

The electrochemical oxidation and reduction of gold in cyanide-containing electrolytes is represented by

$$Au(CN)_2^- + e \rightleftarrows Au + 2CN^- \quad [1]$$

The standard electrode potential, $E°$, of this reaction at ~19°C was first determined by Bodländer (15) in 1903 to be −0.611V (Gibbs-Stockholm convention) with respect to the standard hydrogen electrode potential (SHE). More recently, Maja (16) has measured a value of −0.60V at 25°C. In practice, the equilibrium potential of the $Au(CN)_2^-/Au$ couple is affected by the reactions

$$H_2O \rightleftarrows H^+ + OH^- \qquad K_w = 1.008 \times 10^{-14} \quad [2]$$

$$HCN \rightleftarrows H^+ + CN^- \qquad K_a = 4.93 \times 10^{-10} \quad [3]$$

$$HAu(CN)_2 \rightleftarrows H^+ + Au(CN)_2^- \qquad K_a \geqq 10^{-1} \quad [4]$$

$$CN^- + H_2O \rightleftarrows HCN + OH^- \qquad K_h = 2.04 \times 10^{-5} \quad [5]$$

$$Au^+ + 2CN^- \rightleftarrows Au(CN)_2^- \qquad K_s = 1.1 \times 10^{39} \quad [6]$$

The equilibrium constants (17-19) are for a temperature of 25°C.

The pK_a values of HCN and $HAu(CN)_2$ at 25°C are 9.31 and ≤1, respectively. Thus in alkaline phosphate solutions at pH ~ 7-8, the principal cyanide-containing species are $Au(CN)_2^-$ and HCN. The reversible electrode reaction [1] may be rewritten accordingly as

$$Au(CN)_2^- + 2H^+ + e \rightleftarrows Au + 2HCN \quad [7a]$$

or

$$Au(CN)_2^- + 2H_2O + e \rightleftarrows Au + 2HCN + 2\,OH^- \quad [7b]$$

The standard potential of reaction [7] at 25°C is estimated to be +0.501V (SHE), or *ca.* +0.257V *vs.* a saturated calomel electrode (SCE). In the phosphate gold solution employed in this work [0.0694M $KAu(CN)_2$, pH 8], the thermodynamic reversible potential of the Au(I)/Au couple at 25°C is *ca.* (−0.758 − 0.1183 log [HCN])V(SCE). In gold-plating studies, the concentration of free HCN or CN^- in solution increases continuously with the quantity of gold deposited (Eq. [1] and [7]). Further, the rest potential of a gold electrode may be affected by adsorbed CN^- ions or a surface film of AuCN. Thus under actual operating conditions the true reversible potential is usually not well determined.

In well-buffered phosphate gold solutions, the pH is primarily controlled by the dissociation reaction

$$H_2PO_4^- \rightleftarrows HPO_4^{2-} + H^+ \quad [8]$$

The pK_{a2} values at 25° and 50°C are 7.20 and 7.18, respectively; the temperature coefficient of dissociation is thus very low. In contrast, the dissociation of HCN has a much greater temperature dependence. At 45°C the pK_a of HCN is 8.78 (19) and at 70°C is estimated to be ~8.3. This implies that substantial quantities of free CN^- will be released into a pH 8 solution by the electroreduction of $Au(CN)_2^-$ at the high temperatures (50°-80°C) usually employed in electroplating. In addition to the hydrolysis reaction (5), a number of other chemical side reactions can affect the concentrations of CN^- and HCN at the electrode surface [*cf.* Reinheimer (20)] and hence alter the equilibrium potentials of reactions [1] and [7].

Experimental

Experimental studies were conducted in the electrochemical cell illustrated schematically in Fig. 1. The small volume of this cell (~100 ml) minimizes consumption of gold salts. Rotating disk electrodes (RDE)

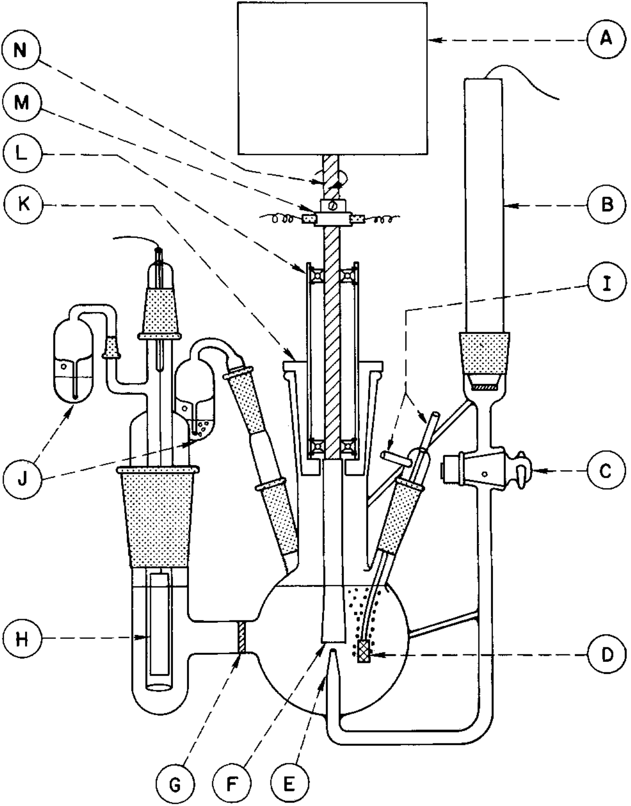

Fig. 1. Electrochemical cell with rotating disk electrode (RDE): A = d-c motor; B = saturated calomel reference electrode; C = Teflon stopcock; D = gas bubbler; E = Luggin capillary; F = RDE; G = fritted Pyrex disk; H = gold counterelectrode; I = gas inlets; J = gas outlets; K = Teflon gland; L = sealed ball bearing assembly; M = silver slip ring and graphite alloy brushes; N = stainless steel shafting.

were fabricated by silver soldering or mechanically joining platinum or gold disks to the ends of ¼ in. diameter, precision-ground stainless steel shafting (PIC Design Corporation, Type A3). The lower RDE section around the joint was sealed in epoxy cement (21) (Union Carbide Corporation, ERL 3794 resin plus ERL 2807 curing agent, 5:1 by weight) to prevent leakage of electrolyte up the shaft. The upper, exposed section of the shaft was encased in dual-wall heat-shrinkable polyolefin tubing (Raychem Corporation, SCL Thermofit). After applying another overcoat of epoxy, the insulation was machined to a flared flat end on a lathe to expose the active electrode surface (Fig. 1). This surface was then metallographically polished to a mirror finish, using 0.3 μm alumina (Linde A) for the final polish. RDE shafts press-fitted into Teflon rods were found not to be leak free at the higher temperatures used in this work.

In order to maintain an inert atmosphere over the electrolyte, the RDE shaft was passed into the cell through two precision gas-tight ball bearings [Barden Corporation, Type SR4FF(3) R21 G6]. Electrical contact to the shaft was made through two silver-graphite alloy brushes and a coin silver slip ring, (Graphite Metallizing Corporation, Types H9434 and 1165-8). The shaft rotational speed was accurately controlled over the range 100-10,000 rpm with a d-c motor (RAE Motor Corporation, Model M6) and programmable power supply (Kepco Incorporated, Model JQE 100-2.5M HS), using a d-c tachometer generator (Servo-Tek Products, Model SA-740A-7) in the feedback loop. An optical pickoff (General Radio Company, Type 1536A) and preset counter (Hewlett Packard, Model 5214L) were used to measure the exact angular velocity of the RDE.

Electrolyte solutions were prepared by dissolving ACS reagent grade salts in ultrapure conductivity water. The basic composition of the phosphate gold solution is

Salt	g/liter	Molarity
$KAu(CN)_2$	20	0.0694
$K_2HPO_4 \cdot 3H_2O$	40	0.175
KH_2PO_4	10	0.0735

The pH of the electrolyte was adjusted to 8.0 with KOH. Depolarizing agents were introduced by adding small aliquots of stock solutions of the appropriate metal oxides or salts. For investigation of the underpotential deposition of the trace metal additives, it was found necessary to preelectrolyze the phosphate electrolyte extensively, using a gold gauze or mercury pool cathode to remove residual metallic impurities. Oxygen was purged from the cell by bubbling argon through the solution. This gas was prepurified by passage over a titanium getter in a furnace at 800°C (Centorr Associates, Incorporated, Model 2-B-20), in order to remove trace hydrocarbons, oxygen, and carbon dioxide, and was then presaturated with water vapor by passage through a bubbling tower filled with supporting electrolyte. The cell electrolyte was maintained at the desired temperature (25°-70°C) by immersing the electrochemical cell of Fig. 1 in a controlled-temperature water bath.

Electrode potentials and currents were controlled with a Princeton Applied Research Model 173 potentiostat and Model 175 universal programmer. All experimental potentials reported in this work are referred to a SCE at room temperature.

Results and Discussion

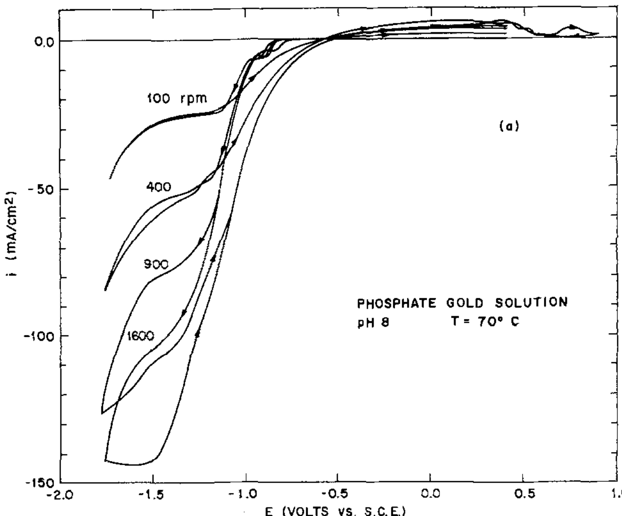
A series of metallic and semimetallic ions from Groups IB, IIB, IIIB, IVB, and VB was added in trace quantities (ppm) to phosphate gold solutions and tested for their depolarizing action on the electrodeposition of gold. A number of these ions are known to adsorb at underpotentials on gold (10), but many are only sparingly soluble in alkaline solution. Of the elements tested (Cu, Ag; Zn, Cd, Hg; Ga, In, Tl; Sn, Pb; As, Sb, Bi), only Hg, Tl, Bi, and Pb induced significant depolarization. In addition, concentrated solutions of Cs^+ ions were found to produce a slow depolarization effect.

Steady-state voltammetry.—Figures 2 and 3 illustrate the form of the steady-state polarization curves measured for the cathodic reduction of $Au(CN)_2^-$ ions and the anodic dissolution of Au metal in a phosphate gold bath at 70°C. A platinum RDE was employed as substrate at the rotational speeds indicated and was stripped[1] after each run in order to prevent buildup of the active electrode area. The platinum disk is not attacked by the cyanide released during the cathodic reduction (Eq. [1] and [7]). After the first few monolayers of gold were deposited during each cathodic scan at 10 mV/sec, the electrode behaved effectively as a gold RDE.[2]

Consider first the cathodic current curves. The initial cathodic scan begins at 0.0V. At a potential close to −0.8V, a small prewave is observed whose amplitude is independent of the stirring rate. This wave has been attributed to the reduction of specifically adsorbed $Au(CN)_2^-$ ions (12, 18). The integral charge passed in this wave in the present case, however, is *ca.* 28 mC cm^{-2}, corresponding to the deposition of ∼125 monolayer equivalents of gold on the disk surface, based on

[1] The gold deposit was chemically dissolved in a proprietary cyanide solution (Technic Incorporated, Techni Strip Au) at a temperature of 60°-70°C.

[2] At a current density of 100 μA cm^{-2}, the equivalent of one close-packed monolayer of gold (∼1.4 × 10^{15} atoms cm^{-2}) is deposited in 2.2 sec.



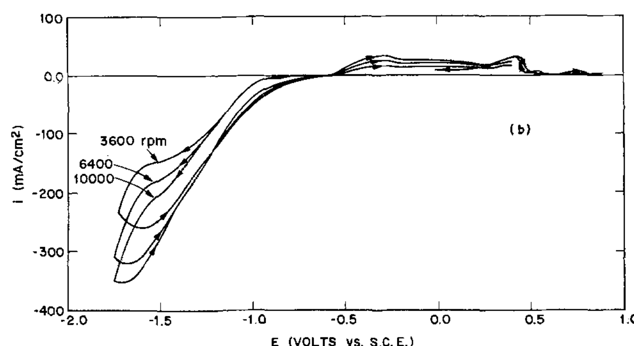


Fig. 2. Steady-state current-potential curves for the reduction and oxidation of gold at a rotating disk electrode in a phosphate buffered gold plating solution with no additives present. [$Au(CN)_2^-$] = 0.0674M, pH 8, 70°C. Potential scan rate = 10 mV sec^{-1}. Rotational speed range: (a) m = 100-1600 rpm. (b) m = 3600-10,000 rpm.

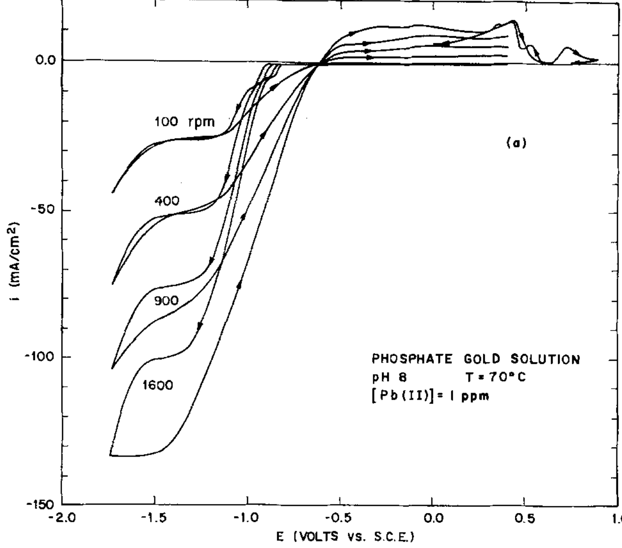

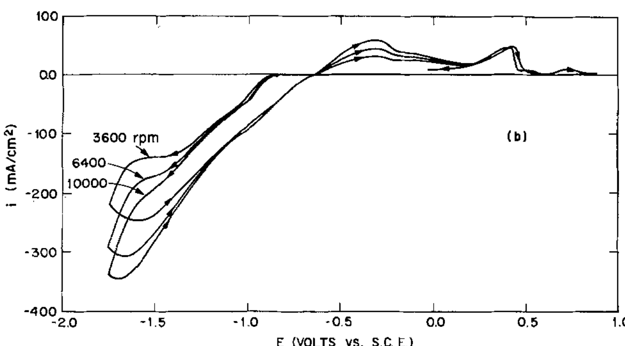

Fig. 3. Reduction and oxidation of gold in a phosphate gold plating solution containing 1 ppm Pb (II). Other conditions are the same as for Fig. 2.

its geometric area. This indicates either that adsorption of $Au(CN)_2^-$ on the surface is extremely rapid or, more probably, that this prewave is due to the reduction of an insoluble surface film such as AuCN or $Pt(CN)_2$ left by the stripping process. At more negative potentials, the current rises rapidly owing to the onset of reduction of $Au(CN)_2^-$ ions transported to the surface by convective diffusion. A well-defined limiting current region is observed at low rotational speeds, but at higher speeds the plateau region has a steeper slope. Finally, at potentials more negative than $-1.5V$, H_2 gas is evolved rapidly at the electrode surface. [The reversible potential of the hydrogen electrode reaction in this solution is $\sim -0.7V$ (SCE).] During the reverse scan, appreciable hysteresis is observed at the higher rotational speeds. This is mainly due to the continuous increase in macroscopic surface area of the electrode with metal deposition time. In the limiting current region, the deposition rate is proportional to $\sim m^{1/2}$, where m is the disk rotational speed (rpm). The fact that the hysteresis becomes nearly constant at the higher speeds may indicate a change in the crystal growth form with increasing current density and decreasing diffusion layer thickness. Such morphological effects have been observed by Cheh and Sard (9). Evolution of hydrogen gas bubbles at the electrode produces turbulence in the diffusion layer, increasing the rate of mass transport of $Au(CN)^{2-}$ to the surface and further accelerating the growth rate of the deposit.

As the current falls below the diffusion-limited value during the reverse scan, it is evident that the rate of metal deposition is markedly enhanced over that in the initial cathodic sweep. As kinetic control becomes dominant over mass transport control near the foot of the reduction wave, the magnitude of the current is determined by the total area of the microscopically rough deposit rather than the projected area of the disk. Such deposits typically have surface asperities in the range 0.1-1 μm in diameter and hence high real surface areas (9). When dilute solutions of the gold salt (*e.g.*, 1 mM) are employed, the hysteresis in the polarization curves is greatly reduced.

Anion desorption at the most cathodic potentials may also be effective in activating the surface. Anions such as CN^-, HPO_4^-, and OH^- are strongly adsorbed on gold electrodes at potentials positive to the point of zero charge and their readsorption is generally slow and kinetically limited (23). Since CN^- or HCN is continuously released during deposition (Eq. [1] and [7]), however, it is probable that this effect is of minor importance compared to the increase in area of the active surface.

As the electrode potential passes through the quasi-reversible potential at $-0.62V$, the current becomes anodic. The gold deposit on the surface begins to redissolve in the solution to form $Au(CN)_2^-$, complexing with the cyanide (CN^- or HCN) released during the cathodic scan (Eq. [1] and [7]). As the potential becomes more positive, the current rapidly becomes diffusion limited since the free cyanide concentration is very low. Two prominent peaks at 0.43 and 0.73V, as well as smaller peaks at -0.05 and $-0.3V$, indicate the possible formation or oxidation of gold cyanide or basic gold cyanide complexes. The nature of these products is not yet well established (22, 24). Between the two most anodic peaks, the surface is passivated by an Au_2O_3 or $Au(OH)_3$ surface film, which begins to form at $\sim 0.45V$.

Pb(II) additions.—Figures 3a and b show the form of the steady-state polarization curves measured in the phosphate gold solution with 1 ppm Pb(II) added (as PbO). These runs were carried out in the same solution as that employed for the runs of Fig. 2a and b. Comparison of the cathodic branches of Fig. 2b and 3b reveals that in the limiting current region the i-E curves are virtually identical, but in the kinetically controlled region above $-1.2V$ there is a pronounced shift of the waves to less negative potentials in the case of the lead-containing solution. A marked depolarization effect is thus induced by only trace quantities of Pb(II) in the electrolyte. The magnitude of this potential shift increases with disk rotational speed since deposition of the lead depolarizer is controlled by its convection diffusion rate and a finite time is required for steady-state surface coverage and depolarization conditions to obtain (see below). It is this kinetically controlled region with high flow rates and current densities below 30 mA/cm^2 which is usually of greatest interest for gold-plating applications (25).

In the anodic current region of Fig. 2b and 3b it is evident that there is an increase in the limiting current densities for the dissolution of Au(O) in the lead-containing solution. This is simply due to the progressive accumulation of OH^- and CN^- in the solution with total cathodic charge passed. At $pH \geq 8$, the phosphate electrolyte is no longer well buffered. It should be noted that in each series of runs, the reversible potential is almost invariant, independent of the changing cyanide concentration in the solution. This suggests that the potential of the unpolarized gold electrode is determined by a cyanide surface layer, as mentioned above. In the lead-containing solutions, this potential is shifted negatively by ~ 60 mV. This may imply that the anodic dissolution of gold is also accelerated by the presence of lead in the solution. Indeed, such effects have been observed for the dissolution of Au in more concentrated cyanide solutions (24, 26). The lead catalyst on the surface is thus bifunctional, accelerating both the cathodic deposition and anodic dissolution kinetics of gold.

Tl(I) additions.—The steady-state polarization curves for a phosphate gold solution with 1 ppm Tl(I) added (as $TlNO_3$) are very similar to those obtained with

Pb(II) additions. Again, a significant depolarization effect is evident at the higher mass transport rates. In separate studies we have confirmed the finding of Cathro and Koch (24) that an addition of 10 ppm Tl^+ to alkaline cyanide solution markedly enhances the anodic dissolution rate of gold. Thus thallium also acts as a bifunctional catalyst on gold surfaces.

Galvanostatic transients.—The nature of the depolarization effects induced by trace metal additives is more clearly revealed by polarization studies under conditions of forced convection and constant current, than by slow potential scanning, since time-dependent effects caused by surface area changes are minimized.

Pb(I) additions.—Figure 4 illustrates the potential transients observed during the electrodeposition of Au metal onto a gold RDE at a series of current densities in the presence and absence of Pb(II). In the lead-free solution, the absolute overpotential for metal deposition $\eta = |E - E_r|$ (E_r is the reversible potential) rapidly attains an almost constant value which changes only slowly with time. Comparison with Fig. 2b reveals that at $m = 3600$ rpm the deposition rate is solely under kinetic control. The slow potential relaxation at long deposition times probably results from an increase in surface area with deposit thickness, but may also be caused by a depolarization effect produced by deposition of residual impurities from the electrolyte.

In the solution containing 1 ppm Pb(II), an initial increase in η is followed by a decrease of 8-30 sec duration, as Pb(O) begins to accumulate on the Au surface. The difference in steady-state overpotential values, *i.e.*, the depolarization, between the lead-free and lead-containing solutions is $\sim$ 200 mV. Now the reduction of $Au(CN)_2^-$ has a Tafel slope, $\partial\eta/\partial \log i$, of 101 mV/decade (9). Hence at constant potential, the presence of 1 ppm Pb(II) in the phosphate gold solution would be expected to increase the reduction rate of $Au(CN)_2^-$ *ca.* one hundredfold.

Figure 5 shows the potential transients observed during deposition of Au metal onto a platinum RDE. The initial large potential step is associated with the high activation overpotential required for the electroreduction of $Au(CN)_2^-$ (see Fig. 2b). Superimposed on this step is a negative spike of 100-200 mV amplitude resulting from adion supersaturation during the initial formation of three-dimensional gold nuclei on the foreign substrate surface. As these nuclei grow, the surface area available for deposition expands and η rapidly decreases. Subsequently the growth centers coalesce and η rises to its final steady-state value. The time required for this to occur is inversely proportional to the deposition rate.

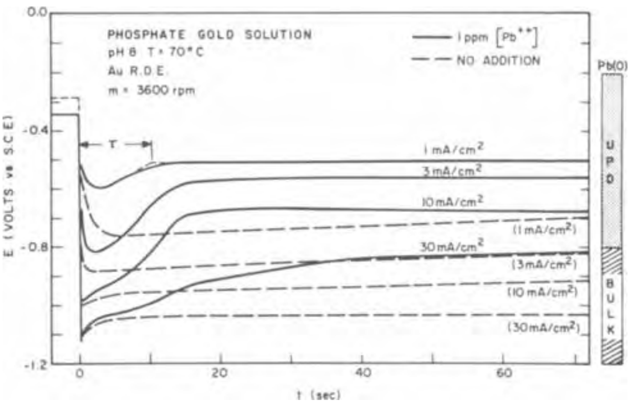

Fig. 4. Potential-time transients observed during the galvanostatic reduction of $Au(CN)_2^-$ at a gold RDE in the presence and absence of 1 ppm Pb (II). The depolarization time, τ, is calculated as shown. Also shown are the approximate potential ranges for underpotential and bulk metal deposition of Pb(O).

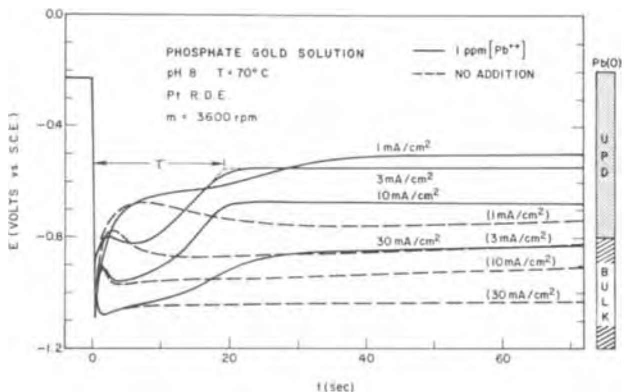

Fig. 5. Galvanostatic reduction of $Au(CN)_2^-$ at a platinum RDE in the presence and absence of Pb(II).

The depolarization time, τ (Fig. 4 and 5), is a function of the Pb(II) concentration in solution (27), its transport rate to the electrode surface, and the applied current density i (*i.e.*, the gold deposition rate). Figure 6 shows the variation of τ with i and $m^{1/2}$. Since the Pb(II) concentration is extremely low, its rate of deposition onto the surface is mass transport limited and inversely proportional to the convective diffusion layer thickness, δ. At a RDE, the diffusion layer thickness for species j is

$$\delta_j = \frac{D_j}{L_j \omega^{1/2}} \qquad [9]$$

where $\omega = 2\pi m/60$ is the angular velocity of the disk

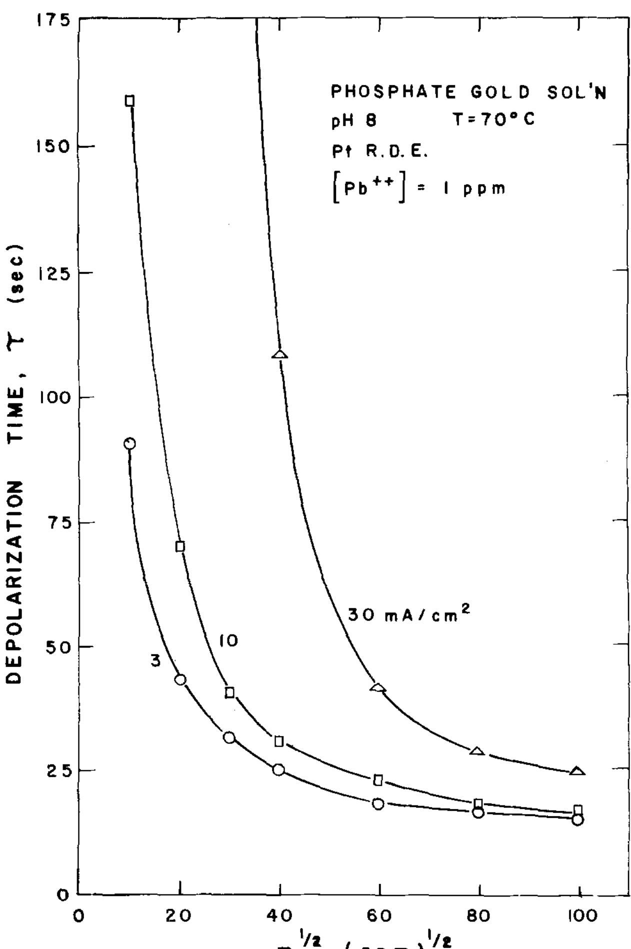

Fig. 6. Dependence of the depolarization time, τ, on the applied current density and disk rotational speed during the galvanostatic reduction of $Au(CN)_2^-$ at a platinum RDE. [Pb(II)] = 1 ppm.

(rad sec^{-1}) and L_j, the Levich constant, is defined by (28)

$$L_j = \frac{0.62048\, D_j^{2/3} \nu^{-1/6}}{1 + 0.2980(D_j/\nu) + 0.14514(D_j/\nu)^{2/3}} \quad [10]$$

Here D_j is the diffusion coefficient (cm^2 sec^{-1}) of species j, and ν is the kinematic viscosity (cm^2 sec^{-1}) of the solution; the quantity ν/D_j is the Schmidt number. The diffusion-limited flux of j to the surface is thus

$$J_j = L_j\, \omega^{1/2}\, C_j^o \quad [11]$$

where C^o_j is the bulk solution concentration. For m = 3600 rpm and [Pb(II)] = 1 ppm = 4.8×10^{-6}M, the maximum rate of supply of Pb(II) to the electrode surface is 9×10^{-11} mole cm^{-2} sec^{-1}, which is equivalent to the deposition of 0.057 close-packed monolayer of Pb(O) per second. Here we have assumed that the diffusion coefficient of Pb(II) is similar to that of $Au(CN)_2^-$ in phosphate gold solutions ($\sim 1.7 \times 10^{-5}$ cm^2 sec^{-1} at 70°C). Now at low rotational speeds, electroreduction of $Au(CN)_2^-$ in 0.069M solution is under mixed kinetic and mass transport control (*cf.* Fig. 2 and 3), but for $m \geqq 3600$ rpm and $i \leqq 30$ mA cm^{-2} the gold deposition rate is limited solely by the kinetics of reaction [7]. A current density of 1 mA cm^{-2} corresponds to the deposition of 4.5 close-packed monolayer equivalents of Au(O) per second, which is greater than the maximum rate of deposition of Pb(O) by a factor of $\sim 10^2$. We might therefore expect that a large fraction of the discharged Pb atoms would be buried beneath the continuously plating Au metal and incorporated as impurities in the bulk deposit. The final Pb atom concentration in the bulk metal has been found to be proportional to the Pb(II) concentration in solution (4). However, the solubility of lead in gold is practically nil below 500°C (29). Thus there is a strong tendency for Pb atoms to segregate from the bulk to form an adsorbed layer on the surface, as has been observed in measurements of surface diffusivity at high temperatures (30). This segregation may occur by backdiffusion along grain boundaries. If it is assumed that the initial surface concentration of Pb adatoms is low, as evidenced by the rest potential, then the depolarization time τ (Fig. 4 and 5) may be interpreted as the time required to establish a steady-state surface coverage of Pb(O). At low rotational speeds, long relaxation times are encountered because the rate of deposition of Au(O) (kinetically controlled) far exceeds that of Pb(O) (mass transport controlled). At high rotational speeds, steady-state conditions are established much more rapidly because of the faster Pb(II) transport rate. As yet the relative rates of supply of Pb(O) to the surface by electrochemical discharge of Pb(II) and backdiffusion of Pb(O) from the bulk deposit are not known.

It is important to note that for m = 3600 rpm and [Pb(II)] = 1 ppm, the values of τ shown in Fig. 4 are $\sim$ 20 sec. It was shown above that under these conditions the flux of Pb(II) to the surface is equivalent to the deposition of $\sim$ 0.057 close-packed monolayer of Pb(O) per second. If the lead atoms are not buried by the overdepositing gold, one complete monolayer of Pb(O) would form in $\sim$ 17.5 sec. The close agreement of these values is remarkable and highly suggestive that the steady-state surface coverage by lead atoms during actual plating conditions is high. Preliminary x-ray photoemission spectroscopy (ESCA) measurements indicate that $\sim$ 0.1-0.2 monolayer of lead is present on the surface of samples plated under similar conditions (31). We are also attempting to measure this surface coverage directly *in situ* using high speed chronocoulometry techniques.

Tl(I) additions.—Figure 7 illustrates the potential transients observed during the electrodeposition of Au metal onto a platinum RDE in a phosphate gold solution in the presence and absence of 1 ppm Tl(I). The

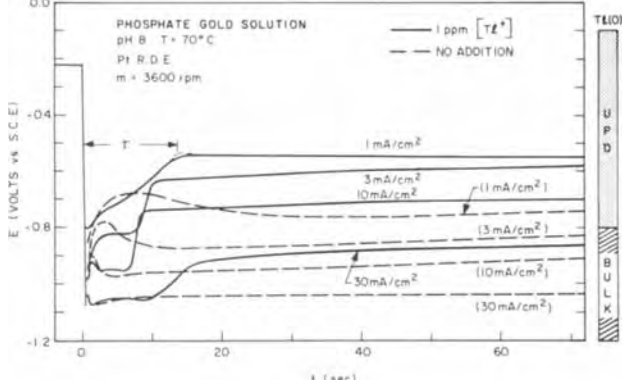

Fig. 7. Galvanostatic reduction of $Au(CN)_2^-$ at a platinum RDE in the presence and absence of 1 ppm Tl(I).

depolarization curves are qualitatively similar to those observed with the Pb(II) additive (Fig. 5), but here the potential relaxations are more abrupt. The magnitudes of the depolarization are slightly smaller than those for lead.

Thallium salts are much more soluble than lead salts in alkaline solution because they do not hydrolyze appreciably (19). In phosphate gold solutions containing 10 ppm Tl(I), the depolarization times are approximately ten times less than in Fig. 7, as expected from Eq. [11]. Figure 8 shows the variation of τ with i, $m^{1/2}$, and $C^o_{Tl(I)}$. At the higher concentrations, the relaxation times become almost independent of m and i. This

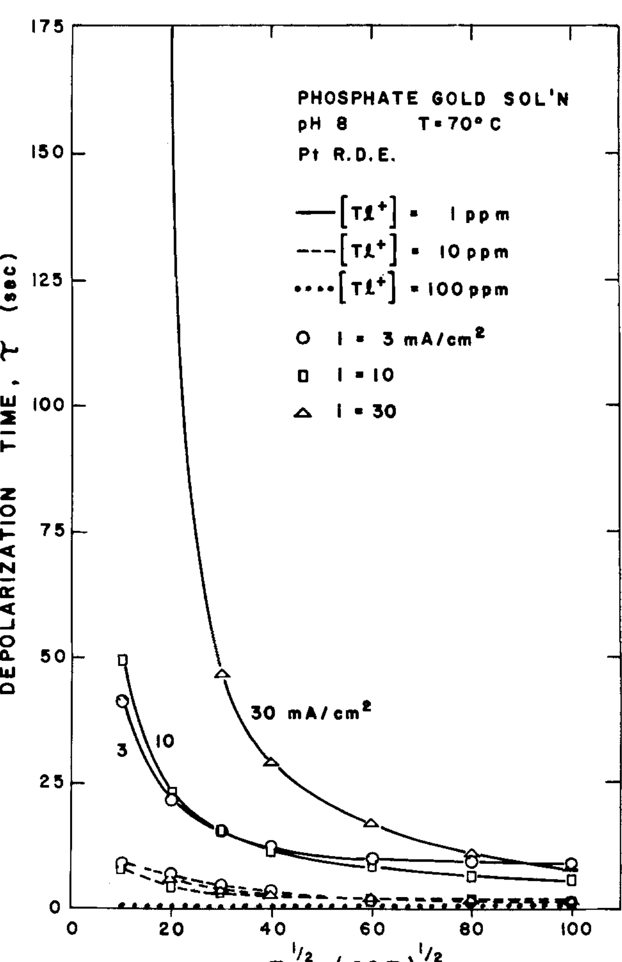

Fig. 8. Dependence of the depolarization time, τ, on applied current density, disk rotational speed, and Tl(I) concentration during the galvanostatic reduction of $Au(CN)_2^-$ at a platinum RDE.

is consistent with a report (3) that thallium does not codeposit from such solutions to form an Au-Tl alloy.

Bi(III) additions.—Marked depolarization effects are also observed when 1 ppm Bi(III) is added to the phosphate gold solution, as shown in Fig. 9. In this case, an initial depolarization is observed which is comparable to those observed for the Pb(II) and Tl(I) additives. But the depolarization times are longer for Bi(III) and, in addition, η increases again at longer deposition times. This might be attributed to the formation of a surface alloy. However, the solid solubility of Bi in Au at 25°C is virtually nil (29). Further, electrochemical studies of the deposition of Bi(O) on Au (32, 33) have revealed no evidence of alloy formation, contrary to the behavior observed for Bi(O) on Pt (34). In the present case, however, the large Bi atoms (d = 3.40Å) are codeposited with the smaller Au atoms (d = 2.88Å) and may form a supersaturated solid solution, as observed for electrodeposited Ag-Bi alloys (29). (Note that d_{Ag} = 2.88Å = d_{Au}). The increase in η may, therefore, result from a reconstruction of the deposit to relieve lattice strain. Alternatively, it may be caused by a growing together of three-dimensional crystallites with consequent decrease in electrode surface area. This phenomenon requires further investigation using electron microscopy techniques.

Hg(II) additions.—Owing to its smaller atomic radius (r_{Hg} = 1.57Å), mercury is able to alloy with gold and at 25°C has a solubility of 16 atom percent (a/o) (29). As shown in Fig. 10, significant depolarization effects are observed in phosphate gold solutions containing 1 ppm Hg(II). The potential relaxation times are five to ten times longer than those for the lead, thallium, or

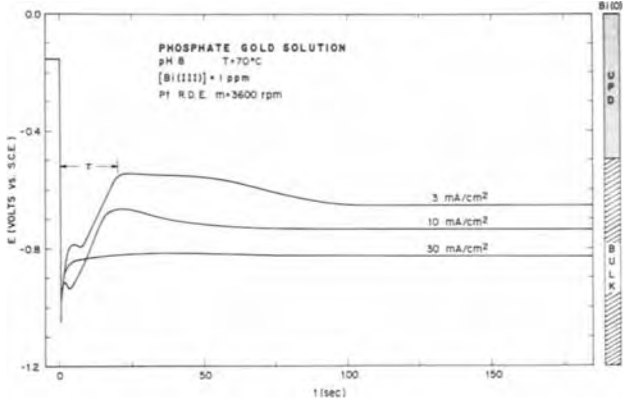

Fig. 9. Galvanostatic reduction of Au(CN)$_2^-$ at a platinum RDE in the presence of 1 ppm Bi(III).

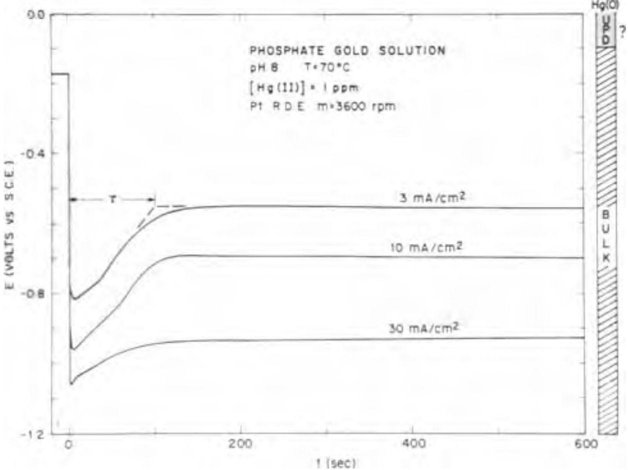

Fig. 10. Galvanostatic reduction of Au(CN)$_2^-$ at a platinum RDE in the presence of 1 ppm Hg(II).

bismuth additives. This is attributed to an amalgamation process which lowers the steady-state surface concentration of Hg adatoms.

Cs^+ additions.—Weakly hydrated Cs^+ ions, which are specifically adsorbed on negatively charged electrodes, are notable for their ability to enhance the electroreduction of negatively charged anions (12-14). This enhancement may occur through (*i*) a decrease in electrostatic repulsion (Frumkin ϕ_2 effect); (*ii*) ion-pair formation in the double layer, which also reduces electrostatic repulsion; (*iii*) ligand bridging with the adsorbed cation, which increases the charge transfer rate; (*iv*) a lowering of the activity coefficient of the activated complex; (*v*) discreteness-of-charge effects; (*vi*) ionic atmosphere and solvent reorganization effects. To test whether such effects could be responsible for the depolarization phenomena observed in the electroreduction of $Au(CN)_2^-$, relaxation times were measured as a function of current density, disk rotational speed, and Cs^+ ion concentration. The depolarization times were found to be exceedingly long, comparable to those observed in phosphate supporting electrolytes which had not been preelectrolyzed. No enhanced depolarization effect was observed at low Cs^+ ion concentrations ($[Cs^+] \lesssim 0.01M$). Further, τ was found to decrease with increasing $[Cs^+]$ and m. It is therefore concluded that Cs^+ ions *per se* are inactive in catalyzing the electroreduction of $Au(CN)_2^-$. The depolarization effects observed in concentrated $CsNO_3$ solutions are attributed to heavy metal ions introduced as impurities with the cesium salt.

Underpotential deposition of heavy metals.—The specific adsorption of metal ions on foreign substrates and their reduction at potentials anodic to the equilibrium potential for the metal ion/metal couple extends over a several hundred millivolt range. In order to correlate the catalytic effects of the Pb(II), Tl(I), Bi(III), and Hg(II) additives on the electroreduction of $Au(CN)_2^-$, their underpotential deposition (upd) range on a gold RDE was measured in preelectrolyzed phosphate buffer solutions at 70°C. A more detailed interpretation of the upd phenomena will be given elsewhere. What we wish to establish here are the relative ranges of monolayer and bulk metal deposition and whether specific adsorption of the heavy metal ions occurs at the gold surface. For purposes of correlation, the approximate underpotential and bulk deposition ranges of the heavy metals investigated in this study have been indicated in Fig. 4, 5, 7, 9, and 10.

Lead.—The standard potential of the reaction

$$Pb^{++} + 2e \rightleftarrows Pb \qquad [12]$$

at 25°C is −0.126V (SHE). From temperature coefficient data (35) the standard potential at 70°C referred to an SHE at the same temperature is calculated to be −0.146V. In a 1 ppm Pb^{++} solution (4.8 μM) at 70°C, the equilibrium potential of the Pb^{++}/Pb couple is therefore −0.327V. In alkaline phosphate solutions this potential is not realized because of the tendency of Pb^{++} ions to complex with hydroxyl and phosphate anions (19).

Figures 11a and b display the *i-E* curves measured for the cathodic deposition and anodic stripping of Pb(O) at a gold RDE in preelectrolyzed phosphate supporting electrolyte (*p*H 8, 70°C) containing 1 ppm Pb(II). Since the bulk solution concentration of the lead additive is very low, a disk rotational speed of 4900 rpm was employed to maintain a rapid supply of this species to the electrode surface. Again assuming that the diffusion coefficient of Pb(II) is similar to that of $Au(CN)_2^-$, we find from Eq. [11] that the limiting transport rate at m = 4900 rpm is equivalent to the deposition of 0.067 close-packed monolayer of Pb(O) per second. Thus at a scan rate of 10 mV/sec the underpotential deposition of lead is essentially free from mass transport control; monolayer deposition is com-

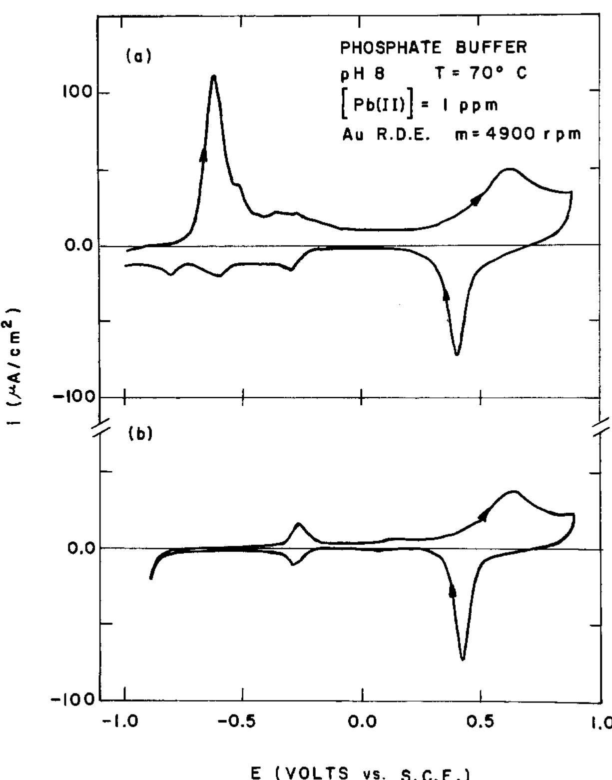

Fig. 11. Oxidation of Pb(O) and reduction of Pb(II) at a gold RDE in aqueous phosphate buffer solution (pH 8, 70°C). [Au(CN$_2^-$] = 0, [Pb(II)] = 1 ppm. Potential scan rate = 10 mV sec^{-1}. (a) Disk held at −1.0V for 20 min before start of anodic scan. (b) Cyclic scans with no hold.

plete within the time required to scan through a voltage interval of 0.15V.

Prior to the commencement of the anodic sweep in Fig. 11a, the electrode was held for 20 min at −1.0V (SCE) in order to deposit bulk Pb metal. The large anodic current peak at −0.62V corresponds to the stripping of this phase. Current peaks due to the anodic oxidation of underpotential Pb(O) occur at −0.52, −0.35, and −0.26V. In the cathodic scan, upd peaks are observed at −0.30, −0.60, and −0.80V.

Figure 11b shows the *i-E* curves measured during a cyclic voltammetric scan under the same conditions as Fig. 11a but with no cathodic hold. Only a single upd peak at −0.28V is observed in the cathodic scan. A conjugate peak of approximately equal amplitude appears in the anodic scan. The integral coulombic charge passed in the cathodic peak of width ~0.18V is ~100 μC/cm², based on the geometric surface area of the disk. For a surface roughness factor of 1.5-2, this charge is equivalent to the deposition of ~0.2 close-packed monolayer of Pb(O) on the surface. To first order this charge is independent of the applied potential scan rate and disk rotational speed. This implies that the Pb(II) species is not removed from the surface during the cyclic scan but remains adsorbed in the double layer. This phenomenon is discussed in further detail in the analysis of underpotential bismuth deposition.

Thallium.—The standard potential of the reaction

$$Tl^+ + e \rightleftarrows Tl \quad [13]$$

at 25°C is −0.3363V (SHE). At 70°C the standard potential referred to a SHE at the same temperature is calculated to be −0.396V. In a 1 ppm Tl(I) solution (4.9 μM) at 70°C, the equilibrium potential of the Tl^+/Tl couple is thus −0.758V. This thermodynamic reversible potential is closely approached in alkaline phosphate solutions because Tl^+ ions are not strongly complexed (19).

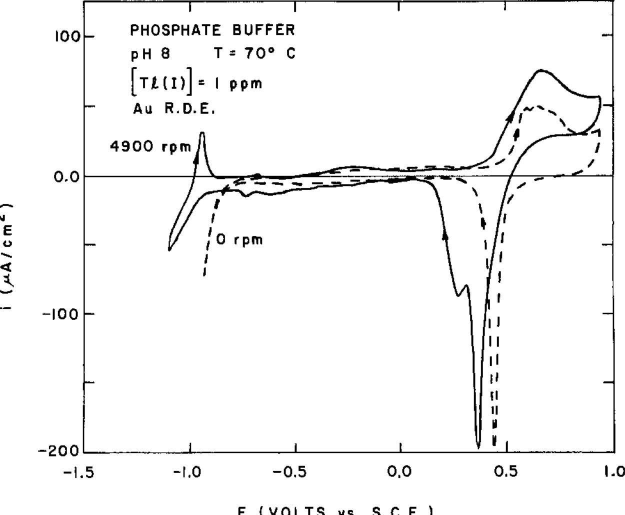

Fig. 12. Oxidation of Tl(O) and reduction of Tl(I) at a gold RDE in phosphate buffer solution. Scan rate = 10 mV sec^{-1}. – – – [Tl(I)] = 0, *m* = 0 rpm. ——— [Tl(I)] = 1 ppm, *m* = 4900 rpm.

Figure 12 illustrates the *i-E* curves measured for the cathodic deposition and anodic stripping of Tl(O) at a gold RDE (m = 4900 rpm) in the phosphate buffer solution containing 1 ppm Tl(I). The cyclic voltammogram for the stationary disk in thallium-free solution is also shown for reference. In contrast to lead, bulk thallium metal readily deposits at a potential very close to its theoretical reversible potential in this solution [−1.00V (SCE)]. In the anodic scan at 10 mV/sec, this phase is rapidly stripped at −0.9V. A small, narrow current peak corresponding to the oxidation of underpotential Tl(O) appears at −0.7V. This is followed by a very broad oxidation peak with a maximum at −0.25V. Corresponding upd peaks are observed in the cathodic scan. Although not well resolved on this scale, additional cathodic underpotential peaks appear at −0.43 and −0.60V. These are not distinguishable at higher sweep rates (≥30 mV/sec).

A remarkable effect occurs in the potential region of anodic oxide formation on the gold electrode in very dilute Tl(I) solutions. A steady-state anodic current of 29 μA/cm² is observed for a disk rotating at 4900 rpm (Fig. 12). This is attributed to the oxidation reaction

$$Tl^+ \rightarrow Tl^{3+} + 2e \quad [14]$$

The standard potential of this reaction at 70°C is +1.29V (SHE) or ~1.05V (SCE), but this potential is shifted negatively by the formation of the sparingly soluble solid phase $Tl(OH)_3$ (36). Comparison of the areas inside the oxide formation-reduction loops of the solid and dashed curves in Fig. 12 shows that the formation of an adsorbed O or anodic oxide layer on gold is only slightly inhibited by the presence of Tl^+ ions. During the reverse cathodic scan from −0.95V, the gold oxide reduction peak is shifted to more negative potentials and broadened. On the trailing edge of this peak appears a secondary peak at −0.38V. The latter peak is attributed to the cathodic dissolution of $Tl(OH)_3$, *viz.*

$$Tl(OH)_3 + 2e \rightarrow Tl^+ + 3\,OH^- \quad [15]$$

At higher sweep rates (≥30 mV/sec) this peak appears only as a small shoulder at the base of the gold oxide reduction peak because the rate of formation of the $Tl(OH)_3$ surface film is controlled by the convective diffusion rate of Tl^+ ions to the surface and the sweep rate. In more concentrated solutions of Tl(I), gold oxide formation is suppressed and gold dissolution enhanced.

It has been postulated (24, 26) that this increase in the gold corrosion rate is due to inhibition of the

formation of the passivating oxide layer by adsorbed thallium atoms. However, Tl(O) cannot exist on the surface at this high potential. An alternative catalytic mechanism which may explain the specificity of the dissolution process is

$$3Tl^+ \rightarrow 3Tl^{3+} + 6e \quad [16a]$$

$$3Tl^{3+} + 2Au \rightarrow 2Au^{3+} + 3Tl^+ \quad [16b]$$

Conversely, since Tl(I) is a strong reducing agent, the adsorbed O or gold oxide layer may be reduced chemically as soon as it is formed electrochemically. In acid solution, for example

$$Au + 3H_2O \rightarrow Au_2O_3 + 6H^+ + 3e \quad [17a]$$

$$3Tl^+ + Au_2O_3 + 6H^+ \rightarrow 3Tl^{3+} + 2Au + 3H_2O \quad [17b]$$

$$3Tl^{3+} + 6e \rightarrow 3Tl^+ \quad [17c]$$

Removal of the oxide prevents the gold electrode from becoming passive and enhances its corrosion rate. Since in both of these mechanisms Tl(I) is continuously regenerated, only trace amounts are required to catalyze the gold dissolution process. Adsorption of the Tl(I) species is not required for either of these postulated mechanisms to be operative. Their applicability is currently under investigation.

Bismuth.—In the *p*H range 3.4-8.6, the reduction of Bi(III) to Bi(O) is formally represented as

$$BiO^+ + 2H^+ + 3e \rightleftarrows Bi + H_2O \quad [18]$$

At 25°C the standard potential of this reaction is +0.320V (SHE). Hence, at *p*H 8 the equilibrium potential of the BiO^+/Bi couple in a 1 ppm Bi(III) solution (4.8 μM) is −0.109V. The temperature coefficient of $E°$ has not been reported (35), and hence the equilibrium potential at 70°C cannot be calculated directly.

Figure 13 shows the *i-E* curves measured for the cathodic deposition and anodic stripping of Bi(O) at a gold RDE (m = 4900 rpm) in preelectrolyzed phosphate buffer solution (*p*H 8, 70°C) containing 1 ppm Bi(III). The potential scan rate was 10 mV/sec. Curves a, b, and c were measured after a potential hold at −0.9V (SCE) of 0, 1, and 2 min to reveal the bulk Bi(O) stripping peaks at −0.3V. The origin of the small anodic peaks at −0.24, −0.09, and +0.25 are attributed to the anodic oxidation of underpotential Bi(O), although the most positive peak has no apparent cathodic counterpart.

During the cathodic scan the gold oxide reduction peak at +0.4V is broadened and attenuated, possibly due to the adsorption of Bi(III) on the oxide surface (33) but more probably in the present case (*p*H 8), due to the reduction of higher valent bismuth oxides such as Bi_4O_7, Bi_2O_4, or Bi_2O_5 which can be formed at potentials >0.6V (SCE) (36). At low scan rates (10 mV/sec) a shoulder appears on the leading edge of the gold oxide reduction peak. This shoulder is not observed at faster sweep rates (≥30 mV/sec).

On repetitively scanning over the potential range −1.0 to +1.0V at 30 mV/sec with a stationary disk (m = 0), only a single Bi(III) reduction peak at −0.15V and a conjugate anodic peak (a doublet) of equal amplitude at −0.10V are observed (Fig. 14a). The integral coulombic charge passed in each current peak is ~300 $\mu C/cm^2$, based on the geometric surface area of the disk. Assuming a surface roughness factor of 1.5-2. this charge corresponds to the amount required to deposit or oxidize 0.3-0.4 close-packed monolayer of Bi(O) on the electrode surface. If m is increased to 3600 rpm at the same potential scan rate, a bulk stripping peak at −0.32V and the underpotential peak at −0.26V reappear (Fig. 14b), while the conjugate current peaks are shifted to −0.19V and their amplitude is halved. These results imply that the redox process associated with these current peaks is not diffusion controlled. At m = 3600 rpm the limiting rate of con-

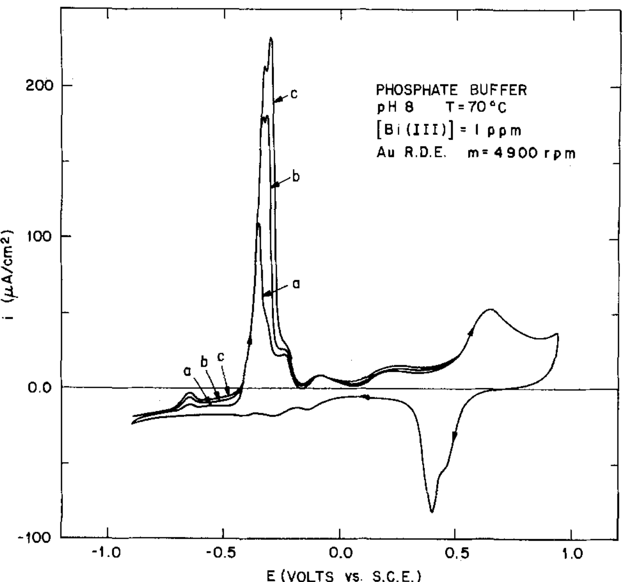

Fig. 13. Oxidation of Bi(O) and reduction of Bi(III) at a gold RDE in phosphate buffer solution. Scan rate = 10 mV sec^{-1}. (a) Disk held at −0.9V for 0 min before anodic scan, (b) 1 min hold at −0.9V, (c) 2 min hold at −0.9V.

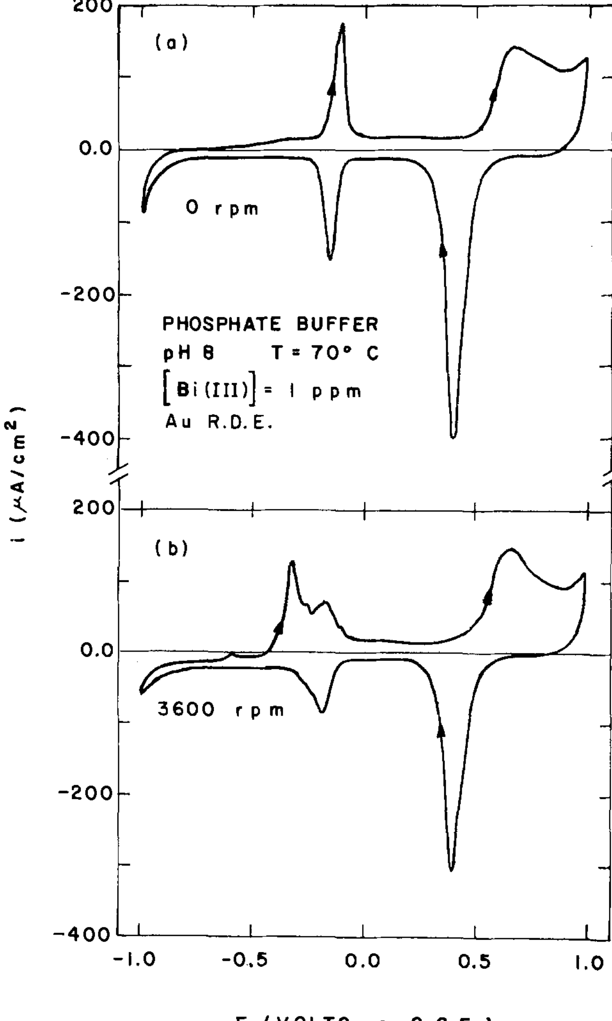

Fig. 14. Linear sweep voltammogram for the underpotential deposition and oxidation of Bi(O) at a gold disk electrode in phosphate buffer solution. Scan rate = 30 mV sec^{-1}. (a) Stationary disk, m = 0 rpm. (b) Rotating disk, m = 3600 rpm.

vective diffusion of Bi(III) to the surface in this very dilute solution corresponds to the deposition of ~0.06 monolayer per second. However at $m = 10$ rpm (a stirring rate greater than that due to natural convection at a stationary RDE), the maximum deposition rate is only 3×10^{-3} monolayer per second. At a scan rate of 30 mV/sec, the duration of the cathodic current peak is ~6 sec, time for less than 0.02 monolayer of Bi(O) to deposit on the stationary disk. These results indicate clearly that a substantial fraction of the Bi(III) species does not diffuse away from the surface but remains adsorbed in the double layer. The kinetics of the charge redistribution among the various adsorption states of bismuth requires further investigation.

The conclusion that Bi(III) species remain adsorbed at the gold electrode is further confirmed by studies in more concentrated solutions. In a 10 ppm Bi(III) solution (4.8×10^{-5}M), the formation of the anodic gold oxide film is strongly inhibited and a steady-state limiting current is observed over the range −0.1-1.0V which is presumed due to the anodic dissolution of gold. Similar results are observed in 1 ppm Bi(III) solutions after deposition of bulk Bi metal at −0.9V for 5-20 min.

Mercury.—In alkaline solutions, mercury metal is oxidized directly to the mercuric state with the formation of sparingly soluble HgO. The standard potential for the reaction

$$HgO + 2H^+ + 2e \rightarrow Hg + H_2O \quad [19]$$

is +0.926V (SHE) at 25°C. At pH 8, the equilibrium potential of the Hg(II)/Hg(O) couple is +0.453 (SHE) or ~ +0.209V (SCE). For the reduction of the sparingly soluble hydroxide

$$Hg(OH)_2 + 2e \rightleftarrows Hg + 2\,OH^- \quad [20]$$

the standard potential is +1.034V (SHE). In a 1 ppm Hg(II) solution (5.0 μM) at pH 8, the equilibrium potential of the Hg(II)/Hg(O) couple is +0.404V (SHE) or ~ +0.159V (SCE).

Figure 15 shows the *i-E* curves measured for the cathodic deposition and anodic oxidation of Hg(O) at a gold RDE ($m = 4900$ rpm) in preelectrolyzed phosphate solution (pH 8, 70°C) with a scan rate of 10 mV/sec. In the cathodic scan a limiting current plateau is preceded by two small current peaks at 0.0V (SCE) which may correspond to underpotential deposition. In the anodic scan, the peak at +0.14V corresponds to the oxidation of Hg(O) to $Hg(OH)_2$. The tail on the anodic side of this peak is attributed to the slow back-diffusion of mercury to the surface of the amalgamated gold electrode. The anodic peak at +0.5V is thought to be due to the enhanced anodic dissolution of gold resulting from the inhibition of oxide layer formation. Since the gold RDE surface is extensively damaged by amalgamation, we have not studied these processes in further detail.

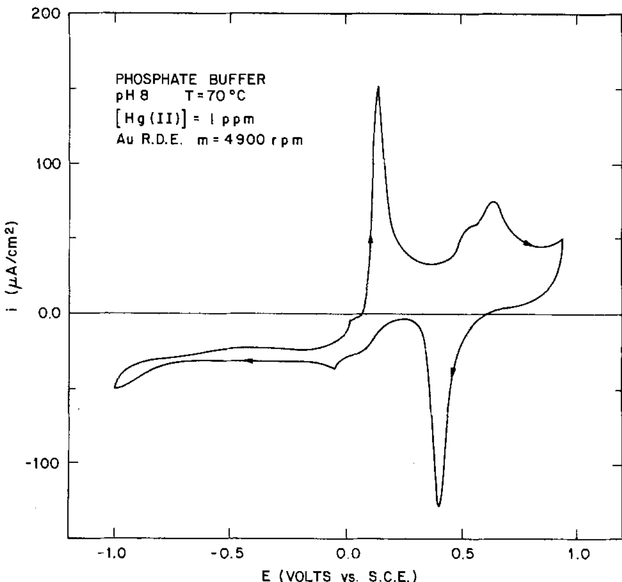

Fig. 15. Oxidation of Hg(O) and reduction of Hg(II) at a gold RDE in phosphate buffer solution. $m = 4900$ rpm. Scan rate = 10 mV sec^{-1}.

Mechanism of the depolarization effect.—Several physical and chemical mechanisms must be considered in attempting to account for the pronounced depolarization effects encountered in the electroreduction of $Au(CN)_2^-$ in the presence of trace quantities of heavy metal ions. Since these additives are present at extremely low concentration (~5 μM) in the bulk solution, it is evident that their rate of transport to the cathode surface is much too low (see above) for them to react directly with the $Au(CN)_2^-$ ions at or near the surface. Rather, the depolarizing species must initially be concentrated in some ionic or neutral adsorption state on the surface which enables them to increase the rate of one or more sequential steps in the electrodeposition reaction. Alternatively, the depolarizer may cause the reduction of $Au(CN)_2^-$ to occur by a different mechanism.

The over-all reaction of metal deposition from an aqueous solution is represented by

$$[M^{z+}(H_2O)_n] + ze \rightarrow M_{lattice} + nH_2O \quad [21]$$

This reaction comprises the following elementary steps: (*i*) transport of the hydrated metal ion, $[M^{z+}(H_2O)_n]_{sol}$, from the bulk solution to a position at the outer Helmholtz plane in the ionic double layer; (*ii*) tunneling of an electron from the electrode to the ion in a suitably deformed solvation sheath; (*iii*) diffusion of the partially hydrated adion across the surface to a step site or crystal nucleus; (*iv*) migration of the particle to a fixed lattice position, *e.g.*, a kink site or edge vacancy; and (*v*) final dehydration and discharge of the adion and incorporation of the metal atom into the lattice. It is clear that if the electrodeposition reaction is to be accelerated by an adsorbed depolarizer, then this species must either remain in its initial state on the surface or else be rapidly regenerated after each reduction event. On the other hand, if the depolarization is caused by incorporation of the large heavy metal atoms into the bulk lattice as the deposit grows, then the mechanism must operate through a long-range physical effect which propagates to the surface plane where reduction occurs. We now consider a number of mechanisms which can contribute to the depolarization phenomenon.

Electrocrystallization effects.—The trace foreign metal additives found most effective as depolarizers (Hg, Tl, Pb, Bi) in the electrodeposition of gold from alkaline phosphate solutions all have atomic radii substantially greater than that of gold ($r_{Au} = 1.44$Å; $r_{Hg} = 1.57$Å; $r_{Tl} = 1.71$Å; $r_{Pb} = 1.75$Å; $r_{Bi} = 1.70$Å). This suggests that the depolarization effect induced by these heavy metal atoms might result from their incorporation into the bulk gold lattice. In real metal crystals, screw dislocations originate at impurity sites or faults. Deposition or dissolution of metal at low overpotentials generally proceeds through these dislocations, with the growth site perpetuating itself (37, 38). Generation of an increased dislocation density in the interior of the crystal could produce, in turn, an increase in the concentration of step sites on the surface and hence a decrease in crystallization overpotential.

There are a number of arguments against this mechanism being the one responsible for the depolarization effect. Firstly, the magnitude of the depolarization (>0.2V) is much larger than the crystallization overpotentials (37) observed for the deposition of a metal

Fig. 16. Temperature dependence of the depolarization effect induced by 1 ppm Pb(II) in the galvanostatic reduction of $Au(CN)_2^-$ at a platinum RDE. $m = 3600$ rpm, $i = 3$ mA cm^{-2}.

onto a substrate of the same metal. Secondly, the depolarization effect has a strong temperature dependence. As shown in Fig. 16, the depolarization time in the phosphate gold solution containing 1 ppm Pb(II) increases as the temperature is lowered until at 25°C a depolarization is no longer observable. If the dislocation mechanism were operative, we would expect the opposite behavior, since higher temperatures should anneal the lattice strain more rapidly and also increase the rate of segregation of lead atoms to the surface or grain boundaries. Secondly, a pronounced depolarization effect is also observed for Hg(II) additives (Fig. 10). Mercury, however, is able to form a substitutional alloy with gold since the difference in their atomic radii is less than the Hume-Rothery limit of ~15%. Hence incorporation of adsorbed mercury atoms into the bulk deposit would not be expected to increase the dislocation density to the same extent as lead and the deposit should be relatively free of internal stress from this source. In contrast, gold deposits plated from a solution containing more than 2 ppm Pb(II) are found to be brittle (8). This may result from an impedance to the movement of dislocations in the bulk caused by the foreign metal atoms, or by their segregation to grain boundaries. Finally, according to classical electrocrystallization theory (37), the current density should be independent of the number of screw dislocations per unit area. From these considerations we conclude that generation of bulk dislocations is not the primary factor which induces the depolarization effect.

Another electrocrystallization effect that must be considered is the rate of two- or three-dimensional nucleus formation on the substrate surface. It is generally believed that polycrystalline metal deposits contain such a high concentration of defects and dislocations that nucleation cannot be a rate-determining step in the crystal growth process. However, in the presence of strongly adsorbing inhibitors it has been postulated (39) that the surface may act as though it were dislocation free since these inhibitors are preferentially adsorbed at defect sites on the surface. At low current densities, for example, copper deposits build up in layers with a preferred orientation as a result of two-dimensional nucleation and growth. At higher current densities and overpotentials, three-dimensional crystallization and growth is favored and a fine-grained deposit with no preferred orientation is formed. In the case of gold electrodeposition, a high concentration of potential inhibitors is generated continuously by the electroreduction process itself (Eq. [1] and [7]). Cyanide anions are strongly adsorbed on gold at potentials positive of the point of zero charge [~0.0V (SCE)]. It is not yet known, however, whether they remain specifically adsorbed at the more negative potentials required for electroreduction of $Au(CN)_2^-$. The adsorption of foreign metal atoms such as Pb, Tl, Bi, or Hg may substantially modify the extent of CN^- adsorption. Note that the bulk metal phases of these elements have points of zero charge −0.4 to −0.9V negative to that of gold (40).

High surface coverages by depolarizer metal adatoms may appreciably alter not only anion adsorption but also nucleation rate and the entire crystal growth mechanism. Recent theoretical calculations (41) have shown that impurity atoms which are strongly chemisorbed on the bulk metal surface can act as centers for two-dimensional nucleation. Thus gold adatoms diffusing across the surface may be trapped by lead atoms adsorbed at underpotentials, owing to the strong Pb-Au interaction energy. If the surface coverage by foreign metal adatoms is sufficiently high, then crystal growth will occur primarily at these sites rather than at step or kink sites on the bulk metal surface. This may increase the net reaction rate in several ways, *e.g.*, by (*i*) decreasing the mean surface diffusion length of the gold adatoms, (*ii*) decreasing the size of the surface nucleus, (*iii*) increasing the total step edge length or the number of kink sites at existing steps, or (*iv*) reducing growth inhibition caused by impurity adsorption and step bunching. The foreign metal adatoms may also reduce the work of formation of two-dimensional nuclei on the surface and thus lower the crystallization overvoltage [*cf.* Pangarov (42-48)]. Preferential deposition of gold crystallites with low index planes parallel to the surface would then be expected, rather than the randomly oriented crystals formed at higher overpotentials. As yet the effect of depolarizers on the orientation of gold crystallites has not been studied experimentally and this postulate remains to be tested.

Finally, it should be noted that the magnitude of the depolarization produced by the foreign metal atoms is anomalously large compared to the crystallization overvoltages usually observed for two- or three-dimensional nucleation and growth [*cf.* Ref. (37)]. In addition to the enhanced nucleation and crystal growth rates, double layer and electrocatalytic effects may also contribute to the depolarization. The influence of these is discussed below.

Electrostatic effects.—As mentioned previously, cesium ions specifically adsorbed on negatively charged electrodes can enhance the electroreduction of negatively charged anions (12-14). Similar enhancement is observed for the electroreduction of cations in the presence of specifically adsorbed anions (12, 49-53). In the present work, however, we could find no evidence of an acceleration of the electroreduction of $Au(CN)_2^-$ anions by Cs^+ ions, other than one attributable to impurities in the reagent salt. An alternative means of lowering the electrostatic repulsion between anions and the electrode may be provided by the underpotential deposition of metals. If the adsorbate layer has an electronegativity or work function less than that of the substrate, then a charge transfer will occur which leaves the atoms in this layer with a partial positive charge. Such may be the case for the adsorption of Pb, Tl, Bi, and Hg on Au ($\chi_{Au} = 2.4$, $\chi_{Pb} = 1.8$, $\chi_{Tl} = 1.8$, $\chi_{Bi} = 1.9$, $\chi_{Hg} = 1.9$). While these metals all act as depolarizers in the electroreduction of $Au(CN)_2^-$ in alkaline solution, other additives such as Cu, Ag, Zn, Cd, In, Sn, and Sb do not. The latter all have electronegativities equal to or less than 1.9. Apparently the positive "electrosorption valency" of these adatoms has no specific electrocatalytic effect in this case.

Other evidence that electrostatic effects were not responsible for the depolarization phenomenon was provided by a study of the electroreduction of oxygen on gold in the phosphate supporting electrolyte. As shown in Fig. 17, the addition of 1 ppm Pb(II) to an O_2-saturated phosphate buffer electrolyte (pH 8, $T = 70°C$) markedly accelerates the rate of electroreduction of oxygen on gold in the potential region of partial ki-

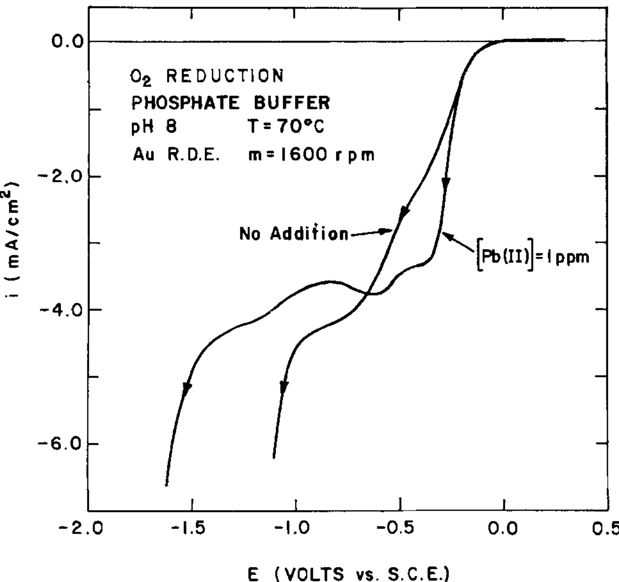

Fig. 17. Steady-state *i-E* curves for the electroreduction of oxygen at a gold RDE in phosphate buffer solution (pH 8, 70°C) in the presence and absence of 1 ppm Pb(II).

netic control. Since the O_2 molecule has no charge, electrostatic effects cannot be responsible for the enhancement of its reduction rate. In this case it is evident that the electrocatalytic effect arises from upd of Pb(O) on the Au electrode surface (*cf.* Fig. 11). Note, however, how the H_2 evolution reaction is poisoned by Pb. Also of interest is the fact that when O_2 is reduced galvanostatically at a low disk rotational speed (900 rpm), the electrode potential exhibits periods of growing and damped oscillation. The origin of this phenomenon is not yet known, but its occurrence suggests that the Pb(O) concentration on the surface fluctuates as a result of reaction with intermediate species (*e.g.*, OH, HO_2, H_2O_2) generated during oxygen reduction.

Electrochemical displacement.—The ability of the heavy metal depolarizers to catalyze both the deposition and dissolution of gold leads us to consider also the possible occurrence of electrochemical displacement reactions. Owing to the high *p*H and the extremely low solution concentrations of the depolarizers, the equilibrium potentials of the metal ion/metal couples lie far negative of their standard potentials. In Table I the thermodynamic reversible potentials of these species at a solution concentration of 1 ppm are compared to that of the Au(I)/Au couple in a phosphate gold solution at 25°C and *p*H 8, with $[Au(CN_2^-] = 0.0694M$ and $[HCN] = 10^{-4}M$. The true reversible potentials of the Pb(II)/Pb and Bi(III)/Bi couples in this solution are probably more negative than the calculated values owing to complexation of the metal cations by OH^-, CN^-, or $HPO_4^=$ anions. The monovalent Tl^+ ions are only weakly complexed by OH^- and not at all by CN^- (19). From these considerations it is evident that the bulk metals Pb, Tl, and Bi are thermodynamically capable of displacing gold from solution, *e.g.*

$$Au(CN)_2^- + Tl + 2H^+ \rightarrow Au + Tl^+ + HCN \quad [22]$$

Table I. Thermodynamic reversible potentials at 25°C and pH 8

Couple	Solution concentrations	E°V (SHE)	E_rV (SHE)
Au(I)/Au(O)	0.0694M $Au(CN)_2^-$, 1.0×10^{-4}M HCN	+0.501	−0.041
Pb(II)/Pb(O)	4.83×10^{-6}M	−0.126	−0.283
Tl(I)/Tl(O)	4.89×10^{-6}M	−0.336	−0.650
Bi(III)/Bi(O)	4.79×10^{-6}M	+0.320	−0.109
Hg(II)/Hg(O)	4.99×10^{-6}M	+1.034	+0.404

Now according to Table I, Hg(O) should not be able to reduce Au(I) since $E_{Hg(II)}/Hg > E_{Au(I)/Au}$. Recall, however, that the Hg^{2+} cation forms soluble, extremely stable complexes with CN^- which are not precipitated in alkaline solution. For example, the stability constant of $Hg(CN)_2$ at 25°C is $10^{35.3}$, whereas that of $Hg(CN)_4^{2-}$ is $10^{41.5}$. These complexes of Hg^{2+} are comparable in stability to $Au(CN)_2^-$ ($K_s = 10^{39.1}$). When the free cyanide concentration is very low ($< 10^{-4}M$), the predominant complex is $Hg(CN)_2$. In alkaline solution (*p*H > 11) at 25°C, the standard potential of the reaction

$$Hg(CN)_2 + 2e \rightleftarrows Hg + 2CN^- \quad [23]$$

is calculated to be −0.190V (SHE). For the corresponding reaction in acid or slightly alkaline solution (*p*H < 8)

$$Hg(CN)_2 + 2H^+ + 2e \rightleftarrows Hg + 2HCN \quad [24]$$

the standard potential is +0.361V. [Recall that the analogous standard potentials for electroreduction of $Au(CN)_2^-$ are −0.600 and +0.501V, respectively.) At *p*H 8, the equilibrium potential of the Hg(II)/Hg couple in a solution with $[HCN] = 10^{-4}M$ and $[Hg(II)] = 1$ ppm is −0.033V (SHE). This is very close to the value of −0.041V calculated for the Au(I)/Au couple in 0.0694M $Au(CN)_2^-$ solution (Table I). At lower cyanide concentrations and also at lower *p*H, $E_r(Hg(II)/Hg)$ lies negative of $E_r(Au(I)/Au)$, as shown in Fig. 18. Under these conditions, mercury metal is electropositive relative to gold and can act as a reducing agent, displacing Au(I) from solution by the reaction

$$2Au(CN)_2^- + 2H^+ + Hg \rightarrow 2Au + Hg(CN)_2 + 2HCN \quad [25]$$

The displacement is also favored by increasing $Au(CN)_2^-$ concentration.

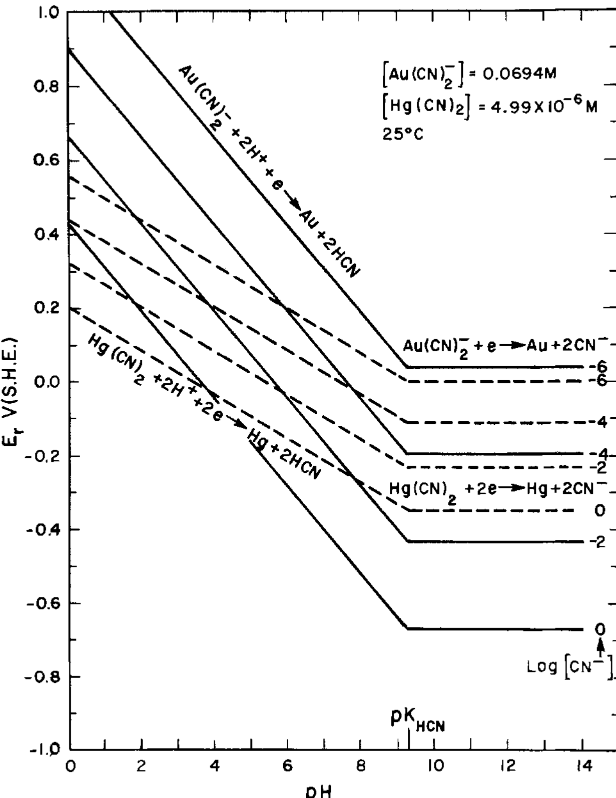

Fig. 18. Variation of the thermodynamic reversible potentials for the reduction of the complexes $Au(CN)_2^-$ and $Hg(CN)_2$ as a function of pH and free cyanide concentrations. $[Au(CN)_2^-] = 0.0694M$, $[Hg(CN)_2] = 1$ ppm $= 4.99 \times 10^{-6}M$, 25°C.

The experimental observation of a pronounced depolarization effect in the electroreduction of $Au(CN)_2^-$ in the presence of 1 ppm Hg(II), which would not otherwise have been expected, strongly suggests that an electrochemical displacement reaction does in fact occur, although nucleation enhancement may also be responsible. The Hg(O) species is rapidly regenerated by electroreduction in the negative potential range employed (Eq. [23]).

The over-all displacement and regeneration process for a depolarizer couple M^{z+}/M may be generally formulated as

$$M + Au(CN)_2^- \rightarrow M_{ad}^{z+} + zAu + 2zCN^- \quad [26a]$$

$$M_{ad}^{z+} + ze \rightarrow M \quad [26b]$$

Several criteria must be satisfied for such a mechanism to be operative. First, the thermodynamic reversible potential of the M^{z+}/M couple must be more negative than that of the $Au(CN)_2^-/Au$ couple in the gold plating solution employed. In the simplified treatment above we have considered only the difference in Nernst potentials of the metal ion/bulk metal couples, assuming the activity of the metal adatom layer to be near unity. This condition is approached near full monolayer coverage but at lower surface coverages the reversible potential of the M^{z+}/M couple is shifted anodically. A positive shift is also produced by specific adsorption of the M^{z+} species in the double layer. Second, the "oxidized" form of the catalyst must remain specifically adsorbed in the double layer since it cannot be replenished at a sufficiently rapid rate by mass transport. It is quite possible that this species is "contact adsorbed" and does not have the full formal charge of the ionic species M^{z+} in solution. Third, the exchange current density of the $M^{z+}/M(O)$ couple must be high in order for the zero-valent species to be regenerated rapidly. Recent studies (10) of the underpotential deposition of silver, lead, and thallium on gold have shown that the exchange current density in these systems is of the order of 10 A cm^{-2}. This implies that charge transfer polarization is negligible and that surface diffusion is the rate-determining step in the deposition process. In the galvanostatic reduction experiments (Fig. 4, 5, 7, 9, and 10), the final steady-state potentials are well clamped. This is consistent with the fact that the exchange current densities of the various M^{z+}/M couples are much greater than that of the $Au(CN)_2^-/Au$ couple. According to this mechanism, the final potential will be determined by the combined polarization curves of the M^{z+}/M and Au(I)/Au couples, as illustrated schematically in Fig. 19. At low current densities gold deposition will occur primarily through the displacement reaction mechanism (Eq. [26]), but at high current densities gold will be deposited mainly by the direct electroreduction mechanism (Eq. [1] and [7]). Finally, although underpotential deposition of a depolarizer is apparently not a prerequisite for catalytic reduction of $Au(CN)_2^-$ (*cf.* Fig. 4, 5, 7, 9, and 10), the formation of M(O) adatoms on the surface enables other slow electrochemical reactions such as O_2 reduction (Fig. 13) to be accelerated at potentials well positive of those where bulk deposition of M(O) begins.

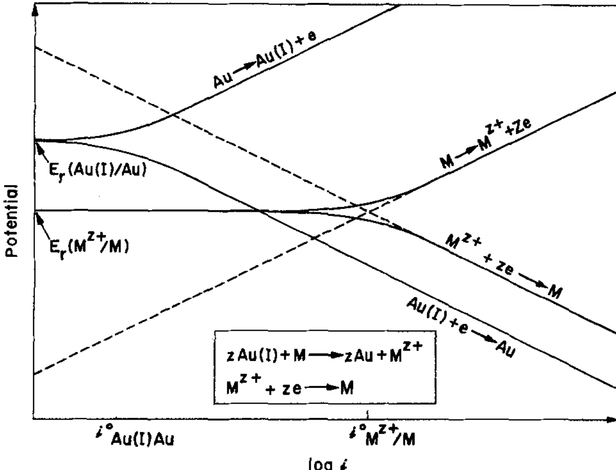

Fig. 19. Schematic representation of an electrochemical displacement reaction. The dashed lines show the variation of the individual anodic and cathodic components of the total current density for the oxidation and reduction of the depolarizer species.

Electroplating applications.—On the basis of the mechanisms described above, it now becomes evident why the addition of trace heavy metal ions such as Tl(I) to gold-plating solutions leads to uniformly distributed gold deposits on irregularly shaped small parts. According to the patent literature (2, 3), best results are obtained in the current density range of 2-10 mA cm^{-2}. Examination of Fig. 7 reveals that the corresponding overpotentials for gold deposition lie in the range of underpotential deposition of Tl(O) on gold. Now underpotential deposition of a metal monolayer occurs uniformly on a foreign metal substrate, rather than in islandlike clusters, since its heat of adsorption is greater than the cohesive energy of its bulk form (33, 34, 54-57). As a result, the displacement reaction will also proceed uniformly on the substrate, thereby leading to good "throwing power" and reducing the amount of gold required to plate the part. Similarly, in selective plating of integrated circuits (6-8), adsorption of the depolarizer will occur preferentially on exposed bare metal surface (*e.g.*, Pd) rather than on a metal surface covered by an oxide (*e.g.*, Ti, Al). As a result, the gold deposition rate on beam leads is enhanced and bridging due to "underplating" on a surface inadequately protected by a photoresist mask is reduced.

Electrocatalysis by heavy metal ions.—Recent studies (58, 59) have shown that a number of slow electrochemical reactions are catalyzed by monolayers of metals (Pb, Tl, Bi) deposited at underpotentials on foreign metal substrates (Pt, Au). Examples include the Fe^{2+}/Fe^{3+} and Ti^{3+}/Ti^{4+} redox couples and the oxidation of formic acid. The catalytic effects have been attributed to the formation of new electronic surface states energetically more suitable for various stages of the oxidation-reduction reactions than the bare substrate. In the present study, however, we have seen that the electrocatalytic effects induced by trace quantities of heavy metal ions in the electroreduction of $Au(CN)_2^-$ are well accounted for on other grounds. Whether such mechanisms are generally applicable remains to be seen. Since upd layers of Pb, Tl, and Bi apparently catalyze a wide variety of electrochemical reactions, it is worthwhile to examine briefly their chemical and physical properties in order to ascertain the possible origin of their electrocatalytic activity. Here we point out only their essential features. A more detailed discussion will be given elsewhere.

Owing to the increase of nuclear charge across each of the transition series, the B metals have a much weaker tendency than the A metals to form ions or to form compounds with nonmetals (60). The B metal ions have high electron affinities and tend to seek out polarizable anions or ligands. The increasing polarizing power of the cations culminates in the final row of B metals: Au, Hg, Tl, Pb, Bi, and Po where the nuclear charge has been built up across the lanthanide as well as the third transition series. This increase in nuclear charge also leads to an increase in ionization potential. Oxidation from the (N-2) valence state N to the group-valence state N is particularly difficult in this last row owing to the inert-pair effect of the $6s^2$ electrons.

Owing to its large size, (d = 2.88Å), the hydration energy of the monovalent Tl^+ ion is expected to be

weak. This is indeed the case. The hydration energy of the Tl^+ ion is only -77 kcal $mole^{-1}$, which is comparable to the value of -61 kcal $mole^{-1}$ found for the Cs^+ ion. Thus contact adsorption of Tl^+ on metal electrodes is favored and is observed experimentally. The large size and electronic polarizability of the Tl^+ ion ($\alpha = 3.9 \times 10^{-24}$ cm^3) also favors specific adsorption on the electrode surface through the action of London dispersion forces. Since the hydration energy of the Tl^+ ion is low, the activation energy required to reorganize its solvation shell prior to charge transfer should be small and hence the exchange current density of this reaction should be high.

For the multivalent cations Hg^{2+}, Pb^{2+}, and Bi^{3+}, the situation is more complex since these species have high hydration energies. Again their large size favors contact adsorption. Further, these ions tend to bond covalently to form extremely stable complexes such as $Hg(CN)_2$. The resulting negative shift in reduction potential enables these species to be effective as catalytic reducing agents.

Conclusions

Underpotential adsorption of heavy metal atoms on gold produces a marked depolarization effect which extends the current density range in which bright, fine-grained electrodeposits can be obtained. Two mechanisms are proposed to be responsible for this effect: (*i*) the enhancement of nucleation rate by strongly adsorbed foreign metal atoms and (*ii*) the occurrence of electrochemical displacement reactions, made possible by the specific adsorption of heavy metal depolarizer ions. A later communication will report the results of depolarization studies in acidic gold electroplating solutions.

Acknowledgments

It is a pleasure to acknowledge helpful discussions with K. J. Bachmann, W. R. Fawcett, G. H. Gilmer, B. Miller, S. Nakahara, D. K. Roe, and E. D. Winters during the course of this work. We also thank Caroline M. Newton for technical assistance.

Manuscript submitted Feb. 3, 1976; revised manuscript received Aug. 17, 1976. This was Paper 334 presented at the Washington, D. C., Meeting of the Society, May 2-7, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by Bell Laboratories.

Transport Coefficients of Ions and Interdiffusivities in Multicomponent Ionic Solution of CaO-SiO_2-Al_2O_3 at 1500°C

K. Nagata[1] and K. S. Goto

Department of Metallurgy, Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT

The transport coefficients L_{ik}, defined by phenomenological equations for Ca^{2+}, Al^{3+}, Si^{4+}, and O^{2-} are evaluated for liquid solutions of CaO-SiO_2-Al_2O_3 at 1500°C. For the calculation, the authors have derived general relations between the transport coefficients and the measurable transport properties, *e.g.*, tracer diffusivity, electric conductivity, etc. of the ionic melt, using an assumption of local thermodynamic equilibrium under isobaric and isothermal conditions. The diagonal terms calculated from the measurable properties in the literature were always positive values on the order of about 10^{-12} mole^2/cal cm sec and the cross terms were also of the same order but were sometimes negative. From the transport coefficients evaluated, the interdiffusivities have been calculated at 1500°C to be $\tilde{D}_{11}^{30} = 1.9 \times 10^{-5}$, $\tilde{D}_{12}^{30} = -9.9 \times 10^{-6}$, $\tilde{D}_{21}^{30} = -5.3 \times 10^{-6}$, and $\tilde{D}_{22}^{30} = 2.2 \times 10^{-5}$ (in cm^2/sec) for 40 w/o CaO-40 w/o SiO_2-20 w/o Al_2O_3 melt, where 1, 2, 3, and 0 mean Ca^{2+}, Al^{3+}, Si^{4+}, and O^{2-}, respectively. The interdiffusivities agreed fairly well with experimental results of other investigators.

In 1972, Varshneya and Cooper (1) experimentally determined the interdiffusivity matrix on ternary solid solutions of K_2O-SrO-SiO_2 at 630°-810°C. This work greatly impressed the present authors because it was the first determination of the interdiffusivities in multicomponent oxide solutions. However, it raised other questions: is it possible to evaluate the transport coefficients of elementary ions in oxide solutions or, what is the relation between the transport coefficients and the interdiffusivities in the multicomponent oxide solutions? The present communication addresses those questions.

When the oxides of CaO, Al_2O_3, and SiO_2 are mixed and heated to 1500°C, they produce a homogeneous liquid solution in a relatively wide composition range. Though there is no direct experimental proof, it is generally believed that the solution is composed of ionic species of Ca^{2+}, O^{2-}, AlO_2^-, $Al_2O_5^{4-}$, SiO_4^{4-}, $Si_2O_7^{6-}$, etc. Therefore, the diffusion fluxes of these ionic species can be expressed by the linear relations with the gradients of electrochemical potential of these ions, which has been discussed by Onsager in 1931 (2) and in 1945 (3). The proportionality constants defined by the linear relation are called "transport coefficients of ions." However, the number of ionic species is clearly too large to apply Onsager's treatment to the oxide melt. Thus, in the present communication, the diffusion fluxes of ions are expressed in terms of the elementary ions of Ca^{2+}, Al^{3+}, Si^{4+}, and O^{2-}.

Transport coefficients of ions or their reciprocal coefficients called "friction coefficients" were determined by Miller (4) in 1966 on aqueous solutions of HCl, LiCl, or NaCl at 25°C. Between 1966 and 1973, Kawamura *et al.* (5-7) determined friction coefficients of ions at 300°-400°C in various fused nitrate solutions. In 1972, Richter (8) also determined friction coefficients at 290°C in other fused nitrate solutions.

These evaluations of the phenomenological coefficients in ionic solutions were preceded by the theoretical works of Klemm (9), Laity (10, 11), and Kirkaldy *et al.* (12, 13). However, the evaluation of the coefficients and the theoretical treatment have been limited to the relatively simple solutions such as dilute solutions and quasi-binary solutions. Also, Cooper *et al.* (14, 15) have discussed some theoretical aspects of ionic solutions of multicomponents but they did not evaluate the transport coefficients on those melts. In a previous paper (16), the authors derived the relation between the transport coefficients and the measurable properties, such as electrical conductivity, tracer diffusivity, transference numbers, and interdiffusivities. However, the relations can be used only for ionic solutions containing single anionic species.

Therefore, in the present communication we attempt to derive very general relations between the phenomenological coefficients and the measurable properties of ionic solutions regardless of the number of cationic and anionic components. Further, the derived equations are used to evaluate the transport coefficients of the elementary ions in 40 w/o CaO-40 w/o SiO_2-20 w/o Al_2O_3 at 1500°C from the electrical conductivity, tracer diffusivities, and transference numbers in the literature. Once the transport coefficients are evaluated, it is also possible to estimate the interdiffusivity matrix. Thus, the penetration curves of interdiffusion have been estimated for the CaO-SiO_2-Al_2O_3 ternary system from the evaluated interdiffusivity matrix and then compared with the penetration curves measured by Oishi (17). Similar calculations were also made for CaO-45 w/o SiO_2 and CaO-$50Al_2O_3$ at 1500°C.

For isothermal and isobaric conditions, the phenomenological equations express the fluxes j in n-component ionic systems in terms of linear functions of electrochemical potential gradients, $\nabla\eta$, as forces, if independent fluxes and independent forces exist in the system. Then, the following equation is obtained

$$j_i = -\sum_{k=1}^{n} L_{ik}\nabla\eta_k \quad (i = 1,2,3,\ldots,n) \qquad [1]$$

where L_{ik}[2] is a transport coefficient which is assumed to be a function of composition, temperature, and pressure but not a function of electrochemical potential gradients. On the other hand, the fluxes are expressed by $j_i = C_i(v_i - v_o)$, where C_i is the concentration of i

[1] Present address: Centro de Ingenieria y Computacion, I.V.I.C., Caracas, Venezuela.

Key words: diffusion constant, ionic melt, blast furnace slag, electrical conductivity.

[2] The relation between L_{ik} defined in this paper and L_{ik}' in the previous paper (16) is $L_{ik} = L_{ik}'/|Z_iZ_k|$.

species, v_i is the local velocity of i species, and v_o is the local reference velocity. Thus, the transport coefficients take different values corresponding to choice of a reference frame. If the local reference velocity is given in the form of $v_o = \Sigma C_i v_i / \Sigma C_i$, which is the average particle velocity and if the units of flux and concentration are, respectively, in mole/cm² sec and mole/cm³, the total flux always becomes zero, *i.e.* $\Sigma j_i = 0$. This means that the fluxes are dependent. Additionally, the forces are dependent because there is the Gibbs-Duhem relation, *i.e.*, $\Sigma C_i \nabla \eta_i = 0$ on the assumption of local thermodynamic equilibrium. In this case, the transport coefficients are not uniquely defined and the Onsager reciprocal relations are not necessarily fulfilled. However, according to the treatment by De Groot and Mazur (18), dependent fluxes and dependent forces can be defined by a sensible set of $(n - 1)^2$ coefficients of L_{ik} (i,k = 1,2,3,..., $n - 1$). Other coefficients can be defined by $L_{in} = -\sum_k^{n-1} L_{ik}$, $L_{ni} = -\sum_k^{n-1} L_{ki}$, and $L_{nn} = \sum_{i,k}^{n-1} L_{ik}$, that is

$$\sum_{i \text{ or } k}^{n} L_{ik} = 0 \qquad [2]$$

and the Onsager reciprocal relations can also be imposed

$$L_{ik} = L_{ki} \qquad [3]$$

Additionally, according to the second law of thermodynamics, there are the following restrictions on L_{ik} (18)

$$L_{ii} \geqq 0 \text{ and } L_{ii}L_{kk} \geqq L_{ik}^2 \qquad [4]$$

because the entropy production during diffusion must be positive.

As pointed out previously (16), only if these interrelations are valid, the number of independent transport coefficients is $\frac{1}{2}n(n - 1)$, so that all of the L_{ik} can be determined by $\frac{1}{2}n(n - 1)$ independent physical properties.

General Equations to Relate L_{ik} to σ, ${}_Ht_i{}^r$, $D_i{}^{tr}$, and $\widetilde{D}_{ik}{}^{AB}$

Let us assume that an ion has a fixed and immutable charge and that local thermodynamic equilibrium and local electrical neutrality prevail in the system. The electrochemical potential of ith ionic species can be defined (19) by

$$\eta_i = \mu_i + Z_i \mathbf{F} \phi \qquad [5]$$

where μ_i is the chemical potential, ϕ is the electrical potential, Z_i is the valence of ith ionic species, and $\mathbf{F}$ is the Faraday constant (96,500 C/equiv.).

Relation between conductivity and L_{ik}.—The total electric current density can be written (18)

$$I = \sum_i^n Z_i \mathbf{F} j_i \qquad [6]$$

under the condition of local electrical neutrality. The conductivity is usually defined as the ratio of the current per unit area to the electrical potential gradient, *i.e.* $I/\nabla\phi$. The chemical potential gradients of the species are zero during the conductivity measurement because concentration gradients do not occur. Thus, the conductivity (Ω^{-1}-cm^{-1}) can be expressed by

$$\sigma = \mathbf{F}^2 S / 4.184 \qquad [7]$$

where

$$S = \sum_i^n \sum_k^n Z_i Z_k L_{ik} \qquad [8]$$

and 4.184 is the conversion factor.

Relation between Hittorf transference number and L_{ik}.—The definition of the Hittorf transference number (20), ${}_Ht_i{}^r$, of ith ionic species relative to rth species as a reference component on passing 1**F**, *i.e.*, $Z_i\mathbf{F}(j_i - j_r C_i / C_r)/I$, gives

$${}_Ht_i{}^r = Z_i \sum_k^n Z_k (L_{ik} - L_{rk} C_i / C_r)/S \qquad [9]$$

The external transference number, $t_i{}^{ex}$, which can be measured relative to the electrode or container of the cell as a reference frame, is related to the Hittorf transference number by the following equation

$${}_Ht_i{}^r = t_i{}^{ex} - t_r{}^{ex} Z_i C_i / Z_r C_r \qquad [10]$$

Relation between tracer diffusivity and L_{ik}.—Let us consider the interdiffusion of an ionic species i and its tracer i* in a multicomponent ionic solution with uniform concentration of other species. In this case the electrical potential gradient $\nabla\phi$ is zero and the chemical potentials of the species, except i and i*, are constant. If it is assumed that isotope effects are negligible, the cross terms L_{ii^*} and L_{i^*i} would be assumed to be zero. This assumption has not yet been experimentally proved but Laity (21) has also used this. From Eq. [1] and the above conditions, $j_i = -L_{ii}\nabla\mu_i$ and $j_{i^*} = -L_{i^*i^*}\nabla\mu_{i^*}$. Noting that any reference velocity is zero and $j_i + j_{i^*} = 0$, one obtains the relation $L_{ii}\nabla\mu_i + L_{i^*i^*}\nabla\mu_{i^*} = 0$. Comparing the equation with the Gibbs-Duhem relation, *i.e.*, $C_i\nabla\mu_i + C_{i^*}\nabla\mu_{i^*} = 0$, one obtains $L_{i^*i^*} = L_{ii}C_{i^*}/C_i$. Then the flux of i* species is written as $j_{i^*} = -(RT/C_i)L_{ii}\nabla C_{i^*}$. On the other hand, the flux of the isotope i* is usually expressed by using tracer diffusivity $D_i{}^{tr}$, *i.e.*, $j_{i^*} = -D_i{}^{tr}\nabla C_{i^*}$. From the comparison of the above two expressions of the flux, the relation between the tracer diffusivity and the diagonal term of transport coefficient can be obtained as

$$D_i{}^{tr} = L_{ii} RT / C_i \qquad [11]$$

The same equation is given by Laity (21) with different derivation.

Relation between interdiffusion coefficient matrix and L_{ik}.—Let us consider the one-directional diffusion, when two long rods with the different compositions are joined at a plane interface. When the two homogeneous ionic phases contact each other, the diffusion potential due to the composition difference can be observed. This diffusion potential can be related to the chemical potentials and the transport coefficients as follows (20). There is no net electric current passing through the system during the interdiffusion experiment, namely, $I = 0$. From Eq. [1], [5], and [6], the diffusion potential gradient can be expressed by

$$\nabla\phi = -(1/\mathbf{F}S) \sum_i^n \sum_k^n Z_i L_{ik} \nabla\mu_k \qquad [12]$$

Eliminating $\nabla\phi$ from Eq. [1], the fluxes are represented only in terms of the chemical potential gradients, *i.e.*

$$j_i = -\sum_k^n T_{ik} \nabla\mu_k \qquad [13]$$

where

$$T_{ik} = L_{ik} - (1/S) \sum_{k'}^n Z_{k'} L_{ik'} \sum_{i'}^n Z_{i'} L_{i'k} \qquad [14]$$

The properties of T_{ik} are

$$T_{ik} = T_{ki} \qquad [15]$$

$$\sum_k^n Z_k T_{ik} = 0 \qquad [16]$$

The former can be derived from the reciprocal relation, $L_{ik} = L_{ki}$ and the latter from Eq. [14].

Let us assume the relations between the chemical potentials of ions and salts according to Wagner (20) in order to express the flux in terms of the chemical potentials of electrically neutral components, because the chemical potentials of ions in the strictly thermodynamic sense are not measurable by any experiment

$$\mu_\alpha/Z_\alpha + \mu_\beta/|Z_\beta| = \mu_{\alpha\beta}/Z_\alpha = \mu_{\alpha B}/Z_\alpha + \mu_{A\beta}/Z_A - \mu_{AB}/Z_A \quad [17a]$$

$$\mu_\alpha/Z_\alpha + \mu_e = \mu_{[\alpha]}/Z_\alpha \quad [17b]$$

$$\mu_\beta/|Z_B| + \mu_p = \mu_{[\beta]}/|Z_\beta| \quad [17c]$$

where $\alpha\beta$,[3] $[\alpha]$, and $[\beta]$ are electrically neutral combinations consisting of a cationic component α, an anionic component β, electron e, and positive hole p. A and B are a master cation and a master anion, respectively, which are selected expediently. Equation [13] can be then rewritten as

$$j_i = -\sum_\alpha T_{i\alpha}\nabla\mu_{\alpha B} + \sum_\alpha (Z_\alpha/Z_A)T_{i\alpha}\nabla\mu_{AB} - \sum_\beta (|Z_\beta|/Z_A)T_{i\beta}\nabla\mu_{A\beta} \quad [18]$$

The flux relative to external coordinates is expressed as

$$J_i = j_i + C_i v_o \quad [19]$$

The continuity equation is written as $\partial C_i/\partial t + \nabla J_i = 0$. Because the total moles of neutral components per unit volume is equal to the sum of the concentrations of cations, $C = \sum_\alpha C_\alpha$, under the electroneutrality condition, the continuity equation is expressed as $\partial C/\partial t = -\nabla\left(\sum_\alpha j_\alpha + v_o C\right)$. Assuming the constant molar volume, *i.e.*, $\partial C/\partial t = 0$ [which has been assumed only to simplify the treatment by Darken (22) for the diffusion problem in a binary metallic system] and integrating under the condition that the reference velocity and the fluxes of components at a distance far from the initial interface of the diffusion couple are zero, one obtains

$$\sum_\alpha j_\alpha + v_o C = 0 \quad [20]$$

Eliminating v_o from Eq. [19], one obtains

$$J_i = j_i - (C_i/C)\sum_\alpha j_\alpha \quad [21]$$

From Eq. [18] and [21], the flux J_i is related to the chemical potential gradients of electrically neutral components which are experimentally measurable.

On the other hand, the flux J_i relative to external coordinates during interdiffusion experiments is expressed as a linear function of the concentration gradients of components. The number of independent concentration gradients is $n - 2$ because of the electroneutrality condition and the Gibbs-Duhem relation,[4] while the number of independent fluxes J_i is also $n - 2$ because of the relations of $\Sigma J_i = 0$ derived from Eq. [20] and $I = \Sigma Z_i J_i = 0$.[5] Thus, one obtains

$$J_i = -\sum_{k\neq A,B} \tilde{D}_{ik}^{AB}\nabla C_k \quad (i \neq A, B) \quad [22]$$

where $\tilde{D}_{ik}^{AB}$ is the interdiffusion coefficient matrix which is experimentally determined by the Boltzmann-Matano method (23, 24).

Rewriting Eq. [22] in terms of the concentration gradients of the electrically neutral components under the condition of electrical neutrality, *i.e.*, $C_\alpha = \sum_\beta C_{\alpha\beta}$ and $C_\beta = \sum_\alpha |Z_\alpha/Z_\beta|C_{\alpha\beta}$, and comparing with Eq. [21], the relation between the interdiffusion coefficient matrix and the transport coefficients can be obtained.

Let us consider the binary oxide system composed of oxides of 1O and 2O, where 1 and 2 are cations and O is oxygen anion. The flux J_1 of cationic component 1 is expressed as follows by Eq. [18] and [21]

$$J_1 = -(RT/C)(T_{11}C_{2O}/C_{1O} - 2T_{12} + T_{22}C_{1O}/C_{2O})(1 + \partial\ln\gamma_{1O}/\partial\ln N_{1O})\nabla C_{1O}$$

where the chemical potential gradient of oxide 2O is eliminated by the Gibbs-Duhem relation and the relation of $\nabla\mu_{1O} = (RT/C_{1O})(1 + \partial\ln\gamma_{1O}/\partial\ln N_{1O})\nabla C_{1O}$ is used. γ_{1O} and N_{1O} are the activity coefficient and mole fraction of oxide 1O, respectively. The volumetric factor $1 - \partial\ln V_m/\partial\ln N_{1O}$ is unity because of the assumption of constant molar volume. On the other hand, the flux of cation 1 is written from Eq. [22] as follows

$$J_1 = -\tilde{D}_{11}^{2O}\nabla C_{1O} \quad [22a]$$

where C_1 is equal to C_{1O} because of electroneutrality. Comparing the above two equations, the following equation is obtained

$$\tilde{D}_{11}^{2O} = (RT/C)(T_{11}C_{2O}/C_{1O} - 2T_{12} + T_{22}C_{1O}/C_{2O})(1 + \partial\ln\gamma_{1O}/\partial\ln N_{1O}) \quad [23]$$

In the case of a ternary oxide system composed of 1O, 2O, and 3O, where 1, 2, and 3 are cations, the fluxes of cation 1 and cation 2 are expressed by

$$J_1 = -\tilde{D}_{11}^{3O}\nabla C_{1O} - \tilde{D}_{12}^{3O}\nabla C_{2O}$$
$$J_2 = -\tilde{D}_{21}^{3O}\nabla C_{1O} - \tilde{D}_{22}^{3O}\nabla C_{2O} \quad [22b]$$

From Eq. [18] and [21], the fluxes of cation 1 and cation 2 are expressed in terms of the chemical potential gradients of oxides. If the cross terms of G matrix (18) are assumed to be zero, the following equations are obtained

$$\tilde{D}_{11}^{3O} = \frac{RT}{C}\left[\frac{C_2 + C_3}{C_1}T_{11} - T_{21} - T_{31} - \frac{C_1}{C_3}\left(\frac{C_2 + C_3}{C_1}T_{13} - T_{23} - T_{33}\right)\right]\left(1 + \frac{\partial\ln\gamma_{1O}}{\partial\ln N_{1O}}\right)_{\frac{C_{2O}}{C_{3O}}}$$

$$\tilde{D}_{12}^{3O} = \frac{RT}{C}\left[\frac{C_1}{C_2}\left(\frac{C_2 + C_3}{C_1}T_{12} - T_{22} - T_{32}\right) - \frac{C_1}{C_3}\left(\frac{C_2 + C_3}{C_1}T_{13} - T_{23} - T_{33}\right)\right]\left(1 + \frac{\partial\ln\gamma_{2O}}{\partial\ln N_{2O}}\right)_{\frac{C_{1O}}{C_{3O}}}$$

[3] Salt, $\alpha\beta$, is written as the stoichiometric number per unit cation, *e.g.*, $AlO_{1.5}$ for alumina. Then the chemical potential per equivalent of the component MX_ν can be expressed by μ_{MX_ν}/Z_M or $\mu_{MX_\nu}/|\nu Z_X|$.

[4] The number of independent electrochemical potential gradients is $n - 1$ from the condition of the Gibbs-Duhem relation on electrochemical potential, while the number of independent concentrations of ions is $n - 2$ from the conditions of electroneutrality and the Gibbs-Duhem relation on chemical potential of ion. The latter conditions are included in the former one.

[5] This condition is true only in the case of the interdiffusion experiment.

$$\tilde{D}_{21}^{30} = \frac{RT}{C}\left[\frac{C_2}{C_1}\left(\frac{C_1+C_3}{C_2}T_{21}-T_{11}-T_{31}\right) - \frac{C_2}{C_3}\left(\frac{C_1+C_3}{C_2}T_{23}-T_{13}-T_{33}\right)\right]\left(1+\frac{\partial \ln \gamma_{10}}{\partial \ln N_{10}}\right)_{\frac{C_{20}}{C_{30}}}$$

$$\tilde{D}_{22}^{30} = \frac{RT}{C}\left[\frac{C_1+C_3}{C_2}T_{22}-T_{12}-T_{32} - \frac{C_2}{C_3}\left(\frac{C_1+C_3}{C_2}T_{23}-T_{13}-T_{33}\right)\right]\left(1+\frac{\partial \ln \gamma_{20}}{\partial \ln N_{20}}\right)_{\frac{C_{10}}{C_{30}}} \quad [24]$$

The following restrictions are needed for a real solution of Ficks second law (25)

$$\tilde{D}_{11}^{30} + \tilde{D}_{22}^{30} \geqq 0$$

$$\tilde{D}_{11}^{30}\tilde{D}_{22}^{30} - \tilde{D}_{12}^{30}\tilde{D}_{21}^{30} \geqq 0$$

$$(\tilde{D}_{11}^{30} - \tilde{D}_{22}^{30})^2 + 4\tilde{D}_{12}^{30}\tilde{D}_{21}^{30} \geqq 0 \quad [25]$$

Evaluation of Transport Coefficients of Liquid CaO-SiO_2-Al_2O_3 Slag at 1500°C

The transport coefficients of $40CaO$-$40SiO_2$-$20Al_2O_3$ (in w/o) liquid oxide at 1500°C are evaluated here because its physical properties are well known from the viewpoint of its industrial importance as blast furnace slag for iron production. This slag system has sixteen coefficients but only six of them are independent, if Eq. [2] and [3] are valid. The physical properties measured in this melt are listed in Table I. The tracer diffusivities of calcium, aluminum, and silicon and the conductivity and the transference numbers of calcium ion and aluminum ion are judged more reliable than other properties.

The tracer diffusivity of calcium in this melt at 1500°C was measured at 2.1×10^{-6} cm²/sec by Towers and Chipman in 1957 (26). This value is in good agreement with the other values extrapolated to 1500°C from the measured values at lower temperature by other investigators (27-29). The tracer diffusivity of aluminum was measured at 1440°-1480°C by Henderson, Yang, and Derge in 1961 (30). The value at 1500°C is estimated to be 6.3×10^{-7} cm²/sec by extrapolating the measured values. The tracer diffusivity of silicon was measured at 1365°-1460°C by Towers and Chipman in 1957 (27). The value at 1500°C is estimated to be 2.3×10^{-7} cm²/sec.

The conductivity in this melt was first measured at 1450°-1600°C by a Wheatstone bridge method by Martin and Derge in 1943 (31). The value at 1500°C is 0.144 Ω^{-1} cm^{-1}. Kammel and Winterhager (32) measured the conductivity at 1320°-1580°C by a Thomson bridge method in 1965. The value at 1500°C is 0.127 Ω^{-1} cm^{-1}. The latter value is considered to be more reliable and used for the following calculations because Kammel and Winterhager used inert platinum electrodes instead of graphite.

The transference numbers of calcium ion in the several melts with different compositions were measured by an isotope method at 1550°C by Esin and Kirianov (34) in 1955 and at 1530°C by Markin, Schwartzman, and Khokhlov (35) in 1958. From their reports the transference number of calcium ion in the $40CaO$-$40SiO_2$-$20Al_2O_3$ melt is nearly unity at 1500°C though the latter report showed that it decreased with experimental time. For the following calculations a value of 0.95 is used. The transference number of aluminum ion has not been directly measured but has been estimated by Adachi and Ogino (36). They considered that aluminum ion contributes to the electrical conduction for compositions of large alumina content. Thus, the present authors estimated it to be 0.04 in the present composition. A value of 0.01 is used for silicon ion.

The transport coefficients in CaO-SiO_2-Al_2O_3 system can be calculated by the following equations which are derived from Eq. [2], [3], [7], [9], and [11]

$$L_{11} = D_1^{tr}C_1/RT$$

$$L_{22} = D_2^{tr}C_2/RT$$

$$L_{33} = D_3^{tr}C_3/RT$$

$$L_{12} = [-(6 + 10C_1/C_0 + 11C_2/C_0)A + 12(4 - C_2/C_0)B + 12(5 + C_1/C_0)C]/40(6 + 2C_1/C_0 + C_2/C_0)$$

$$L_{13} = [(6 + 2C_1/C_0 + 11C_2/C_0)A + 20(C_2/C_0)B - 20(3 + C_1/C_0)C]/48(6 + 2C_1/C_0 + C_2/C_0)$$

$$L_{23} = [(6 + 10C_1/C_0 + C_2/C_0)A - 8(6 + C_2/C_0)B + 8(C_1/C_0)C]/60(6 + 2C_1/C_0 + C_2/C_0)$$

$$L_{10} = -L_{11} - L_{12} - L_{13}$$

$$L_{20} = -L_{12} - L_{22} - L_{23}$$

$$L_{30} = -L_{13} - L_{23} - L_{33}$$

$$L_{00} = L_{11} + L_{22} + L_{33} + 2(L_{12} + L_{13} + L_{23}) \quad [26]$$

where 1, 2, 3, and 0 mean, respectively, calcium, aluminum, silicon and oxygen. Their valences, Z_1, Z_2, Z_3, and Z_0, are, respectively, +2, +3, +4, and −2. A, B, and C in the above equations are

$$A = 4.184\sigma/\mathbf{F}^2 - 16D_1^{tr}C_1/RT - 25D_2^{tr}C_2/RT - 36D_3^{tr}C_3/RT$$

$$B = 2.092\,{}_{H}t_1^0\sigma/\mathbf{F}^2 - 4(1 + C_1/C_0)D_1^{tr}C_1/RT - 5(C_1/C_0)D_2^{tr}C_2/RT - 6(C_1/C_0)D_3^{tr}C_3/RT$$

$$C = 1.395\,{}_{H}t_2^0\sigma/\mathbf{F}^2 - 4(C_2/C_0)D_1^{tr}C_1/RT - 5(1 + C_2/C_0)D_2^{tr}C_2/RT - 6(C_2/C_0)D_3^{tr}C_3/RT$$

The density used for calculation of the concentrations of ions[6] is 2.581 g/cm^3 in 40CaO-40SiO_2-20Al_2O_3 melt at 1500°C. This was measured by Kammel and Winterhager (32).

The results of the calculation are shown in Table II. The values of L_{ik} in the first column were calculated from the physical properties in the above-mentioned literature and satisfy the thermodynamic restrictions of Eq. [4]. In the second to sixth columns, the magnitudes of the errors of the evaluated L_{ik} arising from the original physical properties are shown. From the results it is shown that the cross terms of L_{ik} can take negative values and the magnitude of L_{ik} is on the order of 10^{-12}. The signs of L_{ik} are constant within the errors of the physical properties.

From the evaluated values of L_{ik}, the interdiffusion coefficient matrix defined by Eq. [22b] can be calculated by Eq. [24].[7] The results are shown in the lower part of Table II. The thermodynamic factors in Eq. [24] are given as $(1 + \partial \ln \gamma_{1O}/\partial \ln N_{1O})_{C_{2O}/C_{3O}} = 45.1$ and $(1 + \partial \ln \gamma_{2O}/\partial \ln N_{2O})_{C_{1O}/C_{3O}} = 29.9$ from the data of activities of lime and alumina in CaO-SiO_2-Al_2O_3 melt which were measured by Fulton *et al.* (38).

The interdiffusion coefficient matrix has not yet been reported in the literature. However, Oishi (17) in 1972 reported the penetration curves of lime, silica, and alumina during the interdiffusion between two slags with the compositions 45CaO-35SiO_2-20Al_2O_3 and 35CaO-45SiO_2-20Al_2O_3 (in w/o) at 1500°C for 40 min. The analytical solution of Fick's second law of ternary diffusion with constant diffusion coefficients was given

[6] The concentrations of ions are calculated from the following equations: $C_i = W_{iO}\rho/100M_{iO}$ (i = 1, 2, and 3) and $C_0 = |Z_1/Z_0|C_1 + |Z_2/Z_0|C_2 + Z_3/Z_0\,C_3$ where W_{iO} and M_{iO} are respectively the weight percent and the molecular weight of oxide i*O*.

[7] The following functions, which are derived from Eq. [8], [9], and [14], make it easy to calculate T_{ik}

$$T_{ik} = L_{ik} - a_i a_k S \qquad (i, k = 1, 2, \text{and } 3)$$

where

$$a_1 = [(6 + C_2/C_0)\,{}_{H}t_1^0/2 - (C_1/C_0)\,{}_{H}t_2^0/3 - C_1/C_0]/(6 + 2C_1/C_0 + C_2/C_0)$$

$$a_2 = [-(C_2/C_0)\,{}_{H}t_1^0 + 2(3 + C_1/C_0)\,{}_{H}t_2^0/3 - C_2/C_0]/(6 + 2C_1/C_0 + C_2/C_0)$$

$$a_3 = [-(4 - C_2/C_0)\,{}_{H}t_1^0/2 - (5 - C_1/C_0)\,{}_{H}t_2^0/3 + (1 + C_1/C_0 + C_2/C_0)]/(6 + 2C_1/C_0 + C_2/C_0)$$

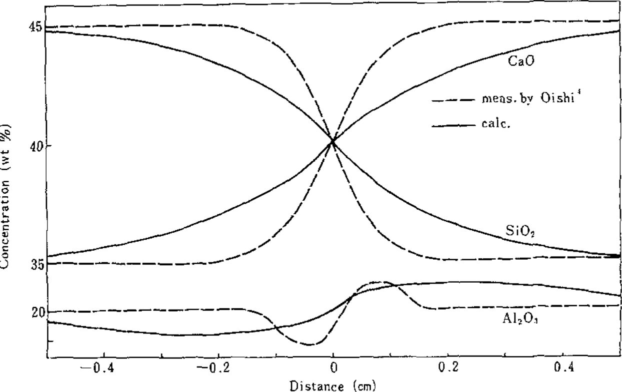

Fig. 1. Penetration curve of CaO, SiO_2, and Al_2O_3 calculated in 40CaO-40SiO_2-20Al_2O_3 slag at 1500°C for 40 min interdiffusion.

by Fujita and Gosting (25) in 1956. Thus, using the evaluated $\tilde{D}_{ik}^{30}$, the penetration curves for the same conditions as those by Oishi have been estimated and are shown in Fig. 1. The agreement between the estimated lines and the measured lines is not very good, but at present it is very difficult to judge which is close to the true one because of experimental errors involved in the original experiments. However, the estimated penetration curve of alumina shows up-hill diffusion and this tendency agrees with that observed in Oishi's experiment.

Similar calculations were made for CaO-SiO_2 and CaO-Al_2O_3 melts, and all transport coefficients were obtained. The interdiffusivities were estimated to be 6.16×10^{-7} cm^2/sec at 1500°C in CaO-50 w/o Al_2O_3 melt and 2.45×10^{-6} cm^2/sec at 1500°C in CaO-45SiO_2 melt. These are in relatively good agreement with other determinations (39).

Estimation of Uncertainties Involved in the Evaluation of L_{ik}

The uncertainty of the transport coefficient can be estimated by the following equations which are derived from Eq. [26]

$$\Delta L_{ii} = a_{ii}^1 \Delta D_i^{tr} + a_{ii}^2 \Delta\rho \qquad (i = 1, 2, \text{and } 3)$$

$$\Delta L_{ik} = a_{ik}^1 \Delta L_{11} + a_{ik}^2 \Delta L_{22} + a_{ik}^3 \Delta L_{33} + a_{ik}^4 \Delta\sigma + a_{ik}^5 \Delta_H t_1^0 + a_{ik}^6 \Delta_H t_2^0 \qquad (i \neq k)$$

where ΔD_i^{tr}, $\Delta\rho$, $\Delta\sigma$, $\Delta_H t_1^0$, and $\Delta_H t_2^0$ are the uncertainties involved in the physical properties and ρ is density.

$\tilde{D}_{21}^{30}$	-5.3×10^{-6}	-1.3×10^{-5}	-5.7×10^{-6}	-2.6×10^{-6}	-7.8×10^{-6}	1.5×10^{-6}	
$\tilde{D}_{22}^{30}$	2.2×10^{-5}	2.1×10^{-5}	2.7×10^{-5}	2.3×10^{-5}	2.2×10^{-6}	2.3×10^{-5}	

* All L_{ik} values satisfy the condition that entropy production is positive.

For the uncertainty of the interdiffusion coefficient matrix, the following equations are obtained from Eq. [24]

$$\Delta\tilde{D}_{ik}^{30} = b_{ik}^1\Delta L_{11} + b_{ik}^2\Delta L_{22} + b_{ik}^3\Delta L_{33} + b_{ik}^4\Delta\sigma + b_{ik}^5\Delta_{H}t_1^0 + b_{ik}^6\Delta_{H}t_2^0$$

The factors a_{ik}^j and b_{ik}^j for the $40CaO\text{-}40SiO_2\text{-}20Al_2O_3$ system are shown in Table III. In the second to sixth columns in Table II, the values of L_{ik} are obtained when the physical properties change by 5-20%. For example, the uncertainty of the conductivity of 5% produces uncertainties in L_{12}, L_{13}, L_{23}, L_{10}, L_{20}, L_{30}, and L_{00} of, respectively, 7, 4, 18, 3, 5, 2, and 4%, and it also produces uncertainties in $\tilde{D}_{11}^{30}$, $\tilde{D}_{12}^{30}$, $\tilde{D}_{21}^{30}$, and $\tilde{D}_{22}^{30}$ of, respectively, 23, 6, 47, and 2%.

Further, the results on $\tilde{D}_{ik}$ include the errors due to neglect of the cross terms of the G matrix. Thus the disagreement in Fig. 1 may be due to these uncertainties.

Conclusions

The present authors have derived the general equations which relate the transport coefficients defined by the phenomenological equation to the measurable physical properties, *e.g.*, electric conductivity, tracer diffusivities, transference numbers, and interdiffusion coefficient matrix on multicomponent ionic solutions. In this communication, the flux of an ionic species has been expressed as a linear function of electrochemical potential gradients of elementary ions but not as a function of realistic ionic species which has been proposed by other investigators (40). One of the reasons is that it is difficult to measure the electrochemical potentials of the complex ions. Another is that if an assumption of "local thermodynamic equilibrium" is true, the simplest but strict way to express the phenomenological equation is as a function of the electrochemical potential gradients of only elementary ions. The assumption of "local thermodynamic equilibrium" seems a very realistic assumption at high temperature.

The approximation of the constant molar volume of the melt was used, but the volumetric factor, $(1 - \partial \ln V_m/\partial \ln N_{iO})$, should be included in the relation between the interdiffusion coefficient matrix and the transport coefficients. However, this factor is usually very close to unity.

From the equations in this communication, one can derive many other useful relations, such as the Nernst-Einstein relation including the cross terms, and relations between the measurable properties and the tracer diffusivities which have no stable isotopes.

Finally, it can be stressed that this treatment of the flux in a multicomponent system can apply not only to ionic solutions but also to alloys when the electron is regarded as an ion.

On the Differential Thermal Analysis of the Platinum-Oxygen System

James P. Hoare,* Robert F. Paluch, and Stuart G. Meibuhr*

General Motors Corporation Electrochemistry Department, Research Laboratories, Warren, Michigan 48090

ABSTRACT

Differential thermal analyses (DTA) curves were obtained on preanodized and HNO_3-passivated platinum (Pt) samples. In both cases two kinds of adsorption states for oxygen on Pt were detected as well as oxygen dissolved in the interior of the Pt metal. The DTA results agree well with the cathodic stripping pulse data obtained earlier.

From x-ray diffraction analysis and vacuum fusion studies on samples of bright Pt passivated in air-saturated concentrated HNO_3, it was concluded (1) that the Pt metal contained enough dissolved oxygen to be considered a Pt-O alloy. It was also found that oxygen could be made to diffuse through a thin Pt foil (2) under conditions of strong anodic polarization (6 mA/cm^2 at 2V) of the back side of the Pt diaphragm in solutions of H_2SO_4 and that this anodization process can cause relatively large quantities of oxygen to be dissolved in the Pt lattice (3, 4). In these studies three kinds of sorbed oxygen were distinguished: surface adsorbed oxygen, dermasorbed oxygen dissolved in the first two or three metallic layers, and absorbed oxygen dissolved in the bulk of the metal. The properties of Pt-O alloys made by passivation in HNO_3 were somewhat different from those made by anodization (3, 5, 6). The HNO_3-passivated Pt is much more stable than the Pt-O alloy obtained from anodization (6).

Babenkova *et al.* (7) investigated the forms of hydrogen sorbed by palladium by measuring the desorption of hydrogen during a linearly programmed temperature rise experiment. They were able to find two forms of adsorbed hydrogen on the surface as well as the hydrogen dissolved in the bulk Pd.

It seemed likely that a differential thermal analysis (DTA) of the platinum-oxygen system might enable one to observe the various forms of oxygen sorbed by Pt as well as to shed light on possible differences in the structure of Pt-O alloy formed by HNO_3 passivation or by anodization.

This report describes some DTA experiments made on Pt-O alloys.

Experimental

All DTA curves were obtained with a furnace platform assembly with which analyses may be made on the sample in any controlled atmosphere at pressures ranging from 1.3×10^{-6} to 2 atm. The reference sample was Al_2O_3 which is thermally inert in the temperature range of the scan, 0-1000°C.

The Pt-O alloy samples were made from small beads (0.11 cm in diameter) melted at the end of a Pt(99.99% pure) wire. These beads were cleaned by repeatedly heating to white heat in a H_2 jet followed by quenching in concentrated HNO_3. Afterward, three beads were mounted in a Teflon cell filled with concentrated HNO_3 (70%) to soak for periods of time greater than 72 hr (6). Another set of three Pt beads were mounted in a Teflon cell filled with 2*N* H_2SO_4 solution and were anodized at 6 mA/cm^2 (2.00 $\pm$ 0.05V) against a Pt gauze counterelectrode for periods of time greater than 24 hr. All Pt-O alloy samples were made at room temperature (24° $\pm$ 1°C).

After formation of the Pt-O alloy, a bead was cut off of the wire and weighed ~37 mg) in a small Pt dish of known weight. In another small Pt dish, an amount of Al_2O_3 powder was placed such that the weight (Pt dish + Pt bead) = weight (Pt dish + Al_2O_3). These dishes were mounted on the thermocouple elements of the furnace platform. After the entire DTA chamber was sealed from the atmosphere the chamber was evacuated and backfilled with N_2 three times before the first DTA run was made. Repeated runs were made in a N_2 atmosphere (inert) before the runs were made in a argon atmosphere containing 6% H_2 (reducing).[1] All DTA curves were obtained only during the increasing temperature sweep which was maintained at a constant rate of 10°C/min.

Key words: adsorbed oxygen on Pt, dermasorbed oxygen, absorbed oxygen in Pt, Pt-O alloys, adsorption sites on Pt.

Results

The DTA curves obtained on a bead which had been preanodized at 6 mA/cm^2 for 24 hr are shown in Fig. 1 and which had been preanodized for 5 days in Fig. 2. The upper traces in each figure were carried out in a N_2 atmosphere whereas the bottom trace was run in the 6% H_2 atmosphere. In Fig. 3, a family of DTA curves are plotted which were obtained on HNO_3 passivated beads, first in a N_2 atmosphere (Fig. 3, curve A) and then in a 6% H_2 atmosphere (Fig. 3, curves B-E). On a Pt bead which had been heated at 900°C in 6% H_2 for 6 hr, the DTA curve of Fig. 3, curve F is obtained.

Discussion

A typical DTA curve obtained on a preanodized Pt bead in a N_2 atmosphere exhibits two broad peaks at about 100°C and at about 400°C as seen in Fig. 1, curve A. When a sample of Pt is anodized, the surface becomes covered with a layer of adsorbed oxygen (Pt-O)

[1] One of the reviewers requested that the DTA on pure gas-free Pt be made, but such a sample so far is not possible to obtain. To clean a Pt surface, it must be either heated in O_2 or anodized which produces oxides on the surface and oxygen dissolved in the Pt metal (2, 3). To remove the sorbed oxygen requires either heating in H_2 or cathodization which charges the Pt with dissolved hydrogen (25-27). The technique for exact H_2 or O_2 titration has eluded us so far.

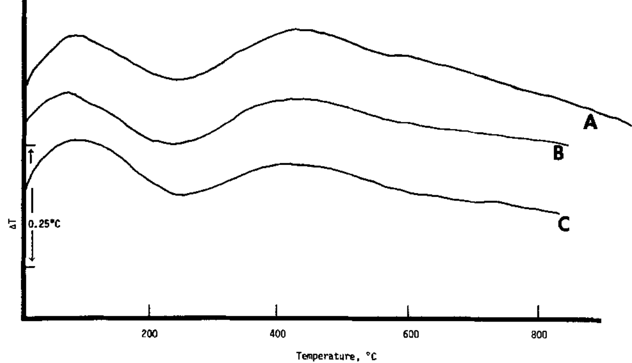

Fig. 1. DTA curves for a Pt bead anodized at 6 mA/cm^2 for 24 hr: curve A, 1st run in N_2; curve B, 2nd run in N_2; curve C, 1st run in 6% H_2.

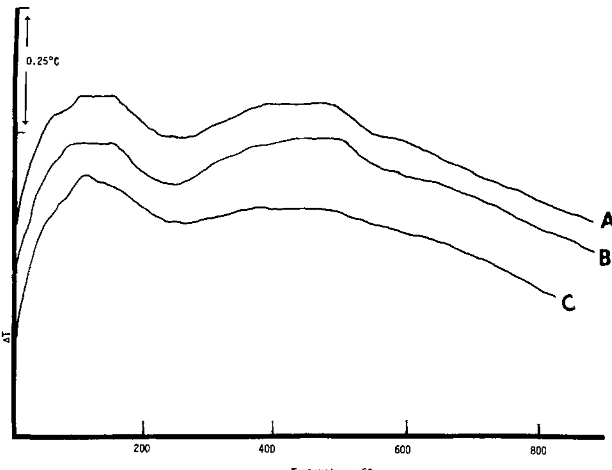

Fig. 2. DTA curves for a Pt bead anodized at 6 mA/cm^2 for 5 days: curve A, 1st run in N_2; curve B, 2nd run in N_2; curve C, 1st run in 6% H_2.

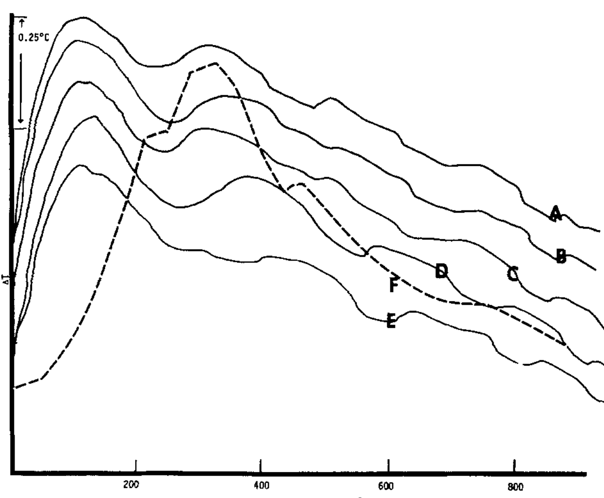

Fig. 3. DTA curves for a HNO_3 treated Pt bead: curve A, a run in N_2; curve B, 1st run in 6% H_2; curve C, 5th run in 6% H_2; curve D, 7th run in 6% H_2; curve E, 11th run in 6% H_2; curve F, after holding the bead at 900°C for 6 hr in 6% H_2.

before O_2 is evolved (3, 8, 9). Above 1.6V the Pt-O sites are converted to PtO_2 sites (3, 10-13). According to the literature (14-16), there are at least two kinds of surface Pt sites for the adsorption of hydrogen on Pt. Evidence for the existence of more than one kind of surface Pt site for the adsorption of oxygen has been presented recently (17-21). We associate the two peaks in Fig. 2, curve A with the decomposition of a thin layer of PtO_2 adsorbed on the two kinds of surface Pt sites (to be designated type I and type II). The decomposition at the more tightly binding sites (type II) produces the second peak at about 400°C whereas that at the weaker binding sites (type I) produces the first peak at about 100°C.

Because of the heterogeneous nature of the adsorption sites on a Pt surface, there is a distribution of binding energies between the surface Pt atoms and the adsorbed O atoms. Such a condition produces a broadening of the DTA peaks for the decomposition of the PtO_2 layers.

When a second temperature scan was made in the N_2 atmosphere, curve B, Fig. 2, was obtained showing two peaks in the same temperature range as those in Fig. 2, curve A. It has been shown (3, 22) that oxygen dissolved in the bulk metal by the anodization process can diffuse to the metal surface to replace the surface adsorbed oxygen which had been stripped away. Consequently, when the PtO_2 was removed from the Pt surface by the temperature scan in Fig. 2, curve A, dissolved oxygen diffusing to the surface replaced the PtO_2 layer by a Pt-O layer which in turn produced the two peaks in Fig. 2, curve B during the second temperature scan. From an x-ray photoemission spectroscopic (XPS) analysis of the interaction of O_2 with Pt in the gas phase, Norton (17) also found that the temperatures at which oxygen was desorbed from the two adsorption states on Pt were separated by 300°C.

It is interesting that the binding energies in the PtO_2 layer (Fig. 2, curve A) occur in the same temperature region as those for the Pt-O layer (curve B). Such an observation is not expected. From electrochemical measurements on Pt anodes in acid solution, it was found (3, 23) that thin layers of PtO_2 in the presence of Pt are unstable below potentials of 1.5V and decompose to Pt-O species. Consequently, when the anodized sample was removed from the cell, washed, dried, and placed in the DTA chamber, the PtO_2 layer had decomposed to a Pt-O layer. Under these conditions, one would expect the DTA curves to be the same in Fig. 2, curves A and B. This necessary transfer of the electrochemically treated sample from the cell to the chamber of the surface analyzing apparatus raises a continuing serious problem for electrochemists. For example, it is doubtful that Dickinson and co-workers (24) were able to observe from an XPS study of anodized Pt a conversion of Pt-O layers to PtO_2 layers. More likely they observed the beginning of oxygen dermasorption (3) in the potential range 1-1.4V.

It appears from Fig. 2, curve A that the DTA curve does not return to the base line (intercept on the ΔT ordinate) between the peaks and that a long tail exists at the high temperature end of the curve. It is suggested here that exothermic heat energy responsible for this behavior is due to the desorption of oxygen which is dissolved in the bulk Pt metal by the preanodization procedure (2, 3). This desorption takes place throughout the range of the temperature sweep providing a background ΔT on which the peaks for the desorption of adsorbed oxygen ride.

When the DTA curve was obtained in the argon atmosphere containing 6% H_2, the second peak was greatly diminished as noted in Fig. 1, curve C and Fig. 2, curve C. In the preparation for the run, the bead was in the presence of H_2 for 10-15 min before the DTA curve was taken. Under these conditions, most of the adsorbed oxygen was reduced by the H_2. However, as the surface oxygen is removed by the H_2, it is replaced by the dissolved oxygen diffusing from the bulk metal to the surface as adsorbed oxygen atoms (Pt-O).

When the adsorbed oxygen is removed by reacting with H_2 gas, water is formed; but, this water is formed in the presence of an adsorbed oxygen layer which is continually being renewed by oxygen diffusing from the bulk metal. Such water molecules are not strongly bound to the metal surface and are easily desorbed. From LEED and Auger (AES) studies of the removal of adsorbed oxygen from Pt by reaction with H_2, the water was found (17, 26) to desorb at temperatures as low or lower than room temperature. It also appears (26) that there are two adsorption states for water on Pt. Any contributions to the DTA curve made by the desorption of H_2O would be swamped out by the large contributions made by the desorption of adsorbed oxygen.

The shape of the DTA curve obtained in N_2 on a HNO_3-passivated Pt bead (Fig. 3, curve A) is different from the one obtained on a preanodized Pt bead (Fig. 2, curve A). Although the peaks for adsorbed oxygen are present (peaks at 150° and at 350°C), additional diffuse peaks appear on the high temperature tail of the curve at 500°, 750°, and at 900°C. Also, the background ΔT is greater in the HNO_3 passivated case indicating the presence of a much larger amount of dissolved oxygen in the bulk metal. We favor the notion that the adsorbed oxygen responsible for the two

peaks in Fig. 3, curve A exists as adsorbed atoms (Pt-O) and not PtO_2 species since the HNO_3 passivated Pt-O alloy had never been anodized and the quantity of charge associated with the cathodic stripping of this oxygen (6) is equivalent to a monolayer of atomic oxygen.

When the DTA curve was obtained in 6% H_2, Fig. 3, curve B, the second peak at 350°C is significantly reduced, but the first peak as well as the large ΔT background remain prominent. Even after 11 runs in 6% H_2, Fig. 3, curve E, the two adsorbed oxygen peaks and the large ΔT background with the diffuse peaks remain.

Guided by our earlier observations (3, 6) from constant current stripping studies obtained on Pt-O alloy beads, we suggested that the peaks on the high temperature tail of the DTA curve may be associated with a series of relatively stable dermasorbed oxygen layers in the Pt-O alloy lattice. The deeper these layers lie, the higher will be the temperature at which the dissociation peak will appear on the DTA curve.

The earlier studies (3, 6) indicated that the HNO_3-passivated Pt-O alloy was very stable even under the extreme reducing conditions of strong cathodic polarization. The corresponding observation is found in the data of Fig. 3 where the Pt-O alloy structure is very evident, even after 11 runs in 6% H_2 (Fig. 3, curve E). After each run, the oxygen adsorption and dermasorption sites were occupied by oxygen diffusing from the metal interior.

It was also observed earlier (3, 6) that the Pt-O alloy structure could be destroyed by heating the sample white hot. In this case the sample was returned to the untreated Pt state. To simulate this condition in the DTA apparatus, the Pt-O alloy sample was heated at 900°C in 6% H_2 for 6 hr. After cooling in 6% H_2, the DTA curve had the shape of Fig. 3, curve F. In this case, the Pt-O alloy structure is destroyed; and in its place, the curve exhibits one broad peak with two shoulders and a high temperature tail. This three-pronged peak may be interpreted in terms of the desorption of adsorbed hydrogen from two and possibly three kinds of adsorption sites known (14-16) to exist on the Pt surface. The large background ΔT may be accounted for by the desorption of dermasorbed (25) and dissolved hydrogen (26, 27) in the bulk metal.

From x-ray diffraction studies of HNO_3 passivated Pt-O alloy samples (1), it was found that the Pt lattice had been expanded suggesting that the dissolved oxygen had entered the Pt lattice. In the case of anodized Pt-O alloy, oxygen diffusion studies (2, 4) indicate that oxygen migrates along the grain boundaries. Consequently, the dissolved oxygen in Pt may reside either in the grain boundaries or interstitially in the Pt lattice (most likely in the octahedral holes of the fcc lattice). Since the presence of stable dermasorbed layers are not detected on the DTA curves for anodized Pt-O alloy in Fig. 2, it is likely that much of the dissolved oxygen resides in the grain boundaries. The presence of stable dermasorbed layers are detected on the DTA curves for HNO_3 passivated Pt-O alloy in Fig. 3 and suggests that dissolved oxygen not only resides in the grain boundaries but also considerable amounts of dissolved oxygen are located interstitially in the Pt lattice.

It has been found from Auger (AES) studies (27) that both H_2 and O_2 are adsorbed on the low index planes of Pt such as the Pt (111) and Pt (100) planes with considerable difficulty. However, the adsorption of H_2 is greatly facilitated on stepped (28) surfaces which expose high index planes. On these stepped surfaces of Pt the dissolution of hydrogen into the metal interior is strongly promoted (27). From a study of the passivation of Pt in O_2-free HNO_3 (6), it was found that the HNO_3 treatment seemed to give the Pt the properties of an oxygen sponge. We suggest that the soaking of polycrystalline samples of Pt in concentrated HNO_3 for periods of time greater than 72 hr etched the Pt surface in such a way that certain high index planes are exposed. These high index planes greatly facilitate the penetration of adsorbed oxygen into the Pt lattice. Apparently, anodization either does not generate the required high index planes or at least not as efficiently as soaking in HNO_3.

One possible physical picture of the two adsorption sites is as follows. One may associate the type I sites with adsorption of oxygen atoms at the edges of steps on the Pt surface whereas type II may be associated with corners along these steps somewhat similar to the diagrams drawn by Bockris and Conway (29) for adions on a metal surface. The two peaks in the DTA curves of Fig. 2 are separated by about 300°C corresponding to an energy difference of about 600 cal/mole or about 0.026 eV. This energy difference may represent the average difference in the binding energy of O atoms at edge sites and at kink or corner sites on the Pt surface.

Possible reasons for the lowering of the second peak in repeated DTA (Fig. 2, curve C, Fig. 3, curves B-E) runs are as follows. First, dissolved oxygen may diffuse to type I sites more easily than to the type II sites. Second, hydrogen may react with oxygen adsorbed at type II sites more rapidly than with that at type I sites. Third, the thermal treatment to which the sample is subjected during a standard DTA run may decrease the number of type II (kink) sites present on the sample surface. At this time, these data do not permit us to distinguish a preferred path from these suggested mechanisms.

In Fig. 3 the difference in energy between the two sites is less than in Fig. 2; and although the position of the first peak is unaffected, the second peak and the dermasorbed peaks are shifted to higher temperatures with each treatment in the hydrogen atmosphere. It appears that the nature of the kink sites is modified by the hydrogen treatment. Possibly the dermasorbed layers are related to the kink sites. Consequently, the nature of the HNO_3 passivated Pt surface is somewhat different than the anodized surface.

These data support the conclusions: that there are two different adsorption sites of oxygen on polycrystalline Pt; that thin layers of PtO_2 are unstable in the presence of Pt and decompose to Pt-O at potentials below 1.5V; that the HNO_3 treatment of Pt generates a more active surface for the dissolution of oxygen in the bulk Pt than anodization; that dissolved oxygen can reside in the grain boundaries or interstitially in the Pt lattice; that HNO_3 passivated Pt-O alloy is more stable and contains more dissolved oxygen than the anodized Pt-O alloy.

Electrochemistry of Mercuric Chloride in Molten Zinc Chloride-Potassium Chloride Eutectic

M. L. Deanhardt[1] and K. W. Hanck*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27607

ABSTRACT

Chronopotentiometric and cyclic voltammetric studies indicate that the electroreduction of Hg(II) in an equimolar $ZnCl_2$-KCl eutectic at 300°C proceeds by a reversible two-electron process to form Hg(O). A disproportionation reaction is observed when Hg(I) is added to the moderately acidic solvent. The formal potential of the Hg(II)/Hg(O) couple is estimated to be 0.800V *vs.* the Zn(II)/Zn(O) reference electrode. A diffusion coefficient of $(2.17 \pm 0.07) \times 10^{-6}$ cm²/sec was observed for $HgCl_4^{2-}$ at 300°C. The presence of a prewave on the cyclic voltammograms of $HgCl_2$ indicates strong adsorption of Hg(O) on the Pt cathode The system is further complicated by the chemical reaction of metallic mercury with the electrode to produce $PtHg_4$. A mechanism consistent with the observed results is proposed.

The electrochemistry of mercury in molten halide solvents is highly dependent on solvent acidity. The reduction of mercuric chloride in molten LiCl-KCl, a basic solvent, was first studied by Laitinen, Liu, and Ferguson (1). They observed a single reduction wave for Hg(II) complicated by saw-tooth-like fluctuations which were attributed to discharge of gaseous mercury at the electrode surface. Mercury (I) was found to disproportionate in the melt at 450°C to Hg(II) and Hg(O).

A more extensive investigation of Hg(II) in molten LiCl-KCl was carried out by Hanck and Deanhardt (2). Based on chronopotentiometric, pulse polarographic, and cyclic voltammetric studies, a two-electron reversible reduction was observed for Hg(II). The electrode reaction was shown to follow a first-order EC mechanism in which the reduction product is sparingly soluble. The chemical step involved the reaction of metallic mercury with the platinum cathode to produce $PtHg_4$.

Hames and Plambeck (3) investigated the electrochemistry of mercury in highly acidic molten $AlCl_3$-NaCl-KCl at 150°C by potentiometric, voltammetric, and chronopotentiometric techniques. The results showed that Hg(II) is reduced in two steps to Hg(I) and Hg(O); however, the chronopotentiograms showed a long sloping region between the plateaus of the first and second steps and the expected ratio of τ_2/τ_1 was not obtained.

Mamantov and co-workers (4, 5) observed three successive two-electron reduction steps for Hg(II) in acidic $AlCl_3$-NaCl at 175°C. The first step produced Hg_2^{2+}, the second produced a new ion, Hg_3^{2+}, and the third yielded metallic mercury.

We have undertaken a study of the electrochemistry of mercury in an equimolar $ZnCl_2$-KCl solvent at 300°C. The acidity of this solvent is less than that of the chloroaluminates but higher than that of LiCl-KCl.

Experimental

Mercuric chloride was purified by sublimation of the reagent grade salt (J. T. Baker). Reagent grade mercurous chloride (J. T. Baker) was dried at 110°C for 1 hr and stored over magnesium perchlorate in a vacuum desiccator.

Preparation and purity of the $ZnCl_2$-KCl eutectic, molten salt apparatus, and electrodes have been described previously (6).

Current-time and current-voltage curves were obtained with a Princeton Applied Research Corporation Model 173 potentiostat/galvanostat. A triangle wave generator constructed using the circuit of Bull and Bull (7) was interfaced with the Model 173 to obtain linear sweep voltammograms.

Data was digitized with an IBM system/7 data acquisition computer which was linked to the IBM 370/165 computer located at the Triangle Universities Computation Center. Interfacing of the laboratory instruments of the system/7 computer has been described in detail (8). In some cases data was collected with a

Results and Discussion

Chronopotentiometry.—Chronopotentiograms of $HgCl_2$ were taken at several different concentrations and current densities. A typical chronopotentiogram is shown in Fig. 1. The analog data were digitized with the IBM system/7 computer and transition times were determined by the method of Noonan (9). Each chronopotentiogram gave a well-defined transition; however, a slight change in slope was observed in the horizontal portion of the curve. This is believed to be a prewave due to the adsorption of Hg(O) onto the platinum electrode and is discussed in a later section. Table I lists the range of concentrations and current densities used in the analysis. The reduction was found to obey the Sand equation; the regression analysis of Table II-A indicates a diffusion controlled process with $I_0\tau^{1/2}/C$ equal to 0.252 ± 0.004 mA-sec$^{1/2}$/cm²-mM. From this slope $nD_{ox}^{1/2}$ was calculated to be (2.95 ± 0.05) × 10^{-3} eq-cm/mole-sec$^{1/2}$.

The reversibility of the electron transfer reaction was determined from the shape of the chronopotentiograms. Plots of E *vs.* log $(\tau^{1/2} - t^{1/2})/t^{1/2}$ were linear indicating a reversible electron transfer reaction. An example of such a plot is shown in Fig. 2; plots were made on 19 chronopotentiograms and the results are summarized in Table II-B. The theoretical slope for a reversible process at 300°C is 113.7/n mV. The experimental data predict a value of 1.98 for n indicating a two-electron reversible process. The diffusion coefficient of Hg(II) based on a two-electron process is (2.17 ± 0.07) × 10^{-6} cm²/sec. The quarter-wave potential, $E_{\tau/4}$, was found to be independent of current density and concentration over the range studied; the average value being 800 ± 10 mV *vs.* the Zn(II)/Zn(O) reference electrode. The theoretical intercept for the reversible log plot should equal the quarter-wave potential; this was experimentally verified as shown in Table II-B. Prewaves on the chronopotentiograms were considered to be negligible and therefore were not subtracted from the data in Tables I and II.

Since a Hg(I) species is known to exist in molten salts (3-5), the reduction of mercurous chloride was also studied using chronopotentiometry. Mercurous chloride disproportionates upon dissolution in molten $ZnCl_2$-KCl yielding a black precipitate and a solution which yields well-defined chronopotentiograms. The slope of the chronopotentiograms were analyzed and the results are summarized in Table II-C. The average slope and intercept of the log plots are nearly identical to the values reported for mercuric chloride. This suggests that Hg(I) is not present in detectable concentration and that Hg(I) rapidly disproportionates to Hg(II) and Hg(O). These results are similar to those observed in basic LiCl-KCl (2); Hg(I) is apparently stable only in strongly acidic melts such as the chloroaluminates.

Cyclic voltammetry.—Digitized cyclic voltammograms of $HgCl_2$ were taken at several different sweep rates, ν, from ~ 0.4 to ~ 115 V/sec; the potential scan was from 1.3 to 0.5V *vs.* the Zn(II)/Zn(O) reference electrode. Effects of uncompensated solution resistance were minimized by using a low concentration of $HgCl_2$ and positive IR compensation provided on the PAR 173 potentiostat. The voltammograms undergo a change in shape as a function of sweep rate as shown in Fig. 3. At slow sweep rates only two waves are observed (waves II and III, Fig. 3). Wave II has the shape of a reversible two-electron process with $(E_{p/2} - E_p)_{II}$ = 55.2 mV; the theoretical value for a soluble two-electron process at 300°C is 54.3 mV (10). The peak potential occurs at 785 mV. The theoretical value of $E_{1/2} - E_p$ is 27.4 mV for a two-electron process; therefore, $E_{1/2}$ is calculated to be 812 mV which is in excellent agreement with the $E_{1/2}$ value obtained from the chronopotentiometric data.

Wave III in Fig. 3A has a sharp, nearly symmetrical shape characteristic of the stripping of an insoluble deposit. The value of $(E_p)_{III} - (E_p)_{II}$ is 138 mV, which is considerably larger than the theoretical value of 54.8 mV for a two-electron reversible process.

Table I. Chronopotentiometric data

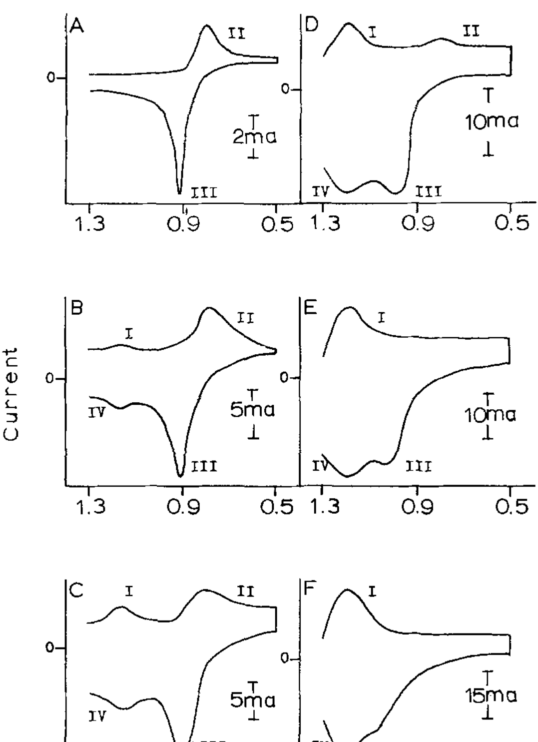

Fig. 3. Cyclic voltammograms of $HgCl_2$ at various sweep rates. $[HgCl_2] = 9.21$ mM. Beginning with curve A, $\nu = 0.378, 3.69, 9.11, 21.4, 30.6$, and 45.8 V/sec, respectively.

The formation of $PtHg_4$ on the electrode surface has been confirmed by x-ray powder diffraction and is discussed in a later section. The oxidation of $PtHg_4$ should occur at a more anodic potential than the oxidation of Hg(O) and therefore would account for the larger than theoretical value observed for $(E_p)_{III} - (E_p)_{II}$.

As the scan rate is increased $(E_p)_{II}$ remains constant and the wave finally disappears with the formation of a prewave (wave I) at 1150 mV. Wave III shifts cathodic with scan rate and broadens approaching the shape expected for a reversible reoxidation of a soluble product; however, at very high sweep rates wave III also disappears with the formation of wave IV at 1150 mV.

The increase in wave I and decrease in wave II with scan rate indicates strong adsorption of the reaction product onto the electrode; waves I and IV represent the reduction of Hg(II) and the oxidation of adsorbed Hg(O), respectively. Effects of adsorption of electroactive species in cyclic voltammetry have been discussed quantitatively by Wopschall and Shain (11). Quantitative measurements of the adsorption parameters of this system were not feasible due to the presence of a chemical reaction following charge transfer (*i.e.*, formation of $PtHg_4$).

Current reversal chronopotentiometry.—The mechanism for the reduction of $HgCl_2$ was further characterized by current reversal chronopotentiometry. A typical reverse current chronopotentiogram is shown in Fig. 4. The difference between $E_{0.250\tau}$ and $E_{0.215\tau_r}$ is greater than that expected for a reversible process (12), due mainly to *IR* drop effects similar to those observed by Delahay and Mattax (13). The theoretical ratio of the reverse transition time to the forward time, τ_r/t_f is equal to $\theta^2/(2\theta + l)$ for the formation of a soluble product where θ equals the ratio of i_f, the forward current, to i_r, the reverse current. If the reduction product is insoluble and plates onto the electrode, $\tau_r/t_f = \theta$.

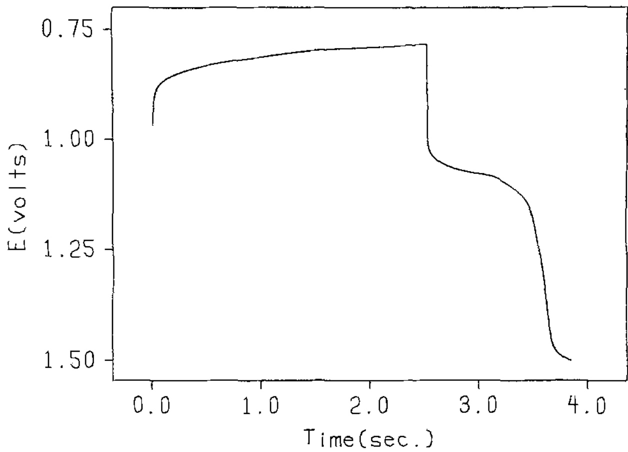

Fig. 4. Current reversal chronopotentiogram of $HgCl_2$. $[HgCl_2] = 117.1$ mM. $i_f = 7.53$ mA/cm^2. $i_r = 7.53$ mA/cm^2.

A series of current reversal chronopotentiograms were performed in which the forward electrolysis time (t_f) and i_f were chosen so that the forward charge was constant throughout a run but t_f varies from *ca.* 0.5 to 3.0 sec. Figure 5 shows the variation of τ_r/t_f with t_f for some 30 current reversal chronopotentiograms at three different values of θ. The concentration of $HgCl_2$ was chosen to be very high in order to obtain a larger range of forward and reverse currents.

At large values of t_f (*i.e.*, low values of i_f), τ_r/t_f approaches a value expected for the reoxidation of a soluble product; however at low values of t_f (*i.e.*, large values of i_f), τ_r/t_f is greater than the value expected for the reoxidation of a soluble reduction product but less than that expected for the reoxidation of an insoluble reduction product. Cyclic voltammetric experiments indicate strong adsorption of the reduction product; Herman and Blount (14) observed an enhancement in the τ_r/t_f ratio when the product was adsorbed on the electrode. Increasing i_f (decreasing t_f), which is analogous to increasing the scan rate in cyclic voltammetry, should increase the value of τ_r/t_f in the case of product adsorption. The data of Fig. 5 confirm the adsorption of the reduction product as suggested by the voltammetric data.

X-ray powder diffraction analysis.—The insoluble product indicated by the voltammetric experiments at slow scan rate was identified by x-ray powder diffraction patterns. A 2 cm length of 26 gauge Pt wire was electrolyzed in a $HgCl_2$ solution at a controlled potential of 0.5V *vs.* the Zn(II)/Zn(O) reference electrode for 10 min. The wire was washed with deionized water, air dried, and mounted in an x-ray diffraction camera.

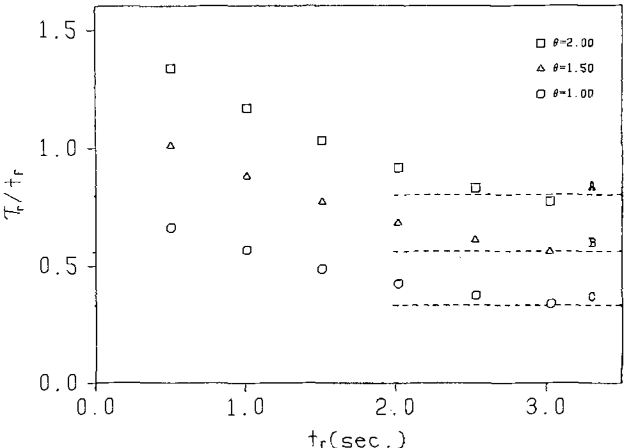

Fig. 5. Variation of τ_r/t_f with t_f. $[HgCl_2] = 117.1$ mM. Forward charge = 10.0 mC. A, B, and C indicate theoretical values of τ_r/t_f for formation of a soluble product.

The sample was exposed to Ni-filtered CuK_α radiation for 18 hr and a diffraction pattern identified as that of $PtHg_4$ was observed. Robbins and Enke (15) found that $PtHg_4$ is formed at room temperature when a Pt wire is allowed to stand in contact with metallic mercury. The reaction of Hg(O) with Pt to form $PtHg_4$ was also observed in the reduction of $HgCl_2$ in molten LiCl-KCl (2).

An additional experiment was performed in which $HgCl_2$ was reduced on a Pt wire at a controlled potential of 0.5V for 5 min and then reoxidized at 1.3V for 5 min. The x-ray powder pattern for this sample was identical to the powder pattern of Pt metal which indicates that $PtHg_4$ is oxidizable in the $ZnCl_2$-KCl solvent.

Reduction mechanism.—The electroreduction of $HgCl_2$ proceeds by a reversible two-electron process to form Hg(O); no evidence was observed for the formation of Hg(I). Based on our measurements of $E_{1/2}$, the formal potential of the Hg(II)/Hg(O) couple is 0.800V *vs.* the Zn(II)/Zn(O) reference electrode. A mechanism consistent with the observed results is

$$Hg^{2+} + 2e^- \rightleftharpoons Hg^o \xrightarrow{Pt} PtHg_4$$
$$k_a \downarrow\uparrow k_d$$
$$(Hg^o)_{ads}$$

If the rate at which Hg^{2+} is electrolyzed is slow, Hg(O) is in contact with the Pt electrode for a longer period of time and $PtHg_4$ is formed on the electrode surface. As the rate of electrolysis is increased, the formation of $PtHg_4$ decreases as indicated by the broadening of peak III in Fig. 3. After the thickness of $PtHg_4$ on the surface of the platinum reaches a certain value, Hg(O) is no longer in contact with metallic Pt and the influence of the chemical reaction diminishes. In the cyclic voltammetric experiments, the forward coulombs of the reduction are small (less than 1 mC) and the fraction of total Hg(O) reacting with the Pt electrode is large; however when the forward coulombs of the reduction are large as in the current reversal chronopotentiometric experiments (10 mC), the fraction of total Hg(O) reacting with the Pt electrode is small, and the system appears as a reversible process yielding a soluble product (see Fig. 5 at large values of t_f).

The system is further complicated by the adsorption of Hg(O) onto the platinum electrode, which probably precedes the formation of $PtHg_4$. The absorption of a reduction product onto an electrode has been described by the Langmuir isotherm (11)

$$\Gamma_R = \Gamma_R^s C_R/(K_R + C_R) \quad [1]$$

where, Γ_R = surface concentration of adsorbed product (moles/cm^2), Γ_R^s = surface concentration of adsorbed product at saturation (moles/cm^2), C_R = concentration of product at electrode surface (moles/cm^3), and $K_R = k_d/k_a$.

When C_R is small, Γ_R is directly proportional to C_R; when C_R is large, Γ_R approaches Γ_R^s. The current for a process involving an adsorbed product is proportional to $\Gamma_R^s\ \nu^{1/2}$ while that for a process uncomplicated by adsorption is proportional to $C^*_O\ \nu^{1/2}$ where C^*_O is the bulk concentration of the oxidized form of the couple. Both processes attempt to reduce the surface concentration of Hg(II); since the adsorption process occurs at a potential anodic of the diffusion process, an increase in the adsorption peak results in a decrease in the diffusion peak. In the case of mercury, Γ_{Hg}^s is much smaller than $C^*_{Hg(II)}$; consequently at low values of ν very little adsorption current is seen. As ν is increased the adsorption current increases while the diffusion peak current decreases. At sweep rates above 45 V/sec all of the Hg(O) produced is adsorbed on the electrode. The fact that the diffusion peak completely disappears indicates that Γ_{Hg} has not reached Γ_{Hg}^s.

Chemical complications of the reversible charge transfer step could perhaps be eliminated by using some other working electrode other than platinum, for example, glassy carbon. This however would probably not add any other information concerning the electrochemistry of mercury in this solvent.

Conclusions

The electroreduction of $HgCl_2$ in an equimolar $ZnCl_2$-KCl solvent proceeds by a reversible two-electron process. The reduction mechanism includes two chemical complications, the adsorption of Hg(O) onto the Pt cathode and the chemical reaction of Hg(O) with the electrode to produce $PtHg_4$.

Manuscript submitted April 19, 1976; revised manuscript received July 19, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Semiconductor Electrodes

VII. Digital Simulation of Charge Injection and the Establishment of the Space Charge Region in the Absence and Presence of Surface States

Daniel Laser and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Transport of free carriers following charge injection to a semiconductor electrode is simulated. The relaxation of the free carrier results in the buildup of the space charge region whose properties are calculated. For an intrinsic semiconductor, the relaxation resembles that of the cations and anions in the diffuse double layer at a metal/electrolyte interface following charge injection to the metal. For an extrinsic semiconductor, some additional specific effects arise, which are discussed. The effect of surface states is considered and the interaction of a surface level with the semiconductor bands is simulated. This interaction results in trapping of charge from the space charge region and delivery of it to the surface. The properties of the space charge region in the presence of surface states are calculated, and their effect on the relaxation process demonstrated.

There has been much interest recently in semiconductor electrodes, and especially in photoeffects and photoelectrochemical experiments which may lead to devices of practical use, such as for solar energy utilization [see (1-3) and references therein]. Although the basic principles of the semiconductor electrode/electrolyte interface were formulated some time ago and have been reviewed extensively (4-8), the quantitative treatment of the behavior of semiconductor electrodes is quite complicated involving carrier diffusion and migration, thermal- and photogeneration, and recombination in the semiconductor itself in addition to the usual mass transfer and kinetic processes in the electrolyte phase and interphase charge transfer steps. Digital simulation methods (9, 10) have been very valuable in the treatment of complex kinetic or mass transfer problems in electrochemical systems. It is the aim of this paper and following ones in this series to apply digital simulation techniques to electrochemistry at semiconductor electrodes and the behavior of the semiconductor/electrolyte interface under illumination. In this paper we discuss the basic concepts of simulation of a semiconductor and the sequence of events following charge injection to a semiconductor electrode and leading to the formation of a space charge region. Following papers will describe the establishment of a photovoltage at an ideally polarized semiconductor electrode under steady illumination and the production of a photocurrent when charge transfer across the electrode/solution interface occurs.

Digital Simulation Model of Formation of Space Charge Region

Although the carrier distribution and field in a semiconductor electrode can frequently be calculated by direct analytical methods (6-8), a digital simulation of it is convenient since these distributions provide the starting point for simulations of the photoeffects of interest. Moreover, simulations allow the investigation of the effect of surface states on the field and are useful in testing the digital model under conditions where some rigorous solutions are known. Consider a semiconductor electrode in contact with an electrolyte solution and at the flatband potential, *i.e.*, the point of zero charge. We now consider the events that occur following the coulostatic injection of charge into the semiconductor. As a dielectric the semiconductor electrode can sustain a charge and an electric field within its volume; however, because of the existence of mobile carriers in the semiconductor, this charge is subject to redistribution and will ultimately accumulate at the semiconductor/electrolyte boundary in a region called the space charge region. Usually the charge distribution in a semiconductor electrode will be found somewhere between the two extreme cases of a metal electrode, where all the charge is essentially located at the surface, and a dilute electrolytic solution in contact with a charged metal electrode, in which the charge (ionic) distribution is very diffuse. The space charge region is of fundamental importance in describing the electrochemical properties of the semiconductor and it is the equilibrium distribution, rather than its mode of formation, that is usually of interest (5). The response of the semiconductor to charge injection is very similar to the relaxation of the diffuse double layer in solution following coulostatic charge injection to a metal electrode recently considered by Feldberg (10). The situation in a semiconductor differs from that for the usual electrolytic solution because of the much higher mobility of the carriers (holes and electrons) the presence of fixed charges (from acceptors or donors) in an extrinsic semiconductor, and the possible importance of dissociation and recombination processes in the semiconductor. The utilization of the basic concepts of electrostatics and mass transfer is very similar to that employed by Feldberg (10), however, so that only a brief outline of the simulation method will be given here. For those interested in utilizing this approach, the computer program is described briefly in the Appendix.

For the injection of positive charge with a charge density, Q (C/m^2), the field at the semiconductor surface (*i.e.*, the semiconductor/solution interphase), E_s (V/m), assuming planar geometry so that lines of force of the field are normal to the electrode surface, will be given by

$$E_s = Q/\epsilon_0\epsilon_r \quad [1]$$

where ϵ_0 is the permittivity of free space, 8.85×10^{-12}f m^{-1}, and ϵ_r is the dielectric constant of the semiconductor relative to vacuum; for a positive charge, E_s is taken as positive pointing toward the solution. If charge is conserved in the semiconductor, the field at the surface ($x = 0$) will always be given by Eq. [1]. In the interior of the semiconductor, $E(x)$ will depend upon the charge distribution. At the instant of charge injection, the field everywhere in the semiconductor will be E_s. This field will cause holes (h^+) to migrate toward the surface and electrons (e^-) to migrate in the opposite direction. This migration is opposed by the diffusion of holes and electrons with the net flux of

* Electrochemical Society Active Member.

Key words: semiconductors, digital simulation, space charge, surface states.

holes and electrons, f_+ and f_-, respectively (with positive flux taken as toward the electrode surface), being governed by Eq. [2] and [3]

$$f_+ = (e/kT)E(x)D_p p + D_p \partial p/\partial x \quad [2]$$

$$f_- = -(e/kT)E(x)D_n n + D_n \partial n/\partial x \quad [3]$$

where D_p and D_n are the diffusion coefficients and p and n are the concentrations of holes and electrons, respectively. The net effect of this mass transfer is the transfer of positive charge to the electrode surface. This new charge distribution will modify $E(x)$. At equilibrium the space charge region is established with no charge remaining in the bulk semiconductor, so that the field there is zero, and with constant concentration profiles for holes and electrons maintained by the counterbalancing of the migrational flux caused by the equilibrium field distribution and the diffusional one. The surface potential, V_s, at all stages is given by Eq. [4], where E_b is the field in the bulk semiconductor

$$V_s = \int_0^\infty [E(x) - E_b]dx \quad [4]$$

Results

Intrinsic semiconductor in the absence of surface states.—For an intrinsic semiconductor (*e.g.*, intrinsic Ge), the response to charge injection and relaxation is quite analogous to diffuse double layer relaxation in solution given by Feldberg (10), with the holes replaced by cations and the electrons by anions (Fig. 1). The surface potential rises from zero to some maximum value and then relaxes to its new equilibrium value. The carriers which are attracted to the surface (*e.g.*, holes) and which at equilibrium show a continuous drop in concentration with distance from surface towards the bulk, show a minimum in their concentration profile during the relaxation [as also observed in solution diffuse double layer formation (10)]. The relaxation processes occur in times 10^4-10^5 smaller than for those in solution because of the higher D values of the carriers in the semiconductor (*e.g.*, 95 cm^2/sec for electrons and 45 cm^2/sec for holes in Ge) compared to those of ions in solution (*ca.* 10^{-5} cm^2/sec). The space charge is essentially established within 10^{-9} sec, a period during which double layer formation in solution will not yet have started. Thus space charge region effects probably can be differentiated from solution double layer ones according to the time window of the experiment.

Extrinsic semiconductor in the absence of surface states.—For a highly doped semiconductor (*e.g.*, n-type Ge) the picture is different. Here, unless strong inversion prevails (*e.g.*, at very positive potentials), the electrical state of the electrode will be mainly determined by the majority carrier distribution (electrons) and the dopant level (the donor atoms), while the minority carriers (holes) will adjust themselves to the field established by the donors and majority carriers. One must also consider the origin of the minority carriers (holes) arriving at the surface during relaxation, because positive charge injection at the metal/semiconductor ohmic contact of the n-type semiconductor occurs largely through electron extraction, rather than hole injection, and the total number of minority carriers originally existing in the bulk semiconductor may be insufficient to populate the space charge layer. A similar problem may apply to an intrinsic semiconductor as well. A typical simulation for n-Ge with a donor level, N_D, of 2.5 × 10^{16} cm^{-3} is given in Fig. 2. The transport of the majority carriers is very fast and they are extracted nearly instantaneously from the surface (and arrive at the metallic contact to compensate for the electrons which were extracted from there by the charge injection). Because most of the charge distribution is assocated with the electron distribution, the electric field and surface potential also quickly achieve

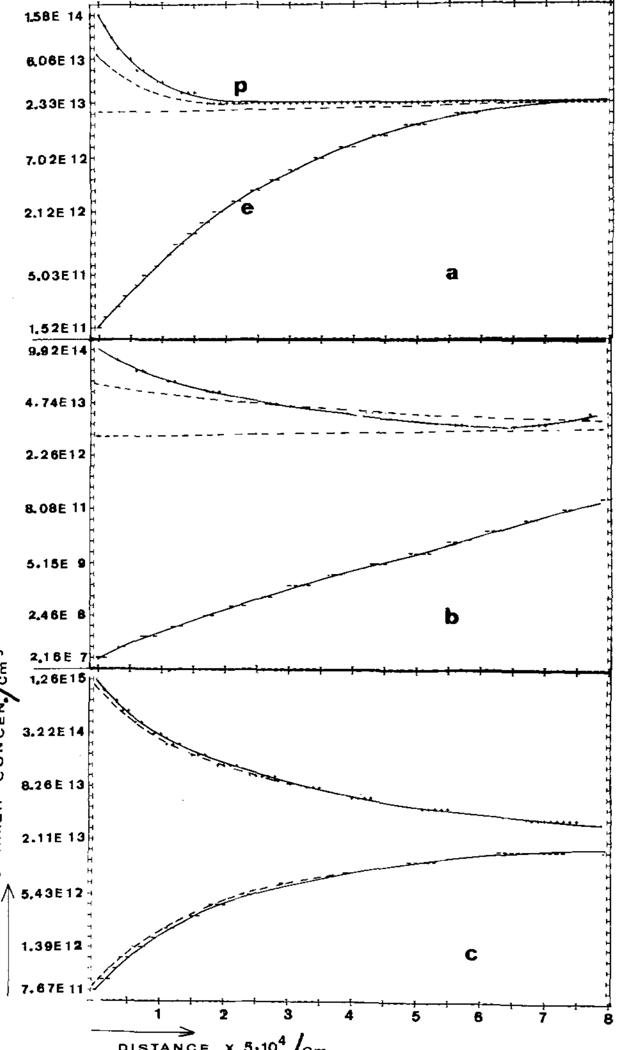

Fig. 1. Free carrier concentration for intrinsic Ge, with and without surface states. $n° = p° = 2.5 \times 10^{13}$ cm^{-3}; $\epsilon_r = 16$ esu, u_n and u_p are 3800 and 1800 cm^2/V-sec, respectively; charge injected = 3.91 × 10^{-7} C/cm^2. Solid lines, without surface states; times after charge injection: (a) 9.474 × 10^{-12} sec (V_s = 0.015V, E_b = 2.37 × 10^3 V/cm); (b) 1.895 × 10^{-10} sec (V_s = 0.106V, E_b = 7.03 × 10^2 V/cm); (c) 1.895 × 10^{-9} sec (V_s = 0.096V, E_b = 2.8 × 10^1 V/cm), V_s at equilibrium = 96 mV, E_s = 2.76 × 10^3 V/cm at all times. Dashed lines, with surface states for which N_t = 2.0 × 10^{11} cm^{-2}, $E_t = E_F°$, k_e = 0.53 × 10^{10} sec^{-1}; k_v = 2.63 × 10^{-5} $cm^3 \cdot sec^{-1}$. For the same times as in the absence of surface states, the results are: (a) V_s = 0.006V, E_s = 2.757 × 10^3 V/cm, ΔQ_{ss} = 3.77 × 10^{-10}C, E_b = 2.62 × 10^3 V/cm; (b) V_s = 0.067V, E_s = 2.71 × 10^3 V/cm, ΔQ_{ss} = 6.77 × 10^{-7}C, E_b = 2.14 × 10^3 V/cm; (c) V_s = 0.094V, E_s = 2.65 × 10^3 V/cm, ΔQ_{ss} = 1.533 × 10^{-8}C, E_b = 31 V/cm.

their equilibrium value. Minority carriers show a relatively slow relaxation to their equilibrium value, because their low bulk concentrations can provide only small fluxes toward the surface. The holes are supplied to the surface and enter the space charge region (taken arbitrarily as the point where the electric field drops to 10^{-4} times its surface value) mainly by diffusion. Thus, adjacent to the space charge region, which is the region of primary interest, a relatively wide diffusion layer [known as the "quasi-neutral region" (11)] will be formed. There the electrical field is nearly zero and minority carriers are transported across it by diffusion in a manner analogous to the diffusion of ions toward an electrode in solution in the presence of an excess of supporting electrolyte. In the experiment under consideration here, the quasi-neutral region will eventually disappear. In other kinds of experiments, however, *e.g.*, those connected with a con-

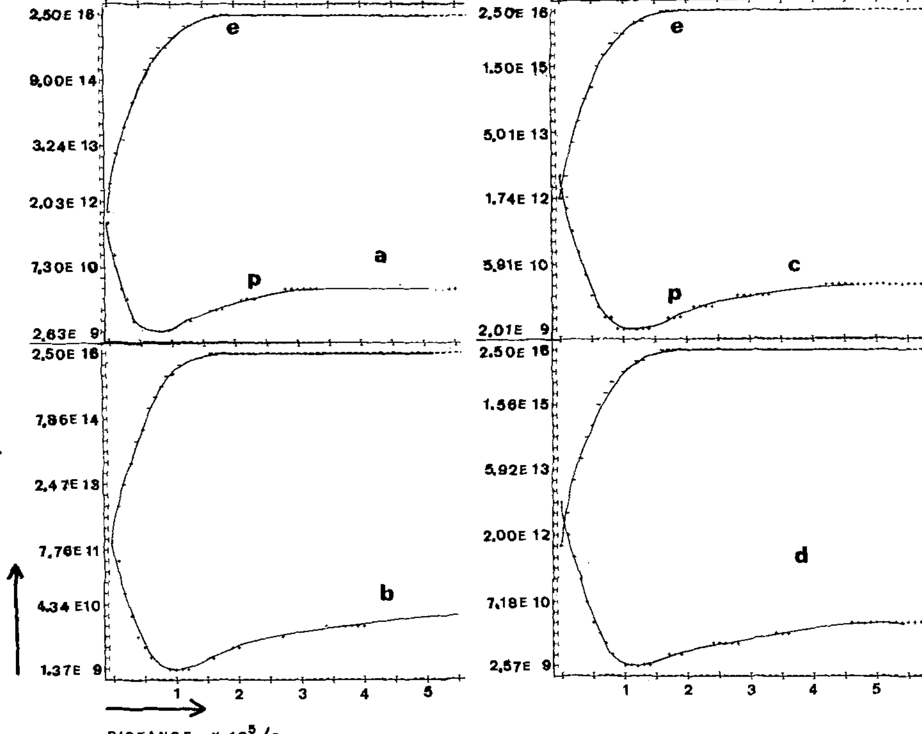

Fig. 2. Free carrier concentration following charge injection to n-type Ge. $n^\circ = 2.5 \times 10^{16}$ cm^{-3}, $p^\circ = 2.5 \times 10^{10}$ cm^{-3}; $\epsilon_r = 16$ esu; $u_n = 3800$ cm^2/V-sec, $u_p = 1800$ cm^2/V-sec; injected charge $= 4.96 \times 10^{-6}$ C/cm^2. Time after charge injection: (a) 2.37×10^{-12} sec ($V_s = 250.5$ mV); (b) 4.74×10^{-11} sec ($V_s = 251$ mV); (c) 2.37×10^{-10} sec ($V_s = 251$ mV); (d) 4.74×10^{-10} sec ($V_s = 251$ mV). $E_s = 3.50 \times 10^4$ V/cm and $E_b < 2 \times 10^{-3}$ V/cm for all times shown.

tinuous withdrawal of minority carriers from the electrode surface in a faradaic reaction, a steady-state quasi-neutral region will remain in which the gradient of minority carriers determines the limiting current. The diffusion layer width of the minority carriers is governed by the spontaneous thermal generation of carriers, which is not taken account of explicitly in the simulation. Within the time domain of the simulation (*ca.* 10^{-9} sec) the number of holes generated thermally is negligibly small. For the n-type Ge ($p^o = 2.5 \times 10^{10}$ cm^{-3}) the value for the zero-th order generation rate constant is about 10^{15} cm^{-3} sec^{-1}. This generation will terminate the diffusion layer of holes at some point when, at a given time, the flux divergence of holes will equal their net generation rate. For the sample under discussion, a wide and essentially linear diffusion layer for holes results, which in this relaxation mode gradually collapses. We cannot extend the simulation, which is concerned primarily with the thin space charge region, to such a distance from the electrode surface. Instead the thermal generation of minority carriers was considered indirectly by terminating the diffusion layer for the holes and arbitrarily assigning the hole concentration as the bulk value at some suitably large distance from the space charge region. Hence the simulated transport of holes to the electrode surface may be larger than the rate found for a more rigorous simulation, where the final relaxation of minority carriers would be determined by the thermal generation rate. Experimentally, it seems unlikely that the relaxation of minority carriers can be observed by purely electrochemcial methods, since its influence on the electrode potential is negligibly small. Moreover, a current transient attributable to minority carrier relaxation which might probe their surface concentration would be complicated by the solution double layer relaxation effects. Some other technique, such as internal reflection spectroscopy at wavelengths which correspond to the absorption spectrum of holes and which is sensitive to their surface concentration (12, 13), might be useful.

Effect of surface states.—Surface states and their relevance to the electrochemistry of semiconductor electrodes have been widely discussed (8, 14). We shall confine ourselves here to a simple model and simulate the interaction of a discrete surface level with the semiconductor bands at the surface in a charge injection experiment. In this case, charge is trapped by the surface level causing a simultaneous change in its occupancy. After relaxation, new surface concentrations and surface-state level occupancies will exist, such that the interaction between the level and the band again does not produce a net effect. The total injected charge will be distributed between the semiconductor surface and space charge region lowering the surface field and surface potential of the semiconductor compared to a situation without the surface states. The simulation assumes very fast (perhaps hypothetically fast) surface states which respond immediately to any perturbation in the equilibrium concentration of free carriers, thus modifying their surface concentrations during their relaxation. The final results should be valid for slower surface states as well. For slow surface states, the relaxation of free carriers can be considered complete before interaction between the space charge region and the surface level begins. Assume the existence of a discrete surface level with a concentration density of states N_t, located at an energy E_t with respect to the Fermi energy, $E_F{}^o$, and having an occupancy or filling function, f_t (representing the fraction of traps occupied by electrons). Figure 3 represents schematically this situation and the following expressions will be written for exchanging holes and electrons with the bands (6, 15)

$$R_e = k_e N_t f_t \quad [5]$$

$$R_c = k_c(1 - f_t) N_t n_s \quad [6]$$

$$R_v = k_v N_t f_t p_s \quad [7]$$

$$R_h = k_h N_t (1 - f_t) \quad [8]$$

The k's are the corresponding rate constants for interaction of the surface level with the conduction and valence band, respectively; n_s and p_s are the surface concentrations of electrons and holes. Since the ratios k_e/k_c and k_h/k_v do not depend on the surface potential, their values determined at the flatband potential, V_{fb}, apply at other potentials, as well. At equilibrium at V_{fb}, $p_s = p^o$, $n_s = n^o$, $f_t = f_t{}^o$, $R_e = R_c$, and $R_h = R_v$. Then from Eq. [5]-[8]

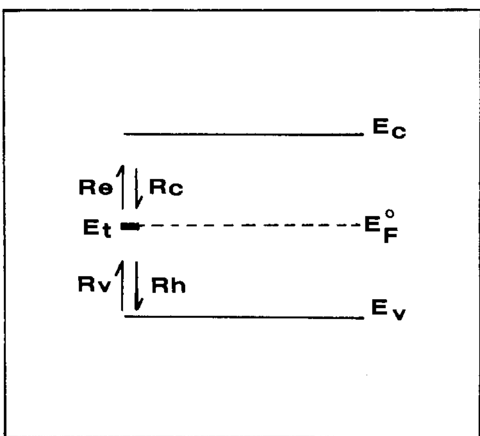

Fig. 3. Schematic model for interaction of a surface level with the semiconductor bands. R_e and R_c are the rates for exchange of electrons with conduction band; R_v and R_h are the rates for exchange of holes with the valence band.

$$k_c = k_e f_t^o/(1 - f_t^o) n^o \quad [9]$$

$$k_h = k_v p^o f_t^o/(1 - f_t^o) \quad [10]$$

Hence, for a given semiconductor, k_c/k_e and k_h/k_v depend only on f_t^o, *i.e.*, on the relative position of E_t to E_F^o. If for any reason (*e.g.*, because of charge injection) n_s and p_s are perturbed from their equilibrium values which have established a certain occupancy of the surface level, a net exchange of holes and electrons between the surface level and the conduction and valence bands will occur yielding

$$R_n = R_e - R_c = k_e N_t \left[f_t - \left(\frac{f_t^o}{1 - f_t^o} \right) (1 - f_t) \frac{n_s}{n^o} \right] \quad [11]$$

$$R_p = R_v - R_h = k_v N_t \left[p_s f_t - \left(\frac{f_t^o}{1 - f_t^o} \right) (1 - f_t) p^o \right] \quad [12]$$

R_n is the over-all rate at which electrons are transported from the surface level to the conduction band at the surface and R_p is the over-all rate at which holes from the valence band at the surface are transferred to the level. Both R_n and R_p have units of flux (cm^{-2} sec^{-1}). The total rate at which the level loses electrons is $R_n + R_p$. This rate, when multiplied by the electronic charge, represents the rate at which the surface level collects positive charge from the space charge region (in A-cm^{-2}). The rate at which the field in the semiconductor at a point just inside the semiconductor/solution interface (where the surface states are presumably located) drops because of this loss of charge is $e(R_n + R_p)/\epsilon_0\epsilon_r$. All of these effects were simulated along with the free carrier transport within the semiconductor phase described previously. When a new position of equilibrium is established, R_p and R_n must vanish. Thus, both rates pass through a maximum when relaxing from one equilibrium situation to another and the values of the rate constants were chosen so that this effect could be observed within the simulation time domain. To obtain this situation we consider Eq. [11] and [12] in a somewhat more operational way. Assume that the semiconductor is initially at the flatband potential and $f_t^o = 1/2$ (*i.e.*, $E_t = E_F^o$; $f_t^o/(1 - f_t^o) = 1$). We call $N_t f_t$ (the number of electrons in the level) SUR and N_t (the maximum number of electrons possible in this level) SURMAX. Then Eq. [11] and [12] can be rewriten as

$$R_n = k_e[\text{SUR} - (n_s/n^o)(\text{SURMAX} - \text{SUR})] \quad [13]$$

$$R_p = k_v[p_s\text{SUR} - p^o(\text{SURMAX} - \text{SUR})] \quad [14]$$

Throughout the simulation n_s, p_s, and SUR change. Before charge injection, $p_s = p^o$, $n_s = n^o$, and SUR = SURMAX/2; thus $R_p = R_n = 0$. Immediately after the charge injection (*e.g.*, of positive charge), n_s becomes smaller than n^o, p_s becomes larger than p^o, and at this instant SUR still is equal to SURMAX/2. As a result, both R_p and R_n become positive; the magnitude of SUR decreases as electrons are delivered to the edge of the conduction band and holes are collected from the edge of the valence band. As long as this mechanism is operative, concentration profiles in the space charge region will remain much more shallow than in the absence of surface states. This is shown in Fig. 1 for intrinsic Ge, where the charge injected was of such a size that the bands were bent in a way that the surface level was practically depopulated of electrons. At the new position of equilibrium, the value of SUR, p_s, n_s, and SURMAX $-$ SUR will cause the bracketed portions of Eq. [13] and [14] to be zero. A new concentration profile as well as a new surface level occupancy will result. Note that within the simulation negative values of R_p and R_n as calculated in Eq. [13] and [14] are possible. This occurrence results in an oscillatory behavior in which carriers move back and forth from the bands to the surface level. This behavior arose with large values of k_e and k_v, resulting in SUR becoming essentially zero within a few simulation steps. In the computer program such effects were prevented by stopping the interaction between the bands and the surface level (*i.e.*, assigning $R_p = R_n = 0$) whenever R_p and R_n were calculated to have a negative value. Table I summarizes the results of simulations and gives values of quantities of interest in the absence and presence of surface states (which are assumed to be at an energy, $E_t = E_F^o$) with the initial condition taken as the flatband potential. Note that for the same total amount of charge injected the surface potential will be smaller in the presence of surface states than in their absence. Notice also that the total charge of the surface states and space charge region equals the injected charge and that the occupancy found for the surface level after the charge injection

APPENDIX

The desired region of interest is divided into space elements of width ΔX (*e.g.*, 25-100Å) which are assigned an index K, from $K = 1$ (the surface element) to $K = KMAX$. The concentration of holes and electrons within each element (p_K, n_K) is assumed constant and the electrical field between element K and $K - 1$ is called E_K. The concentration at this boundary is assumed to have a concentration equal to the average value for the two elements on both sides of this boundary. Thus, *e.g.*, for holes,

$$p_x = \tfrac{1}{2}(p_{K-1} + p_K) \quad \text{[A-1]}$$

According to the simulation technique, the change of carrier concentration in element K, due to the fluxes written in Eq. [2] and [3], within a time interval Δt can be expressed (*e.g.*, for holes) as

$$\Delta p_K = DMP(p_{K-1} - 2p_K + p_{K+1}) + 0.5\,UMP \{E_{K+1}(p_K + p_{K+1}) - E_K(p_K + p_{K-1})\} \quad \text{[A-2]}$$

where DMP and UMP are simulation constants to be discussed later. Such an expression is written for all K's, for holes as well as for electrons. The resulting changes in concentration are then added to the present ones. As a result a new concentration profile is established which is used to calculate the concentration changes for the next time interval. Changes in the electric field due to the concentration change will be written as

$$E_K = E_{K-1} - (e\Delta x/\epsilon_0\epsilon_r)(p_K - n_K + N_D - N_A) \quad \text{[A-3]}$$

where N_D and N_A are donor and acceptor concentrations, respectively. The initial conditions which follow the injection of charge q_{inj} are

$$p_K = p^o,\ n_K = n^o,\ E_K = q_{inj}/\epsilon_0\epsilon_r \text{ (at all } K) \quad \text{[A-4]}$$

The boundary conditions are

$$p_{KMAX} = p^o,\ n_{KMAX} = n^o,\ E_{K=1} = (q_{inj} - \Delta q_{ss})/\epsilon_0\epsilon_r \quad \text{[A-5]}$$

where Δq_{ss} is the charge trapped by the surface level. KMAX should be the value of K within the bulk of the electrode. However, unless a nonlinear space grid is employed, this KMAX will have too large a value for practical calculations for $KMAX \cdot \Delta X$ to extend into the bulk semiconductor. Thus a smaller value of KMAX was used (which was still far outside the space charge region); this results in a somewhat steeper concentration profile for holes so that their flux toward the surface is slightly overestimated. The simulation constants are DMN, DMP, UMN, and UMP. They are defined (e.g., for electrons) as

$$DMN = D_n\Delta t/\Delta X^2 \quad \text{[A-6]}$$

$$UMN = U_n \cdot (\Delta t/\Delta X) = (e/kT)DMN \cdot \Delta X \quad \text{[A-7]}$$

with similar expressions for holes. As usual for simulations (9), both DMN and DMP must be less than 0.5. Similarly, the effect of migration requires that $UMN \cdot E_{K=1}$ and $UMP \cdot E_{K=1}$ both be smaller than 1 (where $E_{K=1}$ is the maximum value of the electric field, at the surface). These conditions impose the following restriction on Δt and ΔX

$$\Delta t/\Delta X < 1/E_{K=1}U_N \quad \text{[A-8]}$$

Typical values which satisfy this requirement are $U_n = 2000\ cm^2\ sec^{-1}\ V^{-1}$, $\Delta X = 5 \times 10^{-7}$ cm, $DMN = 0.45$, and $E_{K=1} = 10^3\text{-}10^4$ V/cm.

Semiconductor Electrodes

VIII. Digital Simulation of Open-Circuit Photopotentials

Daniel Laser and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

A simulation technique is described for the calculation of semiconductor electrode properties at steady state, *e.g.*, at equilibrium in the dark or under constant illumination. Integration of the continuity equation with respect to distance at the steady state yields a relation between the light flux and free carriers, which can be used in a recursion relation to determine the free carrier concentrations and the electric field within the space charge region of the semiconductor electrode. The technique is used to calculate the Boltzmann distribution within the semiconductor electrode and to determine the photopotential in the absence of faradaic current and surface states.

In a previous paper in this series (1) we described a digital simulation method for semiconductor electrodes and the formation of the space charge region in a semiconductor electrode upon charge injection. The main motivation for these simulations has been the recent interest in semiconductor electrodes and their application to photoelectrochemical cells and devices (2). One characteristic of interest is the change in surface potential of a semiconductor/electrolyte interface under illumination, the photopotential. Although theoretical treatments of the photopotential have been given (3, 4), and its magnitude related to the semiconductor properties, surface potential, and light intensity, these treatments usually involve restrictive conditions, (*e.g.*, total light absorption in the space charge region, minority carrier diffusion length much larger than the size of the space charge region). We describe here the digital simulation of the steady-state photopotential which arises upon illumination of a semiconductor electrode previously brought to a given potential and now held at open circuit. Charge transfer reactions, *e.g.*, open-circuit corrosion, are assumed not to occur during this illumination.

Physical Model

The general equation for the processes within a semiconductor electrode under illumination can be obtained by considering the creation of electron/hole pairs by light absorption, their mass transfer by diffusion and migration, and their recombination. Thus the change in concentration of holes, p, at a given location in the semiconductor is given (in one-dimensional form) by

$$\partial p/\partial t = \partial j_p(x)/\partial x + I_o a e^{-ax} - R(x) \quad [1]$$

where I_o is the intensity of light incident on the semiconductor/electrolyte interface (taken as $x = 0$), a is the coefficient of light absorption of the semiconductor, $j_p(x)$ is the total flux of holes at x, and $R(x)$ the rate of electron/hole recombination. We are concerned here with the steady-state photopotential. Thus with $\partial p/\partial t = 0$, integration of Eq. [1] yields

$$j_p(x) - j_p(0) = \int_0^x R(x)dx - I_o(1 - e^{-ax}) \quad [2]$$

where $j_p(0)$ is the flux of holes crossing the interface, or the hole contribution to the faradaic current density, i_p. Thus

$$j_p(x) = i_p/e - I_o(1 - e^{-ax}) + \int_0^x R(x)dx \quad [3]$$

A similar expression can be written for electrons

$$j_n(x) = i_n/e + I_o(1 - e^{-ax}) - \int_0^x R(x)dx \quad [4]$$

where $j_n(x)$ and i_n are the electron flux and the electron contribution to the faradaic current density, respectively. The light flux and electron flux are taken as positive going into the semiconductor from the solution and the hole flux is positive going out of the semiconductor to the solution. (A representation of the fluxes is shown in Fig. 1.) Equations [3] and [4] hold at all x, both within and outside of the space charge region. The net current density at any x, i, is given by Eq. [5]

$$j_p(x) + j_n(x) = (i_p + i_n)/e = i \quad [5]$$

i.e., at steady state a current (which may be zero) flows through the semiconductor phase. Equations [3] and [4] are employed in a digital or finite difference form in the simulation. The procedure follows the usual digital simulation approach (5). The semiconductor region of interest is divided into space elements of width Δx which are assigned an index K, from $K = 1$ (surface element) to $K = KMAX$ (Fig. 1). The carrier concentration within each element is assumed constant and represents the average value of p_K and n_K for holes and electrons, respectively, at that location. The electric field at the left boundary (the solution side) of element K, *i.e.*, between it and element $K - 1$, is denoted E_K and the carrier concentration at this

Table I. Comparison of differential and finite difference notation

Quantity	Differential notation	Finite difference notation
Distance, x		$(K - \frac{1}{2})\Delta x$
Migration flux of holes, $j_{p,m}$	$u_p E p$	$\frac{1}{2} U_p E_K (p_K + p_{K-1})$
Diffusional flux of holes, $j_{p,d}$	$D_p (\partial p/\partial x)$	$D_p (p_{K-1} - p_K)/\Delta x$
Electric field, E	$(1/\epsilon_0\epsilon_r) \int_0^x Q(x)dx$	$(e\Delta x/\epsilon_0\epsilon_r) \sum_{K=0}^{KMAX} (p_K - n_K + N_D - N_A)$
Recombination rate, $R(x)$ (*e.g.*, for excess holes in an n-type semiconductor)*	$K_r n(x) (p(x) - p^{eq})$	$(n_K/\tau_p n_b) (p_K - p_K^{eq})$

* $\partial p(x)/\partial t = k_r n(x) p(x) - k_f$, where k_r is the recombination rate constant given by $1/\tau_p n_b$ and k_f is the formation constant, given by $k_r n^{eq} p^{eq}$ (the superscript eq denotes the equilibrium concentrations in the n-type semiconductor). The equation in the table results when $n^{eq} \simeq n(x)$.

boundary is taken as the average of that of the two adjacent elements [*e.g.*, $\frac{1}{2}(p_K + p_{K-1})$]. A comparison of the differential and finite difference notation used in the simulation for expressing fluxes and other quantities of interest is given in Table I.

Initial conditions. The Boltzmann distribution.—The distribution of the carriers and the electric field in the semiconductor biased to a known potential (thus containing a known excess charge) and at equilibrium in the dark serves as the initial state preceding calculation of the photopotential. This equilibrium distribution is of fundamental importance in understanding and predicting the electrochemical behavior of semiconductor electrodes and is assumed to be essentially obeyed even in nonequilibrium situations (4-6). This distribution is usually obtained by using Fermi statistics for the occupancy of allowed energy states for which $\exp[(E - E_F)/kT] << 1$ and which physically means that at low occupancy, spin requirements may be relaxed. In addition, the Poisson equation must be solved using charge density terms which are based on the equilibrium distribution of carriers as functions of a coordinate which is not yet explicitly known (7). In general, a closed-form explicit relation between the potential and its gradient cannot be obtained for a doped semiconductor (8). At equilibrium in the dark, there is no faradaic current and no excess free carriers to give nonequilibrium recombination effects. Thus Eq. [3] and [4] yield

$$j_p(x) = j_n(x) = 0 \quad \text{(for all } x) \qquad [6]$$

and at the boundary of each element, the migrational flux is compensated by the diffusional one for both electrons and holes. Equating these fluxes using the digital-form equations in Table I and rearranging, we obtain

$$p_K = \frac{(D_p/\Delta x) - 0.5U_p E_K}{(D_p/\Delta x) + 0.5U_p E_K} p_{K-1} \qquad [7]$$

$$n_K = \frac{(D_n/\Delta x) + 0.5U_n E_K}{(D_n/\Delta x) - 0.5U_n E_K} n_{K-1} \qquad [8]$$

Equations [7] and [8] are used as recursion relations in an iterative computation beginning with the second element ($K = 2$). For the first element (the semiconductor surface) the boundary conditions are (9)

$$p_1 = p^o \exp(eV_s/kT) \qquad [9a]$$

$$n_1 = n^o \exp(-eV_s/kT) \qquad [9b]$$

where V_s is the applied surface potential governing the distribution. The U and D values in Eq. [7] and [8] are related to each other via the Einstein relation

$$U(\text{cm}^2\,\text{sec}^{-1}\,\text{V}^{-1}) = D/kT = 39D(\text{cm}^2\,\text{sec}^{-1}) \qquad [10]$$

at room temperature. A recursion relation for the electric field, E_K, which takes account of the semiconductor properties (dielectric constant, doping level) is obtained from Gauss' law

$$E_K = E_{K+1} + (e\Delta x/\epsilon_0\epsilon_r)(p_K - n_K + N_D - N_A) \qquad [11]$$

The boundary condition used with this relation is that in the bulk semiconductor ($K \geqq$ KMAX), $E_K = 0$. The simulation proceeds by using the applied potential in the boundary condition, Eq. [9], and then calculating n_K and p_K ($K = 1$ to KMAX) assuming any arbitrary initial distribution (usually taken as a uniform one, *i.e.*, a flatband condition). The E_K values are then calculated, using Eq. [11]. Alternate calculations of n_K, p_K, and E_K are continued until the three arrays are constant with respect to further iterations. The resulting values, besides satisfying Eq. [7]-[11], also show the following features: (*i*) a numerical integration over the electric field from the bulk to the surface of the semiconductor yields the surface potential governing the distribution (which enters into the simulation only in assigning p_1 and n_1), thus demonstrating self-consistency in V_s; (*ii*) the product $p_K n_K$ is constant and equal to n_i^2 (*e.g.*, for Ge $n_i^2 = 6.25 \times 10^{16}$ cm^{-6} at room temperature) for all K.

A problem arises in the selection of KMAX. If this value is too large, the simulation does not converge to a constant solution. Since the value of KMAX, representing the thickness of the space charge region, is not known in advance, an arbitrary value which will yield a solution is chosen and when a convergent solution is obtained, KMAX is increased. The calculation terminates with the highest value of KMAX which still gives a constant solution. Inspection of the result shows that only the very diffuse part of the space charge region, which contributes insignificantly (<1%) to the electrical state (fields, potentials) of the semiconductor cannot be displayed.

Note that in contrast to our previous simulation of space charge region formation in a semiconductor following charge injection which portrayed the time dependence of the fields and concentration profiles (1), the method employed here derives only the equilibrium properties at a given potential. The concept of time is omitted and the intermediate results have no physical meaning. Typical equilibrium concentration profiles of the mobile carriers in intrinsic and n-type Ge at several surface potentials obtained by the simulation are shown in Fig. 2-4. Figures 2 and 3 illustrate the final equilibrium situation under the same conditions as the relaxation results given previously (1). A comparison of the surface potential and space charge layer thickness (or Debye length) for a highly doped semiconductor obtained by the approximate "depletion layer" treatment, which underlies the Schottky-Mott plot (10), and our calculation is given in Table II. Note that the approximation becomes less applicable at low potentials when the concentration of the existing carriers in the space charge region cannot be neglected. Other related properties of the space charge at equilibrium, *e.g.*, surface conductivity and capacitance, can be calculated as well using the simulation results. The space charge region capacitance is obtained as the additive contribution of the individual space charge elements connected in series, each having a capacitance of $C_K = q_K/E_K\Delta x$ where q_K is the charge in element K. The surface conductivity may be deduced by considering

the elements as representing resistors connected in parallel, each with a conductivity of $e\Delta x(U_n n_K + U_p p_K)$.

The photopotential effect.—Assume the initially biased semiconductor (now at open circuit) is illuminated with a constant light intensity. We now calculate the open-circuit, steady-state photopotential using an iterative procedure similar to that just described. A treatment of the time-dependent relaxation of carrier concentration, field, and surface potential under closed-circuit conditions is treated in the next paper in this series (11). The process at open circuit is a coulostatic one; charge in the semiconductor is conserved and the effect of light is simply to rearrange the concentration and field profiles within the semiconductor. (The same would hold true even when a faradaic current flows, if the number of holes crossing the interface is balanced by electrons extracted at the semiconductor ohmic contact or vice versa.) Consider an n-type semiconductor biased at a positive potential with respect to the soluion. Under illumination the photogenerated holes will accumulate at the semiconductor surface and the electrons will move to the space charge region/semiconductor bulk boundary. The dimensions of the space charge region will change to accommodate these shifts in carrier concentration. The total charge, and hence the surface field, will remain constant, so that the semiconductor space charge region can be compared to a capacitor with a given charge which undergoes a decrease in its width resulting in an increase in capacitance and thus a decrease in the voltage drop across it under illumination. The steady state is characterized by the value of E_s, the surface field, known from the initial condition (Boltzmann distribution), and by the "minority injection level," here, the hole concentration immediately beyond the space charge region, which is directly proportional to illumination intensity. Analytical procedures exist for the rigorous determination of the injection level of minority carriers (here, holes) (12). For Ge, one can assume the existence of a diffusion layer, L_p, through which excess holes diffuse into the bulk (where $L_p = \sqrt{D_p \tau_p}$). L_p is much wider than the space charge region thickness (L_1) and if light is absorbed mainly in the space charge region, the expression obtained for the flux of holes at the space charge region/bulk boundary ($x = L_1$) is (3)

$$j_p(L_1) = D_p(\partial(\Delta p)/\partial x)_{x=L_1} = D_p(p_{L1} - p°)/L_p \quad [12]$$

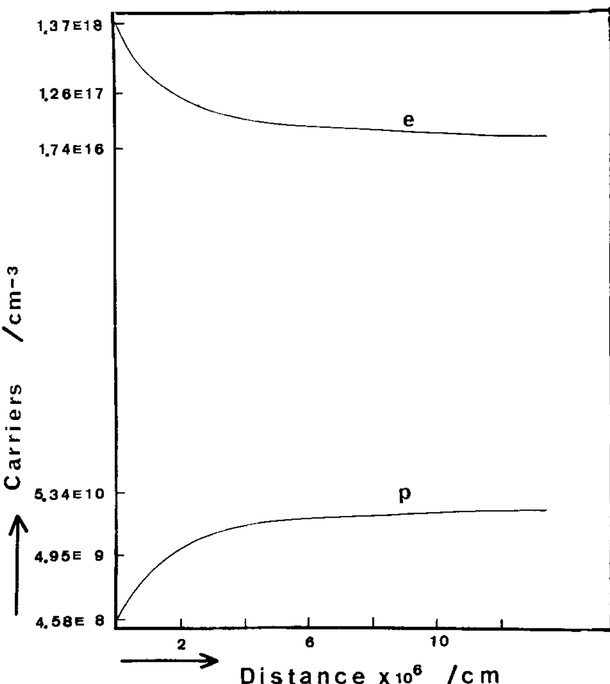

Fig. 4. Carrier concentration at equilibrium for n-type Ge (sample as in Fig. 2). $V_S = -100$ mV.

* Assumed to consist of only immobile donors; $N_D = 10^{17}$ cm^{-3}; $\epsilon_r = 100$ esu.
** $L_1 = Q/l \cdot N_D$ (depletion layer width).
*** $V_s = E_s/2L_1$ (E_s, surface field; V_s, surface potential).

From Eq. [3] this same flux is given by

$$j_p(L_1) = -I_o(1 - e^{-aL_1}) + \int_0^{L_1} R(x)dx \quad [13]$$

Equations [12] and [13] allow the assignment of an initial value to p_{L1} (assuming at first no recombination in the space charge region) which is modified during the simulation due to the recombination term, using the given values of I_o, a, and the semiconductor properties ($D_p\tau_p$). The equivalent expression for the electrons is

$$n_{L1} = n^o + (p_{L1} - p^o) \quad [14]$$

because in this region electroneutrality essentially holds (13). In more complicated cases, when L_p and L_1 are comparable in magnitude, light is absorbed outside the space charge region as well and linearization of the diffusion layer is unjustified. In this case a simulation involving a fuller treatment of the diffusion layer can be undertaken to find the injection level.

p_{L1} and n_{L1} serve as boundary conditions for the recursion formula between the elements, this time taken from the space charge region/semiconductor bulk boundary to the surface which at the steady state, according to Eq. [3] and [4] and Table I, is given by

$$p_K = \frac{L(K) - \Sigma R(K) + [0.5\, U_p E_{K+1} + (D_p/\Delta x)] \cdot p_{K+1}}{(D_p/\Delta x) - 0.5\, U_p E_{K+1}} \quad [15a]$$

$$n_K = \frac{L(K) - \Sigma R(K) - [0.5\, U_n E_{K+1} - (D_n/\Delta x)] \cdot n_{K+1}}{(D_n/\Delta x) - 0.5\, U_n E_{K+1}} \quad [15b]$$

where

$$L(K) = I_o(1 - e^{-a(K-\frac{1}{2})\Delta x}) \quad [\mathrm{cm^{-2}sec^{-1}}] \quad [16]$$

$$\Sigma R(K) = \sum_{K=1}^{K} \left(\frac{p_K - p_K^{eq}}{\tau_p} \frac{n_K}{n^o} \Delta x \right) \quad [\mathrm{cm^{-2}sec^{-1}}] \quad [17]$$

The electric fields are calculated with Eq. [11], this time proceeding from the surface to the bulk because the surface field is known.

Thus, starting with the semiconductor in the dark at a surface potential V_s, the condition under illumination is simulated by repetitively using Eq. [12]-[17] until three new constant arrays (holes, electrons, and electric field) are obtained. A numerical integration over the fields yields a new surface potential, V_s', where the photopotential, ΔV, is $V_s - V_s'$.

Results

The simulated distribution of carriers with and without illumination is shown in Fig. 5; Fig. 6 compares the electric fields under these conditions. The dependence of the photopotential on the equilibrium surface potential which exists before illumination obtained by the simulation compared to the calculation method of Johnson (4) is given in Fig. 7 and the relation between the photopotential and the illumination intensity obtained by these two methods is shown in Fig. 8. Johnson's method of obtaining the photopotential usually uses the assumption that the Boltzmann distribution and the same analytical expression relating the potential and the field for the semiconductor holds both in the dark and as well as in the light (3, 4). This assumption was checked by the digital simulation and indeed we find that Eq. [18] and [19] hold

$$p_s' \simeq p_{L1}' \exp(eV_s'/kT) \quad [18]$$

$$n_s' \simeq n^o \exp(eV_s'/kT) \quad (n_{L1}' \simeq n^o) \quad [19]$$

where the primed quantities denote values under illumination. This assumption applies, as has been pointed out previously (12), because there is fast transport within the semiconductor phase. Thus only a very slight imbalance between the diffusional and the migrational fluxes (compared to their absolute magnitude) has to exist to provide the nonequilibrium flux which corresponds to moderate illumination. Hence, in practice, even under illumination, the carriers and electrical field will be distributed in such a way that $u_i n_i E_i \simeq D_i(\partial n_i/\partial x)$, which leads to the same functional relation as in the dark.

Semiconductor Electrodes

IX. Digital Simulation of the Relaxation of Photogenerated Free Carriers and Photocurrents

Daniel Laser and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

A digital simulation of the photoprocess at a semiconductor electrode is described. The simulation model accounts for photogeneration, recombination, and transport of excess free carriers within the semiconductor phase. The origin of the photopotential in the absence of faradaic current is elucidated. Quantitative current efficiency-potential curves for the photocurrents under a variety of conditions are calculated for n-type TiO_2 and these are compared to experimental results.

In previous papers in this series we have introduced the use of digital simulation methods for the treatment of semiconductor electrodes. In Ref. (1) the relaxation of free carriers following charge injection, with and without surface states, was described. In Ref. (2) a method of deriving the semiconductor electrode characteristics, equilibrium or steady state, at open circuit in the dark or under constant illumination, was presented. When a semiconductor electrode at equilibrium and in contact with solution is illuminated, a certain time elapses before the photoeffects are observed. During this time a redistribution of free carriers and charges in the electric field in the space charge region occurs. [When the semiconductor electrode/solution interface is blocked to charge transfer, the new distribution of free carriers in the space charge region under illumination will cause a change in the potential of the electrode (the photopotential effect).] Frequently, illumination of the electrode is accompanied by charge transfer to solution species and this gives rise to a photocurrent. For example, irradiation of n-type TiO_2 with light of energy larger than the bandgap energy will result in the oxidation of water (3, 4), while

* Electrochemical Society Active Member.

Key words: semiconductors, digital simulation, photoelectrochemistry, photogalvanic cells.

cathodic photocurrents arise at p-type semiconductor electrodes (5, 6). Numerous examples of photogalvanic effects and analytical treatments of these have been given (7, 8)

In this paper we treat the transient behavior of a semiconductor electrode following the onset of illumination and the photocurrents which are produced. The semiconductor electrode characteristics which affect the magnitude of the photocurrent are discussed and a comparison of the simulated light intensity-current and current-potential behavior with some experimental results given.

Relaxation of Photogenerated Carriers in the Absence of Faradaic Current: Physical Model

The rate of change of the concentration of excess free carriers (*e.g.*, holes, the minority carriers in an n-type semiconductor) during illumination is governed by their rate of generation by the adsorbed light, their recombination, and their transport

$$\partial \Delta p/\partial t = g(x) - (1/\tau_p)(n(x)/n_b)\Delta p + D_p(\partial^2 \Delta p/\partial x^2) + U_p \partial[\Delta(E \cdot p)]/\partial x \quad [1]$$

where $\Delta p = p(x) - p(x)^{eq}$, $\Delta E = E(x) - E(x)^{eq}$. A similar expression can be written for excess electrons, Δn. The electrical field vector in the x direction is governed by Gauss' law

$$\frac{d\Delta E(x)}{dt} = \frac{e}{\epsilon_0 \epsilon_r{}^{\infty}} \int^{x} \left[\frac{d}{dt}(p - n) \right] dx \quad [2]$$

Equations [1] and [2] were written in finite difference form by using the same space division and representation of fluxes given in Table I of Ref. (2); the actual expressions are given in the Appendix. The general notation and the terms in Eq. [1] and [2] are the same as those given in Ref. (1) and (2) and are discussed only briefly here. The generation function for free carriers by light, $g(x)$, can be written as

$$g(x) = I_0 a \exp(-ax) \quad [\text{cm}^{-3}\text{-sec}^{-1}] \quad [3]$$

I_0 is the incident light flux at the electrode surface ($\text{cm}^{-2}\text{-sec}^{-1}$) and a is the absorptivity of the light [cm^{-1}]. We assume here that all of the light absorbed leads to free carrier formation. The treatment is easily modified for less than unit efficiency of carrier formation by the introduction of a quantum efficiency factor. The term $(1/\tau_p)\Delta p$ is the usual expression (9) for the recombination rate of excess minority free carriers in the semiconductor bulk, where the process is assumed to be pseudo-first order with respect to the excess minority carriers (*i.e.*, $1/\tau_p = k_r n_b$, where n_b is the bulk concentration of electrons and k_r is the second order recombination rate constant). The term $n(x)/n_b$ is introduced to account for this effect inside the space charge region, where the concentration of electrons is not equal to the bulk value. The last two terms on the right-hand side of Eq. [1] are the divergence of the flux of excess free carriers by diffusion and migration. For a numerical calculation of the migration term, the properties of the semiconductor at equilibrium [$p(x)^{eq}$, $E(x)^{eq}$] have to be known. Similarly, calculation of the recombination term requires knowledge of $n(x)^{eq}$, in addition to $\Delta n(x)$. Thus, a simulation of the semiconductor electrode free carrier and electric field distribution in the dark at a given potential V_s, as given in Ref. (2), provides the initial conditions which precede simulation of the photoeffects. The usual simulation techniques were employed [see the Appendix and Ref. (10) and (11)]. Changes in Δp and Δn which occur during a short time interval, Δt, based on the carrier concentrations and fields from the previous time interval, were calculated. These changes are used to calculate new values of $p(x)$ and $n(x)$, as well as a new field distribution $E(x)$, by Eq. [2]. These new values are then used for calculation of the values of Δp and Δn in the next time interval, etc. The distribution of excess free carriers and electric field are mutually dependent, since $E(x)$ depends upon the charge and the migration of the free carriers depends upon the field.

Results

The distributions of excess carriers for an n-type TiO_2 electrode at two different times after the onset of illumination are shown in Fig. 1. In this example, the n-TiO_2 electrode at equilibrium in the dark was assumed to be initially biased positively ($V_s = 0.8$V) to form a depletion layer. In the time interval considered, only very slight changes in electric field are observed. The changes in the charge density distribution, although noticeable, are still very small compared to the charge density at equilibrium or to the changes in charge density which exist at the steady state. Consider some aspects of the relaxation process which can be observed from the transient behavior. The generation function is an exponential one with respect to distance from the surface so that with the semilog axes of Fig. 1 it would be drawn as a straight line with a slope of $-a$. However, except for the very first instants following the onset of illumination, the shape of the perturbation (the light generation function) is not apparent. Because of the rapidity of the transport processes in the semiconductor phase, the distribution of excess free carriers reflects rather the momentary existing driving forces (electric fields and concentration gradients). Thus, the excess holes accumulate at the semiconductor surface (assuming no outlet to solution), while the electrons accumulate near the space charge region/bulk boundary. At this stage, some of the holes which are produced outside the space charge region and which escape recombination enter the space charge region by diffusion. Only at a later time, when the surface concentration of holes increases further, are they reflected back from the surface by diffusion, so that at the steady state [as in Ref. (2)] a flux of holes leaves the space charge region toward the bulk. At this time the concentration excess of holes outside the space charge region is about equal to the concentration excess of electrons ($\Delta n = \Delta p$). This steady-state situation could not be achieved within the time domain of the transient simulation. The reason for this will be discussed in some detail, because it is directly related to the general problem of simulation of the photoprocess. The steep concentration and field profiles which exist inside the space charge region require a

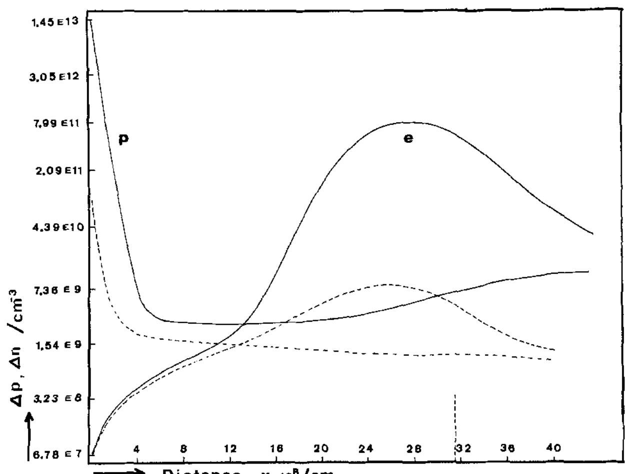

Fig. 1. Excess carrier concentrations in n-type TiO_2 (dashed line) 1.44×10^{-11} sec and (solid line) 1.16×10^{-9} sec after turning on illumination (10^{16} photons cm^{-2} sec^{-1}). $V_s = 0.8$V (in dark); $n° = 10^{17}$ cm^{-3}; $p° = 0$; $\epsilon_r = 100$ esu; $U_n = 100$ and $U_p = 50$ $\text{cm}^2\text{-sec}^{-4} \cdot \text{V}^{-1}$; $a = 5 \times 10^4$ cm^{-1}; $\tau_p = 10^{-9}$ sec. Vertical dashed line shows space charge region/bulk semiconductor boundary.

fine division of space elements ($\Delta x \simeq$ 20-50Å) to represent the quantities there to a sufficient accuracy in the digital simulation. Because of this, combined with the high value of the transport coefficients of the free carriers, a very short time interval must be used as a simulation time step (*ca.* 10^{-14} sec) and the total simulated time is limited to the nanosecond range even after 10^5 simulation steps. For reasonable fluxes of light to be calculated (*e.g.*, 10^{16} photons cm^{-2} sec^{-1}), the excess of free carriers added to the space charge region within this time interval is far smaller than the amount which will be present there at the steady state to produce the photopotential. An attempt to overcome this problem by using higher light fluxes or slower transport coefficients (which, numerically, have the same effect) results in a distorted picture in which the generation of carriers is very exaggerated with respect to their transport. Thus the transport processes (migration and diffusion) dominate all others. The speed at which these driving forces, especially inside the space charge region, dissipate a large portion of any local perturbation (provided it is not too large) is what underlies the possibility of using the Boltzmann distribution in cases where actual equilibrium does not exist (7, 8). The simulated transient behavior allows us to deduce the sequence of events which leads to the steady state and causes the photopotential effect. This is shown schematically in Fig. 2. The charge density distributions at equilibrium in the dark and under illumination are given in Fig. 2a. Figure 2b shows the redistribution of the charge density caused by the changes Δp and Δn in the light. The total charge is conserved and so is the surface field, but its distribution shows an accumulation of positive charge at the surface and a loss of positive charge at the space charge region/bulk boundary (where the excess of electrons which accumulate there compensates for the diffuse positive charge of the space charge region). The corresponding electric field distributions are shown in Fig. 2c. The area between the field curves, *i.e.*, the integration of the difference in the electric field with respect to distance from the bulk semiconductor to the surface, is the decrease in surface potential due to illumination, the photopotential

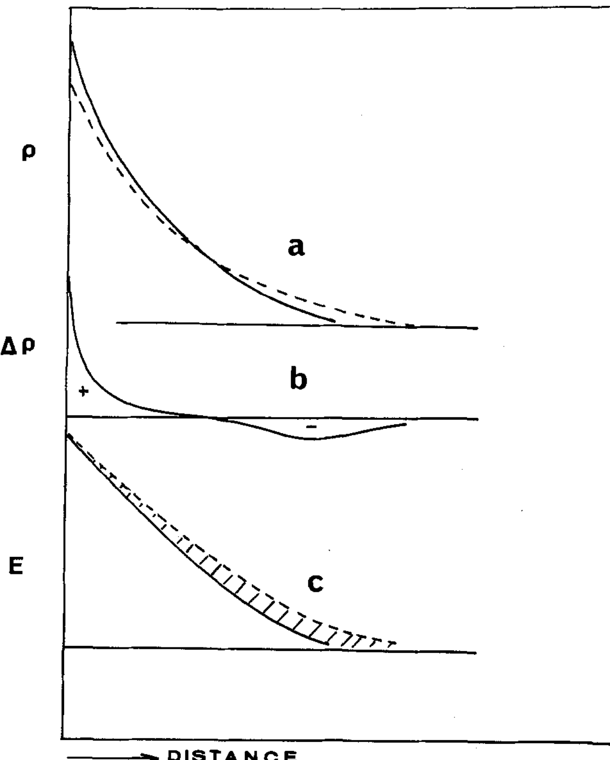

Fig. 2. Schematic representation of the production of the photopotential. (a) Charge density (ρ) distribution in the space charge region (dashed line) in the dark; (solid line) under illumination. (b) Excess charge density distribution with illumination due to redistribution of excess carriers as shown in Fig. 1, ($\Delta\rho^+ = \Delta\rho^-$). (c) Electrical field (dashed line) in the dark and (solid line) under illumination. The area between the curves represents the photopotential.

Photocurrent in the Absence of Kinetic Complications

If charge transfer across the semiconductor/solution boundary is possible, the situation differs from the open-circuit case described above. Two extreme cases can be considered. If the rate constant for charge transfer is infinitesimal, the open-circuit case, which is characterized by very small faradaic currents and the photopotential effect, is approached. At the other extreme, if the charge transfer to solution is limited only by the combined effect of generation/recombination and transport of carriers within the semiconductor phase, only a small accumulation of excess free carriers occurs leading to a smaller photopotential and larger faradaic currents. Thus, the rate constant for charge transfer to solution will have a key role in determining both the photocurrent and the electrical state of the semiconductor.

We simulate here the fast charge transfer case and calculate the photocurrent which is determined by the processes within the semiconductor phase. We use n-type TiO_2, a stable semiconductor electrode for which the photocurrent has been widely described (3, 4), as a model. The very low concentration of minority carriers (holes) in this sample somewhat simplifies the calculation because no oxidation current (hole injection to solution) exists in the dark.

The photocurrent density due to photogenerated holes within the semiconductor biased to positive potentials is expressed as the product of the charge transfer rate constant k_p ($cm \cdot sec^{-1}$) and the hole concentration at the surface ($x = 0$) (or in the simulation for space element, $K = 1$)

$$i_{p,f} = ek_p p(o) \quad [4]$$

The rate constants were chosen to be sufficiently large that the steady photocurrent calculated in the simulated time domain was independent of the value of k_p. The surface concentration of holes was found to be inversely proportional to k_p. The effect of the magnitude of k_p is shown in Fig. 3. The electron distribution is also affected by k_p, because for every hole which is injected into the solution, an electron is collected by the metallic contact to the semiconductor electrode

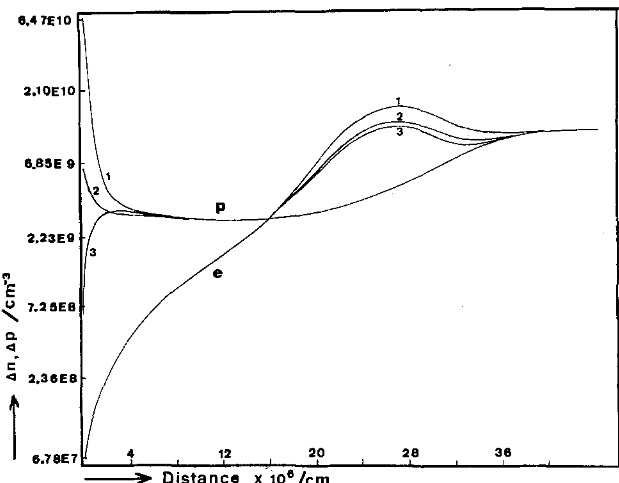

Fig. 3. Effect of k_p on the concentration profiles of excess free carriers. All conditions as in Fig. 1, except with holes transfer to solution with k_p values of (1) 1.39×10^5; (2) 1.39×10^6; (3) $k_p = 1.38 \times 10^7$ cm/sec. In all cases the calculated photocurrent, $i_{p,f}$, was 1.437 mA.

and is delivered to the counterelectrode. Although the effect of k_p is most prominent at the semiconductor surface, it also determines the whole level of excess holes inside the space charge region and hence the flux of holes which will enter this region. Under actual conditions the situation may be far more complex because k_p may depend upon the potential drop in the Helmholtz layer at the semiconductor/solution interface, $\Delta\phi_H$, *e.g.*, it could be given by $k_p^o \exp(\beta e \Delta\phi_H/kT)$ and where k_p^o may have a much smaller value than that used in the simulation. At the instant after illumination only a small photocurrent is expected, resulting in a pronounced accumulation of excess carriers in the space charge region, in a manner similar to that for the open-circuit case. This accumulation causes a photopotential to be built up gradually, which in a potentiostatic experiment will result in a gradual change in $\Delta\phi_H$ and in an increase in k_p. At the steady state the charge transfer rate will be sufficiently fast to prevent any further accumulation of excess free carriers inside the space charge region. We did not simulate this suggested sequence of events which extends over two completely different time domains. Moreover, k_p could not be made too small because under these conditions, even after a lengthy computation, a steady state was not achieved. Therefore, we can only speculate that as long as migration is the predominant driving force (high fields and band bending) and k_p is not so small that a high accumulation of excess carriers is produced inside the space charge region thus changing considerably the fields there, only a minor dependence of photocurrent on k_p is expected. At low band bending, on the other hand (which would usually occur at the foot of the photocurrent-potential wave), diffusion may be the main transport process. The photocurrent will then strongly depend upon the diffusional flux of the holes inside the space charge region and towards the surface, which in turn will be determined by the concentration profile present and thus on k_p.

Results

Photocurrent-potential curves assuming rapid charge transfer to solution under several different sets of conditions were simulated (Fig. 4). Curve a represents the steady-state currents for the electrode initially (in the dark) held at the indicated potential where all of the imposed potential is assumed to drop inside the semiconductor space charge region. No photopotential is observed. The dashed line a shows the calculated curve if electrons are allowed to cross the surface as well, to reduce the species just formed by the hole injection process, or to react with holes at the surface at a rate which is proportional to the absolute concentration of electrons at the surface. Both processes will have the same effect in reducing the net oxidation current. This back-reaction effect could be of importance, since the photosensitized oxidation at the semiconductor electrode frequently produces a species which is thermodynamically reducible at the electrode potential. For any value for the rate constant, k_n, chosen for this "back-reaction" effect, the observed photocurrent is found to rise very steeply (almost discontinuously) with potential. This steep rise is caused by the fact that the absolute electron concentration at the surface is an exponential function of potential. Such abrupt rises in photocurrent are not observed experimentally. A calculation in which the excess of electrons at the surface, rather than their absolute numbers, determines their contribution to the photocurrent is shown as curve a″. A simple model for surface recombination, similar to that which was presented previously (1) results in the expression

$$i_f = e[k_p \Delta p(o) - k_n \Delta n(o)] \qquad [5]$$

For the case under consideration, for holes, $\Delta p \simeq p$, while for electrons, $\Delta n = n - n^{eq}$. This effect modifies somewhat the foot of the photocurrent-potential wave.

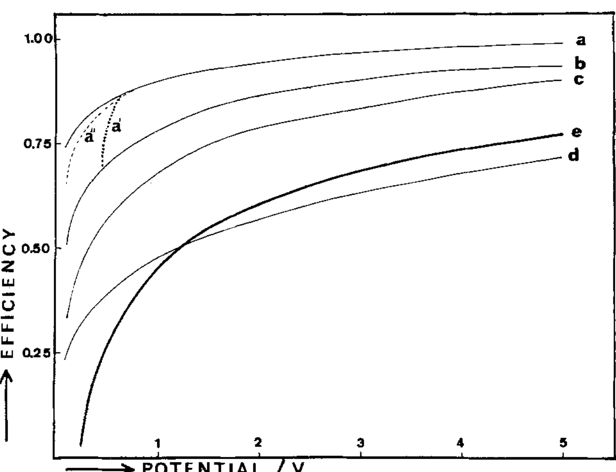

Fig. 4. Simulated photocurrent-potential curves for n-TiO_2. Electrode as in Fig. 1, $I_o = 10^{16}$ photons $cm^{-2}sec^{-1}$, $k_p = 2.78 \times 10^6$ cm/sec, except as noted below. Efficiency $= i_{p,f}/I_o$, with $i_{p,f}$ given in holes per second. (a) $\tau_p = 10^{-9}$ sec; (a′) as in (a), assuming electrons cross to solution at a rate proportional to their absolute number at the surface, with a rate constant $k_n = 1.39 \times 10^6$ cm-sec^{-1}; (a″) as in (a) assuming electrons cross to solution at a rate proportional to their excess number at the surface, $k_n = 1.39 \times 10^6$ cm-sec^{-1}; (b) as in (a″), $a = 3 \times 10^4$ cm^{-1}; (c) as in (b), $\tau_p = 10^{-10}$ sec; (d) $a = 3 \times 10^4$ cm^{-1}, $\tau_p = 5 \times 10^{-11}$ sec, $n° = 4 \times 10^{17}$ cm^{-3}; (e) experimental efficiency curve for a single crystal TiO_2 for water photo-oxidation (c axis normal to solution) measured at 375 nm; solution pH = 4.0; the potential axis in this case is the electrode potential vs. SCE.

At more positive potentials the excess of surface electrons is negligible (since they are repelled from the surface) compared to the excess of holes, and no "back-reaction" effect is noticed.

Two other factors govern the photocurrent and enter into the simulation. The first is the bulk recombination rate constant for the excess minority carriers ($1/\tau_p$). This influences the number of holes which are generated outside the space charge region which will be collected by the space charge region and delivered to the surface. Photogenerated holes which are produced at a distance greater than $\sqrt{\tau_p D_p}$ from the space charge region/bulk boundary are practically lost and will not contribute to the photocurrent. The effect is illustrated by Fig. 5. An extremely high bulk recombination rate constant can even reverse the direction of

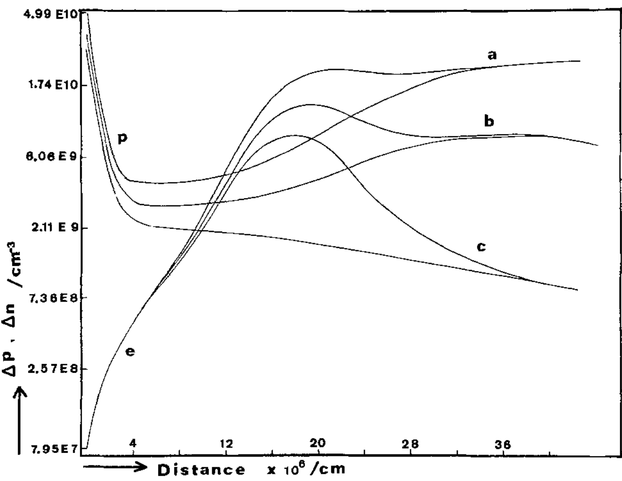

Fig. 5. Effect of bulk recombination rate constant for excess holes on the photocurrent and concentration profiles of excess free carriers. Electrode and illumination as in Fig. 1; $V_s = 0.4$V. (a) $\tau_p = 10^{-9}$ sec, $i_{p,f} = 1.096$ mA; (b) $\tau_p = 10^{-10}$ sec, $i_{p,f} = 0.8881$ mA; (c) $\tau_p = 10^{-11}$ sec, $i_{p,f} = 0.7186$ mA.

diffusion of holes, resulting in a hole flow from the space charge region to the bulk semiconductor. A second factor, directly related to the first, is the relative dimension of the space charge region to the light penetration depth. A more efficient photoprocess will be observed if practically all of the photogeneration process of free carriers occurs within the space charge region where the excess of holes suffer very little recombination and are delivered promptly to the surface by migration. The depletion layer thickness is determined by the potential imposed on the semiconductor electrode and its width can be taken as being proportional to the square root of the imposed potential (12). The upper quantum efficiency limit, which asymptotically approaches unity, represents the situation of a high surface potential resulting in an extended space charge region in which all of the light is absorbed. All of these simulated observations are consistent with Gartner's approximate treatment of the subject (12). Curves b, c, and d in Fig. 4 show the calculated results for variations in a, τ_p, and N_D (which influences the thickness of the space charge region). Curve e shows an experimental efficiency curve measured at a single crystal of TiO_2 in a pH = 4.0 solution with a monochromatic light of wavelength 375 nm. While the calculated saturation current can be adjusted to fit the experimental one, a larger discrepancy is revealed between the simulated and the experimental curve on the rising portion of the wave. A better fit to the experimental results will probably require consideration of the previously discussed kinetics of the charge transfer and other solution processes as well.

APPENDIX

Equation [1], the corresponding equation for electrons, and Eq. [2] were simulated according to the procedure shown in the Appendix of Ref. (1) and the space division and digital notation which were used in Table I of Ref. (2). For holes in the case of n-TiO_2, with a bandgap of 3.0 eV, we can write

$$p^{eq}\Delta E \simeq 0 \quad \text{and} \quad \Delta p \Delta E \simeq 0 \qquad \text{[A-1]}$$

$p^o = p^{eq} \simeq 0$ across the whole semiconductor. The change of concentration of holes in element K within a time interval Δt is

$$\Delta p_K = L_K - (\Delta t/\tau_p)\cdot(n_K/n_b)\cdot p_K + DMP(p_{K-1} - 2p_K + p_{K+1}) + 0.5\, UMP\{E_{K+1}(p_K + p_{K+1}) - E_K(p_K + p_{K+1})\} \qquad \text{[A-2]}$$

For electrons, a more complicated expression arises because of the importance of the term $U_n\partial\Delta(E\cdot n)/\partial x$

$$\Delta(E\cdot n) = E^{eq}\Delta n + n^{eq}\Delta E \qquad \text{[A-3]}$$

where $\Delta n = n - n^{eq}$ and $\Delta E = E - E^{eq}$. Here, the term $n^{eq}\Delta E$ cannot be neglected, especially near the space charge region boundary. The resulting expression for electrons is

$$\Delta(\Delta n) = L_K - (\Delta t/\tau_p)(n_K/n_b)p_K + DMN(\Delta n_{K-1} - 2\Delta n_K + \Delta n_{K+1}) + 0.5\, UMN\{E_K{}^{eq}(\Delta n_K + \Delta n_{K-1}) - \Delta E_{K+1}{}^{eq}(\Delta n_K + \Delta n_{K+1}) + \Delta E_K(n_K{}^{eq} + n_{K-1}{}^{eq}) - \Delta E_{K+1}(n_K{}^{eq} + n_{K+1}{}^{eq})\} \qquad \text{[A-4]}$$

In Eq. [A-2] and [A-4] the following terms apply

$$L_K = (I_o a)\exp[-a(K - 1/2)\Delta x] \qquad \text{[A-5]}$$

$$DMN = D_n\Delta t/\Delta x^2 \qquad DMP = D_p\Delta t/\Delta x^2$$

$$UMN = U_n\Delta t/\Delta x \qquad UMP = U_p\Delta t/\Delta x$$

The resulting change in the electric field caused by changes in Δp_K and Δn_K is

$$\Delta E_K = (e\Delta x/\epsilon_o\epsilon_r)(\Delta p_K - \Delta n_K) + \Delta E_{K+1} \qquad \text{[A-6]}$$

The following boundary conditions apply

$$\Delta p_{K\to\infty} = 0, \quad \Delta n_{K\to\infty} = 0, \quad E_{K\to\infty} = 0 \qquad \text{[A-7]}$$

The calculation cannot be extended in reasonable simulation times to K values that rigorously will satisfy the conditions of Eq. [A-7]. Instead, the following boundary condition was chosen

$$\Delta p_{KMAX} = \Delta p_{KMAX-1}\exp\{-\Delta x/(\tau_p D_p)^{1/2}\} \qquad \text{[A-8]}$$

$$\Delta n_{KMAX} = \Delta p_{KMAX} \quad \Delta E_{KMAX} = 0$$

where $\Delta x \cdot KMAX$ is far outside the space charge region but still not in the bulk.

For the first element ($K = 1$) (the semiconductor surface) within the semiconductor, only transport to the second element occurs. Charge transfer to solution is expressed, when desired, as the product of a rate constant k_p with the hole concentration in the first element. The initial conditions are the equilibrium distribution of carriers and electrical fields which are first obtained by the simulation procedure previously described (2).

LIST OF SYMBOLS

a	absorptivity of light
D_p, D_n	diffusion coefficients of holes, electrons
$E(x)$	electric field
$E(x)^{eq}$	electric field at equilibrium
$\Delta E(x)$	change in electric field with respect to equilibrium $[E(x) - E(x)^{eq}]$
$g(x)$	generation function of light
i_f	total faradaic current
$i_{p,f}$	faradaic current due to holes
I_o	flux of light
k_p, k_n	charge transfer rate constants for holes, electrons
k_r	recombination rate constant
K	simulation distance index
$n(x)$	electron concentration
$n(x)^{eq}$	electron concentration at equilibrium
n_b	electron concentration in bulk semiconductor
Δn	excess concentration of electrons $[n(x) - n(x)^{eq}]$
$p(x)$	hole concentration
$p(x)^{eq}$	hole concentration at equilibrium
p_b	hole concentration in bulk semiconductor
Δp	excess concentration of holes $[p(x) - p(x)^{eq}]$
Δt	simulation time interval
U_p, U_n	mobility of hole, electron
x	distance from electrode surface
Δx	simulation space element thickness
β	transfer coefficient
$\Delta\phi_H$	potential drop in the Helmholtz layer
ϵ_o	permittivity of free space (mks)
ϵ_r	dielectric constant
τ_p	average lifetime of excess minority carrier (hole) in bulk n-type semiconductor

Analysis of Multiple Reaction Sequences in Flow-Through Porous Electrodes

Richard Alkire* and Ronald Gould**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The role of multiple reactions in flow-through porous electrodes has been investigated theoretically. The reaction sequences studied include simultaneous deposition of several metals, deposition of a metal in the presence of a redox system, and an ECE sequence which is characteristic of many electro-organic synthesis reactions. The model accounts for mass transport, multiple charge transfer reactions, homogeneous chemical reactions, ohmic and geometric parameters. Results are compiled in a series of graphs which elucidate electrode behavior over a wide region of parameter space.

One advantage of electrochemical processes is that a high level of selectivity for a desired reaction product can often be achieved through careful control of the potential under which reaction proceeds. On the other hand, the attainment of economically high volumetric reaction rates often requires optimizing around competing needs for large surface area, adequate mass transfer, and low ohmic resistance. Although flow-through porous electrodes are advantageous for achieving high reaction rates per unit volume, these devices often exhibit substantial potential variations over their interior surface so that the original electrochemical advantage of selectivity may thereby be lost. The purpose of this investigation is to develop theoretical methods for predicting the selectivity of flow-through porous electrodes in systems where multiple reactions occur, and to illustrate how such predictions can be compiled for use in engineering design.

Literature Review

The use of fixed bed porous electrodes with a single electrode reaction has been recently reported for stripping copper (1), depositing antimony (2) and copper (3-5), carrying out redox reactions with iron (6) and ferricyanide couples (5, 7, 8), detecting dissolved gases (9-11), and for precipitating anionic species (12). Earlier work has been reviewed with emphasis on battery applications (13) for which a single electrode reaction is the preferred mode of operation. The extensive publications of Sioda, reviewed in Ref. (13), are especially noteworthy since they established many experimental procedures and theoretical methods of analysis. Many additional porous electrode studies are known which involve multiple electrochemical reactions in order to accomplish simultaneous removal of several metal ions from mixed solutions (14-21); separation of quinones (22), radioactive nuclides (23), and halide ions (24); and reduction of metal ions in the presence of competing reactions (25). Reaction schemes involving coupled electrochemical and homogeneous chemical steps have also been used in porous electrode cells for coulometric and preparative applications (12, 26-29), and for electro-organic synthesis applications (30-36). It is abundantly clear that multiple reaction sequences are commonly encountered in many fixed bed porous electrode applications.

Theoretical considerations of multiple reaction effects in porous electrodes have led to the development of simple criteria for choosing the flow velocity and applied current such that (*i*) the potential distribution is sufficiently uniform that side reactions are avoided (8, 13, 37), or (*ii*) the residence time is convenient for maximizing the production of an intermediate species in a sequential reaction (27). In both cases, the approximate procedures are based on the need to attain a high degree of selectivity in the presence of multiple reactions. Therefore it seems appropriate to develop a more extensive theoretical basis for predicting the current and potential distribution behavior of porous electrodes in the presence of multiple homogeneous and heterogeneous reactions.

Theoretical Formulation

The geometry of the porous electrode system under study is indicated in Fig. 1a. Electrolyte flows in the direction of the y coordinate; the electrode is of thickness l. The counterelectrode may be located either upstream or downstream from the porous electrode; in Fig. 1a, a downstream location is shown. Other details of cell construction are not shown since they are not included in the model equations. Electrolyte flows through the porous electrode, supplying reactants to the interior surface where electrochemical reaction occurs. The local reaction rate is a function of position since the potential and species concentrations vary along the reactor length owing to ohmic and transport limitations.

Figure 1b illustrates how the processes in the interior region of the porous electrode are envisioned by the model. The solid surface of the interior region, upon which electrochemical charge transfer occurs, is of arbitrary shape and is accounted for in the model only by a specific area term. The species concentration distributions at the solid surface, $c_i^s(y)$, are different from the species concentration distributions in the well-mixed core, $c_i(y)$, owing to the presence of a mass transfer diffusion layer between core and surface. The diffusion layer is assumed to occupy only a small fraction of the electrolyte volume so that (*i*) if homo-

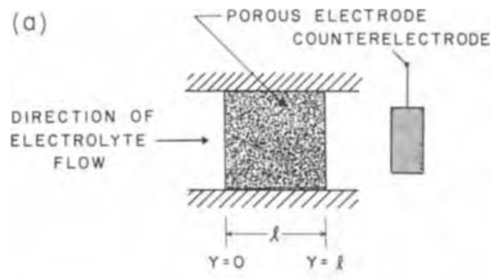

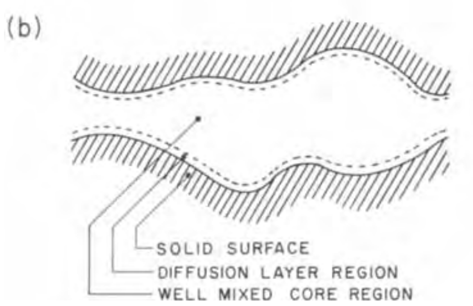

Fig. 1. (a) Configuration of electrode system. (b) Model of pore interior region.

geneous chemical reactions occur, they occur primarily in the well-mixed core region, and (*ii*) convection and axial diffusion effects occur only in the core region.

The equations representing the system are based on several assumptions: (*i*) isothermal operation takes place under steady-state conditions, (*ii*) the electrode is isopotential, its porosity is uniform, and the pore dimensions are large with respect to the double layer thickness, (*iii*) conduction in the electrolyte obeys Ohm's law, and migration effects are negligible, and (*iv*) convection through the porous electrode is by steady plug flow without channeling. These constraints allow the model equations to be written in one-dimensional form wherein both the heterogeneous electrode reactions and the homogeneous chemical reactions appear as pseudohomogeneous source terms.

In the electrolyte there are i reactive solute species which take part in a total of j reactions, which may be either heterogeneous or homogeneous. The stoichiometry of the reactions is defined by

$$\sum_i \nu_{ij} M_i^{+z_i} = n_j e^- \quad [1]$$

In addition to the i reactive solute species, there may be additional inert species which do not take part in the reactions and which are not taken into account in the analysis.

The steady-state one-dimensional species conservation equations are

$$D_i \frac{d^2}{dy^2}[c_i(y)] - v\frac{d}{dy}[c_i(y)] = \sum_j \nu_{ij} S_{ij} \quad [2]$$

Any particular reaction involving species i will be either heterogeneous (electrochemical) or homogeneous (chemical). Heterogeneous reactions take place on the interior surface and obey a rate equation in which the surface concentration appears

$$S_{ij} = \frac{a}{n_j \mathbf{F}} f_j^e[c_i^s(y), \phi(y)] \quad [3]$$

Homogeneous reactions take place in the "core" of the flowing electrolyte within the porous electrode and obey rate equations in which the core concentrations appear

$$S_{ij} = f_j^h[c_i(y)] \quad [4]$$

The specific form of the rate equations f_j^e and f_j^h will of course depend on the particular reactions as is illustrated below with several examples.

The local concentration difference between surface and core are related to the heterogeneous reaction rate through the mass transfer coefficient (5, 6, 13)

$$f_j^e[c_i^s(y), \phi(y)] = \nu_{ij} n_j k_i \mathbf{F}[c_i^s(y) - c_i(y)] \quad [5]$$

The one-dimensional charge balance equation is

$$\frac{d^2}{dy^2}[\phi(y)] = \frac{a}{\kappa}\sum_j f_j^e[c_i^s(y), \phi(y)] \quad [6]$$

Equations [2], [5], and [6] comprise a set of (2i + 1) relations which are sufficient in number to determine the (2i + 1) unknown functions: $c_i(y)$, $c_i^s(y)$, and $\phi(y)$. Whereas Eq. [5] is algebraic, [2] and [6] are differential equations and therefore require boundary conditions.

When the counterelectrode is upstream

at $y = 0$

$$c_i = c_i^o$$

$$\phi = \phi^o$$

at $y = l$

$$\frac{dc_i}{dy} = \frac{d\phi}{dy} = 0 \quad [7]$$

When the counterelectrode is downstream

at $y = 0$

$$c = c_i^o$$

$$\frac{d\phi}{dy} = 0$$

at $y = l$

$$\frac{dc_i}{dy} = 0$$

$$\phi = \phi^o \quad [8]$$

Several different types of reaction sequences were investigated. For each particular system, the set of (2i+1) model equations was solved with use of a numerical procedure. The equations were first linearized about a trial solution and written in finite difference form. The resulting set of simultaneous tridiagonal matrices was then inverted with an IBM 360/75 computer (38). The solution of the nonlinear problem was gained by successive approximation until convergence to within 0.01% was obtained for all unknown functions. The number of iterations needed for convergence was dependent on the particular system under study, but was usually less than 15. The choice of 100 mesh points usually gave results which were accurate to within the line width used in graphical representation of the results.

Results and Discussion

Three different example reactions have been investigated: cathodic deposition from electrolyte containing a mixture of metal ions, cathodic deposition of a metal from an electrolyte containing an aggressive redox couple, and a reaction sequence involving both electrochemical and homogeneous chemical reactions. In each example, the number of parameters is sufficiently large that it is not possible to compile simple rules of thumb which will adequately describe the electrochemical system. Conversely, the conduct of computer calculations over wide regions of parameter space have indicated qualitative trends which might not have been identified on the basis of intuition alone. These trends are discussed for each example reaction.

Multiple Metal Deposition

Consider first the case where two metals are electrodeposited simultaneously from a mixture of their ions. Although more complicated rate equations could be used to suit special circumstances, let us assume that

the deposition of each metal proceeds independently of the other (that is, i = j) with the reversible rate expression

$$f_i^e = i_{oi}\left\{\exp\left[\frac{\alpha_i n_i \mathbf{F}}{RT}(\phi + \phi_{ri})\right] - \frac{c_i^s}{c_i^o}\exp\left[\frac{-\beta_i n_i \mathbf{F}}{RT}(\phi + \phi_{ri})\right]\right\} \quad [9]$$

In Eq. [9], the quantity ϕ is the potential with respect to the rest potential of the ion of the most noble metal, while ϕ_{ri} is the rest potential of the ion of the most noble metal with respect to species i. The rest potential difference is computed with use of ionic concentration of reactants as they enter the porous electrode.

The model equations can be made more compact by grouping the system parameters as follows

$$\Phi = \frac{\mathbf{F}\phi}{RT} \qquad C_i = \frac{c_i}{c_i^o} \qquad Y = \frac{y}{l}$$

$$\Phi_{ri} = \frac{\mathbf{F}\,\phi_{ri}}{RT} \qquad \zeta_i = \frac{vl}{D_i}$$

$$\xi_i = \frac{i_{oi}al^2\mathbf{F}}{\kappa RT} \qquad \chi_i = \frac{i_{oi}al^2}{n_i\mathbf{F}D_i c_i^o} \qquad \Gamma_i = \frac{ak_i n_i \mathbf{F}^2 l^2 c_i^o}{\kappa RT} \quad [10]$$

By eliminating the surface concentration between Eq. [2] and [5], and by using the groupings of Eq. [10], the model equations become

$$C_i'' - \zeta_i C_i' = -\chi_i \mathbf{F}_i$$

$$\Phi'' = \sum_i \xi_i \mathbf{F}_i \quad [11]$$

where

$$\mathbf{F}_i = \frac{e^{\alpha_i n_i(\Phi + \Phi_{r_i})} - C_i e^{-\beta_i n_i(\Phi + \Phi_{r_i})}}{1 + \dfrac{\xi_i}{\Gamma_i} e^{-\beta_i n_i(\Phi + \Phi_{r_i})}}$$

Results will be given for the counterelectrode placed downstream from the porous electrode

at $Y = 0$

$$C_i = 1$$

$$\frac{d\Phi}{dY} = 0$$

at $Y = 1$

$$\frac{dC_i}{dY} = 0$$

$$\Phi = \Phi^o$$

Were there only one metal ion undergoing reduction, the situation would be analogous to that investigated previously by Alkire and Gracon. The physical significance of the more important parameters in Eq. [10] is summarized in Table I. In addition to these, the quantity Φ_{r_i} represents the Nernstian rest potential under the upstream concentration conditions of reaction i with respect to a reference potential, usually chosen to be the rest potential of one of the reacting species.

Table II provides the range of parameter values for which calculations were carried out and reported below. In this study, interest centered primarily on the role of convective mass transport on reactor behavior near the limiting current. Therefore the parameters of greatest interest are the convective velocity (ζ_i) and the mass transfer coefficient (Γ_i). Under the conditions investigated, the role of kinetics and diffusion was purposely made negligible through judicious choice of parameters. In other words, the results below are essentially insensitive to the value of ξ_i and χ_i used in the calculations. For still further simplification the same value of ζ_i was used for each species so that the subscript was deleted. Similarly, the same values were used for all Γ_i except as noted.

Table I. Physical significance of system parameters

ζ_i:	Ratio of advection rate to axial dispersion rate in porous bed
Γ_i:	Ratio of ohmic resistance to internal mass transfer resistance
ξ_i:	Ratio of ohmic resistance to charge transfer resistance
χ_i:	Ratio of axial dispersion resistance to charge transfer resistance

Table II. Range of parameter values used in the calculations

	Parameters held constant	Parameters varied	Range of variation
1. Multiple metal deposition			
2 components	$\chi_i = \chi = 10.0$	$\zeta_i = \zeta$	-10^1 to -10^5
	$\xi_i = \xi = 0.5$	$\Gamma_i = \Gamma$	10^0 to 10^6
	$\Phi_{r_1} = 0.0$		
	$\Phi_{r_2} = 7.0$		
4 components	$\chi_i = \chi = 10.0$	$\zeta_i = \zeta$	-10^0 to -10^3
	$\xi_i = \xi = 0.4$	$\Gamma_i = \Gamma$	10^0 to 10^6
	$\Phi_{r_1} = 0.0$		
	$\Phi_{r_2} = 5.0$		
	$\Phi_{r_3} = 10.0$		
	$\Phi_{r_4} = 15.0$		
2. Redox + metal deposition			
	$\chi_i = \chi = 10.0$	$\zeta_i = \zeta$	-10^2 to -10^4
	$\xi_i = \xi = 0.5$	$\Gamma_i = \Gamma$	10^1 to 10^6
	$\lambda = 1.0$		
	$\Phi_r = 5.0$		
3. Coupled heterogeneous + homogeneous reactions			
	$\chi_1 = \chi_2 = 3 \times 10^3$	$\zeta_i = \zeta$	10^1 to 10^8
	$\chi_4 = \chi_5 = 3 \times 10^5$		
	$\xi_i = \xi = 10.0$	$\Gamma_1 = \Gamma_2$	10^{-4} to 10^4
	$\lambda_1 = 0.01$	$\Gamma_4 = \Gamma_5$	10^{-6} to 10^3
	$\lambda_2 = 1.0$	$\Lambda_1 = \Lambda$	10^{-1} to 10^6
	$\Phi_r = 1.0$		

Figures 2 through 4 provide the current distributions predicted during the deposition of two metals, one of which (N) is more noble than the other (A). For each case studied, the electrode operated under the conditions of quantitative recovery of the ion of the more noble metal. The several curves in each figure correspond to different rest potentials between the two reactions. The current density given on the ordinate is defined by

$$\sum_i \int_0^1 J_i dY = 1 \quad [12]$$

That is, the integral of the total current over the entire electrode surface is normalized to the same value (unity) for each individual calculation.

Figure 2 shows the current distributions calculated for a high conductivity electrolyte with a slow flow rate for which both species were removed quantitatively from solution. The more noble metal is always deposited preferentially in the upstream regions. The less noble metal is deposited more uniformly to an extent which depends on the rest potential difference between the two reactions. These distributions indicate that while both metals may be deposited quantitatively, it may be difficult to recover the metals separately by postelectrolysis sectioning of the porous bed.

In comparison with Fig. 2, the distributions shown in Fig. 3 are for a higher flow rate but lower electrolyte conductivity. The more noble metal is deposited in upstream regions at the limiting current. Because of ohmic resistance effects, the less noble metal is deposited further downstream, nearer the counterelectrode; the current distribution exhibits a maximum owing to depletion of the ion of the less noble metal. If the rest potential difference is sufficiently large, the two metals can be made to deposit in distinctly different regions of the porous bed although the residence time for the less noble metal may be insufficient to allow its quantitative recovery. For the examples in Fig. 3, the percentage recovery of the ion of the less noble metal was 100, 99.5, and 90.6 for Φ_r = 3, 5, and 7, respectively. Figure 3 indicates that a properly

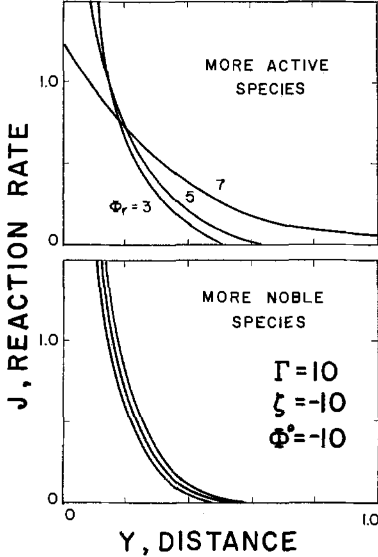

Fig. 2. Current distribution for deposition of two metals, low flow rate.

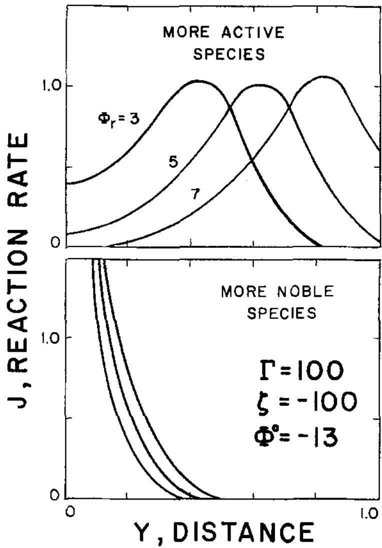

Fig. 3. Current distribution for deposition of two metals, medium flow rate.

designed electrode can remove metals quantitatively into different regions of the porous bed so that their subsequent recovery may be convenient.

The current distributions given in Fig. 4 are for a still higher flow rate and still lower electrolyte conductivity. The more noble metal is deposited in upstream regions, but not in the far upstream regions owing to ohmic limitations. The recovery of the less noble metal is in the exit region and may be very low if the rest potential difference is large. For the examples in Fig. 4, the percentage recovery of the less noble metal was 99.1, 86.2, and 41.2 for $\Phi_r = 3$, 5, and 7, respectively. Figure 4 shows that while the two metals may be deposited in separate regions, it may not be possible to remove both of them quantitatively.

It is clearly evident from Fig. 2 through 4 that the quantitative recovery of two metals in separate regions of the porous bed can be achieved only through proper design of the electrolysis system. Figure 5 summarizes the regions of parameter space which determine the recovery and separability of the metals. The different line codes correspond to different rest potentials between the two reactions. Within region A, the two metals are deposited in distinctly separate regions of the porous bed, and the more noble metal is recovered quantitatively. In region A, recovery of the less noble

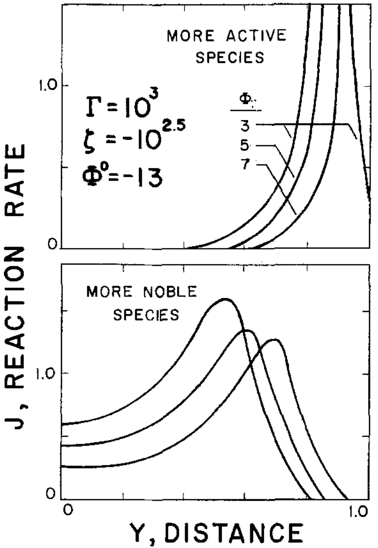

Fig. 4. Current distribution for deposition of two metals, high flow rate.

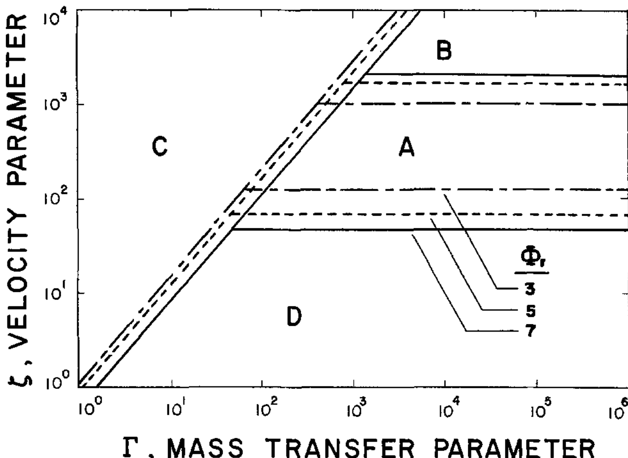

Fig. 5. Summary of deposit characteristics for two metals

metal varies from 100%, at the lower boundary, to essentially 0% at the upper boundary. In region B, the flow rate is so large that the residence time is insufficient to permit quantitative removal of the more noble metal; very little of the less noble metal is recovered in this region. With region C, the mass transfer coefficient is too small to allow quantitative recovery of the more noble metal. In region D, both metals are deposited quantitatively but the deposits overlap to an appreciable extent.

Figure 5 illustrates that, even under uniform electrolyte flow, the system behavior is quite sensitive to variations in the flow rate. It is often the case in practice, however, that channeling occurs owing to nonuniform flow distribution or bed packing. Therefore, it is of crucial importance that porous electrode systems be carefully designed so as to minimize undesirable hydrodynamic effects such as channeling.

The simultaneous deposition of more than two ionic species can also be modeled by the same procedure, although it is not convenient to present a graphical summary as was done with two metals. Figure 6 illustrates one example current distribution calculated for the simultaneous deposition of four species with rest potentials of 0, 5, 10, and 15 dimensionless units. The dashed lines correspond to the partial current distributions for each individual species; the solid line gives the total current distribution. It is seen that with a properly designed system, the four species can be deposited quantitatively in four distinctly different regions of the electrode.

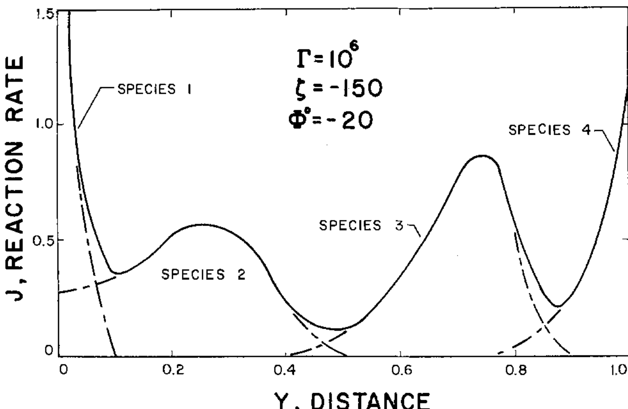

Fig. 6. Current distribution for deposition of four metals

Metal Deposition in the Presence of a Redox Couple

The reduction of a desired metal ion from a solution containing a more easily reduced species is encountered in several important industrial processes. If the more easily reduced species is the oxidized form of a redox couple, then a typical parallel reaction sequence is

$$M_1^{z_1} + e^- \rightarrow M_2^{z_2} \quad \text{(redox)}$$

$$M_3^{+n} + ne^- \rightarrow M_3^o \quad \text{(metal deposition)}$$

For the calculations reported below, the redox rate expression had the form

$$j_{e,\,\text{redox}} = i_{o1} \left\{ \frac{c_2^s}{c_2^0} \exp\left[\frac{\alpha_1 n_1 \mathbf{F} \phi}{RT}\right] - \frac{c_1^s}{c_1^0} \exp\left[\frac{-\beta_1 n_1 \mathbf{F}\phi}{RT}\right] \right\} \quad [13]$$

while the metal deposition reaction had the form of Eq. [9].

By the same algebraic procedures described previously, the equations of the model are

$$C_1'' - \zeta_1 C_1' = -\chi_1 \mathbf{F}_1$$
$$C_2'' - \zeta_2 C_2' = \chi_2 \mathbf{F}_2 \quad [14]$$
$$C_3'' - \zeta_3 C_3' = -\chi_3 \mathbf{F}_3$$
$$\Phi'' = \xi_1 \mathbf{F}_1 + \xi_3 \mathbf{F}_3$$

where

$$\mathbf{F}_1 = \mathbf{F}_2 = \frac{C_2 e^{\alpha_1 \Phi} - C_1 e^{-\beta_1 \Phi}}{1 + \dfrac{\xi_1}{\Gamma_1}[e^{\alpha_1 \Phi} + \lambda_1 e^{-\beta_1 \Phi}]}$$

$$\mathbf{F}_3 = \frac{e^{\alpha_2 n(\Phi + \Phi_r)} - C_3 e^{-\beta_2 n(\Phi+\Phi_r)}}{1 + \dfrac{\xi_3}{\Gamma_3} e^{-\beta_2 n(\Phi + \Phi_r)}}$$

The boundary conditions for a downstream counter-electrode are

at $Y = 0$

$$C_i = 1$$
$$\Phi' = 0$$

at $Y = 1$

$$C_i' = 0$$
$$\Phi = \Phi^o$$

Were there only the redox reaction occurring, the situation would be analogous to that investigated previously by Alkire and Gracon. The physical significance of the important parameters in Eq. [14] is given in Table I. In addition to these, the quantity

$$\lambda_1 = \frac{c_2^o}{c_1^o} \quad [15]$$

represents the concentration ratio of the redox couple in the inlet stream.

Table II gives the values of the systems parameters used in the calculations reported here. The results calculated for the redox-metal sequence have indicated that the system behaves in many respects like the two-metal system described above. The current distribution for the metal deposition reaction is shown in Fig. 7 for four different operating conditions; the interpretation of these results is similar to that in Fig. 2-4 for the less noble metal. In Fig. 7, curve (a) shows the metal deposition distribution obtained under conditions of slow flow in a high conductivity solution. Deposition occurs in the upstream region and the metal is removed quantitatively; operation corresponds to region D of Fig. 6. By comparison, curve (b) corresponds to a more conductive solution moving at higher velocity. The ohmic resistance suppresses the large reaction rate at the upstream region and the reactive portion of the porous bed is thus too thin to capture all the reactants so that the metal recovery is less than 100%; operation is in region C of Fig. 6. Curve (c) corresponds to a desirable situation where the metal is deposited quantitatively in the interior regions of the bed. Reaction in upstream regions is suppressed by ohmic resistance limitations while the mass transfer coefficient is sufficiently high that quantitative removal of the metal is achieved further downstream; operation is on the lower boundary of region A in Fig. 6. In curve (d), the electrolyte conductivity is still lower and the velocity still higher so that the reaction zone is very near the downstream edge of the bed and the percentage metal recovery is low. Operation corresponds to the lower boundary of region B in Fig. 6; under such conditions, attempts to achieve high metal recovery efficiencies by mass transfer enhancement alone would be futile.

Figure 7 has shown that recovery of a metal from a redox containing system depends upon proper choice of the rate of reactant supply, the mass transfer rate, and the electrolyte conductivity. Figure 8 summarizes how the metal collection effectiveness depends upon ζ, Γ, and Φ_r. The collection effectiveness decreases with flow velocity owing to the reduced residence time within the packed bed. The collection effectiveness improves with an increased mass transfer coefficient since the reactive pore surface is thereby made more accessible. The collection effectiveness is adversely affected by the presence of the redox agent to an extent which depends upon Φ_r.

Coupled Heterogeneous and Homogeneous Reactions

Since the number of different sequences of coupled reactions which may be encountered is large, the purpose of presenting the following results is limited to (*i*) showing that, given sufficient experimental data,

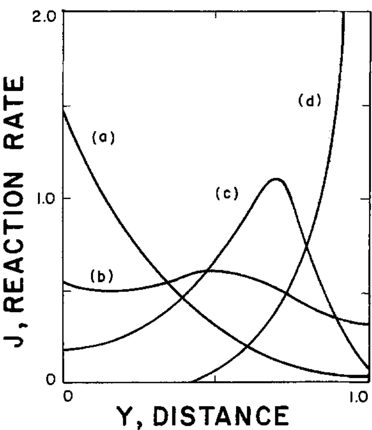

Fig. 7. Deposit distribution for deposition in presence of redox couple. (*a*) $\zeta = -10$, $\Gamma = 10$; (*b*) $\zeta = -10^2$, $\Gamma = 10$; (*c*) $\zeta = -10^2$, $\Gamma = 10^4$; (*d*) $\zeta = -10^3$, $\Gamma = 10^6$.

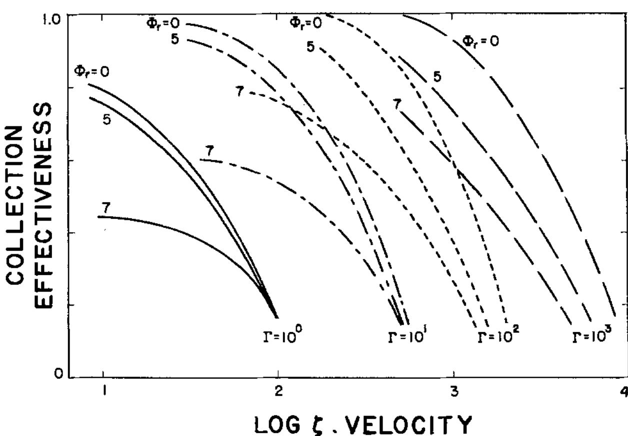

Fig. 8. Metal collection effectiveness for deposition in presence of redox couple.

any combination of reactions can be modeled to provide an engineering analysis of flow-through porous electrodes, and (*ii*) showing that, given a specific reaction sequence and design objective, a limited number of theoretical calculations can be compiled to provide design criteria for meeting those objectives.

For the sake of discussion, let us consider a mechanism of the form

$$M_1 + e^- \rightarrow M_2 \qquad \text{(electrochemical)}$$
$$M_2 + M_3 \rightarrow M_4 \qquad \text{(chemical)}$$
$$M_4 + e^- \rightarrow M_5 \qquad \text{(electrochemical)}$$

in which the desired target molecule for production is species 4. Although any other rate equations could be used to suit special situations, let us assume that the two electrochemical reactions proceed with reversible Butler-Volmer kinetics as in Eq. [13], while the chemical reaction is irreversible and of first order

$$S_{22} = S_{32} = -S_{42} = -k_c c_2 c_3 \qquad [16]$$

By following the manipulations described in previous examples, the equations for the model system are found to be

$$\begin{aligned} C_1'' - \zeta_1 C_1' &= -\chi_1 \mathbf{F}_1 \\ C_2'' - \zeta_2 C_2' &= \chi_2 \mathbf{F}_1 + \Lambda_1 C_2 C_3 \\ C_3'' - \zeta_3 C_3' &= \Lambda_2 C_2 C_3 \\ C_4'' - \zeta_4 C_4' &= -\chi_4 \mathbf{F}_3 - \Lambda_3 C_2 C_3 \\ C_5'' - \zeta_5 C_5' &= \chi_5 \mathbf{F}_3 \\ \Phi'' &= \xi_1 \mathbf{F}_1 + \xi_4 \mathbf{F}_3 \end{aligned} \qquad [17]$$

where

$$\mathbf{F}_1 = \frac{C_2 e^{\alpha_1 n_1 \Phi} - C_1 e^{-\beta_1 n_1 \Phi}}{1 + \dfrac{\xi_1}{\Gamma_1}(e^{\alpha_1 n_1 \Phi} + \lambda_1 e^{-\beta_1 n_1})}$$

$$\mathbf{F}_3 = \frac{C_5 e^{\alpha_3 n_3 (\Phi + \Phi_r)} - C_4 e^{-\beta_3 n_3 (\Phi + \Phi_r)}}{1 + \dfrac{\xi_4}{\Gamma_4}[e^{\alpha_3 n_3 (\Phi + \Phi_r)} + \lambda_2 e^{-\beta_2 n_2 (\Phi + \Phi_r)}]}$$

The boundary conditions have been chosen for an upstream counterelectrode

at $Y = 0$
$$C_i = 1$$
$$\Phi = \Phi^o$$
at $Y = 1$
$$C_i' = 0$$
$$\Phi' = 0$$

In addition to the groups in Table I, the following dimensionless groups arise in this example

$$\Lambda_1 = \frac{k_c l^2 c_3^o}{D_2} \qquad \Lambda_2 = \frac{k_c l^2 c_2^o}{D_3}$$
$$\Lambda_3 = \frac{k_c l^2 c_2^o c_3^o}{D_4 c_4^o} \qquad \lambda_1 = \frac{c_2^o}{c_1^o}$$
$$\lambda_2 = \frac{c_5^o}{c_4^o}$$

The calculations reported below were made with parameter values given in Table II. In the inlet stream, species 1 and 3 have the same concentration while species 2, 4, and 5 are 1% of C_1 and C_3. The less interesting parameters were held constant for all calculations in order to focus attention on the more important parameters ζ, Γ, and Λ.

The calculations provide detailed predictions of the dependence of concentration, potential, and current distributions upon variation of system parameters. From these results, the efficiency for the production of species 4, the desired target molecule, was determined by

$$\begin{aligned} \text{Production efficiency} &= \frac{C_4^{\text{outlet}} - C_4^o}{C_4^{\max} - C_4^o} \\ C_{4\max} &= (C_1 + C_2 + C_4)_{\text{inlet}} \end{aligned} \qquad [18]$$

where $C_4^{\max}$ is the maximum attainable concentration of species 4 if entering species are quantitatively converted to species 4.

Figure 9 illustrates how the production efficiency (PE) varies with Γ and Λ for one specific value of convective velocity, $\zeta = +10$. These data were calculated with sufficiently large applied potentials that behavior was controlled either by sluggish mass transfer processes or by sluggish homogeneous chemical kinetics. It is seen in Fig. 9 that the PE is always low when mass transfer limitations are severe (small Γ) since the formation of C_2 by the first electrochemical reaction is suppressed. Similarly, the PE can be low with excellent mass transfer (large Γ) since the reaction proceeds past the target to yield high conversion to species 5. It is also seen that the PE is low when the homogeneous chemical reaction rate is slow (small Λ), thereby suppressing the formation of species 4. High yields of the final product species can be obtained only when both the chemical reaction rate is sufficiently high and the mass transfer characteristics are carefully designed. For the case illustrated in Fig. 9, conditions necessary for product yields greater than 90% would be

$$\begin{aligned} 0.1 < \Gamma < 1 \\ \Lambda > 100 \end{aligned} \qquad [19]$$

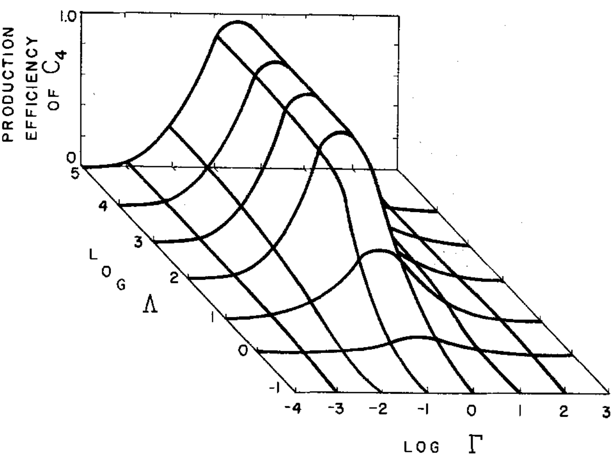

Fig. 9. Effect of Λ and Γ on production effectiveness for species 4 in ECE reaction sequence.

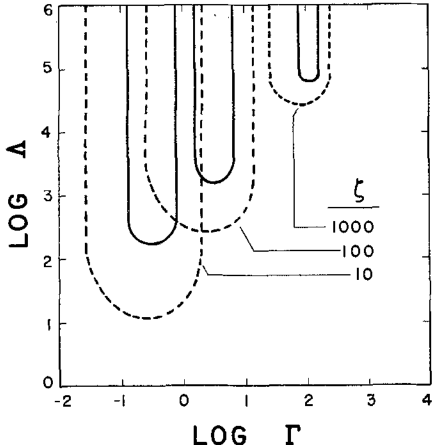

Fig. 10. Effect of system parameters on region of high production effectiveness for species 4 in ECE sequence.

For the system under consideration the design criteria cited in Eq. [19] are specific for the velocity used in Fig. 9. The dependence of these criteria upon flow rate is given by the solid lines in Fig. 10. For each velocity shown in Fig. 10, the solid lines enclose the "plateau" region seen in Fig. 9 over which the production efficiency is 90% or above. In a similar fashion, the dashed lines in Fig. 10 define the region within which the production efficiency is 50% or above. It is recognized that high flow rates lead to lower conversions since the residence time decreases linearly with velocity while the internal mass transfer coefficient increases only as the 1/3rd power of the flow rate. Optimum electrode performance is seen to be highly sensitive to the electrolyte flow rate.

By following similar procedures, the model could also be used to define regions of operation which would maximize yields of the other products in the reaction sequence such as C_2 or C_5.

Conclusions

Attempts to model complex porous electrode systems must rely on restrictive assumptions and perhaps artificial visions of physical reality in order to render the problem amenable to mathematical treatment. It is therefore of continued importance that controlled experimental studies be conducted on multiple reaction systems in order to test whether the assumptions used here betray physical reality beyond engineering tolerance. In particular, it would be important to test whether the diffusion layer is thin with respect to the pore size so that homogeneous chemical reactions would occur primarily in the "core" region of flowing electrolyte, as assumed.

The examples chosen here for theoretical discussion represent only a small number of possible reaction sequences found in the area of electrosynthesis. The model can incorporate many other types of sequences. In addition, the model could be applied to corrosion-type applications where there is no net current flowing in an external circuit (39, 40). That is, simultaneous anodic and cathodic reactions could occur within a bipolar porous flow-through electrode. Examples of applications would include cementation of Cu(II) during flow through a porous bed of iron, and leaching of Cu^0 from a porous bed with use of Fe(III) electrolyte.

Each example discussed above has illustrated that porous electrode behavior can be very sensitive to changes in convective flow rate. Therefore it is clearly important to avoid nonuniform flow effects which arise from localized channeling within the porous bed. Controlled experiments on channeling are suggested in order to improve understanding of the nature of channeling and its effect on electrode behavior.

The investigation has shown that while a high level of selectivity is possible in multiple reaction systems, the rational engineering design of a porous electrode is critically important if the desired selectivity is to be realized. The model presented here should contribute toward the development of more efficient electrode systems.

Microstructural Aspects of Grid Corrosion in the PbO_2 Electrode

Dennis Marshall and William Tiedemann*

Globe-Union, Incorporated, Corporate Applied Research Group, Milwaukee, Wisconsin 53201

ABSTRACT

A radical change in microstructure was examined for its effect on the mode of corrosive attack and corrosion rate for a 5 weight percent antimonial lead alloy. Metallography on as-cast microstructures indicates a transition from interdendritic to general attack with increasing overpotential. The potential region for general attack corresponds to a breakdown in the passivating abilities of PbO_2 and is marked by a sharp rise in the corrosion current. A simple heat-treatment, which alters the structure of the eutectic material, reduces interdendritic attack over the entire potential region studied.

Considerable research has been devoted to determining the merits of lead alloys for use as current collectors in the lead-acid battery (1). Because corrosion is a major mode of failure, much of this effort has been focused on the anodic behavior of lead and its alloys as they are used in the PbO_2 electrode.

Characterizing the corrosion of lead is complicated by the diversity of phases within the corrosion layer and experiments with pure lead (2-4) show the composition of the film varies with both time and potential. Below the equilibrium $PbO_2/PbSO_4$ potential the corrosion layer contains numerous oxides and $PbSO_4$; above this potential the α and β phases of PbO_2 dominate.

In addition to imparting the physical strength required for present day automotive battery designs, alloying further complicates the corrosion process by introducing additional phases and increasing the number of microstructural variables. Most notable of these is the classical problem of localized attack of segregated materials such as the eutectic structure or intermetallic compounds. This effect has been well documented for the lead-acid system (6-11) and is particularly damaging not only for the effects on mechanical integrity but also for its contribution to internal resistance, a factor which limits battery performance. Moreover, other effects such as active mass to grid bonding, active mass morphology, and reduced overpotentials for gassing have all been attributed to alloying, particularly antimony (1).

Partly because of the corrosion problem and primarily because of price, the antimony level in present battery grid alloys is dropping and, correspondingly, so is the strength. One of the possible solutions to the strength problem is heat-treatment, a process which is readily adaptable to antimonial leads. But in addition to the mechanical advantages, heat processing extensively alters the microstructure, raising questions as to its effect on subsequent corrosion life. Thus it was for the purpose of understanding the influence of heat-treatment on the corrosion behavior of antimonial alloys that this study was undertaken.

* Electrochemical Society Active Member.

Key words: grid corrosion, lead dioxide electrode, heat-treatment, antimonial lead alloy microstructure.

Experimental Procedures

Corrosion samples were prepared by hand casting a commercial antimonial grid alloy into an aluminum mold. The nominal alloy composition is shown in Table I. Specimen geometry consisted of a sphere 1.44 cm in diameter with an integral wire, 0.65 cm long and 0.28

Table I. Composition of alloy used in this study

Element	Weight percent
Antimony	5.00 ± 0.25
Arsenic	0.45 ± 0.05
Tin	0.40 ± 0.05
Copper	0.035 ± 0.025
Sulfur	0.007 ± 0.003
Lead	Remainder

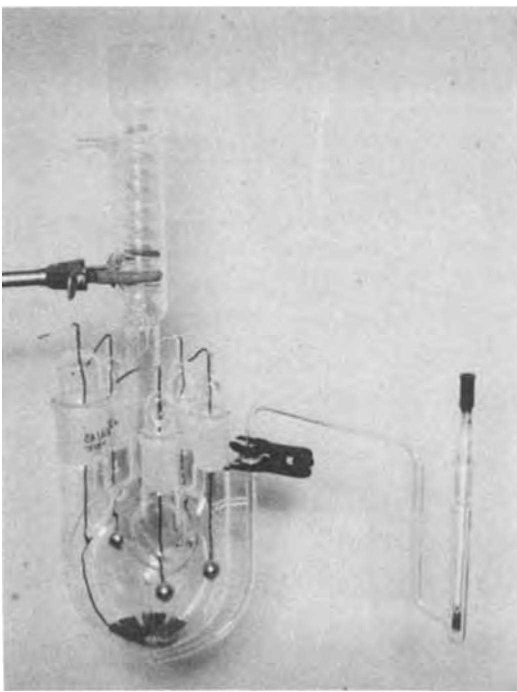

Fig. 1. The corrosion cell used in these experiments. A counter-electrode, fashioned from sheet lead, is shown at the bottom of the reservoir. Three samples are also visible located about the opening to the reference electrode shown at the right.

cm in diameter, attached. Total surface area, including a small protrusion corresponding to the mold gate, was 7.1 cm^2. Mold and pot temperatures were 160° ± 0.5° and 324° ± 3°C, respectively. Leads were attached to the integral wire with 63/37 solder and rosin flux followed by ultrasonic cleaning in acetone. Samples to be corroded in the heat-treated state were first heated at 240°C for 1-2 hr and quenched into room temperature water. Experiments with air-quenched and furnace-cooled samples were also carried out to examine the effects of precipitate formation within the primary lead phase. Leads were then attached as mentioned above.

The specimens were corroded in a refluxing-type apparatus pictured in Fig. 1. The reference electrode compartment was connected via an acid bridge, the end of which projected up through the bottom of the cell with its opening located at the center of the acid reservoir. Since changes in the corrosion layer are known to be time dependent, this construction permitted as many as four samples to be corroded simultaneously under nearly identical conditions, and then pulled for analysis at various time increments. The reservoir was filled with 900 ml of 1.27 sp gr sulfuric acid solution (4.61M). Temperatures were arbitrarily chosen at 32°, 49°, and 65.5°C (90°, 120°, and 150°F) and were maintained within ± 0.5°C in a water bath. However, as temperature only changed the degree and not the type of corrosion, only the results for 49°C are presented here.

Voltages for three separate cells were potentiostatically controlled using one Wenking and two custom-built potentiostats. In all cases potential variation held to ± 1 mV in the range from 1.170 to 1.500V with respect to Hg/Hg_2SO_4 in 4.6M acid.

The extent of corrosion was measured both in terms of weight loss of lead and the electrochemical capacity of the corrosion layer. For the former, the lead wire was detached from the sample at the solder joint and the corrosion layer chemically stripped in a solution of the following composition: 87 cm^3 H_2O, 10g NaOH, 2g mannitol, and 1g hydrazine dihydrochloride. Immersion time was limited to 30 min to preclude the deposition of lead from solution onto the sample. The lead content of the solution, in parts per million, was determined by atomic absorption and the result converted to milligrams of lead per square centimeter. Sample capacities were measured by constant current cathodic stripping in 1.27 sp gr H_2SO_4, using a Hewlett Packard 6181B d-c source. Only that portion of the sample up to the solder joint was immersed in the acid. Discharge potentials were monitored with a Keithley 616 digital electrometer and recorded on a Honeywell 194 strip chart recorder. Capacity was taken to a cutoff of 0.9V *vs.* an Hg/Hg_2SO_4 reference electrode.

Samples for metallography were mounted in a room temperature curing epoxy and sectioned to approximately one-half their diameter. Rough grinding was done wet on silicon carbide paper using 240, 400, and 600 grits. Rough polishing was done on a wheel using 5.0 and then 0.3μ alumina and distilled water on billiard cloth. A Syntron vibratory polisher was used in conjunction with Leco Finish-Pol abrasive and microcloth for final polishing. The pH of the slurry was adjusted to reduce oxidation of the alloy during polishing.

This final polish technique was useful here since the microstructure and mode of attack were of interest; where the structure of the corrosion layer must be retained, this final polish method cannot be used due to localized discharge and friability of the layer.

Results and Discussion

Structural effect of heat-treatment.—Figure 2 illustrates the radical effect heat-treatment has on the alloy microstructure. High temperatures, in this case only 12°C below the Pb-Sb eutectic temperature, effect some homogenization of the supersaturated grains and eutectic matrix. Thermodynamically, the grains can accept nearly 3.5% antimony at the heat-treating temperature, but 1-2 hr was not adequate to accomplish any significant solutioning of eutectic antimony in primary lead. A point count analysis (12) revealed no significant reduction in the volume percent eutectic antimony after heating. Instead, a reduction in surface energy was favored and diffusion along the surfaces of the antimony particles caused them to round off, reducing the continuity of the eutectic structure. This effect is general to lower antimonial alloys (13) and other alloy systems as well (14). The reduction in surface area would also tend to reduce any antimony flux into adjacent dendrites.

Unlike the antimony within the primary lead, eutectic Sb is exposed directly to corrosive attack and any change in its structure may be expected to alter corrosion even though there was no change in composition. As it relates to strength, the change in eutectic morphology is of secondary importance since low antimony alloys harden by precipitation. Since the solubility of antimony diminishes with temperature, precipitate distribution is readily controlled by quenching rate.

Weight loss measurements.—Figure 3 compares the weight loss data for samples corroded in the as-cast and heat-treated states at 49°C. The general magnitudes of these weight losses, as well as time trends in the data, are in excellent agreement with earlier findings by Lander (15, 16).

For equivalent times, weight losses at any potential are less for the heat-treated samples with the minimum in the curve shifting slightly to the right. Assuming the predominant lead species in the corrosion layer is Pb^{+4} (5), effective corrosion currents were calculated from weight loss differences between 24 and 48 hr and the result plotted as the upper set of curves in Fig. 4. A comparison of rates shows the greatest benefits of heat-treatment are obtained at higher potentials where PbO_2 no longer provides a suitable barrier to corrosion. The sharp rise in corrosion is accompanied by profuse gassing which is at least partly responsible for the negative curvature between 1.35 and 1.47V. Earlier studies, involving the direct observation of

sample surfaces *in situ* with corrosion, showed vigorous gas evolution was capable of dislodging portions of the corrosion layer (17). This was verified qualitatively by analyzing the increasing amounts of PbO_2 lying at the bottom of the reservoir at high potentials.

These findings are consistent with metallography on the corrosion interface shown in Fig. 5 and 6. For potentials up to about 1.29V, corrosion of the as-cast structure proceeds interdendritically. Since the dendrites are passivated by PbO_2, interdentritic attack will advance ahead of that on the primary lead until the surface area of the exposed dendrites increases sufficiently to offset the higher rate of eutectic attack. The relative rates will, of course, be altered by whatever potential drop and pH changes occur across the layer. This situation will be at its worst where abnormally long solidification times lead to larger dendritic arm spacings and the corresponding reduction in dendrite surface area.

From 1.35V and up the dendrite arms were consumed at an increasing rate until finally, at 1.47V, passivation was lost and dendrite attack caught up with the eutectic and corrosive penetration was relatively uniform.

Photomicrographs of heat-treated samples show that interdendritic attack was suppressed over the entire potential range, although the extent of the benefit is limited at lower potentials. But more importantly, a comparison of the metallography for both structures provides considerable insight into the significance and behavior of the eutectic material.

Beginning at 1.41V, heat-treated samples corrode intergranularly. Although morphological changes in the interdendritic and intergranular antimony resulting from heat-treatment are similar, rationalizing the differences in the corrosion of these two regions requires some consideration of what happens to the lead in the boundaries.

Since heating alters the shape of the eutectic antimony particles, antimony moving away from an old

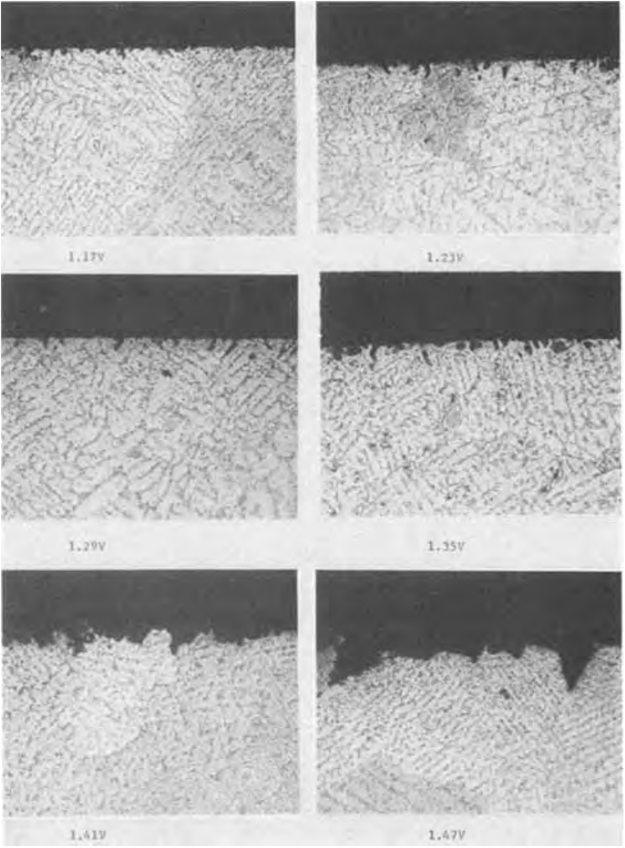

Fig. 6. Cross sections of corroded surfaces of heat-treated samples anodized at various overpotentials. (500×).

site must be immediately replaced with lead. While this process is general to all boundaries, the resulting diffusion of lead leaves the interdendritic regions substantially changed when compared to the grain boundaries. Lead diffusing to old antimony sites may deposit epitaxially onto the primary lead on either side of a boundary. If it is a dendrite boundary there is no choice but to assume the crystallographic orientation of that grain whereas lead in the grain boundary may assume either orientation. The result is that lead dendrites within a grain grow together, closing in behind the receding eutectic antimony, while the grain boundary is essentially unchanged from this aspect. Corrosion, therefore, preferentially penetrates the grain boundary since any interdendritic attack will be stopped by a layer of passivated lead bridging between dendrites. In contrast, metallography on as-cast samples suggests that interdendritic and intergranular boundaries look relatively the same since there is no preferential attack.

These observations parallel the earlier work by Burbank and Simon (11) who observed a reduction in interdendritic penetration at reduced alloy content. At compositions equal to or less than about 0.5% Sb, there is a loss of eutectic continuity and they observed preferential intergranular penetration. Thus, heat-treatment accomplishes very much the same thing as a reduction in alloy content.

During the process of stripping corrosion films, small grayish residues were found in the bottom of the sample beakers. Upon investigation it was determined that the material was metallic lead, actually lead dendrites, which has been undercut and isolated in the corrosion layer. Since the stripping solution did not attack lead, dissolution of the corrosion layer released the lead particles which then settled to the bottom. This residue was collected from each sample corroded for 24 or 48 hr, dissolved in nitric acid, and quantified by atomic absorption. The results are plotted in Fig. 7.

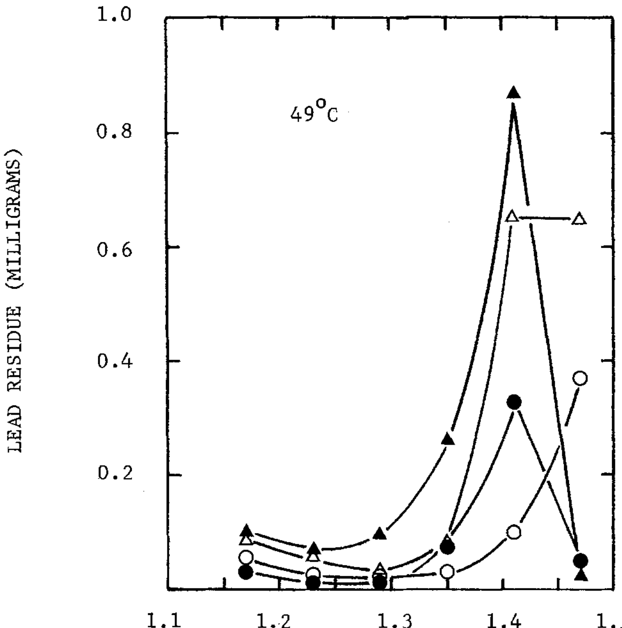

Fig. 7. Lead residue entrained in the corrosion layer. ●, 24 hr as cast; ▲, 48 hr as cast; ○, 24 hr heat-treated; △, 48 hr heat-treated.

As expected from the metallography, the difference in residue at low potentials is small. Of far greater significance is the change associated with the transition in corrosion mode. Between 1.29 and 1.41V, residues for heat-treated samples are smaller owing to the reduction in interdendritic attack. But, at 1.47V, lead is no longer passivated and the dendrites of the as-cast structure are consumed before they become isolated. Extensive metallography indicated that even where there were marked changes in dendrite arm spacing, corrosion was uniform at 1.47V.

Contrastingly, residues for heat-treated samples remain high at this potential as a result of intergranular attack in which much larger particles become isolated. Comparing the values for 24 and 48 hr at 1.41 and 1.47V the residue gain diminishes, probably because the grains are being consumed at an increasing rate.

Cathodic stripping.—The capacities of samples discharged at constant current were determined to a cutoff potential of 0.9V. For comparison's sake, these capacities were multiplied by two since those obtained chemically were calculated on the basis of a four-electron exchange.

Table II compares the amount of lead in milligrams per square centimeter involved in the discharge of as-cast samples with that incorporated in the entire layer as determined by chemical stripping. Only a portion of the corrosion layer is accessible during discharge; more material could have been reached using lower currents but this was precluded by self-discharge problems with the thin layers. Consequently, stripping currents were adjusted upward to the range 0.025-0.1 mA/cm^2 such that self-discharge would not significantly influence measured capacity. This in turn meant measured capacity was limited by polarization and that the percentage of material reached would be a function of the physical nature of the layer.

Referring again to Table II, the amount of material accessible during discharge varies with the corrosion potential. The fact that it reaches a low point in the middle potential region suggests there is something characteristically different about the layer which affords lead the maximum protection, *e.g.*, differences in composition, density, or surface area.

From the capacities of samples corroded at different times but the same potential, corrosion currents were calculated as follows

$$i\ (\mu A/cm^2) = \frac{C_i - C_o}{t_i - t_o}$$

where C_o and t_o are the capacity and corrosion time for the first sample and C_i and t_i are the representative parameters for successive samples corroded under the same conditions.

These data were plotted as the lower set of curves in Fig. 4. Here again the measurements show a sensitivity to layer structure not seen by chemical means with the minimums in the curves being more depressed and shifted to the right. However, unlike the chemical data, differences between as-cast and heat-treated samples occur principally in the region of the minimum with the heat-treated specimens showing larger corrosion currents. This apparent reversal is attributed to certain structural changes occurring in the corrosion layer which are intimately linked to alloy microstructure. Referring to Fig. 8a, the as-cast dendrites are clearly outlined by holes in the layer resulting from the leaching of antimony and grain boundaries appear as jagged, deeply etched grooves, also resulting from antimony leaching. At higher magnifications, Fig. 8c, the holes appear as a nearly continuous network rimmed by closely spaced clusters of crystals. For heat-treated samples, the dendrites are distinguishable only at higher magnifications where the antimony holes can be resolved. In Fig. 8b, grain boundaries appear as slight ripples but have no other structural peculiarities compared to the remainder of the film.

Figures 8e and f reveal the extremely fine substructure which is credited for the differences in electrochemical behavior. The fact that this substructure is more uniform over the surface of the dendrites in the heat-treated sample suggests that solid solution antimony, now more homogeneously distributed, is influential in film formation. The as-cast dendrites also contain some of the substructure but are principally identified by a sparse growth of clusters containing larger crystals.

Quenching was also given some consideration for its possible influence on the corrosion of heat-treated samples. In addition to water quenching, specimens were both air and furnace cooled to room temperature from 240°C, all in an effort to modify antimony precipitation. Any possible effects arising from these treatments were not detectable by metallography nor were there any differences in the corrosion currents shown in Fig. 4.

These results indicate that changes in corrosion behavior are due to an alteration of the eutectic structure plus whatever homogenization occurs during heating,

Table II. A tabulation of selected data showing the amount of material involved in cathodic stripping compared with the total material present (chemical stripping) in the corrosion layer of as-cast samples

while precipitate formation is relatively unimportant. This means the corrosion benefits of heat-treatment may be retained independent of the mechanical strength.

Conclusions

The corrosion of a nominal 5 weight percent antimonial grid alloy in the as-cast state was found to change from interdendritic to a uniform mode of attack with increasing overpotential. A heat-treatment, consisting of a 1-2 hr soak at 240°C was effective in curtailing interdendritic attack especially at the higher potentials and also effected a reduction in the corrosion rate. However, heat-treated samples do corrode intergranularly at high potentials, a mode of attack not seen

in as-cast specimens. This difference is attributed to changes in the eutectic structure.

Results of an electrochemical and microstructural examination show the structure of the corrosion layer is sensitive to changes in both overpotential and alloy microstructure.

Acknowledgment

The authors wish to acknowledge the assistance of Mr. A. Matuszewski in the experimental work and Mr. A. Ortiguera for the metallography. Appreciation is also extended to Globe-Union, Incorporated for permission to publish these findings.

Manuscript submitted Dec. 15, 1975; revised manuscript received July 22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by Globe-Union, Incorporated.

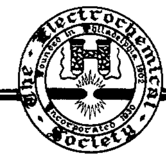
Technical Note



Origin of Ridge Growth on a Copper Single Crystal (110) Face in Acid Copper Sulfate Bath

S. Nageswar

Department of Chemistry, Central College, Bangalore University, Bangalore, India

According to the screw dislocation theory of crystal growth of Burton, Cabrera, and Frank (1), pyramids are expected to grow on any plane in pure solution. Ridge-type growth is observed mainly on the (110) plane when deposited from a moderately pure solution (2-4). However, ridges are also observed on the surface of different orientations when the solution is not pure (5-7). Very careful experiments were carried out from highly purified solutions to study the pyramidal growth on the (110) single crystal plane of copper and attempts were made to explain the origin of ridge growth.

The experimental procedure has been described in detail elsewhere (6). All glass vessels were immersed in an acid mixture ($HNO_3 + H_2SO_4$, 1:1) overnight and then washed with distilled water followed by conductivity water. The solution was prepared using triple-distilled conductivity water, preelectrolyzed for 12 hr at 10 mA/cm^2. The preelectrolyzed solution was then treated with activated charcoal and neutral alumina. H_2SO_4 (AR grade) was redistilled separately and treated with activated carbon. A bath of 0.25M $CuSO_4$ + 0.1M H_2SO_4 was then prepared.

The (110) plane was first mechanically polished on 3/0 and 4/0 emery paper using ethyl alcohol as a lubricant. Then the specimen was washed under running distilled water for 10 min and finally washed with conductivity water. To remove the damaged portion, the mechanically polished surface was subjected to electropolishing in 50% orthophosphoric acid bath at a constant cell potential of 1.2V (8).

Key words: rectangular pyramids, (110) plane, copper electrodeposits.

Results and Conclusions

Ridges are noticed on the (110) plane of copper from moderately pure solution at all current densities (2, 5, 10, and 20 mA/cm^2) as observed by earlier workers (2, 3). The direction of the ridge alignment is along [110] at 2 and 5 mA/cm^2, as noticed by earlier workers (4). Furthermore, it has also been noticed that the ridges align in the [100] direction if the overpotential is below 100 mV and in the [110] direction above 100 mV (4).

In the present work, occasional rectangular pyramids were observed at a thickness corresponding to 2 C/cm^2 when copper was deposited from highly purified acid copper sulfate solution at 20 mA/cm^2 (Fig. 1). At a thickness corresponding to 4 C/cm^2, the deposit consisted of a higher density of rectangular pyramids as shown in Fig. 2. When the thickness of the deposit was 6 C/cm^2, there was a merging of rectangular pyramids (Fig. 3), the alignment of which was in the [110] direction. At a thickness of 8 C/cm^2, there was a higher density of merging pyramids. Big ridges were observed at a thickness of 10 C/cm^2. These ridges were also aligned along the [110] direction (Fig. 4).

The rate of formation of rectangular pyramidal growth depends upon the mean lifetime of an adion on the surface, the distance between the kinks, and the

Fig. 1. Formation of rectangular pyramids at 2 C/cm^2 at 20 mA/cm^2 on the (110) copper plane. 625×.

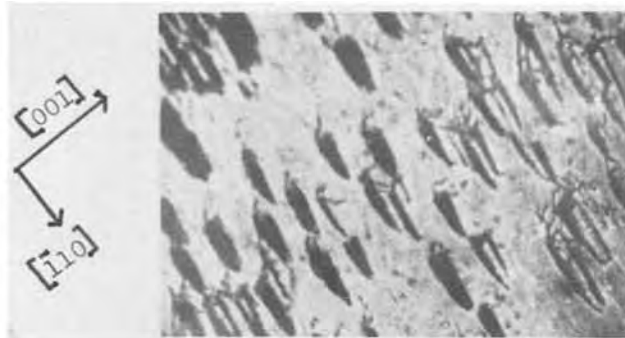


Fig. 3. Merging of rectangular pyramids at 8 C/cm^2 at 20 mA/cm^2 on the (110) copper plane. 625×.

Fig. 2. More number of rectangular pyramids at 4 C/cm^2 at 20 mA/cm^2 on the (110) copper plane. 625×.

Fig. 4. Formation of ridge-type growth at 10 C/cm^2 at 20 mA/cm^2 on the (110) copper plane. 625×. (10 C/cm^2 = 3.6 μm).

exchange current density according to Vermilyea (9). In the case where the exchange current density is more than the current density applied, the dislocation step remains straight and does form a pyramid through spiral formation. If the net current density is greater than i_0, pyramidal growth occurs on the surface. At low overpotentials the surface structure plays a decisive role in determining the rate of deposition. Furthermore, the incorporation of adions is easier along the [100] direction compared to the [110] direction as expected, since atomic density along the [100] is lower than along the [110] (10, 11). Hence, pyramids and ridges are aligned along the [100] direction at low overpotentials (2), and at high overpotentials they are aligned along the [110] direction.

Acknowledgments

The author wishes to express his grateful thanks to Dr. M. Shadaksharaswamy and Prof. T. D. Bhasker for their keen interest in the work and encouragement and to U.G.C., New Delhi, for financial support.

Electrophoretic Mobilities of Cadmium Hydroxide, Nickel Hydroxide, and Silver Oxide in Ni-Cd and Ag-Zn Battery Electrolytes

S. W. Mayer (pp. 159-162, Vol. 123, No. 2)

S. D. James:[1] It gets increasingly hard to accurately measure electrokinetic effects at high salt concentrations. This difficulty arises because, in a dispersion, the measured electrical effect is always a combination of interfacial and bulk processes. Consider a solid dispersed in a salt solution. As salt concentration rises two things happen: first, the diffuse part of the electric double layer is compressed toward the solid, thus diminishing interfacial influence;[2] simultaneously, solution conductance rises, thus augmenting bulk solution influence. Eventually the interfacial contribution is lost in a much larger bulk solution effect. Apparently this usually occurs well below a salt concentration of 0.1*N* since electrokinetic effects have rarely, if ever, been reported above this value.[3] However, in the paper under discussion, unusually high electrophoretic mobilities are reported for battery oxides in 34 and 43 w/o KOH, *i.e.*, at up to 10*N*. So if these data are valid, they represent a major advance in the electrokinetic literature. However, before this work can be accepted, the following questions must be answered.

1. How does the author calculate the tabulated mobilities? Using his raw data, I calculate that these mobilities and the derived zeta potentials should be about one thousand times higher than those he reports in Tables I-III. If my calculations are correct, the mobilities of the species range up to 2 cm/sec and their zeta potentials up to 1700V in 11M KOH (43 w/o). Since ζ hardly ever exceeds a few hundred mV even in dilute solution and falls with increasing ionic strength,[3] such data seem highly questionable.

For the author's benefit I will itemize one of my calculations. I used his Eq. [2] in the form

$$m = W/t\,\sigma\,i\,f\,d$$

where m is electrophoretic mobility in (cm/sec^{-1})/(V cm^{-1}), σ is specific resistance of suspension in Ω cm, W, in grams, is observed change in mass of collection cell after the passage of i amp for t sec, f is product of volume fractions of solid and liquid, and d, in grams per cubic centimeter, is density difference between solid and liquid. This is the form in which the equation has been used by previous workers.[4] I will now calculate m and ζ corresponding to the first data line of the author's Table I. This refers to electrolysis of a suspension, 13.9 w/o cadmium hydroxide in 34 w/o KOH which is also 0.8 w/o in potassium carbonate. From his figures of 13.9 and 6.4 for the weight percent and density (g/cm^3) of cadmium hydroxide and using the density of 34 w/o KOH, 1.33 g/cm^3 as that of the liquid phase, f is calculated as $0.033 \times 0.97 = 0.032$. Also, $d = 6.4 - 1.3 = 5.1$ g/cm^3; $W = 0.031$g; $i = 0.005$A; $t = 360$ sec. As an approximation for σ, the specific resistance of the suspension, I used the value for pure, 34 w/o KOH at room temperature, *viz.*, 1.9 Ω cm (2.5 Ω cm for 43 w/o KOH). Thus, $m = 0.031/(360 \times 1.9 \times 0.005 \times 0.032 \times 5.1) = 0.056$ (cm sec^{-1})/(V cm^{-1}). This mobility is 700 times greater than that tabulated by Mayer (*viz.*, 0.00008).

A similar calculation made for the second data line of Table III produces $m = 1.62$ (cm sec^{-1})/(V cm^{-1}) for silver oxide in 43 w/o KOH, which is 960 times Mayer's tabulated figure. In calculating ζ from m, Mayer evidently used η/D values of about 0.00045 poise in Tables I, II and 0.00079 in Table III. Using these values and applying his Eq. [3], I arrived at zeta potentials of 33 and 1660V for the two mobilities calculated above. [In checking the author's calculations of m, I assumed that the second column of his tables refers to his primary measurement, namely the observed increase in weight of the collection cell ($=W_1$) rather than to the derived quantity which heads the column, "mg of suspension collected at anode (cathode)," ($=W_2$). The two quantities are related by $W_1/W_2 = d$/(solid density). For the Ag, Cd, and Ni hydroxides, this ratio is 0.81, 0.80, and 0.68, respectively. Thus, even if my assumption is wrong, the biggest error involved is only 32%.]

2. How did the author avoid incurring serious errors from the electrolytic formation of gases at his stainless steel electrodes? At a steel cathode the passage of 0.005A for 360 sec should generate 0.228 cm^3 of hydrogen at 1 atm and 25°C. The resulting expulsion of 0.228 cm^3 of a 1.4 g/cm^3 suspension would lighten the collection cell by 0.319g, an amount greater than most of the author's tabulated W's. (It is unlikely that reduction of suspended particles of metal oxide would significantly share the cathodic current.) At a stainless steel anode, this error would be smaller, first because not more than 0.114 cm^3 of oxygen could be evolved and second in proportion to the fraction of current carried by anodic dissolution of the steel. However, the resulting dissemination of heavy metal ions would seriously contaminate the suspension.

3. How did the author prevent his determination of W from including large errors caused by the settling of solid particles during the experiment? In my own experience with this type of measurement (using the Model 1202 apparatus of Micromeritics Instrument Corporation, Norcross, Georgia, spinning at 30 rpm) errors of up to 0.2g were common unless the suspension was very well dispersed. It seems unlikely that, up to 12M KOH (45 w/o), the author's suspensions were well-enough dispersed to avoid settling errors since flocculation normally occurs at these high ionic strengths. (When I repeated the author's silver oxide suspension preparation, I obtained a very coarse and rapidly settling precipitate, quite unsuited for electrophoresis measurements.)

4. What were the exact details of the author's experimental arrangement? This is hard to visualize from the scant description in the article. He states that he used the method of Sennett and Olivier as modified by Long and Ross. However, in this modification the apparatus was (almost by necessity) stationary while the author's setup was rotated at 30 rpm.

Effect of Temperature on Electrode Kinetic Parameters for Hydrogen and Oxygen Evolution Reactions on Nickel Electrodes in Alkaline Solutions

M. H. Miles, G. Kissel, P. W. T. Lu, and S. Srinivasan
(pp. 332-336, Vol. 123, No. 3)

B. Chatterjee:[5] In the paper under discussion, the exchange current density i_o for the hydrogen evolution reaction (HER) is shown to compare closely with that for the oxygen evolution reaction (OER), except at 80°C. Since i_o is a major kinetic parameter in an electrochemical reaction, the above comparison, especially at low overpotential (η), would suggest a similar rate of reaction and rate-controlling mechanism for HER and OER. This view is, however, not supported by the results of the paper under discussion where dissimilar activation energies for the two reactions are given. (For example, a higher activation energy for OER would imply a lower reaction rate than that for HER.) This apparent discrepancy can be resolved by estimating the chemical reaction rate constants at various temperatures. Such an approach is conceivable due to the similarity in the basic mechanism of chemical and electrochemical reactions in alkaline solution.[6] It is known that for cathodic reaction (HER) the relation between the chemical rate constant K_c and the potential V is given by

$$K_c = (i/n\mathbf{F}) \exp(-\alpha V\mathbf{F}/RT)$$

where i is the applied current density, n is the number of electrons involved in one set of reaction, α the transfer coefficient, **F** the Faraday constant (96.5 kC mole^{-1}), R the gas constant (8.317 J mole^{-1} K^{-1}), and T is the absolute temperature in °K. The corresponding equation for anodic reaction (OER) is

$$K_a = (i/n\mathbf{F}) \exp[(1-\alpha)V\mathbf{F}/RT]$$

In the present calculation, the potential V at a particular temperature is obtained from the first slope of the dual Tafel regions of Fig. 3 in the paper under discussion, at a constant current density of 10 mA/cm^2. Results in Table I are estimated by assuming a single electron transfer mechanism and using the α-values as given by Miles *et al.* From Table I one can now get a better idea of the rate of HER relative to OER at a particular temperature. The Arrhenius plot of $\log_{10}K$ against $1/T$ is linear for HER, and the activation energies are about 6 and 11 kcal mole^{-1} at low and high η, respectively. These values compare closely with those reported in the paper under discussion for the change of $\log_{10}i_o$ with $1/T$. The linear Arrhenius plot for OER which includes data at 80°, 150°, and 208°C (at high η) gives an activation energy (of about 11 kcal mole^{-1}) similar to that for HER at high η. However, unlike HER, there is a sudden increase in the rate constant for OER as the temperature is raised from 208° to 264°C. Thus, except for anodic reaction at 264°C which will be discussed next, one would expect due to similar activation energy both HER (high η) and OER being controlled by an identical rate-determining process, such as electrochemical desorption as suggested in the paper under discussion. At low η, the Tafel slope of $2RT/3\mathbf{F}$ for HER which is lower than $2RT/\mathbf{F}$ at high η is associated with rate constants which give a lower activation energy of about 6 kcal mole^{-1}. It seems probable that chemical desorption (Tafel recombination) is the rate-determining step for HER at low η.

The anodic Tafel slope of $RT/3\mathbf{F}$, *i.e.*, $\alpha = 3.3$ at 264°C is shown in the paper under discussion to be lower than the cathodic slope of $2RT/3\mathbf{F}$ at low η. However, despite the different α-values the i_o values are reported nearly the same for anodic (1.0×10^{-3} A/cm^2) and cathodic (0.93×10^{-3} A/cm^2) reactions (Tables II and III of the paper under discussion). It is difficult to rationalize this apparent inconsistency of the experimental results in terms of the suggested magnetic change of the oxide which will be paramagnetic in all cases at 264°C. However, one can suggest that since α is inversely proportional to the thickness of the double layer,[7] it is likely that during anodic polarization of nickel in alkaline solution the thickness of the double layer by certain mechanism is almost nonexistent at 264°C compared to that produced by the cathodic reaction. This can explain the abruptly high rate constant for OER at 264°C. Such a theory may be confirmed by experiments outlined elsewhere[7] on the effect of suitable additives on overpotential for both HER and OER in alkaline solution. The other suggestion to explain the above inconsistency of results would be to analyze them in terms of surface coverage by intermediates (oxide or peroxide).[8]

M. H. Miles,[9] G. Kissel,[10] P. W. T. Lu,[11] and S. Srinivasan:[10] We appreciate the interest shown by Dr. Chatterjee in our paper and believe that he raised an interesting question regarding the similar i_o values for the HER and OER at high temperatures. Unfortunately, however, his calculations of the chemical rate constants contain the following serious errors.

1. The use of the potential, V, *vs.* the dynamic hydrogen electrode (DHE) at 10 mA/cm^2 by Dr. Chatterjee rather than the overpotential, η, makes the numerical values of the chemical rate constants dependent on the choice of a reference electrode. The equations

$$\eta_a = V - E_{ROE}$$

$$\eta_c = V - |\eta_{DHE}|$$

can be used to calculate the necessary anodic and cathodic overpotentials by using the numerical values for E_{ROE} and $\eta_{DHE}|$ given in Table I of our paper. The equations given by Dr. Chatterjee for calculating the chemical rate constants also have sign errors in the exponential terms. However, he apparently compensated for this in his calculations.

2. Dr. Chatterjee's calculation of the anodic rate constant is incorrect. Our reported anodic transfer coefficient for the OER, α_a, should be used directly in the exponential term rather than $1 - \alpha$. This error accounts for Dr. Chatterjee's unusually high anodic rate constant of 1.9×10^{19} mole cm^{-2} sec^{-1} at 264°C. Even for a diffusion-limited reaction, the rate constant should be less than about 10^{-3} mole cm^{-2} sec^{-1} according to Fick's first law. The correct expression for calculating the anodic rate constant is

$$k_a = \frac{i_a}{n\mathbf{F}} e^{-\alpha_a \mathbf{F}\eta/RT} \quad [1]$$

and a value of 3×10^{-9} mole cm^{-2} sec^{-1} is obtained

Table I. Estimated chemical rate constants (*K*) at 10 A/cm^2 current density for the cathodic and the anodic reactions on polished nickel electrodes in 50 w/o KOH solutions

T (°C)	Cathodic reaction (HER) K_c (mole cm^{-2} sec^{-1}) low η	high η	Anodic reaction (OER) K_a (mole cm^{-2} sec^{-1}) low η	high η
80	—— 2.0×10^{-9} ——		—— 1.5×10^{-13} ——	
150	1.1×10^{-8}	6.8×10^{-8}	—— 2.6×10^{-13} ——	
208	2.5×10^{-8}	7.6×10^{-8}	2.3×10^{-6}	1.3×10^{-11}
264	3.2×10^{-8}	7.0×10^{-8}	—— 1.9×10^{19} ——

for the OER reaction at 264°C by using $n = 4$ equiv./mole, $\alpha_a = 3.3$, and $\eta = 0.03$V at a current density of 0.010 A/cm.

Due to these errors, all of the chemical rate constants given by Dr. Chatterjee are incorrect and his comments based on these values are invalid. From Eq. [1], $k_a = i_o/n\mathbf{F}$ at zero overvoltage, hence the correct chemical rate constants are proportional to the exchange current densities, and their temperature dependencies would lead to the same activation energies as reported in our paper.

Several explanations can be offered for the similar i_o values observed for the HER and OER at high temperatures. The HER occurs on a bare nickel surface while the OER occurs on an oxide-covered surface. The roughness factor, therefore, may be considerably larger for the nickel anode surface than for the nickel cathode surface. This would tend to reduce the actual differences in i_o values for these two reactions. Also, increasing the temperature has a greater effect on the reaction of higher activation energy, hence the true differences in i_o values for HER and OER would diminish at higher temperatures.

Comparisons of i_o values are difficult due to the various parameters which affect the exchange current density. For the mechanism of the HER at high temperatures suggested in our paper

$$H_2O + e^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_{ads} + OH^- \qquad \text{(fast)}$$

$$H_2O + H_{ads} + e^- \overset{k_2}{\rightarrow} H_2 + OH^- \qquad \text{(slow)}$$

the exchange current density under Langmuirian conditions at low η is given by

$$i_o = 2\mathbf{F}k_2 \frac{k_1}{k_{-1}} \frac{(a_{H_2O})^2}{a_{OH^-}} e^{-(1+\beta)\mathbf{F}\Delta\phi_e/RT} \qquad [2]$$

where β is the symmetry factor (usually about 0.5) and $\Delta\phi_e$ is the absolute potential difference across the interface at equilibrium.[12,13] The ratio of rate constants, k_1/k_{-1}, is the equilibrium constant for the fast discharge step. According to LeChatelier's principle, k_1/k_{-1} will decrease with increasing temperature, hence this will tend to offset the normal increase of k_2 with increasing temperature. This would account for the small increase in i_o for the HER at low η reported in our paper and explain the low $\Delta H^{\ddagger}$ (8 kcal/mole) observed. For this same reaction mechanism at high η, the exchange current density

$$i_o = 2\mathbf{F}k_2 a_{H_2O} e^{-\beta\mathbf{F}\Delta\phi_e/RT} \qquad [3]$$

is directly proportional to the rate constant, k_2, for the slow step. This would explain the larger $\Delta H^{\ddagger}$ (14 kcal/mole) observed at high η.

Assuming the following mechanism for the oxygen evolution reaction

$$OH^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} OH_{ads} + e^-$$

$$OH_{ads} + OH^- \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} O_{ads} + H_2O + e^-$$

$$O_{ads} + O_{ads} \overset{k_5}{\rightarrow} O_2$$

the exchange current density is given by

$$i_o = 4\mathbf{F}k_3 (a_{OH^-}) e^{\beta\mathbf{F}\Delta\phi_e/RT} \qquad [4]$$

if the first electron transfer is the slow step. Since i_o is directly proportional to k_3, the observed $\Delta H^{\ddagger}$ value of 18 kcal/mole could be related to the activation energy for this slow step. Since $\Delta\phi_e$ may be quite different at the equilibrium potential for the OER as contrasted with the HER, it is difficult to relate the experimental differences in i_o found for these two reactions to the rates of the slow steps involved. Above 250°C where the nickel oxide becomes paramagnetic, the recombination of adsorbed oxygen atoms becomes the slow step, hence the expression for the exchange current density changes to

$$i_o = 4\mathbf{F}k_5 \left(\frac{k_3}{k_{-3}}\right)^2 \left(\frac{k_4}{k_{-4}}\right)^2 \frac{(a_{OH^-})^4}{(a_{H_2O})^2} e^{4\mathbf{F}\Delta\phi_e/RT} \qquad [5]$$

For this mechanism, i_o no longer relates simply to the rate constant for the slow step. Equations 4 and 5 show that it is even difficult to compare i_o values for a given reaction if a change in the slow step occurs. For example, despite the significant rate increase observed for the OER between 208° and 264°C, the exchange current densities do not reflect this improvement in the kinetics.

In summary, the results presented in our paper are consistent with the above expressions, and, in fact, this theoretical analysis lends support to our original conclusions.

A Rutherford Backscattering Analysis of Anodic Tantalum-Titanium Oxides

R. L. Ruth and N. Schwartz*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Sputtered tantalum-titanium alloy thin films have been anodized in 0.01% aqueous citric acid, and the atom distribution, stoichiometry, and thickness determined by Rutherford backscattering analysis and stylus measurement. The anodic oxide film consists of a uniform amorphous mixture of Ta_2O_5 and TiO_2 with about 3% of the oxide at the electrolyte interface consisting of almost pure TiO_2. During anodization a small fraction of the titanium dissolves in the electrolyte. The apparent growth constant of the anodic oxide on $Ta_{0.49}Ti_{0.51}$ films is 1.88 ± 0.02 nm/V. The density of the oxide is determined as (5.9 ± 0.2) × 10^3 kg/m^3. From aqueous contact capacitance measurements, the dielectric constant of the alloy anodic oxide is 24.7 ± 0.9.

In an earlier paper (1), Schwartz and Peters investigated the suitability of tantalum-silicon alloys for use in tantalum thin-film component applications. Subsequently Silverman and Schwartz (2) related the properties of anodic oxide films formed on the tantalum-silicon alloy to their composition determined by Rutherford scattering. It has been found from this and other studies that alloying the tantalum with other metals generally increases the reliability of tantalum oxide thin-film capacitors. In cases investigated to date, however, this alloying has been accompanied by a decrease in the capacitance density of the film. It would be desirable to find a material which could maintain or improve the capacitance density characteristics while also increasing reliability.

Polycrystalline bulk titanium dioxide has a dielectric constant ranging from 48 to 110 depending upon phase (3), while in a recent review (4), the dielectric constants of anodic titanium oxides have reported values from 40 to 105, with some values as low as 21. These values are generally higher than those reported for anodic tantalum oxide of 26.7-27.6 (5, 6). The anodization of bulk Ta-Nb alloys (7) and bulk Ta-Ti alloy (8) have yielded oxide films with capacitance densities, and possibly dielectric constants, higher than that of tantalum alone, and it was anticipated that Ta-Ti anodized alloy films would have a higher capacitance density than comparable concentrations of silica (1) or alumina (5) in anodic tantalum pentoxide. To explore the possibility of Ta-Ti as a single material thin film system for passive integrated circuits, Peters and Schwartz (9) investigated tantalum-titanium for capacitor applications and its relation to the present tantalum thin-film technology. These results indicate that tantalum-titanium anodic oxide capacitors are superior to normal beta-tantalum based capacitors with respect to cathodic voltage life test stability. Oohashi and Yamanaka (10) had previously studied the resistive properties of tantalum-titanium alloy sputtered films.

* Electrochemical Society Active Member.

Key words: alloys, sputtering, dielectric properties.

This paper reports the results of a Rutherford backscattering analysis of approximately $Ta_{0.5}Ti_{0.5}$ alloy samples and their anodic oxides as a function of anodizing voltage. Compositions of the films were determined before and after anodization, and a profile of the composition of oxides and unanodized films as a function of thickness were extracted from the spectra. Such information should yield insight into the mechanisms involved in the anodization process, and also complement the work done in earlier studies. For example, silicon and titanium can both have a bulk oxide valence of +4. If the mechanism of the two alloy anodizations were the same with respect to cation transport, then both silicon and titanium should have similar distributions in the anodic oxide. In the case of tantalum-silicon, anodization results in a duplex oxide, with an outer Ta_2O_5 layer, and an inner layer consisting of a uniform mixture of Ta_2O_5 and SiO_2 (2). One purpose of this study was to determine whether the same distribution existed in tantalum-titanium anodized layers. Secondly, in order to understand the change in capacitance density with titanium additions, it is necessary to know the oxide film thickness. In a potentially complex oxide film, such as a duplex film, optical thickness determination techniques are difficult to interpret, and Rutherford scattering gives a direct result in terms of number of atoms per square centimeter, the atom distribution as a function of thickness, and stoichiometry.

Experimental Procedure

Sputtering, anodization, stylus measurement.—The films used for this study were prepared in essentially the same way as described earlier (2).

The fused silica substrates used for the deposition were cleaned sequentially in: hot trichloroethylene vapor, ultrasonic agitation in detergent, boiling hydrogen peroxide, and overflow rinse in deionized water. The samples were dried in nitrogen at 110°C to remove bulk water and given a final half-hour bake at 550°C in air to remove traces of organic contaminants. After insertion into the vacuum station, the substrates were

first heated at 500°C to remove gases adsorbed on the surface during exposure to air, and then cooled to 120°C. Deposition was accomplished by d-c diode sputtering of a composite cathode consisting of tantalum with titanium foil stretched across the surface. The sputtering was carried out in a glass bell jar pumped by a 6-in. oil diffusion pumping system with a liquid nitrogen trap. The atmosphere during deposition was argon at a pressure of 20×10^{-3} Torr (2.7 Pa). Sputtering from the 232 cm^2 cathode was done at a potential of 5 kV, a current density of 0.19 mA/cm^2, and an interelectrode spacing of 7 cm. Following a 45 min presputtering period during which the substrates were covered by a shutter, the films were deposited in 24 min. During the deposition, due to the energy of the discharge, the temperature rose from 120° to 180°C. The deposition rate varied from 0.8 to 1.2 nanometers/min depending on the relative areas of the tantalum and titanium at the cathode. For this study, the deposition resulted in films of approximately 50 atom per cent (a/o) Ti. The crystal structure was determined using a Read Camera (11), and found to be highly oriented single phase bcc with a cell constant of 0.3307 ± 0.0002 nm.

For anodization, each 2.5 × 7.5 cm slide was scribed and broken into six 1.25 × 2.5 cm samples. On each sample, a thin piece of Minnesota Mining and Manufacturing electroplater's tape was used to mask the expected location of the electrolyte-air interface, and contact was made to the film with a small alligator clip. Anodization was performed in 0.01% citric acid using a tantalum cathode with an Electronic Measurements Incorporated constant current/constant voltage power supply. The current density during anodization was held at 1.5 mA/cm^2 until the desired voltage was reached, and then constant voltage was maintained for 20 min. The electroplater's tape was able to mask with a definition of 0.2 mm. All of the interference colors of the anodic oxide were bright and clear, indicating no obvious crystallization. Moreover, Read Camera x-ray analysis (11) indicated that all of the anodic oxides were amorphous with respect to Cu radiation.

For one sample, the thicknesses of the alloy film and the alloy anodic oxide were determined using a stylus method (12) after creating sharp steps using an electrochemical etching method in NH_4Cl/absolute methanol solutions (13). This electrochemical etch completely undercuts the anodic oxide at the alloy-oxide interface leaving a transparent oxide which when dried is firmly adherent to the substrate allowing the stylus to traverse the step from the oxide-substrate very reproducibly.

The capacitance densities of the samples were determined on known areas of the samples in 8*N* sulfuric acid to minimize cell resistance, and on thin film capacitors with evaporated nichrome-gold counterelectrodes.

Backscattering.—Silverman and Schwartz describe the basic concepts behind the use of Rutherford backscattering in their work on the tantalum-silicon system (2). As in that study, the backscattering facility used was the Bell Laboratories van de Graaf accelerator. This apparatus, along with the equations used in analysis of the data, have been described in detail in an earlier paper (14).

In this study five anodized specimens were examined. All had been prepared from the same sputtered 2.5 × 7.5 cm slide in order to provide a similar starting point for each case. Each sample was then anodized to a different final voltage: 46, 84, 134, 178, and 229V. In all cases the tantalum-titanium film was thick enough such that the alloy film was not consumed during anodization. Each specimen was analyzed in two different areas: (*i*) the original metal film, and (*ii*) the anodized film on top of the original metal film. Beam current was approximately 5 nA, and about 25 min was required to obtain counting statistics good to 1% for the titanium and oxygen regions of the spectra, resulting in a total integrated beam charge of 6 μC. The helium ion beam energy was 1.90±0.01 MeV. Energy resolution of the spectra was limited by the resolution of the silicon surface barrier detector to about 15 keV.

Results

Figure 1 is the backscattered energy spectrum for the unanodized region of the sample subsequently anodized to 229V. The yields for the lower energy regions (titanium, argon, and substrate silicon-dioxide) have been magnified by a factor of 4 for clarity. Marks on the abscissa indicate the energies that detected particles would have if they were scattered by tantalum, titanium, argon, silicon, and oxygen atoms at the surface of a sample, calculated for the initial projectile energy of 1.90 MeV. The positions of the leading edges of the tantalum and titanium regions indicated on the figure show that both elements are present at the surface. Argon is trapped in the sputtered film during deposition, and one can see the trailing edge of the argon region on the left side of the titanium peak. The leading edge of the argon is hidden by overlap with the titanium peak.

Composition information can be extracted from data like Fig. 1 by comparing the yields of the various elements after removing the Z^2 dependence of the scattering cross section. Determining the tantalum yield was straightforward since the background is less than 0.5% of the tantalum counts. The titanium and argon, however, presented a problem because of the overlap. Since other spectra indicated that argon is present up to the film surface, one could identify the leading and trailing edges of the argon region. In order to determine the magnitude of the argon yield, the assumption was made that argon is distributed uniformly throughout the film; this assumption is based on the results in the Ta-Si system, as well as the way the sputtering is done. One could then determine the argon yield from the height of the region to the left of the titanium plateau, and subtract an appropriate number of counts from that portion of the titanium plateau that overlaps the argon. Unlike the tantalum region, the background under the argon and titanium is significant and was subtracted from both totals.

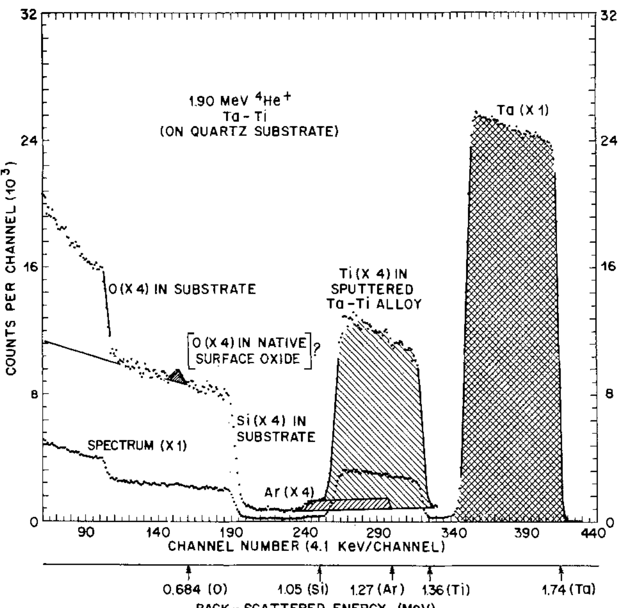

Fig. 1. Backscattered energy spectrum from a sputtered tantalum-titanium film about 260 nm thick, subsequently anodized to 229V. The yields for energies below those of the Ta region are shown magnified by a factor of 4. The energies marked on the abscissa are those of particles backscattered by the various elements (Ta, Ti, Ar, Si, O) at the surface of a film. The Ta, Ti, and Ar yields from the film are shaded and identified as are the Si and O yields from the fused silica substrate.

Average		$Ta_{0.47}Ti_{0.49}Ar_{0.038}$

* This is the voltage to which the alloy film was subsequently anodized.

Table I shows the film composition determined for the unanodized samples. The argon level was ~4 a/o, consistent with earlier findings (2). The metals were present in the ratio 49 a/o Ti/47 a/o Ta.

It is also possible to determine a profile of composition through the film using the raw data from a given spectrum. To do this, the yields from each element found at a given position in the film were considered. Backgrounds were subtracted from the yield of each element. Then each element's yield was adjusted to account for the scattering cross section dependence on atomic number. Peak widths of the lighter elements were increased to account for the decreasing width that accompanies a decrease in the atomic mass of the scattering species. Then a correction was made to account for the $1/E^2$ scattering dependence so that scattering deep in the film, where projectile particles move with decreased energy, would be normalized to scattering near the surface. Finally, the yields were arbitrarily normalized. In order to generate this depth information, the stopping powers, initial ion energy, and energy width of the multichannel analyzer, along with the raw spectra, were used as input to a computer program that calculated the relative atomic concentrations of the individual elements as a function of depth. In this case there was no overlap of yields from the elements of interest. Brice (15) has published a rigorous treatment of the analysis problem that uses the stopping powers and reference spectra taken with the experimental setup used for the multiple element spectrum. Brice's treatment can also handle cases where there is partial overlap of the elemental yields.

The profile of Fig. 2 shows the result of such a procedure performed on the data of Fig. 1. In this figure, as well as Fig. 4, 5, and 6, the depth resolution is limited by the detector sensitivity which is equivalent to four channels, while the error in the relative atom concentrations is ±1% for Ta, ±3.5% for Ti, and ±5% for O. Concentrations of tantalum and titanium through the alloy film shown in Fig. 2 are quite uniform. There is a slight decrease in the titanium concentration as the alloy film grows which is probably due to the Ti

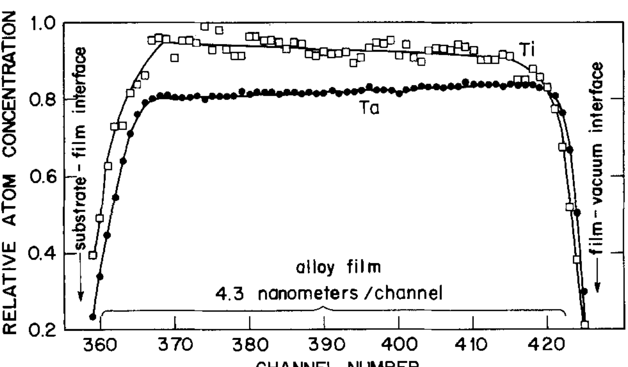

Fig. 2. Depth profile extracted from the spectrum of Fig. 1. Argon, which does not appear in the profile, was assumed to be uniformly distributed throughout the film in determining the Ti yield.

wires on the Ta cathode getting slightly coated with back-sputtered Ta and thus effectively decreasing the Ti sputtering area. Since argon is overlapped almost entirely by the titanium yield, it was assumed to be uniformly distributed throughout the film for this calculation.

The as-deposited samples were also used to determine the initial Ta-Ti alloy film thickness. When composition is known, one can use Bragg's rule to determine stopping powers for the mixtures, from

$$\left.\frac{dE}{dx}\right|^{AB} = (\text{wt. frac. A}) \left.\frac{dE}{dx}\right|^{A} + (\text{wt. frac. B}) \left.\frac{dE}{dx}\right|^{B} \quad [1]$$

where the stopping powers used by the authors are expressed in units of $MeV/g/cm^2$ (16). The stopping powers can then be used to calculate kinematic factors for the different elements

$$[s]_A{}^{AB} = k_A \left.\frac{dE}{dx}\right|_{in}^{AB} + \left.\frac{dE}{dx}\right|_{out}^{AB} \quad [2]$$

where

$$k_A = \left[\frac{M_A - m_{He}}{M_A + m_{He}}\right]^2 \quad [3]$$

where M_A and m_{He} are the masses, respectively, of the scattering atom and helium. Using this kinetic factor, $[s]$, and the experimental energy width from the spectrum, ΔE, one can calculate the alloy film mass surface density

$$d_s = \frac{\Delta E_x}{[s]_x{}^{xy}} \quad [4]$$

The above analysis yields an average d_s of $(264 \pm 13) \times 10^{-5}$ kg/m^2. The density of the alloy film can be evaluated from the lattice constant by

$$d = \frac{2[n_{Ta}A_{Ta} + n_{Ti}A_{Ti} + n_{Ar}A_{Ar}]}{N \times a^3} \quad [5]$$

where n_i = experimental atom fractions, N = Avogadro's number, a = experimental lattice constant, 0.3307 nm.

Use of Eq. [5] results in a density of 10.2×10^3 kg/m^3. This value is in agreement with the value calculated from the bulk lattice constant (0.32084 nm) (17) of 10.7×10^3 when it is corrected by a factor of 0.964 to result in a value of 10.3×10^3. This factor of 0.964 is based on the ratio of the observed sputtered tantalum film density (18) to bulk tantalum density, and is caused by the incorporation of argon and other defects in sputtered films.

The density of 10.2×10^3 kg/m^3 in combination with the determined surface density of $(264 \pm 13) \times 10^{-5}$ kg/m^2 results in an average film thickness of 259±13 nm. This value is in excellent agreement with the stylus instrument value of 262±5 nm determined directly on an etched step.

Figure 3 is a spectrum taken from the sample anodized to 89V. The yield in the higher energy region due to scattering from tantalum and titanium is reduced due to the presence of oxygen which contributes to the energy loss of the helium ions and thus reduces the number of tantalum and titanium atoms per unit energy loss. In the low energy part of the spectrum one can see the oxygen yield in a position corresponding to oxygen at the surface and in the anodized part of the film.

The composition of the anodized region was determined for each of the five samples. Boundaries of the oxide plateaus in both the tantalum and titanium peaks were determined using a technique reported earlier by Mitchell *et al.* (19). The channel number of the plateau's low energy boundary (half-height) was taken to be the channel number of the midpoint between the oxide plateau and the as-deposited plateau. The oxy-

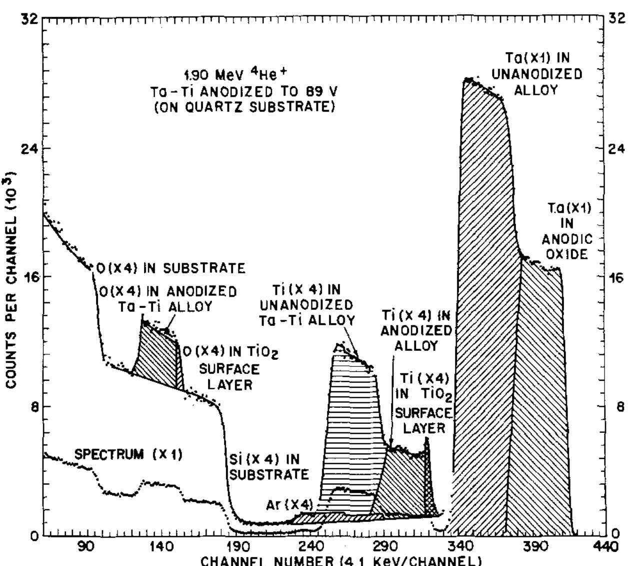

Fig. 3. Backscattered energy spectrum from a sputtered tantalum-titanium film anodized to 89V. The Ta and Ti regions are now each divided into two areas, anodized and unanodized as marked on the figure. Si and O in the substrate are shown as in Fig. 1, but now O yield from the oxide region appears superimposed on the substrate Si. The oxygen yield is consistent with the assumption that the oxides formed are Ta_2O_5 and TiO_2.

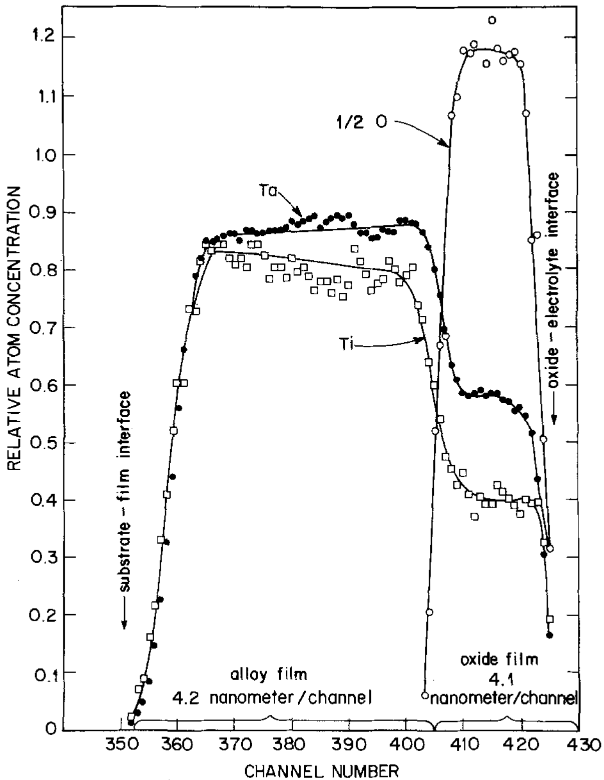

Fig. 4. Depth profile extracted from the spectrum of the 46V sample. Composition is relatively uniform in the as-deposited and anodized areas.

gen yield from the oxide was found by drawing a line along the silicon substrate yield and extending it under the oxygen yield. Determining the argon yield involved considerable uncertainty since the leading argon edge is under the titanium plateau. The assumption was made that the argon remained essentially stationary with respect to the original metal/air interface and so the amount in the anodized region could be estimated reasonably well.

Table II shows the results of a compositional analysis for oxide regions of the five samples. Average compositional ratios for Ta:Ti:O:Ar are 1.2:1:5.3:0.1, respectively. Table II suggests that the oxides are Ta_2O_5 and TiO_2, since the excess oxygen indicated in the table is within the previously stated $\pm 5\%$ error for oxygen. In cases where the Ta and Ti spectra overlap, they can be separated because part of the Ti peak can be discerned as a partial projection above the Ta spectrum.

Figures 4 through 6 show depth profiles extracted from the spectra of the samples anodized to 46, 89, and 134V. (Meaningful profiles could not be extracted from the other two spectra because of overlap of tantalum and titanium dioxide yields.) Figures 5 and 6 plainly show a characteristic that can also be seen on the raw spectra: the appearance after anodization of a narrow peak at the high energy edge of the titanium dioxide region. Close examination of the leading edges of the tantalum spectra from the original and anodized samples shows that the tantalum region has moved to lower energy indicating that there is titanium, but not tantalum, present at the surface of the film. This shift is seen at the right edge of Fig. 6. One can see that the titanium is oxidized, because the yield from oxygen in the oxide begins at the surface energy; this surface oxide is assumed to be titanium dioxide. The spectra from samples anodized to 178 and 229V also indicate the presence of this titanium dioxide surface layer, but indirectly since overlap of the tantalum and titanium regions obliterate the titanium leading edge. In these cases one can observe only that the leading edge of the tantalum region has shifted to a lower energy and that oxygen remains at the surface. From the depth profiles and spectra, then, one finds that anodization can lead to the formation of an oxide surface layer that is very rich in titanium and ends up almost entirely as a titanium oxide. The layer is not apparent (either absent or unresolvable) at the lowest anodizing voltage investigated, but it appears for higher voltages with a thickness dependent on the magnitude of the voltage.

Oxide film surface densities were determined for the anodized films in a manner similar to that described above for the as-deposited samples. Results are plotted in Fig. 7 *vs.* the anodization voltage for each sample. The solid line is the least squares fit (20) for all points with an apparent anodization constant of $(1.15 \pm 0.02) \times 10^{-5}$ kg/(m²-V).

Table II. Relative atomic concentrations of tantalum-titanium anodic oxides produced by anodization. In addition to the observed oxygen level for each sample, the expected oxygen level, assuming the presence of only Ta_2O_5 and TiO_2, is given.

Average				105

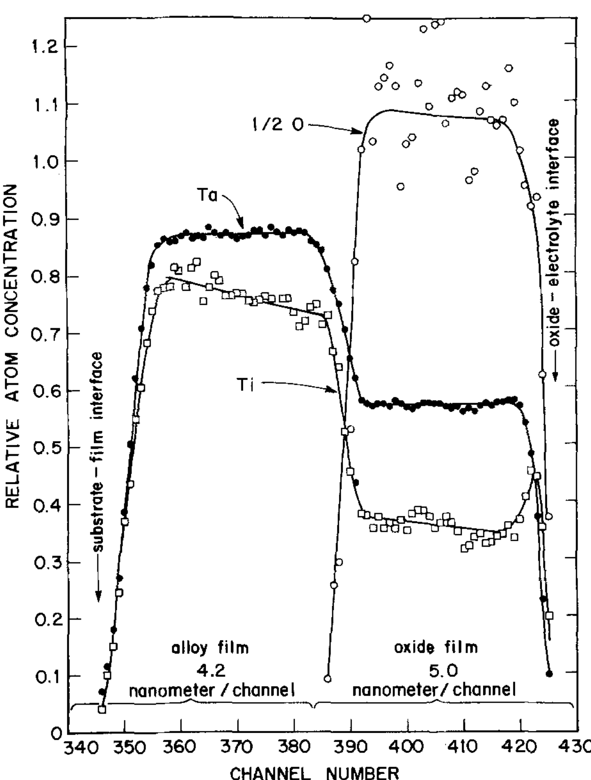

Fig. 5. Depth profile extracted from the spectrum of Fig. 3. Composition is relatively uniform in the different areas except near the surface where an increase in Ti concentration and a corresponding decrease in Ta occurs.

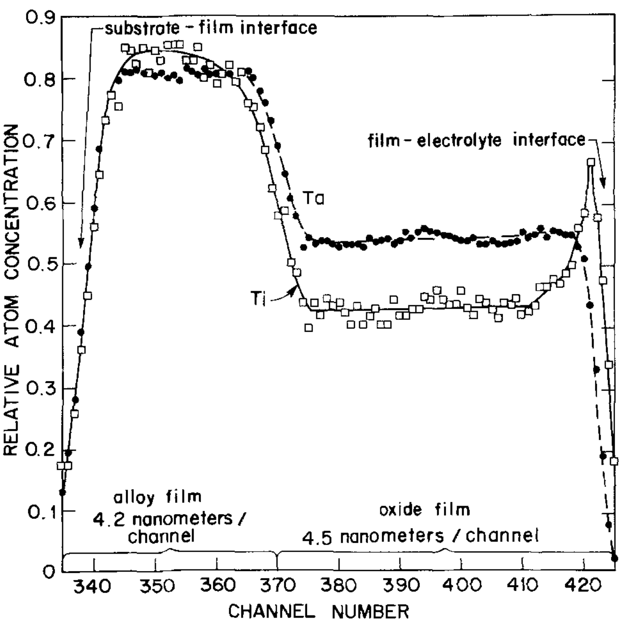

Fig. 6. Depth profile extracted from the spectrum of the 134V sample. Indicated results are similar to those of Fig. 5.

The density of the anodic oxide film was determined for one sample from the surface density (sample 3, Table III) of $(157\pm4) \times 10^{-5}$ kg/m^2 and the stylus determined thickness of 266 ± 19 nm, resulting in a value of $(5.9\pm0.2) \times 10^3$ kg/m^3.

The determined density of the anodic oxide, $(5.9\pm 0.2) \times 10^3$ kg/m^3, can be compared to a value estimated from the densities of anodic tantalum oxide and "anodic" titanium dioxide. The value of the former is 7930 ±3% (6). The value of the latter is an average of the bulk values (21) of brookite and anatase decreased by a factor of 0.967 to account for the observed

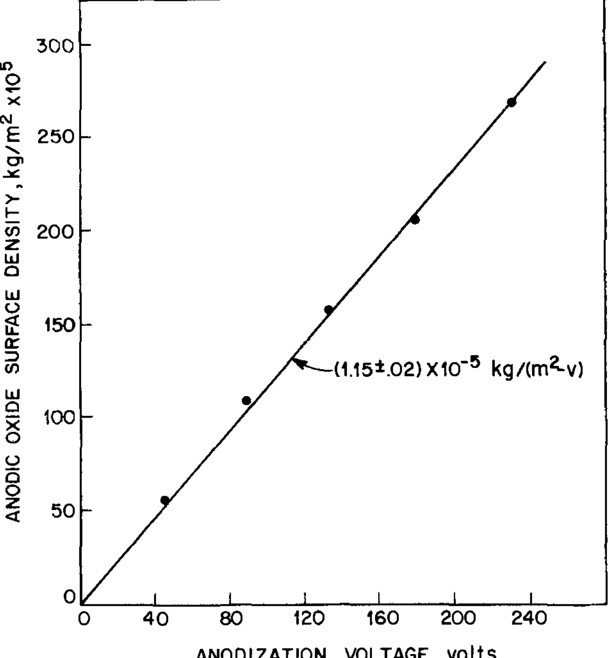

Fig. 7. Graph showing a plot of anodized film surface density determined from the Rutherford backscattering for the five samples vs. the anodizing voltage for each.

density ratio of anodic tantalum oxide/bulk tantalum oxide (*i.e.*, 7930/8120). These estimates lead to a value of 3870 kg/m^3 for anodic titanium dioxide. The density can then be calculated by a formula which seems to be quite accurate for determining bulk alloy densities

$$d_{calc} = \frac{\Sigma n_i A_i^o}{\Sigma n_i V_i^o} \quad [6]$$

$$V_i^o = A_i^o/d_i^o \quad [7]$$

where n_i is the atom or mole fractions, A_i^o is the atomic or molecular weights, V_i^o is the atomic or molecular volumes, and d_i^o is the bulk densities. In these calculations, 1780 kg/m^3 is used for argon (21). For sample 3, the density is calculated by

$$d_{calc}^1 = 0.98 \frac{n_{Ta_2O_5}A_{Ta_2O_5} + n_{TiO_2}A_{TiO_2} + n_{Ar}A_{Ar}}{n_{Ta_2O_5}V_{Ta_2O_5}^o + n_{TiO_2}V_{Ta_2O_5}^o + n_{Ar}V_{Ar}^o} + 0.02\frac{A_{TiO_2}}{V_{TiO_2}^o} = 6.08 \times 10^3 \text{ kg/m}^3$$

Table IIIA. Oxide film surface mass densities, volume densities, and thicknesses

Sample No.	Anodization voltage (V)	Surface density kg/m² × 10⁵	Volume density kg/m³	Thickness nm
1	46	56	6240	90
2	89	109	6380	171
3	134	157	6080	258
4	178	205	6070	338
5	229	257	6070	423

Table IIIB. Approximate values for outer TiO_2 layer determined from the shift of the leading tantalum edge, before and after anodization (Density TiO_2: 3870 kg/m^3)

Sample No.	Anodization voltage (V)	Surface density kg/m² × 10⁵	Approximate thickness nm
1	46	0	0
2	89	1.6	4
3	134	3.2	8
4	178	4.8	12
5	229	6.4	17

The second term in this equation accounts for the small TiO_2 layer on the surface. A comparison of this value to the determined value of 5.9×10^3 indicates that this method for anodic oxides is accurate to about 3%, and is within the probable error of the real value.

The density can also be calculated by another possible rule which sums the mole fraction times the bulk densities for each component

$$d_{calc}^2 = \Sigma\, n_i d_i^o \qquad [8]$$

which for sample 3 would be

$$d_{calc}^2 = 0.98\,[n_{Ta_2O_5} d_{Ta_2O_5}^o + n_{TiO_2} d_{TiO_2}^o + n_{Ar} d_{Ar}^o] + 0.02\, d_{TiO_2}^o = 5.10 \times 10^3 \text{ kg/m}^3$$

This value when compared to the actual value of 5.9×10^3 might indicate that there was about 14% porosity in the oxide. To evaluate the possibility of porosity, capacitance measurements were made in an aqueous electrolyte and metal counterelectrodes with the assumption that porosity of the order 14% would result in a considerably higher capacitance for the former.

Figure 8 shows the reciprocal capacitance/area (m^2/F) as a function of anodization voltage in $8N$ sulfuric acid, as well as the reciprocal capacitance/area for nichrom-gold counterelectrodes for a sample anodized to 230V and a comparable figure for beta-tantalum based capacitors. At 230V, the capacitance for the wet electrolyte and metal counterelectrode differ by only 3%, indicating no high degree of porosity. Moreover the capacitance/area of the tantalum-titanium anodic oxide at 230V is 7% lower than that obtained for beta-tantalum capacitors. The least squares line in Fig. 8 gives a value for the slope equal to $(8.6 \pm 0.3)\ m^2/(F\text{-}V)$.

The ability of Eq. [6] to calculate the true density for sample 3 was used to calculate variations in density for the other oxide films (see Table IIIA, column 4), due to composition variations because of loss of titanium (see below); these densities were used to calculate thicknesses (Table IIIA, column 5). The oxide thicknesses are plotted against anodization voltages in Fig. 9, and the solid line is the least squares fit to the points. The least squares evaluated slope is 1.88 ± 0.02 nm/V. This anodization constant in combination with the value of $(8.6 \pm 0.3)\ m^2/(F\text{-}V)$ allows a calculation of the dielectric constant as 24.7 ± 0.9. All of these values are collected in Table IV.

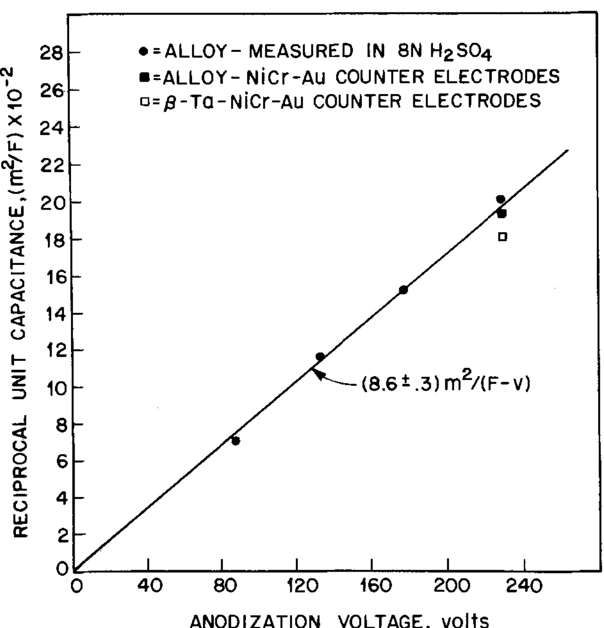

Fig. 8. Graph of reciprocal unit capacitance density against anodization voltage.

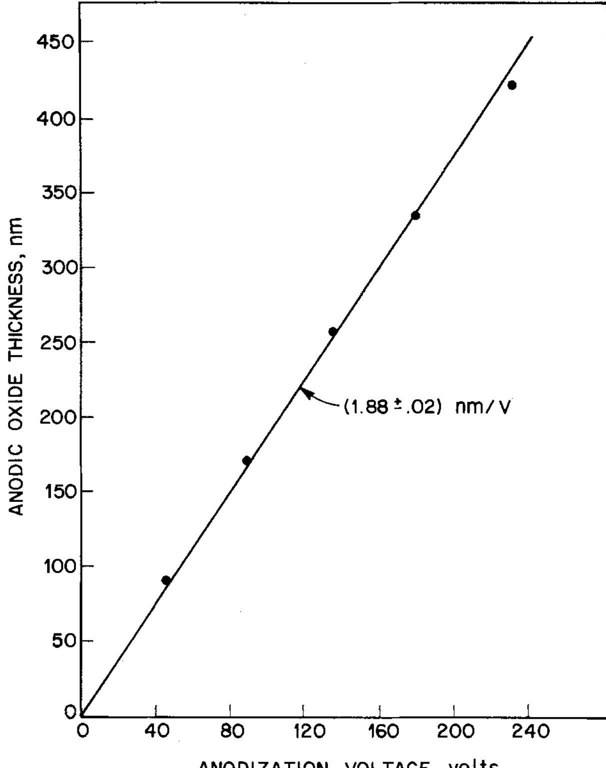

Fig. 9. Graph of thickness of anodic oxide against anodization voltage.

The profiles of Fig. 4-6 show that behind the surface titanium dioxide layer the oxide composition is relatively uniform. They do indicate, however, that the metal atom compositions in the anodized and unanodized regions are different, *i.e.*, that titanium may have been lost from the system during anodization. The possibility was checked by summing the titanium and tantalum yields in both the unanodized and anodized spectra for the sample anodized to 134V. The Ta:Ti ratio for the unanodized sample was 9.54:1. For the anodized sample, however, the ratio was 10.3:1, indicating a titanium loss of about 8%. Loss of titanium during anodization was finally confirmed by a chemical Coprex analysis (22) of the citric acid solution after anodization: titanium was detected in an amount indicating an 18% loss from the film. No test was made for tantalum in the solution, but anodization of tantalum alone in this electrolyte has never previously given any indication of tantalum dissolution. Table V gives the Ti:Ta ratios in the metal alloy and anodic oxide, as well as the percentage loss in Ti. There may

be a slight tendency for the Ti loss to be higher at lower anodization voltages.

Discussion and Conclusions

In this study, anodic oxides were grown on sputtered tantalum-titanium thin films. Analysis of the as-deposited films indicated that the tantalum and titanium were distributed uniformly throughout the films by the sputtered process. Analysis after anodization revealed that a relatively uniform distribution of tantalum and titanium existed in the anodized region of the film in contrast to the duplex film in the anodized tantalum-silicon alloys. Three other growth effects were apparent:

1. In all but the 46V (low voltage) sample, a thin surface layer of titanium dioxide was formed during anodization. The thickness of the layer was directly dependent on the final anodization voltage; and most of the layer was essentially devoid of tantalum.

2. A change in the relative amounts of tantalum and titanium in the anodized region indicated a relative loss of titanium during anodization which was essentially confirmed by analysis of the solution for titanium after anodization.

3. The oxide growth constant of 1.88 nm/V is approximately equal to that of both tantalum (2) and titanium (4) alone, and also approximately equal to that of Ta-Si anodization (2).

As mentioned in the introduction, one reason for investigating Ta-Ti films was that the dielectric constant of titanium dioxide in bulk, and frequently in anodic oxides, is greater than that of Ta_2O_5. Because of this high bulk dielectric constant and the previous experimental results (7, 8), it was considered possible that addition of titanium to the tantalum would increase the capacitance density of the resulting oxide. The capacitor film studies (9) showed that the capacitance density decreases with increasing titanium dioxide content, but reaching only a 7% loss at about a $Ta_{0.5}Ti_{0.5}$ alloy as indicated in Fig. 8; this decrease is less than that obtained with equivalent additions of Al_2O_3 (5) or SiO_2 (1).

The present study shows that the anodization constant of 1.88 nm/V for this Ta_2O_5-TiO_2 combination is about equal to that for either Ta_2O_5 or TiO_2 alone. The value of the dielectric constant, 24.7, is less than that of anodic tantalum oxide. There is no clear model for calculating the dielectric constants of solid solutions, but it is apparent that the addition of TiO_2 to anodic Ta_2O_5 is not particularly efficient in raising the dielectric constant using these particular anodization conditions.

A further analysis of the previous tantalum-silicon data (2) is given below and indicates that during anodization of those films the tantalum cation transport mechanism is essentially the same as that for bulk tantalum alone, while the silicon remains relatively stationary. This mechanism leads in the tantalum-silicon case to the formation of a duplex oxide with an outer Ta_2O_5 layer and an inner uniform mixture of Ta_2O_5 and SiO_2. The present study found that a duplex oxide is also formed but in this case with a very small amount of titanium dioxide at the surface while a uniform "amorphous" mixture of Ta_2O_5 and TiO_2 composed the bulk of the oxide.

The data of the previous study (2) on the tantalum-silicon system can be interpreted in the following way. Examination of Fig. 4 in Ref. (2) indicates that the leading edge of the argon atom distribution is associated with the leading edge of the silicon atom distribution. Since the leading edge of the argon atom distribution was originally associated with the surface of the tantalum-silicon film at the electrolyte interface, it essentially acts as a transport marker if it does not move significantly during the anodization. Implanted argon has been used previously by Pringle (23) in bulk tantalum to determine the transport numbers of tantalum and oxygen to be 0.25 and 0.75, respectively. He also demonstrated that the argon does not move significantly during the anodization, and it is reasonable to make the assumption in the present tantalum-silicon alloy case. With that assumption, it can be calculated that the tantalum cation transport is about 0.3, quite close to the pure bulk tantalum transport number; silicon cation transport is essentially zero, and it is oxidized by the migration of oxygen inward where the oxygen transport number is about 0.7.

A possible explanation for the feature that the tantalum cation moves in this system, while the silicon cation does not, is based on the fundamental equation of cation transport for anodic oxides

$$i_1{}^+ = i_1{}^0 \, e^{-\frac{(W - q_1 aE)}{kT}} \quad [9]$$

where $i_1{}^+$ = fraction of current carried by cation 1; $i_1{}^0$ = pre-exponential constant; W = activation energy separating two potential minima for a single cation jump; $q_1 aE$ = decrease of the barrier height W due to the movement of a particle with effective charge, q_1, with half the jump distance, a, in a field, E; k = Boltzmann constant; T = absolute temperature. If a second cation exists in an alloy system, then its transport equation is

$$i_2{}^+ = i_2{}^0 \, e^{-\frac{(W - q_2 aE)}{kT}} \quad [10]$$

where it is assumed that, because of the common environment, W, a, and E are essentially equal for the two cationic species, while $i_1{}^0$ and $i_2{}^0$ are of the same order of magnitude. The ratio of the two currents then is

$$\log \frac{i_1{}^+}{i_2{}^+} = \frac{(q_1 - q_2) aE}{2.303\, kT} \quad [11]$$

For $q_1 - q_2$ equal to 1, a equal to about 1.0×10^{-8} cm, and E equal to $5.5 \times 10^{+6}$ V/cm, the ratio of

$$\frac{i_1{}^+}{i_2{}^+} = 8.5 \quad [12]$$

Thus for two cationic species differing by unit charge, one will essentially migrate, while the other will remain stationary. For the tantalum-silicon system the end point stoichiometry indicates that the oxide consists of a mixture of Ta_2O_5 (Ta = +5) and SiO_2 (Si = +4). It is reasonable to assume that during transport, if the cations move at all, that their charge will differ by unity, and therefore, from the above equation, segregation will take place. This appears to be one possible explanation for the duplex film formed in the tantalum-silicon case.

The stoichiometry of the tantalum-titanium anodized film indicates a mixture of Ta_2O_5 (Ta = +5) and TiO_2 (Ti = +4), and the above argument would require the formation of another duplex film. The appearance of a relatively uniform distribution in this case may be attributed to one of two possible mechanisms:

1. Since the argon leading edge is hidden by other peaks, it cannot be used as an internal transport marker. Therefore, it is quite possible that the entire cation transport mechanism has changed and its rate is essentially zero. On this basis, oxidation occurs by oxygen moving inward. This possibility may be compatible with some reports (4) that anodization of titanium takes place by oxygen migration. In this mechanism the small TiO_2 fraction at the surface would be due to a relatively small transport of titanium cations to the surface.

2. An alternative assumption can be made that the cation transport has not essentially changed from the pure tantalum or tantalum-silicon cases. This would imply that a major fraction of movement of the tantalum and titanium occurs by identical cation transport numbers with a very small fraction of the titanium moving by some faster mechanism. Rigo and Seijka (24) have proposed both a short and long range mech-

anism of niobium transport in the duplex structure of anodic oxides of tantalum films on bulk niobium. In the present tantalum-titanium alloys, a small amount of long range transport of titanium seems to exist to provide the small, pure, TiO_2 film at the surface. An intriguing possibility for this long range fast transport is that it is due to the titanium ionizing to two different charge states. If this latter proposal is finally proven to be accurate, one can describe the effective charges of the various species as: Si $= n - 1$; Ta = Ti $= n$ (small amount of Ti $= n + 1$).

Actually in order to make any concrete conclusions about relative effective ionic charges, detailed experiments are required with true transport markers and dilute concentration of the alloying element to ensure that the assumption of equal i_1^0, i_2^0, W, a, and E holds for Eq. [9] and [10].

We have demonstrated in these studies that relatively minor changes in the nature of the chemical species, such as Si to Ti, causes a major change in the atom distribution. This sensitivity may lead to experiments which can probe in detail the fundamental mechanistic steps in anodic oxidation. In the past, arbitrary assumptions had to be made about the cation charge number, which led to unusually high values of "a", the half-jump distance. Further experiments of this sort may clear up this ambiguity.

Acknowledgments

The authors gratefully acknowledge valuable discussions and comments by C. D. Thurmond, W. Brown, R. P. Frankenthal, J. Poate, and A. English. Particularly, Ms. S. Vincent was responsible for the Coprex analysis, and F. G. Peters for the preparation of the Ta-Ti alloy films. We wish to thank the reviewers for very probing comments.

Mechanical Failure of Anodic Films on Aluminum and Tantalum

Y. H. Choo* and O. F. Devereux**

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Anodized specimens of aluminum and tantalum were deformed in laboratory air; strain to failure and the failure characteristics of the oxide film were evaluated optically. Barrier-type anodic aluminum oxide films of thickness greater than ~400Å failed at ~0.925% strain normal to the tensile axis and apparently suppressed substrate slip emergence. Thinner anodic films on aluminum failed along substrate slip traces at ~1.12% strain. These films did not suppress slip emergence, but were apparently stronger. The presence of a porous oxide superimposed on thin barrier-type films caused them to fail in the thick film mode; this was the only effect of a porous layer. Anodic films on mechanically polished tantalum failed at ~0.28% strain, independent of thickness, but showed a failure mode dependence on thickness analogous to that of aluminum. Films on chemically polished tantalum substrates always failed in simple tension, but showed a thickness dependence, failing at ~0.14% strain for thicknesses greater than ~680Å, and ~0.20% strain for thicknesses less than that value. Failure of these films was accompanied by separation of the films from the substrate.

Environment-sensitive failure processes such as stress corrosion cracking and corrosion fatigue involve a complex interplay of chemical and mechanical aggression and are far from well understood. Oxide film failure is seen by many investigators as a necessary prelude to the initiation and propagation of cracks in these processes (1-7). The literature dealing with the mechanical behavior of oxide films is not voluminous, and reported values of mechanical properties, *e.g.*, Young's modulus, film strength, and film failure strain, exhibit large variations. Edeleanu and Law (8) strained thick porous anodic films on aluminum in tension and found them to be elastic, with failure occurring at 1-2% strain normal to the tensile axis. Bradhurst and Leach (9, 10) deformed aluminum specimens bearing barrier-type anodic films, detecting film failure by a variety of electrical methods to occur at 1-3% strain. For 1500Å films removed from the substrate, a failure strain of 2.48% and a Young's modulus of $\sim 41 \times 10^3$ MN/m^2 were determined. Also using electrical detection methods, Bubar and Vermilyea (11, 12) found thin anodic films on aluminum to exhibit some ductility, while thick films were brittle. They also observed a large ductility, as much as 50% elongation prior to fracture, in anodic tantalum oxide films tested in this wet manner, in marked contrast to the value of 0.83% reported by Eliezer and Brandon (13), who used a (dry) bulge test technique. In earlier work Young (14) had attributed this discrepancy to the presence of a surface film on chemically polished specimens. This film gave rise to poor adhesion of the anodic oxide, with consequent oxide detachment and brittle behavior, whereas removal of this "preanodic" film by leaching in boiling water resulted in a very adherent, ductile anodic oxide. Grosskreutz (15, 16) found anodic aluminum oxide films, both adherent to and separated from the substrate, to be elastic to fracture with the strain at failure being in the range of 0.1-0.3%. In adherent films fracture was seen both at slip steps and normal to the tensile axis. Humidity was found to have a significant effect on the oxide modulus with films displaying the bulk modulus under vacuum, but a value an order of magnitude lower at ambient humidity. In these studies fracture strain was seen to increase with humidity. Grosskreutz found a similar correlation between the water content of various environments and the density of cracks created in anodic films on aluminum alloys by straining (17); as discussed later the crack density is directly related to the moduli of the film and substrate. Brandon *et al.* (18, 19) found a dependence of the failure strain and strength of barrier-type anodic aluminum oxide films on thickness. These parameters generally increased with thickness, although some results indicated a marked decrease in strength in films thicker than ~ 2000Å. The elastic modulus in these studies was seen to decrease as film thickness increased to 750Å, beyond which it was constant.

Some observations have been made on the effect of an oxide film on the mechanical behavior of the substrate. Block *et al.* (20, 21) observed that thick anodic oxide films inhibited slip emergence at the surface of aluminum single crystals except where film cracking or buckling had occurred, and that the oxide/substrate interface was capable of withstanding significant shear strain. Although Block *et al.* reported some strengthening of the substrate by the anodic film, Leach *et al.* (22-24) reported a nearly 50% increase in the strength of a thin aluminum wire when coated with a 2600Å anodic film, provided the film remained intact. The effect vanished upon film failure at ~ 2% strain. They also observed an increase in elongation in the presence of an anodic current, inferring that the oxide no longer strengthened the substrate but became ductile under the influence of an ionic flux. This they attributed to a field-activated diffusional mechanism for plastic deformation of the oxide, similar to the Herring-Nabarro model. Devereux *et al.* (25) have studied the failure strain of anodic films formed on an aluminum alloy as a function of the *p*H of an aqueous environment using electrical detection methods. A small, but significant *p*H dependence was seen with failure strain being maximum at *p*H 8, which was assumed to be the zero point of charge of the anodic film.

The following report deals primarily with the failure of anodic films on aluminum, with some observations on tantalum, these materials appearing to represent extremes of mechanical behavior in the aforecited studies. The environment in all cases was laboratory air. Particular attention was devoted to the dependence between film failure and deformation of the substrate.

Experimental Procedures

Aluminum.—A high purity aluminum ingot (99.99%) was sliced into plates 6.35 mm in thickness which were subsequently rolled into sheets of 0.254, 0.508, and 0.762 mm thickness. These sheets were cut into

Key words: anodic oxide, aluminum oxide, tantalum oxide.

rectangular specimens 127 × 12.7 mm, from which were machined tensile specimens with a gauge length of 31.75 mm and a gauge width of 6.35 mm. Compression specimens of square cross section, 5.08 × 5.08 × 15.24 mm, were also prepared by slicing. All specimens were mechanically polished through 600 grit SiC paper to remove surface and edge irregularities, and were ultrasonically cleaned in benzene for 30 min. Following this preparation, the specimens were annealed, chemically polished, electropolished, and anodized according to the previously described procedures (26).

Deformation of both tensile and compression specimens was accomplished with a Hounsfield Type W tensometer fitted with a variable speed d-c drive motor. In this apparatus the applied load was measured by noting the movement of a mercury column caused by deflection of a calibrated spring beam. Strain was measured by means of an Instron extensometer of 25.4 mm gauge length clipped to the specimens. This was monitored with a Daytronic Model 300D transducer amplifier equipped with a Type 96 strain gauge input module. All tests were performed in laboratory air of nominal temperature ~ 23°C and nominal relative humidity ~ 40%. Strain rates were typically 0.03%/min. Specimens were deformed to predetermined values of strain while under observation with a low power (60×) binocular microscope. Deformed specimens were examined in detail with a high quality optical metallograph equipped with a Nomarski-type interference system. Films removed from deformed specimens were also examined by transmission electron microscopy.

Measurements of the Young's modulus of adherent oxide films on aluminum were made by performing flexure tests on small beams, 57.15 × 6.35 × 0.0765 mm. Deflection, before and after application of an anodic film of known thickness, was measured with a cathetometer under both end loading and center loading. Loads of 3 to 20 mg were used, and deflection was measured to 0.01 mm.

Tantalum.—Specimens were prepared from polycrystalline tantalum sheet of 99.9% purity and 0.254 mm thickness following, in essence, the above procedure. After ultrasonic cleaning, however, specimens were polished using one of two methods: chemical polishing for 20 sec in a solution of 5 parts by volume sulfuric acid (98%), 2 parts nitric acid (70%), and 2 parts hydrofluoric acid (48%) or mechanical polishing through 0.05 μm alumina dust. Specimens were subsequently anodized in a solution of 1 weight percent (w/o) ammonium borate in double distilled water, using an anodizing potential in the range of 10-100V and an anodizing time of 3 hr. In order to study the morphology of such films, sample films were stripped using both cathodic polarization (14) and cellulose tape techniques. Mechanical testing was similar to that described for aluminum. The behavior of films formed on substrates subjected to leaching in boiling water was not studied.

Results

Aluminum oxide films.—Failure strain determination—To determine the effect of porous oxide growth on the failure strain of anodic aluminum oxide films, annealed and electropolished specimens were anodized at 50V for periods ranging from 45 min to 24 hr, corresponding to porous oxide layers from 0 to 1550Å in thickness superimposed on a barrier layer 650Å in thickness (26). Film failure was defined by the appearance of a distinct discontinuity in the film when viewed at 1000× subsequent to imposing a predetermined strain upon the specimen. Typical results are shown in Fig. 1, which indicates an apparent lack of failure strain dependence on porous layer thickness. A similar independence of anodizing time was seen for films formed at other potentials. Anodizing potential did effect failure strain, however, as shown in Fig. 2. The data shown represent the lowest strain

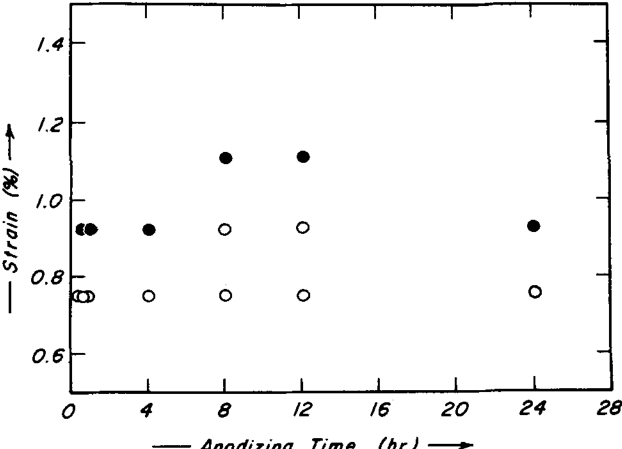

Fig. 1. Failure strain vs. anodizing time for anodic films formed on aluminum at 50V. Solid points denote failure; open points, unfailed specimens.

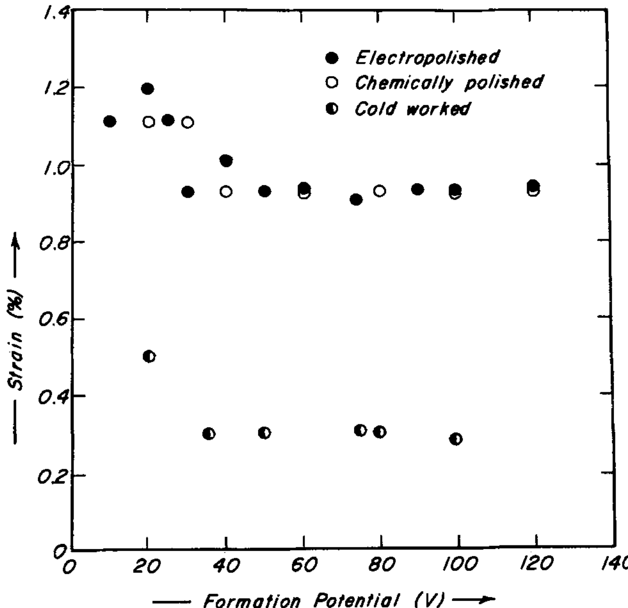

Fig. 2. Failure strain vs. formation potential for anodic films formed on aluminum.

value at which film failure was noted for a given anodizing potential. A distinct trend toward higher failure strains for films formed at potentials less than 30V is evident. Films formed on annealed and chemically polished substrates behaved in a similar manner, exhibiting no dependence of failure strain on anodizing time and the same dependence on anodizing potential, shown in Fig. 2, as did films formed on electropolished substrates. Also shown in Fig. 2 are data pertaining to films formed on substrates that were cold-worked prior to chemical or electropolishing. Although exhibiting a similar dependence on anodizing potential, these films failed at significantly lower strain values, indicating a dependence on the stress state of the substrate.

Fracture behavior.—In general two types of fracture were observed: (*i*) fracture along substrate slip steps at the failure strain of ~ 1.1% seen in films at potentials of less than 30V, and (*ii*) fracture approximately normal to the tensile axis at the failure strain of ~ 0.9% seen in films formed at potentials of 30V or more. In each case, as straining progressed failure in the other fracture mode occurred. That is, in films formed at less than 30V cracks were observed to form normal to the tensile axis at strains larger than required for the initial failure along slip steps, while in the thicker films which failed initially normal to the tensile axis further straining causes failure along

slip steps. Initial failure in fracture modes (*i*) and (*ii*), above, is shown in Fig. 3 and 4, respectively. A film formed at 35V, which initially showed fracture lines normal to the tensile axis when strained to 1.5%, is shown in Fig. 5 after straining to 10%. Displacement of the normal fracture lines by the subsequently occurring slip failure is evident.

In these studies, formation of substrate slip lines was clearly evident, especially in the case of electropolished specimens, at strains as low as 0.5%. Careful optical examination did not reveal film fracture, however, at these low strain values. Removal of the films and examination by transmission electron microscopy substantiated this fact, *i.e.*, that the anodic oxide films were able to tolerate a considerable amount of substrate slip without failure. Although it is not clearly evident, Fig. 3 illustrates both substrate slip without film failure, in grains labeled A, and substrate slip with accompanying film fracture along the slip traces, in grains labeled B. Clearly, failure occurred first in those grains which suffered the greatest deformation, *i.e.*, those grains whose primary slip systems were most favorably oriented with respect to the maximum resolved shear stress, 45° to the tensile axis. In general, there is no indication of fracture initiation at grain boundaries, although the fractures seen in Fig. 3 clearly terminate with the slip traces at the boundaries. In the case of thicker films, *e.g.*, as shown in Fig. 4, normal fracture lines propagated independently of substrate slip traces and of grain boundaries. This case is clearly distinguishable from that illustrated in Fig. 5, where subsequent occurrence of fracture at slip traces caused displacement of the normal fracture lines. Similarly, in the case of thick films formed on chemically polished substrates, the normal fracture lines propagated unaffected by the marked hillock structure characteristic of chemical polishing, as shown in Fig. 6. In no case was deformation seen to have caused detachment of an aluminum oxide film from the substrate.

The mode of fracture of films formed at potentials less than 30V did exhibit a dependence on anodizing time, *i.e.*, on porous layer thickness. For example, a 25V film anodized for 45 min failed initially along substrate slip traces as described above, but a 25V film anodized for 8 hr failed in the normal fracture mode. Films formed at potentials of 30V or greater failed initially in the normal mode irrespective of anodizing time. Films formed on cold-worked substrates failed in the same manner as did those on annealed substrates, *i.e.*, normal fracture in thick films and fracture along substrate slip traces in thin films. Although film failure normal to the tensile axis was always seen as sharp, well-defined, continuous fracture lines, two types of fracture behavior were seen along substrate slip traces. In one, a sharp, well-defined, straight fracture along the slip trace was seen; in the other short fracture segments, each wholly or partially normal to the tensile axis, formed along each slip trace. The latter behavior is shown in Fig. 7.

In general, film fracture did not initially occur uniformly throughout the specimen gauge length, especially in the case of cold-worked substrates. Initial film failure occurred first in regions where there was a local concentration of shear deformation. In the

case of thick films, the region in which normal fracture lines were seen progressed along the specimens as did the region of substrate deformation, with fracture lines eventually becoming uniformly distributed throughout the gauge length of the specimen. On continued deformation, new fracture lines formed approximately midway between existing fractures. This process continued up to a certain strain level, beyond which no new cracks initiated. Accordingly, the average spacing between normal fracture lines is plotted in Fig. 8 as a

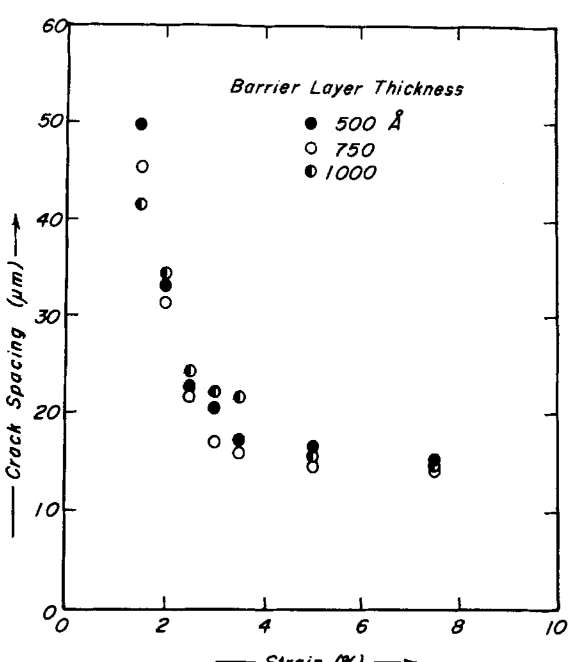

Fig. 8. Terminal crack spacing vs. strain for anodic aluminum oxide films of various (barrier-layer) thicknesses.

function of strain for several different film thickness values. These films were formed for 45 min only, and thus are simple barrier-type films. Using a stress relaxation analysis, Grosskreutz and McNeil (27) demonstrate that such data should follow

$$\ln(\epsilon/\epsilon_0) \approx (4g/d)\,[1 - (d/d_0)] \qquad [1]$$

where d is crack spacing and ϵ is strain, with (d_0, ϵ_0) representing a convenient reference point. The significance of g was not established. As shown in Fig. 9 the present data follow Eq. [1] approximately until the crack spacing approaches the critical value of 15 μm beyond which further strain does not produce new cracks. It is not clear why the 1000Å film deviates from the behavior exhibited by the 500 and 750Å films.

Upon deforming compression specimens anodized in the range of 20-100V, film failure along substrate slip traces was seen in the strain range 1.4-1.7% as shown in Fig. 10. Upon further straining to 2.3-3.0% regularly spaced cracks were seen to form parallel to the compression axis, *i.e.*, in the direction of substrate dilation. Assuming constant substrate volume, the compressive strain of 2.3% corresponds to a tensile strain of 1.15% in good agreement with the strain at which normal failure was seen in the tensile tests.

Young's modulus of adherent aluminum oxide.—An anodized aluminum beam may be regarded as a composite beam of two materials and may be analytically reduced to an equivalent beam of one

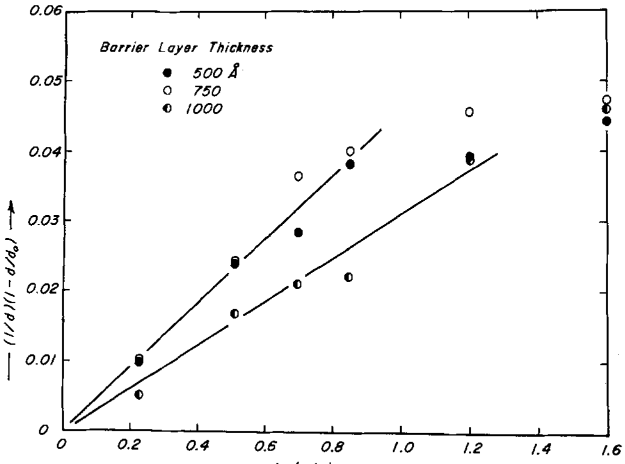

Fig. 9. Data of Fig. 8 plotted according to Eq. [1]

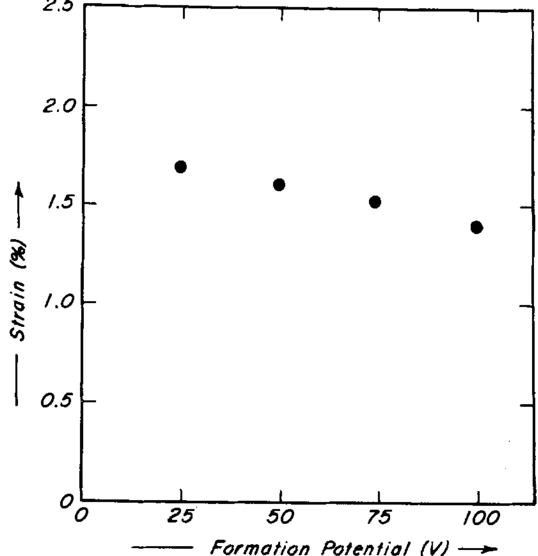

Fig. 10. Failure strain vs. formation potential for anodic aluminum oxide films on compression specimens.

material by transforming the dimensions of the beam section in accord with the ratio of the elastic moduli of the two materials. In doing so, we may express the flexure formula for a cantilever beam in end loading as

$$E_o = \frac{4Rl^3 - E_m X t_m^3}{2[4Xt_o^3 + 3Xt_m t_o(t_m + 2t_o)]} \quad [2]$$

where E_o and E_m are the moduli of the oxide and metal, respectively; R, the load/deflection ratio; l, the length of the beam; X, the width of the beam; and t_m and t_o, the thickness of the metal and of the oxide, respectively. The thickness of the oxide may, of course, be established by the anodizing ratio, and the thickness of the metal may be related to its thickness before anodizing, t_i, and the oxide thickness through the oxide density (28)

$$2t_o = 1.38(t_i - t_m) \quad [3]$$

Equation [2], thus contains on the right-hand side only measurable or calculable parameters and is valid for small deflections, corresponding roughly to the elastic range of the beam. In evaluating the load ratio, R, however, for a number of beams, it was found to be a function of the applied load as shown for a typical beam in Fig. 11, decreasing approximately linearly with increasing load before leveling off to an apparently constant value. This unexpected behavior was attributed to inaccuracy in measurement of the deflection, suggesting that the constant value of load ratio seen at higher loads was the true value. The modulus was estimated in this manner to be 41.4 $\times$ 10^3 MN/m^2 (6 $\times$ 10^6 psi), in good agreement with values obtained by Bradhurst and Leach (9) and Grosskreutz (15).

Tantalum.—Anodizing characteristics.—In potentiostatic anodizing of high purity tantalum in aqueous ammonium borate, the anodic current decreases rapidly with time for the first 1/2 hr, followed by a slower continuous decrease, the anodic current being $\sim$ 1 μA/cm^2 after 3 hr and approaching 0.1 μA/cm^2 after several more hours. This is in contrast with the gradual increase in current with time seen in anodizing of aluminum coincident with pore formation and, indeed, there is no indication of pore formation in anodic tantalum oxide films. In comparison to chemically polished substrates, the leakage current on mechanically polished substrates was somewhat higher and took longer to stabilize. Although films formed on mechanically polished substrates were very adherent and could not be stripped, those on chemically polished substrates were only weakly adherent and easily removed by cathodic polarization or by cellulose tape. A transmission electron micrograph of such a film is shown in Fig. 12. Although electron diffraction by these films revealed an amorphous structure regardless of formation potential, crystallization was seen to occur in the microscope in localized areas due to electron beam heating. These areas had a diffraction pattern consistent with that of β-Ta_2O_5.

Fig. 12. Transmission electron micrograph of anodic tantalum oxide film formed on chemically polished substrate at 50V for 3 hr.

Failure strain determination.—For purposes of observing failure strain in anodic tantalum oxide, films were formed at potentials ranging from 20 to 100V, corresponding to thicknesses ranging from 340 to 1700Å based on the anodizing constant of 17 Å/V (11, 12). Failure strain is shown in Fig. 13 as a function of formation potential for both chemically polished and mechanically polished substrates. The behavior of films formed on chemically polished substrates is analogous to that of aluminum oxide films in that a discernable increase in failure strain is seen for films formed at potentials of 30V or lower, being $\sim$ 0.14% for the thicker films and increasing to $\sim$ 0.2% for thinner films. In contrast, films on mechanically polished substrates fail at a significantly higher strain, $\sim$0.28%, and exhibit no potential, *i.e.*, thickness, dependence.

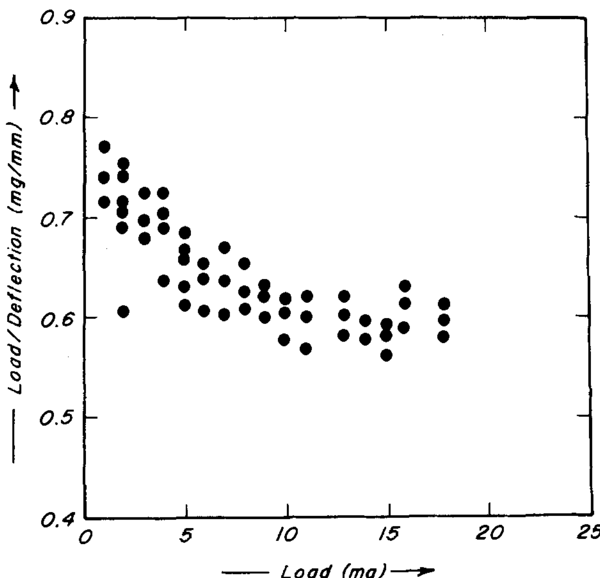

Fig. 11. R = load/deflection vs. load for composite aluminum/aluminum oxide beam.

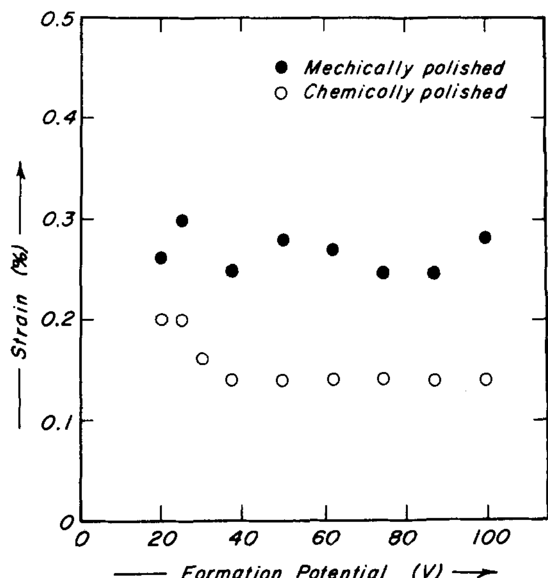

Fig. 13. Failure strain vs. formation potential for anodic films formed on tantalum.

Fracture behavior.—As mentioned above, film fracture was observed at strains as small as 0.14% in chemically polished specimens, coincident with substrate yield. No film detachment or film fracture was observed in the elastic strain region of the substrate; however, at the onset of yielding the film was seen to detach in localized areas, but only where substrate slip had occurred. Fracture initiation in the film appeared to be approximately coincident with film detachment. The localized regions of film detachment within areas of substrate yield initiated at substrate grain boundaries or triple junctions and propagated parallel to the tensile axis; film fracture appeared to be associated with the substrate grain boundaries, but propagated essentially normal to the tensile axis. These features are seen in Fig. 14, in which both film fractures and substrate grain boundaries can be distinguished. Detached areas of oxide film are evidenced by the optical interference patterns. Macroscopically, areas of film detachment were indicated by a marked change in interference color; for example, regions of substrate yield in 100V specimens were a vivid yellow in appearance in contrast to the normal blue of the unstrained film. This is due to an alteration of the interference condition occasioned by replacing the high index metal phase at the second reflecting interface by a low index air phase, thus altering the phase change upon reflection (14). Due to the very weak nature of the substrate-film bond, the stress relaxation mechanism of Grosskreutz and McNeil (27) did not appear to be operative, the normal film fracture lines displaying a somewhat random spacing as seen in Fig. 15.

In contrast, films formed on mechanically polished substrates showed no indication of detachment, either by change in interference color or by the occurrence of interference fringes, upon straining of the substrate. Fracture lines tended to be short and irregular, appearing normal to the tensile axis in thicker films, Fig. 16, and following substrate slip in thinner films, Fig. 17, in analogy to the behavior seen in aluminum oxide films.

Discussion

Aluminum.—Failure parameters.—As previously noted, other investigators (8, 9, 15) have found a considerable range in the failure strain of anodic aluminum oxide, bracketing the values found in this investigation. To a certain extent this may be attributed to differences in both forming and testing environments; however, it is also reasonable to suspect inaccuracies in fracture detection methods, especially indirect techniques relying upon electrical measurements. The optical technique used in this investigation appears to offer a definitive means of establishing a strain range within which film failure occurs, as established by subsequent transmission electron microscopy of detached films. Clearly the failure strain of anodic aluminum oxide films is independent of variations in substrate preparation, provided that the films remain adherent during testing, of porous layer thickness, and of barrier layer thickness beyond thicknesses of the order of 400Å. Bradhurst and Leach (9) observed a similar increase in fracture strain for thin anodic films on aluminum, although at higher strain values, and Beams *et al.* (29) observed an increase in

the tensile strength of electrodeposited silver films with decrease in thickness.

Similarly, a range of values has been reported for the Young's modulus of anodic oxide films on aluminum. Grosskreutz studied this parameter as a function of humidity and found it to vary from 20.7×10^3 MN/m^2 (3×10^6 psi) in saturated air to the bulk value, 386×10^3 MN/m^2 (56×10^6 psi), in vacuum, with ambient humidity giving a value of the order of 53×10^3 MN/m^2 (15). The modulus measurements of Bradhurst and Leach (9) in laboratory air are essentially in agreement with the present study, while the biaxial modulus value obtained by Eliezer and Brandon (13) corresponds to a Young's modulus of $\sim 124 \times 10^3$ MN/m^2. In the latter case, however, the film environment is ill-defined inasmuch as the test technique involved distending the film into an evacuated chamber by means of laboratory air pressure; therefore the effective film environment may be expected to have been somewhat less humid than ambient. Assuming validity of the value obtained in this study as representative of air at 40% relative humidity, the thicker films in this study failed at a stress of $\sim 0.38 \times 10^3$ MN/m^2 (55,000 psi).

Regular spacing of fracture lines.—Once the continuity of a film on a substrate in tension has been interrupted by fracture, the film is no longer under axial loading and stress within the film must be applied by means of a shear stress at the film/substrate interface. Once the substrate deforms plastically, it is reasonable to regard this stress to have a uniform value of τ, the shear flow stress of the substrate. Grosskreutz (17) has shown that the tensile stress in the film may then be written

$$\sigma = \frac{\tau}{t_o} x \qquad [4]$$

where, again, t_o is the thickness of the film and x is a length parameter parallel to the tensile axis, measured from a film fracture line. The tensile stress in the film is maximum at the midpoint between fractures; hence as the stress level increases film segments are progressively halved until the crack spacing attains a minimum value, d_c, such that the maximum stress developed is inadequate for film fracture. Thus, the fracture stress of the film may be estimated from the observed minimum crack spacing by (17)

$$\sigma_f = \frac{\tau d_c}{2t_o} \qquad [5]$$

Equation [5], however, shows a direct dependence of crack spacing on film thickness which was not observed in this study. It is reasonable to interpret this as implying an inverse dependence of film strength upon film thickness; however, this is not in agreement with the observations by Brandon and Eliezer (19). Using the observed yield stress of the substrate, $\sigma_y = 10.34$ MN/m^2, and the Tresca yield criterion, τ may be estimated as 5.17 MN/m^2. With the observed value of the critical crack spacing, $d_c \simeq 15$ μm, the film fracture strength may be estimated as 517 MN/m^2 for a 750Å film, in rough agreement with the value estimated from the observed film modulus.

Film fracture at slip steps.—The effectiveness of a superficial film as a barrier to dislocation egress and consequent slip step development is dependent on the relative moduli of the film and substrate, the thickness of the film, and the strength of the film-substrate adhesion (16). The force exerted by a film on a dislocation in the substrate has been analyzed in detail (30-32); in general it may be stated that if the film modulus is lower than that of the substrate, dislocations are attracted to the interface, whereas if the film modulus is greater an energy well for the dislocation exists some distance from the interface, with the distance increasing as the ratio of the moduli increases. Hence as the film modulus increases above that of the substrate, a greater suppression of surface plasticity in the substrate is predicted. This has not been borne out by studies of the effect of various metallic coatings on copper single crystals (33); however, Grosskreutz (16) observed entrapment of dislocations in anodized aluminum deformed in vacuum (high modulus film), but not in anodized aluminum deformed in air (low modulus film). In accord with this observation, Grosskreutz (34) found the fatigue life of anodized aluminum to be greater in vacuum than in humid air. Furthermore, increasing the thickness of the anodic film had a beneficial effect in vacuum, where the film modulus was greater than that of the substrate, but not in humid air, where the reverse was true. In studies of a somewhat different nature, Alden and Backofen (35) observed a beneficial effect of oxide films on the fatigue life of aluminum, provided that the film was repeatedly reformed.

In detailed analyses, Grosskreutz (15) and Grosskreutz and McNeil (27) interpreted the two fracture modes of anodic oxide in terms of interfacial adhesion stress and film strength; thick films having sufficient strength to withstand shear loading by slip steps on the substrate surface and, instead, separate from the substrate and fail normal to the tensile axis, while thin films failed by shear at slip steps without detachment. In the present investigation, however, the oxide was seen to exert considerable influence on plastic flow in the substrate in agreement with the observations of Block *et al.* (20, 21); with thin films, less than $\sim$ 400Å thick, distinct slip band formation and development of surface undulation were seen on deformation, but were absent when the anodic film was thicker. This influence can be manifested by the film offering a resistance to slip step emergence, thus altering the operative substrate slip systems as shown in Fig. 18. In Fig. 18 (a), two slip directions are shown operating on the same crystallographic plane. Even modest resistance to slip step emergence in one of these two directions, as by a surface film, however, will restrict slip to just one system, as shown in (b). Fracture along the slip steps generated in surface A in Fig. 18(b) is caused by shear loading normal to the plane of the film, whereas film fracture due to slip of the mode occurring on surface B is by shear loading parallel to the plane of the film. It is postulated that these different modes of film failure along lines of substrate slip are represented by the observed sharp, continuous fractures and by the discontinuous fractures as shown in Fig. 7, respectively. It must be noted that under ambient humidity the oxide film, being of lower modulus, should attract, rather than repel, dislocations suggesting that it would not offer resistance to slip step emergence. However, in order for a slip step to form at the surface, the film must rupture along the slip step or it must accommodate the step through deformation or through separation from the

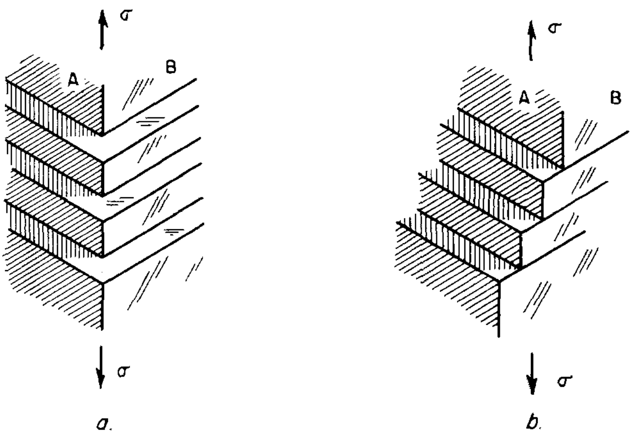

Fig. 18. Schematic representation of crystallographic substrate slip. (a) No film on surface A or B. (b) Film on surface B resisting slip step emergence.

substrate. These processes are governed by properties of the film and of the interface and are unrelated to substrate properties. Thus, even a weak or low modulus film must exert some effect on slip step emergence irrespective of its effect on dislocation movement.

Observations in this study clearly showed that sufficiently thin films could accommodate a certain degree of substrate slip without failure. The manner by which this may be accomplished has been subject to considerable speculation (15). Clearly simple deformation of the film around the contour of a sharply defined slip step is unrealistic due to the very high values of local strain that would be entailed. Film detachment is possible, but would still involve high local strain; there is, furthermore, no indication that such detachment does occur. The authors consider it feasible to postulate that the slip seen beneath intact oxide films is not, in fact, comprised of large, discrete steps, but of broad slip bands comprised of steps of atomic dimensions. This would permit film deformation along the substrate surface without necessitating inordinately high local strain values or local detachment of the film. Clearly, however, the strain in the film will be highest at such slip bands, thus film failure would necessarily occur along the bands. In the case of thicker films, where deformation of the substrate surface is suppressed, local regions of higher strain do not exist and the films simply fail normal to the applied loading. This analysis is clearly oversimplified, but appears to offer a viable rationale for the observed phenomena.

Tantalum.—The failure strain values reported in this study for anodic films on tantalum, $\gtrsim$ 0.14%, are markedly different than those reported by Bubar and Vermilyea (11, 12), whose substrates were leached in HF following the chemical polishing procedure, and somewhat smaller than that of Eliezer and Brandon (13), whose value of 0.83% is reported as a "maximum" value, in general accord with the observations of Young (14). Analysis of the failure mode of anodic films on chemically polished tantalum substrates is simplified by the very weak adherence of such films. Clearly the films became detached by substrate deformation and their subsequent failure normal to the tensile axis was unaffected by the substrate surface. The films on mechanically polished substrates, however, were strongly bonded and behaved in a manner analogous to those on aluminum. It is interesting to note that a failure behavior intermediate between these cases could be obtained by lightly abrading chemically polished substrates prior to anodizing. The weak bonding on chemically polished substrates has been attributed to a superficial film associated with the polishing procedure (14, 36), possibly fluorine-rich (37), and to "flawed" regions (38). It is not clear why the mechanically polished specimens did not yield the ductile behavior previously observed in strongly adherent films.

Conclusions

Anodic aluminum oxide films of thickness greater than a critical value of ~ 400Å tested in ambient air fail at a strain of ~ 0.925% independent of thickness. These films apparently suppress emergence of slip in the substrate and fail normal to the tensile axis (or, in the case of compressive loading, parallel to the compressive axis), forming regularly spaced cracks with a limiting, high strain spacing of ~ 15 μm. The Young's modulus of these films was determined to be $\sim 4 \times 10^4$ MN/m^2, implying a failure stress of the order of 380 MN/m^2. Films thinner than the critical thickness failed at a higher strain value of 1.12% along substrate slip traces, apparently due to their inability to suppress slip emergence and the consequent higher local strain at these sites. There is clearly an implication that film failure strain decreases with thickness. This behavior was unaffected by the manner of substrate surface preparation or by the presence of a superimposed porous oxide layer except that a thick porous layer superimposed on a thin barrier layer caused it to behave as a "thick" film. No evidence of film detachment due to deformation was seen.

Anodic films on mechanically polished tantalum failed in a manner analogous to those on aluminum, at a strain of ~ 0.28%. This value did not show a thickness dependence, however. Films on chemically polished tantalum substrates readily separated from the substrates on straining and failed in simple tension, normal to the tensile axis. Films thicker than ~ 680Å failed at a strain of ~ 0.14%, while thinner films failed at strains of 0.2%.

The Anodic Oxidation of Iron: Overpotential Analysis for a Two-Phase Film

J. L. Ord* and D. J. De Smet*,[1]

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

The galvanostatic oxidation of iron in a neutral borate buffer of pH 8.4 has been studied using open-circuit transients to analyze the overpotential dependence of the optical and electrical properties of the process. A minicomputer which can control the current through the cell and read the potential of the electrode performed the experiments under program control, recording transients on magnetic tape at specified intervals, and recalling them later for least squares analysis. A self-nulling ellipsometer which is also linked to the computer is used to follow the process optically. Both the optical data and the Tafel slopes determined from transient analysis exhibit a structure characteristic of an oxide film composed of two distinct phases: an inner layer of Fe_3O_4 and an outer layer of Fe_2O_3. The field in the inner Fe_3O_4 layer appears to limit the process, and this field does not go to zero at the potential at which the protective outer layer of Fe_2O_3 begins to reduce. The electrochemical behavior of the system appears to be in accord with the predictions of a field-controlled two-phase model of the process.

The extensive literature on the passivity of iron, from the original letters of Schoenbein (1) and Faraday (2, 3) through to the present time (4, 5), shows a continuing interest in the subject, but fails to present a comprehensive description of the phenomenon. This situation has come about because workers in the field have approached the problem with different viewpoints, chosen experimental conditions suited to their measurement technique, and ended up studying somewhat different phenomena. For example, studies of the anodic oxidation of iron which take care to avoid deposition of FeOOH from reaction products in the electrolyte give quite different results from studies in which FeOOH deposition occurs. One cannot say that one of these approaches is right and the other wrong, but a strong case can be made for studying anodic oxidation and electrodeposition separately rather than under conditions where both processes take place at the same time. Different results are also obtained depending on whether measurements are made under steady-growth or steady-state conditions. Steady growth is usually assumed to take place under galvanostatic oxidation across a restricted potential range, whereas a steady state is usually assumed to be reached after potentiostatic oxidation for an hour, although the system probably has no true steady state. Steady-growth conditions are usually chosen to study the kinetics of film growth, whereas steady-state conditions are more often chosen as the starting point for studies of the film itself. Our interest in this paper is in the oxidation process, and we make both our electrochemical measurements and our optical measurements under steady-growth conditions.

In recent years the most commonly used electrolyte for work on the passivity of iron has been the pH 8.4 boric acid-sodium borate buffer made popular by Cohen and co-workers (6-9). This electrolyte, chosen initially by Cohen in order to obtain reliable cathodic reduction data, turns out to be ideal for optical work also. This is because an iron electrode can be passivated at a low enough current density to avoid roughening of the optical surface in the electrolyte and, in addition, the optical data return to their initial values after cathodic reduction. Some care must be taken when using the electrolyte because the behavior of iron in it is sensitive to both dissolved oxygen and ferrous ions. If the electrolyte contains appreciable dissolved oxygen, an iron electrode will spontaneously passivate with no current applied. If the electrolyte is free of dissolved oxygen, ferrous ions are stable in it and will deposit anodically to form a layer of FeOOH at all but the lowest potentials in the passive region.

The answer to the question of whether or not the borate buffer is a typical neutral electrolyte depends on the aspect of passivity in question. In one important respect the borate buffer is very special: the presence of dissolved oxygen in the electrolyte is not necessary for the passivation of iron. This is not true for sulfate or perchlorate electrolytes. This special property of the borate electrolyte appears related to the fact that FeOOH layers deposited in borate electrolyte contain boron and take on an amorphous structure rather than the crystalline structure they have when deposited in sulfate or perchlorate electrolyte (11-15). In an earlier paper from this laboratory (16), it was argued that passivation results from a reaction in which the surface of the layer Fe_3O_4 formed in the active state is oxidized to FeOOH. It appears that boron involvement in this monolayer of FeOOH is necessary to render the electrode passive. Once passive, iron behaves the same way under further oxidation in borate and perchlorate electrolytes which are free of ferrous ions. Since our primary interest in this paper is in the mechanism of ionic conduction and film growth in the passive state, the borate buffer

Key words: iron, oxidation, ellipsometry.

acts as a typical neutral electrolyte which happens to be convenient for this work.

Some time ago, a paper from this laboratory (17) argued on the basis of electrochemical evidence that the field in the oxide film limits conduction in the passive state, and that this field goes to zero at the Flade potential, the potential below which iron reverts to the active state. Since that time, two attempts have been made in this laboratory to test this argument by correlating the electrochemical measurements with optical measurements of film thickness made with an ellipsometer. In the first attempt (18), Tafel slopes from open-circuit transient analysis, proportional to film thickness in a field-limited model, were correlated with optical measurements of film thickness made with a manual ellipsometer. Although a linear dependence was found, the measured quantities were not proportional, and it was concluded that the layers formed in the active and passive states have quite different properties although no difference could be detected optically. In the second attempt (16), an automated self-nulling ellipsometer was used for the optical measurements, and the reciprocal capacitance from a-c impedance measurements was taken as an electrochemical measure of the film thickness. The greatly improved resolution of the optical measurements enabled two layers to be distinguished, but neither layer was found to have a thickness proportional to the reciprocal capacitance. Although the optical measurements presented a clear picture of a two-phase film, little progress could be made in clarifying the conduction mechanism.

In this paper we continue our study of the oxidation of passive iron using sensitive recording and analysis techniques to increase the resolution of our electrochemical measurements. The increase in resolution enables us to determine the electrochemical properties of the two phases detected optically, and a much simpler model of the conduction process emerges with a different significance given to the Flade potential.

Experimental

The optical measurements were made with a self-nulling ellipsometer which has been described in detail elsewhere (19). The instrument has a resolution of 0.01° in the settings of its polarizing prisms, and nulls both polarizer and analyzer approximately twice each second under the optical conditions encountered in this experiment. The standard deviation in the null readings was less than the resolution of the instrument, therefore an increase in resolution was obtained by averaging the data if the properties of the film were not changing too rapidly. A helium-neon laser is used as the light source, and an angle of incidence of 60° is chosen to accommodate a cell made from an equilateral glass prism. The cell is fitted with standard taper joints for mounting the electrode holder, platinum counterelectrode, mercurous sulfate reference electrode, and gas dispersion tube. The cell has inlet and outlet connections enabling deaerated electrolyte to be added from a 2 liter reservoir, and electrolyte contaminated with ferrous ions to be pumped from the cell. The electrolyte, an equivolume mixture of $0.15N$ sodium borate and $0.15N$ boric acid of pH 8.4, was maintained at room temperature, 23°C. All potential values are relative to the mercurous sulfate reference electrode which uses a $0.1N$ K_2SO_4 salt bridge.

The cylindrical single crystal sample of iron used as the working electrode is clamped between Teflon washers in a glass electrode holder. A flat on one side of the cylinder is used for the optical measurements. A surface area of approximately 1.25 cm^2 is exposed to the electrolyte in this configuration. The sample was chemically polished before being inserted into the cell. Subsequently, several oxidation-reduction cycles were run in order to reduce roughness and stabilize the optical surface prior to beginning the experiment.

The laboratory computer, a Hewlett-Packard 2114B, was programmed to perform the experiments with little operator intervention and record the data on magnetic tape for later recall by analysis programs written in BASIC. The operating program was similar in many respects to one used earlier in a study of the anodic oxidation of platinum (20). Both the electrochemical control circuitry and the circuitry which operates the ellipsometer are built into multiplexed input-output interface of the computer. The computer reads the digital output from the ellipsometer, and uses digital-to-analog and analog-to-digital converters to control the current through the cell and read the electrode potential. A video terminal and an X-Y point plotter are used extensively for graphical display during the performance of the experiment and the analysis of the data.

Descriptions of the analysis of open-circuit transients appear in the literature (21, 22) and a current paper describes the digital techniques used in this laboratory (23). The basic equations governing open-circuit transients are obtained by writing the external current in the cell circuit, i_e, as the sum of the current charging the capacitance, i_c, and the faradaic current through an element in parallel with capacitance, i

$$i_c + i = i_e \quad [1]$$

For an activation-controlled process, the exponential dependence of current density, i, on potential, V, can be written

$$i/i_o = \exp((V - V^*)/V_o) \quad [2]$$

where V^* is the zero of overpotential, i_o is the exchange current density, and V_o is the Tafel slope expressed in natural logarithms. With $i_e = 0$, i_c written as CdV/dt, and i given by Eq. [2], Eq. [1] becomes

$$CdV/dt + i_o \exp((V - V^*)/V_o) = 0 \quad [3]$$

This equation can be integrated, assuming C, i_o, V_o, and V^* all constant, to give

$$V = V_1 - V_o \ln(1 + t/T) \quad [4]$$

where the time constant T is defined by

$$T = CV_o/i_1 \quad [5]$$

and i_1 and V_1 are the values of i and V at $t = 0$. Transients are fitted by varying T in Eq. [4] until a linear V *vs.* $\ln(1 + t/T)$ least squares analysis gives the minimum deviation in V. V_o is given directly by the slope of the fitted line.

The open-circuit data are recorded in a form well suited to this type of analysis. The potential is read at millisecond intervals, but data are stored at equal potential intervals rather than time intervals in order to produce a uniform point density along the least squares line. The 12 bit analog-to-digital converter has a 1/2 mV resolution and by summing eight successive readings taken over a 200 μsec interval this resolution can be improved somewhat. The accuracy of the fitting procedure can be expressed in a variety of ways. The range over which the data are fitted is one for which dV/dt changes by a factor of ten. The standard deviation in V from the fitted least squares line is typically less than one least significant bit of the 12 bit converter for this fitting range. Expressed as a fraction of the potential range over which the transient is fitted, the deviation is on the order of 0.1%. The least squares analysis estimates the standard deviation in the V_o values to be on the order of 0.1%, but a complete replication of an experiment gives V_o values which differ by as much as 1%.

Results

The experiments used to generate the data consist of a series of oxidation-reduction cycles with oxida-

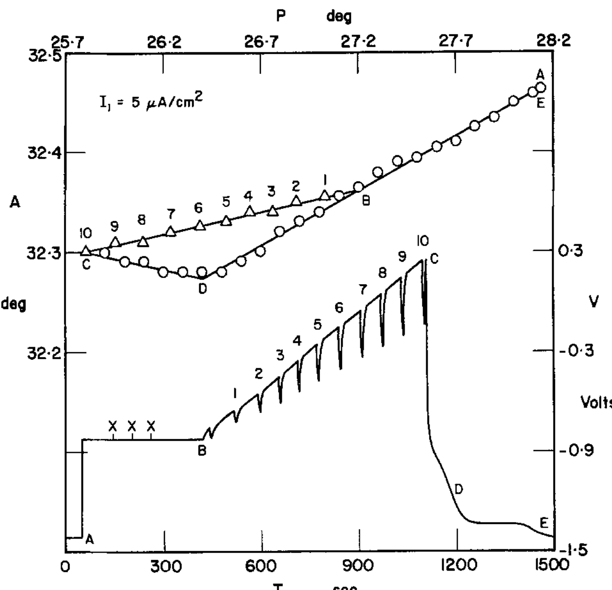

Fig. 1. Oxidation-reduction cycle with open-circuit transients for an iron electrode in deaerated borate buffer: oxidation at −0.825V (vs. Hg_2SO_4) from A to B with electrolyte changes at X, oxidation at $i_1 = 5$ μA/cm² from B to C with open-circuit transients applied at the points indicated, reduction at 10 μA/cm² from C to E.

tion current densities of 5, 20, and 80 μA/cm² and a common reduction current density of 10 μA/cm². The potential-time plot of a cycle with an oxidation current density of 5 μA/cm² is shown in the lower portion of Fig. 1. At point A the reduction segment of the previous cycle is complete, and the working electrode is passivated at a current density of 1 mA/cm² until the potential reaches −0.825V where it is held until the current density drops to 1 μA/cm² (point B). At the three points labeled X, the circuit is opened briefly while the electrolyte is pumped from the cell and replaced by fresh, deaerated electrolyte which is free of ferrous ions. At point B the 5 μA/cm² oxidation current density is applied to the working electrode, and oxidation continues until the potential reaches 0.25V at point C. During the oxidation, open-circuit transients are recorded at 0.1V intervals from −0.75 to 0.25V. The open-circuit transient at −0.75V does not provide adequate data for analysis, but the other transients, labeled 1 through 10 in the figure, can all be analyzed to determine values for the Tafel slope, V_0, and reciprocal capacitance, $1/C$. Cathodic reduction at 10 μA/cm² begins at point C and continues through two potential arrests until the surface of the working electrode is free of oxide at point E.

Optical data consisting of the null settings of the polarizer, *P*, and the analyzer, *A*, are recorded at 1 sec intervals throughout the experiment except during changes of electrolyte. Representative optical data are plotted in the upper portion of Fig. 1. On a *P vs. A* plot, the optical data fall on four distinct line segments, A-B, B-C, C-D, and D-E. The points plotted during galvanostatic oxidation between B and C are the points labeled 1 through 10 at which analyzable open-circuit transients were recorded. The reduction data, plotted at 0.1° increments in *P*, fall on two distinct line segments, C-D and D-E, which correlate with the two potential arrests observed on reduction. The data obtained during passivation from A to B superimpose on the reduction data between these points. The line segments shown in the figure were fitted to the data using a least squares technique. Note that the *A* scale is expanded five times over the *P* scale in order to show the structure in the data.

Cycles with oxidation current densities of 20 and 80 μA/cm² differ little from the 5 μA/cm² cycle plotted in Fig. 1. The potential-time plots differ only in the time scale between B and C, and the optical data show structure which differs only in the lengths of the various line segments. The optical data for all three current densities are plotted in Fig. 2 with the upper two cycles offset 0.1° and 0.2° in A to avoid overlap. As can be seen in the figure, the lengths of line segments B-C, C-D, and D-E all decrease somewhat with increasing oxidation current density. The expanded A scale enables some indication of the reproducibility of consecutive cycles to be seen in the figure. The cycles were performed in the sequence middle, top, bottom, and the uneven vertical spacing between cycles is the result of a drift in A of 0.01° over the course of the three cycles. Following the third cycle, the series of three cycles was repeated, and the optical data obtained agreed with the data plotted in Fig. 2 to within 0.02° in both *P* and *A*.

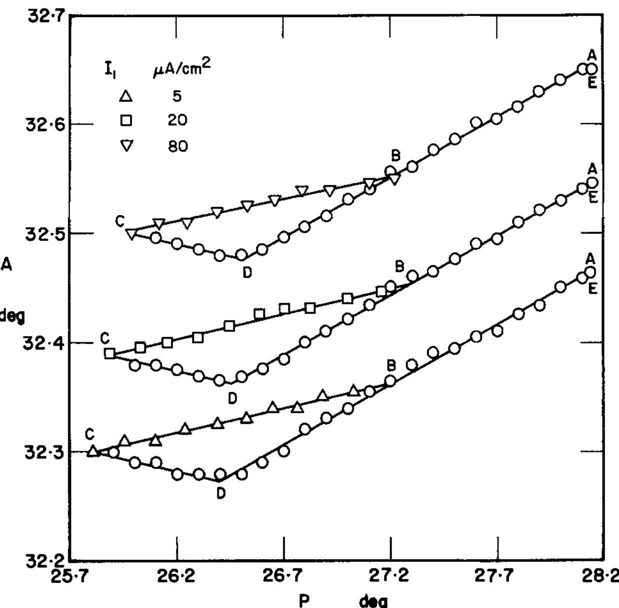

Fig. 2. Optical *P-A* plot for oxidation-reduction cycles with $i_1 =$ 5, 20, and 80 μA/cm². The cycle plotted at the bottom is the one from Fig. 1, and the upper two cycles are offset 0.1° and 0.2° in A to avoid overlap.

The optical data show an inflection during cathodic reduction on a *P-t* plot as well as on a *P-A* plot. In Fig. 3, *P* is plotted *vs.* time for the cathodic segments of the three cycles plotted in Fig. 2. In each case, the data show an inflection at the point labeled D′ which

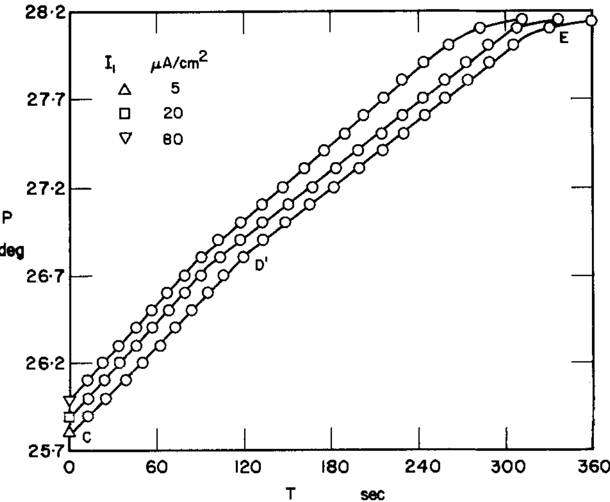

Fig. 3. Time dependence of the optical parameter *P* during reduction at 10 μA/cm² for the three cycles plotted in Fig. 2. The inflection at D′ occurs later than the *P-A* inflection at D.

is reached somewhat later than point D, the P-A inflection point which marks the end of the first reduction plateau.

Analysis of the open-circuit transients gives values for the Tafel slope, V_o, and the reciprocal capacitance, $1/C$, at ten values of the initial potential, V_1, and three values of the oxidation current density, i_1. These data, along with the corresponding thirty optical data points, form the data set on which subsequent analysis is based. Since the linear relation between P and A during galvanostatic oxidation does not depend on the oxidation current density, only one optical variable, P, is required to specify the optical data.

The first step in carrying the analysis further is to determine i_o and V^*, the remaining unknown parameters in Eq. [2]. If either one can be determined, the other can be calculated using Eq. [2]. Neither i_o nor V^* can be determined from the analysis of a single open-circuit transient, but common values for both can be determined for a set of transients with a common i_1 provided V_o depends linearly on V_1. Two arguments may be advanced in support of constant values for i_o and V^*, one based on economy of parameters, the other on the physical significance of the parameters themselves. On thermodynamic grounds, V^*, the zero of overpotential, is expected to be independent of both i_1 and V_1. On the other hand, the exchange current density, i_o, will be sensitive to any variation in the concentration of charge carriers at the activation barrier, and hence may depend somewhat on i_1, but should not depend on V_1 for constant i_1.

The analysis to determine i_o and V^* from sets of V_o values can be displayed graphically on a plot of V_o *vs.* V_1. In Fig. 4, V_o values are plotted as a function of V_1 for i_1 equal to 5, 20, and 80 $\mu A/cm^2$. For each of the three oxidation current densities, the upper six points with V_1 values from -0.25 to 0.25V fall on a straight line. Graphically, the value of V^* common to all points on the line is given by the intercept of the line on the V_1 axis, and $\ln(i_1/i_o)$ is given by the reciprocal of the slope of the line. The intercepts of the least squares lines with i_1 equal to 5, 20, and 80 $\mu A/cm^2$ give V^* values of -1.305, -1.303, and -1.292V, respectively, and their slopes give corresponding values for i_o of 4.24, 8.25, and 24.8 $\times 10^{-5}$ $\mu A/cm^2$. The differences between the V^* values do not appear significant, particularly in view of the range of the extrapolation involved in their determination, and hence they can be averaged to give a value for V^* of -1.300V which applies to all open-circuit transient data with V_1 equal to -0.25V or greater. The increase by a factor of six in i_o as i_1 increases by a factor of sixteen is significant, consequently i_o cannot be considered to be independent of i_1. For V_1 values less than -0.25V, either i_o, V^*, or both differ from the values which apply in the linear region.

It should be emphasized that the dependence of V_o on V_1 and i_1, and of i_o on i_1 are dependences on the conditions which applied at the time the circuit was opened, and do not imply that the parameters V_o and i_o have explicit potential or current density dependence. This can be illustrated very simply in the case of the parameter V_o by plotting it as a function of P as is done in Fig. 5. The plotted line, fitted by least squares to the eighteen points for which V_1 is -0.25V or greater, provides a reasonable fit to the data at all three oxidation current densities, thus V_o is solely a function of film thickness in this region.

Equation [5] enables a value of the capacitance to be calculated for each open-circuit transient once V_o and T have been determined. In Fig. 6, reciprocal capacitance values calculated using Eq. [5] are plotted as a function of V_1 for each of the three values of i_1. As was the case for V_o in Fig. 4, the six points with V_1 values of -0.25V or greater fall on straight lines. The two lines with i_1 values of 20 and 80 $\mu A/cm^2$ cannot be distinguished in the figure, and intersect the V_1

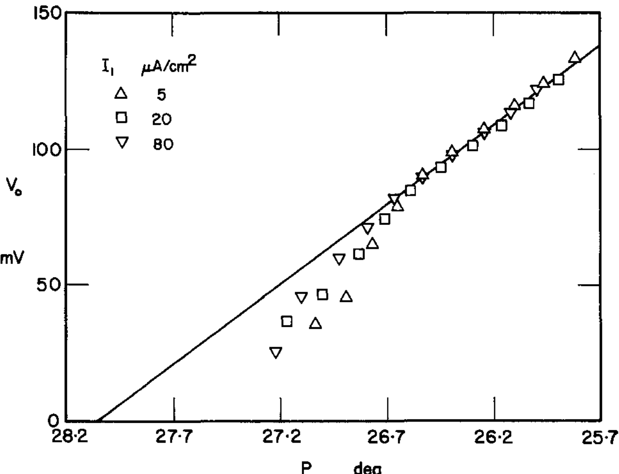

Fig. 5. Tafel slope from open-circuit transient analysis as a function of the optical parameter *P*. The line is fitted to the upper six points at each oxidation current density.

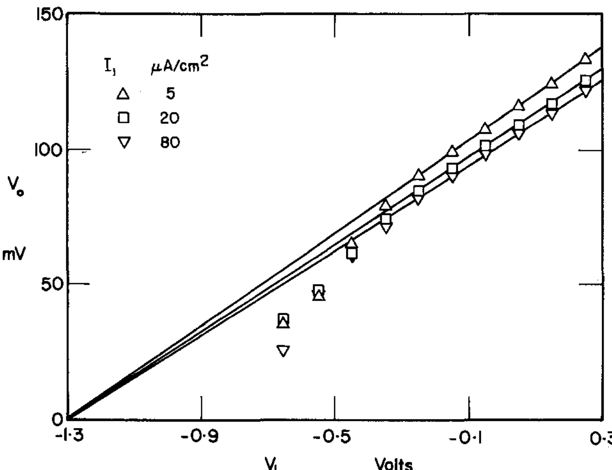

Fig. 4. Tafel slope from open-circuit transient analysis as a function of the initial potential. The lines are fitted to the upper six points at each oxidation current density.

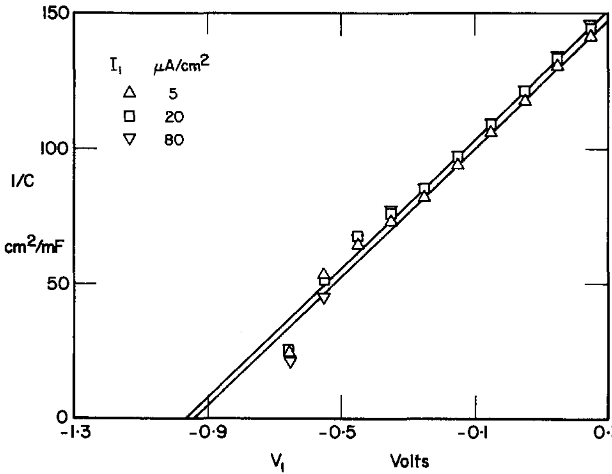

Fig. 6. Reciprocal capacitance from open-circuit transient analysis as a function of the initial potential. The lines are fitted to the upper six points at each oxidation current density.

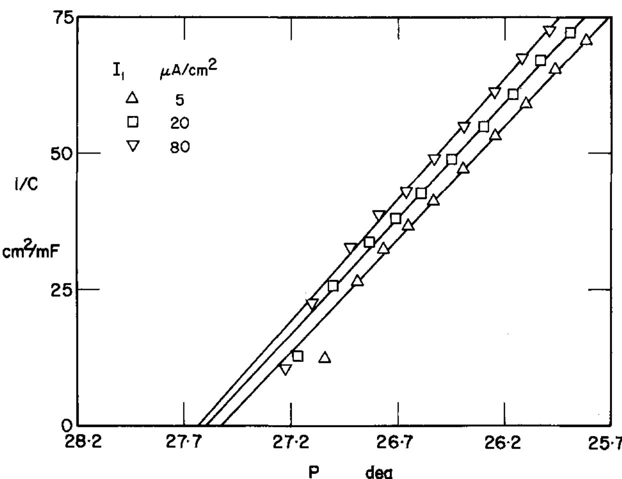

Fig. 7. Reciprocal capacitance from open-circuit transient analysis as a function of the optical parameter *P*. The lines are fitted to the upper six points at each oxidation current density.

axis at −0.965 and −0.963V, respectively. The line with i_1 equal to 5 μA/cm² intersects the V_1 axis at −0.936V. These intercepts differ by more than 1/3V from the V_0 intercept which was identified as the zero of overpotential. The plot of reciprocal capacitance *vs.* *P* in Fig. 7 shows a linear dependence on film thickness at each value of i_1, but the lines at different values of i_1 are distinct, and the reciprocal capacitance cannot be said to be solely a function of film thickness above −0.25V as was the case for the Tafel slope.

Discussion

Although the evidence is indirect, ellipsometric measurements can be used to advantage in attempts to determine the structure of very thin films. The ellipsometric data reported here show the same structure exhibited by those we reported in an earlier paper in which we concluded that the oxide film is composed of a layer of Fe_3O_4 covered by an outer layer of Fe_2O_3. This identification of the component layers agrees substantially with both the early (6-9) and recent (24) work of Cohen and co-workers, but disagrees with other recent work which identifies the oxide either as entirely FeOOH (4), or as γ-Fe_2O_3 covered by FeOOH (25-28). The latter study (by Sato and co-workers) makes extensive use of ellipsometry to support the proposed model of the oxide film, and identifies Fe_3O_4 as a product of cathodic reduction.

The question as to whether or not a layer of FeOOH is present on the surface is one which ellipsometry can answer directly. Although it is not possible to deduce refractive indexes uniquely from ellipsometric *P-A* data for films which are very thin, the converse problem of detecting the growth of a film of known index can be dealt with directly. FeOOH films have been studied in detail in this laboratory (15), and their refractive indexes are known. The films grown in borate buffer are transparent amorphous films with a refractive index of 1.70 at λ = 6328Å. On a *P-A* plot with the scales used in Fig. 2, growth of a film of FeOOH displaces optical data upward to the left at approximately three times the slope of line segment C-D. Thus the data in Fig. 2 indicate that FeOOH is not a significant component of the anodic oxide under our experimental conditions. Optical data obtained under conditions where FeOOH is a significant component of the oxide film were included in a previous paper (16). Sato and co-workers (27), although lacking the instrumental resolution for direct detection of FeOOH deposition, found that the thickness of a potentiostatically grown oxide film depends on the speed of passivation, and attributed this to the deposition of FeOOH from ferrous ions produced during active state dissolution. In their more recent work (28), they avoid the deposition of FeOOH by growing an initial 25Å of oxide using a pH 11.5 electrolyte in which iron has no active state. From this work they conclude that the oxide film grown in borate buffer has an outer layer of FeOOH, but their ellipsometric measurements still lack the resolution to detect two layers directly, and their optical analysis uses one common refractive index for the entire oxide film.

The question as to whether Fe_3O_4 is present as a surface layer during anodic oxidation or is a product of cathodic reduction raises a very basic question concerning the interpretation of optical data. We have assumed that cathodic reduction simply planes away the surface of the film without producing bulk changes in it. This assumption is implicit in the statement that at point C the oxide film is composed of superimposed layers whose sequential removal displaces the optical data first from C to D, then from D to E. Alternate explanations of the structure in the optical data are certainly possible. Sato and co-workers (26) found an inflection in the time dependence of their optical data on the second reduction plateau, and concluded that prior to this point Fe_3O_4 is a reaction product, and after this point Fe_3O_4 is itself reduced. We observe an analogous inflection at point D′, but find a smaller slope change at this point, presumably because our electrode has no FeOOH layer. Our optical data could be interpreted in terms of a model in which the film at point C composed of an inner Fe_3O_4 layer (E-D′) covered by an outer Fe_2O_3 layer (D′-C) which reduces along C-D leaving a residual layer of Fe_3O_4 (D′-D). We feel that we have insufficient evidence to choose between this model and our original model with an outer layer which leaves no Fe_3O_4 behind on reduction. Our data are not consistent with a model in which most or all of the Fe_3O_4 layer is a product of cathodic reduction. We conclude that both Fe_2O_3 and Fe_3O_4 are present as superimposed surface layers in the passive state.

The analysis of overpotential for the growth of a two-phase anodic oxide film is analogous in some ways to the treatment of corrosion processes by mixed potential theory. In corrosion processes two reactions take place at a common potential and the total current is the sum of the individual reaction currents, whereas for a two-phase oxide the current density is the same through each layer and the individual layer overpotentials appear in series. Although a detailed treatment of ionic transport through a two-phase film is not feasible in view of our limited understanding of ionic transport through single phase films, we can predict the general features of the dependence of current density on potential for this system. Since the electrochemical behavior of the system appears relatively insensitive to the thickness of the outer layer (16), we will assume that the field in the inner layer limits the process, and set up a two-phase model of this type for comparison with the experimental data. Each phase will have its own characteristic zero of overpotential, and the electrochemical behavior of the system will depend on both the position of the potential relative to these points and on the relation between current density and overpotential. The zero of overpotential of the layer in the higher oxidation state, $V(Fe_2O_3)^*$, will be higher than that of the layer in the lower oxidation state, $V(Fe_3O_4)^*$. The relation between current density and overpotential for a metal covered by a reducible oxide layer which can both support high fields and conduct electrons (by tunneling or other mechanisms) has some special characteristics. On the anodic side, oxidation requires ionic transport through the film, and this is usually a field-limited process. Electronic conduction is not involved because the electrolyte does not act as a source of electrons below the oxygen evolution potential. On the cathodic

side, reduction of the film does not require ionic transport, but does require conduction of electrons from the metal to the film-electrolyte interface.

At potentials well above both $V(Fe_3O_4)^*$ and $V(Fe_2O_3)^*$, the field in the inner layer will control the process, and the Tafel slope, expressed in field units, will be constant. Since the Tafel slope is measured in potential units rather than in field units, it will vary linearly with potential under galvanostatic oxidation, extrapolating to zero at $V(Fe_3O_4)^*$. As the potential approaches $V(Fe_2O_3)^*$, the measured value for the Tafel slope will drop below the line for higher potentials, extrapolating to zero near $V(Fe_2O_3)^*$. This is due to the fact that an electronic current will begin to flow as the potential crosses $V(Fe_2O_3)^*$, and the remaining overpotential across the inner layer will not discharge until the outer layer has been reduced. In this model the system does not tend toward an equilibrium state under open-circuit conditions; the difference between $V(Fe_2O_3)^*$ and $V(Fe_3O_4)^*$ effectively acts as an overpotential driving an ionic current through the inner layer, and the electronic current which balances it reduces the outer layer.

The experimental results exhibit the general features predicted by the two-phase model. The plot of V_o *vs.* V_1 is linear at high potentials as expected for a field-controlled process, and extrapolates to zero at $V_1 = -1.300V$. This is a reasonable value for $V(Fe_3O_4)^*$, lying as it does just above the second reduction plateau. At lower potentials, the V_o values inflect more sharply toward the axis, giving $V(Fe_2O_3)^*$ a value of about $-0.850V$, just above the first reduction plateau, and below $-0.825V$, the potential used to passivate the electrode in these experiments. The passivation potential is just above the Flade potential, the lowest potential at which the electrode can be said to be truly passive. The position of $V(Fe_2O_3)^*$ between the first reduction plateau and the passivation potential is exactly where the model requires it to be, but it has been argued that this potential is much too high for any known bulk oxide of iron. For this reason it would be tempting to identify the outer layer as FeOOH were it not for its refractive index. In our previous paper (16) we noted that the passivating layer of FeOOH became incorporated in the outer layer of Fe_2O_3 on further oxidation, and concluded that the Fe_2O_3 layer is partially hydrated, by which we mean that some of the Fe_2O_3 has FeOOH bonding. It may well be that the characteristic potential of the oxide is very sensitive to this FeOOH bonding. It is certainly true that the first reduction plateau is not sharply defined under our experimental conditions, and is much sharper if the experiment is modified to include a potentiostatic region between the galvanostatic oxidation and reduction cycles. Under extended potentiostatic treatment, the first reduction plateau sharpens, and the outer portion of the Fe_2O_3 layer begins to show an index closer to that of FeOOH.

The reciprocal of the slope of the V_o *vs.* V_1 plot gives the value of the exponent in Eq. [2] at the oxidation current density in question. This is a convenient dimensionless parameter which can be used in the comparison of the anodic oxidation of different metals. At 80 $\mu A/cm^2$, V_1/V_o has the value 12.7 for iron, whereas it has the value 11.3 for tantalum and 7.9 for platinum at this current density. Elementary models of high field ionic conduction have this exponent proportional to the product of the valence of the mobile ion, the jump distance, and the field in the layer, but we feel that such models are not adequate to describe anodic oxidation, and we will not attempt to compare valences, jump distances, or fields. These elementary models also have a preexponential factor which is independent of oxidation current density, but this is not what we find experimentally for either iron or tantalum (29).

The plot of V_o *vs.* P demonstrates that the Tafel slope depends only on film thickness and reinforces the view that the process is field limited. Given a value for the ratio between layer thicknesses, we could use the P intercept from the V_o-P plot to test the assumption that it is the field in the inner layer which limits the process. Both the lack of unique values for the refractive indexes of the layers and the possibility of some conversion of Fe_2O_3 to Fe_3O_4 during reduction make it impossible to determine the thickness ratio with sufficient accuracy to make such a quantitative test possible. On the basis of our results, we cannot rule out the possibility that a significant fraction of the overpotential may appear across the outer layer.

The conclusions reached in this study differ from those reached in our earlier work. We attempted essentially the same experiments reported here in our first optical work on iron (18), but we were using a manual ellipsometer at that time, and we recorded open-circuit transients on a strip-chart recorder. As a result, we missed the structure in both the optical and Tafel slope data. We concluded that the Flade potential was the zero of overpotential for passive state oxidation, and that no overpotential appeared across the layer formed in the active state. Later work with a self-nulling ellipsometer (16) correctly resolved the optical structure, but still identified the Flade potential as the zero of overpotential for passive state oxidation, and had to describe the inner layer as made up of two layers with differing electrochemical properties in order to fit the data. The main experimental advance in this study has been the improvement in our open-circuit transient technique which enabled us to detect the structure in the Tafel slope data. Although our data show a more complicated structure than did our earlier data, our conclusion is much simpler: the anodic oxide of iron behaves in exactly the manner one would predict for a two-phase film.

Cathodoluminescence and Photoluminescence of Tb^{+3} Activated $LaAlO_3$

ABSTRACT

Stable $LaAlO_3$ has been prepared and activated by Tb^{+3}. The compounds show a strong cathodoluminescence. When excited by the appropriate wavelengths in the u.v., they show a strong photoluminescence, at least equal to $LaPO_4$:Ce, Tb. The chromaticity coordinates, equivalent wavelengths, luminance, energetic yield, and the position of the phosphors in the chromaticity diagram have been determined. Strong $^5D_3$-^7F_J emission was found at low Tb concentrations with CR excitation, while at higher Tb concentrations the green $^5D_4$-$^7F_5$ transition predominates.

In 1955, Terol and Ward (1) published their work on the luminescence, especially the cathodoluminescence, of rare earth activated $LaAlO_3$. They said that only the Pr^{+3}, Sm^{+3}, and Eu^{+3} activated compounds, obtained by firing of the coprecipitated raw material at 1150°C, give some effective cathodoluminescence, and only few samples were found to luminesce under 2537Å excitation. They mentioned also that Cr^{+3} in $LaAlO_3$ shows no luminescence, although when this ion is dissolved in the perovskitelike structure of $LaAlO_3$ (which has a sixfold coordination towards the oxide ions, similar to ruby), it should fluoresce strongly.

Later, Forat, Jansen, and Trévaux (2) pulled Cr^{+3} and Nd^{+3} activated $LaAlO_3$ single crystals which showed strong luminescence. Because of these contradictory statements, we decided to reinvestigate $LaAlO_3$ as a host lattice for rare earth activators. In this paper we relate the synthesis of stable terbium-activated lanthanum aluminates $La_{1-x}Tb_xAlO_3$ with x ranging from 0.001 to 0.10 and give the results of the investigation of their optical characteristics.

Experimental

Sample preparation.—Samples were prepared by coprecipitation of La^{+3}, Tb^{+3}, and Al^{+3} by NH_3. We used La_2O_3 and Tb_4O_7 (99.995%) from Péchiney and crystal grade $AlNH_4(SO_4)_2$ (Ugine). The dried hydroxides were fired twice at 1350°C for 24 hr in air. The body color of the undoped compound was white, that of the Tb-activated compounds was yellow brown. Firing them at 1000°C for 4 hr under forming gas gives a white material.

X-Ray analysis.—Powder diffraction patterns were taken in a 11.46 cm Debye-Scherrer camera with filtered Cu Kα radiation from a Seiffert x-ray generator. Other diffraction diagrams were obtained from both a Seiffert and a GE XRD5 automatic x-ray recorder. Crystal parameters were calculated with the help of an IBM 270 and a special program for refining parameters.

Optical analysis.—The emission spectra under 2250Å excitation were taken with a Cary 17, the excitation spectrum by monochromatic excitation from 850 to 4000Å, and by detecting the global-emitted radiation from $^5D_3$ and $^5D_4$ to the ^7F_J states by 9558 EMI detector.

The emission spectra under electron excitation, luminance, efficiency, decay time, and chromaticity coordinates were obtained by depositing the phosphors under standard conditions on cathode-ray screens and exciting them with 15 kV, 4 μA/cm^2. The emitted radiation was analyzed by an automatic recording spectrometer fitted to a C.S.F. computer (St. Egreve, France).

Results

X-ray diffraction control.—The synthesis of $LaAlO_3$ and $La_{1-x}Tb_xAlO_3$ was closely checked by x-ray diffraction. When the compounds were fired below 1300°C, and for shorter times, the reaction was not complete and the lines of unreacted La_2O_3 were found in the x-ray diagram. Terol *et al.* (1), who fired the compounds at 1150°C, probably had no single phase material in their possession. They mentioned that $LaAlO_3$ would hydrolize slowly in air, and then $La(OH)_3$ lines would be found in the diffraction pattern. We put $LaAlO_3$ prepared at 1350°C in contact with water for 5 days. After drying, no La_2O_3 or $La(OH)_3$ lines were found in the x-ray diffraction diagram. Table I gives the crystal parameters of some of the compounds.

Optical analysis.—Excitation by u.v. radiation.—Only weak fluorescence is observed when $LaAlO_3$:Tb is excited by short (2537Å) or long (3650Å) wave Hg lamps. These aluminates show only weak Tb^{+3} absorption at these wavelengths. The main Tb^{+3} absorption bands are situated at about 2225Å and between 3400 and 3900Å (excitation spectra, Fig. 1 and 2).

In contrast to other Tb-activated compounds, for example $LaPO_4$:Tb, the absorption in the long u.v. wavelength range is stronger than in the short wavelength region. The absorption bands of the aluminates

are shifted by about 200Å toward longer wavelengths, from those found in $LaPO_4$:Tb (4). Further, another group of Tb-absorption bands, similar to those found recently by Bourcet (4) in $LaPO_4$·Tb. is observed between 3300 and 3900Å. The excitation peak at 2450Å

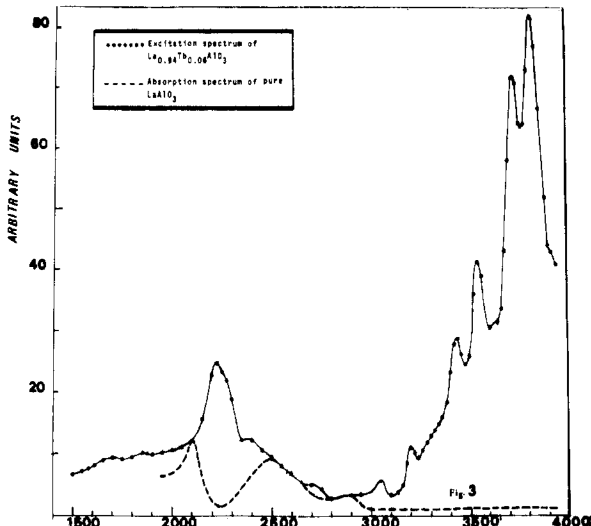

Fig. 2. Excitation spectrum $LaAlO_3$:Tb compared to the absorption spectrum of pure $LaAlO_3$.

(for $x = 0.002$), at 2425Å (for $x = 0.012$), or 2380Å (for $x = 0.06$) is certainly due to lattice absorption. Its shift, a function of the Tb concentration, is supposed to be due to the change, or perturbation, of the crystal field of $LaAlO_3$ by the introduction of the smaller Tb^{+3} ions into it.

Figure 3 shows the emission spectra of $La_{0.998}Tb_{0.002}AlO_3$ and $La_{0.94}Tb_{0.06}AlO_3$ under u.v. excitation. With low Tb concentration levels ($x = 0.001$-0.008), the emission takes place mostly from the $^5D_3$ level to the ^7F_J manifold, as is usually observed 5-7, while at higher concentrations the main emission occurs from the $^5D_4$ level, giving rise to a more or less saturated-green fluorescence. For excitation below 2000Å, strong transients are observed in the Tb emission intensity. Indeed, the emission intensity increases by a factor of two during the first 10 min of excitation. This is followed by a strong and long-lasting phosphorescence. The over-all emission of $LaAlO_3$Tb is strong when excited with the appropriate wavelength, and compares favorably to $LaPO_4$: Ce, Tb. Lifetime of the $^5D_4$-^7F_J transitions is about 400 μsec at 293°K, that of $^5D_3$-^7F_J (weak activator level) about 1 μsec.

CR excitation.—Lanthanum aluminates, $La_{1-x}Tb_xAlO_3$ with $x = 0.001$, 0.002, 0.005, 0.006, 0.007, 0.009, 0.010, 0.0011, 0.012, 0.016, 0.04, 0.06, 0.08, and 0.10 were excited by electrons. Figure 4 gives the emission spectra of $La_{1-x}Tb_xAlO_3$ with $x = 0.002$, 0.006, and 0.10, which are similar to those under photon excitation. The increase of Tb emission observed after a long obtained u.v. excitation does not occur with a long-lasting (5-15 min) CR excitation. No phosphorescence is observed either. It seems to us that the CR excitation at 15 kV employed in this work may be compared to u.v. excitation at wavelengths longer than 1200Å. The persistence is given by Fig. 5. It is the same for all activator concentrations.

Table II gives chromaticity coordinates, equivalent wavelengths, luminance, and energetic yield. With $x = 0.007$, a first global emission maximum exists; a second is found at $x = 0.06$ where the green emission peaks. Figure 6 shows the position of the emission of several samples in the chromaticity diagram.

We have found in these compounds, with CR excitation, the same resonant energy transfer from the Tb-$^5D_3$ states to the Tb^{+3} ground level at higher Tb concentrations, as found earlier with photon excitation (5, 6). At low Tb concentrations ($x < 0.005$), the distances between the Tb^{+3} ions are greater than the critical transfer distance and the possibility of energy transfer from an unexcited Tb^{+3} ion in the $^5D_3$ state to the ground level of an excited Tb^{+3} ion in its vicinity is small. The emission then takes place simultaneously from the $^5D_3$ and $^5D_4$ states to the ^7F_J manifold, with a somewhat greater probability for the $^5D_3$-^7F_J transitions. At higher Tb concentrations, an energy transfer from the $^5D_3$ level to the $^7F_6$ level of a Tb ion in the neighborhood takes place and the emission now occurs mainly from $^5D_4$ to the ^7F_J manifold.

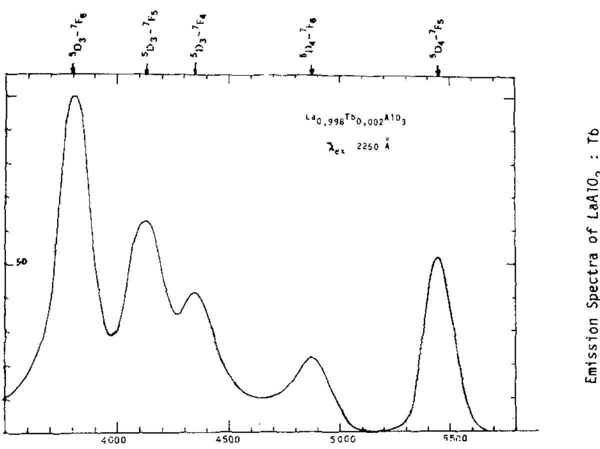

Fig. 3a. Emission spectrum of $La_{0.998}Tb_{0.002}AlO_3$

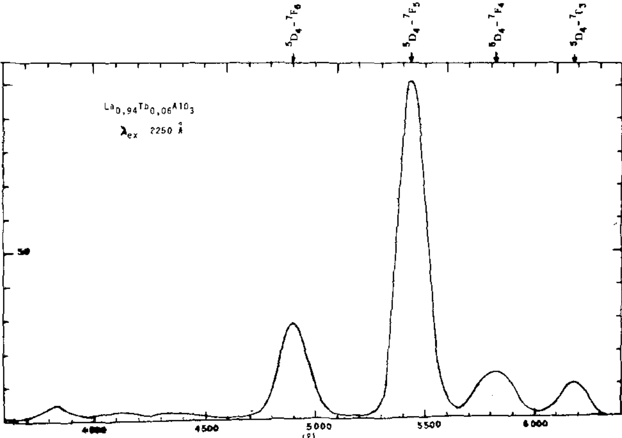

Fig. 3b. Emission spectrum of $La_{0.94}Tb_{0.06}AlO_3$

Fig. 3. Emission spectra of $La_{1-x}Tb_xAlO_3$ under u.v. excitation

The corrected values of luminance (Table II) give an idea of the emission intensity of the $^5D_3$-^7F_J and $^5D_4$-^7F_J transitions. The luminance (Cd/m^2) with $x = 0.007$ is about 20 times higher as that for $x = 0.001$. At low concentrations, Tb^{+3} cannot collect the CR energy. At high concentrations, Tb^{+3} ($^5D_3$) is depopulated by ion-ion exchange ($^5D_3$, $^7F_6 \rightarrow {}^5D_4$, $^7F_0$). Only at intermediate concentrations can CR energy be collected and can $^5D_3 \rightarrow {}^7F$ emissions compete against this interfering ion-ion energy exchange. The existence, even at strong u.v. or CR excitation, of a great number of nonexcited Tb ions in the lattice available for the energy transfer $^5D_3$-(Tb^{+3} excited) $\rightarrow$ $^7F_6$ (Tb^{+3} fundamental) means that the over-all excitation probability, this will say the absorption, is not very high in this Tb-activated compounds. A second intensity peak is found at $x = 0.06$ where the green ($^5D_4$-$^7F_5$) emission peaks. The energetic yield peaks at $x = 0.007$. Contrary to the results of Bourcet (4) and Denis (8) with photon excitation, we find that the $^5D_4$-$^7D_6$ transition intensity (with CR excitation) is largely independent of the Tb content (Fig. 4).

Discussion

The luminescence performance shown by these compounds under CR excitation is similar to that of the industrial P-1 phosphor. Table III gives the position of the main Tb emission lines in $La_{1-x}Tb_xAlO_3$ with $x = 0.002$ and 0.06 for comparison to those of $Ca_{0.99}Tb_{0.01}WO_4$.

Table IV gives lifetime values of the Tb^{+3} transitions measured by several authors with different Tb^{+3} activated lattices and by us with $LaAlO_3$:Tb. In accordance with theory, the lifetimes of the $^5D_3$-^7F_J transitions are always smaller than those of the $^5D_4$-^7F_J, except with $Sr_{2.86}Tb_{0.08}(PO_4)_2$ where Bril (9) observed for both transitions the same high value of about 5 msec. Brandstadter, Reisfeld, and Larach (10) have observed a strong and long-lasting glow when a

Tb-activated glass was bombarded by fast electrons. Crabtree (11) explains the high lifetime of $^5D_4$ transitions of Tb in CR-excited SnO_2 by the existence of trapped electrons which are slowly released and then excite the Tb $^5D_4$ level. He gives no information on the behavior of the $^5D_3$ levels. We found in CR-excited $LaAlO_3$:Tb^{+3}, with low or high Tb concentrations, a large emission duration of about 10 msec (Fig. 5), for both the $^5D_3$ and $^5D_4$ transitions. Creation of traps by impinging electrons, as supposed by Crabtree, could be the reason. Recently, another mechanism has been proposed: the oxidation of the Tb^{+3} ions to Tb^{+4} occurs during excitation, their reduction to trivalency after excitation takes place via excited Tb^{+3} states which decay to the ground state by light emission [see also Ref. (13)]. However, Tb^{+4} ions present in $LaAlO_3$ are not converted easily back into the trivalent state. Indeed $LaAlO_3$:Tb^{+4} must be heated in a reducing atmosphere in order to be converted to $LaAlO_3$:Tb^{+3}. When coprecipitated $La_{1-x}Tb_x(OH)_3$ and $Al(OH)_3$ are heated in air only a brownish compound is obtained, even with as little as 0.05 mole percent (m/o) of Tb^{+3}, probably a mixture of $LaAlO_3$, Al_2O_3, and Tb_4O_7. No fluorescence nor any change of its brown body color into a white one ($LaAlO_3$:Tb^{+3}) was observed when $LaAlO_3$:Tb^{+4}, left to itself, was exposed to u.v. radiation or cathode rays or was heated in air. From this it may be concluded that the Tb^{+4} reduction process does not occur in the present case. Creation of traps may also occur when $LaAlO_3$:Tb is excited by 1215Å radiation.

In Bril's compound [CR-excited $Sr_{2.86}Tb_{0.08}(PO_4)_2$], cation vacancies exist. The long lifetime he found for both transitions (5 msec) makes us think he did not measure the lifetime of the Tb transitions but that of one of the above-mentioned energy-releasing processes. As the $^5D_3$ emission remains strong even at high Tb concentration, we can assume that in this particular case the cation vacancies partially prevent the $^5D_3 \rightarrow {}^5D_4$ energy transfer, indicating that the spontaneous multiphonon cross-relaxation process ($^5D_3 \rightarrow {}^5D_4 \rightarrow$ ($^7F_6 \rightarrow {}^7F_0$) is hindered in this compound.

The Optical Anisotropy of the Anodic Oxide of Vanadium

J. C. Clayton[1] and D. J. De Smet*

Department of Physics and Astronomy, The University of Alabama, University, Alabama 35486

ABSTRACT

Ellipsometric measurements made during the anodic oxidation of vanadium can be most easily interpreted by assuming that the anodic oxide film is optically anisotropic with an optic axis parallel to the direction of film growth. This behavior is similar to that found by others for the anodic oxides of tantalum and niobium. The optical anisotropy of the vanadium oxide is found to depend on the applied electric field, but the dependence is not a simple power law since the anisotropy does not vanish when the electric field is removed from the film. This is in contrast to the behavior of tantalum and niobium. For these materials the anisotropy disappears when the electric field is removed.

Recent ellipsometric studies of the anodic oxidation of tantalum by Cornish and Young (1) and of the anodic oxidation of niobium by Yee and Young (2) demonstrate that these anodic oxides are optically anisotropic with an optic axis parallel to the direction of the film growth when the electric field strength in these films is large. Further, they conclude that when the electric field is removed these films become optically isotropic. These two works support and extend the work of Ord, Hopper, and Wang (3), who employed ellipsometry to demonstrate that changes in the applied electric field cause changes in both the thickness and the refractive index of the anodic oxides of tantalum, niobium, and tungsten. These authors interpreted their data in terms of an optically isotropic model of the film because they examined the film at thicknesses where ellipsometric measurements can most sensitively distinguish between changes in film thickness and changes in refractive index. As it turns out, at these thicknesses ellipsometry is quite insensitive to the optical anisotropy found by Young and coworkers. Nevertheless Ord had suggested that a complete analysis of ellipsometric data for anodic oxides might show evidence of optical anisotropy (4).

Since the anodic oxides of both tantalum and niobium exhibit a field-dependent optical anisotropy it is pertinent to ask if such an anisotropy is a general property of anodic oxide films. The purpose of the present work is to demonstrate that the anodic oxide of vanadium, which is in many respects similar to other anodic oxides (5), shows an anisotropy similar to those of tantalum and niobium under high field conditions. We will also show that with vanadium, unlike tantalum and niobium, the anisotropy does not completely vanish when the electric field is removed from the film.

Experimental

The instrumentation and sample preparation techniques used have been described adequately elsewhere (6). We state for the sake of clarity that the ellipsometric measurements presented here were made with the sample *in situ*, and that our ellipsometer has a quarter-wave plate between the polarizer and the sample, oriented so that its fast axis makes an angle of $-45°$ with the plane of incidence. Two optical cells were used in this work. They were identical in construction but one of them appeared to have windows

Key words: anisotropy, anodic oxide, vanadium, ellipsometry, index of refraction.

with lower birefringence than the other. Since we report our data directly as the measured polarizer and analyzer values at null and do not choose to make corrections to our data for cell window birefringence, we will make only qualitative statements concerning data obtained using the second, or poorer, cell. Since our automatic ellipsometer provides many more data points than can be effectively displayed, the figures show only representative data points.

The mathematics of interpreting ellipsometric data for a uniaxial film with its optic axis perpendicular to the film surface on an isotropic substrate is straightforward. Cornish and Young (1) give a brief outline of the necessary changes that must be made to the usual equations of ellipsometry and den Engelsen (7) and Dignam, Moskovits, and Stobie (8) have independently published complete solutions to this particular problem.

Results

Before presenting the experimental data that demonstrate optical anisotropy in the vanadium oxide it is in order to recall the effects that optical anisotropy will have on ellipsometric measurements. Figure 1 shows the null settings of the polarizer and analyzer for the growth of the anodic oxide of vanadium under our experimental conditions. The null setting for zero thickness is marked "start" and the data trace out a curve in a clockwise direction as growth proceeds. After approximately 1500Å of film have been formed the experimental curve passes approximately through the starting point and almost retraces itself. We shall refer to each repetition of the data as a loop.

The effect of a uniaxial anisotropy with an optic axis parallel to the direction of film growth is to displace successive loops parallel to the P axis by an amount that depends on the size of the anisotropy and in a direction that depends on whether the film is uniaxial positive or uniaxial negative. For our particular configuration of the ellipsometer a uniaxial positive film ($n_e > n_o$) will cause successive loops, to be displaced toward lower values of P whereas a uniaxial negative film ($n_e < n_o$) will cause successive loops to be displaced toward higher values of P. Under these circumstances it is apparent that an anisotropy of this form will be most easily detected in the regions where P is either a minimum or a maximum.

Turning now to the experimental data, Fig. 2 shows the behavior of the null settings of the ellipsometer, plotted as open circles, for portions of three loops of the anodic growth curve for a film grown at a constant current density of 394 $\mu A/cm^2$. Data taken in a region near the minimum value of the polarizer are shown in the left-hand portion of Fig. 2 and those near the maximum of the polarizer are shown in the right-hand portion of this figure. The data in this figure are presented using expanded scales relative to Fig. 1. As is evident from this figure, successive loops are displaced toward increasing values of P. Thus we conclude that under constant current conditions the anodic oxide film on vanadium is a uniaxial negative material. This anisotropic behavior can also be seen by carefully examining Fig. 1. The squares in this figure, which represent data obtained for the second loop, are displaced slightly to the right of the circles.

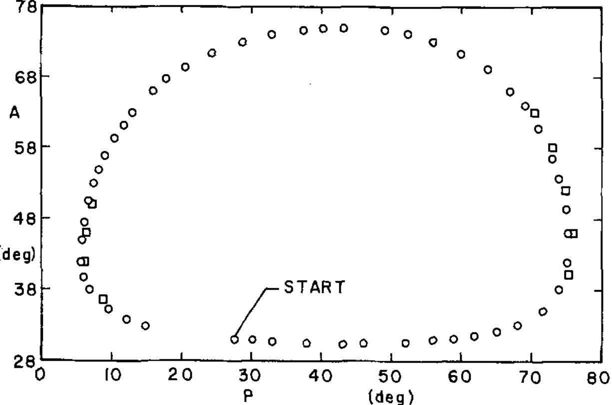

Fig. 1. Ellipsometer null settings for the growth of an anodic oxide film on vanadium at a current density of 275 $\mu A/cm^2$. Circles, first loop; squares, second loop.

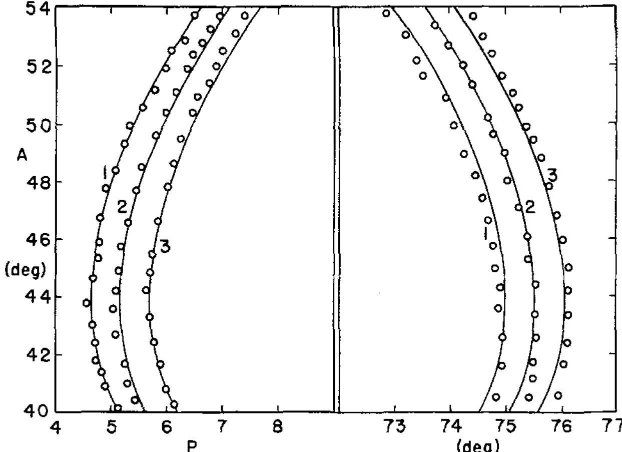

Fig. 2. Ellipsometer null settings in the regions of minimum and maximum P for the growth of an anodic oxide film on vanadium at a current density of 394 $\mu A/cm^2$. Data points are represented by circles and the solid lines represent the calculated behavior for a uniaxial film with an optic axis normal to the surface of the film for which n_o = 2.349 and n_e = 2.328. The refractive index of the substrate is assumed to be 3.838 — 3.560i.

Also shown in Fig. 2 are solid lines that represent the calculated behavior of the ellipsometer null settings assuming that we are dealing with a growing film with an ordinary refractive index of 2.349 and an extraordinary refractive index of 2.328 on a substrate of refractive index 3.838 − 3.560i. The values of the optical parameters used in calculating these lines were estimated by making initial guesses of their values and then varying the value of each parameter in turn until a calculated curve was found that better approximated the experimental data in the sense that the root-mean-square deviation of the distance between the point and the curve was reduced. This procedure was repeated using reduced variations of the parameters until the RMS deviation ceased changing significantly. Therefore we have not actually calculated n_o and n_e from the experimental data, rather we have made reasonable estimates of the values of these parameters using a curve-fitting procedure. Nevertheless, these values of the optical parameters are in good agreement with the experimental data; therefore we assume that they closely approximate the true characteristics of the sample.

We must point out that there are other possible ways to interpret this data that cannot, *a priori*, be ruled out. First, since the anodic oxide of vanadium dissolves slowly in the electrolyte employed here we must determine whether a dissolution product adhering to the outer surface of the film can cause the observed ellipsometric behavior. Calculations have been performed using a model in which a second film is placed on top of the anodic oxide using a large range of thickness ratios for the two films and a number of values for the refractive index of the outer film. In no case were we able to generate curves that show the general characteristics of our experimental data for all three loops. Therefore, although we have not exhausted all possible combinations of numbers, it is very unlikely that this interpretation can apply to the results presented here.

Thus far we have only looked at the behavior of the film under constant current and hence constant field

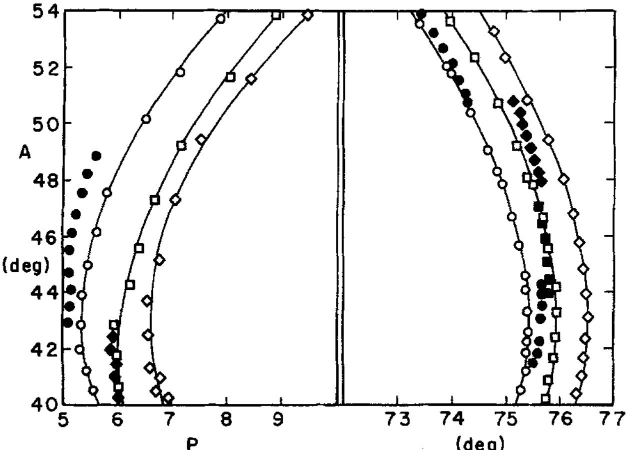

Fig. 3. Ellipsometer null settings (open symbols) in the regions of minimum and maximum P for the growth of an anodic oxide film on vanadium at a current density of 394 $\mu A/cm^2$. The filled symbols represent data obtained under open-circuit conditions. Circles, first loop; squares, second loop; diamonds, third loop. The solid lines are drawn only as an aid in following the data.

conditions. Let us now examine the behavior of the optical data for a film for which the circuit is opened and the electric field is allowed to decay to zero. Figure 3 shows data for an experiment in which an anodic film was grown at an applied current density of 394 $\mu A/cm^2$. At intervals during the growth of this film the circuit was opened and the electric field was allowed to decay to zero. The data shown in Fig. 3 were obtained using a poorer quality optical cell, therefore we will make only qualitative statements about the behavior of the film based on these data.

The open symbols in Fig. 3 are the P-A points obtained with an applied anodic current. The open circles are for the first loop of the P-A curve, the open squares are for the second loop, and the open diamonds are for the third loop. The solid lines through the open symbols in this figure do not represent a fit to the data but are added as an aid in following the shape of the curve. The filled symbols are the data points obtained when the circuit is opened and the field decays to zero. The closed circles are the open-circuit data points for the first loop of the P-A growth curve, the closed squares are the open-circuit P-A values obtained for the second loop of the growth curve, etc. After the circuit had been open for some time, the anodic current was again applied and growth of the film continued; the optical data returned to the growth curve.

The behavior of the optical data is not difficult to explain. Looking at the data near the minimum value of P for the first loop, as growth proceeds A increases. When the circuit is opened the P-A values jump abruptly away from the growth curve and upward in A, indicating that the refractive indexes and perhaps the thickness of the film have changed. As open-circuit conditions are continued the optical data move downward in A, indicating that the film is decreasing in thickness. This is not unexpected since the film is slightly soluble in the electrolyte. When the anodic current is reapplied the ellipsometer null settings jump back to the growth curve (at a lower thickness since some of the film has dissolved) and then proceed again along the growth curve. A similar interpretation can be made for the data obtained near the maximum value of P.

The significant point to be made about the data shown in Fig. 3 is that the ellipsometric measurements made during the time that the circuit was opened do not lie on a single curve for all three loops of the data. That is, even under open-circuit conditions the data corresponding to the second loop lie to the right of the data taken for the first loop, and the data for the third loop lie still further to the right. This indicates that the film is anisotropic even under open-circuit conditions. Since the circuit was open long enough (3-4 min) that the electric field decayed several orders of magnitude, if not actually to zero, we conclude that the anodic oxide of vanadium has a uniaxial negative optical anisotropy under conditions where there is no applied electric field.

It is also evident from Fig. 3 that the optical anisotropy diminishes when the electric field is removed from the film. For example, in the right-hand side of Fig. 3 it is apparent that for a given value of A the data taken under open-circuit conditions for the three loops have a smaller separation in P than the data taken with a current applied to the electrode. Thus part of the optical anisotropy is intrinsic to the film itself and part of it is caused by the applied electric field or current.

Discussion

In the previous section we have shown that the optical properties of the anodic oxide of vanadium are similar to those of the anodic oxides of tantalum and niobium since each of these materials has an optical anisotropy with an optic axis parallel to the direction of film growth. Further, all of these films are uniaxial negative and the anisotropy depends on the applied current density or electric field, decreasing with decreasing field. Vanadium differs from tantalum and niobium only because it shows some optical anisotropy under zero field conditions.

It is interesting to compare the difference between the ordinary and extraordinary refractive indexes, $\Delta n = n_o - n_e$, and the steady-state electric fields for these three materials at comparable applied current densities. Assuming current densities in the range 300-400 $\mu A/cm^2$, for tantalum $\Delta n = 0.0039$ at a field of 6×10^6 V/cm, for niobium $\Delta n = 0.0056$ at a field of 4.3×10^6 V/cm, and for vanadium $\Delta n = 0.021$ at a field of 2.7×10^6 V/cm. (The values of Δn and the electric field for tantalum and niobium have been calculated using equations given in Ref. (2) in conjunction with current-field plots presented by Young and Zobel (10) and assuming a current density of about 320 $\mu A/cm^2$.) Thus we note that for a given applied current density the material with the highest electric field has the lowest optical anisotropy and the material with the lowest electric field has the highest optical anisotropy.

The fact that the optical anisotropy of the vanadium oxide does not entirely disappear when the electric field is removed from the film may be due to a number of factors. First, it is possible that the amount of time required for the film to adjust changes if the electric field is greater than the amount of time for which the circuit was opened. However, Cornish and Young (1) found that upon suddenly applying a field to a film-covered tantalum electrode there is an exponential approach to the steady state with a time constant of about 10 sec and a similar behavior when the field is removed. We would expect approximately the same time constant with vanadium as Cornish and Young found for tantalum. Therefore, although we cannot entirely rule out this possibility, it is not a likely explanation since the 3-4 min that the circuit remained open ought to be more than enough time for any simple relaxation process to occur.

Another possible explanation of the residual anisotropy is that the film formed on vanadium, unlike those on tantalum and niobium, may be crystalline. Although we have not performed any measurements to determine this, Keil and Salomon (12), using x-ray diffraction, report that an anodic film formed on vanadium in this electrolyte is amorphous or only very slightly crystalline. Also, Arora and Kelly (13) concluded, on the basis of electron diffraction data, that only very thin anodic films on vanadium showed polycrystalline structure; films thicker than about 200Å were found to be amorphous.

Since it has been alleged that the anodic oxide film formed on vanadium may contain pores (9), we must examine the possibility that the anisotropy observed under zero electric field can be explained in terms of pores. If pores are present they would introduce a structural anisotropy that could cause an optical anisotropy or form birefringence. Let us assume that a porous structure can be modeled by an assembly of parallel cylindrical rods with an index of refraction n_1 immersed in a medium with an index of refraction n_2. Such a structure will be optically anisotropic and the relation for the difference between the ordinary and extraordinary refractive indexes is given by (11)

$$n_e^2 - n_o^2 = \frac{f_1 f_2 (n_1^2 - n_2^2)^2}{(1 + f_1) n_2^2 + f_2 n_1^2} \quad [1]$$

Here f_1 and f_2 are the fractions of the total volume occupied by the rods and the medium, respectively, and the equation is valid for $f_1 << 1$. Whether we consider the index of refraction of the rods to be greater than that of the medium or less than that of the medium the values of $n_e^2 - n_o^2$ will always be positive, indicating that this structure will be uniaxially positive. The anodic film on vanadium gave data that are consistent with a uniaxial negative material. Thus the observed optical anisotropy cannot be caused by pores. This does not exclude the possibility that pores exist, it merely indicates that they cannot be used to explain the experimental data.

One point that we have avoided until now is the functional dependence of the changes in the optical constants and the film thickness on the electric field. Young and co-workers (1, 2) found that for tantalum and niobium the changes in refractive index vary as the square of the electric field; that is, $\Delta n_o = -aE^2$ and $\Delta n_e = -bE^2$, where $\Delta n_o = n_o(E) - n(E = 0)$ and $\Delta n_e = n_e(E) - n(E = 0)$. Implicit in this statement of the electric field dependence of the optical constants is the fact that when the electric field is zero the film is isotropic. While the experimental data presented by Young and co-workers support this conclusion for tantalum and niobium, it is clearly not true for vanadium. Also, since the anodic oxide of vanadium shows a residual anisotropy when the electric field is zero, it would not be unreasonable to suspect that this residual anisotropy may depend on the value of the electric field at which the film was formed. This would preclude any analysis that assumes that the state of the film at any time depends only on the conditions that prevail at that instant. We do not know whether this suspicion is justified, but until further evidence is available it would be improper to attempt an analysis of the dependence of the optical constants on the electric field for vanadium based on the present data.

The determination of the electric field dependence of the optical parameters and thickness for the anodic oxide of vanadium presents experimental difficulties. The fact that the film formed on vanadium is slightly soluble means that any changes in film thickness due to changes in the electric field will be superimposed on changes in thickness due to dissolution. In addition, with vanadium we cannot make measurements at different values of the electric field (the same in the sense that the film contains exactly the same amount of material) because of dissolution. Finally, the possibility that the field dependence may depend on the history of the film suggests that a number of very careful experiments must be conducted before any further conclusions can be drawn.

Manuscript submitted June 28, 1976; revised manuscript received Aug. 11, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Effects of Additions to SnO_2 Thin Films

A. F. Carroll and L. H. Slack

Department of Materials Engineering,
Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT

The effects of adding Sb and In to pyrolytic SnO_2 films were investigated. The large rise in resistivity for larger additions of Sb was studied using x-ray diffraction, effects of heat-treatment, determination of activation energy, and scanning electron microscopy. These results indicate that the rise is caused by a gradual loss of crystallinity and demonstrated the important effects of thermal history on the films' structure and electrical characteristics.

Undoped SnO_2 thin films formed by pyrolytic deposition have an appreciable conductivity in the range of 10^2-10^3 $(\Omega\text{-cm})^{-1}$ (1, 2, 4-7). Additions of a Group III element, In, cause the films resistivities to increase while additions of the Group V element, Sb, cause it to decrease (2-5). This doping effect on resistivity is due to a controlled valency mechanism (3). It is interesting that large additions of Sb cause the films resistivity to increase, reversing the trend predicted by the controlled valency mechanism.

Conductivity of pure SnO_2 films has been attributed to a combination of chloride ions and oxygen vacancies which result from incomplete decomposition of $SnCl_4$ and incomplete oxidation of the film to

Key words: antimony oxide additives, indium oxide additives, film crystallinity, heat-treatment, bonding.

stoichiometric SnO_2 (2, 3). These defects are considered to be electron donors. Nonstoichiometric SnO_2 has been represented by $Sn^{4+}{}_{1-\beta}Sn^{2+}{}_{\beta}O^{2-}{}_{(2-\beta)}$ (3) which contains β moles of oxygen vacancies which can donate 2β moles of electrons for conduction.

Additions of only 3 mole percent (m/o) In caused resistivity to increase by 10^4X (5). Small additions of Sb caused resistivity to decrease by approximately 10X to a minimum value. This minimum occurred at additions of 0.9 m/o (2), 0.6 m/o (4), and 3 m/o (5) Sb. Vincent (3) represented the composition of these films by: $Sn^{4+}{}_{(1+\alpha)}Sb^{5+}{}_{\alpha}e_{\alpha}O^{2-}{}_{2}$. This formula indicates the absence of Sn^{2+} ions and associated oxygen vacancies. Arai (2) believed that heat-treating of Sb-doped films did not alter resistivity, indicating that there were indeed no Sn^{2+} ions or associated oxygen vacancies. These low resistivity films have exhibited negligible temperature dependence of resistivity indicating that an impurity band overlaps the conduction band (6).

Since small additions of Sb are known to increase conduction electron concentration, one would expect larger additions to do the same. However, the unexpected rise in resistivity has been attributed to impurity scattering (2), atomic disorder (5), and precipitation of Sb_2O_5 (4). A thermodynamic study of Sb_2O_3 and Sb_2O_5 stability has concluded that formation of Sb_2O_5 in SnO_2 films was not feasible (3).

The present study was undertaken to gain further insight into the effect of In and Sb additives on electrical conductivity in SnO_2 films. Of particular interest was the rise in resistivity occurring at high levels of Sb. Causes for this rise were sought, using determinations of structure and activation energy, and heat-treatment studies.

Procedure

SnO_2 films were formed pyrolytically by spraying a very finely dispersed 2.85 μm solution of $SnCl_4 \cdot 5H_2O$[1] dissolved in ethanol (8). Controlled additions of $SbCl_3$[1] or $InCl_3 \cdot 4H_2O$[2] were made to the spray solution to effect a change in Sb or In content of the films. The high degree of dispersion allowed deposition to be carried out at the relatively low temperature range of 300°-350°C.

All samples were examined by x-ray diffraction using filtered CuK_α radiation.[3] The apparatus used a graphite crystal monochrometer to increase the resolution of the diffracted signal. Attenuation of the glassy halo originating from the substrate was used to determine thickness of each film (9).

Electrical resistivity was measured by a four-terminal d-c method (10) in which Au-Nichrome thin film strips served as electrodes. For the heat-treated samples a four-point probe apparatus was used on uncoated SnO_2 in order to avoid interaction of Au film with the SnO_2 film during heating. An electrometer[4] was used for voltage measurement in this method facilitating conductivity measurements over a range of 10^{10}. A hot-probe technique was used to determine sign of charge carriers.

Temperature dependence of electrical resistivity was measured by placing resistivity samples in a controlled temperature furnace capable of obtaining precise temperatures with negligible gradient. Activation energy of electrical conduction was calculated from slopes of graphs of log resistivity *vs.* $10^3/T$ (°K).

Scanning electron microscopy (SEM)[5] was employed to examine film morphology. Energy dispersive analysis by x-rays used with SEM identified the compositions of structural features in the films.

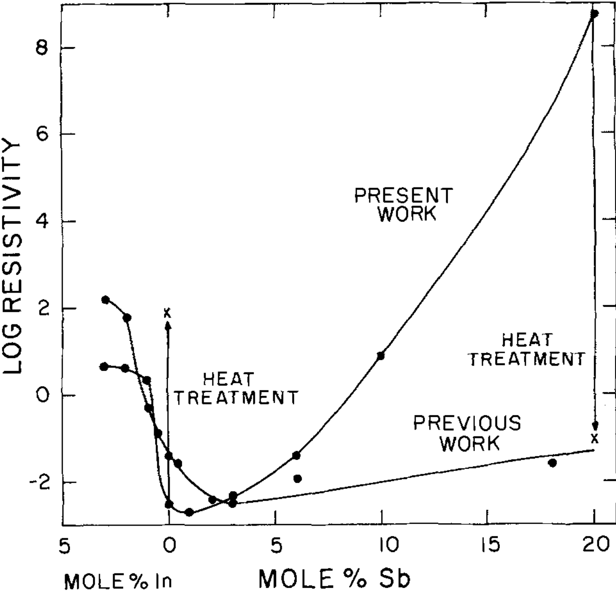

Fig. 1. Resistivity of SnO_2 thin films as a function of additive concentration.

Results

Electrical characteristics.—Logarithm of the films resistivities is plotted as a function of mole percent of antimony or indium in Fig. 1. One curve corresponds to films prepared in this work in which the glass substrates were held at 350°C during deposition and the second to films prepared at 600°C in a previous study (5). Small additions of antimony caused the film resistivity to decrease. For additions greater than 1 m/o the resistivity increased, with additions of 10 and 20 m/o of Sb causing very large increases in resistivity. However, these large additions of antimony in films prepared at 600°C caused only a small increase in resistivity. Small additions of indium caused increases in the film resistivity for both the low temperature and high temperature films. All films with resistivities below 10^2 Ω-cm were found to be n-type; the carrier sign of the more resistive film could not be measured.

Two of the films, one with no impurities and the other with 20 m/o antimony, were heat-treated. The changes in resistivity caused by 200 hr of heat-treatment at 600°C are indicated in Fig. 2. The variation in the films resistivities as a function of heat-treatment time is shown. The resistivity of the undoped tin oxide film increased by about three orders during the first 50 hr of heat-treatment, remained constant for the next 100 hr, and showed a rise at

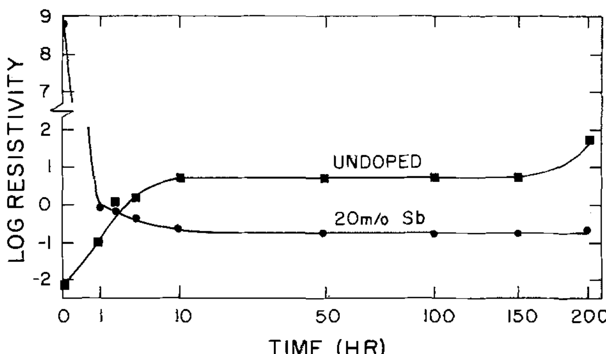

Fig. 2. Resistivity of thin film SnO_2 as a function of heat-treatment duration at 600°C.

* $Sb_4O_5Cl_2$.
** See Fig. 1.

200 hr of heat-treatment. The resistivity of the film containing 20 m/o Sb dropped approximately nine orders of magnitude during the first hour of heat-treatment at 600°C and dropped approximately one more order of magnitude during the following 50 hr of heat-treatment, after which it was constant. The films' activation energies for electrical conduction are listed in Table I. The activation energies varied in the same sense as did the films resistivities.

Film structure.—X-ray diffraction patterns of films containing 6 m/o antimony or less corresponded to the pattern of naturally occurring SnO_2, cassiterite. Some differences in crystal orientation occurred with changing Sb content as indicated by changes in the relative intensity of the peaks (Table I) but the (101) peak was consistently strong. A very weak peak corresponding to a peak of $Sb_4O_5Cl_2$ was detected in samples with 1 and 3 m/o Sb. Films having additions of 10 or 20 m/o Sb had no x-ray diffraction peaks. The sample with 20 m/o Sb partially crystallized during the first hour of heat-treatment at 600°C. The diffraction patterns of this sample before and after 1 hr of heat-treatment are shown in Fig. 3. Continued heating to 200 hr brought no further change in the diffraction patterns. Samples with additions of 1 and 3 m/o In also exhibited the cassiterite structure with some variation in the crystal orientation.

Scanning electron micrographs of films containing 0 and 20 m/o Sb and the 20 m/o Sb after heat-treatment are shown in Fig. 4. Each of these films has varying amounts of spherically shaped crystals on the surface of an underlying film. The texture of this underlying film is seen to change with antimony content. The pure film had a coarser texture than did the one containing 20 m/o Sb, but the latter film acquired a coarser texture after the heat-treatment. EDAX detected small amounts of chlorine in these films.

Discussion

Undoped tin oxide films have n-type extrinsic conduction. The Sn^{+2} ions, associated with the oxygen vacancies, and the residual Cl^- ions are both capable of being electronic donors and probably both are responsible for this extrinsic conduction.

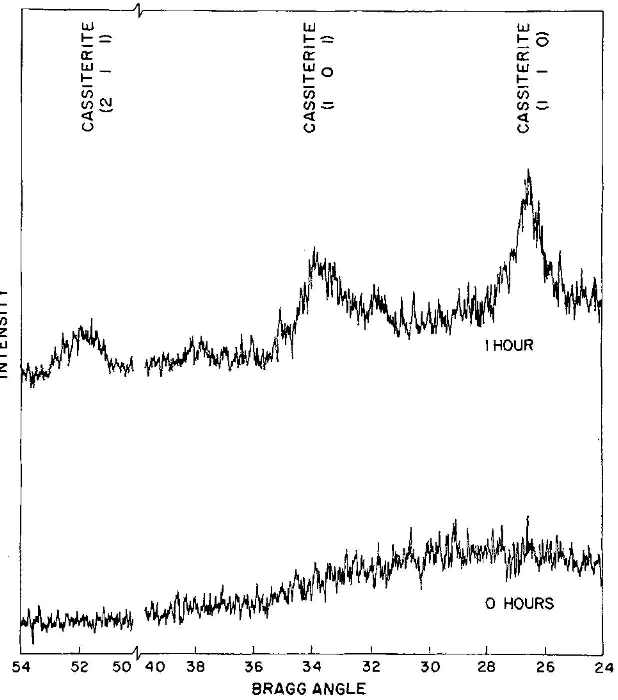

Fig. 3. X-ray diffraction of thin film SnO_2 with 20 m/o Sb before and after heat-treatment.

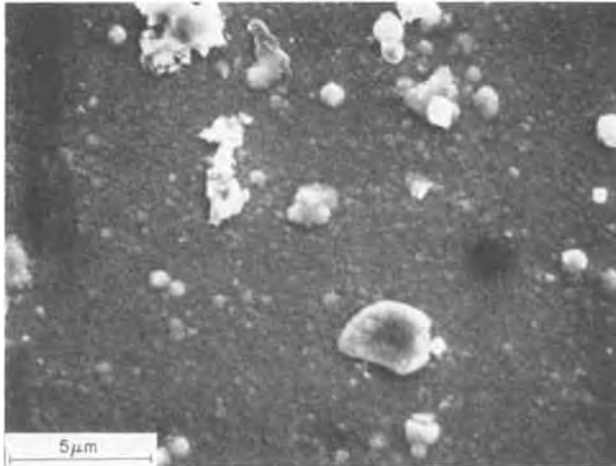
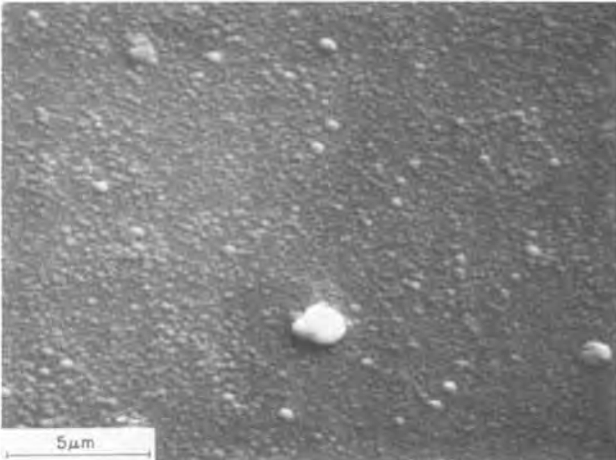
The rise in resistivity noted when the undoped film was heat-treated is most likely due to oxidation of the film which removed many of the oxygen vacancies. The chloride ions, substituting for oxygen ions, probably account for the remnant n-type conduction after prolonged heat-treatment.

The rise in resistivity seen when indium was added, and the decrease when antimony was added, can be accounted for by the controlled valency model proposed by Vincent (3). According to this model, the antimony would be considered to enter the cassiterite lattice as trivalent ions. Thermal energy could excite electrons from these ions into the crystal's conduction band. This excitation renders the antimony ions pentavalent. Likewise, the indium ions would enter the lattice as In^{+3} but could accept electrons from the crystal's valence band, thereby becoming monovalent or divalent.

The controlled valence mechanism would apply to solids with ionic bonding. A consideration of the differences in electronegativities (14) of Sn and O shows the Sn—O bond to be equally ionic and covalent. A covalent model for semiconduction would consider In (Group III) and Sb (Group V) atoms to serve as acceptors and donors in tin (Group IV) oxide, as they do in covalently bonded Si and Ge (Group IV). The controlled valency and covalent models both qualitatively predict the observed resistivity *vs.* impurities behavior, and both mechanisms may be operative.

Since small additions of antimony cause the resistivity to drop by providing more donors, one would expect that large additions would cause the resistivity to drop further. The observed large rise is accompanied by a loss in crystallinity. This loss of crystallinity becomes progressively more pronounced as more antimony is added, causing the film to become more resistive. In the extreme case in which 20 m/o Sb is added, the film is noncrystalline and essentially insulating. This effect is too large to be accounted for by impurity scattering.





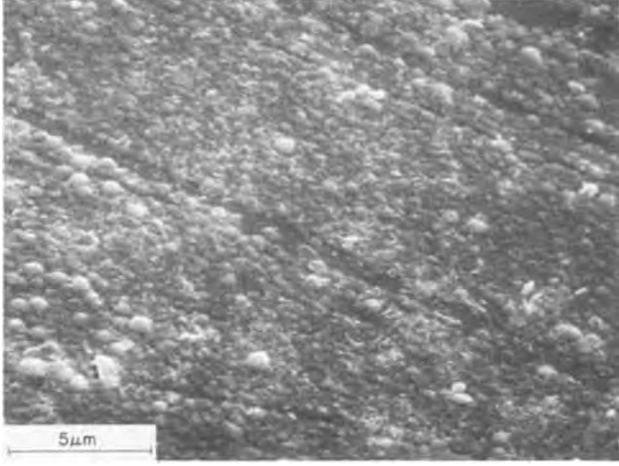


Fig. 4. Scanning electron micrographs of SnO_2 films: (top) unannealed pure SnO_2, (middle) unannealed SnO_2 with 20 m/o Sb, (bottom) SnO_2 with 20 m/o after 200 hr heat-treatment.

Amorphous semiconductors (11, 12) behave as high resistivity intrinsic semiconductors whether they are pure or not. Impurities and other defects in the already defective structure of amorphous semiconductors do not act as donors or acceptors as they would in crystalline ones. One reason for this behavior is that the irregular structure of an amorphous semiconductor has atomic sites where impurities can reside without breaking covalent bonds. If no substitutions are made in the network of primary bonds, then the impurities will not be donors or acceptors.

When the 20 m/o Sb film was heat-treated, one would expect the film to become more stoichiometric and the resistivity to rise as it did for the pure film. However, the resistivity dropped by ten orders of magnitude. This drop was accompanied by the reappearance of a crystal structure and a coarsening of the texture as seen in the scanning electron microscope. In this case, the regaining of crystal structure had a stronger influence on resistivity than did the achievement of stoichiometry. If one would estimate that the removal of oxygen vacancies would cause the resistivity to rise by four orders of magnitude for the 20 m/o film as it did for the pure one, then the regaining of the crystal structure caused the resistivity to drop by fourteen orders of magnitude. The new equality of film resistivity after heat-treatment to that of a corresponding film of the previous study indicates that heat-treatment causes a similar crystal structure in both.

In the previous study in which the films were deposited at 600°C, the highly doped films had lower resistivities because they were more crystalline. However, even at this high temperature of deposition, crystallinity is partly destroyed by the large additions of antimony. This demonstrates the sensitivity of structure and resistivity to the thermal history of the film. Antimony oxide in the formation of bulk silicate glasses is known to be a glass former (13) and is acting as such in these SnO_2 thin films.

The thermal history of the films governs both the oxygen vacancy concentration and the lack of crystallinity. It is, therefore, not surprising that the resistivity *vs.* Sb content varies so much from one investigator to another. When low deposition temperatures are used, higher degrees of amorphousness are obtained for the higher antimony contents giving rise to large resistances, and larger numbers of oxygen vacancies will be frozen into the structure causing resistivity to be lower especially at lower concentrations of Sb. This condition tends to make the minimum point occur at a very low level of antimony concentration. Conversely, as the temperature of deposition is increased, it will tend to make the resistivity rise at low Sb content because oxygen vacancies are being eliminated, and will cause the resistivity to drop at the higher concentrations because the films have a higher degree of crystallinity. These effects tend to move the minimum in the resistivity curve to larger Sb concentrations.

The films with low resistivities had very low activation energies for electrical conduction. This indicates that there were so many donors that a donor band forms which approached or overlapped the conduction band. As resistivity rises with In additions, the activation energy rises because a number of the donors have been compensated for by the In, thus decreasing the donor bandwidth. As resistivity rises as a result of Sb additions, the observed rise in activation energy is due to the elimination of donors again causing the width of the donor band to decrease, increasing the energy needed to excite electrons from the narrowed donor band to the conduction band.

Conclusions

The ten order of magnitude rise in resistivity found when Sb concentration is increased in SnO_2 films from 1 to 20 m/o is caused by a loss of crystallinity. These films behave as typical amorphous semiconductors in which impurities do not serve as electron donors or acceptors.

Heat-treatment caused resistivity of undoped SnO_2 films to rise by four orders of magnitude due to film oxidation removing oxygen vacancies. Heat-treatment caused resistivity of the film with 20 m/o Sb to decrease by ten orders of magnitude because crystallinity was partially restored. These opposing effects

explain why the location of the resistivity minimum is sensitive to deposition conditions.

Ion Beam Etching of Silicon Dioxide on Silicon

L. Mader and J. Hoepfner

Siemens AG, Research Laboratories, D-8000 München 70, Germany

ABSTRACT

An argon ion beam, 7.5 cm in diameter, with an energy of 0.6 keV and a current density of 0.5 mA/cm^{-2} is generated in an ion beam etching system using a Kaufman-type ion source (1), then neutralized by electrons. The principles of ion beam etching are outlined and SEM micrographs of ion etched grooves in thermally grown SiO_2 layers are shown. Grooves 1 μm wide and 0.4 μm deep were obtained using Shipley AZ 1350 H photoresist. The groove profiles are in good agreement with those predicted with the aid of an ion etching model. The slope angle of the sidewalls of the grooves is typically 65°. Redeposition effects reduce the effective ion etch rates for grooves of small linewidths. If the SiO_2 layer is ion etched down to the silicon substrate, a silicon surface layer of about 100Å thickness will be damaged. This damage can be completely removed by wet chemical etching. The enhanced etch rate of ion-damaged SiO_2 surface layers in buffered hydrofluoric acid is used to taper steps in thermally grown SiO_2 in a controllable process.

Although chemical etching is still the most widely used method for the generation of patterns for semiconductor devices, physical etching methods such as rf sputter etching and ion beam etching are attracting growing interest because of certain inherent advantages (2-4).

In order to qualify an etching process, the following criteria have to be taken into account:

Are there dimensional changes as compared with the mask dimensions?

What type of contours do the sidewalls of the etched features have?

Is the etching process selective?

Is any contamination or damage introduced during the etching process?

Is the etching process effectively controllable?

The purpose of this paper is to discuss these criteria for ion beam etching. Our investigations are confined to the insulator layers of semiconductor devices.

Ion Beam Etching Apparatus

The principle of the ion beam etching apparatus[1] used for our experiments is shown schematically in Fig. 1. The system comprises two chambers. The ions generated in a plasma in the upper chamber are extracted from the plasma into the main vacuum chamber by an extraction grid at ground potential. Electrons emitted from a heatable filament are allowed to drift into the ion beam to neutralize its space charge in order to avoid charge buildup on the insulator layers of the substrate. As a result, a neutralized and collimated monoenergetic beam of about 7.5 cm diameter impinges on the sample surface at the normal incidence angle. For our experiments we used argon ions with an energy of 600 eV; the current density was 0.5 mA/cm^2. The distance between

[1] VEECO Microetch System.

the grids and the shutter, where the current density is measured, is about 10 cm.

The 5 cm wafers were bonded onto a water-cooled target holder, using a vacuum oil[2] to assure thermal contact. The advantages over rf sputter etching are that, since the samples are etched in a field-free and plasma-free environment, there are no restrictions as to shape, size, and material of samples or the sample holder. The samples can be moved and tilted during etching in order to change the ion incidence angle and consequently the etch rate. The pressure in the main vacuum chamber is between one and two orders of magnitude below typical rf sputtering pressures.

Principles of Ion Beam Etching

Etch rate as a function of ion incidence angle.—For the ion etching of silicon dioxide layers partially covered with photoresist (Fig. 2), the conditions at the photoresist sidewalls are of special importance. In these regions, the ion incidence is not normal to the photoresist surface; in Fig. 2 an angle is defined to denote the deviation from normal incidence. The etch rate for all materials increases as α increases, reaches a maximum, and then falls off to zero at glancing incidence (5-8). Figure 3 shows our measurements of the ion etch rates in angstroms per minute for silicon, silicon dioxide, and photoresist AZ 1350 H as a function of the ion incidence angle. Unpatterned samples were used in the experiments. Tilting the samples changed the ion incidence angle relative to the surface of the substrate. The etch rates were determined by measuring the layer thickness after etching with a stylus apparatus. In the case of the monocrystalline silicon with a (100) surface orientation, the loss in weight of the wafers was measured. The curves in Fig. 3 show that the fastest etch rates are obtained at an incidence angle of about 60° even though the number of incident ions per square centimeter at 60° is only half that at normal incidence. The maximum etch rates are a factor of two to three higher than the etch rates at normal incidence. Silicon is etched at about the same rate as silicon dioxide, which means that etching does not stop at the silicon-silicon dioxide interface when silicon dioxide layers are etched. The etching process is nonselective.

Ion beam etching profiles using photoresist masks.—The simple diagrams in Fig. 4 illustrate schematically how the profiles of patterns change during ion beam etching as a function of the dependence of the etch rate on the ion incidence angle as shown in Fig. 3.

[2] Dow Corning 705 diffusion pump fluid. As the oil is only on the back of the wafers, it is not bombarded by ions and can therefore easily be removed by organic solvents.

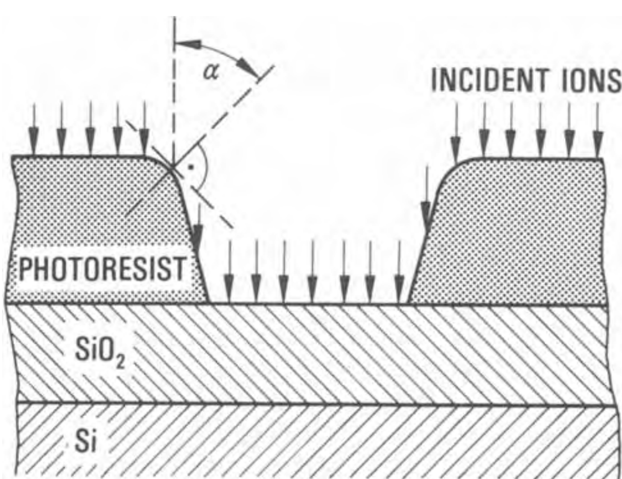

Fig. 2. Schematic diagram showing non-normal incidence of ions at photoresist sidewalls.

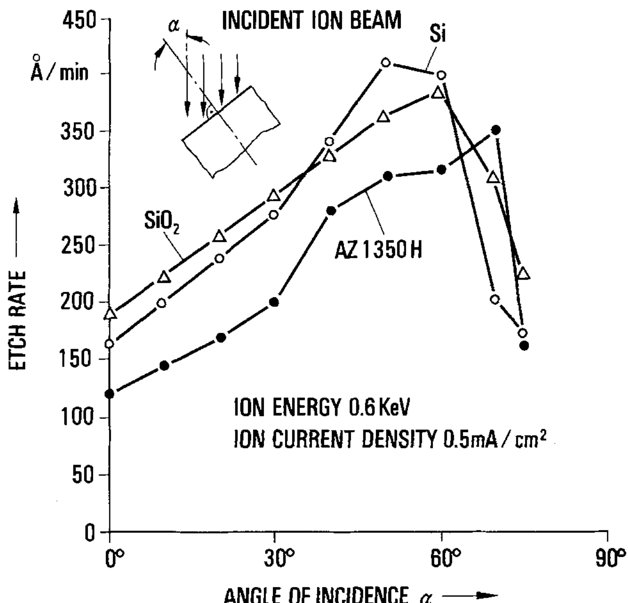

Fig. 3. Measured ion etch rates of silicon, silicon dioxide, and AZ 1350 H photoresist at different ion incidence angles.

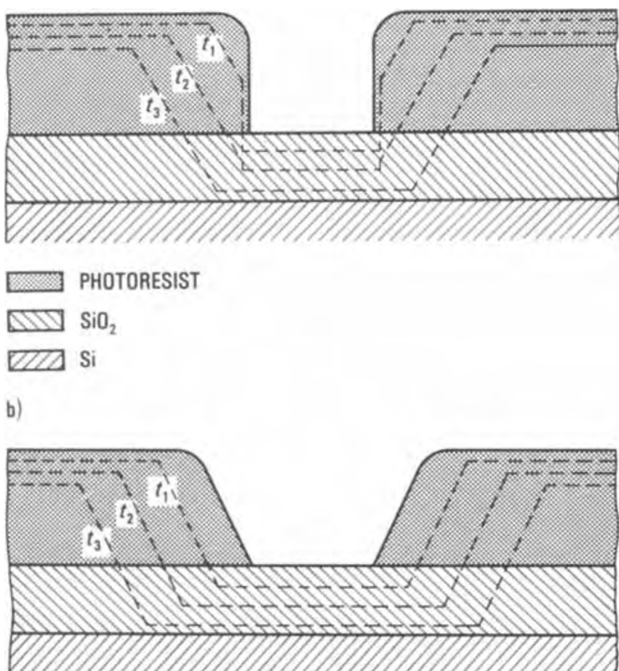

Fig. 4. Calculated profiles of a silicon dioxide film covered with a photoresist pattern during three different etch intervals t_1, t_2, and t_3 (dashed lines). The intervals t_1, t_2-t_1, and t_3-t_2 are equal. (a) Almost vertical photoresist sidewalls before ion etching; (b) 60° slope angle of sidewalls.

In Fig. 4(a) the photoresist sidewalls are assumed to be almost vertical, while in Fig. 4(b) a sidewall slope angle of 60° is assumed. The profiles (dashed lines) were determined using a step-by-step construction similar to that proposed by other authors (8-10). The procedure is as follows: first the initial photoresist contour is divided into small elements, the angle of each element relative to ion incidence is then determined, and the displacement of each element after a short etch interval, Δt, is read from the reference curves in Fig. 3. By this procedure the profile after time Δt was constructed. Starting with this profile, a new profile is obtained after the etch interval $2\Delta t$, and so on. Figure 4 shows the calculated

profiles after three different etch intervals t_1, t_2, t_3. The intervals t_1, t_2-t_1, and t_3-t_2 are equal.

Several conclusions can be drawn from the profiles in Fig. 4(a). As the ion etch rate of silicon dioxide is 1.5 times greater than that of photoresist in regions of normal ion incidence (Fig. 3), the photoresist should be at least two-thirds as thick as the silicon dioxide layer to be etched. In regions where the slope angle of the photoresist sidewalls is close to 90°, the etch rate is negligible. This means that these portions of the profile are not altered by ion etching. The largest alterations of the profile occur in those regions where the ions impinge at an angle of about 60°. This is the case along the upper edges of the photoresist sidewalls. A 60° facet is etched more rapidly than a plane normal or parallel to the ion beam and thus the facet grows in area. As a result, the vertical portion of the sidewalls gradually disappears until, by the end of the interval t_2, the walls exhibit a uniform slope angle of about 60°.[3]

Up to this time, no measurable broadening of the etched silicon dioxide geometry occurs at the bottom edge and the silicon dioxide linewidth corresponds to the initial photoresist linewidth. The etch depth in the silicon dioxide layer by the end of the interval t_2 is about half the photoresist thickness. This means that, if the photoresist sidewalls are vertical or almost vertical, silicon dioxide layers thinner than half the photoresist thickness can be etched without any broadening in linewidth. Etching of thicker layers leads, however, to such broadening as illustrated in Fig. 4(a) by the profile recorded after the interval t_3. In the case shown in Fig. 4(b), where the photoresist sidewalls are assumed to have a slope angle of 60° just prior to etching, the silicon dioxide geometries start broadening right at the beginning of ion etching. The 60° angle remains throughout the entire etching period.

Mask materials for ion beam etching.—As noted above, photoresist can be suitably used as a mask for ion beam etching of SiO_2. However, the contours of the sidewalls of the etched SiO_2 patterns depend on the thickness of the resist mask and the slope angle of the sidewalls of the mask.

If a resist mask (AZ 1350 H) 1 μm thick with vertical slopes is used, a SiO_2 layer of about 0.2 μm can be etched with vertical sidewalls and without linewidth change [see Fig. 4(a)]. Further etching leads to a slope angle of about 60° at an etch depth of about 0.4 μm [Fig. 4(a), interval t_2]. If a thicker layer is etched with this mask, linewidth broadening will occur [Fig. 4(a), interval t_3].

This broadening effect can be avoided, however, by choosing mask materials which exhibit a lower ion etch rate than photoresist, *e.g.*, titanium, vanadium, or chromium (11, 12). The ion etch rate of these materials can be further reduced by injecting oxygen during etching (11, 12). We have made comparative studies of the effect of oxygen on the etch rate of titanium, aluminum, silicon dioxide, and photoresist. The etch rate depends critically on the partial pressure of the oxygen.[4] As shown in Fig. 5, the etch rates of titanium, aluminum, and silicon dioxide decrease, while that of photoresist (AZ 1350 H) increases. Drawbacks involved in using metal masks instead of photoresist masks are that more process steps are required and the edges of the metal geometries are often less smooth than the photoresist edges. Moreover, ion-etched geometries exhibit almost vertical sidewalls, which has an adverse effect on edge coverage in semiconductor device fabrication.

[3] Since the maxima of the etch rates of SiO_2 and photoresist AZ 1350 H lie at the same angle within the measuring accuracy, a uniform slope angle can be expected.

[4] For these experiments a mixture of argon and oxygen is fed into the plasma chamber. The total pressure is kept constant ($4 \cdot 10^{-4}$ Torr).

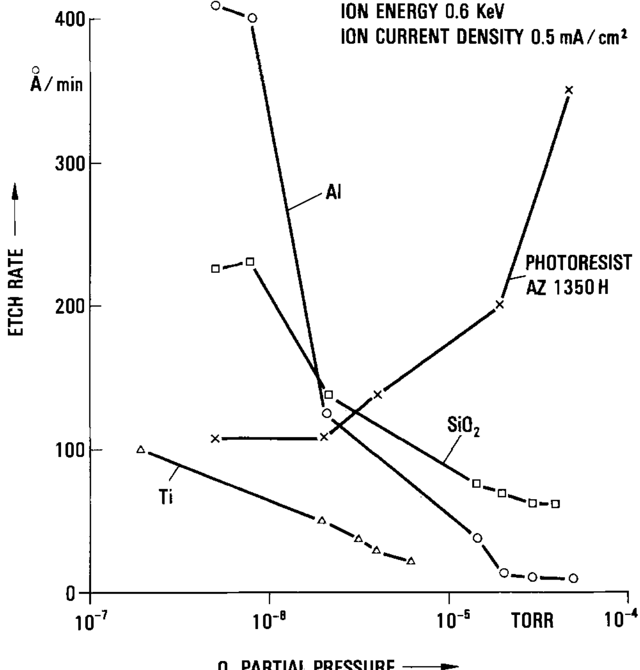

Fig. 5. Measured etch rates of AZ 1350 H photoresist, silicon dioxide, aluminum, and titanium as a function of partial pressure of the oxygen. The etch rates of silicon dioxide, aluminum, and titanium decrease, while that of the photoresist increases with increasing oxygen pressure.

Experimental

Sample preparation.—Thermally oxidized silicon wafers with a diameter of 2 in. were used as substrates. The silicon dioxide thickness ranged between 0.06 and 1 μm. After coating the wafers with AZ 1350 H photoresist about 1 μm in thickness, patterns were generated by conventional contact-printing photolithography. Excessive heating of the samples during ion etching was prevented by bonding the wafers with vacuum oil to a water-cooled copper plate. After etching the photoresist was soaked in dimethylformamide and removed by ultrasonic agitation.

Ion-etched silicon dioxide patterns.—SEM micrographs of ion-etched silicon dioxide geometries in Fig. 6, 7, 8, and 9 confirm the validity of the described ion etching model.

The micrograph in Fig. 6(a) shows an AZ 1350 H photoresist line 1 μm thick and 7 μm wide deposited on a thermally grown silicon dioxide layer 1 μm thick before ion etching. The photoresist sidewalls are almost vertical. The micrograph in Fig. 6(b) shows the silicon dioxide geometry after ion etching and the removal of the residual photoresist. The silicon dioxide is 1 μm thick and its width, measured at the base, is 6 μm. The reduction in linewidth from 7 to 6 μm is readily explained from the etching model [Fig. 4(a)]. The edges of the silicon dioxide line are smooth and the slope angle, which can be determined from the SEM micrograph in Fig. 6(b) by simple geometrical inferences, is 65°.

Figure 7 shows a 1 μm wide and 0.4 μm deep ion-etched groove etched in a silicon dioxide layer. Compared to the photoresist geometry, which was 1 μm thick and 1 μm wide with almost vertical slopes similar to those shown in Fig. 6(a), no change in linewidth can be determined. This result corresponds to the case shown in Fig. 4(a) (dashed line denoted t_2), where the vertical sidewalls assumed 60° slopes without dimensional change.

The SEM micrograph in Fig. 8(a) represents a chemically etched double layer structure consisting of a 0.5 μm thick silicon dioxide layer and a 0.1 μm

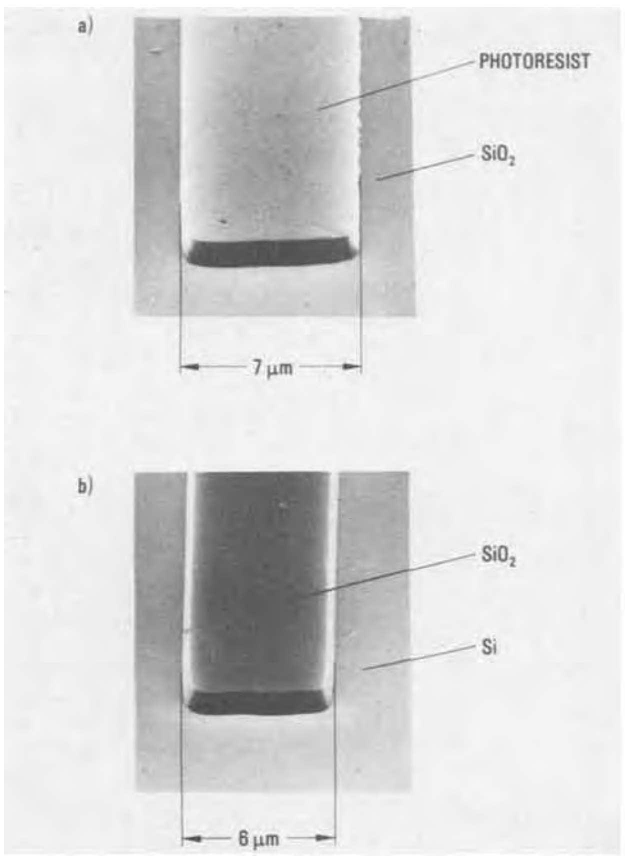

Fig. 6. (a) SEM micrograph (viewing angle 70°) of an AZ 1350 H photoresist line 1 µm thick and 7 µm wide deposited on a thermally grown silicon dioxide layer. (b) Corresponding silicon dioxide geometry 6 µm wide and 1 µm thick after ion etching and removal of the residual photoresist. The reduction in linewidth from 7 to 6 µm is explained with the ion etching model shown in Fig. 4(a). The slope angle of the silicon dioxide sidewalls is 65°.

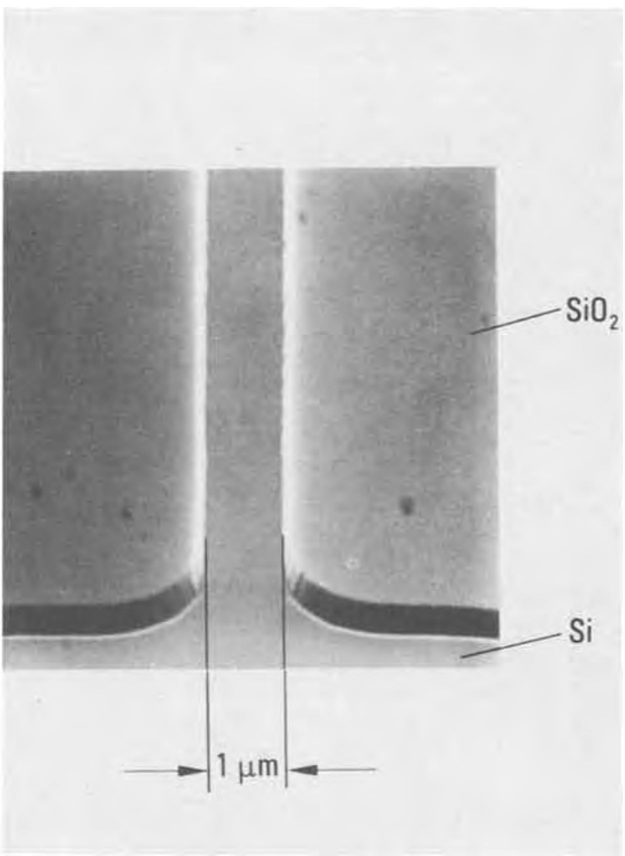

Fig. 7. SEM micrograph (viewing angle 70°) of a 1 µm wide and 0.4 µm deep ion-etched groove in a silicon dioxide layer. No change in linewidth as compared to the original groove in the photoresist was observed. The slope angle of the silicon dioxide sidewalls is 65°.

thick phosphorus silicate glass (PSG) layer with about 8 mole percent (m/o) of phosphorus pentoxide. Due to the fast etch rate of PSG in buffered hydrofluoric acid, the slope angle of the silicon dioxide layer is only 18°, the slope of the PSG layer is almost vertical. The SEM micrograph in Fig. 8(b) shows the geometry after ion etching of the same double layer. As the ion etch rates for PSG and for silicon dioxide are much the same, the slope angle is again uniformly 65°.

Similar results were obtained with silicon nitride/silicon dioxide and polycrystalline silicon/silicon dioxide double layer structures as well.

One specific geometrical effect must be taken into account if the geometries to be etched are to run over steps. Due to the faster etching of sloped regions (*Fig. 3*), *these steps exhibit lateral shift.* Figure 9(b) shows the ion-etched gate region of a MOSFET where the edges of the source and drain regions have been displaced by the distance Δx.

Redeposition effect.—The model discussed does not include the effect of the redeposition of sputtered material (13). Redeposition means that some of the sputtered particles leaving an etched groove become deposited on its sidewalls, from where they are resputtered and redeposited in the groove. If this effect is pronounced, grooves of different widths will be etched at different effective etch rates. Figure 10 shows ion-etched grooves in silicon dioxide with linewidths of 1.25, 2.5, 5, and 10 µm. A titanium pattern was used as a mask. The larger etch depths in the wider grooves are clearly visible. The area surrounding the grooves is etched away as well. The 0.8 µm oxide step thus created is visible in the micrographs of Fig. 10.

In Fig. 11 the experimentally obtained etch rates are plotted as a function of linewidth for photoresist and titanium masking. Using a titanium mask, the effective etch rate remains constant for grooves with linewidths down to about 10 µm, but decreases by roughly 50% for linewidths of about 1 µm. If photoresist is used as the masking material, the corresponding decrease in etch rate is, however, only 25%.

Surface damage caused by ion etching.—We have observed from the ion backscatter as well as from MOS capacitance-voltage measurements that ion-etched surfaces suffer severe damage (14). If a silicon dioxide layer thermally grown on a single crystal silicon substrate is ion-etched down to the silicon substrate, a silicon surface layer about 100Å thick is damaged. An argon concentration of about 10^{21} atoms/cm^3 can be measured for the ion energy and dose used. Furthermore, during ion etching particles are sputtered from metal parts inside the ion etching apparatus such as the tungsten neutralization filament, the molybdenum accelerating grids, and the copper ground plate. These particles contaminate the silicon surface and cause deep energy levels at the silicon-silicon dioxide interface (14). Their concentration is highly dependent on system parameters, specially on the extraction system of the grids (15). The contaminated and damaged surface layer can, however, be completely removed by wet chemical etching with a diluted HNO_3/HF etchant.

We have observed that the damaged region near the surface of silicon dioxide layers exhibits a higher

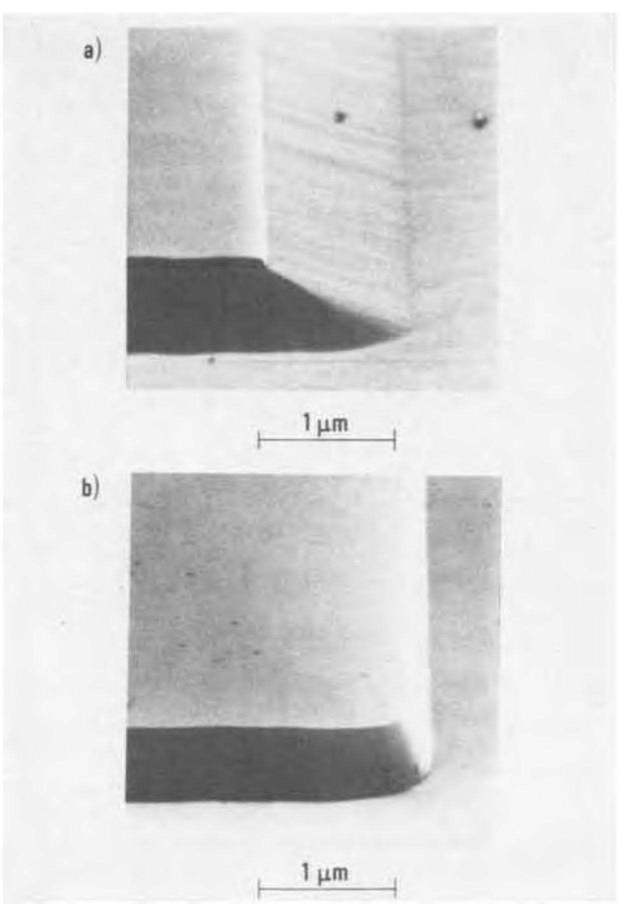

Fig. 8. (a) SEM micrograph (viewing angle 70°) of a chemically etched double layer consisting of a 0.5 μm thick silicon dioxide layer and a 0.1 μm thick phosphorus silicate glass (PSG) layer. Due to the fast etch rate of PSG in buffered hydrofluoric acid, the slope angle of the silicon dioxide layer is only 18°, whereas the slope of the PSG layer is almost vertical. (b) SEM micrograph showing the corresponding step in the same double layer after ion etching. As the ion etch rates for PSG and for silicon dioxide are much the same, the slope angle is uniformly 65°.

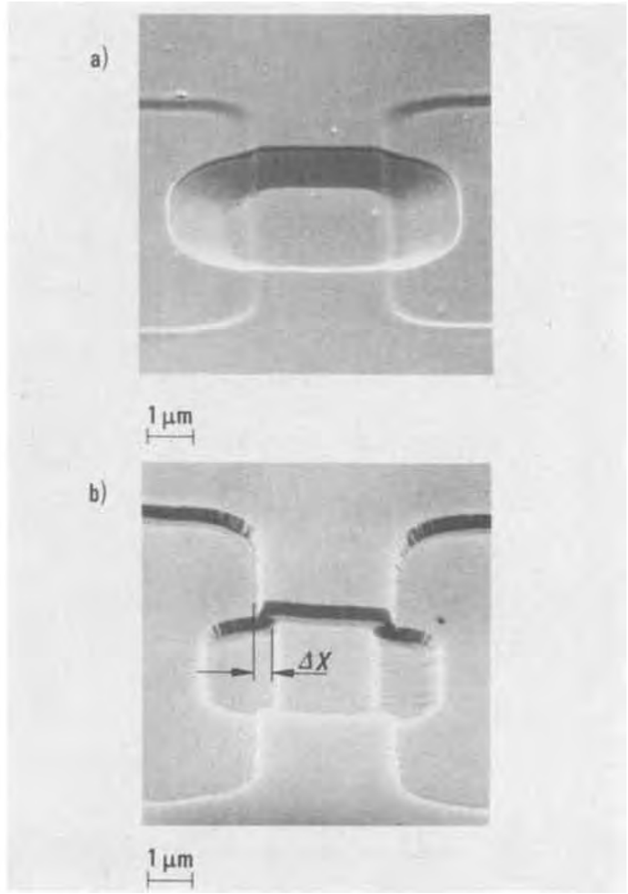

Fig. 9. (a) SEM micrograph (viewing angle 70°) of a chemically etched gate region in a MOSFET. (b) SEM micrograph showing the same gate region after ion etching. The steps generated during reoxidation after the source and drain diffusion appear laterally displaced by the distance Δx due to the faster etching of sloped regions.

etch rate in buffered hydrofluoric acid than undamaged silicon dioxide layers. This effect can be used to taper the edges of silicon dioxide patterns. A similar effect has been reported by Moline *et al.* (16) for ion-implanted silicon dioxide films. Figure 12 shows its mechanism. Prior to photoresist pattern generation, the silicon dioxide surface of the sample shown in Fig. 12(b) was exposed for only 10 sec to an ion beam with an energy of 0.6 keV and a beam current of 0.5 mA/cm^2. Then a photoresist pattern is created on top of the SiO_2 layer. Due to the higher etching rate of the 100Å thick damaged part of the SiO_2 layer, an etched SiO_2 pattern with tapered edges is produced. Figure 12(b) shows the result. The slopes of the silicon dioxide lines are uniform; the slope angle is about 25°. Figure 10(a), in comparison, shows chemically etched SiO_2 lines without ion bombardment prior to photoresist coating. This method can be used to taper steps in thermally grown SiO_2 in a controllable manner (17).

Summary

The ion beam etching process described is effectively controllable and yields reproducible results. Ion-etched grooves in silicon dioxide exhibit no significant dimensional change relative to photoresist geometries as long as the etching depth does not exceed half the resist thickness. The slopes of the sidewalls of the etched grooves are uniform. Typical slope angles are 65°. Adhesion between the mask and the substrate to be etched is without influence on the etch profile. As the ion etching process is nonselective, the silicon substrate can still be etched to a certain extent even if the silicon dioxide layer is etched down to the silicon surface. Redeposition effects reduce the effective ion etch rates for grooves of small linewidths. The damage suffered by the silicon surface layer due to ion bombardment can be completely removed by wet chemical etching. The enhanced etch rate of ion-damaged silicon dioxide surface layers in buffered hydrofluoric acid is used to taper steps in thermally grown silicon dioxide in a controllable manner.

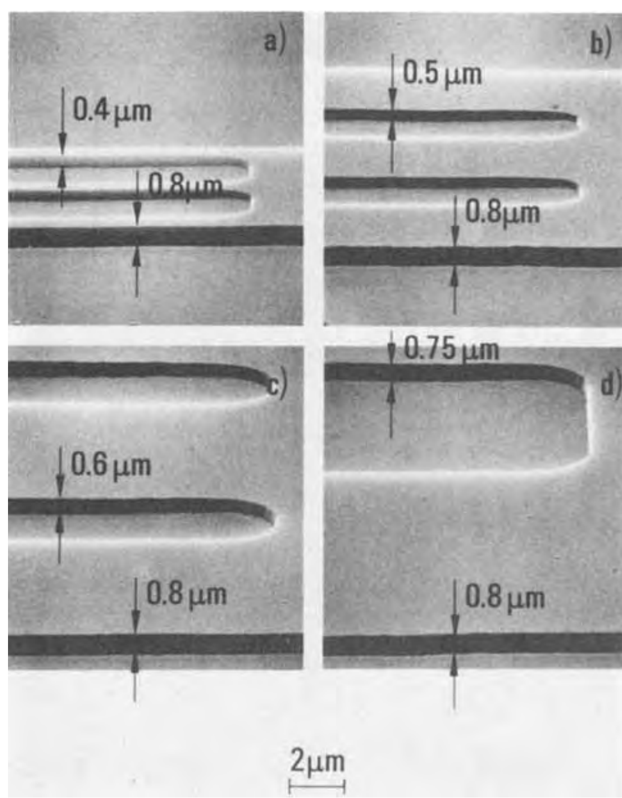

Fig. 10. SEM micrographs (viewing angle 70°) of grooves in silicon dioxide ion etched under the same conditions. The widths of the grooves are (a) 1.25 μm, (b) 2.5 μm, (c) 5 μm, and (d) 10 μm. The masking material for ion beam etching was titanium. As the sidewalls of the etched grooves are almost vertical, the magnification ratio given for the horizontal direction of the SEM micrograph can also be used to calculate the step depths with good approximation The calculated etch depths are denoted in (a)-(d).

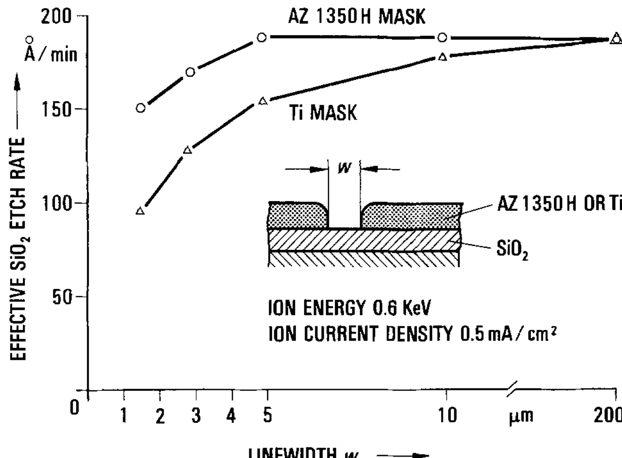

Fig. 11. Measured etch rates (see Fig. 10) vs. linewidth for photoresist and titanium masking. Using a titanium mask, the effective etch rate remains constant for grooves with linewidths down to about 10 μm, but decreased by roughly 50% for linewidths of about 1 μm. If a photoresist mask is used the corresponding decrease in the ion etch rate is only 25%.

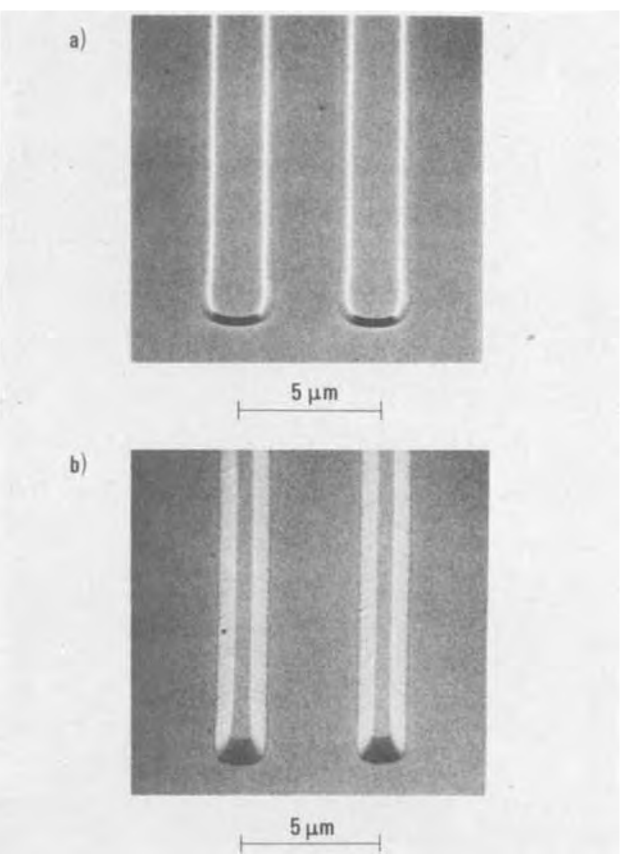

Fig. 12. SEM micrograph (viewing angle 70°) of chemically etched silicon dioxide lines: (a) without ion bombardment prior to photoresist coating, (b) after ion pretreatment. Compared to the lines in (a), the lines in (b) exhibit straight and smooth sidewalls with tapered slopes at an angle of 30°. The silicon dioxide surface layer was bombarded for about 10 sec by argon ions with an energy of 0.6 keV and a beam current of 0.5 mA/cm^2 prior to photoresist pattern generation.

Annihilation of Stacking Faults in Silicon by Impurity Diffusion

H. Hashimoto, H. Shibayama, H. Masaki, and H. Ishikawa*

Fujitsu Laboratories Limited, Nakahara-ku, Kawasaki, Japan

ABSTRACT

The stacking faults grown into silicon during thermal oxidation were shrunk by high temperature heat-treatment in a nitrogen atmosphere. The activation energy for fault shrinkage was 5.2 eV, and nearly equal to that of silicon self-diffusion, 5.13 eV. The shrinkage phenomenon is due to the removal of silicon atoms, which form the stacking faults of extrinsic type, by diffusion via vacancies. Therefore the shrinkage rate depends on the vacancy concentration in silicon. The high concentration diffusion of boron, phosphorus, and arsenic in silicon generates the excess vacancies induced by donor doping, or by the stress due to solute lattice contraction of the impurity. The shrinkage of stacking faults by these excess vacancies was investigated. The faults shrank rapidly and disappeared for a short time in comparison with simple heat-treatment. The annihilation of stacking faults in silicon was also influenced by the coulomb interaction or the complex formation between the negatively charged vacancy and impurity.

Thermal oxidation is one of the important processes in the manufacture of silicon planar transistors and other devices. Crystallographic defects such as stacking faults are often introduced in silicon in this oxidation process (1-5). When stacking faults lie across a p-n junction, excess reverse leakage currents in the junction are increased (6). Therefore, it is necessary to suppress stacking fault generation. If a crystal free from mechanical damage and grown-in defects, which act as the nucleation, is used, stacking faults are not generated. However, it is difficult to obtain such a crystal. Accordingly, the suppression of stacking fault generation and shrinkage of the faults by HCl oxidation (7), or the preoxidation gettering of silicon wafers by misfit dislocations due to phosphorus diffusion (8), etc. have been carried out. Stacking faults also can be shrunk by high temperature heat-treatment (9).

In this study, the shrinkage of stacking faults was investigated first. It was found that the shrinkage related intimately to the vacancy concentration in silicon. The vacancy concentration depends not only on treatment temperature, but also on impurity doping. And so the relation between the annihilation of stacking faults and the excess vacancies which were induced during impurity diffusion into silicon was studied, and the mechanism of the annihilation is discussed.

Experimental

The specimen wafers used in these experiments were 1-5 Ω-cm (100) oriented dislocation-free silicon crystals grown by the Czochralski method. They were doped with phosphorus for n-type and boron for p-type. The surface was mechanically polished and the thickness was about 250 μm. After appropriate treatments, they were etchd in a $HF:HNO_3 = 1:5$ solution for 2 min to remove the surface mechanical damage. The oxidation of silicon was carried out at 1200°C in dry oxygen for 210 min. This thermal oxidation grew a stacking fault in the silicon crystal about 40 μm long, provided that the fault size was defined as the fault length on the silicon surface. After oxidation, the samples covered with grown oxide were treated at 1100°-1200°C in dry nitrogen to investigate the shrinkage process of stacking faults. In order to reveal the stacking faults, the samples were etched in a Sirtl solution (10) after dissolving the oxide layers in HF.

Furthermore, the annihilation behavior of stacking faults by impurity diffusion into silicon was examined. Boron, phosphorus, and arsenic were diffused into silicon wafers having stacking faults. Impurities were diffused into silicon from doped oxide sources except for the diffusion of high arsenic concentration. The doped oxide sources were deposited onto silicon wafers by the reaction of silane, hydride of impurities, and oxygen. The reaction temperature was 350°C for the deposition of borosilicate and phosphosilicate glasses, and 450°C for arsenosilicate glasses. The diffusion was carried out at 1100°C in dry nitrogen. For the diffusion of high arsenic concentration, a capsule method was used, because the high arsenic diffused layers were not obtained by diffusion from the doped oxide source in the nitrogen atmosphere (11). The silicon wafers were placed in a quartz tube together with arsenic. The tube was then evacuated and sealed. The diffusion was also carried out at 1100°C. The surface concentration of diffused layers was determined using the anodic oxidation-resistivity technique (12) and Irvin's data (13).

Results

Shrinkage of stacking faults by heat-treatment.—The shrinkage of stacking faults by heat-treatment in the nitrogen atmosphere was examined first. The silicon samples which had stacking faults about 40 μm long were treated at 1100°-1200°C in dry nitrogen. The shrinkage rate of the stacking faults is shown in Fig. 1 as a function of treatment time. Stacking faults could be shrunk easily by high temperature heat-treatment. A linear relationship was found between fault length and heat-treatment time. The shrinkage rate *vs.* the

Key words: silicon, stacking faults, diffusion.

reciprocal of treatment temperature is plotted in Fig. 2. The activation energy of shrinkage determined from this figure was 5.2 eV.

Influence of boron diffusion on annihilation.—Boron was diffused into silicon samples having about 40 μm long stacking faults at 1100°C in dry nitrogen. The surface concentrations of diffused layers were 4.3×10^{19}-2.7×10^{20} cm^{-3}, and their diffusion depths were 2.5-4.4 μm. After boron diffusion, the samples were etched in a Sirtl solution for 10 sec. Typical photographs of the specimen surfaces are shown in Fig. 3. The stacking faults in the surface region disappeared in all samples during boron diffusion. When the surface concentration increased to more than 1×10^{20} cm^{-3}, the slip dislocations due to solute lattice contraction of boron were generated (14).

In order to investigate the annihilation of stacking faults in the boron diffused layers and underneath them, another experiment was carried out. The samples were etched in a $HF:HNO_3 = 1:5$ solution as shown in Fig. 4. Then the specimens were etched in a Sirtl solution. The results are shown in Table I. For the relatively low surface concentration, 4.3×10^{19} cm^{-3}, the stacking faults still remained in the diffused layer near the diffusion front of the boron. Increasing the surface concentration, the stacking faults within the diffused layers disappeared. For the sample, of which the surface concentration was 1.7×10^{20} cm^{-3}, the stacking faults underneath the boron diffused layer were annihilated. Moreover when the surface concentration was increased to 2.7×10^{20} cm^{-3}, stacking faults remained and were not annihilated underneath the boron diffused layer.

Influence of phosphorus diffusion on annihilation.—The diffusion of phosphorus was identical with the boron diffusion described in the previous section. The phosphorus surface concentrations in diffused layers were 5.3×10^{19}-3.6×10^{20} cm^{-3}, and their diffusion depths were 2.9-3.1 μm. After phosphorus diffusion, the annihilation behavior of stacking faults was observed using the method illustrated in Fig. 4 and Sirtl etching. The results are shown in Table II. The stacking faults in the phosphorus diffused layers were annihilated during phosphorus diffusion in the concentration range of this experiment. However, the stacking faults underneath the diffused layers remained and were not annihilated. The slip dislocations which were observed for the diffusion of high boron concentration were not generated by the diffusion of high phosphorus concentration.

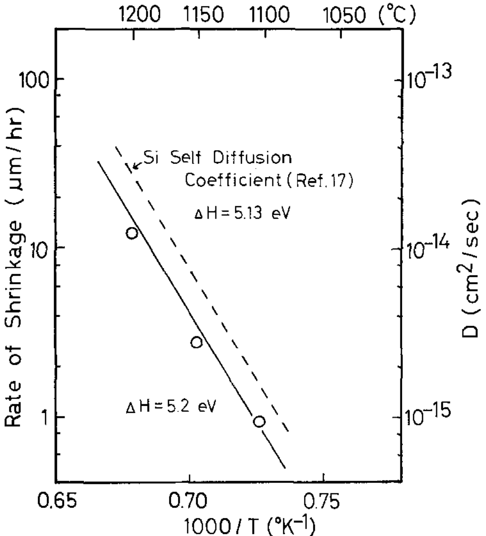

Fig. 2. Rate of shrinkage vs. reciprocal heat-treatment temperature, showing its relationship to the silicon self-diffusion coefficient.

Influence of arsenic diffusion on annihilation.—For the arsenic diffusion of comparatively low concentration, arsenic can be diffused in the nitrogen atmosphere using the doped oxide source method. In order to obtain diffused layers of high arsenic concentration by this method, arsenic must be diffused into silicon in oxygen. The treatment in the oxygen atmosphere grows stacking faults. Therefore a capsule method was used for the diffusion of high arsenic concentration. The surface concentrations of arsenic in diffused layers were 2.2×10^{19}-3.0×10^{20} cm^{-3}. If arsenic diffuses in silicon to about 3 μm in depth from the surface, a fairly long diffusion time is required because of the small diffusivity of arsenic in silicon (15). Stacking faults are considerably shrunk during such heat-treatment for long times. The diffusion depths of arsenic were limited to 0.6-1.2 μm. Table III shows the results of stacking fault distribution in the specimens after arsenic diffusion. The stacking faults in the arsenic diffused layers disappeared for the diffusion of relatively low surface concentration. This is the same behavior as phosphorus. When the surface concentration increased more, the stacking faults remained even in the arsenic diffused layers. For the sample of which the surface concentration was 3.0×10^{20} cm^{-3}, the faults near the silicon surface were hardly shrunk.

Discussion

The stacking faults are generated in silicon by heat-treatment in an oxidizing atmosphere. They can be shrunk by high temperature heat-treatment in an unoxidizing atmosphere. Sanders *et al.* (16) determined the activation energy for fault shrinkage to be 2.1 eV. This energy is smaller than the result of the present experiment, 5.2 eV. They made an annealing experiment using the ultrathin foils of silicon having stacking faults. The thermodynamics in such thin foils may be different from that of the bulk crystal. Therefore, the discrepancy of the activation energy probably came from the difference in the experimental conditions. The value in the present experiment, 5.2 eV, was nearly equal to the activation energy of silicon self-diffusion, 5.13 eV (17). In the shrinkage phenomenon it is considered that silicon atoms, which form the extra plane of the extrinsic-type stacking faults (3), are diffused outward via vacancies, and stacking faults are shrunk. Provided that this shrinkage mechanism is valid, the shrinkage of stacking faults depends strongly on the vacancy concentration in silicon. The vacancy concentration is influenced not only by treatment temperature, but also other factors. That is to say, the vacancies are increased with donor doping (18) or with the stress by solute lattice contraction of an impurity in silicon (19). These excessively induced vacancies are

well known and are discussed as impurity diffusion in silicon (20). The excess vacancies cause the enhanced diffusion of the impurity.

If the vacancy in silicon acts as an acceptor (21), the vacancy concentration is changed by the shift, due to doping, of the Fermi level (18). The concentration of charged vacancies is given by

$$[V^-] = [V]/\{1 + \exp[(E_{VAC} - E_F)/kT]\} \quad [1]$$

where E_{VAC} and E_F are the vacancy and Fermi levels, respectively, and $[V]$ is the total concentration of vacancies, which is the sum of charged and neutral vacancies. Assuming that the concentration of neutral vacancies is independent of impurity doping (22), and using Eq. [1], the ratio of the total vacancy concentration in extrinsic silicon doped with impurity, $[V]_D$, to intrinsic, $[V]_I$ can be expressed by

$$\frac{[V]_D}{[V]_I} = \frac{1 + \exp[(E_{FD} - E_{VAC})/kT]}{1 + \exp[(E_{FI} - E_{VAC})/kT]} \quad [2]$$

where the suffixes, D and I, indicate the doped and intrinsic condition. The simple vacancy in silicon is known to be an acceptor having the energy level of 0.4 eV below the conduction band (21). Hence, in silicon heavily doped with a donor impurity, Eq. [2] becomes

$$\frac{[V]_D}{[V]_I} \cong \exp[(E_{FD} - E_{FI})/kT] = n/n_i \quad [3]$$

where n and n_i are the electron concentration in doped and intrinsic silicon, respectively. The vacancy concentration increases in silicon heavily doped with a donor-type impurity.

When phosphorus was diffused into silicon having stacking faults and its surface concentration exceeded the intrinsic carrier concentration, the stacking faults in the diffused layers were annihilated for a short time. The annihilation was probably enhanced by the donor-induced vacancies. Arsenic is the same type of donor as phosphorus, but the behavior differed somewhat from that of phosphorus. The annihilation effect of stacking faults in the arsenic diffused layers decreased as the surface concentration of arsenic increased. For the sample of which the surface concentration was 3.0×10^{20} cm^{-3}, the faults almost entirely remained in

the arsenic diffused layer. Considering the discrepancy between total arsenic in silicon diffusion profiles obtained by Irvin's data and those determined by neutron activation analysis, and the dependence of the arsenic diffusion coefficient on concentration, Fair pointed out that ($V_{Si}As_2$) complexes were formed and acted as vacancy sink (23, 24). The vacancy concentration probably became insufficient for the annihilation of stacking faults in the diffusion of high arsenic concentration.

The stacking faults were also rapidly annihilated by boron diffusion. For boron diffusion, $[V]_D/[V]_I$ in Eq. [2] is unity, so that the same excess vacancies as donor doping are not induced. The covalent radius of boron is 0.89Å, which is smaller than that of silicon, 1.17Å. The stress due to solute lattice contraction is introduced in silicon doped heavily with boron. This stress causes the slip dislocations (14). When boron was diffused in silicon and its surface concentration exceeded about 1×10^{20} cm^{-3}, the slip dislocations were observed as shown in Fig. 3. The excess vacancies might be emitted from these defects during their generation, and might have enhanced the annihilation of stacking faults. However, for the samples of which the surface concentration of boron exceeded 1.7×10^{20} cm^{-3}, the annihilation effect decreased slightly. If the boron concentration approaches near to the solid-solubility limit, interstitial boron atoms probably increase. These interstitial atoms oppositely act as vacancy sink to occupy the lattice sites. And so, the annihilation effect by boron diffusion of extremely high concentration might be decreased.

Another remarkable phenomenon of boron diffusion was that the stacking faults underneath the boron diffused layer were annihilated under the adequate condition. This phenomenon is considered as follows. The negatively charged vacancies repulse with boron atoms, because boron is an acceptor. Then, the vacancies are able to diffuse deeply far from the diffusion front of boron. They possibly annihilate the stacking faults underneath the boron diffused layer. Therefore, this phenomenon was not observed for the diffusion of a donor impurity such as phosphorus and arsenic. In case of the diffusion of a donor impurity, the negatively charged vacancies are drawn to donors and remain mainly in the diffused layer. Because of this, the stacking faults underneath the diffused layer were not annihilated by diffusion of phosphorus and arsenic. This behavior differs remarkably from that of boron.

Conclusions

The stacking faults generated in silicon during thermal oxidation are shrunk and annihilated by heat-treatment in a nitrogen atmosphere. This phenomenon is due to the removal of silicon atoms, which form the extrinsic-type stacking faults, by diffusion via vacancies. Therefore, the excess vacancies induced in silicon by the diffusion of donor-type impurities or by the stress due to solute lattice contraction of impurity, enhance the annihilation of stacking faults. This behavior is also influenced by the coulomb interaction between the negatively charged vacancy and impurity, or the complex formation between the vacancy and impurity.

From the results of these experiments, useful information for studying the various phenomena in other fields can be obtained. For instance, using the annihilation data, one can make clear the mechanism of anomalous diffusion of impurity in silicon, which is not sufficiently known.

ABSTRACT

The etching of silicon in HNO_3-HF based systems proceeds by a sequential oxidation-followed-by-dissolution process. In those composition regions where the solution is very low in HNO_3 and rich in HF, the rate-limiting process is the oxidation step. Consequently, electron concentration, surface orientation, crystal defects, and catalysis by lower oxides of nitrogen play an important role. In those compositions where HF is in limited supply, dissolution of the formed oxide is the rate-controlling step and diffusion of the complexing fluoride species is the important factor. Therefore, crystal orientation and conductivity type independence as well as hydrodynamic control are the consequences. In order to meaningfully select an etching composition to solve a specific processing problem, it is necessary to understand this composition-mechanism interaction. Corollary with the mechanism understanding, sample geometry effects have been followed as a function of solution composition. The HF-HNO_3-H_2O solution composition plane has been characterized into various regions where the two basic mechanisms interact and specific procesing utilization is shown. Similar results are shown for the system HF-HNO_3-$HC_2H_3O_2$. In addition, a number of particular etching problems are posed, and solutions offered, that make use of these composition characterizations, and show how one can use their information to solve other practical processing problems.

Most of the data on silicon etching that one can find in the literature involve studies of the mechanisms and kinetics of the dissolution process (1-4). There are a few examples of practical applications, but they deal primarily with crystallographic aspects of the etching, *e.g.*, defect delineation (5) or anisotropic crystal plane etching (6). Because of the sophistication of present-day silicon technology, it appears to be desirable to be able to control the geometrical aspects of a silicon slice, *e.g.*, from sharp, possibly peaked corners and edges to smooth and rounded edges and corners, merely by controlling the chemical etching environments. It would, therefore, seem appropriate to present some data on the geometrical effects observed on the etching of silicon rectangular parallelepipeds in solutions of HNO_3, HF, and H_2O with and without $HC_2H_3O_2$. These observations were made at the same time as the previously published kinetics data were being obtained (1,2), but it is only recently that many requests for geometric information have made us aware of the usefulness of disseminating these configurational data.

In order to make the picture more complete, some of the original iso-etch-rate figures will also be included, for comparison purposes.

Experimental Procedure

The technique used for the etching and thickness monitoring has been adequately described in previous publications (1-3). However, in order to make this paper useful, we will have to repeat some of the experimental detail, but will stress only the salient features of the sample and solution preparation methods and how the geometric aspects were followed.

The sample dice were rectangular parallelepipeds (0.125 × 0.125 × 0.025 in. on side) cut from n-type silicon slices with resistivities about 2 Ω-cm. The dice were cut so that the large-area surfaces were along the (111) plane while the remaining surfaces were not controlled with respect to any particular crystal plane. Also, the dice were used as received, which means that the exposed surfaces contained saw damage.

All dice were etched three times, and each etch was performed in a fresh portion of the same solution. Since each etching period had been chosen to remove 4 to 6 mils from the specimen, it may be assumed that the work damage had been removed after the first etch. The third etch was performed with a few milligrams of $NaNO_2$ added to the solution for possible catalytic purposes (1). After each etching step, the sample was rinsed in distilled water, dried, and measured for dimensional changes with a micrometer to ± 0.05 mils, and then the geometry of the specimen was examined under a microscope.

Concentrated hydrofluoric acid, as normally supplied, may vary in concentration from 48 to 52 weight percent (w/o). Similarly, nitric acid may vary between the limits of 69 and 71%. In order to establish control over the composition of the etching solutions, it was necessary to standardize the stock acids from which the solutions were to be made. This was done by titrating samples of the acids against a standard sodium hydroxide solution. Potassium acid phthalate was used as the primary standard for the sodium hydroxide. The first bottle of hydrofluoric acid analyzed at 49.25%, and this concentration was accordingly selected as the standard HF reagent concentration. All subsequent bottles of hydrofluoric acid were adjusted to 49.25 ± 0.05% by the addition of 60% HF or water as dictated by the chemical analysis. In a similar manner, the value 69.51% HNO_3 was established as the standard nitric acid concentration and all subsequent stock bottles of nitric acid were adjusted to this value ± 0.05% by the appropriate addition of water or 90% HNO_3. In a second series of experiments designed to cover a larger area of the composition range, 90.45 ± 0.05% HNO_3 and 59.75 ± 0.05% HF were the standard reagents used. In a third series of experiments, glacial acetic acid was used as a diluent, and the only water present was that found in the original HNO_3 or HF reagents.

[1] All of the data used in this paper were obtained while the authors were employed at Hughes Aircraft Company.

Key words: silicon, etching, geometry control.

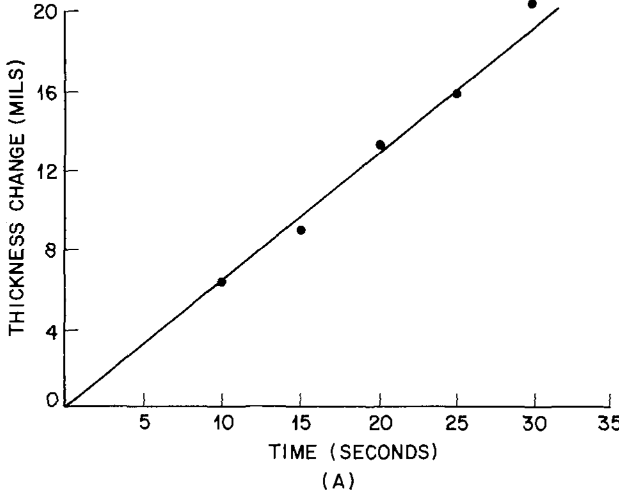
The etching was done in a Teflon beaker 1 in. in diameter and 2½ in. deep. Agitation was provided by an electric stirrer equipped with a polyethylene paddle. The dice were etched one at a time in 10 cm^3 of solution, and duplicate results were obtained by repeating the entire experiment. To quench the reaction at the proper time, a large volume of water was poured into the beaker. The etching technique was later modified when the higher concentration reagents were used. Here the dice were etched two at a time, in 20 cm^3 of solution, while encased in a small perforated polyethylene basket. The basket and dice were agitated for the required time in the solution, then immersed in a beaker of cold water to quench the reaction. The agitating action consisted of approximately 150 vertical strokes per minute, with the etching jig rotated between the thumb and middle finger as rapidly as possible during the up and down strokes.

All etching was performed in a constant temperature bath regulated at 25.00° ± 0.02°C. Unfortunately, the heat transmission of polyethylene and Teflon is so poor that the temperature of the bath could not be realized in the etch solution, and even after long periods of equilibration the maximum initial etch temperature was only 24.70°C. As a further consequence of the poor heat transmission of the etching container, the more rapid etches were run under essentially adiabatic conditions.

It was realized early in the study that in some etch compositions the rate of attack on the die would be so high that if the specimen were left in the solution for one minute, either the sample would be etched away completely or it would be so thin that it would be very difficult to handle. For this reason an attempt was made to choose an etch time for each composition such that only 4 to 6 mils of material would be removed. The etch rate was then linearly extrapolated to obtain the 1 min value. The justification for the extrapolation is illustrated by Fig. 1 where the change in sample thickness is plotted as a function of time for two different etch compositions. It is quite possible that for compositions where the etch rate is very high, the linear relation between the amount of material removed and the time is not valid for the entire minute, since the reaction is known to be strongly exothermic and to proceed under adiabatic conditions. Nevertheless, it is believed that by limiting the etch time to minimize the effect of changes in experimental conditions, one could obtain numbers by linear extrapolation which are reasonably valid. The change in concentration of the etch system during the experiment was also considered an important factor. However, if one allows only about 0.005 in. of silicon to be etched away during the operation, this would correspond to reacting only about 0.4 mequiv. of silicon, and the change of concentration of the reagents due to reaction would be at most 1%, which is a negligible consideration.

Since the etching systems under study here were composed of three components (*i.e.*, HF, HNO_3, and H_2O) with a fourth component present only when $HC_2H_3O_2$ was added, it was decided to represent the solution concentration field with a triangular coordinate system. The decision was also made to set two of the vertexes at 100 w/o of the concentrated HF or HNO_3 acids and to make the third vertex 100% added water or glacial acetic acid. This normalization of the axes to the concentrated acids results in data good only for the particular concentrations chosen as the basis for the study. The weight percent system, though, allows for ready conversion to other concentration units such as mole fraction and molality, and knowledge of the specific gravity of the solution[2] also enables one to calculate the molarity of the solution. By converting the concentrations to mole fractions, one can compare any concentration system with any other.

[2] The specific gravity of each solution was measured, but for brevity we will not discuss this point further.



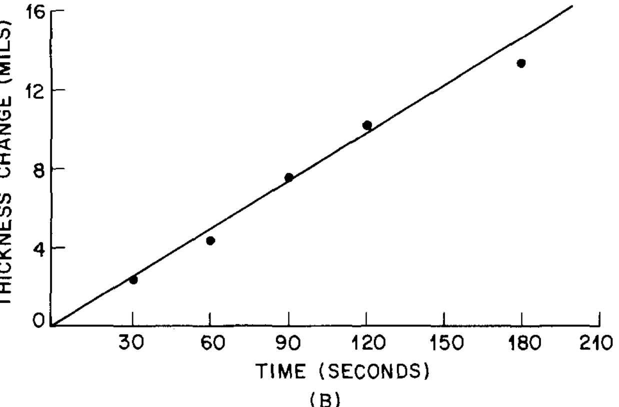


Fig. 1. Change of die thickness plotted as a function of die exposure time: (A) solution composed of 55% HF, 45% HNO_3; (B) solution composed of 30% HF, 70% HNO_3.

The solution composition field was subdivided into a number of evenly spaced points representing different compositions. The amounts of each reagent corresponding to each composition were then calculated, and the solutions were prepared by putting together the required amounts of reagents. The hydrofluoric acid was weighed out directly to ± 0.01g, but the weights of nitric acid and water were converted to volumes and measured out in a burette to ± 0.01 cm^3.

Experimental Results

Figures 2 and 3 represent the iso-etch-rate contours determined for the normal and high concentration

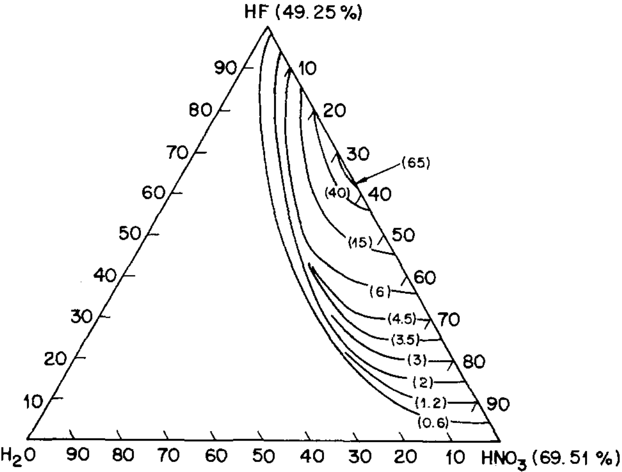

Fig. 2. Curves of constant rate of change of die thickness (mils per minute) as a function of etchant composition, in the 49% HF-70% HNO_3 system.

reagents [to obtain the etching rate on either of the (111) faces, divide the listed value by 2], with added water as the third vertex. Figures 4 and 5 are the same data, illustrating the shape of the etch-rate surface as a function of solution composition. The various regions and the mechanisms involved in the dissolution process were adequately covered previously (1-3). We shall just note that in the region around the HF vertex the reaction is primarily oxidation-reduction controlled, and in the region around the HNO_3 vertex, the reaction is primarily diffusion controlled. A consequence of the diffusion-governed kinetics is that different crystallographically oriented surfaces should all etch at the same rate. For two widely different etch compositions, the rate of attack on the (111) plane has been found to be identical to the rate of attack on the (110) plane. In preferential etch systems (*e.g.*, NaOH), the (111) is the slowest etching plane and the (110) plane is one of the fastest etching planes.

Figures 6 and 7 are plots of the same solution composition fields, respectively, but in the latter two figures are shown the observed geometry effects on the initially rectangular parallelepipeds.[3] In these two figures it is seen that the geometry of the etched specimen undergoes a gradual transition as the etching formula is changed along the HNO_3-HF axis. In the high HF region the specimens have rough, pitted surfaces and sharply peaked corners and edges. At about

[3] Although solid lines are drawn from which sharp discontinuities could be inferred, this is not the case. There are graded regions in going from one area to another, but this would make illustration well-nigh impossible.

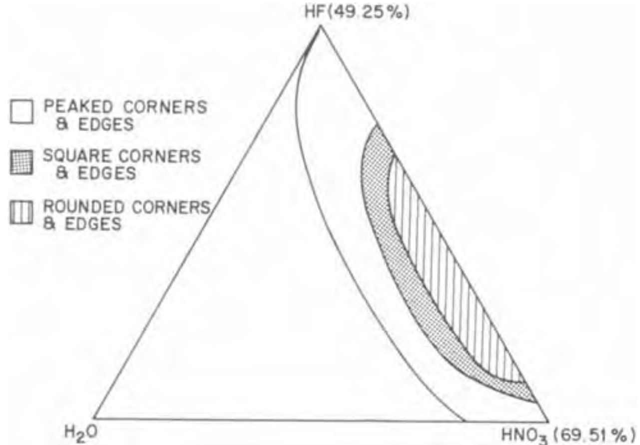

Fig. 6. Resultant geometry of the etched die as a function of the etchant composition in the 48% HF-70% HNO_3 system.

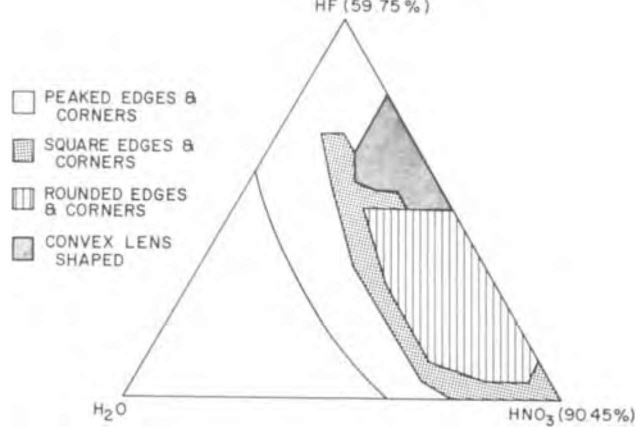

Fig. 7. Resultant geometry of the etched die as a function of the etchant composition in the 60% HF-90% HNO_3 system.

25% HNO_3 on this axis (Fig. 6), the geometry becomes square and the surface has a matte appearance. Further increase of HNO_3 above 35% is accompanied by progressive rounding of the corners and the development of a highly specular surface. The latter geometry and appearance prevail over the remainder of the composition range except that in the very high HNO_3 region the geometry again becomes peaked. A tendency toward peaking of corners is also observed as the composition is varied toward increasing water.

The natural tendency of a diffusion-controlled reaction is the development of rounded corners and edges, since the availability of reagent is greater at the corners and edges of the specimen than in the center. A factor must therefore exist that enhances the rate of attack of the reagent in the central portion of the specimen. This factor is the effect of catalysis on the reaction rate. We know that in some etching solutions, a work-damaged surface will etch readily while a preetched surface will be very difficult to etch. In the latter case, it has been observed that if the etching action can be started by any one of a number of means (*e.g.*, seeding the solution with a die having a damaged surface), there is then no difficulty in sustaining the reaction. This phenomenon can be explained on the basis that one of the reaction products catalyzes the reaction. To verify this hypothesis, certain solutions were seeded with $NaNO_2$ in order to generate nitrogen oxides (1). The results are shown in Fig. 3; the enhancement of the etching rate by the addition of $NaNO_2$ in the high HF region and in the high H_2O region is evidence of catalysis. The reaction is thought to be autocatalytic throughout the entire composition range, but the effect of added catalyst is negligible in those regions where the rate is sufficiently high so that any generated catalyst would far exceed the added amount. Since the reaction is autocatalytic, swirling dissipates the catalyst more rapidly from the corners and edges than from the central portion of the specimen. This might explain the high degree of attack in the central portion of the die relative to the attack on the edges and corners.

The rough surfaces of specimens etched in the high HF region can also be correlated with the autocatalytic mechanism. When the HNO_3 concentration is low, the reaction can begin only at low activation energy sites, such as crystal imperfections. From these sites, the reaction spreads to adjacent areas as the catalyst diffuses. If the reaction is slow, the catalyst is liberated slowly and there is a high probability that it will be dissipated before it can act to propagate the reaction. When the HNO_3 concentration is very low, the surface can be seen to be covered by isolated pits and craters. As the HNO_3 concentration increases, the density of pits and craters increases until they finally merge into a rough "orange peel" pattern. When the concentration of HNO_3 becomes sufficiently large, the entire surface becomes susceptible to attack, and as HF becomes the rate-limiting reagent, the surface becomes smooth and specular.

The ratio of the attack rate on the two (111) planes to that on the four unoriented surfaces is greater than unity in the high HF region, and much less than unity in the high HNO_3 region. This can also be correlated in the high HF region with the greater dependence of the rate on catalyst, and in the high HNO_3 region with the diffusion mechanism. Because of the greater availability of reagent at the edges, this region should show an enhanced etch rate with respect to the center. The fact that the edges etch more slowly than the center in the high HF region indicates that the dissipation of the catalyst is the predominating factor governing the behavior of etchants rich in HF. In the region of etch composition where the oxidation step ceases to be rate determining, the etch rate on the edges of the specimen is in accord with the expectation that these areas will etch faster.

Another observation lending itself to interpretation in terms of the autocatalytic nature of the reaction is the peculiar dependence of the etching rates on the water concentration. In the lower region of Fig. 2 and 3, the contour lines run parallel with lines of constant HF for a considerable distance and then suddenly break upward. The rates at constant HF are independent of increasing water or decreasing HNO_3 up to a critical value. Around this critical point, the rates vary sharply with composition. It is reasonable to assume that as the concentration of nitric acid decreases, a point is reached where the rates become dependent on the nitric acid concentration, and thus on the coupling of the generated catalyst with the reacting system. The decrease in rate resulting from a decrease in the nitric acid concentration is amplified by the decreased coupling of the catalyst with the surface, so that as a result of this "positive feedback" effect the rates are strongly affected by relatively small changes in etch composition.

In the 60% HF-90% HNO_3 system there is a composition region (see Fig. 5 and 7) where the rate reaches a plateau value and the geometry is extremely rounded. This is a region of extremely rapid reaction rates, and the mechanism in this region is not very well understood; however, it is thought to involve the formation of a vapor barrier at the silicon surface owing to the high generation rate of SiF_4.

Figures 8 and 9 are, respectively, the equivalent kinetic and geometry data for the acetic acid diluent system. A comparison of Fig. 2 and 8 clearly brings out the relationship between the two etching systems. The rates in the two systems obviously must converge to identical values along the HF-HNO_3 axis. In the

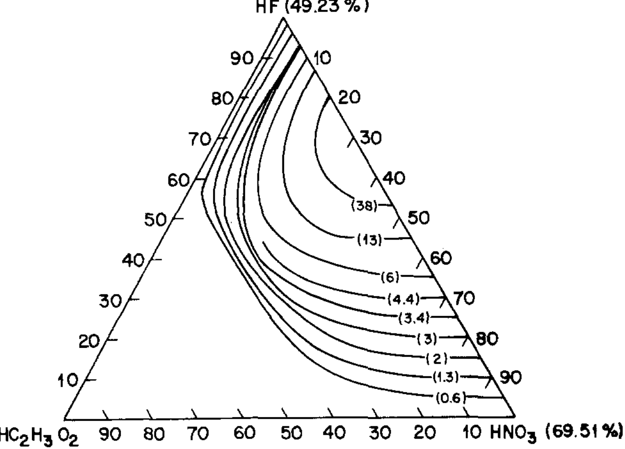

Fig. 8. Curves of constant rate of change of die thickness (mils per minute) as a function of etchant composition in the 48% HF-70% HNO_3-$HC_2H_3O_2$ system.

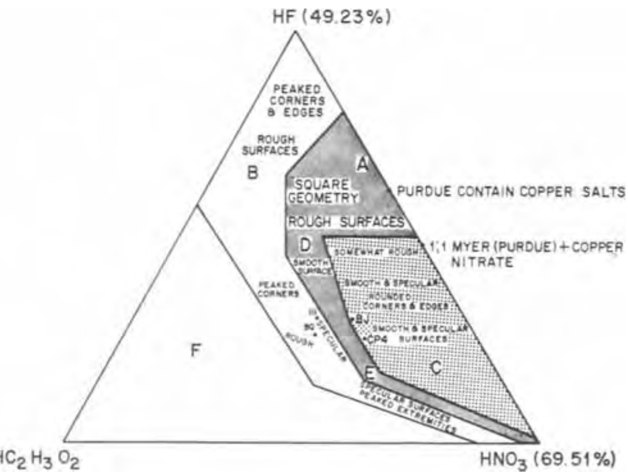

Fig. 9. Resultant geometry of the etched die as a function of the etchant composition in the 48% HF-70% $HC_2H_3O_2$ system.

lower portion of each plot, the constant etch-rate contours of both systems run identical courses over a considerable range of compositions. In the upper portion of each plot, however, the contours diverge immediately upon the addition of diluent. The noteworthy feature here is that the contours for the acetic acid system run parallel with lines of constant nitric acid concentration and the plot in general bears a striking resemblance to the high concentration acid system shown in Fig. 5. The equivalent etching systems HF + HNO_3 + diluent are seen to show a much greater tolerance for acetic acid than for water as the diluent.

Earlier in this section it was shown that in the high HF region the etch rates are affected by the oxidizing ability of the nitric acid and the reaction is critical with respect to the coupling of the generated catalyst. The tolerance of the system for acetic acid is thus in accord with the known enhanced oxidizing power of nitric acid in acetic acid over that of nitric acid in water (7,8). The addition of acetic acid does not reduce the oxidizing power of the nitric acid until a fairly large amount of the diluent has been added. Therefore, the rate contours remain parallel with lines of constant nitric acid over a considerable range of added diluent.

The same explanation is valid in the high HNO_3 region. The sudden dependence of the etch rates on the amount of added diluent has been associated with a transition from an oxidation-independent mechanism to an oxidation-dependent mechanism. The effect of the acetic acid is primarily to defer the onset of the oxidation-dependent mechanism until a very large amount of this diluent has been added.

The striking similarity of the water diluted etching system and the acetic acid diluted system, coupled with the consistency of the etch rates irrespective of the nature of the diluent, provides an additional argument in favor of the diffusion-governed mechanism previously proposed. The fact that the etch rates are not affected by the enhanced reactivity of the nitric acid in acetic acid can only be explained on the basis that the rates are diffusion limited, not reactivity governed.

The acetic acid diluent etch composition plane may also be subdivided into general areas having different geometric etching characteristics (see Fig. 9). The principal difference between the two systems is that the areas in the acetic acid system are more extensive.

In Fig. 9, we have indicated several commonly used etches. The BJ etch and the CP4 etch are seen to be located in area C, and they should have similar properties. On the basis of our interpretation of the reaction mechanism in this area, we would venture that the bromine in the CP4 formula serves no useful function in the etching of silicon to obtain a specific geometry. The same comment may be made with respect to the copper in the Purdue etches. There may be factors, though, which we have not evaluated, such as resulting electrical properties of devices etched with these solutions, that might show a need for the additive. From our point of view, however, the use of an additive in such compositions is pointless.

The 111 etch is interesting because it lies in a region where the resultant surfaces are specular, but where the corners tend to peak. It should produce better geometry retention than the BJ etch and it should be more reliable in the absence of added catalyst than its neighbor, the BQ etch. The latter is very critical, with respect to slight changes in composition, and with respect to the silicon surface. Infinitesimal composition changes such as the addition of one drop of acetic acid to 20 cm^3 of etchant, or the use of 48.5% HF instead of 48.9% HF to prepare the solution, have been observed to cause the second etch rate (*i.e.*, etching of a work-damage-free surface) to vanish. It has been observed that the etch rate in the BQ composition may have practically any value between zero and the diffusion-limited value for that composition. However, these disadvantages may possibly be overcome by the introduction of a catalyst, and the BQ etch might prove to be quite useful in device work.

In summary, the behavior of the water diluted and acetic acid diluted etches based on HF and HNO_3 is qualitatively very similar and is governed by the same considerations. The differences are primarily quantitative and reflect the greater tolerance of the system for acetic acid than for water. This does not mean that the acetic acid diluted system is less critical than the water diluted system, with respect to composition, but merely that a greater amount of diluent may be added before the system becomes critical with respect to diluent or composition. Except in the high HF region, both systems are initially indifferent to the addition of diluent, and the etching behavior is unaltered until the composition is reached where the direction of the contours begins to change. Then feedback mechanisms come into play and the behavior of the solution becomes erratic. It is significant that the etching characteristics reflect the critical dependence of the etch rate on the local catalyst concentration in this region, so that a favorable geometry is obtained at the expense of erratic or unpredictable behavior of the etchant. Any attempt to make the etchant noncritical, such as an increase in temperature or the excessive addition of catalyst, will simultaneously produce a change in the geometry of the specimen to that characteristic of a diffusion-limited mechanism.

In the high HF region, the solution is critical with respect to the addition of water, because the critical amount of diluent is already contained in the concentrated stock HF. The use of acetic acid in this region may serve some purpose in making the area less critical, and some useful sizing etches may be found here. It is surprising that the common etches containing acetic acid, such as CP4, were not formulated in this region, but in the region where the addition of acetic acid seems to serve no useful purpose. (The amount of acetic acid in CP4 is a little less than critical.)

It is often said that acetic acid moderates the reaction and slows the rate. This is not true in the high nitric acid region and in the high hydrofluoric acid region. However, in the vicinity of the maximum etch rate, the acetic acid does have the alleged effect.

It seems on the basis of the small amount of information we have presented that any etching behavior attainable with an acetic acid diluted etch can be duplicated with a water diluted etch. The choice of diluent is thus a matter of individual preference.

Applications

A process specification for the fabrication of a semiconductor device usually includes one or more chemical etching steps. The etching operation is employed for the attainment of certain objectives such as the reduction of reverse current, machining to size, or the removal of unwanted material. The diversity of circumstances under which the etching is performed, coupled with the infinite variability of the etching formulas, has created a fertile field for the sorcerer and alchemist to practice their arts. It was inevitable that some excellent etching procedures should have been discovered in the course of time. However, these procedures were applicable only to the attainment of limited objectives with specific devices. Every situation became a separate problem which had to be coped with on a hit-or-miss basis, without the guidance of scientific principles. In such a state of affairs, a method for the selection of the optimum etch to accomplish a given objective appeared to be extremely valuable.

A key to the selection of an etch is an understanding of the etching characteristics of a solution as a function of the composition. The physical factors that influence the etching behavior have aready been discussed. It may now be desirable to recapitulate some of the concepts developed above and show how they can be applied to the formulation of an etching solution having certain specific properties.

For convenience, the solution composition plane in Fig. 6 will be divided into six regions (see Fig. 10). The characteristics of each region will be discussed in relation to the basic physical processes that play important roles in these regions. When this foundation has been established, a few basic rules of thumb will be given for formulating etching solutions that can be applied to specific practical problems.

Let us first focus attention on area A in Fig. 10. As Fig. 6 shows, the rates in this region are very rapid. Control of the amount of etching in this area is very difficult, because of the extreme sensitivity of the rate to small fluctuations in composition. There are also very few desirable characteristics in this region to make etching in it worthwhile. For these reasons, no etching compositions in area A will be considered further.

Area B covers the largest range of compositions. The boundary between B and F is located where the etch rates become too low to be generally practical for device fabrication. The compositions in area F have not been investigated, and no further reference to this area will be made.

The behavior of region B is best understood if one considers the compositions in the upper portion of the field. It is also convenient here to refer to the contours represented in Fig. 3 because the greater range of compositions enables observation of the behavior of the system which can only be estimated by extrapolation from Fig. 2. On the other hand, the latter system is the most useful from the practical standpoint of application because of the ready availability of the materials, the decreased hazard to personnel, and the greater ease of handling, all of which are obtained at no sacrifice in versatility whatsoever.

In the high HF region, nitric acid and catalyst are both necessary for the reaction to proceed at a perceptible rate. In the absence of added catalyst, therefore, it is necessary to find a "spark" to kindle the reaction. Such a spark exists in the presence of crystal imperfections and high energy sites. Once these undergo attack, catalyst is generated and the reaction spreads to adjacent sites. The propagation of such a reaction is clearly dependent upon the experimental conditions. Vigorous stirring may dissipate the catalyst so rapidly that the reaction is quenched. Further reaction is then dependent upon the existence of additional sites at which it can be kindled anew. For this reason, a previously etched surface, from which all work damage can be presumed to have been removed, will not be attacked by certain etch compositions in this region. On the other hand, in the absence of stirring the reaction will proceed rapidly, as the

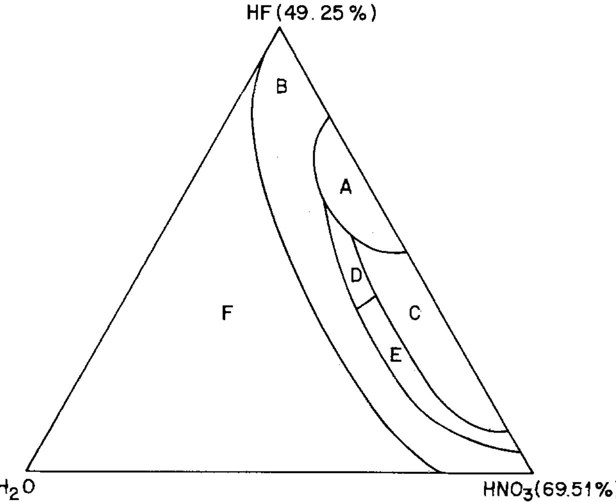

Fig. 10. Subdivision of the composition plane into general areas on the basis of the effect of the changing composition on the etching characteristics in the 48% HF-70% HNO_3-$HC_2H_3O_2$ system.

catalyst will be able to "couple" with the reacting system, thereby increasing the rate to the point where the limiting process of diffusion takes over. Once a reasonable etching rate has been established, the presence of the required catalyst becomes assured and the reaction will, from then on, proceed even under considerable agitation. Also, if the nitric acid concentration is increased, a greater number of reactive sites will be simultaneously attacked, so that the probability of coupling of catalyst with the reacting system is enhanced. When sufficient nitric acid is present to sustain a reasonable rate, the coupling of catalyst with the reaction becomes assured and the etchant will reetch a specimen even in the absence of added catalyst.

The reaction of nitric acid with silicon is, as described previously, an oxidation-reduction process. The essence of such a process is the transfer of electrons from the reducing agent to the oxidizing agent. It is now apparent that factors influencing the availability of electrons will affect the rate. The rates will therefore be subject to modification by the effect of galvanic couples or pn junctions. Etching compositions have been found that will not attack either p- or n-material alone but will, if a junction is present, etch the p-region preferentially.

In region C of Fig. 10, the rates are independent of the nitric acid concentration, and electron transfer processes have a minor effect on the geometry. One might say that the entire surface is covered with a sheath of SiO_2. The more reactive centers may begin to etch first, but they soon become covered with an oxide layer. The oxide protects the reactive center from excessive oxidation while the remainder of the surface "catches up." The net effect is that the hydrofluoric acid, which is the rate-limiting factor, acts on a uniform layer of oxide. The result is a smooth, specular surface with rounded corners and edges. The rounding of the geometry is also affected by the rate of the reaction. When the reaction is fast, the diffusion-governed mechanism produces considerable rounding. By decreasing the hydrofluoric acid concentration, it is possible to decrease the rate to such an extent that catalyst coupling again becomes important in spite of the high concentration of HNO_3. As a result, the geometry is observed to become square or slightly peaked in the extremely high HNO_3 region.

The etching characteristics of region C in Fig. 10 may be summarized as nonselective, producing specular surfaces and rounded geometry. The surface quality is mediocre at the upper end of the region, but it improves considerably a short distance from region A. Any surface detail such as wavy lines can probably be attributed to a nonhomogeneous surface environment such as concentration or thermal differences, or perhaps major crystal defects.

Regions D and E of Fig. 10 correspond to compositions in Fig. 2 where the direction of the contour lines is changing. This indicates a transition of mechanism from an HF-limited process to an HNO_3-limited process. The geometry of specimens etched in regions D and E is square as the result of the transition to a catalyst coupling mechanism. The difference in the etching characteristics between regions D and E lies in the surface quality of the etched die. In area D the reaction is relatively more HNO_3 dependent, and vestigial evidence of selective etching is apparent. The result is a somewhat rough surface. In area E, the reaction is more HF dependent, and highly lustrous, specular surfaces result.

Let us now consider a few practical etching problems. As the first example, let us look at the problem of a suitable sizing etch for thinning a silicon chip. It is desired to remove a rather large amount of material, control the resultant thickness within narrow tolerances, retain square edges and corners, and preferably end up with a smooth surface for the subsequent operation, which could be an evaporation step. Area B is not ideal for such an etch because of the catalyst coupling factor; the rates in this region are too erratic,

and they are also much too sensitive to small composition variations. The surfaces are also a bit too rough, although the geometry is favorable. In region C, the rates vary slowly with composition and the resulting surfaces are good, but the geometry is unfavorable. Possible solutions to the problem lie in the lower portion of area C, where the geometry turns square, or preferably in area E. If a large amount of material must be removed, then a two-stage process is possible where the etch may first be performed in a region of B where the rates are moderate but catalyst coupling is assured, and then finished up with a composition from regions C or E.

For the second example, let it be desired to remove the p-region from a large-area pn junction and to have the n-region relatively unaffected. A solution lies in choosing a "selective" etch, preferably near region F. The etch rate should be so low that the etching is essentially quenched by dissipation of the catalyst. Under these conditions, the attack will stop at the junction provided sufficient agitation is used, and provided that the volume of etch is sufficiently great that a negligible buildup of catalyst concentration occurs.

For the third example, consider the configuration shown in Fig. 11A. The problem is to remove a p-layer adjacent to an aluminum layer in order to contact the base n-type layer. One of the etches normally used gives a configuration such as is shown in Fig. 11B. Severe local etching in the vicinity of the aluminum plateau caused severance of the base area before any substantial portion of the p-region had been etched. The problem here was that a very selective etch was being influenced by the galvanic effects or catalytic effects of the aluminum layer to produce undesirable results. An answer to this problem lay in using a nonselective etch from area E of Fig. 10. An etch composed of $1HF:8HNO_3:1H_2O$ (by weight) was tried, and it gave the configuration illustrated in Fig. 11C.

There is a striking similarity between the problems of the second and third examples. In both instances it was desired to remove a p-layer and stop at a junction. In the former instance a selective etch did the job best because it had the built-in feature of stopping at the right time without danger of overetching. An alternative solution would be to use a nonselective etch, but this would require careful control of the time, temperature, and other factors governing the amount of etch, and also knowledge of the thickness of the p-layer. The presence of the aluminum and a second junction complicated the picture. The selective etching in the vicinity of the aluminum may have been caused by the trapping of generated catalyst first in the corner and later in the cavity. Under these circumstances it became necessary to sacrifice the automatic cutoff feature and use the alternative solution.

In the next example, consider the problem of bringing out the structural detail of a crystal by etching. The solution here also lies in a selective etch from region B or region F. A very slow etch must be chosen in order that catalyst coupling may be held to a minimum and mass action rather than diffusion may determine the mechanism, otherwise smudging of the structural detail might occur. The etch composition should therefore be in region F. Another solution might lie in selecting a nonautocatalytic etching system, in which diffusion is relatively unimportant, such as $NaOH-H_2O$.

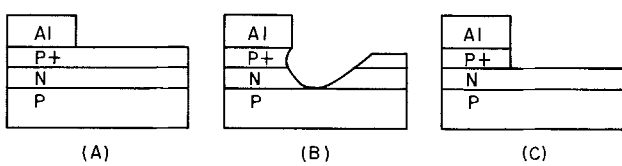

Fig. 11. The influence of solution composition on preferential etching: (A) initial configuration, (B) configuration after etching with $1HF:1HNO_3:2HAc$, (C) configuration after etching with $1HF:8HNO_3:1H_2O$.

For a final example, examine the problem of junction etching for the improvement of the electrical properties and stability of a device. In the high HF region, etching will be localized at the junction, although all areas will be attacked to some extent. The tendency to attack attached leads made of copper, nickel, silver, etc. would be minimized because of the weakly oxidizing nature of the solution. The problem of lead attack is not merely one of weakening the structures, but also one of contamination of the etch by the reaction products. The localized etching in the desired portion of the device may allow for shorter time of exposure of the device to the etch. However, the roughness of the surface may provide a greater surface area for leakage and sharp points from which arcing may take place. Deep erosion of the junction also provides an overhanging roof to the device that is subject to mechanical damage and that constitutes a potential site for arcing. The possibility of severe local etching in the presence of metallic leads, aluminum layers, or crevices is also to be guarded against.

In the high HNO_3 region, the etched surfaces will be smooth. The junction will be visible as a fine line, but no major discontinuity in the surface will be noted. The tendency of the device to etch all over will be partly offset by the factor that the edges will etch faster than the (111) surfaces. The attack on metallic attachments will be somewhat greater than in the high HF region, but the chances of undercutting and local etching will be obviated. The minimized surface area may somewhat reduce surface leakage and the surface smoothness may possibly be conducive to better high voltage stability.

It is unfortunate that our knowledge of the surface, and of the factors contributing to high surface leakage and low breakdown voltage, is too meager to permit a statement of the problem in terms of etching objectives. In this instance, the method was to examine the etching characteristics of each region and make an educated guess as to which approach is the most promising. The answer will then probably be as valid as the premise that etching, and not some other unknown factor, holds the key to better electrical properties.

Acknowledgments

The authors wish to express their gratitude to the many former colleagues at the Hughes Aircraft Company who contributed their helpful comments, suggestions and in some cases direct assistance. S. Pryor, P. Walker, F. Ludwig, and H. Winston are only a few of those who helped. Finally, we would like to thank the management of Bell Laboratories for allowing the time to prepare this paper for public dissemination.

Manuscript submitted May 27, 1976; revised manuscript received Aug. 18, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by Bell Laboratories.

The Identification, Annihilation, and Suppression of Nucleation Sites Responsible for Silicon Epitaxial Stacking Faults

ABSTRACT

A study of the formation of epitaxial stacking faults in 2 in. diameter, dislocation-free (111) silicon wafers used in the fabrication of standard buried collector transistors has been made. The nucleation sites for the epitaxial faults are introduced during the initial oxidation of the wafer and are correlated with the presence of a high density of shallow, flat-bottomed, saucer-shaped etch pits. The saucer pits are selectively annihilated in the diffused or implanted regions during the fabrication of the Sb-doped buried collectors. For the ion-implanted process the annihilation of saucer pits extends laterally from 50 to 100 μm beyond the boundaries of the collectors. Following epitaxial growth, epitaxial stacking faults, at a density of 10^4 cm^{-2}, are only found in those nonburied layer regions which have a saucer pit density of 10^6-10^7 cm^{-2} before epitaxy. Therefore, epi stacking faults are not found in ion-implanted material with a separation between buried collectors of 100 μm or less. Most 3 in. diameter, and the central regions of 2 in. diameter wafers do not have saucer pits or epi stacking faults. This is attributed to an *in situ* gettering of nucleation sites by SiO_2 precipitates, which are known to form in wafers, or regions of wafers, with a high initial oxygen concentration. Additional procedures for deliberately suppressing or gettering the nucleation sites are presented. These include deliberate abrasion, deposition of strained Si_3N_4 layers, introduction of misfit dislocations, and the use of an Sb ion implant, which are performed on the back side of wafers before the initial masking oxidation.

Following the recent wide scale introduction of dislocation-free wafers as starting material in the fabrication of silicon integrated circuits, defect-related problems have arisen which have either not occurred for some time, or may not have previously existed at all. We have found that when 2 in. diameter dislocation-free substrates were introduced into a processing line fabricating diffused buried collector epitaxial transistors, large increases in the density of epitaxial stacking faults, SF_{epi}, occurred. However, the use of 3 in. diameter wafers or a buried layer fabricated by ion implantation did not nucleate SF_{epi}. Also, the epitaxial stacking faults encountered in our diffused process were confined to those regions of the wafer which did not receive a buried layer diffusion before epitaxy. Figure 1 illustrates this phenomenon on a preferentially etched device chip after epitaxy. Note that the SF_{epi} density varies from zero in the buried layer areas to greater than 10^4 cm^{-2} in the nonburied layer regions.

It has previously been pointed out by Pomerantz (1) that wafers which are oxidized before epitaxy will have a high probability of nucleating stacking faults during epi growth. Pomerantz discovered that a characteristic saucer-shaped feature, called an S-pit, appeared after preferentially etching an oxidized wafer. The occurrence (or prevention) of the defect responsible for the S-pit was correlated with the presence (or absence) of stacking faults in the subsequently grown epi layer. Pomerantz also specified two gettering procedures, which, when applied to the back side of wafers prior to oxidation, would prevent the formation of S-pits and epi stacking faults.

Key words: silicon defects, epitaxial stacking faults, gettering.

We have recently rediscovered, while monitoring the defects introduced during epitaxy for standard buried collector transistor structures, the same connection between S-pits and SF_{epi}. In addition, we have found that the S-pits can be annihilated after oxidation, as well as gettered before oxidation by using an appropriate Sb ion implantation. Also, certain 2 in. and most 3 in. diameter wafers contain a built-in gettering ability which we believe to be re-

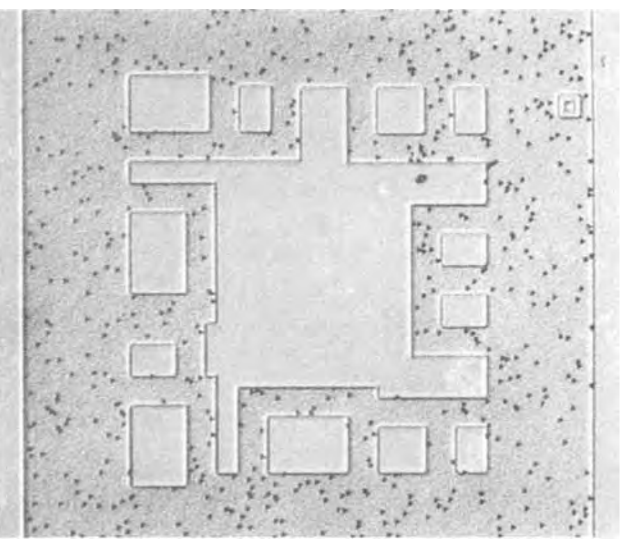

Fig. 1. Epitaxial stacking fault distribution revealed by 5 min Secco etch. The alignment square in the upper right-hand corner has an outside dimension of 50 μm.

lated to the local oxygen concentration in the original crystal. In the present report we briefly review the observations common to Pomerantz's (1) work, and then describe how an understanding of the annihilation of the nuclei in the buried layer, lack of SF_{epi} in ion-implanted wafers, and the absence of nuclei in 3 in. diameter material led us to formulate several procedures for the suppression or gettering of the nuclei.

Experimental Procedures

The starting material used in this study was from Czochralski crystals, (111) oriented, p-type, boron doped with a resistivity from 8 to 20 Ω-cm. The oxygen concentration in both 2 and 3 in. diameter wafers was examined by infrared transmission using a Perkin Elmer 457 spectrophotometer according to ASTM procedure F-121. In order to minimize the effects of slip-type dislocations all furnace operations above 900°C were ramped according to the schedule described by Moerschel (2). Defects were delineated using the preferential etch due to Secco D'Aragona (3) and observed in a Zeiss Ultraphot IV microscope using interference contrast objectives. The approach to the epi stacking fault problem was basically one of pulling wafers after each high temperature process and then microscopically examining them for defect etch features following a Secco etch. Once the defect nuclei were identified, defect interactions during subsequent high temperature treatments could be monitored. Since only three high temperature processes; oxidation, buried layer predeposition, and buried layer drive-in, were required before epitaxy, as listed in Table I, the epi fault problem was resolved in a rather direct way.

Experimental Results

Epitaxial layer growth.—The initial observation of the SF_{epi} was made during the routine inspection of unetched epitaxial wafers using Nomarski interference contrast microscopy. As described above, the stacking faults only appeared in the nondiffused regions of 2 in. diameter wafers as shown in Fig. 1. It was also found that when 3 in. diameter wafers were run side by side with 2 in. diameter wafers on the same epi susceptor SF_{epi} only appeared in the 2 in. diameter material. The epitaxial deposition process was therefore ruled out as the source of SF_{epi} nuclei.

Since SF_{epi} are known to nucleate at the epi/substrate interface the amount of substrate material removed by gaseous HCl etching prior to epi growth was varied. Increasing the etch from the typical 0.5 μm removed to greater than 1.5 μm successfully eliminated the SF_{epi} nuclei. However, this extended etching was not compatible with the requirement of maintaining a buried layer sheet resistance of less than 25 Ω/□. Further studies were therefore continued on substrate wafers before epitaxy.

Diffused buried layer.—Examination of an Sb diffused 2 in. diameter wafer Secco etched after the buried layer drive-in revealed S-pits, as predicted by Pomerantz (1) for oxidized (111) wafers before epitaxy. However, the distribution of S-pits corresponded to the buried layer pattern as shown in Fig. 2. The S-pit density in nonburied layer regions was on the order of 10^6 cm^{-2} or greater, while it was about 10^4 cm^{-2} in the buried layer regions, as shown by the higher magnification micrographs in Fig. 3a and b. Note that the Secco etch produces a true saucer shape, *i.e.*, the pits are round, whereas the Sirtl (4) etch used by Pomerantz (1) yields a faceted triangular pit. Wafers which were etched before the 2 hr 1250°C Sb_2O_3 deposition had a uniform 10^6-10^7 cm^{-2} S-pit distribution over the entire wafer, indicating that the defect responsible for the formation of

(b) Ion implant	300		3.5 × 10^{15} cm^{-2} at 30 keV
4. Buried layer drive-in	1250	8	
5. Epi deposition	1200	10 min	8-10 μm thick

S-pits was being annihilated in the diffused regions during the buried layer predeposition and drive in. Note that the density of SF_{epi} in Fig. 1 is two to three orders of magnitude lower than the S-pit density in Fig. 3b. Evidently only a very small percentage of the defects which give rise to an S-pit act as SF_{epi} nuclei during the growth of the epitaxial layer. In fact, none of the 10^4 S-pits observed in the buried layer regions, see Fig. 3a, nucleate epitaxial faults. Since the actual size of the pit seems less important than the total density, compare Fig. 3a and b, we can speculate that it may require a localized aggregate or colony of S-pit defects to nucleate one epitaxial stacking fault.

It is, of course, possible that there are other defects besides S-pit defects which are actually responsible for SF_{epi}. For example, several hillock-type etch features can be identified in a field of S-pits, see arrow H in Fig. 3b, whereas no hillocks are delineated in the buried layer region of Fig. 3a. It has previously been shown (5) in unoxidized (100) starting material that hillocks, and not saucers, will correlate on a one-to-one basis with the subsequent formation of oxidation-induced stacking faults (OSF). However, in this work the high density of S-pits precludes a reproducible differentiation between H-defects and S-pits, especially since some hillocks transform into saucers on further etching.

It should also be emphasized here that OSF are the primary defects delineated in oxidized (100) material while S-pits predominate in our (111) wafers. It is possible that the nuclei for the OSF in (100) wafers are in some way related to the source of SF_{epi} in (111) wafers. Perhaps it is a combination of a bulk defect, *i.e.*, a hillock, with a surface-induced S-pit defect which gives rise to a small number of active or "super" S-pits which convert to SF_{epi}. Pomerantz (1) made a distinction between large and small saucers which we are not able to do because of the continuous size distribution revealed in both the diffused and nondiffused regions, see Fig. 3. The answer to these questions about specific active nucleation sites will require more sophisticated tools than the optical microscope. For example, a recent analysis of S-pit type defects using electron microscopy and micro x-ray fluorescence has been reported by Petroff and Katz (6). However, in terms of S-pit gettering, annihilation, etc. the more qualitative data provided by the optical microscope in the present paper has proved to be an extremely reliable measure of what to expect during epitaxial growth.

Ion-implanted buried layers.—A Secco etched 2 in. diameter Sb ion-implanted wafer before drive-in is shown in Fig. 4a. Note that the implanted buried layer region, see arrow I, has an S-pit density about one order of magnitude below that in the nonimplanted regions. An annihilation of S-pit defects also occurred during the deposition of the Sb_2O_3 diffusion source layer, as noted above, but that process occurred at temperatures above 1200°C whereas the maximum temperature during implantation is 300°C. Attempts to grow epi on samples that were implanted, but not driven-in, were not successful because the implantation damage had not been annealed and this resulted in very poor epitaxy.

Those implanted samples which were Secco etched after drive-in revealed that it is possible to annihilate S-pits outside the boundaries of the buried layer, as shown in Fig. 4b. The arrow N points to a region completely denuded of S-pits. The range of the denuding action was found to be from 50 to 100 μm, which is larger than the average distance between buried layer contacts in an actual device pattern. The pattern in Fig. 4 is for a low packing density test chip which has a large field of nonimplanted material. The complete annihilation of S-pits in a high density device is shown in Fig. 5. Actually, there are often a few isolated SF_{epi} in the nonimplanted regions of the test chip wafer epi, but for all practical purposes the samples are free of SF_{epi}. The range of S-pit annihilation suggests that techniques for the

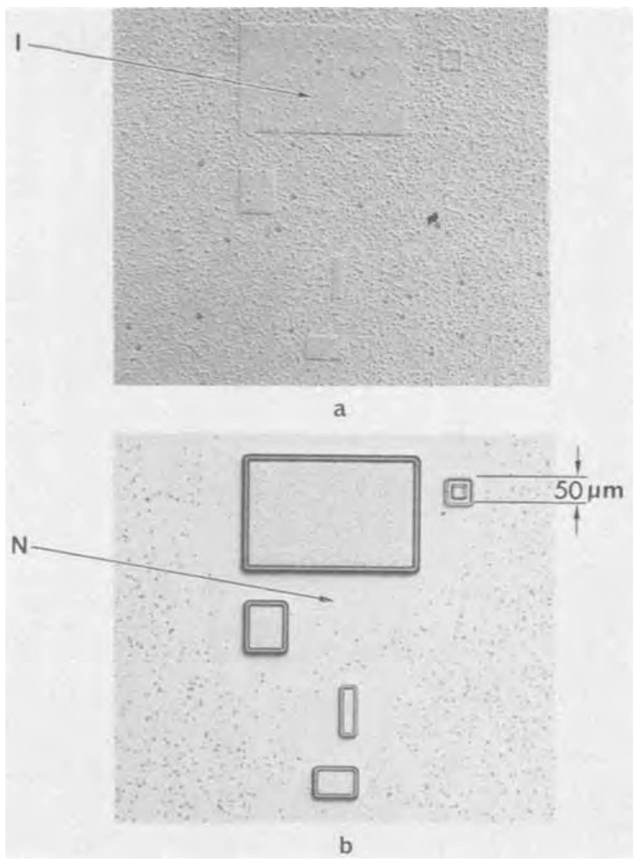

Fig. 4. Saucer pit distribution in ion-implanted wafer (a) before drive-in and (b) after drive-in at 1250°C for 8 hr. Arrow I indicates implanted area while arrow N is a nonburied layer region which is denuded of S-pits.

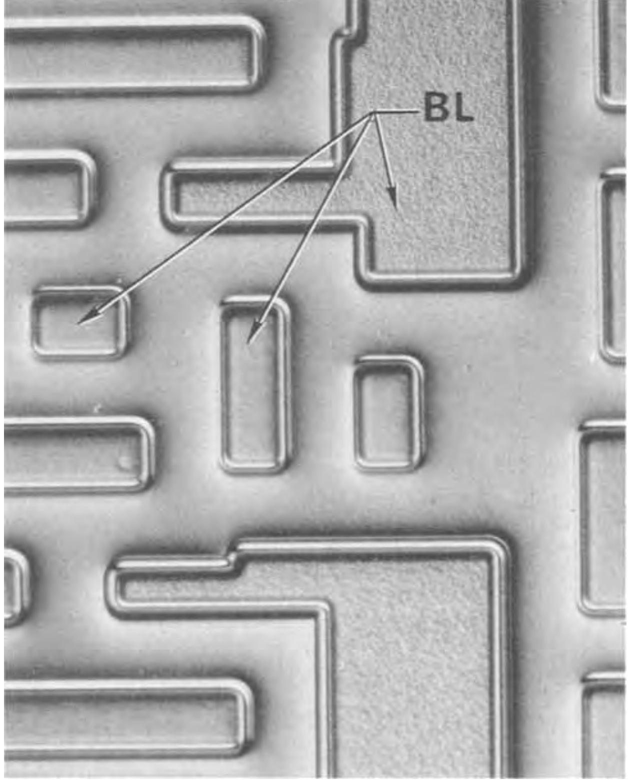

Fig. 5. Saucer pit-free region of ion-implanted device wafer

control of SF_{epi} by diffusion or interaction of nucleation sites is possible, *i.e.*, gettering, as discussed below in the section on crystal growth modifications.

We can conclude at this point that the absence of SF_{epi} in ion-implanted samples, or in the buried layer regions of diffused samples can be monitored by observing the presence or absence of S-pits. The process by which S-pit defects are introduced into wafers is discussed next.

Oxidation-induced S-pits.—Before oxidation (111) Secco etched wafers from Czochralski crystals pulled in our facility would not exhibit the high density of S-pits discussed above, nor did they show any growth related swirl patterns. However, wafers from outside suppliers would often contain 10^6-10^7 cm^{-2} S-pits and hillocks distributed in a swirled or coring pattern. The absence of swirl in our wafers may explain, in part, why we did not observe OSF in oxidized wafers. The swirl etch features are due to defects which are grown-in or native to the original crystal (5) and, in the case of float zone material, have been extensively studied by de Kock (7) and others (8-10). A simple way to distinguish between these native defect centers and process-induced S-pits, which are our main concern in this report, is to step-etch a wafer and see if the etch features are confined to the surface or distributed in depth.

Following this step-etch procedure on oxidized wafers we have found that the S-pits discussed in this report at a density of 10^6-10^7 cm^{-2} are all surface pits. In addition, by using a nonpreferential etch to remove approximately 0.5 μm of silicon before Secco etching it is possible to reduce the S-pit concentration to less than 10^4 cm^{-2}. Since it required an HCl etch of $\sim$1.5 μm to eliminate the SF_{epi} nuclei just prior to epi growth we believe that the depth, or the size, of the S-pit defect increases from less than 0.5 μm to greater than 1.0 μm during the buried layer processing.

Another observation on S-pits in oxidized wafers is the presence of a denuded region in the center of many of the wafers. This is illustrated by the dark zigzag region in the center of the Secco etched 2 in. diameter wafer shown in Fig. 6. The absence of S-pits in these central regions is believed to be related to the radial distribution of oxygen in the original crystal. If the oxygen concentration is high enough, precipitation will occur during the various high temperature treatments (11) encountered during pre-epitaxial processing. When precipitation occurs the 9 μm infrared absorption line (due to interstitial oxygen) decreases, as shown in Fig. 7, and the oxygen, although still present, is now in the form of SiO_2

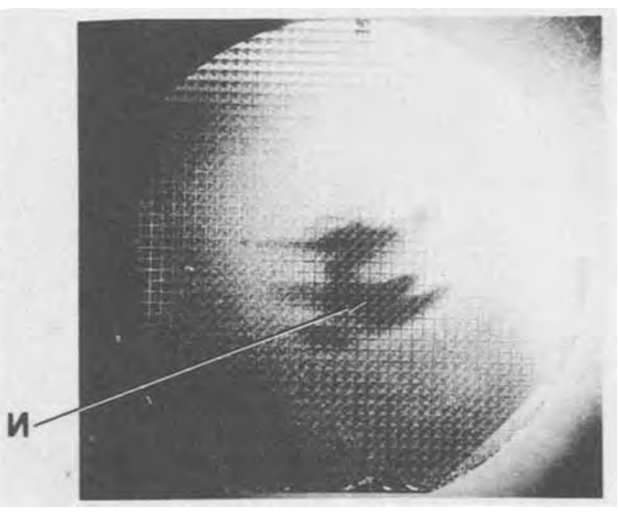

Fig. 6. Secco etched 2 in. diameter wafer with S-pit free region in center of wafer, see arrow N.

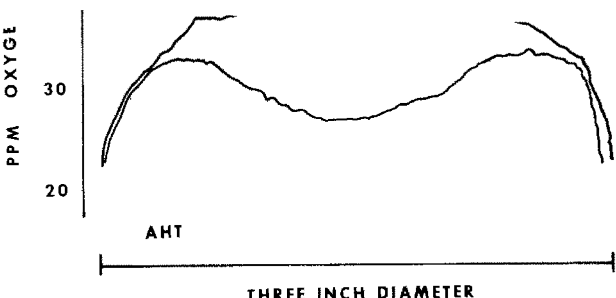

Fig. 7. Radial distribution of oxygen in a 3 in. diameter, 0.090 in. thick sample before (BHT) and after (AHT) a 3 hr precipitation treatment at 900°C.

precipitates. The process is reversible since an increase in the 9 μm absorption line occurs if the material is reheated at temperatures greater than 1300°C. Since the oxygen content of 3 in. diameter wafers is, on the average, about 10 parts per million higher than 2 in. diameter wafers we believe that most 3 in. and the central regions, *i.e.*, high initial oxygen concentration, of certain 2 in. diameter wafers will be protected from S-pit nucleation during oxidation. This is accomplished by the gettering action of the SiO_2 precipitates which act as sinks for S-pit defects giving rise to an *in situ* gettering, as shown by the localized denuded regions in the center of the wafer of Fig. 6. Further verification of the kinetics of oxygen incorporation as it relates to gettering are presented next.

Crystal growth modifications.—Based on the above analysis that an *in situ* gettering accompanies SiO_2 precipitation, it was decided to adjust the crystal growth conditions of 2 in. diameter crystals so they would behave like 3 in. diameter material. This was easily accomplished by using higher seed rotation rates, 20 rpm instead of the typical 5 rpm, which increased the mixing conditions in the melt and enhanced the oxygen incorporation by an additional 5-10 ppm. Wafers processed through epi growth from these 2 in., grown like 3 in. wafers, showed a slight improvement in yield. However, the increase in wafers free of SF_{epi}, from 50 to 66%, was not considered significant enough to warrant changing the 2 in. diameter rotation rates. Additional work along these lines has recently been carried out by Katz and Hill (12) at rotation rates as high as 40 rpm. They have shown that the oxygen content in 2 in. diameter crystals could be maximized such that S-pits and SF_{epi} were suppressed, *i.e.*, the 2 in. wafers behaved like 3 in. wafers. The oxygen and S-pit data presented by Katz and Hill (12) are consistent with our model of an *in situ* SiO_2 gettering mechanism.

It must be pointed out that high oxygen content crystals may, in certain cases, have a deleterious effect on the over-all defect density. That is, if the size of the SiO_2 precipitate is large enough, then the kinetics of the stress relief in the vicinity of an individual precipitate may cause dislocation loops to be punched out. That is, the precipitates may act as a source of dislocations, rather than a sink for SF_{epi} nuclei. An example of this type of behavior is shown in Fig. 8a, which is a Secco etched oxidized 2 in. diameter wafer from an outside vendor whose material often has an oxygen concentration approaching 40 ppm. Note the extremely high (greater than 10^6 cm^{-2}) defect density in the center of the wafer and the presence of a concentric ring pattern of defects toward the outer perimeter. Higher magnification optical micrographs indicate both dislocation

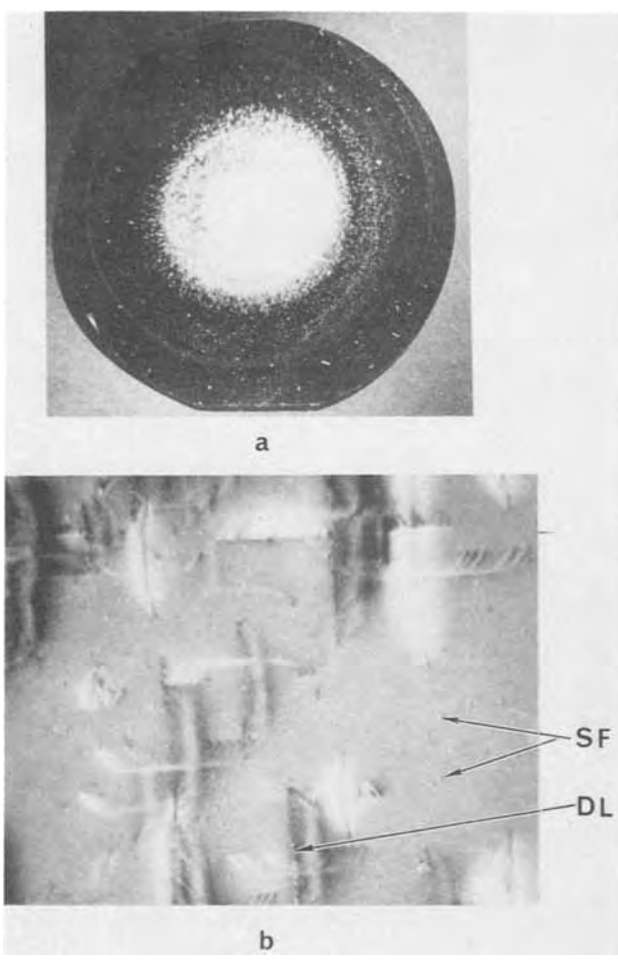

Fig. 8. (a) Macrophotograph of Secco etched 2 in. diameter wafer with excessively high initial oxygen concentration. (b) X-ray topograph of above wafer illustrating dislocation loops and oxidation-induced stacking faults.

etch pits and oxidation-induced stacking faults in the center, while the outer ring pattern consists primarily of stacking faults. A transmission x-ray topograph is shown in Fig. 8b which gives the relative size and density of the dislocation loops (DL) and stacking faults (SF) in the center of the wafer in Fig. 8a. Although the topograph reveals a defect at the origin of the dislocation loops we cannot unequivocally state whether it is a precipitate or just another stacking fault. However, the loop generation in two orthogonal {110} directions is certainly consistent with stress relief around a single strained precipitate.

In addition to the higher rotation rate crystal growth experiments described above, it is possible to adjust the solidification rate of 2 in. diameter crystals to approach that of 3 in. material. Detailed work on the effects of adjustments to the crystal pull rate has been performed on float zone crystals by de Kock (7) and co-workers (13) in order to eliminate the swirl distribution of A and B cluster bulk defects. de Kock's modification was simply to increase the pull rate from about 3 to 5 mm/min. The resulting increase in the microscopic growth rate effected a favorable change in the concentration of native defects, thereby suppressing the formation of swirl defects. For the Czochralski crystals used in our studies, increasing the 2 in. crystal growth rate from 3 to 6 in./hr, which provided a volume solidification rate approximately that of 3 in. diameter crystals, also yielded wafers which were immune to the formation of S-pits and SF_{epi}. A complete understanding of these phenomena will require data on the native defect concentration which are not available to us at this time. However, it is clear that the occurrence of process-induced defects, such as S-pits and SF_{epi}, can be intimately related to the native defect density in the original crystal.

Preoxidation gettering procedures.—In addition to the crystal growth modifications presented above, a careful analysis of the data on the identification and annihilation of SF_{epi} nuclei already discussed led us to design a series of experiments which suppressed the formation of nuclei in individual wafers. These procedures are collectively known as POGO treatments, an acronym for preoxidation gettering of the other side, and are designed to remove potentially active nuclei from the front, *i.e.*, device side, of a wafer and confine them to the back, nondevice, or other side of the wafer. Because of the high mobility of the nuclei, and/or their constituent elements, it was possible to achieve the desired gettering effect in a number of ways. These are reviewed in Table II which uses the POGO nomenclature introduced in a recent review (14). POGO I and IV, which use back side misfit dislocations and deliberate abrasion, respectively, were both effective in eliminating SF_{epi} nuclei, as expected from previous papers (1, 15). It was also found, as described by Petroff *et al.* (16), that depositing a layer of Si_3N_4 with a stress of $\sim 1 \times 10^{10}$ dynes-cm^{-2} on the back of wafers, called POGO II, would also provide the desired gettering action. Although the high temperature POGO V procedures described by Hu (17) and Shiraki (18) for growing oxides free of OSF have not been examined in the context of S-pits and SF_{epi}, they were included in Table II for completeness. However, the POGO III process using Sb ion implantation was examined in detail and generated new data for the suppression or gettering of SF_{epi} nuclei.

Since an Sb implantation dose of 3.5×10^{15} ions cm^{-2} at 30 keV had a range of 50-100 μm for the annihilation of previously formed S-pit defects, a series of preoxidation implants were made into the back side of 2 in. diameter wafers with thicknesses varying from 0.015 to 0.035 in. in 0.005 in. increments. These wafers were then oxidized in steam at 1100°C for 1 hr. A complete suppression of S-pits was achieved for wafers 0.020 in. or less in thickness. For thicker wafers the POGO III treatment became progressively less effective, indicating a gettering range of about 500 μm for the Sb implant used. This is consistent with previous work using misfit dislocations (15), POGO I in Table II, which showed that a 400 μm range was possible for the suppression of OSF nuclei.

The oxidation temperature was varied between 700° and 1100°C for standard 2 in. diameter, 0.015 in. thick wafers to determine the lowest temperature for which Sb implant gettering was effective. After an oxidation as low as 800°C, S-pits were not observed. However, at 700°C the S-pits reappeared, indicating that the diffusion coefficient of the impurity and/or defect responsible for S-pit formation could be estimated. A simple calculation using a 375 μm thick wafer for 60 min yields a diffusion coefficient of 4×10^{-7} cm^2 sec^{-1}, which is typical of values for such commonly observed silicon impurities as copper and iron. Thus, the damage and associated strain introduced by the Sb implant could readily act as a back side sink for these front side or bulk impurities. It should be noted that, since the implant damage is annealed out during the oxida-

Table II. Preoxidation gettering designations

POGO	Requires	Produces
I	Misfit dislocations	Ordered array of line defects
II	Si_3N_4 layer	Strain from a deposited layer
III	Ion implantation	Strain and damage from an imbedded layer
IV	Abrasion	Disordered array of line defects
V	Anneal >1200°C. Add HCl	Dissolution of native defects, clean interface

tion, no gettering is observed during subsequent furnace operations. This is in contrast with misfit dislocation (15) and Si_3N_4 (16), gettering which continue to provide a sink for nuclei.

Conclusions

Based on the above study we have verified that the nucleation sites for epitaxial stacking faults are introduced during the initial oxidation of the wafer. The nuclei are readily correlated with the presence of a high (10^6-10^7 cm^{-2}) density of saucer-type pits after a preferential etch (19). The pits can be selectively annihilated during the fabrication of the Sb-doped buried collectors. Suppression or gettering of the nuclei for epitaxial stacking faults can be achieved by a variety of techniques. These include abrasion, deposition of a strained Si_3N_4 layer, introduction of misfit dislocations, and the use of an Sb ion implant, all of which are performed on the back side of wafers before the initial masking oxidation. Additional *in situ* gettering is observed in material whose oxygen concentration is high enough to lead to SiO_2 precipitation.

ABSTRACT

A $LiNbO_3$ ^{57}Co single crystal Mössbauer source in the reduced state has been used in conjunction with a single crystal $FeCO_3$ (siderite) absorber. From the angular dependence of the polarized γ-rays in a polarimeter arrangement, it could be shown that the principal axis of the EFG at the Fe^{2+} sites is colinear with the c axis of the $LiNbO_3$ crystal which excludes charge-compensating nearest neighbor oxygen vacancies.

Iron-doped $LiNbO_3$ has become of technological importance, mainly as a useful high resolution optical information storage material. Scientifically it is of interest to obtain information regarding the charge and defect state of the iron ions. In the past mostly macroscopic methods have been used in the investigations. In this communication we want to present results by a microscopic method: Mössbauer spectroscopy. Fortunately, the best and most easily handled Mössbauer resonance isotope is ^{57}Fe. Particularly, the hyperfine interaction, that is, the quadrupole splitting, and isomer shift are of interest here. By the latter the valence state can be easily distinguished. We restrict ourselves to Co^{2+} or Fe^{2+}, as parent or daughter isotope, respectively, and particularly to the question regarding the defect configuration. Some results on Fe^{3+} and Fe^{2+} have been published previously (1, 2).

Key words: Mössbauer spectroscopy, $LiNbO_3$, lattice defects.

$LiNbO_3$ single crystals were doped with ^{57}Co or ^{57}Fe, and an annealing treatment at 800°C for 24 hr in pure Ar atmosphere reduced the cobalt or iron entirely; at least, no trace of the trivalent state could be detected by Mössbauer spectroscopy. A conventional Mössbauer spectrum of a $LiNbO_3$:^{57}Co source or $LiNbO_3$:^{57}Fe ab-

sorber, obtained with a single line absorber or source, respectively, exhibits a two line quadrupole splitting ($\Delta E_Q = 1.74 \pm 0.02$ mm/sec at room temperature) and a negative quadrupole coupling constant. The polarization or angular dependence of the quadrupole hyperfine interaction is reflected in the relative line intensities. Extreme line intensity ratios (3:1 and 3:5) are obtained in the cases of parallel or perpendicular arrangement of γ-ray propagation direction and principal axis of the electric field gradient (EFG) in the thin absorber approximation (no saturation effect) and lattice vibrational isotropy (no Goldanskii-Karyagin effect) and, in addition, under the condition that the resonance atom is in a local environment of axial symmetry (asymmetry parameter $\eta = 0$). Our analysis of the relative intensities indicates that we are close to this situation.

A more precise determination regarding the orientation of the axis of the EFG can be obtained by polarization experiments where both source and absorber exhibit quadrupole splittings. In this case four resonance lines are expected. The number of lines is reduced to three if the magnitude of the quadrupole splitting in source and absorber is the same, *i.e.,* degeneracy of the center line at zero velocity occurs. Furthermore, if a unique axis of all Co^{2+} and Fe^{2+} ions exists and the principal axis of the EFG is perpendicular to the γ-ray propagation direction, the emitted γ-rays corresponding to the $\pm 3/2 \rightarrow \pm 1/2$ transition are linearly polarized. (The γ-rays corresponding to the $\pm\frac{1}{2} \rightarrow \pm\frac{1}{2}$ transitions are partially polarized.) Such linearly polarized γ-rays from the source (polarizer) will excite nuclear transitions with appropriate polarization in the absorber (analyzer), in analogy to an optical polarimeter (3). In such a polarimeter arrangement, we have placed a $LiNbO_3$:^{57}Co source in conjunction with a single crystal of siderite ($FeCO_3$) absorber.

From crystal symmetry it is known that the Fe^{2+} ions in $FeCO_3$ have axial symmetry, $\eta = 0$. The quadrupole splitting of $FeCO_3$ ($\Delta E_Q = 1.798 \pm 0.004$ mm/sec at room temperature) (4) is similar to the value of $LiNbO_3$:^{57}Fe, however, the quadrupole coupling constant is positive. The level diagrams of the nuclear resonance states are shown in Fig. 1, indicating the opposite sign of the quadrupole coupling constants in source and absorber. In Fig. 2 Mössbauer spectra are shown of a $LiNbO_3$:^{57}Co source and a $FeCO_3$ (siderite) absorber with the c axes of the two crystals perpendicular to the γ-ray propagation direction.

The spectrum in Fig. 2(a) was obtained with the two c axes parallel and in Fig. 2(b) perpendicular to each other. The resonance line on the side of positive velocity is of interest because it results from the $\pm 3/2 \rightleftarrows \pm 1/2$ transitions in source and absorber. In the perpendicular arrangement, the $FeCO_3$ absorber crystal is transparent for the polarized γ-ray from the source; only a small residual absorption contribution can be detected which is most likely due to imperfections in the mineral $FeCO_3$ single crystal and also due to misalignment of the "polarimeter." The disappearance of the resonance line indicates, that the emitted γ-rays from the $LiNbO_3$:^{57}Co source are indeed linearly polarized to a high degree, and consequently, the principal axis of the EFG at the ^{57}Co or ^{57}Fe nuclear sites are oriented along the c axis and the asymmetry parameter is small or zero. Because the EFG is determined to a great extent by the nearest environment of the ions, any "defect" in the octahedral oxygen configuration would destroy the colinearity of the principal axis of EFG with the c axis and in addition would make $\eta \neq 0$. The conclusion can be drawn that most of the $^{57}Co^{2+}$ or $^{57}Fe^{2+}$ ions in $LiNbO_3$ are not charge compensated by neighboring oxygen ion vacancies. This result does not necessarily contradict the model by Dischler *et al.* (5) because of the higher sensitivity of optical measurements.

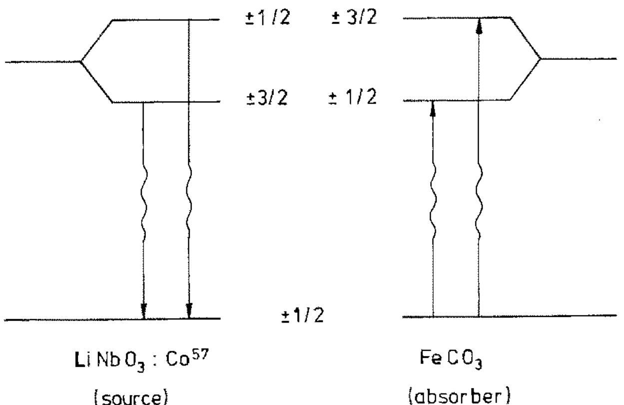

Fig. 1. Quadrupole splitting of the first excited state of ^{57}Fe

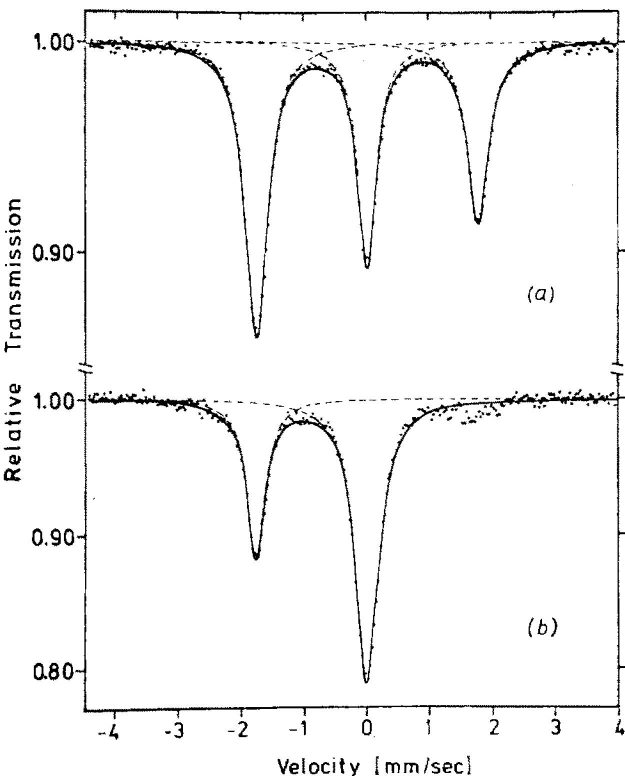

Fig. 2. Mössbauer spectra of a $LiNbO_3$:^{57}Co single crystal source and a single crystal $FeCO_3$ (siderite) absorber at room temperature. Both crystals were oriented with their c axes perpendicular to the propagation direction of the γ-rays. In (a) the c axes in source and absorber were parallel and in (b) they were perpendicular to each other.

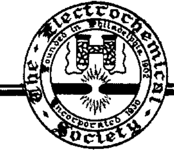
Technical Note



Electroluminescence in Rare Earth Doped Y_2O_3, La_2O_3, and Y_2O_2S Powder Layers

Shosaku Tanaka, Youichi Maruyama, Hiroshi Kobayashi, and Hiroshi Sasakura

Department of Electronics, Tottori University, Tottori, Japan

Electroluminescent phosphors doped with trivalent rare earth ions give sharp line emissions which are characteristic of transitions in the $(4f)^n$ electron configurations and cover the red to blue region. These phosphors are of interest because of the possibility of their application to flat-type color displays. Several investigations of electroluminescence have been reported in rare earth doped ZnS (1-3). However, ZnS is not the most suitable host for trivalent rare earth ions because of the low solubilities of rare earth ions in ZnS (4). In order to remove this disadvantage, Y_2O_3 has been chosen as a suitable host; electroluminescence in this material has already been reported (5, 6). In order to find more suitable host materials, we have chosen Y_2O_3, La_2O_3, and Y_2O_2S and investigated their electroluminescence.

Y_2O_3:Ln phosphors were prepared by the following procedures. Y_2O_3 and Ln_2O_3 powders were dissolved in a 5% hot hydrochloric acid solution. Subsequently, oxalates were precipitated using ammonium oxalate as a precipitant. The oxalates were fired at 1100°C for 3 hr in air. The concentrations of rare earth ions were about 1 atom percent (a/o). La_2O_3:Ln phosphors were prepared by the same method as Y_2O_3:Ln. Y_2O_2S:Ln phosphors were prepared by firing the Y_2O_3:Ln powders in an H_2S atmosphere at 600°C for 3 hr. Either Eu (for red emission), Tb (for green emission), or Tm (for blue emission) was used as activators. Electroluminescence samples, fabricated from the phosphors, were about 50 μm thick, and sandwiched between an Al plate and SnO_2-coated glass.

Electroluminescence spectra for Y_2O_3, La_2O_3, and Y_2O_2S phosphors are shown in Fig. 1. The electroluminescence samples were excited with d-c voltage of 400 ~ 500V. The electroluminescence spectra show narrow lines caused by the transitions in the $(4f)^n$ electron configurations of trivalent rare earth ions (7). The Eu-doped phosphors give rise to a red emission arising from the $^5D_0 \rightarrow {}^7F_2$ transition peaking at about 612 ~ 630 nm. The Tb-doped phosphors give rise to a green emission arising from the $^5D_4 \rightarrow {}^7F_5$ transition peaking at 544 nm and yield the brightest emission. The Tm-doped phosphors give rise to a blue emission arising from the $^1G_4 \rightarrow {}^3H_6$ transition peaking at 455 nm. In the electroluminescence spectra,

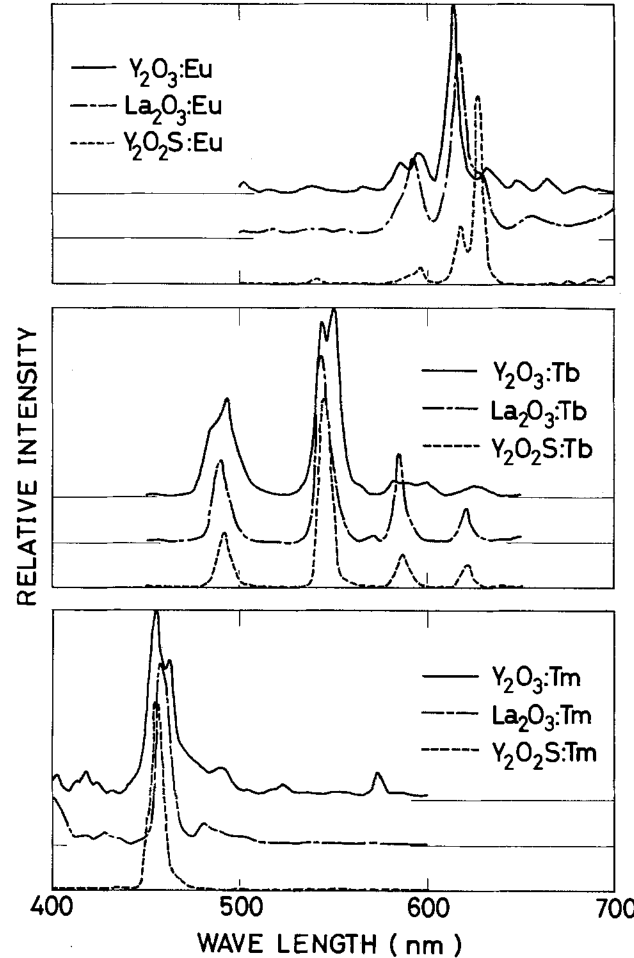


Fig. 1. Electroluminescence spectra for rare earth doped Y_2O_3, La_2O_3, and Y_2O_2S.

no remarkable difference due to the host lattice has been observed.

In Fig. 2 are shown the voltage dependences of current density and brightness for the Tb-doped phosphors in electroluminescence, where the samples were excited by d-c voltage with the SnO_2 electrode negatively biased. The current densities across the

Key words: electroluminescence, rare earth doped phosphors, powder cells.

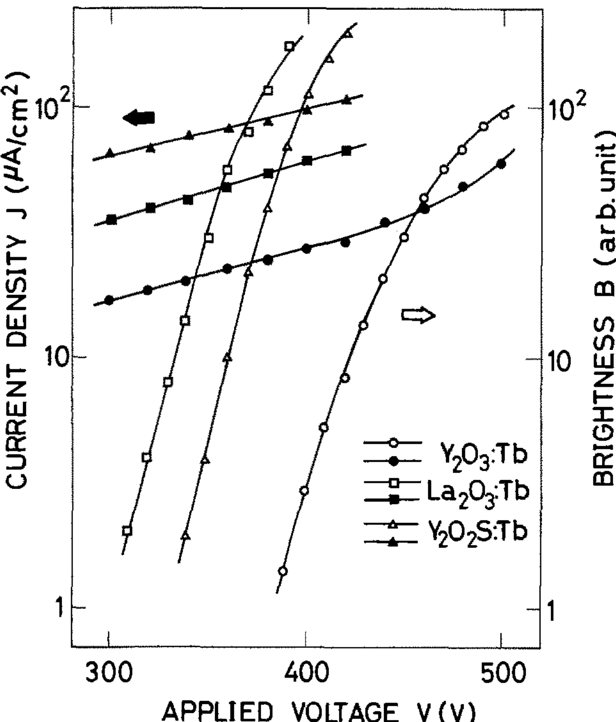

Fig. 2. Voltage dependences of current density and brightness for the Tb-doped phosphors.

samples increase exponentially with applied voltages, and are about 100, 60, and 25 μA/cm^2 for Y_2O_2S, La_2O_3, and Y_2O_3 phosphors, respectively, at 400V. These observations may probably be due to the difference in bandgaps of the hosts, but are not clearly understood yet. The emissions begin to occur at applied voltages of about 300, 330, and 380V for the La_2O_3, Y_2O_2S, and Y_2O_3 phosphors, respectively. These voltages correspond to an average electric field of about 6 $\sim$ 8 $\times$ 10^4 V/cm. The emissions increase exponentially with applied voltage. The La_2O_3:Tb phosphors show the brightest emission of about 10 f-L.

From these experimental results, we may conclude that a La_2O_3 lattice is the most suitable host in order to obtain the brightest electroluminescence among the three phosphors studied. The excitation mechanisms of rare earth ions doped in these host materials are not clear yet and further experiments are now in progress.

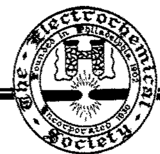
Brief Communication



The Influence of Etch Procedure on the Stability of Transit-Time Devices

D. de Cogan

Department of Electronic and Electrical Engineering, University of Birmingham, Birmingham, England B15 2TT

The performance of microwave devices such as Impatts, Trapatts, and Baritts is known to be extremely sensitive to surface conditions. Silicon-based p^+ n p^+ microwave diodes produced by mesa etching with HF/HNO_3 mixtures initially give an abrupt transition in the current-voltage characteristic, which is typical of punch-through. The sharpness of this transition is often found to be photosensitive. Upon exposure to the atmosphere, the dark characteristic deteriorates progressively and can be related to increasing hydrophilicity of the surface. Immersion in 49% HF makes the surface hydrophobic and temporarily restores the initial hard characteristic. For long term stability, methods of passivation using either thermal oxide or silox are used, but these increase the complexity of processing and introduce resistive regions which lead to microwave losses. Accordingly, in order to achieve maximum efficiency of device operation, it is desirable to produce passive and stable surfaces without oxide layers.

Holmes (1) mentions that a tarnish develops on the surface of silicon etched in HF/HNO_3 mixtures, if it is exposed to the air while etchant is still present. We have found that this tarnish is responsible for the surface instability and can be avoided by proper termination of the etch procedure. Further, it has been observed that the light sensitivity of the current-voltage characteristic can be used as an indicator of surface condition.

Experimental

Punch-through mesa diodes were made as follows. Masking layers of evaporated titanium/gold fol-

Key words: transit-time devices, stability, passivation, photosensitivity.

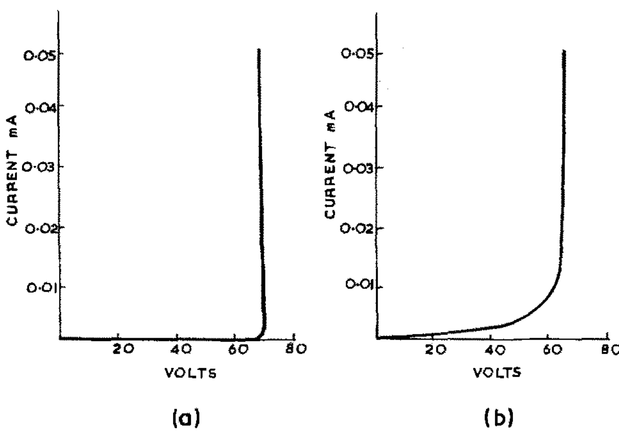


Fig. 1. Current-voltage characteristics of a device which was removed from the etch before rinsing: (a) dark, (b) illuminated.

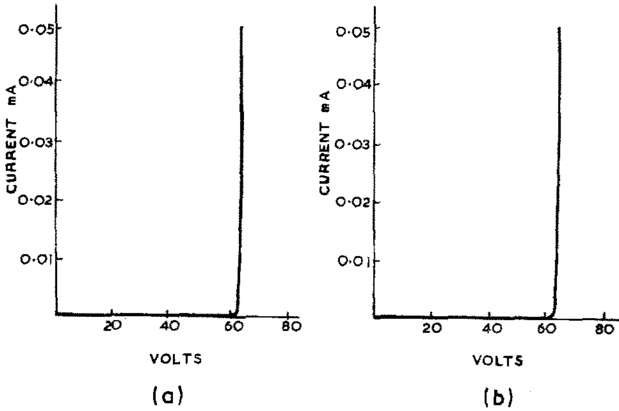

Fig. 2. Current-voltage characteristic of a device which was etched and rinsed before exposure to the atmosphere: (a) dark, (b) illuminated.

lowed by plated gold (1 μm) were placed on top of silicon double epilayer material (0.01 Ω-cm p^+ on 8 Ω-cm n on 0.008 Ω-cm p^+ substrate). 250 μm diameter dots were developed using Shipley positive resist and etched with KI/I_2 to remove gold and HF to remove titanium. The slice was cut in half and one piece was etched in a mixture of 23% HF, 47% HNO_3, 30% acetic acid. At the end of 1 min, the slice, held in a Teflon basket, was removed from the etch and transferred to a beaker containing rinsing water. The slice was then examined using ellipsometry and the presence of a tarnish layer was confirmed.

The other portion was etched in an identical mixture, but at the end of 1 min the beaker containing the etch was flooded with a solution of 1:6 HF in water. This was followed by pure water and only when the slice had been thoroughly rinsed was it moved into the air.

Results

The results given below were typical over the whole slice and have been repeated over many slices. Figure 1(a) shows the current-voltage characteristic for a device which was removed from the etch before rinsing. The influence of illumination can be seen in Fig. 1(b). The dark characteristic had completely deteriorated within 2 hr after etching. Figures 2(a) and 2(b) show the characteristic one month after etching of a device which was etched and rinsed without exposure to the atmosphere. It can be seen that illumination has no effect.

Conclusion

It would appear that the effect of illumination on the current-voltage characteristics of punch-through devices indicates the presence of a contaminating surface layer. Devices with little or no light response seem to remain stable upon exposure to the atmosphere.

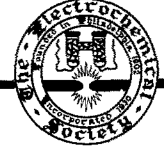
DISCUSSION SECTION



This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 122, No. 11; November 1975; and Vol. 123, No. 1, 3, and 6; January, March, and June 1976.

Simple Method for Separating Completed Diodes from Semiconductor Wafers

J. Klatskin and A. Rosen (pp. 1565-1566, Vol. 122, No. 11)

G. Greco and M. Tomassini:[1] The technological process described in the above-mentioned paper is very close to that developed in our laboratory since 1972 and now patented.[2] In addition, we wish to mention a paper[3] that reports a method for selectively plating heat sinks for microwave diode fabrication. We developed our process in a quite general way in order to be applicable to many different devices (IMPATT, GUNN, BARITT) and we have reported the results on Baritt diodes.[4]

We agree that this technique has many advantages over the more conventional sawing or dicing technique. In addition, we would like to point out that using this selectively plated heat sink method instead of the conventional continuous metal layer remarkably reduces the stresses induced by the metal into the semiconductor. In the case of avalanche diodes, this process has increased device yields due to the reduction of stress-induced microplasmas. As a result, it is possible to drive the diodes with current densities of about 800 A/cm^2 without any particular care and to get an efficiency as high as 10% with a p^+-n-n^+ silicon structure ($f \simeq 10$ GHz).

Finally, we remark that for silicon devices silicon dioxide, thermally grown during the diffusion process,

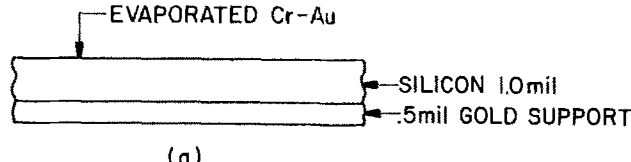

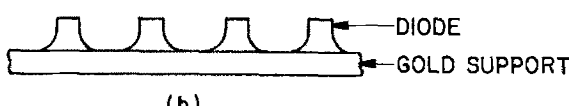

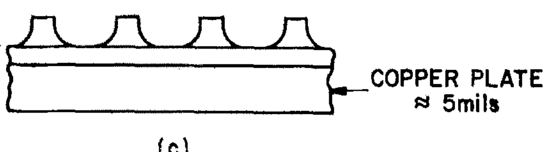

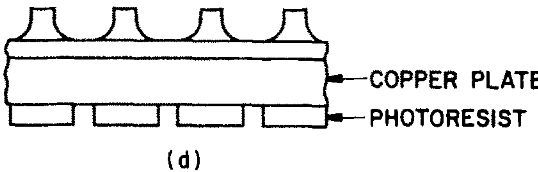

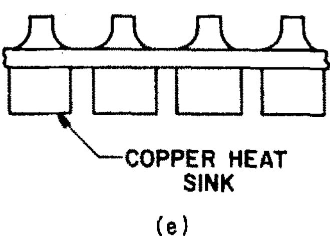

Figure 1

can be used instead of photoresist to get the heat sink patterns. This allows very thick metal layers to grow, thus avoiding the problems that normally arise with the photoresist.

J. Klatskin and A. Rosen:[5] We wish to thank Drs. Greco and Tomassini for bringing to our attention the details of their process. In this regard, it may be of interest to mention that we are currently using a somewhat different approach which tends to increase device yield. In this process a gold layer is plated on the n^+ side of the wafer, Fig. 1a. The semiconductor material is then etched to form a plurality of devices on the previously evaporated and plated gold support, Fig. 1b. A copper heat sink is then formed, Fig. 1c. Note that the heat sink is always formed after completion of device structure (after etching) to reduce stress in the silicon wafer.[6] The diodes can then be separated as shown in Fig. 1d or as previously published in the paper under discussion.

Synthesis and Luminescence Properties of Europium-Activated Yttrium Oxysulfide Phosphors

M. Koskenlinna, M. Leskelä, and L. Niinistö
(pp. 75-78, Vol. 123, No. 1)

G. W. Luckey:[7] In their paper M. Koskenlinna, M. Leskelä, and L. Niinistö describe "a new method of preparing brightly emitting Y_2O_2S:Eu phosphors" by reduction of yttrium sulfite. I believe that it is appropriate to call the authors' attention to Belgian Patent Application No. 777,915 which was published on January 31, 1972, and which describes the preparation of phosphors by the process in their article. Similar information is also given in U.S. Patent 3,705,858 which was issued on December 2, 1972.

M. Koskenlinna, M. Leskelä, and L. Niinistö:[8] We do regret that the patents of Dr. Luckey were missed and we thank him for kindly pointing this out. When comparing the details of U.S. Pat. 3,705,858 to our synthesis, we would like to mention that in examples 1-6 of the patent, sodium sulfite is suggested as the precipitating agent. The use of sodium sulfite probably leads, however, to double sulfite formation,[9,10] which increases the sodium concentrations of the phosphors. This can be avoided by using only sulfur dioxide and rare earth oxides as starting materials, as done in our synthesis.

The Cathodic Corrosion of Aluminum

E. P. G. T. van de Ven and H. Koelmans
(pp. 143-144, Vol. 123, No. 1)

B. Chatterjee:[11] The following comments may be of interest not only to those considering the valuable results in the paper under discussion, but to those interested in such reactions in general.

The Arrhenius plots in Fig. 2 of the paper under discussion show the slope for the cathodic corrosion rate of Al in neutral solution ($5 \times 10^{-4}N$ NaCl) to be identical with that for the chemical dissolution in alkaline solution (0.1% NaOH). Although this would imply that the electrochemical and chemical dissolution behavior of Al is similar, it is not certain if this will apply to alkaline as well as acid solutions. However, results on the chemical dissolution of Al in both alkaline and acid solutions show similar slopes of the Arrhenius plots.[12-15] This indicates that the chemical dissolution of Al is not affected by the type of electrolyte used, namely alkaline or acid solutions. The same concept will apply to the electrochemical dissolution of Al due to its similarity with the chemical dissolution behavior as expressed earlier.

The activation energy for dissolution of Al in 0.4-5% NaOH[12-16] agrees with that reported in the paper under discussion using 0.1% NaOH. This suggests, as mentioned elsewhere,[12] that the alkaline etching of Al is controlled by a single rate-determining cathodic reduction common to all. The hydrogen evolution reaction (HER) is primarily involved in the cathodic reduction process and consists of an intermediate step of discharged hydrogen atoms adsorbed on the metal surface, followed by desorption.[17] An indication of the true

rate-determining step can be obtained by estimating the change of hydrogen overpotential on Al with applied current, *i.e.*, the Tafel slope.[18] From measurements on the potentiostatic cathodic polarization of Al (99.8% purity) in acids (H_2SO_4 of sp gr 1.84 and H_3PO_4 of sp gr 1.75) at a scan speed of 5 V/hr, the Tafel slopes at 25°C are estimated to be similar in all cases[13] and are comparable with the theoretical slope (0.12 V/decade) for proton discharge as the rate-controlling step. The theoretical slope is estimated by assuming a single electron transfer mechanism as expressed in the paper under discussion, and 0.5 as the symmetry factor.[19] Thus, a slow discharge, fast desorption process for HER is considered to be the likely mechanism during dissolution of Al in acids, and the same basic mechanism will apply to alkaline dissolution as well for reasons given earlier. One can, therefore, conclude that both the chemical and electrochemical dissolutions of Al are likely to be controlled by a slow discharge fast desorption HER, and are not affected by the electrolyte, namely alkaline and acid solutions.

Regarding the alkalization effect, it is probably due to the formation of basic oxy-acid complexes of Al[20,21] on the solid surface which would tend to increase the pH of the adjacent solution. The formation of these complexes, hence the alkalization effect, is believed to be accentuated by water, and is thus more likely to occur in aqueous rather than in concentrated acids. Due to large hydration energy and primary hydration number of Al^{3+} ion,[22,23] a high degree of hydration of aluminum ion is expected during dissolution in aqueous acids. It seems[20,21] that a high degree of hydration will facilitate the formation and improve the stability of oxy-acid complexes.

The effect of anions on the dissolution of Al in the paper under discussion is in contradiction to the results given by others.[24] It is not clear if the mechanism suggested for chemical dissolution[24] will apply to the present results on electrochemical corrosion.

H_2-Induced B Diffusion in MOS Devices

D. M. Brown (pp. 412-415, Vol. 123, No. 3)

L. M. Pecora and V. Srikrishnan:[25] The author presents some interesting experimental results which show that at 1100°C and in the presence of hydrogen, boron (B) formed by reduction of B_2O_3 diffuses through a molybdenum (Mo) gate in MOS devices. According to the author, although the chemical reaction $3H_2 + B_2O_3 \rightarrow 2B + 3H_2O$ is unlikely in the bulk ($\Delta G°_{reaction} = 2.15$ eV/B atom), an entropy term arising from the dissolution of B atoms in Mo makes the reduction possible. The author claims that such interstitial dissolution provides the necessary driving force required for catalytic reaction (in this case B_2O_3 reduction), which is otherwise energetically unfavorable. He further claims that this explains the high B diffusivity through the Mo gate, whenever H_2 is present in the ambient.

We would like to point out that when Brown refers to enhanced diffusivity, he means enhanced B atom flux. The diffusion fluxes are determined by intrinsic diffusivities (*i.e.*, diffusion coefficients) and concentration gradients or more generally gradients of chemical potentials.[26] The mixing entropy term Brown refers to is nothing but a part of the chemical potential gradient for diffusion and therefore has nothing to do with the diffusivities. The experimental evidence presented in the paper does not unequivocally show that the presence of hydrogen has any influence on the diffusivity. The enhancement in the diffusion fluxes could very well be a direct consequence of increased B concentration at the interface (or surface) in the presence of hydrogen.

The dissolution of B from the surface, we believe is only a B removal process from the site of the reaction. Brown's suggestion that "the free energy of a reaction can be lowered by the much larger entropy changes associated with the interstitial substrate dissolution of a product within the volume of the catalyst" is extremely misleading. The reaction to be considered then is no longer the original surface reaction alone but one that includes the dissolution (*i.e.*, the removal process) also. Hence, we are not lowering the free energy of a reaction, but actually changing the reaction to include a new process by which the product is removed. More realistically, the removal of the product does not influence the energetics of the reaction, but only perturbs the equilibrium concentration of the product, enabling the reaction to continue. For example, one can consider a catalytic reaction where the removal process is simply a desorption process. The desorption process cannot and does not influence the catalytic ability of the surface.

A possible explanation for the author's observations perhaps can be described as follows. H_2 gets dissociatively chemisorbed on the surface. The reaction of interest is then $6H + B_2O_3 \rightarrow 3H_2O + 2B$ which has a $\Delta G° \simeq -2.3$ eV/B atom. This is obviously much more favorable for producing B at local adsorbed sites than the one Brown has considered. Brown's reasoning that N_2 atoms occupy interstitial sites in the solid and prevent the B atoms from dissolving yields unrealistic amounts of N_2 in Mo interstitials. Since $n \propto N$, for a given Δg, where n is the number of B atoms dissolved and N is the number of interstitial sites available to B atoms, a reduction of 10% in n requires a reduction of 10% in interstitial sites, which means that approximately 10^{21} N_2 atoms/cm^3 must be dissolved. The actual data show 50-100% decreases in n (of B) in the presence of $H_2 + N_2$ mixture, requiring unrealistic amounts of N_2 solution in Mo. A more straightforward explanation is that the surface reaction sites are reduced by the adsorption of N_2 or N-H type molecules. This would result in lower H adsorbed sites, lower B surface concentrations, and hence low B diffusion fluxes.

We believe that the experimental observations are very interesting, but not conclusive on the effect of hydrogen on the diffusion of B into Mo. A good part of the problem, we feel, is firstly Brown's misinterpretation of the dissolution process and its role in changing free energies and secondly his overextension of a simple reaction-dissolution model to explain various phenomena which are not built into the model. The simpler explanations we have proposed seem to explain the observations adequately.

D. M. Brown:[27] Pecora and Srikrishnan contend that "the removal of the product does not influence the energetics of the reaction but only perturbs the equilibrium concentration of the product enabling the reaction to continue." That this statement is not of general validity can be seen by considering the disordering of a perfect crystalline solid. The formation of pairs of Frenkel defects consisting of vacant lattice sites and interstitial atoms is an endothermic process involving the absorption of an amount $n\Delta h$ of energy where n is the number of defects and Δh is the formation enthalpy per defect. If the energetics of the equilibrium state were determined only by the enthalpy

and the vacancies and interstitials did not separate, the crystal could not be disordered. The equilibrium state is determined, however, not by the enthalpy but by the free energy ΔG which involves an entropy term $-T\Delta S$ arising from the distribution of the point defects over the available lattice and interlattice sites. The energetics of the disordering reaction are profoundly influenced by the entropy term which involves a random diffusion process.

A further example of a process for which their contention cannot be sustained is provided by the formation of a binary solid solution by the diffusion of atoms into a crystalline solid from the surface, for which the enthalpy of dissolution Δh has a positive value. The dissolution would not occur if the energetics of the equilibrium state of the system were determined only by the enthalpy Δh and not by the free energy ΔG which involves an entropy term $-T\Delta S$ and a random diffusion process. This process distributes the solute atoms over the available lattice sites and increases the entropy. The energetics of the reaction are again profoundly influenced by the entropy term.

An experimental observation which is of considerable importance in the fabrication of the MOSFET devices and which has to be explained is that a very thin layer of SiO_2 under the Mo gate remains as an insulating oxide film when heated in the presence of hydrogen, whereas a thin layer of B_2O_3 or B_2O_3 in a borosilicate glass is reduced. This observation is adequately explained by the mechanism proposed in the paper. Use of the available thermodynamic data presented in the paper shows that the reduction mechanism for B_2O_3 on the Mo surface proposed by Pecora and Srikrishnan which depends on the dissociative adsorption of hydrogen would be more effective in reducing SiO_2 than B_2O_3 so that, if this were the reaction mechanism, the thin insulating SiO_2 layer could scarcely be expected to survive. In practice, the Mo is covered (*i*) with the borosilicate glass and (*ii*) there is probably a layer of adsorbed oxygen at the glass-Mo interface for which the heat of adsorption of 7.5 eV/molecule is considereably greater than that of hydrogen at 1.7 eV/molecule.[28] It appears that dissociative surface adsorption of hydrogen on Mo is unlikely to occur in these circumstances.

Activities of SnO in the $SnO\text{-}SiO_2$ System

A. E. Grau and S. N. Flengas (pp. 852-856, Vol. 123, No. 6)

Z. Kozuka:[29] In the paper under discussion, Grau and Flengas emphasized that the "closed" cell was better than the "open" cell for emf measurement of the activities of SnO in $SnO\text{-}SiO_2$ liquid solutions. I acknowledge their statement, but I think the undesirable effect caused by the "open" cell was not so much due to the difference of oxygen potentials at the two electrodes because the difference was not so great. The authors' experimental results were in agreement with our results within about 10%, as shown in Table I. Therefore, I cannot understand why line (c) in Fig. 1 of the paper under discussion is in poor agreement with their results. Perhaps our paper was misquoted.

In our experiment, a Sn,SnO reference electrode was used and the solid electrolyte was attacked by the reference electrode. However, it was confirmed that the change of the cell's emf was negligibly small as black stains were not found on the external surface of the $ZrO_2\text{-}CaO$ tube. During our emf measurements, the undesirable effect due to any irreversible reaction was found to be negligibly small in spite of "open" cell characteristics; in our experiment the plots of emf *vs.* temperature were nearly linear even though the emf measurements were made at alternating temperature changes. In a recent separate experiment, it was found that the change of $SnO\text{-}SiO_2$ composition during emf measurement was negligibly small.

Grau and Flengas	150.7	145.0

A. E. Grau[30] **and S. N. Flengas:**[31] The cells used by both Professor Kozuka and by us for the determination of the standard free energy of formation of liquid SnO are schematically described as

$$Sn, SnO/ZrO_2\text{-}CaO/Ni, NiO \quad [1]$$

The corresponding cell reaction is

$$Sn_{(l)} + NiO_{(s)} \rightarrow SnO_{(l)} + Ni_{(s)} \quad [2]$$

The emf *vs.* temperature relationship of Kozuka *et al.*[32] for this reaction may be obtained by dividing Eq. [7] in their paper by the quantity $-2\mathbf{F}$, $\mathbf{F}$ being the Faraday constant. The result of this calculation is

$$E^\circ = 183.2 - 0.0202T \text{ (mV)} \quad [3]$$

Our results, summarized in Eq. [6] of our paper, are

$$E^\circ = 225.5 - 0.0575T \text{ (mV)} \quad [4]$$

The disagreement between Eq. [3] and [4] is better seen in Table II. This is the disagreement we referred to in our paper. The good agreement for the formation potential of liquid SnO indicated by Professor Kozuka in this discussion is unfortunately fortuitous and probably due to the fact that the different data which we have used for the formation potential of NiO[33,34] compensates for the disagreement observed in Table II.

Despite the differences observed in the activity values of SnO reported by Kozuka *et al.*[32] and by us, it is interesting to observe that both sets of results indicate that SnO is one of the most acidic metal oxides with respect to SiO_2. This is encouraging, particularly in view of the experimental difficulties which are inherent to the $SnO\text{-}SiO_2$ system.

ABSTRACT

Stannic oxide in its pure form is an n-type wide-bandgap semiconductor. Its electrical conduction results from the existence of point defects (native and foreign atoms) which act as donors or acceptors. Some unique properties of SnO_2 make the material useful for many applications. Therefore, increasing attention is being paid to studies on this oxide, especially on the methods of preparation, and its electrical and optical properties. The purpose of this series is to provide a general up-to-date review of the investigations carried out and to help identify important areas for further studies. The first part[2] was concerned with the preparation and defect structure of single crystals, sintered polycrystalline samples, and thin films. In this part we review the electrical properties of these materials. The electrical properties of single crystals are well understood and the properties of sintered SnO_2 powder are similar to those of single crystals. However, those of SnO_2 films have not been explained satisfactorily up to the present time. They depend strongly on the manner of preparation and subsequent heat-treatments in various ambients. In the third part,[3] the optical properties of SnO_2 will be reviewed.

The methods of preparation of single crystals, sintered materials, and thin films of tin dioxide have been described in Part I. In this part, a review of the electrical properties of these materials is given. Research on the electrical properties of SnO_2 has been going on since 1910, mainly because of the variety of applications of this wide bandgap semiconductor of rutile structure. A great deal of experimental research has been conducted already, especially in recent years; therefore, it would seem proper to provide in this part a general up-to-date survey of the results obtained and make an attempt to find a more comprehensive and consistent interpretation. The data obtained on single crystals will be considered first as such systems are the most simple. The electrical properties of more complicated sintered powder materials of SnO_2 will be discussed in the second section, and in the third section the properties of the most complicated thin film materials will be described.

Single Crystals

Some data on electrical properties of SnO_2 single crystals are presented in Table I. As can be seen from this table, the measurements have been carried out on the following three types of SnO_2 single crystals: (*i*) pure and intentionally doped crystals of good quality, (*ii*) pure crystals heat-treated at various temperatures and oxygen pressures, and (*iii*) impure single crystals containing various undesirable admixtures.

[3] To be published in THIS JOURNAL, October 1976.
Key words: electrical conductivity, Hall and Seebeck effects, mobility, point defects and impurities.

In this paper we will be concerned mostly with the data obtained from the first two types of crystals.

Pure and intentionally doped crystals.—One criterion for determining the purity of crystals is the charge carrier mobility at low temperatures: the higher this value, the higher the purity and the quality of the crystals. In Table II Hall mobility and carrier concentration data are listed for various samples. As can be seen from Table II, the measurements carried out by Nagasawa *et al.* (5) and Fonstad *et al.* (14) have been conducted on the best quality samples. Therefore, in this section the data obtained by these authors will be given the most consideration.

In Fig. 1 the results of conductivity measurements on SnO_2 obtained by Nagasawa and Shionoya (11) at temperatures of 4.2°-300°K are presented. The specimens had a conduction electron concentration of 1.8×10^{17} cm^{-3} at 300°K. The curve shown in Fig. 1 consists of three different regions, namely: region I in a temperature range from 130° to 300°K, region II from 10° to 130°K, and region III from 4.2° to 10°K. The authors have given the values of the activation energies for the last two regions (*cf.* Table I), but it is difficult to find the physical meaning of these energies because the temperature dependence of resistivity $\rho = 1/en\mu$ in the case of SnO_2 is governed greatly by temperature dependences either of conduction electron concentration, n, or charge carrier mobility μ(e is the electronic charge). It is interesting, instead, that in the temperature range from 4.2° to about 130°K, the conductivity varies by nine orders of magnitude. Thus, pure SnO_2 crystals can be either a good insulator at very low temperatures (about 4.2°K) or a good conductor at a temperature of about 130°K.

The authors assumed in their discussion that the temperature dependence of conductivity in region III results from point defect (impurity) level permutation conduction with appropriate compensation by acceptors such as Fe and Ca (4). If wave functions of donors overlap sufficiently, a point defect band conduction

Table I. Electrical properties of SnO_2 single crystals found by various authors

Year	Author	Reference	Material	Property	Temperature range °K	Conclusions drawn by the author
1962	Kohnke	(2)	Natural cassiterite; a spectroscopic analysis showed Si, Al, and Fe to be most important impurities present with maximums of 0.5%	Conductivity Hall effect Hall mobility	100-500	Ionization energy of donors of 0.7 eV for samples with charge carrier concentration of 10^{14}-10^{15} cm at 300°K. Hall mobility varies from 10 to 300 cm^2/Vsec. Electron effective mass and donor concentration are about 0.8 m_o and 10^{20} cm^{-3}, respectively. Nature of donors is unknown. SnO_2 is a typical broad-band semiconductor.
1965	Marley and Dockerty	(3)	Single crystals, prepared by vapor-transport technique [*cf.* Ref. (1)] Mass spectrographic analysis on undoped samples indicate the presence of Al and Fe in the range of 10-20 ppm. Samples were either heat-treated or antimony doped, and also as-grown	Conductivity Hall effect Hall mobility Seebeck effect	80-900 80-575 300	Donor ionization energy, E_D, decrease with increasing donor concentraton, N_D. At infinite dilution E_D = 0.15 eV. Density-of-states effective mass m^* obtained from Hall effect measurements amounts to 0.22 m_o; instead, the values of m^* found from Seebeck effect measurements vary between 0.12 and 0.18 m_o. Antimony-doped crystals with $N_D > 6.10^{18}$ cm^{-3} are degenerate above 80°K. Above 300°K the polar optical mode scattering mechanism is assumed. At lower temperatures Hall mobility decreases with decreasing N_D. The hypothesis of impurity-level transport is suggested in these temperatures.
1965	Nagasawa, Shionoya, and Makishima	(4)	Pure single crystals with concentrations of order of magnitude of 10^{17} cm^{-3}	Conductivity Hall effect Hall mobility	77-300 300	The conductivity changes by the equation σ = const T^{-2} above 250°K. At room temperature the crystals have the conductivity of a few $(ohm\text{-}cm)^{-1}$ and the mobility of about 200 cm^2/Vsec.
1965	Nagasawa, Shionoya, and Makishima	(5)	Pure single crystals with concentrations of order of magnitude of 10^{17} cm^{-3}	Conductivity Hall effect Hall mobility Seebeck effect	100-300 300	The ionization energy of donors is (0.024 ± 0.004) eV. The density-of-states effective mass obtained from Hall effect experiments is (0.41 ± 0.10) m_o, and from Seebeck effect measurement is 0.33 m_o. Above 160°K the T^{-2} dependence of Hall mobility has been found. The charge carriers are scattered mainly by acoustical phonons with contribution of scattering by optical phonons.
1966	Morgan and Wright	(6)	Crystals contained appreciable amounts of various impurities (7), *e.g.*, 0.04-0.1% Si; Ca, Na < 0.005%; Cr, Fe, Mg, and Al ≤ 0.01%. The samples investigated were doped with antimony	Conductivity Hall effect Hall mobility Seebeck effect	77-1100 77-600 300-1100	The values of electron effective mass varied from 0.10 to 0.17 m_o. These values are obtained by combining Hall and Seebeck effects measurements. Optical mode lattice scattering is proposed above about 300°K, with an impurity scattering contribution below this temperature. The Hall coefficient was constant up to 600°K, which was the highest temperature of measurements.
1968	Wright	(8)	The same crystals as above, and also doped with chromium (about 80 ppm)	Conductivity Seebeck effect Hall effect	100-1100 100-600	In crystals having concentrations of antimony of 5 × 10^{17}-10^{19} cm^{-3} the mobility is about 80 cm^2/Vsec. The electron effective mass is about 0.16 m_o along the a axis and may be a little lower along the c axis. The same conclusions as above concerning the scattering mechanisms apply.
1968	Nagasawa and Shionoya	(9)	Pure single crystals	Hall effect Hall mobility Magnetoresistance	77 and 300	The quasi-free electron scattering process at 77°K is dominantly due to acoustical phonons. At 300°K the resistivity, carrier concentration, and mobility are (0.11-0.33) ohm-cm, (1.3-0.4) × 10 cm^{-3}, and about 200 cm^2/Vsec, respectively. Results of magnetoresistance measurements can be interpreted in terms of a single spheroidal energy valley model.
1968	Van Daal	(10)	Single crystals contained 3.6 × 10^{19} and 1.8 × 10^{20} cm^{-3} of Al; and B, Fe, and Mg on order of magnitude of 10^{18} cm^{-3}	Conductivity Hall effect Hall mobility	4.2-1600	Above 300°K polar optical mode scattering with an average characteristic temperature of 1050°K predominates. Below 300°K the electron mobility is determined mainly by impurity scattering.
1969	Crabtree Mehdi, and Wright	(7)	Crystals having electron concentrations between 10^{17} and 10^{18} cm^{-3}, obtained by reduction in vacuum	Conductivity Hall effect Hall mobility	77-300	At 300°K the values of Hall mobility are between 200 and 250 cm^2/Vsec. The highest value of the mobility at 77°K is 700 cm^2/Vsec. At 300°K the quasi-free electrons are scattered by optical modes. Electron effective mass is 0.17 m_o.
1971	Nagasawa and Shionoya	(11)	Crystals having charge carrier concentration of 1.8 × 10^{17} cm^{-3} at 300°K	Conductivity	4.2-300	Three different regions have been observed: region I (130°-300°K), region II (10°-130°K), and region III (4.2°-10°K). In the first region, the resistivity increases with increasing temperature while in the last two regions the resistivity decreases with increasing temperature with activation energies 0.0137 and 0.0034 eV, respectively.
1971	Nagasawa and Shionoya	(12)	Undoped SnO_2 single crystals heat-treated at temperature 1370°K and in vacuum of 10^{-3} Torr for 24 hr	Hall effect Hall mobility	77-300	Electrical properties of the reduced SnO_2 crystals are similar to those of Sb-doped tin oxide. They may be interpreted with the concept of degenerate semiconductor native defects resulting from nonstoichiometric composition from shallow donor centers.

Table I. Continued

Year	Author	Reference	Material	Property	Temperature range °K	Conclusions drawn by the author
1971	Nagasawa and Shionoya	(13)	Undoped SnO_2 crystals heat-treated at temperature 1570°K in oxygen of about 10 atm	Conductivity	300	The conductivity of the crystals decreases remarkably by the heat-treatment in high pressure oxygen. The conductivity is not uniform with a crystal. The surface layer has much lower conductivity than the interior.
1971	Fonstad and Rediker	(14)	Single crystals	Conductivity Hall effect Hall mobility Schottky barrier	20-625	Donor levels of 34 meV and 140 meV have been found. The first level is due to antimony, the second is due to oxygen vacancy. Above 250°K polar optical mode scattering with characteristics temperature of 1353°K predominates. Below 250°K acoustic deformation potential scattering dominates. Ionized point defect scattering is important at low temperatures.
1971	Button, Fonstad, and Dreybrodt	(15)	Pure single crystals	Hall effect Hall mobility Submillimeter cyclotron resonance	20-300	The samples show a charge carrier concentration of 7 × 10^{15} cm^{-3} and Hall mobility of 250 cm^2/Vsec at 300°K. At 77°K the carrier concentration and mobility were 2 × 10^{15} cm^{-3} and 9000 cm^2/Vsec, respectively. The first accurate measurement of the conduction-band effective-mass tensor components are $m_\perp^* = 0.299\ m_o$ and $m_\parallel^* = 0.234\ m_o$. The density-of-states effective mass is 0.275 m_o.
1973	Samson and Fonstad	(16)	Pure single crystals	Conductivity	970-1620	In the temperature range of 1370°-1620°K and in partial oxygen pressure range of 10^{-2} −1 atm dominant native defects in SiO_2 are doubly ionized oxygen vacancies. The donor levels related to these defects are: 30 meV and 150 meV. The hydrogen introduces a donor level of 50 meV.

will be formed, but if this overlapping is insufficient it will result in a point defect level permutation conduction (17). However, the nature of donors is unknown. It may be either oxygen vacancies or interstitial tin atoms (4) or other impurities.

The temperature dependence of resistivity, found by Nagasawa and Shinoya (11) in regions I and II is consistent with the more detailed results obtained at temperatures higher than 80°K by Fonstad and Rediker (14). The results are shown in Fig. 2. Their sample had a similar conduction electron concentration to the ones discussed above at 300°K. Specifications of three samples investigated by the latter authors are given in Table III. Fonstad and Rediker have also found that in the temperature range from 80° to about 130°K the conductivity σ of SnO_2 increases with increasing temperature, followed by a decreasing of σ with an increase of T at higher temperatures; this is similar to what was found by Nagasawa and Shionoya (11). Thus the complicated temperature dependence of conductivity in SnO_2 crystals is due mainly to the different temperature dependences of n and μ.

Table II. Hall mobility and conduction electron concentration in SnO_2 single crystals at 77°K obtained by various authors

Mobility cm^2/Vsec	Conduction electron concentration (cm^{-3})	Reference
ca. 10	—	(10)
96	8.7 × 10^{19}	(6)
62	8.0 × 10^{18}	
700	—	(7)
ca. 1000	ca. 10^{16}	(5)
8800	1.99 × 10^{15}	(14)

Table III. Values of charge carrier concentration and Hall mobilities at 77°K and 300°K for SnO_2 samples used in Fig. 2-4

Sample	77°K		300°K	
	n (cm^{-3})	μ_H (cm^2/Vsec)	n (cm^{-3})	μ_H (cm^2/Vsec)
A	1.3 × 10^{18}	110	2.2 × 10^{18}	150
B	2.2 × 10^{16}	2200	8.6 × 10^{16}	240
C	1.9 × 10^{15}	8800	8.5 × 10^{15}	260

Two other samples investigated by Fonstad and Rediker had carrier concentrations lower and higher than that discussed above. The temperature dependences of n, μ, and σ for these are shown in Fig. 3 and 4.

In analyzing the temperature dependence of charge carrier concentration for one of the samples (B) the well-known formula derived from nondegenerate statistics was used (18)

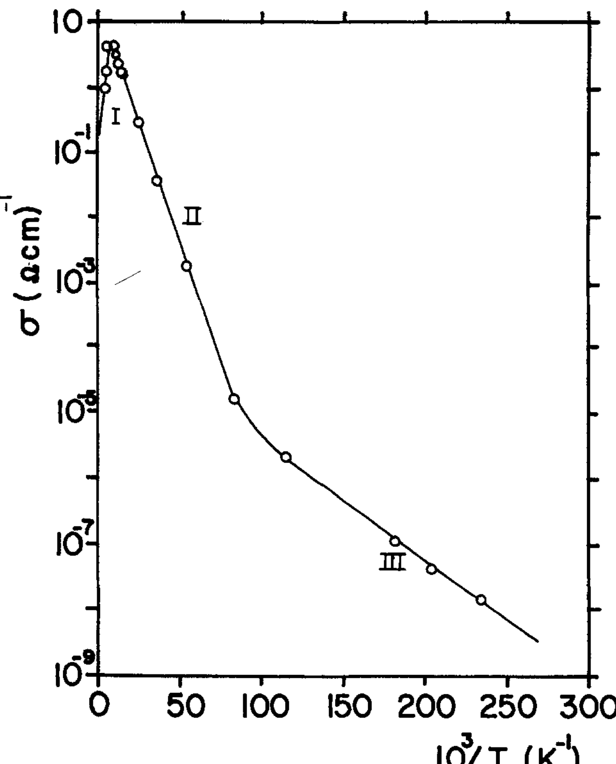

Fig. 1. The electrical conductivity σ of SnO_2 single crystals as a function of inverse temperature (11).

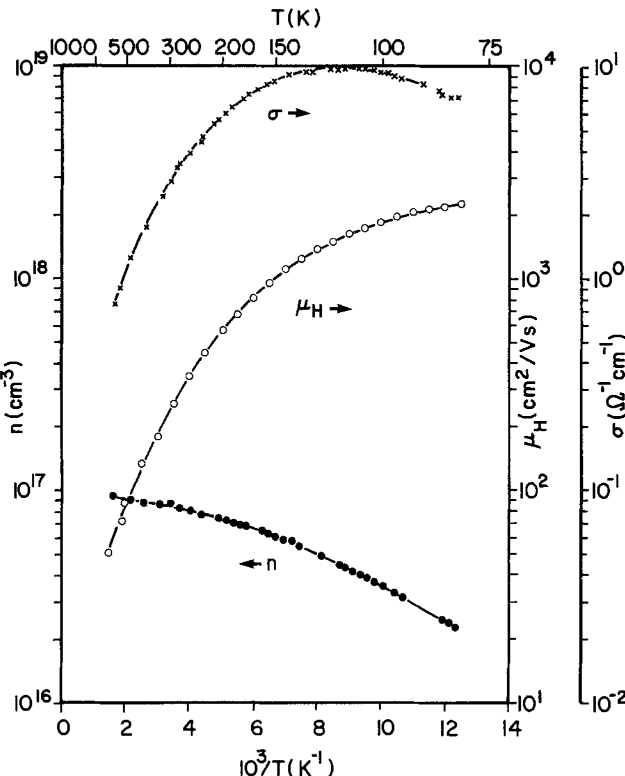

Fig. 2. Conductivity σ, Hall mobility μ_H, and conduction electron concentration n in SnO_2 single crystals (sample B) vs. inverse temperature (14).

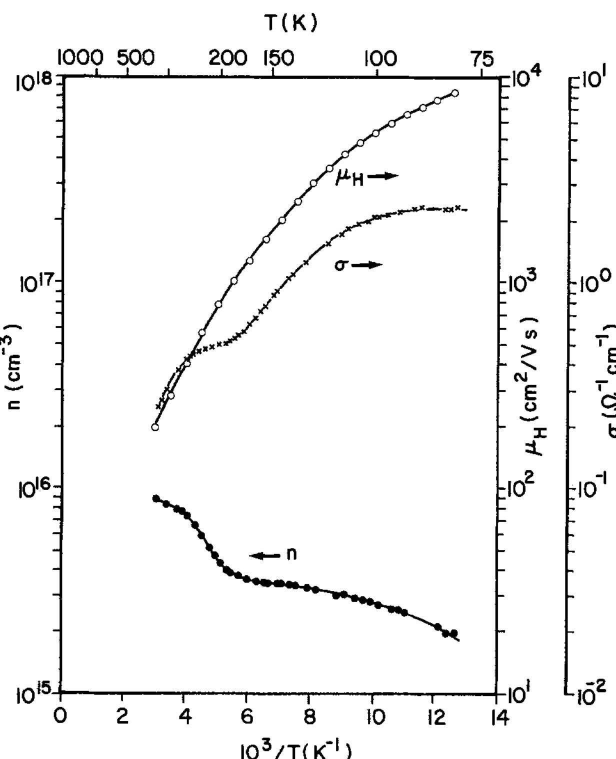

Fig. 3. Hall mobility, conductivity, and conduction electron concentration in SiO_2 single crystals (sample C) as a function of inverse temperature (14).

$$\frac{n(n + N_A)}{(N_D - N_A - n)T^{3/2}} = \left(\frac{2\pi k m^*}{h^2}\right)^{3/2} \exp\left(-\frac{E_D}{kT}\right) \quad [1]$$

where: N_D is the concentration of donors, N_A is the

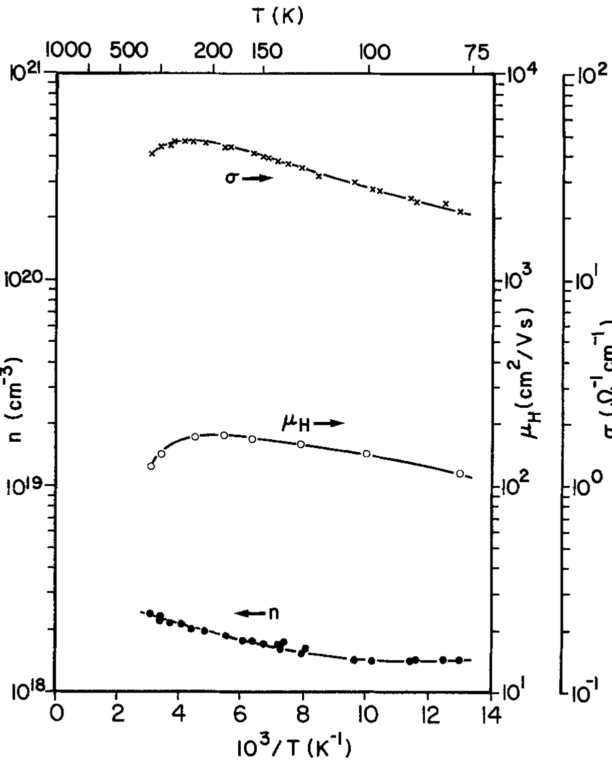

Fig. 4. Conductivity, Hall mobility, and charge carrier concentration in SnO_2 single crystals (sample A) vs. inverse temperature (14).

concentration of acceptors, E_D is the ionization energy of donors, and other symbols have the usual meanings. For this sample, it appears that only one donor level is active and the specimen is not degenerate. For sample C, it is seen that two donor levels are active and, therefore, in this case, Fonstad and Rediker assumed the following more complicated formula

$$n = \frac{N_1}{1 + g_1 \exp[(E_1 - E_F)/kT]} + \frac{N_2}{1 + g_2 \exp[(E_2 - E_F)/kT]} \quad [2]$$

where g is the donor degeneracy factor and E_F is the Fermi level. The subscripts 1 and 2 refer to the shallower and deeper donor levels, respectively.

The Hutson method (19) was applied to find the net donor concentration ($N_D - N_A$), donor ionization energy, E_D, and the carrier effective mass from Eq. [1] and [2]. As can be seen from Fig. 3, only the shallow donor is active below 150°K, and, in this case, the single donor level analysis used for sample B applies. For this reason, the authors assigned the value of g_1 to be $g_1 = 2$, and assumed the second level to be the first ionized state of a double donor, with $g_2 = ½$. This combination gave the best fit for Eq. [2]. A density of states electron effective mass of 0.39 m_o was also found for both samples B and C. Sample A, which had the highest concentration of charge carrier, has been found to be degenerate below 200°K, and the donor level has been estimated to lie between 10 and 15 meV from the slope of the curve log n vs. $1/T$ near room temperature. The net donor concentration ($N_D - N_A$) and donor ionization energies, E_D, obtained by Fonstad and Rediker from the Hall effect experiments using Eq. [1] and [2] are shown in Table IV. In this table, the data of $N_D - N_A$ found by the authors from the measurements of Schottky barrier capacitance vs. bias voltage (20) are also given.

Table IV. Net donor concentration, $N_D - N_A$ in SnO_2 single crystals obtained from Hall effect and Schottky barrier measurements, as well as donor ionization energies, E_D

Sample	$N_D - N_A$ (cm^{-3}) Hall effect	Schottky barrier	E_D (meV)
A	$>2.2 \times 10^{18}$	1.5×10^{18}	10-15
B	9.4×10^{16}	8.4×10^{16}	27.5
C	9.2×10^{15}	7.9×10^{15}	34, 140

The best data has been obtained from the formula

$$\frac{1}{C^2} = \frac{2(V_b - V_B)}{e\epsilon_S A} \cdot (N_D - N_A)^{-1} \quad [3]$$

where C is the small-signal barrier capacitance, V_b and V_B are the barrier voltage and the bias voltage, respectively, ϵ_S is the static dielectric constant, and A is the barrier area. Thus, for uniformly doped samples, the value of $N_D - N_A$ may be obtained from a slope of a plot of $1/C^2$ *vs.* V_B, as this plot has been found to be a straight line. Table IV shows good agreement between the values of net donor concentrations found from the Hall effect and Schottky barrier experiments. It is also noteworthy that in the case of samples of similar charge carrier concentrations, the donor ionization energy found by Fonstad and Rediker for specimen B is almost the same as the one obtained by Nagasawa and Shionoya [27.5 meV *vs.* 24 ± 4 meV (5)].

Fonstad and Rediker have assumed that the shallower donor can be related to antimony doping and that the deeper level may be due to oxygen vacancies. The last suggestion is consistent with the value of donor ionization energy (138 meV) found by Marley and Dockerty (3) in the case of SnO_2 samples heated at 1438°K at low oxygen pressure of 0.06 atm for 282 hr. Thus it is possible that in SnO_2 crystals which are heat-treated this way or which are not very pure, the native defects (*e.g.*, oxygen vacancies) may be completely ionized. The deeper level may then be attributed to the second ionized level of the native point defects. Samson and Fonstad (16) recently came to the same conclusion and have assumed that in tin dioxide, oxygen vacancies predominate in a native disorder. Their results will be discussed in more detail below.

The decrease of the donor ionization energy with increasing donor concentration which is evidenced in Table IV is to be expected. This effect is commonly observed in both elemental and compound semiconductors and was explained by Pearson and Bardeen (21) on the basis of the hypothesis of an appreciable electrostatic attraction between electrons and ionized donors, which increases with increasing donor concentration. These authors have obtained the equation

$$E_D = E_o - aN_D^{1/3} \quad [4]$$

from the investigations of boron-doped silicon, where E_o is the donor ionization energy at infinite dilution, and a is a constant.

Fonstad and Rediker's (14) limited data can also be written by an equation of this type, namely

$$E_D = 0.037 - 2 \times 10^{-5} N_D^{1/3} \text{ (eV)} \quad [5]$$

The general dependence expressed by Eq. [4] has also been observed by Marley and Dockerty (3) for SnO_2 crystals heat-treated in oxygen, but these authors found completely different values of E_o and a. The results obtained by Marley and Dockerty are shown in Fig. 5 and may be described by the equation

$$E_D = 0.15 - 8.7 \times 10^{-8} N_D^{1/3} \text{ (eV)} \quad [6]$$

At present, it is difficult to expand on this problem because of the lack of more detailed experimental data.

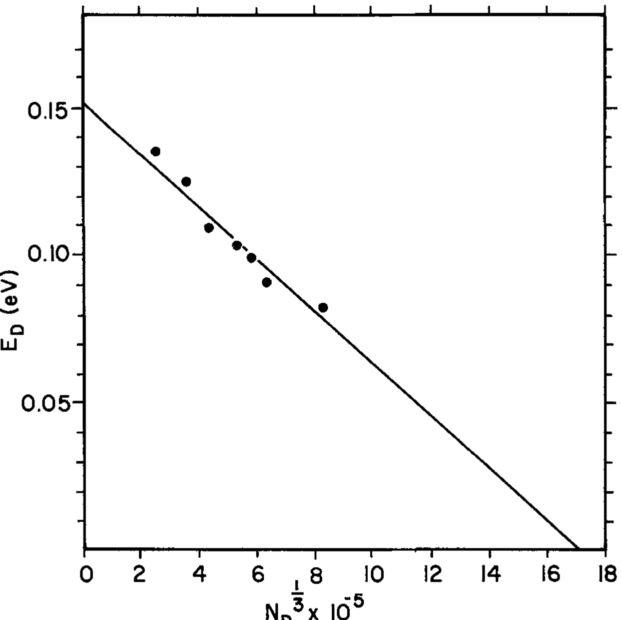

Fig. 5. Donor ionization energy in SnO_2 as a function of donor concentration (3).

The combined data of Hall mobility μ_H *vs.* T for three samples, A, B, and C, investigated by Fonstad and Rediker (14) are shown in Fig. 6. The experimental curves are compared with those obtained from theoretical calculations, assuming either the polar optical scattering of quasi-free electrons or acoustic deformation potential scattering.

The calculations concerning the optical scattering have been carried out on the basis of the theoretical considerations of Eagles (22) and Low and Pines (23)

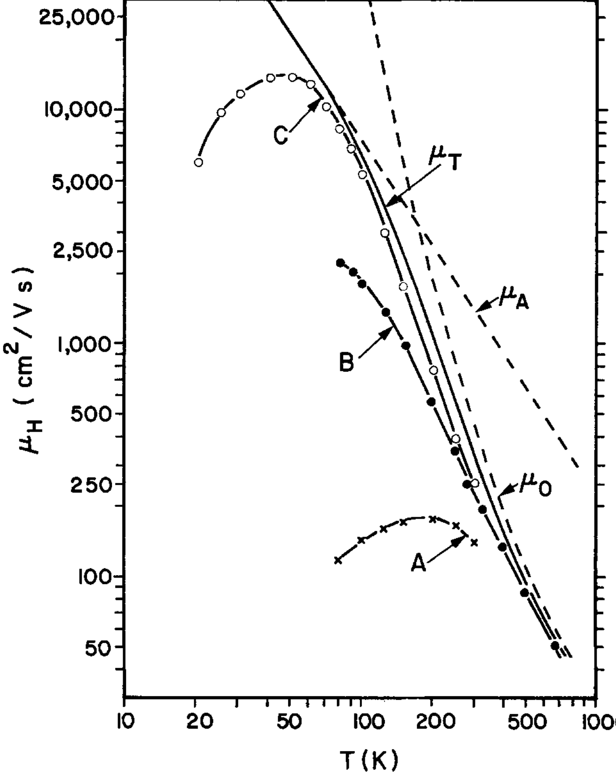

Fig. 6. Hall mobility in SnO_2 single crystals for samples A(×), B(●), C(○) as a function of temperature, and theoretical curves for acoustic deprecation potential scattering mobility (μ_A), polar optical mode scattering mobility (μ_O), and total Hall mobility contribution of the two scattering mechanisms (μ_T).

using the values of frequencies of the longitudinal polar optical modes given by Van Daal (24) and Reddaway (25). The dashed curve labeled μ_o in Fig. 6 is obtained from the equations

$$\mu_o = \frac{1}{\mu_{o1}} + \frac{1}{\mu_{o2}} + \frac{1}{\mu_{o3}} \quad [7]$$

where

$$\mu_{o1} = 1300 \left(\exp \frac{390}{T} - 1 \right) \frac{\text{cm}^2}{\text{Vsec}} \quad [8]$$

$$\mu_{o2} = 495 \left(\exp \frac{515}{T} - 1 \right) \frac{\text{cm}^2}{\text{Vsec}} \quad [9]$$

$$\mu_{o3} = 15.8 \left(\exp \frac{1080}{T} - 1 \right) \frac{\text{cm}^2}{\text{Vsec}} \quad [10]$$

The contribution to mobility from acoustic deformation potential scattering has been calculated on the basis of the theory of Bardeen and Shockley (26). The expression for μ_A is

$$\mu_A = \frac{4.8 \times 10^8}{E^2 T^{3/2}} \frac{\text{cm}^2}{\text{Vsec}} \quad [11]$$

where E is the deformation potential in eV for dilating strain for the conduction band. The dashed curve labeled μ_A in Fig. 6 is obtained if E is assumed to be 8.0 eV.

The total Hall mobility μ_T represented by the solid curve in Fig. 6 is calculated from

$$\frac{1}{\mu_T} = \frac{1}{\mu_o} + \frac{1}{\mu_A} \quad [12]$$

It may be seen from Fig. 6 that the polar optical mode scattering μ_o part predominates above 250°K. Below this temperature the acoustic deformation potential scattering and ionized point defect scattering mechanisms predominate. For the pure sample C with the lowest carrier concentration, the ionized point defect scattering is important except at temperatures below 50°K. Thus, in this case the acoustic deformation potential scattering predominates at temperatures between 50° and 250°K. Similar scattering behavior was also found in SnO_2 single crystals by Nagasawa and Shionoya (5, 9). For the doped sample A with the higher carrier concentration, the ionized point defect scattering already predominates below room temperature. Therefore, the acoustic deformation potential scattering is not observed. This type of scattering appears to be typical for doped SnO_2 crystals also with higher concentrations of impurities (3, 6, 7, 10, 12).

Anisotropies in the conductivity and Hall effect in SnO_2 crystals have been found to be small. At temperatures of 77° and 300°K, the ratio of σ_a/σ_c is 1.0 and 1.2, respectively, and the anisotropy ratio of the Hall scattering coefficient r_a^H/r_c^H is 1.00 and 1.01, respectively.

Pure SnO_2 crystals heat-treated at various temperatures and oxygen pressures.—The influence of heat-treatment at various oxygen pressures on the electrical properties of SnO_2 single crystals has been studied by Marley and Dockerty (3), Nagasawa and Shionoya (12, 13), and Samson and Fonstad (16). The results published by Marley and Dockerty are not discussed in this work because the crystals investigated contained considerable amounts of impurities.

Nagasawa and Shionoya (12) have measured the Hall coefficient and Hall mobility in SiO_2 single crystals as grown and heat-treated in a vacuum of 10^{-5} Torr. The results are shown in Fig. 7 and 8. As can be seen in Fig. 7 for reduced tin oxide, the Hall coefficient is almost independent of temperature. This also holds true for Sb-doped SnO_2 crystals, investigated by Marley and Dockerty (3). Such experimental results may be interpreted satisfactorily in terms of degenerate carrier concentrations in the semiconductor. Figure 8 shows the plots of Hall mobility *vs.* reciprocal temperature for as-grown and reduced SnO_2 single crystals. It is evident that in the temperature range considered, the mobility of conduction electrons in the reduced crystals is governed mainly by the ionized native point defect scattering. Nagasawa and Shionoya (13) have also measured the electrical conductivity in SnO_2 single crystals in high oxygen pressure up to 10 atm. They found that the conductivity decreased remarkably under these conditions. However, the conductivity was not uniform in the crystals. The surface layer was found to have a conductivity much lower than the interior, likely due to the decreased density of oxygen deficiency sites.

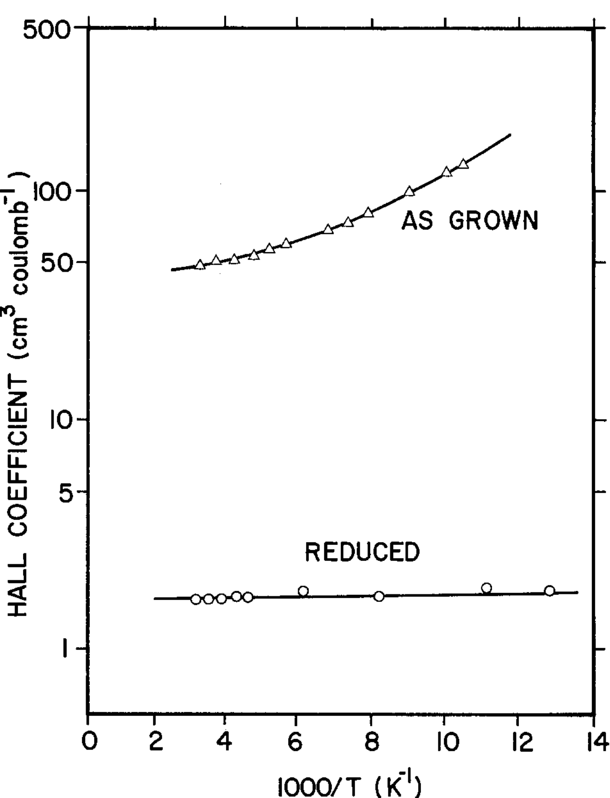

Fig. 7. Hall coefficient as a function of reciprocal temperature for as-grown and reduced SnO_2 single crystals (12).

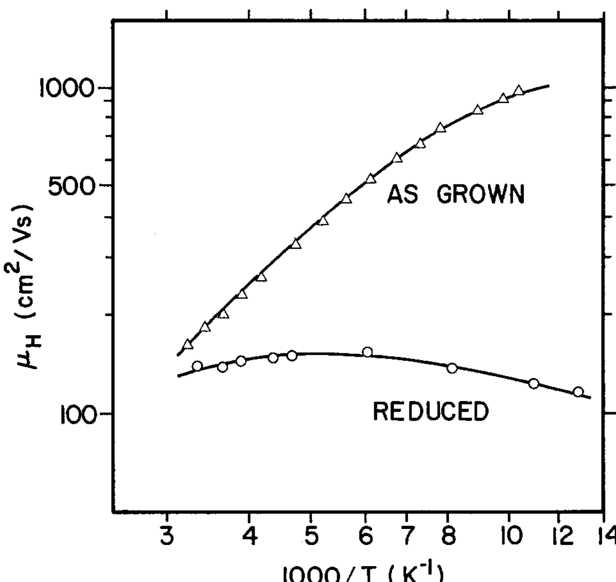

Fig. 8. Hall mobility as a function of reciprocal temperature for as-grown and reduced SnO_2 single crystals (12).

Extensive studies of the variation of the electrical properties of SnO_2 with temperature and oxygen pressure have been carried out recently by Samson and Fonstad (16). The dependence of high temperature conductivity on oxygen pressure in equilibrium conditions found by these authors is shown in Fig. 9. Above 1370°K thermodynamic equilibrium was reached in 5-10 min. Reproducibility above this temperature was excellent. Below 1370°K the time necessary for equilibration was several hours. The curves log σ *vs.* log p_{O_2} have a slope of $-1/6.5$. Therefore, the authors assumed that doubly ionized oxygen vacancies predominate in SnO_2 crystals. [*Cf.* Ref. (1) for the defect structure of SnO_2 crystals.]

Figure 10 shows the results of the Hall effect measurement obtained by Samson and Fonstad in the temperature range from 77° to 300°K on five samples (C, D, E, F, and G) that were annealed at various oxygen pressures and high temperatures and then quenched.

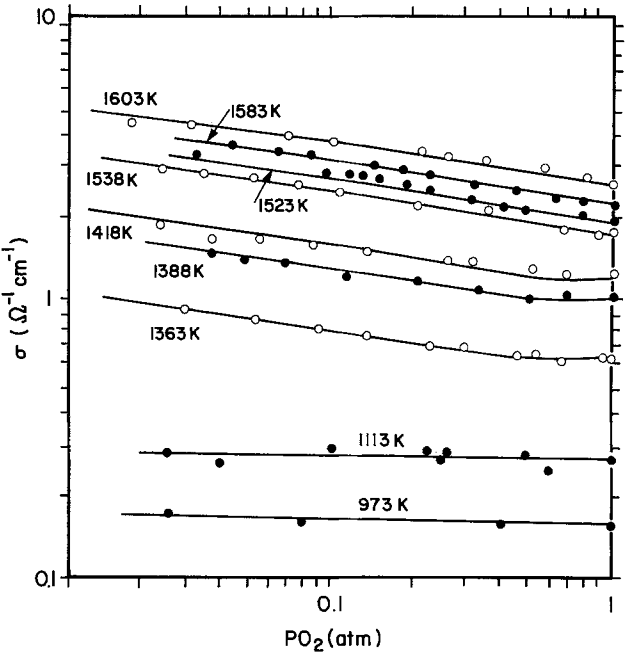

Fig. 9. Electrical conductivity of two SnO_2 single crystals *vs.* oxygen pressure at high temperatures.

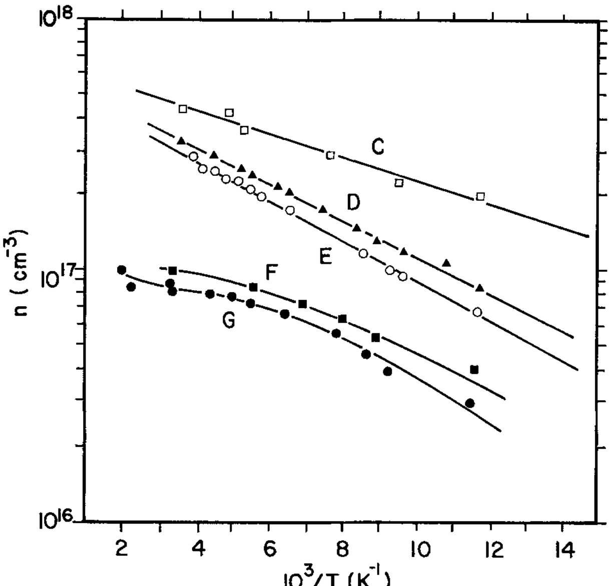

Fig. 10. Conduction electron concentration vs. reciprocal temperature for five samples of SnO_2 heat-treated at various elevated temperatures and oxygen pressures and quenched.

Table V. Specifications of SnO_2 single crystals investigated by Samson and Fonstad (16)

Sample	Annealing temperature (°K)	Oxygen pressure (atm)	Time of annealing (hr)
C	1720	1	14
D	1620	1	14
E	1670	0.21	14
F	1548	1	20
G	1548	1	20

The annealing conditions are listed in Table V. On the basis of analysis of the temperature dependence of conductivity and Hall coefficient, the authors found two donor levels in SnO_2; one at 30 meV and the other at 150 meV. The shallow level has been attributed to the first ionized state of the oxygen vacancy, and the deeper level has been attributed to the second ionized level of the oxygen vacancy.

Fonstad and Samson have found, as have Nagasawa and Shionoya (13), that the heat-treated crystals have high resistivity surface layers of 10^5 ohm-cm or more while the bulk resistivity is about 0.5 ohm-cm. Fonstad and Samson suggested that this high resistivity layer arises from doping by the various ceramic parts in the furnace. It is more likely, however, that this high resistivity surface layer is due to the near-perfect stoichiometry of the crystal in the surface region, which contains few native defects (*i.e.*, oxygen vacancy).

Button and Fonstad (15) have studied submillimeter cyclotron resonance in SnO_2 crystals. They found the conduction-band effective-mass tensor components to be $m_\perp^* \simeq 0.299\ m_0$ and $m_\parallel^* \simeq 0.234\ m_0$. The density-of-states effective mass was found to be 0.275 m_0.

The Seebeck effect in SnO_2 crystals has also been measured by Marley and Dockerty (3) and by Morgan and Wright (6). The results obtained by Morgan and Wright for two samples, having different concentrations of conduction electrons, are shown in Fig. 11. The charge carrier concentrations for specimens 1 and 2 are 8.8×10^{19} and 8.2×10^{18} cm^{-3}, respectively. However, the samples contain large amounts of impurities; therefore, the measurements cannot be interpreted satisfactorily.

Sintered Materials

The electrical properties of sintered tin oxide have been investigated recently by Van Daal (10) and Matthews and Kohnke (27).

The measurement results obtained by Van Daal are presented in Fig. 12 and 13 and the specifications of the samples are given in Table VI. Measurements were performed in 1 atm of oxygen pressure (samples 3 and 6) and in argon with a partial oxygen pressure between 10^{-6} and 10^{-5} atm (samples 1, 2, 4, 5, I). At temperatures below 50°K, the temperature dependences of carrier concentration and conductivity indicate an impurity conduction mechanism. This may be seen from the plots in Fig. 12. The conclusion is also supported by the temperature dependence of Hall mobility (Fig. 13). In the intermediate temperature range between 50° and 700°K, it seems that conduction is due to partially compensated donors, probably originating from impurities. Van Daal found that the ionization energy of donors in this temperature range is at most

Table VI. Main impurity content in units of 10^{17} cm^{-3} for the SnO_2 samples (10)

Sample	Al	B	Fe	Mg
1	2	<8	10	15
2	2	<8	1.5	7
3	5	40	8	20
4	3	<8	15	20
5	50	<8	16	130
6	3	80	3	12
I	360	8	18	12

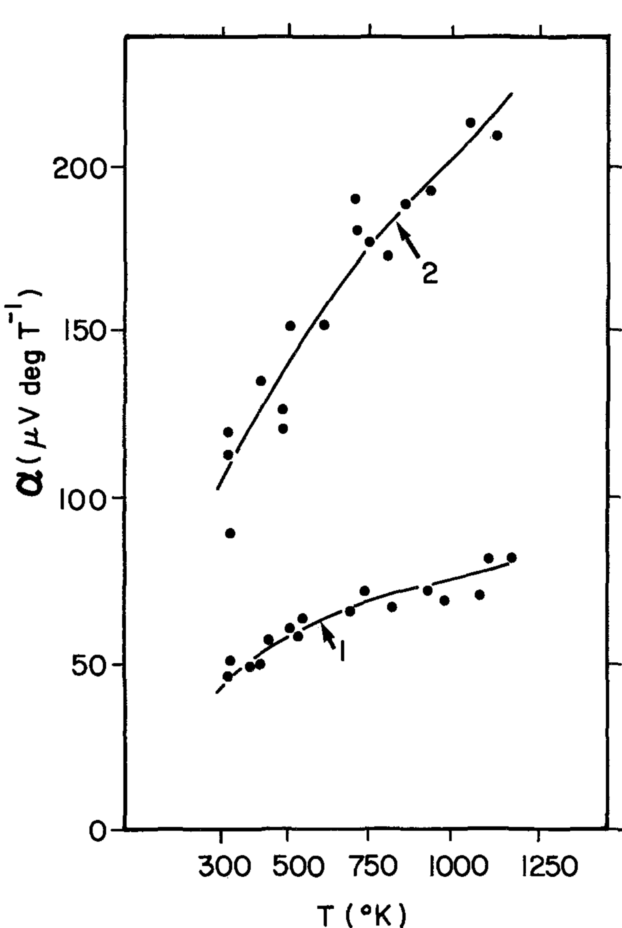

Fig. 11. Seebeck coefficient in SnO_2 crystals as a function of temperature for two samples having different concentrations of conduction electrons: 1, 8.8×10^{19} cm^{-3}; 2, 8.2×10^{18} cm^{-3} (6).

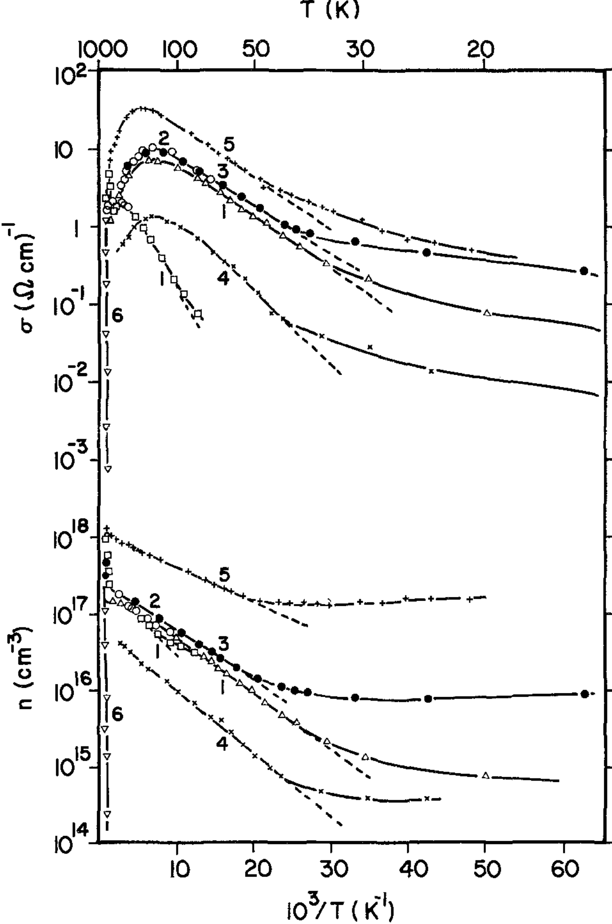

Fig. 12. Electrical conductivity σ and conduction electron concentration n as a function of reciprocal temperature for single crystal, I, and polycrystalline, 1-6, SnO_2 (cf. Table VI). Samples 1, 2, 4, 5, and I were measured in an argon atmosphere, and samples 3 and 6 in 1 atm pressure of oxygen (10).

0.01 eV and that the compensation varies between about 90 and 99%. The impurities were found to be B and Fe. The author assumed that Mg probably gives rise to deep donor levels. Above 700°K, extra donors may be introduced in the tin oxide resulting from diffusion of impurity atoms from the surrounding into the sample. At high temperatures these donors presumably are native defects arising from the reduction of SnO_2. It seems that for sample 6, the conduction electron concentration is mainly due to native defects, which becomes highly compensated. The decrease of Hall mobility for sample 6 is probably due to a grain boundary effect (28).

The decrease of Hall mobility with increasing temperature starting at about 100°K in Fig. 13 is certainly due to lattice scattering, either polar optical modes or acoustic modes. The temperature dependence of mobility between 600° and 1600°K is in agreement with the weak coupling theory for polar scattering [broken curve (29)]. The characteristic temperature of 1050°K was used to calculate the broken curve.

Matthews and Kohnke (27) have investigated the influence of chemisorbed oxygen on the electrical conductivity of Zn-doped sintered stannic oxide. The samples were sintered at 1730°K for 6 hr. In Fig. 14 the temperature dependence of dark current conductivity in samples subjected to a variety of heat-treatment procedures is shown. The dark electrical conductivity has been measured as a function of temperature at fixed ambient gas pressures in surface equilibrium condition. The specifications of the samples and measurement conditions are listed in Table VII. The maximum temperature used in the fixing process was on the order of 373°K which made it unlikely that any bulk changes took place in the specimen.

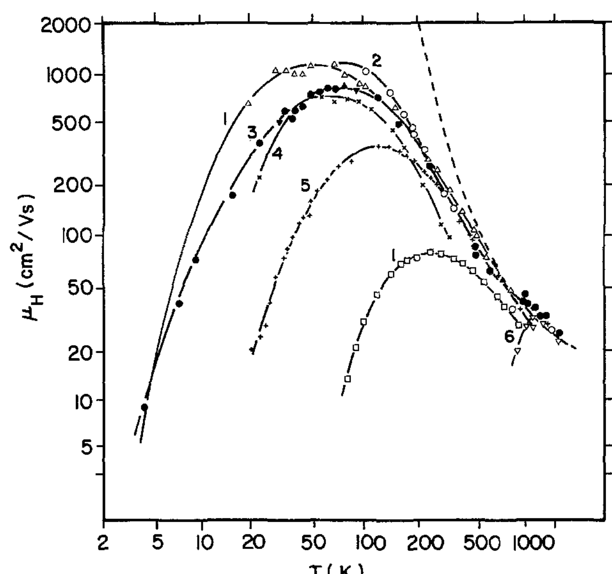

Fig. 13. Temperature dependence of Hall mobility for the same samples of SnO_2 as in Fig. 12. The broken curve represents the temperature dependence of the drift mobility in the case of polar scattering of quasi-free electrons by longitudinal optical modes with the characteristic temperature of 1050°K (10).

Because the ionic sizes of Zn^{2+} and Sn^{4+} are nearly identical (0.74 and 0.71Å for Zn^{2+} and Sn^{4+}, respectively), one can expect that during the sintering proc-

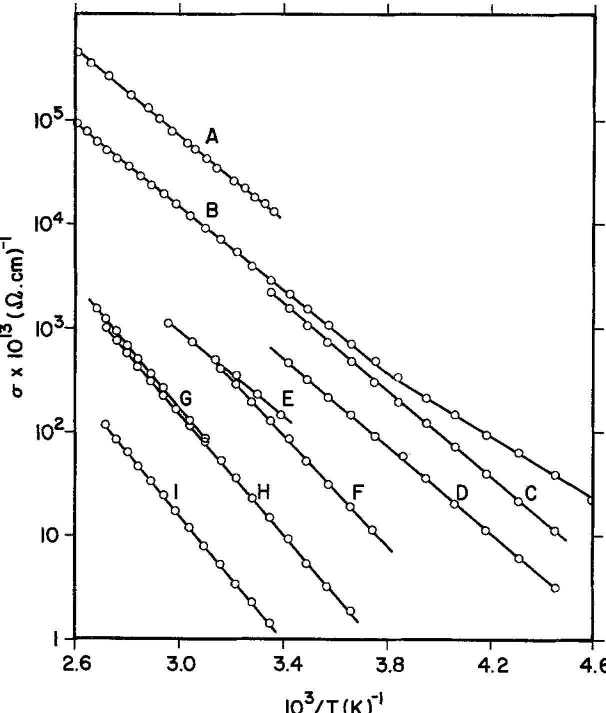

Fig. 14. Electrical conductivity of Zn-doped polycrystalline SnO_2 as a function of the reciprocal temperature after various fixing procedures [*cf.* Table VII (27)].

ess Zn^{2+} are substituted in Sn^{4+} sites. This would give rise to a site imbalance which may be relieved either by the creation of oxygen vacancies or by the introduction of interstitial cations near the Zn_{Sn}^{2+} centers. Probably both processes took place in the experiments. The authors have assumed that Zn-doped SnO_2 sintered samples are of n-type semiconductors with a high degree of bulk compensation and that variations in conductivity after different treatments are the result of additional compensation associated with changes in the surface concentration of chemisorbed oxygen atoms (30). Here again it is possible that the very low conductivities (samples D-I) were caused by rendering the material highly stoichiometric by heat-treatment in air.

Films

The most useful form of SnO_2 is in thick or thin film form. The material is suitable for transparent conductive coatings, electrical resistors, and other devices. The preparation and properties of such films are described in patents (31-51), technical literature (52-53), and in Part I of this review.

Comprehensive studies of SnO_2 films have been carried out by Aitchison (54). He found that stoichiometric tin oxide films have a high resistivity (about 10^8 ohm-cm) at room temperature. The addition of atoms with a valence higher than four, *e.g.*, Sb, has a similar effect to the reduction of SnO_2 films and causes a significant increase in conductivity. Instead, the addition of trivalent atoms, *e.g.*, In, has the opposite effect, *i.e.*, it causes a decrease in conductivity.

Ishiguro *et al.* (55) have found that the conduction electron concentration in SnO_2 transparent films is between 10^{19} and 10^{20} cm^{-3} and the Hall mobility is about 30 cm^2/Vsec. The authors assumed that coulomb scattering of quasi-free electrons by impurity ions was the predominant scattering mechanism in the transparent conducting films. Similar values of quasi-free electron concentrations were obtained by Arai (56).

Imai (57) studied the electrical properties of SnO_2 films which were deposited on fused quartz plates. He measured electrical conductivity and the Hall effect in the temperature range between liquid nitrogen and room temperatures. In this temperature range the properties were found to be reproducible. Irreversible changes occur only when the temperature is raised above 470°K in vacuum. In Fig. 15 the results of conductivity σ and Hall coefficient R_H measurements are shown. As can be seen from the figure, both σ and R_H increase slightly with temperature, and therefore one can assume that the electrons in the SnO_2 specimens are degenerate.

Kuznetsov (58) has obtained dielectric SnO_2 by the hydrolysis of an ether-alcohol solution of $Sn(OC_2H_5)_4$, and he grew semiconducting films by the hydrolysis of $SnCl_4$, oxidation of metallic tin, and decomposition of $SnCl_2$. The electrical conductivity of dielectric SnO_2 formed in this way was 10^{-15} $ohm^{-1}cm^{-1}$ at room temperature. Kuznetsov found that the electrical conductivity of semiconducting SnO_2 films obtained by hydrolysis of $SnCl_4$ does not depend on film thickness

Samples 2 and 3 were obtained by spraying the solution $SnCl_4$ + 1 m/o $SbCl_5$ and $SnCl_4$ + 3 m/o $InCl_3$, respectively (57).

between 500 and 2500Å. He also measured the effect of heating his films in air. In Fig. 16 the dependence of conductivity on the time of heat-treatment is shown. At temperatures up to 500°K the conductivity remains unchanged, while at higher temperatures the conductivity was found to increase first and then to decrease drastically. The author has attempted but could not explain the observed changes satisfactorily. The introduction of Sb however, was found to improve the stability. This is shown in Fig. 17 for two samples at 1070°K.

In Fig. 18 the results of conductivity measurements carried out by Koch (59) are shown. He found that for pure SnO_2 films, with values of σ between 10^{-1} to 3×10^2 (ohm cm)$^{-1}$ (electron concentration n between 10^{18} to 2×10^{20} cm^{-3}) the conductivity at room temperature is proportional to $n^{4/3}$, namely

$$\sigma = \left(0.35 \pm {0.15 \atop 0.08}\right) \times 10^{-24} n^{4/3} \text{ (ohm-cm)}^{-1} \quad [13]$$

This is in accordance with the theory of Howarth and Sondheimer (29) for degenerate electron gas. Koch also found that at room temperature, the quasi-free electrons are scattered mainly by longitudinal optical modes.

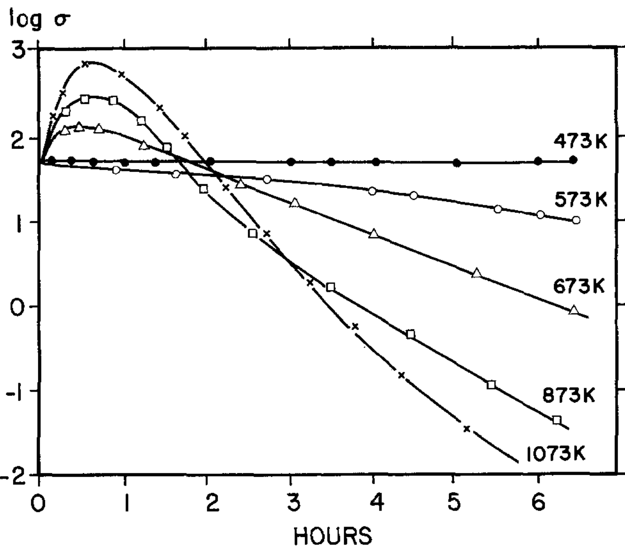

Fig. 16. The influence of heat-treatment in air on electrical conductivity of SnO_2 films (58).

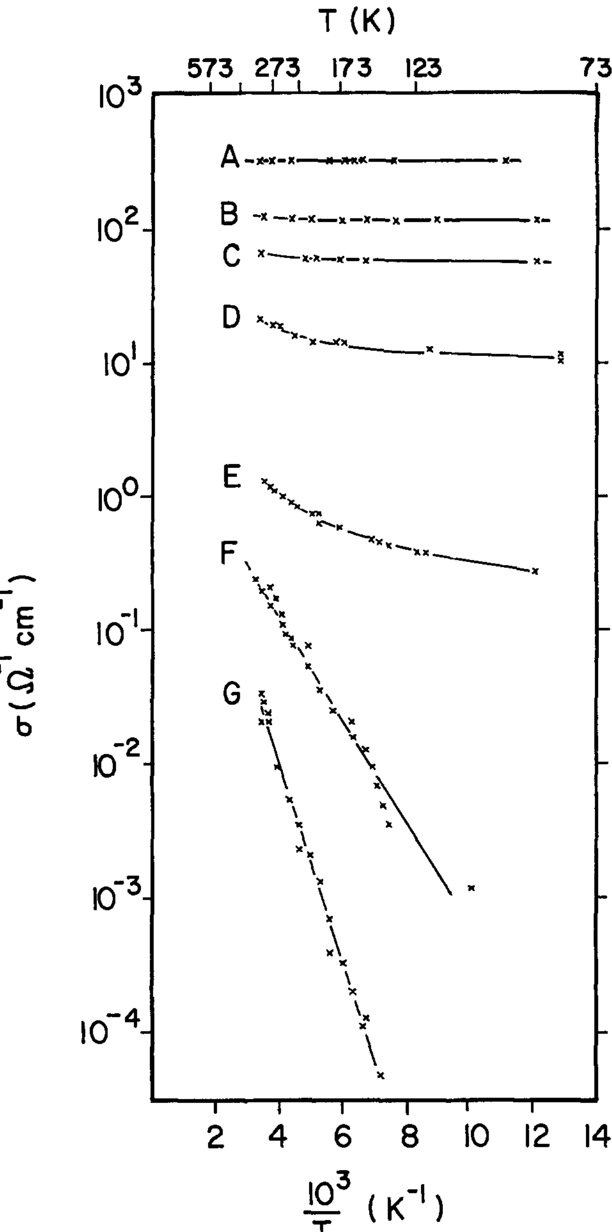

Fig. 18. Temperature dependence of conductivity for various SnO_2 films (59) with electron concentration n ranging from 10^{18} (curve G) to 2×10^{20} cm^{-3} (curve A).

The temperature dependence of conductivity obtained by Inagaki *et al.* (60) for SnO_2 films with different amounts of antimony is presented in Fig. 19. The Sb concentration listed is the percentage of $SbCl_3$ (wt)/ $SnCl_4 \cdot 5H_2O$ (wt) in the solution used for film deposition. These authors have also measured films below 100°K and found the slope to be negative.

Bartholomew and Garfinkel (61) have investigated the electrical properties of stannic oxide films grown by the reaction

$$SnCl_2 + O_2 \rightarrow SnO_2 + Cl_2$$

They observed that surface and volume resistivities of such films change slightly when heat-treated in the temperature range below 470°K. However these data have not been reproducible from sample to sample.

Nishino and Hamakawa (62) have studied the electrical properties of $Si\text{-}SnO_2$ heterojunctions. Tin oxide films were deposited by the evaporation of tin on a silicon substrate and the oxidation of tin films in a furnace. They found that such SnO_2 films show the properties of a degenerate n-type semiconductor. The current-voltage characteristics of $Si\text{-}SnO_2$ n-n hetero-

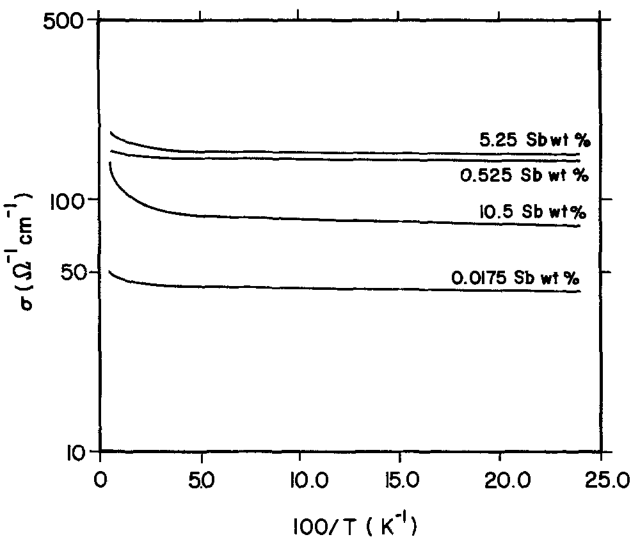

Fig. 19. Electrical conductivity of SnO_2 films with different Sb contents as a function of reciprocal temperature (60).

junctions was found satisfactory for the purpose of rectification.

Elliott *et al.* (63) have measured the charge carrier concentration for a variety of SnO_2:Sb specimens as a function of donor concentration. They found disparities which they attributed to chlorine impurities in the samples.

Aboaf *et al.* (64) have measured the conductivity and Hall effect in SnO_2 films deposited in various ambients at room and liquid nitrogen temperatures. All films were found to be of n-type, the charge carrier concentration being about 10^{20} cm^{-3}. The conductivity and charge carrier concentration was the same at the two temperatures indicating that impurity centers were almost completely ionized at 77°K. The conductivity of the films deposited in nitrogen was weakly dependent on the temperature of deposition. The conductivity of these films annealed in oxygen at 1233°K for 1.5 hr decreased by an order of magnitude. The authors ascertained that the changes in conductivity and charge concentration were due not only to variation of deviation from the stoichiometric composition but also to change in chlorine content.

Lepic (65) investigated SnO_2 films doped with boron and antimony in the temperature range from 213° to 448°K. He found that electrical conductivity behavior is governed mainly by quasi-free electron scattering. In samples heavily doped with boron, the scattering by ionized point defects dominates, but generally the films exhibit a complicated interplay of acoustical and optical phonon scattering. It should be noted that the conductivity of pure SnO_2 films may range over several decades (*e.g.*, Fig. 18) for a given temperature, as a function of sample preparation or postdeposition treatment. It is thought that this variation is due to the variability of stoichiometry of the film, similar to that found in the surface layer of single crystals and in sintered materials, and not due to impurities. This idea is based on the authors' work with SnO_2 film, which showed large irreversible changes in conductivity when heated in oxygen gas at various pressures.

Conclusions

Pure single crystals of SnO_2 show two donor levels; a shallow one at 30 meV and a deeper one at 150 meV. These donor levels can be attributed to first and second ionization energy of oxygen vacancy (or interstitial tin ions). Donor ionization energy, E_D decreases with increasing donor concentration, N_D, according to the equation $F_D = E_o - aN_D$, where a is a constant. Degenerate crystals may be obtained either by heavily doping with antimony or by heat-treating in vacuum on the order of 10^{-5} Torr. Heat-treating in air or oxygen produces crystals with high resistivity surface layers of 10^5 ohm-cm or more while the bulk resistivity remains at about 0.5 ohm-cm.

Above room temperature the conduction electrons are scattered mainly by the polar optical mode. Below this temperature the electrons are scattered both by the acoustic deformation potential and ionized point defects (native and foreign atoms). For the pure crystals, the ionized point defect scattering is important at temperatures below 50°K. Thus, in this case, the acoustic deformation potential scattering dominates between 50°K and room temperature. For heavily doped or reduced crystals, only ionized point defect scattering dominates below room temperature.

The behavior of electrical conductivity, quasi-free electron concentration, and Hall mobility in sintered samples of SnO_2 as a function of temperature is similar to that of impure single crystals. In-doped SnO_2 sintered specimens are of n-type with a high degree of bulk compensation. Heat-treatment of such samples at temperatures up to 374°K causes variations in conductivity due to additional compensation associated with changes in the surface concentration of chemisorbed oxygen atoms.

The electrical properties of SnO_2 films depend on the method of preparation and subsequent heat-treatment in various ambients at temperatures above 470°K. Below this temperature the specimens are rather stable.

Conducting transparent films have a quasi-free electron concentration of 10^{18}-10^{20} cm^{-3}, and mobility about one order of magnitude smaller than in single crystals. The electrical properties of SnO_2 films have not been characterized satisfactorily due to the variations caused by sample preparation and purity.

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

This paper reviews some of the principal applications of electrochemistry to fabrication of semiconductor devices. Some of the electrochemical techniques used in fabrication of early semiconductor devices, such as chemical polishing, plating of contacts, dislocation etches, and junction delineation techniques continue to be used in manufacturing of present-day devices. Principal newer uses of electrochemistry are in anisotropic etching of patterns in single crystal Si, in preferential etching of layers of a certain conductivity type or doping level without dissolution of an underlying (or adjacent) layer of Si of different type or doping level, in anodization of aluminum metallization on Si devices, and in Au plating for conductive layers in several types of silicon devices. A wide variety of other electrochemical techniques are being used in material and device characterization, and in fabrication of developmental-type devices.

Electrochemical techniques were extensively used in the 1950's to manufacture semiconductor devices. The technologies being used in 1975 continue to employ, in somewhat modified form, some of the principles and techniques developed in the 1950's. The purpose of this paper is to review briefly some of the principal types of electrochemical techniques which were used in early semiconductor device fabrication, and to then describe the types of electrochemical techniques presently being used in fabrication of semiconductor devices.

* Electrochemical Society Active Member.
Key words: integrated circuits, silicon devices, chemical etching, materials characterization.

In the early 1950's, the most commonly manufactured semiconductor devices were diodes, rectifiers, and transistors (1-4). Small-signal transistors were most commonly pnp alloy-junction bipolar germanium (1, 3, 5). The chips used were chemically polished, alloyed, and then a chemical polish was used for clean-up etching (3). Subsequently, electrolytic clean-up etching in alkaline solutions was introduced; in this process the emitter and collector leads were biased positively and injection of minority carriers (holes) into the base resulted in electrolytic etching of a shallow moat around the periphery of the emitter and collector electrodes.

In the early 1950's, the process of jet electrolytic etching for producing narrow-base devices was introduced (6). Acidic fluoride solutions were used, with intense light applied to generate the minority carriers required to etch n-type Ge. Emitter and collector contacts were formed by jet electroplating of In metal on Ge to form surface barrier-type contacts. Subsequent variations included In and Cd microalloyed types in Ge, and jet-etched Si transistors (7). Leads were attached by soldering of wires to which In or Sn solder alloys had been plated in molten form (8).

Electrochemical techniques were also extensively used in characterizing early semiconductor material and device structures. Examples included etching and staining techniques to reveal junction locations (9, 10), and etching techniques to delineate dislocations (11) and other crystallographic imperfections.

The introduction of vapor phase Ge homoepitaxy and improved Si technology led to substitution of batch (wafer) processing techniques for processes in which individual device chips were handled. As a result, many of the previously used electrochemical techniques were no longer required. The evolution of planar Si integrated circuits from relatively simple arrays to very complex circuits with requirements for vastly improved cost, performance, and reliability has led to the reintroduction of a number of electrochemical techniques. Principal newer uses are in anisotropic etching of patterns in single crystal Si, in preferential etching of layers of a certain conductivity type or doping level without dissolution of an underlying layer of Si of different type or doping level, in anodization of aluminum metallization on Si devices, and in Au plating for conductive layers in several types of silicon devices. A wide variety of other electrochemical techniques are being used in material and device characterization, and in fabrication of developmental-type devices.

The theory and principles of electrochemistry of semiconductors have been studied in detail since the early 1950's, and available information has been reviewed in a number of articles (12-15) and books (16-20).

Chemical Polishing

Chemical polishes were extensively used in early semiconductor device fabrication, including removal of work damage from lapped slices, mesa etching, and clean-up etching of Ge and Si alloy-junction devices. Chemical polishes for Ge and Si generally contain an oxidizing agent plus a complexing agent to increase solubility of the reaction products. Commonly used solutions contain nitric acid and hydrofluoric acid, respectively, to accomplish these functions.

A number of years ago, silicon wafers were principally finished by chemical polishing or by mechanical polishing. More recently, a number of techniques for chemical-mechanical polishing (21-24) have been in widespread use. One process employs a solution containing copper ions plus fluoride ions (22, 25, 26). Another type of process employs a suspension of silica particles (21, 22, 27) in an aqueous solution adjusted to a suitable alkaline pH. Chemical-mechanical polishing processes to some extent combine the benefits of both mechanical and chemical polishing, providing relatively flat wafers similar to those obtained by mechanical polishing, with a relatively low level of mechanical damage. After chemical-mechanical polishing, silicon wafers are thermally oxidized prior to device fabrication (the thermal oxidation is generally performed to obtain the oxide mask which is then patterned for planar diffusion). The oxidation process results in conversion of approximately 0.5 μm of the silicon surface to SiO_2, and thus serves as a final etching step. Chemical-mechanical polishing techniques have also been used with compound semiconductors (28, 29).

Methods, solutions, and applications for chemical polishing of germanium, silicon, and a wide variety of compound semiconductors such as GaAs (30, 31) have been described (32-36).

Chemical etchants continue to be used to prepare mesa-type geometries in high voltage devices. They are also used to remove mechanical damage in beveled high voltage structures.

Anisotropic Etching of Silicon

Anisotropic (crystallographically preferential) etching of (100) orientation Si wafers is widely used to permit close control of lateral etching dimensions in silicon integrated circuits (37, 38). Etching solutions and conditions are employed which result in dissolution of the Si in (100) directions at a rate which is several orders of magnitude higher than the rate in the (111) directions. Anisotropic etching through a patterned SiO_2 mask produces sharply defined V grooves, with the edges [(111) planes] at an angle of 55° from the (100) surface of the wafer, and the depth determined by the width of the opening in the oxide mask used to define the pattern (39). Typically, alkaline solutions containing alcohol are used (40, 41).

Anisotropic etching of the silicon is used to permit fabrication of high density integrated circuits, and to improve performance. Anisotropic etching has been used to manufacture a variety of Si devices (42), including V-groove isolation structures with Ti-Pt-Au metal lines crossing relatively shallow oxidized V grooves (43, 44), dielectric-isolated circuits in which edges of the oxide-isolated single crystal islands are delineated by anisotropic etching (45), air-isolated beam-lead circuits, Si-on-sapphire integrated circuits (46, 47), and beam-lead sealed-junction transistors and circuits in which the chip separation is accomplished by anisotropic etching. In high density oxide-isolated integrated circuits, (100) orientation silicon wafers are etched with a pattern of V grooves, followed by oxidation and subsequent deposition of a relatively thick layer of polycrystalline silicon. The wafers are then lapped and polished to provide single crystal regions of silicon, each surrounded by a wall of thermally grown silicon dioxide (44, 45, 48, 49).

Anisotropic etching has been used to produce a pyramidal-type surface texture on silicon solar cells, thus eliminating the need for an antireflection coating and improving cell efficiency (50, 51). Anisotropic etching of silicon has also been used to prepare thermal printers based on heating of transistor-resistor elements in silicon regions separated by V grooves (52), and to fabricate nonblooming vidicons (53). Developmental-type applications of anisotropic etching have included preparation of silicon diffraction gratings (54) and preparation of substrates of controlled topography for assessment of edge coverage of vapor-deposited films. Anisotropic etchants also have been used to produce etch figures which permit crystallographic orientation to be accomplished optically (55).

A considerable amount of information has been published on the effects of etchant composition, substrate doping level (41, 56), and etching conditions on rate of etching of various orientations of silicon (37, 40, 57-62). Anisotropic etching of germanium has also been described (63).

Selective Etching

A number of new types of silicon integrated circuits are based on procedures which etch a layer of silicon of one conductivity type, but do not etch an underlying layer of a different conductivity type, or of a different dopant concentration. Both chemical (64, 65) and electrochemical techniques (66-74) have been used for this type of application.

One type of electrochemical technique which is being used to fabricate developmental structures is to perform electrochemical etching under conditions such that an n^+ layer is dissolved but an underlying layer of n-type Si is not attacked. In this technique, electrolytic etching proceeds until all of the n^+ material is dissolved, but does not etch the n-type layer if the donor level is less than approximately 2×10^{16} atoms/cm^3. Typical conditions would employ 5% aqueous HF

solution (66, 69), and total darkness. Substrates and conditions must be employed which do not result in localized avalanche breakdown in the n-type silicon (70, 75, 76).

An example of an application is the process for obtaining thin single crystal silicon layers on an insulating substrate (67, 72, 77). In one case, the final structure consists of a thin single crystal layer over an SiO_2 layer over a thick supporting layer of polycrystalline silicon (67, 72). Such structures would be used in some of the same applications as silicon on sapphire.

Several types of processes for controlled electrochemical etching of wafers have been described, including electrolytic etching to remove p-type layers from pn substrates, and to remove n^+ layers from n^+n substrates. Another variation is to apply an external bias to a structure such that chemical etching of one type of layer occurs, but the process stops when the underlying layer is reached (68). Etch rate ratios for active *vs.* passive regions of greater than 200:1 have been obtained (68).

Alkali-alcohol-type etchants have been shown to etch only n-type silicon in samples containing pn junctions. Chemical etching techniques in which selected etchants dissolve Si of one doping level, with relatively little attack on an underlying (or adjacent) Si layer of different doping level, have also been used to prepare specialized device structures.

Diffusion, Anodization, and Passivation

The process of obtaining doped layers in silicon devices by diffusion from conventional sources, whether based on gas sources, solid wafer sources, doped oxide, or spin-on techniques, embodies essentially chemical or displacement plating, in that the silicon wafer at high temperatures reduces an oxide of the dopant at the oxide-silicon interface. Examples include borosilicate, phosphosilicate, and arsenosilicate glasses.

Anodization has been used to form capacitors in silicon linear integrated circuits. More commonly, thermal oxidation is used for that purpose at present. Much information has been published on anodization of Si (78-80).

Anodization of a number of III-V compounds has also been used to form overlying oxide layers. With indium antimonide detectors, for example, anodization has been used to improve surface-related electrical characteristics. With gallium arsenide, anodized layers have been used as a mask for subsequent diffusion (81). Anodization of GaP and Ga(AsP) has also been studied (82, 83). Properties of anodic oxides of InSb (84) and of GaAs (85-88) have been described. Anodic etching has been used to fabricate GaAs diodes (89).

Electrophoresis (deposition of charged, suspended particles from a liquid onto a surface of opposite polarity) is being used to selectively deposit glass particles on silicon power device surfaces, with the deposited glass subsequently fused to form a smooth, patterned layer of passivating glass in grooves or at the edge of etched mesas (90). For these applications the frit is generally a lead borosilicate-type glass, and the deposit, after fusion, may be 10-30 μm thick.

The process of anodization of silicon under conditions which result in a film of porous elemental silicon (91), followed by oxidation, has been used to obtain special patterned oxidized structures with absence of steep topographic steps (74, 92, 93). Anodization of silicon to form a thick porous oxide has also been used to obtain isolated integrated circuit elements (94).

Device Metallization and Processing

The electroless plating of nickel, which was used for electrodes in early transistor types, continues to be used for metallization of certain power silicon devices (90, 95). One technique employs chemical (galvanic) plating of noble metals on exposed silicon contact regions to attain catalyst films for initiation of electroless Ni plating (95). Electroless plating has also been used to form ohmic contacts to certain III-V compounds (95).

Anodization of Al has been used to delineate patterns of metal in multilevel-metallized integrated circuit arrays (96-105). In one process the first level Al metallization is selectively anodized, with regions which are to remain Al metal masked by a photoresist pattern. The anodization process, while producing a volume of oxide somewhat larger than that of the aluminum metal from which it was formed, results in a surface topography which is free of steep steps, and is not difficult to cover with delineated lines in the second level metallization pattern. Anodization has also been used to delineate tungsten (106) and platinum (107) patterns, and to trim thin film resistors (108).

Anodization of aluminum metallization on silicon devices has been employed to form a thin anodic layer over Al conductors to attain beveled edges (109), and to decrease susceptibility of the aluminum to hillock formation (110) or to failure due to electromigration (current-induced mass transport) (111-113).

Gold plating is extensively used to deposit layers which are part of the metallization system in silicon devices, including both beam-lead-type devices (114) and other types of silicon devices with gold metallization systems (90, 115). Typically, the metal system is titanium-platinum (or titanium-palladium) deposited by vacuum techniques, followed by application of photoresist patterns and buildup, locally, of gold by electrodeposition in unmasked areas. Plating solutions and deposition conditions must be maintained to assure close control of lateral spreading of the resist-defined deposited gold layer (116) and of purity, hardness, and roughness of the gold (117-121). Jet plating techniques have been applied to permit use of higher current densities (122, 123). Electroless gold deposition techniques have also been shown to be feasible for fabrication of beam-lead devices (124, 125). Electroplating has also been used to form raised pads for flip chip or other wireless simultaneous bonding approaches (126, 127).

Electroplating is very widely used in preparation of lead frames, headers, studs, and other parts for assembly and packaging of semiconductor devices (95, 126). In preparation of lead frames for semiconductor devices, nozzles are sometimes used to direct the plating solution to those areas where a spot of electrodeposited gold is desired (128). While masking is sometimes used, it is possible to adjust conditions to achieve well-defined localized deposits without masking (128).

Electrochemical Techniques for Control of Semiconductor Device Manufacturing Processes

In addition to the direct use of electrochemical processes in fabrication of semiconductor devices, electrochemical processes are also extensively used in the characterization and evaluation of semiconductor materials and device structures, and in related processes. For example, several types of special etchants are widely used to define dislocations in silicon (129-132), germanium, gallium arsenide (133, 134), gallium arsenide-phosphide, indium antimonide, and other semiconductors (132). For silicon, Dash etch (11) was extensively used in early device fabrication. To a large extent Sirtl etch (135, 136) and a modified etch developed particularly for (100) silicon (137) have supplanted the earlier etchants (130, 131, 138).

One of the most widely used control methods for determining the depth of junctions in semiconductor device manufacturing today is based on angle lapping and staining techniques (138). While several refinements to the techniques have been made, the basic techniques are similar to that developed for early germanium and silicon transistors. Special etching solutions are also used to delineate high-low junctions in silicon, thus permitting determination of the depth of diffusion into substrates or determination of the thick-

ness of epitaxial layers (32). Etching techniques for revealing junctions in compound semiconductors such as PbS (139) have also been described. In general, junction delineation techniques depend on the difference in the electrochemical potential existing between p-type and n-type regions of the semiconductor under the illumination conditions employed. Somewhat similarly, the mechanism by which dislocation etchants define dislocations is based on the fact that localized, defective regions become anodic whereas more nearly perfect surrounding regions become cathodic in the etchant. Thus, in general, less perfect regions etch more rapidly than high quality crystalline regions. Etchants are also used to reveal resistivity striations (38, 140-142) and swirls in silicon and in other semiconductor materials. Copper displacement plating has been used to delineate imperfections in polished silicon substrates (143).

Reverse osmosis (application of pressure to an aqueous solution in contact with a semipermeable membrane) is being used in purification of water used in semiconductor device processing (144-146). The measurement of stability of thermally grown oxides to determine alkaline ion content is essentially an electrochemical process, with alkali ions moving in the amorphous silicon dioxide layer at temperatures such as 300°C in an electric field. Electrochemical processes (147), such as copper plating, electrophoretic decoration, electrolytic etching, and use of liquid crystal techniques (148) have also been used to assess the integrity of various types of dielectrics in semiconductor devices (149).

Electrolytic etching has been used to reveal dislocations in emitter and base regions of diffused silicon transistors (150). Anodic decoration techniques have also been used (151, 152) to reveal defects in devices.

One technique for profiling diffused layers in silicon is based on successive anodization followed by etching and measurement of sheet resistivity (153). This process is still being used in laboratory studies of profiles of diffused or ion-implanted structures. An electrochemical technique for automatic depth profiling of gallium arsenide has recently been described (154).

The prevention of corrosion of metallization materials in semiconductor devices constitutes a very important application of electrochemical principles. In the case of aluminum-metallized silicon devices, both cathodic and anodic corrosion have been shown to lead to electrical opens (155-159). With devices containing gold metallization, gold dendrites formed in humid atmospheres can produce shorts between conductors (118, 120, 158-163).

Conclusions

Some of the early applications of electrochemistry for semiconductor device fabrication continue to be used, and in some cases almost in the same way as in the 1950's. In other cases, improvements and extensive modifications have been made. Some of the early applications, such as in germanium devices and in nonoxide-passivated silicon devices, have been supplanted by the use of other types of devices, primarily oxide-passivated silicon devices. Principal newer uses of electrochemistry are in anisotropic etching and preferential etching of certain layers of silicon, and in gold plating for conductive layers of metallization in several types of silicon devices.

Many of the early electrochemical techniques used for characterizing semiconductor materials and device structures, such as junction delineation techniques and dislocation etches, continue to be used in modified form in present-day silicon material assessment and process control.

Acknowledgments

The authors would like to thank a number of people who contributed to the preparation of this review, including N. Feldstein, W. Kern, G. Lozier, and J. Vossen for reading the manuscript and making helpful suggestions.

Manuscript submitted Oct. 14, 1975; revised manuscript received March 19, 1976. This was Paper 157 presented at the Dallas, Texas, Meeting of the Society, Oct. 5-9, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1977 JOURNAL. All discussions for the June 1977 Discussion Section should be submitted by Feb. 1, 1977.

Publication costs of this article were assisted by RCA Laboratories.

ABSTRACT

Stannic oxide in its pure form is an n-type wide-bandgap semiconductor. Its electrical conduction results from the existence of point defects (native and foreign atoms) which act as donors or acceptors. Some unique properties of SnO_2 make the material useful for many applications; therefore, increasing attention is being paid to studies on this oxide, especially on the methods of preparation, and its electrical and optical properties. The purpose of this series is to provide a general up-to-date review of the investigations carried out and to help identify important areas for further studies. The first part[2] was concerned with the preparation and defect structure of single crystals, sintered polycrystalline samples, and thin films, and in the second part[3] we reviewed the electrical properties of these materials. In this part we discuss the optical properties of SnO_2 single crystals and films. This concludes our review of the physical properties of SnO_2 materials.

The methods of preparation of single crystals, sintered materials, and thin films of tin dioxide and their defect structure have been described (1) in Part I of this series. In Part II the electrical properties of these materials in pure and doped forms have been reviewed (2). In this last part we discuss the optical properties of tin dioxide solids.

The optical properties of this material are unique in two respects. First, SnO_2 is one of the few electrical conductors that is optically transparent in the visible range of wavelengths in its undoped form, and second, it is the simplest oxide semiconductor of noncubic structure with nonorbital complications. The first feature is often applied to fabricate transparent conductive coatings on, *e.g.*, glass, while the second provides a good medium to study symmetry effects in crystal potentials, etc. For these reasons the optical properties of various types of tin oxide materials have been studied extensively in the past.

In this paper we review the work done to date on the optical behavior of SnO_2 single crystals and films. A summary of major efforts is listed chronologically in Table I. It covers published results in the period 1954-1974.

Single Crystals

Optical absorption.—Short wavelength properties.— The first investigations of optical properties of SnO_2 single crystals were carried out in 1962 by Kohnke (8) on natural cassiterite. From the short wavelength cutoff, he found a fundamental optical energy gap, E_g, to be ≥ 3.54 eV with a thermal shift dE_g/dT of -6×10^{-4} eV/°K measured in the temperature range from 80° to 415°K. The lower limit for the optical forbidden energy gap of 3.54 eV is in good agreement with the value of 3.44 eV obtained by Kohnke and Hurt (38) from the maximum of the conductivity spectral response curve. Kohnke also observed a sharp absorption of wavelength of 3.07 μm which he attributed to the presence of O-H groups oriented in a plane perpendicular to the c axis of the crystal. He observed a long wavelength cutoff region at about 7.2 μm with a slight transmission having a maximum at 7.55 μm.

The first investigations of optical absorption in synthetic crystals of tin oxide were carried out by Summitt and Borrelli (9, 10, 15) and Summitt (18) on single crystals grown from the vapor phase by Marley and MacAvoy (1, 39). They calculated the absorption coefficient, K, from the relation (40)

$$T = \frac{(1 - R^2) \exp(Kd)}{\exp(2Kd) - R^2} \quad [1]$$

and from tables (41). In the expression, T is the transmittance, R is the reflectivity, and d is the crystal thickness.

The ultraviolet absorption coefficient of SnO_2 as a function of photon energy was measured by Summitt, Marley, and Borrelli (9) and is shown in Fig. 1. As can be seen from the figure, pronounced dichroism exists in the u.v. region. The absorption edge for radiation polarized parallel and perpendicular to the c axis is separated by approximately 0.3 eV.

As it is well known (42), the absorption coefficient is related to photon energy for direct transitions as

$$K = K_0(h\nu - E_g)^{1/2} \quad [2]$$

where E_g is the vertical separation between valence and conduction bands, and K_0 is a constant. By plotting the experimental values of K^2 *vs.* photon energy and extrapolating to zero absorption, the width of the energy gap may be obtained. Using this method, the

Table I. Optical properties of SnO_2 materials

Year	Author	Reference	Materials	Properties	Temperature range, °K	Conclusion drawn by author
1954	Aitchison	(3)	Films prepared by hydrolysis of $SnCl_4$	Reflection Absorption	300	SnO_2 is transparent from 0.2 to 14 μm.
1958	Ishiguro, Sasaki, Arai, and Imai	(4)	Films prepared by hydrolysis of $SnCl_4$	Transmission Reflection	300	Fundamental absorption gap is about 4 eV. Plasma frequency of the carriers lies in the near infrared region. Coulomb scattering of impurity ions is the predominant scattering mechanism in the transparent conducting films.
1958	Ishiguro, Sasaki, Arai, and Imai	(5)	As above	Refractive index	300	Lifetime of the plasma wave is about 2.6×10^{-15} sec.
1959	Miloslavskii	(6)	Pyrolytic decomposition of $SnCl_2$ and $SnCl_4$	Absorption Transmission	120-470	The absorption by impurity atoms was observed. Two bands were observed: a narrow band with a maximum at 16.4 μm and a wide band with maximum at 8.5 ÷ 9 μm. Both absorption bands increased with increasing conductivity.
1960	Arai	(7)	Conductive and nonconductive SnO_2 films and SnO films	Absorption Reflection Transmission	130-300	The absorption edge for conductive and nonconductive SnO_2 films is found to be (3.82 ± 0.030) and (3.71 ± 0.025) eV, respectively. The temperature change of absorption edge for both materials is -2.0×10^{-4} eV/°K.
1962	Kohnke	(8)	Natural single crystals	Absorption Transmission	80-415	Fundamental energy gap is 3.54 eV. $\frac{dE_g}{dT} = -6 \times 10^{-4} \frac{eV}{K}$ A sharp absorption observed at 3.07 μm is attributed to O-H groups.
1964	Summitt, Marley, and Borrelli	(9)	Single crystals grown by vapor transport technique	U.V. absorption	300	The u.v. absorption coefficients are as high as 10^3 cm^{-1}. The use of polarized light revealed a large dichroism, the absorption edges differing by about 0.3 eV for radiation polarized parallel and perpendicular to the c axis. Both edges represent intrinsic transitions with the direct energy gaps 3.93 and 3.57 eV for radiation polarized parallel and perpendicular, respectively. Thresholds for phonon coupled transitions occur approximately at 3.7 and 3.4 eV, but indirect transitions appear to involve several lattice vibrational frequencies.
1965	Summitt and Borrelli	(10)	As above	Infrared absorption	50-900	Near infrared absorption coefficient (0.5-0.6 μm) varies directly with the concentration of carriers over the range $n = 10^{17}$ to 2×10^{18} cm^{-3}, and the third power of wavelength.
1965	Reddaway and Wright	(11)	Single crystals grown by vapor reaction method	Absorption Refractive index	300	There are indirect transition edges at 2.55 and 2.45 eV and direct transition edges at 3.7 and 4.1 eV for polarization perpendicular to the c axis and parallel to this axis, respectively.
1965	Nagasawa Shionoya, and Mikishima	(12)	Single crystals grown by hydrolysis of $SnCl_4$	Transmission	300	Bandgap is estimated to be about 3.5 eV.
1965	Houston and Kohnke	(13)	Single crystals grown from cuprous flux	Photoconduction	80-400	Measurements of thermally stimulated current indicate the existence of trapping levels at 0.21, 0.52, and 0.60 eV. The results of intrinsic thermal quenching measurements indicate the existence of a compensated acceptor level lying 0.33 eV above the valence band.
1966	Houston and Kohnke	(14)	As above	Photoconduction	100-400	The optical quenching of photoconductivity is found in a single band extending from the fundamental optical gap at 4.0 eV down to a cutoff indicative of a 1.3 eV activation energy.
1966	Summitt and Borrelli	(15)	Single crystals grown by vapor transport technique	U.V. absorption	20-1300	Experimental results are fitted by the expression $E_g(T) = E_g^o - c\left[\exp\left(\frac{\Theta}{T}\right) - 1\right]^{-1}$ where $\Theta = 196°$ and 414°K for radiation parallel and perpendicular to the c axis, respectively, and c is a constant.
1966	Nagasawa and Shionoya	(16)	Single crystals grown by hydrolysis of $SnCl_4$	Absorption	1.3-300	Four main lines were observed in the absorption structure at 1.3°K. This structure is assumed to be originated from a direct forbidden exciton transition.
1967	Spence	(17)	Films obtained by evaporating and subsequently oxidizing tin	Absorption	300	The dependence of the absorption coefficient upon film resistivity is noted and an impurity peak at about 3.4 eV is observed. It is suggested that an indirect edge lies near 2.7 eV and a direct edge near 4.3 eV.
1968	Summitt	(18)	Single crystals grown by vapor transport technique	Infrared absorption	300	The infrared reflection spectrum has been observed and analzed by the classical dispersion theory. For the cassiterite structure four lattice vibration modes may interact with infrared radiation, three with radiation polarized perpendicular to the c axis, and one with radiation polarized parallel to the c axis. Static dielectric constants have values of 9.58 and 13.5 for directions parallel and perpendicular to the c axis, respectively.
1968	Wright	(19)	Single crystals grown from gas phase	Absorption	77 and 300	The summary of the results published in Ref. (11) and (54).

Table I. (Continued)

Year	Author	Reference	Materials	Properties	Temperature range, °K	Conclusion drawn by author
1968	Van Daal	(20)	Single crystals grown from gas phase	Reflection	300	Polar optical modes with an average characteristic temperature of 1050°K dominate lattice scattering.
1968	Van Daal	(21)	Natural single crystals	Reflection	300	Static dielectric constants have values of 9.0 ± 0.5 and 14 ± 2 for directions parallel and perpendicular to the c axis, respectively.
1968	Nagasawa and Shionoya	(23)	Single crystals grown by hydrolysis of $SnCl_4$	Zeeman effect	1.8	The exciton symmetries and possible band symmetries are obtained on the basis of group theory and appear to be consistent with the valence band of O 2p functions and the conduction band of Sn 5s functions
1969	Crabtree, Mehdi, and Wright	(24)	As above	Infrared absorption	300	For charge carrier concentrations n_e from 6.5×10^{16} to 8×10^{17} cm^{-3}, the absorption coefficient K is proportional to n_e. The log-log plot of K against λ gives a good straight line with slope 2.5-2.6. The results are in agreement with the theory of Visvanathan for optical mode scattering.
1969	Nagasawa and Shionoya	(25)	As above	Absorption	80-370	The absorption tails observed above 200°K are in agreement with Urbach's rule.
1969	Cunningham, Marton, and Schlesinger	(26)	As above	Photoconduction	300	Photoconductivity is found to have a peak response at 370 nm. Excitation spectrum for blue fluorescent emission is similar to that of photoconductivity.
1969	Cunningham, Marton, and Schlesinger	(27)	As above	Photoconduction	300	The rate of photoconductivity decay is found to depend on the crystal environment.
1970	Fillard, Gasiot, and deMurcia	(22)	Single crystals grown by vapor transport technique	Photoconduction	77-500	On the basis of thermally stimulated emission, 5 trap levels were found in the forbidden band: 0.22, 0.44, 0.47, 0.56, and 0.7 eV
1970	Nishino and Hamakawa	(28)	System Si-SnO_2, films of SnO_2 grown by oxidation of evaporated tin on surface of Si single crystal	Transmission Photovoltage	83, 298	Si-SnO_2 n-n heterojunction has the photoresponse in the wide wavelength region from 400 to 1200 nm at room temperature.
1971	Nagasawa and Shionoya	(29)	Single crystals grown by hydrolysis of $SnCl_4$	Absorption Transmission	300	The value of p in the relation $K \sim \lambda^p$ increases with free electron concentration, which may be explained by influence of ionized point defect scattering.
1971	Nagasawa and Shionoya	(30)	As above	Absorption Transmission Photoconductivity	300	Absorption intensity is slightly lower for the oxidized crystal. Sufficiently oxidized crystals exhibit rather large photoconductivity when irradiated with u.v. light. Spectral dependence of photocurrent shows two peaks at 3.37 and at about 3.8 eV.
1971	Nagasawa and Shionoya	(31)	As above	Zeeman effect	1.3-80	The results of Zeeman effect measurements are consistent with group theoretical predictions based on a crystal field-split valence band of oxygen 2p functions and a crystal field-split conduction band of tin 5s functions both having their extrema at $\vec{k} = 0$. The effective Rydberg constant, the bandgap energy, and the anisotropic exciton-reduced-masses are estimated as 0.0345 and 3.5969 eV (at 1.8°K), and $\mu_x = 0.33\ m_o$, $\mu_z = 0.30\ m_o$, respectively.
1971	Nagasawa and Shionoya	(32)	As above	Absorption	7-350	At low temperatures, the spectrum for $\vec{E} \perp c$ begins with second class exciton transitions at Γ point, while at temperatures above 200°K, the spectrum is interpreted in terms of Urbach's rule. For light $\vec{E} \parallel c$, the relation $K^{2/7} \sim h\nu$ is found and a possible explanation is that the spectrum arises from fourth class direct transitions at Γ point.
1972	Fillard, Gasiot, deMurcia, and Tran Trong Quynh	(33)	Single crystal grown by vapor transport technique	Phosphorescence Photoluminescence Photoconductivity	77 and 300	The active region is located near the surface and the blue light originates from nonconducting states probably located in the bulk.
1974	Crabtree	(34)	Single crystals grown by hydrolysis of $SnCl_4$ Doped with europium	Cathodoluminescence	300	The spectrum comprises the intrinsic emission band of the host lattice and bands due to the presence of the europium ion. The europium is incorporated in the host lattice as Eu^{3+}.
1974	Crabtree	(35)	As above, doped with terbium	Cathodoluminescence	300	The spectra comprise the intrinsic emission band of the host lattice and bands due to the presence of the terbium ion. The terbium is incorporated in the host lattice as Tb^{3+}.
1974	McRoberts and Fonstad	(36)	Single crystals grown using the reaction $SnCl_4 + 2H_2 + O_2 \leftrightarrows SnO_2 + 4HCl$	Thermoabsorption	25-115	For light polarized perpendicularly to the c axis, a fine structure is observed which may be associated with the exciton-phonon quasi-bound state.
1975	Kim and Laitinen	(37)	Thin films obtained by hydrolysis of $SnCl_4$	Photocurrent	300	Photocurrent in SnO_2 electrode is dependent on the intensity of the light, wavelength, and the applied potential. The photocurrent spectrum showed a sharp decrease near the bandgap energy.

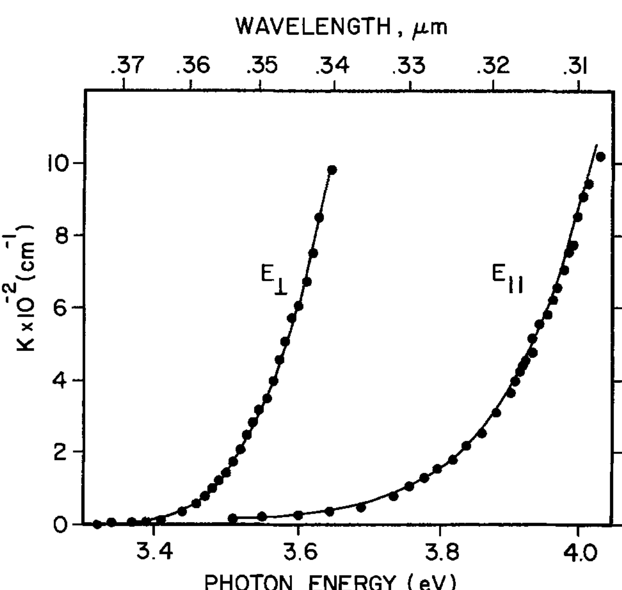

Fig. 1. U.V. absorption coefficient in SnO_2 single crystals vs. photon energy for radiation polarized parallel and perpendicular to the c axis.

same authors obtained values of 3.93 and 3.57 eV for the parallel and perpendicular gaps, respectively. Summitt *et al.* assumed that the lower curved portion of K^2 *vs.* $h\nu$ dependence represents the allowed indirect phonon assisted transitions, which could vary as (42)

$$K = K_0'(h\nu - E_g' \pm E_p)^2 \qquad [3]$$

where E_g' is the minimum forbidden energy gap and E_p is the phonon energy. When a single phonon frequency is involved, the plot of $K^{1/2}$ *vs.* phonon energy should consist of two linear regions which extrapolate to $E_g' + E_p$ and $E_g' - E_p$, from which one can obtain both E_g' and E_p. Extrapolating the linear portions to zero absorption, Summitt *et al.* obtained $E_g' + E_p =$ 3.72 and 3.42 eV for parallel and perpendicular gaps, respectively. Broadening occurred at the bottom of both edges, but it was found to be much larger at the parallel edge. Broadening of the perpendicular component suggests that several phonon frequencies participate in the absorption. Assuming $E_p \leq 0.08$ eV (the highest optical lattice mode), the data obtained by Summitt *et al.* give estimates for the minimum energy gaps of E_g' (parallel) ≤ 3.7 eV and E_g' (perpendicular) ≤ 3.4 eV.

Differences in the shape of absorption curves at the two edges at low absorption were assumed to arise from forbidden transitions for light polarized parallel to the c axis. To account for these observations, oxygen 2p levels were assumed to split in the D_{4h} crystal lattice into two valence bands, with a difference between the upper edges of about 0.3 eV.

Summit and Borrelli (15) investigated the temperature dependence of the u.v absorption edges in SnO_2 crystals in the range between 20° and 1300°K. Their results for parallel and perpendicular edges are shown in Fig. 2.

Above room temperatures both edges shifted linearly with temperature, where $\Delta E_g/\Delta T = 1.2 \times 10^{-3}$ eV/°K. Between 20° and 300°K the shift in the parallel polarized edge was about 1.4 times larger than that in the perpendicular edge. Experimental results were fitted by the expression

$$E_g(T) = E_g{}^o - c\left[\exp\left(\frac{\theta}{T}\right) - 1\right]^{-1} \qquad [4]$$

where $E_g{}^o$ corresponds to $T = 0$ and c is a constant. The best fits were obtained when $\theta = 196°$ and 414°K for parallel and perpendicular edges, respectively.

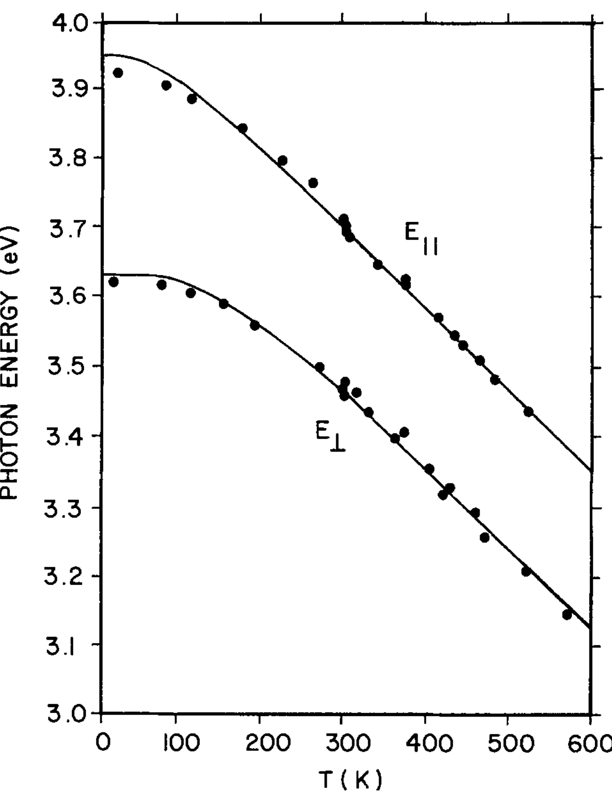

Fig. 2. Temperature dependence of the u.v. absorption edges in SnO_2 single crystals at absorption coefficient ≈ 75 cm^{-1} for radiation polarized parallel and perpendicular to the c axis. Points are experimental values and curves are calculated from Eq. [4] where values of the parameters are: $E_g{}^o = 3.947$, $c = 0.231$, $\theta = 195.8$ for the parallel edge, and $E_g{}^o = 3.631$, $c = 0.510$, $\theta = 414.7$ for the perpendicular edge.

Equation [4] may be derived theoretically. For example, for isotropic crystals it has been shown (43, 44) that $\Delta E_g(T)$ fulfilled the following equation

$$\Delta E_g(T) \sim \left[\exp\left(\frac{h\omega_l}{kT}\right) - 1\right]^{-1} \qquad [5]$$

where ω_l is the frequency of the longitudinal optical mode. Although theory has been developed in detail only for isotropic crystals having a single ω_l, this proportionality is expected to apply generally to anisotropic polar crystals such as the tetragonal SnO_2.

These results show that the temperature shift of each edge may be determined by a single lattice frequency and that this frequency is different for the two edges. It also suggests that interaction with an electron in one of the two valence bands is dominated by one mode while a second mode controls interaction in the other valence band.

Wright *et al.* (11, 19, 24) have studied the optical properties of SnO_2 crystals, obtained in their laboratory (1). Reddaway and Wright (11) studied the refractive index in the range from 0.35 to 10 μm, and the absorption coefficient from 0.31 to 0.5 μm. They reported direct absorption edges at 3.7 eV for polarization perpendicular to the c axis and near 4.1 eV for polarization parallel to it. As was mentioned above, Summit, Marley, and Borrelli (9) in similar studies obtained the values as 3.6 and 3.9, respectively. For indirect absorption edges, Reddaway and Wright determined 2.55 eV for polarization perpendicular to the c axis and 2.45 eV for parallel polarization. The authors observed also a peak at 3.36 eV for parallel polarization, possibly with an excited state at 3.72 eV.

Extended investigations of optical properties of SnO_2 single crystals of good quality (1) have been carried out by Nagasawa and Shionoya (12, 16, 23, 25, 29-32). Nagasawa, Shionoya, and Makishima (12) estimated

the optical bandgap to be about 3.5 eV. As it was mentioned previously, Kohnke observed a sharp absorption line at 3.07 μm in natural SnO_2 crystals, which he attributed to O-H groups. Since the crystals investigated by these authors were prepared using water as one of the starting materials, the existence of O-H groups is quite possible. However, no detectable absorption lines were observed. The crystals grown by this method were found to show the luminescence of a broad band with a maximum at 0.63 μm by the excitation of mercury light at room temperature.

To obtain information about the nature of the band extrema in SnO_2, Nagasawa and Shionoya (25, 32) studied in detail the temperature dependence of the optical absorption edge in single crystals of this material. Absorption edge spectra for light polarized parallel and perpendicular to the c axis, obtained by Nagasawa and Shionoya at various temperatures, are shown in Fig. 3. As it is seen in this figure, large dichroism and shape difference between spectra for light polarized parallel ($\vec{E} \parallel c$) and perpendicular ($\vec{E} \perp c$) to the c axis are remarkable for the whole temperature range investigated (7°-370°K). This has been pointed out previously by Summitt *et al.* (9, 15). The spectra for $\vec{E} \perp c$ become steeper with decreasing temperature while the spectra for $\vec{E} \parallel c$ do not show any noticeable change in shape with temperature except for the movement of the entire curve with temperature.

As can be seen in Fig. 4, the energy and temperature dependences of the absorption coefficient in the spectra for $\vec{E} \perp c$ above 200°K are well described by the empirical Urbach's rule (45) which is expressed by

$$K = K_o \exp[\sigma_o(h\nu - E_o)/kT] \quad [6]$$

where K_o and E_o are material constants and σ_o is a constant on the order of unity. Equation [6] can also be written as

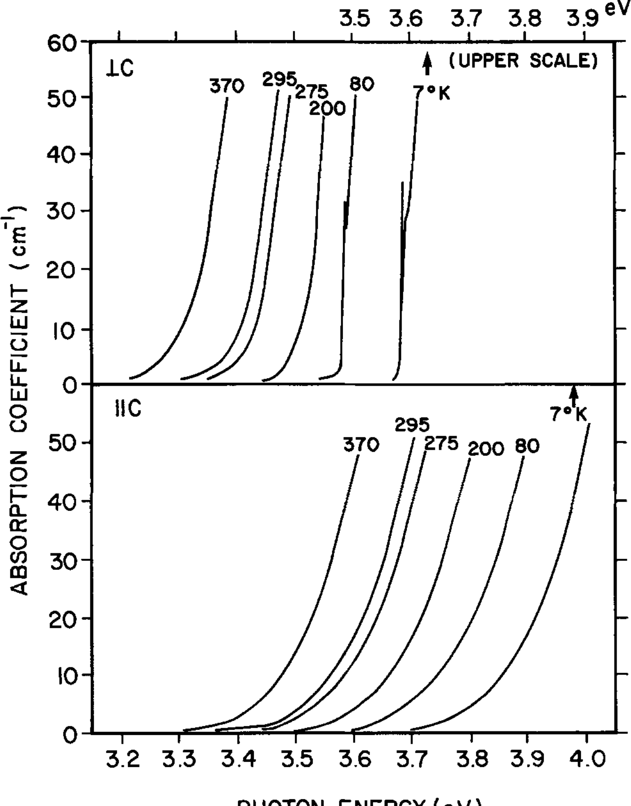

Fig. 3. The anisotropic fundamental absorption edge spectra in SnO_2 single crystals at various temperatures for light polarized perpendicular and parallel to the c axis. The spectra at 7°K are shifted in the energy scale to avoid overlap with those at 80°K.

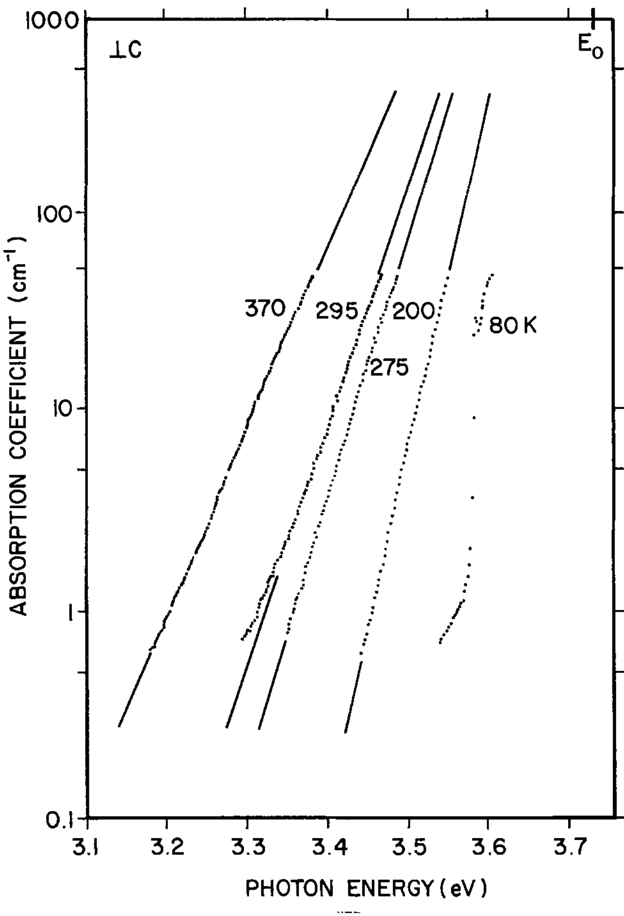

Fig. 4. Edge absorption spectra ($\vec{E} \perp c$) of SnO_2 single crystals at various temperatures. Points are experimental ones, while solid lines are calculated from Urbach's rule, where values of the parameters are $K_0 = 1.5 \times 10^5$ cm^{-1}, $\sigma_0 = 0.70$, and $E_0 = 3.75$ eV.

$$(h\nu)_K = \ln(K/K_o) \cdot \frac{kT}{\sigma_o} + E_o \quad [7]$$

where $(h\nu)_K$ is the photon energy for which the crystal shows an absorption coefficient K. From Fig. 5 it is seen that the data obtained by Nagasawa and Shionoya above 200°K are also in agreement with Eq. [7]. It was assumed by these investigators that the Urbach tail is attributed to transitions from a Γ_5^- valence band (direct allowed for $E \perp c$) about 0.15 eV below the top, Γ_3^+, valence band. Nagasawa and Shionoya, and also Agekyan (46, 47), have established the bottom conduction band and top valence band extrema symmetries as Γ_1^+ and Γ_5^+, respectively. Urbach's empirical rule has been found to hold for a number of semiconductors and insulators (45); however, no satisfactory theory of this rule has appeared as yet.

Long wavelength properties.—Summitt and Borrelli (10) investigated the infrared properties of synthetic SnO_2 crystals and found that the absorption coefficient may be expressed in terms of the carrier concentration, n_e and wavelength, λ, as

$$K\ (\text{cm}^{-1}) = 1.72\ n_e \lambda^3 \quad [8]$$

where n_e is given in 10^{18} cm^{-3} and λ in μm. Their experimental results are shown in Fig. 6. The investigations were carried out at a wavelength between 1 and 3 μm. The magnitude and wavelength dependence does not change over the range 50°-300°K, but the absorption increases slightly while the wavelength dependence decreases with increasing temperature between 300° and 900°K. Equation [8] suggests that this absorption is due to quasi-free electrons.

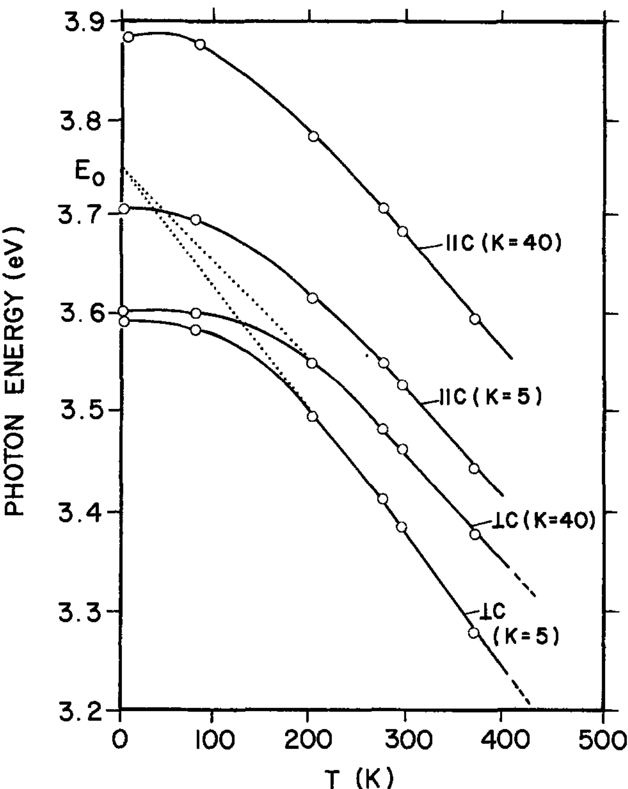

Fig. 5. Absorption curves near the fundamental absorption edge in SnO_2 single crystals. Dotted lines are calculated from Eq. [7] with values of parameters $K_0 = 1.5 \times 10^5$ cm^{-1}, $\sigma_0 = 0.70$, $E_0 = 3.75$ eV.

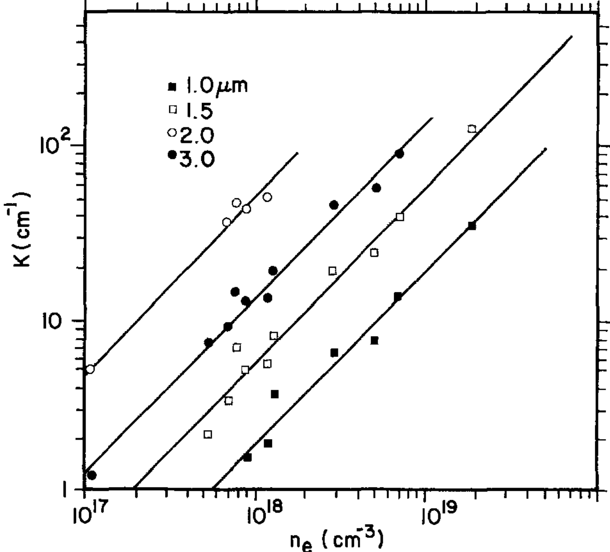

Fig. 6. Absorption coefficients K of SnO_2 single crystals at constant wavelength vs. carrier concentrations.

In the case of absorption by free carriers, the absorption coefficient, K, is generally related to the wavelength, λ, in the form $K \sim \lambda^p$, where p is the numerical factor dependent on the charge carrier scattering process. For acoustic mode scattering (40, 48, 49), the free-carrier absorption coefficient is theoretically proportional to λ^2 ($p = 2$) and for optical phonon scattering (50), $p = 2.5$. The value of p is known to exceed 3 for ionized defect or impurity scattering (49-51). The dependence of the absorption coefficient on λ^3 below 300°K obtained by Summitt and Borrelli suggests that acoustic phonon scattering is not dominant at 300°K. The linear variation of K with n_e suggests that scattering by ionized impurities is also unimportant at room temperature, because expressions for ionized impurity scattering (49-51) indicate that the absorption coefficient varies with the product n_eN, where N is the concentration of ionized impurities and native point defects. Thus, the results obtained by these authors suggest that the major scattering in the range of temperatures investigated is by optical phonons. Summitt (18) investigated the infrared reflection spectrum of SnO_2 single crystals at room temperature in the wavelength range 10-50 μm. The experimental reflectance curves are shown in Fig. 7(a) and (b) for radiation polarized perpendicular and parallel to the c axis, respectively. The points are experimental, and the solid curves are computed from the classical dispersion oscillator theory (52, 53) using the parameters which gave the best fit to the experimental curves.

In the classical oscillator analysis of the reflection spectrum, it is assumed that the real and imaginary parts of the complex dielectric constants are related to a set of oscillator parameters by the equations (52)

$$\epsilon' = n^2 - k^2 = \epsilon_\infty + \sum_j \frac{4\pi\rho_j\nu_j^2(\nu_j^2 - \nu^2)}{(\nu_j^2 - \nu^2)^2 + \gamma_j^2\nu_j^2\nu^2} \quad [9]$$

$$\epsilon'' = 2nk = \sum_j \frac{4\pi\rho_j\nu_j^2\nu_j^2\gamma_j\nu}{(\nu_j^2 - \nu^2)^2 + \gamma_j^2\nu_j^2\nu} \quad [10]$$

where ϵ_∞ is the high frequency dielectric constant, $4\pi\rho_j$ the strength, γ_j the width, and ν_j the frequency of the jth oscillator. The reflectivity, R, of radiation at normal incidence is related to the refractive index, n, and the extinction coefficient, k, by

$$R = [(n-1)^2 + k^2]/[(n+1)^2 + k^2] \quad [11]$$

The number of oscillators in the analysis should be the minimum number necessary for good agreement with the experimental data, but also should agree with the number deduced from group theoretical analysis of the crystal structure. The results of calculations by Summitt for the cassiterite structure agree well with the experiment if four lattice vibration modes interact with infrared radiation, namely three oscillators for

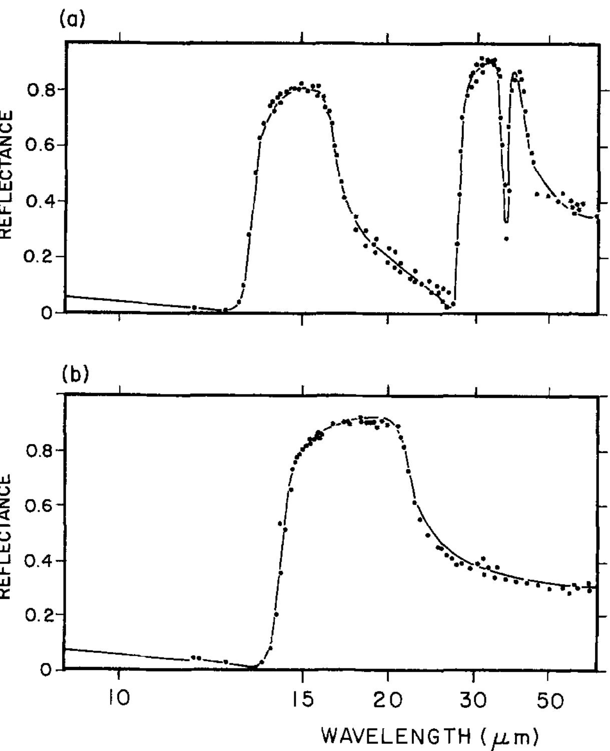

Fig. 7. Infrared reflectance spectrum of SnO_2 single crystals. Points are experimental values and solid curves are computed from Eq. [9], [10], and [11] using the parameters of Table II; (a) radiation polarized perpendicular to the c axis. (b) radiation polarized parallel to the c axis.

radiation polarized perpendicular to the c axis and a single oscillator for radiation parallel to the c axis. The oscillator parameters giving the best fit to the experimental curves are listed in Table II. The longitudinal oscillator frequencies found for the best fit to the experimental reflection curves are 243, 284, and 605 cm^{-1} for radiation polarized perpendicular to the c axis and 465 cm^{-1} for radiation polarized parallel to the axis. Low frequency dielectric constants were estimated from this analysis to be 13.5 and 9.58 for $E \perp c$ and $E \parallel c$, respectively. The $E \perp c$ value was confirmed directly in a substitution bridge measurement yielding 15 ± 1 for the frequency range 10^2-10^6 Hz. Reddaway (54) found the refractive index of crystals to be 2.0 at 0.53 μm for polarization perpendicular to the c axis and 2.11 for polarization parallel to it. The absorption from 0.7 to 3 μm in antimony-doped SnO_2 crystals was found by Reddaway to be approximately proportional to λ^3. This is in agreement with Summitt and Borrelli (10) and is reasonably consistent with optical mode polar scattering. As it was mentioned above, the theory of free-carrier absorption in this case was given by Visvanathan (50), and the measured absorption coefficient agrees approximately with this theory.

Crabtree, Mehdi, and Wright (24) studied the infrared absorption at room temperature for reduced crystals with different carrier concentrations, n, and confirmed that from 6.5×10^{16} to 8×10^{17} cm^{-3} the absorption coefficient, K, is proportional to n_e, which is in agreement with the results obtained by Summitt and Borrelli (10). The dependence of log K against log λ is shown in Fig. 8 and gives a straight line with slope 2.5 for the lower values of n_e and 2.6 for the higher. These slopes are in excellent agreement with the theory of Visvanathan (50) for optical mode scattering and confirm that this is indeed the scattering process at room temperature. The higher slopes observed by Summitt and Borrelli (10) and Reddaway (55) are probably due to the influence of the presence of impurity scattering. On the basis of Visvanathan's (50) calculations and data shown in Fig. 8, Crabtree *et al.* found the electron effective mass to be 0.17 m_0.

For the optical reflection in the Reststrahl region, Van Daal (20, 21) also concluded that polar optical modes with an average characteristic temperature of 1050°K dominate lattice scattering. He found that the static dielectric constant for directions parallel and perpendicular to the c axis has values of about 9.0 ± 0.5 and 14 ± 2, respectively. These values are similar to those obtained by Summitt (18). This is in contradiction with the commonly accepted values of 24.0 and 23.4 found in the literature. The latter values are based on optical reflection data at room temperature for normal incidence of polarized light in the far infrared, obtained as early as 1919 by Liebisch and Rubens (56).

Nagasawa and Shionoya (29) studied optical transmission spectra of as-grown and reduced SnO_2 crystals.

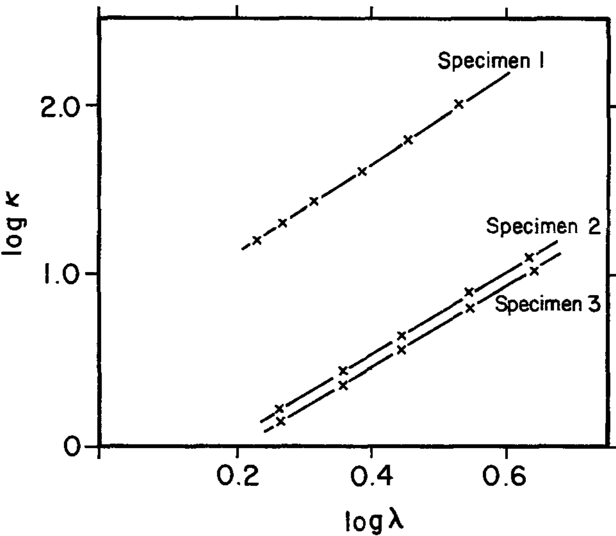

Fig. 8. Infrared optical absorption coefficients of SnO_2 single crystals as a function of wavelength. The charge carrrier concentrations for specimens 1, 2, and 3 are 8×10^{17}, 10^{17}, and 6.5×10^{17} cm^{-3}, respectively.

The results are shown in Fig. 9. Contrary to the results of Summitt and Borrelli (10), the data of Nagasawa and Shionoya show that the value of p in relation of $K \sim \lambda^p$ increases with conduction electron concentration from $p = 2.2$ and 2.5 for the as-grown crystals to $p = 3.1$ for the reduced crystal. This may be due to the influence of ionized point defect scattering at room temperature. Nagasawa and Shionoya (30) also observed that absorption intensity is slightly lower for oxidized crystals which is caused by decreasing the amount of defect centers. Sufficiently oxidized crystals were found to exhibit rather large photoconductivity when irradiated with u.v. light.

Exciton effects.—Nagasawa and Shionoya (16) working with good quality (1) single crystals observed near the fundamental absorption edge a series of sharp lines having absorption coefficients less than 100 cm^{-1}. Their results, obtained at 1.3°K, are shown in Fig. 10. It turned out that the photon energies of the main lines found satisfy the relation for hydrogenlike series, and that the line corresponding to the principal quantum number $n = 1$ is missing. This experimental relation can be expressed by the following equation (16)

$$E_n = 3.5971 - 0.0330/n^2 \text{ (eV)} \quad [12]$$

or by (31)

$$E_n = 3.5969 - 0.0314/n^2 \text{ (eV)} \quad [13]$$

where the quantum number $n = 2$, 3, 4, and 5 represents the energy states corresponding to the first, second, third, and fourth line in the structure, respec-

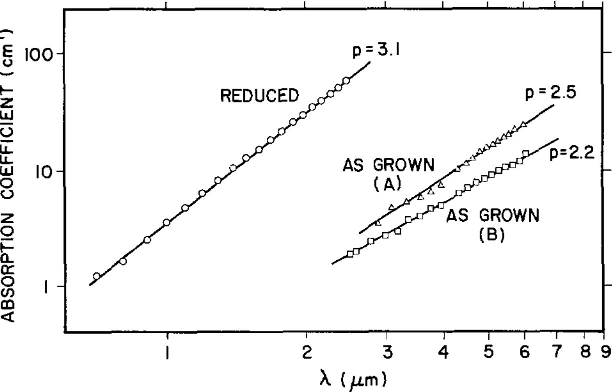

Fig. 9. Free-carrier absorption in as-grown and reduced SnO_2 crystals at room temperature. Straight lines present a relation $K \sim \lambda^p$.

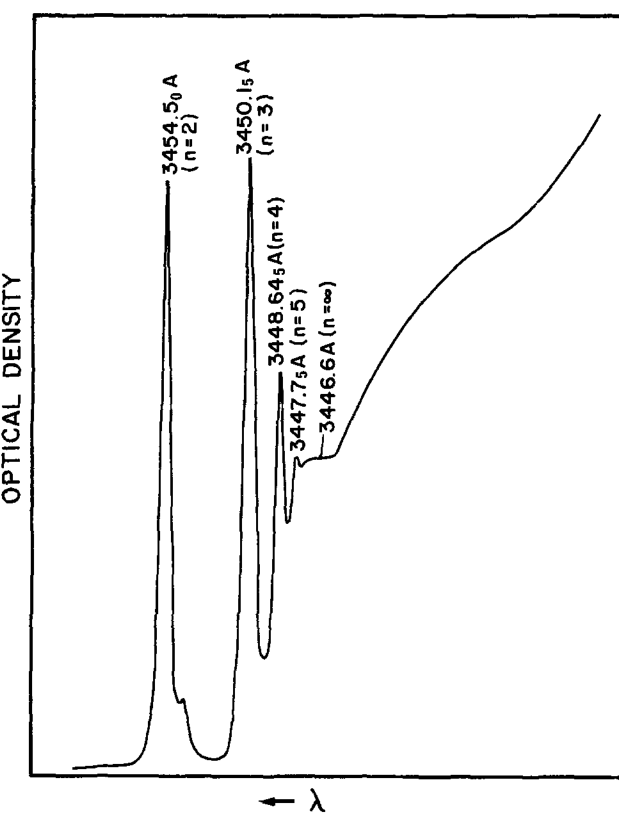

Fig. 10. Structure of the fundamental absorption edge of SnO_2 single crystals at 1.3°K. Photon energies of the main lines fulfilled the relation for hydrogenlike series when the number $n = 1$ is missing.

tively. Based on the fact that in the hydrogen series relation the line with $n = 1$ is missing and also that the absorption coefficients of the lines are quite small, the authors concluded that the observed structure originates from a direct forbidden (second class) excitation transition (57).

To elucidate these spectra, Nagasawa and Shionoya (23) investigated the Zeeman effect of the exciton at 1.8°K. The magnetic field was perpendicular to the c axis and parallel to the wave vector of the exciting photon $\vec{q}$. In the magnetic field new absorption lines appeared on the higher energy side of each zero-field line and their intensities increased with increasing magnetic field strength. With the magnetic field parallel to the c axis no new lines were found, but broadening and energy shifts of the zero-field lines were observed. From group theoretical predictions based on a crystal field-split conduction band of tin 5s functions, both having their extrema at $\vec{k} = 0$ (Γ point), Nagasawa and Shionoya concluded that zero-field lines are transitions from the crystal ground state to the hydrogenic $nP_{\pm 1}$. They also concluded that in a magnetic field perpendicular to the c axis of the crystal, $P_{\pm 1}$ and P_0 states will be mixed, and in accord with this, P_0 increases in strength as the field is increased if the measurement is made in the geometry of $\vec{H} \perp$ c and $\vec{H} \parallel \vec{q}$. One may now assign the new lines as nP_0. In Fig. 11, peak positions of the $nP_{\pm 1}$ and nP_0 lines which were observed with the geometry $\vec{H} \perp$ c and $\vec{H} \parallel \vec{q}$ are plotted against magnetic field strength. The energy shifts observed in the higher states are quadratic with respect to magnetic field strength, and hence may be due to the diamagnetic Zeeman effect, while those in $n = 2$ states are mainly due to linear Zeeman effects.

An anisotropic-exciton-mass formalism has been derived by Hopfield and Thomas (58) and also by Wheeler and Dimmock (59), using the ellipsoidal effective-mass approximation. Wheeler and Dimmock (59) calculated exciton state energies in the absence of an external magnetic field. The expressions obtained for exciton states nP_0 and $nP_{\pm 1}$ are, respectively

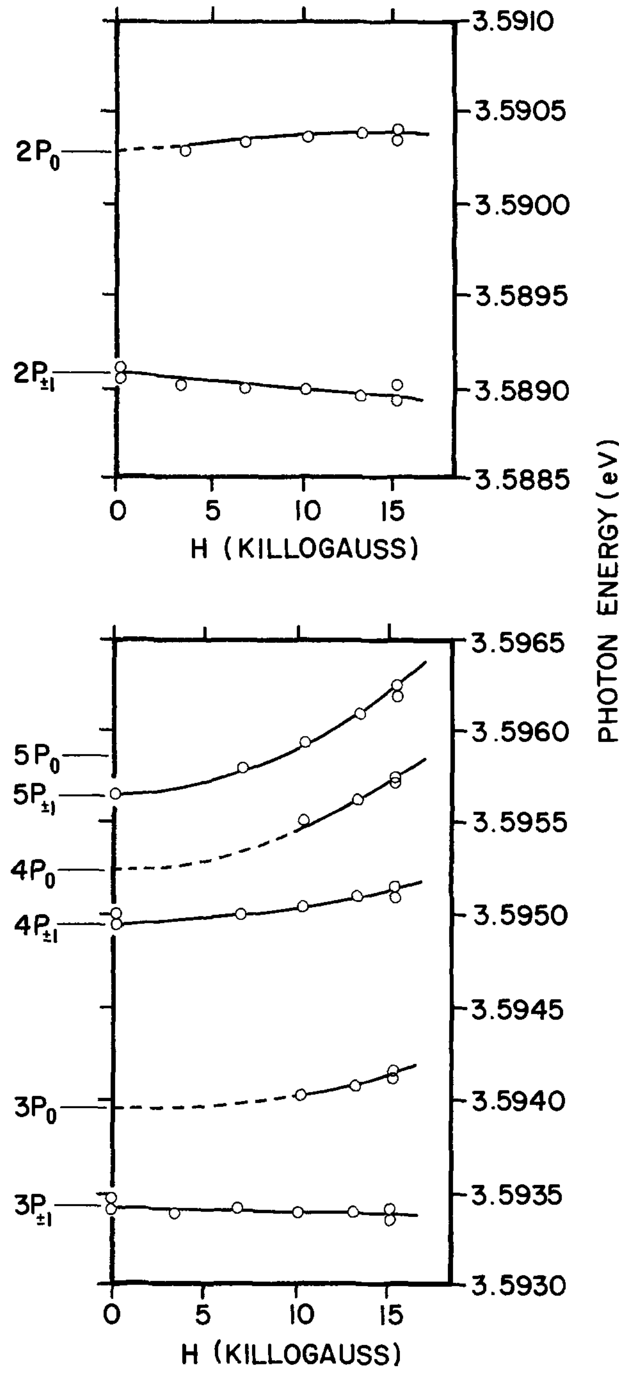

Fig. 11. The Zeeman effect of the exciton states in SnO_2 single crystals at 1.8°K for $\vec{H} \perp$ c and $\vec{H} \parallel \vec{q}$. On the left are shown the zero-field energies of the exciton states calculated semiempirically using the anisotropic-exciton-mass formalism.

$$E_n = E_g - \frac{R_{eff}}{n^2} (1 + 3\alpha/5 + 9\alpha^2/28) \quad [14]$$

$$E_n = E_g - \frac{R_{eff}}{n^2} (1 + \alpha/5 + 9\alpha^2/140) \quad [15]$$

where E_g and R_{eff} are the bandgap energy and the effective Rydbert constant, respectively, and α is an anisotropy parameter defined as

$$\alpha = 1 - \mu_x\epsilon_x/\mu_z\epsilon_z \quad [16]$$

where μ and ϵ are the exciton-reduced-mass and the

low-frequency dielectric constant, respectively. Using the expressions [14], [15], and [16], Nagasawa and Shionoya (23) calculated energies of nP_0 and $nP_{\pm 1}$ states (for $n = 2, 3, 4$, and 5). The values obtained are also shown in Fig. 11. Using the anisotropic-exciton-mass formalism, the authors also calculated the effective Rydberg constant, the bandgap energy, and the anisotropic exciton-reduced-masses at 1.8°K. These were found to be 0.0345 eV, 3.5969 eV and $\mu_x = 0.33\ m_o$, $\mu_z = 0.39\ m_o$, respectively. The results of Zeeman effect measurements obtained by Nagasawa and Shionoya (23, 31) are consistent with group theoretical predictions assuming oxygen 2p valence band and tin 5s conduction band, both split by crystal field.

At low temperatures the spectra in SnO_2 crystals begin with second class exciton transitions at Γ point. The absorption spectra for light polarized parallel to the c axis do not show linearity in a log K *vs.* T plot and hence do not fit Urbach's rule (45). It is possible that these spectra are due to phonon-assisted indirect transitions. Nagasawa and Shionoya (32) found that the best linearity between K and photon energy is obtained when $K^{2/7}$ is plotted against $h\nu$. They suggested that the spectra for $E \parallel c$ may arise from fourth class optical transitions, but this conclusion should be confirmed by other investigations. By extending the calculations of Elliott (60) on the first and second class transitions to the fourth class transition, Nagasawa and Shionoya found the following relation for energies far away from the edge

$$K = \frac{96\pi\nu e^2 x^8 N (2\mu)^{9/2}}{175\, c \cdot \hbar^9} \cdot E^{7/2} \qquad [17]$$

where e is the electron charge, x is a quantity which is of the order of the atomic radius, N is the number of unit cells in the crystal, $\mu = m_e m_h/(m_e + m_h)$ is the excitation reduced mass, and $E = h\nu - E_g$. The experimental results of Nagasawa and Shionoya are qualitatively in agreement with Eq. [17]. The gradual onset of the $E \parallel c$ edge is attributed to the fact that the $\Gamma_3^+ \rightarrow \Gamma_1^+$ transition is triply forbidden for $E \parallel c$. It has been suggested by Nagasawa and Shionoya (30) that the lowest energy direct-allowed transitions to the conduction band for $E \parallel c$ occur from a Γ_2^- valence band several tenths of an eV below the Γ_3^+ and Γ_5^- bands.

McRoberts and Fonstad (36) studied the thermally modulated optical transmission (61) of SnO_2 crystals near the fundamental absorption edge, using polarized light, at temperatures 25°, 80°, and 115°K. Temperature modulation was accomplished by passing a pulsed heating current through the samples via ohmic contacts at the ends. The frequency of modulation was typically about 6 Hz. The transmitted signal was detected by a photomultiplier whose output was fed to two phase-sensitive synchronous amplifiers used in parallel to detect the 6 Hz signal, which was proportional to the change in transmitted intensity, ΔI, and 210 Hz signal, which is proportional to the transmitted intensity, I. The ratio, $\Delta I/I$, was then recorded directly using an analog divider. Neglecting reflection and thermal expansion, the measured quantity $\Delta I/I$, is proportional to the dK/dT and to $dK/d(\hbar\omega)$ or wavelength derivate of the spectrum.

The effect of temperature modulation is most evident by comparing the data taken at different temperatures. As can be seen from Fig. 12, 13, and 14, the primary change is the change in bandgap evidenced as the shift of the entire structure to lower energy with increasing temperature. One can also see the broadening of the exciton structure, observed first by Nagasawa and Shionoya, as the temperature is increased. At 115°K (Fig. 14) only the $n = 2$ exciton line is distinct.

The structures A, B, C, and D in Fig. 12, 13, and 14 have not been reported previously. They do not appear for the light polarized parallel to the c axis. McRoberts and Fonstad have suggested that these structures may be due to the exciton-phonon quasi-bound state (EPQBS) of Toyozawa (62). According to these authors, peak A may be associated with the EPQBS formed by the 1s exciton level and 46 meV LO phonon. Peak B can be associated with the 2s exciton level and 46 meV LO phonon; peak C with the 1s exciton level and 95 meV LO phonon. Finally, peak D may also involve the $n > 1$ exciton states with the 95 meV LO phonon, with little EPQBS binding energy indicated. Fonstad and McRoberts have also suggested that peak

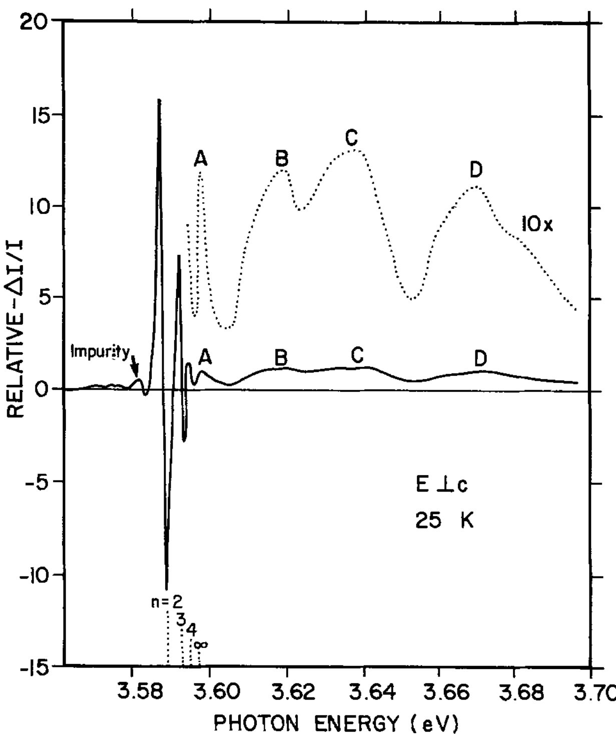

Fig. 12. Thermoabsorption, $\Delta I/I$, at 25°K in SnO_2 single crystals for light polarized perpendicular to the c axis. The temperature quoted refers to the sample temperature before application of the modulating signal. The positions marked on the horizontal axis are placed using the line spacings determined at 1.3°K by Nagasawa and Shionoya.

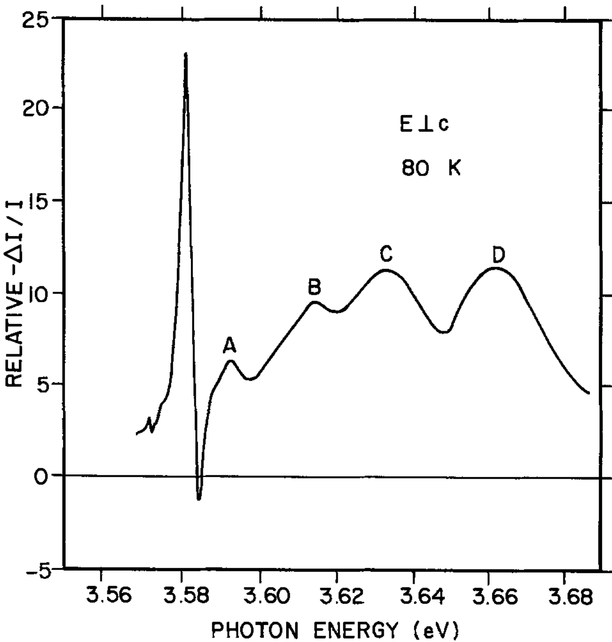

Fig. 13. Thermoabsorption, $\Delta I/I$, in SnO_2 single crystals at 80°K for light polarized perpendicular to the c axis.

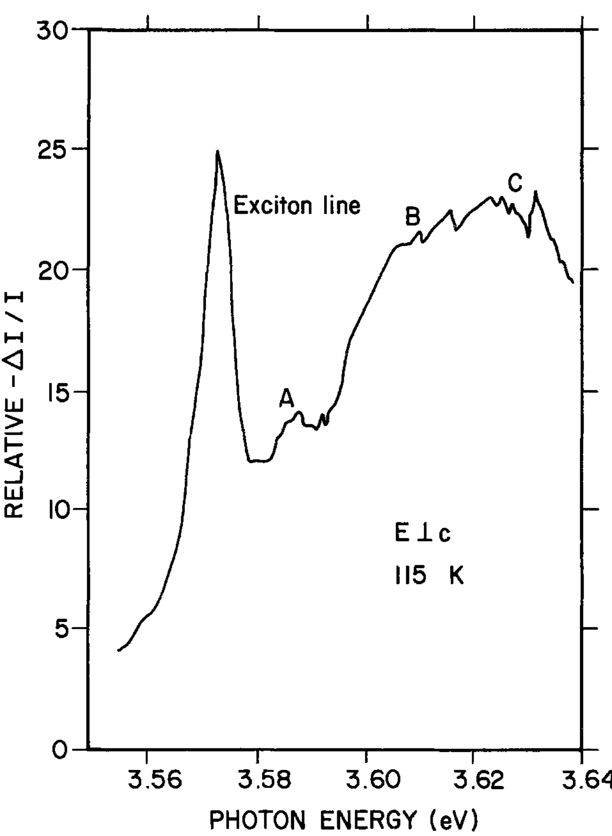

Fig. 14. Thermoabsorption, $\Delta I/I$, in SnO_2 single crystals at 115°K for light polarized perpendicular to the c axis.

A is possibly attributable to a step in K produced by truncation of the EPQBS Lorentzian lineshape at the band edge (63). Since this step would occur over an energy interval of width kT, it is a quantitative reason for the decline in its derivative with increasing temperature, as well as for the general narrowness of peak A.

The results obtained by Fonstad and McRoberts for light parallel to the c axis indicate the onset of a direct-allowed transition around 0.4 eV higher than the $E \perp c$ absorption edge.

Arlinghaus (64) calculated the energy band structure of SnO_2 by a self-consistent augmented plane wave (APW) method. The calculation predicts SnO_2 to be a semiconductor with an allowed direct bandgap of 3.68, corresponding to the transition $\Gamma_5^+ \rightarrow \Gamma_1^+$ for light polarized perpendicularly to the c axis. The analogous optical direct gap for parallel polarized light corresponds to the $\Gamma_1^- \rightarrow \Gamma_1^+$ transition at 4.07 eV. Forbidden direct transitions are predicted around 3.5 eV. Indirect transitions of somewhat lower energy are also predicted. The values obtained on the basis of theoretical calculations are consistent with the experimental data discussed above.

Photoconduction.—Houston and Kohnke (13) investigated photoconduction in SnO_2 single crystals grown by a flux method from a cuprous oxide flux. The results of thermally stimulating current procedure indicated the existence of three trapping levels with average activation energies of 0.21, 0.52, and 0.60 eV. Comparison with dark conductivity data implied the 0.60 eV trap to be associated with the compensated portion of these donor states responsible for the normal n-type conductivity. The results of intrinsic thermal quenching measurements indicated the existence of a compensated acceptor level lying 0.33 eV above the valence band. The ratio of hole to electron capture cross sections for this level was found to be 7×10^2. The authors also found other semidiscrete levels (1.0, 1.3, and 1.8 eV below the conduction band). However, it should be remembered that crystals grown by the flux technique may contain many uncontrolled impurities and therefore it is difficult to interpret the results obtained by Houston and Kohnke. In further measurements carried out on the same single crystals the same authors (14) found the optical quenching of photoconductivity in a single band extending from the fundamental optical gap at 4.0 eV down to a cut off indicative of a 1.3 eV activation energy, which is not in agreement with the value 0.33 eV obtained by these authors from above-mentioned thermal quenching measurements. Thermally stimulated emission in SnO_2 single crystals grown by the Marley-MacAvoy technique (39) were studied by Fillard, Gasiot, and Murcia (22). They found 5 trap levels in the forbidden band at 0.22, 0.44, 0.47, 0.56, and 0.7 eV.

Cunningham, Marton, and Schlesinger (26, 27) investigated the photoconductivity in SnO_2 single crystals grown by the hydrolysis of $SnCl_4$. Photoconductivity was observed only in samples with resistivity higher than 10^4 ohm-cm. The spectral dependence of photoconductivity and the optical transmission spectrum obtained by these authors are shown in Fig. 15. Photoconductivity was found to have a peak response at 370 nm corresponding to the absorption edge. Nagasawa and Shionoya (30) found two peaks at 37.37 and 3.8 eV in the spectral dependence of photocurrent in oxidized SnO_2 single crystals grown by the same technique. Their results are shown in Fig. 16. The first peak was claimed to have a fairly good reproducibility from sample to sample, while the other showed a remarkable difference in sensitivity from sample to sample.

Cunningham, Marton, and Schlesinger (27) found the photoconductivity to be characterized by long rise and decay times. This is shown in Fig. 17. The rate of decay was found to depend on the crystal environment. As can be seen from the figure, in argon and nitrogen the curve was the same, and was independent of the gas pressure. The same decay curve was obtained in a vacuum of 10^{-5} Torr. Introduction of air, oxygen, or water vapor to the measurement chamber during the experiments gave rise to a marked increase in the rate of decay. On the other hand, the introduction of hydrogen caused a slight increase in conductivity. The authors found that the magnitude of steady-state photoconductivity varied with oxygen pressure as it is shown in Fig. 18. They suggested that photoconductivity in the crystals investigated

arose from photogeneration of electron hole pairs, hole trapping at O^{2-} ions, and desorption of oxygen atoms. The decay of photoconductivity in an oxygen atmosphere was suggested to be caused by absorption of oxygen atoms and retrapping of electrons to give chemisorbed O^- ions, while the decay in an inert gas atmosphere or in vacuum was suggested to proceed via trapping of electrons by intrinsic surface traps. The authors also assumed that the influence of water vapor on the photoconductivity decay is caused by OH^- ions, which behave as surface acceptors as do chemisorbed O^- ions. On the other hand, hydrogen may give rise to a surface donor state, which would account for the observed increase in photoconductivity.

Luminescence and phosphorescence.—Luminescence of as-grown SnO_2 single crystals has received some attention (26, 33-35, 65). Cunningham, Marton, and Schlesinger (26) found that an excitation spectrum for blue fluorescent emission is similar to that of photoconductivity. They also observed thermoluminescence above room temperature after gamma irradiation, namely, two main glow peaks, both corresponding to a blue emission.

Phosphorescence emission from high resistivity SnO_2 single crystals using Hg bulb as the exciting source was investigated by Fillard *et al.* (33). The results are presented in Fig. 19. As can be seen from the figure, three emission bands exist centered at wavelengths 0.44, 0.56, and 0.64 μm. The authors found that at 77°K the total emitted light shows a complex dependence on time, due to many kinds of levels involved; at room temperature the signal decreases exponentially with a time constant $\tau = 2.25$ sec. The photoluminescence excitation spectrum has been found by these authors to be similar to that of the phosphorescence.

Crabtree (34, 35) investigated cathodoluminescence in SnO_2 crystals, as-grown and doped with europium and terbium. Luminescence was caused by bombarding the crystals with 10 keV electrons. The cathodoluminescence spectrum obtained by these authors for as-grown crystals is shown in Fig. 20. The broad featureless band obtained is like that found by Fillard *et al.* The emission spectrum of europium-doped SnO_2 shown in Fig. 21 seems to comprise the intrinsic emission band of the host lattice and bands due to the presence of the europium ions. In a rare earth ion, such bands are due to electronic transitions occurring among the inner, shielded 4f electrons. The orbits of the 4f electrons are so deeply buried within the electronic shell that the energy levels are only slightly perturbed when the ion is placed within a crystal. The spin-orbit splitting of the energy levels is about 1000 cm^{-1}, while the

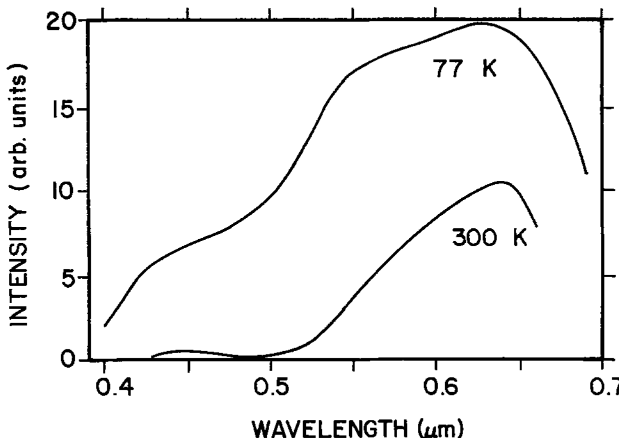

Fig. 19. Phosphorescence spectra in SnO_2 single crystals taken immediately after excitation at 77° and 300°K.

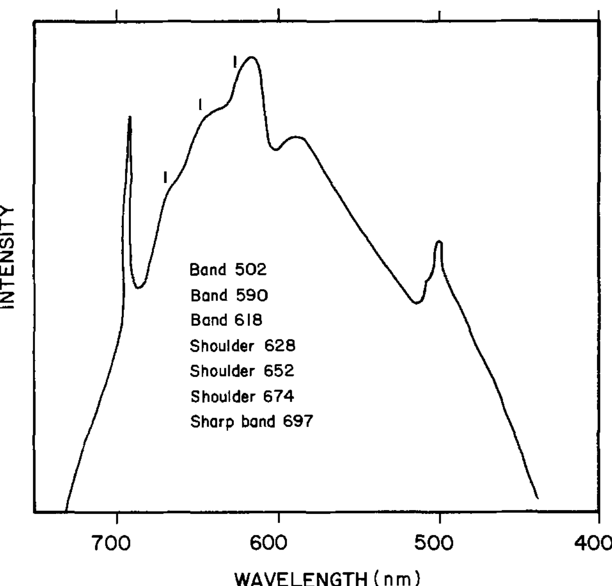

Fig. 21. Cathodoluminescence spectrum of SnO_2 crystals doped with europium.

splitting of a given J level due to the crystalline field is about 100 cm^{-1}. Hence emission bonds are relatively sharp and do not change much when a given rare earth ion is placed in different hosts. It seems that the europium ion is incorporated as Eu^{3+} in SnO_2. Similar results have been obtained in the case of SnO_2 doped with terbium (35).

Tin Oxide Films

The optical properties of tin oxide films were investigated by many authors [(3-7, 17, 28, 37) see Table I]. Tshiguro, Sasaki, and Arai (4) measured the transmission and reflection of highly conductive SnO_2 films obtained by hydrolysis of $SnCl_4$ on fused quartz or rock salt substrates. The conduction electron concentration in the samples was 10^{19}-10^{20} cm^{-3}. These specimens were almost perfectly transparent in the visible region and the fundamental absorption began at about 0.3 μm extending to a shorter wavelength. In the infrared region, the transmissivity decreased gradually whereas the reflectivity began to increase. The authors found that the fundamental absorption gap was at about 4 eV and the plasma frequency of carriers lay in the near infrared region. They also found that the carriers in transparent conducting films were scattered mainly by ionized impurities. The refractive index of SnO_2 films obtained by Tshiguro *et al.* (5) was found to vary with the wavelength from 1.92 at $\lambda = 0.5$ μm to the minimum value 0.87 at about 3.5 μm and 5.53 at 30 μm.

Miloslavskii (6) investigated the optical properties of highly conductive ($\sigma = 10^2$-10^3 ohm^{-1} cm^{-1}) transparent SnO_2 films prepared by spraying anhydrous $SnCl_2$ and $SnCl_4$ or alcohol solutions of these compounds on glass, and pyrolytic decomposition of these substances at 770°-870°K (66). The conduction electron concentration was 10^{18}-10^{20} cm^{-3}. The observed index of refraction was $n = 1.98 \pm 0.2$ for $\lambda = 0.59$ μm. Absorption was studied in SnO_2 films deposited on thin plane-parallel plates of rock salt single crystal. Two absorption bands were observed, namely: a narrow band with a maximum at 16.4 μm and a wide band with maximum at 8.5-9 μm. The intensity of both absorption bands increased with increasing conductivity. In the case of films with high conductivity, widening and overlapping of the absorption bands were also observed. As the temperature decreased from 490° to 130°K, a considerable increase of absorption coefficient of the two bands was observed. On the other hand, films of SnO_2 obtained by oxidizing thin films of tin deposited by vaporization in vacuum had a considerably lower conductivity (about 1 ohm^{-1} cm^{-1}) and were transparent throughout the measured range of the spectrum (1-18 μm). Miloslavskii assumed that the appearance of the absorption bands in the films obtained by pyrolytic decomposition of chlorides is related to the introduction of a large number of impurity atoms, and attributed it to electron transitions from the ground state of the impurity centers to higher energy levels. He suggested that the long wavelength band corresponds to a transition of an impurity atom to an excited energy state, while the short wavelength broad band is due to a transition to the SnO_2 conduction band. This is indicated by the asymmetrical shape of the absorption band, *i.e.*, a slow drop in absorption in the high energy range and a sharper drop in the long wavelength range. The increase of these bands as the temperature decreases is caused probably by an increase in the degree of occupancy by electrons in the ground state. It seems that the chlorine atoms are the impurity centers.

Miloslavskii also investigated the optical absorption and electrical conductivity of SnO_2 films doped with antimony. The films were obtained by spraying $SnCl_4$ containing a small amount (several percent) of $SbCl_3$. He found that increasing the concentration of $SbCl_3$ caused increases in both the electrical conductivity and the absorption of these films. The films showed considerable absorption in the infrared region. The short wavelength end of the infrared absorption extends into the visible range, which imparts a blue color to the films and reduces transmissivity to 50-70%. The absorption observed was suggested to be due to free electrons, contributed by the Sb donors to the SnO_2 conduction band.

The influence of free carriers on the optical absorption of conductive and nonconductive SnO_2 films was investigated by Arai (7). Conductive SnO_2 films were prepared by hydrolysis of $SnCl_4$ and were also obtained by vacuum evaporation of chemically prepared SnO powder. Nonconductive SnO_2 films were obtained from conductive SnO_2 or SnO by heating them in air. Arai found that in the visible region of the spectrum, optical properties of conductive and nonconductive SnO_2 films were similar. However, in the u.v. region there were some differences observed between the absorption behaviors of these materials. This is shown in Fig. 22. The absorption edge was found to be at 3.82 ± 0.030 and 3.71 ± 0.025 eV for conductive and nonconductive SnO_2 films, respectively. The temperature change of absorption edge for both these materials was -2.0×10^{-4} eV/°K. Differences in the transmissivity and reflectivity of conductive and nonconductive SnO_2 films were observed also in the infrared region. It is likely due to the difference of the concentration of free electrons. Figure 23 shows the transmission and reflection curves of conductive SnO_2 films doped with antimony, in the infrared region as measured by Arai.

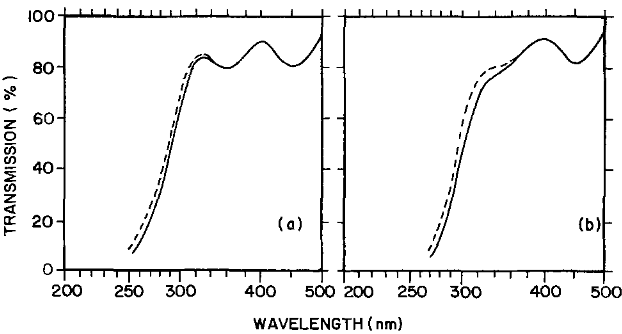

Fig. 22. Temperature change of transmission for SnO_2 films; (a) conductive films. (b) nonconductive films. Full line at 303°K; dotted line at 128°K.

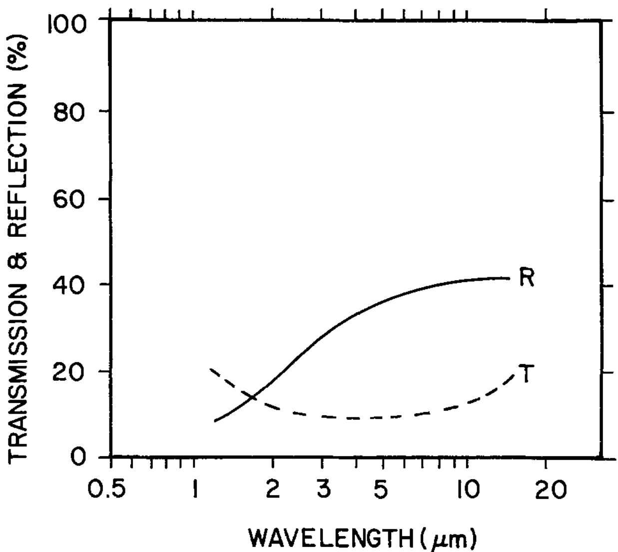

Fig. 23. Transmission and reflection curves of conductive SnO_2 films doped with 1% antimony.

Spence (17) measured the optical absorption edge of vacuum-evaporated films of SnO_2 at room temperature. The absorption coefficient was determined by the simple formula

$$K = (2.303/d) \log_{10} (1/T)$$

neglecting the reflectance; where d is the thickness in cm and T is the transmission in percent. From the dependences of K, K^2 and $K^{1/2}$ *vs.* photon energy, and the extrapolation of linear portions of these curves to zero absorption, Spence found that the absorption edge occurs at about 3.7 eV, with direct transitions indicated at about 4.3 eV and indirect transitions at about 2.7 eV. The impurity peak reported at 3.36 eV was also observed. The value of the absorption edge is similar to that found by Arai, and the values of direct and indirect transitions are close to those measured by Reddaway and Wright (11) in SnO_2 single crystals.

The optical properties of Si-SnO_2 n-n heterojunctions were investigated by Nishino and Hamakawa (28). They carried out measurements of transmission over the wavelength region from 220 to 1400 nm. Transmission spectra for two samples at room temperature are shown in Fig. 24. The films have the ability to transmit about 90% and are almost transparent in the wavelength region above 350 nm. The absorption edge is seen near 350 nm as in the SnO_2 films investigated by Arai (7). This edge is not sharp because of a polycrystalline film. The photovoltage spectra for Si-SnO_2 n-n heterojunctions measured at

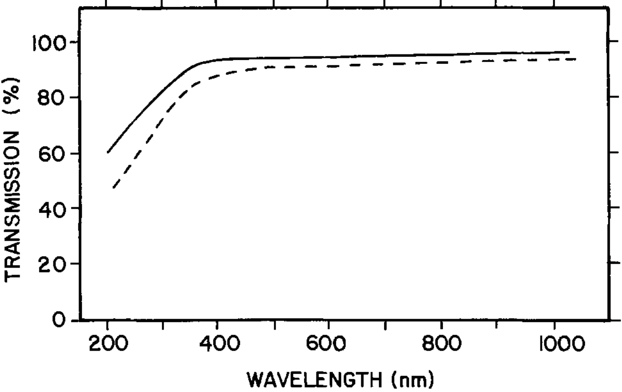

Fig. 24. Transmission spectra at room temperature for two conducting SnO_2 films deposited on quartz.

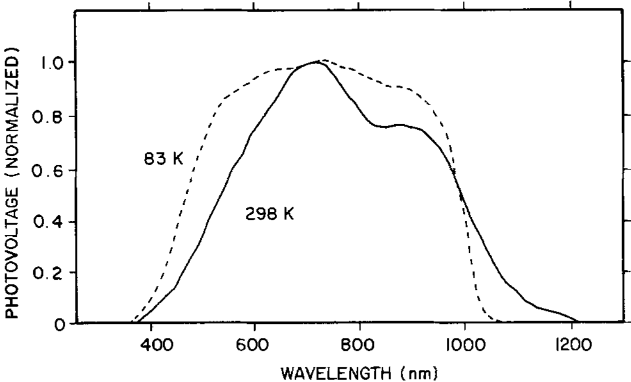

Fig. 25. Photovoltage spectra in Si-SnO_2 n-n heterojunction measured at two temperatures. Amplitude of photovoltage is normalized at the maximum value.

298° and 83°K are shown in Fig. 25. These relative spectra are normalized at the maximum values of photovoltage. The photovoltaic response is seen to spread in a wide wavelength range from 400 to 1200 nm. The wavelengths giving the maximum photovoltage are the same for both spectra at 710 nm. It is seen that the Si-SnO_2 photodiode would be applicable as a photosensor having the response in a wide wavelength region which is wider than a commercial silicon photodiode.

Kim and Laitinen (37) investigated the electrochemical behavior of thin film SnO_2 electrodes under sub-bandgap energy photoexcitation. They found that photocurrents were dependent on the intensity of the light, wavelength, and the applied voltage. The photocurrent spectrum showed a sharp decrease near the bandgap energy. The authors assumed that this photocurrent is due to the oxidation of water in the electrolyte by holes at the permitted energy levels in the bandgap region. These energy states may be formed by the presence of impurities.

Conclusions

Allowed direct transitions in SnO_2 crystals were found at 3.57 eV (3.7 eV) and 3.93 eV (4.1 eV) for radiation polarized perpendicular and parallel, respectively. Indirect transitions were found at 3.42 and 3.72 eV for light polarized perpendicular and parallel to the c axis, respectively.

At low temperatures, the spectrum for $E \parallel c$ begins with second class exciton transitions at the Γ point, while at temperatures higher than 200°K, the spectrum may be interpreted in terms of Urbach's rule. It was suggested that the spectrum for $E \parallel c$ may arise from fourth class optical transitions. Studies of the thermally modulated optical transmission showed structures for $E \parallel c$ which may be due to the exciton-phonon quasi-bound state of Toyozawa.

Static dielectric constants have been found to be 9 and 14 for radiation polarized parallel and perpendicular to the c axis, respectively. Investigations of infrared absorption showed optical polar scattering of carriers at room temperature. Electron effective mass was found to be 0.17 m_o. Anisotropic exciton-reduced-masses have been estimated to be $\mu_x = 0.33\ m_o$ and $\mu_z = 0.30\ m_o$.

Measurements of photocurrents in SnO_2 crystals showed many trapping levels of unknown origin. Photoconductivity was found to have a peak at 370 nm and to be characterized by long rise and decay times. The rate of decay was found to depend on the crystal environment.

The luminescence and phosphorescence spectra of SnO_2 crystals were also investigated but these phenomena are not elucidated yet. The optical properties of SnO_2 films are approximately similar to that of single crystals.

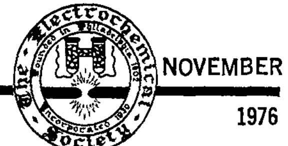
JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS



NOVEMBER 1976

Building a Better Electrochemical Mousetrap[1]

Robert Burns MacMullin

Robert B. MacMullin presents the Electrochemical Engineering and Technology Award Address.

Mr. President: This award, much appreciated by me, comes in the late November of my career. On this fine day in early May, it seems appropriate to return the cash part of the Award to the Society for reinvestment in the Fund, hopefully to encourage younger men to write and to publish the future chapters in electrochemical engineering science and technology.

Electrochemical engineering is not really a new discipline. There used to be a Course XIV by that name at MIT. I graduated as a chemical engineer, Course X, and drifted into electrochemistry from necessity. After all, the Mathieson Alkali Works Incorporated had been making chlorine and caustic soda at Niagara Falls since 1897. In 1920 I was to become familiar with acres and acres of Castner amalgam cells, the rocking variety, which then operated at about a thousand amperes. My first assignment was not electrochemical at all, just chemical: finding new uses for by-product chlorine. Up to that time, all the chlorine was converted to old-fashioned bleaching powder which was used, among other things, for the disinfection of outdoor toilets! As time went on, I became involved in devising better mercury cells, and even in making other commodities, such as metallic magnesium, in new types of electrolytic cells.

I stayed with Mathieson until 1945. Since then, as a consultant, I have been helping clients in their efforts to make a wide variety of products by the electrochemical route. My field, then, is electrosynthesis, or if you prefer, electrowinning such things as metals, inorganic chemicals, and organics.

In the early days electrochemical engineering was, by and large, an art. In 1920, you flew by the seat of your pants. As time went on, theoretical electrochemistry became better understood. Young engineers learned some of the lingo, and began applying it on a scale of kiloamperes rather than milliamperes. This more scientific approach has come to be called electrochemical engineering. Even so, art still plays an important role. Innovation is an art, and you can't contribute much to electrochemical engineering without making innovations.

It is beyond my competence to describe the whole field, even if there were time. I have been personally involved in a number of unexpected and rather startling developments, and I propose to share a couple of these with you, to show what I mean by innovation. As a guideline, I will take as my theme, "Building a Better Electrochemical Mousetrap."

YOU DREAM OF A BETTER MOUSETRAP
The world is waiting for it. Why not an electrochemical mousetrap?
YOU START TO WORK ALONG CONVENTIONAL LINES
You design the mousetrap, making use of all available technology.
YOU MAKE A DISCOVERY WHICH SEEMS TO VIOLATE ALL PRECONCEIVED NOTIONS
The mousetrap doesn't work the way you hoped it would, but strangely works better if you turn it upside down, or inside out, or if you leave out a part.
YOU HASTEN TO UNRAVEL THE MYSTERY
You try everything in the book, including thermodynamics, kinetics, engineering, plus a little black art. You wind up with a new set of rules, including scale-up.
YOU WAKE UP, YOU HAVE YOUR BETTER MOUSETRAP, BUT
It is ahead of its time, no market.
or, It's too costly to make, you can't sell it.
or, You may dream again of a still better mousetrap. Backers are scarce.
or, Everthing clicks. You build a plant and run into other problems.
or, Your dream is fulfilled, and eventually you get out of the red.

It so happens that both my chosen examples wound up in the same category: they were ahead of their times. They both follow the pattern for the better mousetrap. The inventions, of course, were adequately patented, but patents are poor media for describing the drama of innovation. The sophisticated electrochemical technology that was born still lies buried in corporate archives. Both examples deal with my long interest, bordering on passion, for electrochemistry in porous media. The first example concerns the electrowinning of titanium metal, and the second, the electrofluorination of hydrocarbons.

Electrolytic Titanium

Right after World War II, there was considerable excitement over the possibility of using titanium metal in airframes and in gas turbines. Ti, a strong refractory metal with a density of only 4.5, became glamorous, and there was a scramble to develop viable, economic processes for its manufacture. (Fig. 1). The Kroll process led the way, using magnesium metal to reduce titanium tetrachloride. I'll call this "tickle 4" for short. The substitution of Na for Mg followed soon after. The $TiCl_4$ was made by the reductive chlorination of rutile, a rather expensive titanium oxide ore. Only step 3 is electrolytic, and both Mg and Na were commercially available, and looking for new outlets.

In 1950 the New Jersey Zinc Company got the idea of building a better mousetrap, an electrochemical mousetrap (Fig. 2). They already had a stake in Quebec Iron and Titanium Limited which produced titanium slag high in TiO_2 from cheap Canadian ilmenite. More than eight years of effort and many millions of dollars were spent in perfecting this process and demonstrating it in a large pilot plant, using commercial prototype cells. Meantime, titanium lost its glamour when the Air Force canceled its plans for titanium aircraft. All hands then turned to the problem of finding other uses for the metal. The NJZ process was moth balled and rests in its cocoon to this day.

I propose to describe some of the electrochemical paradoxes that were encountered during this eight-year campaign to make a better mousetrap, and how a new technique in electrochemical engineering was developed to resolve the paradoxes.

A low melting eutectic of potassium, lithium, and sodium chlorides was chosen as supporting electrolyte, and cells were operated at about 550°C, 200° above the freezing point (Fig. 3). Now, $TiCl_4$ does not ionize, and has a very limited solubility in such a bath. The lower chlorides, however, are quite soluble, and ionize. The trick, then, was to carry out the process in stages, either sequentially, or in designated zones in the cell, as shown in Fig. 4.

How do you keep these zones separated? If you don't separate them, the lower chlorides would be rechlorinated at the anode, and the current efficiency would be essentially zero. Obviously a permeable diaphragm of some sort was needed. A variety of porous ceramics was tried, but they all failed in one way or another.

KROLL TYPE PROCESSES

1) $TiO_2 + C + 2Cl_2 = TiCl_4 + CO_2$
rutile

2) $TiCl_4 + 2Mg = Ti + 2MgCl_2$

3) $2MgCl_2 \xrightarrow{\text{electrol.}} 2\,Mg + 2Cl_2$

2) $TiCl_4 + 4Na = Ti + 4NaCl$

3) $4\,NaCl \xrightarrow{\text{electrol.}} 4Na + 2Cl_2$

Figure 4

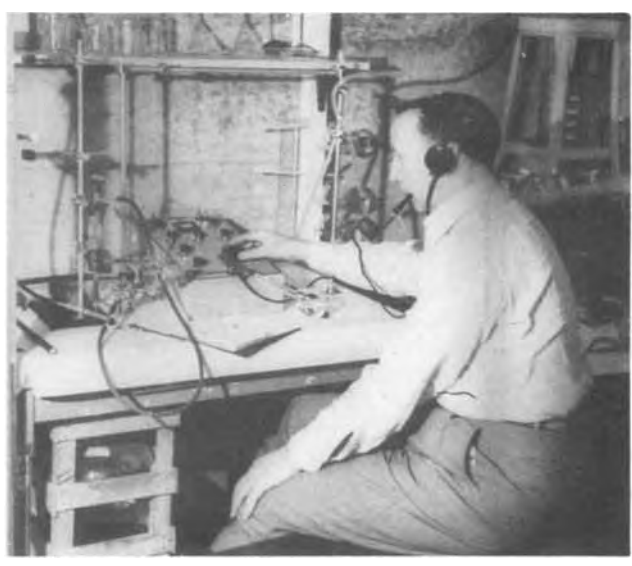

Figure 5

In 1955 I got the notion to do some research on my own, in my small cellar laboratory, on the characteristics of porous beds and structures (Fig. 5). I worked out the relation between permeability to viscous flow, and the electrical conductivity of such porous structures when saturated with electrolyte. The relation is shown in Fig. 6.

This equation is valid only if the solid matrix of the porous structure does not conduct. It is based on the notion that, in a porous insulator saturated with fluid electrolyte, the constraints to laminar fluid flow should be the same as the constraints to electrical current flow. In both cases, the flux is proportional to the gradient. The truth of this was easily demonstrated, using 1000 Hz a.c., and also using d.c.

$$\frac{m^2}{P} = k\frac{\rho}{\rho_0}$$ MacMullin, Muccini 1956

If you switch to a porous matrix that conducts, such as porous metal or porous graphite, and use a.c., both the electrolyte in the pores and the matrix itself conduct, and the pathways for current flow are not the same as for fluid flow (Fig. 7).

On the other hand, if you use d.c., and take care that the potential between the electrolyte in the pores and the metallic matrix does not exceed the decomposition potential of the electrolyte, as in the center figure, no electrons are exchanged between the phases. The d.c. is constrained to the pores, and the analogy between fluid flow and electrical flow is restored.

Lastly, if the voltage drop across the conducting porous solid exceeds the decomposition voltage of the electrolyte, as in the lower figure, the matrix also conducts. The erstwhile porous diaphragm becomes a bipolar electrode, and its usefulness as a separator is destroyed.

Once these concepts were understood, let us see how the NJZ team made use of them. Why not use the dendritic, and therefore porous, deposit of titanium metal on the cathode as the diaphragm? The geometry is best seen on the drawing of a landmark patent by C. E. Barnett, U.S. Pat. 2908619 (Fig. 8).

Chlorine is evolved on the central graphite anode 11. The cathode is a cylindrical Inconel sheet 3, closed on the bottom 4, and the walls are punched out with round holes, or windows 5. $TiCl_4$ is introduced through pipe 13 dipping into the bath in the catholyte zone. A small concentration of $TiCl_3$ and $TiCl_2$ can be quickly built up by adding some off-grade Ti powder to this zone, since it will react with $TiCl_4$. When the current is turned on, a dendritic deposit of Ti metal forms and quickly spreads over the holes. From then on, the anolyte and catholyte zones are separated.

What happens then? There are no soluble Ti ions in the anolyte, so Ti cannot deposit on the near (proximal) side of the cathode. However, the d.c. flows through the pores in the metal diaphragm to the other side where the soluble Ti ions are, and deposit Ti metal on the back (distal) side of the cathode. The way the deposit grows is shown in the next sequence of figures.

On the left in Fig. 9, an enlarged view of the holed cathode. On the right, a cross section showing cathode and anode.

In Fig. 10, current paths are shown with solid lines, and the Ti deposit with dashed lines. Left, the current has been turned on and dendrites of Ti cover the holes. Right, the deposit starts to spread out over the cathode and the distal deposit becomes continuous.

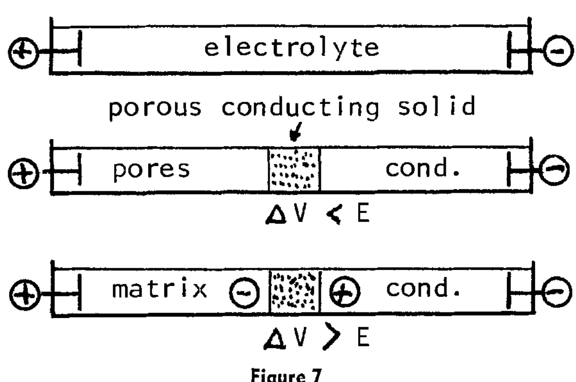

Figure 7

Figure 8

Left in Fig. 11, a heavy deposit is built up at high current density. Right, last stage and prior to opening the cell, the soluble Ti chlorides are stripped from the catholyte at a lower current density. The fully developed deposit is several inches thick. Continuation would lead to deposition of Na on the proximal side. At this point the cathode is pulled from the cell and harvested.

Now let's look at the voltage distribution for the clue as to how thick the deposit may be before Na deposition ruins the current efficiency (Fig. 12). E_a is the equilibrium potential for Cl_2 evolution from the chloride melt, and η_a is the chlorine overvoltage. The slope of the *IR* drop in the bath is its resistivity. The slope is

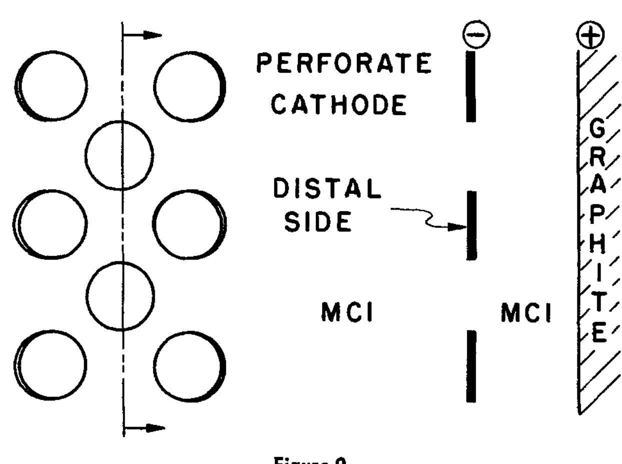

Figure 9

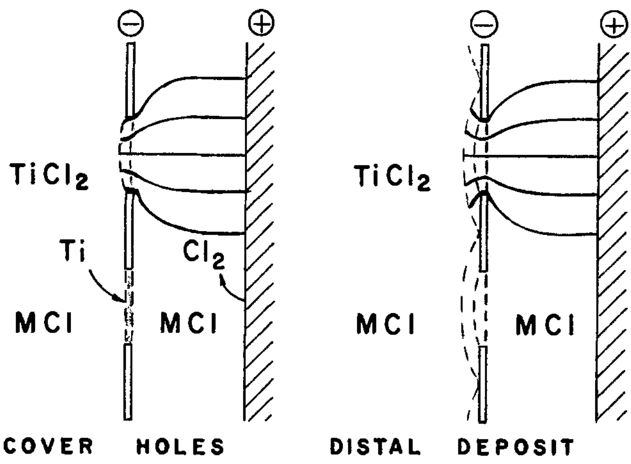

Figure 10

END STEADY STATE

VOLTAGE DISTRIBUTION FOR DISTAL DEPOSITION

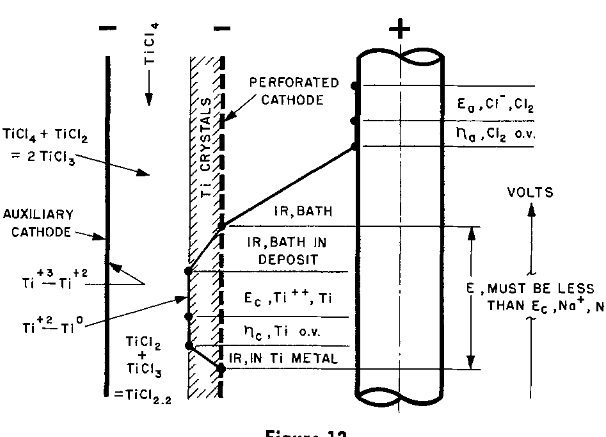

Figure 12

higher within the deposit because only the pores conduct. $TiCl_4$ is fed between the two cathodes and reacts with the $TiCl_2$ present to form $TiCl_3$. The $TiCl_3$ is reduced to about $TiCl_{2.2}$ at the auxiliary cathode, which may be the pot wall.

E_c is the equilibrium potential for deposition of Ti metal, and η_c is the overvoltage, actually quite small. Electrons are given up by the Ti deposit at the bath interface, and there is a small *IR* drop as the current flows into the Inconel cathode.

Now the voltage drop marked *E* must be kept less than the alkali metal deposition potential, otherwise the alkali metal, Na in this case, will form on the proximal surface of the cathode. The sodium would back react with the chlorine, and this would be fatal to the current efficiency.

We are now ready to apply some electrochemical engineering to the unique and startling concept of metal deposition on the back side of a cathode!

Figure 13

Figure 13 presents the salient facts about the bath and the deposit.

An easy way to measure the resistivity of the deposit as it builds up is to open the cell switch and measure the back emf (Fig. 14). The slope of the line is the resistivity. The slope, naturally, depends on the percent of Ti in the deposit, as this determines the void fraction ϵ occupied by electrolyte.

At this point I will digress to explain, in a simple way, how current flows through the pores of several kinds of diaphragm.

Figure 15 shows a sheet made porous by punching out straight capillaries of uniform cross section, normal to the sheet. The pores are filled with electrolyte of resistivity ρ_0. The resistivity of the specimen is ρ, and it is easy to see that ρ is inversely proportional to the open area of the pores, which is identical to the void fraction ϵ of the sheet. We will characterize the sheet resistivity by the dimensionless number $N_r = \epsilon \cdot \rho/\rho_0$. For this special kind of diaphragm, $N_r = 1$.

A more natural kind of porous body (Fig. 16) contains uniformly dispersed pores of irregular shape, these pores being interconnecting and isotropic. If we apply a voltage gradient along the x axis, only the pores lined up in this direction conduct. Those lined up in the y and z directions see no voltage gradient

Figure 16

and do not conduct. For this kind of diaphragm we find that $N_r = 2.5$ to 3, approximately.

Figure 17 shows a dispersion of nonconducting spheres, such as glass beads or gas bubbles, in a conducting medium. The matrix, in this case, is the liquid medium, rather than the solid. According to Dr. Tobias, the resistivity ratio equals the void fraction to the minus 3/2 power. Therefore, $N_r = \epsilon^{-0.5}$.

If our diaphragm is made up of layered fibers (Fig. 18), as in sheet asbestos, or mats of metal, glass or carbon fibers, the resistivity ratio turns out to be surprisingly close to that given by the Tobias equation. From work done by Dr. Meredith, $\rho/\rho_0 = \epsilon^{-1.54}$ over the range of interest. Therefore, $N_r \simeq \epsilon^{-0.54}$.

How does the dendritic deposit of titanium behave? Does it resemble any of the diaphragms just shown? The dendrites are treed, and contain some spherical nodules as well.

Observe in Fig. 19 how the N_r changes with the density of the deposit. We can easily vary the percent of Ti in the deposit by adjusting the concentration of the soluble Ti in the catholyte, and also by varying the current density.

In Fig. 20 we have plotted the relative conductivity of the deposit against the volume fraction of salt in the deposit. See how the conductance of the deposit decreases as the weight percent Ti is increased. As indicated, one line shows, for comparison, what the curve should be for dispersed spheres, and another line, for layers of fibers. The agreement is good at about 45% Ti. Beyond about 50% Ti the relative conductivity rapidly declines, and at 70%, approaches that of a typical porous solid with interconnecting pores, such as porous porcelain. The preferred deposit contains 45% Ti, which is easily achieved in actual operation.

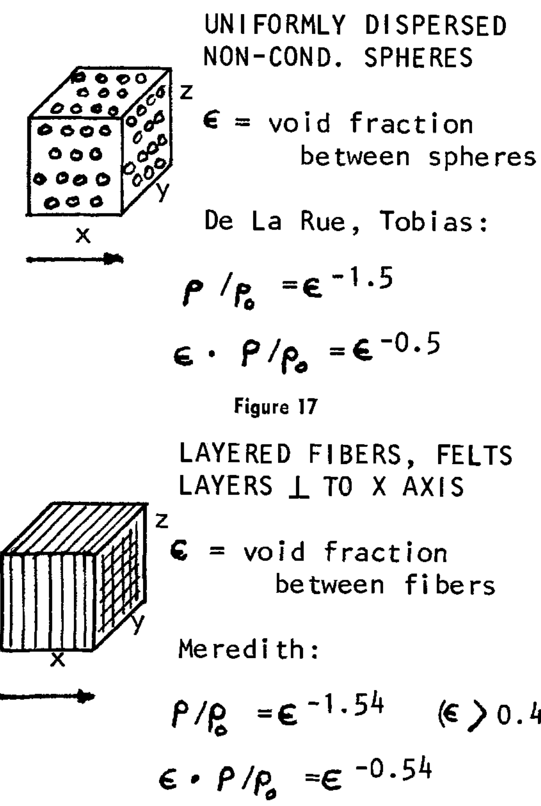

Figure 18

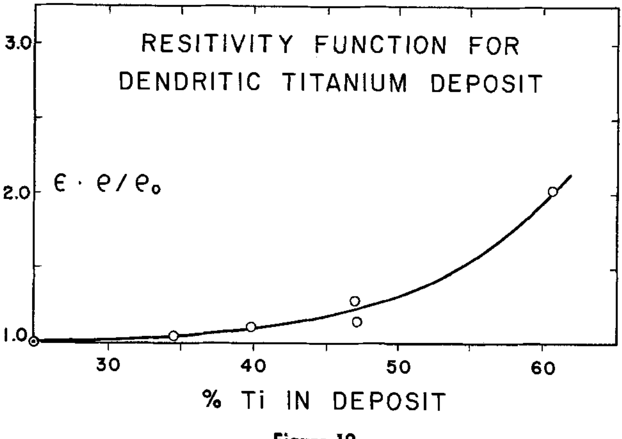

Figure 19

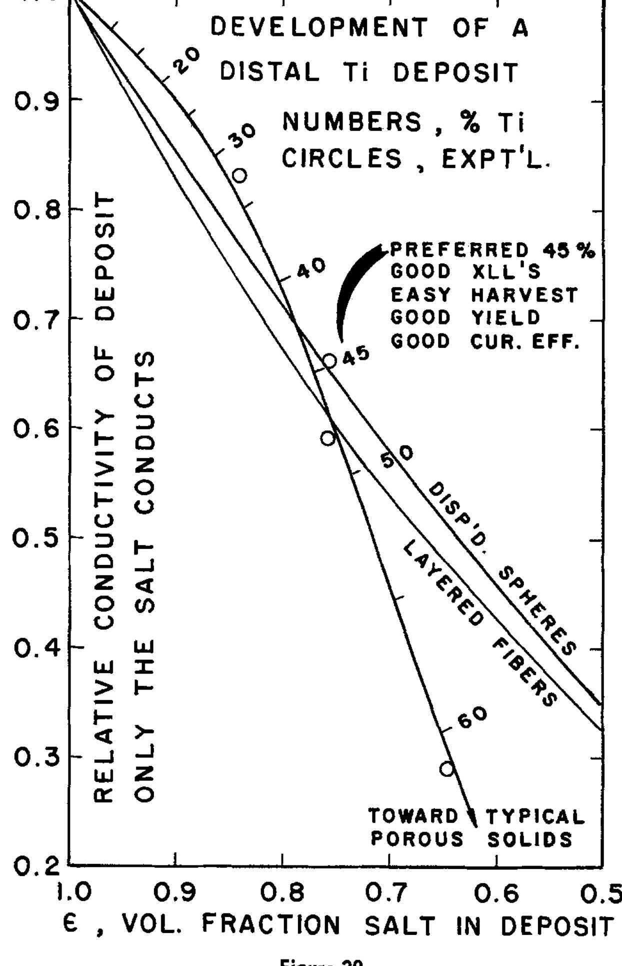

Figure 20

For a safe back emf of 3.2V, Fig. 21 shows the allowable product of current density and thickness of deposit, as a function of the percent of Ti in the deposit.

Figure 22 shows that heavier deposits are obtained by sacrificing current density. In any case, the optimum kind of deposit would appear to contain 45% Ti. From here on, the engineering problem consists in evaluating the trade-offs between amount of metal harvested, and the time required to build the deposit. Optimization studies indicated the data shown in the next figure.

Harvesting the Ti from a cell is the last step of a four-step cyclic process (Fig. 23). The pilot plant cells, rated

Figure 23

at 14 to 18 kA, were thus able to produce 600 lb of metal, from which 500 lb of on-grade sponge was recovered. The harvesting of the Ti turned out to be absurdly simple. When the cathode is lifted out of the cell, the still-molten salts in the deposit protect it from oxidation in the air. If exposed, it is pyrophoric. If you drop the loaded cathode onto a hard surface before the salt freezes, the impact causes the whole deposit to slump off. The deposit is then allowed to freeze, and the frozen salt protects it from the atmosphere. Oxidation losses during further processing are minimal.

Figure 24 presents some key figures for a conceptual, semicommercial plant having a nominal capacity of 10 short tons of on-grade sponge per day. The average cell voltage is 8.2V, and the current efficiency is over 75%. About 80% of the harvested deposit can be recovered as on-spec Ti, and the off-spec Ti is recycled to the cells. The energy consumption is about 10 d-c kWhr per pound of on-spec metal.

Figure 25 is the conceptual flow diagram for making titanium ingots from titanium slag. There are three recycling operations. Chlorine from the cells, together with a small makeup, is used to make $TiCl_4$. The salt in the deposit is leached out and recovered because of its valuable lithium content. Off-spec Ti fines, contain-

ing nonmetallic impurities, are recycled to the cells for the buildup step. There is a small charge for additional ampere hours as they are refined in subsequent steps. The on-spec sponge has a Brinell hardness less than 100, and is equal to the best metal made by the Kroll process.

Summarizing, I think this case history illustrates very well our theme about the better electrochemical mousetrap. The conventional approach didn't work because we couldn't find a suitable ceramic diaphragm. So we left out the diaphragm. We punched holes in the cathode to force deposition of metal onto the back side of the cathode, a truly revolutionary idea. The consequences of this mode of operation were fully explored and applied to the problem of scale-up. The better mousetrap worked very well on a large pilot scale. But: the better mousetrap was ahead of its time, the market wasn't there, and the dream of commercial rewards has remained unfulfilled to this day.

Electrochemical Fluorination of Hydrocarbons

Prior to 1966, the only known method for electrochemical fluorination of organic compounds was by the technique invented by J. H. Simons (Fig. 26). The organic was dissolved in a bath of anhydrous HF containing some KF to make it conductive. Nickel electrodes were immersed in the bath, and fluorine gas was generated at the anodes, hydrogen gas at the cathodes. The F_2 thus generated reacted with the H atoms in the organic, as shown. The heat generated exceeds that required to break the carbon-carbon bond, and scission of the carbon chain was frequently encountered.

As reported in *This Journal* in 1964, researchers at Phillips Petroleum Company had successfully electrochlorinated liquid hydrocarbons at a porous, flow-through carbon anode, using aqueous hydrochloric acid as the electrolyte. It then occurred to them that it might be possible to electrofluorinate hydrocarbon gases or vapors in a conventional fluorine cell. The only change would be to use a porous carbon anode, so that the hydrocarbon feed could be forced through the anode. The electrolyte was anhydrous $KF \cdot 2HF$, the strength being maintained by adding HF as fast as it was depleted by electrolysis. They tried it, and it worked.

Curiously, there was no breakdown of the carbon chain. Why? As it turned out (Fig. 27), they weren't fluorinating with F_2 gas, but with an intermediate addition product $C \ldots F_x$. The voltage required to liberate free F_2 from HF is about 2.9V, while that required to form the complex is only about 1.75V. From this information, the heat of the reaction shown in the figure is only about 60 kcal, not enough to break any carbon-carbon bonds.

Another curious thing was noted. The bath did not seep into a used porous anode. Why? The fluorinated surface of the carbon, inside and out, was hydrophobic to the electrolyte. To force the bath into the pores would require a hydrostatic pressure great enough to overcome the repulsion of the hydrophobic surface. For

Figure 27

a depth of immersion of 4 to 6 inches, the porous anode remained dry.

This led Messrs. Fox, Ruehlen, and Childs to the idea of introducing the feed gas into the open bottom of the porous anode (Fig. 28). The bath, pressing against the sidewalls of the immersed anode, sealed off the escape of gas, which then exited above the bath level. The feed gases rose through the dry porous anode like hot gases in a chimney. When the current was turned on, the $C \ldots F_x$ was formed at the anodic surface and, *mirabile dictu*, the hydrocarbon gas was fluorinated as it flowed by! Thus, the concept of the porous flow-by electrode was born. Up to 60 or more percent of the available hydrogen atoms in the feed could be replaced by fluorine in one pass up through the chimney! It looked like action, or rather reaction at a distance, something like Newton's concept of gravity. Radial gas diffusion seemed inadequate to explain the effect. Maybe the F atoms were hopping from site to site.

At this point the electrochemical engineers had a field day trying to model the actions and interactions. They asked for more data as fast as one theory after another went into the dustbin. They finally arrived at a

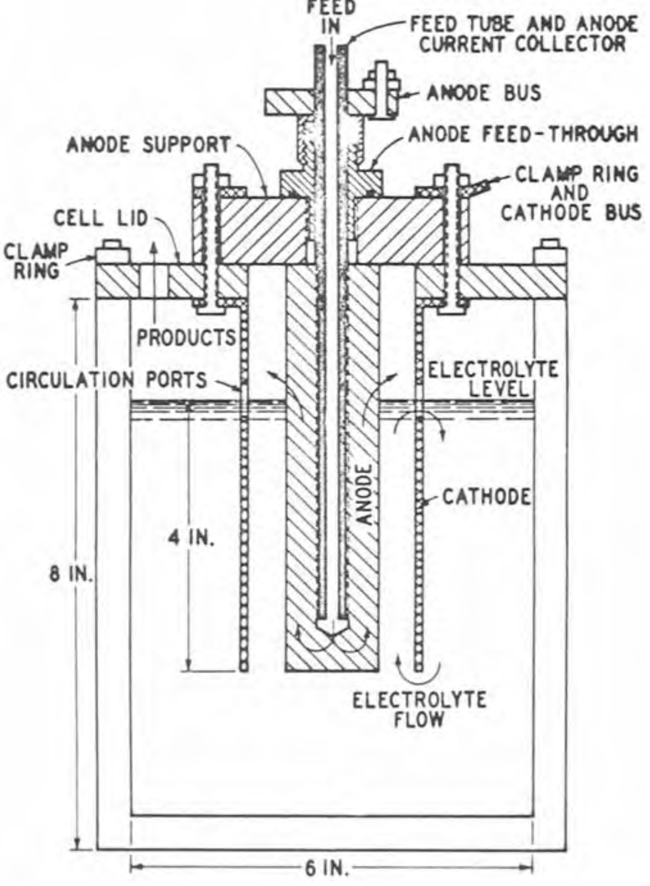

Figure 28

set of rules for scale-up to commercial sized prototypes. The field day lasted more than two years.

Consider the porous anode. We want the feed gas to rise through the anode without breaking out. If any breaks out, it can no longer be fluorinated. The gas pressure at any level equals the pressure where introduced, less the pressure drop in flowing up the anode up to that level. The pressure gradient at any level depends on the permeability of the porous structure, the gas flow rate, and the viscosity of the gases, as shown in Fig. 29. But, as the gas ascends, it reacts with the fluorine complex at a rate which depends on the current density at that level. Heat is generated, the temperature changes, and the volume of the gas changes. So does its composition and viscosity. All this information was processed in a computer program, and pressure and temperature profiles were printed out for just about any kind, size, and shape of anode we could imagine.

If the grain size of the porous carbon was too coarse, it had high permeability, and hence capacity, but was structurally weak. If too fine, it was nice and strong, but too low in capacity. We settled on a porous carbon having a permeability in the range of 20 to 30 API Darcies. We predicted that we could increase the immersion from 6 up to 12 inches, thus doubling the current rating of the anode. It worked. Anybody want to try for 24 inches? This worked, too, but there were complications. The bath did seep into the deep end, and seal off some of the pores, the bigger ones. We asked for a pressure and temperature traverse of a 24 inch deep anode in a working cell.

Figure 30 illustrates such a traverse made while fluorinating EDC to produce, eventually, $C_2Cl_2F_4$, or F-114. Note that the gas pressure p_g is less then the hydrostatic pressure p_h at all levels, proving that there was no gas breakout through the sidewalls.

Figure 31 is a similar traverse, same current, but with a much greater gas flow rate. Here also, no breakout. The temperature profiles were a surprise. A heat balance indicates that the bath seeping into the bottom of the anode percolates up along with the gas, and then exits higher up. This internal circulation of liquid not only tempers the reaction, but also dissolves HF from the gas phase and transfers it back to the main body of the bath, thus increasing the capacity by removing a reaction product. Furthermore, it explains in part the "reaction at a distance" paradox previously mentioned.

$$\frac{dp}{dx} = \frac{u\ n}{P\ g}$$

$$\text{press grad} = \frac{\text{veloc} \times \text{viscos}}{\text{permeability} \times g}$$

Figure 29

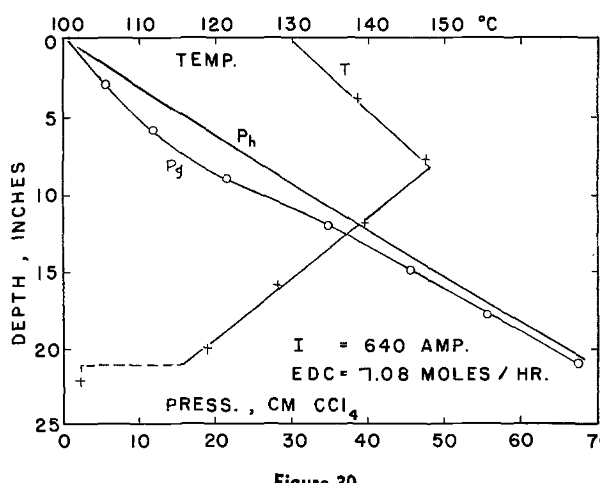

Figure 30

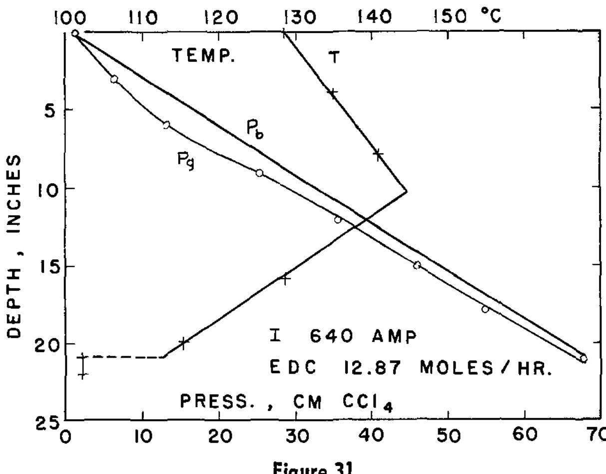

Figure 31

In order to use these data to estimate maximum permissible current densities and gas feed rates, we had to refine our mathematical model to allow for electrolyte invasion into the pores of the deep anodes. The first step was to measure the distribution of pore sizes in the porous carbon by means of a mercury porosimeter (Fig. 32).

We used the data to calculate the hydraulic radius m of the remaining porous structure as a function of the percentage of the pores invaded (Fig. 33). In a porous structure, m is simply the ratio of the specific volume of pores to the specific surface of the pores. It has the dimensions of length, shown as microns by the line labeled m in the figure.

Now, the permeability is proportional to m^2, and has the dimensions of area, or square microns, which is

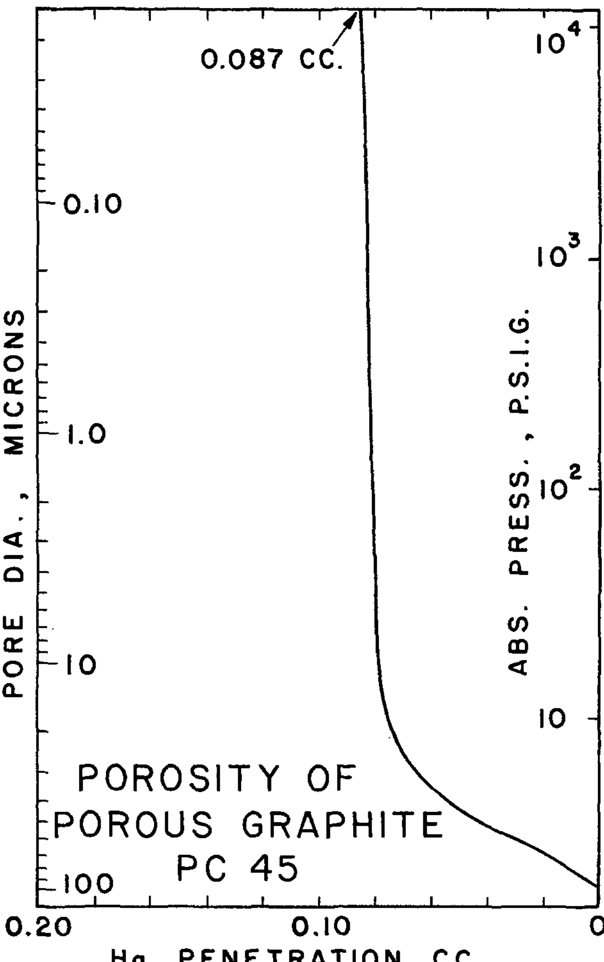

Figure 32

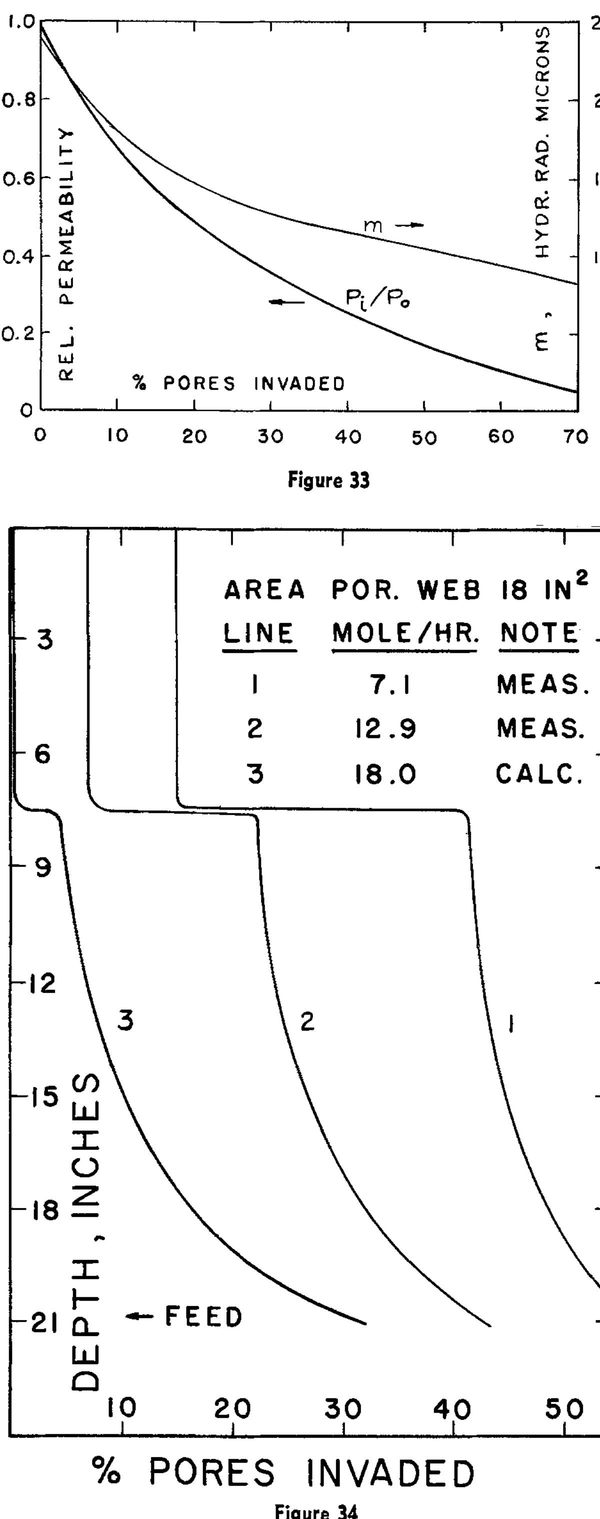

Figure 33

Figure 34

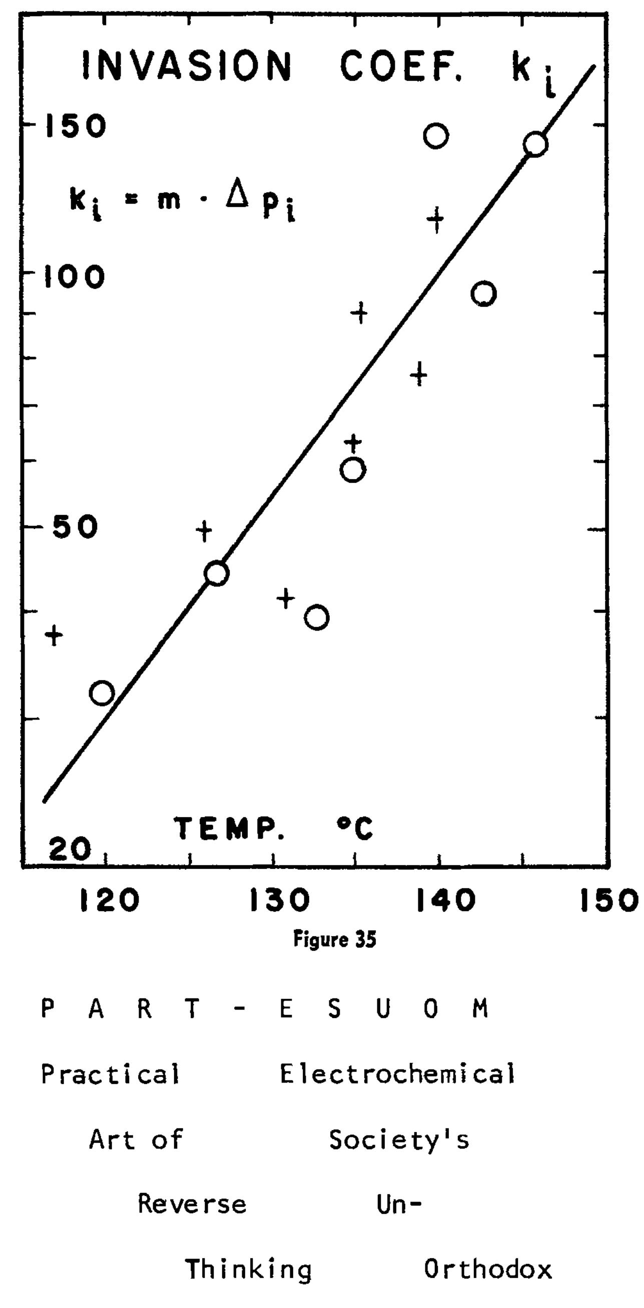

Figure 35

Figure 36

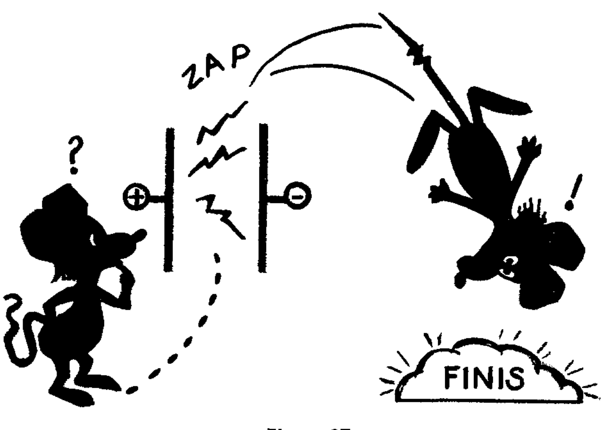

Figure 37

about the same as the conventional API Darcy unit. The lower curve shows the relative permeability of the anode as a function of the percentage of pores invaded. We can now crank this function into our computer program and arrive at the results shown in Fig. 34.

Curve 1 and curve 2 show the invasion profiles for the two traverses previously shown. Of the two, curve 2 is at the higher gas flow rate. Question: how much higher can we push the gas rate? The answer is shown in curve 3. The maximum permissible gas flow, without breakout, is about 18 gmole/hr.

One further result of our studies is the finding of an "invasion coefficient," defined as the product of the hydraulic radius and the differential pressure between electrolyte and gas, at any particular level (Fig. 35). That is, $k_i = m\ (p_h - p_g)$. This invasion coefficient appears to be a function of anode temperature. The increase of K_i with temperature is undoubtedly related to changes in fluidity and surface tension of the electrolyte with temperature. The algorithm for the inva-

sion coefficient is a necessary subroutine for the computer program.

Summing up, it was necessary to unravel the paradoxes of the porous flow-by anode before proceeding with the design of a prototype commercial cell and the conceptual plant to go with it. There were other problems, to state it mildly, but these were all eventually solved. I think this bit of case history illustrates very well how electrochemical engineers are forced to innovate when confronted with problems for which there is no background technology whatever.

It further illustrates how the original concept of an electrochemical mousetrap never caught a mouse, and how the alert researchers redesigned the mousetrap to make it work very well indeed. As yet there is no large commercial plant, but you can purchase small lots of a new line of pure fluorocarbons from the Phillips people, prepared in this unique way.

Turning the mousetrap around (Fig. 36), we see that this stands for: Practical Art of Reverse Thinking—Electrochemical Society's Un-Orthodox Mousetraps.

That's all! (Figure 37.)
