Impedance of Silver Oxide-Zinc Cells

H. A. Frank,* W. L. Long, and A. A. Uchiyama*

Jet Propulsion Laboratory, Pasadena, California 91103

ABSTRACT

Over 100 sealed AgO-Zn cells were subjected to prolonged periods of storage over a range of temperatures and storage modes including open circuit, trickle charge, and float charge. Impedances of these cells were monitored throughout and to the end of the storage period at which point their transient voltage characteristics were observed at the onset of discharge. Results revealed that the impedances of these cells tended to increase with time on stand and that the magnitude of the impedance rise was dependent primarily on temperature and to a lesser degree on storage mode. Typical values for 50 A-hr cells were usually less than 100 mohm at time zero (immediately after activation) and from 1 to 30 ohm after 6-10 months of storage. Transient voltages of these cells were noted to drop sharply during the first msec of discharge and then to rise and reach a stabilized value during the following few seconds. Magnitude of the initial drop as well as the stabilized voltage values were found to be related to impedance but not in a linear manner. Magnitude and duration of the low transient voltages may be unacceptable in some applications of these cells. Cause for the impedance variations is attributed to changes that occur at the positive electrode. Results provide new and useful information for designers and users of AgO-Zn-based power systems.

During the course of test and evaluation of AgO-Zn cells and batteries for Mariner spacecraft (1), it was deemed advisable to measure, among other characteristics, internal cell impedance in that these impedance measurements were known to be nondestructive and to provide additional back-up data along with weight, voltage, capacity, etc., to insure uniformity and functionality of the flight cells.

Periodic review of the tabulated data revealed what was believed to be a trend towards increased impedance with increased time on stand. This observation was deemed significant for two reasons. First, the trend had not heretofore been reported in the literature. There was in fact found to be a relative scarcity of information on impedances of AgO-Zn cells (2). Secondly, the trend could conceivably cause voltage regulation problems on the Mariner power system or any other AgO-Zn-based power system which was to be subjected to long periods of stand before use.

As a result of these considerations, it was deemed advisable to initiate a separate and detailed study on the impedance characteristics of AgO-Zn cells. First, it was desired to obtain data on the impedance variations of these cells during the course of stand over a range of temperatures and storage modes including open circuit, trickle charge, and float charge. Next, it was desired to examine the transient voltage characteristics of these cells at the onset of discharge after the stand period. Finally, as a supplemental objective, it was desired to examine any possible correlation between impedance and state of charge of AgO-Zn cells.

Key words: AgO-Zn cells, impedance of electrochemical cells, storage modes, transient discharge voltages.

Experimental

The cells which were employed in this study were the same as those which were flown on the Mariner VI and VII spacecraft. These were manufactured by the Electric Storage Battery Company and were designated as Model 257. The cells were packaged in plastic (ABS) cases as three-cell monoblocks as shown in Fig. 1. Rated capacity of each was 50 A-hr. Each cell contained 12 positive and 13 negative plates and its electrolyte consisted of 153g of 45% KOH. Each of the 12 positive plates contained 13.8g of active material with width, height, and thickness of 6.45 cm, 7.82 cm, and 0.65 cm, respectively. Eleven of the 13 negative plates were located in the center of the cell stack.

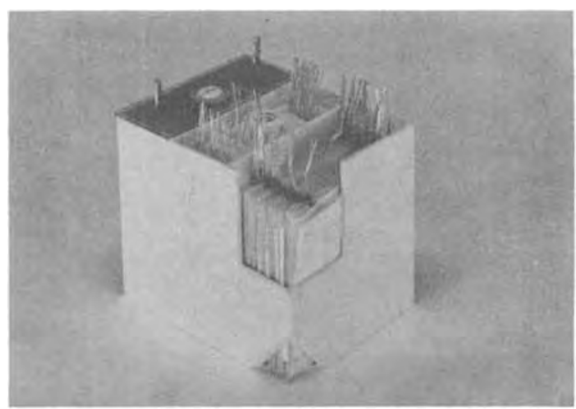

Fig. 1. AgO-Zn monoblock (3 cells, 50 A-hr each)

These were identical and each contained 11.7g of active material, had the same width and height as above, and thickness of 0.11 cm. The other two negative plates were the end plates in the stack. These contained 5.7g of active material, the same width and height as above, and thickness of 0.07 cm. Absorber material on the positive plates consisted of one turn of polypropylene with thickness of 0.015 cm. Retainer material on the negative plates consisted of one fold of a cellulose material (Viscon Type RD.35) with thickness of 0.008-0.013 cm. Separation consisted of six turns of 0.025 cm cellophane on each positive plate. The positive plates were prepared by first milling sheets of silver powder dispersed in a plastic pore former which was later burned off in a sintering process. Two sheets were then pressed on either side of a silver grid and the assembly was then sintered to form a plate. The negative plates were prepared by pressing a mixture of ZnO, HgO, and Teflon on both sides of a silver grid. The cell was assembled by installing the unformed plates (Ag and ZnO), adding electrolyte, and then forming the plates by charging at 1.85A. Excess electrolyte was then drained from the cell and the cell was finally sealed and ready for use. Over-all cell weight was 660g.

All impedance measurements were made with a commercial milliohmeter (Keithley Instruments Model 503) modified by placing a 12,000 m**F** electrolytic capacitor in series with its constant current leads and voltage sensing leads. The instrument operated by delivering 40 Hz square wave current (0.033-0.0001A rms) in the current leads and measuring voltage drop across the voltage sensing leads with a synchronous vacuum tube voltmeter. The meter contained several ranges from 1 mohm to 100 ohm. Calibration checks with precision shunts were performed periodically and accuracy of all ranges was always found to be within $\pm 2\%$ of full scale.

Test procedures, unless otherwise noted, were the same for each cell and consisted of the following. First, the impedance and open circuit voltage of the cells were measured in the "as-received" condition from the manufacturer. Next, the cells were given a "top-off" charge to insure that they were fully charged at the beginning of the test period. This "top-off" charge was carried out at constant current of 0.6A to a cutoff voltage of 1.97V. At this point, the cells were divided into several groups, each of which was placed on a different mode of stand. One group was left in the open circuit, fully charged condition and placed in an environmental chamber at 4°C. Two other groups were similarly left in the open circuit, fully charged condition and placed in other environmental chambers at temperatures of 21° and 38°C. One group was discharged 50% and then placed on open circuit stand at room temperature, 21°C. Another group was discharged 100% and then placed on open circuit stand again at room temperature. Three other groups were placed on stand under the condition of constant current trickle charge at room temperature and at currents of 2, 5, and 10 mA. Finally, one group was placed on stand under the condition of constant potential "float" charge at 1.87 V/cell and at room temperature. Voltages and impedances of all cells were measured periodically at intervals of at least once per week.

The transient discharge voltage measurements were carried out on three-cell monoblocks rather than on single cells. The monoblocks were wired with heavy duty cable across 4.5 ohm loads (to give a nominal current of 10A) and discharge was triggered with a heavy duty mercury switch. Monoblock voltages were measured with both an oscilloscope (Tektronix, Model 535 A, equipped with a Polaroid camera) and an oscillograph (Sanborn, Model 297).

Results

Impedance and voltage variations of the cells during the various modes of stand are given in Fig. 2 through 10. In each of these figures the shaded areas cover the range in values of impedance and voltage for the indicated number of cells. Figures 2, 3, and 4 give the characteristics of cells on stand in the open circuit and fully charged condition at temperatures of 4°, 21°, and 38°C, respectively. Figure 5 gives the characteristics of cells on stand in the open circuit and 50% discharged condition at 21°C. Figure 6 gives the characteristics of cells on stand in the open circuit and 100% discharged condition at 21°C. Figures 7, 8, and 9 give the characteristics of cells on stand at 21°C, with application of constant current trickle charge currents of 2 mA, 5 mA, and 10 mA, respectively. Figure 10 gives the characteristics of cells on stand at 21°C with application of a constant potential "float" charge of 1.87 V/cell.

Figures 11 and 12 give typical variations in impedance and voltage of these cells during the course of charge and discharge.

Table I gives the impedance values of a cell before and 1.0 sec after a discharge period at 10A.

Figures 13, 14, and 15 give the voltage characteristics of three typical monoblocks during the onset of discharge. Table II summarizes the pertinent data from these figures and also gives additional monoblocks and cell data. The first two columns in Table II designate the monoblock numbers and their respective cell numbers. The next two columns give the individual cell and monoblock open circuit voltages, respectively, after they had equilibrated at room temperature and before discharge. The next two columns give the individual cell and monoblock impedances before the discharge period. The next column gives the minimum monoblock voltage during the first millisecond of discharge as per the oscilloscope trace. The last column gives the "stabilized" monoblock voltage after the first few seconds of discharge as per the escillograph trace.

Figures 16 and 17 give the relationship between a cell's impedance and its transient voltages at the onset of discharge. These curves were obtained by normalizing the data in Table II.

Figures 18 through 21 give the impedance and voltage histories of cells which exhibited short circuit failure modes. Finally, Fig. 21 gives the effect of ambient temperature on the impedance of three typical cells, and Table III gives the resistivity of silver and its oxides.

Discussion

Falk and Salkind state that the impedance of sealed silver batteries is usually quite low and that typical values for partially discharged cells range from $0.07/C$ to $0.40/C$ ohm, where C is the cell capacity in A-hr (3). On this basis, the impedances of the 50 A-hr cells employed herein would be expected to range from 1.4 to 8 mohm. Inspection of Fig. 5 and Table I reveals that the initial impedances of partially discharged 50 A-hr cells ranged from 5 to 11 mohm. Therefore, there appears to be good agreement between the observed and literature values of Ag-Zn cell impedance.

Examination of Fig. 2, 3, and 4 reveals a gradual increase in impedance with time for cells on open circuit stand in the fully charged condition. The change in impedance with time was noted to increase somewhat with ambient temperature. For example, the impedances of cells stored for 8 months were noted to be in the range of 1.3 to 3.3 ohm at 4°C, 2.5 to 3.5 ohm at 21°C, and 9.0 to 16.0 ohm at 38°C. Open circuit voltages of the cells stored at 4° and 21°C were noted to remain relatively constant near 1.86V throughout the entire test period. Open circuit voltages of the cells stored at 38°C were however, noted to decline slightly during this period with a

minimum value of 1.847V for one cell. Examination of Fig. 5 reveals a somewhat lower rate of increase in impedance with time for cells which were stored in the 50% discharged condition. Impedances of a few such cells given in Fig. 5 were found to remain in the range of 0 to 10 mohm throughout the entire test period. Open circuit voltages of these cells remained in the range of 1.59 to 1.62V throughout the test. Examination of Fig. 6 reveals that cells which were stored in the fully (100%) discharged condition exhibit a constant and low impedance in the range of 2 to 3 mohm throughout the entire test. Open circuit voltages of these cells remained in the range of 1.58 to 1.60V during this time.

Examination of Fig. 7, 8, and 9 reveals an unusual but yet consistent shape of the impedance-time curves for cells which were stored with application of a constant current trickle charge. Impedance is noted to first pass through a maximum, then a minimum, and finally to continue a gradual increase with increase in stand time. A rigorous explanation of the shape of these curves is not available at the present time. It is noted, however, that the transition from the maximum to the minimum in the impedance curves occurs at a point in time when the cell voltages rise from the 1.9V level to the 2.0V level. Since gassing (O_2 evolution) is known to occur at the higher voltages, it is quite likely then that the unique shape of the impedance-time curves is associated with gassing and pressure rise. Aside from this point, however, there is noted to be good correspondence, at least in the early stages of stand, between the shape and slope of the impedance *vs.* time curves for cells stored in this mode and those stored on open circuit. In addition, it is noted that those cells which were stored at the higher current levels of 5 and 10 mA (not necessarily recommended by the manufacturer) developed leaks after periods of 6 to 2 months, respectively. These current levels are therefore excessive for long-term

storage of this size cell and the maximum level for safe storage is estimated to be near 2 mA.

The variation of cell impedance with time on stand is attributed to chemical changes that occur within the positive silver electrodes. At any given time the species which are present in this electrode are the higher oxide, AgO, the lower oxide, Ag_2O, and silver metal, Ag. In a freshly and fully charged cell, the predominant species is the higher oxide AgO which, as indicated in Table III, has a relatively low resistivity. Hence, the impedance of a freshly charged cell should

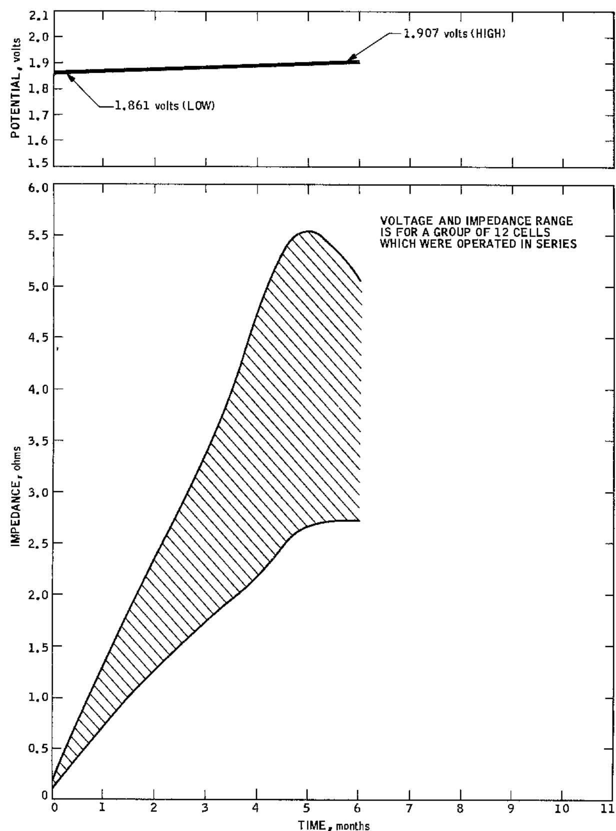

Fig. 7. Voltage and impedance of cells on 2.0 mA constant current trickle charge at 21°C.

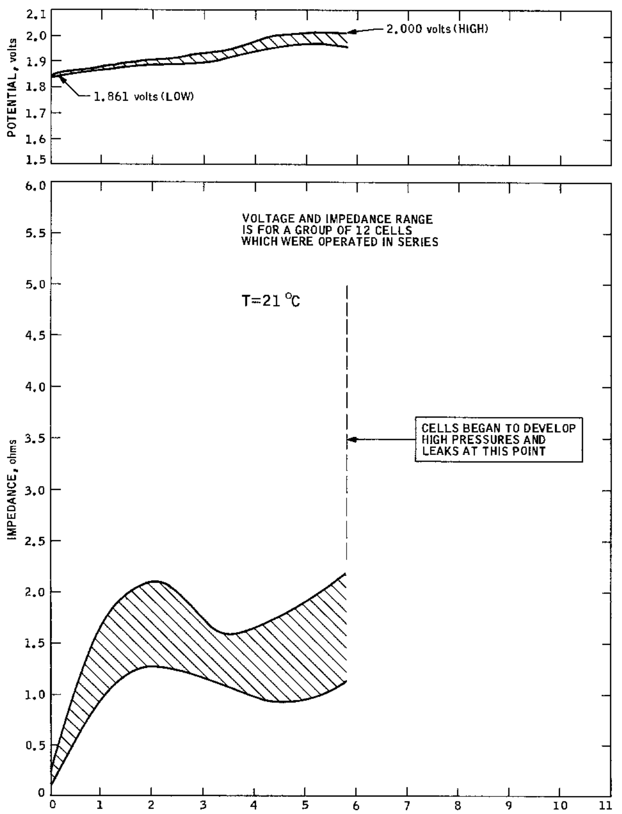

Fig. 8. Voltage and impedance of cells on 5.0 mA constant current trickle charge at 21°C.

and has been found to exhibit relatively low impedance as evidenced by the above results. During the course of extended periods of stand, the higher oxide, AgO, is slowly converted to the lower oxide, Ag_2O, via two possible chemical reactions. The first of these involves decomposition of the higher oxide to form the lower oxide and oxygen ($2AgO \rightarrow Ag_2O + \frac{1}{2} O_2$) (4). The second involves reaction of the higher oxide with metallic silver particles and the silver grid to form the lower oxide ($Ag + AgO \rightarrow Ag_2O$) (5). The net result of these reactions is believed to be the formation of a layer of Ag_2O which completely surrounds the electrode. As noted in Table III, the resistivity of the Ag_2O material is exceptionally high so that the growth of the layer of this material is the most likely explanation of the observed trend towards increased impedance with time on stand. Support for this explanation is given in a prior study of Ag electrodes by Cahan *et al.* (6). The observed trend toward increased rate of change of impedance at elevated temperatures is compatible with the above in that the above reactions proceed faster at the elevated temperatures and proceed to form the layer at a faster rate. The fact that the partially and completely discharged cells did not exhibit as large a rise in impedance as the fully charged cells is also compatible with the above in that these cells contain appreciable amounts of highly conductive silver particles (see Table III) that provide low resistance electrical paths. The fact that the cells on both constant current and float charge (Fig. 7-10) also exhibited increased impedance with time on stand would at first glance appear to be contradictory to the above explanation regarding a buildup of a layer of Ag_2O. The basis for this contradiction would be that the application of a charge current would tend to reconvert the high resistance layer of Ag_2O back to the lower resistance AgO material. The only explanation for the observed results in these cases is, then, that the rate of formation of the Ag_2O layer (by the above reactions) is greater than the rate of conversion of the Ag_2O layer to AgO material (by electrochemical reaction). Some basis for this explanation can be established by comparing known rates of formation of Ag_2O *via* decomposition of AgO with the rates at which Ag_2O would be electrochemically reconverted to AgO by the currents employed in these tests. Ruetschi, for example, shows that at 45°C the decomposition rate of AgO in

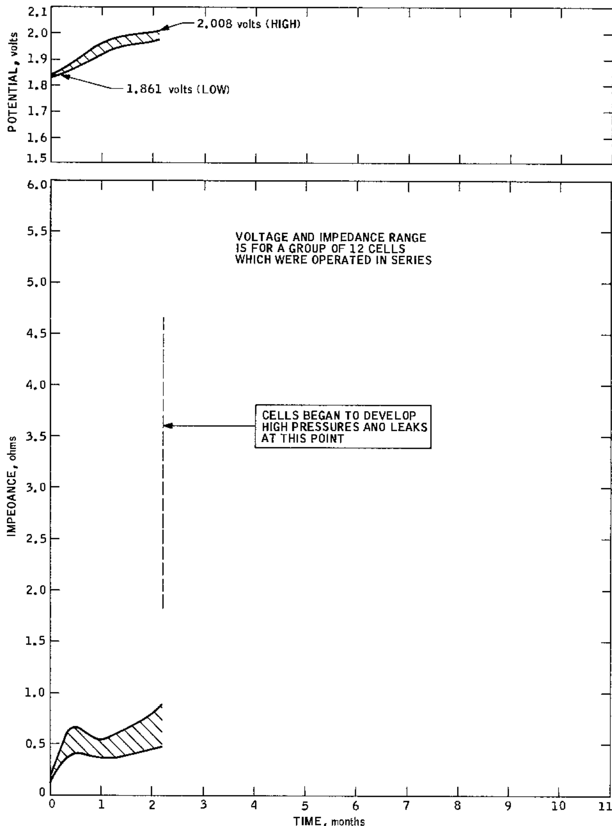

Fig. 9. Voltage and impedance of cells on 10.0 mA constant current trickle charge at 21°C.

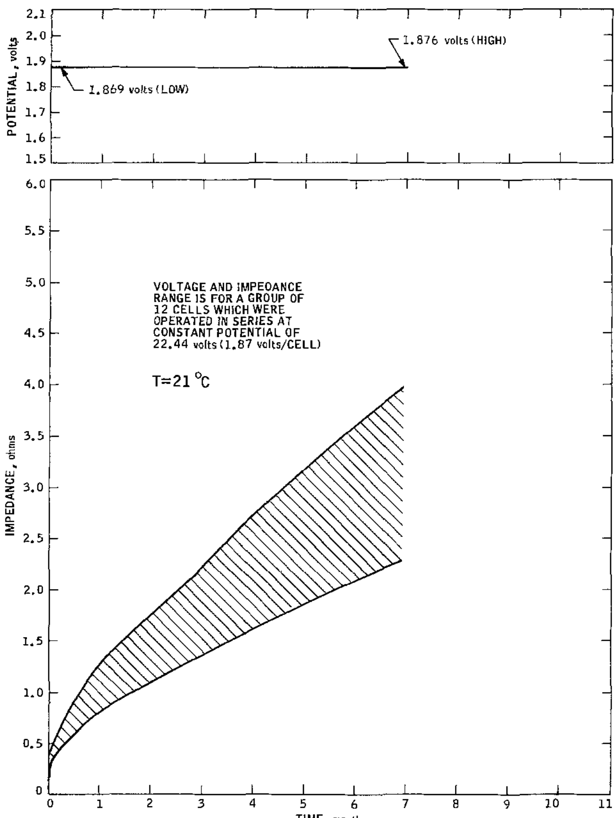

Fig. 10. Voltage and impedance of cells on constant potential float charge at 1.87 V/cell at 21°C.

45% KOH is, in terms of the reaction product, equivalent to approximately 0.1 cm^3 O_2/hr-g AgO (7). Since these cells contained 166g of active positive material, the maximum rate, assuming all the material is AgO, would be 16.6 cm^3 O_2 hr. Under these conditions, then, the cell would be forming Ag_2O at a current equivalent rate near 80 mA. The current equivalent rate at which Ag_2O is simultaneously being reconverted to AgO is equal to the charge currents which varied from 2 to 10 mA for the constant current tests and near 2 mA for the constant potential tests. Comparison of these currents, therefore, reveals that the rates of formation of Ag_2O are, at least in these examples, appreciably greater than the rates at which this material is reconverted to AgO. Therefore, there is some basis to believe that high resistance layer of Ag_2O can be formed for the condition of stand with application of small currents by constant current or constant potential charge.

Inspection of Fig. 11 reveals a sharp maximum or peak in voltage during the early portion of a constant current charge of this type cell. Cell impedance was also noted to exhibit a maximum or peak during this same time period. This phenomena has been previously reported in the literature (8, 9), and may again be associated with the formation of a high resistance layer of Ag_2O which completely surrounds the electrode. The sharp rise would correspond to the time during charge when the layer of high resistance Ag_2O is completely formed and decline would correspond to the onset of production of lower resistance AgO material.

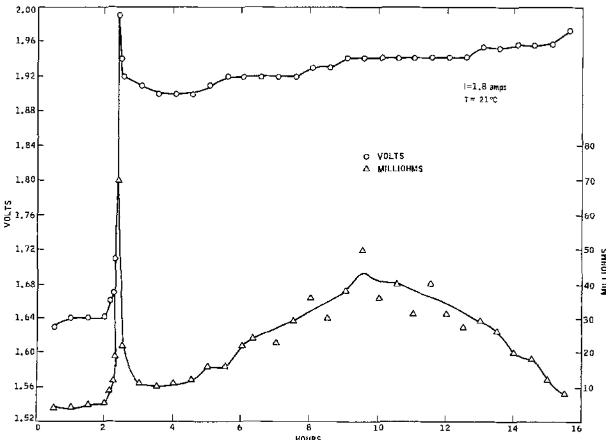

Fig. 11. Voltage and impedance during charge

Inspection of Fig. 12 reveals that cell impedance is quite low and in the range of 0 to 10 mohm during discharge. The gradual decline in impedance and slight rise in voltage during discharge is attributed to the formation of increasing amounts of highly conductive metallic silver particles. The frequency of performing measurements during this test was quite long (approximately once each 15 min), so that it was not possible to examine the initial transient voltage and impedance characteristics during the early (0-10 sec) portion of discharge. These characteristics were, however, observed in subsequent tests as described below.

Typical voltage traces of three monoblocks during the onset of discharge at 10A are given in Fig. 13, 14, and 15. The upper curve in each case gives the high-

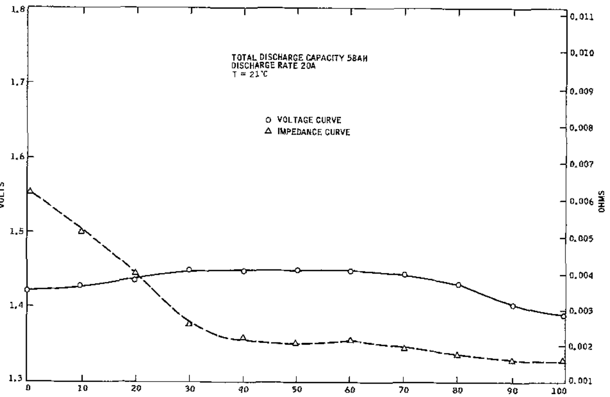

Fig. 12. Voltage and impedance during discharge

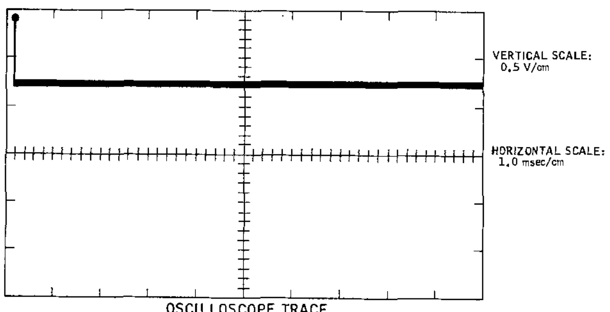

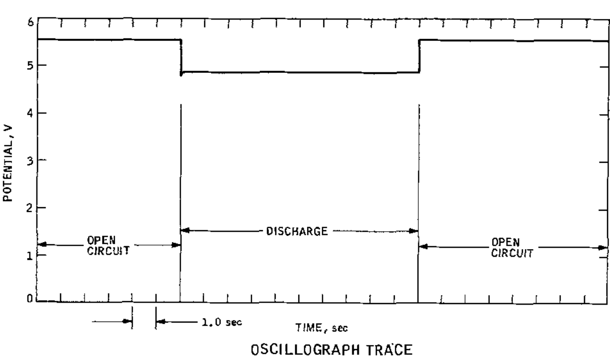

Fig. 13. Transient voltage characteristics of a monoblock with relatively low impedance at the onset of discharge at 10A at 21°C (monoblock No. 3).

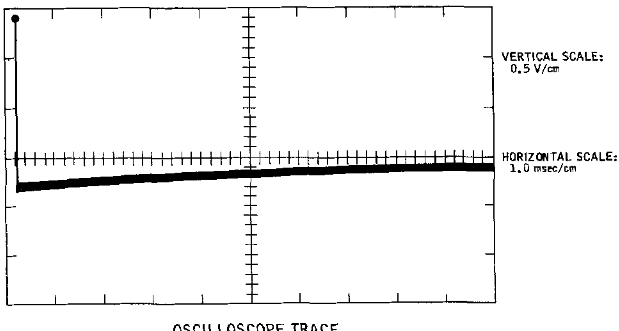

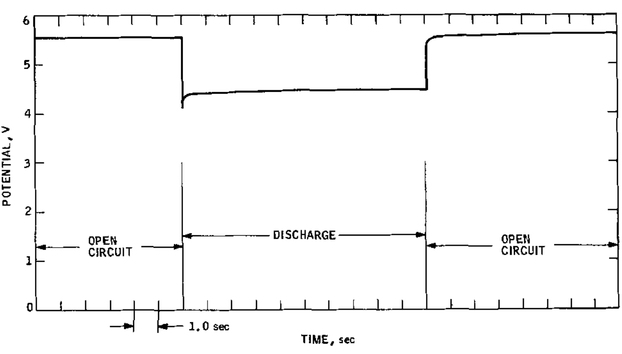

Fig. 14. Transient voltage characteristics of a monoblock with relatively high impedance at the onset of discharge at 10A at 21°C (monoblock No. 8).

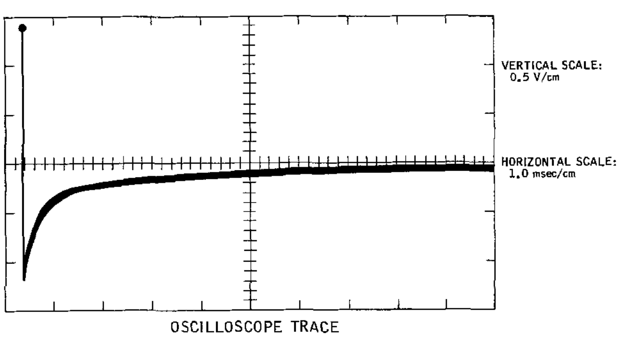

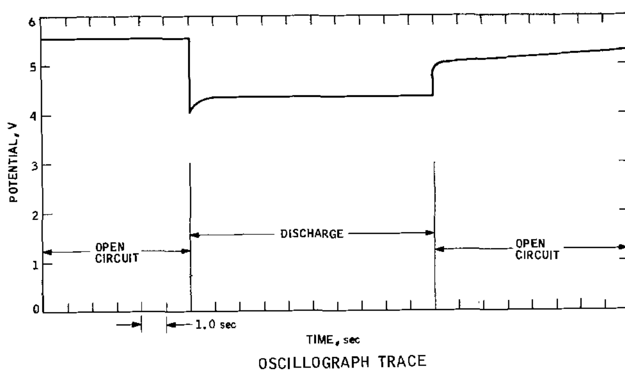

Fig. 15. Transient voltage characteristics of a monoblock with very high impedance at the onset of discharge at 10A at 21°C (monoblock No. 10).

speed oscilloscope trace and the lower curve gives the somewhat lower speed oscillograph trace. Table II summarizes the pertinent data from the traces of these and nine other monoblocks and also gives additional monoblock and unit cell data. Monoblocks 1 through 4 may be classified as "low resistance" units in that their over-all impedances range from 0.21 to 0.30 ohm (0.07-0.10 ohm/cell). These exhibit minimum voltages of 4.60-4.83V (1.52-1.61 V/cell) during the first msec of discharge and stabilized voltages of 4.75-4.85V (1.57-1.61 V/cell) almost immediately thereafter. Monoblocks 5 through 8 may be classified as medium resistance units in that their over-all impedances range from 1.01 to 1.31 ohm (0.34-0.44 ohm/cell). These exhibit minimum voltages of 3.63-3.88V (1.21-1.29 V/cell) during the first msec of discharge and stabilized voltages of 4.40-4.56V (1.47-1.52 V/cell) within a few seconds thereafter. Monoblocks 9 through 12 may be classified as high resistance units in that their over-all impedances range from 10.80 to 12.10 ohm (3.60-4.03 ohm/cell). These exhibit minimum voltages of 2.95 to 3.00V (0.98-1.00 V/cell) during the first msec of discharge and stabilized voltages of 4.30-4.44V (1.43-1.48 V/cell) within several seconds thereafter. These results indicate a trend of increased time for cell voltage to reach a stabilized value at the beginning of discharge with increased cell impedance. The results also indicate a trend of lower cell voltages with increased cell impedance as discussed in detail below.

The above monoblock data were normalized on a unit cell basis and are given in Fig. 16 and 17 in terms of unit cell voltage *vs.* coresponding unit cell impedance. Figure 16 pertains to the minimum voltages which were consistently attained during the first msec of discharge at 10A. Figure 17 pertains to the stabilized voltages which were consistently attained after several seconds of discharge at 10A. Also included in these figures, for design purposes, is the

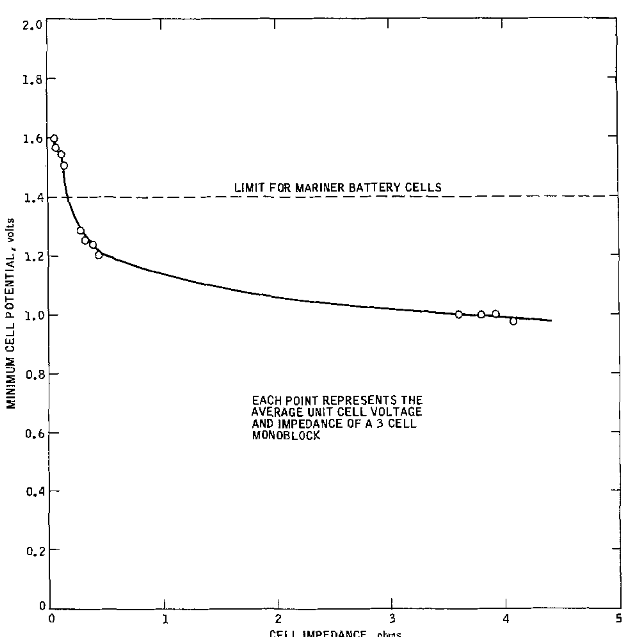

Fig. 16. Minimum cell voltage during first msec of discharge at 10A and at 21°C.

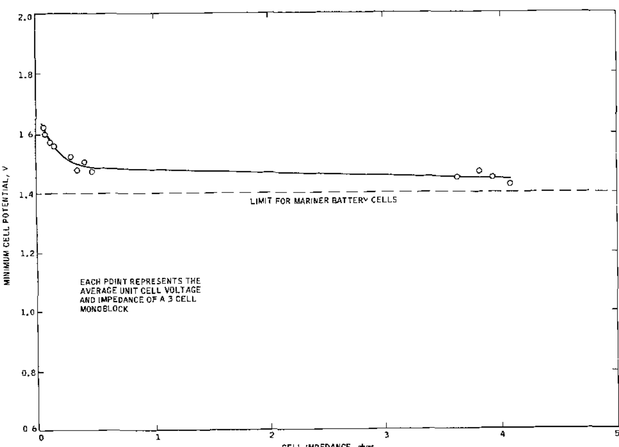

Fig. 17. Stabilized voltages after first few seconds of discharge at 10A and at 21°C.

minimum voltage specification limit for the Mariner cells. From a simplified "Ohm's law" point of view (where voltage is a linear function of impedance at constant current), one might at first predict that these curves should be approximately linear and have a slope of 10 V/ohm. This prediction would at least be thought to be applicable to the curve in Fig. 16 wherein the voltage measurements should not be influenced to any large degree by polarization phenomena in that the measurements were taken at very short periods of time after the start of discharge. Detailed examination of Fig. 16 reveals that only a portion of the curve is in accord with the above relation. This portion is for cells with impedances less than about 0.3 ohm. The curve reveals appreciably higher voltages than would be predicted from the Ohm's law relation for cell with impedances in excess of 0.3 ohm. Detailed examination of Fig. 17 reveals that essentially the whole curve is in disagreement with the above relation. In this case the discrepancy is even larger than the above, *i.e.*, voltages are even higher than in Fig. 16 for corresponding impedance values.

Explanation for the above phenomena is twofold in nature. First, it is quite likely that polarization effects are present and that these effects account for a portion of the above-noted discrepancies. Secondly it is quite likely that there is a decline in cell impedance shortly after the start of discharge. Evidence to this effect was obtained in a special test wherein the impedance of one cell was measured before and 1.0 sec after a discharge at 10.0A. Results given in Table I revealed that the impedance dropped sharply during this period from 3.400 to 0.015 ohm. Based on results of the oscilloscope and oscillograph tracers, it appears that most of this decline in impedance occurs within the first msec of discharge. Although a rigorous explanation for this phenomena cannot be offered at the present time, it is quite likely that it is associated with the electrochemical reduction of the highly resistive layer of Ag_2O. Regardless of the explanation, however, the result establishes a very practical and significant point in that it suggests a method for avoiding the large transient voltage drops of high impedance cells, *i.e.*, by merely subjecting them to a short "conditioning" discharge before employing them for their primary discharge application. The "conditioning" discharge may be carried out at the C/5 rate for 1.0 sec.

During the course of this investigation there were noted to be several cells, especially those at elevated temperatures, which exhibited sudden voltage declines and subsequent failure. Since logs had been maintained on the voltages and impedances of these cells, it was decided to examine these data in detail in order to establish if these cells exhibited any unusual variations in impedance. In this manner it might be possible to employ the impedance measurement as a means of identifying faulty or deteriorated cells. Figures 18 through 21 give plots of the voltages and impedances of four such cells. Examination of these plots reveals

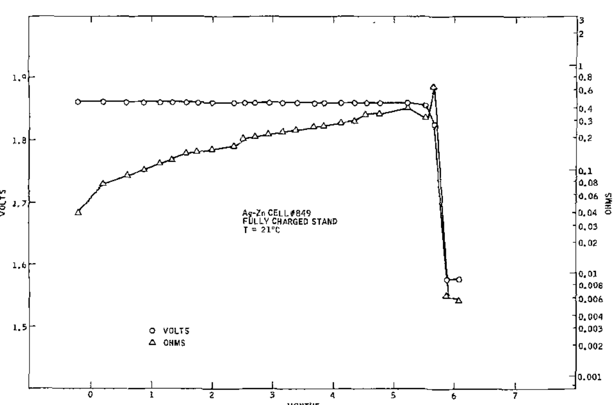

Fig. 18. Deterioration of AgZn cell No. 849

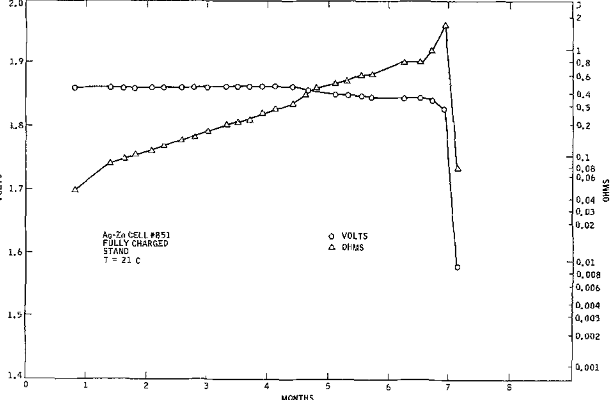

Fig. 19. Deterioration of AgZn cell No. 1069

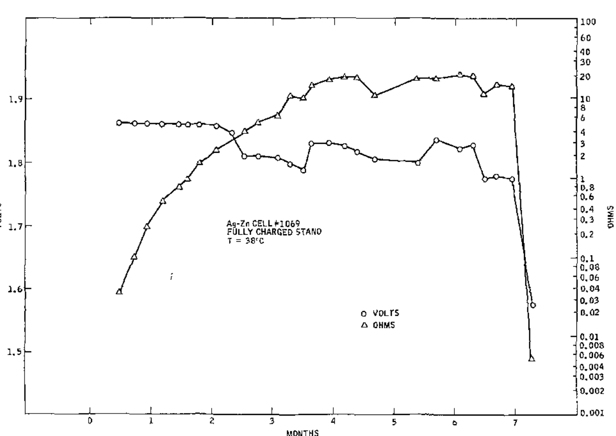

Fig. 20. Deterioration of AgZn cell No. 1071

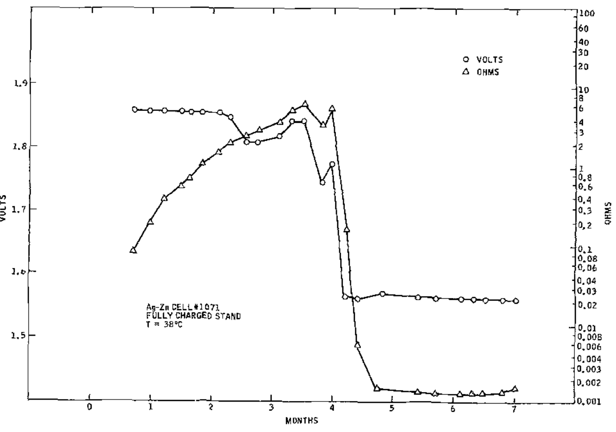

Fig. 21. Deterioration of AgZn cell No. 851

no unusual variations in the impedances of these particular cells up to the point of failure. During this time these cells exhibit a gradual rise in impedance in a similar manner to other cells which did not exhibit failure. At the time of failure, however, these cells exhibit a sharp decline in impedance and also cell voltage. On this basis, then, there does not appear to be any convincing evidence that these impedance measurements may be used to predict the condition or state of charge of Ag-Zn cells in their early stages of life. The feasibility of employing impedance measurements for this purpose cannot, however, be ruled out altogether with the information obtained to date.

The effect of temperature on impedance of these cells is given in Fig. 22. The upper curves give the variation for two typically high resistance cells which had been in storage for almost three years in the fully charged condition at 4°C. The lower curve gives the variation for a typically low resistance cell which had

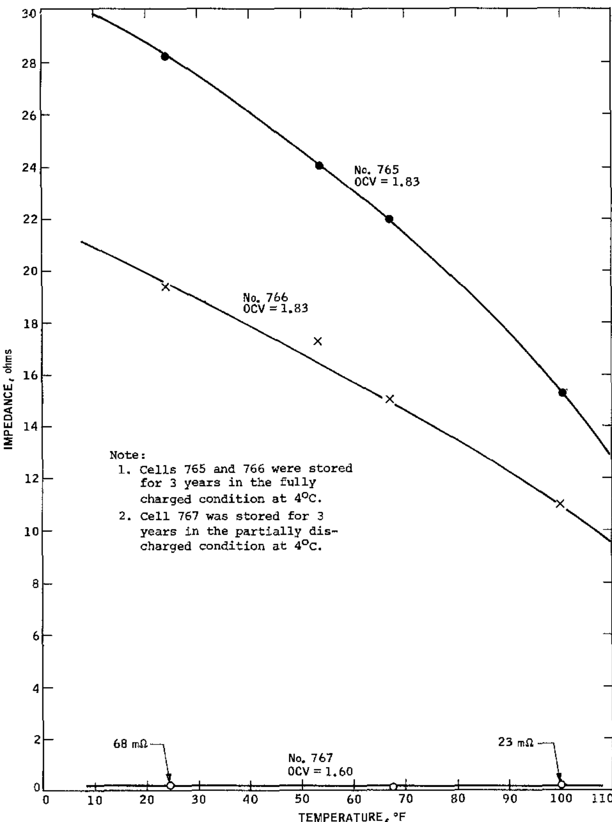

Fig. 22. Effect of temperature on impedance of AgZn cells

been in storage under the same conditions as above but had been partially (about 10%) discharged at room temperature before these impedance measurements. Results indicate that the impedances of all of these cells decline with temperature and in an essentially linear manner in the range of 4° to 38°C.

Finally, it is well to mention that there is some, but not conclusive, experimental data to confirm the belief that the positive electrode, and in particular the Ag_2O film, is responsible for all the above-observed variations in impedance and voltage. It is conceivable that changes in the negative electrode, the separator, and electrolyte may also occur and may account for some of the observed phenomena. Additional and more fundamental studies involving the use of reference electrodes and microscopic examinations would be required to resolve this issue. Such studies have been outlined and will be carried out at a later date. Results obtained to date do, however, stand by themselves in that they provide the designers of AgO-Zn-based power systems with a great deal of practical and heretofore unpublicized data on the impedance characteristics of these cells.

Conclusions

Significant findings of this study are summarized below.

1. Impedances of AgZn cells have been found to increase during prolonged periods of storage. The rate of change of impedance with time has been found to increase at elevated temperatures and to be influenced to some degree by the mode of storage.
2. In accordance with prior literature, there has been found to be a peak in the voltage-time curve of Ag-Zn cells during the early portion of constant current charge
3. Impedances of Ag-Zn cells decrease appreciably and rapidly within the first msec of discharge.
4. The instantaneous voltage drop during the first msec of discharge has been found to increase with initial cell impedance, but not in a linear manner.
5. Cell voltages exhibit a partial recovery after the instantaneous voltage drop. The level of recovery and recovery times vary with initial cell impedance. Recovery times for the cells employed here were in the range of essentially zero to several seconds.
6. In order to satisfy demanding voltage regulation requirements, it would be well to subject aged cells to a short preliminary discharge prior to subjecting them to their primary discharge.

Thin-Film Galvanic Cell $Pb/PbF_2/PbF_2,CuF_2/Cu$

John H. Kennedy* and James C. Hunter**

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Thin-film solid-state galvanic cells were fabricated using Pb metal as anode, PbF_2 as electrolyte, and CuF_2 as cathode. Because of the high resistivity of CuF_2, it was codeposited with PbF_2 to form a more conductive mixed cathode layer. Such cells developed open-circuit voltages from 0.61 to 0.70V, compared to 0.70V theoretical. Cells were discharged at room temperature with current densities of >10 $\mu A/cm^2$. At elevated temperatures the current densities attainable were considerably higher. Cells discharged under constant load exhibited relatively constant voltage during discharge and a sudden drop-off at the end of discharge. Cathode utilization for the cathode-limited cells was typically 30-40%. Attempts to recharge these cells were unsuccessful.

Thin-film solid-state galvanic cells have been a subject of considerable recent interest. The combination of solid electrolyte materials with thin-film techniques holds promise of yielding miniaturized batteries with high energy density, wide operating temperature range, and long shelf life. Such batteries could complement other miniaturized electronic devices, such as integrated circuits, thin-film resistors, and thin-film capacitors.

Masters, Vouros, and Clune (1, 2) have developed vacuum-evaporated thin-film galvanic cells using silver as anode; silver chloride, bromide, or iodide as electrolyte; and platinum as cathode. This was a concentration cell with rather low power. Goldberg (3) patented improved methods of forming the electrolyte layer in this cell.

Ervin (4) patented a sprayed-in-place cell using a silver anode, silver rubidium iodide electrolyte, and tellurium tetraiodide cathode.

Sator and Perrot (5, 6) constructed thin-film cells of the type $Pb/PbCl_2/AgCl/Ag$. These were developed further by Moulton *et al.* (7), and by Swindells and Lanier (8). Swindells and Lanier also developed an improved cell of the type $Mg/MgCl_2$, $LiCl/AgCl/Ag$. In this cell the $MgCl_2$ electrolyte was doped with up to 50% LiCl by weight to increase its conductivity.

Liang, Epstein, and Boyle (9) constructed thin-film cells of the type $Li/LiI/AgI/Ag$. These cells developed over 2V, and could provide current densities of over 100 $\mu A/cm^2$.

In a previous paper we reported the solid electrolyte properties of PbF_2 (10). For thin films, σ values of $>1 \times 10^{-6}$ $(ohm\text{-}cm)^{-1}$ were obtained. This conductivity is sufficient that PbF_2 might be of use as electrolyte in thin-film galvanic cells.

CuF_2 is a possible choice for a cathode material. The following reaction

$$\text{anode:} \quad Pb + 2F^- \rightarrow PbF_2 + 2e^-$$

$$\text{cathode:} \quad CuF_2 + 2e^- \rightarrow Cu + 2F^-$$

$$\text{over-all:} \quad Pb + CuF_2 \rightarrow PbF_2 + Cu$$

$$\Delta G = \Delta G_f(PbF_2) - \Delta G_f(CuF_2) = -32.1 \text{ kcal/mole}$$

leads to a cell voltage of 0.7V. In fact, CuF_2 has already found use as a cathode material in nonaqueous liquid electrolyte batteries (11, 12).

Several problems had to be overcome in order to use CuF_2 as a cathode material in these liquid electrolyte batteries. CuF_2 is a highly resistive material; $\rho > 10^{10}$ ohm-cm at 25°C (13). In order to use it as a cathode material it was necessary to increase its conductivity. Mixing the CuF_2 with graphite has been tried with some success (14). This only increases the electronic conductivity which may be sufficient with a liquid electrolyte. In a solid-state system, however, it would also be helpful to increase the ionic conductivity of the cathode. Recharging of liquid electrolyte cells with CuF_2 cathodes has also proven difficult (15), and there is indication of large overvoltage effects in these cells. The high resistivity of CuF_2 was expected to be a problem in solid-state thin-film cells, but it was not clear whether overvoltage effects would be comparable to those in the liquid electrolyte cells.

The presence of water can have large effects on the performance of CuF_2 cathodes for the liquid electrolyte systems. It is desirable to have completely anhydrous CuF_2, as even small amounts of water react with the Li anodes used in such cells. Water in the cells also increases the solubility of CuF_2 in the electrolyte, leading to dissolution of the cathode and discharge of the cell. Therefore, high purity anhydrous CuF_2 has been used in these cells. Care must also be taken to insure that CuF_2 remains anhydrous, as it tends to absorb water to form the dihydrate

$$CuF_2 + 2H_2O \rightarrow CuF_2 \cdot 2H_2O \qquad \Delta G \cong -6 \text{ kcal/mole}$$

The presence of water would also be expected to cause problems in the formation of thin-film cells with CuF_2 cathodes. Heating CuF_2 in the presence of water leads to decomposition, with the formation of CuO, HF, and H_2O (16, 17). Even if only small amounts of water were present, the outgassing and resultant spattering could make deposition of good films impossible. In addition, films of CuF_2 may have to be coated to protect them from being attacked by moisture in the air.

Some other fluoride materials are even less stable than CuF_2 and would yield correspondingly higher voltages. Thus a cell with AgF cathode would have a theoretical OCV of 1.3V, while a PbF_4 cathode would lead to an OCV of 2.56V. However, these latter materials are so unstable that it is questionable whether such materials could be vacuum evaporated.

In addition, electronic conductivity of PbF_2 becomes appreciable above 1.3V (10) and, thus, the use of high voltage cells could lead to self-discharge.

Even CuF_2 would be expected to cause difficulties in conventional vacuum evaporation. Evaporation from the typical evaporation sources such as tungsten, molybdenum, carbon, or aluminum oxide boats is thermodynamically unfavorable. However, whether or not successful evaporations can be carried out from any of these sources will depend on the rates of reaction, and even on the degree of wetting of the source by the CuF_2. We report here the results of fabricating thin-film galvanic cells with PbF_2 electrolyte and CuF_2 cathodes.

Experimental

Thin-film deposition.—Thin films were prepared by vacuum evaporation in a Fairchild custom evaporator

Key words: copper fluoride, galvanic cell, lead fluoride, solid electrolyte, thin-film cell.

using resistance sources. A Sloan Omni-IIa deposition control unit with quartz crystal oscillator sensor was used to monitor deposition rate and film thickness.

Cells were made with two different geometries. One type of cell (Fig. 1) had twelve small 0.1 cm^2 area cells, while the other type contained four larger 2 cm^2 cells per slide (Fig. 2). Conductivity cells were made by depositing a bottom layer of metal, followed by a layer of the material being studied, and by an upper metal electrode layer. Galvanic cells were made by depositing a bottom layer of anode metal, a middle layer of electrolyte, and two upper layers containing cathode material and cathode current collector. In some cells a layer of Kodak Microneg Photoresist (an organic polymer sensitive to u.v. light) was applied to protect the underlying films from moisture.

X-ray diffraction analysis.—A Philips Electronics x-ray diffraction unit with scintillation counter was used with CuKα x-rays. Powder x-ray spectra were made using the conventional holder. X-ray studies could also be made on thin films by breaking the glass microscope slide substrate in half and inserting the half-substrate in the sample holder. A Philips Electronics x-ray fluorescence instrument was also used, with Mo target and LiF crystal, for elemental analysis.

Electrical measurements.—OCV measurements were made using a Keithley Model 610c electrometer, with input impedance greater than 10^{14} ohm.

A Keithley Model 260 picoampere source was used for constant-current charge and discharge of cells. A Hewlett-Packard Mosely chart recorder Model 7100b was used to record cell voltages during discharge. Resistivity measurements (standard two-electrode technique) were made using a GRC 1650A bridge at 1 kHz.

Results and Discussion

Selection of deposition source.—Attempts to deposit CuF_2 were made from tungsten and molybdenum boats without success. The resulting films were reddish in color and smooth initially, but upon contact with air they rapidly crinkled and lost adhesion to the substrate. X-ray studies showed only a few very tiny peaks, and these could not be assigned. The films probably contained some hygroscopic tungsten or molybdenum fluorides caused by reaction of CuF_2 with the boats.

Deposits from alumina-lined molybdenum boats were also unsuccessful. Resulting films were yellow in color and exhibited very poor adhesion. Decomposition again probably occurred. X-ray studies, hampered by the poor adhesion, showed only some tiny peaks which could not be assigned.

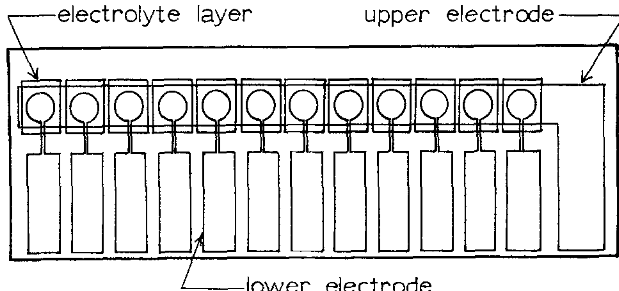

Fig. 1. Thin-film cell configuration of 0.1 cm^2 cells

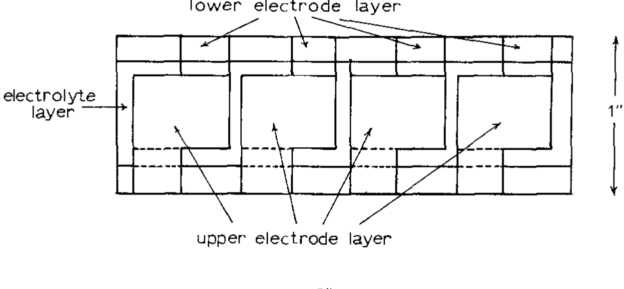

Fig. 2. Thin-film cell configuration of 2 cm^2 cells

Deposition from a carbon source gave films which were identified by x-ray diffraction as anhydrous CuF_2. The adhesion of these films depended on the substrate temperature; films deposited on unheated substrates had poor adhesion, while those deposited on substrates at 220°C adhered extremely well. It was also found that films deposited with considerable spattering had poor adhesion, while films evaporated without spattering exhibited good adhesion. In all of these cases, even for films with poor adhesion, the CuF_2 structure was seen in x-ray studies. Fresh films showed no peaks for any of the hydrated forms of CuF_2 or for any other materials. However, the films were rather dark in color, while pure CuF_2 powder was white. This dark color could be due to the presence of impurities in the film, possibly from partial decomposition to copper metal, or perhaps to the incorporation of some fluorinated carbon compounds from reaction with the evaporation source. This could actually be beneficial for the cathode layer because it might lead to higher electronic conductivity.

Film sensitivity to moisture in air.—CuF_2 films deposited on glass substrates from carbon sources seemed only moderately sensitive to moisture in air. The smoother the film the less sensitive it appeared to be, probably because of the reduced true surface area. A study was made in which both CuF_2 powder and a CuF_2 film were exposed to air, and studied at intervals by x-ray. The fresh CuF_2 powder showed only peaks due to CuF_2, but after exposure to air (>24 hr) a peak assigned to the dihydrate was seen. Another peak due to CuOHF also appeared after longer exposure (>10 days).

The fresh CuF_2 film showed a tiny broad peak due to the dihydrate and/or the oxyfluoride. After 168 days of exposure to air the film's appearance had hardly changed, and an x-ray study at this time showed almost the same features: only a small peak due to the dihydrate and/or the oxyfluoride of about the same height as for the fresh film. However, such a film would react with excess moisture rapidly; for example, holding the slide in one's hand caused crazing and blistering of the film in seconds. Therefore it was concluded that films of anhydrous CuF_2 could be obtained, and with moderate care they could be kept essentially anhydrous. However, for extended use in cells which might be handled frequently it would be necessary to cover the CuF_2 with a protective coating.

Conductivity of CuF_2 thin films.—Conductivity measurements were made on $Cu/CuF_2/Cu$ cells fabricated using the masking geometry described in a previous paper (10). A conductivity value of 1.6×10^{-9} $(ohm\text{-}cm)^{-1}$ was found at 25°C. This is somewhat higher than the values of 10^{-10}-10^{-11} $(ohm\text{-}cm)^{-1}$ reported for pure chemically formed thin films (13). This difference in conductivity could be due to the presence of impurities in the film as proposed above, or to some grain boundary effects. It should be noted that the increase in conductivity was comparable to the increase in conductivity of PbF_2 films compared to pressed pellet or single crystal PbF_2 noted in our earlier paper. A temperature study was performed, and an Arrhenius plot resulted in a value for ΔH of 0.345 eV, somewhat below ΔH values for ionic conduction in fluorides. It was not determined whether the observed conductivity was primarily ionic or electronic, but, in any case, the film conductivity was quite low. It was clear that improved CuF_2 cathode conductivity would be necessary for use in thin-film galvanic cells.

Deposition of mixed PbF_2-CuF_2 films.—PbF_2 and CuF_2 were codeposited from the same boat to achieve mixed films with improved ionic conductivity. This was similar to the practice of mixing cathode and elec-

trolyte as used in pressed-pellet cells. The PbF_2 has a lower melting point than CuF_2 (822°C *vs.* 950°C) and was observed to evaporate at lower temperatures. However, it was found that a mixture of the two could be codeposited. One would expect that the initial composition of the evaporant would be relatively rich in PbF_2 while later in the deposit it would be relatively rich in CuF_2. If one deposits a cell in the sequence Pb layer, PbF_2 layer, CuF_2-PbF_2 mixture layer, Cu layer, then one would have the favorable situation of a gradation from PbF_2-rich to CuF_2-rich through the cathode film, with a very high effective contact area between electrolyte and cathode. The actual composition of the cathode film would depend on the initial composition of the mixture in the evaporation source and to what extent the evaporation proceeded. With initial composition of approximately 70 mole per cent (m/o) CuF_2, and evaporating a large part, but not all, of the mixture, one might estimate over-all composition of about 50 m/o CuF_2.

X-ray studies were made on the codeposited mixed films. Some structure was seen in early films (Fig. 3a), with peaks attributable to both PbF_2 and CuF_2. However, as care was taken to avoid spattering of the mixture in the boat, and to avoid both the earliest and latest fractions of the deposit by using a shutter in front of the substrate, films were obtained which showed little or no structure under x-ray diffraction (Fig. 3b). Only one very broad peak around 27° could be seen, possibly due to CuF_2. Thus it appeared that the mixed films had a very fine-grained or amorphous nature. Studies of such films with scanning electron microscopy showed no visible grains.

Conductivity of mixed films.—Conductivity measurements were made on mixed films with copper electrodes. Values for σ were in the range 10^{-6}-10^{-8} $(\text{ohm-cm})^{-1}$, depending on the extent of the deposit. Longer deposit times with larger amounts of CuF_2 gave the lower conductivity values. Even so, a marked improvement was achieved compared to the pure CuF_2 films. Another benefit of the mixed films was the ease of deposition. The CuF_2-PbF_2 mixture melted at a lower temperature than the pure CuF_2, leading to improved outgassing characteristics and less spattering during deposition. In addition it was found that smooth adherent films could be obtained without substrate heating.

Galvanic cells.—Cells of the type $Pb/PbF_2/PbF_2$, CuF_2/Cu were deposited using the 0.1 cm^2 area masks.

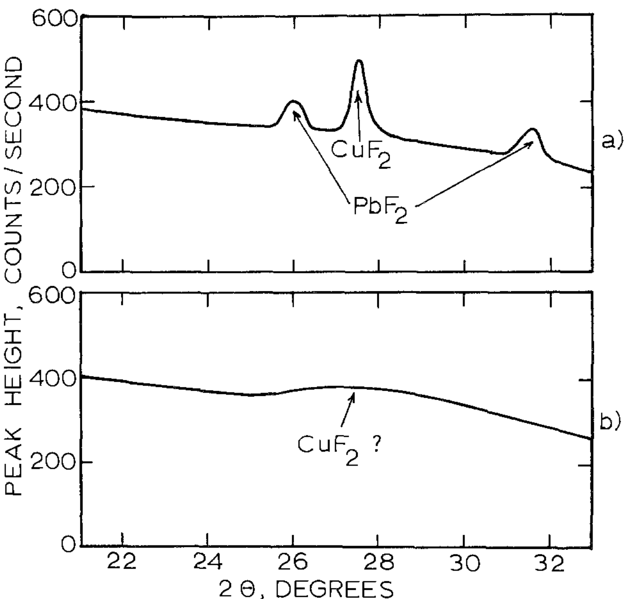

Fig. 3. X-ray spectra of mixed PbF_2/CuF_2 films: (a) early film, with PbF_2 and CuF_2 peaks, (b) later film, with almost no structure apparent.

In addition, some cells were made with 2 cm^2 area. The best cells were made without any substrate heating. Substrate heating for the cathode layer led to better adhesion of that layer, but caused the lifting of the underlying layers. Heating the substrate for all the layers led to increased numbers of shorted cells, probably due to increased Pb and PbF_2 grain size and correspondingly increased numbers of pinholes. The yields of nonshorted 2 cm^2 cells were smaller than for the 0.1 cm^2 cells, but with care to avoid spattering of deposits moderate yields of the larger cells could be obtained. Some cells that were found to be initially shorted eventually "healed," but with lower than normal capacity. Finished cells were coated with Kodak Microneg photoresist to protect the CuF_2 from moisture. Some cells were left uncoated for comparison, and within days these films crazed and blistered. The sealed cells did not show any deterioration after weeks of exposure to air.

The OCV's of cells ranged from 0.56 to 0.70V. However, the lower OCV's were obtained for cells deposited from early fractions of the deposition mixture, and these cells had poor performance. Although no appreciable $CuF_2 \cdot 2H_2O$ was detected by x-ray, it is interesting to note that the following cell reaction

$$Pb + CuF_2 \cdot 2H_2O \rightarrow PbF_2 + Cu + 2H_2O$$

has a theoretical OCV of 0.57V. This value agrees with the lowest cell values observed and may represent cells which had inadvertently been exposed to water vapor.

The cells with good performance had OCV's of 0.61-0.70V. The occurrence of lower than theoretical OCV in some cells could also indicate the presence of electronic leakage in the cells. However, the electronic conductivity of pure PbF_2 has been found to be quite low (10), so this was probably not the reason for lower OCV's. Figure 4 shows the OCV of a cell as a function of time. Initial voltage was 0.63V and subsequently rose to 0.66V. Even after several weeks the OCV was the same, and the cell was subsequently discharged with no apparent loss of capacity on storage. Therefore it appeared that the lower OCV's were not due to electronic leakage.

Another possible explanation of OCV lower than theoretical is that a solid solution of CuF_2 and PbF_2 was present, and the OCV would then indicate the CuF_2 activity at the active site. The x-ray data indicated an amorphous phase (Fig. 3b) supporting this possibility.

Cells were discharged under various loads and at different temperatures, and the cell voltages measured *vs.* time. Figure 5 shows a typical discharge curve for a small 0.1 cm^2 area cell at 25°C with a 3.3 megohm load. Upon first application of the load the cell voltage dropped to 0.22V, but as the cell started to discharge, the cell voltage rose gradually to 0.46V. This "activa-

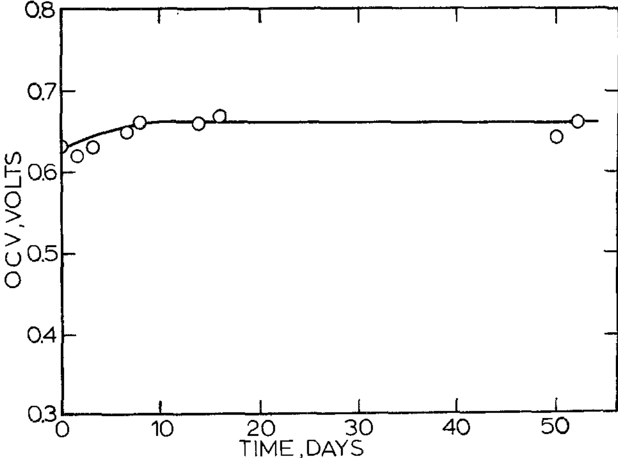

Fig. 4. OCV as a function of time for $Pb/PbF_2/PbF_2,CuF_2/Cu$ cell.

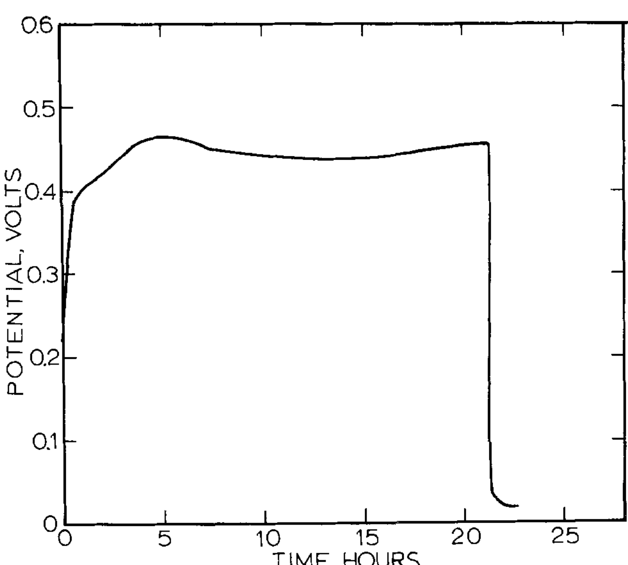

Fig. 5. Discharge curve at 25°C through 3.3 megohm load

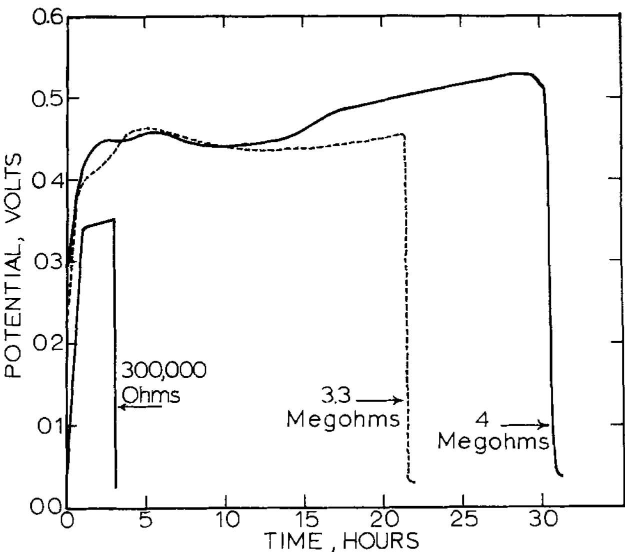

Fig. 6. Discharge curves at 25°C through various loads

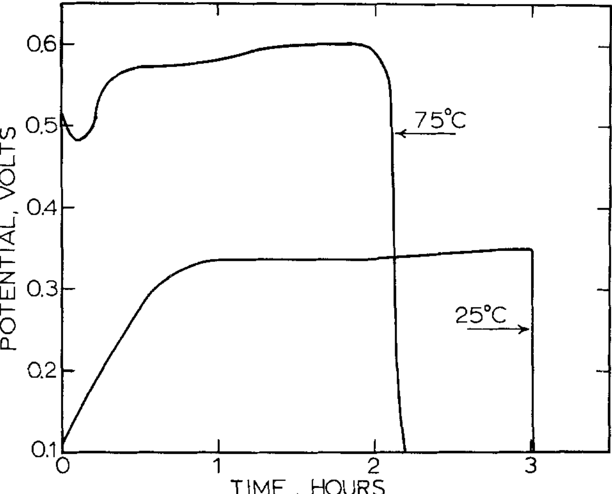

Fig. 7. Discharge curves at 25° and 75°C through 300,000 ohm loads.

tion effect" has been present for other solid-state batteries (18). The voltage then remained nearly constant during the rest of the discharge. Finally, the cell voltage dropped rapidly to 20-50 mV. The open-circuit voltage of such cells measured with an electrometer was still over 0.5V, although it was no longer possible to draw appreciable current from them. This is understandable if we consider the geometry of the cells. With the small 0.1 cm^2 cells, the cathode mixture and the upper copper electrode were deposited in the form of a long strip common to all the cells. But only the CuF_2 located directly above the smaller Pb electrodes could react easily. Once this CuF_2 was consumed there was still sufficient CuF_2 not directly above the Pb electrodes to establish the OCV, but only very low currents could be maintained with the extremely high resistance through the longer electrolyte path.

Figure 6 shows discharge curves for 0.1 cm^2 cells under various constant loads at 25°C, and Fig. 7 shows discharge curves with 300,000 ohm loads at 25°C and at 75°C. From the maximum current densities observed in Fig. 7 and assuming an OCV of 0.7V, one can use an Arrhenius relationship to obtain a ΔH value of 0.33 eV. This is quite close to the value obtained from a conductivity cell of pure CuF_2 mentioned earlier, and is smaller than the value of 0.54 eV found for conductivity cells of PbF_2. This supports the contention that the rate-determining step in the cell reaction involves the CuF_2 cathode material.

Table I summarizes the data for discharge of several cells of both 0.1 and 2 cm^2 area. The actual capacity of the cells is listed, both in terms of coulombs of charge and in terms of equivalents of CuF_2. These cells were all constructed with an excess of the anode material. Therefore, if the amount of CuF_2 present in the cathode film were known, the actual per cent utilization of cathode material could be calculated. However, the fact that a mixed film was used for the cathode, and that the x-ray diffraction studies gave no peaks prevented calculations based on these methods. The cells were estimated to be about 50 m/o CuF_2 from the evaporation conditions and a check on this assumption was made by studying some of the CuF_2-PbF_2 films using x-ray fluorescence analysis. Results showed 52-56 m/o CuF_2 in the films. The percentage utilization for the cells listed in Table I was calculated using this information. For the small cells it can be seen that the maximum utilization was 40% with most of the discharges in the range of 30-40%. Therefore, it appears that only a fraction of the available capacity of the cells could be used. A possible explanation is that much

Table I. Performance of $Pb/PbF_2/PbF_2,CuF_2/Cu$ thin-film galvanic cells

of the CuF_2 was isolated in the PbF_2-rich part of the cathode film, without electronic contact to the Cu electrode, or became isolated during discharge. A lack of complete utilization of cell capacity has also been reported by Liang *et al.* (9) for the Li/LiI/AgI/Ag system.

The Pb/CuF_2 cells with high OCV showed no evidence of self-discharge with storage. One particular cell was stored for over six weeks to measure OCV. The cell was subsequently discharged with no loss of capacity. This is in contrast to the thin-film cells of Liang which self-discharged *via* migration of silver ion in the cell (9).

Recharging of cells.—Cell A-78-S1 was discharged for one hour at 1 μA current at 75°C. This was only a partial (~ 33%) discharge. Figure 8 shows that the cell voltage leveled off at about 0.6V, 0.1V below the theoretical OCV. Then the cell was charged at 1 μA. There appeared to be a slight plateau area around 1.1-1.2V, but the voltage then climbed more steeply again. It is clear from Fig. 8 that the cell reaction was not reversible, and that charging this cell was not feasible at 75°C.

All attempts to recharge cells after they had been completely discharged met with failure; only extremely low currents would flow through the cells at reasonable charging voltages. Although these currents led to the proper OCV, the capacity of recharged cells was small. This discouraging result is consistent with the results of similar recharging attempts for CuF_2 in nonaqueous liquid electrolyte batteries.

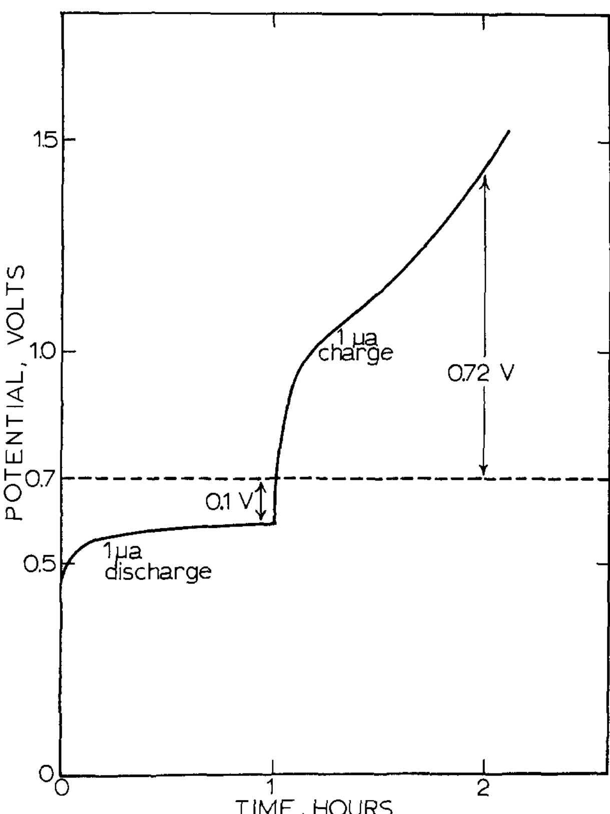

Fig. 8. Attempt to recharge thin-film cell, potential vs. time for 1 μA discharge and 1 μA charge cycles.

Summary

Thin-film galvanic cells using PbF_2 electrolyte, an anion conductor, have been successfully fabricated and discharged electrochemically. It was necessary, however, to codeposit PbF_2 with the CuF_2 cathode material to increase its ionic conductivity. The technique of codeposition is analogous to the conventional technique of mixing electrolyte and electrode material in pressed-powder cells. The Pb/PbF_2/PbF_2,CuF_2/Cu cells exhibited discharge characteristics similar to other thin-film cells reported in the literature, but they were not rechargeable.

The Electrodeposition of Aluminum from Aromatic Hydrocarbon

I. Composition of Baths and the Effect of Additives

E. Peled* and E. Gileadi*

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

ABSTRACT

Electroplating of aluminium on copper and steel substrates was conducted at room temperature. The bath consisted basically of $AlBr_3$ and an alkali metal bromide such as KBr dissolved in a suitable mixture of aromatic hydrocarbons. The bath was operated under conditions resembling industrial operation. Oxygen and humidity were removed by bubbling nitrogen through the bath. The effect of bath composition on the quality of the plated product is discussed in detail. Transference numbers were measured. The aluminium is shown to be present in the form of a negative ion ($Al_2Br_7^-$), the transference number of which is larger than that of the solvated positive ion. The reactions taking place during deposition and dissolution of aluminium in this system are discussed in detail.

Aluminium cannot be electrodeposited from aqueous or other protic solvents because decomposition of the solvent, accompanied by copious hydrogen evolution, occurs at the potential required to deposit the metal, and the current efficiency is essentially zero. Attempts to employ aprotic, polar solvents such as acetonitrile, DMF, pyridine, propylene carbonate, etc., failed,[1] probably since the small, highly charged Al^{+3} ion is very heavily solvated and decomposition of the solvent requires less energy than desolvation of the ion and electrodeposition of the metal. This is particularly so for the solvent molecules in the inner solvation shell which are highly polarized by the central ion.

Aluminium was successfully electrodeposited by Brenner *et al.* (1) from a bath consisting of $AlCl_3$ and $LiAlH_4$ dissolved in diethyl ether. This bath has not been adopted on a wide industrial scale because of its hazardous nature and the high cost of the bath components. Two other baths, one based on $LiAlH_4$ and $AlCl_3$ in tetrahydrofurane (3, 4), the other on molten alkyl aluminium compounds (5), are presently under investigation on pilot plant scale.

Aromatic hydrocarbons represent a unique class of solvents of great interest for electrochemical research and technology. Simple ionic salts, *e.g.*, alkali halides, are insoluble in them because of their low dielectric constant, while covalent salts such as AlX_3, where X is a halide ion other than F^-, are very soluble. Rigorously dried $AlBr_3$ dissolved in an aromatic hydrocarbon yields clear solutions having a pale yellow to orange tint, depending on the hydrocarbon employed. The electrical conductivity is very low (*ca.* 10^{-9} mho $\cdot$ cm^{-1}) (6). However, alkali halides can be dissolved in these systems, yielding an electrolytic solution of medium conductivity (up to 6 mmho cm^{-1}) (7-12), which is sufficient both for electrochemical measurements and for electroplating applications. A maximum in conductivity is reached when the molar ratio of, say, $AlBr_3$ to MBr (where M is an alkali metal or the ammonium ion) is 2:1, indicating that $Al_2Br_7^-$ and M^+ ions are probably formed. There is evidence in the literature showing that the solvation number of these ions (when M = H) is different in different hydrocarbons (13). The stability of the solvated $Al_2Br_7^-$ ions (and possibly of some $AlBr_4^-$ ions which may also be present when the amount of MBr added is increased) depends on the hydrocarbon used. In the presence of HBr[2] it is found to increase in the order benzene < toluene < xylene < mesitylene (14). Cryoscopic measurements indicated that in the presence of alkali halides, larger aggregates having the general formula $(Al_2Br_7^-M^+)_n$, where n may be as large as four, may also be formed (10, 12, 15).

Plotnikov and co-workers studied these systems about forty years ago and showed that it was possible to electrodeposit aluminium on platinum or copper from solutions of $AlBr_3$/MBr in benzene, toluene, and xylene (7, 16-20). However, the deposits obtained were in most cases of poor quality, the cathodic current efficiencies were low, and the solvents were decomposed in the course of electrolysis (10). Pospekhov, who reviewed the field in 1937, concluded that these systems were not suitable as plating baths for industrial applications (19). Recently, the system of $AlBr_3$ dissolved in xylene with HBr added was investigated in detail (21, 22). Aluminium was electrodeposited with high current efficiencies of *ca.* 90%. Two side reactions were also observed, *viz.*, reduction of the solvent and hydrogen evolution. Capuano and Davenport published recently a patent (23) and two papers (24, 25) in which the electroplating of aluminium from solutions of $AlBr_3$ in mixed aromatic hydrocarbons was reported. The quality of plating was found by these authors to depend on the hydrocarbons used. Thus, for example, benzene mixed with durene gave very poor results, while toluene mixed with ethyl benzene yielded excellent deposits. A main feature of the work of Capuano and Davenport is that all experiments were performed in the presence of small amounts of water (introduced by partial saturation of the hydrocarbon used as solvent with water before addition of $AlBr_3$), or with HBr continuously added (23-25). Water or HBr were considered by these authors to be indispensable components of the plating bath, without which aluminium could not be electrodeposited.

In the present work a systematic study of the effect of the composition of the baths on the quality of aluminium electrodeposited on copper or steel substrate, is presented. Special emphasis is placed on the effects of: (*i*) different aromatic hydrocarbons, (*ii*) organic and inorganic salts, and (*iii*) hydrobromic acid on the performance of the plating baths.

Experimental

Solutions were made up of AR-grade chemicals without further purification. All experiments were performed in airtight cells under an atmosphere of dry nitrogen. The inert gas flow was maintained continuously from the time a solution was made up until it was finally discarded (in many cases this lasted several months). The cell, electrodes, plating procedure, and preparation of metal surfaces were described in an earlier publication (26). Most experiments were

* Electrochemical Society Active Member.

Key words: aluminum, electrodeposition, nonaqueous plating bath, aromatic hydrocarbons, aluminum bromide.

[1] Reviews of previous work are given in Ref. (1, 2).

[2] $AlBr_3$ is very hygroscopic and any moisture absorbed immediately causes the formation of HBr and aluminium hydroxide or hydroxybromide.

conducted at cathodic current densities of 5-10 $mA \cdot cm^{-2}$, but in some cases a wider range of 0.5 to 40 $mA \cdot cm^{-2}$ was employed. Cathodic and anodic current efficiencies were determined by weighing the samples before and after electrolysis at a constant current. Since the main purpose of the present study was to evaluate the influence of various bath components and additives on the quality of electrodeposits and on the cathodic and anodic current efficiency under conditions resembling industrial operation, the cells were opened for changing samples in the regular laboratory atmosphere and the highly hygroscopic $AlBr_3$ was used as purchased without further drying.[3] Thus, it may be assumed that varying small amounts of humidity entered the bath and HBr was present in small quantities in all experiments.

The purity of electrodeposited aluminium was determined in the following manner: The sample was rinsed in a warm (60°C) 1M NaOH solution for a few seconds to remove the outermost oxide layer. It was subsequently washed in water, dried in acetone, and weighed. All the aluminium was then dissolved in warm 1M NaOH, the substrate was dried and weighed again. The total amount of aluminium in solution was determined gravimetrically with 8-hydroxy quinoline and this was compared to the weight-loss observed above.

Transference numbers were measured in a conventional Hittorf cell. Copper wires (1 mm diam) were used in the form of a helix for both electrodes. Electrolysis was conducted for 1.5-2 hr at a constant current of 20 mA. The volume of both anode and cathode compartments was 5 cm^3. The solution, prepared under anhydrous conditions, consisted of 0.7M KBr and 2.0M $AlBr_3$ in toluene. The concentrations of potassium and aluminium in the anolyte were determined by atomic absorption spectroscopy. Electrolysis time was calculated to give only a small concentration change (*ca.* 10%). In this way errors due to dissolution of copper and conduction of current by copper ions were minimized. The use of a copper anode insures that changes of concentration of potassium and aluminium in the anolyte are only caused by migration. Use of an aluminium anode would require a knowledge of the current efficiency of anodic dissolution, which has not been measured under the experimental conditions prevailing in this experiment.

Results

The basic system.—The basic system consists of a solution of $AlBr_3$ in toluene (or benzene) in roughly equal weights. If prepared under rigorously dry conditions, this would have very low conductivity and electrodeposition would not be possible. However, under the conditions maintained in all experiments reported here, some moisture, and hence some HBr, was always present, giving sufficient conductivity to allow electroplating. The basic system and the same system with either an alkali bromide (or iodide) or a Lewis base added were tested.

Aluminium bromide in toluene or benzene.—Aluminium bromide is very soluble in aromatic hydrocarbons. Two or three molar solutions of $AlBr_3$ in benzene or toluene were prepared and tested. A tarlike organic deposit containing little or no aluminium was formed if benzene was the solvent. In toluene a gray to black deposit was produced and the current efficiency for aluminium deposition was less than 50%. Results were generally irreproducible and satisfactory electrodeposits could not be obtained in these systems.

The effect of addition of hydrocarbons and amines.—Aromatic hydrocarbons such as ethylbenzene, mesitylene, and naphthalene were added in quantities ranging from 3 to 15 weight per cent (w/o) to the basic system of $AlBr_3$ in toluene. White gray electrodeposits having a metallic appearance were observed. A similar improvement in the quality of the electrodeposits resulted from the addition of dimethyl aniline or triethyl amine in comparable concentrations. The cathodic current efficiency was still highly irreproducible and ranged from 20% to nearly 100% in different experiments. Heavy dendrite formation was observed. The conductivity of the solutions varied with time and typically decreased from an initial value of 1-2 $mmho \cdot cm^{-1}$ to *ca.* 0.1 $mmho \cdot cm^{-1}$ within a few days.[4]

The effect of addition of alkali halides.—Alkali bromides or iodides were added to solutions of $AlBr_3$ in toluene. The concentrations were about 0.1-1.0M. The conductivity of the baths was increased and stabilized in the range of 0.5-6 $mmho \cdot cm^{-1}$, depending on concentration. Dendrite formation was significantly reduced and the cathodic current efficiency was higher in most experiments. Deposits obtained in freshly prepared solutions were generally poor, but after a few days, and after several samples had been plated, the quality of electrodeposits was greatly improved and was comparable to those described above. Better results were generally observed in the presence of iodides than with bromides.[5] The baths tended to be unstable and were found to deteriorate after a few weeks of operation.

The complete plating bath.—The experiments described above have shown that the basic system of $AlBr_3$ in benzene or toluene with either a Lewis base or an alkali bromide did not yield satisfactory results. A suitable bath should contain both an alkali bromide (or iodide) and a Lewis base such as a large aromatic hydrocarbon or an amine. The effect of the addition of different compounds from these classes is discussed below.

The effect of alkali halides.—A solution of $AlBr_3$ (2-3M) in toluene, with ethylbenzene or naphthalene in concentrations ranging from 3-30 w/o was employed in these experiments. Bromides or iodides of Li^+, Na^+, K^+, and NH_4^+ were added in concentrations of 0.1-1.0M. Excellent electrodeposits were obtained. The current efficiency increased with the concentration of the salt, and the tendency to form dendrites decreased. The purity of the electrodeposited aluminium was 99.5%, equal to the purity of the aluminium anodes used in these experiments.

When the concentration of the alkali salt was higher than 1M, codeposition of the salt and possibly of organic matter occurred. In some cases, when only *ca.* 70% of the electrodeposit consisted of aluminium, this was immediately apparent upon inspection of the sample. In other cases, when the purity was as high as 95%, apparently smooth and uniform electrodeposits were obtained, but these exhibited very poor corrosion resistance. Codeposition of salt appeared to be more severe in the presence of iodides than with bromides at comparable concentration.

Addition of alkali chlorides caused a decrease in current efficiency and gave rise to electrodeposits of poor quality. In the presence of alkali fluorides a white powder was formed in the bath and the current efficiency for aluminium deposition decreased.

The effect of cations on bath performance.—Addition of bromides of Li^+, Na^+, K^+, and NH_4^+ gave indistinguishable results. A few attempts were made to electrodeposit a Mg/Al alloy by adding $MgBr_2$ in 0.1M concentration. (The solubility of this salt is much lower than that of alkali bromides or iodides.) In these experiments only aluminium was electrodeposited.

Several quaternary ammonium bromides (tetramethyl and tetraethyl ammonium bromide, ethyl pyri-

[3] Studies in rigorously dried systems are under way and will be reported elsewhere (27, 28).

[4] The initial conductivity depends on the amount of moisture present in the $AlBr_3$ used or that entering the cell accidentally during preparation of the solution. This may depend on a number of factors such as the temperature and relative humidity, the skill of the experimenter, etc.

[5] It is very likely that part of the $AlBr_3$ could be replaced by AlI_3 in all plating experiments, yielding similar or even better results. In view of the higher cost and lower stability of AlI_3, this would be of little industrial interest, however.

dinium bromide, and pyridinium hydrobromide) were tested in a bath containing $AlBr_3$ in a mixture of, say, toluene and ethylbenzene. These cations caused an apparent improvement in the results. Very smooth deposits were obtained and dendrite formation was completely suppressed. The current efficiency was close to 100% (except in the case of pyridinium hydrobromide where it was only 60-80%). However, the coatings offered poor corrosion protection. Chemical analysis showed that the concentration of aluminium in the electrodeposit was *ca.* 95% or less, and incorporation of salt took place.

In order to minimize the incorporation of these salts in the electrodeposit and yet make use of their beneficial effects, another series of experiments was conducted. In these, the bath contained an alkali bromide in the usual concentration range (*ca.* 0.5M) and a small amount (0.01-0.1M) of quaternary ammonium bromide. An improvement in bath performance was observed. Thick and smooth deposits could be formed with few or no dendrites. However, some salt was still incorporated in the electrodeposit; its purity was only 98% and its resistance to corrosion was poor.

The organic cations had a distinct effect on plating from a solution containing only one hydrocarbon. It was already pointed out that a solution of $AlBr_3$ and MBr in benzene gave tarlike deposits, while in toluene it gave grayish dark aluminium deposits with low cathodic current efficiency. The addition of 0.01 w/o ethyl pyridinium bromide made it possible to electrodeposit aluminium from a solution of $AlBr_3$ in benzene at low current efficiencies (although the quality of the electrodeposit was poor). The addition of 0.02 w/o of the same material to the toluene based solution yielded smooth deposits at high current efficiencies, although some salt was still incorporated in the deposited film.

The effect of Lewis bases.—Two classes of compounds were tested in these experiments: (*i*) derivatives of benzene having one or several side chains or naphthalene and its derivatives, and (*ii*) aromatic and aliphatic amines and some ethers.

In the first group the compounds tested were: ethyl benzene, diethyl benzene, ethyl-methyl benzene, triethyl benzene, mesitylene, durene, hexamethylbenzene, ter-butyl benzene, naphthalene and its ethyl and methyl derivatives, and anthracene and its methyl derivatives. These compounds are known to be stronger Lewis bases than toluene or benzene. They were added in concentrations of 0.1M up to several molar to baths consisting of $AlBr_3$ (2-3M) and MBr (0.1-1M) in toluene. Greatly improved results were observed upon the addition of derivatives of benzene and naphthalene (and of naphthalene itself). The cathodic current efficiency was close to 100% at current densities of 5-10 $mA \cdot cm^{-2}$, and high-quality, pure electrodeposits were obtained.[6] At higher current densities the cathodic current efficiency was found to decrease significantly (at 30 $mA \cdot cm^{-2}$ it was down to 40%). The anodic current efficiency was close to 100% when current densities of 1-10 $mA \cdot cm^{-2}$ were used for several hours. However, the decrease of weight of anodes after several weeks of operation was higher than that calculated from the total charge passed. This is probably caused by mechanical disintegration of the anodes and to a lesser degree by chemical dissolution which takes place in solutions which have not been rigorously purified and dried (27-29). Addition of anthracene and its derivatives also improved the performance of the baths, but to a lesser extent. These baths tended to deteriorate rather rapidly. In certain baths containing a high concentration of naphthalene (*ca.* 2M and comparable to the concentration of $AlBr_3$), codeposition of salt was observed. No such effect was observed when the concentration of naphthalene was below 1M.

In the second group the compounds tested were: pyridine, tri-ethyl-amine, and N,N dimethyl aniline.

[6] Further details on tests of the quality of electrodeposits are given elsewhere (26).

These compounds are even stronger Lewis bases. Their presence in solution in concentration of a few tenth molar improved the properties of the plating bath in a manner similar to the effect of the hydrocarbons in the first group above. Chemical dissolution of the copper cathodes was observed in freshly prepared solutions containing any one of the above-mentioned amines. Electrolysis of such solutions yielded a highly decorative gold colored deposit of a copper/aluminium alloy which, however, had very poor corrosion resistance. After aging the bath for a few days, chemical dissolution stopped and pure aluminium electrodeposits were obtained.

A higher concentration of N,N dimethyl-aniline of *ca.* 0.7M prevented electrodeposition of aluminium.

In an additional series of experiments, tetrahydrofuran in molar concentration equal to that of $AlBr_3$ was added instead of an amine. A tarlike deposit containing some aluminium was formed.

The effect of HBr.—A solution of $AlBr_3$ and naphthalene in toluene was saturated with HBr. The conductivity of the resulting solution was 13 $mmho \cdot cm^{-1}$. The copper cathode (surface area 10 cm^2) dissolved rapidly in this solution (weight loss was 0.08 g/hr) and aluminium could not be electrodeposited. Hydrobromic acid was removed from solution by bubbling dry nitrogen. The decrease in concentration can be followed in this system (where no alkali bromide was added) by the decrease in conductivity. Aluminium could be deposited only when the conductivity was less than 8 $mmho \cdot cm^{-1}$. At 5 $mmho \cdot cm^{-1}$ the current efficiency was 35% and at 1 $mmho \cdot cm^{-1}$ or less it was close to 100%. In the last solution the rate of corrosion of the copper cathode on open circuit was only 5 mg in 24 hr, more than two orders of magnitude slower than in a solution saturated with HBr.

The effect of oxygen.—Oxygen does not react chemically with the components of the bath at a significant rate. Thus, it may be allowed to saturate the bath and can subsequently be removed by bubbling an inert gas without adversely affecting its performance. However, during electroplating oxygen must be absent since its reaction at the electrodes prevents deposition of aluminium and causes rapid deterioration of the bath. In an experiment conducted in a solution saturated with oxygen, the voltage between a copper cathode and an aluminium reference electrode rose within minutes from a few millivolts to many volts. At the end of electrolysis the copper cathode was coated with a black tar which did not contain aluminium.

The effect of ions of heavy metals.—Ions of heavy metals, such as copper and iron, interfere with the electrodeposition of aluminium. Alloys of various composition are electrodeposited, the adhesion to the substrate metal is usually poor, and the deposits are gray and have poor corrosion resistance. Heavy ions can be removed by preelectrolyzing on a dummy cathode.

Transference numbers.—Preliminary experiments were performed to determine approximately the transference numbers of potassium and aluminium, by the Hittorf method. A solution of 0.7M KBr and 2M $AlBr_3$ in toluene was employed. Two copper electrodes were used in the cell and chemical analysis of the solution in the anode compartment was carried out. The concentration of potassium was found to decrease while that of aluminium was found to increase. The transference numbers were: $t_{K^+} = 0.3 \pm 0.1$ and $t_{Al_2Br_7^-} = 0.7 \pm 0.1$. If one were to assume that aluminium was present mainly in the form of the smaller ion $AlBr_4^-$, its calculated transference number would be $t_{AlBr_4^-} = 1.4 \pm 0.2$ which is clearly unacceptable.

The solubility of $AlBr_3$ and KBr in cyclohexane.—Aluminium bromide was dissolved in 70 cm^3 cyclohexane in an atmosphere of dry nitrogen, giving a clear, colorless solution which was 0.7M in $AlBr_3$. Dry KBr (2.1g) was added and the solution was stirred for

24 hr. Most of the KBr did not dissolve and the concentration of potassium in solution was 4×10^{-4}M. The conductivity was below 10^{-7} mho · cm^{-1}. No attempt was made to electrodeposit aluminium from this system.

Discussion

The structure of the electrolyte.—Aluminium bromide, which has predominantly covalent bonds, is soluble in aromatic hydrocarbons and in cyclohexane. The resulting solution is nonconducting. Simple ionic salts, such as KBr, are not soluble in hydrocarbons, but are readily soluble in an aromatic hydrocarbon containing $AlBr_3$. The solubility of KBr (and other alkali bromides or iodides) is dependent on the concentration of aluminium bromide. In solutions that have not been dried rigorously, it does not exceed the molar ratio of KBr:$AlBr_3$ (1:2), corresponding to the formation of $Al_2Br_7^-K^+$. When a higher proportion of alkali bromide is dissolved, some $AlBr_4^-K^+$ is probably formed, but the above ratio never exceeds 1:1.

The fact that KBr cannot be dissolved to any significant extent in a solution of $AlBr_3$ in cyclohexane is rather interesting in view of the fact that the dielectric constants of cyclohexane and, say, toluene are nearly the same. It would appear that the difference is due to the great difference in polarizability of the two types of solvents, which allows stabilization of the ions in the aromatic but not in the alicyclic system. It is interesting to note in this context that the dielectric constant of a solution of toluene containing 50 w/o $AlBr_3$ was found to be 2.75 (30) while that of pure toluene is 2.28.

The transference numbers reported here, which indicate that aluminium appears in solution as negative ions, are in agreement with the earlier interpretation of Plotnikov *et al.* (7, 10, 11). The fact that $t_+ < t_-$ indicates that the potassium ion is more heavily solvated.

The conductivity observed in these solutions is much lower than for aqueous solutions of comparable concentration. Thus, a solution of 1M $Al_2Br_7^-K^+$ in toluene has a conductivity of *ca.* 5 mmho · cm^{-1}, while the conductivity of an aqueous 1M KCl solution is *ca.* 100 mmho · cm^{-1}. This difference can be ascribed to several factors: (*i*) the viscosity of the organic solution is about four times higher (31), (*ii*) the radius of the solvated ions is larger, and (*iii*) partial association of the positive and negative ions may occur.

Double layer capacity measurements, to be reported elsewhere (29), as well as earlier work on solvation, indicate that the solvated radius of ions in this system is larger than in water. This, together with the difference in viscosity, could explain a major part of the difference in conductivity, indicating that ion pair formation is not predominant in this system. This would appear unusual, in view of the low dielectric constant, but can be understood as resulting from the large solvated radii of the ions, which keeps them far apart and reduces the electrostatic attraction forces between them.

Vapor pressure measurements have shown that in toluene one molecule of the solvent is attached strongly to each Al_2Br_6 molecule forming a π complex (32). When HBr was also present, complexes of the type $ArH_2^+Al_2Br_7^-$ (14) or $3Ar \cdot Al_2Br_6 \cdot HBr$ were found (13). The solvation number in this case varies for different aromatic hydrocarbons.

Reactions at the cathode and the anode.—The alkali halides added to the solution of $AlBr_3$ in a mixture of aromatic hydrocarbons serve two purposes: (*i*) to increase and stabilize the conductivity, and (*ii*) to convert most of the aluminium present in solution to the negative ion $Al_2Br_7^-$ (or to $AlBr_4^-$ in the presence of a high concentration of MBr), as indicated by transference number measurements.

The primary cathode reaction could be either

$$Al_2Br_6 + 6e_M \rightarrow 2Al + 6Br^- \quad [1]$$

or

$$Al_2Br_7^- + 6e_M \rightarrow 2Al + 7Br^- \quad [2]$$

When the ratio of molar concentrations of MBr:$AlBr_3$ is much lower than 0.5, both reactions may occur. As this ratio approaches 0.5, Eq. [2] probably becomes predominant. Since the simple Br^- ion is apparently not stabilized in this system,[7] Eq. [1] must be followed by a chemical reaction of the type

$$6Br^- + 6Al_2Br_6 \rightarrow 6Al_2Br_7^- \quad [3]$$

giving the over-all reaction

$$7Al_2Br_6 + 6e_M \rightarrow 2Al + 6Al_2Br_7^- \quad [4]$$

Thus, less than one electron is passed in the over-all reaction for each Al_2Br_6 molecule reaching the surface.[8] This can be put differently by stating that for each molecule of Al_2Br_6 discharged at the electrode, six molecules of Al_2Br_6 are required to complex the free Br^- ions left behind. Thus, if the current density is too high and/or stirring insufficient, a deficiency of Al_2Br_6 molecules may develop in the diffusion layer causing codeposition of the alkali bromide.

Equation [2] will be followed, for the same reasons, by the chemical step

$$7Br^- + 7Al_2Br_6 \rightarrow 7Al_2Br_7^- \quad [5]$$

Combining Eq. [2] and [5] gives the same over-all reaction, represented by Eq. [4].

As the ratio of MBr:$AlBr_3$ approaches or even exceeds 0.5, the primary electrode reaction becomes predominantly that shown in Eq. [2], but this could now be followed by a reaction such as

$$7Br^- + 7Al_2Br_7^- \rightarrow 14AlBr_4^- \quad [6]$$

which leads to the over-all reaction

$$4Al_2Br_7^- + 3e_M \rightarrow Al + 7AlBr_4^- \quad [7]$$

Here again poor mixing or a high current density could cause a deficiency of $Al_2Br_7^-$ at the electrode and result in codeposition of the salt. In this situation the number of electrons passed in the over-all reaction per molecule of $AlBr_3$ (calculated) reaching the surface is $n = 3/8$.

At the anode the situation is obviously reversed. The over-all reaction given in Eq. [4] is likely to predominate, since this requires only three ions of $Al_2Br_7^-$ for each atom of aluminium dissolved, while in Eq. [7] one would require seven ions of $AlBr_4^-$, the concentration of which is very low in most situations.

If the supply of $Al_2Br_7^-$ ions to the anode is insufficient due to their low concentration in solution (when the ratio of MBr to $AlBr_3$ is small compared to 0.5), insufficient stirring, too high current density, or a combination of these factors, anodic dissolution cannot occur at the desired rate, the potential will rise, and side reactions (probably decomposition of the solvent or bromine evolution) will occur which shorten the lifetime of the plating bath.

From the above discussion it may be concluded that the concentration of MBr in solution should be chosen so that it is sufficiently high to provide good conductivity, good throwing power, and efficient anodic dissolution, yet sufficiently low to avoid codeposition of the salt. The importance of proper stirring and of limiting the current density employed becomes evident for both cathodic and anodic reactions.

If oxygen is present in the solution during electrolysis, the anode is covered with an oxide layer and anodic dissolution is diminished. Bromine evolution occurs (10) and this reacts with the solvent to form a

[7] This may be inferred from the fact that MBr is soluble in an aromatic hydrocarbon only in presence of $AlBr_3$.

[8] This is an interesting point for the calculation of the diffusion limited current to be expected in, say, a potentiostatic transient. If the concentration of aluminium is expressed formally as the molar concentration of $AlBr_3$, the number of electrons passed in the over-all reaction, according to Eq. [4] will be $n = 3/7$, rather than 3, as one might be led to assume.

variety of high molecular weight compounds, causing rapid deterioration of the bath. At the cathode oxygen is apparently reduced instead of aluminium and an oxide layer is also formed, as evidenced by the rapid increase in measured voltage drop between the cathode and an aluminium wire reference electrode.

The effect of quaternary ammonium salts in small concentrations is probably due to strong adsorption of the ion at the electrode surface. This also accounts for the tendency of incorporation of salts into the electrodeposits, causing poor corrosion resistance, as described above.

The effect of HBr and of Lewis bases.—All the experiments described in this paper were performed under conditions which may resemble industrial operation. Thus, all solutions contained a small amount of HBr, formed as a result of interaction of $AlBr_3$ with moisture entering the cell during changing of the samples It is known (13, 14) that the reaction of HBr with $AlBr_3$ and the aromatic hydrocarbon ArH gives rise to a complex of the form $ArH_2^+Al_2Br_7^-$ which can be reduced at the cathode. The stability of this complex increases in the order benzene $<$ toluene $<$ m-xylene $<$ mesitylene. Reduction of the protonated hydrocarbon competes with electrodeposition of aluminium, and hence the cathodic current efficiency decreases with increasing concentration of HBr until a point is reached where it becomes negligible. This can account for the fact that in the work of Capuano and Davenport (23-25), where moisture or HBr were added on purpose, the cathodic current efficiency was never found to exceed 85%. In the present work, where the level of HBr was kept low, current efficiencies approaching 100% were observed in solutions containing a mixture of hydrocarbons and an alkali halide.

Benzene is a weak Lewis base and hence even a small amount of HBr prevents electrodeposition of aluminium. Toluene is a stronger base and electrodeposition does occur under the same conditions, but at low current efficiencies. When mesitylene is used as the main solvent, or when it is added to toluene in substantial quantities, a higher level of moisture can be tolerated in the system (up to a few tenths per cent H_2O), still yielding good electrodeposits at high cathodic current efficiencies. The same is true for naphthalene and for derivatives of benzene with highly branched side chains. It would appear that in all these cases the proton is stabilized by the aromatic hydrocarbon, which is a strong Lewis base compared to benzene or toluene, and reduction of the ArH_2^+ complex occurs at a much slower and often negligible rate. Aliphatic and aromatic amines, which are even stronger Lewis bases, can serve the same purpose.

Acknowledgments

The authors wish to thank Mr. Meron, Head, Department of Materials Engineering, Israel Aviation Industries, and Mr. Tillis of the same department for their encouragement in the course of this work. Thanks are also due to Mrs. I. Armel and Mr. Y. Canfi for their technical assistance in performing the experiments described in this paper.

Manuscript submitted June 24, 1975; revised manuscript received Sept. 8, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Technical Notes

The Electrode Potential of the Chromate (VI)-Lithium Chromate (V) System in Molten Lithium Chloride-Potassium Chloride Eutectic

Katsumi Niki*

Department of Electrochemistry, Yokohama National University, Minami-ku, Yokohama 233, Japan

and Isamu Uchida* and Herbert A. Laitinen*

Department of Chemistry, University of Florida, Gainesville, Florida 32611

The electrochemical reduction of chromate ion, CrO_4^{2-}, in lithium chloride-potassium chloride eutectic melt (1), and the effect of various divalent metal ions (2-5) and water (6), have been studied extensively. Laitinen and Bankert (1) observed that the reduction of chromate ion was a single, irreversible and diffusion controlled three-electron process, yielding an unstable initial product believed to be Li_5CrO_4. Recently Uchida and Laitinen (6) isolated $LiCrO_2$ as the reduction product from moist melts. On the other hand, Niki and Laitinen (7) found that Li_3CrO_4, which is assumed to be one of the intermediate compounds in the reduction of CrO_4^{2-} in LiCl-KCl melt, is relatively stable in LiCl-KCl melt. Because of the limited solubility of Li_3CrO_4 there is an equilibrium in the disproportionation reaction: namely

$$3Li_3CrO_4(\text{solid}) \rightleftarrows 2CrO_4^{2-} + 8Li^+ + 2\,O^{2-} + \underset{\underset{LiCrO_2(\text{solid})}{\uparrow\downarrow Li^+}}{CrO_2^-} \quad [1]$$

In the present work, the electrode potential of CrO_4^{2-}/Li_3CrO_4 and the equilibrium of the disproportionation reaction of Li_3CrO_4 were investigated to correlate these values to the electrochemical behavior of chromate ion.

Experimental

Reagent.—Li_2CrO_4 was prepared by neutralizing CrO_3 by Li_2CO_3, and then it was recrystallized and dried at 200°C under vacuum for about 8 hr. All chemicals used in the present work were either the AR or the primary standard grade. The LiCl-KCl eutectic melt was supplied by Anderson Physics Laboratories, Incorporated, Champaign, Illinois.

Li_3CrO_4 electrode.—A mixture of the stoichiometric amount of Li_2CrO_4 and Li_2CO_3 was maintained at 450°C in a platinum crucible for 5 hr under vacuum. Then the temperature of the mixture was increased gradually. When a liquid phase formed at about 550°C, a platinum flag 0.06 mm thick and 6.37 mm in diameter with 36 gauge platinum wire as an electrical lead, was immersed in the melt. After the platinum surface was wetted by the viscous melt, it was pulled out from the melt. Then the temperature of a furnace was increased up to 750°C. The viscous melt solidified and black crystals covered the surface of the platinum flag. The platinum flags covered by Li_3CrO_4 were stored in a vacuum desiccator and used as indicator electrodes. Fine Li_3CrO_4 crystals formed in the crucible were also stored in a vacuum desiccator and used for the disproportionation reaction measurement. The purity of Li_3CrO_4 was better than 99% as determined from the close agreement between the observed ratio of Cr(VI): Cr(III) in a 6*N* HCl solution with the theoretical ratio of 2:1 and the agreement between the weight of Li_3CrO_4 taken and calculated from the total Cr recovered. Li_3CrO_4 was handled under nitrogen atmosphere.

Electrochemical measurement.—The electrochemical cell assembly has been described in detail (8). A known amount of Li_2CrO_4 was added to each compartment containing 3 ml of the melt in the cell, and the exact concentration of chromate ion in the melt was determined by coulometric titration after the potential measurement (2). The electrode potentials of the Li_3CrO_4 electrode in the chromate solutions were measured with a Leeds and Northrup Student Type 8687 volt potentiometer against the Pt(II)/Pt electrode. The preparation and construction of Pt(II)/Pt electrode have been described (8-9).

All potentials shown in this work are given with respect to the 1*M* Pt(II)/Pt electrode, and all experiments were carried out at 450° ± 1°C.

Disproportionation of Li_3CrO_4.—About 200 mg of Li_3CrO_4 was added to each 3 ml compartment in the cell. These compartments were of Pyrex glass with a fritted glass bottom which acted as a salt bridge. The melt was stirred occasionally with a glass rod and maintained for about 30 min. After equilibrium has been attained, the electrode potential of the Li_3CrO_4 electrode in these melts was measured and then a sample of the melt containing chromate ion was taken by the sampling tube for the determination of chromium (7).

Analysis of chromates.—Analytical procedures for the chromium compounds were the same as in the previous work (7).

Results and Discussion

Equilibrium potential of CrO_4^{2-}/Li_3CrO_4 system.—The electrochemical cell used for the equilibrium potential measurement of the CrO_4^{2-}/Li_3CrO_4 system was

$$Pt/Li_3CrO_4/CrO_4^{2-}\ (\text{in Li, KCl})//\ Pt(II)\ (1.0M\ \text{in Li, KCl})/Pt$$

* Electrochemical Society Active Member.

Key words: chromium (V), lithium chromate (V), electrode potential, molten salt, disproportionation.

The half-cell reaction on the left-hand side of the cell is given by

$$CrO_4^{2-}(soln) + 3Li^+ + e^- = Li_3CrO_4(solid) \quad [2]$$

If the cell reaction is reversible, the equilibrium potential of the CrO_4^{2-}/Li_3CrO_4 system is given by

$$E = E^{\circ\prime} + \frac{RT}{\mathbf{F}} \ln \frac{a_{CrO_4^{2-}}}{a_{Li_3CrO_4}} \quad [3]$$

Since Li_3CrO_4 is solid and the activity coefficient of CrO_4^{2-} is assumed to be unity, Eq. [3] leads to

$$E = E^{\circ\prime} + 0.1435 \log C_{CrO_4^{2-}} \quad \text{(at 450°C)} \quad [4]$$

The equilibrium potential of the Li_3CrO_4 electrode with various concentrations of chromate ion is shown in Fig. 1. The electrode attained an equilibrium potential within 10 min and gave a stable value for more than 1 hr when the concentration of CrO_4^{2-} was greater than 0.02*M* in the melt. At lower concentrations of CrO_4^{2-} ($<$0.015*M*), Li_3CrO_4 on the platinum electrode was probably oxidized to CrO_4^{2-} by PtO on the platinum surface and the concentration of chromate ion became higher in the vicinity of the electrode. Accordingly, the electrode potential of the Li_3CrO_4 electrode became more positive than that expected from the Nernst equation (4).

The equilibrium potential (V *vs.* Pt(II), 1*M*/Pt) of the CrO_4^{2-}/Li_3CrO_4 system at 450°C is given empirically by

$$E = -(0.761 \pm 0.004) + 0.141 \log C_{CrO_4^{2-}} \quad [5]$$

The slope of the Nernst equation agreed well with a one-electron process corresponding to Eq. [2].

Disproportionation of Li_3CrO_4 in LiCl-KCl melt.— In our previous work (7), it was shown that Li_3CrO_4 disproportionates to CrO_4^{2-} and $LiCrO_2$ in the LiCl-KCl melt. If the disproportionation reaction of Li_3CrO_4 takes place in the melt according to Eq. [1], when the LiCl-KCl melt is saturated by both Li_3CrO_4 and $LiCrO_2$, then the equilibrium constant for this disproportionation reaction is given by

$$K = [CrO_4^{2-}][O^{2-}] \quad [6]$$

The concentration of CrO_4^{2-} ion in the melt in the presence of excess amounts of Li_3CrO_4 was (0.0107 ± 0.0002)*M* and the equilibrium constant for the reaction [1] is given by

$$K = [(1.07 \pm 0.002) \times 10^{-2}]^2 = (1.15 \pm 0.04) \times 10^{-4}\ \text{mol}^2\ \text{l}^{-2} \text{ (at 450°C)}$$

When the concentration of CrO_4^{2-} was 1.0*M* in the melt in the presence of excess amounts of Li_3CrO_4, the electrode potential of the CrO_4^{2-}/Li_3CrO_4 is $-$0.761V (*vs.* 1.0*M* Pt(II)/Pt) and the concentration of O^{2-} in the melt can be calculated to be $1.145 \times 10^{-4}M$. Figure 2 shows the semiquantitative pO^{2-}-potential diagram of chromium, which we have described qualitatively in a previous paper (7).

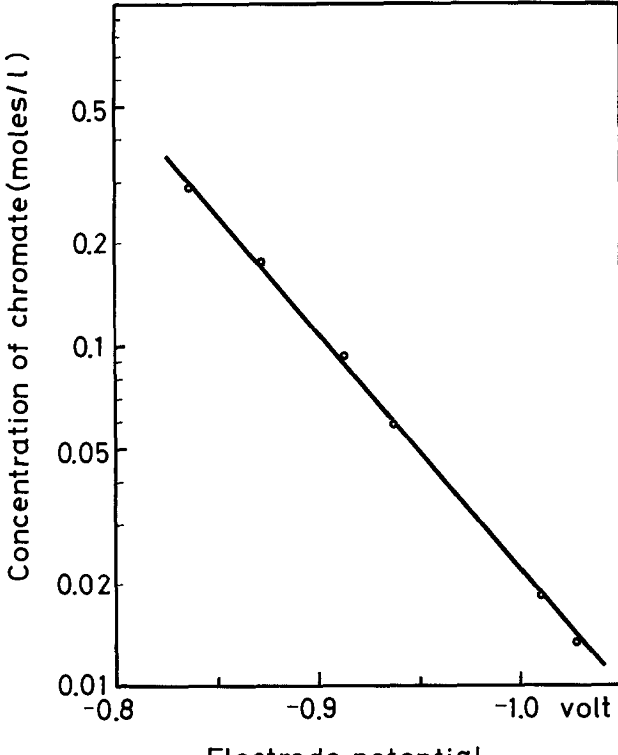

Fig. 1. Equilibrium potential of CrO_4^{2-}/Li_3CrO_4 system in LiCl-KCl eutectic melt at 450°C.

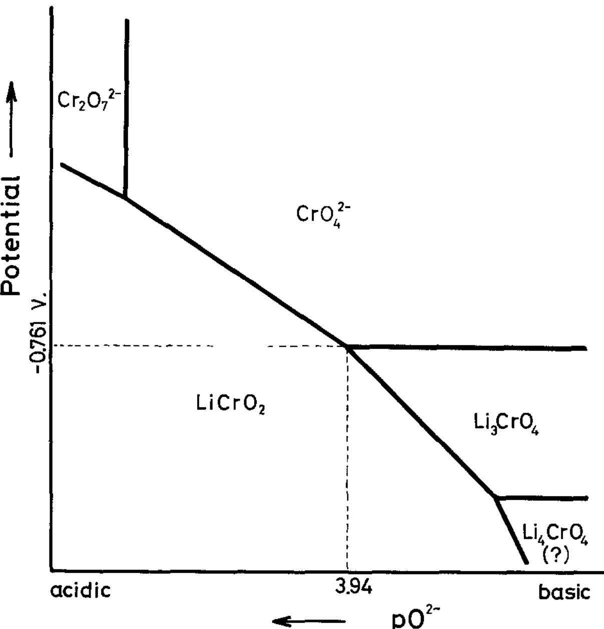

Fig. 2. Potential-pO^{2-} diagram of chromates in LiCl-KCl eutectic melt at 450°C.

The Rotating Cone Electrode

E. Kirowa-Eisner and E. Gileadi*

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

The rotating disk electrode and rotating ring-disk electrodes have long become standard tools in the study of electrode reactions. Other configurations such as the rotating hemisphere (1) and rotating ring (2) or ring-ring electrodes (3) have also been tested experimentally and the relevant equations derived. In all these cases, the rate of mass transport, and hence the limiting current density, was always found to be proportional to the square root of the angular velocity, ω, as derived by Levich for the rotating disk electrode (4). Recently it was shown (5) that a substantial degree of eccentricity of the rotating disk electrode could be allowed (up to *ca.* 64% of the radius of the disk) without affecting the limiting current at all.

One of the experimental problems often occurring when a rotating disk electrode is employed is a tendency for a gas bubble to be trapped at the center of the disk where the radial forces are balanced. This occurs particularly when vigorous gas evolution takes place.

Use of a rotating ring instead of a disk has been suggested to overcome this difficulty (2, 3). This may solve the problem partially since, if the bubble trapped at the center of rotation is not too large it will leave the electrode itself unshielded. However, the existence of a bubble at the center of the disk will alter the conditions of flow and, hence, introduce an error in the measurement of the limiting current density.

Recently it has been suggested (6) that a rotating cone electrode could be used instead of a rotating disk. In this configuration, a bubble at the tip of the cone would not be stable, and smooth flow past the electrode surface may be expected even in reactions in which vigorous gas evolution occurs. Preliminary experiments showed that the linear relationship between i_L and $\omega^{1/2}$ was maintained for this configuration.

Mass transport to a conical electrode has been considered by several authors (7-10). In all these studies the electrode was stationary and the fluid was forced past it. The boundary layer problem for a rotating cone has been treated by a number of authors (11-13) for heat and mass transport situations not related to electrochemical systems. The equations for a rotating cone electrode have been derived recently by Newman and Mohr (14) in a form commonly used by electrochemists. The result for the local mass transfer rate at the limiting current is

$$j = 0.62 C_b \sqrt{\nu\omega \sin\theta}\, Sc^{-2/3} \qquad [1]$$

The over-all mass transfer rate for a conical electrode of base radius r is

$$J_{tot} = 0.62\pi C_b r^2 \sqrt{\frac{\nu\omega}{\sin\theta}}\, Sc^{-2/3} \qquad [2]$$

where the Schmidt number Sc is a dimensionless quantity given by $Sc = \nu/D$.

These equations may be rewritten in simple form to relate the limiting current density i_L and the limiting current I_L on a rotating disk (4) and rotating cone having the same base radius. Thus

$$i_L(\text{cone}) = i_L(\text{disk}) \sin^{1/2}\theta \qquad [3]$$

$$I_L(\text{cone}) = I_L(\text{disk}) \sin^{-1/2}\theta \qquad [4]$$

Experimental

The equations given above show that the rotating cone electrode can be a useful tool in electrode kinetic studies just as the rotating disk, and the very same equations can be used to separate the activation-controlled current from the total current measured under conditions of mixed mass transport and activation control. In this work the validity of the above equations was tested experimentally, care being taken to achieve the highest possible experimental accuracy. Equations [3] and [4] were tested in a solution of 4.00 mM hydroquinone in 2.0*M* KCl.

The electrodes, solution, and experimental setup.—As shown in Fig. 1, a platinum cylinder of 4.80 mm diameter and 11 mm length was press fitted into a Teflon holder (outer diameter 12 mm). The same electrode was machined to different angles ($\theta = 60°$-$25°$) on an accurate lathe. The electrode assembly was centered carefully to within 0.02 mm to minimize wobble. The accuracy of the angles machined was $\pm 1/4°$.

A flat platinum electrode about 2 cm^2 area, situated at a distance of about 2 cm from the rotating electrode served as the counterelectrode. A commercial mercury/mercurous sulfate electrode (Radiometer Type K601) served as the reference.

All chemicals were analytical grade and were used without further purification. Hydroquinone was dried at 80°C. All solutions were prepared in triple-distilled water.

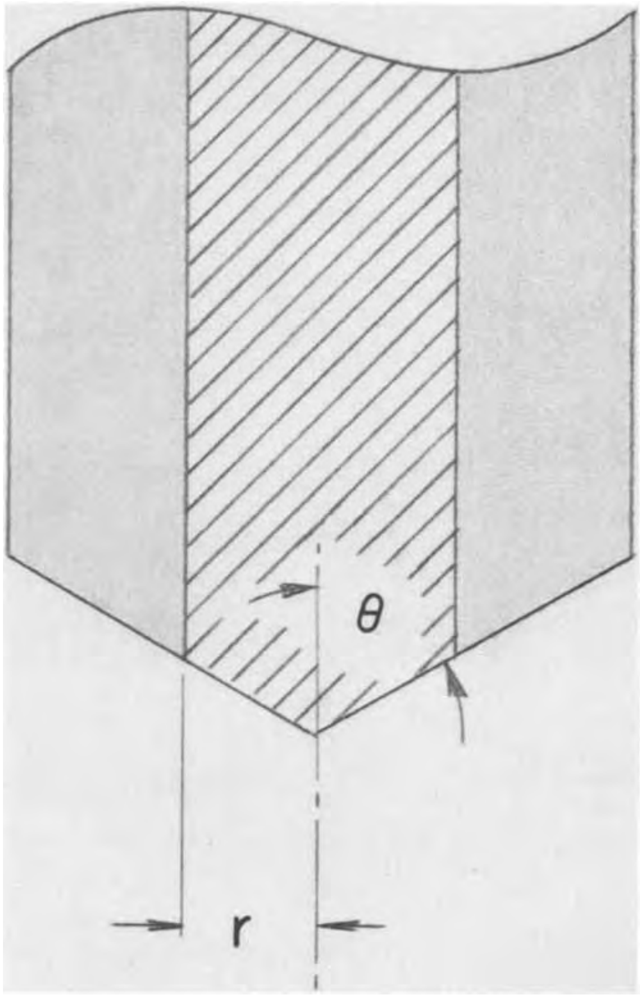

Fig. 1. Structure of cone electrode, defining the cone angle θ and radius r. Shaded area is Teflon holder.

* Electrochemical Society Active Member.
Key words: rotating electrodes, mass transport.

Measurements were performed potentiostatically, with an Elron Model CHP-1 potentiostat. No *IR* correction was necessary, since measurements were taken in the limiting current region. A Pine Instrument rotator and a Metrohm Type EA 870-20 thermostated cell were used. Currents were recorded on a Yokogawa Type 3077 X-Y recorder.

Procedure.—Each new electrode was degreased with acetone, cleaned in nitric acid (1:1), and washed with triple-distilled water, all in an ultrasonic cleaner. Before each run the electrode was pretreated electrochemically in 0.5*M* H_2SO_4 in a procedure similar to that proposed by Gilman (15,16). This consisted of the following sequence of potential (*vs.* NHE) and time: 1.85V (10 sec); 1.20V (25 sec); 0.10V (25 sec). The sequence was repeated several times, after which a cyclic voltammogram was taken to verify the cleanliness of the surface.

The pretreated electrode was washed with triple-distilled water and transferred to the cell containing about 80 cm^3 of 4.00 mM hydroquinone solution in 2*M* KCl, which had been deaerated with purified nitrogen. The conical electrode was immersed about 2 cm below solution level. No bubbles were formed even at the highest rotation velocity of 10^4 rpm employed.[1]

The potential was set to a value of 1.02V *vs.* NHE, in the region of limiting current, and the current was measured. Each measurement was restricted to 5 sec to minimize changes in concentration of hydroquinone during the whole run. At least five runs in freshly prepared solutions were made for each angle of the cone, and the limiting current was measured at nine rotation velocities, between 4×10^2 and 1×10^4 rpm.

Results

The dependence of the limiting current I_L on the square root of the rotation velocity ω is shown in Fig. 2 for different values of the angle θ. The correlation factor for a single line was very high, in the range of 0.99995-0.99999. The standard deviation of the slope was 0.5% for the rotating cone (based on seven measurements) and 0.2% for the rotating disk (based on six measurements).

In Table I the experimental slopes of $\partial i_L(\text{cone})/\partial \omega^{1/2}$ are compared with the values calculated according to

[1] In an early experiment, where a thicker Teflon sleeve was employed, bubbles were formed at intermediate rotation velocities.

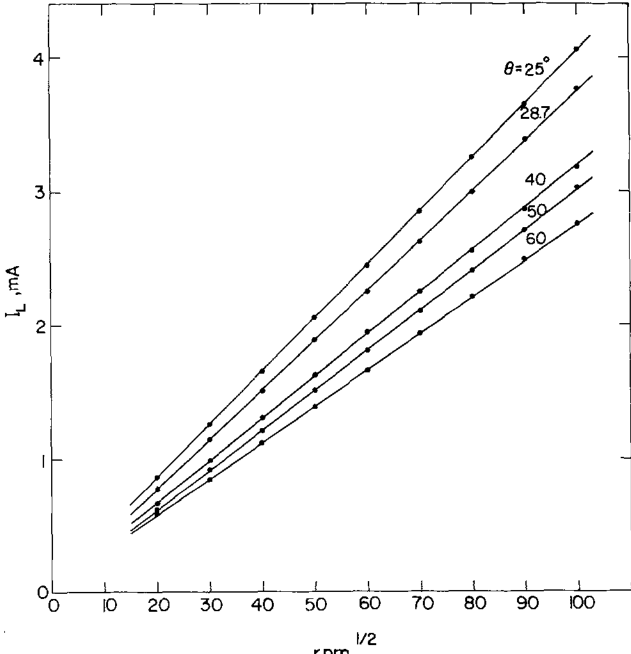

Fig. 2. Limiting current/angular velocity relationship at different cone angles, θ. 4 mM hydroquinone, 2*M* KCl, 25°C. Radius of cone base: 2.4 mm.

Table I. Comparison of experimental and calculated limiting current densities on rotating cone electrode for 4.00 mM hydroquinone in 2*M* KCl.

Cone angle (°)	$\partial i_L(\text{cone})/\partial\omega^{1/2}$ μA cm^{-2} rpm$^{-1/2}$ Experimental for $400 \leq \omega \leq 10^4$ rpm	Calculated after Eq. [3]	Difference between experimental and calculated values, per cent For $400 \leq \omega \leq 10^4$ rpm	For $400 \leq \omega \leq 3.6 \times 10^3$ rpm
25	93.0	91.4	+1.8	+1.3
28.7	98.6	97.4	+1.2	+0.5
40	111.2	112.7	−1.3	+0.2
45	118.3	118.2	+0.1	+0.1
50	125.9	123.0	+2.4	+0.2
60	131.4	130.8	+0.5	+0.5

Eq. [3]. A slight positive deviation occurs, which is probably due to imperfections of the surface of the cone electrode causing turbulence, particularly at higher rotation velocities. If the above slopes are recalculated on the basis of the same data but restricted to the range of $4 \times 10^2 \leq \omega \leq 3.6 \times 10^3$ rpm, agreement between theory and experiment is improved as shown in the last column of Table I. It can be concluded that the current at the rotating cone electrode behaves according to the theoretical equations given above.

Acknowledgments

The authors wish to acknowledge the help of Professor J. Newman and Dr. C. M. Mohr, Department of Chemical Engineering, University of California at Berkeley, in discussion of the theoretical equations of the rotating cone electrodes.

Thanks are also due to Mrs. G. Costica for technical assistance and Mr. N. Lavie and Mr. Y. Dreilinger for construction of the conical electrodes.

Brief Communication

A Calculation of the Entropy Maximum for the Double Layer in Terms of the Water Molecule Structure

J. O'M. Bockris* and M. A. Habib

School of Physical Sciences, The Flinders University of South Australia, Bedford Park, S. A., 5042, Australia

Oriented dipoles of water at interfaces were first introduced into electrochemical concepts by Lange and Mischenko (1). [See also Bockris and Potter's (2) initial numerical use of the concept.] Recognition of the effects of their presence lacked wide acceptance. Watts-Tobin and Mott (3, 4) and others (5) attributed the anodic capacitance hump to water orientation as a function of potential, thereby signifying that the most random orientation of water dipoles should be at a potential positive to the pzc. This is not consistent with the experimental fact that the dependence of the surface-excess entropy of the electrode-solution interface measured by Hills and Payne (6) and by Harrison *et al.* (7) on electrode charge is near parabolic with a maximum at $q = -4$ to $-6\ \mu c\ cm^{-2}$. Reeves (8) separated out the contribution to surface-excess entropy by water dipoles. This solvent-excess entropy also shows a maximum at $q \approx -4\ \mu c\ cm^{-2}$. Levine, Bell, and Smith (9) considered the orientation of water molecules in the double layer, but did not calculate the corresponding entropy charge relation. Conway and Gordon (10) considered the entropy change due to water molecule displacement during the adsorption of organic molecules in terms of the original model of water molecule in the double layer due to Bockris, Devanathan, and Müller (11). The conclusion was that the entropy associated with the water molecules would pass through a maximum at the pzc, and this is at variance with the new experimental data (8). Nevertheless, we have found the solvent entropy-electrode charge relation can indeed be quantitatively interpreted in terms of an oriented water layer (3, 4, 11) at the interface.

Let there be N unassociated solvent dipoles present on the metal surface among which $N_{\uparrow}$ are with their oxygen end towards the surface (up dipoles) and $N_{\downarrow}$ are in the reverse position (down dipoles) so that $N = N_{\uparrow} + N_{\downarrow}$. The orientational entropy is then given by

$$S = k \ln \frac{N!}{N_{\uparrow} N_{\downarrow}!} \qquad [1]$$

or

$$S = \frac{1}{2} kN[2 \ln 2 - \{(1 + R) \ln (1 + R) + (1 - R) \ln (1 - R)\}] \qquad [2]$$

where

$$R = (N_{\uparrow} - N_{\downarrow})/N \qquad [3]$$

Considering the interaction of a dipole with the double-layer field and the surrounding dipoles, $N_{\uparrow}$ is given by (22)

$$N_{\uparrow} = N_{\square} \exp\left[\frac{1}{kT}(-\Delta G^{c}_{\uparrow} + \bar{\mu}X - U\bar{c}R)\right] \qquad [4]$$

where $N_{\square}$ = number of vacant sites available to unassociated water molecules, $\bar{\mu}$ = the effective dipole moment of the water molecule adsorbed on the electrode, X = the double-layer field, $\bar{c}$ = number of nearest neighbors which interact with the central water, U = interaction energy of a dipole with its nearest neighbor, and $\Delta G^{c}_{\uparrow}$ = the nonelectrostatic part of the chemical term in the free-energy adsorption. Similarly

$$N_{\downarrow} = N_{\square} \exp\left[\frac{1}{kT}(-\Delta G^{c}_{\uparrow} - \bar{\mu}X + U\bar{c}R)\right] \qquad [5]$$

With $X = 4\pi q/\epsilon$ and

$$-[(\Delta G^{c}_{\uparrow} - \Delta G^{c}_{\uparrow})/kT] = -[\Delta\Delta G^{c}/kT] = b \qquad [6]$$

one gets

$$R = \frac{\exp\left[\dfrac{8\pi\bar{\mu}q}{\epsilon kT} - \dfrac{2U\bar{c}R}{kT} + b\right] - 1}{\exp\left[\dfrac{8\pi\bar{\mu}q}{\epsilon kT} - \dfrac{2U\bar{c}R}{kT} + b\right] + 1} \qquad [7]$$

The position of the maximum in orientational entropy may be obtained by differentiating Eq. [2] with respect to q and equating $dS/dq = 0$, *i.e.*, at the maximum

$$\frac{1}{2} kN\left[\ln \frac{1 - R}{1 + R}\right]\frac{dR}{dq} = 0 \qquad [8]$$ [1]

Since $1/2\ kN \neq 0$, either $\ln[(1 - R)/(1 + R)] = 0$ or $dR/dq = 0$. From Eq. [7]

$$\frac{dR}{dq} = \frac{2Ae^{y}}{(e^{y} + 1)^2 + 2Be^{y}} \qquad [9]$$

where

$$A = \frac{8\pi\bar{\mu}}{\epsilon kT};\quad B = \frac{2Uc}{kT};\quad \text{and}\quad y = Aq - BR + b \qquad [10]$$

[1] Equations [2] and [8] were published by Hills and Hsieh (21) after these authors had been given an early version of the present paper for review by the present authors. The origin of the equations was acknowledged in their paper.

* Electrochemical Society Active Member.

Key words: double layer, entropy maximum, water orientation.

From Eq. [9] and [10] it is evident that $dR/dq \neq 0$. Hence Eq. [8] is satisfied only when $\ln[(1 - R)/(1 + R)] = 0$. Thus, the solution of Eq. [8] is $R = 0$. Hence from Eq. [7]

$$(q)_{S=S_{max}} = -\frac{b\epsilon kT}{8\pi\bar{\mu}} \quad [11]$$

The water molecules are preferentially adsorbed at the pzc (13-15) which means $|\Delta G^c_{\uparrow}| > |\Delta G^c_{\downarrow}|$, *i.e.*, b is positive (Eq. [6]). According to Bockris, Devanathan and Müller (11), $\Delta\Delta G^c$ may be due to a difference in the image interaction in the two orientations favoring the case in which the oxygen atom is towards the metal, since the dipole is then about 0.05×10^{-8} cm closer to the metal (11, 16). Then (11), $\Delta U_{image} = -3/2\, \bar{\mu}^2 d/r_w^4$, where d is the difference in distances between the metal surface and the centers of "up" and "down" dipoles. With $\bar{\mu} = \mu/\sqrt{3}$ (3), $d = 0.05$Å, $r_w = 1.38$Å, and $\mu = 1.84D$, we obtain $\Delta U_{image} = -1.42$ kj mole^{-1}. Due to the difference in positions of the centers of "up" and "down" dipoles, there will be a difference in the dispersion interaction energies of each of these two types of dipoles with the metal surface. The difference from two orientations is then (16), $\Delta U_{disp} = C[\{1/(\bar{R} - d)^3\} - \{1/(\bar{R} + d)^3\}]$, where $\bar{R}$ is the distance between the centers of the adsorbent atom Hg and adsorbate water dipole, and C is given by (16-18)

$$C = \frac{\pi n m c^2 \alpha_1 \alpha_2}{\alpha_1/\chi_1 + \alpha_2/\chi_2}$$

where m is the electronic mass; c the velocity of light; α_1, α_2 are the polarizabilities; χ_1 and χ_2 are diamagnetic susceptibilities of the metal and adsorbate atom or molecule, respectively; and n is the number of adsorbent atoms per cm^3. Now (16), $\alpha_{water} = 1.44 \times 10^{-24}$ cm^3, $\alpha_{Hg} = 5.05 \times 10^{-24}$ cm^3; $\chi_{water} = -2.16 \times 10^{-29}$ cm^3, $\chi_{Hg} = -5.61 \times 10^{-29}$ cm^3; and $n = 4.26 \times 10^{22}$ (19). With these values and taking $d = 0.05 \times 10^{-8}$ cm and $\bar{R} = r_w + r_{Hg} = (1.5 + 1.38) \times 10^{-8}$, one gets $\Delta U_{disp} = -1.3$ kj mole^{-1}. The total energy difference $\Delta\Delta G^c$ is then $\Delta\Delta G^c = \Delta U_{image} + \Delta U_{disp} = -1.42 - 1.3 = -2.72$ kj mole^{-1}. Thus, $b = -\Delta\Delta G^c/kT = 1.1$. With this value of b and $\epsilon = 6$ (20), the position of maximum orientational entropy is found from Eq. [11] to occur at $q = -3.5$ μc cm^{-2} at 25°C [experiment, -4 μc cm^{-2} (8)]. The position of the entropy maximum is independent of U, C and N (Eq. [11]). The orientational entropy as a function of q as calculated from Eq. [2] is shown in Fig. 1. If, instead of 0.05Å, the electrical center of "up" dipole is taken as 0.1×10^{-8} cm closer to the metal than that of "down" dipole, then $\Delta U_{image} = -2.80$ kj mole^{-1}, and $\Delta U_{disp} = -2.6$ kj mole^{-1}. With this value of $\Delta\Delta G = -2.8 - 2.6 = -5.4$ kj mole^{-1}, the orientational entropy maximum is found to occur at $q = -6.9$ μc cm^{-2} (experiment, -4 μc cm^{-2}). It follows that the two-state ("up" and "down") water dipole layer is consistent with the experimental findings (6-8) that the position of the maximum of the water component of the entropy of the double layer occurs on the negative side of the pzc, and that the mean of the range of the theoretical calculations of the q_{max} is about 1 μc cm^{-2} negative to that observed.

On this basis, interfacial water molecules have zero orientation (*i.e.*, are most loosely bound) at a potential cathodic to the pzc. This is inconsistent with the attribution of a capacitance hump to dielectric saturation, as has been the view of a number of workers (3, 5, 9), because such a hump occurs only at charges positive to the pzc. The alternative model of the anodic capacitance hump, *i.e.*, the anion repulsion model (11, 12) is consistent with the entropy results.

Manuscript submitted May 14, 1975; revised manuscript received Aug. 29, 1975.

Low Temperature Oxidation of Silicon Studied by Photosensitive ESR and Auger Electron Spectroscopy

Jerzy Ruzyllo,[1] Ikuo Shiota, Nobuo Miyamoto, and Jun-ichi Nishizawa*

Tohoku University, Research Institute of Electrical Communication, Sendai, Japan

ABSTRACT

The effect of hydration of silicon oxide surfaces on the thermal oxidation process has been investigated, and the following three-step model for the thermal oxidation of silicon has been proposed: (*i*) In the temperature range of oxidation up to 600°C the number of Si-OH groups on the surface increases very rapidly with increasing temperature of oxidation, mainly due to the oxidation of Si-H groups from the etched surface; (*ii*) at 600°-800°C there is a gradual dehydration of the oxide surface due to the transformation of Si-OH into Si-O; and (*iii*) above 800°C, the oxidation process is little affected by surface hydration but there exists an anomaly in hydration around 800°C.

Electron spin resonance (ESR) absorption studies on the Si-SiO_2 system are known (1, 2) to be very useful for obtaining valuable information on the electronic properties of its interface defects. These investigations have usually been performed on samples with relatively thick oxide layers grown at temperatures above 1000°C. In this work, however, the surfaces of thin silicon oxide layers grown at the low temperature (200°-900°C) are investigated by means of a photosensitive ESR method which is based on a new detection mechanism.

The nature of the ESR centers reported here is not essentially different from that reported previously (3, 4) for the etched silicon surface where the ESR centers were described to be related to adsorbed water on structural surface hydroxyl groups. Nevertheless, the characteristic dependence of photoinduced ESR lines on the oxidation temperature, as referred to in earlier work (3), has to be given a detailed explanation of the mechanism of oxidation of silicon at low temperature. In addition, recent interest in silicon MIOS memory devices and MOS tunnel diodes with a structural feature of having a thin oxide layer grown at low temperature has made this subject of research more important.

The oxide layer was also investigated by Auger electron spectroscopy in order to analyze the oxide composition. This procedure allowed us to establish the relation between the oxide hydration and oxide layer composition and consequently to propose a new model for the thermal oxidation of silicon by taking into account the change of oxide hydration. The rate of this hydration is a critical factor for the determination of oxidation steps.

Experimental

N-type, (111) oriented, single crystal silicon wafers with high resistivity (250 and 500 ohm-cm) were used, together with some of the high-resistivity (100) oriented samples. Before oxidation, samples were etched in a $4HNO_3$:2HF:$1CH_3COOH$ solution and then rinsed in deionized water. Dimensions of the samples after etching were about $1 \times 0.3 \times 0.02$ cm.

The samples were oxidized in an atmosphere of either dry or wet O_2 in the temperature range 200°-900°C and then quenched in air to room temperature within a few minutes after oxidation.

The light with a higher energy than the energy gap of Si was illuminated at right angles to the sample surface which was dipped in liquid nitrogen and located at the center of the TE_{102} rectangular resonant cavity. Photostimulated ESR measurements have been made by a Varian Model 4502-15 X-band spectrometer with a sensitivity of 2×10^{11} spins/gauss.

The appearance of photoinduced ESR lines is based on a mechanism different from the ordinary ESR absorption in which the paramagnetic absorption losses at the resonance are detected as the change in quality factor Q of the resonant cavity. In the present case, however, the change in quality factor Q is directly related to the phenomenon of spin dependent photoconductivity (5) where the photogenerated free carriers in bulk silicon undergo an enhanced surface recombination through the saturated paramagnetic surface states. Therefore, the reduction of dielectric loss caused by the resonant decrease of free carriers substantially overcomes the ordinary paramagnetic absorption loss. The resulting large photoinduced ESR lines always have an inversed phase of the ordinary ESR absorption lines. This mechanism will be discussed in detail elsewhere (6), but it should be noted that the tunneling of the photogenerated carriers from silicon to paramagnetic surface states distributed both on the oxide surface and inside its layer is essential for the present detection method.

In consequence, the application of this method is limited to the systems where the ESR centers are located within the tunneling distance of carriers photogenerated in silicon. The estimation of the g-value has been made by a comparison of obtained ESR lines

Key words: low temperature oxidation, surface hydration and dehydration, photoinduced ESR, Auger.

with those from the standard samples (Mn^{2+} in MgO) with known parameters.

Analysis of the oxide composition and measurements of the oxide thickness have been performed by means of Auger electron spectroscopy combined with argon sputter etching. Auger spectra were taken in the vacuum range of 10^{-9} Torr immediately after the primary electron beam was collimated on the sample surface in order to avoid the accumulation of the beam-induced effects.

Results

The detected ESR lines have been found to be the superposition of the two lines with g-values of 2.007 and 2.004. The most characteristic feature of the observed over-all photoinduced ESR line was the strong dependence of its height on the oxidation temperature (the line height means a peak-to-peak value of the first derivative curve of the absorption type). This dependence is shown in Fig. 1 for both dry and wet oxidation. In Fig. 2 the change in the shape of the over-all ESR line is shown. The results shown in Fig. 1 and 2 reflect that the observed photoinduced ESR lines are sensitive to the content of water in the oxidizing ambient. On the other hand, no influence has been observed by changing the substrate orientation from (111) to (100).

The measurements of Auger electrons from the oxidized surfaces were performed in order to clarify the change in ESR line height with increasing temperature of oxidation. The results revealed that the changes in the Auger peaks of silicon and oxygen are related to the observed behavior of ESR lines. The 91 and 1618 eV Auger peaks which correspond to the $L_{2,3}VV$ and the KLL Auger transition for elemental silicon, respectively, decrease with increasing temperature of oxidation, while the 1606 eV KLL transition peak for silicon in silicon oxide and the 512 eV oxygen KLL transition peak increase with increasing temperature of oxidation. This relationship is shown in Fig. 3. There is an abrupt increase in the amount of oxygen when the oxidation temperature exceeds 600°C. This phenomenon is accompanied by the increased rate of oxide growth (Fig. 4).

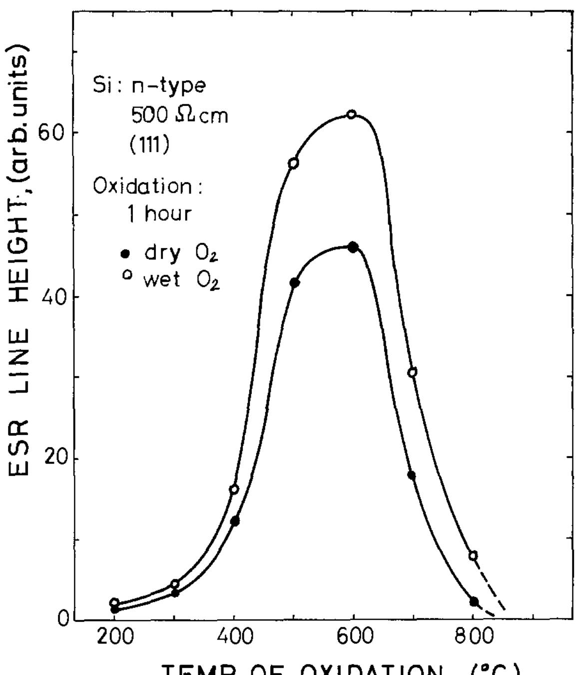

Fig. 1. Change in over-all photoinduced ESR line height with oxidation temperature of silicon in wet and dry O_2 for 1 hr. The curves represent average values from several experimental runs. No ESR signals were observed in the samples oxidized at 900°C.

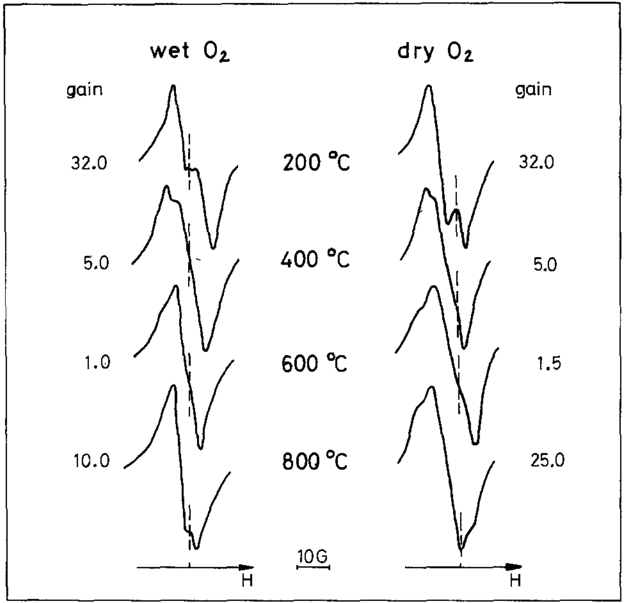

Fig. 2. Changes in line shape of over-all photoinduced ESR lines with oxidation for 1 hr.

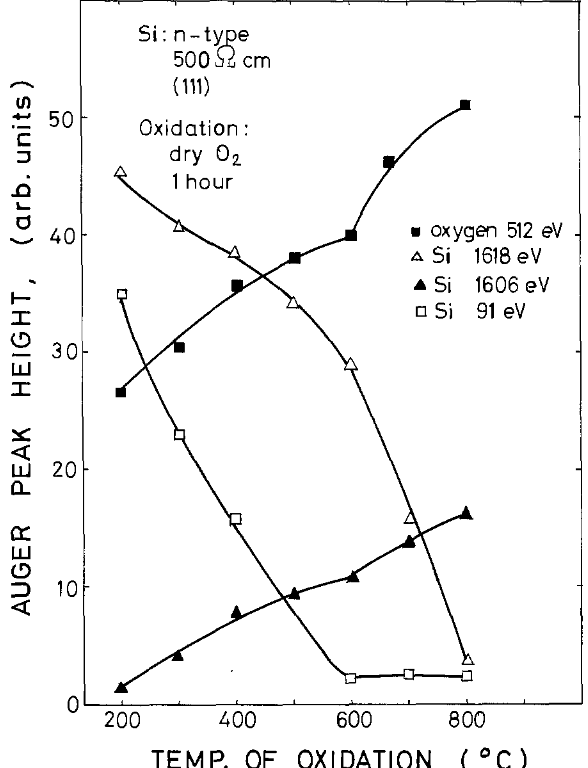

Fig. 3. Relative change in the Auger peak height with oxidation temperature.

The dependence of the ESR line height on the oxidation time at 600°C is presented in Fig. 5, and that at 800° and 900°C in dry O_2 is given in Fig. 6. It can be seen from Fig. 6 that during the oxidation at 800°C the ESR line height remains almost unchanged compared with the case of 600° and 900°C oxidation, although the oxide layer is increased in thickness with increasing oxidation time as shown in Fig. 7. Also, silicon 1606 eV and oxygen Auger peaks are characterized by a smooth and slight increase (10%) with oxidation time at 800°C (from 10 to 60 min). Further information about the investigated centers was obtained by vacuum baking before and after oxidation. In this case, oxidation was 1 hr at 600°C and vacuum baking 1 hr at 350°C in 10^{-5} Torr. ESR measurements

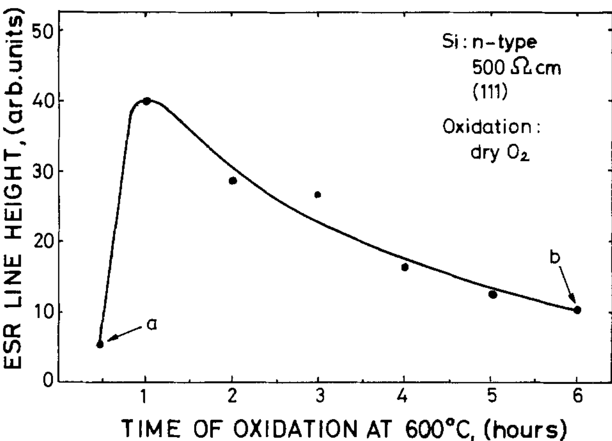

Fig. 5. Change in over-all photoinduced ESR line height with oxidation time at 600°C. At point a and b, the oxide thickness was about 20 and 40Å, respectively.

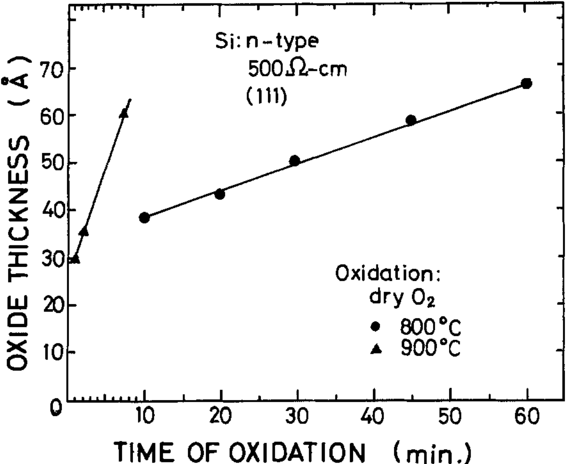

Fig. 7. Silicon oxide thickness vs. oxidation time at 800° and 900°C.

were made after cooling to room temperature, while retaining the samples in vacuum, and no ESR lines were then detected. However, the ESR line appeared again after introducing air into the vacuum system at room temperature, although its intensity was considerably weaker. The effect of the prevacuum baking on the ESR lines is shown in Fig. 8. The gradual decrease of the ESR line height in the oxidized samples after vacuum baking (curve 1) can be attributed to the same effect as in the case of the merely vacuum-baked samples (curve 2) (3, 4). The difference in height of ESR lines between the two cases clearly shows an influence of the oxidation process. It should be noted that no ESR lines are observed from the samples prevacuum baked above 900°C.

Discussion

The over-all photoinduced ESR line height may be an adequate measure for the surface hydration, *i.e.*, the number of Si-OH groups on the oxide surface. The reason for the appearance of the two component ESR lines is difficult to clearly establish. In previous work (4), a tentative model was proposed in which the two ESR lines originate from two different structures resulting from the interaction of Si-OH groups with a water molecule adsorbed on the surface. It is well known that Si-OH groups on the surface take the form either isolated from each other or connected through hydrogen bonding (7). Correlating two types of Si-OH groups to the two-component ESR lines may present another possible model.

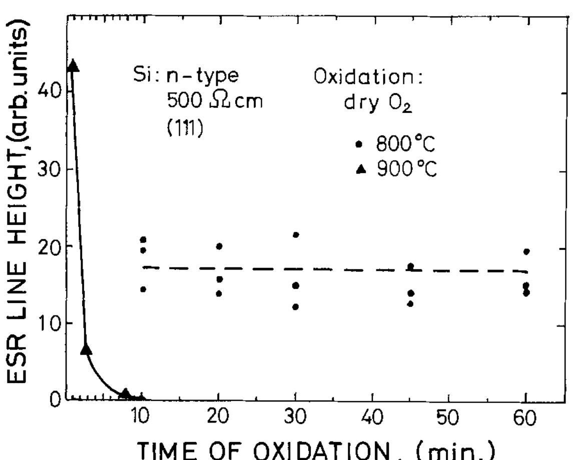

Fig. 6. Change in over-all photosensitive ESR line height with oxidation time at 800°C (broken line shows scattering of data in this case) and 900°C.

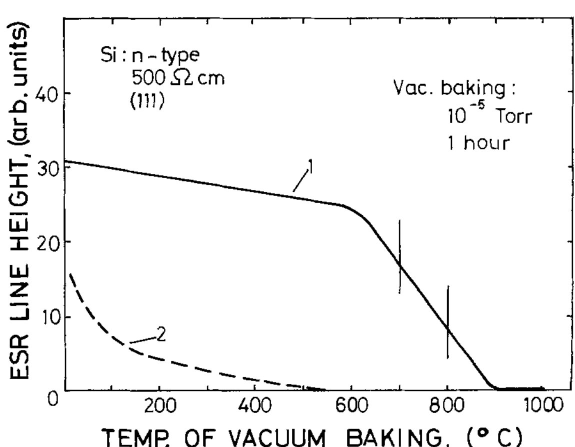

Fig. 8. Effect of vacuum baking; curve 1, vacuum baked and then oxidized at 600°C for 1 hr in dry O_2; curve 2, vacuum baked only (3).

It is obvious from Fig. 8 that the oxidation process produces an additional amount of Si-OH groups to those originally existing on the etched surface. One of the mechanisms of Si-OH formation is considered to be related to the oxidation of Si-H groups on the etched silicon surface. This reaction does not depend on the water content in the oxidizing atmosphere and occurs at the same rate whether the atmosphere is dry or wet O_2. In addition, Si-OH groups can also be formed due to the reaction of water with the weakly bonded Si-O-Si which can exist on the etched silicon surface. This phenomenon occurs more preferably in the wet oxidizing atmosphere, which is responsible for the higher ESR line intensity in the samples oxidized in wet O_2 (Fig. 1).

Let us consider the behavior of KLL Auger peaks for silicon and oxygen in the oxide layer with regard to the change in ESR line height with oxidation temperature. In the temperature range of oxidation from 200° to 600°C, the amounts of silicon (1606 eV) and oxygen increase with increasing temperature (Fig. 3). This increase, however, is not accompanied by the rapid growth of the oxide layer (Fig. 4). Therefore, the additional amount of oxygen that appears in the oxide layer is used for both the oxidation of Si-H groups at the oxide surface and the oxidation of unoxidized silicon within the oxide layer. The former is reflected in the increase of ESR line height (Fig. 1), and the latter in the decrease of silicon shown by the 91 and 1618 eV Auger peaks in Fig. 3.

From the above discussion the transformation of Si-H to Si-OH through oxidation appears to be the origin for the rapid increase of ESR line height in the temperature range up to 600°C.

It is known that Si-H bonds, with three oxygens bonded to one silicon, are stable up to about 600°C. This effect might be one of the reasons why the increase of the ESR line height is virtually stopped when the oxidation temperature reaches 600°C (Fig. 1) but a prolonged oxidation at 600°C causes Si-OH bonds to reduce as seen from Fig. 5. The same effect was also observed in the case of the 900°C oxidation, but in this case the destruction of Si-OH bonds proceeds very rapidly and no ESR lines were detected after 10 min oxidation (Fig. 6). At this oxidation temperature an initial increase of the ESR line height (as is in the case of oxidation at 600°C) was not observed, probably because of the immediate destruction of Si-H bonds after oxidation. With regard to these results, an anomalous behavior of the ESR line on isothermal oxidation at 800°C should be emphasized. As can be seen from Fig. 6, the ESR line height remains unchanged up to the 1 hr oxidation, although some scattering of the experimental data is observed. It should be noted that the oxide thickness was about the same in both the 800° and 900°C oxidation (Fig. 7), so that such a different behavior cannot be attributed to the photosensitive ESR method used in this work. Therefore, some peculiar effects are expected to occur at the oxidation temperature of 800°C in terms of surface hydration.

The same approach in terms of surface hydration should be fundamentally made to explain the change in ESR line height above 600°C as shown in Fig. 1, since the tendency of decreasing ESR line height was also recognized in the samples with the same oxide thickness formed at different temperatures above 600°C. In the case of wet oxidation, however, Si-OH groups may exist up to a higher temperature. This might be a reason for the higher ESR line height of the wet oxidized samples. In the case of oxidation for 1 hr, the critical temperature at which the ESR lines completely vanish, is probably close to 900°C (Fig. 1), but this temperature cannot be directly considered as a temperature of complete dehydration of the oxide surface, because of the excessively thick oxide layers of these samples which are beyond the thickness limit for the ESR detection method applied in the present work (6).

Conclusions

The process of thermal oxidation of silicon below 800°C has been found to be affected by the hydration of the oxide surface and it has been proposed to divide the process into three steps corresponding to each stage of surface hydration, *i.e.*, the temperature ranges of oxidation, $T \leqq 600°C$, $600° < T < 800°C$, and $T \geqq 800°C$. In the first temperature range, the number of Si-OH groups on the surface increases very rapidly mainly due to the oxidation of Si-H groups, and reaches the highest value for samples oxidized at 600°C. Simultaneously, the oxidation of the unoxidized silicon in oxide layers on etched surfaces occurs, but very slow oxide growth is observed. The process of oxide surface dehydration, resulting from the destruction of Si-OH bonds, begins in the second range of oxidation, and proceeds through the change of Si-OH into Si-O. The rate of dehydration is lower in the case of wet oxidation. For $T \geqq 800°C$, the effect of surface hydration has little influence on the oxidation process but there exists an anomaly around 800°C in terms of surface hydration.

It is suggested that the results presented in this work can be of interest in the fabrication of MNOS memory devices on silicon where the oxide layer is usually formed under conditions similar to those of these experiments. Also the properties of oxide-nitride interfaces are of great importance for the characteristics of the devices. In addition, these results give valuable information on the mechanism of low temperature passivation (8) of silicon surfaces.

High Quality RF-Sputtered Silicon Dioxide Layers

H.-U. Schreiber[1] and E. Fröschle

Institut für Halbleitertechnik, RWTH Aachen, D-5100 Aachen, Germany

ABSTRACT

Very homogeneous SiO_2 layers were prepared by rf sputtering of SiO_2 in Ar or Si in O_2 with Ar on Si substrates which had been cleaned *in situ* by sputter etching. After a short anneal in N_2 (20 min at 1050°C and a 10 min postmetallization anneal at 500°C), surface charge, surface-state density, and stability were similar to those reported for good, thermally grown oxides. Best results were obtained with reactively sputtered SiO_2.

Insulating layers of rf-sputtered silicon dioxide are often used in integrated circuit technology for multilayer wiring and passivation (1). However, their homogeneity, electrical breakdown strength, and interface quality were, up to the present time, inferior to those of thermally grown oxide films. Some improvement in breakdown strength could be made by bias sputtering, as proposed by Maissel *et al.* (2, 3). In this method sputter etching takes place during deposition. The purpose of the work described here was to investigate whether sputter etching before depositing the SiO_2 also gives improved breakdown characteristics, and to find methods for preparing sputtered oxide layers on Si substrates with an interface quality comparable to that for thermally grown oxide.

Sputtering Apparatus

For our rf-sputtering experiments we used a commercial MRC apparatus which was somewhat modified to suit our particular requirements. It has a shielded substrate carrier to which the rf power can be switched. This allows sputter etching of the silicon substrate before sputtering SiO_2 onto it. The rf generator with matching network had a maximum output of 1 kW at 13.56 MHz. The diameter of the targets and the substrate electrode was 12.5 cm, their separation 5 cm. The most important differences from the standard design were the following: First, we used a turbomolecular high-vacuum pump instead of the usual oil-diffusion pump. This gives a vacuum free of oil vapor. Next, we added an apparatus for loading and unloading under dust-free conditions. It consisted of a blower with 0.3 μm filter, a plastic hose, and a Plexiglas cylinder with air lock surrounding the sputtering chamber. Third, we inserted a tunable L-C network between substrate and ground for bias sputtering as was also done by Logan (4). The reason for this will become clear from the schematic drawing of the sputtering module and its equivalent circuit shown in Fig. 1. The dark space before the electrodes is represented by a capacitor shunted with a diode.

If the substrate electrode is connected, as usual, directly to ground in the same way as all the metallic parts of the sputtering module, the rf current is distributed through all these surfaces. The current through the substrate electrode is therefore so small that not much bias appears there and sputtering of this surface does not take place. By tuning out the capacitive part of the dark space impedance in front of the substrate electrode, most of the rf current will flow this way, giving it nearly the same bias as the target electrode.

Experimental

Most of our experiments were done with MOS capacitors having evaporated Al electrodes of 0.3-1.5 mm diameter on SiO_2 films of 0.16 μm thickness which were sputtered onto {111}-orientated n-type silicon wafers with donor concentrations of $5 \cdot 10^{15}$ cm^{-3}. High quality capacitors were mostly fabricated as follows:

(*i*) Before sputtering the Si wafers were thoroughly cleaned with standard chemical methods. Rubbing with a cotton pad soaked with detergents before the chemical cleaning and spinning off the quartz-distilled water after the last step reduced the pinhole density significantly.

(*ii*) Best results were obtained if the wafers were laid onto a SiO_2 disk of 3 mm thickness and 12.5 cm diameter, covering the substrate electrode totally, but lying on it loosely.

(*iii*) For *in situ* cleaning, 1 μm of the Si wafer was sputter etched away in Ar. At 3×10^{-3} mm Hg the etch rate with 400W of rf power was approximately 5×10^{-6} cm/min. To minimize radiation damage the rf power was decreased toward the end in steps of 6 min at 50, 40, 15, and 10W.

(*iv*) SiO_2 was then sputtered either from a SiO_2 target (impurities $<<$ 0.3%, VP grade of MRC) in Ar of 5×10^{-3} mm Hg pressure or reactively from a Si target (impurities $<<$ 0.001%, VP grade of MRC) in a mixture of O_2 (1.5×10^{-3} mm Hg) and Ar (0.8×10^{-3} mm Hg). With 300W of rf power the deposition rates were 1.8×10^{-6} and 5×10^{-7} cm/min, respectively.

(*v*) To reduce the radiation damage further, the wafers were annealed 20 min at 1050°C in N_2. The outermost 0.015 μm SiO_2 was etched away afterwards in buffered HF giving better electrical stability.

(*vi*) The Al contacts of the MOS diodes were fabricated by high-vacuum evaporation of 0.3 μm Al out of a Na-free tungsten coil using a metal mask with 64 holes.

(*vii*) As often done with thermally grown oxides, a post-Al annealing of 20 min in N_2 at 500°C followed as the last step.

Breakdown characteristics.—For measurement of the current-voltage characteristics we used MOS capacitors of the dimensions shown in Fig. 2. They were probed with whiskers, the Al usually being positive. However, reversing the polarity had little effect on the data. As shown in Fig. 2 the current-voltage characteristics of

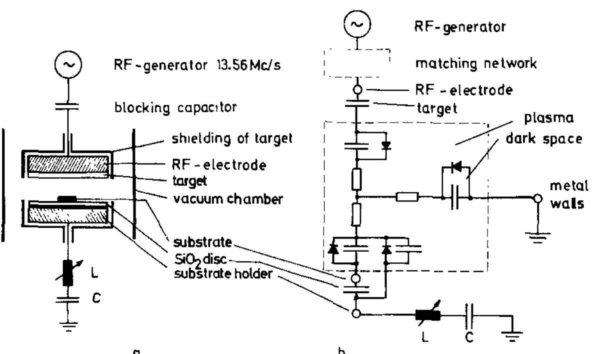

Fig. 1. Schematic (a) and equivalent circuit (b) of the rf sputtering system with L-C tuning network for bias sputtering.

Key words: MOS diodes, breakdown, flatband voltage.

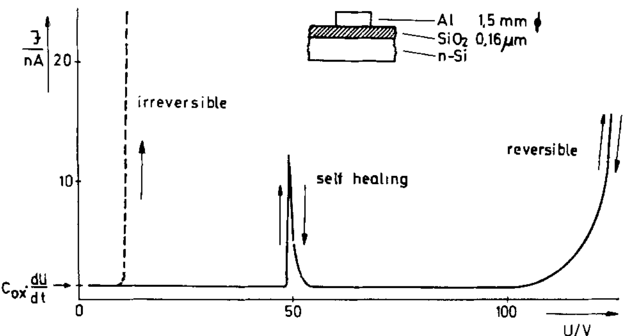

Fig. 2. MOS diode and typical breakdown characteristics

good MOS capacitors, measured by applying a ramp voltage with constant slope, are composed of constant charging currents at small voltages and sharply rising currents at higher ones. The latter are probably caused by the onset of Poole-Frenkel conductance (5) and are reversible, if limited by a high resistance.

Large defects presumably give permanent breakdowns; small pinholes, however, only temporary shorts. Figure 3 shows a scanning electron micrograph of an area where self-healing breakdown has taken place. The breakdown occurred in the middle of the round crater where the Si and the SiO_2 were melted. The heat arising from the breakdown also caused melting of the aluminum in the neighborhood. The metal receded by surface tension, thereby removing the short between Si and Al. The best results were achieved with silicon wafers, cleaned with the procedure described and sputter etched 1 μm before the SiO_2 deposition. The small spread in the characteristics of the 64 MOS diodes on a wafer and their high freedom from defects is apparent from Fig. 4. Less than 3% of them broke down at electric field strengths below 6 MV/cm.

For evaluating the influence of the different treatments, the percentage of diodes showing their first breakdown in a given field interval was plotted as a function of the electric field at breakdown. "First breakdown" was taken to be the first self-healing event which was detected by a very sensitive measuring circuit or a rise of current to more than 10^{-8}A. With standard chemical cleaning nearly all MOS diodes broke down at fields below 2 MV/cm, as was also found in Ref. (3), without bias sputtering. By rubbing off the wafers with a cotton pad soaked with detergent before the final chemical cleaning with boiling HNO_3 and by spinning off the quartz-distilled rinsing water as a last step, the breakdown strength could be greatly improved (Fig. 5a).

Very high homogeneity was achieved by removing through sputter etching at least 1 μm of the Si wafer before depositing the SiO_2 (see Fig. 5b, 5c, and 9a). Continued etching did not give further improvement, if the wafers had been cleaned as described before. With standard cleaning a sputter etch of 5 μm was required to obtain the same result (6, 7). The etching was done mostly *in situ,* but no difference was found if the wafer were removed from the apparatus and stored in dust-free air for some minutes before depositing SiO_2.

Influence of bias sputtering.—To test whether these results may also be obtained by etching the substrate during and not before deposition, some experiments with bias sputtering were made. By tuning the inductance as described above, the substrate bias was varied giving a variation of the coefficient of re-emission, K_R, from 0.3 to 0.9. K_R was measured by a similar technique as used in Ref. (3). As done by Logan (4) and Maissel (3), we too measured the voltage, U_B, between the substrate holder and ground (see Fig. 1) and used it as an indicator of bias conditions. U_B, however, is not identical with the true bias between substrate surface and plasma.

As shown in Fig. 6 the mean field for first breakdown decreased rapidly with increasing bias. Scanning electron micrographs of SiO_2 layers sputtered onto Si with high bias showed partially refilled scratches and craters (Fig. 7). They appear to be caused by breakdown during sputtering because no such structures were observed without bias. Similar effects were found also by McCaughan (11). The difference between our measurements and the results of Maissel *et al.* (3) who reported a distinct improvement by bias sputtering in the range of $K_R = 0.3$-0.6 could not be resolved. Perhaps it may be contributed to by the absence of oil and grease vapors in our system which gives reasonably good breakdown characteristics even without sputter etching.

Interface properties of Ar-sputtered SiO_2 on Si.—In order to test the usefulness of sputtered SiO_2 for MOS devices oxide charge, interface-state density and stability were measured under various sputtering and

annealing conditions on MOS diodes with Al electrodes of 0.3 mm diameter. These measurements were made using the conventional high-frequency (3 MHz) capacitance-voltage method. Flatband voltage, V_{FB}, and oxide-charge density, N_{ox}, were determined by comparison of experimental with theoretical curves (8). The determination of V_{FB} of sputtered SiO_2 films is considerably more accurate than with thermally grown ones because much less impurity redistribution should take place. The interface-state density, N_{ss}, near the conduction band was estimated after Ref. (9) from C-V measurements at 300°K and 77°K. Stability was measured by the standard temperature-bias test in which the MOS diodes were stressed for 20 min at 200°C with +30V (2 MV/cm) on the Al electrode and subsequently cooled down with the voltage on. The resulting shift of the flatband voltage should be less than 0.1V on good gate oxides for MOS devices.

Without annealing, the densities of surface charge and especially of surface states were very high for sputtered SiO_2. Therefore, we used an annealing procedure, which is also often used on thermal oxides. First, we used a high-temperature treatment of 20 min at 1050°C in N_2. This was followed by a short etch in buffered HF to remove the outermost 0.015 µm of the SiO_2 before Al deposition and a 10 min anneal at 500°C in N_2 after metallization. After this procedure, dry thermal oxides on {111} Si give flatband voltages of 1-2V, shifting less than 0.1V in the stress test if clean, Na-free tungsten filaments are used for evaporating the Al. Their surface-state densities are negligible.

For sputtered SiO_2 on sputter-etched Si this anneal was not able to reduce the surface-state density below 10^{11} cm^{-2} eV^{-1} if the rf power was not decreased toward the end of the etching. We usually did this in steps of approximately 6 min at 50, 40, 15, and 10W. The main etching was done at 400W (3.2 W/cm^2) in Ar at a pressure of 3×10^{-3} mm Hg, giving an etch rate of 5×10^{-6} cm/min. Using this process, flatband voltages of 8V corresponding to 10^{12} oxide charges/cm^2, a shift of 0.5V during the stress test and surface-state densities less than 3×10^{10} cm^{-2} eV^{-1} were achieved. For obtaining this stability it was necessary to separate the Si wafer from the substrate holder by a SiO_2 disk which allowed some heating up during sputtering and prevented contamination of the wafer by material etched away from the substrate holder. If the disk was cemented with epoxy to the water-cooled substrate holder, relatively large flatband shifts were observed, even after an anneal at 1050°C.

The effect of the annealing temperature on N_{ox} and N_{ss} is shown in Fig. 8. From it can be concluded that an annealing step at a temperature of at least 1050°C is essential for obtaining usable films. The annealing and etching caused some deterioration of the breakdown strength as may be seen from Fig. 9. This effect could possibly be reduced by using cleaner annealing conditions.

Sputtering in O_2-Ar mixtures.—The relatively high flatband voltage could be reduced by adding a small amount of O_2 to the sputtering ambient (see Fig. 10). For more than 3 volume per cent (v/o) O_2 the flatband voltage on {111} Si was less than 1V. The same effect could be achieved by bias sputtering if the bias was higher than 50V (see Fig. 11), but in this case the stability was not as good as without bias. O_2 addition without bias did not cause the stability to deteriorate. However, the observed shift of 0.5V is too high for good MOS devices. It was probably caused by the Na content of the SiO_2 target which was only 99.7% pure.

Because targets of very pure silicon are easily available, reactively sputtering of Si in an Ar-O_2 mixture

was also tried. As may be seen from Fig. 12, very stable SiO_2 layers with low flatband voltage could be made in a range of 40-80% O_2. The flatband voltage shifted less than 0.1V during the usual 200°C-2 MV/cm temperature-voltage stress tests. Regarding breakdown strength and surface-state density N_{ss}, we found no difference in layers made by sputtering SiO_2 in Ar.

Conclusions

The present study has shown that it is possible to deposit, by means of sputtering, SiO_2 layers on Si, which after suitable annealing have the same quality as the best SiO_2 layers prepared by thermal oxidation. The high intrinsic prebreakdown strength, shown in Fig. 4 (7.5 MV/cm at 10^{-6} A cm^{-2}), compared with the usual sputtered SiO_2 layers (1) may probably be attributed to the freedom from oil and grease vapors of the sputtering ambient. Very high homogeneity and low densities of weak spots could be achieved by sputter etching approximately 1 μm of Si before the deposition, thus removing all dirt and foreign particles from the wafer.

Sputter etching, however, leaves a damaged layer near the surface of the Si and, also, Ar ions are implanted. As shown by Yamamoto (10), with back scattering analysis 20 min annealing in N_2 is sufficient to remove the Ar but does not heal out the damage of the Si completely. This agrees with our results. The rf power had to be reduced toward the end of the etching to keep the damage of the Si so low that it could be removed by the same annealing procedure which is also customarily used on thermal SiO_2. It is also sufficient to remove enclosed Ar (12) and defects in the sputtered SiO_2 (13). Upon such annealing in N_2 at 1050°C before and at 500°C after Al deposition, MOS diodes of very good quality could be made, especially by reactively sputtering Si in an O_2-Ar mixture. Their flatband voltage was below 1V and shifted less than 0.1V during a 20 min temperature-voltage stress test with 2 MV/cm at 200°C. The interface-state density was below 3×10^{10} cm^{-2} eV^{-1}.

Rf sputtering from a SiO_2 target in pure Ar resulted in higher surface-charge densities than with reactively sputtered SiO_2, probably because of oxygen vacancies (14). They could be avoided by adding 3% O_2 to the Ar. Stability during the bias-temperature stress test, however, was not as good as with reactively sputtered SiO_2, probably because of lower purity of the target.

Anodic Processing for Multilevel LSI

G. C. Schwartz* and V. Platter

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Anodic processing for multilevel LSI is attractive because planar structures can be made. For complete flexibility of design, it is advantageous that portions of the first level of interconnection metallization be isolated initially from silicon, and that the required contact to silicon be made using overpasses on a subsequent level. Anodic processes previously described required that there be a direct contact to silicon for each land to be defined. This restriction can be circumvented by depositing a thin conductive layer before deposition of the interconnection metallurgy and eventually converting it to an insulator The requirements for a suitable underlay are given, and the choice of hafnium for this purpose is explained. The details of the anodic processing are described and discussed. Conversion of the underlay to an insulator requires both anodization until barrier layer growth ceases and oxidation at elevated temperature; 450°C in steam for 30 min yields excellent results. The leakage current between closely spaced conductors is decreased substantially by the use of this underlay process as compared to the previously descibed anodic processes.

For multilevel aluminum or aluminum alloy land systems in LSI, anodic processing has two main advantages over conventional subtractive etching. First, planar structures can be fabricated. This eliminates the reliability hazards associated with covering large and often steep metal edges with an insulator. Also photolithography difficulties are reduced. Second, there is substantially less loss in cross-sectional area. Therefore the current-carrying capability of a conductor formed anodically is greater than that formed conventionally using the same mask.

Anodic processing substitutes conversion of the unwanted metal to an insulating film for the removal of unwanted metal. Because relatively thick (10,000Å) metal films are required for the circuitry, the unwanted metal is converted to porous anodic oxide as barrier layer growth is limited. Oxalic acid is used as the electrolyte in the completely planar process (1) since it is compatible with photoresist, it can be decomposed at the completion of anodic processing, and, at the appropriate current densities, the voltages are suitable for semiconductor device fabrication.

All previously described anodic processes (1, 2, 3) had required that there be a direct contact to silicon for every land to be defined. This requirement arises from the need to supply current to the lands after the anodization is apparently complete, so that the residual aluminum which clings to the edges of the lands forming bridges between closely spaced conductors can be converted to insulating anodic oxide. But for complete flexibility of design of integrated circuits with multilevel metallization, it is often desirable to isolate from silicon, initially, portions of the first-level metallization and use "overpasses" on a subsequent level. To be able to isolate, anodically, such electrically "floating" conductors, we have adopted a scheme developed by Romankiw (4) for anodic processing, making the changes necessary to achieve the very low leakage levels required for integrated circuits, but not for the applications for which Romankiw designed his procedure.

Before deposition of the aluminum or aluminum alloy film used for the interconnection pattern, Romankiw proposed that a thin metal film be deposited to carry current to the lands which are not connected to silicon. This film must subsequently be converted to an insulator. We have concluded that the metal used as an underlay must meet certain requirements: (*i*) it must be able to be converted to an insulator under conditions compatible with semiconductor device processing and with the presence of the overlying anodic oxide; (*ii*) it must not react chemically with the electrolyte used to form the porous anodic oxide; (*iii*) if it can be anodized, it must anodize at or very close to 100% efficiency to avoid oxygen evolution which may cause lifting of the overlying anodic oxide; (*iv*) it must adhere well to the substrate and the overlying anodic oxide must adhere well to it; and (*v*) it must not degrade device performance.

The most suitable underlay we have found is hafnium. It forms a barrier layer upon anodization in oxalic acid with no perceptible oxygen evolution. Moreover, the anodization ratio of hafnium is high (11.6Å Hf/V) which means that the final voltage to which the formed structures will be subjected at the completion of anodic processing will be relatively low since underlay films 150-200Å thick are suitable. Hafnium can be oxidized thermally at low temperature. A discrete hafnium layer is maintained when the metals hafnium and aluminum (or aluminum alloy) are deposited sequentially at elevated substrate temperature to insure good adhesion, yet adequate interdiffusion occurs during the final anneal at the completion of the anodic processing. The interdiffusion has been demonstrated by the use of helium ion backscattering. In Fig. 1 is shown the backscattering spectrum for aluminum in a film consisting of 2μ of aluminum with a hafnium layer 1000Å thick on its surface, both before and after heat-treatment in helium at 400°C for 1 hr. It can be seen that after the anneal, aluminum has reached the surface of the film. Adequate interdiffusion occurs even when the hafnium is exposed to air before deposition of the interconnection metallurgy. Individual test transistors made with and without a hafnium underlay have identical electrical characteristics.

The resistivity changes in an aluminum (17,000Å)-hafnium (240Å) film during anneal at 400°C in an inert atmosphere are shown in Fig. 2. When an evaporated aluminum film is annealed at a temperature above its deposition temperature, an initial decrease in resistivity is always observed. This is probably due to a decrease in defects in the grain boundaries. The subsequent small increase in resistivity can be attributed to dissolution of the hafnium and to intermetallic compound formation. However, this increase is very small and would not affect the performance of the interconnection metallization.

Anodic processing is performed as described in a previous paper (1); this method uses a two-current mode

for the isolation anodization of the Al/AlCu film since this had resulted in the best line profile. A typical curve for the isolation anodization in 8% oxalic acid of the metal film Al/AlCu/Hf is shown in Fig. 3.

A current density of 3.5 mA/cm² is used at the start of the anodization. At point A in Fig. 3 the aluminum cap has been anodized completely and there is an upward inflection in the voltage curve indicating the beginning of the AlCu layer (5). A control circuit automatically reduces the current (to 1 mA/cm²) when a time which corresponds to the anodization of about two-thirds of the film is reached; *i.e.*, at point B. At point C the anodization is apparently complete because the voltage starts to rise (to a preset limit), and the current starts to decay. Thus, point C is also the beginning of the "decay period." The time it takes to

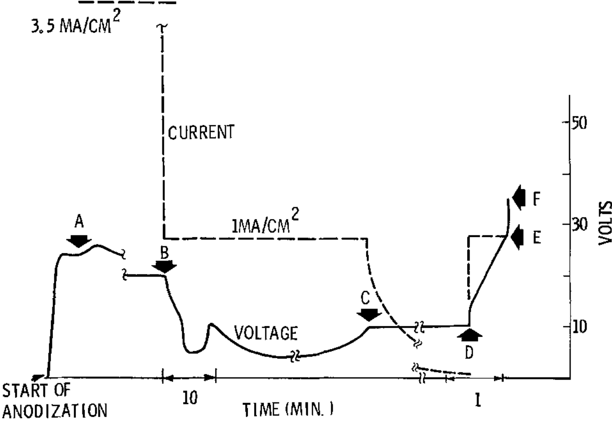

Fig. 3. Constant current anodization in 8% oxalic acid of the film: Al/AlCu/Hf-insulated substrate.

reach point C depends upon the thickness of the film and the copper concentration in the AlCu film. At 3.5 mA/cm² aluminum anodizes at about 750 Å/min; an AlCu (4%) film anodizes at about 450 Å/min at the same current density.

Point C is also the beginning of the "decay period." In Fig. 4, are shown scanning electron micrographs of three pairs of conductors, separated by 3, 6, and 15μ,[1] as they appear after a relatively short "decay period." The anodic aluminum oxide has been removed in phosphochromic acid to reveal any metal particles. It can be seen that the isolated aluminum particles (the "cosmetic defects") are completely converted to anodic aluminum oxide, but that closely spaced lines are bridged. In Fig. 5 the final isolation after suitable "decay" is shown; this would correspond to point D in Fig. 3. From Fig. 4 it is quite clear that the more widely spaced lines are isolated more rapidly, but Fig. 5 shows that the final line width is independent of the spacing. The "decay" time required in any given application will depend on the thickness of the interconnection metallization and the smallest spacing in the pattern being formed. For 1.5μ metal, 45 min are required to isolate the 3μ space.

The time interval C-D is preset and, when point D is reached, the voltage is allowed to rise automatically

[1] For the 15μ spacing, one of the conductors is not shown in the photograph because the spacing was too wide for the second of the pair to be included in the field of view of the SEM at that magnification.

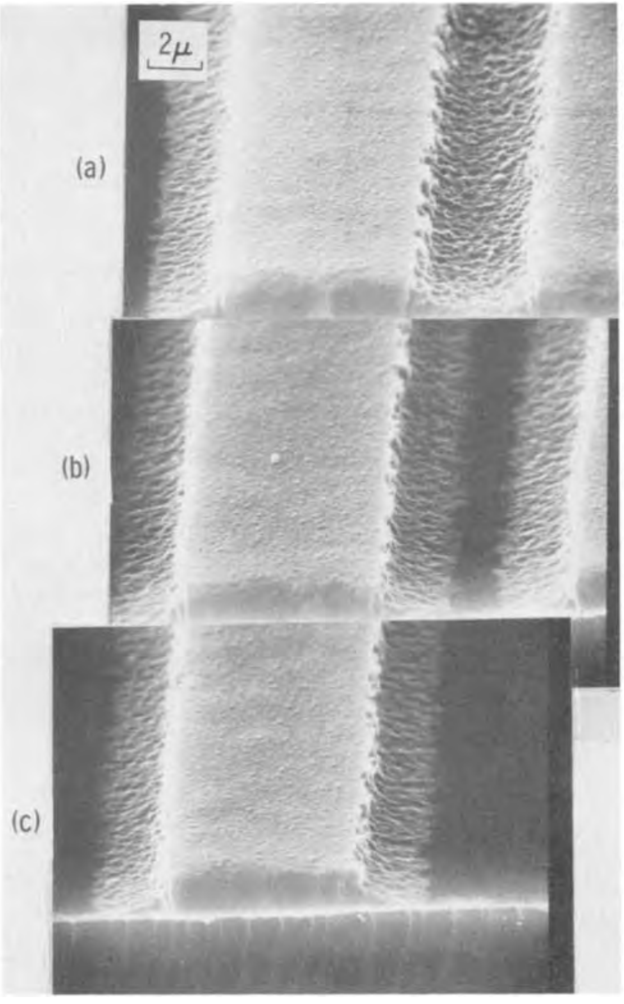

Fig. 4. Scanning electron micrographs showing the effect of a short current decay on the isolation of adjacent conductors. The anodic aluminum oxide has been removed in phosphochromic acid. Three pairs of lines are shown: (a) Space between conductors ~ 3μ, (b) Space between conductors ~ 6μ, and (c) Space between conductors ~ 15μ (second conductor not shown).

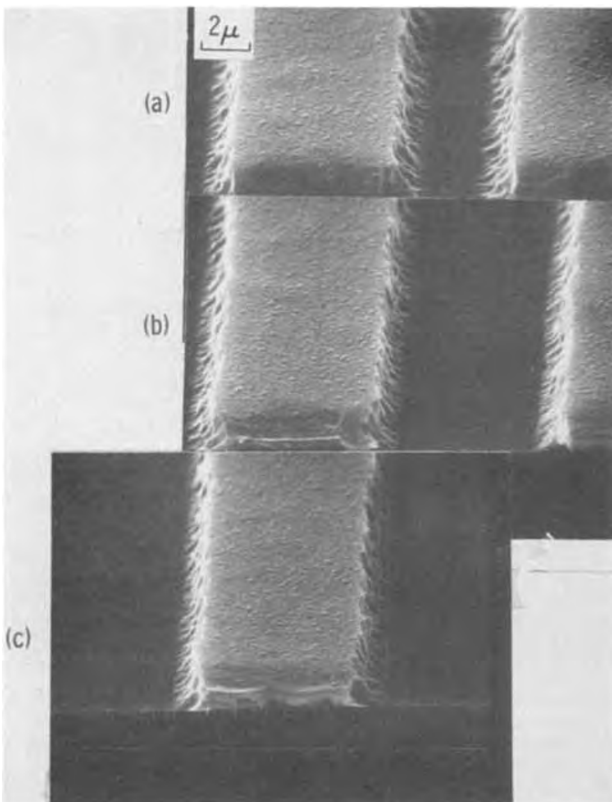

Fig. 5. Scanning electron micrographs showing the effect of adequate current decay on the isolation of adjacent conductors. The anodic aluminum oxide has been removed in phosphochromic acid. and the hafnium is anodized to form a barrier layer as shown by the linear increase in voltage at constant current (1 mA/cm^2). At point E, the voltage rises abruptly; when it reaches a preset limit, F, the circuit is opened automatically. Because barrier layer growth ceases at voltage E, it is said that the hafnium is "completely" anodized. The anodizing ratio, 11.6Å Hf/V was determined by anodizing, at 1 mA/cm^2 in oxalic acid, a series of hafnium films of known thickness and determining the voltage at which the abrupt rise occurred. The voltage E is, within a few volts, the value expected from the known thickness of the hafnium underlay. It should be emphasized that during the "decay period" the voltage should be well below E to insure current flow to the otherwise isolated residual metal.

However, even after the apparent complete anodization of the underlay, adjacent conductors are still electrically shorted, no matter how long the "decay period." Therefore the residue of the underlay metal must be oxidized thermally. The conditions for oxidation of this residual thin layer are much more severe than might be predicted from the published data on the low temperature oxidation of such metals (6). The presence of the overlying layer of porous anodic oxide greatly inhibits the oxidation, even though the barrier layer at the base of the pores is quite thin (the anodization is finished at a low voltage) and probably does not have the integrity usually associated with the barrier layer formed on pure aluminum because the copper dissolves in the electrolyte. The residual layer can be oxidized in dry oxygen at 450°C for 30 min, but using steam as the oxidation medium causes a substantial reduction in leakage current between adjacent conductors. Typical leakage values for a variety of pro-

cessing conditions are given in Table I. It can be seen that using the underlay process with steam oxidation results in leakage current about 100 times smaller than that obtained by standard processing, *i.e.*, no underlay, but every conductor connected directly to silicon. During the steam oxidation of the residual underlay, the porous anodic oxide is sealed, making it less vulnerable to attack by the reagents used to form the interlevel via holes.

However, unless the underlay is anodized until barrier layer growth ceases, it is not possible to oxidize it (to achieve suitable leakage values) at a temperature and for a time reasonable for semiconductor devices. We have also shown that the underlay does not react, to any significant extent, with either an SiO_2 underlay or a porous anodic aluminum oxide overlay, since a 450°C anneal in a nonoxidizing atmosphere for the same length of time does not produce any detectable reduction in the leakage current between adjacent conductors.

In Fig. 6 are shown scanning electron micrographs of our standard test structure in which the porous anodic oxide has been removed in phosphochromic acid to reveal the residual aluminum particles. In (a) are anodically processed "floating" lines; in (b) are lines anodically processed in the "standard" way; *i.e.* no underlay, but every line connected directly to silicon; and (c) are anodically processed "floating lines" when the hafnium underlay process is used.

Conclusions

We have described a method of anodic planarization for LSI which eliminates the necessity of direct contact to silicon for every conductor formed. The method consists of using a hafnium underlay beneath the aluminum or aluminum alloy interconnection metallization and anodizing the hafnium underlay to "completion" after isolation and decay, then oxidizing the residue of the underlay in steam at 450°C for 30 min. Semiconductor devices with electrical characteristics identical to those made by conventional processing have been made using this technique.

Ion Backscattering Study of Cu_2S Formation on Single Crystal CdS

J. A. Borders*

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

Ion backscattering has been used to study the formation of Cu_2S layers on single crystal CdS due to the chemical ion exchange reaction

$$2Cu^+ + CdS \rightarrow Cu_2S + Cd^{++}$$

The reaction is found to proceed most rapidly on the A (Cd) face, slower on the B (S) face, with the reaction proceeding slowest on faces perpendicular to the $<11\bar{2}0>$ axis. Reactions on the A and B faces are characterized by a very nonuniform Cu_2S-CdS interface, whereas the interface for reactions along the $<11\bar{2}0>$ is much more uniform. The reaction in the latter case may be controlled by surface nucleation, and layer formation subsequent to formation of a 300-500Å thick layer is much slower. The formation of Cu_2S on the A and B faces has an activation energy of 0.9-1.5 eV. Preparation of the surface by polishing leads to a larger rate of Cu_2S formation and Cu_2S-CdS interfaces which are more uniform as a function of depth than those in etched samples.

Energetic ion backscattering is a relatively recent tool for the study of the near-surface layers in solids. It is the only nondestructive technique for measuring the depth distribution of atomic composition over micron-thick layers with significant depth resolution (100-200Å). So far, ion backscattering has been applied mainly to studies of thin-film interdiffusion and interfacial reactions, particularly in the area of semiconductor device technology (1), but there have been few applications to studies of surface chemical reactions.

* Electrochemical Society Active Member.

Key words: cadmium sulfide, copper sulfide, thin film solar cells, ion backscattering analysis.

A technologically important system where a surface chemical reaction plays an important role is the CdS-Cu_2S system. This system is one of the most frequently mentioned candidates for thin-film solar cells and extensive phenomenological information is available. In this paper we report the results of an investigation of the formation of Cu_2S layers on the surfaces of single crystal CdS using 2.0 MeV He ion backscattering. The ion backscattering provides a direct measure of the depth distribution of atomic composition in the first few thousand angstroms of the sample. Temperature dependences of the depth distributions enable the reaction energetics to be determined over a limited temperature region. The important effects of crystallographic orientation of the CdS substrates have been measured and the effect of surface preparation of the CdS was briefly investigated.

Experimental

Samples of single crystal CdS were obtained from Eagle-Pitcher and Clevite Corporation in the form of thin platelets of thickness ~0.5 mm. These specimens included both platelets with the C axis in the plane of the platelet and samples with the C axis perpendicular to the platelet. The platelets were cut to the appropriate sample dimensions (6.5 × 6.5 mm) for the backscattering experiments. The A (0001) and B (000$\bar{1}$) faces of the samples with the C axis perpendicular to the plane of the sample were identified by a 1 min etch in a 50% by volume mixture of HCl and H_2O. Optical microscope observations indicate that small hexagonal structures begin to form on one of the surfaces. By comparison with known preferential etching (2) behavior in a solution of HNO_3, CH_3COOH, and H_2O in the volume ratios 6:6:1, the surface showing the hexagonal structures was identified as the A (Cd) face. Samples with the C axis in the plane of the platelet were etched for 30 sec in 30% by volume HCl in H_2O. The crystallographic orientation of these samples was determined by x-ray diffraction to be $\langle 11\bar{2}0 \rangle$.

Two samples, an A-face sample and a sample with the C axis in the plane of the surface, were polished to an optically clear finish on a polishing wheel using 0.25 μm diamond paste as an abrasive. These samples were then gently swabbed with 30% HCl for 5 min to remove surface damage yet retain the optically smooth surface finish.

The Cu_2S layers were formed by dipping in a copper chloride solution developed by Fahrenbruck (3). This dipping treatment forms Cu_2S by the reaction

$$2Cu^+ + CdS \rightarrow Cu_2S + Cd^{++}$$

with the excess cadmium going into solution. Distilled H_2O was boiled in a flask while argon was bubbled through the H_2O. After 20 min, 19.8 g/liter CuCl, 37.3 g/liter KCl, and 13.9 g/liter NH_2OHHCl were added without disturbing the argon atmosphere in the flask. The solution temperature was then stabilized at the desired dipping temperature and the samples immersed for the desired time while attached to a stainless steel paddle. After dipping, the samples were immediately rinsed with distilled H_2O, dried, and inserted in the sample holder for the backscattering analysis.

In order to verify that samples reached thermal equilibrium quickly at the shortest dipping times (15 sec), samples of all orientations which had been subjected to two successive 15 sec dips were compared to samples dipped once for 30 sec. For samples of the same orientation there was no difference in the amount or depth distribution of Cu_2S formed by the two procedures.

All analyses were accomplished with 2.0 MeV He^+ ions at a nominal beam current of 3.0 nA and a beam spot size of 1.0 × 1.0 mm. Scattered ions were detected at a laboratory angle of 160° in a silicon surface barrier detector. Further amplification and analysis was done using standard nuclear spectroscopy electronics, pulse pile-up rejection circuitry, and a PDP-11-based pulse height analysis system (4).

Data Analysis

A typical ion backscattering spectrum from a CdS sample with a thin layer of Cu_xS, where $x \simeq 2.0$ as will be discussed, is shown in Fig. 1 (top). These data are for (0001) CdS dipped for 2 min at a solution temperature of 65°C. In Fig. 1 (bottom) is a spectrum taken of an untreated sample of CdS. The formation of the Cu_2S surface layer is manifested in two ways: (*i*) the Cd edge is shifted to lower energies due to passage of the ions through and energy loss in the Cu_2S and (*ii*) the appearance of scattering due to the Cu atoms themselves. Since the Cu scattering at a given depth occurs at a lower energy than Cd scattering from the same depth, the analysis of the data is more complex than for a heavier atom layer on a lighter atom substrate. It is assumed that the reader is familiar with measurements of the depth dependence of atomic composition by ion backscattering. For a detailed discussion of the principle of the technique and how the information is obtained see Ref. (1). Brice has developed a technique for the extraction of the scattering yields of each component of a binary target (5) and has written a computer code which performs this function. The code as written requires a rather large computer, but by making some restrictions in the capabilities and generality of the code, we have been able to implement this program in a PDP-11 with 28K core. The program is written in an interpretive language and thus requires about five hours to analyze 100 channels.

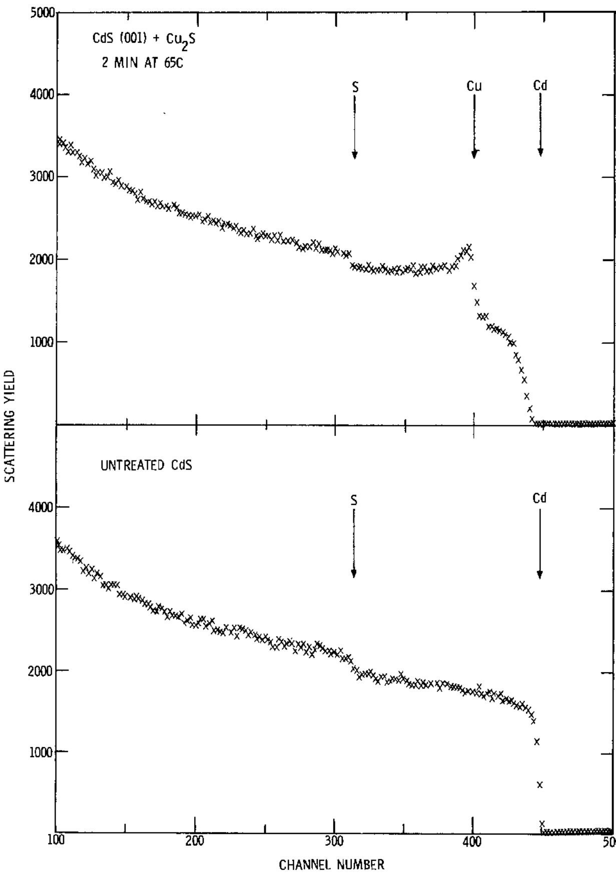

Fig. 1. Backscattering spectra from a sample of CdS (A face) dipped for 2 min at 65°C (top) and an untreated sample of CdS (bottom). The labeled arrows represent the channel where surface scattering from the three constituents will occur.

Several assumptions must be made in order to interpret the data. Since the Brice program is only applicable to binary targets, we have assumed that all the Cd is in the form CdS and all the Cu in the form $CuS_{0.5}$. CdS is the only known compound in the CdS binary system and $CdCl_2$, which would be the reaction product in the dipping reaction, is water soluble. The reasons for the assumption that all the Cu is in the form $CuS_{0.5}$ or equivalently Cu_2S are not so obvious. The $CuS_{0.5}$ form is used rather than Cu_2S to normalize both molecules to one metallic atom apiece, since we are measuring the helium ion scattering from Cd and Cu and not from S. The solubility of Cu in CdS has been measured by Sullivan (6) and can be expressed as

$$[Cu] = 6.6 \times 10^{22}\ \text{atom/cm}^3 \times \exp[-0.505\ \text{eV}/kT] \quad [1]$$

At the temperatures we are concerned with in this work, 65°-85°C, the solubilities calculated from Eq. [1] vary from 2-5 $\times$ 10^{15} atom/cm^3. However, the scattering of Cu at the surface in general is superimposed on Cd scattering from deeper in the sample, and the scattering from one atom of Cd is greater than the scattering from one atom of Cu by a factor $(Z_{Cd}/Z_{Cu})^2 = (48/29)^2 = 2.74$. Because of these problems, we are limited to measuring copper atomic concentrations $\geqq$ 1/100 of the Cd atomic concentration. This works out to a practical limit of about 2 $\times$ 10^{20} Cu atom/cm^3. Thus any copper which we detect must be tied up in a compound, since the maximum solubility of copper in CdS is below our practical detection limits for this system by a factor of 10^5.

It is well documented that the Cu-S phase diagram is complicated (7). A large number of Cu_xS compounds exist near a value of $x = 2.0$. Ion backscattering cannot measure microstructure. At best it measures atomic ratios averaged over the beam area (typically ~1 mm^2 as a function of depth. Other workers have shown by x-ray diffraction techniques (7) that the Cu_xS compound which forms on single crystal CdS during the dipping reactions is predominantly Cu_2S. For our purpose, however, the exact stoichiometry of the Cu-S compound makes little difference. Thus as we refer to Cu_xS, we have assumed $x = 2.0$ for calculations. It is possible that ternary Cd-Cu-S compounds are formed, which would change some of the conclusions presented here. However, x-ray diffraction measurements (7) by other workers did not show evidence for such compounds.

Stopping power data for He ions in CdS are limited (8) and none exist for He in Cu_2S, so values for Cd, Cu, and S were used (9) to generate values of the stopping power of CdS and $CuS_{0.5}$ for He ions as a function of energy by assuming Bragg's Rule for additivity of atomic stopping powers applied to CdS and $CuS_{0.5}$. These values were then fit to the Brice formula (10) to give an analytic expression for the electronic stopping power, ϵ. The values of ϵ used, along with the resultant Brice parameters, are listed in Table I.

Since the Brice techniques depend on comparing the scattering from the heaviest component of a two-component sample to the scattering from a reference sample composed of the pure heaviest component, the amount of the lighter component required to produce the observed reduction in scattering from the heavier component is calculated and its scattering yield is subtracted from the total scattering spectrum at the appropriate energy. The exact choice of this energy is critical. If the energy is slightly too high or too low, a dip or bump will be produced in the calculated scattering yield from the heavier component with a corresponding bump or dip in the calculated scattering yield from this lighter component at a greater depth. Fortunately, if the chosen energy is close to the appropriate energy, these inaccuracies are limited in magnitude and depth and can easily be removed manually. The contribution of the sulfur to the scattering spectrum has been completely neglected in using the Brice extraction technique. This is not a serious error as long as we confine ourselves to analyses of spectra at energies above that expected for scattering from sulfur atoms at the surface.

Figure 2 shows the results of the extraction process for the data of Fig. 1. The upper part of the figure shows the CdS scattering after subtraction of the $CuS_{0.5}$ scattering which is shown in the middle section. The lower part of the figure shows the depth distribution of $CuS_{0.5}$.

Results and Discussion

The effect of crystallographic orientation of the CdS substrate on the rate and nature of Cu_2S formation was rather large. Figure 3 shows backscattering spectra for samples of the three orientations after dipping treatment at 85°C for 45 sec. The A-face and B-face samples show similar behavior with more Cu_2S being formed on the A face than on the B face. Both of these samples have a well-defined surface layer of pure Cu_2S. Behind the surface layer the ratio of $[Cu_2S]/[CdS]$ as a function of depth decreases mono-

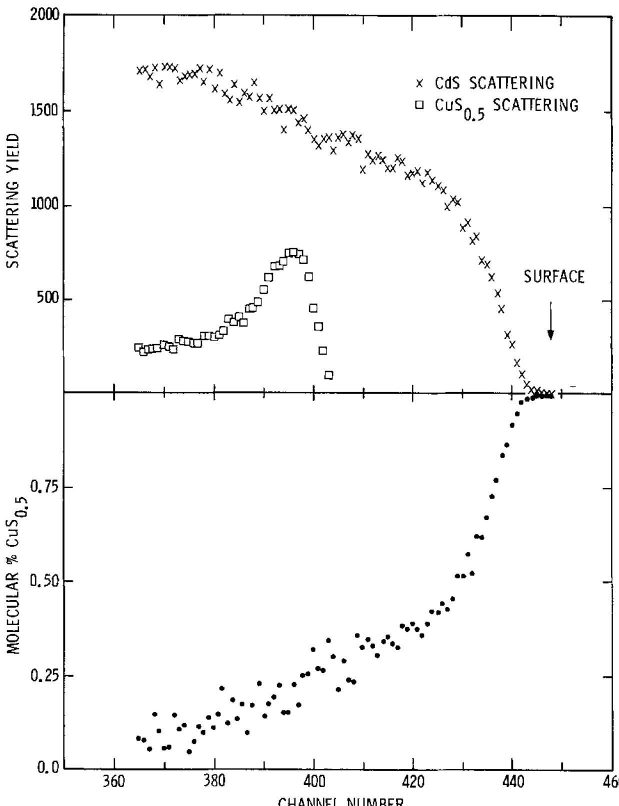

Fig. 2. The top of this figure shows the scattering from Cd (X) and Cu (□) assuming that they are always present in the forms CdS and $CuS_{0.5}$, respectively. The original data is that from the top of Fig. 1. In the bottom of Fig. 2 the molecular concentration of $CuS_{0.5}$ is calculated from the separated spectra shown above it.

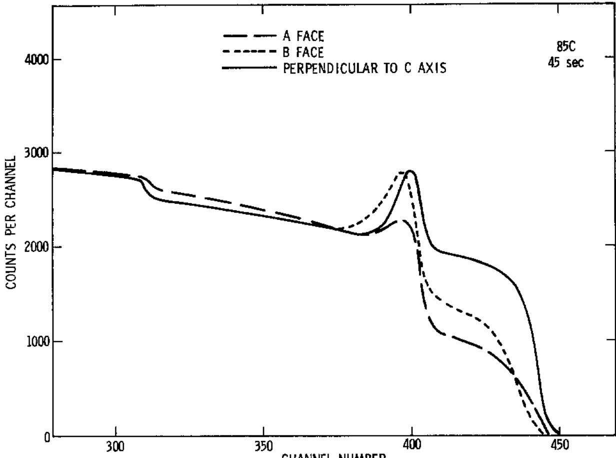

Fig. 3. Backscattering spectra from samples of the three different orientations studied for a dipping treatment of 45 sec at 85°C. The lines were drawn through the actual data points for clarity.

tonically with increasing depth as can be seen from the Cd scattering yield in the energy region between channels 410 and 450. In contrast, the <11$\bar{2}$0> sample shows a surface layer of Cu_2S with no significant Cu scattering at depths beyond the surface layer. This can also be seen in the sharpness of the Cd scattering edge for the <11$\bar{2}$0> sample indicating a Cu_2S-CdS interface at very well-defined depth.

The behavior on the <11$\bar{2}$0> sample can be analyzed without recourse to the Brice subtraction technique. By simply integrating the counts under the copper scattering peak, a measure of the Cu_2S formation is obtained. Data of the formation of Cu_2S on the face perpendicular to the <11$\bar{2}$0> axis are shown in Fig. 4 as a function of dipping time at various temperatures and for both polished and etched samples dipped at 75°C. The general behavior of the curves shows a rapid formation of Cu_2S followed by a period of slower growth. In all cases investigated, the growth slowed at thicknesses between 1.5 and 2×10^{17} $CuS_{0.5}$ molecules cm^{-2}. If we assume that this layer is Cu_2S with a bulk density of 5.6 g/cm^3 (11), the thickness range is 350-500Å. The rapid increase in the amount of Cu_2S observed, followed by a slower growth is most probably related to nucleation of the Cu_2S layer on the surface of the CdS. Such effects have previously been suggested by Fahrenbuck (3). In the spectra which showed very small amounts of Cu_2S, the Cu scattering peak is not energy-resolution limited, but is wide enough to correspond to ~300Å of Cu_2S. As the treatment time is lengthened, the peak increases in height without appreciable widening, suggesting that Cu_2S nucleates at favorable spots on the surface and the nuclei are about 300Å thick. After a layer of Cu_2S has been formed over the entire surface, the process is no longer controlled by nucleation, but either by the reaction rate for the conversion of CdS to Cu_2S or by diffusion of Cu through the already formed layer of Cu_2S.

As discussed in the previous section, the Brice technique has been applied to the A-face spectra to generate data on the depth distribution of Cu_2S on samples of that orientation. Figure 5 shows data on the depth distribution of Cu_2S subject to the assumptions explained in the previous section. The solid lines are drawn through the actual data points which resemble the data points shown in the bottom half of Fig. 2.

These depth distributions resemble diffusion profiles, but it is important to realize that they cannot be diffusion profiles. The amounts of Cu measured in these experiments are many orders of magnitude above the amounts which can be dissolved in CdS as explained in the previous section. This result suggests that there is lateral variation in Cu_2S formation across the area of the analyzing beam. At any given depth there are regions of Cu_2S and regions of CdS. Since the amount of Cu_2S decreases monotonically with increasing depth in the CdS, a model of cone-shaped regions of Cu_2S growing into the CdS is suggested. Such behavior could easily arise if growth took place preferentially at defects such as dislocations. But whatever the course, Cu_2S growth parallel to the C axis appears to take place with a very nonuniform interface, whereas the interface is much more uniform for growth perpendicular to the C axis.

If the growth of the Cu_2S is limited by the ion-exchange reaction rate, the concentration *vs.* depth should be linear beyond the initial surface layer. If the limitation is diffusion of Cu through the Cu_2S layer which has already formed, a plot of the logarithm of concentration *vs.* depth squared should be a straight line. Unfortunately, our data are not sufficiently accurate to distinguish these two forms of kinetic behavior. This does not, however, prevent us from obtaining data on the energetics of the reaction. As has been previously observed (12), by plotting the time-to-equivalent backscattering spectra on an Arrhenius-type diagram, the slope of the line connecting equivalent spectra gives the activation energy

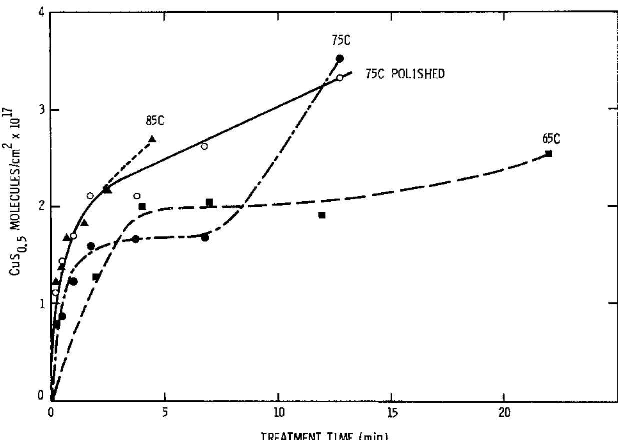

Fig. 4. Total amount of $CuS_{0.5}$ formed on <11$\bar{2}$0> samples as a function of time at different dipping temperatures 65°C (■), 75°C (●), 85°C (▲). Also shown are data for a polished sample treated at 75°C (○).

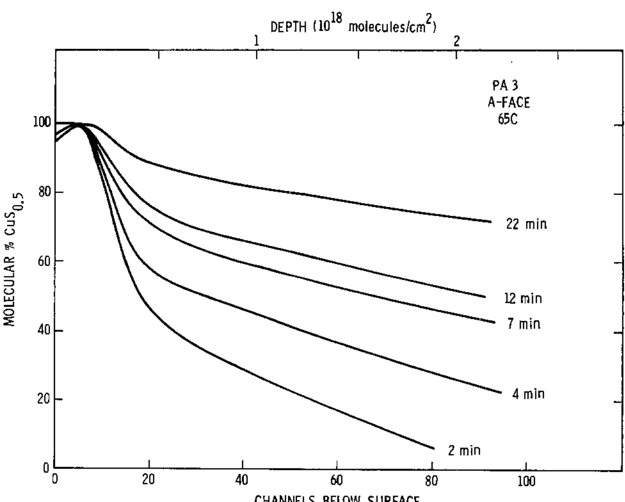

Fig. 5. Depth distributions of $CuS_{0.5}$ as a function of energy (lower horizontal axis) and equivalently depth (upper horizontal axis). These concentrations are the average over a 1 mm beam-spot area.

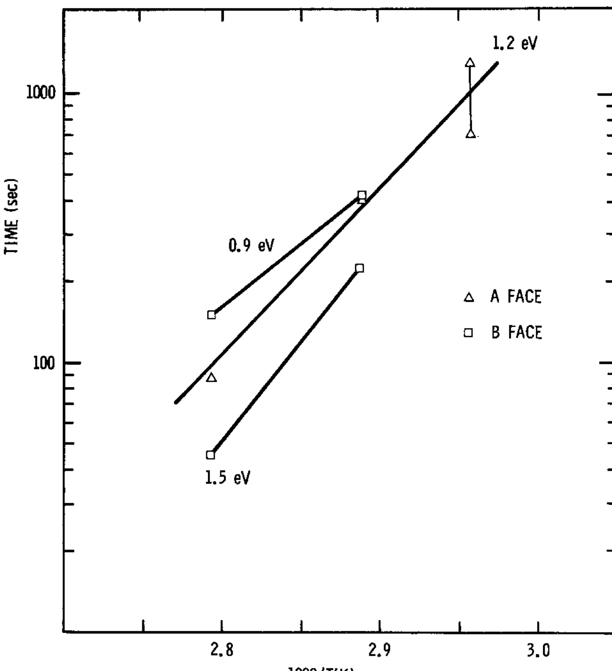

Fig. 6. Arrhenius plot of time to equivalent spectra for A-face (△) and B-face (□) samples. The heavy lines connect the equivalent points. The two points at 65°C connected by a vertical line indicate that the equivalent spectrum fell somewhere between the two points.

of the process. Data for the A and B faces are shown in Fig. 6. There is some scattering in the slope, most probably due to difficulties in picking exactly equivalent spectra, but the data are fairly consistent with an activation energy of 0.9-1.5 eV. It must be cautioned that if more than one process is active during the time taken to produce the spectra, the activation energy derived from Fig. 6 will not be simply related to either individual process, but this is the case in other methods of determining activation energies as well.

Some preliminary results on the effect of surface preparation were obtained on samples which had been polished to an optical finish using 0.25 μm diamond paste. Figure 4 shows the growth of Cu_2S *vs.* dipping time for a polished and a normal-etched <11$\bar{2}$0> sample dipped in a 75°C solution. The short time behavior of the polished sample shows much faster growth than the etched sample, but the curves then cross at high values of Cu_2S layer thickness.

For A-face samples which had been polished, the difference between polished and etched samples is the most apparent. As can be seen in the spectra shown in Fig. 7, the Cu scattering for polished samples shows a less rapid change in Cu_2S concentration *vs.* depth than for the etched sample. Indeed, the polished sample almost has a uniform layer of Cu_2S which grows linearly in time, but as can be noticed from the Cd scattering remaining in the region between channels 410-450, the layer is not uniform.

We suggest that these results indicate the Cu_2S formation on CdS is very dependent on surface damage and on the crystalline perfection of the near-surface layers of the host CdS crystal.

Conclusions

The results contained in this paper represent the first application of energetic ion backscattering to the study of an aqueous chemical reaction. While mostly phenomenological, information has been obtained on Cu_2S formation on single crystal CdS in a thickness region of technological importance (0-5000Å). There exist no other data in this region of interest. We

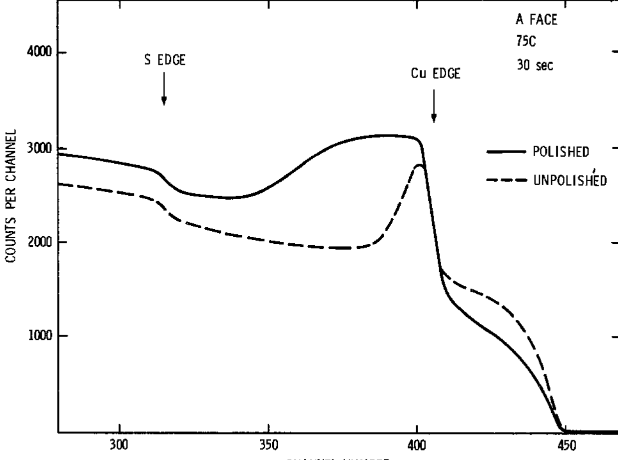

Fig. 7. Backscattering spectra from a polished and an unpolished A-face sample. Both samples were dipped for 30 sec at 75°C. The lines were drawn through the individual data points.

have demonstrated that the reaction is faster on the A face than the B face, and faster along the C axis than perpendicular to it. Estimates of the energetics of the reaction along the C axis have been obtained. We have shown that the Cu_2S layer formed on single crystal CdS is not uniform in depth, but is propagated into the crystal with great lateral nonuniformity. It is suggested that dislocations may enhance Cu_2S formation due to the local lattice strain. Also, the effects of surface preparation of Cu_2S layer formation have been shown to be quite large.

CdS is a complicated material and samples from different suppliers or samples from the same supplier, but cut from different boules, behaved very differently. However, if we are to ever understand the mechanisms of Cu_2S formation on thin-film CdS where the effects of polycrystallinity and grain morphology may very well be large, we must first attempt to understand what happens in the simpler system of Cu_2S on single crystal CdS.

The Effects of Processing on Hot Electron Trapping in SiO_2

R. A. Gdula

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Avalanche injection of hot electrons into the insulator of an MOS capacitor has been used to study electron trapping in SiO_2. Oxides formed by thermal oxidation in dry O_2, O_2 + HCl, O_2 + H_2O, steam, and chemical vapor-deposited (CVD) SiO_2 were subjected to avalanche charging. Pure, dry thermal SiO_2 was found to trap up to 2.6×10^{12} e/cm^2. The trapping efficiency of SiO_2 varied by three orders of magnitude, depending on forming and annealing conditions.

Goetzberger and Nicollian (1) reported the occurrence of avalanche-produced hot carriers as early as 1966. Subsequently, the conditions under which hot carriers can be produced in MOS structures were outlined (2), and hot carrier injection was used to study high current densities and trapping in SiO_2 (3, 4). At about the same time, it was discovered that hot carrier injection could degrade the performance of silicon planar transistors (5, 6) and produce instabilities in MOSFET's (7). A practical use for the phenomenon was found with the introduction of the FAMOS[1] device (8). These problems induced further studies (9-13).

Avalanche injection of hot carriers into SiO_2 can be conveniently produced using a simple MOS capacitor. A high frequency (> 1 kHz) a-c signal of sufficient amplitude is impressed across the capacitor. Once each cycle the silicon beneath the field plate becomes depleted because the inversion layer cannot form quickly enough. When the field in the silicon becomes strong, large quantities of minority carriers are created by ionization multiplication, and the Si is said to avalanche. These minority carriers are accelerated toward the Si-SiO_2 interface by the field across the depletion region. Some achieve sufficient energy to overcome the potential barrier (~3.25 eV) at the interface and enter the SiO_2. Most drift through the SiO_2 and are collected on the metal field plate, but some become trapped in the SiO_2. The details of this trapping and how it is affected by processing are the subject of this paper.

Experimental Procedures

Sample preparation.—Silicon wafers (5.7 cm diameter, boron-doped, p-type, <100> orientation of various resistivities) were quartered, stripped in concentrated HF, and given an inorganic cleaning in hot aqueous solutions of NH_4OH + H_2O_2 and HCl + H_2O_2 finished by copious rinsing in deionized water. SiO_2 films were formed by thermal oxidation at 1000°C in various ambients, or provided by CVD. When required, annealing in N_2 or Ar was performed at 1050°C for various lengths of time. Pure aluminum was evaporated from an e-gun source through metal masks to form 5.32×10^{-3} cm^2 capacitors. Aluminum was also deposited on the wafer back sides and annealed in N_2 at 400°C for 20 min to provide ohmic contacts to the silicon. Mobile charge levels were checked by the *I-V* loop technique (14, 15) after biasing the capacitors at $+2 \times 10^6$ V/cm, 200°C, for 10 min. Mobile charge levels in all cases were found to be $< 3 \times 10^{10}$ charges/cm^2. SiO_2 film thickness was measured with an ellipsometer.

Key words: avalanche injection, hot minority carriers, annealing.
[1] Floating gate avalanche injection metal oxide semiconductor.

Measurement techniques.—Starting with a virgin (unprobed) capacitor, the high frequency (1 MHz) *C-V* characteristic was determined. Then the capacitor was avalanched for specified time periods ranging from 1 sec to several thousand seconds using the circuit of Ref. (4). The average d-c current flowing through the sample was monitored by a Keithley Model 615 electrometer operating in the normal mode. The sample was then reconnected to the *C-V* measuring apparatus through a switch box and the *C-V* characteristic redetermined. The number of hot electrons injected into and passed through the SiO_2 per unit area and collected on the Al field plate ($N_{collected}$) was calculated from the area of the field plate and the integrated area under the *I vs.* time curve. A measure of the number of electron charges trapped per unit area (ΔN_{eff}) was calculated from the shift between the *C-V* traces using the equation

$$\Delta N_{eff} = \frac{\Delta V_{FB} \epsilon_o K_{SiO_2}}{q D_{SiO_2}} \quad [1]$$

where ΔV_{FB} is the lateral displacement of the *C-V* traces at the flatband condition in volts, ϵ_o is the permittivity of free space (farad/cm), K_{SiO_2} is the SiO_2 dielectric constant (taken to be 4), q is the electronic charge in coulombs, and D_{SiO_2} is the SiO_2 thickness (cm). Although Eq. [1] assumes all the trapped charge is located in a uniform sheet at the Si-SiO_2 interface which may not be strictly correct, ΔN_{eff} is useful in predicting the behavior of actual MOSET devices. For most of the work it was found convenient to keep the current through the oxide constant by continuously adjusting the applied voltage. All measurements were made with the sample in darkness.

Results and Discussion

Operating conditions.—It quickly became apparent that the silicon substrate doping level had a profound effect on sample behavior. The applied voltage necessary to sustain avalanche currents (at $J_{dc} = 2 \times 10^{-6}$ A/cm^2) varied drastically as a function of N_A as seen in Fig. 1. (*J* represents the particle current through the device.) This is in agreement with the work of Goetzberger and Nicollian (2) who considered the edge of the depletion region to be a step junction. According to their data, uniform avalanche behavior can be expected in the 10^{16}-10^{18} atom/cm^3 doping range. At lighter doping levels edge breakdown dominates, and at higher doping levels direct tunneling occurs. For the purposes of this investigation, it was found convenient to use the 7×10^{15} to about 1×10^{17} range; accordingly, most of the samples investigated were constructed on 0.4 or 2 ohm-cm material.

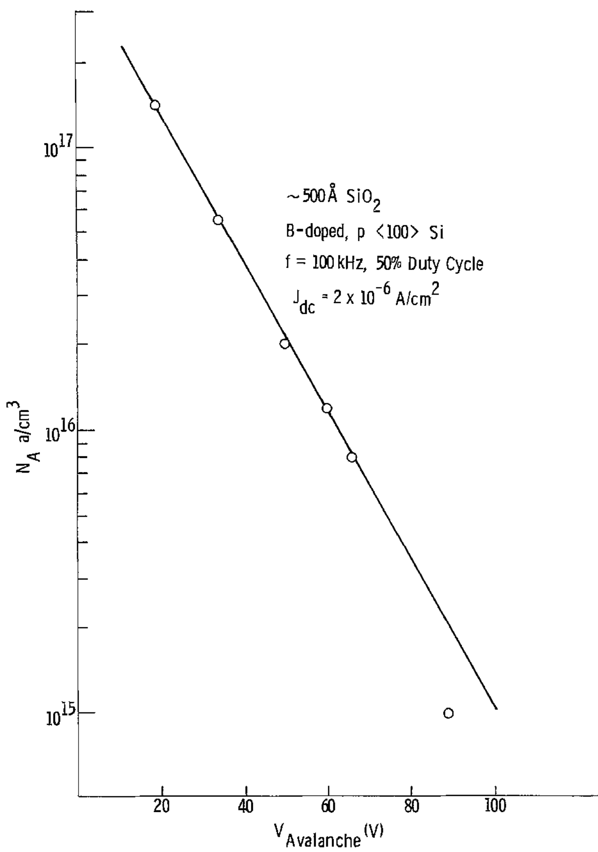

Fig. 1. Applied voltage necessary to sustain an avalanche current of 2×10^{-6} A/cm^2 as a function of Si doping level.

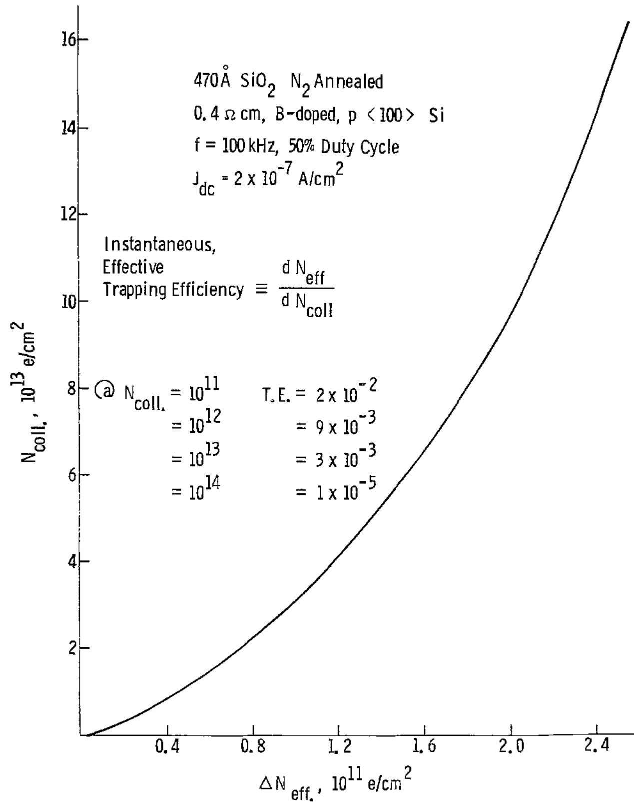

Fig. 2. Typical linear plot of MOS capacitor data

It was also quite apparent that the avalanching conditions affected behavior. For example, $J_{dc} < 10^{-7}$ A/cm^2 did not cause C-V shifts > 10 mV (the accuracy of the measurements) in reasonable experimental times (~ 100 sec), while $J_{dc} > 10^{-3}$ A/cm^2 caused insulator dielectric breakdown or a peculiar damage change in the silicon that shows up as an abnormal C-V trace and gives zero C-V shifts even for passage of very large numbers of electrons. Frequency, duty cycle, and pulse shape also affected J_{dc}. For the results described here, the apparatus was operated within the following conditions: $J_{dc} = 2 \times 10^{-7}$ to 2×10^{-5} A/cm^2, $f = 100$ kHz, duty cycle = 50%, pulse rise time = 0.8 μsec, and pulse fall time = 0.16 μsec.

Typical data and conditions.—Typical data on a virgin MOS capacitor whose oxide was thermally grown in dry O_2 at 1000°C and subsequently N_2 annealed is shown in Fig. 2. From such a plot the important parameter, instantaneous effective trapping efficiency *TE*, defined as

$$TE \equiv \frac{dN_{eff}}{dN_{collected}} \quad [2]$$

may be calculated. It is instructive to note that initially *TE* is quite high, trapping 2 electrons for every 100 electrons passing through the oxide, but *TE* gradually falls off to very low values. When very large numbers of electrons have passed through the structure, the trapping appears to saturate and then relax as shown in Fig. 3, which shows more extensive data from the identical sample discussed in Fig. 2. This maximum trapping is another important parameter, as it puts an upper bound on the threshold shifts of MOSFET devices and in principle allows a calculation of trapping density in the dielectric film. However, assumptions as to the spatial distribution of the charges are required. Moreover, we expected a saturation of the C-V shift but not a reversal of it. Reversal implies a reduction in the net moment of charge which could be caused either by detrapping of electrons or compensation by positive charges.

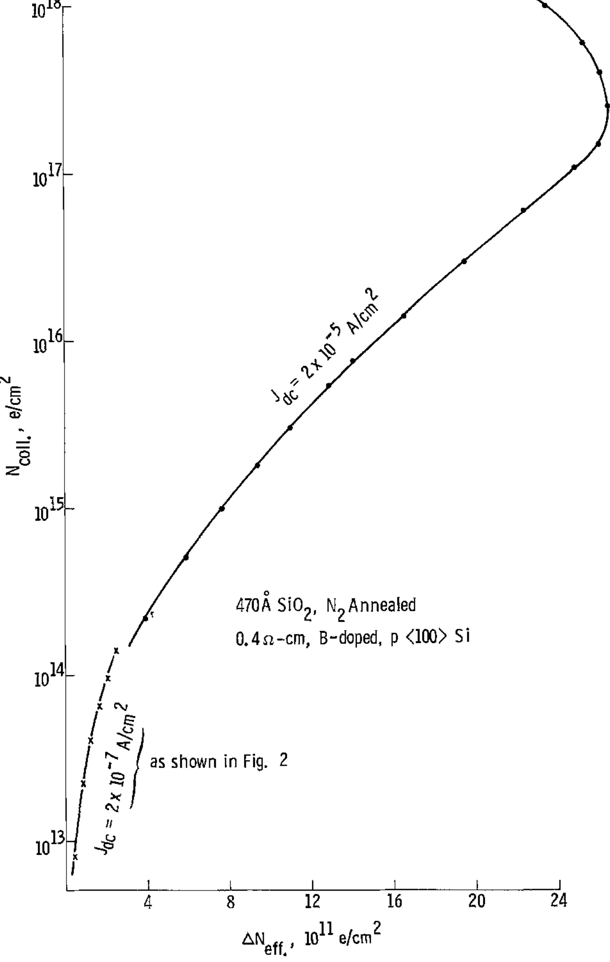

Fig. 3. Typical log-normal plot of MOS capacitor data

A simple experiment was performed to determine the stability of these trapped hot electrons in SiO_2. A typical sample of N_2 annealed, dry thermal oxide ~ 570Å thick had an initial $N_{eff} = 0.78 \times 10^{11}$ positive charge/cm². It was avalanche charged at $J_{dc} = 2 \times 10^{-5}$ A/cm² for 1000 sec. As quickly as possible (in about 10 sec) the C-V characteristic was retraced and N_{eff} was found to be 11.24×10^{11} negative charges/cm². Thereafter the C-V trace was redetermined at specified intervals with the capacitor allowed to float in between. The results are given in Fig. 4. Less than 10% of the charge was lost in 270,000 sec and 11 C-V trace sweeps (−5 to +5V) over that time. This sample was also subjected to $\pm 5 \times 10^6$ V/cm fields for 100 sec with no significant detrapping. This is in agreement with Nicollian *et al.* (9) who also found their trapped electrons to be quite stable.

To assess the magnitude of the oxide field during avalanche charging, a series of samples with N_2 annealed, dry thermal oxide was made with D_{SiO_2} varying from 250 to 1200Å. Under standard conditions (f = 100 kHz, 50% duty cycle) the applied voltage was determined to sustain avalanche in each sample at $J_{dc} = 2 \times 10^{-6}$ A/cm². These are shown in Fig. 5. By extrapolating the line to zero oxide thickness, the silicon is found to avalanche at 25.7V. Since the field in the silicon cannot exceed the avalanche field, any voltage above $V_{avalanche}$ must be dropped in the oxide. The slope of the line yields $E_{ox} = 1.7 \times 10^6$ V/cm at the start of avalanche. During long-term avalanching, E_{ox} would increase to only about 3×10^6 V/cm because $V_{applied}$ was continuously increased to keep J_{dc} constant. Therefore, detrapping of electrons is unlikely.

For some isolated samples fast surface-state densities were measured by the quasistatic C-V technique (16). Fast state density at V_{FB} was found to change little, sometimes decreasing, sometimes increasing for

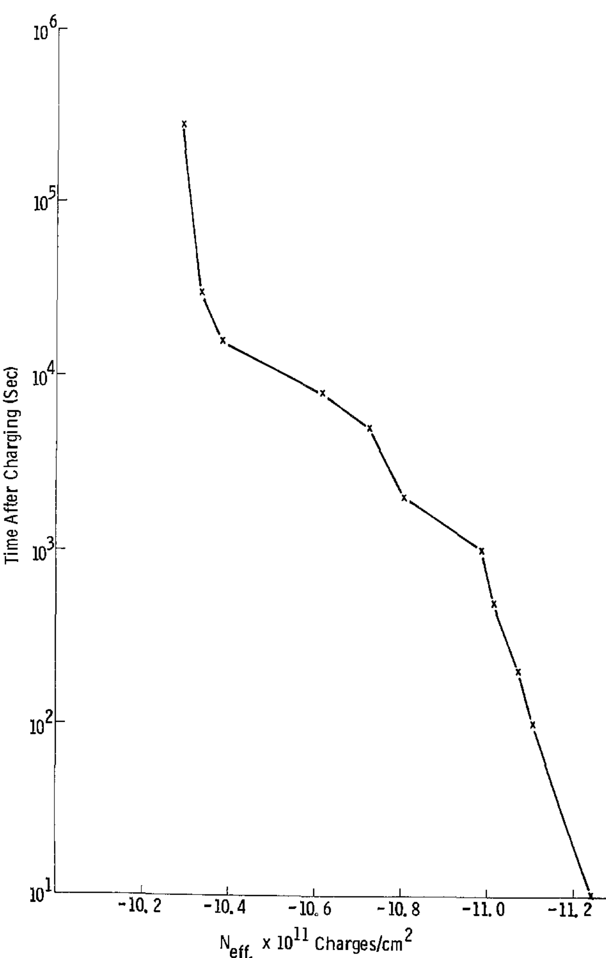

Fig. 4. Detrapping of charge-dry thermal SiO_2, floating

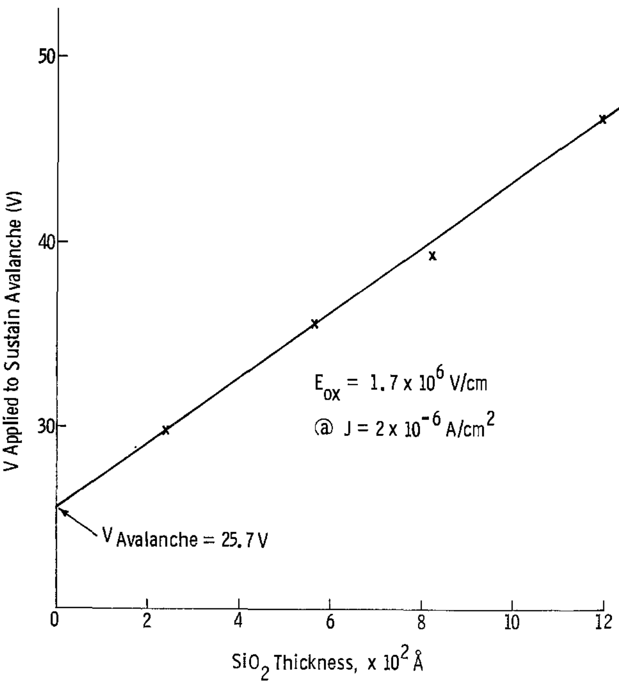

Fig. 5. $V_{applied}$ required to sustain avalanche at $J_{dc} = 2 \times 10^{-6}$ A/cm² as a function of oxide thickness.

$N_{collected} < 10^{16}$ e/cm², but increased dramatically in the region where the C-V shifts slowed down and reversed direction. It is likely then that the reversal of N_{eff} is due to fast surface-state generation. This severely complicates the task of determining the true number of electrons trapped, and hence the use of ΔN_{eff} for comparative purposes.

Effects of oxide processing.—To compare trapping in SiO_2 formed by various typical processes, a series of samples was made having $D_{SiO_2} \approx 500$Å, with no high-temperature annealing. Thermal SiO_2 films were grown in dry O_2, dry O_2 + 3% HCl, dry O_2 + 3% H_2O, and steam. CVD oxide films were deposited using the $SiH_4 + O_2$ reaction at 800°C. BSG films containing ~5 weight per cent (w/o) B_2O_3 were deposited using the same reaction with diborane as the dopant source, also at 800°C. These samples were avalanche-charged at $J_{dc} = 2 \times 10^{-5}$A until the trapping saturated. Their behavior is compared in both Fig. 6 and Table I; the results are quite amazing. SiO_2 was made to accumulate $> 5 \times 10^{12}$ negative charges/cm². Also there is a three order of magnitude difference in the rate of trapping between dry thermal oxide and B-doped CVD oxide. The data suggest that the degree of trapping depends somehow on the OH concentration incorporated in the oxide during forming. The hydroxyl content of the samples listed in Table I was determined from the 2.73 μm absorption peak in the ir spectrum following

Table I. Trapping parameters of SiO_2 formed by different processes on 0.4 ohm-cm, B-doped, p <100> Si

Oxide type	Initial V_{FB} (V)	Effective saturated trapping density (× 10^{11}/cm²)	Effective trapping efficiency (× 10^{-6}) [a]	Hydroxyl concentration (w/o)
Dry O_2	−1.28	17	5.7	Not detected
Dry O_2 + 3% HCl	−1.28	18	16	Not detected
Dry O_2 + 3% H_2O	−1.24	23	58	—
Steam	−1.51	39	180	0.10
CVD	−1.20	56	520	0.44
B-doped CVD	−0.80	57	5000	0.45

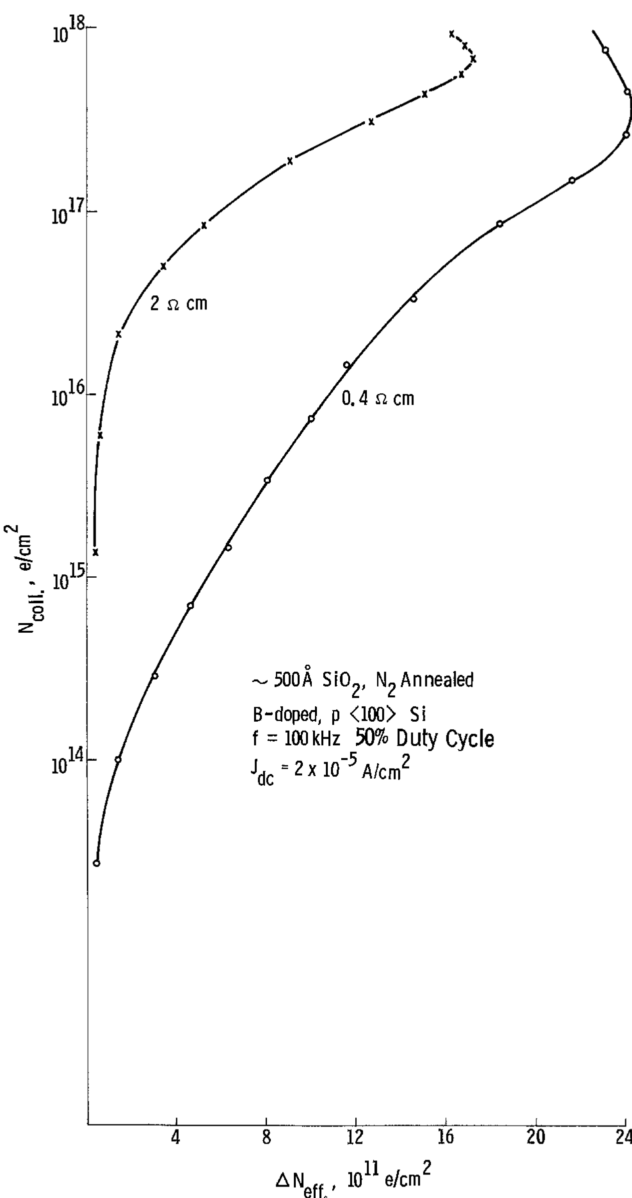

Fig. 7. Trapping in dry, thermal SiO_2 grown on Si of different B-doping levels.

the method of Hetherington and Jack (17). The values for the CVD oxides are well within the levels that can be expected (18). The 0.1 w/o OH measured for the steam oxide is slightly less than that reported by Burkhardt using radio tracer techniques (19). The hydroxyl concentration of the dry O_2 + 3% H_2O sample was not measured. No OH in the dry O_2 + 3% HCl sample could be detected by our measurements although, by inference, some should be present in the oxide due to the fact that about 15% of HCl dissociates at 1000°C, according to the equilibrium reaction

$$2HCl + \frac{1}{2} O_2 \rightleftharpoons H_2O + Cl_2 \quad [3]$$

so the oxidizing ambient contained about 0.5% H_2O by calculation. There should be no detectable OH concentration in thermal SiO_2 grown in dry O_2 (18). The OH group has been reported (3, 4, 9) to be associated with an electron-capturing center in SiO_2. It also appears from our current data that boron incorporated in SiO_2 is associated with a strong trapping center. This has been observed by Young for the case of B implanted in SiO_2 (20). If B in SiO_2 is associated with an electron trapping center, this may explain why dry thermal SiO_2 grown on heavily B-doped silicon traps more than SiO_2 grown on lightly B-doped silicon. Figure 7 shows comparisons for two samples processed under identical conditions (oxide grown in dry O_2 at 1000°C, annealed in dry N_2 at 1050°C for 15 min). Because of the favorable segregation coefficient, B is incorporated into the growing SiO_2 film. It is expected that a greater boron concentration in the oxide will result from growth on a more heavily B-doped substrate. The data shows that thermal oxide on 0.4 ohm-cm B-doped silicon traps more efficiently than thermal oxide on 2 ohm-cm, B-doped silicon.

Since the OH group in SiO_2 has been associated with an electron trapping center, and since OH can be expunged from SiO_2 by heating, it is instructive to determine the effects of high-temperature annealing. Accordingly, oxide samples from the same experiment as those reported in Fig. 6 and Table I were annealed in dry N_2 at 1050°C for 15 min. The results are reported in Table II. As divergent as the results were before annealing, after N_2 annealing all the SiO_2 films behaved quite similarly. The effect due to OH appears to have been leveled. Trapping decreased in the most efficient films, but increased in the least efficient films. This adverse effect of annealing on the least efficient films may be due to additional boron incorporation into the oxide during annealing. The BSG sample was not tested

Table II. Trapping parameters of SiO_2 after high-temperature N_2 annealing

Oxide type	Initial V_{FB} (V)	Effective saturated trapping density ($\times 10^{11}/cm^2$)	Effective trapping efficiency ($\times 10^{-6}$)[a]
Dry O_2	−0.91	25	59
Dry O_2 + 3% HCl	−0.85	22	24
Dry O_2 + 3% H_2O	−0.86	22	29
Steam	−0.77	28	66
CVD	−0.65	24	29

[a] When 1×10^{12} electrons/cm² have been trapped.

because boron diffusion occurred during annealing, and no C-V trace could be obtained.

Additional annealing experiments were done with 500Å oxide films grown in dry O_2 + 5% HCl. These samples were annealed for up to 300 min in N_2 and 960 min in Ar at 1050°C. These were then avalanche-charged and the results are shown in Fig. 8 and 9. Clearly annealing reduced trapping; after very long anneals these HCl-SiO_2 samples approached the behavior of dry O_2 SiO_2.

Conclusions

1. Hot electron avalanche injection is an effective method to study how processing affects trapping in SiO_2 films on silicon.
2. Pure, dry, thermal SiO_2 was found to trap as many as 2.6×10^{12} electrons/cm².
3. The trapping efficiency of SiO_2 films can vary by three orders of magnitude, depending on the formation method.
4. The trapping ability of SiO_2 varies with its OH concentration, which in turn is affected by the forming process. OH groups in SiO_2 are associated with electron trapping centers.
5. Boron in SiO_2 may also be associated with an electron trapping center.
6. High-temperature annealing in a moisture-free ambient can reduce trapping in SiO_2 due to OH groups.

Ionic Conductivity of Doped Beta-Lead Fluoride

John H. Kennedy* and Ronald C. Miles*

University of California, Department of Chemistry, Santa Barbara, California 93106

ABSTRACT

The electrical conductivity of β-PbF_2 in single crystal and pressed pellets was measured by a-c bridge techniques. Aliovalent cation fluoride doping was used to elucidate the conductivity mechanism in the extrinsic region, 25°-180°C. Conduction was shown to be via fluoride ion vacancies. Potassium fluoride dopant increased the ionic conductivity of β-PbF_2 from 5×10^{-7} to 1×10^{-3} ohm^{-1}-cm^{-1} at room temperature. However, galvanic cells utilizing the higher conductivity of the doped material failed due to formation of a passivation layer of pure α-PbF_2 at the anode/electrolyte interface.

Some of the properties of lead fluoride have been known since Tubandt studied the transport number in 1921 (1). However, the solid-state ionic defect formation and conduction mechanisms have only been recently investigated. Lead fluoride occurs in two phases which exist at room temperature. The α-phase has an orthorhombic unit cell structure and is similar to the lead halides, $PbCl_2$ and $PbBr_2$. Beta-lead fluoride is cubic like CdF_2 and CaF_2, as are all transition metal fluorides whose cation-to-anion radius ratio is greater than or equal to 0.73. In a previously published part of our study of polycrystalline material we verified Tubandt's finding that at least the β-PbF_2 fluorite structure conducted by anionic migration, and that the α-PbF_2 structure probably exhibited a similar mechanism (2). We also confirmed Sauka's findings that the α-phase was metastable at room temperature and atmospheric pressure, while the β-phase is apparently stable up to the melting point. The conductivity of lead fluoride at high temperature near the melting point (822°C) was investigated by Derrington and O'Keeffe (3). They found unusually high values which they attributed to "dynamic ion disorder" of the fluoride sublattice. At lower temperatures, Schoonman *et al.* found two Arrhenius slopes and a knee where they met at about 200°C in single crystals of β-PbF_2 (4). Both Derrington and O'Keeffe (3) and Schoonman *et al.* (4) ascribed the high temperature conductivity of β-PbF_2 to fluoride interstitial ions which were formed by a Frenkel mechanism. The other cubic fluorides are also known to form interstitial defects in that manner (5-7). However, Schoonman stated that the knee he observed at 200°C was most likely a shift from interstitial movement to vacancy movement at lower temperatures, rather than being the usual transition from an intrinsic to extrinsic region. This was based on the fact that the upper slope was too low to be a heat of formation, and the trace impurities present should have generated fluoride vacancies.

In order to understand the low temperature conduction mechanism of β-PbF_2, aliovalent impurities were doped into the β-PbF_2 lattice. The concentration of defects will change with doping in order to maintain charge neutrality. As the following equations show, each KF introduced into β-PbF_2 may create a fluoride ion vacancy or consume an existing interstitial, while each trivalent cation fluoride such as BiF_3 can consume an existing vacancy or create an interstitial

$$KF(PbF_2) \rightarrow K'_{Pb} + F^x_F + V^{\cdot}_F$$

$$KF(PbF_2) + F'_i \rightarrow K'_{Pb}$$

$$BiF_3(PbF_2) + V^{\cdot}_F \rightarrow Bi^{\cdot}_{Pb} + 3F^x_F$$

$$BiF_3(PbF_2) \rightarrow Bi^{\cdot}_{Pb} + 2F^x_F + F'_i$$

A change in the conductivity of β-PbF_2 upon doping with known impurities will determine whether the material is conducting via vacancies or interstitial ions.

Experimental

Aliovalent doping.—Orthorhombic α-PbF_2 (ROC/RIC 99.999% pure) was used without further purification. Aliovalent cation fluorides were doped into β-PbF_2 by diffusion and by making use of the α- to β-phase transition. A melt of the mixtures was not used in this study since decomposition of lead fluoride was noted after melting. Also, melting alone does not insure that the dopant has moved into the lead fluoride lattice. Instead, mixtures were heated beyond the phase transition temperature of about 350°C. It was anticipated that during the phase transition the impurities would be incorporated into the new crystal lattice.

The mixtures were made by successive dilution and mixed overnight on a ball mill. They were then loaded into vials and sealed either under nitrogen or vacuum. Each vial was heated to about 500°C. When x-ray analysis showed that the lead fluoride had been converted to the cubic form, pellets were pressed at about 50,000 psi in a Perkin-Elmer evacuable KBr die. This caused some reconversion to the orthorhombic form so that the pellets had to be reheated in sealed vials with PbF_2 packing. No impurity lines or movement of peaks which would indicate a change in lattice spacing were observed in the x-ray spectra.

Conductivity measurements.—The experimental procedures used have been reported previously (2). It has since been found that the electrodes which gave the least a-c frequency dependence were those applied by vacuum deposition of lead metal onto surfaces precleaned by glow-discharge followed by an application of graphite (Aquadag) to protect the thin

* Electrochemical Society Active Member.

Key words: aliovalent doping, fluoride ion conductivity, galvanic cells, lead fluoride, solid electrolyte.

film of lead. Single crystals were measured with the Aquadag alone as the electrode material due to their sensitivity to thermal shock. Also the GRC-1650A impedance bridge previously used was modified by addition of an external, parallel variable capacitor which greatly improved the detector nulls. The series equivalent of the cell resistance could be found by (8, 9)

$$R_s = R_B/[1 + (\omega R_B C_B)^2]$$

where R_s = cell series resistance, R_B = bridge resistance, C_B = bridge capacitance, and ω = angular velocity.

Only in the case of the single crystals where painted graphite alone formed the electrodes was the $\omega R_B C_B$ term significant. As previously described, the frequency-dependent terms were separated by use of empirical functions.

Single crystals.—Single crystals of pure and doped β-PbF_2 were grown by Stockbarger's technique of pulling from the melt as described by Jones (10). It was necessary to premelt the starting material under a flow of HF to eliminate impurities which would have otherwise caused decomposition. Two single crystals were grown, one of undoped PbF_2 and the other of 1 mole per cent (m/o) KF-doped PbF_2. Both crystals were extremely brittle and for this reason temperature studies were somewhat limited.

Results

Total conductivity.—NaF, KF, and BiF_3 were used to dope impurity cations into β-PbF_2. The resulting changes in electrical conductivity determined by the a-c bridge can be seen in Fig. 1. Both NaF and KF increased the conductivity while BiF_3 decreased the conductivity. The slopes of the Arrhenius plots are listed in Table I in terms of a heat of activation. The conductivities and Arrhenius slopes of the NaF-doped samples were lower and steeper, respectively, than those of the KF-doped samples of the same doping concentration. However both appeared to have activation energies that approached 0.21 eV as the doping was increased.

Electronic conductivity.—Wagner polarization cells were made from samples of pure as well as NaF- and BiF_3-doped samples of β-PbF_2. The cells were constructed by vacuum deposition of a thin film of lead on one side of a pressed pellet of β-PbF_2 followed by painting the other side with colloidal graphite (Aquadag). Polarization curves were taken at room temperature and under vacuum. An equation relating the observed current to the electronic conductivity and some results for undoped lead fluoride at 150°C were given previously (2). The NaF-doped samples gave currents which were below the detection limit of the apparatus which was about 1×10^{-10} ohm^{-1}-cm^{-1}. New data for undoped cubic lead fluoride at 25°C are shown in Fig. 2 and were ambiguous as to whether the current was carried by electrons or holes. However these new lower conduction values for purer lead fluoride than used previously are in reasonable agreement with those observed by Schoonman (11). The electronic conductivity for BiF_3-doped β-PbF_2 is shown in Fig. 3 and indicates electron carriers. Except for the BiF_3-doped material, the electronic conductivity measured was far below the total electrical conductivity observed. At room temperature, the conductivity of 1 m/o BiF_3 in β-PbF_2 was 6.4×10^{-8} ohm^{-1}-cm^{-1}, while the electronic conductivity was 4.0×10^{-8} ohm^{-1}-cm^{-1}. Since the electronic

contribution to the total conductivity was so large, the Arrhenius plot for the BiF_3-doped β-PbF_2 was not considered in the elucidation of the ionic conduction mechanism.

Discussion

The increased conductivity observed when β-PbF_2 was doped with monovalent cation fluorides was due to an increase in ionic conductivity since the electronic conductivity was observed to decline. The extrinsic semiconductor nature of β-PbF_2 which was apparent when BiF_3 was doped into the lattice has been observed before by Chan and Shields (12) and also by Arkhangel'skaya *et al.* (13).

The fact that the ionic conductivity of β-PbF_2 increased upon doping with KF and NaF, while it decreased when BiF_3 was introduced, indicated that the ionic current was carried by mobile, fluoride ion vacanies when the temperature was below about 180°C. Above this transition point the steeper slope may represent an intrinsic region where the conducting defects ($V^{\cdot}_F$) are being formed in significant number by thermal generation, or it may represent a shift to a new conduction mechanism, *i.e.*, fluoride interstitials as suggested by Schoonman *et al.* and Derrington and O'Keeffe. If both slopes are extrinsic, however, one must assume nonequilibrium between vacancies and interstitials.

If the knee in the Arrhenius slope represented a transition from an extrinsic to an intrinsic region as the temperature increased, then the activation energy of the extrinsic lower slope was ΔH_m, the heat of movement, while the intrinsic upper slope was $\Delta H_m + \Delta H_f/p$, the sum of the heat of movement and of formation. The constant, p, represents the number of defects formed, and would be 2 for a Frenkel or 3 for a Schottky mechanism. The values for these two slopes were

$$\text{lowest slope} = \Delta H_m = 0.21 \text{ eV}$$

$$\text{highest slope} = \Delta H_m + \Delta H_f/p = 0.66 \text{ eV}$$

The value for ΔH_f would be 0.90 eV (Frenkel) or 1.35 eV (Schottky). Both of these values are rather low and cast doubt on the extrinsic-intrinsic regions hypothesis. Based on the melting point of PbF_2 (822°C) an estimate for ΔH_f (Frenkel) is 2.72 eV (4).

Our doping studies show that fluoride ion vacancies are the conductive species, and vacancies can be formed by either a Schottky or Frenkel mechanism. However, studies at higher temperatures (3, 4) have indicated that fluoride ion interstitials are the predominant conductive species. Since interstitials are formed by a Frenkel mechanism and not the normal Schottky mechanism (anti-Schottky defect requires the formation of lead interstitials in addition), it is logical to assume that a Frenkel mechanism prevails at all temperatures with vacancies being the predominant conductive species at low temperature (<200°C) and with interstitials becoming predominant at high temperatures because their heat of movement is higher. However, the possibility of both Schottky and Frenkel mechanisms existing in PbF_2 cannot be ruled out.

It should be noted that a transition from vacancy to interstitial conduction would allow Arrhenius plots of doped samples to cross the undoped line. Potassium fluoride doping would increase the concentration of vacancies and enhance vacancy conduction at low temperature but would decrease the concentration of interstitials and therefore decrease conductivity at high temperature. A transition from extrinsic to intrinsic would not predict such a crossing. Figure 1 shows that the doped lines may cross the undoped lines in the 200°-300°C region. For more data concerning crossing see Ref. (15).

It is dangerous to try and fit results for polycrystalline materials into mathematical models designed for purely bulk effects. Therefore, the doping results were checked by growing a single crystal of 1 m/o KF-doped β-PbF_2. It was possible that there might be several pathways by which the conducting species, $V^{\cdot}_F$ and possibly F'_i ions, were moving which would complicate the heats of movement. This effect had been described by Mizuta and Yanagida (14) in the case of CaF_2, which also conducts by fluoride ion vacancies. They found that the Arrhenius activation energy depended on the history or degree of sintering of the polycrystalline material, and that there were three extrinsic heats of movement: bulk, grain boundary, and grain surface. However, the single crystal of doped PbF_2 gave essentially the same values of conductivity and Arrhenius slope as the polycrystalline material (Table I). Therefore, in this case, the ionic transport mechanism was not dependent on the polycrystalline nature of the material.

A method for calculating the concentration of defects in the undoped material assuming it is extrinsic in nature can be developed from doping studies using the conventional equation

$$\sigma = ne\mu$$

For the undoped material containing an extrinsic concentration of defects, n_o

$$\sigma_o = n_o e\mu$$

and for the doped material

$$\sigma = (n_o + n_d) e\mu$$

Since extrinsic conductivity is assumed, the addition of defects by doping (n_d) will not affect those present in the undoped material (n_o). If we assume for the moment that mobility does not change with doping level then

$$\frac{\sigma}{\sigma_o} = 1 + \frac{n_d}{n_o}$$

A plot of σ/σ_o *vs.* n_d should be a straight line with a slope of $1/n_o$. This plot is shown in Fig. 4. Straight lines were not obtained, and the upward curvature indicated higher conductivities than predicted at high doping levels. If one reviews the activation energies given in Table I it can be seen that the activation energy decreased as alkali metal concentration increased. Thus, the basic assumption which is made in most doping studies that the mobility does not change with doping level was not true in this case. If we take a more general approach, namely

$$\sigma T = \sigma^o e^{-\Delta H_m/kT}$$

where the preexponential term, σ^o, is directly proportional to the concentration of conductive species, then

$$\sigma^o{}_o = kn_o$$

and

$$\sigma^o = k(n_o + n_d)$$

Again a ratio of conductivities can be used to give

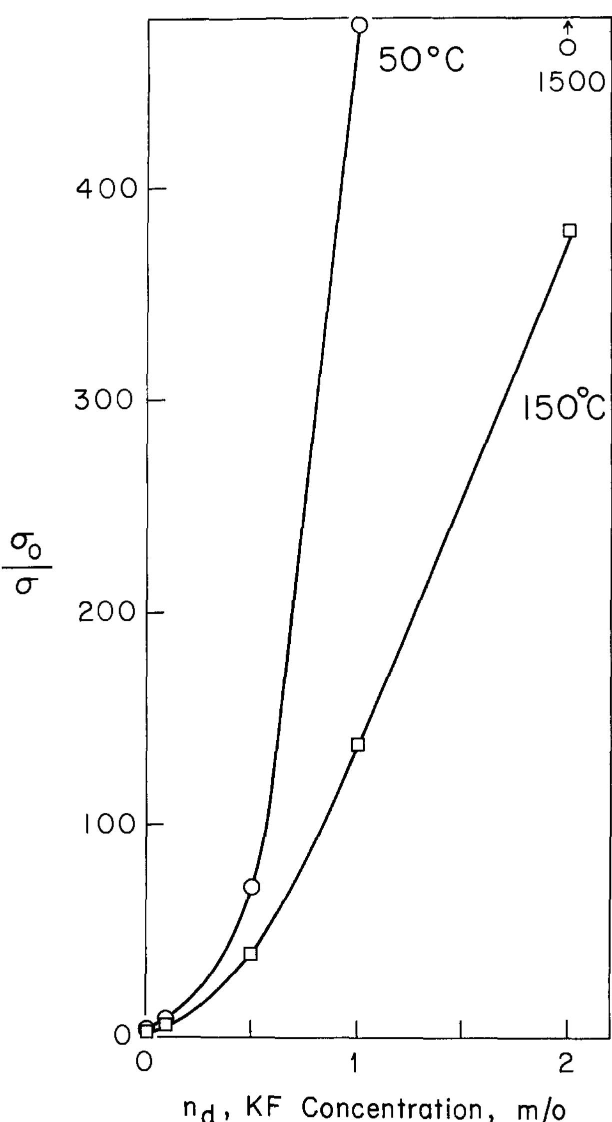

Fig. 4. Conductivity as a function of KF doping level. ○ 50°C, □ 150°C.

$$\frac{\sigma^o}{\sigma^o{}_o} = 1 + \frac{n_d}{n_o}$$

In this case the extrapolated infinite temperature values are used and a plot is shown in Fig. 5. A value of 0.5 m/o for the concentration of extrinsic defects in undoped lead fluoride was obtained from the slope. However, the conductivity was considerably lower than with 0.5 m/o KF doping because the heat of movement was higher for undoped PbF_2 than for KF-doped PbF_2.

A plot of ΔH_m as a function of doping level is shown in Fig. 6. It appears that the heat of movement for vacancies can vary from above 0.5 eV in nominally pure PbF_2 to 0.21 eV in highly doped PbF_2. The sensitivity of the activation energy to impurity level explains why several different values have been observed by various investigators for nominally pure β-PbF_2 from below 0.5 eV (2) to 0.7 eV (4).

A change in the extrinsic heat of movement has not been previously reported for analogous solid electrolytes. This may be the result of the high doping levels used in this study or may be specific to PbF_2. A concentration of 1 m/o KF is large enough to place a potassium ion within several cell lattice constants of any other ion in the lattice. The difference then between the KF and NaF doping experiments may be the result of different charge densities between sodium and potassium which would affect the energy barriers the fluoride ion vacancy experiences at these high doping levels as it migrates.

Recently a paper was published describing similar experiments with lead fluoride (15). Most of the results are in general agreement with those presented here, however some differences were observed. Doping with YF_3 increased conductivity while our results with BiF_3 showed a decrease in conductivity. This difference between the MF_3 compounds should be studied in more detail. Liang and Joshi also described a linear increase in conductivity with doping up to 1 m/o. We have observed more curvature especially

at the higher doping levels (as high as 2 m/o). Finally, we have observed a gradual decrease in activation with increased doping level while Liang and Joshi observed only the high slope for undoped samples and the low slope for doped samples. We agree on both the high and low slope limiting values, but interpretation depends somewhat on whether or not intermediate values are observed. Additional studies should be undertaken to examine these differences and to design experiments which will discriminate between various conductivity mechanisms which have been postulated.

Galvanic cells.—Potassium fluoride-doped β-PbF_2 was used as an electrolyte in galvanic cells to test its high conductivity. Solid-state cells were constructed with CuF_2 and AgF as cathode materials. The anticipated open-circuit voltages of 0.70 and 1.30V were achieved, but the cell potentials fell rapidly when placed under load and current drawn.

In order to examine the electrolytic properties exclusive of the galvanic cell configuration, a Pb/PbF_2/Pb cell was constructed by applying a thin film of lead to serve as a cathode on a pressed pellet (2 m/o KF doped-PbF_2), and pressing a plate of lead metal against the opposite side of the pellet. In this cell, lead metal would be deposited at the cathode and lead fluoride would be formed at the anode. However, the lead fluoride formed would be pure and would not show the high conductivity of the doped material unless KF were able to diffuse into the newly formed layer. The formation of pure PbF_2 would be similar to the formation of a passivation layer and explain the poor performance of the galvanic cells.

Two Pb/PbF_2/Pb cells were run, one at 100°C and the other at 250°C. They yielded currents of several hundred microamperes and about 1 mA, respectively, at an applied voltage of one volt. After one day, the current of the cell at 250°C was essentially zero. The cell at 100°C took several more days until the current decayed to near zero. About 9 coulombs of charge passed through the higher temperature cell while about 2 coulombs passed through the lower temperature cell.

Inspection of both lead plate anodes under a microscope revealed deposits, roughly circular in shape. In some places, the deposits had coalesced, but nowhere were they any higher than 40μ. There were no corresponding pits in the adjacent pellet surfaces. X-ray analysis of the deposits showed the presence of α-PbF_2 and Pb_2OF_2 but no β-PbF_2 (Table II). Apparently deposition occurred at a number of preferred active sites and ceased when they were consumed. Possibly these sites were merely high pressure contact points between the lead plate and the pressed pellet of doped electrolyte. It has been shown previously that β-PbF_2 converts to α-PbF_2 when under pressure (2). This could explain why the lead fluoride was formed in the α- rather than β-form. Thus, even though doped β-PbF_2 has quite high ionic conductivity its use may not be possible in lead anode galvanic cells because the anode product will be low conductivity pure α-PbF_2.

Table II. X-ray data of lead anode surface

2θ, degrees	d, A	I	I/I_o (Pb)	I/I_o (α-PbF_2)	I/I_o (Pb_2OF_2)	Assignment
26.83	3.320	56			100	Pb_2OF_2 (3.33)
27.10	3.288	10		100		α-PbF_2 (3.290)
27.70	3.218	3		30		α-PbF_2 (3.222)
29.12	3.064	7			13	Pb_2OF_2 (3.07)
29.20	3.056	7		70		α-PbF_2 (3.058)
31.00	2.882	43			78	Pb_2OF_2 (2.88)
31.26	2.859	58	100			Pb (2.855)
36.28	2.474	20	35			Pb (2.475)
38.15	2.357	8		80		α-PbF_2 (2.364)
42.31	2.134	6		60		αPbF_2 (2.135)
44.40	2.039	16			29	Pb_2OF_2 (2.03,2.04)

Comments: Two peaks from Pb_2OF_2 were missing, d = 2.86 (I/I_o = 60) and d = 2.70 (I/I_o = 70). The first was probably masked by the lead at d = 2.855. α-PbF_2 was also missing one peak, d = 2.475 (I/I_o = 26). Undoubtedly it was masked by the lead peak at d = 2.475. Only one x-ray out of three taken showed a very small peak at d = 3.425 which could be attributed to β-PbF_2 at d = 3.428. X-ray diffraction of a lead plate after being heated at 250°C for several days showed that none of the lead oxide peaks from this spectrum corresponded to the x-ray diffraction pattern shown above.

Conclusion

It has been shown that β-PbF_2 conducts by fluoride ion vacancy movement when at temperatures below 180°C. Furthermore, the conductivity can be considerably enhanced by doping with monovalent cation fluorides. The presence of monovalent cations also appears to decrease the heat of movement for the vacancies. Its usefulness in a solid-state cell, however, is possibly limited due to the formation of an anode passivation layer consisting of low conductivity pure α-PbF_2.

Ackowledgment

This paper was taken in part from the Ph.D. dissertation of RCM, University of California, Santa Barbara, 1974. The authors acknowledge financial support of this project by the National Science Foundation, Grant No. GH-37144. The authors also thank Mr. Neil Nighman for his help in growing single crystals of lead fluoride. One of the authors (JHK) thanks the Japan Society for the Promotion of Science for a visiting professorship grant and Professors T. Takahashi and O. Yamamoto for helpful discussion.

Manuscript submitted March 4, 1975; revised manuscript received July 14, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by the University of California.

The Preparation and Properties of (111)Si Films Grown on Sapphire by the SiH_4-H_2 Process

H. M. Manasevit,* F. M. Erdmann, and A. C. Thorsen[1]

Rockwell International, Electronics Research Division, Anaheim, California 92803

ABSTRACT

An experimental study of the effects of various parameters on the properties of (111) and (100)Si films grown on sapphire (α-Al_2O_3) by the SiH_4 pyrolysis CVD method has been carried out. The following were examined: autodoping, growth temperature and growth rate, As-doped n-type films, p-type films doped with B, properties as a function of film thickness, and the effect of reactor configuration. It was determined that at growth rates of ~2-6 μm/min in a vertical reactor n-type (111)Si films grown at temperatures of 1050°-1100°C on Al_2O_3 substrates oriented near the $(11\bar{2}0)$ plane are electrically superior to those grown on $(01\bar{1}2)Al_2O_3$ and $(10\bar{1}4)Al_2O_3$ over the temperature range 950°-1100°C. Films with electron mobilities as high as 600-700 cm^2/V-sec for carrier concentrations of 10^{16}-10^{17} cm^{-3} were obtained. P-type Si films grown using B_2H_6 as the dopant source were also electrically better on $\sim(11\bar{2}0)Al_2O_3$ [(111)Si-growth] than on $(01\bar{1}2)Al_2O_3$ [(100)Si growth], Hall mobilities being ~2-3 times larger for hole concentrations 10^{16}-10^{17} cm^{-3}. A comparison of film properties of n-type films as a function of thickness indicated both the (100) and (111)Si films behave essentially the same way, *i.e.*, the average mobilities show a steady decrease with decreasing film thickness. These studies revealed the strong interrelationships that exist among the various parameters involved in optimizing Si growth on insulators and indicated that growth conditions (*i*) must be optimized for the particular substrate orientation chosen; (*ii*) differ for those substrate orientations which lead to the same Si orientation; (*iii*) are dependent on reactor geometry; and (*iv*) should be optimized for the particular film thickness desired.

Silicon-on-sapphire (SOS) is now over a decade old, having been first announced by our laboratory in 1963 (1). However, only in the last few years has a pronounced interest in SOS been demonstrated.

A major emphasis has been placed on the use of $(01\bar{1}2)Al_2O_3$ as the substrate orientation since it controls the growth of (100)-oriented Si, which is preferred for MOS structures in bulk Si because surface states are minimized; however, better electrical properties have been reported for (111)Si/(0001)Al_2O_3 films grown by chemical vapor deposition (2). The best films were grown at the relatively high temperature of ~1200°C (2). Two other principal orientations that were identified during our early studies (3) as influencing the growth of (111)Si are $(10\bar{1}4)Al_2O_3$ and $\sim(11\bar{2}0)Al_2O_3$. This paper reports the results of a study to compare the properties of (111)Si films grown on these orientations with (100)Si films grown on $(01\bar{1}2)Al_2O_3$. Some studies were also performed on $(11\bar{2}3)Al_2O_3$, which induces Si growth about 7.5° off the (111)Si plane. Substrates cut ~5° off the $(11\bar{2}0)$ plane of Al_2O_3 toward the $[10\bar{1}0]$ direction were used to ensure that the growth was single crystal with the (111) plane of Si parallel to the $(11\bar{2}0)$ plane of Al_2O_3 (3).

Experimental

Except as noted, the Si growth studies involved the formation of films by the pyrolysis of SiH_4-H_2 mixtures in the apparatus depicted in Fig. 1. It consists of a vertical 60 mm OD quartz tube 38 cm long, containing a SiC-covered carbon pedestal ("Ti-Kote," Texas Instruments) which could be rotated and inductively heated; a manifold made from 1/4 in. stainless steel (Type 316) tubing; appropriate flow meters (Brooks Instruments) for monitoring the gas flows; Teflon connectors (Beckman Instruments) to facilitate reactor exchange; and provision for separate evacuation of the flow lines and the reactor. During the working day, a continual flow was maintained in the gas lines; only the reactor portion and connections were evacuated between experiments.

The H_2 carrier gas was Pd-purified, and the He was grade 6™ from Airco. The dopant sources used contained 200 ppm AsH_3 in H_2 (Airco) and 195 ppm B_2H_6 in H_2 carrier gas (Scientific Gas). Temperatures of the SiC-coated carbon pedestal were measured with an optical pyrometer and were not corrected for any apparent emissivity changes caused by the intervening quartz chamber wall. Total gas flows of 6 lpm were used in the experiments described.

The substrates, which in most cases possessed an oval shape, were fabricated from 0.5 in. diameter Verneuil and Czochralski rods obtained from Union Carbide (San Diego, California), and Crystal Optics (Ann Ar-

bor, Michigan). They were oriented at Rockwell and cut and polished at Insaco (Quakertown, Pennsylvania), and at Rockwell. Measurements of film conductivity type, resistivity, carrier concentration, and carrier mobility were made utilizing either the van der Pauw method (4) or the more accurate and conventional Hall-effect bridge method. The Hall-effect bridges etched in Si on a given substrate orientation fortunately were, in most cases, placed in the same direction with respect to the crystallographic axes in the plane of the substrates. The importance of this point is discussed later.

Results and Discussion

Study of autodoping in (100) and (111)SOS films.—Autodoping from the Al_2O_3 substrates has been shown to cause appreciable doping of epitaxial Si films grown in H_2 (5, 6). In order to determine more precisely the extent of this doping in our reactor, a number of intentionally undoped (100)- and (111)-oriented, ~2 μm thick films were grown in H_2 as a function of temperature from 1050° to 1150°C at a growth rate of ~2 μm/min. The carrier concentration data are shown in Fig. 2 for the unannealed films. Each data point represents an average value for data obtained from 1 to 3 samples. Slight changes in growth temperature appreciably altered the extent of autodoping, since the acceptor concentration varied by over two orders of magnitude for growth temperature changes of just 100°C, *i.e.*, $2\text{-}3 \times 10^{15}/cm^3$ at 1050°C to $\sim 3\text{-}5 \times 10^{17}/cm^3$ at 1150°C. Autodoping appeared to be slightly less in (111)Si on $\sim(11\bar{2}0)Al_2O_3$ than for (100)Si on $(01\bar{1}2)Al_2O_3$ for a given growth temperature. Further studies on the effect of Al_2O_3 in a system containing Si are presented as an Appendix to this paper.

Effect of growth temperature on film properties.—The electrical properties of As-doped films grown at a rate of ~2 μm/min in our reactor indicated equivalent quality (111)Si on $(10\bar{1}4)Al_2O_3$ and (100)Si on $(01\bar{1}2)Al_2O_3$ at growth temperatures from 950°-1050°C for donor concentration from 10^{16} to 10^{18} cm^{-3}. When $\sim(11\bar{2}0)Al_2O_3$ was examined as a substrate for (111)Si growth, it was found necessary to use temperatures in excess of 1050°C to obtain reflective n-type films. Determination of the correct carrier concentration for films grown at these temperatures was of course complicated by an autodoping species from the Al_2O_3 substrate, which served to compensate the As added and had to be removed before the net donor concentration could be established. For this reason, an 1100°C anneal first in O_2 and then in N_2 was employed for all films grown at or above 1050°C before measurement in order to render the contaminant electrically inactive.

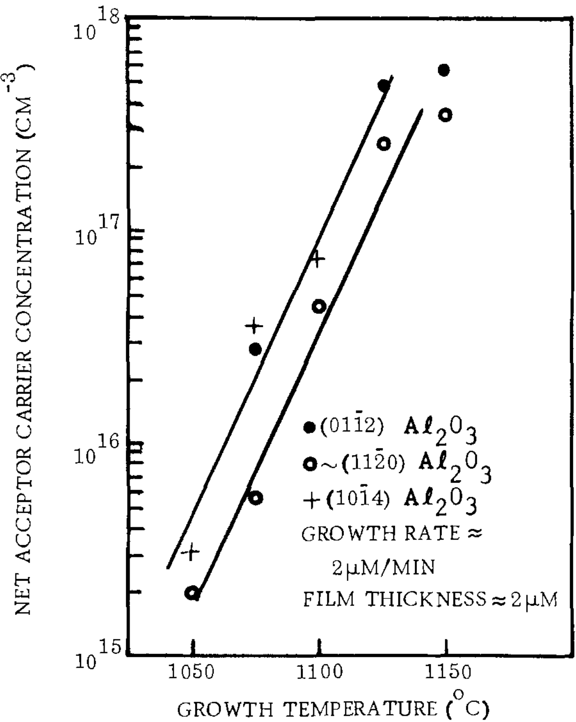

Fig. 2. Variation of net acceptor carrier concentration due to Al autodoping as function of growth temperature for intentionally undoped and unannealed Si/Al_2O_3 films. (Data points are averaged values.)

In Fig. 3, the mobilities of films grown on $(01\bar{1}2)$ and $\sim(11\bar{2}0)Al_2O_3$ substrates are plotted as a function of growth temperature. At each temperature data for a number of films with net donor concentrations between 1 and 5×10^{16} cm^{-3} are averaged; the bars indicate the range of mobilities over which the points are averaged, and the number next to the point indicates how many samples contributed to the average value plotted. It was found that for a growth rate of ~2 μm/min the electron mobility in (100)Si (values of ~500-550 cm^2/V-sec) was nearly independent of growth temperature (T_g) for $1040°C \leq T_g \leq 1100°C$. For (111)Si growth on the Al_2O_3 orientation near the $(11\bar{2}0)$ plane, film mobilities appeared to improve with increasing growth temperature and exceeded those obtained for (100)Si by about 25% (values of 650-700 cm^2/V-sec) at the higher growth temperatures.

Growth of Si on various other Al_2O_3 orientations at high growth temperature was also examined. The $(10\bar{1}4)$ and $(11\bar{2}3)Al_2O_3$ orientations were used as substrates for Si growth at temperatures from 1075° to 1150°C. For film thicknesses of 1.5-1.9 μm and donor concentrations of $1\text{-}2 \times 10^{16}$ cm^3, the $(10\bar{1}4)$ and $(11\bar{2}3)$ orientations yielded films with mobilities of 400-500 cm^2/V-sec over the whole temperature range, values inferior to those measured in the better (111)-oriented films grown on $\sim(11\bar{2}0)Al_2O_3$.

Effect of growth rate on film properties.—Growth rate-mobility data for 2 μm-thick films grown at 1075°C on $(01\bar{1}2)Al_2O_3$ and also on $\sim(1120)Al_2O_3$ are plotted in Fig. 4. The data suggest an improvement in film properties at growth rates exceeding 1 μm/min; the mobility maxima occur in films grown at a rate of about 4 μm/min for $(01\bar{1}2)Al_2O_3$ and about 2 μm/min for films grown on substrates with an orientation near $(11\bar{2}0)Al_2O_3$. These films were grown under conditions of constant dopant gas flow. However, as shown in Fig. 5, an exponential relationship exists between growth rate and carrier concentration. Such a relationship is not expected since the growth rate is a linear function of SiH_4 flow rate. That is, a simple dilution of the

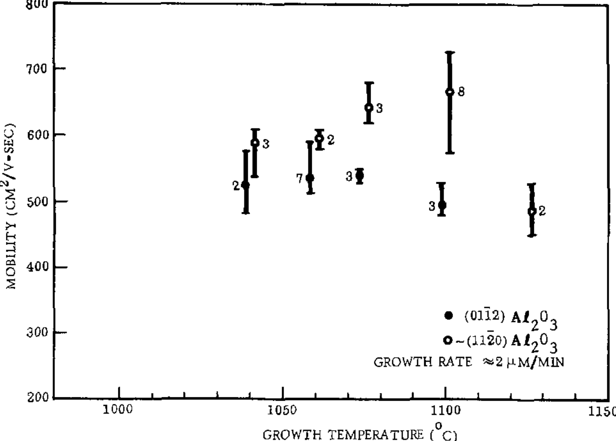

Fig. 3. Variation of Hall mobility with growth temperature for Si/Al_2O_3 films having net donor carrier concentration of $1\text{-}5 \times 10^{16}$ cm^{-3}. (Films were annealed before electrical measurement.)

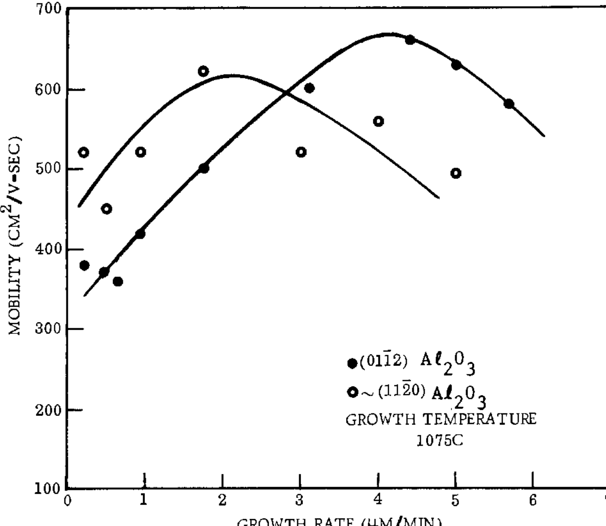

Fig. 4. Variation of Hall mobility with growth rate for n-type Si/Al_2O_3 films grown at 1075°C. (Annealed at 1100°C in O_2 and N_2.)

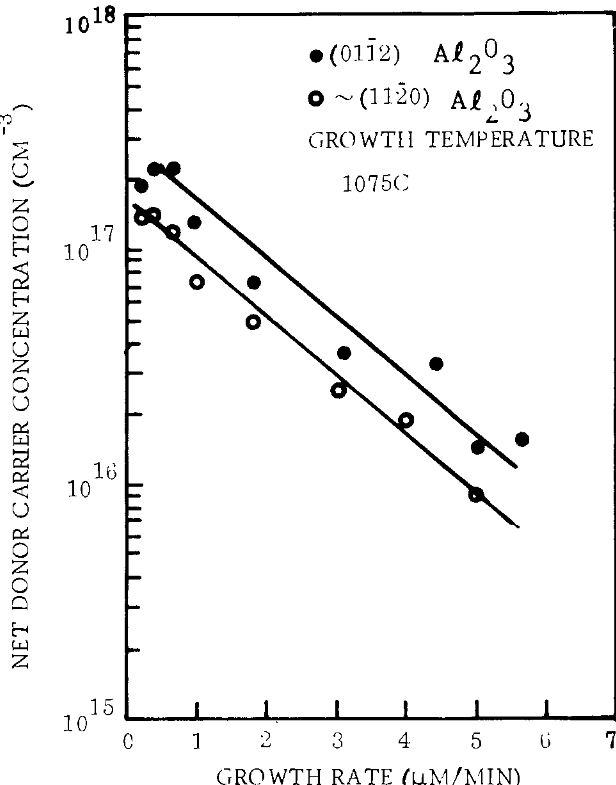

Fig. 5. Variation of net donor carrier concentration with growth rate for Si/Al_2O_3 films grown at 1075°C with constant dopant-gas flow rate. (Annealed at 1100°C in O_2 and N_2.)

dopant gas by the increasing silane flow rate would be expected to lead to a linear variation of carrier concentration with growth rate. In any case, a substantial part of the mobility decrease at the low rate is a consequence of an increasing carrier concentration. Unfortunately, studies relating growth rate to mobility at constant donor concentrations and different temperatures were not made in our reactor. The data, however, do indicate the importance of making gas-phase doping concentrations consistent with growth rate when one attempts to grow a homogeneously doped film by a dual-rate growth process (7).

One can also note from Fig. 5 that the donor concentration measured in films on $\sim(11\bar{2}0)Al_2O_3$ are consistently lower than those grown simultaneously on $(01\bar{1}2)Al_2O_3$. This is consistent with the results on autodoping shown in Fig. 2 and suggests that both donor and acceptor dopants are incorporated less easily into the (111)-oriented Si lattice.

Properties of p-type, B-doped Si/Al_2O_3 films.—Doping experiments with Si films on Al_2O_3 for the purpose of achieving p-type films were undertaken with diborane (B_2H_6) as the source of B. Calibration data for a range of carrier concentrations from $\sim 3 \times 16^{16}$ to $\sim 2 \times 10^{20}$ cm^{-3} were established for ~2 μm thick, p-type Si films grown at ~2 μm/min on $(01\bar{1}2)Al_2O_3$ at 1025°C (unannealed) and on $(01\bar{1}2)$, $\sim(11\bar{2}0)$, and $(10\bar{1}4)Al_2O_3$ at 1075°C (annealed); the data are shown in Fig. 6.

Since the data points essentially define a single straight line for both the unannealed and annealed films, the annealing was effective in removing the p-type autodoping species without disturbing the B-species in the film. Hall mobility as a function of hole concentration for the films is shown graphically in Fig. 7. The electrical properties of the B-doped (100)Si are similar to those previously reported in the literature

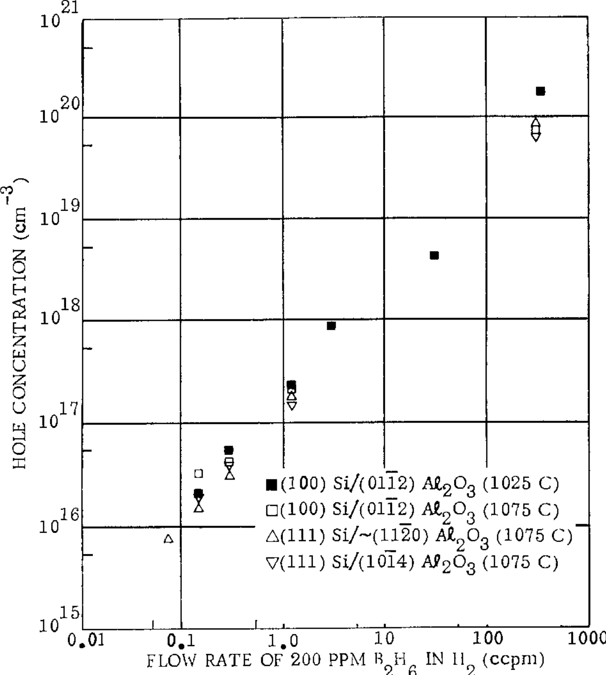

Fig. 6. Calibration curve for growth of p-type Si/Al_2O_3 films using B_2H_6 dopant source. The films were annealed at 1100°C in O_2 and N_2.

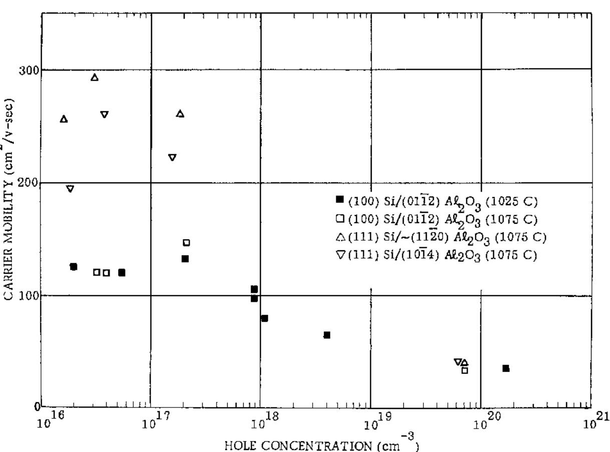

Fig. 7. Electrical properties of p-type Si/Al_2O_3 films doped with boron.

(8) and are equivalent for films of the same carrier concentration grown at 1025° and 1075°C; therefore, either growth temperature appears to be adequate for p-type (100)Si growth.

The electrical data for the p-type films grown on ~(11$\bar{2}$0) and (10$\bar{1}$4)Al_2O_3 were most encouraging, with mobilities exceeding those measured on (01$\bar{1}$2)Al_2O_3 twofold or more for hole concentrations in the 10^{16}-10^{17} cm^{-3} range. The results are close to those values for bulk Si and appear to be the largest yet recorded for Si films only 2 μm thick on Al_2O_3. Almost equivalent properties were obtained for p-type (111) films grown on (10$\bar{1}$4) and ~(11$\bar{2}$0)Al_2O_3. This was surprising since, as previously noted, n-type films grown in H_2 on ~(11$\bar{2}$0)Al_2O_3 were superior to those grown on (10$\bar{1}$4) substrates. Very high mobilities have also been reported for (111)-oriented p-type films grown on (111)spinel (9). These have been explained by a piezoresistance effect due to the compressive stress in the films.

Variations in Si film properties with thickness.—It has been reported on many occasions that the electrical properties of heteroepitaxial semiconductor films tend to be inferior close to the substrate on which growth occurs (10, 11). A comparison was therefore made of the variation of electrical properties with film thickness for relatively thin, annealed, n-type (100) and (111)Si films grown at 1100°C.

From Fig. 8, it can be observed that the carrier concentration remained relatively constant, decreasing only slightly for thinner films, but the average mobilities showed a more pronounced decrease with decreasing film thickness for both orientations. Films that were reduced stepwise in thickness by polishing and then remeasured electrically also showed the same general thickness dependence on average mobility and carrier concentration. The average mobilities for (111)Si films ~0.5-1.0 μm thick grown on ~(11$\bar{2}$0)Al_2O_3 also appear to be slightly superior to those found in (100)Si films grown in our vertical apparatus. However, they are essentially the same as those reported by Cullen and Corboy (12) for (100)Si-on-sapphire grown in their reactor at 1000°C. (See next section.)

Effects of reactor configuration on film properties.—Because of differences in growth reactors found in various laboratories, several experiments were conducted to investigate the effects that different reactor geometry may have on film properties. Experiments were performed on (01$\bar{1}$2)Al_2O_3 and ~(11$\bar{2}$0)Al_2O_3 in a horizontal reactor system which normally would accommodate up to four 2 in. diameter wafers per run. Even though the typical growth rate used in this reactor (~1 μm/min) was not the same as that used most often in the vertical reactor, and the H_2 carrier-gas flows (~40 lpm) were substantially greater than those used in the vertical system (6 lpm), the limited data obtained are considered meaningful because they supported the purpose for which the experiments were performed.

The growth temperature was varied from 960° to 1100°C. The visual appearance of those films grown at 1075° and 1100°C indicated a deterioration of film quality; therefore, only those films grown in the range 960°-1075°C were evaluated electrically.

The electrical data shown in Fig. 9 indicate a uniform increase in electron mobility with decreasing growth temperature for 1.0-1.4 μm thick films grown on (01$\bar{1}$2)Al_2O_3, *i.e.*, from a value of about 325 cm^2/V-sec at 1075°C to approximately 600 cm^2/V-sec at 960°C for carrier concentrations in the range ~2-6 × 10^{16} cm^{-3}.

The mobilities of films grown simultaneously on ~(11$\bar{2}$0)Al_2O_3, on the other hand, showed a maximum of over 600 cm^2/V-sec at ~1050°C, with only a slight decrease at 1030° and 1075°C. The results are different from the data obtained on films grown in the vertical reactor system, for in this set of experiments, (100)-oriented Si films were produced with properties essentially as good as those measured in (111)-oriented Si. It is apparent that the determination of optimum film growth parameters relate to the growth apparatus being employed, and a comparison of results from different laboratories must always be made with this fact in mind.

Anisotropy considerations.—During the latter part of the studies just described, it was established that the electrical properties of SOS are not isotropic in the plane of the film (13, 14). Using a specifically designed double Hall-bridge pattern etched in the Si film so that independent measurements of Hall mobility were made every 18° in the plane of the films, Hughes and Thorsen determined the amount of anisotropy as described by a parameter A [$A \equiv (\mu_{max} - \mu_{min})/\mu_A$, where $\mu_A = (1/2)(\mu_{max} \pm \mu_{min})$] of 9% for (100)Si/(01$\bar{1}$2)$Al_2O_3$ (13) and about 40% for (221)Si/(11$\bar{2}$2)Al_2O_3 (14). Preliminary data indicate anisotropy in mobility for (111)Si films also, averaging 16% for

(111)Si growth on ~(11$\bar{2}$0)Al_2O_3 and 30% for (111)Si growth on (10$\bar{1}$4)Al_2O_3 (15).

These variations in mobility could have led to considerable scatter in the electrical data if circular substrate wafers had been used in these studies prior to the discovery of anisotropy in these films. But, because of the oval shape of the substrate and the operator's tendency to place a square-shaped Hall-effect bridge in approximately the same direction in the Si film relative to the sides of the substrate (and hence to the crystallographic axes of the substrate), it is believed that most of the data obtained can be correlated with the parameter changes made. Since the average anisotropy in mobility for (111)Si on ~(11$\bar{2}$0)Al_2O_3 is only slightly greater (7%) than that found for (100)Si on (01$\bar{1}$2)Al_2O_3, we feel that the higher mobilities measured in 2 μm thick (111)Si films on ~(11$\bar{2}$0)Al_2O_3 grown in the vertical reactor are in fact real and consistent with an improved film quality. A correlation between electrical data and device data is now required to determine if ~(11$\bar{2}$0)Al_2O_3 is a superior substrate orientation for devices made in silicon-on-sapphire.

Summary and Conclusions

An experimental study of the effects of various parameters on the properties of (111) and (100)Si films grown on Al_2O_3 by the SiH_4-H_2 pyrolysis CVD method was carried out in a vertical growth system. It was established that significant autodoping occurs in Si on Al_2O_3 at temperatures greater than about 1050°C.

Essentially equivalent (100)- and (111)-oriented, n-type Si films grew on (01$\bar{1}$2) and (10$\bar{1}$4)Al_2O_3 substrates at deposition temperatures of 950°-1050°C (below autodoping range) and at growth rates of ~2 μm/min.

Al_2O_3 substrates having orientations near the (11$\bar{2}$0) plane, which were not previously used in heteroepitaxy growth parameter studies, were also utilized for (111)Si heteroepitaxy, but required temperatures > 1050°C for the growth of films with good electrical properties. For growth rates of ~2 μm/min, films were obtained with electron mobilities of 600-700 cm^2/V-sec for net carrier concentrations of 10^{16}-10^{17} cm^{-3}, which exceeded the mobilities we obtained on either (01$\bar{1}$2)Al_2O_3 or (10$\bar{1}$4)Al_2O_3. At higher Si growth rates (up to ~6 μm/min) and deposition temperatures T_g, good quality films (μ~500-600 cm^2/V-sec) were also formed on (01$\bar{1}$2)Al_2O_3 (1040°C $\leq T_g \leq$ 1100°C).

At the high growth temperatures it was found necessary to "homogenize" the electrical properties of the films by an O_2, N_2 anneal in order to deactivate the autodoping species.

P-type Si films were also grown using B_2H_6 as the dopant source. As in the case of the n-type films, better films were obtained on ~(11$\bar{2}$0)Al_2O_3 [(111)Si growth] than on (01$\bar{1}$2)Al_2O_3 [(100)Si growth]; Hall mobilities were ~2-3 times larger for films with net hole concentrations 10^{16}-10^{17} cm^{-3}.

A comparison of film properties of n-type films as a function of thickness indicated both the (100) and (111)Si films behave the same way, *i.e.*, the average mobilities show a steady decrease with decreasing film thickness. The average mobilities were slightly superior for ~0.5-1.0 μm films grown ~(11$\bar{2}$0)Al_2O_3.

These studies revealed the strong interrelationships that exist among the various parameters involved in optimizing Si growth on insulators. Evaluation of the electrical properties of Si films on those orientations that produce the best Si overgrowths demonstrated that growth conditions (*i*) must be optimized for the particular substrate orientation chosen; (*ii*) differ for those substrate orientations which lead to the same Si orientation; (*iii*) are dependent on reactor geometry; and (*iv*) probably should be optimized for the particular film thickness desired. In addition, care must be exercised in measurement techniques when using mobility as a figure of merit because of the differences caused by anisotropy considerations.

APPENDIX

In order to examine further the effect of the presence of Al_2O_3 in a system containing Si, two experiments were performed, one in H_2, the other in He. An oval Al_2O_3 wafer (13 × 16 mm) was placed on a ~60 ohm-cm n-type HF-dipped mechanically polished Czochralski-grown Si wafer. The composite was heated in the CVD reactor at a pedestal temperature of 1100°C for 1 hr in H_2 or in He, with these carrier gases flowing at a rate of 5 lpm. For the H_2 case, after the Al_2O_3 was removed, a mesa about 1 μm high which profiled the oval wafer was in evidence, and the Si which had been exposed to the H_2 was eroded considerably. The Si mesa and surrounding area were p-type and etched. Angle-lapping and staining revealed a relatively uniform p-type layer ~2.4 μm thick at the mesa and a somewhat irregularly shaped layer ~1.7 μm thick in the etched area where the wafer was positioned. A van der Pauw measurement of the mesa, which was cut from the rest of the wafer, gave the following properties: ρ = 3.5 ohm-cm; $p = 6.3 \times 10^{15}$ cm^{-3}; μ = 284 cm^2/V-sec.

A subsequent anneal for 1/2 hr in O_2 plus 2 hr in N_2, a process which has usually been found sufficient to deactivate the Al-containing impurity species in thin SOS films, diffused the p-type impurity further into the substrate and at the same time converted the top of the p-type layer to n-type. An additional 18 hr of anneal (1/2 hr O_2 + 17½ hr N_2) almost converted the whole layer to n-type, as evidenced by only a residual stain of the layer at its deepest penetration.

Without Al_2O_3 present in the reactor, another unused piece of the same Si wafer used in the above experiment remained n-type and relatively high resistivity after treatment in H_2 for 1 hr at 1100°C.

Some attack of the Si by Al_2O_3 was also in evidence when He was used as the carrier gas, but the etching was much less severe; essentially no mesa was formed. The Si surface just below the Al_2O_3 was converted to p-type, however, as in the H_2 experiment.

These results demonstrate the need for minimizing the reactions between Si, Al_2O_3, and H_2. They also suggest that some reaction products may be generated during the early stages of Si growth which could affect the mode of nuclei formation, be incorporated into the growing film, and affect the crystallinity of the films at the Si-Al_2O_3 interface. Such impurities may constitute an additional factor in determining the defect structure in SOS films, in addition to that attributed to lattice mismatch and strains at the Si-Al_2O_3 interface. Autodoping can presumably be minimized by the use of an inert atmosphere, lower growth temperatures, and high growth rates to seal the Al_2O_3 surface as fast as possible.

Amorphous CVD Al_2O_3 Films by Ta-Doping and Their Physicochemical Properties

Paul J. Tsang,* Ronald M. Anderson, and Serge Cvikevich

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Tantalum-doped alumina films were deposited by the pyrolysis of a vapor mixture of $TaCl_5$ and $AlCl_3$ in the presence of hydrogen and carbon dioxide in the temperature range of 800°-950°C. The Ta content seems limited to 5.5 mole per cent of Ta_2O_5. The films, with only a minute amount of Ta, are crystalline, having the properties of pure alumina films. When the Ta content exceeds a certain level, the films become amorphous. Amorphous films have an optical index of refraction of 1.68 and a dielectric constant ranging from 9.5 to 12.0. Amorphous films are etchable in the diluted, buffered HF solution and show a d-c conduction governed by the Poole-Frenkel effect.

Chemical vapor deposited (CVD) alumina (Al_2O_3) films, because of their negative dielectric charges (1), have found applications as gate insulators for the conventional, insulator-gated, field-effect transistors (IGFET) (2-4) and as the field insulators for n-channel MOSFET IC's (5). In addition, it has been shown that electrically alterable read-only memory FET's can be fabricated using layered Al_2O_3-SiO_2 gate insulators (6). The capability of alumina to resist radiation damage (7) also makes it attractive for devices used in space applications.

The chemical vapor deposition of alumina films can be achieved by either thermal decomposition of Al organometallic compounds (8) at temperatures below 600°C, or by the pyrolysis of aluminum halides (9, 10) at temperatures higher than 700°C. The alumina films formed at lower temperatures are mostly amorphous, whereas the high temperature films formed by the pyrolysis of Al halides are crystalline.

Generally, films used for device fabrication are deposited above 800°C because they are relatively stable during device processing and possess good dielectric strength. Unfortunately, the grain boundaries of the high temperature crystalline films are potential, long-term failure sites. In addition, the high temperature crystalline films are not etchable by the buffered HF solution, the photolithographic etchant most commonly used in microelectronics fabrication. Extra processing steps are required if these films are used. To provide ease of device fabrication and film integrity, amorphous Al_2O_3 films formed at high temperatures are therefore desired.

Many elements present as impurities are capable of retarding the transformation of the metastable γ-Al_2O_3 phase into the stable α-phase, due to their preference in occupying the tetrahedral sites in the oxygen lattice (11). In addition, the introduction of impurity during film formation may also favor the growth of amorphous films due to an increase in configurational entropy (12), and/or due to the impurity-induced change of film nucleation and growth behavior (13). It may therefore be possible to form amorphous CVD Al_2O_3 films at relatively high temperatures by impurity doping. This paper describes the deposition and physicochemical properties of amorphous Al_2O_3 films doped with Ta and formed in the temperature range that is normally used for forming crystalline pure alumina films.

Experimental

Film deposition.—It is well known that at temperatures above 700°C, CVD Al_2O_3 films and Ta_2O_5 films can be formed by the pyrolysis of $AlCl_3$ (9) and $TaCl_5$ (14), respectively, in the presence of H_2 and CO_2 through the following probable reactions

$$2AlCl_3 + 3CO_2 + 3H_2 \rightarrow Al_2O_3 + 3CO + 6HCl \quad [1]$$

$$2TaCl_5 + 5CO_2 + 5H_2 \rightarrow Ta_2O_5 + 5CO + 10HCl \quad [2]$$

In this work, the formation of Ta-doped alumina was achieved by the pyrolysis of a vapor mixture of $AlCl_3$ and $TaCl_5$. The $AlCl_3$ and $TaCl_5$ vapors were generated by heating $AlCl_3$ and $TaCl_5$ powders.[1]

The film deposition system is shown in Fig. 1. It consists of a reaction chamber, a $TaCl_5$ vapor saturator, an $AlCl_3$ vapor saturator, and feed lines which interconnect the halide vapor saturators through precision flow meters and control valves to allow close control of the $AlCl_3$ and $TaCl_5$ mixture flow to the reaction chamber for film deposition. All the feed lines and valves that connect the saturators to the reaction chamber were heated to 145°-160°C to prevent any halide condensation. A rf heated, silicon carbide-coated

Key words: thin films, dielectric amorphous alumina, Ta-doping, Poole-Frenkel electrical conduction.

[1] $AlCl_3$ powder of 99.999% pure was purchased from Apache Chemical Company and the high purity resublimed $TaCl_5$ powder was purchased from Alpha Inorganics (Ventron).

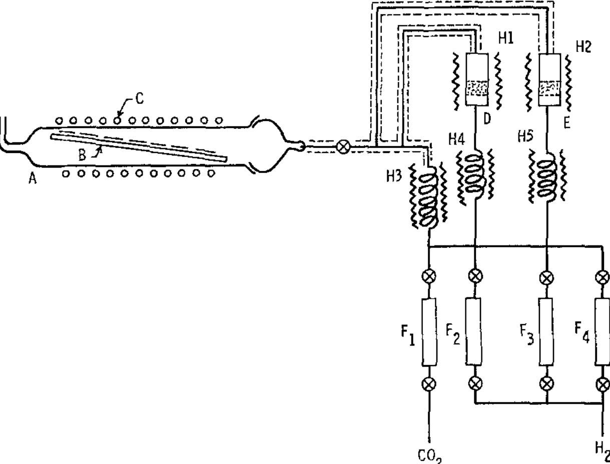

Fig. 1. Film deposition system. A, reactor; B, substrate susceptor; C, rf heating coil; D and E, $AlCl_3$ and $TaCl_5$ saturators; H1 to H5, heaters; F1 to F4, flow meters.

graphite susceptor was used as a film substrate holder and heater. The temperatures of the substrates were measured by a Leeds and Northrup optical pyrometer and are reported in this paper uncorrected. The "true" substrate temperatures are, in general, 15° higher.

The $AlCl_3$ and $TaCl_5$ powders in their vapor saturators were heated to 115° and 130°C, respectively. At these temperatures, $AlCl_3$ and $TaCl_5$ vapors of approximately the same pressure of 4.3 mm Hg were generated (15, 16), and the vapors were then carried out of the saturators by hydrogen gas, which itself was preheated to the saturator temperatures through separate lines and heaters. The saturation levels of the halide vapors in H_2 carrier gas were not measured, but the consistencies of their saturation were checked before and after the Ta-doped alumina film deposition by measuring the growth rate of Al_2O_3 and Ta_2O_5 control films. Hydrogen was also used as a main diluent. It was first mixed with CO_2 and was then heated to about 400°C. The preheated H_2 and CO_2 mixture, after picking up the halide-carrying H_2 flows that come out of the saturators, was fed into the reaction chamber for film deposition.

By varying the flow ratio of $AlCl_3$ and $TaCl_5$ the present system can deposit either pure Al_2O_3 or Ta_2O_5 films or Ta-doped alumina films in the temperature range of 800°-950°C. The films were deposited on either bare or slightly oxidized Si substrates (usually p-type <100>). In the former case, the as-received substrates were chemically cleaned before film deposition, whereas in the latter case, the substrates were chemically cleaned and then oxidized to form 50-60Å of SiO_2 before film deposition. The pure alumina films deposited in this system are polycrystalline and have physicochemical properties similar to those reported by Doo and Tsang (17) and others (18). The pure Ta_2O_5 films deposited in this system at 900°C have an averaged, ellipsometrically measured, index of refraction of 2.30 $\pm$ 0.10 and a dielectric constant (measured at 1 MHz) larger than 43. These are in good agreement with the findings reported by Knausenberger and Tauber (14). Transmission electron microscope (TEM) examinations of these Ta_2O_5 films show that they are β-Ta_2O_5 and have a microstructure similar to that observed by Spyridelis *et al.* (19). The Ta-doped alumina [henceforth called $(Ta)Al_2O_3$] films are smooth and shiny in appearance but show an orange-peel surface texture when examined by a high-power phase-contrast microscope.

The conditions for film deposition were studied. As in the case of pure alumina films, the most important factor affecting film deposition and film quality was the mole (or volume) ratio of CO_2 to the halides. It was observed that a CO_2 to total halide mole ratio of larger than 500 to 1 is required in order to deposit films with good insulating properties. All the films studied in this experiment were deposited with the CO_2 to total halide mole ratio equal to or larger than 800 to 1. In order to obtain homogeneous, single modal films with uniform thickness, the total halide content in the feed gas was kept to less than 0.1% by properly adjusting the flow rate ratio of the main H_2 diluent and the halide-carrying H_2 gas. With this halide concentration in the gas phase and with the $TaCl_5$ to $AlCl_3$ mole ratio being kept at less than 1.8 to 1, the $(Ta)Al_2O_3$ film deposition was similar to that of pure alumina films, *i.e.*, the film growth was predominated by the surface reactions. The growth rate of the films was primarily determined by and slightly varied by the $AlCl_3$ concentration in the gas flow, and was increased exponentially with the decreasing reciprocals of the deposition temperatures in the range of 800°-900°C studied, with an apparent activation energy similar to that of pure alumina films as shown in Fig. 2. The addition of $TaCl_5$ to the gas flow has an effect of reducing the over-all growth rate of the film. As can be seen in Fig. 3, the film growth rate was decreased monotonically with increasing $TaCl_5/AlCl_3$ mole ratio up to 1.8 to 1. When this halide ratio was increased beyond 1.8 to 1, a drastic increase in film growth rate and a change of film morphology from single modal to bimodal were observed. The study of the film deposition was not pursued beyond the halide ratio of 1.8.

The Ta content of the films was determined by the electron microprobe method, using the pure CVD Al_2O_3 and Ta_2O_5 films obtained in the present system as standards. The Ta content of the film increases with the increasing volume (or mole) ratio of $TaCl_5$ to $AlCl_3$ in the feed gas. By assuming full saturation of the halides in the H_2 carrier gas (*i.e.*, each cubic centimeter of H_2 passing through the saturator carries out 4.3/760 cm^3

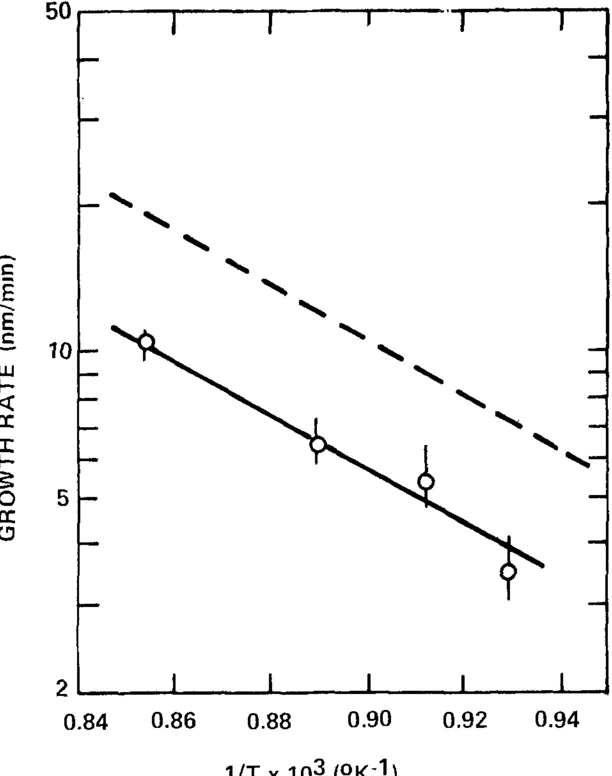

Fig. 2. Arrhenius plot of the growth rate of the $(Ta)Al_2O_3$ films in the temperature range of 800°-900°C (solid curve). The total halide concentration in the gas phase was 2.5×10^{-4} and the $TaCl_5/AlCl_3$ ratio was kept at 1.3 to 1. The dotted curve in the figure shows the growth rate of pure alumina films in the same temperature range.

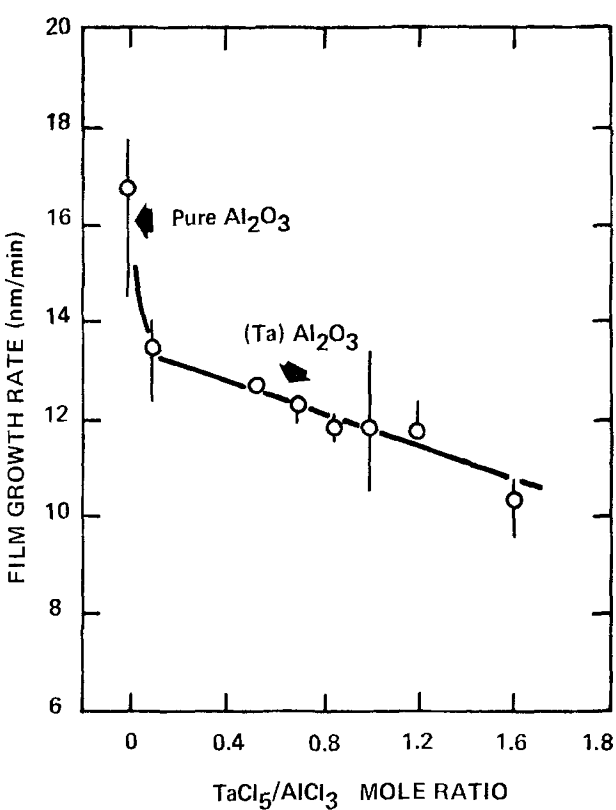

Fig. 3. The growth rate of the $(Ta)Al_2O_3$ film at 900°C as a function of the $TaCl_5/AlCl_3$ mole ratio in the gas phase. The total halide concentration in the gas phase was varied from 1.8-3.0 $\times$ 10^{-4}, with the $AlCl_3$ concentration in the gas phase kept constant at 1.8 $\times$ 10^{-4}.

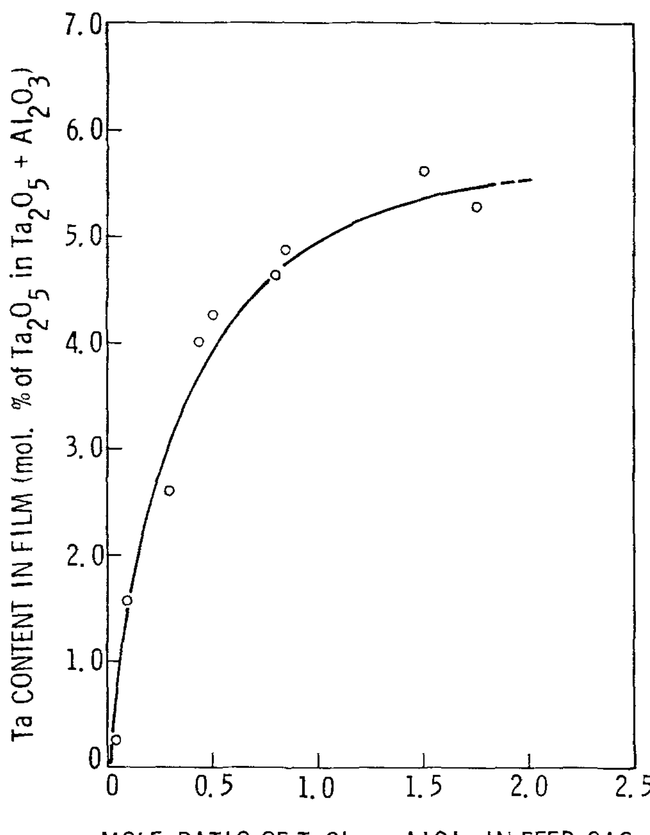

Fig. 4. Ta-content of the $(Ta)Al_2O_3$ film deposited at 900°C as a function of mole ratio of $TaCl_5/AlCl_3$ in feed gas.

halide vapor), we were able to relate the Ta content of the film [in mole per cent (m/o) of Ta_2O_5 in the film] with the volume ratio of $TaCl_5$ to $AlCl_3$ in the feed gas, as shown in Fig. 4.[2] The Ta content of the film rises rather rapidly with the $TaCl_5$ to $AlCl_3$ ratio and levels off at about 5.5 m/o of Ta_2O_5. The saturation of Ta in the film shown in Fig. 4 may be attributed to system limitations. However, since a drastic increase in film growth rate and a change of film morphology from single modal to bimodal were observed as the $TaCl_5$/$AlCl_3$ ratio was increased beyond 1.8 to 1, the saturation level in Fig. 4 may also suggest the limitation of incorporating Ta_2O_5 into the CVD$(Ta)Al_2O_3$ films. A limited Ta solubility in the amorphous $(Ta)Al_2O_3$ films formed by the pyrolysis of Ta-pentaethoxide $[Ta(OC_2H_2)_5]$ and $AlCl_3$ was also reported by Matsuo (20).

Measurements of film properties.—Crystal structure.—X-ray diffractometry and the transmission electron microscope (TEM) were used to study the crystallinity and structure of the films. For the x-ray diffraction study, the as-received films were used. The samples for TEM studies were prepared by back etching the silicon substrate with a mixture of HF + $2HNO_3$ + $3CH_3COOH$ through a wax mask. This leaves a 1 mm circle of unsupported film stretched over the etched hole in the silicon wafer which is suitable for TEM examination.

Film properties.—The etchability of the film in various chemicals was measured at room temperature by observing thickness change with immersion time in the chemical. The film thickness, before and after etching, and the film optical index of refraction were measured by ellipsometry.

[2] Since good consistency of the halide saturation levels in the H_2 carrier gas was seen, the effect of less than full halide saturation in Fig. 2 would be the multiplication of a factor of less than unity to the $TaCl_5$ to $AlCl_3$ ratio. However, the general characteristics of the Ta content *vs.* $TaCl_5$ to $AlCl_3$ ratio would still prevail.

Electrical characteristics.—The conventional MIS (metal insulator semiconductor) type samples were fabricated for electrical measurements. In general, pure aluminum was used as the top electrode; however, in the case of d-c conduction measurements, gold top electrodes were used in some samples to study the effect of injecting electrode material on the film's conduction. To provide ohmic contact to the Si substrate, a layer of Al was evaporated onto its back side and the sample was subsequently annealed at 420°C for 20 min in forming gas. This postmetal anneal also served to reduce surface-state charge of the sample. The capacitance of the MIS samples was measured by a Boonton 710A capacitance meter at 1.0 MHz, while the breakdown strength of the films was measured by the linear *I-V* ramping technique.

In the film d-c conduction measurements, current transients were observed at lower applied voltages which decay to a quasi steady state in 3-4 min. Therefore, in order to eliminate the transient currents, the *I-V* characteristics of the films were obtained by applying an incremental stepwise voltage to the sample and measuring the film current 10 min after the voltage application at each voltage step.

Results and Discussion

Structure and crystallinity of the films.—Films deposited at 900°C with only a minute quantity of Ta doping ($Ta_2O_5 \leq 0.1$ m/o) are crystalline and have the same crystal structure as that of the pure Al_2O_3 films examined. X-ray diffractometry performed on these low Ta content films, and the pure alumina films, produced patterns consisting of the few strongest lines of κ-Al_2O_3. However, the transmission electron diffraction (TED) pattern of the same films contained a very large number of diffraction lines. The list of interplanar spacings generated from the electron diffraction pattern does not completely match those of any of the alumina phases found in the literature although most of the κ-alumina reflections are accounted for. It is

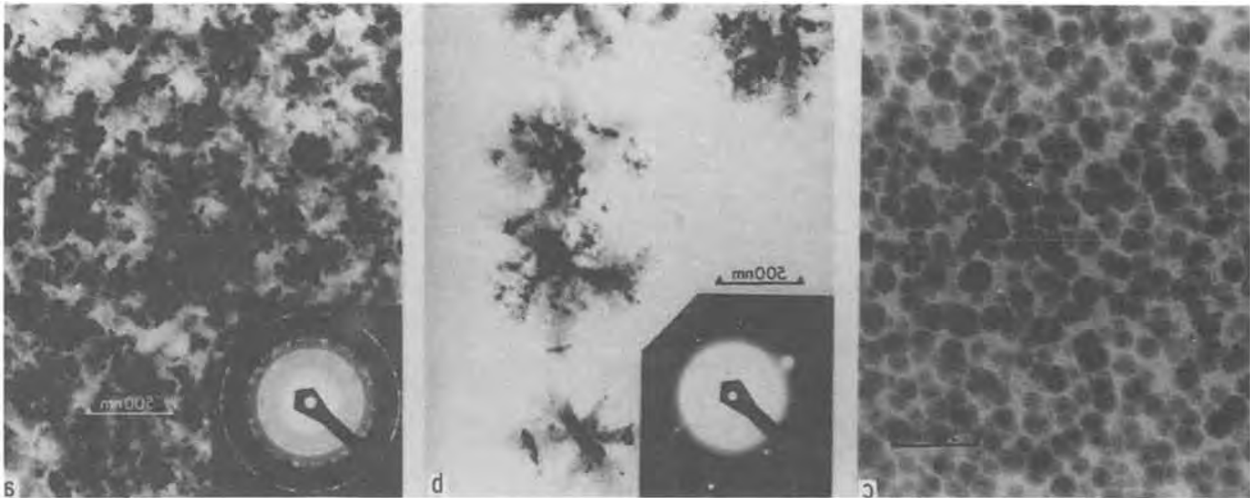

Fig. 5. TEM microstructures of the (Ta)Al_2O_3 films deposited on bare silicon: (a) film deposited at 900°C containing ~4.1 m/o Ta_2O_5 showing amorphous materials appeared at the film's grain boundaries; (b) film deposited at 900°C containing ~5.5 m/o Ta_2O_5, showing amorphous matrix with κ'-crystallites; and (c) film deposited at 825°C containing ~4.8 m/o Ta_2O_5. No TED pattern was obtainable from this film; the dark dots in the photo, indicated by arrow, are believed to be κ'-embryos.

possible that the extra diffraction lines seen in these CVD alumina films resulted from the occupation by Al atoms of the abnormal octahedral sites of the distorted spinel lattice of the κ-alumina giving rise to κ-alumina structure factor forbidden reflections. Since a complete crystallographical determination of the film is out of the scope of the present experiment, detailed structure analysis was not pursued. However, we were able to obtain the lattice parameters of an orthorhombic unit cell which accounts for the majority of the observed reflections. Calculated interplanar spacings are compared with observed reflections in Table I. We will designate the crystal structure of the films as κ'-Al_2O_3, as a variation of κ-Al_2O_3, for the convenience of later discussion. These lightly doped films had grain size of the order of 100 nm.

1.395 (100%)[b]	1.395	004	1.395 (100%)

[a] Interplanar spacings calculated using an orthorhombic unit cell with lattice constants a_o = 9.06, b_o = 8.41, c_o = 5.58Å.
[b] The 1.395 line is the 100% intensity line in the TED pattern and for κ-alumina. In general, the TED intensities differed from the κ-alumina intensities. This is expected, as electron diffraction intensities usually do not track x-ray intensities and the TED pattern shows preferred orientation effect.

A decrease in film crystallinity with increasing Ta content was seen. TEM examination of films deposited at 900°C showed that diffuse grain boundaries were first formed in the film when a small amount of Ta was added. As the Ta content of the films was increased, the diffuse grain boundaries were replaced by amorphous material, Fig. 5a. At about this point, the film ceased to produce coherent x-ray diffraction patterns, although the κ'-alumina pattern was still obtainable via electron diffraction. The amorphous grain boundary width expanded at the expense of the crystalline grains, as the Ta content of the film was increased. The entire film became amorphous when the Ta_2O_5 content of the film reached about 5.5 m/o.

The effects of Ta on the alumina film deposition are, apparently, to inhibit crystal nucleation and to retard grain growth. The effect was more prominent when the films were deposited on oxidized, rather than bare, Si substrates. When the films were deposited directly on bare silicon substrates, there were always some discrete κ'-crystallites included in the film, as shown in Fig. 5b, which, from TEM examination, were nucleated from sites on the silicon surface. The nucleation of the κ'-crystallites was greatly suppressed when the films were deposited on oxidized silicon wafers.

The same crystalline to amorphous structural transition was seen in films deposited at lower temperatures. It was found that by lowering the film deposition temperature the minimum amount of Ta required to produce amorphous films was reduced. At 800°C, complete amorphous films can be found with Ta_2O_5 content as low as 4.5 m/o. Figure 5c shows a near amorphous film deposited at 825°C, with Ta_2O_5 of 4.8 m/o. The film did not show a TED pattern, although TEM revealed bimodal morphology of the film. The dark dots in Fig. 5c are believed to be embryos of κ'-crystallites which were brought out by the silicon etching during TEM sample preparation. Films with the same Ta content would be partly crystalline if deposited at 900°C. On the other hand, it would be completely amorphous if it were deposited at 800°C.

Throughout the entire film structure studies, the β-Ta and/or β-Ta_2O_5 diffraction lines were never observed. Table II summarizes the structural change of the film with its Ta content and the deposition temperature.

Physicochemical properties of the films.—As in the case of the pure alumina films, the etchability of the (Ta)Al_2O_3 films in concentrated HF and NH_4F buffered HF (BHF) solutions depends on the crytallinity of the film. A highly crystallized film (film with well-defined

x-ray and TED patterns) will not be etched by concentrated HF. On the other hand, a completely amorphous film (film structureless under TED examination) can be readily etched by a diluted BHF solution. The etch rate of the amorphous film in a 10:1 BHF solution is about 240 Å/min and seems to be independent of Ta content. The partly crystalline films with a mixture of amorphous and κ'-Al_2O_3 phases can also be etched with diluted BHF but the differences in etch rates of the two phases yields a rough surface. At room temperature, none of the common acids, such as HNO_3, HCl, and H_2SO_4, were found to etch the (Ta)Al_2O_3 films, whether crystalline or amorphous. In hot (185°C) H_3PO_4, uniform etchings of all the (Ta)Al_2O_3 films were observed. The partly crystalline films had an etch rate of approximately 240 Å/min while the etch rate of the amorphous films exceeded 500 Å/min.

The measured values of the index of refraction, n, of the crystalline and partly crystalline films were scattered; they fell in the range of 1.70-1.80. On the other hand, the index of refraction of the amorphous films remained a consistent value of between 1.66 to 1.68 without regard to the Ta content of the film.

Dielectric characteristics of the films.—The dielectric constants of the films were calculated from the capacitance and the thickness of the films. The dielectric constant K of the crystalline and partly crystalline films ranged from 8.0 to 10.0. No correlation between K and the Ta content of the film could be found. The dielectric constants of the amorphous films were found to range from 9.5 to 12.0, and seemed to increase slightly with Ta content of the film.

The dielectric breakdown strength E_b of the films, measured from the Al-(Ta)Al_2O_3-Si (MAS) structures, was found to be 5-7 MV/cm. E_b's measured on the Al-(Ta)Al_2O_3-SiO_2-Si (MAOS) structures (with 55Å underlying SiO_2) were, in general, larger than 7.0 MV/cm. Table III summarizes the physicochemical properties of the film.

The C-V characteristics of the Al-(Ta)Al_2O_3-Si (MAS) diodes are shown in Fig. 6. Curve (a) shows a typical C-V plot of a MAS diode with a highly crystallized, low Ta content (Ta)Al_2O_3 film. Except for the "sense" of the C-V hysteresis, it is very similar to that of a MAS diode with a pure Al_2O_3 film. From the C-V

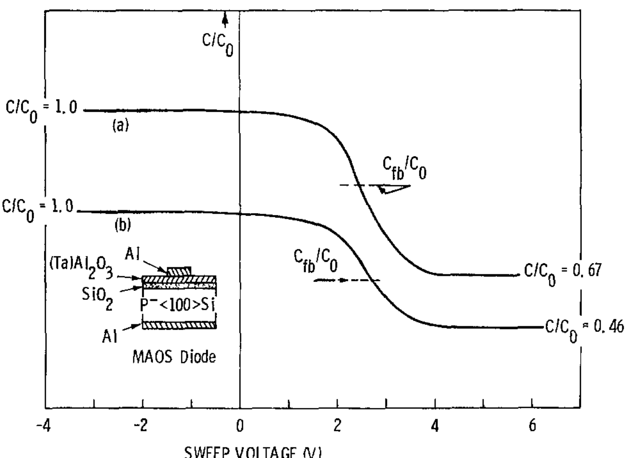

Fig. 7. C-V characteristics of MAOS capacitors: (a) with partly crystalline film; (b) with amorphous film.

hysteresis sense, it appears that acceptor-type, slow surface states exist at the Si-(Ta)Al_2O_3 interface. The density of these surface states appears to increase with the decreasing crystallinity of the film. This is seen in the extremely large C-V hysteresis in the MAS diodes with the partly crystalline film [Fig. 6, curve (b)] and with the amorphous film [Fig. 6, curve (c)]. The assumption of the existence of surface states at the Si-(Ta)Al_2O_3 interface is further confirmed by the absence of C-V hysteresis in the MAOS diodes (Fig. 7).

From the positive flatband voltage of the MAS and MAOS diodes examined, it was found that negative charges of the order of 10^{12} q/cm^2 exist in the (Ta)Al_2O_3 film and/or at the SiO_2-(Ta)Al_2O_3 interface. In the MAS diodes, the dielecric charge seems to decrease with the crystallinity of the films. In the MAOS diodes, the crystallinity of the film has little effect on the dielectric charge level, Table IV.

D-C conduction of the films.—Figure 8 shows the d-c conduction of an amorphous film deposited at 800°C. The ln (J/E)'s, where J is the current density and E is the applied field, were plotted against the square

1206-2	MAOS	+2.70	1.10 × 10^{12}	Amorphous

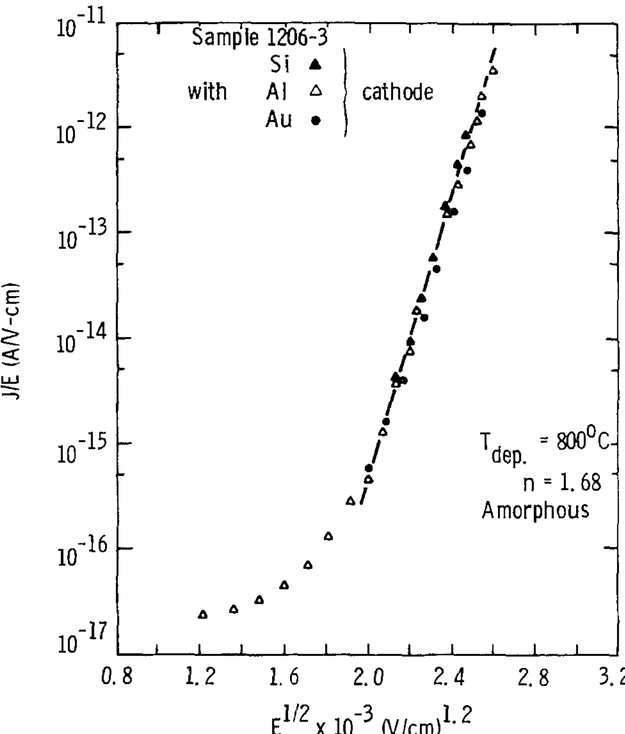

Fig. 8. J-E characteristics of an amorphous film deposited at 800°C.

root of the applied field. It can be seen that (*i*) a linear relationship between ln (J/E) and $E^{1/2}$ exists at fields higher than 3.5×10^6 V/cm; and (*ii*) J is independent of the injecting electrode material. The exponential dependency of film current density on $E^{1/2}$ and the insensitivity of J on the electrode material indicate that the conduction is controlled by the Poole-Frenkel (PF) effect (21). The slope $\mathcal{S}_{PF}$ of the ln (J/E) *vs.* $E^{1/2}$ plots shown in Fig. 6 yields a value of 1.6×10^{-2}.

It is known that the PF effect (21) arises from the field-assisted thermionic emission of electrons (or holes) from the coulombic traps in the films. The PF conduction of a film that contains only coulombic traps takes the form of Eq. [3] (22), which has a slope $\mathcal{S}_{PF}$ of the ln (J/E) *vs.* $E^{1/2}$ plot equals to $\beta_{PF}/2kT$, where $\beta_{PF} = (e^3/\pi\epsilon_0\epsilon_f)^{1/2}$ is the Poole-Frenkel constant

$$J = e\mu E(N_cN_d)^{1/2} \exp - (\psi_d - \beta_{PF}E^{1/2})/2kT \quad [3]$$

where e = electric charge, μ = charge (electron) mobility, N_c = density of states of the film's conduction band, N_d = density of the film's coulombic traps, β_{PF} = Poole-Frenkel constant, and ψ_d = energy of the film's coulombic trap.

The PF constant and the slope of the ln (J/E) *vs.* $E^{1/2}$ plot, can be calculated by knowing the dynamic dielectric constant ϵ_f of the film, or the films' optical index of refraction, n, since to the first approximation, the dynamic dielectric constant of the film equals the square of the film's optical index of refraction (23). Using the measured value $n(=1.68)$ of the 800°C film, a theoretical $\mathcal{S}_{PF}$ of 0.785×10^{-2} is calculated, which is only half of the experimental value. The large experimental $\mathcal{S}_{PF}$ seen in the film can be explained if, besides the coulombic traps, the existence of neutral traps in the films is assumed (24). In this case, the Poole-Frenkel conduction of the film takes a different form due to the change of the Fermi energy caused by the presence of neutral traps. With the coulomb traps, of density N_d, and neutral traps, of density N_t, coexisting in the film, the Poole-Frenkel current density J takes the form of Eq. [4]

$$J = e\mu N_c(N_d/N_t)^{1/2} \exp - (\psi_d - \beta_{PF}E^{1/2})/kT \quad [4]$$

where N_t is the density of film's neutral traps, which has a slope of the ln (J/E) *vs.* $E^{1/2}$ plot equal to β_{PF}/kT, and yields a value of 1.57×10^{-2} if $n = 1.68$ for the 800°C films is used for calculation. This is in very good agreement with experimentally obtained values.

The current-temperature measurement of the films at constant fields shows an exponential dependency of the conduction current with the reciprocal of the measuring temperature. From the ln (J/E) *vs.* $1/T$ plots, the apparent activation energy of the film conduction, ϕ, was obtained. ϕ was found to vary linearly with $E^{1/2}$, as expected from Eq. [4]. Extrapolating the ϕ *vs.* $E^{1/2}$ curve to zero field yields the coulombic trap energy of 1.80 eV below the conduction band of the film.

Similar I-V characteristics were seen in the films deposited at higher temperatures. However, the slope of their ln (J/E) *vs.* $E^{1/2}$ plots were smaller, ranging from 1.14×10^{-2} to 1.3×10^{-2}. In addition, a small dependency of J on the injecting electrode material was also seen. In the films deposited at higher temperatures, some κ'-(Ta)Al_2O_3 crystallites were always present in the amorphous film matrix. It is possible then that these crystallites increase either the relative neutral trap density or the dynamic dielectric constant, or both. Both of these effects would result in a reduction of the slope of the Poole-Frenkel plot of the film (24, 25).

Summary

Present work has shown that Ta-doped Al_2O_3 films can be formed by the pyrolysis of a vapor mixture of $TaCl_5$ and $AlCl_3$ in the presence of hydrogen and carbon dioxide in the temperature range of 800°-950°C. The maximum Ta doping level of the 900°C films appears to be limited to 5.5 m/o of Ta_2O_5. With only a minute amount of Ta, the films are crystalline, having the properties of pure alumina films. When the Ta content exceeds a certain level, the film becomes amorphous. The amorphous films have a smaller optical index of refraction and a slightly larger dielectric constant, as compared with pure alumina films. Amorphous films are etchable in diluted, buffered HF solution at room temperature.

Probably due to the smaller energy bandgap (20), the d-c conduction of the amorphous films was found to be governed by the Poole-Frenkel effect. The energy level of the coulombic traps was found to be 1.80 eV from the conduction band of the film.

The films have negative dielectric charge and good dielectric properties in general. The amorphous film's etchabilty, in buffered HF solution, makes its use more attractive for microelectronic applications.

Flame Fusion Growth of Spinel and Sapphire Crystals for ESFI SOS Technology

R. Falckenberg

Siemens AG, Forschungslaboratorium, München, Germany

ABSTRACT

A modified flame fusion process has been developed to grow crystals at low cost for use as substrate for the ESFI® SOS technology. Mg-Al spinel and sapphire single crystals with diameters up to 50 mm have been grown. Differences between both kinds of crystals are described concerning the behavior during the widening phase and the cooling phase of the growth process. Crystalline perfection was investigated in both crystals by the x-ray topography.

Mg-Al spinel as well as sapphire crystals are used as an insulating substrate material for the ESFI® SOS technology (1). For the synthesis of these crystals we investigated the flame fusion process, because it is a technique requiring no crucibles. Therefore it offers a possibility of lower costs compared to the Czochralski method, especially if iridium crucibles have to be used. As compared with crucible-grown crystals, the perfection of Verneuil crystals is worse; the electrical properties, however, of silicon films deposited on both kinds of substrates (2-4) do not show a significant difference. Verneuil sapphire (5) and spinel are produced on a large scale for jewels and bearings; severe limitations, however, exist especially as far as crystals of large diameter and suitable orientation are concerned. The diameter required for substrate wafers is between 50 and 75 mm; the orientation is <100> and <$\bar{1}$012> for Mg-Al spinel and sapphire, respectively.

Two phenomena can be observed, if such crystals are grown by the flame fusion process: (*i*) cracking of the crystals during the cooling down phase and (*ii*) melt runover during the widening phase of the growth process.

With spinel crystals, it could be shown that cracking can be avoided by modifying the technique (6). The idea of the modification is to essentially exclude the temperature shock a crystal suffers at the end of the growth process when the flame is quenched. This is done by a ceramic furnace insert which deflects the flame gases immediately below the growth front of the growing crystal; from the beginning of the growth process, the bulk of the crystal is in thermal equilibrium with this insert. During the cooling down, the cooling rate is determined by the heat capacity of the insert. By this method, even the stoichiometric variation of Mg-Al spinel could be grown (Fig. 1).

The phenomena of melt runover can be understood by considering a model which explains the mechanism of crystal widening (9). According to this model an increase in flame power leads to remelting of a thin layer of already crystallized matter immediately below the growth front. The excess melt runs down at the crystal rim and forms a protrusion along the solid-liquid transition line. This line goes around the top of the crystal. The lower part of the protrusion solidifies. This model conception requires the radial temperature gradient at the solid-liquid transition line to stay below a certain critical magnitude, if the formation of a protrusion that is widening of the crystal is to occur.

Now alone the fact that a large crystal diameter requires a large growth chamber leads to low wall temperatures inside the growth chamber and consequently to an increase of the temperature gradient in question. Device parameters affecting the gradient are furnace insulation, multiple burners (10-12), displaceable heat shields and additional heating of the side walls of the growth chamber. An example of a displaceable insert device and additional heating for the modified flame fusion technique is shown schematically in Fig. 2. In contrast to afterheaters (13-16), which are thought for an *in situ* annealing of a crystal after the growth process, additional heating during crystal growth has to be confined to side walls of the growth chamber situated at (and above) the level of the solid-liquid transition line of the crystal. Additional heating below this level

Key words: flame fusion process, spinel, sapphire, SOS, ESFI.

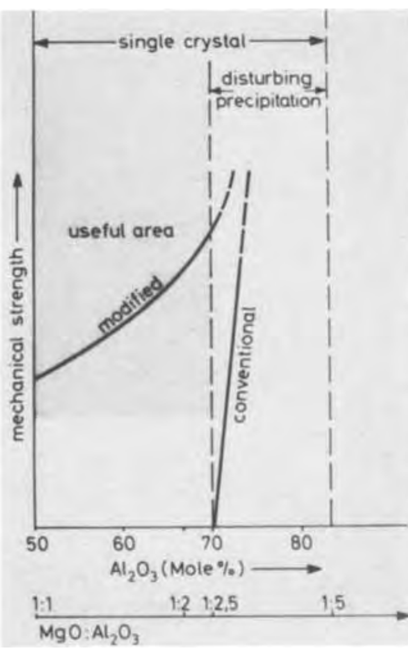

Fig. 1. Spinel substrate growth by flame fusion. The useful area is limited by too low mechanical strength (7) and by precipitations (8) arising during thermal treatment which disturb the epitaxial growth of silicon films.

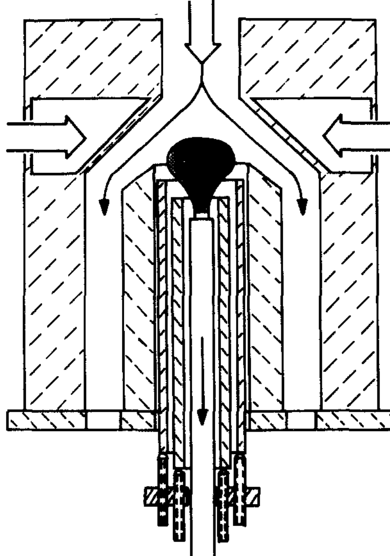

Fig. 2. Furnace with telescopic insert and additional heating of the side walls of the growth chamber for the growth of large diameter crystals.

would, at the high temperatures required, lead to an unstable growth situation due to the decrease of the axial temperature gradient along the crystal.

In Table I the results are shown which were obtained with spinel of a molar composition MgO: Al_2O_3 = 1:2 and with sapphire. All the changes of the device parameters shown are acting in a direction as to keep the radial temperature gradient at the level of the solid-liquid transition line below a critical value. Above this value widening of the crystal would not be possible without melt runover. In a displaceable heat shield device as depicted in Fig. 2 but without additional heating, spinel crystals could be grown up to a diameter of 50 mm (Fig. 3). In the identical device, sapphire crystals could be grown only up to a diameter of 38 mm; trying to enlarge the diameter further led to melt runover. According to the model of crystal widening, the radial temperature gradient had to be further decreased. With the device shown in Fig. 2 we

Table I. Influence of device parameters on the diameter of Mg-Al spinel and sapphire crystals

Device parameters	Maximum crystal diameter [mm]	
	spinel	sapphire
poor furnace insulation, 2-tube burner	20	—
furnace insulation reinforced, 2-tube burner	35	—
furnace insulation reinforced, 3-tube burner	40	—
furnace insulation reinforced, 3-tube burner, telescopic insert	50	38
additional heating of side walls	—	53

used additional oxyhydrogen burners heating the side walls of the growth chamber. In this way sapphire crystals with a diameter up to about 50 mm could be grown (Fig. 3). A further enlargement was not possible in this device because of the inner diameter of the growth chamber being only 60 mm.

At the end of the growth process the flame was quenched. The spinel crystals obtained were mechanically stable; annealing before machining was not necessary. Sapphire crystals of <$\bar{1}$012> orientation cracked if the diameter was larger than ~45 mm; strength and diameter could be increased further by choosing a different orientation, *e.g.*, <$\bar{1}$010>.

For x-ray topography spinel and sapphire crystals were cut into wafers perpendicular to the growth axis. The spinel samples were lapped with SiC, polished with Al_2O_3, thoroughly cleaned with Ultrasonics, etched with hot phosphoric acid, treated with sulfuric acid, and rinsed with distilled water. The final thickness of the samples was 300 μm. With the sapphire slices, lapping as well as polishing was done with diamond paste. Figure 4 shows the x-ray topographies demonstrating the crystal quality. The spinel crystal shows a number of subgrains with deviations in orientation from the growth axis <100> of up to 2°. The sapphire crystal essentially shows only tensions with a deviation from the growth axis not exceeding 1°.

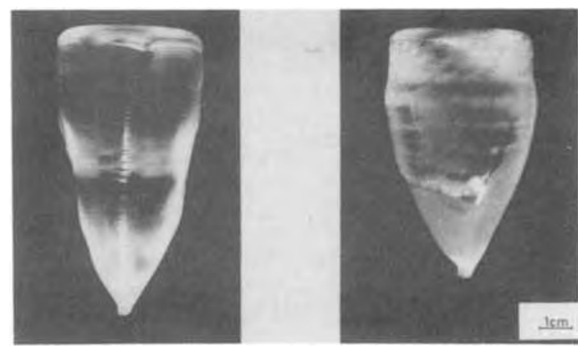

Fig. 3. Mg-Al spinel single crystal (molar composition MgO:Al_2O_3 = 1:2) and sapphire crystal, grown by the modified flame fusion process. Orientation <100> and <$\bar{1}$012>, respectively.

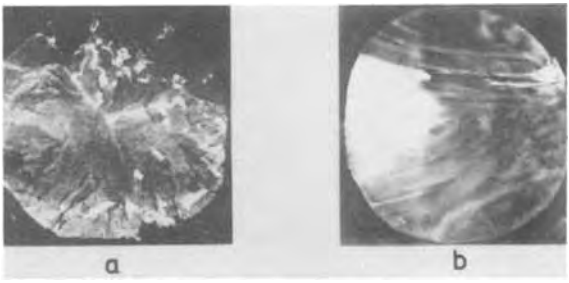

Fig. 4. X-ray topographies (Lang mode) of Mg-Al spinel (a) and sapphire (b), the reflecting planes being {400} and {012} respectively. Radiation Mo K α_1.

Growing spinel and sapphire distinct differences have been found in the way the crystals behaved during the widening phase as well as during the cooling down phase of the growth process. Different behavior in the diameter increasing may be due to differences in the thermal conductivities, emissivities, and *IR* absorptions; values which apply at high temperatures are known only for the *IR* absorption which indeed is lower for sapphire than for spinel. About the sensitivity of cracking measurements with polycrystalline Al_2O_3 material have been conducted by Schwartz (17), there are however no investigations of Mg-Al spinel, which could be compared with these results.

MOS (Si-Gate) Compatibility of RF Diode and Triode Sputtering Processes

A. K. Sinha

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Using a Si-gate CMOS tester the MOS compatibility has been demonstrated of a metallization process involving triode sputter etch cleaning of Si prior to PtSi contact formation, triode sputter deposition of Ti/TiN/Pt layers, and rf diode sputter etching of the Pt using Ni as a sputter etch mask. The radiation damage induced in the gate regions of CMOS capacitors by each step of this metallization process has been evaluated, and the surface states and oxide charge resulting from the damage have been shown to be completely annealable using hydrogen. Triode sputter etch cleaning of the Si prior to PtSi formation was found to introduce considerable radiation damage. All of this damage could be removed after sintering and stripping the unreacted Pt by a hydrogen anneal at a temperature in the range of 375°-400°C and for times in the range of ½ to 1 hr. Subsequent triode sputter deposition of Ti/TiN/Pt leads to the generation of only a small peak ($\sim$1-2 $\times$ 10^{10} cm^{-2} eV^{-1}) in the N_{ss} distribution in the lower half of the bandgap. Sputter etching of Au and Pt in an rf-diode system at rf power levels of 2 W cm^{-2} (sputter etch rate $\sim$900 Å/min for Au) also leads to considerable radiation damage. However, for a lower rf power of $\sim$1.2 Wcm^{-2}, which is practical if Pt only is sputter etched, little additional damage is observed over and above that induced during triode sputter deposition of Ti/TiN/Pt. Our results indicate that if a hydrogen anneal is performed prior to the final metal deposition (*i.e.*, prior to the structure being sealed if a Si_3N_4 layer is used), then excess hydrogen can be trapped in the SiO_2 and poly-Si layers. A low temperature inert ambient anneal (*e.g.*, 325°C, 1 hr, vacuum) can then be used subsequent to final metal deposition, during which hydrogen is redistributed, neutralizing any surface states at the Si/SiO_2 interface.

A recent technology for Si_3N_4-sealed MOS-LSI devices utilizes chemical vapor deposited (CVD) poly-Si for the first level conductor (gates) separated from the second level metallization (contacts and interconnections) by an intermediate dielectric layer consisting of CVD SiO_2 followed by Si_3N_4 (1). The second level metallization processing involves the use of filament evaporation to form Pd_2Si/Ti/Pd. Evaporation was chosen over sputtering because (*i*) sputtering as opposed to filament evaporation can cause radiation-induced damage (2), leading to unwanted interface states and trapped charge in the MOS structures, and (*ii*) it was considered very difficult to anneal out any radiation damage since the combination of metal contacts and Si_3N_4 in the intermediate dielectric layer seals the device from the hydrogen required for low temperature (< 450°C) annealing of the interface states (3, 4). Sputter deposition has certain obvious advan-

Key words: heat-treatment, LSI processing, metallization, uniform gold process.

tages though, an important one being that the step coverage is better than that usually obtained by evaporation (5). Poor step coverage by second level metallization is especially undesirable in the contact areas, since it can provide paths for migration of impurities such as Na and Au.

The objective of the present work was (*i*) to characterize any radiation-induced damage in Si-gate MOS structures due to triode sputter deposition and etching, and rf diode sputter etching, and (*ii*) to devise annealing schemes that would eliminate such damage in Si-gate devices sealed with Si_3N_4. For this purpose, a realistic test vehicle was used in which most of the thin gate oxide areas are covered by layers of poly-Si and intermediate level dielectrics.[1] The uniform gold process (7) was utilized for metal pattern generation for second level metallization. This process has been successfully used for metal gate MOS and bipolar devices. For bipolar devices, the metallization scheme consists of PtSi/Ti/TiN/Pt/Au which is metallurgically more reliable than the Pd_2Si/Ti/Pd/Au system. The uniform gold process is LSI compatible, since only one critical photoresist step is required as opposed to two for the standard Pd or Pt etch processes. The process studied involves triode sputter etch cleaning prior to PtSi contact formation, triode sputter deposition of Pt for PtSi, triode sputter deposition of Ti, TiN, and Pt layers, and electroplating of Au and Ni. The Au and Pt layers are removed by sputter etching in an rf diode system using selectively plated Ni as the mask. Each of the steps and combinations, thereof, have been evaluated with regard to the radiation-induced damage they produce in the above-mentioned MOS structure. An effective annealing scheme has been devised which utilizes intentionally trapped hydrogen to anneal out interface states in sealed MOS structures.

MOS Test Structure and Processing

Figure 1(a) shows a photomicrograph of a completed chip of the CMOS tester; the upper left corner shows the MOS capacitors on n-Si substrates and on the p-tub. Details of the MOS capacitors including metal contacts (rectangular-shaped pads, 4 × 10 mil, over square window, 3 × 3 mil) to the poly-Si electrodes (area = 10^{-3} cm^2) and that (square-shaped pad, 4 × 4 mil over window, 3 × 3 mil) to the p-tub are shown in Fig. 1(b), whereas Fig. 1(c) shows schematically a cross section through the unmetallized portion of the two capacitors, including the n^+ and p^+ guard rings. The Si substrates consisted of <100> n-type material doped with As to $N_D \approx 1.5 \times 10^{15}$ cm^{-3} whereas the p-tubs were doped with B to $N_A \approx 1.5 \times 10^{16}$ cm^{-3}. The gate oxide (1000Å thick) was grown on a freshly exposed Si surface prepared by stripping 1μ thick steam-oxide off the gate areas. The oxidation was done in HCl-cleaned quartz tube furnaces in a dry O_2 ambient at 1100°C (40 min) following which the oxidized Si wafers were annealed in Ar, also at 1100°C (30 min) using the same furnace. The first level (gate) metallization consisted of poly-Si doped with P to a sheet resistance of ~10 ohm/□. The poly-Si electrodes were defined using steam-grown oxide (2500Å) as a mask. The p^+ areas ($N_A \sim 2 \times 10^{19}$ cm^{-3}) were formed using 1000Å of B-doped "Silox" oxide (followed by 2000Å of undoped SiO_2, both made by reacting SiH_4 and O_2 at 480°C) as a diffusion source, with a drive-in at 1100°C (2 hr, N_2). Next, n^+ areas ($N_D \sim 10^{20}$ cm^{-3}) were doped using PBr_3 (1100°C, 30 min). The intermediate dielectric layer separating the first level poly-Si metallization from the second level metallization normally consists of a composite layer of 1μ SiO_2 and 1-2000Å Si_3N_4 through which windows are opened down to the diffused Si areas as well as to the poly-Si. In the present experiments, the Si_3N_4 layer was omitted. However, the annealing schemes were devised keeping this Si_3N_4-sealing layer in mind.

The second level (contact and interconnection) metallization consists of PtSi ohmic contacts to n^+ and p^+ Si areas and to poly-Si, Ti/TiN/Pt/Au interconnections up to the termination areas, where a third level of metallization (beam leads) is built up by selectively electroplating thick Au beams (~12μ). The characteristics of the sputtering stations (8) used in our experiments are given in Table I.

Finally, the back side of the Si wafers was cleaned and metallized with evaporated Al to form a large area ohmic contact to the n-Si substrate. Contacts to the p-tub were provided on front side of the wafer, along side each n-channel capacitor as shown in Fig. 1(b).

[1] Extensive studies were recently carried out by McCaughan *et al.* (2) on apparently "unannealable-degradation" of thin oxide films and interfaces due to various sputter deposition and back-sputtering processes; however, their test structures involved direct exposure of the gate oxide to various plasmas, following which the gate electrodes were evaporated.

MOS Measurement Technique

For MOS measurements, the test facility consisted of an Electroglas 910 prober equipped with a Temptronix TP35 thermochuck; the whole apparatus was completely enclosed in a dry N_2 glove box containing air interlocks. High frequency (1 MHz) C-V measurements were made at sweep rates of 100 mV/sec and quasi-static measurements were made at sweep rates of 20 mV/sec using the slow-ramp technique described by Kuhn (9). On a limited number of samples, mea-

Table I. Characteristics of the triode and rf diode machines/processes used in the present work

(A) Triode machine
Plasma in the Ti confinement tube: 80V, d.c., 10A
Ta filament (cathode of confinement tube): 54A, a.c.
Ar pressure: 2μ

(a) Sputter etch cleaning mode
Substrate table (Al coated with Pt): 500V peak-to-peak, rf (~250W rf power)
Catch plate (stainless steel) grounded
Si sputter etch rate ≃400 Å/min

(b) Sputter deposition mode
Target (Ti or Pt, 12 in. diam): −500V, d.c.
Substrate table: grounded through the rf power supply
p_{N_2} for TiN: 7×10^{-5} Torr
Deposition times: 1 min for 500Å Pt
3½ min for 1000Å Ti
2 min for 100Å TiN
3 min for 1500Å Pt

(B) Rf diode sputter etching machine
Rf power: 2 Wcm^{-2} at 13.7 MHz (14 in. diam cathode)
Cathode self-bias: 1800V peak-to-peak, −900V, d.c.
Pressure: 20μ (80% Ar, 20% air)
Cathode/anode spacing: 2 in.
Au sputter etch rate: 900 Å/min

surements were also made of the minority carrier storage time, oxide breakdown voltage, and the mobile charge density. The storage times were determined by pulsing the MOS capacitors into deep depletion and then plotting the recovery of inversion capacitance as a function of time.

The high frequency and quasi-static C-V data were analyzed in the manner described, *e.g.*, by Wagner and Berglund (10). The Si-doping level $N_{D,A}$ was estimated from the measured inversion capacitance, C_{inv} (Fcm^{-2}) and the flatband voltage, V_{FB}, was estimated from the calculated flatband capacitance C_{FB}. For nonideal C-V curves, the net oxide charge, Q_t (cm^{-2}) at flatband can be calculated using the relationship (11)

$$Q_t = (\phi_{MS} - V_{FB}) \cdot \frac{C_{ox}}{q} \quad [1]$$

where ϕ_{MS} is the work function difference between the metal gate and the Si-substrate (for n^+ poly-Si, its Fermi level was assumed to coincide with the Si-conduction band edge), C_{ox} is the oxide capacitance (Fcm^{-2}), and q is the electronic charge. This simple equation does not allow one to separate the true fixed charge, Q_{SS} (always positive) from charges (N_{st}, positive or negative) trapped in the surface states. The latter are responsible for distortions in the high frequency C-V curves. The interface states density, N_{SS} ($cm^{-2}\,eV^{-1}$) was calculated from the dispersion in the quasi-static and high frequency curves, in accordance with the relationship (12)

$$N_{SS} \doteq \frac{C_{ox}}{q} \cdot \left[\frac{1}{1/C_{qs} - 1} - \frac{1}{1/C_{hf} - 1} \right] \quad [2]$$

where C_{qs} and C_{hf} are normalized values (on a scale of 1.0, which represents the accumulation capacitance) of the quasi-static and the high frequency capacitances, respectively, at a given gate bias. The N_{SS} results from Eq. [2] are truly valid only in the potential range extending from about flatband point to the midgap. In a number of cases, the quasi-static C-V curves were analyzed in detail to give N_{SS} as a function of the relative surface potential, ψ_S, which was calculated from the area under the quasi-static curve (12)

$$\psi_S = \int_{V_0}^{V} [1 - C_{qs}] \cdot dV \quad [3]$$

The N_{SS} *vs.* ψ_S results for p- and n-channel capacitors were plotted on the same graph labeling $\psi_S = 0$ at midgap, so that $\psi_S(FB) \approx + |\phi_F|$ for the p-channel and $- |\phi_F|$ for the n-channel capacitor. Positive values of ψ_S then signify the upper half of the bandgap and the negative values represent the lower half of the bandgap.

The Over-all Metallization Process

Figure 2 shows typical high frequency C-V curves (solid lines) for p- and n-channel capacitors subjected to the over-all metallization process outlined in Table I. Also shown for comparison are the dashed C-V curves (high frequency and quasi-static), which correspond to well-annealed CMOS capacitors. The solid C-V curves reflect certain obvious effects of radiation damage; they are greatly distorted indicating a high density of surface states, N_{SS}. The negative shift of both C-V curves is taken as an indication of a large positive charge Q_{SS}. One consequence of the large Q_{SS} and high N_{SS} is to significantly decrease the apparent threshold voltage for the corresponding MOS transistor from the intended values of approximately $\mp 1.5V$ (for p- and n-channel, respectively) to about -5.0 and $-1.0V$, respectively, as indicated in Fig. 2.

For an understanding of the MOS damage shown in Fig. 2, the effects were studied of each of the three radiation-damage inducing steps in the metallization process, namely, sputter etch cleaning of Si, sputter deposition, and sputter etching of the deposited metallization. These results are considered below.

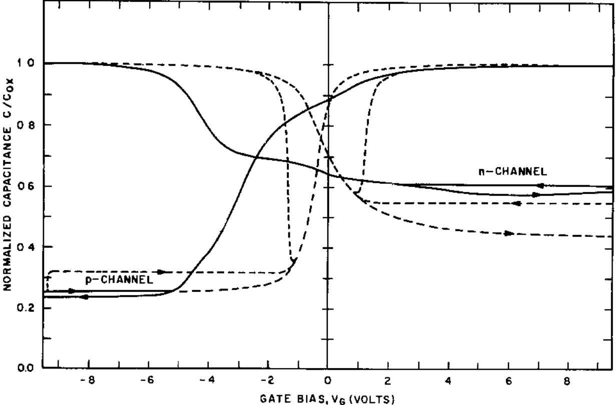

Fig. 2. High frequency C-V curves for CMOS capacitors subjected to the standard metallization process (solid lines). The dashed lines show C-V curves (high frequency and quasi-static) for well-annealed capacitors, with no radiation damage.

Sputter etch cleaning.—The preferred practice of forming PtSi ohmic contacts to Si (13) involves *in situ* rf-sputter etch cleaning of the exposed Si areas (*e.g.*, source, drain, and guard rings in the Si substrate, and contact areas of the n^+ poly-Si gate); this is followed by sputter deposition of Pt and sintering of the Pt layer to form PtSi ohmic contacts. For sputter etching, an rf potential is applied to the substrates, and the substrates achieve a negative self-bias equal to approximately one-half the peak-to-peak rf potential. As a result of this potential, the substrates are subjected to bombardment by energetic Ar^+ ions extracted from the plasma. With no metal barriers present yet, direct damage can occur, in the case of IGFET's (insulated gate field effect transistors), at the edge of the gate oxide/Si interface which gets exposed when windows are formed in the source and drain areas. In the case of test capacitors, a similar situation arises at the p^+ contacts to the p-tub. Moreover, indirect damage can result from Ar^+-ion bombardment of the poly-Si layer over the Si/SiO_2 interface. Although the exact mechanisms are not apparent, sputter etch cleaning was found to be the most severe radiation-damage inducing step of the metallization process.

The radiation damage induced by sputter etching is expected to be cumulative, *i.e.*, it will depend upon the product of the intensity of radiation and time of exposure. The effect of the duration of sputter etch cleaning is shown in Fig. 3 and 4 which show complete C-V curves (high frequency and quasi-static, p- and n-channel) for samples sputter etch cleaned for 3 min and 1 min, respectively. Subsequent to sputter etching but prior to C-V measurements both of these samples were coated with 500Å of sputtered Pt, sintered at 650°C (20 min) in Ar/10% air ambient and the unre-

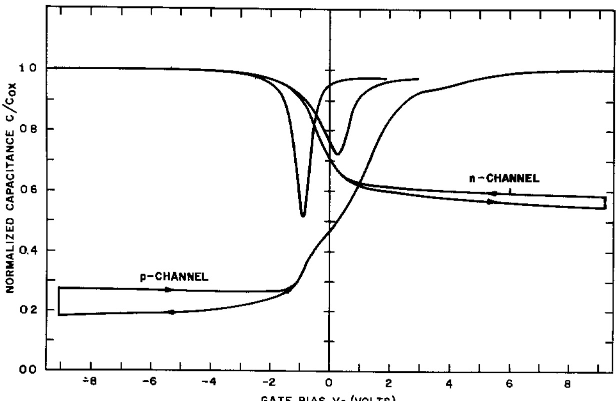

Fig. 3. C-V curves for CMOS capacitors processed through 3 min of sputter etch cleaning and PtSi formation in the contact windows.

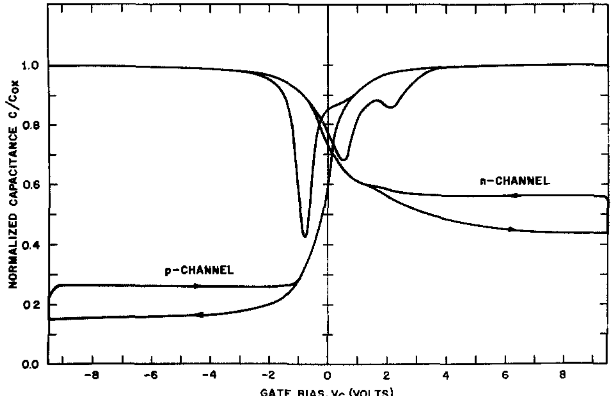

Fig. 4. C-V curves for CMOS capacitors processed through 1 min of sputter etch cleaning and PtSi formation in the contact windows.

acted Pt was etched away using hot *aqua regia*. The high frequency C-V curve for the p-channel capacitor of Fig. 3 is severely distorted and shifted in the positive direction. The positive shift of the p-channel C-V curve is also seen for the sample of Fig. 4 which was sputter cleaned for 1 min, but it is considerably less in extent. These positive shifts (apparent negative Q_t) appear to be the result of a large N_{SS} effect.

The data in Fig. 3 and 4 were analyzed to give a distribution of surface states density N_{SS} with the relative surface potential ψ_S (Fig. 5). In both cases, *i.e.*, for 3 and 1 min backsputter cleaning, the N_{SS} *vs.* ψ_S distributions are similar; they show a shallow minimum near the mid-gap and a well-defined peak near the p-channel flatband point in the upper half of the forbidden band. The area under the peak of Fig. 5(a) was used to estimate N_{st}, the (negative) charge (-6.5×10^{11} cm^{-2}) associated with the interface traps which, in the present case, act as acceptor states. Moreover, the shift in high frequency C-V curves for p-channel capacitors gives Q_t ($= Q_{SS} + N_{st}$) as -3.4×10^{11} cm^{-2}, so that the radiation-induced Q_{SS} appears to be $\sim 3 \times 10^{11}$ cm^{-2}. A similar calculation for the case of Fig. 5(b) gives the trapped charge N_{st} as -10^{11} cm^{-2} and the radiation-induced Q_{SS} as $\sim 2 \times 10^{10}$ cm^{-2}. In both cases, negative N_{st} dominates Q_{SS}, but only for p-channel capacitors presumably because the portion of the forbidden gap available for occupancy by negative charges increases on going from midgap to flatband of p-channel capacitors; a reverse situation holds for n-channel capacitors.

Nearly ideal MOS characteristics are restored, *i.e.*, the surface states are completely neutralized upon hydrogen annealing either of the above two samples at, *e.g.*, 380°C for ½ hr. This is evident from the data shown in Fig. 6 according to which both p- and n-channel capacitors have a $Q_{SS} \sim 0$ (*i.e.*, $< 10^{10}$ cm^{-2}) and midgap $N_{SS} < 10^{10}$ cm^{-2} eV^{-1}. In the case where the intermediate oxide is covered with Si_3N_4, the H_2 annealing would primarily occur by lateral migration of the H atoms across the wall of the contact windows, *i.e.*, in the region between the top Si_3N_4 layer and the PtSi layer present at the bottom of the contact apertures. The device is not fully sealed (against H_2) until the contact windows are covered with Ti/TiN/Pt metallization upon subsequent sputter deposition.

Ti/TiN/Pt triode sputter deposition.—Triode sputter deposition of Ti/TiN/Pt was carried out on wafers which contained sintered PtSi ohmic contacts and were H_2-annealed for times in excess of those required to neutralize the previously present interface states. Metal pads were then defined over the contact areas by chemical etching in conjunction with usual photolithographic techniques. During the sputter deposition step, most of the particle bombardment is due to low energy neutrals, however, during the early stages of deposition, until a continuous layer (1000-2000Å) of metal film is formed, the Si-gate areas (~5000Å thick) are exposed to the u.v. radiation and voltages of the plasma, which can produce radiation damage (14).

The effect of triode sputter deposition is shown in Fig. 7 in the form of high frequency and quasi-static C-V plots. It may be seen that sputter deposition after PtSi formation and H_2 anneal does not appreciably distort the high frequency C-V curves, but the quasi-static C-V curves show evidence of interface states, whose distribution is shown in Fig. 8. This N_{SS} distribution has a peak in the lower half of the bandgap; however, the N_{SS} values are relatively low (in the range of $1\text{-}7 \times 10^{10}$ cm^{-2} eV^{-1}) so that the effects of any charge trapping are not reflected by appreciable distortion of the high frequency C-V curves.

Sputter etching for metal pattern generation.—The radiation damage induced in MOS Si-gate structures by rf diode sputter etching for metal pattern genera-

tion (uniform gold process) has been recently investigated (15). It was concluded that the damage is primarily due to x-rays (bremmstrahlung and characteristic) generated by secondary electrons accelerated from the cathode which strike the anode. Since many types of MOS SIC's may require gold only on the beam leads and not on the intrachip metallization, sputter etch processes for metal patterning with and without gold (*i.e.*, those utilizing high and low rf power levels, see below) on the intrachip metallization were compared. Two sets of conditions were evaluated. First, samples containing PtSi/Ti/TiN/Pt and H_2-annealed after PtSi formation were uniformly plated with gold (1μ) and selectively plated with a Ni mask. The Au and Pt layers were removed by sputter etching for 30 min at an incident rf power to the cathode of 2 Wcm^{-2}. This condition corresponds to a cathode d-c self-bias of -900V, an rf peak-to-peak voltage of 1800V, and a gold sputter etch rate of $\sim$900 Å/min. Second, samples, containing PtSi/Ti/TiN/Pt were selectively plated directly with Ni and the Pt removed by sputter etching for 20 min at an incident rf power to the cathode of 1.2 Wcm^{-2}. This corresponds to a cathode self-bias of -500V, d.c., and an rf peak-to-peak voltage of 1000V. Elimination of Au on the intrachip metallization makes it practical to consider sputter etching at lower power levels which should be milder conditions as far as MOS damage is concerned.

The C-V data for the sample sputter etched at a power of 2 Wcm^{-2} are shown in Fig. 9. Considerable damage has occurred to the CMOS capacitors as reflected in the large positive Q_t (4-5 $\times$ 10^{11} cm^{-2} eV^{-1}) and N_{SS} values. The distribution of N_{SS} *vs.* ψ_S is shown in Fig. 10. The N_{SS} shows a peak in the upper half of the bandgap near the flatband point for the p-channel capacitor. From the area under this peak, the charge N_{st} trapped in the surface states is estimated as $\sim 10^{11}$ cm^{-2}. This is relatively small compared to Q_t ($= Q_{SS} + N_{st}$) so that irrespective of the sign of N_{st}, Q_{SS} will be a large positive number (3-6 $\times$ 10^{11} cm^{-2}). Thus, in contrast with the case of sputter etch cleaning, here the radiation-induced positive Q_{SS} dominates N_{st}. At this stage, it is not possible to determine whether the N_{st} is associated with acceptor states (*i.e.*, $N_{st} \sim -10^{11}$, $Q_{SS} \sim$ 5-6 $\times$ 10^{11} cm^{-2}) or with donor states (*i.e.*, $N_{st} \sim 10^{11}$, $Q_{SS} \sim$ 3-4 $\times$ 10^{11} cm^{-2}).

The effect of sputter etching at the lower power of 1.2 Wcm^{-2} is shown in Fig. 11. Although this sample shows only a slight increase in Q_t, the MOS degradation is manifested by an order of magnitude increase in N_{SS} over that characteristic of well-annealed samples (see, *e.g.*, results given below). The resulting distribution of N_{SS} with ψ_S is shown in Fig. 12. It is characterized by a minimum near the midgap. These N_{SS} values are comparable to those induced by sputter deposition of Ti/TiN/Pt layers (Fig. 8) so that it appears that the simple expedient of reducing the rf power used for sputter etching was effective in mini-

mizing additional damage during the sputter etch step. Furthermore, a partial annealing[2] of the N_{SS} due to trapped H_2 (see below) might have also occurred during sputter etching to give the appearance of only a small net increase in N_{SS}.

[2] Although the Si wafers are clamped to a water-cooled cathode plate for efficient cooling during sputter etching, surface temperatures in the range 100°-200°C are attained.

Use of Trapped Hydrogen for Annealing Interface States

The combination of a Si_3N_4 seal and sputtered Ti/TiN/Pt metallization in the contact windows would render devices impervious (at practical postmetallization processing temperatures) to hydrogen which is required to neutralize the surface states associated with dangling bands at the Si/SiO_2 interface (16). Although the upper limit of postmetallization H_2-annealing temperature can be set by a variety of reasons, for systems containing Au, it will definitely be below the Au-Si eutectic point (370°C), and in the case of Al thin films it will be $\lesssim$ 450°C because of excessive hillock formation and grain growth. Our results indicate that part of the hydrogen previously introduced (during 380°C, 1/2 hr H_2 anneal) in the devices after PtSi formation in the contacts gets trapped into the SiO_2 and poly-Si layers of the device. A subsequent anneal in an inert ambient such as *vacuo*[3] causes this trapped hydrogen to redistribute and anneal out the additional interface states produced by Ti/TiN/Pt sputter deposition and Pt sputter etching steps. The results of a vacuum anneal at 325°C (1 hr) are shown in Fig. 13 for a sample that received triode Ti/TiN/Pt sputter deposition and Pt removal by diode sputter etching. Nearly ideal MOS characteristics have been restored after the 325°C "redistribution anneal." The midgap surface states density is reduced by about an order of magnitude $\sim 4 \times 10^9$ cm^{-2} eV^{-1} for the p-channel device and to $\sim 9 \times 10^9$ cm^{-2} eV^{-1} for the n-channel device. The resulting Q_{SS} is nearly zero (*i.e.*, $< 10^{10}$ cm^{-2}) for both cases and the calculated threshold voltages are found to be approximately $\mp 1.5V$, respectively, for the p- and n-channel devices, as expected.

Additional measurements of storage time, oxide breakdown voltage, and mobile charge were made on a limited number of MOS capacitors subjected to the hydrogen-redistribution anneals. Figure 14 shows typical plots of the normalized MOS capacitance as a function of time after the capacitors were driven into deep depletion by a pulse voltage of $-10V$ or $+10V$ for the p- and n-channel devices, respectively. The capacitors gradually recovered to the equilibrium state of inversion. The resulting transients were analyzed by the procedure suggested by Heiman (17). For the p-channel capacitors, the τ was estimated at midpoint of the transient as 0.1 and 0.23 msec whereas for the n-channel capacitor on diffused p-tubs, τ was found to be

[3] Vacuum annealing was initially tried to ensure moisture-free samples. Equally good results have been obtained by annealing in N_2 or forming gas but only provided the samples had earlier received a H_2-annealing treatment prior to sputter deposition.

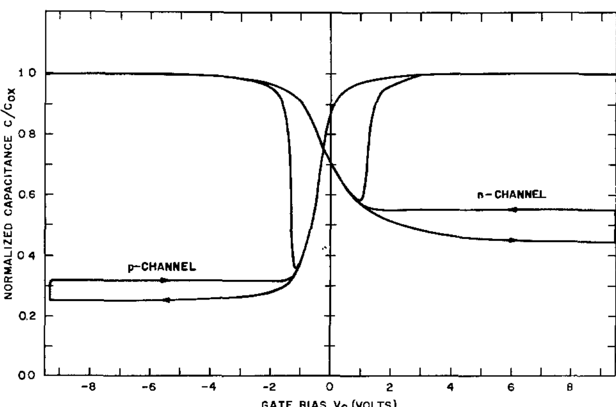

Fig. 13. Nearly ideal C-V curves of CMOS capacitors processed through PtSi contacts, H_2 anneal, Ti/TiN/Pt sputtering, Pt sputter etch, and a final vacuum anneal (324°C, 1 hr) to redistribute the previously trapped H_2.

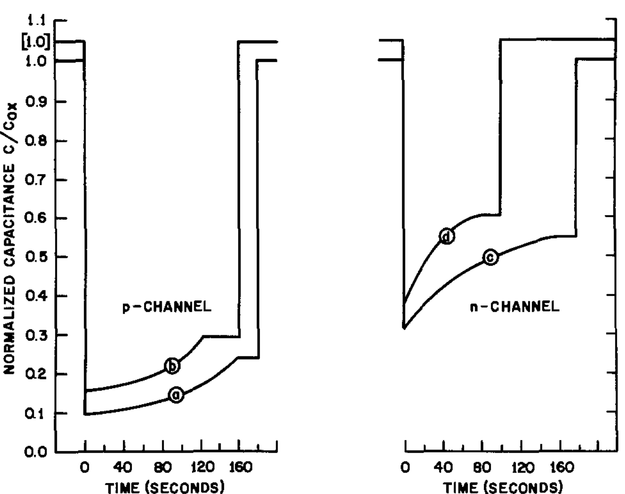

Fig. 14. Normalized MOS capacitance vs. time for capacitors of Fig. 13 driven into deep depletion: (a) and (b) p-channel; (c) and (d) n-channel.

much shorter at 9 and 5 μsec. These values are generally representative of those expected for well-annealed MOS samples.

Gate-oxide breakdown voltages were also measured for a limited number of capacitors after the H-redistribution anneal. These ranged from 30 to 65V (for 1000Å thick gate oxide) with a median of about 50V.

Bias-stress aging experiments were carried out (±10V on gate oxide, 250°C, 30 min) on the annealed samples with a view to determine any mobile charge (Na^+) in the gate oxide. The total flatband shifts were always less than 0.1V indicating that the present CMOS device processing (which included a 1000°C PBr_3 getter step) was effective in keeping the mobile charge density acceptably below 10^{10} atom cm^{-2}, and that mobile charges were not activated in the gate oxide as a result of the above processing steps.

Long-term negative bias-temperature aging studies (4) were not carried out, but they would be required to verify the permanence of the anneal. In view of the low values of N_{SS} that were achieved, there is reason to believe that significant charge trapping and consequent shifts in threshold voltage should not occur.

Conclusions

Using a Si-gate CMOS structure, the MOS compatibility has been demonstrated of a process involving (*i*) triode sputter etch cleaning of contact areas, triode sputter deposition of Pt (for PtSi) and Ti, TiN, Pt layers, and rf diode sputter etching of the Pt layer and (*ii*) use of trapped hydrogen for annealing interface states in sealed MOS structures. The conclusions reached should be of general validity to Si-gate MOS devices, even though details of the radiation damage may depend critically on the specific structure employed.

1. The dominant modes of damage were found to be generation of surface states, radiation-induced Q_{SS}, and lifetime degradation, all of which are annealable using hydrogen.

2. The triode sputter etch cleaning step introduces surface states whose distribution shows a peak in the upper half of the bandgap. A large negative charge in the surface traps appears to dominate the (positive) radiation-induced Q_{SS}.

3. The triode sputter deposition process (following PtSi contact formation and H_2 annealing) of Ti/TiN/Pt layers leads to a small peak in N_{SS} in the lower half of the bandgap.

4. Rf diode sputter etching (of Au and/or Pt) at high powers (2 Wcm^{-2}) produced a peak in N_{SS}, also in the upper half of the bandgap. In this case a large positive radiation-induced Q_{SS} dominates any charges associated with surface traps. For low power sputter etching (1.2 Wcm^{-2}), the N_{SS} distribution contains no peaks, only a shallow minimum is present near the midgap and no charge trapping is observed.

5. In sealed MOS structures which are impervious to hydrogen during postdamage annealing, hydrogen can be introduced and trapped in the oxide layer prior to the deposition of the final metallic layer seal. A low temperature, inert ambient anneal (*e.g.*, 325°C, 1 hr vac) can then be employed, subsequent to sputter deposition of the metallic layer, whereby the hydrogen redistributes by migration to the Si/SiO_2 interface and repairs the MOS damage.

6. MOS structures subjected to the above H-redistribution anneal have midgap N_{SS} in the 10^9 cm^{-2} eV^{-1} range, nearly zero Q_{SS} (*i.e.*, $< 10^{10}$ cm^{-2}), and lifetime of 10-100 μsec. With careful processing, no mobile charges are introduced or activated by the above processes.

Acknowledgments

The author is indebted to E. F. Labuda for many helpful suggestions in the course of this work, and for reviewing the manuscript. Appreciation is also extended to L. B. Fritzinger for his generous assistance with metallization processing, to T. E. Smith for technical assistance with the MOS measurements, and to E. H. Nicollian, H. J. Levinstein, and R. S. Wagner for their suggestions.

Manuscript submitted July 16, 1975; revised manuscript received Sept. 22, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Bell Laboratories.

Characterization of Thin Anodized Films on Aluminum with Soft X-ray Spectroscopy

W. L. Baun

Air Force Materials Laboratory (MBM), Wright-Patterson AFB, Ohio 45433

and T. J. Wild and J. S. Solomon

University of Dayton Research Institute, Dayton, Ohio 45469

ABSTRACT

Two methods utilizing x-ray spectra from the electron microbeam probe for the determination of aluminum oxide film thickness for a broad range of thicknesses are described. One method uses the direct measurement of oxygen K emission while the other uses the changes in fine features of the x-ray spectra with changes in oxide film thickness. For oxides formed by barrier anodization technique, films as thin as 20-30Å and as thick as several thousand angstroms could be measured by these methods.

The thickness of thin films is usually determined by optical methods such as ellipsometry or interferometry or by an indirect method such as calculation from the evaporation of a known weight of material in a vacuum evaporator. Depth profiling techniques in which an inert gas ion beam sputters away surface layers while the surface is sampled are being used increasingly. Such depth profiling is done with ion scattering spectroscopy (ISS), secondary ion mass spectroscopy (SIMS), Auger electron spectroscopy (AES), and electron spectroscopy for chemical analysis (ESCA). Both the optical methods and techniques depending on sputter etching give good results in selected cases. However, the optical methods suffer greatly when the film is not uniform and the substrate is not flat (macroscopic) and smooth (microscopic). Other factors such as the film being a color which absorbs the probing radiation also can interfere with optical measurements such as ellipsometry. The accuracy of methods using sputter etching depends on a knowledge of the film sputtering rate, which even for pure materials varies greatly (depending on experimental conditions, especially ion beam voltage). There are also problems due to ion beam crater shape (sampling from the sides as well as the bottom of the crater), redeposition of sputtered material back into the crater, surface roughness, and other factors.

Each of the aforementioned techniques gave good results on idealized aluminum oxide films on aluminum. Such samples were prepared by vacuum evaporating aluminum on glass microscope slides and anodizing under barrier conditions at low voltages. When real samples which had been cut by shear techniques from bulk sheet stock subjected to surface oxidizing etches or to standard surface preparation prior to anodization were investigated, very poor results were often obtained probably due to surface roughness. X-ray emission technique similar to that used by Sewell *et al.* (1, 2) for thin films of Ta_2O_5 on Ta by means of oxygen K measurement looked attractive for determining thickness of aluminum oxide on aluminum. In addition, the striking changes in the fine features of aluminum K spectra with changes in chemical combination (3, 4) showed promise for characterizing these films, both from the standpoints of thickness and structure.

Experimental

The Hitachi XMAS electron microbeam probe analyzer equipped with a dispersing KAP crystal and an ultrathin polypropylene-windowed flow proportional detector was used for results on oxygen K radiation shown here. For aluminum K spectra high resolution was provided by use of an ADP dispersing crystal. The electron beam potential was 10 kV with 1×10^{-6}A electron beam current using approximately 5 μm^2 beam. X-ray data was collected by step-scan techniques on paper tape and inputted to a time-share computer, X and Y intercepts for each point were calculated, and plots were prepared by a digital plotter. Samples were prepared in a stirred bath of 1% ammonium borate in ethylene glycol. Except as discussed later, anodizing voltages were maintained (constant voltage) in a range which gave a barrier anodized film.

Background on X-ray Spectra

The fine features of x-ray emission spectra may be used to determine chemical bonding. By operation at low voltages and other techniques the method can provide near-surface characterization on areas as small as 1 μm^2. Aluminum K spectra are especially sensitive to changes in chemical bonding. Figure 1 shows the K band (K_β) from aluminum metal and an anodized film. The large shift in the band as well as the appearance of K_β' in the oxide due to a molecular orbital transition forms the basis of using these fine features. Also shown in Fig. 1 is the K satellite group, the principal lines of which are stronger than K_β and are thus usually easier to use. The use of these features assumes that the oxide is on the surface and that a uniform change from "metal" to "oxide" spectra will take place when going from no film on the surface to a point where all x-ray emission emanates from the oxide film. This upper limit was about 4000Å in this work where 10 keV electrons were used but could be increased by an increase in operating voltage.

Results

The most obvious method of using x-rays to determine oxide thickness is that of direct measurement of oxygen K intensities similar to the method of Sewell *et al.* (1, 2, 5). Such results are shown in Fig. 2 where the OK intensities obtained from anodized films on aluminum are plotted *vs.* the anodizing voltage. The anodization constant was determined to be 14 Å/V using ellipsometric techniques on vacuum-evaporated Al films anodized under the same conditions as the samples described earlier. Note that the intercept is not at zero, probably due to oxygen in solution in the bulk and to the natural oxide film which immediately covers an aluminum surface. The linear

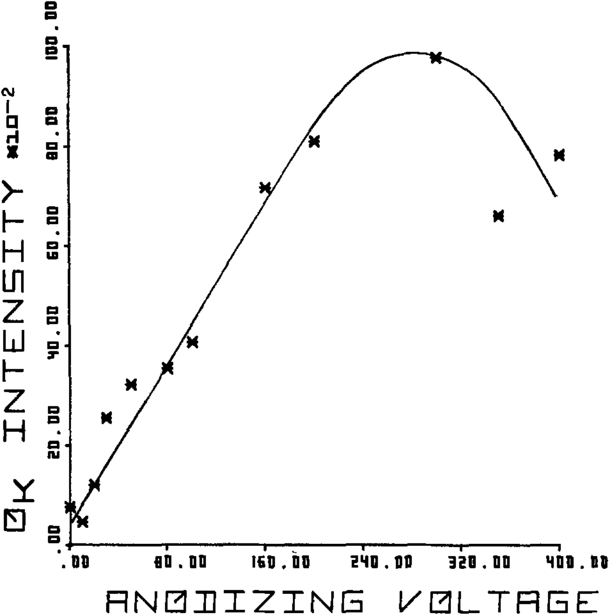

Fig. 2. Oxygen K x-ray intensities vs. anodizing voltage for aluminum (1% ammonium borate in ethylene glycol).

portion of the curve may be more nearly exponential if more points were added and better precision were achieved. Such a shape would be in keeping with electron and x-ray attenuation in the films, and would be in better agreement with the data of Mitchell and Sewell (5) on aluminum. However, data shown here, because of the use of a higher take-off angle and higher electron energies, would be less susceptible to absorption effects compared with the results of Mitchell and Sewell.

The changes in Al K x-ray spectra provide another method of determining oxide film thickness. Figure 3 shows the orderly change in the K band which involves valence electrons in going from Al metal to a thick 400V film. For reference, a spectrum is also shown for sapphire. Sapphire, the corundum structure. exhibits two maxima on the main K band, while anodized films show only one, indicating that the anodized film is not corundum structure and that x-ray fine features are sensitive not only to nearest neighbors, but also to the way in which they are arranged in the compound. $K_{\beta'}$ originates only from the oxide due to a molecular orbital transition, and therefore becomes stronger with increasing oxide thickness in relation to the K band as seen in Fig. 4. Work is continuing to determine if the observed scatter is due to statistical measurement problems such as surface

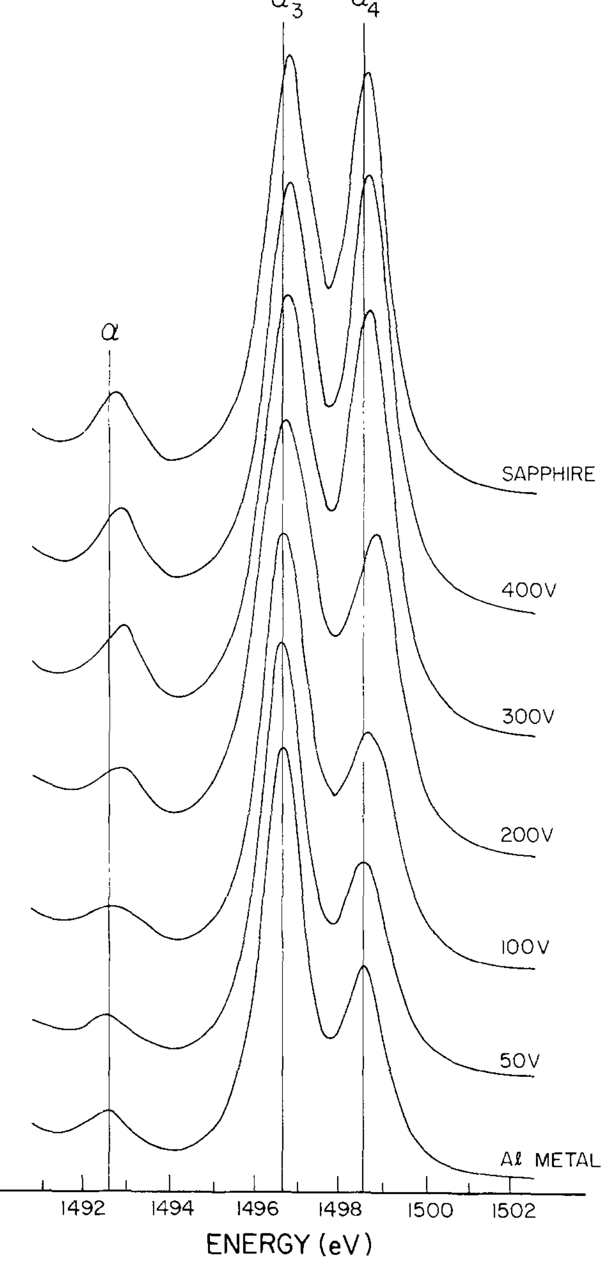

Fig. 5. Al K satellites for samples anodized at various voltages compared to Al_2O_3, sapphire.

charging or whether changes in anodization conditions or inhomogeneities in the film are responsible.

The strong satellites $K\alpha_3$ and $K\alpha_4$ which originate from multiply ionized states, provide another method of measuring film thickness as seen by the continuous change in the spectra in going from pure metal to a thick 400V film as seen in Fig. 5. The spectrum from sapphire in this case is virtually identical to the spectrum from the thick anodized film indicating that the satellite lines are not sensitive to structural changes. The ratio $K\alpha_4/K\alpha_3$ is shown in Fig. 6. Notice in this plot the curve comes to a maximum and remains constant once the ratio has attained a value of approximately unity representing emission from only oxide. In measurements of OK intensities a similar effect was seen except that a maximum was reached followed by a decline giving the appearance that the film was becoming thinner with increasing anodizing voltage. It was suspected that a change in mechanism of anodization was responsible for the curve shape and current *vs.* time recordings were made at constant voltage for both high and low voltages. It was found for this electrolyte concentration that barrier oxide films are formed up to 250V; above this voltage a combination of barrier and porous film exists. Hoar and Yahalom (6) have shown detailed results of current density *vs.* time for aluminum anodization in which the curves may be analyzed as having one component which is due to barrier film forming and a superimposed component due to pore formation. Figure 7 illustrates this phenomenon for the electrolyte used here where A is current-time relationship for 50V and shows a typical curve for a barrier film while B is obtained at 300V and shows first barrier formation during the early sharp surge followed by a break in the curve indicating porous oxide formation. Electron micrographs of replicas at high magnification show the increase of the pore structure in the higher voltage oxide. Therefore, apparently the bend in the OK intensities represents a change in oxide bulk density rather than the oxide becoming thinner at higher voltages. That is, because of the pores, there are fewer oxygen sites per unit area. In addition it is possible that in the porous oxide the stoichiometric ratio between oxygen and aluminum is different from the barrier oxide. How-

ever, in a nonaqueous system such as used here, this is unlikely.

Conclusions

The x-ray emission method, either the direct measurement of oxygen K intensities, or the measurement of changes in the fine features of x-ray spectra, gives thickness information on aluminum oxide on aluminum over a wide range of thickness from about 20Å to several thousand Å. The technique lends itself to practical samples which are not amenable to measurement by methods enumerated earlier. The range of thickness could be increased compared to the results shown here. That is, much thicker films could be measured by using higher electron beam voltage.

Acknowledgments

The ellipsometry measurement of film thickness of oxides on vacuum-evaporated films by Neil T. McDevitt is appreciated by the authors.

Synthesis and Luminescence Properties of Europium-Activated Yttrium Oxysulfide Phosphors

Markus Koskenlinna, Markku Leskelä, and Lauri Niinistö

Department of Chemistry, Helsinki University of Technology, SF-02150 Otaniemi, Finland

ABSTRACT

A new method of preparing brightly emitting $Eu{:}Y_2O_2S$ phosphors is described. Yttrium sulfite doped with Eu is used as starting material and the Eu-activated oxysulfide is obtained from it either directly by reducing the sulfite with carbon monoxide, or by first oxidizing sulfite and then reducing the obtained oxysulfate. The properties of the phosphors and the effect of impurities on their luminescence spectra are briefly discussed.

Due to its bright luminescence under cathode ray excitation, europium-activated yttrium oxysulfide is a widely used red-emitting phosphor in color television picture tubes (1). Several methods have been reported for the synthesis of rare earth (RE) oxysulfides; they include reaction of RE oxides with various sulfur-containing reagents (*e.g.*, H_2S, CS_2, NH_4SCN) (2-4), reduction of RE sulfates by hydrogen (5, 6) and by carbon monoxide (7), reaction between RE oxides and sulfides (8), and methods employing sulfurizing fluxes (9, 10).

Key words: luminescence, phosphors, yttrium oxysulfide, europium oxysulfide.

In our previous study concerning the thermal decomposition of RE sulfites it was found that under certain conditions they form oxysulfides in reducing atmospheres (11). Based on that reaction, this report describes a new method for the preparation of brightly emitting europium-activated yttrium oxysulfide phosphors. Their properties are also briefly discussed, with special emphasis on the effect of impurities on the luminescence brightness.

Experimental

Materials and analytical methods.—Three different grades of yttrium oxide (99.9, 99.99, and 99.999% with

respect to RE impurities) were used in the experiments. The purity of europium oxide was 99.9%. Both oxides were produced by Kemira Oy, Oulu, Finland.

The purity of the starting materials as well as that of the phosphors was analyzed with an AEI MS702 mass spectrometer, using spark-source excitation and electrical detection. The amount of europium present in the sulfites and phosphors was analyzed by atomic absorption spectrometry with a Perkin-Elmer 303 instrument. The purities of deionized water, ethanol, ether, and acetic acid used for washing the phosphors were also checked by AAS.

X-ray diffraction.—The homogeneity and crystallinity of the sulfites and oxysulfides were checked by x-ray diffraction using a Philips powder diffractometer with Ni-filtered CuK_α radiation. The accurate unit cell parameters of the synthesized oxysulfides were calculated by a least-squares procedure from x-ray diffraction photographs taken with a Guinier camera (Enraf-Nonius FR 552). Potassium chloride was used as internal standard, and the films were measured with a microdensitometer.

Thermal analysis.—The formation of Eu: Y_2O_2S from the sulfite was investigated in a Mettler Thermoanalyzer by simultaneously recording the TG, DTG, and DTA curves. The flow rate of CO was 90 cm^3/min. The sample holder was an aluminum oxide crucible (diam 8 mm, depth 20 mm). The stability of the activated phosphor in vacuum ($4 \cdot 10^{-5}$ atm) was checked in another experiment where it was heated from 25° to 1000°C. The heating rate in both experiments was 6°/min.

Luminescence measurements.—Luminescence spectra of the phosphors were measured with a Hitachi Perkin-Elmer fluorescence spectrometer, Type MPF-3A. In relative intensity measurements the instrumental parameters were as follows: sensitivity: 2; slit: 2 μm; filter: UV-D25 (excitation), UV-39 (emission); wave length: 324 nm (excitation), 500-700 nm (emission).

Scanning electron microscopy.—SEM pictures were taken with a JEOL scanning electron microscope, Type JSM-U3.

Synthesis of the oxysulfide phosphors.—Y_2O_3 containing the desired amount of Eu_2O_3 was suspended in water. A slow stream of sulfur dioxide was led into this suspension until the RE oxides dissolved. Complete precipitation of RE ions as sulfites was achieved by boiling the solution and simultaneously leading nitrogen gas through to remove excess sulfur dioxide. Due to the small difference in solubilities of yttrium and europium sulfites, the crystalline precipitate contained europium sulfite homogeneously dispersed in yttrium sulfite. It was washed with deionized water and dried with ethanol and ether. As an example of the amounts of reagents and the time required the following values can be given: Y_2O_3 1.5g, Eu_2O_3 0.149g [6 mole percent (m/o)], H_2O 150 cm^3, SO_2 100 cm^3/min for 1.5 hr, and boiling time 1 hr.

The sulfites obtained can be reduced to oxysulfides by the action of carbon monoxide at 600°-900°C. In a typical experiment, 0.5g of sulfite was reduced in a quartz reaction vessel (volume 80 cm^3) by leading in carbon monoxide (100 cm^3/min) for 60 min at 750°C.

An alternative route, requiring slightly higher reduction temperatures, consists of the oxidation of sulfites in air to oxysulfates and then their reduction by carbon monoxide to oxysulfides. For example, 0.5g of sulfite was fired in air at 950°C for 1 hr and the oxysulfate thus obtained was reduced by CO (100 cm^3/min) at 830°C during 1 hr.

Finally, in order to improve the crystallinity and luminescence properties of the oxysulfide, it was fired in nitrogen for 1 hr at a temperature 50°-100°C higher than the reduction temperature. Cooling was also carried out under nitrogen in order to avoid the formation of oxysulfate by oxidation.

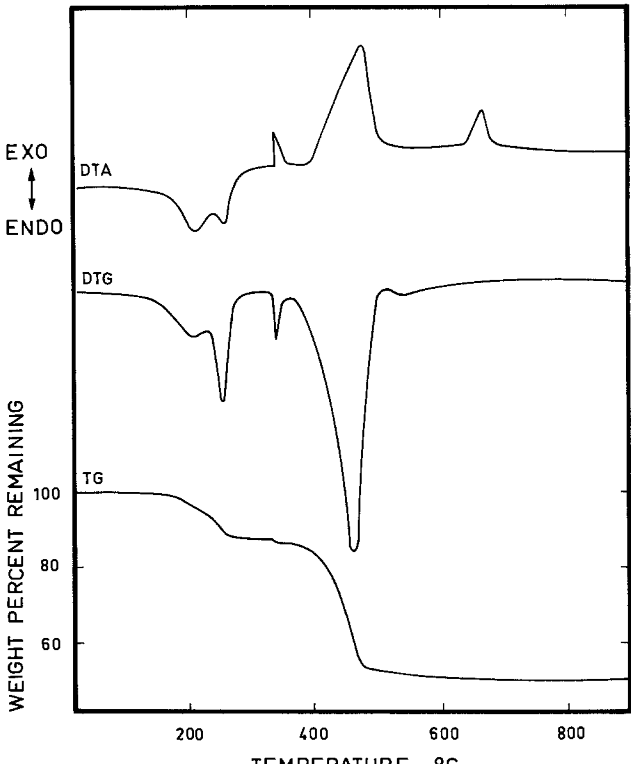

Fig. 1. Results of thermal analysis showing the formation of oxysulfide by carbon monoxide reduction of yttrium sulfite trihydrate containing 6 m/o Eu.

Results and Discussion

Preparation of phosphors.—Results of thermal analysis indicated that first an endothermic dehydration reaction takes place in the temperature range 150°-270°C (Fig. 1). The observed weight loss corresponds to three molecules of water. The anhydrous sulfite is then reduced to oxysulfide in a two-stage exothermic process. The first step, at 330°-340°C, clearly visible in both DTA and TG curves, is due to the reduction of europium sulfite; yttrium sulfite is reduced at the higher temperature range of 360°-490°C. The exothermic peak not involving a weight change at 640°C is probably due to recrystallization of the phosphor.

The over-all weight loss (46.60%) calculated from the TG curve is smaller than the theoretical value (47.90%), indicating the formation of other sulfides besides the desired oxysulfide. The sulfides may be washed from the product by dilute acetic acid in which they are readily soluble (12). This lowers the yield, however, because oxysulfide is slightly soluble in acetic acid.

In this work the reaction temperature was optimized with respect to luminescence intensity and yield. Figure 2 shows the amount of material soluble in 2.5M acetic acid (mainly sulfides) and the luminescence intensity of the remaining oxysulfide phosphor. Temperatures around 700°C seem to be best for oxysulfide formation, but the optimum temperature with respect to both yield and intensity is somewhat higher, around 750°C. If an alternative preparative route employing the reduction of oxysulfate is used, the amount of material soluble in acetic acid remains fairly constant (approx. 5%), but the optimum intensity is obtained with reaction temperatures of 800°-850°C and a post-synthesis N_2 anneal at 900°-950°C. There seem to be no significant differences in luminescence properties of phosphors prepared by the two alternative methods.

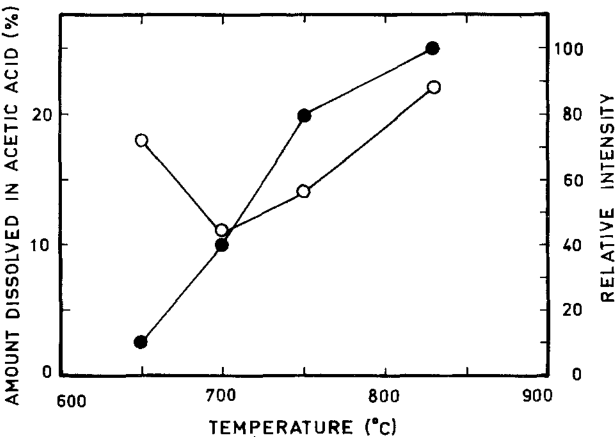

Fig. 2. The amount of material soluble in acetic acid (2.5M) in phosphors prepared by direct reduction of sulfites (open circles) and their relative brightnesses (filled circles) as functions of the reducing temperature.

Properties of the phosphors.—The phosphors prepared were pale brown. Their thermal stability in the absence of oxygen was good; heating in vacuum ($4 \cdot 10^{-5}$ atm) up to 1000°C caused the weight to drop only 0.8%.

According to x-ray diffraction patterns the phosphors were well crystallized. The unit cell parameters for Eu: Y_2O_2S with different Eu contents are given in Table I; they show a slight increase with increasing europium concentration.

Firing in nitrogen improves the luminescence properties significantly by increasing the crystallite size of the phosphor. This was visible in the line widths of the powder patterns taken before and after firing in nitrogen. The increase of particle size was also observed in SEM pictures. The intensity obtained after 1 hr firing may be as high as 5-10 times the original.

Effect of impurities on the luminescence spectra.—In the present study yttrium oxides of three different purities were employed in order to study the effect of impurities in the starting materials on the luminescence properties. Table II lists results of a mass spectrometric analysis of these starting materials, numbered I to III in order of increasing purity. Oxysulfide phosphors prepared under similar conditions from these oxides showed a relative luminescence intensity of 40, 50, and 100 for samples I/a, II/a, and III/a, respectively.

Much higher impurity levels, however, may be introduced during the preparation and subsequent handling. Table II also lists the results of mass spectrometric analyses for Eu: Y_2O_2S phosphors prepared from these starting materials by (*a*) direct reduction of yttrium sulfite by carbon monoxide, (*b*) reduction after oxysulfate conversion and, for comparison, by (*c*) sulfurization of Eu: Y_2O_3 in a sulfur-sodium carbonate-potassium carbonate flux (10), or (*d*) by method same as (*c*) but with mechanical dispersion (13). When comparing the analytical results for different phosphors it should be kept in mind that although spark source mass spectrometry is a very sensitive method of analysis, its precision with the logarithmic scanning method can be estimated to be at best only ±20%.

* Roman numbers I, II, and III refer to Y_2O_3 of 99.9, 99.99, and 99.999% purity, respectively. Small letters after the solidus indicate the method of preparation: (a) reduction of sulfite, (b) reduction after conversion to oxysulfate, (c) use of sulfurizing flux with dispersion of Eu in Y_2O_3 by oxalate precipitation, and (d) use of sulfurizing flux with mechanical dispersion of Eu in Y_2O_3. In the preparation of the three last phosphors, a quartz boat inside a steel reactor was employed; in other preparations apparatuses made entirely of quartz were used. The impurities originating from the activator (6 m/o Eu in all phosphors) have been taken into account in the values for the yttrium oxides.

The results show clearly that the use of a quartz boat significantly increases the silicon content. Nevertheless, the impurity levels for the present method are generally lower than those associated with the flux method, where in spite of careful washings, high contents of alkali and alkaline earth metals originating from the flux are introduced into the phosphor in addition to the high content of silicon from the quartz vessel. The presence of steel, even though not in direct contact with the sample, causes the Fe and Mn contents to rise significantly, as can be seen in the values for the last three phosphors prepared in the quartz vessel inside a steel reactor (Table II).

It is well known that minute amounts of other rare earths influence the luminescence properties of Eu: Y_2O_2S phosphors. Only Tb and Pr have been reported to increase the luminescence intensity (14), all other RE's reduce the brightness and/or lead to other undesired effects; *e.g.*, dysprosium increases the decay time (15).

Much less information is available on the effect of ions other than RE's on the luminescence properties of europium-activated yttrium oxysulfide phosphors. Mathers (15) reports that alkali metals are not usually considered detrimental to the spectra in amounts less than 100 ppm. At higher amounts they have been found to increase the brightness somewhat; the upper limit of alkali concentration has been reported to be 3000 ppm (16). Conversely, too high calcium and iron concentrations lower the brightness (15); no reports seem to be available on the effect of silicon on the spectra.

Table III lists the luminescence spectra with line identification of the same samples for which mass spectrometric analyses were performed (17). The effect of other rare earths on the spectra of Eu: Y_2O_2S phosphors is noticeable in a few cases. For instance, the $^5D_2 \rightarrow {}^7F_4$ transition, which is the strongest line due to terbium (18), is only present in the spectra of phosphors prepared from the 99.99% yttrium oxide, which contained 25 ppm terbium (Tables II and III).

The most striking feature of the spectra is, however, the differences in the relative line intensities of the

* The sample numbering is explained in Table II. In each sample the strongest line has been given the value of 100. The relative intensity values for different samples determined with instrumental parameters described in the text, were as follows (sample III/a 100): I/a 40, II/a 50, III/a 100, I/b 48, III/b 90, III/c 90, and II/d 2.
** Unassigned.
*** Unresolved.

sample containing most impurities (II/d) as compared with the other spectra. This sample also had the lowest relative brightness, a value of only 2, whereas III/a had the highest value of 100, and III/c had a value of 90. The difference between the samples III/c and II/d is certainly due not only to impurities in the starting materials but also to different dispersion methods of the activator. In sample II/d Eu_2O_3 was mechanically dispersed in Y_2O_3 (13); in the other sample (III/c), oxalate precipitation and subsequent firing were employed in obtaining the oxide (10).

The iron concentrations introduced in the phosphors by the steel reactor seem not to be so high as to have a distinct effect on the over-all brightness. This can be seen by comparing, for instance, the samples I/a (relative brightness 40) and I/b (relative brightness 48) prepared in quartz and steel reactors, respectively (Tables II and III). However, the effect of an individual element other than a RE on the spectra is difficult to evaluate on the basis of present material and it would require a further study.

Summary

The reduction of Eu-doped yttrium sulfite hydrate by carbon monoxide offers a new possibility for the preparation of Eu: Y_2O_2S phosphors. The reaction and annealing temperatures required are not significantly lower than in the case of sulfate reduction. However, an advantage of the present method over the sulfate route lies in the ease and completeness of precipitating homogenous starting materials for the synthesis.

The rare earth impurities in the starting materials as well as other impurities mainly introduced during processing can seriously degrade the luminescent properties of the phosphors.

On the Kinetics of the X-Ray Irradiation-Caused Degradation of Photoluminescence of Some Phosphors

George T. Bauer*

Webster Research Center, Xerox Corporation, Rochester, New York 14644

ABSTRACT

The growth of absorption and the degradation of photoluminescence of calcium tungstate and zinc silicate phosphors have been studied as functions of x-ray exposure. The characteristics of the growth curves are observed to be very similar to those reported for F centers in alkali halides. Based on the theoretical analysis of the kinetics, the fast initial growth of the absorption is interpreted as arising from the imperfections present in the phosphors prior to irradiation, while the following slow linear rise is attributed to the effect of new radiation-induced imperfections. From the two stages of growth curves, the two periods of degradation of photoluminescence observed could be quantitatively explained. These results indicate that the u.v. and visible absorption of radiation-produced color centers is the major cause of degradation of the phosphors studies. The observed dark recovery of absorption and of luminous efficiency after ceasing the irradiation of the phosphors was also found to be a correlated effect.

The degradation of phosphors as the effect of exciting irradiation is known to be a limiting factor in many applications. The degradation of the luminescence of some x-ray or u.v.-irradiated single crystals and phosphors has been attributed to the absorption of the irradiation-produced color centers (1, 2). In a previous publication, we reported results on the effects of x-ray and ultraviolet irradiation on different types of phosphors (3). We found that a decrease of luminous efficiency of the irradiated phosphors was always accompanied by increased absorption. In most cases, the absorption coefficient increased in the absorption band as well as in the emission band. The absorption bands could be partially or completely bleached out by a one-hour heat-treatment at 400°C. The reflectance data and glow curves of x-ray-irradiated phosphors were very similar to the ones obtained after long-term u.v. irradiation. These results indicate that the formation of color centers by irradiation in phosphors is a quite common phenomenon and is not restricted to those few basic types that had been studied in this respect by other authors (1, 2).

Our work also resulted in some increased insight into the various processes which are going on in the phosphors when irradiated. In certain phosphors, such as calcium tungstate and zinc silicate, the irradiation-caused degradation could be completely interpreted in terms of the absorption of irradiation-produced absorbing centers. Some part of the exciting energy in this phosphor is absorbed in radiation-produced color centers instead of being absorbed in the luminescent centers. A part of the emitted luminescent light is also absorbed by color centers. According to the experiments, the light emitted by color centers—if any—did not contribute to the luminous efficiency of these phosphors. In some other materials (for example, phosphate-type phosphors) glow curve measurements indicated an additional loss (3) which seemed to be connected with an energy transfer process between activator and color centers. In these cases, the induced traps should give rise to radiationless transitions or to emission outside the visible range.

In our previous measurements (3), the irradiation times did not vary over a wide range, and, consequently, did not yield enough information concerning the time dependence of the degradation of the phosphors. It appeared that for those particular phosphors in which the absorption of radiation-produced color centers is the only cause of degradation, the time dependence of this process should be described by the time-dependent change of their absorption coefficient. Thus, the problem can be reduced to interpreting the growth of absorption of these phosphors.

The growth of absorption of x-ray-irradiated alkali halides, a classical problem of color center research, has been studied by a number of authors (4, 5). In general, the physical processes which result in the growth of absorption were found to be rather complicated. However, in several cases, good agreement between theory and experiments (6, 7) was reported. Such detailed studies, although they might provide a better understanding of the degradation process, were not conducted for irradiated phosphors. The reason for the lack of such efforts should be attributed not only to the well-known complexity of the problem, but also to the difficulties encountered in measuring the absorption coefficient of powder phosphors. However, the absorption coefficient can be determined accurately enough for such purposes from measurements of diffuse optical properties of phosphor layers (8, 9). The problem can be simplified further because, as has been shown previously (3), only the relative values of the absorption coefficients of phosphors as a function of exposure are needed to interpret quantitatively the effect of color centers in the degradation process.

In this work, we study the time-dependent degradation of x-ray-irradiated $CaWO_4$:Pb and Zn_2SiO_4:Mn.Pb,As. The phosphors were made available to us by Westinghouse Corporation. The main effect of irradiation in these phosphors seems to be that it changes the visible and ultraviolet absorption of the phosphors. Long-term x-ray exposure induces only barely detectable new glow peaks over room temperature. Therefore, those other effects of x-rays which are related to energy transfer processes are neglected.

The choice of x-rays for irradiation was based on practical considerations. The irradiation time needed with x-rays is relatively short and the penetration depth is large, making it possible to use known techniques for the measurement of optical properties of powder phosphors.

However, based on the similarity of the effects of x-rays and u.v. on optical characteristics of phosphors, we may expect the results obtained here to hold also for degradation produced by other forms of excitation.

The theory and the experimental work can be divided into two major parts: the first is concerned with

* Electrochemical Society Active Member.

Key words: luminescence, phosphor degradation kinetics, color centers.

the growth of absorption; the second is the basic problem, the time-dependent degradation of the selected phosphors. Some efforts have also been concentrated on the study of dark recovery of the absorption and luminescence.

Theory

Calculation of the growth of the absorption.—We suppose that the growth of absorption of the irradiated phosphors can be attributed to the increase in concentration of the irradiation-produced color centers. As it is known from the extensive literature (4), the presence of imperfections in the crystal (*e.g.*, vacancies, interstitials, impurities) gives rise to color center formation. In the two sample phosphors, the concentrations of the activator and the color centers before and after the irradiation are small; that is, the absorption is in the "weak" region. Also, as indicated by relatively high quantum efficiency of the photoluminescence of the phosphors (10), absorption by impurities is negligible. The phosphor prior to irradiation already contains electron or hole-type imperfections of concentration N_o, and the irradiation produces new imperfections. The concentration of the new imperfections is proportional to I_o, the intensity of the x-rays, and to the elapsed time, τ, of irradiation. The total imperfection concentration, N, can be expressed by Eq [1]

$$N = N_o + a_2 I_o \tau \quad [1]$$

The growth of $C_i(\tau)$, the color center concentration, can be described by Eq. [2]

$$\frac{dC_i(\tau)}{d\tau} = a_1 I_o [N_o + a_2 I_o \tau - C_i(\tau)] - a_3 I_o C_i(\tau) - a_4 C_i(\tau) \quad [2]$$

According to the first term in Eq. [2], the irradiation produces new color centers and the rate of the concentration growth is proportional to the intensity of irradiation, I_o, and to the concentration of the available unfilled imperfections. The second term indicates that the radiation destroys color centers and that the rate of destruction is proportional to their instantaneous concentration, $C_i(\tau)$, and to I_o. The third term on the right of the equation expresses the fact that spontaneous recovery which does not depend on the intensity of the radiation may also occur, a_1, a_2, a_3, and a_4 are rate constants in Eq. [1] and [2].

The integral of Eq. [2], taking into account the boundary condition, is

$$C_i(\tau) = f_o(1 - e^{-g_o \tau}) + h_o \tau \quad [3]$$

where

$$f_o = \frac{I_o^2 (a_1^2 N_o + a_1 a_3 N_o - a_1 a_2) + a_1 a_4 I_o N_o}{[I_o (a_1 + a_3) + a_4]^2} \quad [4]$$

$$g_o = I_o(a_1 + a_3) + a_4 \quad [5]$$

$$h_o = \frac{I_o^2 a_1 a_2}{I_o(a_1 + a_3) + a_4} \quad [6]$$

From the $C_i(\tau)$ concentration and $\sigma_i(\lambda)$, the capture cross section of the color centers for absorption, the induced absorption coefficient can be expressed (3) as $C_i(\tau)\sigma_i(\tau)$. Adding the induced absorption to the value of the initial absorption of the phosphor prior to the irradiation, $a(\lambda, \tau = 0)$, the whole absorption is

$$a_i(\lambda, \tau) = a(\lambda, \tau = 0) + C_i(\tau)\sigma_i(\lambda) \equiv a(\lambda, \tau = 0) + f_o \sigma_i(\lambda)(1 - e^{g_o \tau}) + h_o \sigma_i(\lambda)\tau \quad [7]$$

Based on the experimental fact that no reciprocity failure was found within the applied exposure range, we introduce the exposure, $E = i\tau$, instead of τ, where i is the anode current in the x-ray tube. The relative absorption coefficient $[a_{ir}(\lambda, \tau)]$ expressed with E from Eq. [7] is

$$a_{ir}(\lambda, E) = a_r(\lambda, E = 0) + f(1 - e^{-gE}) + hE \quad [8]$$

The coefficients f, h, and g differ from $f_o\sigma_1$, $h_o\sigma_1$, and g_o, respectively, only by numerical factors.

The decrease of the luminous efficiency.—As shown previously (3), the luminous efficiency, L_i, of an x-ray-irradiated phosphor can be expressed in terms of the unirradiated one, L, by the initial absorption coefficient $a_r(\lambda, E = 0)$ and by the absorption coefficient of the irradiated phosphor $a_{ir}(\lambda, E)$ both measured at the wavelength of excitation

$$\frac{L_i}{L} = m_v(E) \frac{a_r(\lambda, E = 0)}{a_{ir}(\lambda, E)} \quad [9]$$

where $m_v(E)$ is that part of the loss which is caused by self-absorption of the emitted light by the irradiation-produced color centers. An approximate expression for $m_v(E)$ is given in Ref. (3). The exposure-dependent change of the L_i/L relative efficiency with respect to λ wavelength excitation is from Eq. [8] and [9]

$$\frac{L_i}{L} = m_v(E) \frac{a_r(\lambda, E = 0)}{a_r(\lambda, E = 0) + f(1 - e^{-gE}) + hE} \quad [10]$$

Spontaneous recovery of the absorption coefficient and of the luminous efficiency.—In Eq. [2], the rate constant, a_4, is related to the spontaneous bleaching of the phosphor at room temperature. In phosphors in which such a phenomenon actually occurs, both the absorption and the luminous efficiency might recover partially or return to their original values after the irradiation has stopped. Based on Eq. [2], the change in the concentration of the color centers at a time τ^* elapsed after ceasing the irradiation at time τ_o is

$$\frac{dC_i(\tau^*)}{d\tau} = -a_4 C_i(\tau^*) \quad [11]$$

The integral of Eq. [11] is

$$C_i(\tau) = C_i(\tau_1) e^{-a_4 \tau^*} \quad [12]$$

Let $a_{ir}(\lambda, \tau^*)$ be the relative absorption coefficient of the phosphor after τ^* elapsed time of dark recovery. Multiplying Eq. [12] by the capture cross section of the color center related to λ, the wavelength of excitation, and adding the initial absorption of the phosphor prior to the irradiation $a_r(\lambda, E = 0)$ to the induced absorption, we obtain for the time dependence of the relative absorption coefficient

$$a_{ir}(\lambda, \tau^*) = a_r(\lambda, E = 0) + \sigma_i(\lambda) C(\tau_1) e^{-a_4 \tau^*} \equiv a_r(\lambda, E = 0) + a_{ir}(\lambda, E = i\tau_1) e^{-a_4 \tau^*} \quad [13]$$

Let us consider that the visible absorption does not change during the recovery. That is

$$m_v(\tau_1) = m_v(\tau_1 + \tau^*) \quad [14]$$

Then, based on Eq. [9] from Eq. [13] and [14], we obtain for the recovery of the luminous efficiency

$$\frac{L_i}{L} = \frac{a_r(\lambda, E = 0)}{a_{ir}(\lambda, \tau^*)} = \frac{a_r(\lambda, E = 0)}{a_r(\lambda, E = 0) + a_{ir}(\lambda, E = i\tau_1) e^{-a_4 \tau^*}} \quad [15]$$

Experimental

Irradiation and optical measurements.—The phosphors were irradiated by 50 kV unfiltered tungsten x-rays. The measurements of the relative absorption coefficient and of the luminous efficiency of the phosphors were based on diffuse reflectance measurements made on 2 mm-thick powder layers. The apparatus used for the irradiation, excitation, and optical measurements of the phosphors was described previously

(3). An important aspect of the optical measurements is that they were carried out on two characteristic wavelengths: one of these wavelengths is in the tail of the absorption band of the phosphors, the other is within the emission band. The absorption of the irradiation-induced color centers in a wavelength which corresponds to the tail of the absorption band can be quite high compared to the absorption of the phosphor prior to irradiation. The decrease of luminous efficiency related to excitation occurs in the peak of the absorption band, and it is easier to measure this change (3). Some measurements have been also made near the peak of the excitation band.

The absorption coefficients of the irradiated phosphors used in this study, as measured by diffuse reflectance, $R(\lambda)$, were small enough to use the weak absorption limit of the expression (9) for the relative absorption coefficient

$$a_r(\lambda) = \frac{(1 - R(\lambda))^2}{R(\lambda)} \qquad [16]$$

The relative luminous efficiency of the irradiated phosphor in terms of the unirradiated one, L_i/L, can be expressed using the relative brightness I and I_i, and reflectances, $R(\lambda)$ and $R_i(\lambda)$, of the phosphor before and after irradiation, respectively (10)

$$\frac{L_i}{L} = \frac{I_i}{I} \frac{1 - R(\lambda)}{1 - R_i(\lambda)} \qquad [17]$$

Results

The growth of absorption.—The change of the relative absorption coefficient of calcium tungstate was measured at three different wavelengths. One of these wavelengths (2537Å) is well within the absorption band of the phosphor while another one (3120Å) falls in the tail of the absorption band. Measurements were also carried out at 4358Å, a wavelength inside the emission band. Two series of measurements with different irradiation times were made; the first using 50 kV, 40 mA, and the second using 50 kV, 4 mA tungsten x-rays. Figures 1 through 4 show $a_{ir}(\lambda, E)$, the measured relative absorption *vs.* the relative exposure, $E = i\tau$, where i is the anode current in mA and τ is the elapsed time of irradiation in minutes. Figure 1 shows the growth of the relative absorption coefficient measured at 3120Å in the exposure range 0-40 mA·min. Some measurements were made by irradiation with 50 kV, 40 mA tungsten x-rays (solid points) while others were made with 50 kV, 4 mA tungsten x-rays (open points). The geometrical configurations of the samples were the same for both exposures. As this and following figures indicate, the relative absorption coefficients can be considered as a function of the product, $i\tau$. That is, within the anode current range applied in this work, the reciprocity failure is negligible. Therefore, in the following figures, the absorption as well as the luminous efficiency of the phosphors is plotted *vs.* the relative exposure, E.

The absorption coefficient of calcium tungstate measured at this wavelength suddenly increases right after beginning the irradiation. Figure 2 shows that this part of the fast growth of absorption is followed by a very slow linear rise. This initial sudden rise of the growth curve is characteristic for both phosphors studied at every measured wavelength.

Figures 3 and 4 show the exposure dependence of absorption of the calcium tungstate measured at 4358Å. The curve has the same characteristic as the one measured at 3120Å. However, the absorption of the phosphor prior to the irradiation is near zero at this wavelength. The growth of absorption is also smaller than on the curve measured at 3120Å. According to our model, this means that the capture cross section for absorption of the radiation-induced color centers is smaller in the visible than well inside the absorption band. Here, too, the sudden rise of the absorption at low exposures is followed by a slow linear rise (Fig. 4). The value of reflectance of the calcium tungstate was found to be very small ($R \simeq 0.07$) at 2537Å and did not show any change within the applied range of exposure. Obviously, the capture cross section and concentration of the activators are much higher than

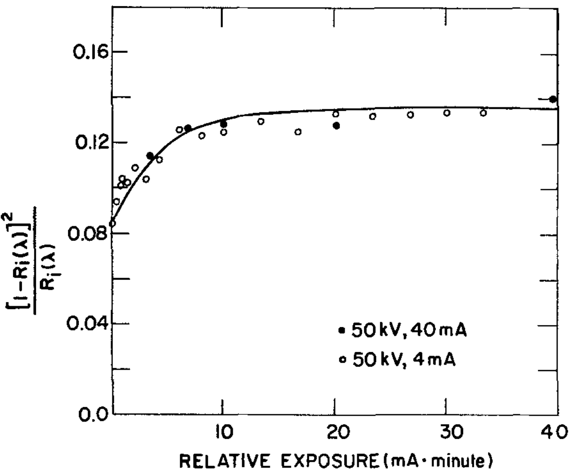

Fig. 1. X-ray-exposure dependence of the relative absorption coefficient of calcium tungstate at 3120Å (short-term exposures). Dots measured; line calculated.

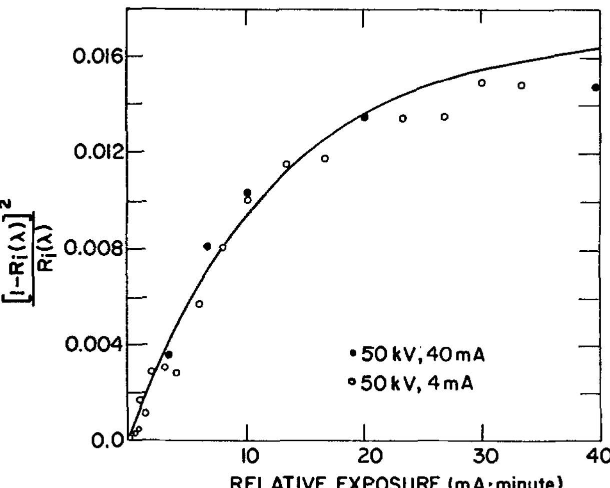

Fig. 3. X-ray-exposure dependence of the relative absorption coefficient of calcium tungstate at 4358Å (short-term exposures). Dots measured; line calculated.

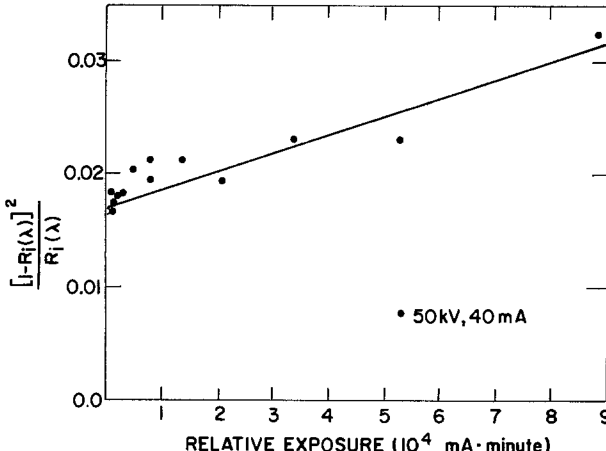

Fig. 4. X-ray-exposure dependence of the relative absorption coefficient of calcium tungstate at 4358Å (long-term exposures). Dots measured; line calculated.

those of the induced color centers and the latter cannot significantly contribute to the whole absorption.

The exposure dependency of the change of the relative absorption coefficient of zinc silicate samples has been measured at 3650Å (Fig. 5) and 4358Å (Fig. 6). The growth of absorption of the zinc silicate is similar to that of the calcium tungstate. Again, a sudden rise is followed by a slower, more gradual growth. If we

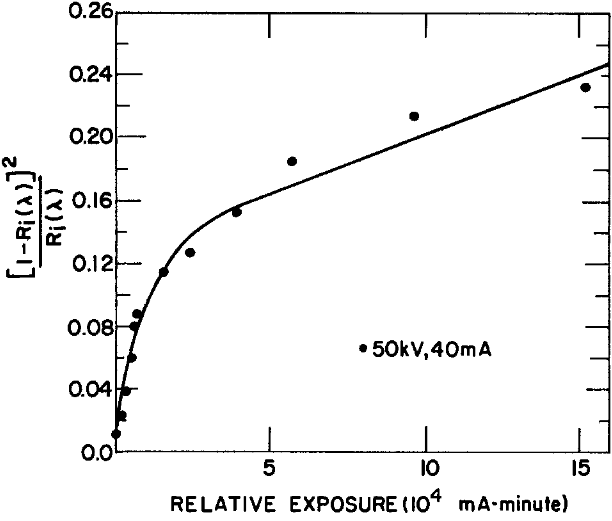

Fig. 5. X-ray-exposure dependence of the relative absorption coefficient of zinc silicate at 3650Å. Dots measured; line calculated.

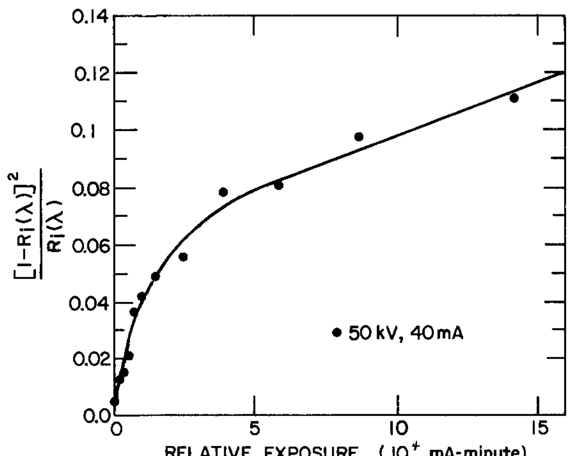

Fig. 6. X-ray-exposure dependence of the relative absorption coefficient of zinc silicate at 4358Å. Dots measured; line calculated.

compare Fig. 5 to Fig. 6, we can see that if the same exposure is applied, the increase of the absorption coefficient is smaller at 4358Å than at 3650Å. 40 mA for 63 hr x-ray exposure causes only a very slight change (from $R \approx 0.08$ to $R \approx 0.07$) in the reflectance of zinc silicate measured at 2537Å.

The degradation of the luminous efficiency.—The brightness of the irradiated samples was measured while exciting the phosphors at the same wavelength at which the reflectance measurements were completed. The changes of the luminous efficiency of calcium tungstate related to excitation at 2537 and 3120Å are shown in Fig. 7 and 8. The luminous efficiency is again a function of the exposure only, that is, the reciprocity failure is negligible, as was also found for the absorption.

Comparing the absorption and luminous efficiency results, Fig. 1 and 7 and Fig. 2 and 8, respectively, it

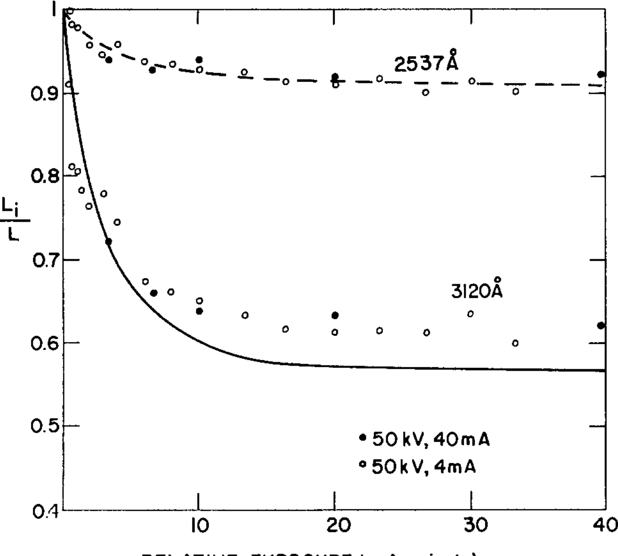

Fig. 7. X-ray-exposure dependence of the relative luminous efficiency of calcium tungstate related to excitation at 2537 and 3120Å (short-term exposures). Dots measured; continuous line calculated.

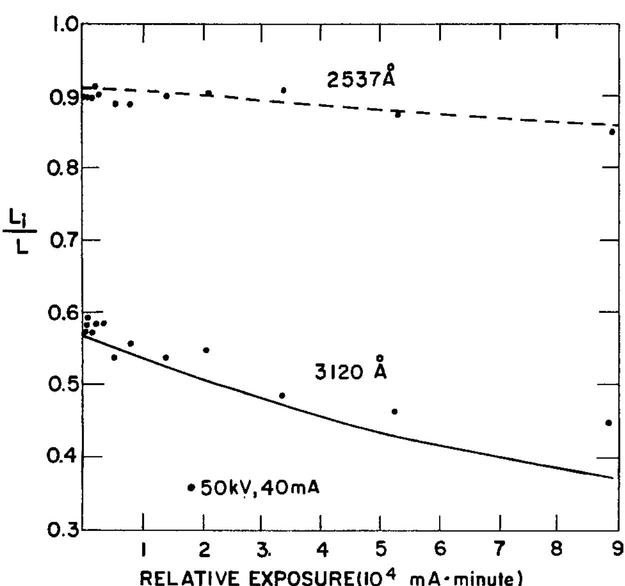

Fig. 8. X-ray-exposure dependence of the relative luminous efficiency of calcium tungstate related to excitation at 2537 and 3120Å (long-term exposures). Dots measured; continuous line calculated.

is noticeable that the sudden increase of the absorption measured at 3120Å (within the exposure range 0-10 mA·min) coincides with a sudden decrease of the luminous efficiency. After 10 mA·min of exposure, the decrease of luminous deficiency slows down, which corresponds to the slower rise of absorption which also occurs at longer exposures. The decrease of the luminous efficiency is significantly smaller at 2537Å than at 3120Å.

The degradation of zinc silicate is more extensive and the close correlation between the radiation-induced change of absorption and luminous efficiency can also be seen in this case. After several minutes of irradiation, the luminous efficiency of zinc silicate related to 3650Å excitation drops below 10% of its initial value (Fig. 9). This is obviously connected with the change of the absorption which increases after the same exposure to about ten times its initial value (Fig. 5).

Spontaneous bleaching.—The stability of color centers is known to be dependent on the temperature of their environment. The observed connection between degradation and color center formation of irradiated phosphors suggested a study of the dark recovery of irradiated calcium tungstate at room temperature. In order to avoid the possible bleaching effect of the sources used for excitation, each sample was used for only one measurement. The samples studied were irradiated by 50 kV, 40 mA x-rays for 10 min and kept in the dark until the time of measurement. As Fig. 10 shows, the absorption of the sample measured at 3120Å suddenly decreases after the irradiation ceases. Later, the change slows down. The same character of recovery was observed when the relative absorption of the samples was measured at 4358Å (Fig. 11). The dark recoveries of the measured luminous efficiencies related to 2537 and 3120Å excitation are shown in Fig. 12. The decrease of the absorption after the interruption of irradiation is accompanied by an increase of luminous efficiency of the phosphor. The extent of the recovery related to 3120Å excitation is greater than that related to excitation at 2537Å.

Comparison of the experiments with theory.—The exposure dependence of the relative absorption coefficient, $a_{ir}(\lambda, E)$ was calculated for the studied phosphors at the wavelength of the measurements from Eq. [8]. Applying the least squares method, the best fits for calcium tungstate could be achieved with constants

shown in Table I. The calculated curves together with the measured points are shown in Fig. 1-4. The curves calculated for zinc silicate with the constants shown in Table II are plotted in Fig. 5 and 6. The calculation of the exposure-dependent change of the luminous efficiencies of calcium tungstate (Fig. 7 and 8) and zinc silicate phosphors (Fig. 9) were based on Eq. [10]. The values of $m_v(E)$ in Eq. [10] were calculated from the measurements (3). Within the range of exposures, the variation of $m_v(E)$ was found to be very small com-

Table I. Calcium tungstate

	λ = 3120A	λ = 4358A
f	$5.18 \cdot 10^{-2}$	$1.69 \cdot 10^{-2}$
g (in mA · min)	$2.33 \cdot 10^{-1}$	$8.03 \cdot 10^{-2}$
h (in mA · min)	$7.68 \cdot 10^{-7}$	$1.64 \cdot 10^{-7}$

Table II. Zinc silicate

	λ = 3650A	λ = 4358A
f	$1.14 \cdot 10^{-1}$	$5.7 \cdot 10^{-2}$
g (in mA · min)	$1 \cdot 10^{-4}$	$8 \cdot 10^{-5}$
h (in mA · min)	$7.53 \cdot 10^{-7}$	$3.3 \cdot 10^{-7}$

pared to the change of the relative absorption $a_{ir}(\lambda, E)$. The other parameters that appear in Eq. [10] were taken from the absorption data shown on Table I or II.

Except for the initial region, the recovery of the absorption of calcium tungstate after 10 min of irradiation by 50 kV, 40 mA x-rays cannot be fitted by Eq. [13]. However, as Fig. 12 shows, the recovery of L_i/L luminous efficiency can be fitted well applying Eq. [15], using the measured values of the relative absorption coefficients $a_{ir}(\lambda, \tau^*)$ and $a_r(\lambda, E = 0)$.

Discussion

Theoretical interpretation of the experimental results gives a more complete understanding of the degradation kinetics of the model phosphors studied. Let us discuss first the growth of absorption. The initial fast period and the slow linear rise of the growth curves which follows can be correlated with the imperfections originally present in the phosphors and the ones formed by the radiation, respectively. If a_2 in Eq. [2] is equal to 0, then, from Eq. [4], [5], [6], and [7], h in Eq. [8] is also equal to 0, but f and g do not vanish. The second linear section, hE, of the growth of absorption curves (Fig. 2, 4, 5, 6) is connected with the new imperfections because, in Eq. [1], a_2 is the rate constant of the generation of new imperfections by the radiation. The first fast rise of the curves (Fig. 1, 3, 5, 6) that corresponds to the second term, $f(1 - e^{-gE})$, in Eq. [8] is connected mainly with the imperfections already present in the phosphors prior to the irradiation. This second term approaches the value of f to within 1% after an exposure of $E > 60$ mA·min for calcium tungstate and $E > 4.6 \cdot 10^4$ mA·min for zinc silicate.

These results are very similar to those obtained for the growth of F centers in KCl by other authors (5, 6, 7). The accuracy of our measurements was not enough for a definite identification of an inflection point on the growth curves (6) which would indicate that the initial and the radiation-induced vacancies behave differently (7). In Ref. (5-7), the optical density measurements were made near the peak of the characteristic band of the F centers in the alkali halide crystals studied. The concentration of the F centers could be determined from absorption measurements (11). In our case, the types of centers are not yet identified; the reflectance measurements (3) indicate that several different types could have formed in the phosphors by irradiation, and their absorption bands might overlap. There is another indication from this work that in calcium tungstate at least two different color centers are produced by the irradiation. Comparing Eq. [7] and [8] if only one type of color centers was formed, g in Eq. [8] would not be a function of the wavelength-dependent, capture cross section of the color centers, but would be related only to their concentration. In calcium tungstate, g was found to be a function of the wavelength of measurement (Table I) while in zinc silicate, within the error of measurement, g had the same value at both measured wavelengths.

The calculated curves of degradation which are based on the calculated growth of absorption curves fit the measured values for zinc silicate reasonably well (Fig. 9), while there is some deviation from the measured values in the case of calcium tungstate (Fig. 7 and 8). We attribute these deviations to the error of the measurement rather than to other unknown effects. We can rather safely say that the u.v. and visible absorption of irradiation-produced color centers is the major cause of the degradation of the photoluminescence of these phosphors. Other effects of the irradiation, if any, are negligible in this respecct. Comparing the results obtained for the degradation to the analysis (above) of the growth of absorption curves, it is quite obvious that according to our model the initial fast degradation is connected with the imperfections prior to the irradiation of the phosphors while the following slow change can be attributed to new imperfections formed by the irradiation. A closer model of the absorption (12) and the energy levels involved could not be determined from our measurements which are related to the time-dependent change of the absorption and of the luminescence only.

We do not completely understand why the recovery of absorption follows the calculated values, Eq. [13], only during the initial period of recovery. In order to explain the experimental findings that the absorption (Fig. 10 and 11) and luminous efficiency (Fig. 12) do not completely regain the original value after irradiation stops, further study is needed. However, calculating the recovery of the luminescence from Eq. [15] with the experimentally measured absorption values during the recovery, good agreement with the experiments could be obtained (Fig. 12). The recovery phenomenon in general and this result in particular are additional proof that degradation is strictly connected with the absorption of color centers produced in the phosphors.

A reasonable approach to slowing down the initial fast degradation of phosphors should be the elimination of the imperfections originally present by annealing, by charge compensation, or by other methods. The rate and extent of the dark recovery should also be important in most applications, although it is not yet known how it can be influenced. Enhancing the absorption of the luminescent centers by increasing the activator concentration also seems feasible. However, it is restricted by the phenomenon of concentration quenching.

Low Energy Ion-Electron Luminescence: A New Technique for the Excitation of Inorganic Phosphors

Jerry Kramer

GTE Laboratories Incorporated, Waltham, Massachusetts 02154

ABSTRACT

A new technique for the excitation of inorganic phosphors by low kinetic energy ions (<40 eV) and low kinetic energy electrons (<20 eV) has been demonstrated and characterized. The characteristic light output of the phosphor has been used as a probe of the excitation mechanism. An empirical relationship between the light output and the ion and electron currents has been determined and used to ascertain the change in light output as a function of ion and electron kinetic energy and ionization potential. The excitation mechanism starts with the formation of holes by the ion beam. Although the holes are mobile in the lattice, some of the holes get trapped. In a second step electrons interact with these trapped holes to create an excited state(s) of the phosphor. Energy is transferred to the luminescent centers resulting in the characteristic emission of the phosphor. The slow or rate-limiting step in the production of light by low energy ions and electrons is the emission of light. Of the ten phosphors examined for low energy ion-electron excitation, six showed detectable levels of light output and, hence, we conclude that this excitation technique is quite general. The efficiency of light production observed for Y_2O_3-Eu is ~1 photon per 40 N_2^+ ions and no effort has been made to increase this efficiency. We refer to the light produced by this excitation technique as low energy ion-electron luminescence (LEIEL).

This paper presents a new technique for the excitation and subsequent characteristic emission of an inorganic phosphor. This new technique is based upon the interaction of low kinetic energy ions (<40 eV kinetic energy) and electrons (< 20 eV kinetic energy) with a phosphor.

Two schemes which are widely employed today for phosphor excitation involve electromagnetic radiation or charged particles with high kinetic energy, usually in excess of 1 keV (1). In the case of electromagnetic radiation, the exciting species are generally u.v. photons or higher energy x-rays. For charged particles, the exciting species are either negatively charged electrons (cathodoluminescence) or positively charged ions (ionoluminescence). For both electrons and ions the luminous output is kinetic energy dependent, increasing with kinetic energy.

A third excitation scheme is radical recombination luminescence (RRL), a phenomenon often referred to in the early literature as candoluminescence (2). RRL was initially observed when flames, a rich source of radicals, were "played upon" phosphor surfaces. More recent work has utilized microwave discharges as radical sources and confirmed the validity of radical excitation. RRL involves the recombination of two neutral species (which may be the same) on a phosphor surface. The energy of excitation can be thought of, naively, as equal to the recombination energy of the two radicals, or, equivalently, to the bond energy of the molecular bond formed in the recombination. As an example, in the case of two hydrogen atoms, the excitation energy would be 4.5 eV. For the sake of comparison, a 4.5 eV photon would have a wavelength of ~2750Å. The efficiency of RRL is quite low. Typical efficiencies for RRL of about 1 photon/10^5 radicals are found experimentally. These low efficiencies relate, in part, to an excitation mechanism involving many steps, only one of which involves the formation of a bond between the two radicals.

An interesting extension of these ideas involves the use of oppositely charged species to excite luminescent materials. The available recombination energy of low kinetic energy ions and electrons can be thought of as approximately equal to the ionization potential of the neutral atom or molecule formed in the recombination. The ionization potentials of most neutrals range from about 10 to 25 eV. The corresponding wavelengths of photons of that energy span the range from about 1250 to 500Å. Conceptually, the excitation of phosphors by ions and electrons can be thought of as primarily a potential energy phenomenon, rather than a kinetic energy process.

The idea that ions and electrons could excite a phosphor has been speculated upon in the literature of flame-excited luminescence (2). However, controlled

Key words: luminescence, phosphors, ions.

experiments to test this hypothesis have not been reported to date.

We present the first experiments on the excitation of luminescence in inorganic phosphors by low kinetic energy ions and electrons. The phenomenon is found to be complex, being very much dependent upon the interaction of the ions and electrons with the phosphor. The phosphor does not act as a simple third body which accepts the recombination energy of the ions and electrons. In contrast to RRL, the efficiency of light production by low kinetic energy ions and electrons is quite high.

Experimental

The low energy ion-electron luminescence (LEIEL) apparatus is shown schematically in Fig. 1. The glass outer envelope of the system is connected to glass-to-metal seals and copper-gasketed stainless steel flanges which are used for supports and feedthroughs. The use of flanges permitted independent removal of the following four main components: (*i*) the ion source, (*ii*) the electron source, (*iii*) the phosphor support, and (*iv*) the vacuum system. Positive ions, generated in the ion source, and electrons from the electron source interacted with a phosphor sample. The light produced was spectrally analyzed by a monochromator and detected by a photomultiplier tube. Modulation of the charged beam(s) discriminated against the background d-c light signal as well as metastables and allowed measurement of the phase shift of the modulated light signal relative to the modulated charged beam.

The ion source and ion optics are from a Process Analyzers, Incorporated Quad 1200 RGA ionizer with electronic circuitry from a Quad 250B ionizer controller. The ion source potential was positive with respect to ground and determined the ion kinetic energy (maximum 40 eV). The first and third grids of the Einzel lens were at ground potential and the second grid at −90V to discriminate against electrons. The ion beam was modulated by applying a square wave potential (positive with respect to the ion source) to the first grid of the Einzel lens. Ions left the third grid and drifted ~5 cm to a phosphor plate oriented at a 45° angle to the axis of the ion beam. The only modification of the ion source consisted of replacing the tungsten filament with a directly heated oxide filament. This change significantly reduced background light. With an oxide filament emission current of 150 μA, 50 eV ionizing energy, and a source pressure of 6×10^{-4} Torr of N_2, an ion current of $\sim 6 \times 10^{-8}$A was detected at the phosphor plate. The detected ion current was not significantly altered when a phosphor was on the plate. A baffle, attached to the third grid, served to reduce the pressure in the phosphor region, relative to the source region, by a factor of ~20.

Since mass discrimination has not been incorporated into the apparatus, ion beams derived from diatomic neutrals will contain some monatomic ions. All experiments, however, were run with an ion source ionizing energy of 50 eV and were reproducible. For simplicity, we shall refer to an ion beam, derived from N_2 neutrals, as N_2^+ ions with the understanding that N^+ ions are also present.

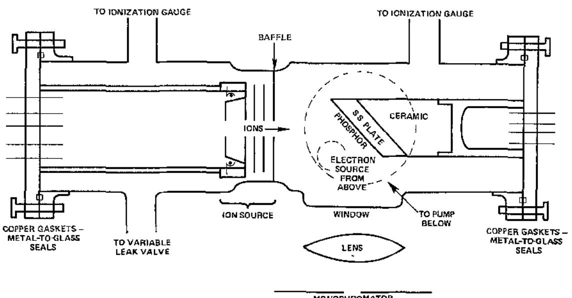

Fig. 1. Schematic diagram of the low energy ion-electron luminescence apparatus (viewed from above).

The electron source consisted of the heater, Ba/SrO cathode, and the first two grids from a Sylvania ST 4716 A CRT electron gun. The indirectly heated cathode was at a negative potential with respect to ground (normally −3V). The first grid was negative with respect to the cathode and was used to control the electron current. The second grid was positive with respect to the cathode and a square wave potential on grid two produced a modulated electron beam. The electron beam, which is normal to the phosphor plate and elevated 45°, originated ~3 cm from the phosphor plate.

At the low electron source cathode to phosphor potentials used in these experiments, the electron kinetic energy is dependent upon the contact potential of the phosphor and the oxide cathode as well as the cathode bias. These contact potentials are, in general, not known and we report the cathode bias which, within an additive constant, equals the electron kinetic energy. Since our results are correlated with a change in electron kinetic energy, knowledge of the actual electron kinetic energy is not necessary. We also note that surface charging will change the electron kinetic energy at a given cathode bias.

All phosphors, except one, have been obtained from GTE Sylvania. The exception, $SrAl_2O_4$-Eu, has been synthesized and characterized previously (3-5). Phosphors are settled from acetone onto a stainless steel flat and baked at ~400°-500°C for 15 min. Typical calculated phosphor thicknesses were about 10μ. The stainless steel flat was attached to an insulating ceramic block and a lead from the flat connected to an electrometer to ground.

The apparatus was evacuated by a 4 in. oil diffusion pump filled with Convalex 10 pump oil. A Freon-cooled baffle above the pump reduced backstreaming and a gate valve isolated the system from the pump. Pressures below 1×10^{-7} Torr, as measured by an ionization gauge in the ion source region, were obtained routinely and provision existed for baking the apparatus to 400°C.

The detection scheme is shown schematically in Fig. 2. A modulated electron beam plus an unmodulated ion beam produced a modulated light signal from the phosphor. The light was passed through a ¼ meter Jarrell-Ash monochromator and detected by a 1P28 PMT. The photomultiplier tube current generated a voltage across a 10^4 ohm resistor to ground and the a-c voltage was detected by a PAR HR-8 lock-in amplifier.

The phase of the modulated light was determined relative to an external reference from the Tektronix 161. The phase of the modulated current signal was also determined relative to the same external reference and the difference between these two phases was taken as the phase shift.

Modulation techniques, in addition to providing phase shift data which can be correlated with radiative lifetimes for first order processes, discriminate against background d-c light from filaments and possible effects from metastables. Modulation of both beams with continuously variable phase provides mechanistic information about the interaction of the ions and electrons with the phosphor.

In general, the charging of phosphor surfaces by low energy electrons necessitated the following experimental sequence. The ion source was turned on and an initial ion current $I_T°$, was detected by the electrometer. (It is assumed that the ion current detected at the electrometer is proportional to the ion current which strikes the phosphor surface.) Electrons were then added in incremental amounts and the decrease in $I_T°$ was taken equal to the electron current, I_e, an indirectly measured quantity. At each new value of I_e, the light output was measured and the phase shift could be determined.

As arbitrary standard conditions, we have studied the interaction of a beam of electrons modulated at 100 Hz with the electron source cathode biased 3V nega-

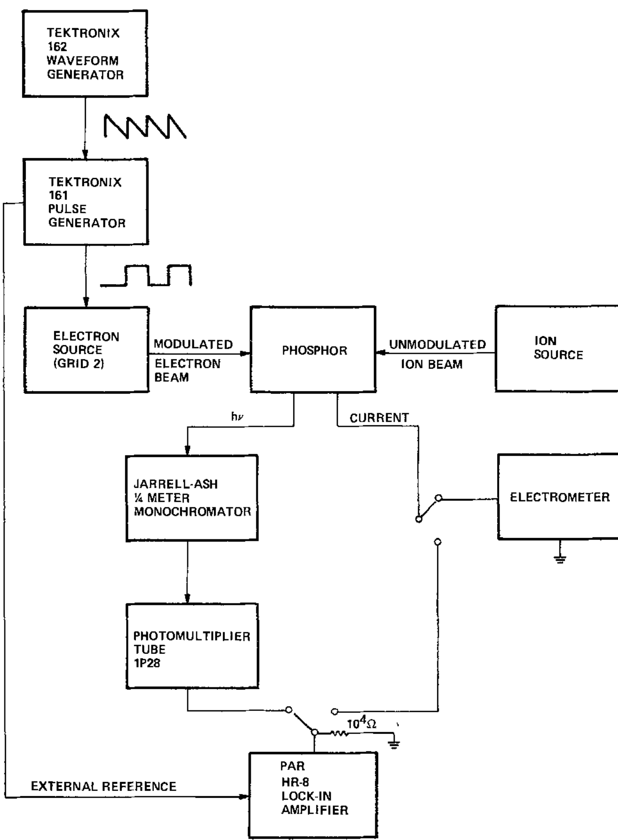

Fig. 2. Schematic diagram of the detection schemes. Modulation of the ion beam instead of the electron beam requires that the square wave go to grid 1 of the ion source rather than grid 2 of the electron source. Incorporation of a second Tektronix 161, triggered by the same 162, generates a modulated ion beam as well, with continuously variable phase with respect to the modulated electron beam.

tive with respect to the phosphor plate, and an unmodulated beam of 40 eV kinetic energy N_2^+ ions. Typical ion currents, $I_T°$, were in the range of 1-10 $\times$ 10^{-8}A and almost all data was determined for $|I_T°|>|I_e|$.

Results

We find that the interaction of a beam of low kinetic energy electrons and ions with a phosphor leads to the production of visible light characteristic of that phosphor. This light output has been used as a probe of the excitation mechanism: to probe the mechanism we measured the change in light output as a function of the external variables of the experiment. Initially, the quantitative relationship between light output and ion and electron currents was determined. This relationship provided a basis of comparison for the effect of variables such as electron and ion kinetic energy and ionization potential on the light output. Most of the experiments involved the interaction of ions and electrons with a Zn_2SiO_4-Mn phosphor. However, nine other phosphors were also studied in order to determine: (*i*) the generality of the phenomenon, which we shall refer to as low energy ion-electron excitation (LEIEE), (*ii*) the relative efficiencies of the different phosphors, and (*iii*) whether the quantitative relationships observed for Zn_2SiO_4-Mn held for the other phosphors.

The LEIEL spectrum of Zn_2SiO_4-Mn was the same as the emission spectrum observed by the more conventional excitation schemes of photoexcitation or cathode-ray excitation of the same phosphor. In the quantitative results which follow, the light output for Zn_2SiO_4-Mn was measured without slits on the monochromator (~300Å bandpass) and centered at 5280Å. Zn_2SiO_4-Mn has a broad emission, peaking at 5280Å, and a bandwidth at half-height of 410Å (6).

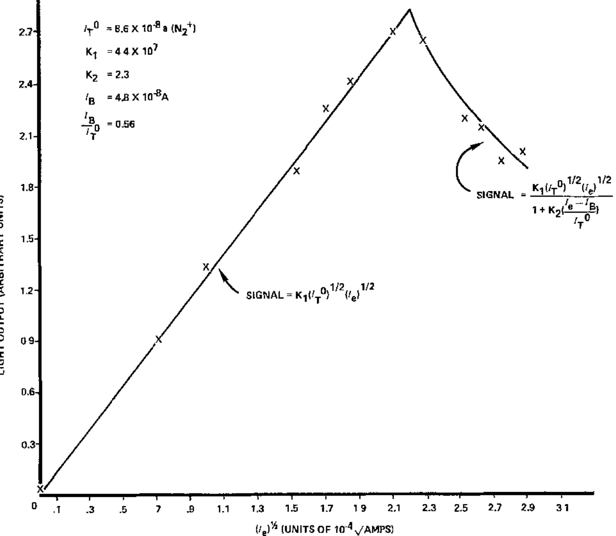

Fig. 3. Light output vs. $(I_e)^{1/2}$. Experimental conditions: Zn_2SiO_4-Mn; 40 eV N_2^+ ions, unmodulated; electrons modulated at 100 Hz, cathode biased 3V negative. Crosses refer to the experimental points and the solid line to the empirical equation.

The light output of Zn_2SiO_4-Mn *vs.* $(I_e)^{1/2}$ is shown in Fig. 3 for our arbitrary standard conditions. Qualitatively, the light output increased with increasing I_e and then started to fall off. This falloff was not associated with a change in the emission spectrum. The electron current at which falloff began was arbitrarily called I_B. The dependence of light output on $I_T°$ was determined by running experiments at different initial ion currents. The initial ion current could be varied by changing the neutral gas pressure or the emission current of the filament in the ion source and equivalent results were obtained with each method.

The relationships observed for ions at 40 eV were

$$S = \text{light output} = K_1(I_T°)^{1/2}(I_e)^{1/2} \text{ for } (I_e < I_B) \quad [1a]$$

and

$$S = \frac{K_1(I_T°)^{1/2}(I_e)^{1/2}}{1 + K_2\dfrac{(I_e - I_B)}{I_T°}} \text{ for } (I_e > I_B) \quad [1b]$$

K_1 is the scaling factor for output at values of $I_e < I_B$, the constant K_2 determines the magnitude of the falloff, and $I_B/I_T°$ relates to when the falloff begins.

In Table I we tabulate the constants K_1, K_2, and $I_B/I_T°$ (95% confidence levels) determined for our arbitrary standard conditions at a large number of different initial ion currents and also the constants determined at an ion kinetic energy of 20 eV. For our standard conditions we found that the falloff began when 55% of the initial ion current had been neutralized. Halving the ion kinetic energy to 20 eV resulted in a marked

decrease (~ half) in the light output (K_1) at $I_e < I_B$ and, in addition, the falloff was not observed in four out of five runs. Hence, at 20 eV ion kinetic energy, $I_B/I_T°$ approaches unity.

In Fig. 4 we plot the light output *vs.* $(I_e)^{1/2}$ for ion kinetic energies of 20 eV, 30 eV, and 40 eV. We see that whereas no falloff is observed at 20 eV and the 40 eV curve follows the relationships of Eq. [1], the results at 30 eV indicate that the light output has saturated.

More negative values of electron source cathode bias led to increased electron kinetic energy and, as shown in Fig. 5, increasing electron kinetic energy led to a linear increase in the light output (K_1) at $I_e < I_B$. Also, increasing electron kinetic energy resulted in larger values of $I_B/I_T°$. In comparing the effect of increasing electron and ion kinetic energy, we found that both led to an increase in light output. However, the behavior observed for $I_B/I_T°$ was opposite: increasing electron kinetic energy increased $I_B/I_T°$ while increasing ion kinetic energy decreased $I_B/I_T°$.

Ions, derived from N_2 neutrals, were used in most of our experiments. In order to explore the effect of ionization potential on the light output we examined

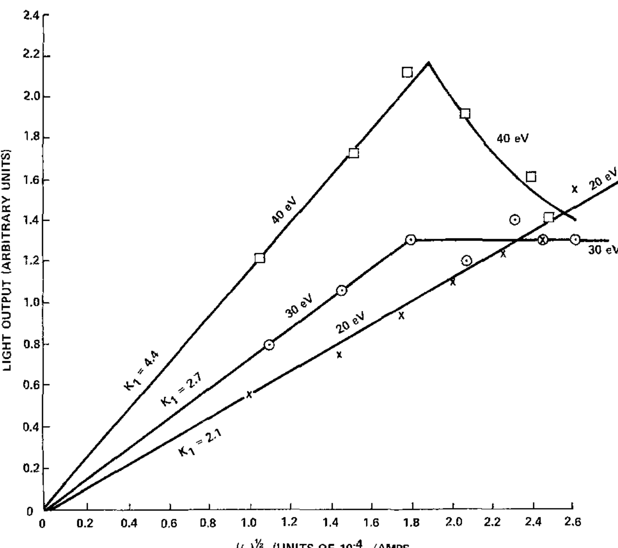

Fig. 4. Light output *vs.* $(I_e)^{1/2}$ for different ion kinetic energies. Experimental conditions: Zn_2SiO_4-Mn; electrons modulated at 100 Hz, cathode biased 3V negative; N_2^+ ions unmodulated, 40 eV (□), $I_T° = 7.0 \times 10^{-8}$A, 30 eV (⊙), $I_T° = 6.9 \times 10^{-8}$A, and 20 eV (×), $I_T° = 7.2 \times 10^{-8}$A.

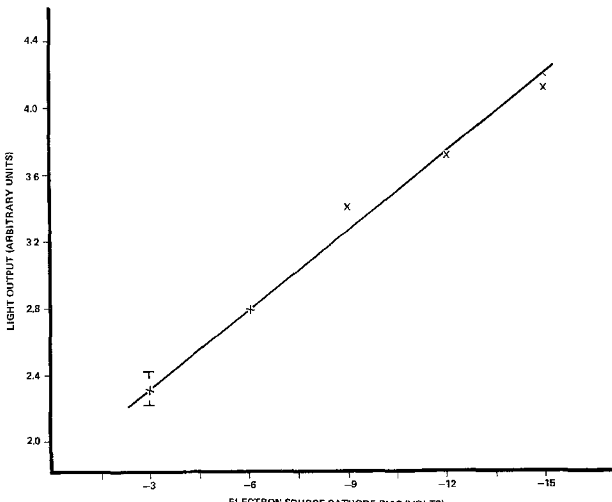

Fig. 5. Light output *vs.* electron kinetic energy. Experimental conditions; Zn_2SiO_4-Mn; 40 eV N_2^+ ions, unmodulated; electrons modulated at 100 Hz.

the light output for all the inert gas ions and CO^+. Polyatomic neutral sources could not be used because mass separation was lacking and O_2 was excluded because of potential damage to the oxide filaments. The light output for the various ions used showed the same dependence on $I_T°$ and I_e (including falloff) as observed with N_2^+. In Fig. 6 the light output, K_1, for $I_e < I_B$ is shown *vs.* the ionization potential of the neutrals (7). A gradual increase in light output ongoing from He^+ to Ne^+ to Ar^+ (decreasing IP) was observed and then the signal remained constant through Xe^+. The ions derived from diatomic neutrals, N_2^+ and CO^+, showed lower light outputs than the monatomic ions, Ar^+ and Kr^+, respectively, with comparable ionization potentials.

The interaction of two charged beams with a phosphor allowed each beam to be modulated separately or to modulate both beams with continuously variable phase between them. We have shown the results of four different modulation schemes in Table II. As our basis of comparison, we considered the constants K_1, K_2, and $I_B/I_T°$ for unmodulated 40 eV N_2^+ ions and electrons modulated at 100 Hz. We observed that modulating both beams, in phase and out of phase, did not have a large effect on the constants in the light output equation. A small decrease in K_1 for the case of both beams modulated out of phase was most apparent. In addition, note that the falloff was observed for both of these modulation schemes. In contrast, modulating the ion beam with an unmodulated electron beam resulted in very weak light output, too weak to be quantitatively measured. Finally, it was noted that modulating both beams out of phase at 20 Hz still produced a strong signal relative to both beams modulated in phase at 20 Hz.

Modulation of the electron beam plus an unmodulated ion beam produced a modulated light output.

N_2^+ (KE = 40 eV) Modulate ions—100 Hz	—	—	—

[a] 95% confidence levels.
[b] Units of $(A)^{-1}$.
[c] Dimensionless.

This light output was phase shifted with respect to the current beams and the magnitude of the phase shift was dependent upon the modulation frequency. The phase shift could be determined for each incremental addition of electron current to the initial ion current, $I_T°$. The magnitude of the phase shift was also dependent upon whether I_e was less than I_B or greater than I_B.

Before the falloff, $I_e < I_B$, the phase shift was approximately constant for each incremental addition of I_e. The quantitative relationship between phase shift, θ, and the modulation frequency, $f = \omega/2\pi$, was

$$\frac{\omega}{\tan\theta} = \frac{1}{\tau} = \frac{1}{\tau_0} + c\omega \qquad [2]$$

where c is a constant and τ is a first-order decay time. In the limit of zero frequency, τ_0 equals 2.6×10^{-3} sec. Rearrangement of Eq. [2] yields

$$\tan\theta = \frac{\omega\tau_0}{1 + c\omega\tau_0} \qquad [3]$$

These results are shown in Fig. 7.

After the falloff, the phase shift gradually decreased. Associated with this change was a change in the phase of the current beam and the light as well as the difference between them. Phase shifts determined near $|I_T°| \approx |I_e|$ did not show the same dependence upon frequency as shown in Eq. [2]. Near $|I_T°| \approx |I_e|$ the phase shift data could be fit to the equation

$$\frac{\omega}{\tan\theta} = \frac{1}{\tau} \qquad [4]$$

and $\tau \approx 1.5 \times 10^{-3}$ sec.

When both beams were modulated, the phase shift of the light correlated with the modulated electron beam, rather than the modulated ion beam. The magnitude of the phase shift was the same for modulation of both beams or the electron beam alone.

Nine other phosphors were examined for their LEIEL properties (8). A list of the phosphors studied and their relative efficiencies are shown in Table III. The luminescence observed showed no deviation from the normal emission spectrum. All phosphors, with sufficient emission to be quantitatively examined, showed the same dependence on $I_T°$ and I_e, including falloff, as Zn_2SiO_4-Mn. This relationship, (Eq. [1a]), with corrections for phosphor bandpass, PMT spectral response, and phosphor decay time, was used to determine the relative efficiencies. Selected checks of the effect of ion and electron kinetic energy and ionization potential on the light output revealed the same behavior as observed with Zn_2SiO_4-Mn. The only deviation from the results observed with Zn_2SiO_4-Mn related to phase shifts. Neither Y_2O_3-Eu nor YVO_4-Eu showed the linear frequency dependence on lifetime of Eq. [2] observed with Zn_2SiO_4-Mn at $I_e < I_B$.

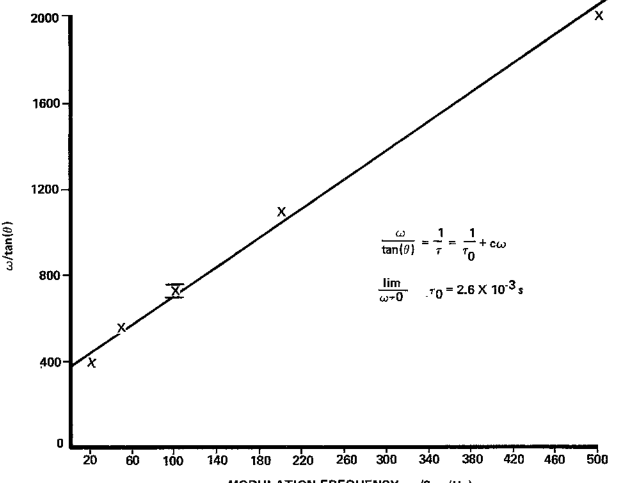

Fig. 7. Relationship between phase shift and modulation frequency ($I_e < I_B$). Experimental conditions: Zn_2SiO_4-Mn; 40 eV N_2^+ ions, unmodulated; electrons modulated, cathode biased 3V negative.

Table III. The relative LEIEL efficiency of different phosphors

Phosphor	Efficiency[a,b]
Y_2O_3-Eu	10
YVO_4-Eu	5
Zn_2SiO_4-Mn	5
$Ba_2P_2O_7$-Ti	3
$MgWO_4$	2
$SrAl_2O_4$-Eu	1
ZnCdS-Cu[c]	Very weak (?)
$Ca_5F(PO_4)_3$-Sb,Mn	Very weak (?)
$CaSiO_3$-Mn-Pb	Not observed
ZnS-Ag[c]	Not observed

[a] Light output corrected for emission bandpass, PMT spectral response, and lifetime. Experimental conditions: 40 eV N_2^+ ions, unmodulated, $I_T° = 8 \times 10^{-8}$A; electrons modulated, cathode biased 3V negative.

[b] Arbitrary units.

[c] These samples were not baked in air to prevent formation of an oxide coating on the surface.

When both beams were modulated at 20 Hz out of phase, the first six phosphors in Table III showed significant light outputs relative to in-phase modulation at 20 Hz. This was true even for $SrAl_2O_4$-Eu with a decay time of ~10 μsec to 10% initial brightness (3). By way of comparison, LEIEL in $SrAl_2O_4$-Eu was also observed at an electron beam modulation frequency of 10 kHz, the limit of the square wave generator.

$SrAl_2O_4$-Eu and Y_2O_3-Eu both had sufficient conductivity to conduct a modulated low kinetic energy electron beam (cathode = −15V) without significantly charging the phosphor surface. In both cases, no evidence of light was observed at the normal sensitivity used for LEIEL, even though the electron current was ~5-10 times the initial ion current normally used in an experiment.

In order to obtain a rough measure of the absolute quantum efficiency of the LEIEL process we have utilized ZnO. ZnO is excited by very low kinetic energy electrons and the quantum efficiency for 10 eV electrons is about 1 photon per 200 electrons (9). The ZnO light output, which is proportional to I_e, was measured at a modulated current of 8×10^{-8}A and 10 eV kinetic energy (cathode-phosphor bias) and corrected for PMT response, bandpass, and phosphor decay time. We have compared the light output of ZnO with the light outputs of the various phosphors in Table II at the experimental conditions given. The light output of ZnO was approximately equal to the light output for $MgWO_4$. Hence, we conclude that at an initial ion current, $I_T°$, of 8×10^{-8}A $MgWO_4$ has a maximum light output upon the addition of electrons corresponding to about 1 photon per 200 N_2^+ ions. No effort has been made to increase the yields for any phosphor.

Discussion

We begin our discussion by considering the effect of electrons and ions alone on the phosphor, followed by the development of a model and subsequent refinements derived from quantitative data.

Electron-phosphor interactions.—When electrons interact with a phosphor, secondary electrons are emitted from the phosphor (10). The secondary electron emission coefficient, defined as the ratio of secondary electrons to primary electrons, is dependent upon the electron kinetic energy. At low kinetic energy the secondary electron emission coefficient of the phosphor is less than unity and in time the phosphor charges to the negative bias of the electron source cathode. For many phosphors, at approximately 50-200 eV, the secondary emission coefficient rises above unity and no negative charging is observed (11). Finally, at still higher kinetic energies (~1-60 keV) the secondary electron

emission coefficient falls below unity again (11). In addition to producing secondary electrons, primary electrons also interact with a phosphor to produce visible light *via* cathode ray excitation (1). The kinetic energy threshold for the production of light is typically several hundred electron volts, however, notable exceptions such as ZnO have thresholds below 3 eV (9). For the continuous production of light, the phosphor must not charge negatively. In two phosphors used for the LEIEL experiments, charging did not occur at the typical electron kinetic energies of our experiments. It is significant that no light was detected in these two phosphors.

Ion-phosphor interactions.—The interpretation of ion-phosphor interactions is more complicated than electron-phosphor interactions. The complications arise because an ion has potential as well as kinetic energy by virtue of its ability to recombine with an electron. At high-ion kinetic energies (for example >1000 eV), the ion bombards the phosphor and the interaction is dominated by the kinetic energy. As with the primary electrons, one observes secondary electron emission (12) and the production of light (ionoluminescence) (1). At low ion kinetic energies, the ion spends a much greater time near the surface of the phosphor and, hence, the potential energy of the ion can play a more dominant role. When low kinetic energy ions, with sufficient potential energy, approach within a few angstroms of a phosphor surface, neutralization of the ion can occur before the ion strikes the phosphor surface in a process involving the phosphor, the ion, and an electron from the valence band of the phosphor. Ion neutralization and the subsequent effect on the phosphor are best considered by reviewing some of the elementary theory of ion neutralization spectroscopy (12-14).

In Fig. 8 we see a diagram of the interaction of an ion with a phosphor surface (15). $E = 0$ represents the vacuum level of the phosphor as well as a free electron and ion separated to infinity. The incoming ion approaches the phosphor surface and at some critical distance, s, dependent upon the ion kinetic energy, an electron from the valence band tunnels through the potential barrier to neutralize the incoming ion. The neutralized ion retains much of its kinetic energy (velocity) and continues toward the phosphor, striking the surface as a neutral. For neutralization to occur, the recombination energy of the ion, which in first order neglects the interaction with the phosphor and can be taken as the ionization potential (IP), must be greater than the energy from the top of the valence band to free space (ϕ^*). The valence electron, upon tunneling from the valence band, creates a hole and generally this hole is formed very close to the surface. If the IP $> \phi^*$, excess energy must be dissipated and if IP $> \phi^* + \Delta E_g$ (the bandgap), a second electron from the valence band can be excited into the conduction band in an Auger-type process creating an electron-hole pair. Finally, if the IP $> 2\phi^*$, secondary electrons can be emitted.

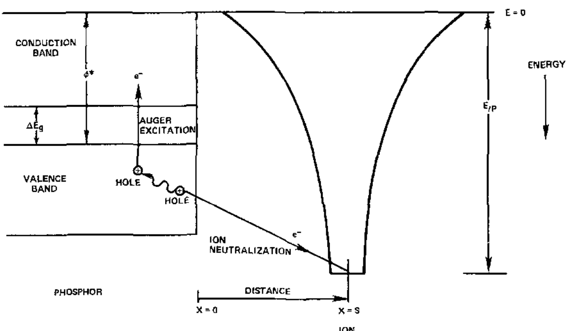

Fig. 8. Schematic energy diagram of low kinetic energy ion-phosphor interaction.

In semiconductors the secondary electron emission coefficient is only very weakly dependent upon ion kinetic energy, but the secondary electron yield increases dramatically for ions with increasing ionization potentials (16). Because of the high conductivity of the semiconductors, no surface charging was observed. For an insulator such as amorphous selenium, surface charging is most apparent (14). In the case of SiO_2 films, ion neutralization processes lead to degradation of the MOS quality SiO_2 films (17) and impurity migration from the surface to the Si substrate (18).

In our experiments on phosphors, surface charging, if present, was not pronounced enough to repel the incoming unmodulated ion beam. Compared to an unmodulated ion beam, square wave modulation halved the detected ion current with the phosphor present. For identical settings of the ion source, nearly the same ion current was detected by the electrometer with and without a phosphor present. From these observations we conclude that most of the holes formed upon neutralization have sufficient mobility to reach the electrometer and prevent charge buildup.

Formation of a trapped hole.—In the LEIEL experiments luminescence was only observed when ions as well as electrons interacted with the phosphor. By modulating both beams out of phase it was determined that the two charged species did not have to be coincident for light to be produced. This result suggested two possible roles for the ions. The first was that the electrons excited the phosphor *via* a conventional cathodoluminescent type excitation and that ions passively provided charge neutrality. A second mechanism assumes a more active role for the ion in the excitation process. Our results suggest that the active role for the ions is dominant.

Low energy ions (>100 eV) interacting with metal surfaces show almost a 100% neutralization efficiency: ~0.1% reflected ions and metastable atoms are observed (19). At the opposite end of the conductivity scale, the insulator, amorphous Se, shows a 100% charging efficiency in the region of low surface charge, and no difference was observed in charging behavior among any of the ions at any energy (<200 eV) in the limit of zero surface charge (14). If we make the logical assumption that all the different ions are neutralized with 100% efficiency at the phosphor surface, then the observed differences in light output as a function of ionization potential indicate an active role for the ions. The square root dependence on the ion current in the light output equation is also suggestive of an active ion role. For two phosphors, electron charging did not occur at low electron kinetic energy and no luminescence was observed when the positive ion current was zero. Thus, for these two phosphors, the ions must play an active role and this strongly suggests that the ions take an active role in all the other phosphors.

One could argue that the decreased light output observed when only the ions are modulated is indicative of a passive role for the ions. The ions could preserve charge neutrality and the electrons produce a d-c light signal undetected by the lock-in amplifier. A more likely explanation, which preserves the active role, involves the formation of a trapped hole by the ion. If the ion beam creates a trapped hole whose lifetime is long with respect to the modulation frequency, then modulation of the ion beam at that frequency will lead to a decreased a-c light signal (20). This explanation requires that the ion beam creates an intermediate excited state of the phosphor which cannot luminesce. When both beams are modulated out of phase, the phase of the light output correlates with the electron beam rather than with the ion beam. Hence, we conclude that the electron beam interacts with the trapped hole of the phosphor to create an excited state(s) that leads to luminescence.

In the case of phosphors, temporary trapping of holes has been shown to lead to luminescence in $SrAl_2O_4$-Eu (5). Although the Eu^{+2} emission in $SrAl_2O_4$-Eu has a

fast (10 μsec) decay to 10% of initial brightness, a long-lasting persistence of many seconds is observed (3). This luminescence has been shown to be associated with trapped holes that are thermally deactivated. We note that LEIEL was observed in $SrAl_2O_4$-Eu. In $SrAl_2O_4$-Eu the hole trapping levels are associated with defects in the lattice. In general, a second possibility for a hole trap is the activator ion itself. For example, Mn^{+2} could act as a hole trap by forming Mn^{+3}. Upon deactivation of the Mn^{+3} to Mn^{+2} with an electron, the Mn^{+2} could be left in an excited state and hence, might luminesce. A third possibility is that two mobile holes will dimerize and be trapped. This concept has been postulated with regard to CaF_2 and will be amplified later (21).

All our results point to the formation of a trapped hole by the ion beam. The correlation between the electron beam and the light output, determined from the phase shift, and the ability to produce light with the beams out of phase supports the idea that electrons interact with the trapped holes in a second step to produce an excited state(s) of the phosphor. The light emission from LEIEL agrees with the other conventional excitation schemes and, hence, the same emitting state is most probably involved in the different excitation schemes. This is entirely reasonable, in that most phosphor excitation schemes with widely varying energy inputs lead to the same emission spectrum of the phosphor. Finally, the phase shift in Zn_2SiO_4-Mn extrapolated to zero modulation frequency yields a first order decay time of 2.6×10^{-3} sec which is similar to the value of 2.5×10^{-3} sec at 15°C determined by photoexcitation of the same sample (22).

Possible mechanisms and kinetic energy dependence.—The light output equations for ions at 40 eV are

$$S = \text{light output} = K_1(I_T^\circ)^{1/2}(I_e)^{1/2} \text{ for } (I_e < I_B) \quad [1a]$$

and

$$S = \frac{K_1(I_T^\circ)^{1/2}(I_e)^{1/2}}{1 + K_2\dfrac{(I_e - I_B)}{I_T^\circ}} \text{ for } (I_e > I_B) \quad [1b]$$

We note that the falloff does not begin when electrons are first added to the phosphor, but only after a significant fraction of the initial ion current has been neutralized. As seen in Fig. 4, the falloff at 30 eV is different, being better represented by a term in the denominator of the light output equation which reflects saturation, and that at 20 eV no falloff is observed. Common to the results at these three kinetic energies, however, is the light output equation, $K_1(I_T^\circ)^{1/2}(I_e)^{1/2}$, for $I_e < I_B$. We start by discussing a possible mechanism which might give rise to the square root behavior of the ion and electron currents.

Ions interact with the phosphor at low kinetic energy and are neutralized when they approach within a few angstroms of the phosphor surface. The neutralized ion continues its path toward the phosphor and strikes the phosphor surface as a neutral with some kinetic energy. Results on low energy ions (25-600 eV) interacting with a tungsten wire indicate that at the energies used in those experiments approximately 50% of the kinetic energy of the ion is transferred to the tungsten lattice by the neutralized ion (23). The incoming ion is neutralized when an electron from the valence band of the phosphor tunnels to the approaching ion leaving a hole at the surface of the phosphor. In the case of metals or semiconductors, the mobility of the holes formed (or electrons) is high enough to prevent charge buildup at the surface, while in the case of insulators such as amorphous selenium, rapid charge buildup with an initial 100% efficiency is observed at the surface. For phosphors with conductivities between insulators such as amorphous selenium and semiconductors, we postulate that positive charge buildup at the surface is kept down because the kinetic energy of the neutralized ion frees the hole from the surface of the phosphor and creates a mobile hole. Recent experiments in low energy ion bombardment effects in SiO_2 have also postulated this "knock-on" effect with regard to impurity migration (17). The increasing ability to free holes from the surface of the phosphor may explain the increase in light output before falloff observed with increasing ion kinetic energy.

Holes, once freed from the surface region, are mobile and can migrate to the phosphor substrate and be collected by the electrometer or they may be trapped along the way. The square root dependence on the ion current in the light output equation mechanistically suggests that two mobile holes combine to form a trapped hole. The rate of production of trapped holes, dp_t/dt, is proportional to the rate of creation of holes, I_T°, minus the rate at which trapped holes are formed in a process dependent upon the square of the hole concentration, p. Thus

$$\frac{dp_t}{dt} = \beta I_T^\circ - kp^2 \quad [5]$$

and at steady state $dp_t/dt = 0$ and

$$[p] \alpha (I_T^\circ)^{1/2} \quad [6]$$

The dimerization of holes has been postulated previously in work done on CaF_2 (21). X-irradiation of CaF_2 doped with Tm^{+3} produces self-trapped (V_K) centers at liquid N_2 temperatures. Tm^{+3} ions enhance V_K production by trapping electrons and hence, are converted to Tm^{+2} ions. Upon warming the crystal to room temperature, about 90% of the V_K centers are changed to nonparamagnetic hole centers (24). The nonparamagnetic nature and complex decay kinetics of these room temperature hole centers are compatible with the formation of hole pairs as the stable hole centers.

In analogous fashion, the dependence of the light output on the square root of the electron current suggests that two electrons may be involved in the production of light. The light output would be expected to increase with increasing electron kinetic energy if the excitation of a valence electron were involved in initiating the luminescence. This may explain the results of Fig. 5 which shows the light output *vs.* electron kinetic energy. Two other factors which might be relevant are that increasing electron kinetic energy will lead to less negative surface charging of the phosphor because of the increasing secondary electron emission coefficient, and that different electron kinetic energies will lead to different penetration depths of the electrons into the phosphor. Also at very low electron kinetic energy, cathodoluminescent processes show a "dead layer" effect which has been attributed to surface recombination (25). Our understanding of LEIEL, however, is not sufficiently developed to examine these three effects in any detail.

In order that the light output be proportional to the square roots of the two currents the light output must also be proportional to the first power of the hole concentration and the first power of the electron concentration. From the analysis above, however, the light, output should be proportional to the square of the hole and electron concentrations. At this time we cannot resolve this discrepancy, nor can we suggest an alternative mechanism which might fit the data better. We might also add that the influence of the hole concentration gradient from surface to substrate on the light output is not known, nor is the effect of the diffusion of the holes and electrons.

Falloff.—The falloff in light output is shown in Fig. 4 for a number of different ion kinetic energies. The falloff represents a competition between radiative and nonradiative processes. Interestingly, this competition does not begin at the start when electrons are added, but only after a finite percentage of the ion current has been neutralized. This suggests that the falloff in light output must be triggered by some state of the system.

Secondly, the functional form of the falloff changes dramatically with ion kinetic energy and does not even occur at an ion kinetic energy of 20 eV.

The triggering of the falloff is kinetic energy dependent. For electrons, increasing the kinetic energy increases the percentage of the ion current which is neutralized before falloff occurs. In contrast, increasing the ion kinetic energy from 20 to 30 eV decreases the percentage of the ion current which is neutralized before falloff occurs. This opposite behavior for oppositely charged species suggests that an electrostatic phenomenon may be responsible for the falloff. We also note that when the falloff occurs, the phase of the ion and electron beams change with respect to a reference. Charging of the phosphor surface would lead to distortion of the square wave ion plus electron signal and, hence, produce a phase shift.

Effect of ionization potential.—Our results show that the kinetic energy of the ion beam has a much greater effect on the light output than the chemical identity of the ion, *i.e.,* the ionization potential. However, when the ionization potential is less than ϕ^* (Fig. 8), insufficient energy is available for neutralization by an electron tunneling from the valence band, and, hence, the light should be very low or nonexistent. In contrast to our results, the secondary electron emission observed in ion neutralization spectroscopy is strongly dependent upon the ionization potential, increasing with increasing ionization potential, and very weakly dependent upon the ion kinetic energy (16). This suggests that for LEIEL the ability of an ion with high ionization potential to form an electron-hole pair in a secondary Auger process either does not lead to luminescence, or that any luminescence obtained from the Auger process is swamped by a different luminescent process which has a weak inverse dependence on the ionization potential.

The hole produced by the incoming ion, once freed from the surface of the phosphor, can either migrate to the substrate and be neutralized or be trapped in the bulk. A competition exists between these possibilities. One factor which may influence this competition is the energy of the hole initially formed, relative to the top of the valence band. Those holes formed closer to the top of the valence band may have a higher probability of being trapped. For a given ion current, ions with smaller ionization potentials capable of being neutralized by valence electrons will produce a greater percentage of holes closer to the top of the valence band, and hence more light will be produced per unit ion current.

The decreased light output of N_2^+ relative to Ar^+, and CO^+ relative to Kr^+, may relate to the ability of diatomic species to vibrate and rotate (26). Excitation of vibrational and rotational modes of N_2 and CO at the time of neutralization may decrease the percentage of the ion kinetic energy which is transferred to the phosphor relative to monatomic species. In general, some of the effect of ionization potential on light output may also relate to the inherent efficiency of kinetic energy transfer by the neutral to the lattice.

Although holes may be trapped either at the surface or in the bulk, our results suggest that the trapped holes responsible for luminescence are in the bulk. If a surface phenomenon were involved, one would expect that vacuum conditions, sample preparation, and time would play a major role in the light output obtained. Reproducible results were obtained, however, over periods of months without changing samples or baking the apparatus. In addition, fresh samples could be inserted into the system and, with no other preparation than evacuating the system, luminescence could be observed. Surely, by the modern standards of surface science, our phosphor surfaces were not clean.

Mass sputtering by ion beams with kinetic energies in excess of 500 eV is commonly used to clean surfaces. Low energy ion-surface collisions have produced optical radiation which arises from sputtered material (27). Some samples showed thresholds as low as ~50 eV (27). Although sputtering could be occurring in our experiments during ion irradiation, the low ion currents and low kinetic energies argue against significant amounts of sputtering.

Phase shifts.—The phase shift of the light output in Zn_2SiO_4-Mn *vs.* ω before the falloff is shown in Fig 7. We will only consider the region before falloff because of possible electrostatic complications that arise after falloff.

The relationship between the phase shift and ω in Zn_2SiO_4-Mn before falloff (assuming that τ is a constant independent of ω) is

$$\theta = \tan^{-1} \frac{\omega\tau_0}{1 + c\omega\tau_0} \quad [7]$$

where c is a constant. This differs from the normal equation for a first-order decay process by the $1 + c\omega\tau_0$ term in the denominator. Extrapolation of the phase shift to zero frequency to eliminate frequency dependent effects yields a first-order decay time, τ_0, of 2.6 msec. Zn_2SiO_4-Mn shows a first-order decay to below 10% of initial brightness and photoluminescent decay data from this laboratory on the same sample yields a first-order decay time of 2.5 msec at 15°C (22). The excellent agreement between these two values implies that the slow step in the production of light by LEIEL is the emission of light. In support of this conclusion, the first-order decay times for YVO_4-Eu and Y_2O_3-Eu were in reasonable agreement with the values obtained by other methods. Also the transit time of the ions to the phosphor is much faster than the luminescent decay times.

The $1 + c\omega\tau_0$ term in the denominator of the phase shift, although unusual, is reproducible. It may, however, be unique for Zn_2SiO_4-Mn in that it was not observed with Y_2O_3-Eu or YVO_4-Eu. The fact that the $1 + c\omega\tau_0$ term was not observed with Y_2O_3-Eu or YVO_4-Eu also tends to rule out experimental artifacts as the origin of the $1 + c\omega\tau_0$ term. A mechanism which might explain the physical origin of the $1 + c\omega\tau_0$ term is not apparent.

An alternative interpretation of the experimental data is that the phase angle, θ, is equal to $\tan^{-1}(\omega\tau)$ as expected for a first-order process, but that τ changes with frequency. This interpretation, however, requires that increasing frequency leads to apparent radiative lifetimes which are increasingly shorter than the natural lifetime obtained by photoluminescence. It is unreasonable that the lifetime could decrease by a factor of 5 ongoing from a modulation frequency of 20 to 500 Hz, especially with no indication that the lifetime was reaching a steady value.

Other phosphors.—Of the ten phosphors studied, six showed detectable levels of light by the LEIE excitation technique. From this result we conclude that LEIEL is a reasonably general phenomenon and that the technique should be capable of exciting a large number of phosphors. The fact that all six phosphors showed the same functional dependence on $I_T°$, I_e, and I_B in the light output equations as well as the same qualitative effect of electron and ion kinetic energies and ionization potential on light output indicates that the same general excitation mechanism leading to light production is operative in all of these phosphors. The linear frequency dependence of the emitting state lifetime observed in Zn_2SiO_4-Mn may be peculiar to that material.

Calibration of the light output with a ZnO standard shows that the LEIEL process is quite efficient. Y_2O_3-Eu has a maximum light output (just before falloff begins) with 40 eV N_2^+ ions and cathode bias of −3V which corresponds to about 1 photon per 40 N_2^+ ions. No effort was made to maximize the light output of these phosphors by altering the phosphor itself. There seems no reason to believe that a phosphor optimized for u.v. or electron excitation will be optimized for LEIE excitation.

LIST OF SYMBOLS

LEIEL	low energy ion-electron luminescence
LEIEE	low energy ion-electron excitation
$I_T°$	the initial ion current passing through the phosphor and detected by an electrometer
I_e	the electron current determined from the decrease in $I_T°$ upon the addition of electrons
I_B	the electron current at which the light output starts to deviate from a $K_1(I_T°)^{1/2}(I_e)^{1/2}$ dependence
f	the frequency at which the ion or electron beams, or both, are modulated
ω	the modulation frequency, f, divided by 2π
θ	the phase shift of the light output signal relative to the modulated current signal
τ	the first-order decay time to $1/e$ of initial value
ϕ^*	the energy difference from the top of the valence band to free space
ΔE_g	the bandgap

Structures and Optical Properties of Rf-Sputtered $Bi_{12}GeO_{20}$ Films

Tsuneo Mitsuyu, Kiyotaka Wasa, and Shigeru Hayakawa

Wireless Research Laboratory, Matsushita Electric Industrial Company, Limited, Kadoma, Osaka, Japan

ABSTRACT

Thin films of $Bi_{12}GeO_{20}$ were prepared on glass and silicon substrates by rf-sputtering with the growth rate of 0.04-1.5 μm/hr. The crystalline structure of the films varied mainly with the substrate temperature: the amorphous state was obtained below 150°C of the substrate temperature; polycrystalline with fcc form between 150° and 350°C; and polycrystalline with bcc form above 400°C. The (111)-oriented aluminum films deposited on glass substrates were found to enhance the preferred orientation of the bcc films in the <321> direction. These sputtered films exhibited the near ultraviolet optical absorption edges at 460-620 mμ, and a broad absorption at about 20 μm in the infrared region.

$Bi_{12}GeO_{20}$ (BGO) in the body-centered cubic (bcc) system is strongly piezoelectric, optically active, photoconductive, and exhibits an electro-optic effect. Large single crystals of BGO are made by the Czochralski method (1) and are studied for fabricating ultrasonic devices (2).

Thin films of BGO are usable for the fabrication of thin-film surface acoustic wave devices. The BGO films reduce the dimension of the acoustic devices owing to their low sound velocities (3) and also have a potential in the fabrication of thin-film optical devices such as light modulators, deflectors, and switches (4). Several processes are used to make the BGO film: chemical vapor deposition (CVD), liquid phase epitaxial growth, and cathodic sputtering. The CVD method was examined to deposit the single crystal BGO films on a surface of monocrystalline substrates by Silvestri *et al.* (5). In addition, several workers have succeeded in fabricating highly oriented or single crystalline films of multicomponent oxides such as ferroelectric $Bi_4Ti_3O_{12}$ and $LiNbO_3$ by cathodic sputtering (6-8). The cathodic sputtering process has the advantage that a wide variety of materials can be deposited on various substrates with little cross contamination.

Recently we have fabricated thin films of BGO on heterogeneous substrates by rf sputtering. This paper describes the structure and some optical properties of rf-sputtered BGO films.

Experimental Procedures

An rf diode sputtering apparatus of a hemispherical electrode system was used for depositing the BGO films. The electrode configuration of the sputtering apparatus is schematically shown in Fig. 1. A polycrystalline BGO hemispherical target 25 mm in diameter was used as cathode. The target was prepared as follows: First, powder of Bi_2O_3 (purity, 99.8%) and GeO_2 (purity, 99.99999%) mixed at the mole ratio of 6:1 was pressed into a column and the column was prebaked in air for about 4 hr at 800°C in order to synthesize BGO grains. Then, the grains were pressed into a column again and were sintered in air at the same firing condition to the prebaking process. Finally, the sintered column was formed into a hemispherical shape. The x-ray diffraction pattern and the corresponding lattice constant of the target well agreed with the ASTM data (card No. 23-71) for the bcc phase of the BGO. Borosilicate glass and (111)-oriented single crystal wafers of Si were used as substrates. These substrates were placed on a holder located behind the anode. Table I shows typical sputtering conditions for the film preparation. Under these conditions the BGO films were prepared with a growth rate of 0.04-1.5 μm/hr. The sputtered films were 0.15-3.0 μm thick.

Key words: bismuth germanium oxide, rf sputtering, piezoelectric film, optical absorption.

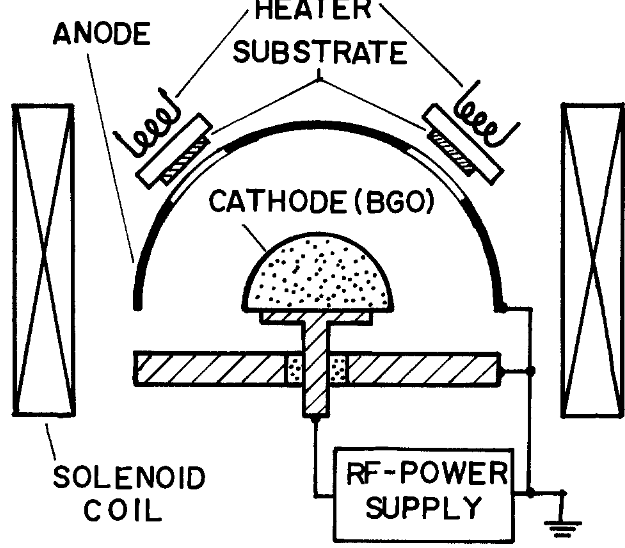

Fig. 1. Electrode configuration of rf-sputtering system

Crystalline structures of the films sputtered on the glass and Si substrates were determined by x-ray diffraction and reflection electron diffraction (RED). Optical transmission spectra were examined at room temperature. The glass substrates were used in the visible region and the Si substrates, in the infrared region.

Results and Discussion

It was observed that the crystalline structure of the sputtered films scarcely depended on the substrate material or the growth rate, but strongly depended on the substrate temperature during the sputtering process. At the substrate temperature below 150°C

Table I. Sputtering conditions for the film preparation

Target area	9 cm^2
Target-substrate spacing	2-3 cm
Sputtering gas	Ar(50%) + O_2(50%)

Magnetic field	100G
Substrate temperature	100°-500°C

(not deliberately heated) the sputtered films were amorphous. These films were yellow and transparent. At the substrate temperature between 150° and 350°C, the sputtered films were dark brown and showed a different x-ray diffraction pattern with that of the bcc phase. From the x-ray analyses, this phase is found to be the impure phase of Bi_2O_3 with a face-centered cubic (fcc) form which has been designated as δ^*-Bi_2O_3 by Gattow and Schröder (9). A comparison of the x-ray diffraction data for the film obtained in our experiment with the data for δ^*-Bi_2O_3 prepared from a composition $6Bi_2O_3 \cdot GeO_2$ by Gattow and Fricke (10) (listed as $Bi_{12}GeO_{20}$ in ASTM card No. 17-812) is given in Table II. The lattice constant a = 5.55Å for the former is slightly smaller than a = 5.57Å for the latter. This fcc phase is considered to be a metastable state since it has transformed easily into the bcc phase by annealing at 400°C for 1 hr. This consideration is confirmed by the fact that the bcc phase is found to be stable at any temperature below the melting point of 935°C (11). In the bulk BGO, the fcc phase can be obtained only by quenching a melt (10). It is noted that in the sputtering film growth process, the metastable fcc phase can be easily grown without any additional quenching process.

Films of the bcc phase were obtained at the substrate temperature above 400°C. The films of the bcc phase were pale yellow and semitransparent. X-ray data for these films and the ASTM data for the pulled single crystal BGO are also given in Table II. The lattice constant for the film is a = 10.16Å which is slightly greater than the ASTM data, a = 10.146Å. At the substrate temperature of 350°-400°C, sputtered films were mixtures of the fcc and bcc phases.

Figure 2 shows typical RED patterns and electron micrographs for the BGO films of the amorphous, fcc, and bcc phases on the glass substrates. It is observed that the crystallites of the bcc phase are much larger than that of the fcc phase. The RED patterns indicate that all these films are polycrystalline and scarcely exhibit a preferred orientation. Similar results were obtained for the films on Si substrates. But a slight tendency of the (321) orientation was observed for the bcc films as shown in Fig. 3 when the glass substrate was coated with a thin (111)-oriented Al layer (vacuum deposited), the growth rate was very low (0.04 μm/hr), and the sputtered film was very thin (0.15 μm).

The crystalline structures of the BGO films sputtered on glass or Si substrates are summarized in Table III.

** A slight tendency of the (321) orientation was observed.

(1), which well agreed with our results for films of the bcc phase. In the infrared region, a broad absorption at a wavelength of about 20 μm was observed for all the three types of film. In the films of the bcc phase, several remarkable peaks were superposed on the absorption band. These peaks may correspond to vibration modes peculiar to the bcc structure of BGO.

The refractive index n was determined from the number of optical interference fringes in the visible transmission spectrum by using the well-known relation $n = m\lambda_1\lambda_2/2t(\lambda_1 - \lambda_2)$, where m denotes the number of fringes between optical wavelength λ_1 and λ_2, and t is the film thickness. Taking $m = 5$ for $\lambda_1 = 720$ mμ, $\lambda_2 = 583$ mμ, and $t = 3.0$ μm for the sputtered amorphous BGO films, we have $n = 2.6$, which is nearly equal to the single crystal value of 2.55 (1). The values for the crystalline BGO films, however, cannot be determined due to their high optical absorption in the visible region.

Summary

We attempted to grow thin films of $Bi_{12}GeO_{20}$ on glass and silicon substrates by rf sputtering with the growth rates of 0.04-1.5 μm/hr. The structure of the sputtered films varied mainly with the substrate temperature T_s as follows: for $T_s \lesssim 150°C$ films were amorphous; for $150°C \lesssim T_s \lesssim 350°C$ films were polycrystalline with the fcc structure which was the metastable impurity form of Bi_2O_3 designated as δ^*-Bi_2O_3; for $T_s \gtrsim 400°C$ films were polycrystalline with the bcc structure which was the normal phase of BGO; for $350°C \lesssim T_s \lesssim 400°C$ the films were a mixed phase of the fcc and bcc structures. Optical transmission study indicated that the ultraviolet absorption edges were located at 510, 620, and 460 mμ for the amorphous, fcc, and bcc phases, respectively, and a broad absorption, at about 20 μm for all films. Although highly oriented BGO films of the bcc phase could not be obtained on glass or silicon substrates, (111)-oriented aluminum films deposited on the glass substrates were found to enhance the preferred orientation of the BGO films.

An Optically Effective Intermediate Layer Between Epitaxial Silicon and Spinel or Sapphire

Ch. Kühl, H. Schlötterer,* and F. Schwidefsky

Siemens AG, Forschungslaboratorien, München, Germany

ABSTRACT

The existence of an optically effective intermediate layer between epitaxial silicon and spinel or sapphire has been proved. By measuring the optical and geometric thickness of the films as a function of film thickness a difference in the thickness values was found which could be interpreted as the thickness of an intermediate layer. This layer was also measured directly with a stylus tracer yielding a thickness of about 40 nm. Reflection electron diffraction and secondary ion mass spectroscopy were performed. A growth model for the silicon films is proposed which assumes that aluminum silicates will be formed due to reactions with the substrate as long as the substrate surface is uncovered. Despite or possibly because of this existing intermediate layer good epitaxial silicon films are obtained.

The fact that strong orientation relationships can be found in the case of epitaxial silicon films on insulating substrate crystals has already been discussed in numerous papers (1, 2). A one-to-one coordination of the atoms of the two corresponding net planes of film and substrate, respectively, is in most cases given as an explanation (3, 4), and the substitution of atoms of the substrate surface by silicon atoms resulting in a Si-O bonding is discussed in literature. To overcome the relatively great mismatch or misfit of the lattice constants and distances which is frequently encountered, multiple fits had been used to match these differences (2, 4), a practice often adopted for epitaxy (5). Especially in the case of silicon-on-sapphire, some disagreement between different investigators was found (4) concerning the exact orientation relationships. Considering all these and similar aspects, one gains the impression that the existence of symmetry elements, especially symmetry axes like three- or fourfold rotation axes perpendicular to the surface plane, is more relevant to achieving good epitaxy than an exact atom-to-atom matching. This impression is confirmed by the fact that transition or intermediate layers are often discovered in connection with the epitaxy of vapor-deposited films (6).

Mercier (7) has used infrared spectroscopy to confirm the presence of Si-Al and Si-O bonds in silicon, films, but it was not possible to determine whether these were situated near the interface or in the silicon film itself. In the case of silicon on Mg-Al spinel and sapphire, we had experimental findings that suggest the existence of an intermediate layer which is in any case optically effective. We therefore studied this system in more detail in order to prove this hypothesis.

Experimental Methods and Results

The epitaxial silicon films on spinel or sapphire studied were produced by chemical vapor deposition in the SiH_4/H_2 system in a water-cooled horizontal reactor at substrate temperatures of 1080° and 1000°C and at growth rates of 1.5 and 2.5 μm/min, respectively. The substrates were single crystals of magnesium-aluminum spinel (Verneuil) with (100) surfaces and single crystals of sapphire (Czochralski) with $(\bar{1}012)$ surfaces.

Thickness measurements.—A simple experimental procedure was adopted, which is shown schematically in Fig. 1. After the epitaxial deposition a mask is applied and the unmasked part of the silicon film has been etched away by an acid etch of 95 ml 65% HNO_3, 5 ml 40% HF, and 1g $NaNO_2$ (8) resulting in a step. The step height, *i.e.*, the geometric film thickness d_G, is measured with a Perthen stylus tracer, Model ECW-L. The measured value may be a little less than the real distance of the silicon surface from the substrate since the acid may not remove all of the film also at the unmasked parts. The optically determined average film thickness, d_O, is calculated by evaluating the extrema of the interference fringes caused by reflection at the assumed optically effective interfaces air/film and film/substrate (9). The refractive index of the silicon films has been assumed to be that of bulk silicon. This assumption is suggested by earlier results and will be justified by the results discussed later on. The reflectance measurements were carried out in the wavelength range 1-2.5 μm with a Zeiss two-beam spectrophotometer, Model DMR 21, which was adapted by the construction of a reflection attachment.

Comparing the film thicknesses obtained with the different methods one observes that in all cases the optical thickness was less than the geometric thickness. We therefore assumed the existence of an intermediate layer giving rise to the difference in height between the substrate surface and the optically effective film boundary. To prove this hypothesis, we thinned several films with an initial thickness of about 1-2 μm in steps of about 0.2 μm by means of an alkaline etch of 30% KOH, 15 ml isopropanol at 84°C (8). After each step thickness measurements were performed with both methods.

In order to avoid falsifications caused by surface roughness, the surface of the film was carefully polished and cleaned after each thinning step.

Figure 2 shows the difference between both types of thickness values as a function of the optical thickness. Though there is a large spread of the values due to experimental error, a systematic positive difference is evident, which we interpret as the thickness of an intermediate layer between film and substrate; the thickness of this layer varies between 40 and 70 nm for different silicon-on-spinel samples. With silicon-on-sapphire, values were found (20-40 nm), which

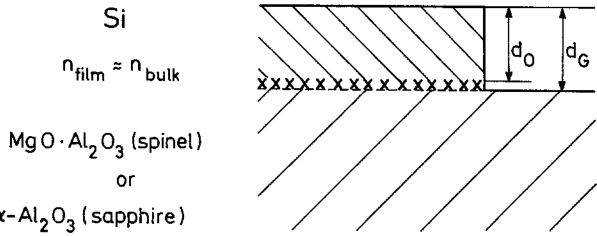

Fig. 1. Optical and geometrical thickness of an epitaxial silicon film on spinel or sapphire (xxx intermediate layer).

* Electrochemical Society Active Member.

Key words: optical interferences, thickness measurement, absorption, electron diffraction, SIMS.

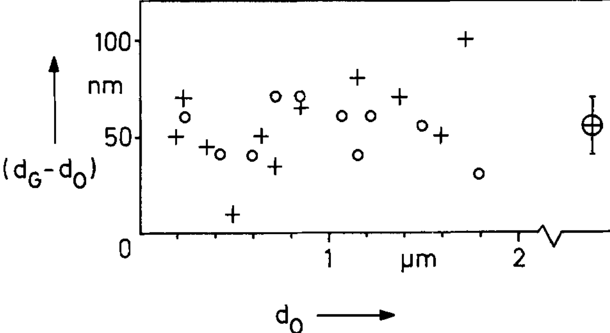

Fig. 2. Thickness of the intermediate layer on spinel vs. optical silicon thickness (+ sample 1, ○ sample 2, ⊕ mean value).

were systematically lower than those of spinel but which also showed some scatter.

Since the difference between geometric and optical thickness turns out to be independent of the film thickness, the refractive index of the film which had been assumed to be that of bulk silicon can be regarded as constant in all parts of the film. In principle, at a given film thickness, one could equalize the results of both measurements by assuming a refractive index n' smaller than that of bulk silicon. But in an earlier paper (10) it had already been shown that this should only be possible if a relatively high oxygen content is present, which is not the case with our films being produced in a reducing hydrogen atmosphere. On the other hand, if the geometric thickness is used for evaluation, n' should decrease strongly with decreasing thickness, but no signs of such a decrease have been found.

But the existence of the intermediate layer could also be proved directly: after the last etching step a scarcely visible layer remained showing a remarkably reduced etch rate compared to the silicon etch rate. In one case it was possible to measure this residual layer employing the step method, as described above. The result was a geometric thickness of about 40 nm. The spectral reflectance of this layer showed no difference compared to the substrate. Therefore, we assume that the optical constants of the intermediate layer scarcely differ from those of the substrate (sapphire: $n = 1.76$, $k = 0$; spinel: $n = 1.71$, $k = 0$ at $\lambda = 1$ μm).

Absorption measurements.—We also calculated the average absorption constant α at the different steps of film thickness according to a method described in a previous paper (11). The results are shown in Fig. 3. We observed a distinct increase in the absorption constant as we approached the substrate/silicon interface ($d_O = 0$). Other measurements, *e.g.*, lifetime and mobility measurements in the silicon films, also indicate a poor crystal quality near the interface (12).

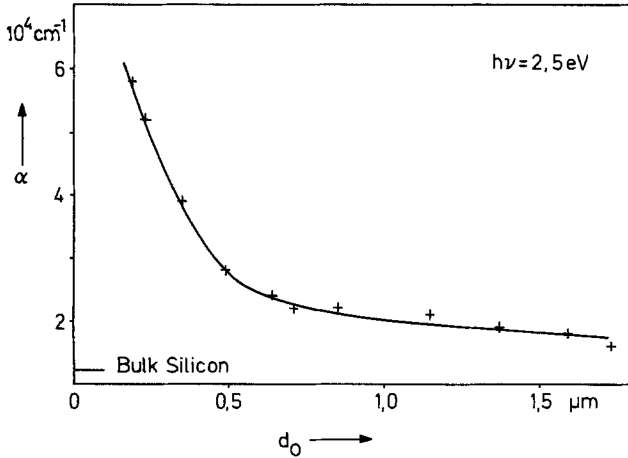

Fig. 3. Absorption constant vs. optical film thickness for a successively thinned epitaxial silicon film on spinel.

These results lead us to assume that a disordered region exists near the bottom of the silicon film, which can be correlated with the intermediate layer.

Analysis of the intermediate layer.—Secondary ion mass spectroscopy.—In order to analyze the composition of the intermediate layer, secondary ion mass spectroscopy (SIMS) was performed (13) using Balzers equipment. The primary beam consisted of Ar^+ ions with an energy of 450 eV and a current density of 10^{-8} A cm^{-2}. The target area was 0.1 cm^2. The surface of three samples was investigated, *i.e.*, a thin silicon film of about 100 nm, an intermediate layer with a thickness of about 40 nm, and a spinel surface as it appears after the acid etch. The most important results are shown in Fig. 4. With decreasing film thickness the magnesium and aluminum signals increase, whereas those of silicon and silicon compounds decrease. It is also seen that the spinel surface is giving signals of silicon and silicon oxides after the removal of the silicon film by the acid etch. This shows that on top of the substrate a thin film has remained containing those materials besides the components of the substrate. So even d_G does not correspond to the real distance between the silicon film surface and the true substrate crystal. That can be understood by the

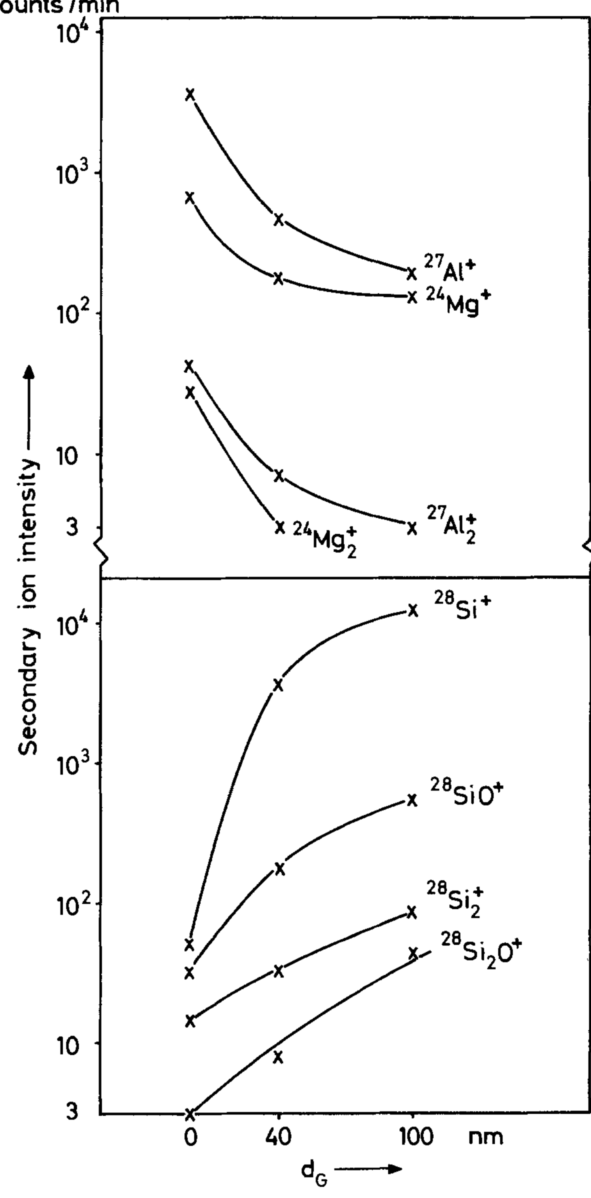

Fig. 4. SIMS analysis of the intermediate layer: intensity of characteristic signals vs. geometric thickness. Upper (lower) part: complex ions originating from the spinel substrate (silicon film).

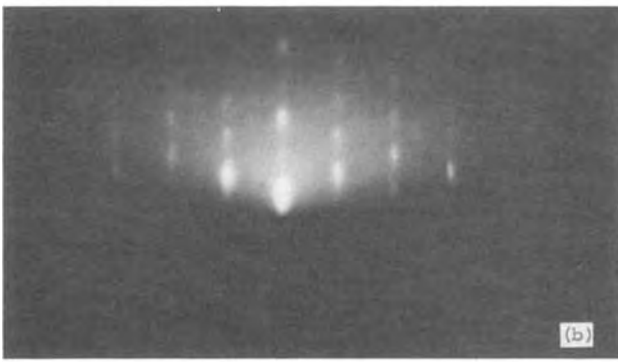
experimental fact that highly doped silicon has a very small etch rate, even with the acid etch.

At a first glance the SIMS result obtained with the silicon compounds is not in agreement with the decrease of the oxygen content expected with increasing distance from the oxide-substrate interface. But here we have to remember that we do not have a true profile measurement, but only the surface investigation of three samples. We therefore assume that the oxygen has not been incorporated during the epitaxial growth, but that the silicon near the surface has been oxidized during and after the etching process. Consequently the concentration of the silicon oxides decreases in the same way as the concentration of silicon itself. Similar results are obtained with silicon films on sapphire.

Electron diffraction.—In order to see a possible structural difference between the substrate and the intermediate layer, reflection electron diffraction was performed with a Siemens Elmiskop (electron energy 80 keV). Figure 5 (a) shows the diffraction pattern of the intermediate layer, whereas for the purpose of comparison, Figure 5 (b) shows the pattern of a spinel substrate, and Figure 5 (c) the pattern of an epitaxial silicon film. In the latter case, besides the Bragg reflection spots, we also see rather distinct Kikuchi lines, indicating the good quality of the film.



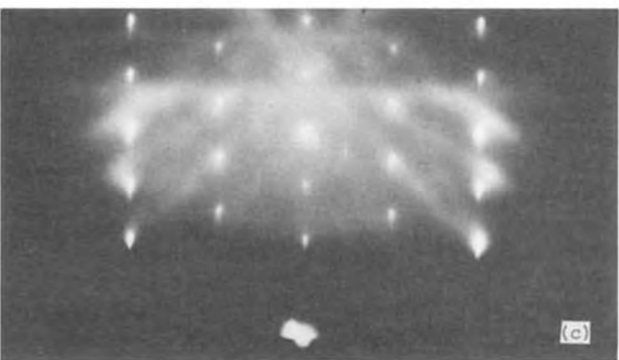


Fig. 5. (a) Electron diffraction pattern of the intermediate layer, (b) electron diffraction pattern of the spinel substrate, (c) electron diffraction pattern of the epitaxial silicon film on spinel. All obtained with (100) surfaces, the incident beam being parallel to [011].

Only part of the reflection spots in Fig. 5 (a) can be identified either as spinel [Fig. 5 (b)] or silicon [Fig. 5 (c)], whereas the other spots are probably due to some crystalline Al-Mg silicates. Unfortunately these spots could not easily be related to the generally known silicates. Nevertheless, the electron diffraction results, together with the SIMS data, suggest that the intermediate layer contains crystalline compounds differing both from the spinel substrate and the silicon film. More exhaustive experiments will have to be conducted to investigate the properties of the intermediate layer.

Discussion

The present investigations have shown that there is a gradual transition from the Al_2O_3 and MgO of the substrates to the pure silicon of the final film, the thickness of the transition layer in the case of sapphire being somewhat smaller than with spinel. The formation of the transition layer obviously is in connection with the well-known chemical reactions during the nucleation phase in the epitaxial growth (14).

For explanation we therefore make use of the following growth model: during the first phase of growth volatile reaction products like SiO and Al_2O are produced and partly included into the growing film (15). The amount of these reaction products will be proportional to the uncovered surface of the substrate since the reaction cannot take place below the silicon nuclei and islands. Therefore this amount decreases with increasing silicon coverage of the surface and, consequently, the concentration of the included compounds will also decrease. At the moment at which the surface is completely covered with silicon, the situation drastically changes as no more oxygen will be included in the silicon film. The consequence is a change of the composition due to the lack of oxygen. As long as oxygen is present, we will have some kind of aluminum silicates, which all indeed have optical constants (16) similar to those of the substrates (Al_2O_3, MgO-Al_2O_3). Therefore the optically effective interface will be located at a thickness containing so much silicon and so little magnesium, aluminum, and oxygen that it is rather the optical behavior of probably highly doped silicon than that of oxide compounds.

The different etch behavior of the alkaline and acid etch is in agreement with the differences in the ratio of etch rates for silicon and silicon oxide films (8). The alkaline etch rate is much more reduced by oxygen than that of the acid etch.

Using the expression "intermediate layer" rather than "transition layer" is, therefore, really appropriate because from the optical point of view it is a layer of definite thickness between substrate and silicon film (15). The experimental observation that this thickness is somewhat less with sapphire than with spinel can be explained by the different nucleation behavior of the two materials. The average thickness which is necessary to cover the substrate completely is smaller in the case of sapphire (15, 17), so that the thickness of the intermediate layer is also smaller. It seems that the intermediate layer matches the differences between substrate and silicon lattice. On the other hand, Distler *et al.* (18) found that the orienting influence of a single crystal substrate can be transmitted even through an amorphous intermediate layer. They studied, among other things, the oriented growth of PbS on top of amorphous carbon on NaCl. The authors give as an explanation of their observation the existence of long-range active centers on the substrate surface which induce epitaxial growth at a remarkable distance. However, Chopra (19) supports the hypothesis that epitaxial growth is an interfacial phenomenon and that the orienting influence of a substrate is confined to its surface plane only and the atoms located in it. Despite Chopra's argument we get good epitaxial silicon films on spinel or sapphire, as can be seen in Fig. 5 (c)

(Kikuchi lines) although an intermediate crystalline layer does exist. We could even assume that the intermediate layer is responsible for the achieved good epitaxial relation since the rather great mismatch between the lattice parameters of film and substrate will be reduced by such a layer.

Acknowledgments

The authors wish to express their thanks to Dr. R. Falckenberg for providing the spinel substrates and to Dr. M. Druminski and Mrs. S. Rheinboldt for providing the epitaxial silicon films. We also wish to thank Dr. R. Buhl, Balzers AG, for SIMS measurements and helpful discussions.

A New Fast Technique for Large-Scale Measurements of Generation Lifetime in Semiconductors

Wolfgang R. Fahrner[1] and Christian P. Schneider

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

This paper describes a technique that permits measurements of generation lifetime in the range of $\gtrsim$ 1 msec to $<<$ 0.1 nsec. For the measurements, a metal oxide semiconductor (MOS) capacitor is biased into strong inversion and subsequently switched into deep depletion. An appropriate experimental setup prints out or displays a typical recovery time, which is introduced into a computer fed by the theoretical generation model and the wafer data. The technique is suitable for process characterization.

The determination of lifetime in silicon (Si) is of great technological importance. Since the basic paper by Zerbst (1), important contributions to the literature have been made by others (2-4). Large-scale measurements of minority carrier lifetime have become desirable for many applications. The usual technique, described by Zerbst, is too cumbersome for large-scale measurements. Faster techniques (5) very often do not give the same results as a Zerbst plot. This paper describes a technique capable of rapid measurements of generation lifetime with good precision. Three, slightly modified, measurement setups using this technique allow coverage in silicon of the wide spectrum of lifetimes which are of practical interest. The measurements are carried out on metal oxide semiconductor (MOS) capacitors. [We used thermally grown oxides 1000 to 5000Å thick. The $<100>$ oriented substrates (mostly p-type) had resistivities of 1-20 ohm-cm. The p-type samples were selected so that no lateral currents occurred due to channel injection. Aluminum dots were evaporated onto the oxide to form MOS capacitors.] A voltage, V_a, is applied to a metal dot, and a steady-state inversion regime is established. Then a voltage step or pulse, ΔV_a, is added. This creates a depletion layer underneath the dot, thus reducing the value of the total measured capacitance and increasing the (absolute) value of the voltage drop across the interface. The time difference, t, between switching ($t = 0$) and reaching a preselected percentage of the equilibrium value is printed or displayed on a counter. This value is fitted to the thermal generation model by computer.

Key words: lifetime, MOS process control, silicon characterization.

Theoretical

This technique is not bound to a specific model of relaxation. For the sake of simplicity, we use the well-known equations given by Zerbst (1) and rewrite them in a convenient form. The applied voltage is the sum of the voltage drop, V_{ox}, across the oxide and the surface potential, ϕ_s

$$V_a + \Delta V_a = V_{ox} + \phi_s \quad [1]$$

Differentiation with respect to time and the use of equations

$$\phi_s = q \cdot N_A \cdot \epsilon_{Si}/(2C_D^2) \quad [2]$$

$$V_{ox} = (Q_D + Q_I)/C_{ox} \quad [3]$$

and

$$dQ_D/dt = C_D \cdot d\phi_s/dt \quad [4]$$

yields

$$(q \cdot \epsilon_{Si} \cdot N_A/2)d(1/C_D^2)/dt + (C_D \cdot q \cdot N_A\epsilon_{Si}/2 \cdot C_{ox}) \cdot d(1/C_D^2)/dt + (1/C_{ox})dQ_I/dt = 0 \quad [5]$$

The integration of Eq. [5] requires knowledge of the generation current, $I_{Gen} = dQ_I/dt$. Most commonly, the thermal generation model

$$dQ_I/dt = qn_i(x_D - x_{Df})/2\tau = I_{th} \quad [6]$$

is adopted. This model is not always valid. Discrepancies are found, especially for long-lifetime silicon at the end of the C-t return curve, where a faster generation mechanism might exceed the decreasing thermal generation. The origins for these deviations may be channel injection, enhanced generation due to inhomogeneities, or defects in both the oxide and the silicon.

In the case of channel injection or injection due to inhomogeneities, a simple model for dQ_I/dt can be assumed, namely

$$dQ_I/dt = I_{Gen} = I_{th} + \alpha I_I$$

where

$$I_I = \begin{cases} I_o = \text{const for } C < C_f \\ 0 \text{ otherwise} \end{cases}$$

measures the contribution of the injection to the total current.

Note that Eq. [6] does not contain any surface contribution $I_s = n_i \cdot q \cdot s_o$ for the following reason: In a comparison of I_s and I_{th}, s_o values in the order of 10-700 cm/sec were reported (6). These data are obtained from techniques based on switching the MOS structure from accumulation to deep depletion. By switching from inversion to deep depletion, as done in this technique, one obtains s_o values in the order of 10^{-2} cm/sec. The reason for the reduction is the screening of the surface by an inversion layer. The lifetimes are found to be in the range of 1 nsec-1 msec. The space-charge width, x_D, depends on the doping concentration, N_A, and the applied voltage. Assuming typical values $x_D = 10^{-4}$ cm $>> x_{Df}$, $s_o = 10$ cm/sec, and $\tau = 50$ μsec, one obtains $I_s/I_{th} = 10$, whereas, with the "inversion screened" s_o value of 10^{-2} cm/sec, I_s is small compared with I_{th}, even for very long lifetimes and small space-charge widths.

In this paper, we adopt the thermal generation model. The reason is shown below, where Eq. [5] is solved for different models for the generation current dQ_I/dt. Combining Eq. [5] and [6], we obtain

$$\frac{C_{ox} + C_D}{C_{Df} - C_D} \cdot \frac{1}{C_D^2} dC_D = \frac{n_i}{2\tau N_A} \frac{1}{C_{Df}} dt \quad [7]$$

This equation can easily be solved by normalization (replacing C_D by $C_D/C_{Df} = C_{DR}$,C_{ox} by C_{ox}/C_{Df}, and C_{Df} by 1) and by changing twice the variable $C_{DR} = 1/x_R = 1/\sqrt{\phi_R}$, where $x_R = x_D/x_{Df}$ and $\phi_R = \phi_s/\phi_{sf}$. The final result is

$$\sqrt{\phi_R} + (C_{Df}/C_{ox} + 1) \ln (\sqrt{\phi_R} - 1) = -t'_R \quad [8]$$

where

$$t'_R = \frac{n_i}{2N_A\tau} \cdot \frac{C_{Df}}{C_{ox}} (t - t_o)$$

This is the basic equation for the measurement of the short lifetimes (low- frequency measurement).

When the MOS capacitance is measured with a high-frequency signal, the total capacitance is $C = C_{ox}C_D/(C_{ox} + C_D)$. In this case, Eq. [7] can be rewritten

$$\frac{1}{C_R^2(1 - C_R)} \frac{dC_R}{dt} = \frac{C_f}{C_{ox}} \frac{n_i}{2\tau N_A} \quad [9]$$

and its solution is

$$\left[ln \frac{C_R}{1 - C_R} \right] - \frac{1}{C_R} = t''_R \quad [10]$$

where C_R is the normalized capacitance, $C_R = C/C_f$. Equation [10] is essentially the same as Heiman's result (5). Heiman, however, did not use this result, but its differential form (Eq. [9]). Furthermore, he switched from accumulation to inversion. For silicon with lifetimes $\tau \geqq 10$ μsec, a Heiman plot gives satisfactory results only during a very short range of the measuring time, as shown below. Equation [10] is used here to measure longer lifetimes (high-frequency measurement). Both Eq. [8] and [10] are plotted in Fig. 1 and 2. In Fig. 1, we reverse the ϕ_R axis because we do the same in the measurement (cf. Eq. [12a], below). Equation [5] has been integrated for

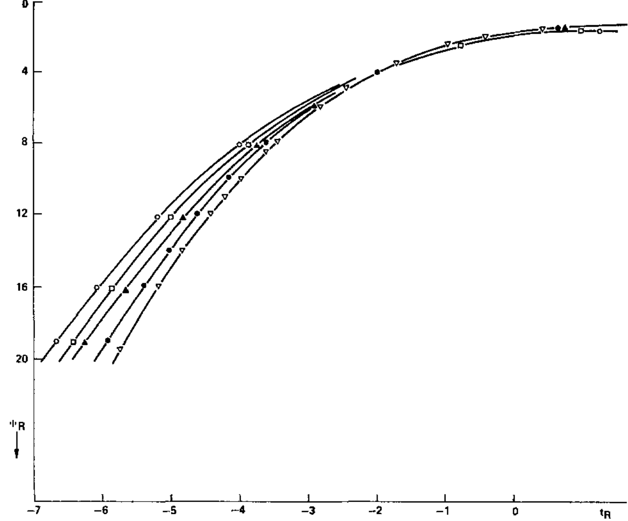

Fig. 1. Relaxation of the surface potential ϕ_R for different values of C_{Df}/C_{ox}. ▽, $C_{Df}/C_{ox} = 0.1$; ●, $C_{Df}/C_{ox} = 0.3$; ▲, $C_{Df}/C_{ox} = 0.5$; □, $C_{Df}/C_{ox} = 0.7$; ○, $C_{Df}/C_{ox} = 0.9$.

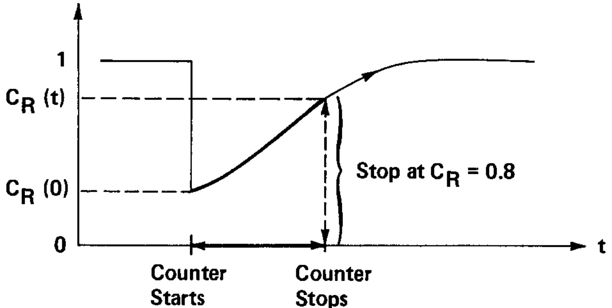

Fig. 4. Representative C-t plot. $t_o = 0$; $C_R = C/C_f$

several other modes of relaxation. Of these, we present one example (Fig. 3), where we add a constant current to the thermal current. The parameter, α, is a measure for the contribution of these additional currents; $\alpha = 0$ means a pure thermal generation. It can be seen that for $C_R \leq 0.9$, if the t_R axis is expanded or compressed, the curves will be similar. On the other hand, a variation of τ has the same effect. Thus, an additional generation current is equivalent to a reduction of the lifetime in the thermal generation model. This observation is valid for any reasonable generation current that decreases toward zero when the capacitance approaches C_f.

We use Eq. [10] (high-frequency measurement) to demonstrate this technique. When we measure two capacitance values $C_R(t)$ and $C_R(t_o)$ at the corresponding times t and t_o, we can calculate τ, because the other parameters involved are easily available. C_{ox} and C_f can be obtained by standard C-V measurements. From these values, N_A can be calculated. The room temperature value of n_i is 1.4×10^{10} cm^{-3}. For t_o we choose the onset of the step or pulse ($t_o = 0$). Rather than measure the capacitance after a fixed time t, we select a fixed capacitance value, e.g., $C_R = 0.8$, and measure the time, t, between switching and reaching the selected capacitance level. Figure 4 shows a schematic C-t plot and the measured time interval.

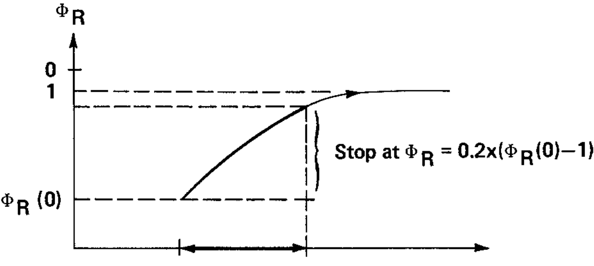

Fig. 5. Representative ϕ-t plot. $t_o = 0$

An analog technique is used in the low-frequency case, Instead of C_R, a specific change of ϕ_R (and its time duration) is measured. Only the counting of the time is slightly different; for example, we count now between $t = 0$ and the time when $\phi_R = 0.2 \times (\phi_R(0) - 1)$ (Fig. 5). This alteration is caused by the experimental conditions (see below).

Experimental and Results

As shown in Fig. 6a and b, the first, high-frequency, measurement setup essentially consists of a 1 MHz capacitance meter, two power supplies, two memories, a voltage comparator, a plotter, and a printer. Care must be taken that one does not switch the voltage through zero, because the majority carrier response is much faster than any switching time. This setup can be used for relaxation times $T = 2\tau N_A/n_i \geq 100$ msec. This lower limit is caused by the transient time of the bridge.

A similar setup is used for T values > 1 msec (Fig. 7). The block diagram of this setup has been published by Princeton Applied Research, Princeton, New Jersey (7). In this case, the output of a lock-in is proportional to C_R. For $T \lesssim 1$ sec, the plotter must be replaced by an oscilloscope. We use a Tektronix sam-

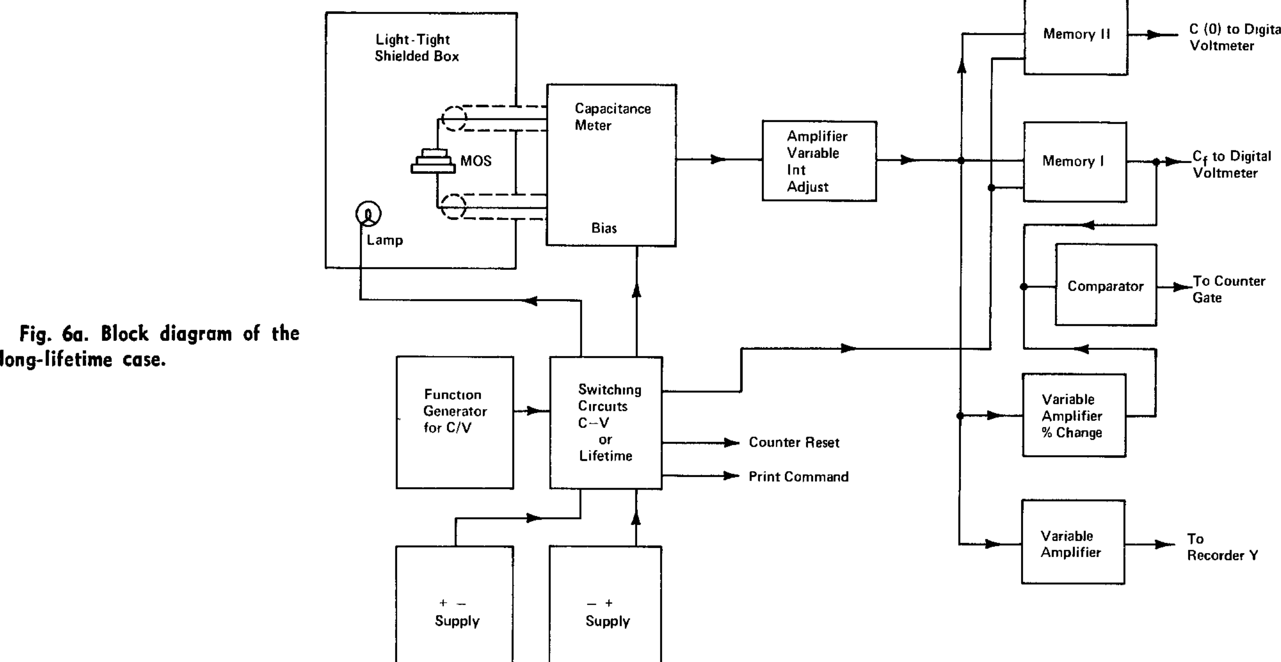

Fig. 6a. Block diagram of the long-lifetime case.

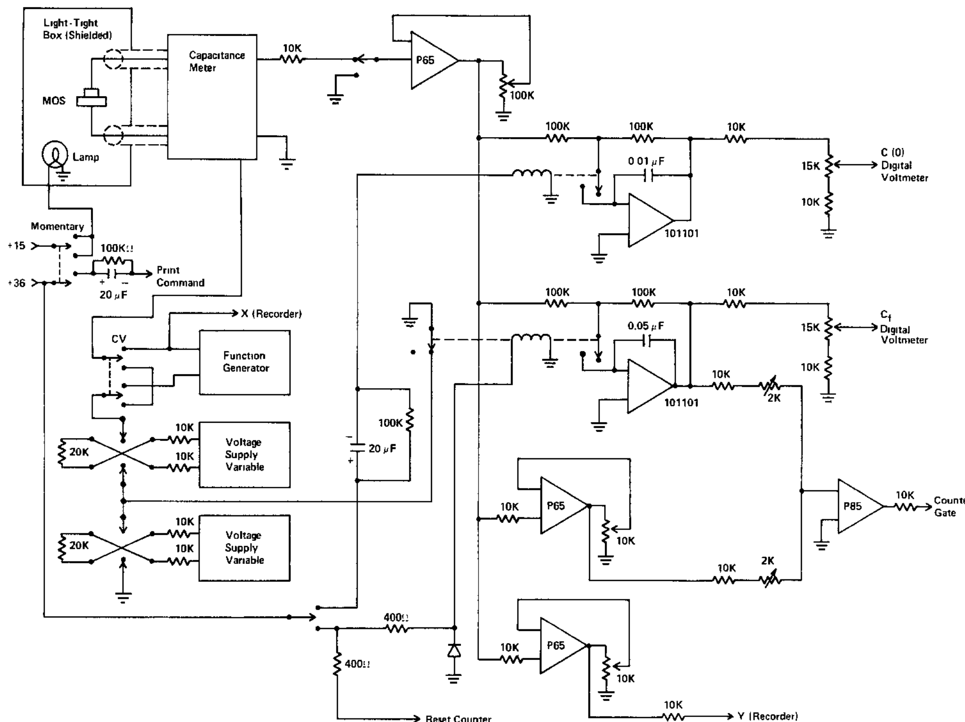

Fig. 6b. Schematic of the long-lifetime case.

pling oscilloscope, which can be connected to a digital counter. We count the time between $t = 0$ and the instant $C_R = 0.8 \times (1 - C_R(0))$ (as an example).

The third setup is used for the "short" lifetime case $T < 4$ sec. As shown in Fig. 8, it consists of a series combination of the MOS capacitor, C, and a standard capacitor, $C_{st} >> C$. The voltage drop, V_{st}, across C_{st} is measured with an operational amplifier. The large parallel resistor, R, defines the d-c potential for the amplifier. The condition $R >> 1/\omega C_{st}$ yields the upper limit for the measurable T values: $T << R \cdot C_{st} \cdot 2\pi$. It is favorable to choose a large value of R rather than of C_{st}, because an increase in C_{st} implies a loss in resolution. We can write

$$V_{st} = V_a(1/C_{st})/(1/C + 1/C_{st})$$

$$V_{st} \approx V_a \cdot C/C_{st} \qquad [11]$$

However, C is a mixture of the high- and low-frequency capacitance and relaxes finally to C_{ox}. Though it might be possible to calculate $C(t)$ analytically, we prefer a different, more convenient interpretation. We write the voltage drop, V_{MOS}, across C as

$$V_{MOS} = V_{ox} + \phi_s$$

Thus

$$V_a = V_{st} + V_{ox} + \phi_s$$

Because C_{st} and C_{ox} are linear capacitors

$$V_{st} \cdot C_{st} = V_{ox} \cdot C_{ox}$$

$$V_a = V_{st}(1 + C_{st}/C_{ox}) + \phi_s$$

and, finally

$$V_{st} = (V_a - \phi_s)/(1 + C_{st}/C_{ox}) \qquad [12a]$$

$$\phi_s = V_a - V_{st}(1 + C_{st}/C_{ox}) \qquad [12b]$$

By measuring V_{st}, we know ϕ_s and can use Eq. [8]. Note that, in Eq. [11] and [12], V_a assumes two different values. For this reason, we do not obtain the same final values before and during the pulse as in Fig. 4, but two values as shown in Fig. 9. The time measurement is again performed with a digital counter connected to a sampling scope. The advantage

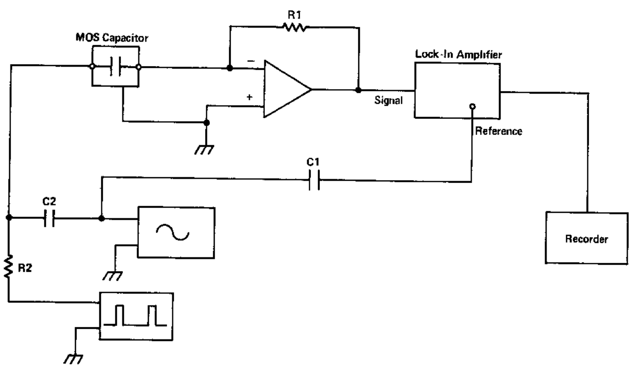

Fig. 7. Block diagram of the medium-lifetime case

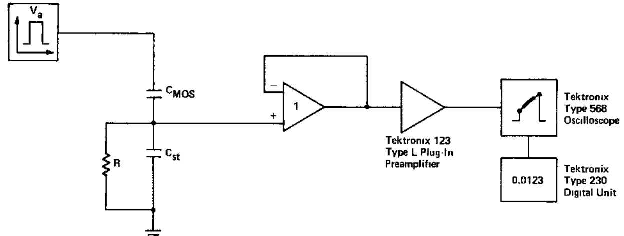

Fig. 8. Block diagram of the short-lifetime case

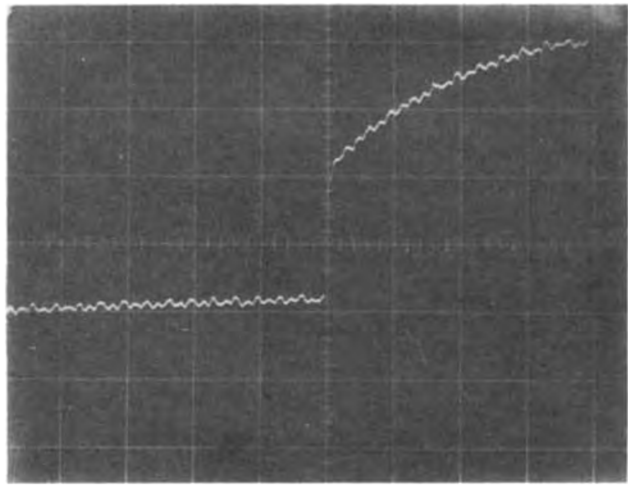

Fig. 9. Photograph of a C-t trace of a low-frequency measurement. Note that the scale factor V_a changes when the pulse is switched on (50 msec/horizontal division).

in using the scope and counter is the speed and accuracy of the reading. The error in reading without the counter can be larger than 100%, especially for small ΔV_a signals. Figure 10 shows how the time marks of the counter are set. The left time mark is set at the onset of the pulse and indicates the start of the counting (left arrow). The stop time mark can be seen at the end of the pulse (right arrow). The time of an 80% vertical transition between the zones is measured as indicated by the heavy line. Note that we are within the upper limit for the RC_{st} (10^7 ohm $\times$ 10^{-7}F) combination, as shown by the slight tilt of the last horizontal line.

In Fig. 11 and 12, the results of two measurements are fitted to the thermal relaxation curve described by Eq. [10]. Good agreement is obtained in Fig. 11, whereas, for the long-lifetime silicon in Fig. 12, the agreement is merely satisfactory. This is in accord with the general observation that in this range ($\tau \approx$ 1 msec) the error becomes 100%. A Zerbst plot (Fig. 13) taken from Fig. 11 gives $\tau = 2.5 \times 10^{-3}$ sec and $s_o = 3.7 \times 10^{-2}$ cm/sec. This technique yields $\tau = 1.3 \cdot 10^{-3}$ sec with $C_{ox} = 130$ pf, $C_f = 75$ pf, $C_R(0) = 0.339$, and $t = 1060$ sec for a selected level $C_R(t) = 0.8$.

These experiments were repeated with different samples. Following are typical results obtained

τ (Zerbst) = 420 μsec — τ (this technique) = 252 μsec
τ (Zerbst) = 144 μsec — τ (this technique) = 108 μsec
τ (Zerbst) = 5.6 μsec — τ (this technique) = 4.6 μsec
τ (Zerbst) = 1 msec — τ (this technique) = 850 μsec

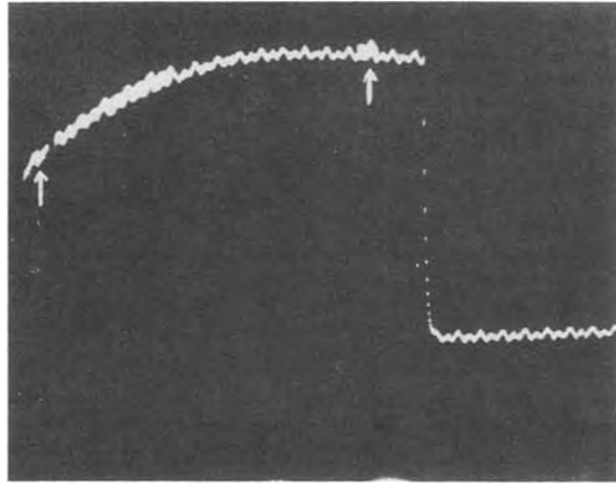

Fig. 10. Photograph of the same sample as in Fig. 9. The time marks and the portion of the curve during which the counter operates are intensified. The sequence of the pulse is reversed compared with Fig. 9.

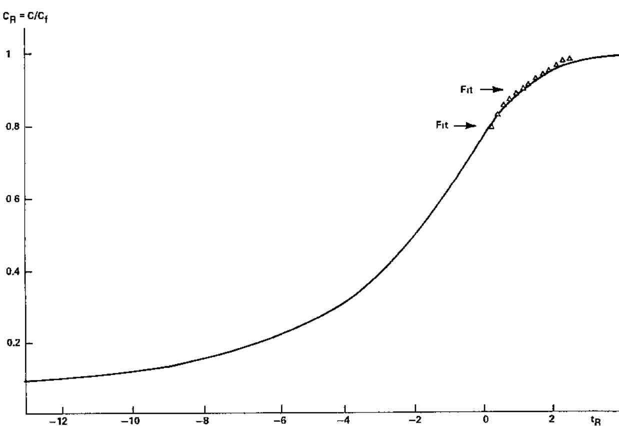

Fig. 11. C-t plot of a sample fitted to the thermal relaxation curve.

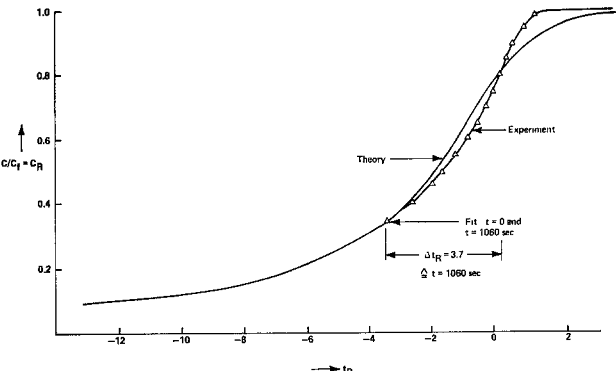

Fig. 12. Same curve as in Fig. 11, taken from another sample

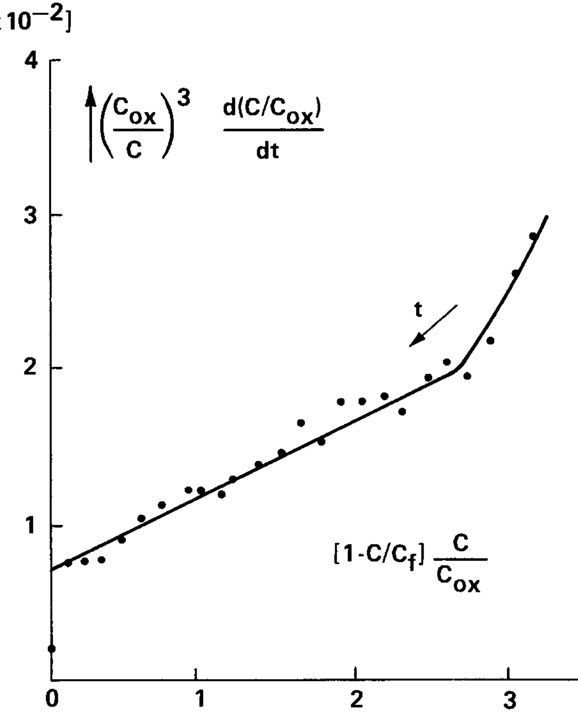

Fig. 13. Zerbst plot for the sample of Fig. 12

Furthermore, we examine how a nonthermal generation mechanism affects the reliability of this technique. This is done by shining controlled intensities of light on the sample or by using mechanically or chemically stressed substrates for the MOS fabrication. The general result is as follows: Whenever a reasonable Zerbst plot is obtained, a lifetime results which agrees with the value of our technique. However, when the Zerbst plot fails, our technique still reports at least an "effective" lifetime, which can be used for process monitoring.

In Fig. 14, we show an example of a Heiman plot. (We define a Heiman plot as the τ *vs.* t curve, where τ has been obtained from a C-t plot with the procedure proposed by Heiman (5); cf. Eq. [9].) The data are taken from the sample used in Fig. 12. It can be seen that the agreement is poor.

It is possible to make the measurements and the data evaluation even more expedient by calculating, rather than measuring, $C_R(0)$. For this purpose, we use the following model: A fast-increase dV_a of the applied voltage displaces a charge $dQ = C(V_a) \cdot dV_a$ across the capacitor, C. Only the majority carriers can follow, and a space charge $q \cdot N_A \cdot dx_{Di}$ matches dQ. Thus, C consists of the series combination C_{ox} and ϵ_{Si}/x_{Di} with the initial condition $x_{Di} = x_{Do}$ or $C = C_f$ for $t = 0$. (Because of this initial condition, we cannot assume $\epsilon_{Si}/x_D >> C_{ox}$ as done by others (8) in solving Eq. [7].) The solution of the differential

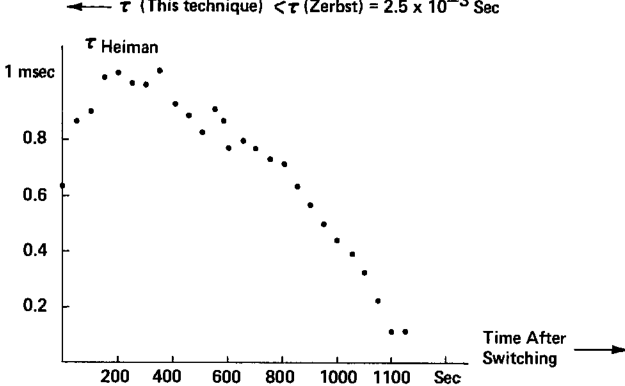

Fig. 14. Heiman plot for the sample of Fig. 12

equation

$$N_A \cdot q \cdot dx_{DI} = (1/C_{ox} + x_{DI}/\epsilon_{Si})^{-1} \cdot dV_a$$

is

$$N_A \cdot qx_{DI}^2/(2 \cdot \epsilon_{Si}) + N_A q x_{DI}/C_{ox} = \Delta V_a + N_A q x_{Do}^2/(2\epsilon_{Si}) + N_A \cdot q \cdot x_{Do}/C_{ox}$$

or

$$x_{DI} = (-\epsilon_{Si}/C_{ox}) + \sqrt{2\Delta V_a \cdot \epsilon_{Si}/(N_A \cdot q) + ((\epsilon_{Si}/C_{ox}) + x_{Do})^2} \quad [13]$$

We obtain a depletion capacitance

$$C_D(0) = \epsilon_{Si}/x_{DI}$$

and

$$C_R(0) = (C_{ox} \cdot C_D(0)/(C_{ox} + C_D(0)))/C_f \quad [14]$$

We check this model by switching an MOS capacitance with ΔV_a values = 1, 2, 3 . . . 10V. The bias V_a is 20 and 40V. The results and the comparison with the theoretical values according to Eq. [14] can be seen in Fig. 15. As expected, there is no measurable difference between the 20 and 40V measurements. The systematic discrepancy between the experimental and theoretical values can be explained by the error in determining the doping concentration. Different measurements give a value between $8 \cdot 10^{14}$ and $1.3 \cdot 10^{15}/cm^3$. The same model can be used to calculate $\phi_R(0)$. It must be emphasized that this model ignores some effects that might reduce the value of $C_R(0)$. Among these, the lateral current paths and the finite thickness of the inversion layer, probably, are most important.

Summary

A new fast technique for large-scale measurements of silicon lifetimes is described. The error limit, compared with a Zerbst plot, is less than 20% for $\tau \leq 10$ μsec and increases to ≈100% for $\tau \approx 1$ msec. This error limit can be reduced by choosing a smaller stopping level $C_R(t)$. For the long-lifetime case, the measurement time is determined by the setting of the selected level and by the τ value of the silicon itself. For the short-lifetime case, it is determined by the time required to find the optimum pulse frequency. The computer time can be disregarded.

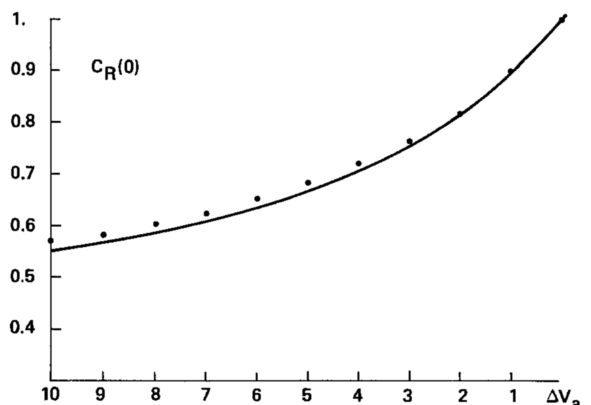

Fig. 15. $C_R(0)$ vs. ΔV_a experiment. Theory: solid line. C_{ox} = 123 pf; $A = 1.765 \cdot 10^{-2}$ cm²; $N_A = 9 \times 10^{14}$ cm⁻³.

Acknowledgments

The authors are grateful to Dr. G. H. Schwuttke for his continuous encouragement and support of this work. A setup similar to our low-frequency setup has been developed independently by K. Ziegler and E. Klausmann for the measurement of equilibrium surface potentials. We are obliged to them for communicating their results in advance of publication.

Deposition and Properties of Silicon on Graphite Substrates

T. L. Chu,* H. C. Mollenkopf, and Shirley S. C. Chu

Southern Methodist University, Dallas, Texas 75275

ABSTRACT

Polycrystalline silicon has been deposited on low-cost graphite substrates by the thermal decomposition of silane and thermal reduction of trichlorosilane with hydrogen in a gas flow system. The microstructures and crystallographic properties of deposited silicon were studied over a wide range of deposition conditions by metallographic and x-ray techniques, respectively. The observed differences in the properties of silicon layers deposited by silane and trichlorosilane processes were attributed to the difference in the chemical reversibility of the reactions. The microstructure of silicon deposited by the trichlorosilane process was improved by the addition of hydrogen chloride to the reactant mixture. Solar cells were prepared from silicon layers deposited on graphite substrates by a one-step process using silane or trichlorosilane and appropriate dopants, and AMO efficiencies of up to 1.5% were obtained.

The current interest in the terrestrial utilization of solar energy by photovoltaic converters has stimulated considerable research and development efforts in low-cost solar cells. Silicon solar cells which have been used reliably in spacecrafts for many years are manufactured from semiconductor-grade silicon and are far too expensive for terrestrial applications. The use of polycrystalline silicon layers on suitable substrates is considered as a promising approach for the fabrication of low-cost solar cells (1). In this approach, the selection of the substrate is an important consideration. Steel is the most economical choice for a large area substrate; however, polycrystalline silicon solar cells deposited on steel substrates were found to have low conversion efficiencies because of the incompatibility of the properties of iron and silicon (2). Graphite is more compatible with silicon in properties than steel. Several types of low-cost graphite have a thermal expansion coefficient similar to that of silicon. Graphite is relatively inert toward silicon at temperatures used for the deposition of silicon. Also, graphite has high thermal and electrical conductivities and may be used as an ohmic contact to the solar cell. Thus, graphite appears to be the most promising substrate for low-cost silicon solar cells at present.

In this work, the thermal decomposition of silane and the thermal reduction of trichlorosilane with hydrogen have been used for the deposition of silicon on graphite substrates. The microstructure and crystallographic properties of silicon deposited under a wide range of conditions were studied. Using appropriate dopants during the deposition process, p-n junction solar cell structures were prepared and characterized. The experimental procedures used for the deposition process and the properties of deposited silicon and solar cells are discussed in this paper.

Deposition of Silicon on Graphite Substrates

The thermal decomposition of silane and the thermal reduction of trichlorosilane have been used extensively for the deposition of silicon. The relative merits of these two processes are fairly well established (3). The decomposition of silane is thermochemically and kinetically more favorable than the reduction of trichlorosilane. Silane is thermochemically unstable at room temperature and higher, and decomposes rapidly at temperatures above 700°C, thus enabling the deposition of silicon at lower temperatures (4). However, the thermal instability of silane tends to promote nucleation by pyrolysis in the gas phase, and the gas-phase nucleation must be suppressed by optimizing the experimental conditions, such as the use of water-cooled reaction tube, low partial pressure of silane in the reactant mixture, etc (3). Furthermore, the reduction of trichlorosilane with hydrogen is chemically reversible while the decomposition of silane is essentially irreversible. Because of these differences, the properties of silicon are sometimes dependent on the chemical reaction used. The thermal reduction of trichlorosilane was emphasized in this work because of its economic advantages.

The deposition of silicon was carried out by using the apparatus shown schematically in Fig. 1. The flow of various gases was directed by appropriate valves and measured by flowmeters. Hydrogen purified by diffusion through a palladium-silver alloy was used as a carrier gas to introduce trichlorosilane into the reaction tube and as a diluent in all deposition reactions. Trichlorosilane was kept in a double-wall stainless steel cylinder with gas inlet and outlet tubes, and a constant temperature fluid was circulated through the jacket of the container to maintain the temperature of trichlorosilane at 15.5° ± 0.5°C. The reactant mixture of the desired composition was introduced into a fused silica reaction tube of 55 mm ID. In the reaction tube, the graphite substrates (PLC graphite supplied by POCO Graphite, Incorporated and CMB graphite supplied by Union Carbide Corporation) were supported on a susceptor, and the susceptor was heated externally by an rf generator. The chemical reaction takes place on the substrate surface, depositing silicon.

The substrate temperature was in the range of 950°-1250°C. In all experiments, the flow rate of hydrogen was maintained at 20 liter/min, and the concentration of the silicon compound in the reactant mixture was adjusted to yield deposition rates in the range of 0.2-3 μm/min. In the silane process, for example, the average deposition rate of silicon at 1050°C was about 0.3 and 1.3 μm/min when the reactant mixture contained 0.03 and 0.13% silane respectively. At silane concentrations below about 0.2%, the deposition rate was essentially a linear function of the concentration of silane in the reactant mixture. The average deposition rate of silicon

* Electrochemical Society Active Member.

Key words: graphite, silane, silicon, solar cells, trichlorosilane.

was essentially independent of temperatures in the range of 1050°-1150°C. At higher temperatures, 1200°C for example, the contribution of gas-phase nucleation becomes noticeable. The deposition of silicon by the trichlorosilane process can be carried out at higher temperatures, 1250°C for example, and at higher rates, 3 μm/min for example, with negligible contribution of gas-phase nucleation. The average deposition rate of silicon at 1250°C can be increased from about 0.25 to 2 μm/min by increasing the concentration of trichlorosilane in the reactant mixture from 0.1 to 1%.

Microstructure of Silicon

Silicon deposited on graphite substrates by silane and trichlorosilane processes was all polycrystalline, and its microstructure was found to depend strongly on the substrate temperature and deposition rate. In general, silicon deposited at low temperatures and high rates consisted of micrometer-size crystallites, and the size of crystallites increased with increasing deposition temperature or decreasing deposition rate.

Silicon layers deposited on graphite substrates at 1000°C or above by the silane process usually consisted of crystallites with well-developed faces, particularly when low deposition rates were used. An example is shown in Fig. 2 where the scanning electron micrograph of the as-deposited surface of a silicon layer deposited on a graphite substrate at 1100°C at a rate of 1 μm/min is reproduced. The grown surface of most crystallites is hexagonal and has been shown to be of a {110} orientation by x-ray diffraction. The six side faces of the crystallites are therefore of (111), $(1\bar{1}1)$, $(\bar{1}11)$, $(\bar{1}\bar{1}1)$, $(\bar{1}1\bar{1})$, and $(1\bar{1}\bar{1})$ orientations. The edges of the hexagons are along $[1\bar{1}0]$, $[\bar{1}12]$, and $[1\bar{1}2]$ directions, and the angle between $[1\bar{1}0]$ and $[\bar{1}12]$ is 54.74°, and that between $[\bar{1}12]$ and $[1\bar{1}2]$ is 70.53°. These relations have also been verified. The vertical cross section of silicon/graphite specimens was studied by conventional metallographic techniques. Figure 3 shows the mechanically polished and chemically etched [Sirtl etch (5), 30 sec] surface of the vertical cross section of a silicon/graphite specimen deposited at 1100°C. The etching process has revealed the grain boundaries, and it is seen that the structural perfection of the silicon layer improved with increasing thickness.

The microstructure of silicon deposited by the thermal reduction of trichlorosilane with hydrogen was studied in more detail. At 950°C and below, the silicon deposit was found to consist of very small crystallites, less than 1 μm in diameter. As the substrate temperature was increased, the size of silicon

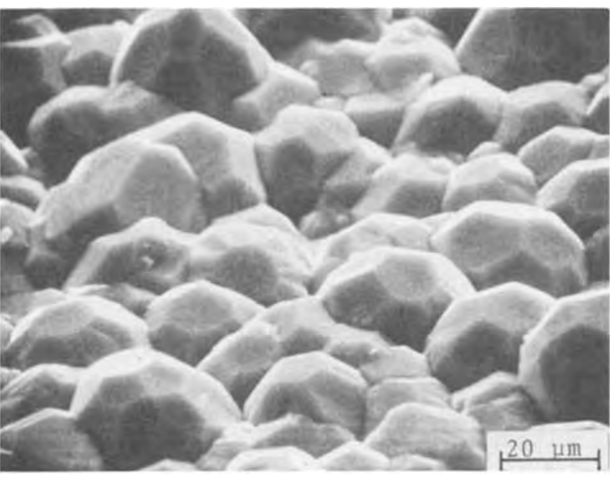

Fig. 2. Scanning electron micrograph of the as-grown surface of a silicon layer deposited on graphite substrates at 1100°C by the pyrolysis of silane at a rate of 1 μm/min.

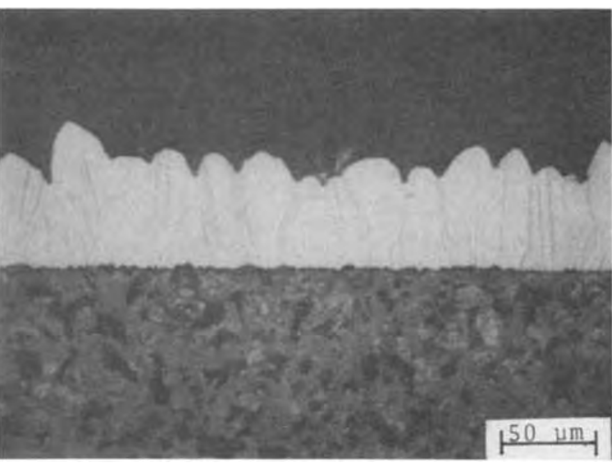

Fig. 3. Mechanically polished and chemically etched surface of the vertical cross section of a silicon/graphite specimen prepared by the pyrolysis of silane at 1100°C.

crystallites increased, and the deposition rate was found to have a very pronounced effect on the microstructure of silicon, particularly at high substrate temperatures. Figure 4 (A and B, respectively) shows the scanning electron micrograph of the as-deposited surface and the mechanically polished and chemically etched surface of the vertical cross section of a silicon sample deposited on graphite at 1000°C at about 1 μm/min. The average size of the crystallites is 3-5 μm, smaller than those obtained by the thermal decomposition of silane. Furthermore, the crystallites in silicon layers from the trichlorosilane process were less uniform in size; considerably larger crystallites were sometimes intermingled with the smaller ones. The presence of crystallites of widely differing sizes could be due to (*i*) the inhomogeneities on the substrate surface affecting the nucleation and growth of silicon or (*ii*) the chemical transport of silicon between neighboring crystallites due to the difference in surface energy or temperature. The transport of silicon does not occur in the silane process since the thermal decomposition of silane is essentially irreversible. When silicon was deposited at 1250°C at about 1 μm/min, the microstructure of the silicon was very similar to that shown in Fig. 4B, except that the average size of crystallites was increased to 8-10 μm. By reducing the deposition rate to 0.25-0.3 μm/min, crystallites as large as 30 μm were frequently obtained. Examples of the as-deposited and cross-sectioned surfaces are shown in Fig. 4C and D, respectively. However, the as-deposited surface became very irregular due presumably to the nucleation and transport processes discussed earlier. The transport process becomes more pronounced at low deposition rates. In extreme cases, the silicon layer was not continuous with gaps between crystallites even when the average thickness of the layer was greater than 50 μm (Fig. 5).

Since large crystallites in silicon layers are preferred for solar cell purposes, high substrate temperatures and low deposition rates must be used. However, silicon layers deposited by the trichlorosilane process under these conditions exhibited such surface roughness that the formation of large-area, uniform, shallow p-n junctions becomes extremely difficult. To modify the nucleation and growth of silicon on graphite substrates, hydrogen chloride was added to the reactant mixture. It has been shown that at low Si/Cl ratios in the reactant mixture, preferential deposition into surface depressions can be achieved (6, 7). This is due presumably to the thermochemical nature of the reaction that at low Si/Cl ratios, the transport of silicon takes place from a low temperature region to a higher temperature zone, opposite to the direction of transport at high Si/Cl ratios (8). Since silicon at the surface of tall crystallites is at a lower temperature than that

of shorter ones, the transport process will reduce the surface irregularity of the deposited silicon layer.

A number of silicon layers were deposited on graphite substrates by the thermal reduction of trichlorosilane containing various concentrations of hydrogen chloride. High substrate temperatures and low deposition rates were used in order to obtain large crystallites. As expected, the addition of hydrogen chloride to the reactant mixture was found to decrease the deposition rate of silicon. For example, the average deposition rate of silicon at 1250°C using a reactant mixture containing 0.13% trichlorosilane and 0.4% hydrogen chloride was about 0.2 μm/min, as compared with an average deposition rate of 0.3-0.35 μm/min without using hydrogen chloride. However, the addition of hydrogen chloride to the reactant mixture has reduced considerably the surface roughness of the deposited silicon. Figure 6 shows the mechanically polished and chemically etched surface of the vertical cross section of such a specimen. A comparison of Fig. 6 and 4D or 5 indicates clearly the advantage of using hydrogen chloride in the deposition process. Once a reasonably uniform silicon layer is formed on the graphite substrate, higher deposition rates may be used without degrading the microstructure of the deposited silicon.

Crystallographic Properties of Silicon

The crystallographic properties of a number of silicon layers deposited on graphite substrates by the silane and trichlorosilane processes under a wide range of substrate temperatures, deposition rates, and dopant concentrations were examined by the x-ray diffraction technique using a General Electric Model XRD-6 diffractometer with CuKα radiation. Polycrystalline silicon powder of random orientations is known to show three strong diffraction peaks associated with {111}, {220}, and {311} reflections with 2θ values of 28.4°, 47.3°, and 56.1° and relative intensities of 100, 60, and 35, respectively (9). The diffraction spectra of the silicon layers were obtained by scanning 2θ in the range of 20°-60°. When the thermal decomposition of silane was used for the deposition of silicon, the {220}/{111} intensity ratio was found to depend strongly on the substrate temperature, deposition rate, and the extent of doping. In general, unintentionally doped silicon layers deposited at low temperatures and high rates exhibited very large {220}/{111} intensity ratios, up to about 1000 indicating that the silicon crystallites show a very strong {110} preferred orientation. This ratio was found to decrease with increasing substrate temperature, decreasing deposition rate, or the introduction of a high concentration of dopants. The crystallographic properties of silicon on graphite substrates are very similar to those on borosilicate/steel substrates (10). However, when the thermal reduction of trichlorosilane was used for the deposition of silicon of various doping levels on graphite at 1000°-1250°C and at 0.2-2 μm/min, the {220}/{111} intensity ratio was found to be in the range of 0.4-5, indicating

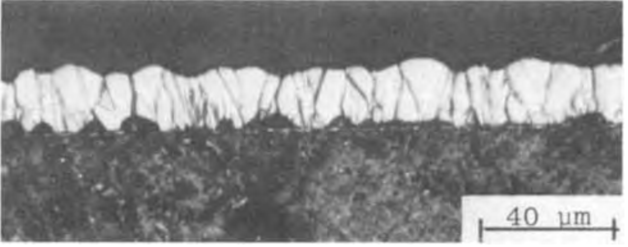

Fig. 6. Mechanically polished and chemically etched surface of the vertical cross section of a silicon/graphite specimen deposited at 1250°C by using a reactant mixture containing 0.13% trichlorosilane and 0.4% hydrogen chloride.

no significant preferred orientation in the crystallites of the silicon deposit. In some silicon layers deposited at 1250°C, crystallites exhibited a slight preferred {111} orientation, as indicated by the {220}/{111} intensity ratios. Figure 7 shows typical diffraction spectra of silicon layers deposited by the silane and trichlorosilane processes. Figure 7A shows the diffraction spectrum of a boron-doped silicon layer deposited on a graphite substrate at 1100°C by the thermal decomposition of silane, where the {220}/{111} intensity ratio is about 150 (the {111} reflection was measured at a considerably magnified scale). Figure 7B shows the diffraction spectrum of an unintentionally doped silicon layer deposited on a graphite substrate at 1000°C and at 0.25 μm/min by the thermal reduction of trichlorosilane, where the {220}/{111} intensity ratio is about 2.8. The difference in the crystallographic properties of silicon deposited by the silane and trichlorosilane processes is presumably also related to the difference in the reversibility of the chemical reactions.

Preparation and Characterization of Solar Cells

Silicon deposited on graphite substrates at temperatures of 1150°C or lower by the silane and trichlorosilane processes without intentional doping was always of high electrical resistivity, due at least in part to the grain boundary effects. When the trichlorosilane process was used for the deposition of silicon at higher temperatures, the deposit was always p-type with an electrical resistivity dependent on substrate temperature and deposition rates. For example, silicon deposited at 1250°C at a rate of 1 μm/min had a resistivity of 5-10 ohm-cm, and the resistivity was decreased to 1 ohm-cm or less when the deposition rate was reduced to about 0.25 μm/min. These results strongly suggest the diffusion of impurities from the graphite substrate into the silicon deposit at high temperatures.

The electrical resistivity of silicon deposited on graphite substrates by both silane and trichlorosilane processes was controlled by using phosphine and diborane as dopants. Polycrystalline silicon p-n junction solar cell structures were prepared on graphite substrates, 3 cm $\times$ 3 cm in area, by depositing successively 10-40 μm of 0.002-0.003 ohm-cm p-type silicon, 8-10 μm of 0.2-2 ohm-cm p-type silicon, and 0.2-0.4 μm of 0.001-0.002 ohm-cm n-type silicon. The use of a relatively thick, boron-doped layer at the initial stage of silicon deposition was to improve the microstructure of silicon in the junction region without contributing appreciatively to the series resistance of the device. The thickness and resistivity of the p^+ and p-silicon layers were obtained by measuring the resistivity profile along the angle-lapped surface of the specimen using a spreading resistance probe. During the angle-lapping process, however, the n^+-silicon layer was always removed due to its small thickness and rough surface. The thickness of the n^+-silicon layer was deduced from the duration of deposition under conditions established for a low deposition rate, and its resistivity was determined by the four-point probe technique.

The electrical resistivity of silicon layers deposited by the silane process was readily controlled by introducing an appropriate amount of the desired dopant into the reactant mixture. When the thermal reduction of trichlorosilane was used for the deposition of silicon, the resistivity of the p-layer was found to be less uniform. Furthermore, the addition of hydrogen chloride to the reactant mixture severely interfered with the control of dopant distribution in the p-silicon layer. This is again due to the chemical transport associated with the reversibility of the trichlorosilane process. During the deposition of the p^+-silicon layer, low resistivity boron-doped silicon was also deposited on the susceptor. Since the susceptor was at a higher temperature than the substrates, silicon and boron were transported from the susceptor onto the substrate by hydrogen chloride during the subsequent deposition, and this transport process resulted in the low and nonuniform resistivity in the p-silicon layer. Therefore, hydrogen chloride was added to the reactant mixture only during the initial deposition of the p^+-silicon layer. Figure 8 shows the mechanically polished and chemically etched surface of the vertical cross section of a solar cell structure on a graphite substrate deposited by using a hydrogen-trichlorosilane-hydrogen chloride mixture and appropriate dopants. The etching process has delineated the p-p^+ junction due to their difference in chemical potentials (11); however, the n^+-silicon layer, about 2000Å in thickness, was removed by etching.

Mesa diodes were isolated from the above structures by evaporating titanium-silver dots of 0.75 mm diameter on the silicon surface followed by masking and etching. Typical current-voltage characteristics of these diodes deposited by the silane process are shown in Fig. 9. The "*n*" value in the diode equation, cal-

culated from the forward characteristics, is 1.9, very similar to that for single crystalline silicon p-n junctions, indicating that the grain boundaries in polycrystalline silicon on graphite substrates do not play a significant role in current conduction. The reverse current density, however, is considerably higher than that in single crystalline silicon p-n junctions.

A number of solar cells were fabricated from n^+-silicon/p-silicon/p^+-silicon/graphite structures deposited by both silane and trichlorosilane processes. A grid contact of about 1500Å titanium and 5 μm silver was evaporated onto the n^+-silicon surface, and the graphite substrate served as the other ohmic contact to the solar cell. The four sides were cut off to remove the silicon deposit on the periphery. The current-voltage characteristics of resulting solar cells, 2.5 cm $\times$ 2.5 cm in area, were measured under illumination with an AMO solar simulator at room temperature. The conversion efficiencies of cells prepared by the silane and trichlorosilane processes were similar and were in the range of 1.0-1.5%. An example of the current-voltage characteristics of a polycrystalline silicon solar cell on a graphite substrate prepared by the trichlorosilane process is shown in Fig. 10. The open-circuit voltage, short-circuit current density, and fill factor are 0.33V, 13 mA/cm^2, and 0.47, respectively, corresponding to a conversion efficiency of 1.5%.

Summary and Conclusions

Polycrystalline silicon layers have been deposited on graphite substrates by the thermal decomposition of silane and the thermal reduction of trichlorosilane under a wide range of conditions. Because of the difference in the chemical reversibility of these two reactions, silicon layers deposited by silane and trichlorosilane processes had different microstructures and crystallographic properties. The microstructure of silicon deposited by the trichlorosilane process may be improved by adding hydrogen chloride to the reactant mixture. Silicon layers containing crystallites with an average size of 20-30 μm can thus be obtained by either process. Solar cells with AMO efficiencies of up to 1.5% were obtained by controlling the dopant distribution in deposited silicon in a one-step deposition process. No appreciable differences in the characteristics of solar cells prepared by the two processes were observed.

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

This paper presents the results of chemical vapor deposited (CVD) silicon dioxide films on silicon from an $SiH_4 + CO_2 + H_2$ system. The kinetics of this reaction have been studied with a barrel reactor. The activation energy (ΔE) of the SiH_4, CO_2 reaction in hydrogen is 106.7 J/g mol (25.4 kcal/g mol) in the temperature range 800°-1050°C. The SiH_4 and CO_2 reaction in hydrogen is shown to be a first-order reaction with respect to $SiH_4(CO_2{:}SiH_4 \geqq 20)$. The deposition rates of SiO_2 are dependent only on deposition temperature and on SiH_4 mole fraction. They are independent of the $CO_2{:}SiH_4$ ratio in the experimental range of 7:1-120:1. Electrical characterization was carried out on MOS capacitors of ~1300Å dielectric thickness. The breakdown field was found to be ($7.8 \pm 0.1 \times 10^6$ V/cm). Measurements of oxide charges, of mobile charges, and of fast surface-state density show that these oxides are stable under positive and negative bias, with maximum shifts of 250 mV after 50 hr stress at 200°C and $\pm 2 \times 10^6$ V/cm electrical field. Postdeposition high-temperature anneal deteriorates the V_{FB} stability under negative-bias temperature stress. The index of refraction depends on the $CO_2{:}SiH_4$ ratio, going above 1.46 at a ratio <10. Ratios of $CO_2{:}SiH_4 \geqq 50$ give reproducible results at an average index of 1.454 ± 0.001. Etch rates in "P-etch" for 1000°C deposited samples are ~50% faster than thermal oxides grown at the same temperature.

Chemical vapor deposited (CVD) SiO_2 films have several advantages in planar semiconductor device processing over the oxidation of silicon. Since no silicon of the substrate is consumed, the junction movement, pileup, or depletion of dopants at SiO_2-Si interfaces is minimized. Thick films of SiO_2, which may be used in the field region of integrated FET circuits, can be deposited with greater ease than thermal oxidation because the deposition rates are not diffusion-limited in the solid. One application of CVD oxides where the thermal oxide does not compete is the use of CVD oxides as photolithographic masks for films not etched in fluorides, such as silicon nitride. Finally, CVD oxides lend themselves to *in situ* processing where two or more films are required and one of these films is SiO_2.

Silica films have been deposited by a variety of chemical systems, at both high and low temperatures (1-10). It was desirable in this case to select a process that would produce SiO_2 films with etch rates close to those of thermal SiO_2, so as to avoid excessive undercutting during etching. Since etch rate is inversely proportional to deposition temperature, the process had to be carried out at a high temperature (1000°C). SiH_4 was preferred over other silicon-bearing compounds (*e.g.*, $SiCl_4$ or $SiBr_4$) because of its gaseous nature and resulting ease of metering control. *In situ* processing also favors SiH_4 because one has only to replace the oxidant with NH_3 to deposit silicon nitride or discontinue the oxidant flow to deposit polysilicon. It was also desirable to use an oxidant that would have a minimal gas-phase reaction with SiH_4 so as to keep the reactor down time to a minimum. This led to the investigation of the SiH_4 and CO_2 reaction. Swann and Payne (4) and Kroll *et al.* (5) reported on the SiH_4-CO_2 system. Our purpose is to investigate further the deposition kinetics, to obtain an empirical rate expression, and to examine the physical and electrical properties of the resulting SiO_2 films.

Experimental

Equipment.—The equipment used for the entire experimental investigation was a vertical, cold-wall, barrel-type, induction-heated reactor (11). The silicon "wafers" were placed on an SiC-coated graphite susceptor. Figure 1 gives a schematic cross-sectional view of the reactor. The fused-quartz chamber is 18 in. (~ 45 cm) long, with an internal diameter of 9 in. (~ 23 cm). The susceptor is placed in the chamber so that its leading edge is ~ 5 in. (12.7 cm) from the molybdenum distributor. The susceptor is hexagonal and is divided into three tiers, or "rings." Each of the six faces of the susceptor makes an angle of ~3° with the central vertical axis. The susceptor is placed on a fused-quartz plate, which in turn is supported by a fused-quartz pedestal. The susceptor, approximately 8.25 in. (21 cm) long, was rotated at about 8 rpm throughout this experimental work. The volume of the annulus between the susceptor and the chamber (*i.e.*, the volume of the deposition zone) is ~5 liters.

The temperature was measured with an optical pyrometer.[2] All temperatures reported were corrected for system transmission losses and for emissivity (12). The reacting and the carrier gases were introduced from the top of the reactor after each had been metered through a separate rotometer. Each rotometer was calibrated. The silane used was a 5% mixture in nitrogen or hydrogen. The SiH_4, CO_2, and the carrier gas (either H_2 or N_2) were filtered (submicron filters) before they passed through their respective rotometers.

Typical deposition conditions and measurement technique.—Three, 2¼ in. (5.7 cm) Si, 11-25 ohm-cm, p-type, <100> wafers were processed in each experimental run, unless otherwise indicated. One wafer each

[2] The temperature along the susceptor length is ±10°C of any reported value.

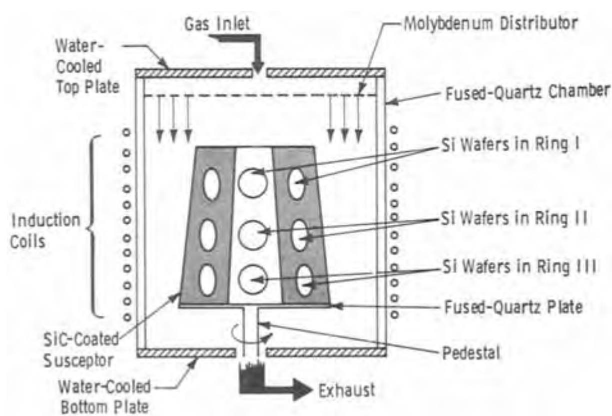

Fig. 1. Schematic cross-sectional view of barrel reactor

Key words: silicon dioxide, dielectric films, MOS, CVD, thin films.

was placed in rings 1, 2, and 3, at a predetermined fixed position. The remaining positions on the susceptor were filled with dummy wafers. Before loading in the reactor, wafers were cleaned ultrasonically in hot (85°C) deionized water (for 5 min), followed by H_2SO_4/HNO_3 (3:1, at 120°C) cleaning (for 10 min), followed by 10:1 dilute HF dip (10 sec). The wafers were then rinsed in running deionized water (for 5 min) and subsequently spin-dried. The wafer surface was hydrophobic after this cleaning.

During the experimental work, the carrier gas flow rate (H_2 in most cases) was varied between 60 and 120 liters/min and the SiH_4 flow rate (5% in H_2 or N_2) between 60 and 1000 cm^3/min. The SiH_4:CO_2 ratio was changed between 7:1 and 120:1. The deposition temperature range was 800°-1050°C; the deposition time was never less than 5 min or greater than 25 min.

The resulting SiO_2 film thicknesses were measured by CARIS[3] (>1500Å) and by ellipsometry (≤1500Å). The index of refraction was always measured by ellipsometry. Five thickness measurements were taken per wafer; these five readings cover ~80% of the total wafer area. Peripheral readings were taken 0.125 in. (3.18 mm) away from the edge of the wafer. The typical within-a-run deposition uniformity was ≤ ±5% at 1000°C and at a total flow rate of ~110 liters/min; the worst case within-a-run uniformity at any temperature and flow (within the experimental range) was ~ ±15%. The deposition rates used in this report are therefore average deposition rates over three rings (*i.e.*, 15 measurements); thus, as a first approximation, we neglected the silane concentration variations along the susceptor length.

Experimental Results

Preliminary experiments.—Preliminary experiments were performed using an H_2 and N_2 mixture as a carrier gas at a deposition temperature of 1000°C. The H_2/N_2 ratio was varied from 0.03:1 to 1.5:1, with similar results. The films deposited were dendritic in appearance. When these films were etched in 5:1 diluted HF, a brown film was left on the silicon surface. Swann and Payne (4) reported similar observations when they used argon as a carrier gas. The brown film on the silicon surface was etchable only in I-etch,[4] suggesting that the brown film is a silicon-rich film (mostly polysilicon).

The use of pure H_2 as a carrier gas prevented the formation of either "dendritics" or the silicon-rich brown film. The SiO_2 films thus deposited were etchable in diluted HF (5:1) and left the silicon surface clean (hydrophobic). The remaining investigations used H_2 as a carrier gas.

Deposition rates (SiH_4-CO_2-H_2 system).—The parameters whose effect on deposition rate of SiO_2 has been investigated are SiH_4 mole fraction, SiH_4:CO_2 ratio, deposition temperature, and H_2 flow rate.

Deposition rate vs. SiH_4 mole fraction.—Figure 2 shows the log of SiO_2 deposition rate as a function of silane mole fraction ($X^0_{SiH_4}$), as determined by the entering gas composition. The slope of the graph is very nearly 1, which shows that the SiH_4-CO_2 reaction in H_2 is a first-order reaction with respect to SiH_4. For Fig. 2, the deposition temperature and the H_2 and CO_2 flow rates were kept constant. Note that the CO_2:SiH_4 ratio varied from ~20 to 200 during this experiment; however, it is important to point out that only the SiH_4 concentration is a variable for Fig. 2. Hence, Fig. 2 is the result of a classical experiment to isolate the order of the reaction with respect to SiH_4 (13).

Deposition rate vs. SiH_4:CO_2 ratio.—Figure 3 graphs the deposition rate as a function of CO_2/SiH_4 ratio for the two SiH_4 mole fractions. The deposition temperature and the H_2 flow rate were kept constant. The deposition rate is independent of the CO_2:SiH_4 ratio in the experimental range of 7:1-120:1. Note that, for a fixed SiH_4 mole fraction (*e.g.*, 1.9 × 10^{-4}), the deposition rate is independent of the CO_2 concentration.

These results are consistent with the classical "method of excesses" or "isolation technique" (14); *i.e.*, when a large excess of one chemical is used as compared with another, the reaction rate is independent of the concentration of the chemical being used in large excess. The lack of dependence of deposition rate on CO_2 concentration, however, is in total disagreement with

[3] Constant angle reflection interference spectroscopy.
[4] I-etch is a mixture of stock solution and HNO_3 in the ratio of 1:5. The stock solution is a mixture of CH_3COOH, HF, HNO_3 in a 1:2:5 ratio, saturated with iodine and allowed to settle overnight (14 hr).

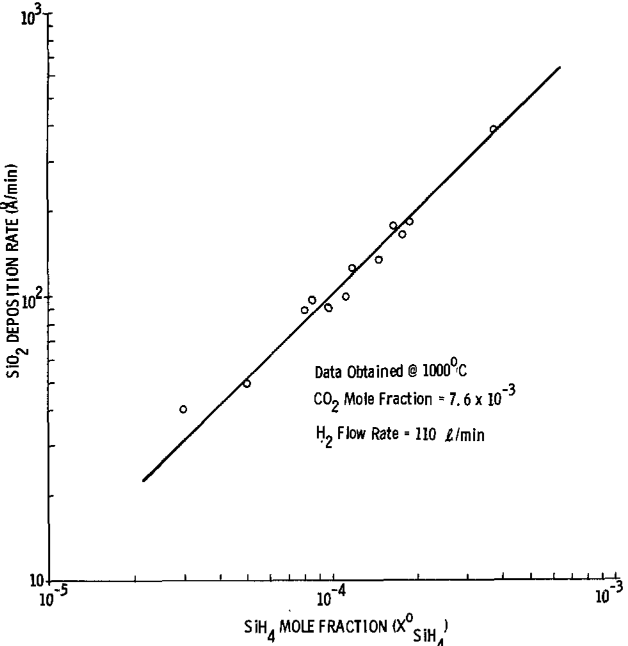

Fig. 2. Deposition rate as a function of SiH_4 mole fraction in the feed. Deposition temperature, H_2 flow, and CO_2 flow kept constant.

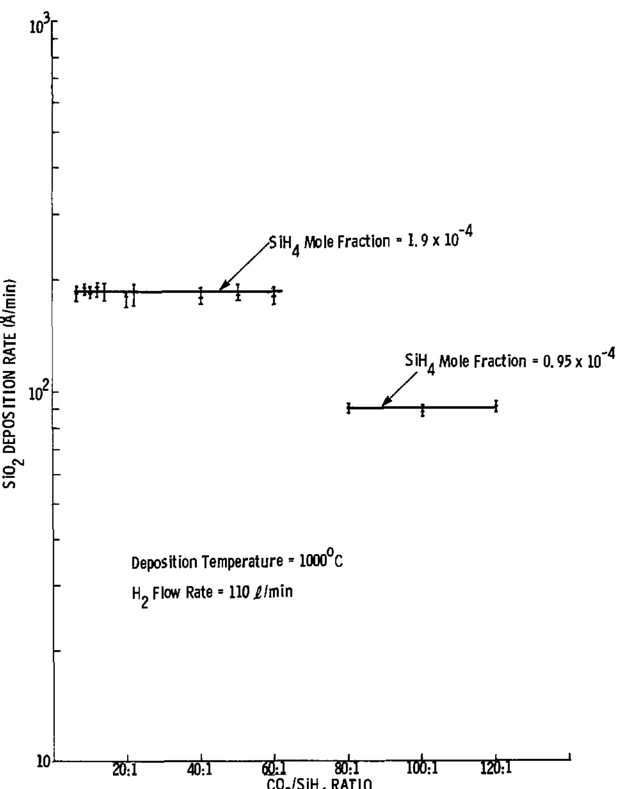

Fig. 3. Deposition rate as a function of CO_2:SiH_4 ratio at two silane mole fractions, at 1000°C and at constant H_2 flow rate.

the results reported by Swann and Payne (4) and by Kroll *et al.* (5). Both papers reported an increase in deposition rate with increasing CO_2: SiH_4 ratio. The likely reason for this discrepancy is the difference in reactor design. In both papers, a pedestal or pancake-type reactor was used where the flow of gas is at right angles to the wafer surface. In our reactor, the flow of gases is nearly parallel to the wafer surface. These two very different flow patterns will have a markedly different mass and energy transfer and, hence, possibly, different results.

Deposition rate vs. deposition temperature.—Figure 4 shows the deposition rate as a function of reciprocal temperature at a constant injected SiH_4 mole fraction of 1.9×10^{-4}. Two CO_2: SiH_4 ratios were used, 12 and 40, and the H_2 flow rate was kept constant at 110 liters/min. The activation energy obtained from Fig. 4 is 25.4 kcal/g mol (106.7 J/g mol).

Deposition rate vs. flow rate.—To determine whether the deposition rate of SiO_2 is limited by the surface chemical reaction rate or controlled by mass transfer, an experiment was performed in which the H_2 flow rate was varied from 60 to 115 liters/min. The deposition temperature was kept constant at 1000°C. The SiH_4 and CO_2 mole fractions were also constant at 1.9×10^{-4} and 1.14×10^{-2}, respectively. Figure 5 shows the results, with the deposition rate plotted against the square root of the flow rate.

For all practical purposes, the deposition rate is independent of the flow rate, and, hence, the SiH_4-CO_2 reaction in H_2 is limited by the surface-chemical-reaction rate, with the experimental flow range 60-115 liters/min.

Rate expression (empirical).—Following the standard procedure for obtaining an empirical rate expression for any heterogeneous reaction (13), and knowing that the reaction is (*i*) independent of CO_2 concentration (Fig. 3), (*ii*) first order with respect to SiH_4 (Fig. 2), and (*iii*) surface-chemical-reaction-limited (Fig. 5), we can arrive at the following rate expression

$$r_{SiO_2} = K_s\, C^0{}_{SiH_4}\, [1 - Y_{SiH_4}] \quad [1]$$

where r_{SiO_2} = deposition rate of SiO_2 (moles/min), $C^0{}_{SiH_4}$ = silane concentration in the feed (moles/liter), K_s = the rate constant for surface chemical reaction (liters/min), and Y_{SiH_4} = fraction of silane converted to deposit.

The fraction of SiH_4 converted to SiO_2 can be calculated by mass-balance, and its value is small, *i.e.,* 0.02-0.15, depending on the deposition temperature. Thus, neglecting Y_{SiH_4} and expressing deposition rate in Å/min and concentration as mole fraction, we can rewrite Eq. [1] as

$$d_{SiO_2} = K'_s\, X^0{}_{SiH_4} \quad [2]$$

where d_{SiO_2} is the deposition rate in Å/min, $X^0{}_{SiH_4}$ is the mole fraction of silane in the feed, and K'_s is the rate constant in Å/min. The value of K'_s has been calculated from the data of Fig. 2, at 1000°C, to be approximately equal to 10^6 Å/min.

Now

$$K'_s = K'_0 \exp[-\Delta E/RT] \quad [3]$$

where K'_0 is the frequency factor in Å/min and ΔE the activation energy. The activation energy is 25.4 kcal/g mole (Fig. 4), and the calculated value of K'_0 is 2×10^{10} Å/min.

Thus, the empirical rate expression for SiO_2 deposition is

$$d_{SiO_2} = 2 \times 10^{10} \cdot \exp[-25\,400/RT] \cdot X^0{}_{SiH_4} \quad [4]$$

where R is the gas constant (1.98 cal/g mole °K) and T is temperature in °K.

Physical properties.—Table I lists the physical properties of SiO_2 grown from the SiH_4-CO_2-H_2 system as a function of deposition parameters and anneal conditions.

Refractive index.—The refractive index was measured by ellipsometry at 5460Å (mercury-light wavelength). The refractive index of deposited SiO_2 is very close to that of the thermal SiO_2 (1.462) (15). Owing to densification, the annealing treatment increases the refractive index of as-deposited samples. There also appears to be some effect due to the CO_2/SiH_4 ratio. However, although CO_2: SiH_4 ratios greater than 20:1 do not seem to affect the refractive index within measurement accuracy, for a deposition temperature of 1050°C and a low CO_2/SiH_4 ratio of 12, the refractive index goes up, indicating that the film may be silicon-rich. As Table I shows, only the third-place decimal in the refractive index was affected by the CO_2: SiH_4 ratio from 20:1 to 120:1. Ratios of SiH_4: $CO_2 \geq$ 50:1 are preferred because the run-to-run refractive index reproducibility is considerably improved (*i.e.,* ±0.001 run-to-run).

* By weight loss method.

Infrared absorption spectra of a limited number of as-deposited samples were taken. All samples were deposited at 1000°C. First absorption maxima lay at ~1070 cm^{-1} for all samples.

Etch rate.—Etch rate was determined by etching the samples in P-etch (15) [15 parts HF (49%), 10 parts HNO_3 (70%), and 100 parts H_2O]. Typically, SiO_2 deposited at 1000°C etched ~50% faster than thermal oxide. In P-etch, the etch rate appears to be a function of deposition temperature (Table I). Sample-to-sample variations in etch rate decreased as the deposition temperature was increased. All samples when annealed in N_2 at 1100°C for a half-hour had an etch rate of between 2.1 and 2.06 Å/sec. The etch rate in 5:1 diluted HF also showed a drop upon annealing; however, this etchant did not delineate the etch rate as a function of deposition temperature.

Density.—Film density was measured by the weight-loss method; *i.e.*, deposited wafers were weighed and then stripped and reweighed. The density of as-deposited samples appears consistently lower than that of annealed samples. The density of all samples varied between 2.1 and 2.3 g/cm³. The density of the annealed sample approached that of thermal oxide (2.27 g/cm³) within measurement accuracy.

Electrical properties.—Several samples were prepared from the SiH_4-CO_2-H_2 system at 1000°C, with the CO_2:SiH_4 ratio varying from 40:1 to 60:1. All wafers were n-type Si, <100>, 8.5-20 ohm-cm, 5.72 cm (2¼ in.) diameter. The total SiO_2 thickness deposited was ~1350Å. Most wafers were split in half after the SiO_2 deposition. One portion of each wafer was then annealed at 1050°C for 15 min in N_2 (standard anneal for thermal SiO_2). Then, clean 20-mil aluminum dots were evaporated on both halves of the wafers. The metallized wafers were annealed at 400°C for a half-hour in N_2.

Following are the results of measurements on MOS capacitors.

Dielectric strength.—Twenty MOS capacitor dots in each sample were biased in accumulation, and the bias voltage was ramped at a rate of approximately 1 V/sec. The capacitor leakage current was monitored with a picoammeter. The dielectric breakdown was considered to have occurred when the leakage was greater than or equal to 2 nA. All samples exhibited the same dielectric breakdown field (E_B). There was no dependence on CO_2:SiH_4 ratio or the postdeposition anneal. The E_B value obtained was 7.8×10^6 V/cm, and the breakdown distribution obtained was very tight in every case, with a standard deviation $\sigma_{E_B} \leq 0.1 \times 10^6$ V/cm.

Dielectric constant.—The thickness measured by ellipsometry and *C-V* measurements agreed within 50Å in all cases. This leads to the conclusion that the dielectric constant lies between 3.8 and 4.0. Annealed halves of wafers were thinner by ~30Å than the nonannealed halves. This means that there is densification of the order of 2-3% upon annealing.

Oxide fixed charges (Q_{ox}).—The fixed oxide charges were measured by means of the *C-V* technique. There was no influence of CO_2:SiH_4 ratio on the fixed charges; however, annealing showed the expected reduction in fixed charges. The Q_{ox} for nonannealed wafers was 2.8 ($\pm$0.2) $\times 10^{11}$ cm^{-2}, and the Q_{ox} for annealed wafers was 1.3 ($\pm$0.5) $\times 10^{11}$ cm^{-2}.

Mobile charges (Q_m).—Mobile charges were measured by applying $\pm 2 \times 10^6$ V/cm for 10 min at 200°C. This technique is similar to the one used by Kriegler *et al.* (16). The shift in flatband under positive bias was converted into mobile charge. In no case was the shift in the flatband under negative bias taken into account, for two reasons:

1. In most cases, the shift in the flatband under negative bias was negligible (*i.e.*, $\leq$25 mV). This also means that the mobile charges were present at the metal/SiO_2 interface.
2. In some cases, the flatband shift was significant under negative bias (*i.e.*, $\geq$50 mV), but the direction of the shift was wrong, *i.e.*, as if more positive charges were being accumulated at the SiO_2/Si interface. This effect (discussed in greater detail under Stability) is due to fast surface-state generation at the SiO_2/Si interface (17).

There was no measured effect of CO_2:SiH_4 ratio on mobile charge. The annealed wafers had a mobile charge of $<1 \times 10^{10}$, whereas the nonannealed wafers showed a mobile charge of 2.7 ($\pm$0.5) $\times 10^{10}$ cm^{-2}. The apparent higher mobile charges in nonannealed wafers are most likely due to run-to-run variations of the Al evaporator. The nonannealed halves of wafers were metallized first. Thermal oxide monitor wafers in the above two metallization runs were checked and showed the same general trend as the CVD oxide wafers.

Fast surface states (N_{FS}).—Fast surface states were determined by the quasistatic technique of Kuhn (18). This technique was modified after Castange (19) and Kerr (20). The modification involved the use of a high-frequency *C-V* trace in place of the ideal. The N_{FS} was obtained from accumulation to onset of inversion by comparison of the high- and low-frequency *C-V* traces.

$$N_{FS} = \frac{C_{FS}}{q} = \left[\frac{C_{LF} \cdot C_{OX}}{C_{OX} - C_{LF}} - \frac{C_{HF} \cdot C_{OX}}{C_{OX} - C_{HF}} \right] \frac{1}{q} \quad [5]$$

where C_{FS} = capacitance due to fast surface states, C_{OX} = oxide capacitance, C_{LF} = low-frequency capacitance at a given voltage on the metal electrode, C_{HF} = high-frequency capacitance at a given voltage on the metal electrode, and q = electronic charge 1.6×10^{19}.

Equation [5], in which all capacitances are per unit area, determines N_{FS} as a function of applied electrode voltage. This voltage can be readily converted into surface potential [*e.g.*, Kuhn (18)], so N_{FS}, as a function of surface potential, is given in this investigation.

The fast surface-state densities are generally small in all samples. Annealed samples show somewhat higher N_{FS} than nonannealed samples. The difference in the two cases, however, is not considered significant,

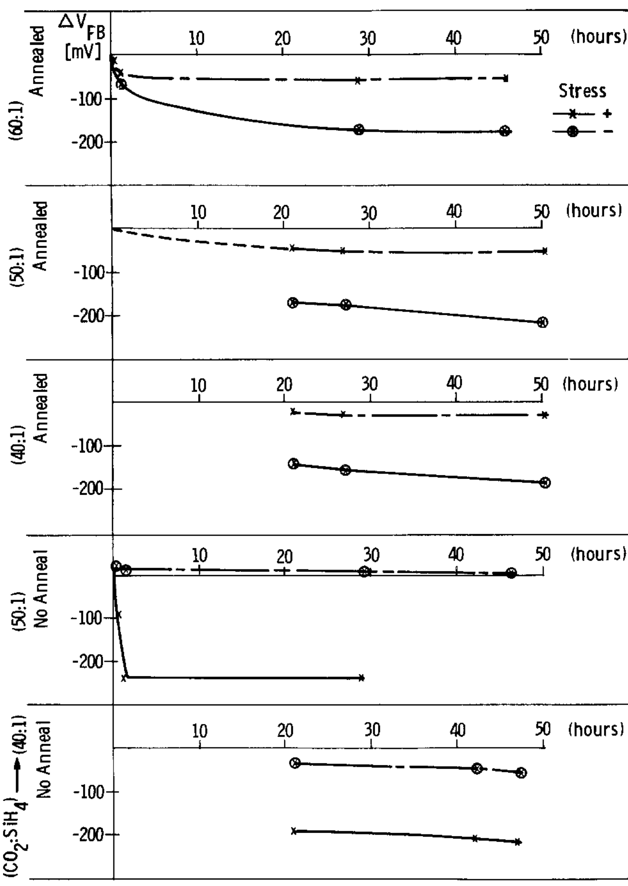

Fig. 6. Change of flatband voltage under the influence of temperature-bias stressing.

and all samples measured can be adequately represented by an N_{FS} value of 1.5 (±0.5) × 10^{10} cm^{-2} · eV^{-1} (at mid-bandgap).

Stability—As shown in Fig. 6, 50-hr stress data on some samples were accumulated at 200°C and 2 × 10^6 V/cm with both polarities on the metal of the MOS capacitor. The positive-bias data confirm the short-term stress data. There is a shift in the flatband voltage within the first hour and then a fast leveling off. This can be explained by the movement of mobile ions. Under negative bias, there is again a negative shift, the final value of which is larger for the annealed wafers than for the nonannealed wafers. There was no discernible dependency of V_{FB} shift on the CO_2:SiH_4 ratio. Negative shifts under negative bias are commonly attributed to an increase of fast surface-state density (17). It was not expected that the nonannealed wafers would display fewer fast surface states after temperature bias stressing.

To check the above expectation, several MOS capacitors on both annealed and nonannealed wafers were stressed for 20 hr at ±2 × 10^6 V/cm and 200°C. Most of the observed shift in V_{FB} occurs within this time span (Fig. 6). Table II presents the initial and final values of the N_{FS} at mid-bandgap. Note that there is a significant difference between annealed and nonannealed samples and, contrary to the above expectation, the annealed samples show higher, fast surface-state density after temperature- and negative-bias stressing. The behavior of the annealed samples is much like the dry, O_2-grown thermal oxides (17), whereas the nonannealed wafers appear to characterize the CVD oxides.

Table II. Fast surface states as a function of temperature-bias stress and postdeposition high temperature (1050°C, 15 min, N_2) anneal

Sample	N_{FS} cm^{-2} eV^{-1} (at mid-bandgap) × 10^{10}		
	Initial	After 20 hr of +2 × 10^6 V/cm and 200°C	After 20 hr of −2 × 10^6 V/cm and 200°C
As deposited	1.1 (±0.3)	1.2 (±0.3)	2.5 (±0.3)
Annealed	1.8 (±0.2))	3.1 (±0.5)	6.6 (±0.7)

* Note: Values in parentheses are twice the standard deviation.

The behavior of the CVD oxides investigated is not believed to be limited to oxides deposited in SiH_4-CO_2-H_2. This effect is most likely due to the deposition temperature used in this case (*i.e.*, 1000°C). Thus, the high-temperature postdeposition anneal deteriorates the stability of the CVD oxides under temperature- and negative-bias stressing.

Discussion

It has been shown that the SiH_4-CO_2 reaction is first order with respect to SiH_4. This was determined by using the "method of excesses," or "isolation," technique (14); *i.e.*, CO_2 had considerably larger concentration than SiH_4. Therefore, as expected, the reaction rate was independent of the CO_2 concentration. The same technique (*i.e.*, excess SiH_4 compared with CO_2) or the use of molar ratios of SiH_4 and CO_2 cannot isolate the reaction order with respect to CO_2, because, in both cases, silicon-rich films are deposited (*i.e.*, no longer SiO_2). There is no other known technique that would isolate reaction order with respect to CO_2. Thus, the experimental data cannot firmly support a reaction mechanism, and none will be postulated here. However, we shall discuss our results in the light of the mechanism previously postulated.

Tung and Caffrey (1), Steinmaier and Bloem (21), and Rand and Ashworth (8) proposed a two-step kinetic mechanism for SiO_2 deposition from $SiCl_4$-CO_2-H_2 and $SiBr_4$-CO_2-H_2. The first step involves so-called "water-gas" reaction

$$H_2 + CO_2 \rightleftarrows H_2O + CO \quad [6]$$

The second step involves oxidation (hydrolysis) of silicon halides with H_2O. Similar two-step kinetics may also be written for SiH_4, the second step being

$$SiH_4 + 2H_2O \rightarrow SiO_2 + 4H_2 \quad [7]$$

These authors realized that intermediate-reaction steps must exist, *e.g.*, that reactions [6] and [7] may proceed via a free-radical chain mechanism or any other equally probable path. It is also generally accepted that the water-gas reaction is the slower and, hence, the rate-controlling step.

Then, Tingey (22) experimentally determined the forward rate expression of reaction [6] in the temperature range of 800°-1050°C. The experimentally determined activation energy for H_2O formation from H_2 and CO_2 is 78 kcal/g mole (22). Therefore, if the water-gas reaction is rate controlling for SiO_2 deposition from SiH_4-CO_2 reaction in H_2, the observed activation energy should be of the order of 78 kcal/g mole. We have obtained an activation energy of 25.4 kcal/g mole for SiO_2 deposition. These results are inconsistent with the water-gas mechanism. Only the Steinmaier and Bloem (21) results are consistent with water-gas reaction. These authors obtained an activation energy of 82 kcal/g mole for $SiCl_4$-CO_2-H_2. However, Tung and Caffrey (1), who also studied the $SiCl_4$-CO_2-H_2 system, reported an activation energy of 51.6 kcal/g mole. Similarly, Rand and Ashworth (8) reported an activation energy of 30 kcal/g mole for the $SiBr_4$-CO_2-H_2 system in the temperature range of 800°-950°C. Thus, hardly any of the activation energy data involving CO_2 and H_2 support the so-called water-gas mechanism.

The inconsistency of the activation energy data led us to perform several experiments, with hopes of answering a two-part question: (*i*) Does H_2O form in our reactor under the experimental conditions of flow? (*ii*) What physical evidence would be produced if H_2O were to form in the reactor? It was assumed that, if H_2O were formed, the thermal oxidation of silicon would occur in the absence of SiH_4. In the presence of SiH_4,

we expected some homogeneous reaction (manifested by reaction-chamber clouding) besides the usual heterogeneous reaction. Several experiments, with results, are presented below.

Cleaned Si wafers were exposed to an H_2 and CO_2 ambient ($\leq 1.2\%$ CO_2) at 1000°C for 1 hr. The wafers were hydrophobic before and after exposure to the H_2 and CO_2 ambient. Ellipsometric measurements showed that the wafers had $\leq$ 15Å of SiO_2 before and after. Now the question arose whether other oxidants produced similar results. This led us to repeat the above experiment with N_2O which resulted in the growth of $\geq$ 600Å SiO_2 on the silicon wafers (23). To check whether the formation of SiO_2 from the N_2O and H_2 reaction was due to the H_2O formation or to the decomposition of N_2O and subsequent oxidation of silicon by oxygen, we repeated the experiment with N_2O and N_2. The resulting film was only ~ 150Å thick (23). Clearly, H_2O is formed when wafers are heated in N_2O and H_2, whereas H_2O is not likely to form from CO_2 and H_2 under the flow conditions of the reactor. This conclusion is consistent with, and supported by, two facts: (*i*) when the SiH_4-N_2O-H_2 system is used for SiO_2 deposition (850°-1000°C), the reaction chamber clouds very rapidly (23), whereas when the SiH_4-CO_2-H_2 system is used there is no evidence of reaction-chamber clouding; (*ii*) the deposition rate of SiO_2 from the SiH_4-N_2O-H_2 system is ~ 2-10 times higher than the SiH_4-CO_2-H_2 system, depending on deposition temperature (850°-1000°C) for identical SiH_4 and oxidant mole fraction (23).

Experiments with mixtures of H_2 and O_2 and of N_2 and O_2 showed results similar to those of H_2 and N_2O and of N_2 and N_2O; *i.e.*, a higher thickness of thermal SiO was grown with the H_2 and O_2 mixture. Clearly, H_2O was being produced by the reaction of hydrogen and oxygen. We then attempted to study the rate of reaction of SiH_4 with H_2O using the SiH_4-O_2-H_2 system. The task, however, was nearly impossible because of the chamber clouding which necessitated reactor cleaning after every run. We were able to obtain deposition-rate data at 800°-850°C, however, before abandoning the effort. The deposition rate of SiO_2 from the SiH_4-O_2-H_2 system was nearly an order of magnitude greater than that obtained from the SiH_4-CO_2-H_2 system for identical temperature, SiH_4, and oxidant mole fractions (24). The results of the experiments with SiH_4-O_2-H_2 and SiH_4-N_2O-H_2 are at variance with the water-gas mechanism for the SiH_4-CO_2-H_2 system because, if H_2O is produced from $CO_2 + H_2$, which subsequently reacts with SiH_4 to produce SiO_2, then the deposition rate of SiO_2 should not significantly change, irrespective of the source of H_2O.

Finally, Tingey (22) experimentally showed that the water-gas reaction is homogeneous, *i.e.*, that H_2O is produced in the gas phase. This should result in the homogeneous reaction of SiH_4 and H_2O; yet the SiH_4-CO_2-H_2 reaction is singularly characterized by the lack of homogeneous reaction, *i.e.*, no clouding of the reaction chamber by gas-phase reaction. The above experimental and activation energy data neither support nor are consistent with the water-gas reaction mechanism for SiH_4-CO_2-H_2. It is therefore probable that the SiH_4-CO_2 reaction could proceed via direct oxidation of silane, as suggested by Swann and Payne (4), some complex free-radical chain mechanism, as alluded to by Rand and Ashworth (8), or any other mechanism that does not include water-gas reaction as a step.

Summary and Conclusion

We have presented the results of SiH_4-CO_2 reaction in H_2 in the temperature range 850°-1050°C. We have used a multiple-wafer reactor in sharp contrast to Swann and Payne's single-wafer reactor. Our results should find more application in CVD practice because the flow of gases is nearly parallel to the wafer surface. Unlike Swann and Payne, we have been able to isolate the order of the SiH_4-CO_2 reaction with respect to SiH_4 and the activation energy and frequency factor of the reaction. However, care should be exercised in extrapolating and using these results to predict the SiO_2 deposition rate for SiH_4 concentrations larger than 0.06-0.07% because, at higher concentrations than these, the SiO_2 films become silicon-rich; *i.e.*, codeposition of Si and SiO_2 occurs.

We have shown that the physical and electrical properties of SiO_2 deposited at 1000°C are comparable to those of steam-grown oxide. In fact, the fast surface-state densities are considerably lower in these CVD oxides than in steam-grown oxides. The low level of fast surface-state density may be attributed to the use of H_2 during deposition. The stability of these oxides under temperature (200°C) and bias $\pm 2 \times 10^6$ V/cm has been demonstrated. The negative effects of post-deposition anneal in N_2 at a temperature higher than the deposition temperature have also been shown.

The use of CO_2 does not result in a homogeneous reaction, especially at higher temperatures, *i.e.*, of the order of 1000°C. This is a significant advantage, since it keeps the reactor down time to a minimum. However, the use of CO_2 has often raised the possibility of carbon inclusion. Though we do not have any direct evidence of the presence or absence of carbon in SiO_2 films deposited from SiH_4-CO_2-H_2, trace quantities of carbon may well be incorporated in these films. None of the measured physical and electrical properties, however, show any unusual or detrimental effects of these trace impurities, if present.

Finally, the CVD SiO_2 film from SiH_4-CO_2-H_2 could be readily used as a photolithographic mask for films like Si_3N_4 and in the field or the gate region of an integrated FET circuit.

Fabrication of P-Channel Silicon Gate LSI Devices with Si_3N_4/SiO_2 Gate Dielectric

Alfred P. Turley,* R. M. McLouski,* P. R. Reid, and D. H. McCann

Westinghouse Advanced Technology Laboratory, Baltimore, Maryland 21203

ABSTRACT

Processing of p-channel silicon gate devices with a Si_3N_4/SiO_2 gate dielectric is described in detail. Some attractive features of this particular process include polysilicon to silicon contacts, improved metal step coverage obtained with a glass flow anneal, low fast surface-state density for good 1/f noise performance, and high parasitic field threshold voltages obtained by ion implantation of arsenic.

Because of the work function difference between p-type polycrystalline silicon gate electrodes and lightly doped n-type silicon substrates, most p-channel silicon gate devices have been fabricated on <111> oriented silicon substrates. This avoids the possibility of very low threshold or depletion mode devices which can result if <100> oriented substrates are used. This result is a direct consequence of the lower fixed positive charge density at the SiO_2-Si interface of <100> oriented silicon substrates. However, for devices used in analog signal processing, the use of <111> material will degrade the 1/f noise performance of such IGFET'S because of the high fast surface-state density associated with this orientation. To take advantage of the better 1/f noise performance obtained on <100> material and still maintain a reasonable threshold voltage (−1.3V), silicon gate devices can be fabricated with a Si_3N_4/SiO_2 gate dielectric. The desired threshold voltage can be obtained by controlling the amount of fixed positive charge at the nitride-oxide interface formed during the nitride deposition. Other advantages of the dual dielectric structure are: (*i*) Si_3N_4 is superior to SiO_2 as a boron diffusion barrier (2), (*ii*) the composite structure has better integrity than a SiO_2 gate, and (*iii*) higher transconductance FET's result from the higher dielectric constant of Si_3N_4.

Other attractive features of this particular process are polysilicon-silicon contacts which allow very high packing densities because they take up less area than metal-silicon contacts, improved metal step coverage obtained with a glass flow anneal (4), and high parasitic field threshold voltages obtained by ion implantation of the surface (except active regions) with arsenic.

Process Sequence

An outline of the process is given in the flow chart in Table I. The starting wafer material is 4-8 ohm-cm, <100>, n-type. The first step is the formation of the gate oxide. This is thermally grown in an atmosphere of 10% HCl + 90% O_2 for 13 min at 1000°C. The resulting oxide thickness is about 300Å. This is followed by the deposition of the gate nitride. About 800Å of silicon nitride is deposited at 750°C with an ammonia to silane ratio of 250:1. In the next step, the first photoengraving operation is performed. A mask is applied to define islands of nitride which will ultimately become the active devices. A photoresist mask is used and the silicon nitride is plasma etched (5). The 300Å of oxide under the nitride stops the plasma etching process. With the photoresist still on the wafer, an arsenic implant is next performed at an energy of 80 keV and a dose of 5×10^{11} cm^{-2}. The photoresist acts as a mask which prevents penetration of the arsenic into active device regions. After photoresist removal, a cross section of a transistor structure appears as in Fig. 1. The transistor gate, source, and drain will be formed in the region defined by the island of silicon nitride. The arsenic implant in the surrounding regions will prevent parasitic transistor action by keeping the surface from inverting at voltages less than −35V. The next processing step forms the field oxide region by steam oxidation at 1100°C.

About 10 kÅ of SiO_2 is grown in 2.5 hr in the regions surrounding the nitride islands. Only about 300Å of the nitride is oxidized. This is removed by dip etching for 30 sec in a 10:1 HF solution. At this point in the process, the structure is annealed in dry O_2 for 30 min at

Table I. Process flow chart

1. Starting material: 4-8 ohm-cm, <100>, n-type
2. Gate oxidation: 300Å (10% HCl + 90% O_2, 13 min at 1000°C)
3. Gate nitride: 800Å (NH_3/SiH_4 = 250 at 750°C)
4. Device window mask (plasma etch Si_3N_4)
5. Ion implant arsenic (E = 80 keV, dose = 5×10^{11} cm^{-2})
6. Steam oxidation: 10 kÅ (H_2 + O_2, 150 min at 1100°C)
7. Etch oxidized nitride (~300Å)
8. O_2 anneal (30 min at 1050°C)
9. Polysilicon-silicon contact window mask
10. Polysilicon deposition (4 kÅ at 700°C)
11. Polysilicon gate and interconnect mask (plasma etch poly and nitride, chem. etch gate oxide to define self-aligned gate)
12. Boron diffusion (diborane source)
    a. Deposition: 18 min at 980°C
    b. Drive: 60 min, O_2 at 1000°C
13. Phosphorus-doped oxide deposition (~5% phosphorus, 15 kÅ)
14. Via and contact window mask
15. Glass flow anneal (O_2, 20 min at 1050°C)
16. Hydrogen anneal (30 min H_2 at 800°C)
17. Dip etch 30 sec in 10:1 HF (removes oxide from windows in doped glass)
18. Metallization (10 kÅ of Al-Si)
19. Metal interconnect mask
20. Sinter metal (30 min, N_2 at 500°C)

1050°C. This anneal converts about 50Å of the nitride surface to oxide and has the effect of stabilizing the structure (6). Figure 2 shows the transistor structure cross section at this point of the process. The device is now ready for opening contact windows for the polysilicon-silicon contacts. Again, a photoresist mask is used and the silicon nitride is plasma etched followed by an oxide etch. Figure 3 shows the device cross section at this point. Polysilicon is now deposited to a thickness of 4000Å with a deposition temperature of 700°C. A mask to define the polysilicon interconnect pattern and the self-aligned gate structure is next applied. A photoresist mask is used and the polysilicon is plasma etched. The plasma etching continues through the polysilicon and the silicon nitride around the gate electrode. A short oxide etch (~300Å) then completes the self-aligning gate definition. The transistor cross section at this point is shown in Fig. 4. A boron diffusion now forms the source and drain and also dopes the polysilicon conductor lines. Reoxidation in dry O_2 for 60 min at 1000°C during the boron drive forms about 700Å of SiO_2 over the polysilicon and source-drain regions. This oxide prevents counterdoping of the p-type regions by the phosphorus-doped oxide deposited in the next step.

This doped oxide is about 15 kÅ thick and contains about 5-6% phosphorus. The structure at this point is shown in Fig. 5. Contact windows and vias are opened in the doped oxide. An anneal is performed on the phosphorus-doped oxide under the following conditions: (*i*) 20 min, O_2 at 1050°C; (*ii*) 30 min, H_2 at 800°C. This high temperature anneal causes the viscosity of the doped oxide to decrease to the point where it begins to flow, giving rise to smooth oxide

edges over polysilicon steps and via and contact windows. A small amount of oxide is formed in the open windows during the anneal. This can be removed by a short dip etch before metallization. The hydrogen part of the anneal is the last high temperature step before metallization greatly reduces the number of fast surface states at the Si-SiO_2 interface in the gate regions, which in turn produces devices with excellent 1/f noise characteristics. The effects of the glass flow anneal are shown in the SEM photograph of Fig. 7. Note the excellent metal coverage of oxide steps.

The processing is completed with a metal deposition (10 kÅ of Al-Si), interconnect photoengraving, and sintering. The completed cross-section transistor structure is shown in Fig. 6. A photograph of a section of a completed device is shown in Fig. 8.

Device Characteristics

The threshold voltage of transistors fabricated by this process is greatly influenced by fixed positive charge formed at the silicon nitride-silicon dioxide interface in the gate dielectric. The magnitude of this charge is strongly influenced by the silicon nitride deposition parameters. Our nitride is deposited at 750°C with an ammonia/silane ratio of 250:1. The parameters that influence charge magnitude are deposition rate and deposition temperature. Temperature has by far the strongest effect with deposition rate being a second-order effect. Figure 9 shows the deposition temperature effect by comparing the *C-V* characteristics of MOS capacitors formed at deposition temperatures of 750° and 800°C. The negative shift of the 800°C curve indicates a larger fixed positive inter-

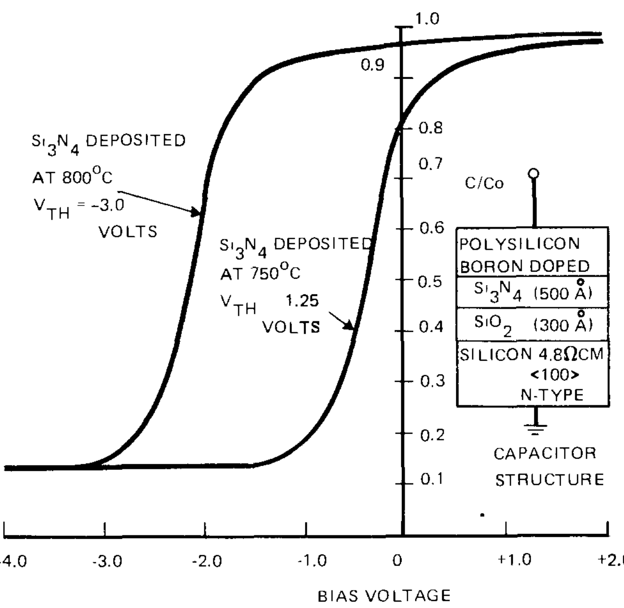

Fig. 9. MOS C-V curves showing the effect of nitride deposition temperature on the magnitude of the fixed charge formed at the nitride-oxide interface.

face charge. This data indicates a nitride charge of 2×10^{12} charges/cm^2 at the 800°C deposition temperature and 7×10^{11} charges/cm^2 at the 750°C deposition temperature. The charge at the nitride-oxide interface is transformed to a charge at the silicon surface (Q_{eff}) by the following equation

$$Q_{eff} = \frac{\frac{\epsilon_{ox}}{\epsilon_n} t_n}{t_{ox} + \frac{\epsilon_{ox}}{\epsilon_n} t_n} Q_n \qquad [1]$$

In this equation, one can think of the term $(\epsilon_{ox}/\epsilon_n)\, t_n$ as an effective oxide thickness of the nitride as far as its dielectric properties are concerned. Since $\epsilon_{ox}/\epsilon_n \sim 0.6$, one sees that 500Å of nitride is equivalent to 300Å of oxide for capacitance calculations.

The threshold voltage is given by the equation

$$V_{th} = \phi_{GS} - \frac{1}{C_i} (Q_{eff} + Q_{ss} + \sqrt{2\epsilon_s q N_d (2\phi_F)}) \qquad [2]$$

Thus one concludes that increasing Q_{eff} will make the threshold voltage more negative. The threshold voltage of 24 devices from different wafers in different runs was measured. The mean and standard deviation were −1.31 and 0.17V, respectively. The transconductance at VGS = −5V was also measured and normalized to unity width to length ratio. The mean and standard deviation were 32 and 3.84 μ-mhos, respectively.

The stability of the threshold voltage was examined by making temperature-bias stressed *C-V* measurements. Figure 10 shows the flatband voltage shift *vs.* time for a +15V bias at 200°C. The instabilities noted are not caused by ionic contamination but by the difference in the resistivity of the nitride and oxide (6). The resistivity of the silicon nitride is less than the oxide resistivity; hence, when bias is applied, the nitride oxide layers form a resistive divider and charge slowly accumulates at the nitride oxide interface. One can increase the nitride resistivity by oxidizing its surface. This small amount of oxide on the nitride surface effectively increases the nitride resistivity and improves stability. This effect is shown in Fig. 10 where

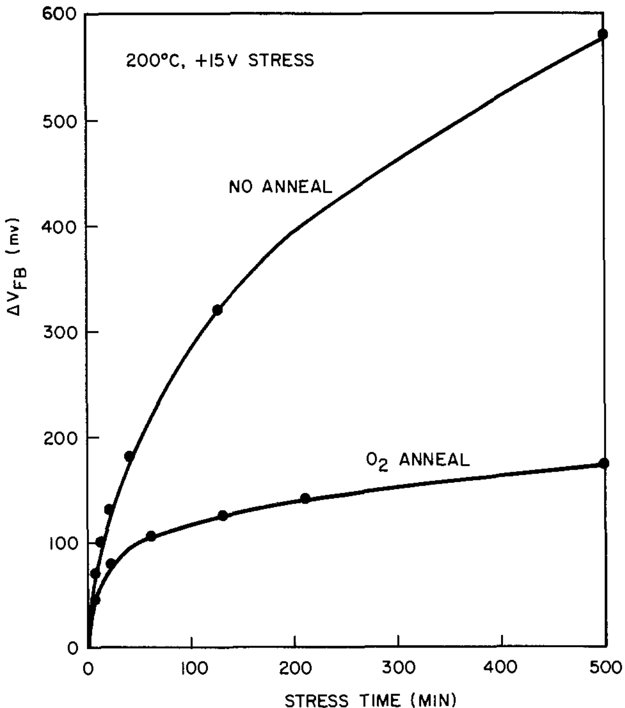

Fig. 10. Flatband voltage shift under temperature-bias stress

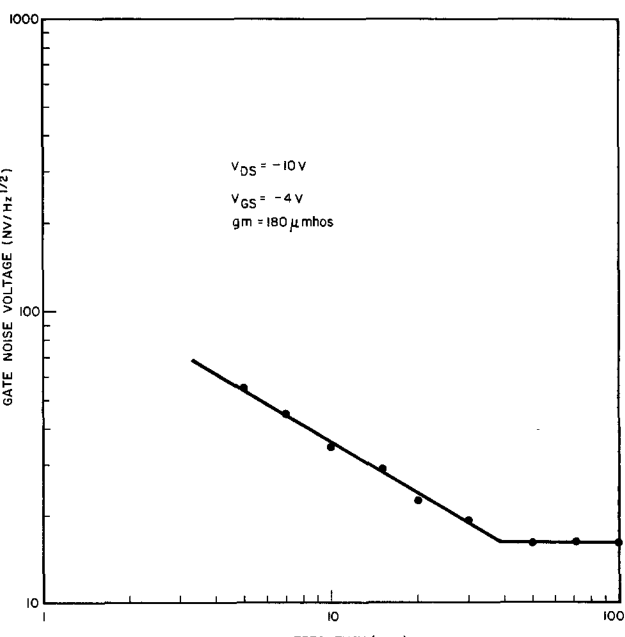

Fig. 11. Noise spectra of typical transistor

oxidized and nonoxidized samples are compared. This is the reasoning behind the oxygen anneal in step 8 of the process as indicated in Table I. Under a negative bias stress of −15V at 200°C, the oxidized samples shifted only 20 MV and saturated to this value after 5 min of stress. The nonoxidized sample shifted 40 MV under the same conditions.

The noise performance achieved with these devices is shown in Fig. 11. Here is plotted the noise voltage referred to the gate *vs.* frequency. The 1/f portion of the noise spectra shows about a 12% improvement over the performance attained with an equivalent device made with a metal gate and an oxide insulator.

Conclusion

We have devised and demonstrated a process for fabrication of p-channel silicon gate MOS devices with a silicon nitride/silicon dioxide gate dielectric for both digital and analog LSI applications. The process features include small area polysilicon-silicon contacts; smoothed, sloped oxide steps for excellent metal coverage; low fast surface-state density with a H_2 anneal; good threshold stability with an O_2 anneal; high parasitic field threshold voltages from ion implantation of arsenic in the field oxide regions.

ABSTRACT

MeV backscattering spectrometry and x-ray diffraction are used to investigate the behavior of sputter-deposited Ti-W mixed films on Si substrates. During vacuum anneals at temperatures of 700°C for several hours, the metallization layer reacts with the substrate. Backscattering analysis shows that the resulting compound layer is uniform in composition and contains Ti, W, and Si. The Ti:W ratio in the compound corresponds to that of the deposited metal film. X-ray analyses with Reed and Guinier cameras reveal the presence of the ternary $Ti_xW_{(1-x)}Si_2$ compound. Its composition is unaffected by oxygen contamination during anneal, but the reaction rate is affected. The rate measured on samples with about 15% oxygen contamination is linear, of the order of 0.5 Å/sec at 725°C, and depends on the crystallographic orientation of the substrate and the d-c bias during sputter deposition of the Ti-W film.

Titanium and tungsten have both been used for many years as materials for metallizing integrated circuits (1). Tungsten is used because its coefficient of expansion closely matches that of silicon, and titanium is used because of its strong adherence to oxides. A metallization scheme has also been developed which uses a mixture of titanium and tungsten (2). Like many of the transition materials, Ti and W both form silicides. The formation of WSi_2 from thin tungsten films on Si has been studied by several authors (3, 4). The formation of $TiSi_2$ by thin films on Si has also been studied (5), though not to as great an extent as WSi_2. To our knowledge, the present investigation is the first to consider the interaction of a mixed thin film with silicon. This study shows that, like Ti and W individually, a thin composite layer of Ti and W deposited on Si by sputtering and annealed in vacuum forms a disilicide. This ternary disilicide is studied using the techniques of x-ray diffraction, ^4He backscattering spectrometry (BS), and Auger electron spectrometry (AES).

Sample Preparation

Films of 1000-1500Å were deposited by RF sputtering from an arc-melted $Ti_{0.3}W_{0.7}$ target onto silicon and carbon substrates. The silicon substrates were n- or p-type, 1-10 ohm-cm single crystal wafers of <111>, <110>, or <100> orientations which had been mechanically polished and chemically etched. The polycrystalline carbon substrates were 0.5 in. squares and were polished and cleaned prior to sputter deposition.

During deposition, the substrates rested on a water-cooled pallet and the deposition temperature was monitored by a shielded iron-constantan thermocouple placed on the substrate surface. Substrates were loaded through a side loader which was evacuated by a cryogenic pumping station so as to prevent contamination of the target during loading.

Prior to loading, the silicon substrates were dipped in HF, rinsed in deionized water, and dried with high purity isopropanol. After loading, the sputtering chamber was evacuated to a background pressure of $\sim 1 \times 10^{-6}$ Torr. Argon of 5*N* purity which had passed through a titanium purifier was used to backfill the chamber. The Ti-W target was given a short presputter to insure a clean surface, and the substrates were sputter cleaned immediately before deposition. During deposition the substrates were held at a negative bias ranging from 0 to 50V with respect to ground. The maximum temperature measured during deposition was about 300°C. The Ti-W films deposited on Si have a resistivity of about 80 μohm-cm, irrespective of the substrates or bias voltage. The films deposited on carbon were analyzed by BS to check for possible contaminants. Carbon substrates rather than Si were used for these measurements so that the BS signal from the substrate would not interfere with signals from possible nitrogen or oxygen impurities. No oxygen or nitrogen could be detected. The samples deposited with -50V bias showed the largest amount of contamination, which consisted of Ar and was less than 2 atomic per cent (a/o). Examination of the films on silicon substrates by SEM at 30K magnification revealed a featureless surface.

Anneals were performed in an evacuated quartz-tube furnace. The furnace was pumped from one end by a LN_2 trapped oil diffusion pump and from the other end by a water-cooled titanium sublimation pump. The vacuum during anneals was typically 7×10^{-7} Torr. The temperature in the center of the furnace was measured by a Chromel-Alumel thermocouple which had been calibrated to an accuracy of $\pm$ 1°C against a mercury thermometer to a temperature of 350°C. The thermometer was calibrated against the freezing point and the boiling point (corrected for barometric pressure) of H_2O. The temperature stability of the furnace was measured to be $\pm$ 2°C over a period of 20 hr. The furnace was constructed so that many samples could be loaded and annealed sequentially during a single pump-down, and samples were always placed at the position within the furnace where it had been calibrated. Samples could be grouped and annealed simultaneously in the furnace.

Analytical Techniques

Backscattering spectrometry (BS).—The experimental setup and analytical method for BS have been reviewed elsewhere (6). In brief, the technique consists of placing a sample in a beam of monoenergetic $^4He^+$ ions and energy analyzing those He atoms which are scattered from the sample. BS with MeV $^4He^+$ ions provides information on concentration profiles in depth with a resolution of about 200Å and to depths of about 3000-5000Å. In thicker films, the depth resolution degrades due to energy straggling within the target. The beam spot is typically 1-2 mm^2 and hence backscattering analysis required samples whose lateral composition is uniform over at least such a dimension.

X-ray analysis.—Two types of x-ray diffraction analyses were performed. The first type uses the Reed Camera (7) geometry which is basically a glancing angle x-ray diffraction setup with a fixed angle of incidence. The structure of the thin-film samples is identified in a manner similar to that employed with the Debye-Scherrer camera. Because of the glancing angle of incidence of the x-rays (8-14° with respect to the specimen surface), a relatively large volume is examined although the samples are thin. For example, at an incident angle of 10° the x-ray path length is 6 times the film thickness. The incident x-ray beam used for the exposure was CuK_α radiation collimated through two pinholes. The diffraction pattern is recorded on film placed along a 5 cm radius from the sample center.

The second type of x-ray diffraction analysis performed used a Guinier camera (8). This is a transmission x-ray diffraction apparatus in which the sample rotates with respect to the beam during exposure. CuK_α radiation was used in conjunction with x-ray film to record the diffraction patterns. The Guinier camera requires thin samples so as to not substantially attenuate the diffracted x-rays. To this end, the rear side of a reacted sample was lapped until the sample thickness was reduced to between 50-60μ. The sample was then ultrasonically cleaned and rinsed in diluted HF. A similar sample of the bare silicon substrate was also prepared in this way. By comparing the x-ray diffraction patterns from both samples, the diffraction lines due to the silicide could be identified.

Given the camera constant and an accurate measurement of the silicide diffraction line spacing, determination of the cell parameters can be made. The camera constant was determined by measurement of the camera radius and verified using the diffraction lines from a strain-free sample of polycrystalline silicon powder. The silicide diffraction line spacing was measured with an optical comparator to $\pm$0.01 mm, which gave an uncertainty of $\pm$0.01Å in the unit constants. The advantage of the Guinier technique is to enable an accurate determination of the cell constants, whereas the Reed camera can detect the presence of phases without special preparation of the specimens.

Auger electron spectroscopy (AES).—AES has been reviewed recently in the literature (9). This technique uses the decay by electron emission of sample atoms which experience inner shell ionization by an energetic electron beam. Energy analysis of these emitted Auger electrons allows one to perform an elemental analysis of the sample surface. Typically, sensitivities of about 1 a/o can be obtained.

Auger electrons originate only from atoms excited in the outermost atomic layers. Hence, elemental depth profiling requires a sequential removal of thin layers between measurements. This can be accomplished by sputtering. To obtain the depth profile of a sample requires knowledge of the sample's sputtering rate and the sputtering time. BS can be used conveniently to determine the film thickness and thereby calibrate the sputtering rate.

AES and BS nicely complement each other. AES is more sensitive than BS for profiling light elements in heavy matrixes, and BS can be used to measure the thickness and composition of the film quantitatively in a relatively short time ($\sim$ 10-20 min).

Results

Characterization of ternary silicide.—Films of Ti-W having about 30 a/o Ti (10% by weight) prepared as described above were vacuum annealed at 800°C for 20 min. The surface changed from the smooth metallic luster of Ti-W to a deep silver-gray. Examination by SEM at 4500$\times$ magnification revealed a uniform and gently undulating surface. The undulations were typically 2.5 μm across and < 0.05 μm in height (as determined by measurement with a Sloan Dektak).

X-ray diffraction analysis by Reed camera revealed the presence of only one compound (Fig. 1). The diffraction pattern corresponds to that described by the ASTM powder diffraction compilation No. 6-0599. This compound has a chemical formula of $Ti_xW_ySi_2$, where $x + y = 1$, with a hexagonal $CrSi_2$-type (C-40) structure. X-ray analysis by the Guinier camera supported the Reed camera results in that no crystal structures other than the C-40 type were detectable. The line spacings from the Guinier photographs gave cell parameters of $a_o = 4.61 \pm 0.01$Å and $c_o = 6.48 \pm 0.01$Å.

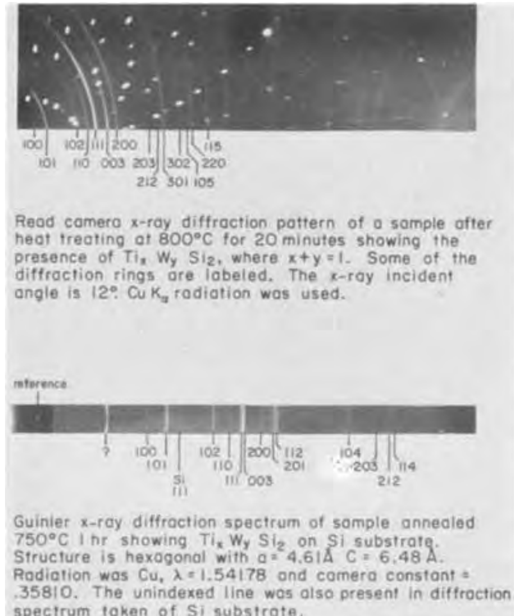

Fig. 1. X-ray diffraction pattern taken with Reed camera (top) and Guinier camera (bottom) of reacted samples.

2 MeV $^4He^+$ BS analysis of films reacted at 725°C for 40 min revealed that the atomic concentration ratio of the films is Ti:W:Si = 0.3:0.7:2.0 (Fig. 2). The compound maintains this composition at temperatures ranging from 675° to 900°C. Additional experiments established that the compound formed was independent of substrate orientation, doping type, substrate bias during sputter deposition, and the sample contamination by oxygen during annealing.

Once formed, the compound adheres strongly to the silicon substrate. The compound seems unaffected by hot H_2O_2, HF, or CP-4, and dissolves only slowly in aqua regia. Indium solder would not adhere to the compound.

Kinetics of silicide formation.—The reaction rate of the compound formation was investigated by BS on samples annealed in vacuum for increasing periods of time. To translate the energy scale of a BS spectrum into a depth scale, we assumed a density of 7.54×10^{22} atom/cm^3 for the compound, as calculated from the measured unit cell parameters. Using this density, 10 keV in a BS spectrum corresponds to about 106Å of compound.

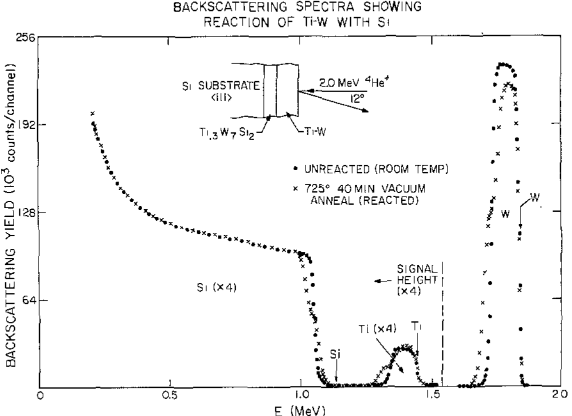

Fig. 2. Backscattering spectra showing a virgin (room temperature) and a covered, annealed (725°C, 40 min, 7 × 10^{-7} Torr) sample of Ti-W on Si. The Si substrate is <111> single crystal n-type with resistivity of 10 ohm-cm. The Ti-W film was deposited with —50V bias. Arrows indicated the position of signals from Si, Ti, and W on the sample surface.

Films deposited on <111> silicon at —50V bias and annealed at 5 × 10^{-6} Torr and 725°C were found to have reaction rates of about 9.7 Å/min. Improving the vacuum to 7 × 10^{-7} Torr and covering the metallized side of the sample with a clean Si wafer during anneal increased the reaction rate by approximately a factor of 2 (Fig. 5). Figure 3 shows a <111> silicon sample of which half of the metallized side was covered with a Si wafer during an anneal at 7 × 10^{-7} Torr and 725°C for 45 min. The uncovered side (top) shows little reaction whereas the covered side (bottom) is almost completely reacted. A subsequent AES analysis of this sample (Fig. 4) reveals that the uncovered half of the sample has a larger concentration of oxygen than does the covered half.

In Fig. 2 the ratio of the signal height of the remaining unreacted tungsten to that of the unreacted silicon substrate is smaller than that same ratio measured on the virgin sample. This was true for partially reacted samples which had been covered and annealed in the highest vacuum attainable. If this difference is attributed to oxygen contamination, then the samples annealed in the cleanest vacuum still contained up to 15 a/o oxygen. Since oxygen has been shown to influence rates, the kinetics studies performed here are to be interpreted with caution and the results should be regarded as preliminary.

Reaction rate studies at 750°, 725°, and 700°C were performed on covered samples annealed at 7 × 10^{-7} Torr. Samples annealed at each temperature were all cut from the same wafer and loaded simultaneously. The samples were then annealed sequentially. When precautions to reproduce the vacuum were taken, the results were reproducible. The analysis of the backscattering yields established that after anneal all the samples were contaminated 15-20%, presumably by

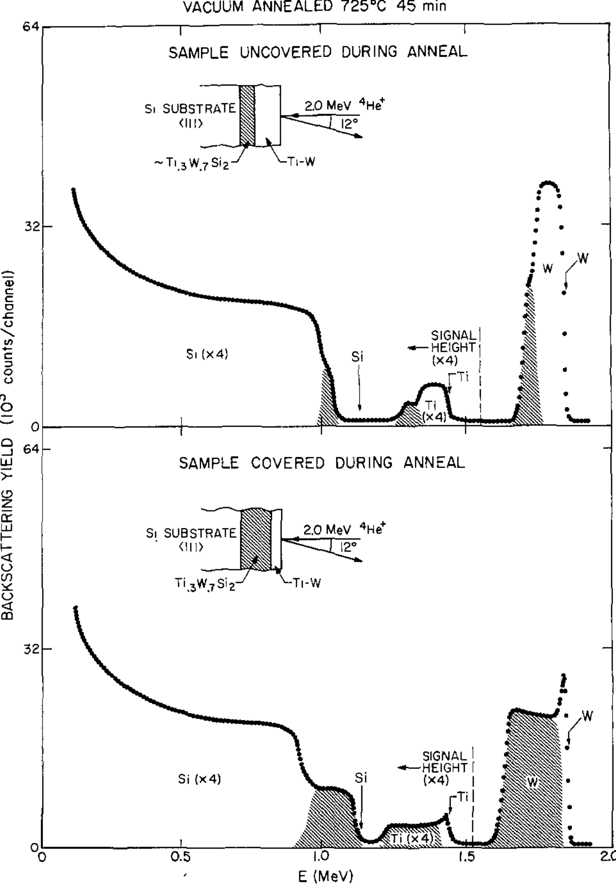

Fig. 3. Backscattering spectra of a partially covered sample annealed at 725°C for 45 min. Top shows portion of sample which was uncovered during anneal and bottom shows covered part. Arrows indicate the position of signals from Si, Ti, and W on the sample surface.

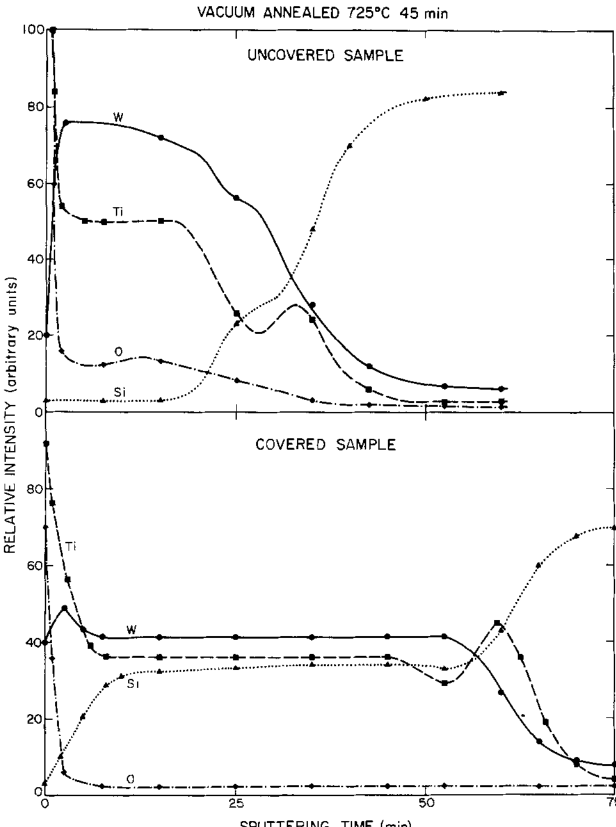

Fig. 4. AES depth profile of W, Ti, Si, and O in the uncovered (top) and covered (bottom) parts of the sample in Fig. 3.

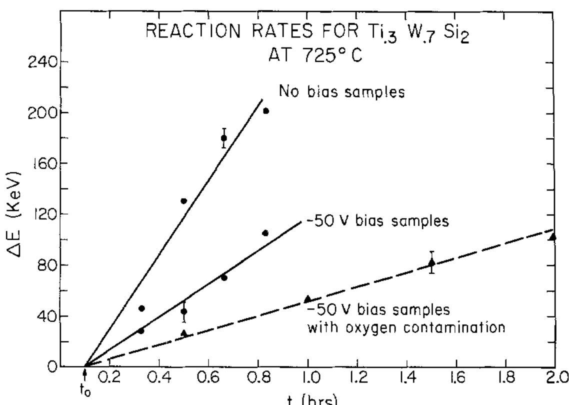

Fig. 5. A plot of compound thickness (expressed in terms of backscattering energy loss) vs. anneal time. The warm-up time for a sample placed in the vacuum furnace is denoted by 't_0'. Lines marked "No bias samples" and "—50 V bias samples" were annealed covered at a vacuum of 7×10^{-7} Torr. Line marked "—50V bias samples with oxygen contamination" refers to samples annealed uncovered at a vacuum of 5×10^{-6} Torr. (10 keV corresponds to about 106Å of compound).

oxygen. The reaction has a linear time dependence at all temperatures and over the entire range of oxygen contamination. An apparent activation energy of 4.5 eV is determined from the reaction rate *vs.* temperature (Fig. 6).

The rate of reaction is influenced by several parameters. This fact was established by comparing two samples which differed only in the parameter of interest. These sample pairs were sandwiched together with the metallized sides face to face and annealed in a vacuum similar to that used in the rate *vs.* temperature studies. This procedure also gave reproducible results. From such comparison, it was established that the reaction rate is influenced by the bias applied during sputter deposition (Fig. 5). Samples deposited on

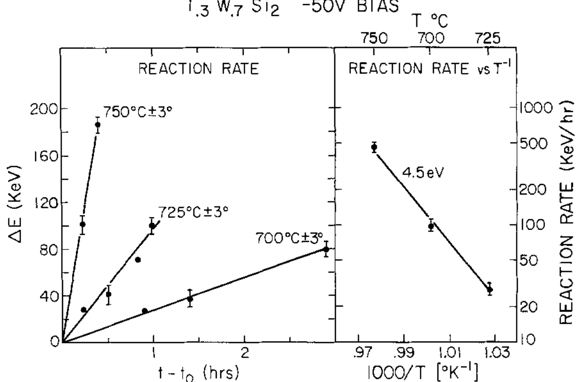

Fig. 6. (Left) plot of compound thickness (expressed in terms of backscattering energy loss for 2.0 MeV $^4He^+$ ions, 10 keV corresponds to about 106Å of compound) vs. anneal time, t, minus warm-up time t_0. (Right) plot of log of reaction rate vs. reciprocal anneal temperature (yields activation energy of 4.5 eV).

<111> silicon substrates react slower than those deposited on <110>, and samples prepared on <100> react the fastest. On the other hand, the dopant type of the Si substrate had no measurable effect on the reaction rate, nor did changes of the doping level from 2 to 10 ohm-cm.

Discussion and Conclusion

Transition metal silicides typically form complete solid solutions when the two constituting binary silicides are isomorphic. A partial solid solution or ternary compound forms when the two binary silicides are nonisomorphic (10). $TiSi_2$ has an orthorhombic (C-54) structure with a packing sequence ABCD, but WSi_2 has a tetragonal (C-llb) structure with a packing sequence ABAB. Hence one expects that a ternary compound will form with Ti, W, and Si. Formation of ternary compounds has also been reported in both the Ti-Mo-Si system and the Ti-Re-Si system (10).

The Ti-W-Si system has been studied by Nowotny (11). He reports a ternary disilicide of composition $Ti_xW_{1-x}Si_2$ for $x > 0.6$ but a mixture of $TiSi_2$ and WSi_2 for $x < 0.6$. In the present case, $x = 0.3$; compound formation is observed nevertheless. This discrepancy between Nowotny and the present work could possibly be due to the fact that Nowotny investigated bulk samples prepared by high pressure sintering at 1300°C while we consider thin-film samples prepared near 750°C.

We attribute the surface distortion after compound formation to the volume expansion the film experiences as a result of Si inclusion. This expansion is substantial since the film undergoes only a small atomic density change (approximately 6.14×10^{22} atom/cm² for the initial Ti-W layer, as calculated from the weighted sum of the elemental densities; approximately 7.54×10^{22} atom/cm³ for $Ti_{0.3}W_{0.7}$ Si_2 calculated for the compound from the x-ray data).

A reduction of reaction rates by oxygen contamination has been observed by Kräutle (12) in the formation of VSi_2 by thin films of V on Si. It is remarkable that the rate of reaction is closely linear in spite of considerable oxygen contamination (Fig. 5). The observations that the rate remains linear at reduced oxygen contamination and that the substrate crystal orientation also influences the rate, is consistent with a reaction-limited mechanism. This hypothesis is further supported by the fact that Borders (4) reports linear rates for the WSi_2 formation. No published data exist for reaction rates of Ti films on Si substrates.

The observed activation energy of 4.5 eV is high. Sinha (13) also reported a high activation energy of 4.4 eV for WSi_2 growing at the expense of PtSi. On the other hand, the activation energies quoted for the formation of WSi_2 films on Si range from 2 to 3 eV (4). Our value of 4.5 eV may thus be the result of

$Ti_{0.3}W_{0.7}Si_2$ growing at the expense of an oxide of titanum and/or tungsten. An argument against this hypothesis is the fact that no oxides of Ti or W were detected in the x-ray photographs. The x-ray analysis, however, is not very sensitive to small oxide concentrations over narrow regions such as the reaction interface. At present, the high value of the activation energy is not understood.

The influence of deposition bias on the reaction rate may also be a contamination effect. The samples with −50V deposition bias had both lower reaction rates and higher argon contamination levels than the sample deposited at zero bias. However, certain parameters of the films such as stress or crystal grain size which could influence the reaction rate, were not well characterized. Differences in these parameters could also contribute to variations in reaction rates between samples prepared at different biases.

Since we were unable to perform anneals without introducing detectable amounts of contamination, the kinetics data presented here are to be considered preliminary. It would also be worthwhile to extend this study to Ti-W films with various initial compositions, or to other disilicide-forming bimetal combinations. The results would be of value to the subject of ternary silicides in general, and to their possible application in silicon device technology in particular.

Acknowledgments

We wish to thank Paul Turner for allowing the use of his sputtering system. We also thank Dr. C. A. Evans, Jr., University of Illinois, Urbana, for his Auger analysis, and Dr. Sten Samson for the use of his Guinier camera and for his help in the x-ray analysis. We express our appreciation to the Kellogg Radiation Laboratory for the use of their 3 MeV accelerator and to Dr. C. A. Barnes for his continuous assistance.

Isochronal Annealing of Silicon-Phosphorus Solid Solutions

P. Ostoja, D. Nobili, A. Armigliato, and R. Angelucci

C.N.R. Laboratorio Lamel, 40126 Bologna, Italy

ABSTRACT

Isochronal annealings of 500 hr per pulse, in steps of 25°C, have been performed in the range 400°-800°C on silicon single crystals of well-known composition bulk-doped with phosphorus. Dopant concentrations were 1.7, 3.3, 3.7 5, 5.8, and 7.5 $\times$ 10^{19} at/cm^3. The annealing curves, determined by electrical resistivity measurements, are reported and discussed. A resistivity increase, attributed to phosphide precipitation, takes place above 400°C in the dopant richest alloy. It is noticed that a high density of dislocations (about 10^8 cm^{-2}) does not alter the kinetics of this process. At 550°C coherent precipitates of interstitial character have been observed by TEM; their density and mean size are consistent with a SiP composition. The features of the defects associated with the dissolution process are also reported. Phosphorus diffusivity for precipitation, calculated at 550°C, turns out to be about five orders of magnitude higher than expected from extrapolation of well-known high temperature values. The solubility of phosphorus in silicon, determined by the kinetics of recovery of resistivity, results as about 7 $\times$ 10^{19} at/cm^3 at 650°C.

Phase equilibria and the related kinetics in the binary systems of silicon and its substitutional dopants are important for basic knowledge. Further, this information presents a relevant interest for the technology and failure physics of silicon devices. Our laboratory is involved in a research program concerning the Si-B and the Si-P systems (1, 2). The present study deals with the precipitation of phosphorus by isochronal annealing of bulk-doped silicon single crystals. The formation of phosphide precipitates in silicon has been observed by several authors, mainly by TEM examinations (3-10). This technique has also been used, together with x-ray topography, in our laboratory (11, 12). All the above studies were carried out

Key words: silicon, phosphorus-doped, annealing, precipitation, solubility.

on specimens doped by diffusion which, therefore, presented concentration gradients. As a consequence, the kinetics of the process have never been analyzed.

Isochronal kinetics constitute an obvious step in determining the temperature above which precipitation takes place at a measurable rate. They can give information on the diffusivity, as well as on the influence of lattice defects on the nucleation of the new phase. The purpose of our work was also the determination of reliable values of phosphorus solubility at low temperature. The status of knowledge in the whole range below the eutectic temperature is lacking: values at 900°C and above are widely scattered (a single research has reported data below this temperature) and no data are available below 700°C (13).

The annealing and quenching method is widely used in phase diagram determinations; its precision can be improved by increasing the annealing time and comparing precipitation and dissolution results. The experimental procedures of this method unambiguously satisfy the condition that both the primary solid solution and its conjugate phase must be competing for equilibrium. It is open to question if this basic thermodynamic condition has been fulfilled in solubility determinations based on measurements of surface concentration of the dopant after predeposition in an oxidizing atmosphere (14).

In the silicon-phosphorus system below the eutectic temperature, the conjugate phase is Si-P, base-centered orthorhombic (14, 15). This structure has recently been confirmed on small phosphide precipitates by electron diffraction studies carried out in our laboratory (12).

Experimental

Our experiments were carried out on (111)-oriented, bulk-doped silicon single crystals. Six compositions were studied. The corresponding phosphorus concentrations are reported in Table I. Slices were nominally dislocation free, with an actual density $< 10^3$ cm^{-2}. These alloys have been the subject of previous investigations concerning the dependence on phosphorus concentration of electrical resistivity and mobility (16, 17), as well as of lattice parameter (18). The concentration of dopant has been determined by neutron activation analysis; by this technique and gamma-scintillation spectrometry we also performed the analysis of about forty metallic impurities. The results of these analyses are reported in a previous paper (16). Oxygen, as well as carbon and nitrogen content, was determined by ion activation analysis. The content of carbon was about 4×10^{17} and that of nitrogen about 1.5×10^{17} at/cm^3. Oxygen concentration was found to range between 6×10^{15} and 3.7×10^{17} at/cm^3; the figures for each composition are reported in Table I. Precise lattice parameter determinations were carried out along the diameter of some representative wafers. Lattice parameter oscillations, although increasing with dopant concentration, turned out to be small, and a homogeneity of 10^{-3}% was ensured near the wafer center from where we obtained our samples. The techniques of chemical analysis and of structural examinations have been described in detail in the above-mentioned papers (16, 18).

Isochronal annealings were performed in the temperature range 400°-800°C in steps of 25°C, by using a vacuum furnace (10^{-6} Torr) for shorter times (21 hr per pulse), and quartz tubes sealed under the same vacuum for longer treatments (500 hr per pulse). The temperature stability was kept better than ±0.5°C even for the longer times by using a CAT control system. The heating and cooling times of our specimens were of the order of some minutes. To follow the annealing behavior, we performed room temperature electrical resistivity measurements after each heating pulse. Our previous work (16) allowed us to obtain a reliable relationship between resistivity and the concentration of electrically active phosphorus in the heavy doping range. Repeatability of our resistivity determinations turned out to be ±0.5%; this was confirmed by measuring in each run unannealed reference dummy samples of composition similar to that of the specimens. Moreover, the experiments were carried out on several samples, at least ten, of each composition. Half of the most heavily doped specimens were deformed by a four-point bending technique (19) in order to observe the influence of the high density of dislocations introduced (about 10^8 cm^{-2}). At the end of selected annealing steps, samples were thinned with the jet-etching technique and observed by TEM in order to follow the structural modifications induced by the annealing process. Our instrument was a Siemens Elmiskop 101 equipped with a ±45° double tilting cartridge.

Table I.

Samples	Resistivity (ohm · cm)	Phosphorus conc (at/cm³)	Oxygen conc (at/cm³)
W/na	3.5×10^{-3}	1.7×10^{19}	6.1×10^{15}
A/na	1.9×10^{-3}	3.3×10^{19}	7.9×10^{15}
M/n4	1.7×10^{-3}	3.7×10^{19}	3.7×10^{17}
M/n3	1.3×10^{-3}	5.0×10^{19}	3.7×10^{17}
M/n2	1.1×10^{-3}	5.8×10^{19}	3.7×10^{17}
M/n1	8.5×10^{-4}	8.5×10^{19}	3.7×10^{17}

Results

Electrical measurements.—The resistivity curves after isochronal annealing of 500 hr per pulse of the samples with phosphorus concentrations 1.7, 3.3, 3.7, 5, and 5.8×10^{19} at/cm^3 are reported in Fig. 1. The resistivity values of the unannealed reference dummy sample, also reported in this plot, refer to electrical measurements performed in the same run as the corresponding annealed specimens. The most diluted compositions clearly exhibit a negative resistivity variation in the temperature range 450°-575°C, with two minima centered at 500° and 550°C, respectively. The

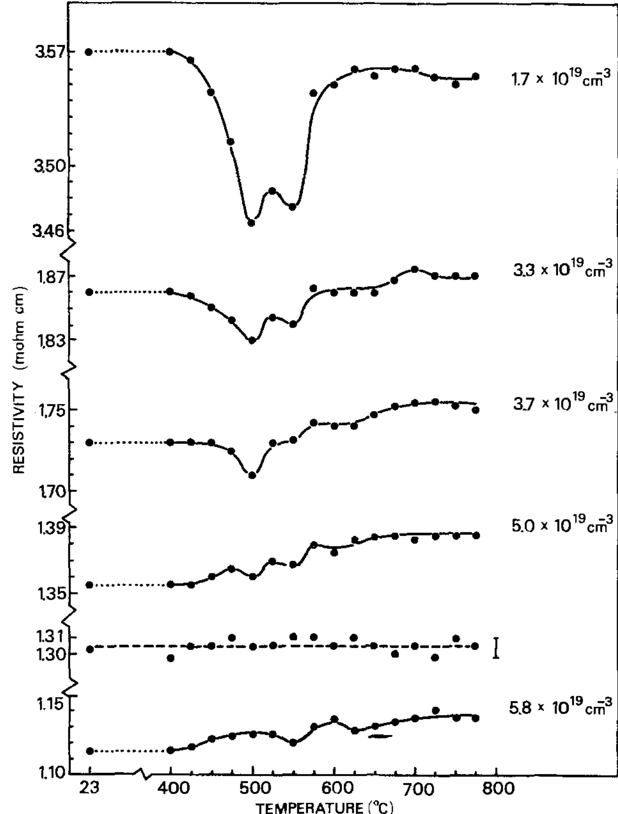

Fig. 1. Electrical resistivity vs. temperature for 500 hr per pulse annealing of Si samples bulk-doped with increasing P concentrations (solid lines). The behavior of the unannealed reference dummy sample is also reported (broken line).

amplitude of this effect decreases with increasing phosphorus, and the minimum at 500°C is not observed in the alloys with dopant concentration exceeding 5×10^{19} at/cm^3. A third slight inflection, centered at about 625°C, is also noticed and is significant considering the reproducibility that we observed between the specimens with the same composition as well as the behavior of the different alloys.

The isochronal annealing kinetics for the P-richest composition (7.5×10^{19} at/cm^3) are reported in Fig. 2. A resistivity increase can be clearly seen above 400°C. The amplitude of this effect is higher as the annealing time is longer, and is of about 11% in curve (a), which corresponds to 500 hr of annealing per pulse. Two small resistivity minima, superimposed on the main peak, are in any case noticed. In curve (a) they are centered at 550° and 625°C, that is, corresponding to the minima observed in Fig. 1. In curve (b), which corresponds to 21 hr annealing per pulse, they are shifted to about 575° and 675°C, respectively. After high temperature annealing the resistivity recovers approximately its original value. At the end of the heat-treatment of 21 hr per pulse [curve (b)], the samples were isochronally annealed for the same time per pulse, at decreasing temperatures. A resistivity increase has been obtained also in this case, thus indicating that the phenomenon is reversible. As will be discussed later, the resistivity peak in Fig. 2 is attributed to a decrease of the concentration of the charge carriers due to precipitation of phosphorus in a supersaturated solid solution. Finally, it is worthwhile to remark that the behavior of the deformed specimens, which contain a high density of dislocations, is indistinguishable from that of the undeformed ones.

TEM examinations.—Due to the destructive character of electron microscopy, a limited number of situations have been studied by TEM in bright and dark field two-beam conditions, as well as by using the weak beam dark field technique (20). Our observations on the most heavily doped specimens, isochronally heated 500 hr per pulse, were carried out after annealing up to 500°, 550°, and 775°C, respectively. Prior to annealing the specimens did not exhibit the presence of any crystallographic defect.

(i) Specimens annealed up to 500°C.—Images taken in different areas of these specimens did not reveal any defect, either in bright or dark field two-beam conditions. Images taken with the weak beam dark field technique clearly displayed, as shown in Fig. 3, a large density of small defects, typically about 50Å in diameter. It was, in any case, difficult to decide from contrast experiments whether such defects were precipitates or dislocation loops.

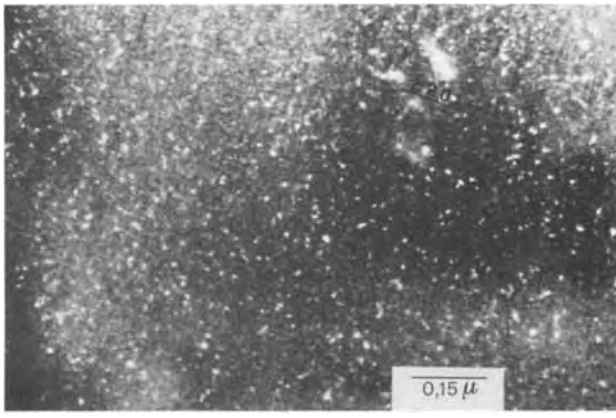

Fig. 3. Small defects in one of the most heavily doped samples annealed up to 500°C. Weak beam $(-g, g)$ image.

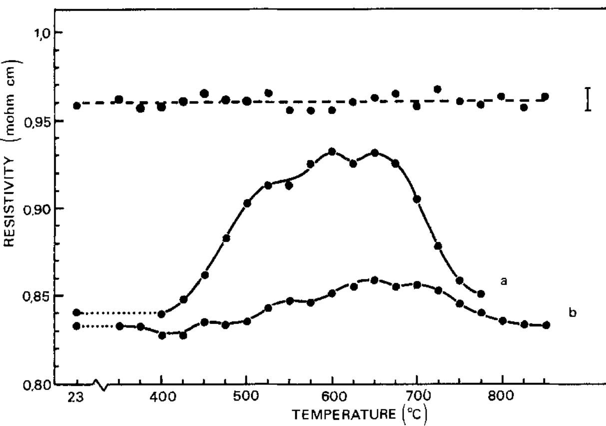

Fig. 2. Electrical resistivity *vs.* temperature for 500 hr per pulse, curve (a), and 21 hr per pulse, curve (b), annealing of Si samples bulk-doped with P (7.5×10^{19} at/cm^3). The same curves hold also for specimens containing a high density ($\sim 10^8$ cm^{-2}) of dislocations. The broken line refers to the unannealed reference dummy sample.

(ii) Specimens annealed up to 550°C.—As reported in previous papers (1, 2), the observations carried out on these samples revealed the presence of a high density (about 6×10^{13} cm^{-3}) of coherent precipitates which, from dark field images, were found to be interstitial in character, with strain parameter $\epsilon = 2.5 \times 10^{-2}$. A typical bright field image of these particles is shown in Fig. 4. From the Ashby and Brown theory it was possible to compute their average radius which came out at about 130Å. These figures, compared with the amount of electrically inactive phosphorus deduced from resistivity data, are consistent with the hypothesis that the particles are SiP precipitates. Weak beam images taken in the same areas revealed again, as shown in Fig. 5, the presence of the small defects already observed in the samples annealed up to 500°C.

(iii) Specimens annealed up to 775°C.—Images taken both from deformed and undeformed specimens exhibited a large amount of dislocation loops. A typical micrograph is reported in Fig. 6, which also evidences one of the dislocations introduced by bending the unannealed specimen. The loops displayed in this picture are of interstitial type, and the same holds for the loops in Fig. 7. Loops like the ones marked B and D in Fig. 6 and M in Fig. 7 are perfect loops with Burgers vectors of the type $a/2 \langle 110 \rangle$. Those marked A and C in Fig. 6 and L in Fig. 7 are stacking fault loops with Burgers vectors of the type $a/3 \langle \bar{1}\bar{1}1 \rangle$. This latter statement becomes apparent if one looks at the weak beam micrograph of Fig. 8, taken in the $(-g,g)$ orientation. The fringes observed in this figure are spaced by 36Å, which is in very good agreement with the

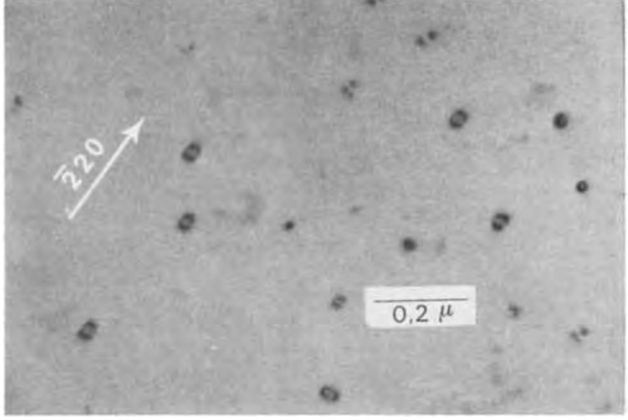

Fig. 4. Coherent precipitates in one of the most heavily doped samples annealed up to 550°C. Bright field image.

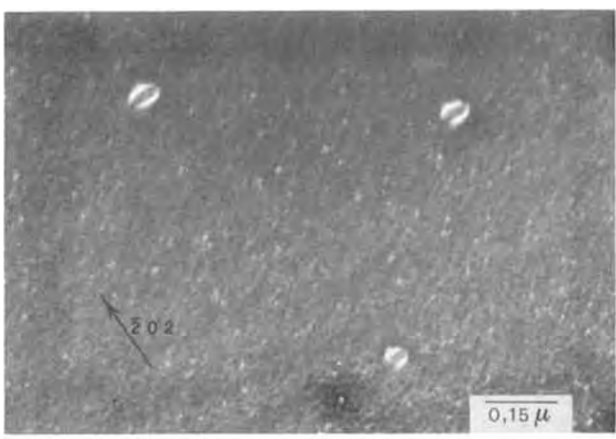

Fig. 5. Coherent precipitates and small defects in the same sample as Fig. 4. Weak beam $(-g, g)$ image.

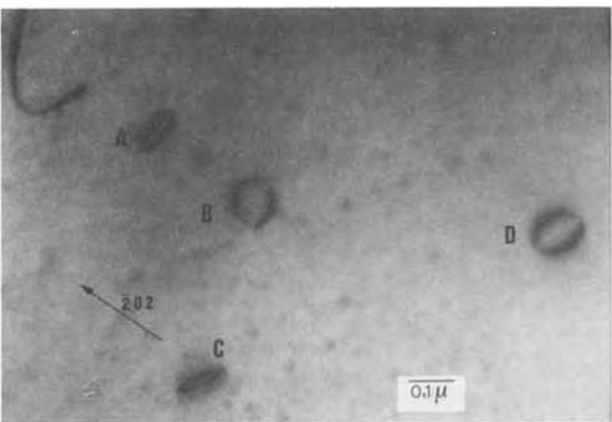

Fig. 6. Perfect dislocation loops (B and D) and stacking fault loops (A and C) in one of the most heavily doped samples annealed up to 775°C. One of the dislocations introduced by bending is also visible. Bright field image.

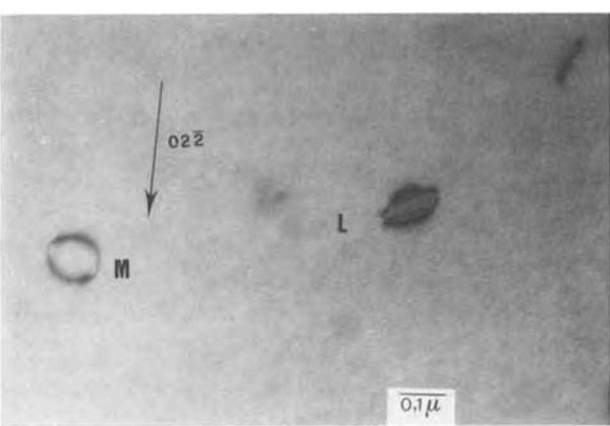

Fig. 7. Perfect dislocation loop (M) and stacking fault loop (L) in the same sample as Fig. 6. Bright field image.

theoretical fringe spacing d obtained from the formula $d = \frac{1}{S'} \cot \alpha$, where S' is the deviation of the $0\bar{2}2$ reciprocal lattice point from the sphere of reflection, and is given by $1/S' = 1/\lambda g^2$. λ is the electron wavelength that, in our case, corresponds to 369×10^{-4}Å, and α is the angle between the surface of the specimen and the $(1\bar{1}1)$-inclined plane of the fault ($\alpha = 70.5°$) (21). A further check is given by the calculation of the spacing of the fringes observed in Fig. 9, taken with $g =$

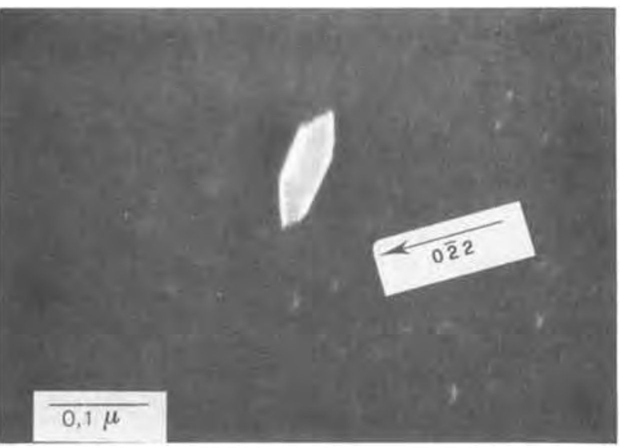

Fig. 8. Weak beam $(-g, g)$ image of the stacking fault loop (L) of Fig. 7, showing the 36Å spaced fringes given by the $0\bar{2}2$ reflection.

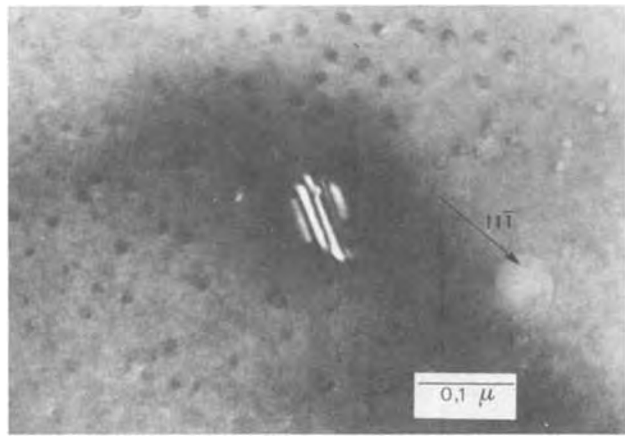

Fig. 9. Weak beam $(-g, g)$ image of the stacking fault loop (L) showing the 144Å spaced fringes, given by the $11\bar{1}$ reflection.

$11\bar{1}$, still in weak beam orientation. One gets $d = 144$Å, in good agreement with the theoretical value of 142Å. A certain number of vacancy loops were also observed, like the ones labeled A and C in Fig. 10, found near the loop G which is of interstitial type. Finally, we notice that the small defects like those shown in Fig. 3 are rare at this stage of annealing; nevertheless they are actually present, although with lower concentration.

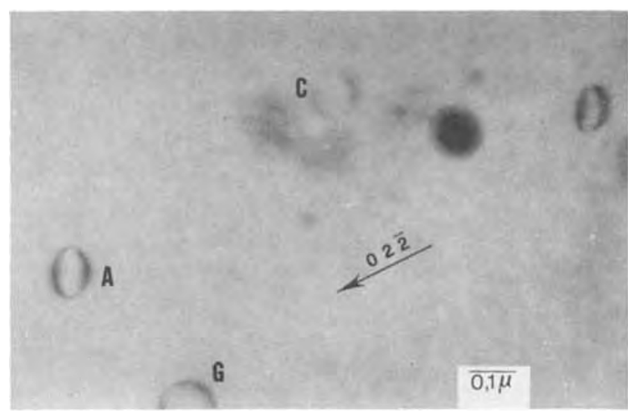

Fig. 10. Vacancy dislocation loops (A and C) together with an interstitial one (G) in the same sample as Fig. 6-9. Bright field image.

Discussion and Conclusion

We consider, first, the resistivity peaks in Fig. 1. The influence of the concentration of phosphorus in the range from 1.7 to 3.8 $\times$ 10^{19} at/cm^3, as well as that of the content of carbon and oxygen, has been studied in a previous work based on isochronal annealing of 21 hr per pulse. It was observed that the amplitude of the peaks does not depend on the concentration of carbon and oxygen (22). Further, these previous results are in agreement with the observation that the amplitude of the main negative peaks, centered at 500° and 550°C, respectively, in Fig. 1, decreases with the increasing phosphorus concentration. Moreover, it can be seen that by increasing the annealing time per pulse the amplitude of the peaks increases, and they result in being more clearly resolved and slightly shifted toward lower temperatures.

These observations suggest that the resistivity peaks in Fig. 1 are probably due to rearrangements of point defects, giving rise to complexes which are dissolved again with increasing temperature, as can be seen from the resistivity recovery at the end of each peak. In fact, if one computes from our experimental data the contribution to the conductivity due to the donors involved in such complexes, one gets a value which remains nearly constant, at least within the experimental errors, throughout the range of concentrations of phosphorus. This consideration allows us to conclude that these donor complexes should not depend on the P content, although the relative amplitude of the dips in Fig. 1 is lower as the resistivity decrement due to the increasing P concentration is higher. Further information on the nature of these phenomena should be obtained by comparing the annealing behavior of n- and p-doped crystals. We shall report in a further work the results of a research in progress on silicon doped with boron.

The resistivity peak in Fig. 2 can be attributed to phosphide precipitation followed by redissolution at high temperature. In fact it is observed only in the most heavily doped alloy; the compositions with a comparable amount of impurities, but less rich in phosphorus, do not show this phenomenon. These conclusions are in agreement with the formation of coherent precipitates of the type shown in Fig. 4. The mean size and density of these precipitates are in keeping with a SiP composition. In addition they are dissolved after annealing up to 775°C, when the resistivity has recovered its original value.

It is unlikely that the small defects shown in Fig. 3 are phosphide precipitates; if so, they should be unstable with respect to the larger ones. On the contrary, a considerable fraction of these defects is still present after annealing up to 775°C. The dislocation and stacking fault loops previously analyzed show the formation of excess point defects, mainly interstitials. They are associated with the dissolution of phosphide precipitates; in fact, these defects are absent in less-doped alloys annealed in the same way. The formation of dislocation loops takes place also in specimens undergoing isothermal precipitation of phosphorus, as evidenced by TEM observations which are at present in progress. The amount of inactive phosphorus resulting from the 500 hr per pulse annealing [Fig. 2, curve (a)] and the onset of the redissolution process at 650°C allows determination of the solid solubility of phosphorus in silicon at this temperature, which is about 7 $\times$ 10^{19} at/cm^3. This figure should be practically unaffected by the interface effects, which can greatly increase the solubility of very fine particles. In fact, the 500 hr per pulse annealing gives rise, as shown in Fig. 4, to a high density of precipitates with radius larger than 100Å. The above solubility is in good agreement with the value of 7 $\times$ 10^{19} at/cm^3 at 700°C reported by Abrikosov *et al.* (23).

All experiments on the heavily doped alloy have shown that the kinetics of precipitation and redissolution are unaffected by the presence of dislocations. This result is interesting also in the aging of electronic devices. A reasonable hypothesis is that the available point defects provide more suitable centers competing for the formation of critical nuclei.

To account for these precipitation phenomena, the diffusivity of phosphorus has to be much higher than that expected. In fact, the diffusion length $\sqrt{Dt}$ calculated at 550°C using diffusivity values determined in our laboratory (24) or well-known data found in literature (13, 25) and taking $t = 1000$ hr turns out to be only a few angstroms. A calculation, albeit crude, of the diffusivity involved in our experiments can be performed using the model of Ham (26), considering the spherical symmetry and the radius ($\sim$130Å) of our coherent precipitates, admitting that the composition is SiP, and assuming, from extrapolation of our experimental data on the isochronal curve (a) in Fig. 2, a solubility of 6 $\times$ 10^{19} at/cm^3 at 550°C. This calculation gives $D \simeq 5 \times 10^{-17}$ cm^{2}sec^{-1}, that is, five orders of magnitude higher than the diffusivity value at 550°C calculated by extrapolation of our high temperature data, as well as of the above-cited data found in literature.

Actually, preliminary results of the data analysis on the isochronal curve, combined with those of isothermal annealing in progress, suggest that the activation energy for diffusion is substantially reduced. The discrepancy could be explained either by a completely different diffusion mechanism, active at low temperature, or by an excess of point defects associated with the precipitation process. Further research is in progress on isothermal annealing followed by TEM observations and lattice parameter determinations with the aim of contributing to the clarification of the precipitation process.

Solid-State Ionics—High-Conductivity Solid Copper Ion Conductors

Organic Ammonium Halide-Copper (I) Halide Double Salts

Takehiko Takahashi,* Noboru Wakabayashi, and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya 464, Japan

ABSTRACT

The copper ion conductivities of the system organic substituted ammonium halide-copper(I) halide have been measured in the solid state, and the relation between the formation of high conductivity compounds and the conformation of organic substituted ammonium halides was examined. No high copper ion conductivity was found in the system unsaturated azacyclic substituted ammonium halide-copper(I) halide, while high copper ion conductivity was found in the saturated azacyclic substituted ammonium halide-copper(I) halide system. For example, the system 1-methylpiperidinium bromide-copper(I) bromide at the composition of 84 mole per cent CuBr gave the conductivity of 8.2×10^{-3} (ohm-cm)$^{-1}$ at room temperature.

Ionic conduction in the system substituted ammonium iodide-silver iodide was studied extensively by Owens (1), Owens, Christie, and Tiedeman (2), and Beradelli *et al.* (3), and many compounds were reported to have the ionic conductivities in the range of 8×10^{-4} to 6×10^{-2} (ohm-cm)$^{-1}$ at 25°C. From the conductivity measurements of a large number of the systems, Owens *et al.* (2) concluded that the formation of ion conductive compounds was related to the size of organic ammonium ions. Recently, double salts formed by the combination of copper(I) halide with N-alkyl-hexamethylenetetramine halide (4), and N,N'-dialkyl-triethylenediamine dihalide (5) have been found to exhibit high ionic conductivity at room temperature. In order to extend the area of high copper ion conductivity solid electrolytes, the electrical conductivities of the products formed by the reaction between copper(I) halides and organic ammonium halides have been measured (6, 7). The relations between the formation of copper ion conductive compounds and the size and conformation of the organic substituted ammonium ion are discussed.

Experimental

Materials.—Copper(I) halides were purified by recrystallizing in the corresponding hydrohalogenic acid. The substituted ammonium halide salts were prepared by the method A used generally, except for ethane-1, 2-bis-piperidinium bromide, and pentane-1,5-bis-morpholinium bromide which were prepared by the method B (8). The typical examples of synthesis are as follows:

Method A: To a solution containing 10 mliters (0.10 mole) of piperidine in 50 mliters of ethyl alcohol were slowly added 14g (0.098 mole) of a methyl iodide solution in 10 mliters of ethyl alcohol and the mixture was refluxed for 1 hr. After being filtered, the precipitate was dried in vacuo on P_2O_5. A yield of 1.5g of product (about 10% yield) was obtained.

Method B: To 3.8g (0.44 mole) of morpholine a solution containing 15g (0.065 mole) of 1,5-dibromopentane in benzene were added slowly at 0°C and the mixture was allowed to stand at room temperature for 2 days. After being filtered, the precipitate was dried in vacuo on P_2O_5. A yield of 22g of product (80% yield) was obtained.

The electrolytes were prepared by combining copper(I) halides (CuX) with substituted ammonium halides (QX). The appropriate quantities of CuX and QX were thoroughly ground together before being pressed to form a pellet under a pressure of 4000 kg/cm^2, and then heated in a sealed, evacuated Pyrex vessel. The reactions were carried out below the decomposition temperatures of the starting materials, which were determined by thermogravimetric analysis.

Electrical conductivity.—The conductivity was measured with a 1000 Hz conductance bridge. The frequency dependence of the resistance was not observed in the frequency range of 1000-10,000 Hz. The conductivity measurement cell was as follows

Cu, Sample (2:1 weight ratio)/Sample/Cu, Sample (2:1 weight ratio)

The sample of about 0.8g was stacked between two

* Electrochemical Society Active Member.

Key words: solid electrolyte, copper ion conductor, copper(I) halide, organic ammonium halide.

electrodes and pressed into a pellet of 13 mm diameter under a pressure of 4000 kg/cm^2. The conductivity was measured in nitrogen gas flow.

Electronic conductivity.—The electronic conductivities of some of the samples have been measured by the Wagner polarization method (9). To cell [I] with a copper anode and a graphite cathode, d.c. was applied at a voltage less than the decomposition voltage of the samples

$$\text{Cu/Sample/Graphite} \qquad [I]$$

The sample was pressed in the shape of pellet, 13 mm in diameter and 3 mm thick. A constant current supplier was used and the resulting voltage was measured with a high impedance digital voltmeter.

Thermogravimetrc analysis (TGA).—The decomposition temperatures of the samples were determined by thermogravimetric analysis, the heating rate of which was 3.3°C/min.

Results and Discussion

The electrical conductivities at room temperature for the organic ammonium iodide-copper(I) iodide systems, viz., tetramethyl ammonium iodide ($(CH_3)_4NI$), 1-methyl pyridinium iodide ($C_5H_5NCH_3I$), 1-methyl pyrrolidinium iodide ($C_4H_9NCH_3I$), 1-methyl piperidinium iodide ($C_5H_{11}NCH_3I$), and 1-methyl morpholinium iodide ($C_4H_9ONCH_3I$)-copper(I) iodide systems, are shown in Table I, where σ_e and σ_i are the electronic and ionic conductivity, respectively. The ionic conductivities of the silver iodide-organic ammonium iodide systems shown in this table were measured by Owens *et al.* (1, 2). In the silver iodide-organic ammonium iodide and copper(I) halide-organic ammonium halide systems as the high silver and copper ion conductivities (1, 2, 4, 5) were found at the composition between 80 and 90 mole per cent (m/o) silver iodide and copper halide, it may be assumed in the present investigation that if high conductivity materials could be formed, they would contain almost the same percentage of copper(I) iodide. So the thermal reaction products containing about 84 m/o copper iodide were examined. Table I shows that the $C_5H_{11}NCH_3I$-CuI and $C_4H_9ONCH_3I$-CuI systems give relatively high conductivities of 8.6×10^{-4} (ohm-cm)$^{-1}$ and 5.8×10^{-4} (ohm-cm)$^{-1}$ at room temperature, respectively. According to x-ray investigation, these systems did not give the diffraction patterns of the starting materials but gave the new phase diffraction patterns, which showed that the new conductive double salts were obtained in these systems at the composition of about 84 m/o CuI. In the $(CH_3)_4NI$-CuI, $C_5H_5NCH_3I$-CuI, and $C_4H_9NCH_3I$-CuI systems, however, no conductive double salts were formed, and the conductivities of these systems were the same order of magnitude as that of CuI and the conduction was mainly due to electrons. The x-ray diffraction patterns of these systems were the same as those of the starting materials. In other unsaturated azacyclic substituted ammonium iodide (the derivatives of the 1-methyl pyridinium iodide)-copper(I) iodide systems, no high conductive material was found in all the systems investigated: 1-hydro pyridinium iodide, 1,4-dimethyl pyridinium iodide, 1,3-dimethyl pyridinium iodide, 1,2,6-trimethyl pyridinium iodide, 1-hydro-3,5-dimethyl pyridinium iodide, 1,3,5-trimethyl pyridinium iodide, 1-methyl quinolinium iodide, and 1-ethyl quinolinium iodide-copper(I) iodide systems, and 1-hydro-2-methyl quinolinium bromide-copper(I) bromide system.

It is of interest to define by what parameters the existence of the conductive compounds were determined. It was suggested by Owens *et al.* (2) that in the silver iodide-organic ammonium iodide systems, the formation of high ionic conductivity compounds was related to the size of the organic ammonium ions. Table I indicates that in the copper(I) iodide-organic ammonium iodide systems, though $C_5H_5NCH_3^+$ and $C_5H_{11}NCH_3^+$ have almost the same size, only the latter gave high conductive materials. Therefore, the parameters other than the size of organic ammonium ions may be important to obtain high copper ion conductivity materials. One of these parameters may be the flexibility of organic ammonium ions; 1-methyl pyridinium ion has a plane structure, while 1-methyl piperidinium ion and 1-methyl morpholinium ion have flexible structures. Further, 1-methyl pyrrolidinium ion has a plane structure and tetramethyl ammonium ion has a rigid tetrahedral structure. That is, the flexible organic ammonium ions give a high ionic conductivity compound when they combine with copper(I) iodide. The other alkyl piperidinium halide, alkyl morpholinium halide, and alkyl piperadinium halide-copper(I) halide systems were examined also and the results of the electrical conductivity obtained are shown in Table II. Of these systems, the highest conductivity of 8.2×10^{-3} (ohm-cm)$^{-1}$ at 20°C is found in 1-methyl piperidinium bromide-copper(I) bromide, the conductivity value of which is comparable to that of N-alkyl hexamethylene-tetramine halide-copper(I) halide double salts reported previously (4) and one order of magnitude higher than that of the copper(I) iodide-1-methyl piperidinium iodide system. Gamma-copper(I) iodide and γ-copper(I) bromide have zinc blende structures, and the structure of copper(I) bromide is more open than that of copper(I) iodide. These results suggest that in the high ionic conductivity compounds, the structure of metal halide may play an important role.

In the 1,2- and 1,4-dimethyl piperidinium bromide-copper(I) bromide systems, the reaction products which gave the x-ray diffraction patterns of new compounds have lower conductivities than the compound in 1-methyl piperidinium bromide-copper(I) bromide system at room temperature, which suggested that the steric effect of substituted groups in the 1,2- and 1,4-dimethyl piperidinium bromide-copper(I) bromide systems may interrupt the diffusion of copper(I) ions.

Conductivity.—The composition dependence of the electrical conductivity was determined for three systems, viz., the 1-methyl piperidinium bromide-copper(I) bromide, 1-methyl piperidinium iodide-copper(I) iodide, and 1-methyl morpholinium iodide-copper(I) iodide systems. Figure 1 shows the conductivity as a function of mole per cent of copper(I) halide. The highest values of conductivity are 8.2×10^{-3}, 8.6×10^{-4}, and 5.8×10^{-4} (ohm-cm)$^{-1}$ for the $C_5H_{11}NCH_3Br$-CuBr, $C_5H_{11}NCH_3I$-CuI, and $C_4H_9ONCH_3I$-CuI systems, respectively, at the composition of about 84 m/o CuX.

The conductivities of $C_5H_{11}NCH_3Br$ 16 m/o-CuBr 84 m/o and $C_5H_{11}NCH_3I$ 16 m/o-CuI 84 m/o were mea-

sured at different temperatures. These samples were not decomposed up to 110°C in nitrogen atmosphere. The logarithmic conductivity *vs.* the reciprocal of the absolute temperature curves for these samples are shown in Fig. 2. These curves give straight lines in the range of temperature studied. The activation energies for conduction calculated from these curves are 3.7 kcal/mole for $C_5H_{11}NCH_3Br$ 16 m/o-CuBr 84 m/o and 5.1 kcal/mole for $C_5H_{11}NCH_3I$ 16 m/o-CuI 84 m/o; these values are almost the same as those of previously reported high copper ion conductivity solid electrolytes (4).

Electronic conductivity.—Electronic conductivity for some systems has been measured by Wagner's polarization method. According to Wagner's theoretical analysis (9) the current density J in cell [I] is given by

$$J = I/A = (RT/L\mathbf{F})[\sigma_e\{1 - \exp(-E\mathbf{F}/RT)\} + \sigma_h\{\exp(E\mathbf{F}/RT) - 1\}] \quad [1]$$

where I is the current, A the cross-sectional area, L the thickness of the sample, E the applied voltage, and $\mathbf{F}$ the Faraday constant, and σ_e and σ_h are the excess electron and hole conductivities of the sample which is in equilibrium with metallic copper. The plots of log I *vs.* E give virtually straight lines whose slopes are close to the value of $\mathbf{F}/2.30RT$ at each temperature. Since the excess electron conduction is negligible, Eq. [1] may be written as

$$\log I = \log \sigma_h ART/L\mathbf{F} + E\mathbf{F}/2.30RT \quad [2]$$

if $E\mathbf{F}/RT >> 1$. The values of σ_h were then calculated

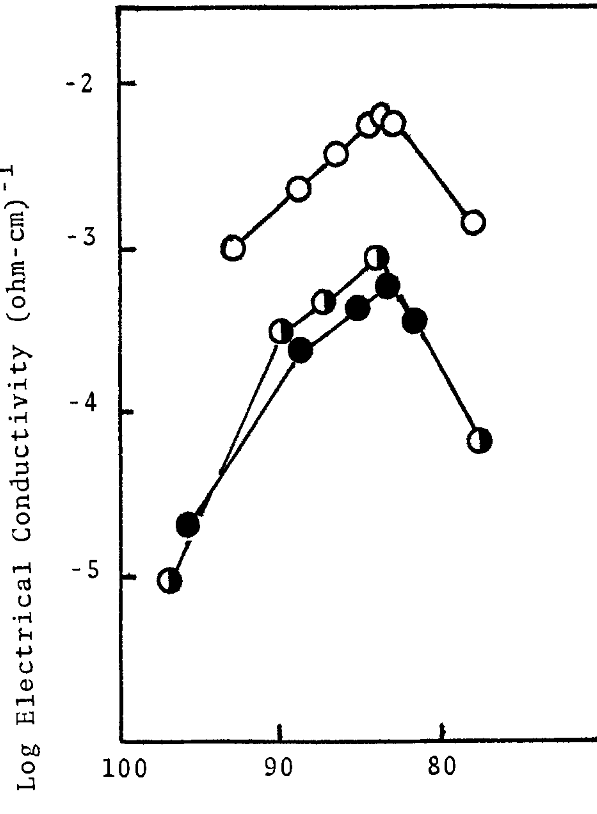

Fig. 1. Composition dependence of electrical conductivity of the binary solid electrolyte systems $C_5H_{11}NCH_3Br$-CuBr (○), $C_5H_{11}NCH_3I$-CuI (◑), and $C_4H_9ONCH_3I$-CuI (●) at 25°C.

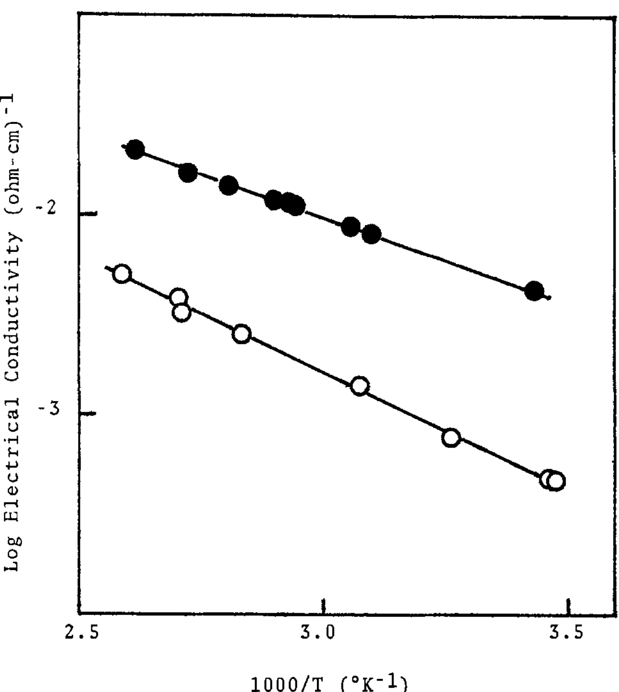

Fig. 2. Temperature dependence of the electrical conductivity of $6CuBrC_5H_{11}NCH_3Br$ (●) and $6CuIC_5H_{11}NCH_3I$ (○).

from Eq. [2]. Figure 3 shows the values of σ_h for the $C_5H_{11}NCH_3Br$-CuBr, $C_5H_{11}NCH_3I$-CuI, and $C_4H_9ONCH_3I$-CuI systems as a function of the composition of CuX at 110°C. The electronic conductivity for these systems decreases with decreasing copper(I) halide content. The conductivity of $C_5H_{11}NCH_3Br$ 16 m/o-CuBr 84 m/o is lower than 3.2×10^{-12} (ohm-cm)$^{-1}$ at 110°C. The temperature dependence of the

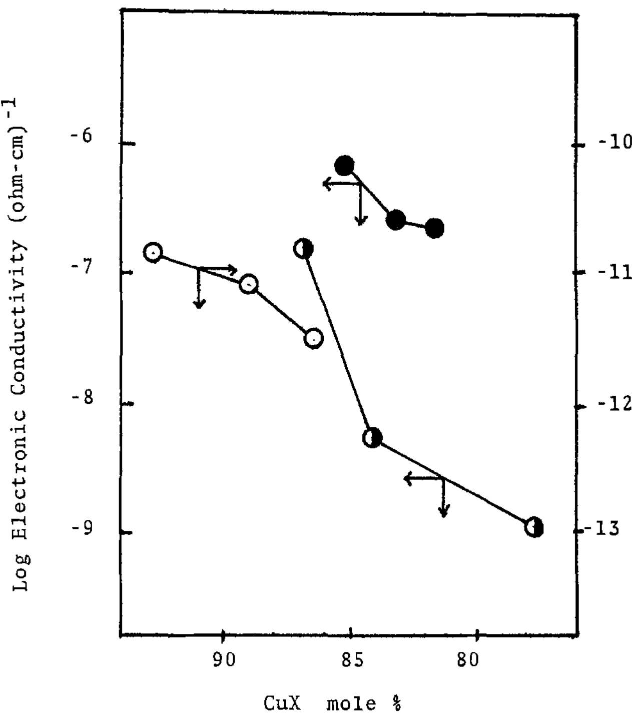

Fig. 3. Composition dependence of the electronic conductivity of the binary solid electrolyte systems $C_5H_{11}NCH_3Br$-CuBr (○), $C_5H_{11}NCH_3I$-CuI (◑), and $C_4H_9ONCH_3I$-CuI (●).

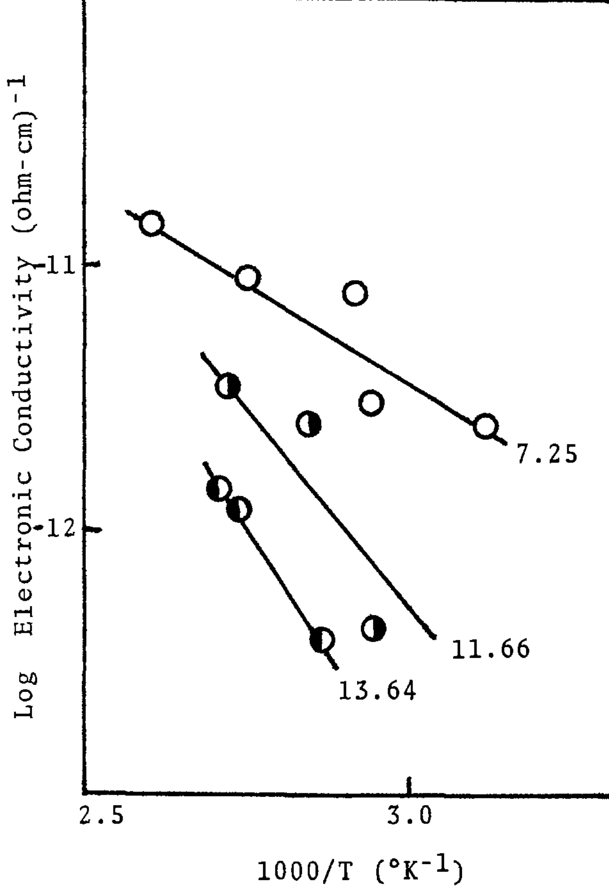

Fig. 4. Temperature dependence of the electronic conductivity of $C_5H_{11}NCH_3Br$-CuBr. $C_5H_{11}NCH_3Br$ (m/o): (○) 7.25, (◑) 11.66, (◐) 13.64.

electronic conductivity of the $C_5H_{11}NCH_3Br$-CuBr system is shown in Fig. 4. Thus, it is concluded that the conduction in the systems $C_5H_{11}NCH_3Br$-CuBr, $C_5H_{11}NCH_3I$-CuI, and $C_4H_9ONCH_3I$-CuI is essentially ionic.

Conclusion

It is concluded from the experimental results that the formation of high copper ion conductivity solids in the organic ammonium halide-copper(I) halide system is related to not only the size of ammonium ion, but also to its flexibility.

Mass Spectrometric Investigation of the Reaction Velocities of BCl_3 and BBr_3 with Oxygen and Water Vapor in a Diffusion Furnace

V. Geiss[1] and E. Fröschle

Institut für Halbleitertechnik, RWTH Aachen, D-51 Aachen, Germany

ABSTRACT

The velocities of the reactions of BCl_3 and BBr_3 with O_2 and H_2O were measured in a diffusion tube. The conditions (gas composition, gas velocity, temperature) were those commonly used in the open tube diffusion process. For the analysis the gaseous reaction products were sampled with a quadrupole mass spectrometer at different locations in the tube. The measurements indicate that with H_2O the reaction proceeds rapidly, but with O_2 very slowly. Therefore, with O_2 present in the gas mixture, large variations of the gas composition occur along the length of the tube. The time behavior of this reaction is described by its half-life and its dependence on temperature and O_2 partial pressure.

A commonly employed method for the diffusion of boron into silicon is the "open tube" technique, using nitrogen with a small percentage of oxygen as a carrier gas and boron halides such as boron trichloride (BCl_3) (2) or boron tribromide (BBr_3) (3-6). If surface concentrations below saturation are desired, the diffusion process is performed in two steps, a boron deposition step at temperature below 1000°C and a drive-in step above 1000°C. The reproducibility of the results depends mainly on the boron deposition step. The oxygen reacts with the boron halides and the silicon to produce B_2O_3 and SiO_2. B_2O_3 and SiO_2 form a borosilicate glass (BSG), which functions as a secondary dopant source during deposition and drive-in.

When using the process in the fabrication of semiconductor devices, a relatively long (typically 10 in.) zone of constant B_2O_3 supply is mandatory in order to obtain uniform deposition on the many silicon substrates in the same run. The quality of BSG which is formed on the silicon wafers at each position in the diffusion tube is strongly dependent on the temperature, gas composition, and gas velocity. In fact, for an arbitrarily chosen set of conditions, the zone where appreciable deposition occurs may even fall entirely upstream or downstream of the position of the sample support. This suggests that the time necessary for carrying the B_2O_3 formation reaction to completion is comparable to that required for the flow of the gas through the tube of the diffusion furnace (6). Thus it appears that the kinetics of B_2O_3 formation play a decisive role in the boron diffusion process. Therefore, we have studied the kinetics by analyzing the gas composition in a diffusion tube using a mass spectrometer. It will be shown that the data obtained lead to a clearer understanding of the system and facilitate optimization of the diffusion process.

Reactions and Equilibrium States

The compositions of the gas phases in thermodynamic equilibrium at 973° and 1053°C were calculated for the diffusion systems BCl_3-O_2 and BBr_3-O_2 using the JANAF Tables (1). The results of these calculations are shown in Tables I and II. Here the partial pressure of the main reaction products which result from reactions of the doping gases with the oxygen are listed. The initial pressures of the doping gases and oxygen correspond to the values which were used in the gas analysis experiments.

[1] Present address: Institut für Werkstoffe der Elektrotechnik, Ruhr-Universität Bochum, D-463 Bochum, Germany.

Key words: gas analysis, doping gases, boron, silicon.

At the temperature used, Cl_2 is dissociated partially and Br_2 largely according to

$$Cl_2 \rightleftharpoons 2\,Cl \qquad [1]$$

and

$$Br_2 \rightleftharpoons 2\,Br \qquad [2]$$

At equilibrium the gas phase consists entirely of the reaction products and residual oxygen. The partial pressure of all boron containing gaseous species is small compared to the boron content of the input gas. From this one can conclude that the main part of the

Equilibrium partial pressures

Substance	Cl	Cl_2	BO_2	B_2O_3	BClO	BCl_3	Σ Bor/% as B_2O_3 liquid
P/atm at T = 973°C	1 10^{-4}	1.9 10^{-4}	2.9 10^{-7}	3.9 10^{-8}	3.4 10^{-8}	8.4 10^{-11}	99.8
P/atm at T = 1053°C	1 10^{-4}	4.6 10^{-5}	1.5 10^{-6}	3.8 10^{-7}	8.6 10^{-8}	3.1 10^{-11}	96.4

Table II. Initial and equilibrium partial pressures of the system BBr_3-O_2 (1)

Initial partial pressures

	$P_{BBr_3(0)}$/atm	$P_{O_2(0)}$/atm
T = 973°C	$3.5 \cdot 10^{-5}$	$1 \cdot 10^{-3}$
T = 1053°C	$3.4 \cdot 10^{-5}$	$1 \cdot 10^{-3}$

Equilibrium partial pressures

Substance	Br	Br_2	BO_2	B_2O_3	BBrO	BBr_3	Σ Bor/% as B_2O_3 liquid
P/atm at T = 973°C	1 10^{-4}	2.8 10^{-6}	1.9 10^{-7}	3.9 10^{-8}	8.0 10^{-11}	5.2 10^{-19}	99.2
P/atm at T = 1053°C	1 10^{-4}	9.5 10^{-7}	1.1 10^{-6}	3.8 10^{-7}	3.2 10^{-10}	7.7 10^{-19}	94.6

boron injected into the diffusion system is deposited as a condensed phase, probably as liquid B_2O_3.

Therefore, good approximations of the over-all reactions are

$$4\,BCl_{3(g)} + 3\,O_{2(g)} \rightleftharpoons 2B_2O_{3(l)} + 12\,Cl_{(g)} \quad [3]$$

and

$$4\,BBr_{3(g)} + 3\,O_{2(g)} \rightleftharpoons 2B_2O_{3(l)} + 12\,Br_{(g)} \quad [4]$$

Calculations of the equilibrium pressures in the systems BCl_3-H_2O and BBr_3-H_2O are given in Tables III and IV. For a very small surplus of water vapor ($P_{H_2O} < 10^{-6}$ atm), as a good approximation the following over-all reactions are valid

$$2\,BCl_{3(g)} + 3\,H_2O_{(g)} \rightleftharpoons B_2O_{3(l)} + 6\,HCl(g) \quad [5]$$

$$2\,BBr_{3(g)} + 3\,H_2O_{(g)} \rightleftharpoons B_2O_{3(l)} + 6\,HBr(g) \quad [6]$$

A larger surplus of water vapor would reduce the amount of the B_2O_3 in favor of HBO_2.

Experimental

For the experiments a three-zone resistance-heated diffusion furnace was used. The nitrogen carrier gas passed through the full length of the tube and could be mixed with oxygen and water vapor (Fig. 1). A smaller part of nitrogen carried the doping gases BCl_3 or BBr_3 through an extra tube to the beginning of the constant temperature zone, where the gases were mixed. Both gases were preheated while flowing through the heated front part of the furnace. Thus the chemical reactions would start at a well-defined position. The temperature was kept uniform, within 2°C over the range of $5 < L < 60$ cm. The velocity of the N_2 carrier gas was mostly $v = 1$ cm/sec. All gases except water vapor were dried to the extent that the residual partial pressure of water vapor was less than 10^{-6} atm. In this way, unwanted reactions of the doping gases already in the supply tubes could be prevented. To avoid contamination of the colder end zone of the quartz tube by condensation, the reaction products were exhausted from the hot zone and dry nitrogen was blown in from the downstream side to provide a gas buffer.

Table III. Initial and equilibrium partial pressures of the system BCl_3-H_2O (1)

Initial partial pressures

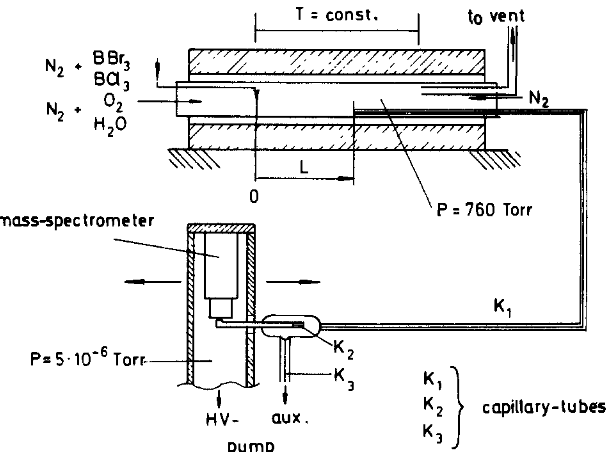

Fig. 1. Diffusion furnace and gas sampling system

For the analysis of the gas composition in the tube, a small part of the gas was pumped through a quartz capillary tube into a quadrupole mass spectrometer. The gas transport through the capillary tube to the spectrometer took about 0.2 sec. It cannot be excluded that during this time the reaction could reverse itself due to cooling. In fact although the stable form of bromine at the temperatures and concentrations in the reaction tube is Br, it was always measured as Br_2, the stable form at room temperature. The calibration of the mass spectrometer was done by controlled dilution of Cl_2, Br_2, BCl_3, and BBr_3 with an error of less than ±10%. The reproducibility of the concentration measurements in the 10^{-4} atm range was about ±3%. The amount of condensed material could be determined from the differences between the partial pressures of the gaseous species at input and their measured value after reaction. The vacuum system together with the capillary tube could be moved in such a way that sampling of the gas was possible in the range $-10 < L < 60$ cm. Changes of the gas composition along the tube could thus be measured as a function of the distance from the doping gas inlet or as a function of time, since the gas velocity was known.

Results

An example of such a mass spectrometric measurement of the reaction of BCl_3 with O_2 at 1057°C is shown in Fig. 2. The decrease of the BCl_3 partial pressure and the increase of the Cl_2 partial pressure are

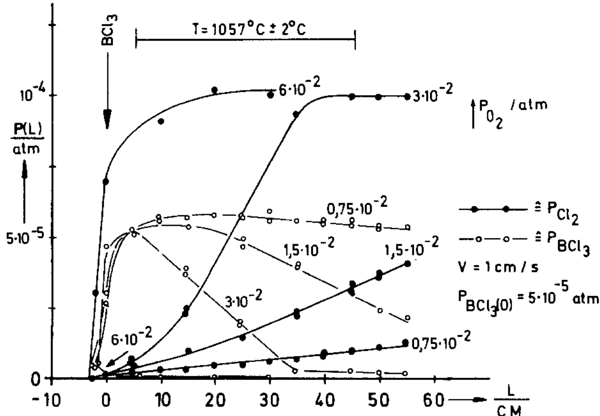

Fig. 2. Reaction of BCl_3 with O_2 as a function of the location in the tube at 1057°C for different O_2 partial pressures.

represented as a function of the distance L from the doping gas inlet with the O_2 pressure as a parameter. The input pressures of BCl_3 and the gas velocity were kept constant for these series of measurements. Increasing the O_2 partial pressure caused an increase of the reaction velocity.

In spite of a considerable surplus of oxygen and the fact that at equilibrium the gas phase contains only the oxidation products, the reaction velocity is remarkably low. The decrease in the partial pressure of BCl_3 is balanced by the increase in that of Cl_2. Other chlorine containing gaseous compounds could not be measured. This appears to confirm Eq. [3] as the correct expression for the over-all reaction. It must be remarked that only the gaseous compounds BCl_3, O_2, and Cl_2 can be analyzed with the mass spectrometer. Cl reacts during sampling to Cl_2. B_2O_3 could not be detected because at the temperatures used it is a liquid and condensed at the tube walls. Figure 3 shows data for the reaction of BCl_3 with O_2 at the lower temperature of 973°C. As expected, lower temperatures cause smaller reaction velocity.

Similar measurements were done with BBr_3 as a dopant (Fig. 4). They agree with the assumption that Eq. [4] represents the over-all reaction. Comparing the BBr_3 and BCl_3 data, it may be seen that for the same O_2 partial pressure and temperature the reaction velocity is very much higher with BBr_3.

In order to characterize the reaction velocity we used the half-life τ_h, *i.e.*, the time in which the initial concentration of the doping gas has been reduced by 50%. The values of τ_h were read or extrapolated from Fig. 2-4 and plotted as a function of the initial O_2 partial pressure (Fig. 5). Similar experiments were done for other initial partial pressures of the doping gases in the region $2 \cdot 10^{-5} < P < 2 \cdot 10^{-4}$ atm. They showed that in this region τ_h is independent of the initial doping gas pressure. This indicates that the reaction is first order in the doping gas. Assuming the

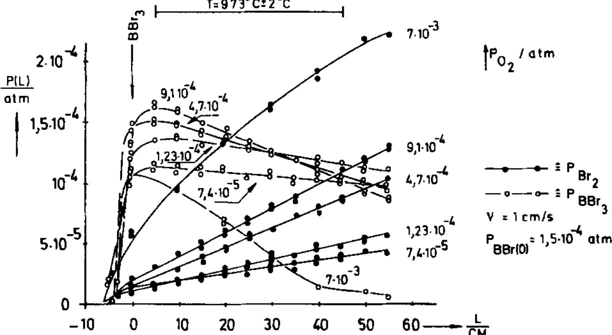

Fig. 4. Reaction of BBr_3 with O_2 as a function of the location in the tube at 973°C for different O_2 partial pressures.

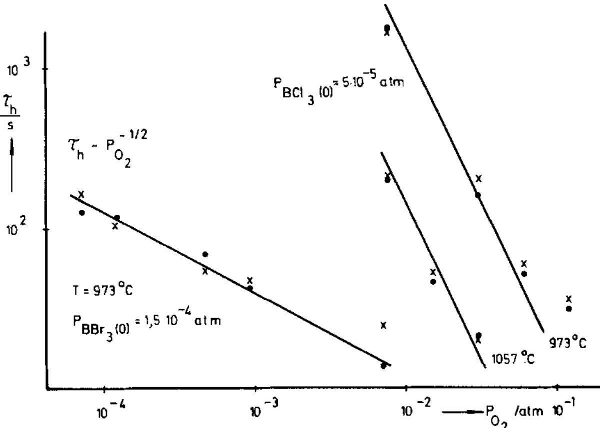

Fig. 5. Half-life τ_h of BBr_3 and BCl_3 as a function of the O_2 partial pressure; left-hand side: BBr_3, right-hand side: BCl_3; ● calculated from BCl_3, BBr_3; × calculated from Cl_2, Br_2 partial pressures.

commonly observed exponential temperature dependence, the following expression can be obtained from Fig. 5 for the half-life of BCl_3 reacting with O_2

$$\tau_h/\text{sec} = 2.2 \cdot 10^{-17} (P_{O_2}/\text{atm})^{-2} \exp (3.9 \text{ eV}/kT) \quad [7]$$

The dependence of the time constant on the oxygen partial pressure is that of a third order reaction in O_2.

The reaction rate of BBr_3 with oxygen was determined only at the lower temperature of 973°C. The dependence of the half-life of BBr_3 on O_2 partial pressure may be expressed as

$$\tau_h/\text{sec} = 1.3 \times (P_{O_2}/\text{atm})^{-1/2} \quad [8]$$

It is somewhat surprising that the pressure dependence of this reaction is very different from the BCl_3 reaction and corresponds to a reaction order between the first and second. At higher temperatures (T > 1000°C), the reaction of BBr_3 with nitrogen starts, which makes the measurement of the oxygen reaction rate impossible.

In order to determine if the walls of the tube had any effect on the reaction rate, some measurements were made after the diffusion tube had been partially filled (up to 20 cm) with quartz wool. No difference in the reaction profiles could be noticed, which proves that the reactions are volume processes.

Using water vapor instead of oxygen, the reaction with both doping gases was found to go to completion near $L = 0$ for all gas velocities investigated even at 973°C. The time constants τ_h were too small to be measured.

Discussion

The foregoing data show that under the commonly used conditions for boron deposition the doping gases BCl_3 and BBr_3 react rather slowly with oxygen, though at equilibrium only the oxidation products are left in the system. Figure 5 shows that at 973°C and with an oxygen pressure of $5 \cdot 10^{-2}$ atm the half-life τ_h for the reaction of BCl_3 with oxygen is about 100 sec. This means that for a gas velocity of 1 cm/sec the reaction cannot be completed within the length of a typical diffusion tube. With BBr_3 more favorable results can be expected since for the above-mentioned conditions the time τ_h is about 6 sec. BBr_3 does not dissociate thermally into boron and bromine at temperatures as low as 200°C, as was hypothesized in Ref. (5). Such a dissociation could not even be noticed at 973°C.

A quantitative comparison between the mass spectrometric measurements and published diffusion measurements is not possible, since in the literature generally no information is given concerning the distance between the doping gas inlet and the first silicon wafer, the linear gas velocity and the temperature pro-

file of the tube. Nevertheless a qualitative comparison can be made.

Parekh and Goldstein (6) describe diffusion investigations in an oxidizing atmosphere using BBr_3 as dopant. In the direction of flow of the gas, they first observed in the diffusion tube an area with decreasing sheet resistance, then one with constant sheet resistance, and finally an area with rising sheet resistance. They showed that the interesting area of constant sheet resistance moves toward the doping gas inlet for rising temperatures and oxygen partial pressures and decreasing gas velocities.

The same behavior was observed in our mass spectrometric investigations for the reaction zone with decreasing dopant pressures and increasing pressures of the reaction products (Fig. 3). Taking our results and those of Parekh and Goldstein together, it follows that constant sheet resistances can be expected when a major part of the doping gas has reacted to form B_2O_3. The B_2O_3 is carried by the gas stream and will condense at the same time on the quartz walls and the silicon wafers. As long as the BSG layer formed in this way has an adequate thickness, constant sheet resistances are obtained upon the drive-in. Since the reaction proceeds very slowly, the amount of the B_2O_3 formed is insufficient in the part of the tube near the inlet. In the third zone the supply of B_2O_3 is depleted because of the continuous condensation of this compound.

Using water vapor instead of oxygen, the doping gases react immediately. When a small surplus of water is used mainly B_2O_3 will be formed. This reaction proceeds even in low temperatures. Therefore all carrier gases must be dried thoroughly to prevent unwanted reactions in the supply tubes.

ABSTRACT

Calculations have been made of the equilibrium conditions under which chemical deposition of B_4C from BCl_3-CH_4-H_2 mixtures takes place. Pure B_4C is mainly obtained for gas-phase mixtures in which $BCl_3/CH_4 > 1$ and $H_2/BCl_3 > 1$. The maximum yield is obtained in the range 1675°-2075°K for the initial composition $BCl_3 = 0.1$, $CH_4 = 0.02$, $H_2 = 0.88$. The dependence of the hydrogen partial pressure on the equilibrium composition is discussed. At high temperatures with a large excess of hydrogen, the tendency is to form gaseous BH_2 and BH_3 instead of condensed species. With decreasing the amount of hydrogen, graphite begins to deposit under $CH_4/BCl_3 << 1/4$ ratios. At lower temperatures the equilibrium content of BCl_2H increases as the H_2/BCl_3 ratio falls. The results of the calculations are confirmed by experimental data.

Chemical vapor deposition is a complex process in which many factors affect the deposition, and thus the process is difficult to optimize. Nevertheless it can be analyzed in terms of thermodynamic, transport, and kinetic factors to find a set of deposition conditions which will produce the desired goal.

The thermodynamic system evaluation is the first step of a complete analysis. The equilibrium composition is obtained by such calculations and sometimes unsuspected reactions may be deduced from atomic balances equations. The thermodynamic analysis has been used by many authors in order to predict the preparation conditions of doped layers, solid solutions, binary or ternary compounds (1-9).

The conclusions obtained from the thermodynamic evaluation may be useful to describe a reaction mechanism. Using a thermodynamic approach, the presence of BCl_2H in the B-Cl-H system was demonstrated at equilibrium, this fact has been used by Carlton (10) to postulate a kinetic model taking into account this

Key words: boron carbide, vapor deposition, efficiency, boron trichloride, methane.

species. The present paper is concerned with a thermodynamic analysis of the B-C-H-Cl vapor system in order to define optimum conditions for deposition of B_4C from BCl_3-CH_4-H_2 gas mixtures. This compound has interesting properties (light weight, extreme hardness, resistance to abrasion, resistance to chemical attack) and is employed in the nuclear, metallurgical, and watch industries.

A number of investigators have attempted to prepare it as coatings, but in most cases the chemical vapor deposition of B_4C seems to be difficult. According to different authors, deposits may be either boron rich or carbon rich depending on the composition of the initial gas phase. Deposits of pyrolytic carbon + B_4C or pyrolytic carbon only may be produced (11-16). Furthermore, there exists no thermodynamic study which gives the solid deposit domains in this system.

Procedure

The computation procedure employed for the determination of the equilibrium in a system taking into account several condensed species is based on the minimization of the free energy and is detailed in a previous paper (18). It is a time-sharing program. The necessary starting data are the free-energy function and the standard heats of formation of the chemical species considered. In calculations of the equilibrium of the system B-C-H-Cl, the following species were chosen: BCl_3, CH_4, H_2, BCl_2H, BH, BH_2, BH_3, B_2H_6, B_5H_9, B_2Cl_4, Cl_2, HCl, C_2H_2 in the gas phase, and B_4C, C(graphite), B(α) in the condensed phase. In addition, we define the total pressure, the temperature, and the initial gas-phase composition (number of moles of species), that is, in our case, for the total pressure P = 1 atm

$$BCl_3 : a \text{ moles} \equiv P_oBCl_3$$

$$CH_4 : b \text{ moles} \equiv P_oCH_4$$

$$H_2 : 1\text{-}a\text{-}b \text{ moles} \equiv P_oH_2$$

Most of our results are presented in terms of efficiency η. η is defined with respect to the content of BCl_3 for all components of boron

$$\eta_{BCl_3}^{BxCyClzHw} = \frac{x\,Qeq^{BxCyClzHw}}{a} 100$$

For C, CH_4, and C_2H_2 the coefficient of conversion is defined with respect to the initial methane

$$\eta_{CH_4}^{CyHw} = \frac{y\,Qeq^{CyHw}}{b} 100$$

Results and Discussion

The general behavior of the equilibrium is shown in Fig. 1-9. The variation of the boundaries of the deposition ranges as a function of the initial partial pressures is shown in Fig. 1-3 for three temperatures (1400°, 1800°, 2200°K). The calculation precision is of 10^{-8} molecule and in this case it follows a same order precision for the individual boundary line evaluations. The dotted line, for the case of B and C atomic balances, represents the stoichiometry of the following reaction

$$4[[BCl_3]] + [[CH_4]] + 4[[H_2]] \rightarrow \langle B_4C \rangle + 12[[HCl]]$$

So the diagram is divided in two regions: the upper part which represents all the input values of composition with an excess of boron (with respect to the above-mentioned reaction); the lower part in which are the reactant concentrations with an excess of carbon.

The B_4C deposit domain is very narrow but it extends into a wide range of initial compositions: into the carbon-excess side for the low partial pressures of BCl_3 and CH_4, that is a large excess of hydrogen; into the boron-excess side for initial mixtures with a moderate dilution with H_2. The domain of pure B_4C is neighbored by the two-phase domains B_4C-C and B_4C-B, it is limited at the lowest part by the gas phase and at its limits by the pure solid-phases B and C.

An increase in the temperature greatly favors the stability of the gas phase and the pure carbon domain. At 2200°K these two phases appear in the upper part of the diagram for high partial pressures of BCl_3 (BCl_3 > 0.7). Figure 4 shows the details of this zone. At lower temperature the results of the calculations indicate the same phenomenon. According to Table I we can see the phase boundaries at 1400°-1800°K for different initial concentrations of CH_4. This table shows

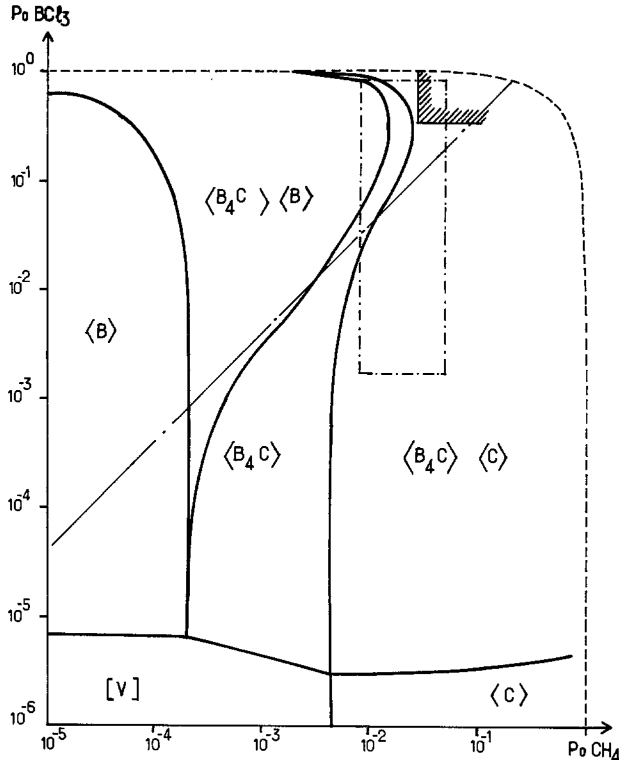

Fig. 1. Deposition domains of the solid species at T = 1400°K, P = 1 atm. / / / = composition range of Fitzer and Röhm (16), — · — = composition range of Moore and Volk (15).

us the precision that the method provides. As a result of the thermodynamic calculation we obtained the gas-phase equilibrium composition. The equilibrium values depend markedly both on the temperature and the excess of hydrogen (that is the ratio H_2/BCl_3).

In the low temperatures side, the predominant species in the gas phase are H_2, HCl, CH_4, BCl_3, and BCl_2H. Dilution with a large excess of H_2 insures the complete reduction of BCl_3 producing free boron; the decomposition of CH_4 is inhibited. As H_2/BCl_3 decreases, the formation of BCl_2H increases. When the value of this ratio is unity, BCl_3 is still present but CH_4 completely disappears to give free carbon and boron carbide.

In the high temperatures side, H_2, HCl, C_2H_2, CH_4, BH_2, BH_3, BCl, BCl_2, and BCl_3 are the major species with a trend to the formation of molecules with B-H or C-H bonds as the excess of hydrogen increases. Then the condensed phases completely disappear. If there is no excess of hydrogen, the molecules with B-Cl bonds are mainly formed in the vapor state and solid

B_4C and C tend to deposit. Figure 5 details the phenomenon shown in Fig. 4. If the input partial pressure of BCl_3 is 0.8 atm, deposition of pure B_4C is impossible for a partial pressure of CH_4 ranging from 1×10^{-5} to 7×10^{-2}. The homogeneous equilibrium is due to the pressure of C_2H_2, BCl_2, BCl, and BCl_2H and to the high content of BCl_3 in the equilibrium vapor. The carbon is easily obtained as soon as the amount of CH_4 in the initial gas is very low (*e.g.*, $CH_4/BCl_3 = 2.5 \cdot 10^{-4}$).

Consequently, it is intended to optimize the input composition of the reactants for a given constant partial pressure of CH_4 ($P_0CH_4 = 2 \cdot 10^{-2}$) and a range of P_0BCl_3 ($0.1 < P_0BCl_3 < 0.75$), that is, in the widest part of the region in which the deposition of pure B_4C occurs. Variation of the equilibrium yield of each vapor species and condensed phases is shown in Fig. 6-8 for

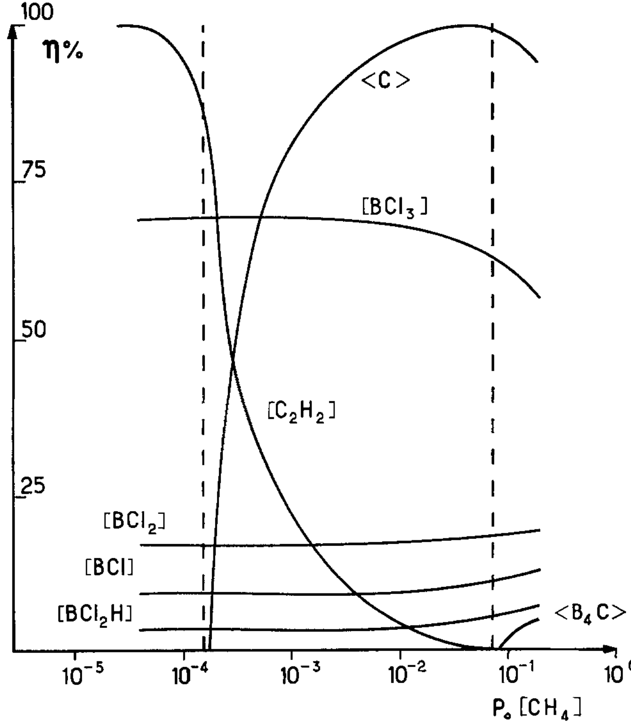

Fig. 5. Variation of the equilibrium yields with P_0CH_4; $P_0BCl_3 = 0.8$ atm, $T = 2200°K$.

1400°, 1800°, and 2200°K. The plots illustrate the evolution of the gas phase reactions as a function of temperature. At 1400°K the pure B_4C is expected to deposit inside a wide concentration range of boron trichloride (from 0.17 to 0.55). At 1800°-2200°K, this range is becoming narrower and is divided in two parts (0.08 < P_0BCl_3 < 0.12; 0.64 < P_0BCl_3 < 0.78) due to the presence of a boron deposit. As shown in Fig. 6-8, the equilibrium amount of boron carbide depends markedly on the initial BCl_3; there is a significant trend toward increasing the solid yield with decreasing the inlet BCl_3 partial pressure. Therefore we choose P_0BCl_3 = 0.1 atm to study the amount of thermodynamically available B_4C in relation to the temperature of deposition. The maximum is found at 1900°K for the input partial pressures, P_0BCl_9 = 0.1, P_0CH_4 = 0.02, P_0H_2 = 0.88 (Fig. 9). In the temperature range 1675°-2075°K, the solid yield is around 75-80%. One must remember that high efficiencies and quality of the deposit may not occur together. Therefore, if a continuous layer is desired, it would be necessary to lower the temperature under 1225°K to be out of a two solid deposit domain.

It is interesting to check the results of the theoretical analysis with experimental data. The work of Moore and Volk concerning the chemical vapor deposition of B_4C from BCl_3, CH_4, H_2 with various concentrations a, b, $c \geqq 0$ has been employed for comparison. Three types of experiments were performed by these authors. The deposition without hydrogen in the temperature range 1823°-2373°K at low pressures lead to B_4C-C deposits. At 2473°K, under precise experimental conditions, C (graphite) is obtained. With moderate dilu-

tion of reactants with H_2, B_4C-C deposits are formed. Deposition with a large excess of H_2 above 1300°K at low pressures can produce massive B_4C and boron- or carbon-rich structures depending on the value of CH_4/BCl_3.

The comparison of some experimental and calculated results for initial compositions without H_2 and with a moderate dilution is presented in Table II. Agreement is good for the first two cases though the conditions of calculation are slightly different. In Fig. 1-3 a temperature rise produces a wide enlargement of the range of pure carbon, in addition this boundary shift is favored with a decrease in pressure; subsequently, a pure C deposit would be obtained for $BCl_3 = 0.2$, $CH_4 = 0.8$, and $T > 2200$°K. In the other cases the computer results are a bit different. The general trend is to find B_4C-C deposition for higher values of total pressure than in the experiments of Moore and Volk, but nevertheless of the same order of magnitude. When large excesses of hydrogen are used, the nature of the deposit in relation to the experimental conditions is not sufficiently specified by these authors to allow a valid comparison with calculations. Nevertheless, the deposition of B_4C-B, B_4C, and B_4C-C above 1300°K, for $0.0098 < a < 0.785$, $0.0079 < b < 0.049$, and $0.166 < c < 0.9823$, as a function of the BCl_3/CH_4 ratio must be compared with Fig. 1-3. They show, in the zone defined by the previous values a, b, and c, the possibility of depositing the different condensed phases. In addition, in this zone, it has been checked that a large reduction of total pressure does not much affect the deposition range of B_4C; that is, Fig. 1-3 can probably be used for lower pressures.

Moreover, in a recent work, Fitzer and Röhm mention that deposit structures consisting alternatively of boron and boron carbide can be obtained due to an oscillating chemical reaction influenced by mass transport phenomena. Though the deposition conditions are imprecisely defined (BCl_3 35%, BCl_3/CH_4 ratios between 10:1 and 1:2, H_2, $1473° < T < 1973$°K, $P = 1$ atm) this experimental observation can be compared with the fact that the range of input compositions used by these authors extend from the B_4C single-phase region to the B_4C-C two-phase region (Fig. 2-3). Thus the different solid phases would be generated by small fluctuations in the initial partial pressures.

Conclusions

This paper has shown the narrowness of the thermodynamic range of deposition of pure boron carbide and has defined the variation of that range with temperature. The solid phases obtained from the system depend strongly on the initial concentration, in contrast to the phenomenon shown in the previous study of the Ti-C-H-Cl vapor system in which the deposition range of TiC was very wide. The thermodynamic approach is very useful for forecasting the best conditions for deposition, and for determining the influence or different parameters on the gas and solid phases. The maximum yield of B_4C (75-80%) is obtained between 1675° and 2075°K for the following partial pressures: $P_oBCl_3 = 0.1$; $P_oCH_4 = 0.02$; $P_oH_2 = 0.88$. In addition, the thermodynamic results agree with some previous experiments. Thus, it seems that a real deposition system would be near an equilibrium system.

Technical Notes

Flux Growth of the Gallium Analog of Beta-Al_2O_3

L. M. Foster* and J. E. Scardefield

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

The importance of the alkali aluminate, β-Al_2O_3, as a solid electrolyte in secondary batteries and other electrochemical applications is well known (10). The gross features of the β-Al_2O_3 structure that allow the high mobility of the alkali ions are clearly recognized, and detailed mechanisms of the conduction process have been proposed (2-7). It is recognized that neither Na^+, Al^{+++}, nor perhaps even oxygen itself is specifically required for the high conduction in this structure, but rather an open, highly defective layer in the lattice is necessary through which an ion species can move with a low activation energy *via* a vacancy mechanism. In beta-alumina the requisite structure must result in part from charge compensation by Na^+ and vacancies when the Mg^{++} of spinel ($MgAl_2O_4$) is replaced by Al^{+++}, but the process is complex and not completely understood.

There is a very large number of other crystals with the spinel structure, and the process of fast ion conduction should be common to many of them if the same charge compensating substitutions can be made. In 1951, Foster and Stumpf (8) described the extensive isomorphism between the alumina and gallia systems and, in particular, prepared the gallium analogs of sodium and potassium beta-alumina.[1] Fast ion conduction has recently been demonstrated in this material (9-11), and it is apparent that it has the same highly defective structure as β-Al_2O_3.

In spite of the similarities between β-Al_2O_3 and its gallium analog, subtle differences are expected which can be exploited to increase our understanding of this interesting class of materials. For example, because Ga^{+++} is slightly larger than Al^{+++}, the slot width—the distance across the conducting plane—is slightly greater in the gallium analog. This should result in higher conductivity for the gallium compound, especially for the larger alkali ions. The uptake of water in the conduction plane, which has a profound effect on the stability and conductivity of the beta-aluminas (12), is also likely to be quantitatively and perhaps qualitatively different in the gallium analogs. Finally, subtle differences between the Al_2O_3-Na_2O and Ga_2O_3-Na_2O systems should make it possible to elucidate features of these complex phase diagrams by providing an alternative system to study.

It is desirable to employ high quality monocrystals in a study of the properties of a new material. The present paper describes progress toward producing such crystals of the gallium analog of β-Al_2O_3 by a flux growth method. With growth parameters thus determined, it should also be possible to prepare monocrystalline layers by a liquid-phase epitaxial technique if a suitable substrate can be found.

Key words: solid electrolytes, crystal growth, flux growth.

[1] The unfortunate nomenclature error that gave rise to β-Al_2O_3 is compounded in the gallia system. The metastable phase, alpha-gallia, was named to show the isomorphism with α-Al_2O_3. If this pattern were continued, the high-temperature-stable phase of Ga_2O_3 would have been called theta to show the analogy to θ-Al_2O_3. This was not done, however, and, instead, stable Ga_2O_3 was designated β-Ga_2O_3 throughout the literature. The gallium isomorphs of β-Al_2O_3 thus remain nameless and will be referred to herein simply as alkali gallates.

Experimental

It is known that foreign ions substitute readily in the β-Al_2O_3 structure, both in the conduction plane and in the spinel body (13, 14). We wished to avoid that complication in the present study and so were restricted to the use of a sodium salt for the flux. However, the use of pure sodium carbonate was known to produce solids far to the Na_2O side of Ga_2O_3-Na_2O phase diagram, and sodium borate produces a series of complex borates. NaCl exhibits very low solubility for oxides and is not suitable for that reason. NaF emerged, therefore, as the most logical choice

Early experiments had shown that $Na_2O \cdot xGa_2O_3$ with the β-Al_2O_3 structure was formed to varying degrees depending on conditions from Ga_2O_3-NaF melts (8). Since some Na_2O was required to produce the gallate, it obviously resulted from partial reaction of the Ga_2O_3 with the flux, thus

$$NaF + Ga_2O_3 = Na_2O + GaF_3 \text{ (or } NaGaF_4) \quad [1]$$

The details of the complex ternary or quaternary system that results are not known. However, it was established empirically that 7.5 weight per cent (w/o) of Ga_2O_3 will completely dissolve in NaF at 1350°C, and that the liquidus at that composition is about 1300°C. When the Ga_2O_3 content was higher than about 8%, primary bar-shaped crystals of β-Ga_2O_3 were found admixed with the $Na_2O \cdot xGa_2O_3$ product. When it was appreciably lower, small needlelike crystals appeared. Their composition was approximately $Na_2O \cdot 2.5Ga_2O_3$, and not the $3Na_2O \cdot 5Ga_2O_3$ phase reported by Boilot *et al.* (9).

Contrary to most solvents that are employed for flux growth of oxides, the NaF in the present case is not the most volatile species. Consequently, one of the preferred growth practices, isothermal vaporization of the flux, is not possible. The most volatile species is GaF_3, or possibly $NaGaF_4$, the gallium analog of aluminum atmolite, $NaAlF_4$. Loss of this material by vaporization forces reaction [1] to the right with the formation of more Na_2O, and changes the composition of the $Na_2O \cdot xGa_2O_3$ product to lower values of x. In fact, control of the GaF_3 activity was absolutely essential for reproducibility in the present experiments. This could be accomplished by employing a controlled "leak," such as a hole of predetermined size in an otherwise sealed container. However, we found it more satisfactory to try to assure zero leak rate by use of tightly pressed-in crucible covers or, in some cases, welded closures.

Growth procedure.—A suitable charge composition was 78.0 NaF, 6.3 Ga_2O_3, and 15.7 NaCl w/o. The NaCl was an inert diluent that was added to facilitate the removal of the flux from the product through formation of the NaF-NaCl eutectic (mp 674°C), and by increasing the solubility of the flux in water.

The dried components were placed into a standard 110 ml conical platinum crucible, and an inverted lid pressed in. If a leak was suspected, the lid was autogeneously welded in. Total charge weights of both 80 and 160g were employed. The charge was held at

1350°C for about 2 hr, then the temperature was lowered at approximately 4°C/hr to 1200°C. The crucible was then inverted so that most of the flux drained away from the crystal product, which generally adhered to the crucible bottom.

When cold, the flux was broken out of the top and the crucible was filled with granular NaCl which was melted and held at approximately 900°C for an additional 2 hr. This further removed residual flux that adhered to the crystals.

Some $Na_2O \cdot xGa_2O_3$ product could be removed at this stage, but generally the crystals adhered tightly to the platinum and, since they are very friable, it was difficult to remove them without damage. Generally it was necessary to boil water in the crucible for an hour or two in order to free them.

Description of product.—Typical flux-grown crystals are shown in Fig. 1. The figure illustrates one of the remaining problems with the method: recovery of the product without damage. Although a profusion of small (1-5 mm), free crystals could be recovered that were excellent for x-ray and optical studies, etc., larger ones generally cracked during cooldown because of differential contraction between the platinum or adhering flux and the crystals. This is a common problem of flux growth of most materials and presumably can be alleviated by further manipulation of the heat flow pattern during growth.

The crystals had the β-Al_2O_3 structure. A comparison of their properties with those of a "standard" β-Al_2O_3 sample obtained from the Carborundum Company is given in Table I. No fluorine was detectable in the crystals by electron microprobe analysis

Discussion and Summary

It has been demonstrated that the gallium analog of β-Al_2O_3 can be grown from a NaF flux. The problems common to most flux growth processes, uncontrolled nucleation and difficulty of recovery of the product, are thought to be solvable with design changes so that larger perfect crystals can be grown. The growth parameters have been sufficiently well established for liquid phase epitaxy to be undertaken as an alternative procedure if a suitable substrate can be found.

The practice of boiling the crystals in water to free them from the crucible, although undesirable, appears not to alter them. An electron microprobe analysis of a water-treated surface gave the same sodium content as an analysis of an internal surface exposed by cleaving. It is possible, of course, that sodium might have been extracted from the very outer atomic layers of the crystal and not be detected by this technique.

The Ga analog of the three-block β''-Al_2O_3 structure was never observed in our experiments, even though the growth temperature was below that where β'' transforms irreversibly to β (approximately 1380°C). The reason cannot be insufficient soda content, as is sometimes stated with respect to the alumina system, since when large volatile losses were permitted, the soda-rich phase of composition approximately $Na_2O \cdot 2.5Ga_2O_3$ appeared, still without any evidence of a β'' phase. As in the aluminum system, the conditions for stability of the three-block phase are unclear, and this is further evidence that the β'' phase is metastable, although stabilization of the β phase by traces of fluoride cannot be excluded.

The Cathodic Corrosion of Aluminum

E.P.G.T. van de Ven and H. Koelmans

Philips Elcoma H.O.C. Laboratory and Philips Research Laboratories, Eindhoven, The Netherlands

When hydrogen is cathodically evolved at a metal in an electrolyte, an increase of the hydroxyl ion concentration at the electrode surface results. This alcalization effect (1) is responsible for the cathodic corrosion of an amphoteric metal like Al (2). Though this phenomenon has been known for decades, detailed information about how the cathodic corrosion depends on current density, ionic composition of the electrolyte, and especially on temperature is still lacking. The present work, in which we consider the influence of these parameters, is part of an effort aimed at a better understanding of the electrolytic corrosion of the Al metallization tracks on integrated circuits during temperature-humidity-bias tests. The corrosion observed after these tests is often mainly cathodic (3, 4).

Experimental

The experiments were done with thin disks of 99.99% Al which formed the end faces of a cylindrical cell of polymethylmethacrylate. The Al disks had a diameter of 2 cm and a thickness of 100 μm. The design of the cell is sketched in Fig 1. During the experiments the current was kept constant. The amount of corrosion produced at both the cathode and the anode was determined from weight-loss measurements. The corrosion products were removed with an aqueous solution of H_3PO_4 and CrO_3.

Results and Discussion

Figure 2 shows, in an Arrhenius plot, how the rate of electrolytic corrosion at both the cathode and anode depends on temperature. The experiments were done in $5 \times 10^{-4}N$ NaCl at a number of constant currents. The rate of corrosion at the anode is independent of temperature at all current densities used. In agreement with others (5) we found that for every three electrons flowing in the external circuit slightly more than one Al atom is oxidized. In our experiments we found $3e$ equivalent to 1.16 Al.

Corrosion at the cathode is more complicated. In the range of low temperatures the lines for the cathodic attack run parallel to the line found for chemical dissolution of the same Al disks in NaOH (see Fig. 2), which suggests that in this temperature range cathodic corrosion is similar to dissolution in an NaOH solution of constant concentration. At higher temperatures the lines for the cathodic corrosion level off to a constant value corresponding to a situation where for every three electrons flowing three atoms of Al pass into solution. Our interpretation is that at higher temperatures all the hydroxyl ions formed by the electrochemical reaction $H_2O + e \rightarrow OH^- + 1/2H_2$ are used up in the ensuing chemical dissolution reaction $OH^- + Al + H_2O \rightarrow AlO_2^- + 3/2H_2$. In the high-temperature range the rate of cathodic corrosion is limited by the electrochemical production of OH^-, *i.e.*, by the current density, independent of temperature. At these high temperatures the over-all reaction is $Al + 2H_2O + e \rightarrow AlO_2^- + 2H_2$, hence, for every electron one Al atom dissolves, as observed. At lower temperatures the rate of corrosion is limited by the chemical dissolution reaction, part of the OH^- ions produced are carried away from the cathode into the bulk of the electrolyte by diffusion and electrical migration. The simple dissolution of Al in NaOH is also limited by the chemical surface reaction $OH^- + Al + H_2O \rightarrow AlO_2^- + 3/2H_2$. Therefore, in the low temperature range, the temperature dependenc of cathodic corrosion is described by an activation energy (0.47 eV/at = 10.8 kcal/mole) equal to that observed for the chemical dissolution of Al in NaOH.

The results of Fig. 2 also show that in the lower temperature range the influence of current density is rather weak, an increase in current density by a factor of ten produces an increase in the rate of cathodic corrosion by a factor of only about two. Apparently in the range of the steady-state OH^- concentrations produced at the current densities used in our experiments, the influence of OH^- concentrations on the chemical dissolution reaction is not very pronounced. The results of Caldwell and Albano (2) also indicate that at low OH^- concentration the influence of concentration is rather small.

We next investigated the influence of ionic composition of the electrolyte on cathodic corrosion. The results for a number of electrolytes, all in a concentra-

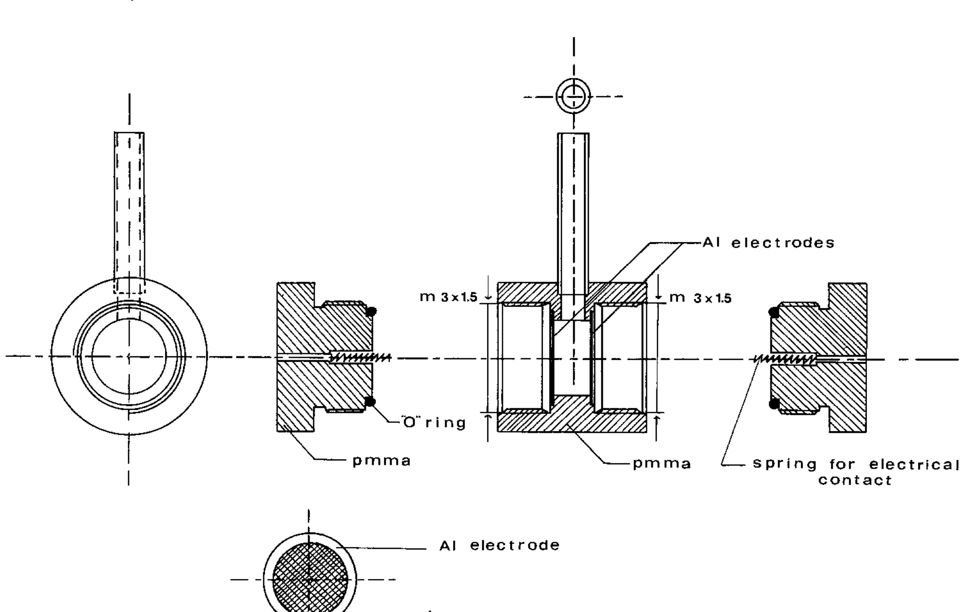

Fig. 1. Design of the cell used in the cathodic corrosion experiments. Cell volume π cm^3.

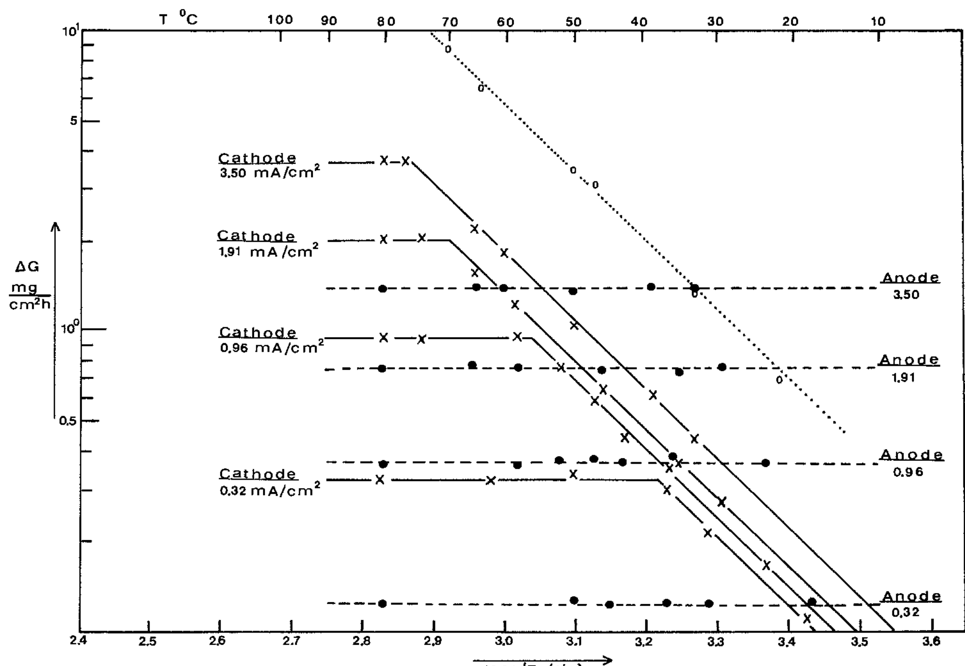

Fig. 2. Arrhenius plot of the rate of cathodic (———) and anodic (- - - - - -) corrosion of Al at various current densities in NaCl $5 \times 10^{-4}N$. Also shown is the line for dissolution of Al in $2.5 \times 10^{-2}N$ NaOH (.....).

tion of 5×10^{-4}M are summarized in Table I. The results of Table I show that the rate of cathodic Al corrosion does not depend on the nature of the anion used and remains unchanged in an acid medium down to a pH of at least 3.3. In both the neutral and the acid solutions the addition of a drop of phenolphtalein gave a red color at the cathode when the current was switched on. This means that for the current density used (1.91 mA/cm^2), even in the acid solutions the pH at the surface of the cathode rises to at least 8.5.

Conclusions

In summary we conclude:

1. The influence of temperature, current density, and ionic composition of the electrolyte on the cathodic corrosion of Al can be interpreted on the basis of the alcalization theory.

2. With regard to the influence of temperature two regions were found: (*i*) a low-temperature region where the increase in cathodic corrosion with rising temperature is governed by an activation energy equal to that observed for the chemical dissolution of Al in NaOH, and (*ii*) a high-temperature region where cathodic corrosion is independent of temperature.

3. In the high-temperature region the cathodic corrosion of Al is proportional to the current density, whereas in the low-temperature region the influence of current density is rather weak.

4. Our experiments show that the cathodic corrosion of Al does not depend on the type of anion used and does not require the presence of large amounts of cations capable of forming a strong base.

Table I. Cathodic corrosion of Al in various electrolytes, current density 1.91 mA/cm^2; $T = 25°C$

Impurity Striations during Faceted Crystal Growth

W. Bardsley and D. T. J. Hurle

Royal Radar Establishment, Great Malvern, Worcestershire, England

The occurrence of impurity striations in melt-grown crystals due to crystal rotation and/or nonsteady convective motion in the melt is now well established. [See, for example, reviews by Hurle (1) and by Gatos and Witt (2).] Recent elegant work by Witt and coworkers (3,4) has shown that while striations occur on both faceted and nonfaceted portions of the growth surface, the operative mechanisms are different. Specifically, in nonfaceted regions striations result from modulation of the microscopic growth rate (3) and are particularly pronounced if "melt-back" occurs during part of the periodic growth cycle. Clearly, the striations arise from modulation of the height of the impurity boundary layer by the varying growth rate. In contrast, on faceted growth surfaces the microscopic growth rate appears to be sensibly constant (4) despite the presence of temperature fluctuations or oscillations in the bulk of the melt and the occurrence of striations is ascribed to modulation of the thickness of the impurity boundary layer by the nonsteady convective motion.

In recent experiments under conditions of near-zero gravity aboard Skylabs III and IV where gravity-induced convection was suppressed, Witt *et al.* (5) demonstrated that striations were eliminated in melt-grown Te-doped InSb except that they observed irregularly spaced striations remaining on peripheral facets [Fig. 17 and 18 of Ref. (5)]. The authors ascribed these anomalous striations to the occurrence of nucleation at the exterior edge of the facet where its rate would be sensitive to vibration or to the arrival of a foreign particle.

The purpose of this note is to report the occurrence of similar striations on an earth-grown single crystal of Ga-doped Ge grown some years ago by the authors during a study of the effects of constitutional supercooling (6-8). However, these striations occurred on microfaceted regions of the crystal growth surface well away from its free surface and had a relatively regular periodicity (Fig. 1). The crystals were grown on a <110> axis by pulling from the melt without rotation of either the crystal or the crucible. The pull rate was 9 cm/hr and the concentration of Ga was adjusted so as to produce a cellular structure over the whole of the growth surface. This cellular structure consisted of a corrugated array composed of {111} microfacets. The section shown in Fig. 1 contains the growth axis and is orthogonal to the axis of the corrugations. Some of the cells exhibit bands of striations. The distribution of the bands and their extent are apparently quite random. They start and stop quite abruptly. The etchant used was 1.3 $HF:HNO_3$ at 70°C; it is of course possible that other etchants might have revealed additional striae, but in any event it is clear that two different modes of growth can occur in any given cell. The fact that the striations start and stop at the same time on each of the pair of facets which make up the cell suggests that nucleation of layer growth on both faces is occurring at the line of intersection, *i.e.* at the apex of the cell. These observations suggest that the process is a fundamental one involving some form of oscillatory coupling between the nucleation event and the solute and thermal fields rather than due simply to foreign particles. The temporal spacing of the striae is of the order of 1 sec. The fact that neighboring cells do not show the same effect at the same time implies that the process must be very sensitive to the longer range solute field. It seems likely that the explanation must involve a mechanism for the periodic growth of the cell apex which modulates the rate of supply of layer sources; an explanation involving step bunching [see, for example, Parker's review (9) on the kinematic theory of layer growth] seems less probable.

Brief Communications

The Effect of a Prior Sirtl Etch on Subsequent Thermally Induced Processing Damage in Silicon Wafers

W. A. Porter, D. L. Parker, and L. G. Reed

Institute for Solid State Electronics, Texas A&M University, College Station, Texas

Sirtl etch (1) has traditionally been used to identify the presence and density of dislocations in silicon. The relationship between the levels of stress in silicon, and the formation of dislocations by thermal cycling has previously been established (2). Furthermore, it has been shown that residual impurities such as chromium left by Sirtl etching can be removed (3), reducing dangers of contamination. This note reports that prior Sirtl etching of silicon wafers results in reduced dislocation densities after subsequent thermal cycling.

Experimental

The photographs in Fig. 1, 2, and 3 are x-ray topographs of the same 2 in. silicon wafer. A modified Berg-Barrett type camera was used with copper radiation and the (440) reflection. The topograph in Fig. 1 was made after diamond scribing a line across the front (polished) side of the wafer, two triangles on the front side, two triangles on the backside (unpolished), and the S-3 nomenclature on the front side. (The two fainter triangles in the topograph are on the back side of the wafer.) The topograph in Fig. 2 was made after the right half of the wafer was given a 5 min Sirtl etch. Note that the scribe marks in the Sirtl etched half are now barely visible. This illustrates the well-known ability of the etch to relieve stress due to lattice damage.

The topograph shown in Fig. 3 was made after an 8200Å oxide was grown in steam at 1100°C. The wafer was processed horizontally on a flat quartz boat with the edges of the wafer near the ends of the scribed line overhanging the edges of the carrier about ¼ in. on each side. Of course, the maximum thermal

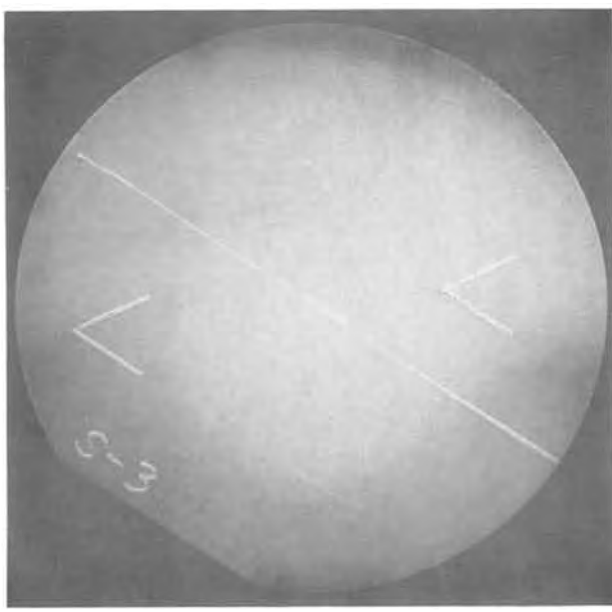

Fig. 1. An x-ray topograph of the 2 in. silicon wafer after scribing.

Fig. 2. An x-ray topograph of the same wafer after the right half was given a 5 min Sirtl etch.

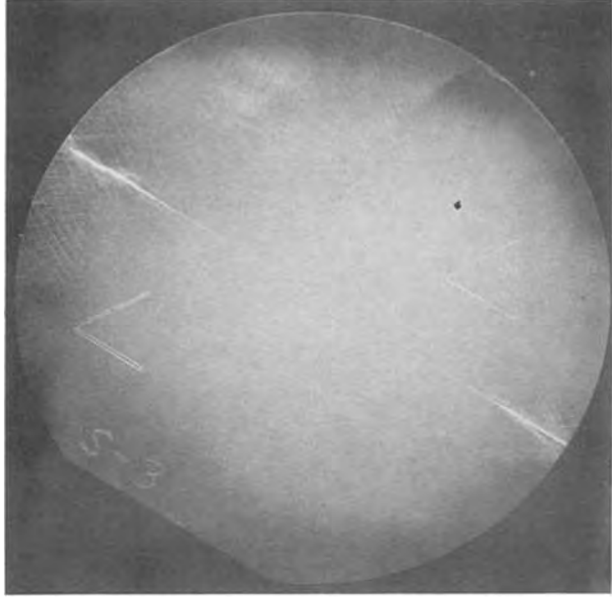

Fig. 3. An x-ray topograph of the wafer after a thermal oxidation step. Note the relative abundance of processing damage on the half of the wafer that was not stress relieved.

stress during insertion and withdrawal from the furnace is produced in the overhanging area of the wafer. Note that there is considerably less process-induced slip damage in the etched half of the wafer. Careful examination of this topograph will reveal the location of the meniscus produced in the etch solution. It is seen at the wafers edge between the S and the 3 and extends to the opposite edge of the wafer.

Conclusion

Visual demonstration using x-ray topography has been given to demonstrate the reduction in thermally generated defects in silicon when a stress relief Sirtl etch is used prior to thermal processing. The potential influence and application of this technique to silicon devices is presently being studied and is the objective of a masters thesis, where preliminary results indicate that a Sirtl etch as short as 30 sec provides significant reduction in subsequent process-induced damage.

Vapor-Phase Growth of Thin GaAs Multilayer Structures

K.-H. Bachem and M. Heyen

Institute of Semiconductor Electronics/Sonderforschungsbereich 56, Technical University, Aachen, Germany

The ability to deposit multilayer epitaxial structures has become an essential requirement for the fabrication of properly functioning GaAs devices. As an example, conventionally constructed MESFET's using a single epitaxial layer grown directly on a semi-insulating substrate exhibit loops and poor saturation behavior in their I-V characteristics. It has been found recently, in this laboratory as well as by other workers (1-3), that these undesirable effects are greatly reduced by depositing an undoped buffer layer between substrate and active film. In the present report we will describe the special technique which we have successfully employed to obtain sequences of differently doped epitaxial layers in one run under well-defined conditions.

A schematic diagram of the apparatus for deposition of epitaxial layers from the $AsCl_3$-H_2-Ga system, as used in this work, is shown in Fig. 1. The reactor is distinguished from conventional systems by the design of the substrate holder (4), as will become clear in the description of a typical loading and deposition sequence. After chemically etching in an aqueous H_2SO_4-H_2O_2 solution and cleaning in organic solvents, the GaAs substrate is subsequently inserted into the depression of the base plate. It is covered by the quartz plate and H_2-flushed cap and introduced into the apparatus. The entire reactor is flushed with H_2 and heated up. The Ga source is saturated with As at 880°C under formation of a GaAs crust. As a next step the source temperature is slowly decreased during which time the reactor is being etched using the upper gas inlet. When the deposition conditions (substrate temperature 750°C, source temperature 850°C) have been reached, the etching is terminated and the deposition flow switched on. The gas phase is allowed to reach a stable composition. At this point, cap and plate are removed to the position shown by the dashed lines, thereby initiating the deposition process. After the desired growth has been effected, the cover is put back in place, thus terminating the deposition. New deposition conditions are now established in the system and the

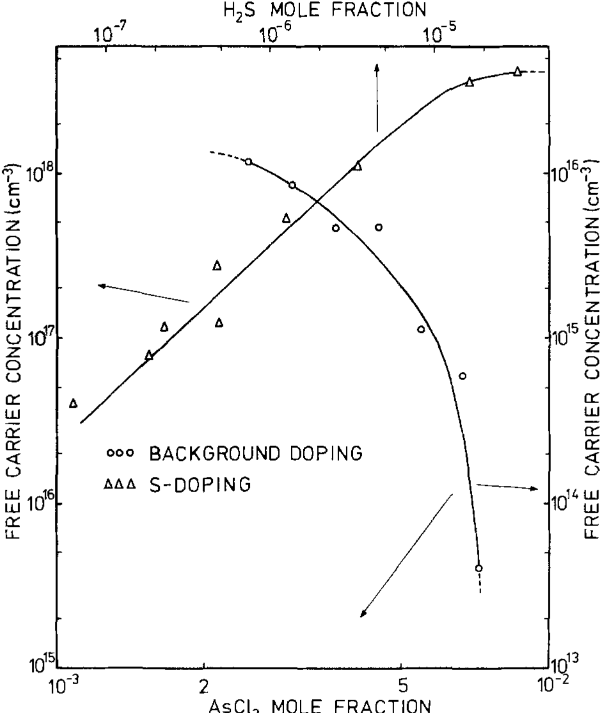

Fig. 2. Variation of the free carrier concentration n (cm^{-3}) with $AsCl_3$ mole fraction (background doping) and H_2S mole fraction at $AsCl_3$ mole fraction of 6.67 · 10^{-3} (S-doping).

apparatus is ready for growth of a next layer for a preset gas-phase composition.

Because the growth rates in the $AsCl_3$-H_2-Ga system are relatively high, the growth of submicron layers requires the ability to select well-defined, very short deposition times. The ability to remove and close the cover in approximately 2 sec means that this second condition is also fulfilled in our apparatus.

In the apparatus, doping levels from the 10^{13} to the 10^{18} cm^{-3} range have been reproducibly obtained, and one can grow a low-doped layer immediately after a high-doped layer without contamination of the former by the latter. The range below $1 \cdot 10^{16}$ cm^{-3} is controlled by the well-known $AsCl_3$ mole fraction dependence of the background doping (2, 6, 7). The larger values are realized by injecting a H_2S-H_2 mixture into the gas stream (Fig. 2). For each run the doping gas was premixed in a stainless steel container from H_2 and a 1000 ppm H_2S-in-H_2 source. It was injected into the reactor at a constant flow rate in all experiments. The concentration in the container was determined photometrically using the methylene blue method (8) after extracting the H_2S from a predetermined volume of doping gas with an aqueous zinc acetate solution.

A typical example of the structures prepared by this method is the following double layer epitaxial film for MESFET application. At the before-mentioned system temperatures, an $AsCl_3$ mole fraction of $7.1 \cdot 10^{-3}$, and a flow rate of 950 ml/min (tube diameter: 60 mm), the film growth rate of 0.3 μ min^{-1} is obtained. Since the structure consists of a 1.5μ thick buffer layer ($n = 4 \cdot 10^{13}$ cm^{-3}) and a 0.1μ active layer ($n = 2 \cdot 10^{17}$ cm^{-3}), a deposition time of only 20 sec is required for the second film. The doping profile obtained from C-V measurements shows a steep transition between the layers; it drops from $1 \cdot 10^{17}$ to $1 \cdot 10^{16}$ in 0.054μ, which is very close to the value calculated by Johnson and Panousis (5) for an idealized steplike doping profile. For the transition between active layer and substrate in the conventional structure, the considerably larger distance of 0.12μ was found for the same drop. This observation is indicative of the boxlike impurity profile attainable with the present apparatus in the case of the double layer structure.

Results on these and other device applications of the described deposition technique will be published elsewhere.

Ni-Cd Cell Simulation: A New Model for Satellite Power Systems Application

A. R. Durando

Chevron Oil Field Research Company, La Habra, California 90631

and C. T. Leondes

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

A new mathematical model has been developed for a nickel-cadmium electrochemical cell for simulation of a satellite solar array-battery power system. Since temperature variations in the system are caused primarily by the thermodynamics of the charge-discharge process and by the coupling between the electrical and chemical phenomena, the new model is intended to stress these characteristics. A mixed theoretical and empirical approach is followed, using fundamental relationships to describe the mechanisms underlying the process and empirical equations to describe those phenomena which are not clearly understood theoretically but are well documented experimentally. The resulting model consists of three nonlinear, time variant, ordinary differential equations with five unknown parameters to be identified to match an experimental trajectory. The three states of the system are the cell reversible potential, temperature, and concentration. The model is applicable to other types of cells with minor modifications.

Many battery power system models in present use rely on table-look-up techniques and describe static conditions, such as capacity and charge-discharge efficiency at standard constant rates (1, 2). The behavior of electrochemical cells is usually represented by purely electrical relationships, where all effects which are not electrical in nature are neglected. Graphic techniques based on battery test data, formerly developed for use in hand calculations (3), have been extended through digital computer applications to handle complete electrical power systems (1). The Power Subsystem Orbital Performance Analysis Program (4) combines the electrical analysis with a transient thermal analysis of that portion of the spacecraft whose thermal characteristics interact with the electric power system. The transient thermal analysis is accomplished by performing successive electrical solutions at relative short time intervals, calculating the heat dissipation and temperature of each of the components of interest, and summing the temperature increments algebraically over the total time period. While the temperature variations are accounted for, they are not described by mathematical relationships based on fundamental mechanisms regulating the thermodynamic processes involved with the cell operation. Other investigators (2) have used a complete set of mathematical relationships for each of the black boxes within the power system. They consider all functional relationships concerning voltage, current, and temperature from the point of view of an equivalent electrical circuit. No chemical and thermodynamical phenomena are described in the model.

Key words: nickel-cadmium batteries, modeling studies, space power systems.

The present model is an attempt to describe the basic phenomena occurring during the charge-discharge operation of an electrochemical cell. All relationships are derived from fundamental equations that are well known in the respective disciplines from which they are taken and are combined to obtain differential equations that represent the transient behavior of the variables of interest. Some empirical equations are used to describe processes for which no better relationships are known, but they do not enter into the dynamics of the system.

The Nickel-Cadmium Cell

The reactions of the nickel-cadmium cell have been the subject of extensive investigation (5-8). A complete description of the chemical process must account for various secondary reactions which may occur depending on the state of charge and the operating conditions. The basic charge-discharge reactions are usually recognized to occur as indicated below. At the negative electrode (anode during discharge) the main reaction may be written

$$Cd + 2\,OH^- \rightleftarrows Cd(OH)_2 + 2e^- \qquad [1]$$

so that on discharge the cadmium metal is emitting bivalent ions, immediately reacting with the hydroxyl ions of the electrolyte (normally KOH) to form cadmium hydroxide (5).

The reactions of the positive electrode are still in

some doubt, but the one most commonly reported is (1, 5)

$$2NiOOH + 2H_2O + 2e^- \rightleftarrows 2Ni(OH)_2 + 2\,OH^- \quad [2]$$

where it can be assumed that trivalent nickel ions are formed by dissolution and dissociation of NiOOH. On discharge they are transformed into bivalent nickel ions, which react almost instantaneously with the hydroxyl ions of the electrolyte, forming nickel (II)-hydroxide.

Among the most significant secondary reactions are those that involve evolution of gases from the electrodes. Of these, only overcharge is considered in this model.

Electrical Model

The framework on which the model is based lies in the electrical analog of the electrochemical cell. The electrical circuit corresponding to the charging phase of the cell operation is shown in Fig. 1. The charging control, U, a voltage applied at the cell terminals, may be a constant, a step function, or a continuous function of time, depending on what charge control policy has been adopted. The counterelectromotive force within the cell is given by the sum of the cell's reversible potential, E_r, and the counterelectromotive force of polarization, E_a. These potentials are described in detail in the sequel. The various impedances in the diagram refer to processes that are well simulated by resistors because of their physical characteristics. R_t corresponds to the cell terminal impedance, assumed constant within the range of application of the model. R_i is the internal impedance, a variable function of various parameters. R_l is a constant impedance corresponding to the cell leakage path. R_o is an impedance corresponding to the overcharge process.

Network analysis of the model in Fig. 1 yields a set of equations which constitute the electrical constraints on the system. Since the circuit as represented contains no energy storage elements (capacitors, inductors), the resulting equations do not contain any dynamic term and correspond to steady-state relationships.

Mesh equations can be established and solved (9) for the currents through each branch of the network, as functions of the state of the system. The solution yields the following equations

$$I_{tot} = \frac{U(R_iR_l + R_iR_o + R_lR_o) - (R_oR_l)E_a + E_r)}{R_t(R_iR_l + R_iR_o + R_lR_o) + R_iR_lR_o} \quad [3]$$

$$I_r = \frac{R_o}{R_o + R_i}\left[\frac{I_{tot}(R_lR_o + R_lR_i) - R_o(E_r + E_a)}{R_i(R_i + R_o) + R_lR_o}\right] - \frac{E_a + E_r}{R_o + R_i} \quad [4]$$

$$I_l = I_{tot}\left[1 - \frac{R_lR_o + R_lR_i}{R_i(R_l + R_o) + R_lR_o}\right] + \frac{R_lR_o + R_lR_i}{R_i(R_l + R_o) + R_lR_o} \quad [5]$$

$$I_o = \frac{I_{tot}R_l(R_lR_o + R_lR_i) + (E_r + E_a)(R_iR_l + R_lR_o)}{(R_o + R_i)(R_iR_l + R_iR_o + R_lR_o)} \quad [6]$$

Fig. 1. Electrical model. U, applied voltage, control; E_a, polarization potential; E_r, cell reversible potential; R_t, cell terminals impedance; R_l, leakage path impedance; R_o, overcharge path impedance; R_i, cell internal impedance; I_{tot}, total current through cell; I_l, leakage current; I_o, overcharge current; I_r, reversible reaction current.

where R_t and R_l are constants; R_o, R_i, E_a, E_r, and U are functions of time. These equations describe the electrical state of the cell and must be satisfied at every instant time during the dynamic evolution of the system. Thus, Eq. [3] through [6] represent a set of algebraic constraints on the dynamic system whose differential equations are derived in the sequel.

Various types of overpotential are exhibited by the nickel-cadmium cell The ohmic overpotential, because of its nature, behaves like a resistance and it can be incorporated with the terminal impedance, R_t, which affects the same current path. The concentration overpotential, caused by the concentration gradient of OH^- ions in solution, is relatively small during normal operation and is neglected here. The activation overpotential, defined as the sum of the discharge and reaction overpotentials (10) (principally caused by hydrogen and oxygen evolution at the electrodes), is accounted for in the model as a counterelectromotive force, E_a, which opposes the flow of current through the reversible path (see Fig. 1). The activation overpotential is electrically in series with the cell reversible potential, E_r, and it changes polarity between charge and discharge, so that it always opposes the direction of flow of the current through the reversible path.

The activation overpotential of a cell depends greatly on its electrical characteristics and on the operating conditions. Most noticeably, E_a depends on the system's state of charge, current, and temperature. The dependence of overpotential upon current density is well represented by the Tafel equations, written as

$$E_a = k_1T + k_2T \log I_r, \quad E_a > 0.05\text{V} \quad [7]$$

$$E_a = k_3TI_r, \quad E_a \leq 0.05\text{V} \quad [8]$$

where k_1, k_2, and k_3 are empirical constants. Equations [7] and [8] can be fitted to any given galvanic cell in terms of polarization *vs.* current data, with temperature as a parameter.

Because of the multiplicity of phenomena affecting the overcharge current, no simple theoretical equation describing the process is found in the literature. An empirical description is adopted here which attempts to represent the behavior of the system with respect to the controlling variables. Experimental tests show that the overcharge current for the nickel-cadmium cell is linearly proportional to the system's temperature for a given applied voltage (11). Furthermore, the cell potential increases very rapidly after the overcharge current sets in, so that a fair approximation is given by the relation

$$I_o = \alpha_1 T e^{\alpha_2(E_r - E_{r,min.})} \quad [9]$$

where α_1 and α_2 are constant parameters, and $E_{r,min.}$ is the minimum value of reversible potential at which the overcharge process becomes significant (usually the value corresponding to the fully charged state). Modeling the overcharge path as a variable impedance, it follows that such impedance may be represented by

$$R_o = \frac{k_4 e^{-k_5(E_r - E_{r,min.})}}{T}, \; E_r \geq E_{r,min.} \quad [10]$$

where k_4, k_5, and $E_{r,min.}$ are empirical parameters to be fitted from experimental data for values of the reversible potential greater than $E_{r,min.}$.

Since the overcharge current is practically negligible for lower values of the cell reversible potential, the corresponding model impedance may be represented by a very large constant value, M, and the model equation then becomes

$$R_o = M, \quad E_r < E_{r,min.} \tag{11}$$

Thus, Eq. [10] and [11] are used in the model and in the solution of the circuit described in Fig. 1.

The internal resistance of the nickel-cadmium cell is found to increase with the reversible potential. At the same time, the internal resistance is inversely proportional to the temperature of the system, as a higher temperature increases the mobility of ions and therefore enhances the transport of electricity through the electrolyte. The following empirical equation is used to represent this behavior

$$R_i = \frac{\beta_1 + \beta_2 E_r^h}{T^j} \tag{12}$$

where β_1 and β_2 are constant parameters, and h and j are exponential values to be found experimentally. Since the resistance dependence on the reversible potential is nearly linear for small potential variations, its description may be simplified by using two straight lines for two ranges of operation (for a given value of T). Similarly, since the temperature dependence is only grossly determinable experimentally, the assumption of inverse linearity seems to be justified for the sake of simplicity. Accordingly, the cell internal impedance is described by the following two equations

$$R_i = \frac{k_6 + k_7 E_r}{T}, \quad E_r \geqq E_{r,min.} \tag{13}$$

$$R_i = \frac{k_8}{T}, \quad E_r < E_{r,min.} \tag{14}$$

where k_6, k_7, and k_8 are constant parameters to be fitted experimentally by standard regression techniques.

Dynamic Equation for Reversible Potential

The dynamic equation for the reversible potential of the nickel-cadmium cell is derived from the Nernst equation for the potential of a galvanic cell. Expressed in terms of activities of the reacting species, the equation may be simplified to

$$E_r = E_r^o + \frac{RT}{\mathbf{F}} \ln [a_{H_2O}] \tag{15}$$

where E_r^o is the standard electromotive force for the cell, R is the universal gas constant, $\mathbf{F}$ is Faraday's constant, and a_{H_2O} is the activity of water in the cell. Under the assumption of ideality the activity of a component may be substituted with its mole fraction, which is easily observable and measurable in practice. Equation [15] then becomes

$$E_r = E_r^o + \frac{RT}{\mathbf{F}} \ln X_{H_2O} \tag{16}$$

Differentiating with respect to X_{H_2O}, expanding the total differential dX_{H_2O}, and substituting it into Eq. [16] yields

$$\frac{dE_r}{dn_{H_2O}} = \frac{RT}{\mathbf{F} n_{H_2O}} [e^{(-\mathbf{F}/RT)(E_r - E_r^o)} - 1] \tag{17}$$

This equation represents the functional relationship between E_r and the chemical composition of the solution in the cell during charge or discharge. Since these processes are accompanied by current flow, Faraday's law may be used to express Eq. [17] in terms of the electrical charge flowing through the cell, dq. The term dn_{H_2O} corresponds to the number of water moles being formed or consumed during the reaction (which corresponds, in turn, to a change in potential dE_r). The mole/equivalent ratio for this reaction is one to one, so that, in applying Faraday's law $N = dn_{tot} = 1$, and the current through the system is

$$I_r = \frac{dq}{dt} = \frac{dn_{H_2O}\mathbf{F}}{dt} \tag{18}$$

Notice that the subscript r here refers to the reversible path of the model, that is, I_r is the current associated with the reversible reactions in the cell only, and no other phenomena. Substituting Eq. [18] into [17] yields

$$\frac{dE_r}{dt} = \frac{RTI_r}{\mathbf{F}^2 n_{H_2O}} [e^{(-\mathbf{F}/RT)(E_r - E_r^o)} - 1] \tag{19}$$

which is the theoretical dynamic equation for the reversible potential, E_r. Substituting the groups $R/\mathbf{F}^2$ and $\mathbf{F}/R$ with p_1 and p_2, respectively, yields the model equation

$$\frac{dE_r}{dt} = \frac{p_1 T I_r}{n_{H_2O}} [e^{(-p_2/T)(E_r - E_r^o)} - 1] \tag{20}$$

where p_1 and p_2 are constant parameters to be identified by data matching, E_r^o is the standard electromotive force for the cell, T and n_{H_2O} are the cell temperature and water concentration, respectively.

Notice that, according to Eq. [20], a positive I_r corresponds to a positive gradient of E_r, as expected for the charging process indicated in the model of Fig. 1. Also, the gradient is directly proportional to the current, I_r, and the temperature, T, and inversely proportional to the water concentration, n_{H_2O}.

Equation [20] contains four variables that are functions of time: E_r, T, n_{H_2O}, and I_r. Of these, only the first three can be expressed by independent differential equations based on physical properties of the system. The fourth variable, I_r, is simply a variable parameter of the model, completely determined by the other variables. Since the equivalent circuit does not contain any capacitors or inductors, the current does not possess any transient characteristics of its own and its value depends only on the circuit equations.

Dynamic Equation for Cell Temperature

Internal heat generation occurs when current flows through the system and electrical work is dissipated by the resistances in the circuit. At the same time, the chemical processes during the charge and discharge phases display very strong exothermic and endothermic characteristics at different stages of the reactions. Temperature phenomena can be accounted for by using fundamental relationships for the electrical work dissipated and the heat of reaction in a heat balance around the cell. Treating the cell in lumped form, the heat balance yields

$$\rho C_p V \frac{dT}{dt} = q_{gen} + q_{in} - q_{out} \tag{21}$$

where ρ, C_p, V, and T are the cell equivalent density, heat capacity, volume, and temperature; q_{gen} is the rate of heat generated within the cell, and q_{in} and q_{out} are rates of heat input and output.

The rate of heat evolution in the nickel-cadmium cell is estimated by analyzing two separate sections of the circuit independently. The first section is the so-called reversible path, according to Fig. 1; the second one corresponds to the rest of the circuit, that is, the overcharge and the leakage paths. Reversible here refers to the chemical characteristics of the reactions, not to the conditions under which they take place. In fact, whenever $U > E_r$, the process occurs under conditions that do not involve maximum electrical work and that are, therefore, thermodynamically irreversible. The current through the path is I_r, that is, that fraction of I_{tot} that contributes to the charging reactions. The heat generated by this process can be estimated if the reversible potential of the cell and the entropy of the reaction are

known. The enthalpy change resulting from the addition of heat and electrical work to the system, ΔH, is given by the first law of thermodynamics

$$\Delta H = Q_{gen} + W \quad [22]$$

Defining W in terms of electrical work, and adding and subtracting the reversible work expressed both in terms of electrical work and free energy, Eq. [22] becomes

$$Q_{gen} = \Delta H - \int UI_r dt + W_{rev} - W_{rev}$$

$$= \Delta H - \int UI_r dt + \int E_r I_r dt - \Delta G \quad [23]$$

But the system's free energy change may be expressed in terms of enthalpy at a given temperature, $\Delta G = \Delta H - T\Delta S$, so that Eq. [23], after simplification, becomes

$$Q_{gen} = \int (E_r - U) I_r dt + T\Delta S \quad [24]$$

Differentiating with respect to time, an equation is obtained for the heat rate of generation in the reversible path, $q_{gen,1}$ which can be further simplified if the temperature of the system changes slowly, *i.e.*, if $dT/dt \cong 0$, to yield

$$q_{gen,1} = (E_r - U) I_r + T \frac{dS}{dt} \quad [25]$$

Since the change in entropy is linearly proportional to the quantity of materials reacted, $(dS/dt)I_r = (\Delta S/\Delta t)I_r = KI_r$, where K is a proportionality constant equal to $\Delta S/\mathbf{F}$. The final equation then becomes

$$q_{gen,1} = (E_r - U) I_r + KI_r T \quad [26]$$

Turning to the heat generated in the other parts of the electrical model, it is apparent that it is well approximated by that fraction of the total power to the system that was not utilized in the reversible path. Since the total power to the system is given by UI_{tot}, defining the charging efficiency as the fraction of total current that contributes to the charging reaction, $\eta = I_r/I_{tot}$, it follows that

$$q_{gen,2} = (1 - \eta) UI_{tot} \quad [27]$$

where $q_{gen,2}$ is the heat generated in the remainder of the circuit.

Combining Eq. [26] and [27], and expressing the reversible current in terms of the charging efficiency, the final equation for the total heat rate of generation is obtained

$$q_{gen} = [I_{tot}(E_r - U) + I_{tot}TK]\eta + I_{tot}U(1 - \eta) \quad [28]$$

where, according to the model in Fig. 1, I_{tot} is the total current through the cell for a given applied terminal potential, U; K is a constant for the process which accounts for the entropy change during the reaction. Substituting this equation into the heat balance, rearranging, and letting $q = q_{in} - q_{out}$ be the net heat transfer through the boundary of the system, gives

$$\rho C_p V \frac{dT}{dt} = [I_r(E_r - 2U + TK) + I_{tot}U] + q \quad [29]$$

Solving for dT/dt and substituting K and $\rho C_p V$ with the parameters p_3 and p_4 to be fitted from real data, the dynamic equation for the temperature of the cell is obtained

$$\frac{dT}{dt} = \frac{I_r(E_r - 2U + Tp_3) + I_{tot}U + q}{p_4} \quad [30]$$

Equation [30] shows that the temperature variations during the charge phase are the net result of competing effects. A positive contribution to the temperature slope derives from the total power supplied to the system, as indicated by the term $I_{tot}U$. The thermodynamic effect, represented by I_rTp_3 varies according to the over-all entropy change during the reaction. During the charge process, for instance, the entropy change is negative so that the term I_rTp_3 contributes negatively to the slope of the temperature equation. Similarly, the net heat flow rate through the boundary, q, is directly proportional to the temperature derivative, so that the temperature of the cell increases when heat is absorbed through the boundary and decreases when heat is lost to the surroundings. All other terms in Eq. [30] are the result of the particular electrical configuration of the model and of the assumptions made in its derivation.

Dynamic Equation for Cell Concentration

The composition of the electrolyte solution in the nickel-cadmium cell varies only because of the water consumption or formation during the process. Thus, the variation of the number of water moles, n_{H_2O}, during the reaction is directly related to the charge flowing through the solution, dq

$$dn_{H_2O} = \frac{dq}{\mathbf{F}} \quad [31]$$

Since the current contributing to the reaction is $I_r = dq/dt$, converting $\mathbf{F}$ to an identifiable parameter, p_4, this equation becomes

$$\frac{dn_{H_2O}}{dt} = \frac{I_r}{p_4} \quad [32]$$

which represents the dynamic equation for the total number of moles in the electrolyte solution. Since I_r is positive during charge and negative during discharge, the number of water moles increases and decreases during the respective operations. This conforms with the expected result, as indicated by the reaction equation, where water is formed during charge and consumed during discharge.

Model Test

For the purpose of testing the behavior of the model, the equations presented here were fitted to typical nickel-cadmium cell data. Specifically, all data used refer to a Gulton 20A-h, sealed, sintered plate cell. The parameters in the dynamic equations were identified according to a procedure based on sensitivity functions (12) and a charge cycle was simulated and compared to experimental data. The results are reported in Fig. 2, 3, and 4.

The model showed the ability to fit the dynamic behavior of a typical nickel-cadmium cell and appears to be a viable tool for studying power systems. The parameters can be identified to match a specific real system, and the resulting equations are manageable from the standpoint of numerical computation. The dynamic description of the temperature in the system, the reversible potential, and the water concentration within the galvanic cell, as well as the electrical variables of interest, such as current through the terminals, over-

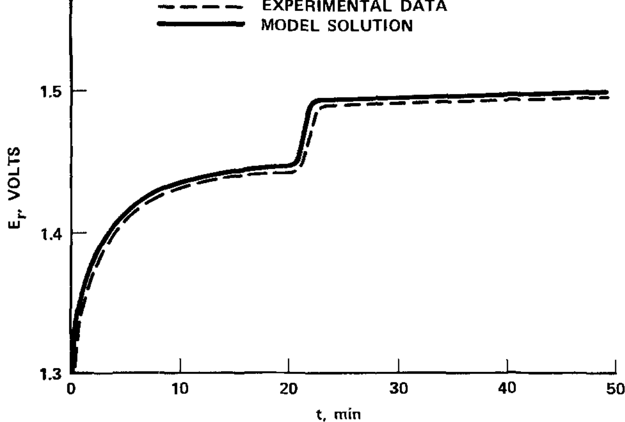

Fig. 2. Reversible potential trajectory

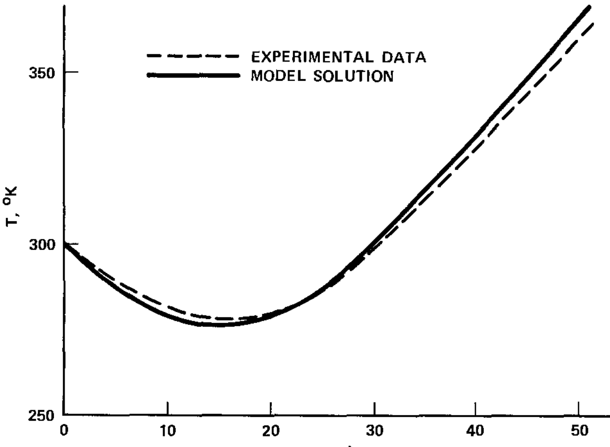

Fig. 3. Temperature trajectory

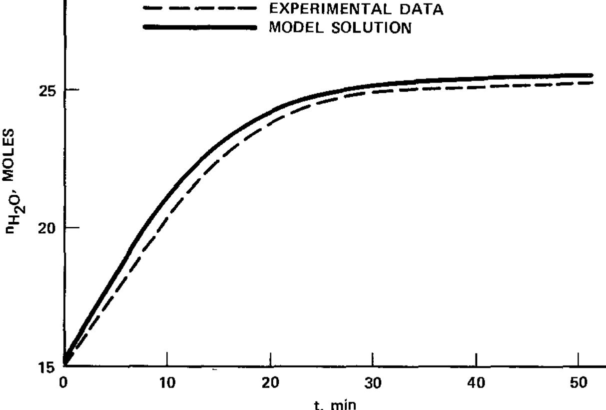

Fig. 4. Concentration trajectory

charge current, and charging efficiency, are available at every time as a result of the transient computations.

Practical Considerations

From the foregoing, the present model consists of three differential equations for the reversible potential, temperature, and concentration, with five parameters to be identified experimentally, and of a set of algebraic constraints derived from the electrical characteristics of the system. Not all the significant phenomena occurring during the operation of the nickel-cadmium cell are purported to be represented in the model. The pressure buildup within the sealed cell, and its effect on the temperature of the system, for instance, are completely neglected. So are the capacity of the cell, its state of charge, and any memory effect which might affect the parameters of the equations. These simplifications are tolerated for the sake of simplicity of the model, which would otherwise become too complicated and possibly intractable for computation. Furthermore, these processes are not well understood and are difficult to describe quantitatively, so that the practical usefulness of a more complicated model is questionable.

The equations derived here correspond to the model shown in Fig. 1, which is a charge model. But the results obtained during the derivation are valid for the discharge phase as well, with the appropriate modifications. Notably, a load must be substituted for the charging potential, U, and the polarity of the activation overpotential, E_a, must be reversed. Furthermore, since the opposite reaction would be taking place on discharge, the value of K in Eq. [29] must be reversed in sign.

The equations, derived for an electrochemical cell, are equally applicable to a battery of cells, as long as no qualitative difference between the various elements is present. Of course, different data would apply, and the model parameters would correspondingly have different values.

Finally, notice that the equations derived are valid with slight modifications for any electrochemical cell. Once the chemical reaction involved is established, and the significant products and reactants are known, the dynamic equation for the reversible potential can be modified accordingly. The different thermodynamic properties of the new system must be taken into account in the heat and concentration equations. In general, then the same set of equations may be fitted to the operating characteristics of a given cell or battery.

Discharge Behavior of Redox Thermogalvanic Cells

Brian Burrows*

Battelle, Geneva Research Centre, 1227 Carouge-Geneva, Switzerland

ABSTRACT

The discharge behavior of thermogalvanic cells based on a dissolved redox couple, namely ferro-ferricyanide, was investigated as a function of redox couple concentration, temperature difference, electrode placement and configuration, and forced convection. The principal source of cell polarization was found to be the rate of mass transfer of electroactive species to the electrode surfaces. This concentration polarization is instrumental in limiting the power output of aqueous redox thermogalvanic cells to values <0.1 mW cm^{-2}. A practical feature of such cells, however, is that a continuous power output can be maintained indefinitely provided that the half-cell temperature difference remains constant.

Thermogalvanic cells are the electrochemical equivalent of thermoelectric devices and can directly convert thermal to electrical energy (1). Conceptually and operationally, however, thermogalvanic cells are considerably more complex since ionic as well as electronic conduction is involved. Thus under discharge conditions the transport and discharge of ions will cause, in general, permanent changes to occur at the electrodes. This is a considerable inconvenience in a practical device.

Despite the inconvenience of mass transfer, a certain amount of interest was shown in thermogalvanic cells for power generation during the early 1960's. In particular, attention was directed to analyzing the properties of cells having molten salt or solid-state electrolytes to take advantage of the large temperature differentials and hence relatively large cell voltages obtainable (2-6).

In these studies it was shown that the material properties of thermogalvanic and thermoelectric cells, as measured by the figure of merit, were comparable. The figure of merit, Z, is defined as

$$Z = \frac{s^2}{\rho k} K^{-1} \quad [1]$$

where s is the Seebeck coefficient in V K^{-1}, ρ is the specific resistivity in ohm-cm, and k is the specific thermal conductivity in W cm^{-1} K^{-1}. Ionic conductors were found to have figures of merit of $\sim 10^{-3}$ K^{-1}, *i.e.*, similar to Z values of semiconducting materials such as PbTe and BiTe used in thermoelectric devices (7). Apart from having similar Z values, both thermogalvanic cells and thermoelectrics have conversion efficiencies which are Carnot limited (7, 8). This was another reason why thermogalvanic cells based on high temperature electrolytes were initially of interest. In fact, though, only two experimental investigations of the power generating or discharge behavior of thermogalvanic cells have been reported (9, 11). In both cases solid electrolytes were used.

Weininger (9) investigated the Ag/α-AgI/Ag and the (Pt)I_2/α-AgI/I_2(Pt) cells at temperatures of 150°-500°C. The latter was also the subject of a patent (10). The polarization behavior of the Na/β-Al_2O_3/Na thermocell was reported by Weber (11) over the temperature range of 200°C at the cold electrode and up to 800°C at the hot electrode. This cell has also been patented (12).

In both of the patented cells it should be noted that the problem of mass transport under current-drain conditions, which was alluded to earlier, was overcome by using a gaseous (I_2) electrode in one case and a liquid (Na) electrode in the other. External connections between the hot and cold electrode allowed mass transfer while ionic transport occurred through the composition-invariant solid electrolyte. Two other versions of high temperature thermogalvanic cells having gas electrodes have also been described in the patent literature (13, 14).

Although the use of gaseous or liquid electrodes circumvents the mass transfer problem it is at the expense of extra complexity in the cell design. As the low d-c voltages obtainable with direct energy conversion devices necessitate the use of large numbers of cells to obtain practically useful voltages, it is imperative that cells be simple, durable, and cheap. Therefore, it was thought that a simpler means of avoiding the mass transfer problem in a thermogalvanic cell would be to use cells based on dissolved redox couples with inert solid electrodes. The liquid electrolyte could be either aqueous or molten salt.

The discharge behavior of redox thermogalvanic cells based on the Fe^{2+}/Fe^{3+} couple in aqueous electrolyte has been recently reported (15). It was shown that continuous power outputs could be obtained from such cells with no change in electrolyte composition or activity of the electrodes. In this paper the results of a more detailed investigation of the discharge behavior of a cell based on the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ couple in aqueous electrolyte is reported. An aqueous electrolyte was chosen for simplicity since the aim of the study was to evaluate the factors which limit the power output.

Experimental

Most of the experiments were carried out in a U-shaped test cell. The arms of this cell were jacketed and the temperatures in each half-cell were controlled to ±0.1°C by a continuous flow of water from two thermostated water baths. A linear cell was also used for some experiments; this was essentially a straightened U-cell. The temperature of the colder half-cell was always maintained at 30°C while that of the hotter half-cell was varied between 50° and 80°C.

Platinum electrodes were used as the working or current-carrying electrodes. These were of the platinum inlay type (No. 39272) supplied by Beckman Instruments Incorporated. The planar surface of these electrodes was 0.196 cm^2 and they were placed centrally in each vertical arm of the U-cell with a distance of about 25 cm separating the electrode surfaces. A length of Pt wire was wrapped around each working electrode with one end of the wire terminating just in front of the electrode face. The Pt wires served as reference electrodes and allowed the individual measurement of the working electrode polarization.

A rotating electrode was fabricated from a Pt-inlay electrode and was used for investigating the influence of forced convection on the polarization in each half-cell. A procedure similar to that described by Marcoux

* Electrochemical Society Active Member.

Key words: direct energy conversion, device, power output, concentration polarization, ferro-ferricyanide couple.

and Adams (16) was followed in making the rotating electrode which was coupled to a d-c motor using a chuck constructed in these laboratories.

The influence of electrode area on cell polarization was investigated using platinized Pt-inlay electrodes. The platinization was carried out in the usual way in a solution of chloroplatinic acid and lead acetate. Pt-foil electrodes were also used in some experiments. These had a total area of 4 cm^2 and were spot welded to thin Pt wires which acted as both support and current collector.

Solutions of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ ions in 0.5M K_2SO_4 were prepared from $K_3Fe(CN)_6$ and $K_4Fe(CN)_6 \cdot 3H_2O$. These salts were supplied by Fluka AG and were > 99% pure. The K_2SO_4 used for making up the supporting electrolyte was > 99% pure. For each experiment a fresh solution of the dissolved redox couple was prepared and deoxygenated for 10 min by bubbling nitrogen through the solution.

The discharge behavior of the redox thermogalvanic cells was investigated by applying constant current between the two working electrodes and recording the cell voltage when steady state had been attained. For each discharge current, the polarization at each working electrode with respect to the Pt wire reference electrodes was also recorded. A digital voltmeter was used to monitor the potentials to ± 0.1 mV.

The resistance of the electrolyte between the two working electrodes was measured with a conductivity bridge (Philips Model PW 9501) at 2000 Hz. For a given electrolyte concentration and temperature difference the same value was obtained using either smooth or platinized Pt electrodes. As a check on the accuracy of the a-c resistance measurements, a current interruptor technique was also used to measure the *IR* drop between the electrodes. Agreement to within ± 5% was found using the two methods for measuring electrolyte resistance.

Results

A typical set of experimental polarization measurements obtained for the redox thermogalvanic cell

$$(30°C)\ Pt/Fe(CN)_6^{3-}\ (M_1),\quad Fe(CN)_6^{4-}\ (M_1)/Pt\ (30°C + \Delta T) \qquad [A]$$

is presented in Table I where i is the discharge current density, V_{cell} is the cell voltage as measured by the potential of the working electrode in the hot half-cell with respect to that of the working electrode in the 30°C half-cell, η_{30} and η_{80} are electrode overpotentials measured with respect to a Pt-wire reference electrode, $V_{IR\text{-}free}$ is the cell voltage after correction for the ohmic voltage drop, $\eta_{IR\text{-}free}$ is the cell overvoltage due to charge-transfer and mass-transfer polarization calculated from the difference V_{cell} (at $i = 0$) − $V_{IR\text{-}free}$ (at $i = i$), and P is the power density given by the product $i \cdot V_{IR\text{-}free}$.

In Table I the effect of temperature on polarization of the individual electrodes is evident as η_{30} is greater than η_{80}. It can also be seen that the sum of the absolute electrode overpotentials ($\eta_{30} + \eta_{80}$) at low current densities corresponds closely to the cell overvoltage ($\eta_{IR\text{-}free}$). These overvoltages should, of course, correspond as the electrode overpotentials contain only a small ohmic component but this component will become significant at high current densities as was observed.

When a constant current was being drawn from a redox thermogalvanic cell [A] with ΔT = 50°C, a steady-state voltage was rapidly attained. This voltage was observed, however, to fluctuate in a more or less cyclic manner with an amplitude which increased with increase in discharge current density. Experiments showed that these fluctuations decreased to insignificant levels when the bulky Pt-in-glass electrodes were replaced by Pt-foil electrodes having a thin Pt wire spot welded to the foil as current collector. This suggests that the oscillations in cell voltage can be largely attributed to convective effects caused by the Pt-inlay electrodes acting as heat sinks.

Discussion

Influence of concentration.—The cell overvoltage-current characteristics for $[Fe(CN)_6^{3-}] = [Fe(CN)_6^{4-}]$ = 0.2, 0.1, 0.05, and 0.02 mole liter^{-1} with a ΔT of 50°C in each case are plotted in Fig. 1. It should be noted that the cell overvoltage has been corrected for the ohmic drop between the two working electrodes and so only includes contributions from mass-transfer and charge-transfer polarization at the electrode/electrolyte interfaces.

The form of the η-log i curves in Fig. 1 is typical of mass transfer-controlled electrode processes. Thus, a limiting current is evident which is proportional to

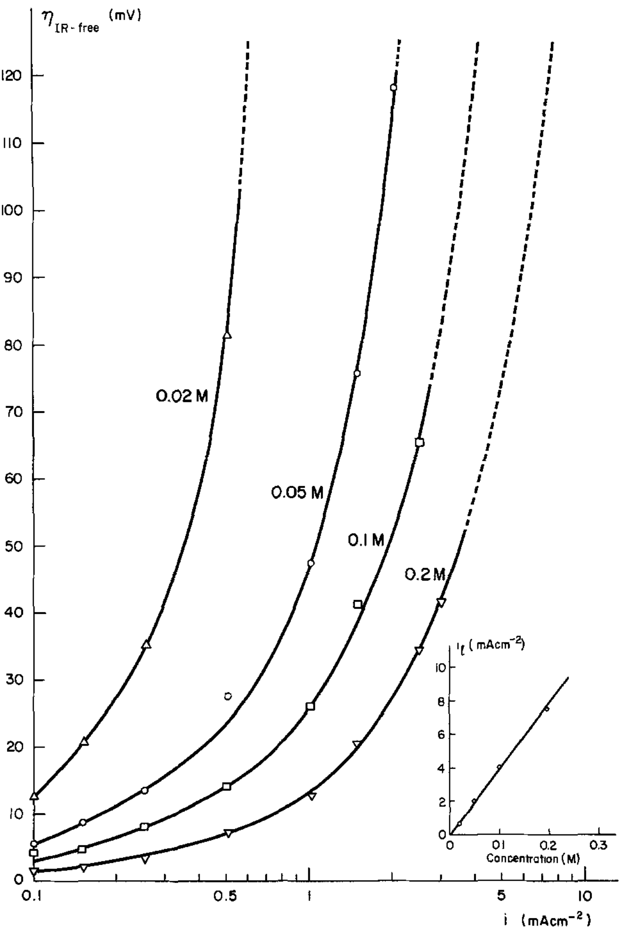

Fig. 1. Cell overvoltage ($\eta_{IR\text{-}free}$) vs. log i for thermogalvanic cells (ΔT = 50°C) based on the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple as a function of concentration. Inset: Limiting current (i_l) vs. concentration.

concentration (see inset to Fig. 1). This is in accordance with the equation relating limiting current (i_l) to concentration of electroactive species for a mass transfer-limited electrode process. This well-known equation (17) is

$$i_l = 10^3 \frac{nFDC}{\delta} \quad [2]$$

where i_l is in mA cm^{-2}; n, **F**, and D have their usual meanings; C is the concentration in mole cm^{-3}; and δ is the thickness of the Nernst diffusion layer in cm. As a quantitative check on the numerical values obtained for the limiting current we can calculate i_l from Eq. [2].

The diffusion coefficients for the $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ ions in 0.5M K_2SO_4 are 8.9×10^{-6} and 8.0×10^{-6} cm^2 sec^{-1}, respectively (18). Taking a mean value for D of 8.5×10^{-6} cm^2 sec^{-1} and $\delta = 3 \times 10^{-2}$ (17), the calculated value of i_l for a 0.1M solution is 2.7 mA cm^{-2}. This value is in excellent agreement with the extrapolated value of i_l for the 0.1M solution in Fig. 1 of 4 mA cm^{-2}. Similarly, it can be shown that the limiting currents for the other concentrations are also in good agreement.

In general, it is the relative values of i, i_l, and i_o which determine the degree of potential loss at an electrode (19). In the cells under investigation it appears that the polarization losses arise from mass-transport limitations which implies that for a given concentration $i_l << i_o$. To check that, in fact, this is the situation, we can estimate i_o for, say, a 0.1M solution of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ ions from the available kinetic data.

The equation relating i_o to concentration and the standard rate constant (k_s) is

$$i_o = n\mathbf{F}\, k_s\, a_o^{1-\alpha}\, a_R^{\alpha} \quad [3]$$

where i_o is in A cm^{-2}, k_s is in cm sec^{-1}; a_o is the activity of oxidant in mole cm^{-3}, a_R is the activity of reductant in mole cm^{-3}, α is the transfer coefficient, and n and **F** have their usual significance.

For the redox reaction

$$Fe(CN)_6^{3-} + e \rightleftarrows Fe(CN)_6^{4-} \quad [4]$$

the standard rate constant has been measured as 2×10^{-2} cm sec^{-1} with a transfer coefficient of 0.5 (18). Using Eq. [3] it can then be calculated that for a solution 0.1M in both $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ ions the exchange current density will be 0.19 A cm^{-2}. This value is an unrealistic maximum since we have assumed that the activities of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ ions are identical to their concentrations. If, in the absence of activity coefficient data, we assume that the activities are only 10% of the concentrations, then i_o would be 19 mA cm^{-2}. This value of i_o is still an order of magnitude greater than the maximum current drawn from the thermogalvanic cells (see Fig. 1) which further confirms that mass-transfer polarization is the primary cause of the cell polarization observed in Fig. 1.

The influence of concentration on power output can be seen in Fig. 2 where P is plotted *vs.* discharge current for $[Fe(CN)_6^{3-}] = [Fe(CN)_6^{4-}] = 0.2$, 0.1, and 0.05M. The power output for each concentration has a maximum value which increases with both current density and concentration. The relationship between P_{max} and concentration is shown in the inset. Since the solubility limit of the ferro-ferricyanide couple is 0.2M in 0.5M K_2SO_4, the maximum observed power output was limited to 93 μW cm^{-2}. The proportionality between maximum power output and concentration of electroactive species is not unexpected in view of the fact that the IR-free cell voltage increases in proportion to the increase in concentration for a given applied current density (see Fig. 1).

Influence of temperature difference.—The influence of ΔT on the V-i characteristics of thermogalvanic

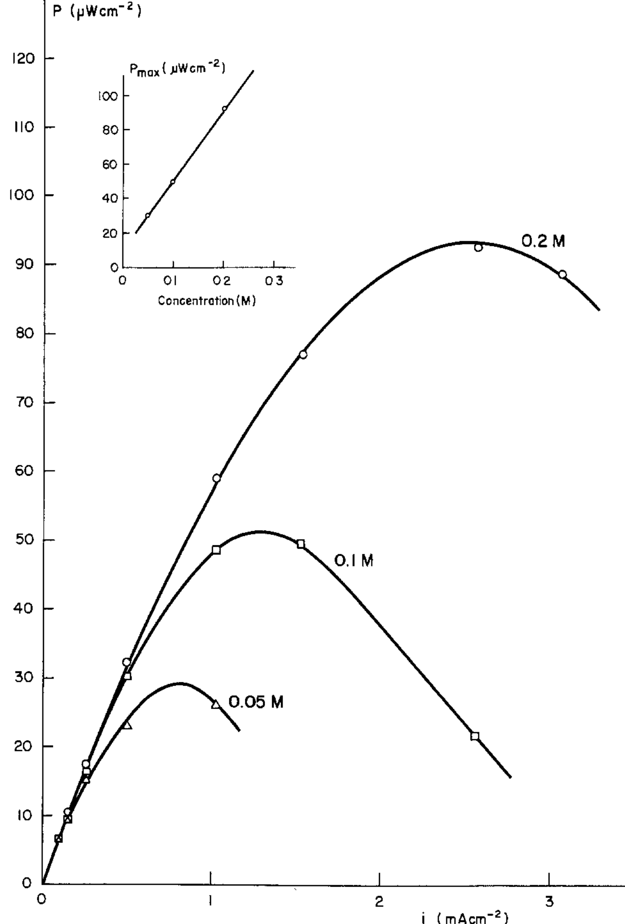

Fig. 2. Power output *vs.* discharge current for thermogalvanic cells ($\Delta T = 50°C$) based on the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple as a function of concentration. Inset: Maximum power output *vs.* concentration.

cells [A] with $[Fe(CN)_6^{4-}] = [Fe(CN)_6^{3-}] = 0.1M$ was investigated for ΔT of 50°, 40°, 30°, and 20°C. The variation of initial cell voltage (V_{cell} at $i = 0$) with ΔT is linear (see Fig. 3) and the slope of 1.4 mV °C^{-1} is the average value of the Seebeck coefficient.

The cell overvoltage ($\eta_{IR\text{-free}}$) *vs.* log i curves were independent of ΔT, *i.e.*, decreasing ΔT from 50° to 20°C did not alter the overvoltage characteristics. This insensitivity of η to ΔT is surprising in view of the observation that $\eta_{30} > \eta_{30} + \Delta T$. One would have expected, for a mass-transfer controlled process, that with decrease in ΔT the cell overvoltage would have increased. Perhaps this effect is counteracted by an equivalent decrease in η due to the decrease in thermal diffusion (Soret effect) at lower ΔT. The temperature differential did, however, influence the power output as shown in Fig. 4 where P is plotted *vs.* i for ΔT of 50°, 40°, 30°, and 20°C. It is evident that P goes through a maximum for each ΔT and in the inset to Fig. 4 the increase of P_{max} with increase in ΔT is shown.

Influence of electrode placement.—The V-i characteristics of cell [A] were also investigated in a linear cell in which the 80°C half-cell was vertically above the 30°C half-cell. Comparison of the cell overvoltage with that measured under identical conditions in a U-cell showed that the polarization behavior was the same. This indicates that any convective effects are localized in the half-cells and do not affect the cell as a whole.

Direct measurements of the temperature gradient at the bottom of the hot (80°C) compartment showed that 2 cm away from the bottom of the compartment the temperature was only 35°C and 3.5 cm into the connecting arm of the U-cell the temperature was 30°C; the same as that in the cold electrode compartment.

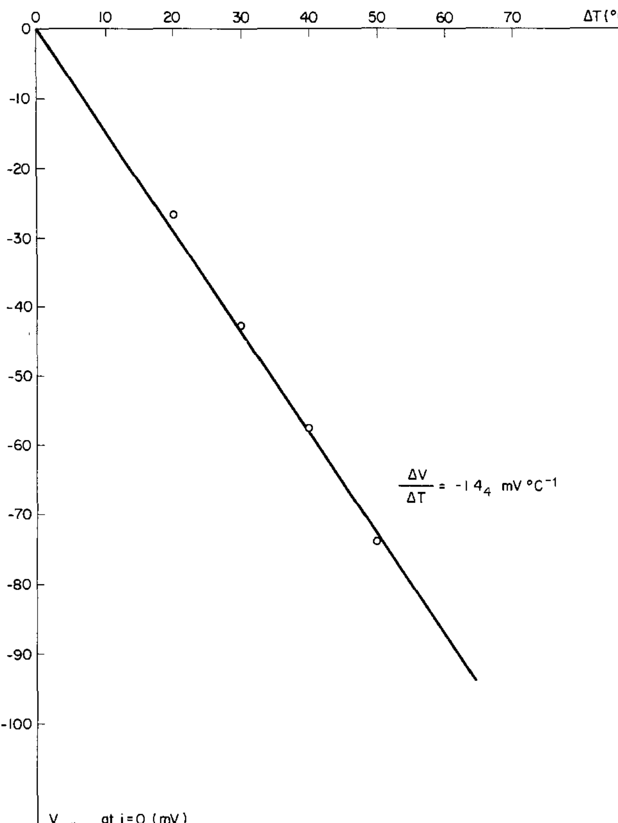

Fig. 3. Initial cell voltage ($V_{80/30}$ at $i = 0$) vs. ΔT for thermogalvanic cells based on the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple (0.1M).

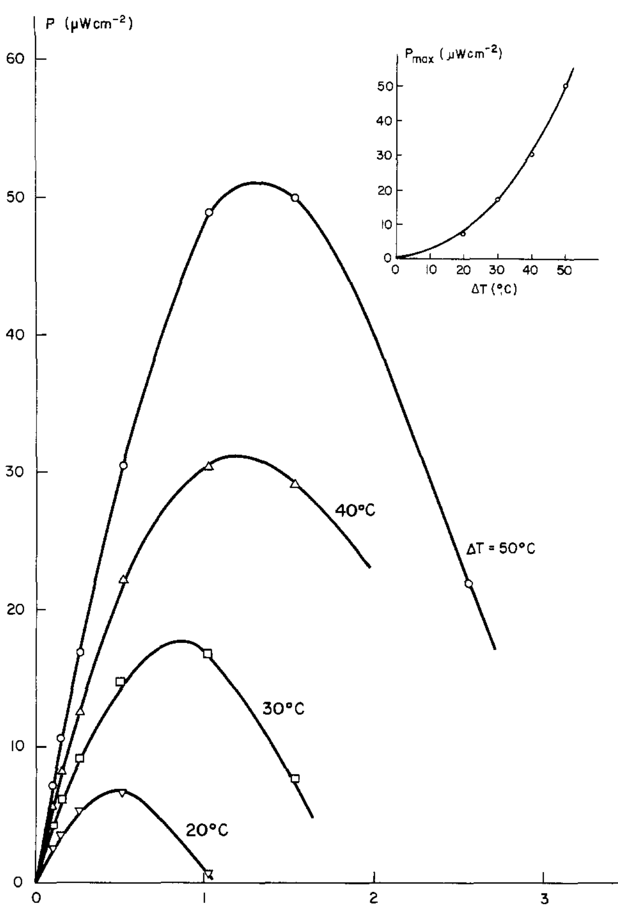

Fig. 4. Power output vs. discharge current for thermogalvanic cells based on the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple (0.1M) as a function of ΔT. Inset: Maximum power output vs. ΔT.

The minimum distance which could, therefore, be maintained between the two electrodes, while still preserving a ΔT of 50°C, is 3.5 cm. Now the values of P used in Fig. 2 and 4 are calculated from IR-free cell voltages and so are ideal values. Correcting the maximum measured power output of 93 μW cm^{-2} (see Fig. 2) to take into account the internal resistance of 6 ohm when the electrode separation is 3.5 cm results in a reduction of P_{max} by 5% to 88 μW cm^{-2}. Thus the influence of electrolyte resistance on maximum power output is relatively minor primarily, of course, because the current is small being only 0.5 mA in the above case.

A second modification of electrode placement was investigated in a U-cell using Pt-foil rather than Pt-inlay working electrodes. Again there was no significant difference between the results obtained with the two electrode configurations but the degree of cycling of the cell voltage was much less in the case of the Pt-foil electrodes indicating reduced convective effects (see Results).

Influence of electrode roughness.—The roughness factor (ratio of real to geometric area) of a platinum electrode can be readily increased by platinizing. The minimum increase which can be obtained is of the order of 100 (20). If, as the results indicate, the polarization in thermogalvanic cells based on the ferro-ferricyanide couple is mass-transfer controlled, then increasing the roughness factor should have no effect on the polarization behavior of the cell (21).

The polarization results obtained for cell [A] with an equimolar 0.1M $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ solution at $\Delta T = 50$°C using platinized Pt-inlay electrodes were, as expected, identical to the results obtained with smooth electrodes.

Influence of forced convection.—Since the power output of redox thermogalvanic cells is constrained by the rate of mass transfer of the electroactive species in solution, it was of interest to determine to what extent forced convection could improve the cell performance. Experiments were again carried out in a cell [A] containing an equimolar 0.1M solution of ferri-ferrocyanide. The results are summarized in Fig. 5. It should be noted that the distance of 25 cm between the two electrodes was such that electrode rotation did not influence the thermal gradient between the two half-cells.

It can be seen that forced convection in either of the two compartments leads to a considerable reduction in overvoltage. Adding together the effects of stirring in both compartments, one can derive a curve for the cell overvoltage in which both electrodes are rotating. Thus, at a discharge current density of 3.5 mA cm^{-2}, forced convection leads to a substantial fourfold reduction in the cell overvoltage which produces in turn a fourfold increase in the power output over the maximum of 52 μW cm^{-2} obtained with stationary electrodes at a current density of 1.3 mA cm^{-2}. For a 0.2M (saturated) solution, which was found to give the maximum power output of almost 0.1 mW cm^{-2}, we could therefore expect an output of about 0.4 mW cm^{-2} under forced convection conditions.

Unfortunately this fourfold increase in power output to a maximum of about 0.4 mW cm^{-2} is still an order of magnitude less than what is obtained using solid-state photovoltaic or thermoelectric devices for direct energy conversion.

In view of the fact that the rate of mass transfer of the ions of the redox couple to the electrodes is the principal cause of cell polarization (which in turn limits the maximum power output) one could, in principle, obtain higher power outputs with redox couples which are more soluble than the ferro-ferricyanide system. Experiments with a thermogalvanic cell based on the ferrous-ferric chloride (2 mole liter^{-1}) system gave, however, a maximum power output of only 42 μW cm^{-2} (15) which illustrates the limitations of going in this direction.

Cell overvoltage ($\eta_{IR\text{-free}}$) vs. log i for thermogalvanic cells based on the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple (0.1M): ⊙ both electrodes stationary; △ rotating electrode in 80°C half-cell; X rotating electrode in 30°C half-cell; □ rotating electrodes in both half-cells (derived curve). OCV: 73.8 mV. Rotation speed: 880 rpm.

This low power output resulted from the fact that the Fe^{2+}/Fe^{3+} couple in HCl had a Seebeck coefficient of only 0.6 mV °C^{-1}, which is only one-third as large as that of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple in K_2SO_4. (The i_o values for the two values are of similar magnitude.) Hence, for two cells with the same ΔT, mass-transfer polarization is a larger proportion of the initial cell voltage for the ferrous-ferric system than it is for the ferro-ferricyanide system.

Thus, in general, it is more advantageous to have a redox couple with a higher Seebeck coefficient than with a higher solubility. Seebeck coefficients are, however, limited to values in the region of 0.5-1.5 mV °C^{-1} (22) and solubilities are limited to 1-2 mole liter^{-1} in aqueous solution so there would seem to be little possibility of obtaining an order of magnitude improvement in the power outputs of aqueous redox cells.

One could, of course, use molten salts as electrolyte media for dissolved redox couples to take advantage of the larger available ΔT and the higher solubilities, and it is conceivable that one could obtain power outputs of up to 15 mW cm^{-2} (15) which would make redox thermogalvanic cells comparable in power density to solid-state thermoelectric and photovoltaic cells (23). The problem with high temperature systems, however, is that materials problems are considerable and an economically viable device is unlikely to be based on molten electrolytes.

A means of augmenting the power outputs of the otherwise attractive redox thermogalvanic cells (continuous steady-state power outputs, invariant electrodes and electrolytes) without recourse to high temperature systems could be through a judicious combination of the photogalvanic effect (24) with the thermogalvanic effect in the one cell. The photogalvanic effect would be primarily used to induce a substantial change in the potential of one (illuminated) electrode with respect to the other (dark) electrode. That is, the high energy photons of the u.v. and visible regions of the solar spectrum would be used for activating a suitable semiconductor or dye-sensitized electrode, thereby changing its normal (unilluminated) rest potential. At the same time, the thermal energy in the *IR* region would be used to heat the electrolyte in the vicinity of the illuminated electrode.

A possible photo/thermogalvanic cell is the following

$$\text{(80°C) } n\text{-}TiO_2/Fe(CN)_6^{3-},\ Fe(CN)_6^{4-}/Pt\ \text{(30°C)} \qquad [B]$$

illuminated (anode) — dark (cathode)

The operation of this cell is shown schematically in Fig. 6. The photogalvanic properties of semiconducting TiO_2 have recently been reported (25, 26) and in cell [B] this electrode would function as an anode, *viz.*

$$TiO_2 + h\nu \rightarrow TiO_2 + 2p^+ + 2e \qquad [5]$$

complementing the anodic reaction of the redox couple in the thermogalvanic cell *via* the reaction

$$p^+ + Fe(CN)_6^{4-} \rightarrow Fe(CN)_6^{3-} \qquad [6]$$

The cell voltage in the absence of illumination would be some tens of millivolts (due to the thermogalvanic effect) but with the TiO_2 electrode illuminated it could be several hundreds of millivolts (due to the photogalvanic effect being superimposed on the thermogalvanic effect). Such photo/thermogalvanic cells are currently under investigation.

Electrophoretic Mobilities of Cadmium Hydroxide, Nickel Hydroxide, and Silver Oxide in Ni-Cd and Ag-Zn Battery Electrolytes

S. W. Mayer

Chemistry and Physics Laboratory, Laboratories Operations, The Aerospace Corporation, El Segundo, California 90245

ABSTRACT

Since cadmium migration damage of separators is a major cause of Ni-Cd battery failures or performance degradation, a series of electrophoretic mobility measurements has been made for cadmium hydroxide suspensions in concentrated KOH battery electrolyte at several concentrations of K_2CO_3 to investigate whether electrophoresis of cadmium hydroxide could be the mechanism for migration to separators. It was found that the mobility of the cadmium hydroxide suspension in an applied electrical field is adequate to account for the observed migration of cadmium hydroxide to separators. The view that high carbonate concentrations in Ni-Cd battery electrolyte may increase cadmium migration damage of separators is consistent with these electrophoretic measurements since it was demonstrated that increasing K_2CO_3 concentration from 0.8 to 6.2% increased cadmium hydroxide migration by a factor of 3. Zeta potentials have been calculated from the data. Similar measurements have been made for nickel hydroxide suspensions in Ni-Cd battery electrolyte at several K_2CO_3 concentrations. The results are consistent with ion probe analyses for nickel in nylon separators exhibiting considerable cadmium migration. Silver oxide mobility reached a maxmum at 5.1% K_2CO_3 and declined at 15.8% K_2CO_3.

A major cause of premature failure in modern Ni-Cd spacecraft batteries (1, 2) is short-circuiting through separators damaged by cadmium hydroxide or cadmium that has migrated into the separator (3). The migrating material is apparent in the separator as a black or dark gray, nonuniform deposit. When the amount of migrated material is so large that extensive penetration into and through the separator occurs, the battery fails, or its performance degrades very severely because of internal short circuits through the separator and consequent rapid self-discharge (2, 3).

The cause of this damaging migration, however, is not well understood. There is some belief that the source of the migrated material is cadmium dissolved in the KOH electrolyte, since the solubility of cadmium ions in this electrolyte is finite, although admittedly very small (1). Tests of cation and anion exchange capacity of the nylon separators, however, show almost no ion exchange capacity, both for separators exhibiting considerable cadmium migration and for new separators (3). Furthermore, the surfaces of the separators nearest the Cd-$Cd(OH)_2$ electrode are always much more contaminated with cadmium than the surfaces furthest from the cadmium electrode. This suggests that the source of the cadmium deposited in the separator is not cadmium ions dissolved in the solution since the solution would penetrate the porous separator uniformly rather than favoring the surface nearest the Cd-$Cd(OH)_2$ electrode. It seemed possible that the deposit on the separator could be particles of insoluble $Cd(OH)_2$ from the negative plate although this source has not previously been mentioned (1, 2). On the cadmium plate, particulate $Cd(OH)_2$ is formed during discharge

$$Cd + 2\,OH^- = Cd(OH)_2 + 2e \qquad [1]$$

Key words: electrophoresis, cadmium migration, silver oxide mobility.

If the $Cd(OH)_2$ particles have a net negative charge in the KOH electrolyte (possibly arising from preferential absorption of OH^- ions as compared to absorption of K^+ ions), they would tend to be repelled by the negative field when the cadmium electrode is being charged and migrate electrophoretically toward the positive field of the nickel hydroxide electrode (4). Migrating negative particles of $Cd(OH)_2$ would first be stopped on the surface of the separator nearest the cadmium electrode. The particles would tend, during subsequent charging, to migrate further towards the positive electrodes through those pores of the separator that are large enough to permit their passage. This mechanism for migration would be consistent with the observed preferential deposition on the surface of the separator nearest the cadmium electrode, followed by penetration into the separator as the number of cycles increases (2).

In order to determine whether this particulate electrophoresis explanation of migration in Ni-Cd cells might be possible, the electrophoretic measurements for $Cd(OH)_2$ described in this report have been made in the 34% KOH electrolyte used in Ni-Cd cells. The electrophoretic mobility and zeta potential measurements for $Cd(OH)_2$ were also conducted in the presence of added K_2CO_3 since it is thought possible that the presence of K_2CO_3 in Ni-Cd batteries increases migration damage (2, 5). After the electrophoresis measurements showed that particulate $Cd(OH)_2$ does migrate towards the positive electrode in KOH, similar sets of measurements were made on nickel hydroxide and silver oxide because of their relevance to Ni-Cd and Ag-Zn spacecraft batteries. Reduction potential measurements were also made to determine whether, during charging of Ni-Cd batteries, potentials were reached near the separators that were sufficient to convert migrated $Cd(OH)_2$ to metallic cadmium particles.

Experimental

Electrophoretic mobility and zeta potential determinations for cadmium hydroxide, nickel hydroxide, and silver oxide were made by the method of Sennett and Olivier (6) as modified by Long and Ross (7). Through the use of a cylindrical sample chamber rotating at 30 rpm, suspensions containing up to 40% of the hydroxide can be investigated. In this variation of the Hittorf technique, a constant potential gradient is applied by means of stainless steel electrodes to the rotating suspension of metal hydroxide particles in KOH electrolyte, and the weight of metal hydroxide migrating in 360 sec to the 2.0 cm diam electrode in a collection cell is determined. The electrophoretic mobility and zeta potential can then be calculated (6).

The samples of metal hydroxide suspension were prepared by adding a solution of the reagent-grade nitrate salt drop by drop, with stirring, to analyzed reagent-grade KOH solutions that had, according to the analysis, only 0.01% CO_2 contamination. The cadmium hydroxide suspension contained 13.9% $Cd(OH)_2$ in 34% KOH. The nickel hydroxide suspension consisted of 5.2% $Ni(OH)_2$ in 34% KOH. To prepare the silver oxide suspension, 70g of $AgNO_3$ were dissolved in 35 ml of water. The solution was stirred drop by drop into 800 ml of 45% KOH.

In order to test the effect of K_2CO_3 on the electrophoretic mobility, the desired weight of anhydrous reagent-grade K_2CO_3 was dissolved in the appropriate suspension. The temperature of the samples was 21°C during the electrophoretic mobility measurements.

Results and Discussion

The electrophoretic mobility m of cadmium hydroxide and nickel hydroxide suspensions in 34% KOH was calculated (6) on the basis of Eq. [2] after the weight had been measured of each hydroxide (in separate experiments) that collected at the positive electrode in 360 sec

$$m(\text{cm/sec per V/cm}) = \frac{WK}{tRifd} \qquad [2]$$

where W denotes the grams of particulate migrating to the electrode in t sec, K is the cell conductivity constant (0.8905), i is the current (set at 5 mA), f is the product of the volume fraction of the particulate with the volume fraction of the electrolyte, d is the density difference between the particulate and the electrolyte, and R is the resistance of the electrolyte suspension of the particulate in the sample chamber as measured with a Wheatstone bridge. The density data used for $Cd(OH)_2$, $Ni(OH)_2$, and Ag_2O were their handbook values of 6.4, 4.1, and 7.4 g/cm^3, respectively. The density of KOH electrolyte has been reported (1). The particle sizes of the suspensions were large enough so that they settled out when allowed to stand 15 min, leaving a clear supernatant electrolyte which showed almost no colloidal Tyndall effect in the beam of a helium-neon laser. Although cadmium is known (1, 5) to have a low solubility in concentrated KOH solutions as a negative ion, the rate of cadmium deposition on the positive electrode was considered to be too small to have a significant effect because the low concentration of the cadmium ion would produce a correspondingly low rate of cadmium deposition.

The zeta potential p (in volts) was calculated (6) by

$$p = 1.3 \times 10^6 \eta m/D \qquad [3]$$

where η is the electrolyte viscosity in poises, D is its dielectric constant, and m is the mobility calculated from Eq. [2].

The cadmium and nickel hydroxides migrated to the positive electrode because the particulates in the suspension apparently had acquired a negative charge by adsorbing hydroxyl and carbonate anions preferentially compared to their adsorption of potassium cations from the electrolyte. Table I presents the data for the weight of cadmium hydroxide particulate collected in the positive electrode cell in 360 sec for the suspension originally containing 13.9% $Cd(OH)_2$ in 34% KOH. Battery electrolyte generally contains K_2CO_3 in addition to KOH as a result of CO_2 absorbed from the atmosphere or of CO_2 produced by separator degradation (1, 2), and it is believed that cadmium migration damage of separators may become more severe as the concentration of carbonate in the electrolyte increases (5, 8). The electrophoretic mobility was consequently measured at three higher concentrations of K_2CO_3, using other portions of the stock suspension of 13.9% $Cd(OH)_2$ in KOH electrolyte. The results, shown in Table I, are consistent with the view that higher levels of carbonate contamination do tend to increase cadmium migration, since the quantity of $Cd(OH)_2$ collected at the electrode increased from 31.0 mg with 0.8% K_2CO_3 present to 181.4 mg at the 9.0% K_2CO_3 level. The 9.0% K_2CO_3 concentration is characteristic of high levels of carbonate contamination occasionally observed (8), and the 0.8% K_2CO_3 concentration is within the normal range for electrolyte in new Ni-Cd batteries (1).

Table I also contains the calculated electrophoretic mobilities and zeta potentials corresponding to each concentration of K_2CO_3. The mobilities do not increase with K_2CO_3 levels as rapidly as the weight of $Cd(OH)_2$ collected at the positive electrode, inasmuch as the re-

Table I. Migration of cadmium hydroxide suspensions in Ni-Cd battery electrolyte

K_2CO_3 concentration, w/o	Suspension collected at anode, mg	Mobility, 10^{-3} cm/sec per V/cm	Zeta potential, mV
0.8	31.0	0.08	46
3.1	60.9	0.11	63
6.2	98.8	0.14	81
9.0	181.4	0.18	104

sistance of the suspension increases with added K_2CO_3. The lowest mobility in Table I is, however, easily sufficient to allow particles of $Cd(OH)_2$ to migrate into the separator and toward the positive plate during the Ni-Cd cell-charging process which would take 10 hr at the C/10 rate. An applied charging voltage of 1.5 between plates separated by 2 mm would provide a potential gradient of 7.5 V/cm. The lowest mobility in Table I would then produce a $Cd(OH)_2$ particle velocity of 20 mm/hr. As the separator is closer to the $Cd(OH)_2$ plate than 0.3 mm, it is evident that even higher charging rates than C/10 provide ample time for $Cd(OH)_2$ to migrate electrophoretically to the separator. The increase in mobility as the carbonate concentration is raised suggests that the $Cd(OH)_2$ particles acquire a higher negative charge because of stronger preferential adsorption for the doubly charged carbonate anion than for the singly charged hydroxyl anion. The observed trend towards increased zeta potentials at higher carbonate concentrations is consistent with higher charge density, because of increased carbonate adsorption, on the cadmium hydroxide particles.

As shown by the data in Table II, higher concentrations of K_2CO_3 did not increase the quantity of $Ni(OH)_2$ suspension that migrated towards the positive electrode. Nickel hydroxide, nevertheless, does have a relatively strong tendency to migrate towards the positive electrode at lower K_2CO_3 levels. During 360 sec in 2.7% K_2CO_3, 132 mg of $Ni(OH)_2$ migrated to the anode, compared to 61 mg of $Cd(OH)_2$ in 3.1% K_2CO_3. It should be noted, however, that the direction of the electrophoretic mobility of the $Ni(OH)_2$ suspension in the Ni-Cd battery would cause the suspension to move toward the $Ni(OH)_2$ positive plate during charging. Consequently, unlike cadmium hydroxide, it would not tend to migrate away from the plate where it should remain for better battery performance and lifetime. The electrophoretic mobility measurements are consistent with the results of separator chemical analyses by ion probe (3), which show that virtually no migration of nickel to separators occurs even when the cadmium migration damage is severe.

The electrophoretic measurements for suspensions of silver oxide in 43% KOH electrolyte of Ag-Zn spacecraft batteries demonstrate that the sign of the charge on Ag_2O suspensions is opposite to that on the cadmium hydroxide or nickel hydroxide suspensions. The quantity of Ag_2O migrating to the cathode in 360 sec increased sharply (Table III) when the K_2CO_3 concentration was raised to 5.1 from 2.0%, but declined at higher concentrations of carbonate. The lowest rate of migration was obtained at the lowest concentration of carbonate. Accordingly, it is not recommended that carbonates should be added to Ag-Zn battery electrolyte to suppress silver migration. Since zinc oxide is soluble in KOH electrolyte, no electrophoretic measurements were needed for zinc oxide in this study.

Table II. Electrophoretic mobility of nickel hydroxide suspensions in Ni-Cd battery electrolyte

5.1	380.1	1.68	1700
8.3	259.1	1.14	1200
15.8	92.2	0.41	420

The electrophoretic mobility data (Table I) for cadmium hydroxide in Ni-Cd battery electrolyte show that the mobility of $Cd(OH)_2$ is sufficient to allow it to reach and penetrate the separator. Such deposits in the separator will be more damaging to battery performance by producing internal shorting between the plates if they are converted from $Cd(OH)_2$, which has a high resistance to electron flow, to cadmium metal which has a low resistance. The mechanisms whereby $Cd(OH)_2$ in the separator can be reduced to Cd metal during battery charging will require extensive investigation before their relative contributions can be evaluated. One mechanism could consist of electron tunneling (9) from the cadmium electrode to $Cd(OH)_2$ deposited on the surface of the separator. Tunneling is very dependent on the distance from the electrode source, and it is uncertain that enough of the separator in a typical Ni-Cd cell is sufficiently close to the cadmium electrode to permit significant tunneling of electrons to the separator. Other mechanisms could depend on the reduction of soluble impurities in the electrolyte at the cadmium electrode during battery charging, followed by diffusion of these reduced impurities to the separator where they would reduce the migrated $Cd(OH)_2$ to Cd metal if their reduction potentials were adequate. These mechanisms are analogous to the nitrate-nitrite shuttle for producing Ni-Cd battery self-discharge (2, 5).

Nitrite, however, is not a sufficiently strong reducing agent to be efficient for the reduction of $Cd(OH)_2$ to Cd metal. The following experimental test was, therefore, made with a 12 A-hr Ni-Cd spacecraft cell to investigate whether sufficiently strong reducing potentials occurred in the electrolyte adjacent to separator surfaces during the cell-charging process. The Ni-Cd cell had been subjected to 100 charge-discharge cycles during preflight testing. Cell state-of-charge at the beginning of the test was 90%. The cell was cut open and the pack of plates was raised from the casing so that about 75% of the plate height remained in the casing. The cell was then immersed in 34% KOH electrolyte (at 25°C) so that electrolyte contact was established with the plates. An Hg-HgO reference electrode, with a bridge containing 31% KOH, was placed in the electrolyte. The reference electrode was connected with a 1.2-cm^2 platinum foil electrode, which was inserted diagonally into the immersed portion of the plate pack, between the sixth cadmium electrode and its adjacent nylon separator. The objective of the platinum foil was to act as a potential-indicating electrode for the Ni-Cd cell electrolyte near the surface of the separator, as the cell was being charged. The cell was charged at 1.4V and 0.50A, and the emf of the platinum foil-HgO reference electrode pair was monitored with a high-impedance digital voltmeter. After 30 min, the observed emf of the electrode pair stabilized near -0.93V and remained at -0.93 ± 0.01V during the 3 hr of cell charging.

This potential is sufficient to reduce much of the $Cd(OH)_2$ in a separator to Cd metal, and indicates that the electrolyte near the surface of the separator does contain reduced compounds or ions capable of converting some of the migrated $Cd(OH)_2$ to Cd in the separator. The reduced compounds in the electrolyte could be impurities, or hydrogen could be formed in solution at the observed voltage of the platinum-foil indicator electrode. One possible impurity that would attain suitable reducing potentials (10) in KOH electrolyte is the stannite ion; another possibility is sulfite ion. Aldehydes formed at the cadmium electrode (during charging) from carboxylic acid produced by degradation of the nylon separator could also act as a soluble reducing agent to convert $Cd(OH)_2$ to Cd metal in the separator. Another possibility is that a combination of several such soluble reducing agents could form the Cd metal that causes internal shorting and consequent battery failure.

Anodic Dissolution of Titanium in Acidic Sulfate Solutions

II. Effects of Ti(III) and Ti(IV) Ions

Eugene J. Kelly*

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

At an active-state titanium electrode, Ti(IV) ions are reduced to Ti(III), and the reduction reaction is first order with respect to the concentration of Ti(IV) ions. The current density corresponding to the reduction reaction adds algebraically to the current densities corresponding to the active-state dissolution of the metal to form Ti(III) ions in solution and to the hydrogen evolution reaction. At constant potential, the rates of the latter two reactions are not affected by Ti(III) or Ti(IV) ions. However, the reduction of Ti(IV) ions is accompanied by a displacement of the open-circuit (corrosion) potential in the noble direction and, consequently, by an increase in the open-circuit corrosion rate. When the concentration of Ti(IV) exceeds a certain critical value, the active-state titanium passivates. At a passive-state titanium electrode, Ti(III) ions are oxidized to Ti(IV), and the oxidation reaction is first order with respect to the concentration of Ti(III). The current density corresponding to the oxidation of Ti(III) ions simply adds to the current density corresponding to the dissolution of the passive metal. The rate of the latter reaction is not affected by Ti(III) or Ti(IV) ions. Electrolyte-coupled active-passive titanium systems, *i.e.*, systems in which active-state and passive-state electrodes are collocated in the same body of electrolyte, are capable of generating the critical concentration of Ti(IV) ions required to passivate the active surface, a "self-healing" phenomenon relevant to localized (pitting, crevice, etc.) corrosion. Also, under appropriate conditions, dissolution rates of titanium in the active state (open-circuit or polarized) may be accurately determined by monitoring the current at the passive sensor electrode in an electrolyte-coupled system.

The first paper in this series (1) described the results of a study of the electrochemical behavior of zone-refined titanium in hydrogen-saturated acidic sulfate solutions (pH $< \sim 2.5$). Although the primary objective of the earlier investigation was the determination of the mechanism of titanium dissolution in the active state and in the active-passive transition (passivation) potential region, the kinetics of oxidation of Ti(III) ions in solution to Ti(IV) at a passive titanium surface, and the effect of this reaction on the current-density/potential curve in the passive state were also examined. It was shown that, at constant potential and pH, the oxidation of Ti(III) ions to Ti(IV) is first order in the Ti(III) concentration, and that the current density corresponding to this reaction simply adds to the current density corresponding to the passive-state dissolution of the substrate metal. The Ti(III) ion had no discernible effect on the dissolution rate of the passive metal. Many authors have noted the increased current density observed at a passive titanium electrode in the presence of Ti(III) ions, and have attributed the effect to the electrodeposition of a thick oxide film (2, 3), or to a peculiar "depassivating effect" in which the Ti(III) ions bring about an increase in the dissolution rate of the passive metal (4, 5). On the other hand, Kuznetsova *et al.* (6) concluded that the dissolution rate of passive titanium is reduced by the presence of Ti(III) ions. Consequently, depending upon the particular author, Ti(III) ions increase, decrease, or have no significant effect upon the dissolution rate of passive titanium.

Weiman (7), Andreeva and Yakovleva (8), and Sinigaglia *et al.* (9), among others, have all observed that, above a certain critical concentration, Ti(IV) ions in solution passivate an active titanium surface. In addition to this observation, Thomas and Nobe (5) con-

* Electrochemical Society Active Member.

Key words: titanium, corrosion, active state, passive state, self-healing.

cluded that at concentrations below the critical concentration required for passivation, Ti(IV) ions inhibit the anodic dissolution of titanium in the active state. All investigators agree that Ti(IV) ions are electrochemically inert at a passive titanium surface and have no effect on the passive-state dissolution rate of the metal.

In the initial portion of this paper, the kinetics of reduction of Ti(IV) ions to Ti(III) at an active titanium surface, and of oxidation of Ti(III) ions to Ti(IV) at a passive titanium surface are examined in detail. An analysis of the effects of these reactions on the current/potential behavior of titanium in the active and passive states is presented, and the effects of Ti(III) and Ti(IV) ions on the dissolution rate of titanium in the active and passive states are determined. The latter portion of the paper is devoted to a study of electrolyte-coupled active-passive titanium systems, *i.e.*, systems in which active and passive electrodes are collocated in the same body of electrolyte. The oxidation of Ti(III) ions at a passive titanium sensor electrode serves as the basis for a very sensitive method for monitoring active-state dissolution rates. In addition, electrolyte-coupled active and passive metal/electrolyte reaction systems are encountered in localized attack of metals (pitting corrosion, crevice corrosion, etc.) (10), and the results of this study add to our understanding of the mechanism involved in localized corrosion.

Experimental

The experimental apparatus and techniques have been described elsewhere (11) and, therefore, only a brief resume is given here. The three-compartment cell assembly (test, reference, and counterelectrode compartments) was made of Pyrex glass and Teflon, and was so designed that solutions could be added to or removed from the cell without exposure to the atmosphere. All compartments were jacketed and maintained at a constant temperature ($\pm 0.02°C$) which, except where noted, was 30°C. A stream of hydrogen was passed through all compartments at all times. The hydrogen source was a Matheson generator which produces ultra pure gas via diffusion of electrolytically generated hydrogen through a palladium membrane Additional stirring in the test compartment was achieved with a Teflon-coated magnetic stirrer.

The titanium electrodes employed in this study were made from zone-refined, polycrystalline titanium (Materials Research Corporation). The cylindrical electrodes were mounted on Teflon electrode holders which exposed either one planar surface or the cylindrical surface or both. All solutions were prepared from reagent grade materials and triply distilled water. Stock solutions of Ti(IV) in 1*N* H_2SO_4 were prepared by dissolving approximately 2g of zone-refined titanium in a sulfuric acid solution (55.6 ml conc H_2SO_4 + 200 ml H_2O) at ~70°C under a helium atmosphere. The resulting deep purple solution was cooled to room temperature, and filtered through a medium porosity glass filter directly into a two-liter volumetric flask. A small amount of the solution was held back. Hydrogen peroxide (30% solution) was added to the volumetric flask until the purple Ti(III) solution just became colorless. The next drop of H_2O_2 produced an orange color which was eliminated by addition of some of the Ti(III) solution that was held back. The addition of increasingly dilute H_2O_2 and Ti(III) solutions was repeated several times, with the final solution in the volumetric flask containing a negligible excess of Ti(III). The solution was then diluted with H_2O to the two-liter mark. Except where noted otherwise, Ti(III) solutions were prepared by anodic oxidation of titanium at E_m (see text) in acidic sulfate solutions having the desired pH.

In those instances where test solutions were analyzed for Ti(III) via permanganate titration, the $KMnO_4$ solutions were 0.5M in H_2SO_4, and were presaturated with H_2. Solution transfer and titration were conducted under a hydrogen atmosphere. A standard peroxide colorimetric method was employed in the determination of Ti(IV) in test solutions (12). A 2 ml sample of test solution was transferred to a 10 ml volumetric flask, 0.2 ml of H_2O_2 (30% solution) was added, and the solution was diluted to the 10 ml mark with 0.5M H_2SO_4. The absorbence was measured at a wavelength of 410 mμ, using a Beckman Model DU Quartz Spectrophotometer with a H_2 lamp and a 1 cm cell.

In experiments involving only one test electrode, a Wenking potentiostat (Model 61 RH) was used in conjunction with a Wenking precision potentiometer (Model PPT-67), and a Hewlett-Packard/Moseley recorder (Model 7100B, Model 17501A plug-ins). In experiments involving two test electrodes (electrolyte-coupled active and passive titanium electrodes), an ORNL potentiostat (Model Q-2003) was used with a potentiostat derived from a Philbrick Model Q3-A2P differential amplifier to form a dual potentiostat. A common reference and counterelectrode completed the four-electrode systems.

All electrode potentials (E) were measured against a saturated calomel electrode and, unless stated otherwise, all E values are given with reference to SCE.

Results and Discussion

In order to acquaint the reader with various aspects of the titanium system, typical steady-state polarization curves are shown in Fig. 1. In 1*N* H_2SO_4, titanium undergoes spontaneous active-state dissolution accompanied by the hydrogen-evolution reaction. As the potential of the titanium is made increasingly positive (noble) relative to the corrosion potential ($E_c = -735 \pm 5$ mV *vs.* SCE), the anodic current density increases to a maximum (i_m) at the critical potential (E_m), and then decreases as the metal is transformed from the active to the passive state. In a previous study (1), coulometric-weight loss measurements at E_m and E_m + 160 mV demonstrated that, in the active and active-passive transition potential regions (*i.e.*, in the potential regions where curves A and D coincide), titanium is oxidized to form Ti(III) ions in solution. In the passive state, the metal is oxidized to form the passive

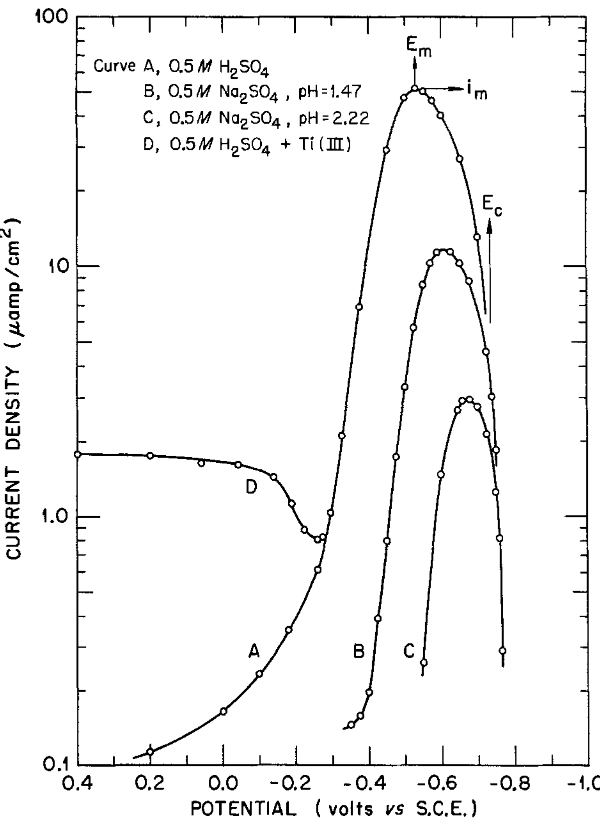

Fig. 1. Effects of Ti(III) concentration and pH on the steady-state anodic polarization of titanium.

film (TiO_2) and Ti(IV) ions in solution. Curves A, B, and C illustrate the effect of pH on the polarization behavior of titanium. If the effect of the hydrogen evolution reaction is taken into account, it may be shown (1) that $d \log i_m/dpH = -2/3$, $d \ln i_m/dE_m = \mathbf{F}/2RT$, and $dE_m/dpH = -(4/3)\ 2.303\ RT/\mathbf{F}$. These diagnostic criteria are satisfied by the mechanism of titanium dissolution presented earlier (1). Here, our interest is focused on the difference between curves A and D, a difference which results from the presence of Ti(III) ions in the electrolyte phase.

Oxidation of Ti(III) ions in solution to Ti(IV) at a passive titanium surface.—In order to examine the oxidation of Ti(III) ions at a passive titanium surface, a titanium electrode was maintained in a steady state at 0 mV *vs.* SCE (curve A), and a solution of known concentration of Ti(III) ions in H_2-saturated 1*N* H_2SO_4 was added in measured volume increments to the test cell containing a known volume of 1*N* H_2SO_4. After each addition, the current density increased, moving from its initial value on curve A toward curve D. Let i_p^* represent the current density corresponding to the passive-state dissolution of titanium in the absence of Ti(III) ions (curve A), and i_p the current density observed when the concentration of Ti(III) is C_3. If the oxidation of Ti(III) ions at the passive surface has an order (n) with respect to the Ti(III) concentration, then

$$i_3 = k_3 C_3^n \quad [1]$$

where i_3 is the current density corresponding to the Ti(III) oxidation reaction, and k_3 is a constant (at constant potential and pH). If i_3 simply adds to i_p^*, and i_p^* is not affected by the presence of Ti(III) ions, then

$$i_p = i_p^* + i_3 \quad [2]$$

and, in view of Eq. [1]

$$i_p = i_p^* + k_3 C_3^n \quad [3]$$

According to Eq. [3], a plot of $\log (i_p - i_p^*)$ *vs.* $\log C_3$ should result in a straight line having a slope equal to n. The experimental data shown in Fig. 2 are in complete agreement with Eq. [3], and prove that $n = 1$ *i.e.*

$$i_p = i_p^* + k_3 C_3 \quad [4]$$

The measurement of i_p at constant potential and pH provides a method for determining the concentration of Ti(III) ions in a solution containing both Ti(III) and Ti(IV) ions.

The preceding analysis requires that, under potentiostatic conditions

$$\partial C_3/\partial t = -A_p i_3/\mathbf{F}v \quad [5]$$

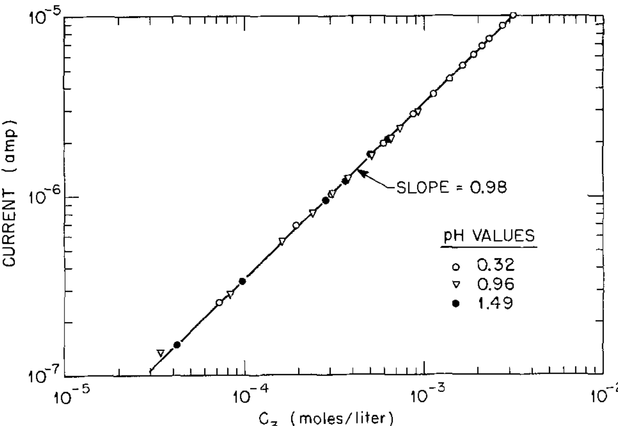

Fig. 2. Oxidation of Ti(III) to Ti(IV) at a passive-state titanium electrode ($E = 0$ mV vs. SCE). Determination of order (n) with respect to Ti(III) concentration (Eq. [3]). Plot of log ($i_p - i_p^*$) vs. log C_3. Data for higher pH values normalized to curve for pH = 0.32 at 1×10^{-6}A.

and

$$\partial C_4/\partial t = (A_p i_3/\mathbf{F}v) + (A_p i_p^*/4\mathbf{F}v) \quad [6]$$

where A_p is the area of the passive electrode, v is the volume of electrolyte, and $\mathbf{F}$ is the Faraday constant. In the section of this paper dealing with the behavior of electrolyte-coupled active and passive electrodes, it will be shown that Eq. [5] and [6] are obeyed, thereby proving the validity of the analysis presented above in the derivation of Eq. [4]. If the increased current density observed at a passive titanium electrode in the presence of Ti(III) ions resulted from a "depassivating" effect (4, 5), Eq. [4] would require the effect to be such that the passive-state dissolution rate of the metal itself be a linear function of C_3. No evidence has been presented to support such a hypothesis. Moreover, Eq. [5] and [6] would not be applicable. The same considerations also lead to the rejection of the hypothesis that Ti(III) ions retard the passive-state dissolution of titanium.

The potential independence of the Ti(III) oxidation reaction at more positive potentials (see curve D) can be attributed to the fact that the reaction rate depends only on the oxide-solution interfacial potential difference, $\Delta\phi_s$. If $d\Delta\phi_{ox}/dE$ is virtually equal to unity, where $\Delta\phi_{ox}$ is the potential difference between the metal and the oxide-solution interface, and E is the electrode potential relative to the reference electrode, then, since $d\Delta\phi_s/dE = 1 - d\Delta\phi_{ox}/dE$, $\Delta\phi_s$ remains essentially independent of E.

If at some point along curve D (Fig. 1), the pH is increased by the addition of concentrated NaOH, the rate of oxidation of Ti(III) ions in solution increases and becomes dependent upon the stirring rate as the reaction passes from activation to mass transport control. A corresponding buildup in film thickness is evidenced by an interference-color sequence in which the initially metallic gray electrode ultimately becomes dark blue. During this process a white precipitate (TiO_2) accumulates in the cell. As the Ti(III) is depleted, the color sequence reverses, and eventually, the electrode returns to its original gray color, and the current density returns to the value given by curve A (Fig. 1). These results are consistent with a pH dependent hydrolysis of Ti(III), with the hydrolysis product being the electrochemically active species. According to Pescok and Fletcher (13), Ti(III) hydrolyzes at low pH (< 3) to form $(TiOH)^{+2}$. If the oxidation of $(TiOH)^{+2}$ to Ti(IV) is the rate-determining step, the corresponding current density may be approximated by $i_3 = \mathbf{F}(D/\delta)k\gamma C_3/[k\gamma + (D/\delta)(1 + a_{(H^+)}/K_h)]$, where k is the rate constant for the rate-determining step, K_h is the hydrolysis constant, γ and D are the activity and diffusion coefficients for Ti(III), and δ is the diffusion layer thickness. Although the hydrolysis of Ti(III) ions in sulfate media has not been examined, the preceding expression is qualitatively consistent with the observed pH effects.

Reduction of Ti(IV) ions in solution to Ti(III) at an active titanium surface.—The upper curve in Fig. 3 is a typical anodic polarization curve for titanium in deoxygenated 1*N* H_2SO_4. At any point along this curve, the net anodic current density (i_a) is given by the algebraic sum of the partial anodic current density corresponding to the oxidation of titanium to Ti(III) ions in solution (i_d), and the partial cathodic current density corresponding to the hydrogen evolution reaction (i_H), *i.e.*, $i_a = i_d + i_H$. It should be noted that, by convention, net and partial anodic (oxidation) current densities are positive, while net and partial cathodic (reduction) current densities are negative. At the open-circuit corrosion potential, E_{corr}, $i_a = 0$ and, consequently, $i_d = |i_H|$. As the potential become increasingly positive relative to E_{corr}, i_d increases and $|i_H|$ decreases. Coulometric-weight loss experiments have shown that at potentials as negative as E_m, $|i_H|$ is negligible compared to i_d ($|i_H| < 0.02\ i_d$ at E_m). The lower curve in Fig. 3 is the anodic polarization curve in 1*N* H_2SO_4 containing

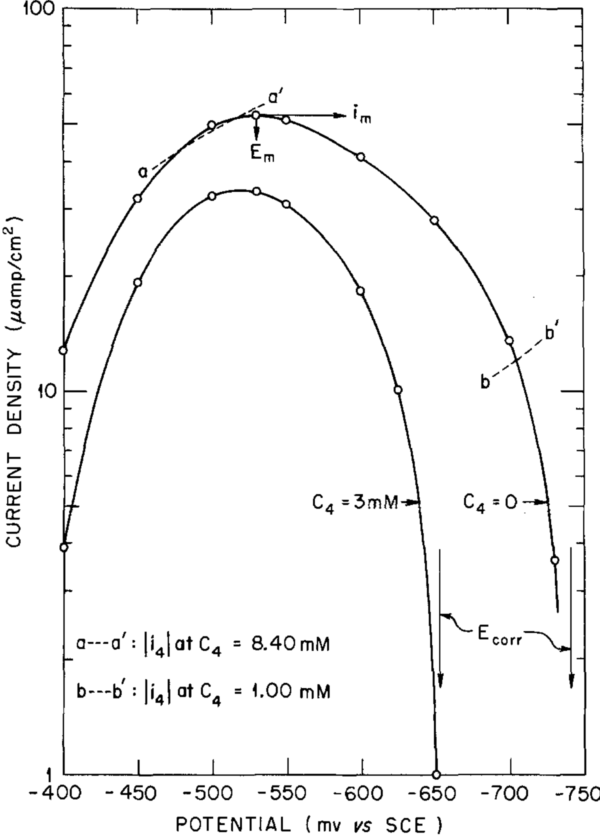

Fig. 3. Effect of Ti(IV) ions on the steady-state anodic polarization of titanium in 1N H_2SO_4. See text for explanation of dashed lines, a- - -a' and b- - -b'.

Ti(IV) ions at a concentration $C_4 = 3$ mM. At first glance, it is easy to see how one might erroneously conclude that Ti(IV) ions inhibit the dissolution of titanium, since the entire anodic polarization curve is lowered by Ti(IV) ions. For example, in a coulometric-weight loss experiment conducted at E_m (−530 mV *vs.* SCE) one might anticipate on the basis of Fig. 3 that, for $C_4 = 3$ mM, the current density calculated from the weight loss data would be 33.3 $\mu A/cm^2$, just as the current density of 52.8 $\mu A/cm^2$ (i_m) was calculated from the weight loss data when $C_4 = 0$. Actually, in either case, the experimentally observed weight loss corresponds to 52.8 $\mu A/cm^2$ (*i.e.*, to i_m).

The effects of Ti(IV) ions on the polarization, dissolution, and open-circuit corrosion behavior of titanium can be explained and completely quantified if one assumes the following: (*i*) Ti(IV) ions are reduced to Ti(III) in the potential region under consideration; (*ii*) Ti(IV) ions have no effect other than to contribute a cathodic current density corresponding to their reduction (i_4), *i.e.*, neither i_d nor i_H are affected by the presence of Ti(IV) ions; (*iii*) it is assumed that Ti(III) ions have no effect on the active-state system (in contrast to their reduction at a passive surface). Then, the net anodic current density is given by Eq. [7]

$$i_a = (i_d + i_H) + i_4 \quad [7]$$

which, in accordance with the second assumption above, becomes

$$i_a = i_a^* + i_4 \quad [8]$$

where $i_a^* = (i_d + i_H)_{C_4=0}$ is given by the upper curve in Fig. 3. The experiments described below prove the validity of the aforementioned assumptions.

A titanium electrode was maintained at E_m in 1N H_2SO_4. The steady-state value of i_a was 54.2 $\mu A/cm^2$. Then, known volumes of a standard solution of Ti(IV) in 1N H_2SO_4 were added to the cell solution and i_a was measured as a function of C_4. The results are shown in Fig. 4. According to Eq. [8], $(\partial i_a/\partial C_4)_E = (\partial i_4/\partial C_4)_E$, and it therefore follows from the results shown in Fig. 4 that

$$i_4 = -k_4C_4 \quad [9]$$

In other words, the reduction of Ti(IV) to Ti(III) is first order in C_4. It should be noted that, unlike the oxidation of Ti(III) in 1N H_2SO_4, the reduction of Ti(IV) ions in 1N H_2SO_4 is, in the absence of stirring, under partial mass-transport control. The partial transport control was totally eliminated in these experiments by use of the magnetic stirrer. Substituting i_4 from Eq. [9] into Eq. [8], one obtains Eq. [10]

$$i_a = i_a^* - k_4C_4 \quad [10]$$

The measurement of i_a at constant potential and pH enables one to determine C_4 in a mixture of Ti(III) and Ti(IV) ions. The addition of Ti(IV) required 2.73 hr. Upon completion of the addition, the electrode was maintained at E_m for another 218.47 hr, during which time samples were periodically removed from the cell and analyzed for Ti(III) via permanganate titration and for total Ti(III + IV) via the hydrogen peroxide spectrophotometric method. The concentration of Ti(IV) was calculated as the difference, $C_4 = C_{Total\,Ti} - C_3$. In Fig. 5, $-i_4$ (calculated by use of Eq. [8]) is plotted against the concentration of Ti(IV) determined by the chemical analyses. The value of k_4 is identical to that determined by the addition experiment (cf. Fig. 4). During the 221.2 hr in which Ti(IV) was present, the titanium electrode exhibited a weight loss of 19.25 mg; this corresponds to a constant dissolution current density (i_d) of 53.24 $\mu A/cm^2$. In the absence of Ti(IV), the dissolution current density values were 54.2 $\mu A/cm^2$ (cf. Fig. 4), 52.8 $\mu A/cm^2$ (cf. Fig. 3, i_m), and 51.6 $\mu A/cm^2$ (used in Fig. 5).

As a consequence of the reduction of Ti(IV) ions to Ti(III) at an active surface, C_4 decreases with time, and C_3 increases. The increase in C_3 is augmented by the dissolution of the metal. In accordance with the

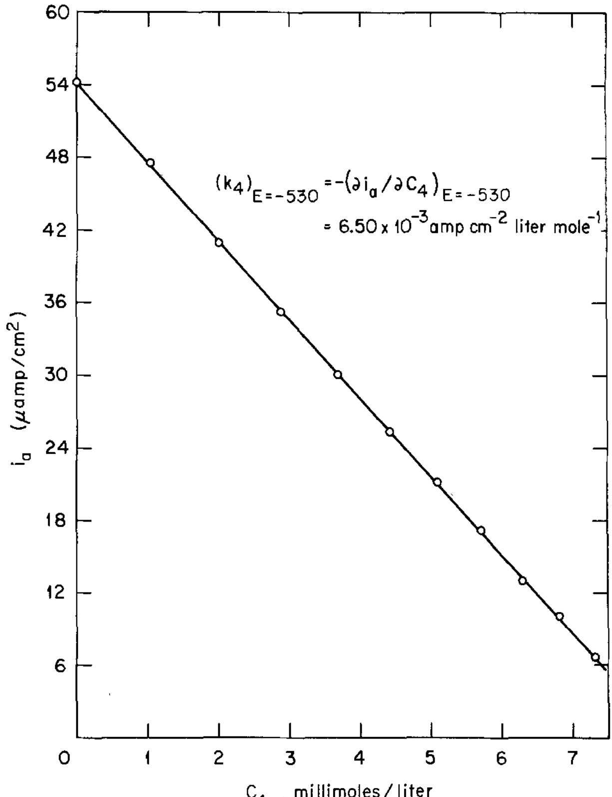

Fig. 4. Effect of Ti(IV) concentration on current density at an active-state titanium electrode ($E = -530$ mV vs. SCE) in 1N H_2SO_4. Direct addition of Ti(IV) ions.

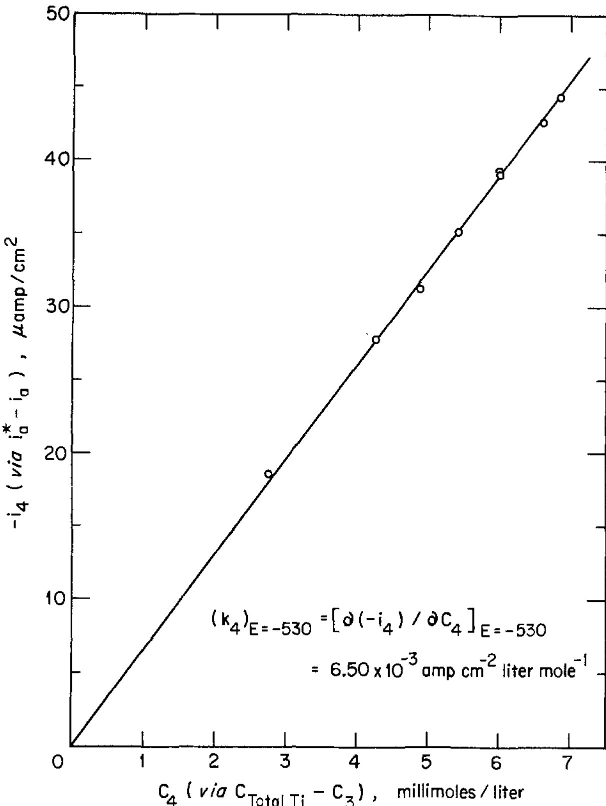

Fig. 5. Reduction of Ti(IV) to Ti(III) at an active-state titanium electrode ($E = -530$ mV vs. SCE) in 1N H_2SO_4. Effect of Ti(IV) concentration on reduction current density (Eq. [9]).

assumptions made at the beginning of this section, one may write

$$dC_4/dt = -A_a|i_4|/\mathbf{F}v \qquad [11]$$

where A_a is the area of the active-state electrode. At constant potential, k_4 is constant. and substitution of $|i_4|$ from Eq. [9] into Eq. [11], followed by integration, leads to Eq. [12]

$$C_4 = C_4^0 \exp(-A_a k_4 t/\mathbf{F}v) \qquad [12]$$

If C_4 from Eq. [12] is substituted into Eq. [10], one obtains the equation describing a potentiostatic current/time transient at an active-state titanium electrode in the presence of Ti(IV)

$$i_a = i_a^* - k_4 C_4^0 \exp(-A_a k_4 t/\mathbf{F}v) \qquad [13]$$

In a typical test of Eq. [13], an electrode ($A_a = 30$ cm^2) was maintained at a constant potential (E_m) in 1N H_2SO_4 until a steady-state value of i_a^* was well established. Then, at time zero, the solution was replaced with 200 ml of 1N H_2SO_4 containing Ti(IV) ions at a concentration of 1.69×10^{-2} moles/liter. The observed value of i_a immediately changed from the net anodic ($i_a^* = 57.8$ μA/cm^2) to a net cathodic value of 50.3 μA/cm^2. Substituting those values in Eq. [13], with $t = 0$, gives $k_4C_4^0 = |i_4^0| = 108.1$ μA/cm^2, and, therefore, $k_4 = 6.40 \times 10^{-3}$ A cm^{-2} liter mole^{-1}. As Ti(IV) is consumed, the observed current density returns to i_a^*. The potentiostatic current density/time transient is shown in Fig. 6. According to Eq. [13], a plot of log ($i_a^* - i_a$) *vs.* t should result in a straight line having an intercept at $t = 0$ equal to log $k_4C_4^0$, *i.e.*, log $|i_4^0|$, and a slope $[\partial \log(i_a^* - i_a)/\partial t]_E = -A_a k_4/2.303\ \mathbf{F}v$. The results are shown in Fig. 7. The value of k_4 calculated from the slope is 6.41×10^{-3} A cm^{-2} liter mole^{-1}, and, from the intercept at $t = 0$, $|i_4^0| = 108$ μA/cm^2. The concentration of Ti(III) during the transient is given by Eq. [14]

$$C_3 = (C_4^0 - C_4) + i_a^* t/3\mathbf{F}v \qquad [14]$$

where use has been made of the fact that, at E_m (-530

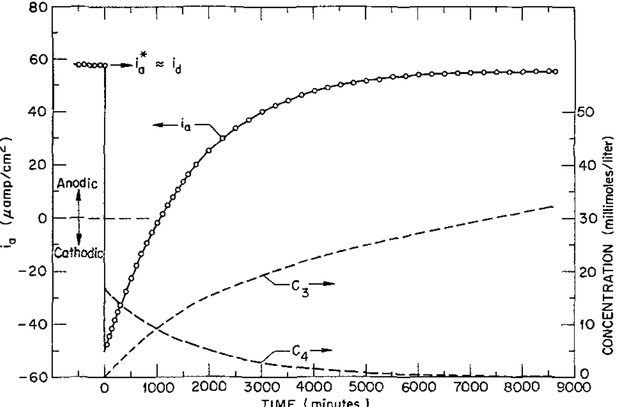

Fig. 6. Potentiostatic current density/time transient at an active-state titanium electrode ($E = -530$ mV vs. SCE) in 1N H_2SO_4. Concentration/time curves calculated via Eq. [12] and [14].

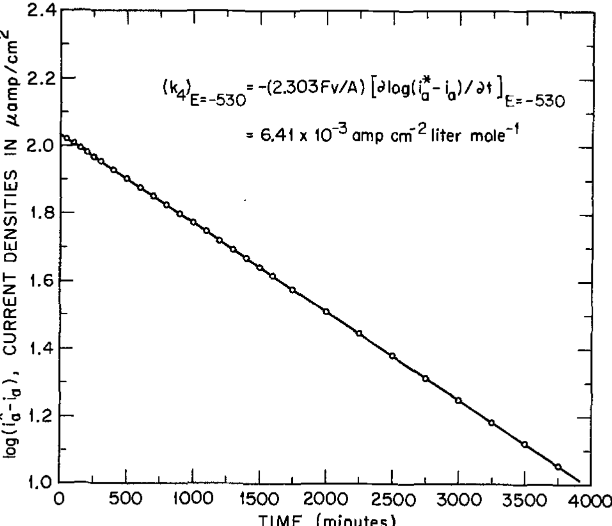

Fig. 7. Test of Eq. [13] using the potentiostatic current density/time transient shown in Fig. 6.

mV *vs.* SCE), $i_d \approx i_a^*$. Equations [12] and [14] were used to calculate C_4 and C_3, respectively, and the results are shown in Fig. 6. The applicability of Eq. [13] over the Ti(III) and Ti(IV) concentration ranges shown in Fig. 6, ranges which embrace those for which i_d has been reported (5) to be a function of both C_3 and C_4, together with the results presented in Fig. 4 and 5, clearly demonstrates that neither ion has any effect on i_d, and confirms the validity of the assumptions listed at the beginning of this section.

It is important to distinguish between the dissolution rate of the metal at a specified potential and the open-circuit dissolution rate (corrosion rate). The former, as shown above, is independent of C_4, but the latter is not. According to Eq. [8], at a specified potential, the difference in the i_a values shown by the upper and lower curves in Fig. 3 is equal to $|i_4|$ and, consequently, the corresponding value of k_4 may be determined by inserting i_4 and the specified concentration of Ti(IV) into Eq. [9]. Then, having thus determined the potential dependence of k_4, Eq. [9] may be used to construct $|i_4|$/potential curves (for example, a-a' and b-b' in Fig. 3) for any value of C_4. At the open-circuit corrosion potential, $i_a = 0$ and, according to Eq. [8], $|i_4| = i_a^*$, *i.e.*, the open-circuit corrosion potential in the presence of Ti(IV) is given by the intersection of the corresponding $|i_4|$/potential curve with the upper curve in Fig. 3. The corrosion potential/C_4 curve calculated in this manner is shown by the dashed curve in Fig. 8. The solid curve (open circles) in Fig. 8 shows the experimentally observed corrosion potential as a

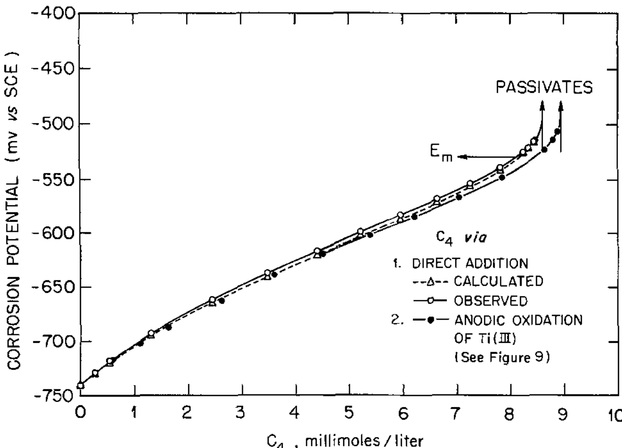

Fig. 8. Effect of Ti(IV) concentration on the open-circuit (corrosion) potential of titanium in 1N H_2SO_4.

function of C_4. The data for the solid curve were obtained by an addition experiment in which known volumes of a standard Ti(IV) solution [Ti(IV) in 1N H_2SO_4] were added to the cell which initially contained a known volume of 1N H_2SO_4. It is important to note that when C_4 reaches the level at which the $|i_4|$/potential curve is tangent to the upper curve in Fig. 3, the titanium should passivate. This was observed to occur at $C_{Ti(IV)} = 8.6$ mM. If k_4 were independent of potential, passivation would have occurred at the concentration for which $|i_4| = i_m$, *i.e.*, at approximately 8.0 mM.

The open-circuit corrosion rate is given by the value of i_d existing at the intersection of the upper curve in Fig. 3 and the $|i_4|$/potential curve. With increasing C_4, the corrosion potential becomes increasingly positive (cf. Fig. 8) and, consequently the corrosion rate increases. Thus, although the dissolution rate of titanium at a specified potential is independent of C_4, the open-circuit dissolution rate (corrosion rate) increases with increasing C_4 to a maximum of i_m, decreases slightly as C_4 increases further to the critical concentration, and, finally, drops sharply as C_4 exceeds the critical concentration and the metal passivates.

Electrolyte-coupled active and passive titanium systems.—The experiments described above involved either an active or a passive titanium electrode. Attention is now directed toward systems in which active and passive electrodes exist simultaneously in the same volume of electrolyte, *i.e.*, toward electrolyte-coupled systems. At the active-state electrode, the metal is oxidized to form Ti(III) ions in solution. At the passive-state electrode, the metal is oxidized to form Ti(IV) ions in solution. In the coupled system, coupling of the active and passive systems is a consequence of the oxidation of Ti(III) ions to Ti(IV) at the passive surface, and the reduction of Ti(IV) ions to Ti(III) at the active surface.

It has been shown (cf. Fig. 8) that the direct addition of Ti(IV) ions can lead to the passivation of an active titanium surface. If Ti(III) ions are oxidized to Ti(IV) at a passive titanium surface (cf. Fig. 2), and if the product of the oxidation reaction is Ti(IV) in solution rather than an electrodeposited TiO_2 oxide, then it should be possible to passivate an active electrode by oxidizing Ti(III) ions to Ti(IV) at a passive electrode sharing the electrolyte with the active electrode. In order to test this conclusion, one electrode ($A_p = 30$ cm^2) was maintained in the passive state ($E = 0.0$ mV *vs.* SCE) in 1N H_2SO_4, while a second electrode, the identical electrode employed in Fig. 3, 4, and 5 ($A_a = 1.58$ cm^2), was left in the active state at open circuit in the same solution. At $t = 0$, the solution was replaced by 200 ml of 1N H_2SO_4 containing Ti(III) ions at an initial concentration of 34.9 mM. The solution was prepared by the method shown in Fig. 6 and, consequently, also contained a small amount of Ti(IV), $C_4^0 = 0.55$ mM. The open-circuit potential of the active electrode was recorded as a function of time, and the result is shown in Fig. 9. The potential of the active electrode became increasingly noble, demonstrating that the oxidation of Ti(III) ions at the passive electrode results in Ti(IV) ions in solution. At a potential slightly more noble than E_m (for reasons explained in the preceding section), the active electrode suddenly passivated ($t = 4514$ min), *i.e.*, the critical concentration of Ti(IV) ions was exceeded. The concentration of Ti(IV) ions in solution was calculated by means of Eq. [15]

$$C_4 = C_4^0 + (A_p/4\mathbf{F}v) \int_0^t i_p^* dt + (A_p/\mathbf{F}v) \int_0^t i_3 dt - (A_a/\mathbf{F}v) \int_0^t |i_4| dt \quad [15]$$

The current at the passive electrode (I_p) was monitored during the experiment, and used to evaluate the first two integrals on the right side of Eq. [15]. The last integral in Eq. [15] arises as a result of the reduction of Ti(IV) ions to Ti(III) at the small active surface. Since $I_p >> |I_4|$, the contribution of the last integral is small, *i.e.*, the last term increases from 0 at $t = 0$ to only 0.833×10^{-3} moles/liter at 4514 min. The evaluation of this integral was accomplished by determining the area under the $|i_4|/t$ curve, the values of $|i_4|$ being read from the upper curve of Fig. 3 for the corresponding potential values shown in Fig. 9. In Fig. 8, the active electrode potentials shown in Fig. 9 are plotted (solid circles) against the corresponding values of C_4. The results obtained in this experiment are in excellent agreement with those obtained by the direct addition of Ti(IV) ions. The critical concentration of Ti(IV) required to passivate the active electrode, $C_4 = 8.94$ mM, compared to $C_4 = 8.6$ mM via direct addition, confirms again the assumptions implicit in Eq. [15]. In particular, the results demonstrate that the current efficiency for the formation of an electrode-posited oxide (TiO_2) via the oxidation of Ti(III) ions

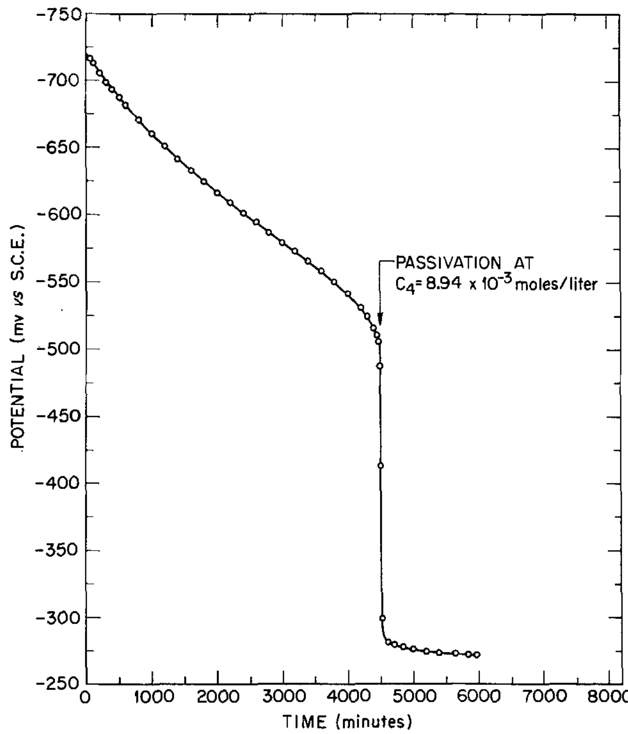

Fig. 9. Ennobling and passivation of an active-state titanium electrode by Ti(IV) ions generated via the oxidation of Ti(III) ions at a passive ($E = 0$ mV vs. SCE) titanium electrode collocated in 1N H_2SO_4. $C_3^0 = 34.9$ mM, $C_4^0 = 0.55$ mM, $A_p = 30$ cm^2, $A_a = 1.58$ cm^2. (Also see Fig. 8.)

at the passive surface is negligible compared to the current efficiency for the formation of Ti(IV) ions in solution. In Fig. 9, the potential of the electrode upon passivation (*i.e.*, $t > 4514$) increases to approximately -275 mV *vs.* SCE, and continues to increase slightly with time. According to Schmets *et al.* (14), the standard potential for the Ti^{+3}/TiO^{+2} couple is approximately 0.10V *vs.* SHE. Using this value, together with the values of C_3 and C_4 existing at $t = 4514$ min, 26.35 and 8.94 m*M*, respectively, one would conclude that if the potential of the titanium electrode upon passivation were determined solely by this couple, the potential would be -208 mV *vs.* SCE. Since the current due to the metal dissolution reaction must be added to that due to the Ti(III) oxidation reaction, the Ti^{+3}/TiO^{+2} couple is not solely responsible for the open-circuit potential, and as observed (-275 mV *vs.* SCE), one should expect a slightly more negative value than -208 mV *vs.* SCE.

In the experiment just described, a potentiostat was used to maintain the passive electrode at a constant potential while the active electrode was left at open circuit. In the experiments which follow, a dual potentiostat was employed to maintain one electrode at a constant potential in the active state and a second electrode at a constant potential in the passive state. The time derivatives of the Ti(III) and Ti(IV) concentrations are given by Eq. [16] and [17]

$$dC_3/dt = (A_a i_d/3\mathbf{F}v) - (A_a i_4/\mathbf{F}v) - (A_p i_3/\mathbf{F}v) \quad [16]$$

$$dC_4/dt = (A_a i_4/\mathbf{F}v) + (A_p i_3/\mathbf{F}v) + (A_p i_p^*/4\mathbf{F}v) \quad [17]$$

If i_3 and i_4 are expressed in terms of C_3 and C_4 via Eq. [1] and [9], respectively, Eq. [16] and [17] may be rewritten as follows

$$dC_3/dt = (A_a i_d/3\mathbf{F}v) + (A_a k_4 C_4/\mathbf{F}v) - (A_p k_3 C_3/\mathbf{F}v) \quad [18]$$

$$dC_4/dt = (A_p i_p^*/4\mathbf{F}v) - (A_a k_4 C_4/\mathbf{F}v) + (A_p k_3 C_3/\mathbf{F}v) \quad [19]$$

Letting $C_T = (C_3 + C_4)$, and adding Eq. [18] and [19], one obtains Eq. [20]

$$dC_T/dt = (1/\mathbf{F}v)(A_a i_d/3 + A_p i_p^*/4) \quad [20]$$

Under the prescribed potentiostatic conditions, i_d, i_p^*, k_3, and k_4 are all constant, and, consequently, Eq. [18]-[20] may be solved to obtain C_3, C_4, and C_T as functions of time

$$C_3 = C_3^0 + \alpha[1 - \exp(-Kt/\mathbf{F}v)] + A_a k_4 \beta t \quad [21]$$

$$C_4 = C_4^0 - \alpha[1 - \exp(-Kt/\mathbf{F}v)] + A_p k_3 \beta t \quad [22]$$

$$C_T = C_T^0 + K\beta t \quad [23]$$

where, in order to simplify writing, α, β, and K represent the following

$$\alpha = (1/K)[(A_p k_3 A_a i_d/3K) + (A_a k_4 C_4^0) - (A_p k_3 C_3^0) - (A_a k_4 A_p i_p^*/4K)] \quad [24]$$

$$\beta = (1/K\mathbf{F}v)[(A_a i_d/3) + (A_p i_p^*/4)] \quad [25]$$

$$K = (A_p k_3 + A_a k_4) \quad [26]$$

If C_3 and C_4 given by Eq. [21] and [22] are substituted into Eq. [4] and [10], respectively, one obtains equations describing the current density-time transients at the passive and active electrodes

$$i_p = i_p^* + k_3 C_3^0 + k_3 \alpha[1 - \exp(-Kt/\mathbf{F}v)] + k_3 A_a k_4 \beta t \quad [27]$$

$$i_a = i_d - k_4 C_4^0 + k_4 \alpha[1 - \exp(-Kt/\mathbf{F}v)] - A_p k_3 k_4 \beta t \quad [28]$$

If $1 >> Kt/\mathbf{F}v$, the exponential term in Eq. [27] may be expanded to yield a limiting expression for i_p

$$(i_p)_{t \to 0} \to i_p^0 + (k_3/\mathbf{F}v)[A_a k_4 C_4^0 - A_p k_3 C_3^0 + (A_a i_d/3)]t \quad [29]$$

i.e., for small values of t, i_p is a linear function of time. Moreover, if $C_4^0 = C_3^0 = 0$ or, more generally, if $(A_a i_d/3) >> (A_a k_4 C_4^0 - A_p k_3 C_3^0)$, the slope of the straight line obtained from a plot of i_p *vs.* t is simply $A_a k_3 i_d/3\mathbf{F}v$, *i.e.*, from the measured value of the slope, one may calculate the dissolution rate of the active-state titanium electrode. Since the slope is proportional to i_d, a change in i_d produced by a change in the potential of the active-state electrode results in an immediate change in the slope $(\partial i_p/\partial t)_E$. Typical experimental results are shown in Fig. 10. The passive electrode was maintained at 0 mV *vs.* SCE in 250 ml of 1*N* H_2SO_4. From 0 to 1600 min, the active electrode was set at E_m (-530 mV *vs.* SCE). Utilizing the fact that at E_m, $i_a = 5.38 \times 10^{-5}$ A/cm^2 $\simeq i_d$, k_3 may be calculated from the slope of the straight line and the measured value of i_a, *i.e.*, $k_3 = 3\mathbf{F}v(\partial i_p/\partial t)/A_a i_a = 1.17 \times 10^{-3}$ A cm^{-2} liter mole^{-1}. At $t = 1600$ min, the potential of the active-state electrode was changed from E_m to -730 mV *vs.* SCE (approximately equal to the open-circuit corrosion potential), and maintained constant from 1600 to 3500 min. If S_1 is the slope of the initial linear segment ($t = 0$ to $t = 1600$), and S_2 is the slope of the second linear segment ($t = 1600$ to $t = 3500$), then $(i_d)_{E=-730} = (i_d)_{E=-530}(S_2/S_1) = (i_d)_{E=-530}/2.53$, *i.e.*, i_d at $E = -730$ mV *vs.* SCE $= 2.13 \times 10^{-5}$ A/cm^2. In addition to confirming the validity of Eq. [29], the results shown in Fig. 10 demonstrate a novel, and very sensitive method for measuring or continuously monitoring dissolution or corrosion rates. It should be noted that in this experiment, the dissolution rate of the active specimen at -730 mV *vs.* SCE, for example, amounted to only 32.1 μg/hr, and only a few hours are needed to determine the slope with sufficient accuracy.

A general test of Eq. [27] and [28] is provided by the data shown in Fig. 11. According to Eq. [27] and [28],

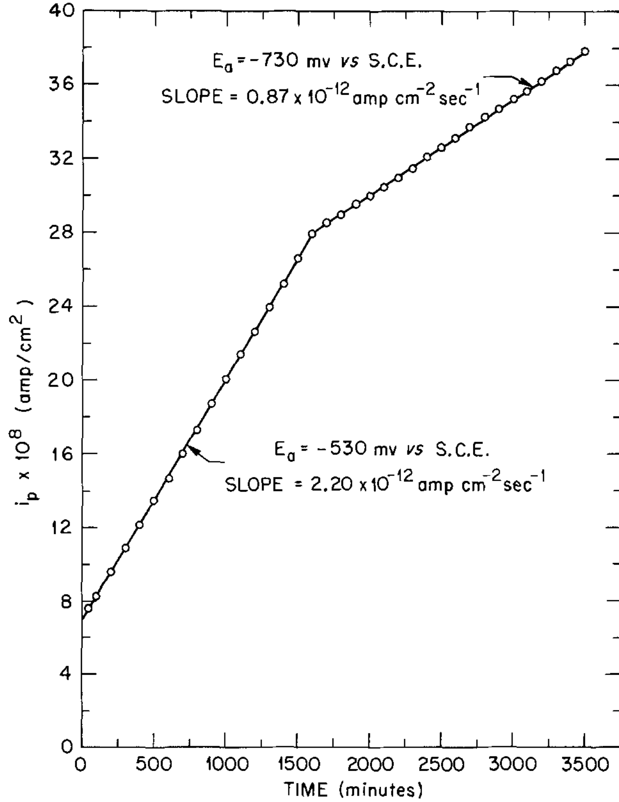

Fig. 10. Determination of dissolution rates of active-state titanium via monitoring the current density at a passive titanium electrode ($E = 0$ mV vs. SCE) collocated in 1N H_2SO_4. $C_3^0 = C_4^0 = 0$. $A_a = A_p = 2.53$ cm^2. Application of Eq. [29].

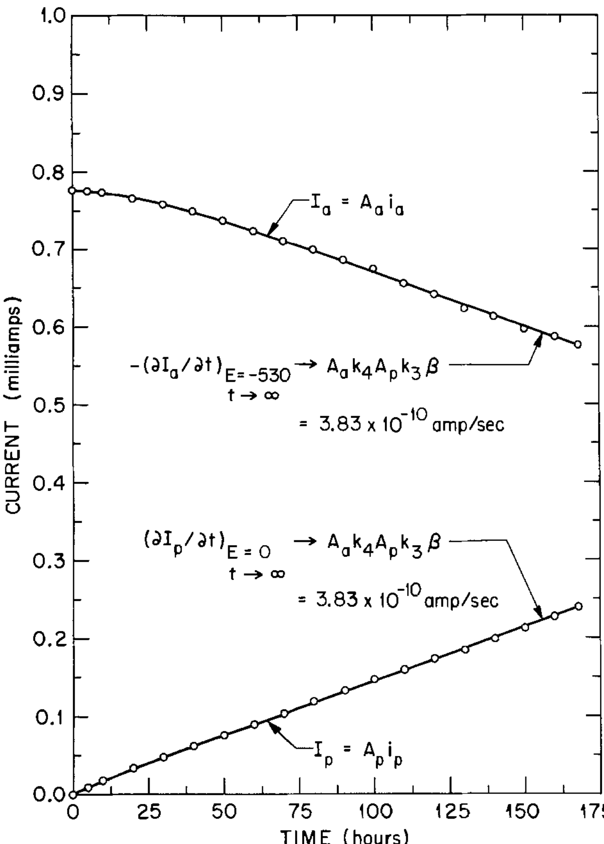

Fig. 11. Current/time transients at electrolyte (1N H_2SO_4)-coupled active ($E = -530$ mV vs. SCE) and passive ($E = 0$ mV vs. SCE) titanium electrodes. $C_3^0 = C_4^0 = 0$. $A_p = A_a = 15$ cm^2, $v = 100$ ml. Test of Eq. [27] and [28].

if currents ($i_a = A_a i_a$ and $I_p = A_p i_p$) rather than current densities are plotted against time, the slopes, $-(\partial I_a/\partial t)_{E=-530}$ and $(\partial I_p/\partial t)_{E=0}$, should approach the same value, $A_a k_4 A_p k_3 \beta$, as $t \rightarrow \infty$. This is confirmed by the results shown in Fig. 11. In this particular experiment, the measured values of $A_p i_p$ and $A_a i_d$ (recalling that, at E_m, $i_a \approx i_d$) were 1.53×10^{-6} A and 7.76×10^{-4} A, respectively. Also, $C_3^0 = C_4^0 = 0$, $A_p = A_a = 15$ cm^2, and $v = 100$ ml. The preceding data permits β to be evaluated via Eq. [25]. From $(\partial i_p/\partial t)_{E=0}$ as $t \rightarrow 0$, k_3 may be evaluated as discussed in connection with Fig. 10. Then, having evaluated β and k_3, one may evaluate k_4 from the aforementioned slope, $A_a k_4 A_p k_3 \beta$. The values found for k_3 and k_4 were 1.12×10^{-3} and 6.31×10^{-3} A cm^{-2} liter $mole^{-1}$, respectively.

The continuous decrease in i_a shown in Fig. 11 is a consequence of the increase in C_4. Given sufficient time, the critical concentration required to passivate an active-state titanium surface would be attained. In other words, even with $C_3^0 = C_4^0 = 0$, an electrolyte-coupled active and passive titanium system can generate a concentration of Ti(IV) ions in the electrolyte phase sufficient to bring about the passivation of the active surface. Using reasonable values for the quantities appearing in Eq. [22], [24], [25], and [26], one may easily show that, for very small volumes of electrolytes the time required to passivate an active surface may be reduced to a few minutes. With regard to localized corrosion (crevice, pitting, etc.), these observations suggest the following situation. As Ti(III) ions egress from the active-state base of a pit or crevice (10, 15-17), they encounter condition under which they are known to be oxidized to Ti(IV) ions in solution (*i.e.*, a passive surface). The resultant Ti(IV) ions are transported back to the base of the pit where they encounter conditions under which they are known to be reduced to Ti(III) ions (*i.e.*, an active surface), and to accelerate the open-circuit dissolution rate of the active-state base. Thus, Ti(IV) ions would have a deleterious effect on pitting or crevice corrosion, but only if the concentration of Ti(IV) remained below the critical concentraton required to passivate the active surface. If the critical concentration is attained, the metal passivates and pitting ceases. This phenomenon of spontaneous self-healing has long been recognized in pitting and crevice corrosion (10). Although one normally associates localized corrosion phenomena with solutions other than the 1N H_2SO_4 (for example, with halide solutions), and such systems involve nonuniform concentrations within the constrained geometry, the electrochemical factors described above remain operative, and the basic rationale provided for the mechanism of self-healing should remain applicable.

Summary

In the active state, titanium is oxidized to form Ti(III) ions in solution. At an active titanium surface, Ti(IV) ions are reduced to Ti(III), and the reduction reaction is first order with respect to the concentration of Ti(IV) ions. At a constant potential, neither the active-state dissolution rate of the metal nor the rate of the hydrogen evolution reaction are affected by Ti(III) or Ti(IV) ions. However, the current density corresponding to the reduction of Ti(IV) ions adds algebraically to the current densities of the metal dissolution and hydrogen evolution reactions and, as a consequence, the open-circuit (corrosion) potential of the active-state titanium becomes increasingly positive (noble) as the concentration of Ti(IV) increases. When the concentration of Ti(IV) exceeds a certain critical value, the active-state metal passivates.

In the passive state, titanium is oxidized to form the passive film (TiO_2) and Ti(IV) ions in solution. At a passive titanium surface, Ti(III) ions are oxidized to Ti(IV), and the oxidation reaction is first order with respect to the concentration of Ti(III) ions. The current density corresponding to the oxidation of Ti(III) ions simply adds to the current density corresponding to the dissolution of the passive metal. The latter is not affected by the presence of Ti(III) or Ti(IV) ions.

When active and passive titanium surfaces are collocated in the same body of electrolyte, coupling of the active and passive systems occurs as a result of the oxidation of Ti(III) ions at the passive surface and the reduction of Ti(IV) ions at the active surface. Such electrolyte-coupled active-passive systems are capable of generating the critical concentration of Ti(IV) ions required to passivate the active surface. This "self-healing" phenomenon is of interest in relation to localized corrosion. In addition, under the appropriate conditions, dissolution rates of titanium in the active-state (open-circuit or polarized) may be determined by monitoring the current at the passive sensor electrode in an electrolyte-coupled active-passive system.

On the Initiation of Crevice Corrosion on Stainless Steel

Göran S. Eklund*

Swedish Institute for Metal Research, Stockholm, Sweden

ABSTRACT

The site of crevice corrosion initiation on stainless steels has been investigated. It has been found that the initiation takes place at sulfide inclusions situated at the junction between a covering layer and the free metal surface with a portion of the inclusion covered and the rest exposed to the solution. A mechanism is suggested based on electrochemical dissolution of the sulfide inclusions.

Crevice corrosion is one of the most common, severe, and difficult to control forms of corrosion experienced with stainless steels. Numerous investigations have been carried out on the subject and a number of crevice corrosion mechanisms have been proposed (1-4, 6). The theoretical interpretation has usually been based on some sort of concentration cell and the explanation of the initiation is in most cases deduced from results obtained on specimens where the attack is already established and in which a low pH, low oxygen concentration in the crevice, etc. have been observed (1, 5, 6). Very few investigations deal with the initiation process itself and the possible sites for initiation.

Several methods for testing crevice corrosion are described in the literature (1, 7-10), but the majority of these can only provide qualitative data. Some workers have used special experimental arrangements in order to obtain more precise data on the corrosion rate and the electrochemical behavior (1, 11). Apparently none of the methods described are suitable for detailed visual studies of the initiating sites at high magnifications.

In this work, crevice corrosion has been studied by interrupting the process at an early stage of development and the corroded areas have been observed by scanning electron microscope (SEM) and analyzed *in situ*. Based on these observations a crevice corrosion initiation mechanism is suggested.

Experimental

The cell used for the experiments was made of transparent perspex and is shown in Fig. 1. The samples were 2 mm thick disks, 25 mm in diameter. After polishing to 1 μm diamond, they were covered with edge protecting lacquer around the circumference. Special care was taken to avoid crevice development at the junction between the lacquer and the free metal surface. A suitable seal around the lacquered edge was effected via an O-ring and clamping arrangement; around 2 cm² of free surface was exposed to the corrosion solution (Fig. 1). On the free metal surface perpendicular to the milling direction, streaks of "Lacomit" were applied; this is known to have poor adherence and the aim was that crevice corrosion attack took place preferentially under this lacquer. The solution used in all experiments was 0.1M NaCl. The initial attack was developed by a galvanostatic technique using current densities of 1, 0.1, and 0.01 mA/cm² giving charge densities of 10, 20, and 40 mAs/cm² over the surface.

After the test the samples were washed with water and alcohol, and then dried in a warm airstream. The washing was carried out carefully to avoid loss of corrosion products. A thin layer of gold was vaporized

onto the surface before observations in the microscope. In order to examine the attack under the Lacomit more closely, the lacquer was removed by acetone on some of the samples.

The materials used were hot-rolled and annealed 18-8 steels with three different levels of sulfur. The three different alloys were made from the same melt via separate additions of sulfur. Disks were punched out from the as-received strips, and the disks were annealed at 1000°C for 1 hr and quenched in water. The metallurgical structure was fully austenitic after this heat-treatment.

The compositions of the materials are given in Table I.

Results

In the optical micrography, Fig. 2, where the Lacomit is still covering the metal surface, the crevice attack has started at a single point and then spread under the lacquer in a butterfly fashion. In the vicinity of the initiation point the lacquer has become detached from the metal surface and bent upward, thus widening the crevice and giving rise to bend contours. This behavior was typical for the crevice corrosion attack observed on all the materials investigated irrespective of whether the mouth of the crevice was facing up or down.

A closer examination of the mouth of a crevice, Fig. 3, reveals that products in the form of rods and spheres have been formed and these are probably inclusions or corrosion products transported to the mouth by a flow of liquid from the interior. By careful removal of the lacquer with acetone, wiping the surface lightly with cotton wool, and then examining the same area, it was possible to establish that the light rods and spheres were in fact corrosion products covering inclusions embedded in the metal matrix. Compare Fig. 3 and 4 showing the same area before and after the removal of the lacquer. X-ray analysis (EDAX) of the inclusions showed that they were manganese sulfides with iron and chromium in solid solution.

In all the alloys investigated, crevice corrosion seems to have started at sulfide inclusions at the junction between the lacquer and the free metal surface, with a portion of each inclusion covered by the lacquer and the rest exposed to the solution. Figure 5 is an example of such an inclusion partly covered with the lacquer. The inclusion has started to dissolve preferentially along the sulfide-metal interface giving rise to a small groove. The dissolution and formation of corrosion products proceeds underneath the lacquer bending it upward as shown in Fig. 6 where the reaction products still remain on the sulfide surface. The frequency of attack increases with the current density, but, on the other hand, the amount of charge influences only the severity of the attacks and results in a lace-like pattern at the mouth of the crevices at the highest values, Fig. 7.

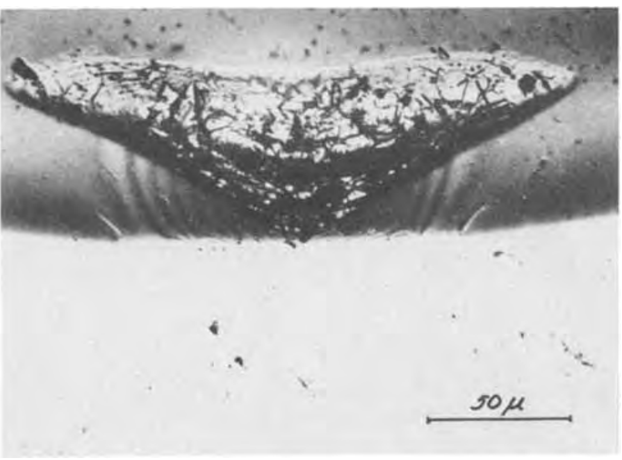

Fig. 2. Crevice corrosion attack under the lacquer covering upper half of picture; lower, brighter part is exposed metal. Notice bend contours on the lacquer around the initiation point.

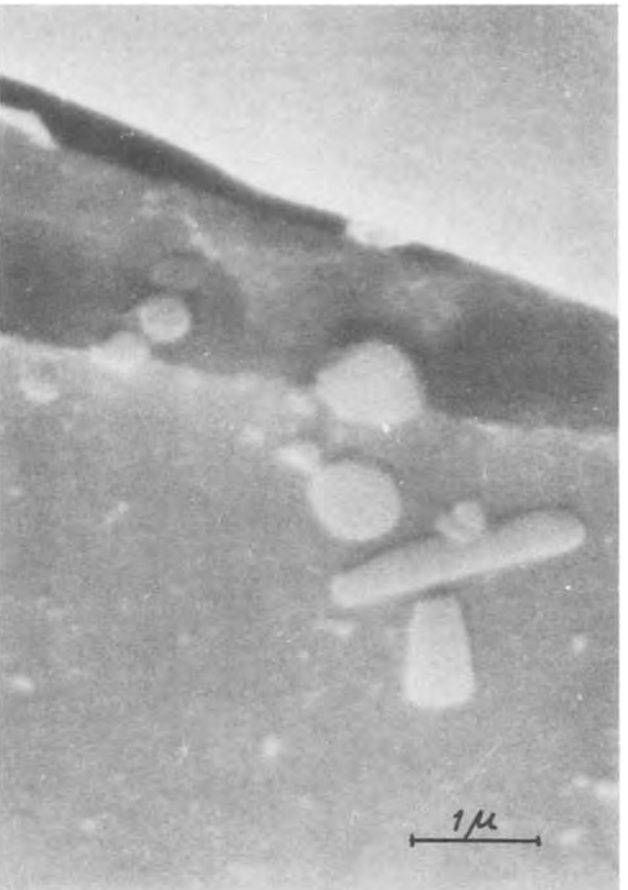

Fig. 3. Corrosion products around the initiation point; the light rods and spheres are manganese sulfides covered with reaction products.

Discussion

As mentioned above, many initiation mechanisms have been suggested but most, however, are based on differences in metal ion or oxygen concentration between the crevice and its surroundings. Consequently the term concentration cell corrosion has been used to describe this form of attack.

Studies by Schafer *et al.* (3) have shown that metal ion and oxygen concentration differences do indeed exist in a crevice, but according to Fontana and Greene (4) this is not the basic reason for the attack. They formulated a mechanism in which metal dissolution as well as oxygen reduction takes place all over the surface including the crevice. The solution in the crevice will soon become impoverished in oxygen and the potential difference thus established between the crevice and the outer surface effects a migration of the chloride ions into the former so as to conserve the charge balance. This explains the high chloride and metal ion concentration and the low oxygen concentration observed in the crevice. The metal chlorides formed in the crevice can now hydrolyze giving a low pH and making it possible for the reaction to proceed.

The results of this investigation however suggest another mechanism. It is shown that the crevice at-

Fig. 4. Same area as in Fig. 3 after removal of the lacquer and wiping the surface with cotton wool. The dark areas represent manganese sulfides free from reaction products.

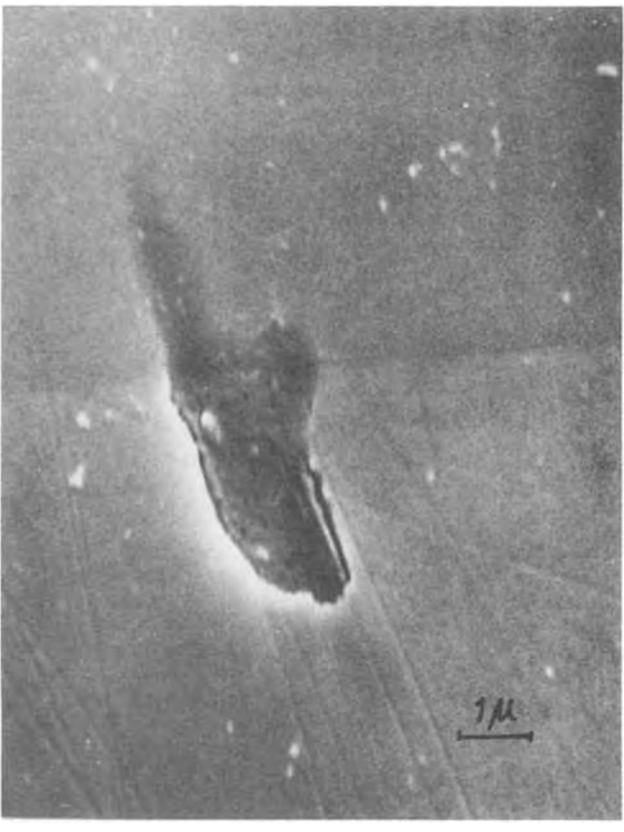

Fig. 5. Inclusion situated at the junction between the lacquer and the free metal surface. Part of the inclusion faintly visible under the lacquer. The inclusion is preferentially dissolved along the sulfide-metal interface.

tacks have started at certain points on the boundary between the lacquer and the free metal surface and then spread underneath the lacquer. Careful examination has proven that the starting points in all cases were sulfide inclusions. It can therefore be assumed that the inclusions take an active part in the initial crevice corrosion reaction.

It is known that sulfide inclusions are to a limited extent electronic conductors and can be polarized to the potential of a passive steel surface (16). At this potential the sulfides are not thermodynamically stable and tend to dissolve. The comparatively low electronic conductivity causing the dissolution to take place preferentially along the metal-sulfide interface, hence resulting in small grooves, is shown in Fig. 5.

Because the sulfides are formed in the melt when the steel solidifies, no oxide layer will exist at the interface between sulfides and metal. Hence, when the sulfides dissolve, a fresh metal surface is exposed to the environment. The solution around this microarea so exposed will be different from that of the bulk and contain hydrogen sulfide and its protolysed products as well as metal ions emanating from the sulfide. Apart from Mn, the metal ions comprise iron and chromium which undergo both complex reactions and hydrolysis with residual oxygen, water, and migrating chloride ions thus creating a low *p*H locally (12).

Eventually, the solution about the microarea will reach a composition such that a passivation of the continuously uncovered metal surface can no longer take place. Metal ions from the matrix enter the solution and the potential drops drastically staying at this low level as long as the metal dissolves.

Now, if the geometrical conditions around the microarea make replenishment of the solution difficult, the hydrolysis of the metal ions from the matrix can maintain the attack. On the other hand, if the solution is diluted, the concentration of hydrogen sulfide and hydrogen ions will decrease and the metal passivates.

The initiation and passivation take place quite a number of times on the metal surface. The sudden potential drops observed during galvanostatic tests at low current densities (17) and the current peaks appearing in potentiostatic tests near the pitting potential (18) can be interpreted as attempts of pitting or crevice corrosion at sulfide inclusions.

An obvious question is why do all inclusions not behave in the above manner? The answer lies in the local differences in sulfide composition resulting in different electronic conductivities which is turn influence the dissolution properties and the ability to generate acid solutions.

Since the composition of the inclusion determines the current density or potential at which its dissolution begins, it is obvious that the higher the applied potential or current, the greater the number of inclusions that are activated and, consequently, the frequency of attack can be increased.

Because dilution of the solution is difficult in narrow crevices, *e.g.*, under debris etc. it is clear that corrosion takes place more easily at partly covered inclusions, than on the free metal surface.

It is well known that the pitting and crevice corrosion potential decreases with increasing sulfur content in the steel (19). There is, however, no reason to believe that the composition and the reactivity of the passive layer should change as a result of small variations in the sulfur content. The mechanism proposed by Fontana and Greene (4) whereby the passive layer dissolves and reduces oxygen in the crevices, hence initiating crevice corrosion, thus seems unlikely.

On the other hand, the composition of the sulfide inclusions should change with the sulfur content of the steel because they are formed from residual liquid in the ingot with different degrees of segregation. Now,

Fig. 6. Sulfide covered with reaction products. The reaction has proceeded under the lacquer causing detachment from the metal surface.

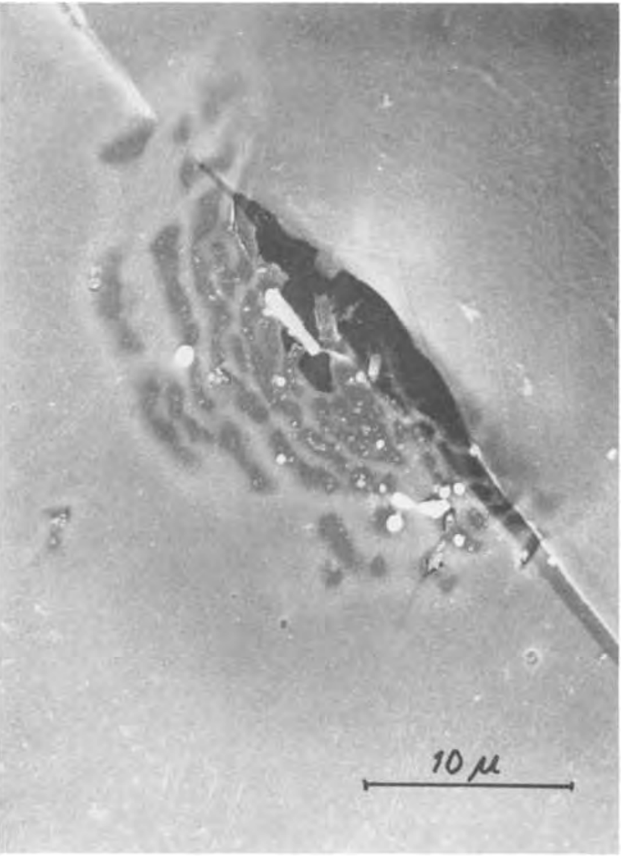

Fig. 7. Mouth of crevice corrosion attack. The reaction is well developed and a characteristic lacelike pattern of corrosion attack is evident.

the kinetics of sulfide dissolution depends on their composition and so, therefore, will the time available for dilution of the solution by diffusion into the region immediately surrounding the microarea; hence, as the rate of dissolution increases, the probability that the uncovered metal surface will become passivated is reduced.

In summary, the above reasoning indicates that the prime cause of crevice corrosion is an electrochemical dissolution of the sulfide inclusions with the formation of an acid solution and an uncovering of virgin metal surface. Dilution of this acid solution is more difficult in crevices and so the attack can propagate in these regions. It must, however, be borne in mind that the proposed mechanism is not limited to sulfides only but can also be applied to other inclusions provided they are capable of being polarized and releasing metal ions which can hydrolyze.

A Study of the Anodic Oxide of Vanadium under Anodic and Cathodic Conditions

J. C. Clayton and D. J. De Smet*

Department of Physics and Astronomy, The University of Alabama, University, Alabama 35486

ABSTRACT

The anodic oxide film formed on vanadium in an electrolyte of acetic acid, sodium borate, and a small quantity of water has been studied using ellipsometric and electrical measurements. These studies indicate that when a cathodic current is applied to a vanadium electrode upon which an anodic oxide film has been grown conversion of the anodic oxide occurs, and a new species or complex is formed on the electrode surface. Re-application of an anodic current converts the film back to its original state. Both the refractive index and the solubility of the cathodically converted film differ from the anodic film. In particular, the cathodically converted film is much less soluble in water than is the anodic film. Ellipsometric data are consistent with a model in which the conversion of the film begins at the oxide/electrolyte interface and proceeds toward the metal. Other possible models are given for comparison purposes.

Several studies of the anodic oxidation of vanadium have appeared in the literature (1-4) subsequent to the first work on this material by Keil and Salomon (5). These authors were able to oxidize vanadium anodically by employing an almost totally nonaqueous electrolyte consisting of acetic acid, sodium borate, and a small amount of water. This electrolyte makes manageable the problem of dissolution of the anodic oxide of vanadium in water and in electrolytes containing large quantities of water.

In the course of our experimental work on the anodic oxidation of vanadium, for some reason that we cannot now recall, we applied a cathodic current to a sample covered with an anodic film. When this was done, we noticed that the film changed its interference color slightly and then gas evolution occurred. Upon removing the sample from the electrolyte and attempting to rinse the film off of the vanadium surface with water, our standard operating procedure, we found this film to be insoluble. This led us to the hypothesis that a cathodic current caused the film to convert to a different form. The purpose of this paper is to examine this hypothesis in some detail and to present a model for the conversion process that accounts for the experimental data.

Ellipsometry has become one of the standard techniques for the study of thin films. This is due in part to the fact that, provided certain assumptions are met, ellipsometry allows the determination of both the thickness and index of refraction of a thin film. Employing an automatic nulling ellipsometer also allows us to monitor, *in situ,* changes which are occurring on the electrode surface. Others have employed ellipsometry to monitor changes in the structure of thin films as these films convert from one form to another; most notably Hopper and Ord (6) concerning the conversion of nickel hydroxide films and Dell'Oca (7) on the conversion of silicon nitride to silicon dioxide.

Experimental

The samples used in our experiments were made from 99.98% pure vanadium rods, ¼ in. in diameter, obtained from Materials Research Corporation. The samples were cut to a length of 0.7 cm and drilled along the axis of the cylinder. A small flat area was ground on the side of the cylindrical surface for ellipsometric measurements. The flat area was hand polished using a stainless steel block and various grades of lapping compound. The final mechanical polish was done with jeweler's rouge. The sample was then mounted between Teflon washers in a sample holder similar to that described by Feller and Osterwald (8) and electropolished for approximately 2 min at a potential of 16V in a mixture of 75% ethanol and 25% sulfuric acid at room temperature (9). This electropolish gave good specular reflection from the flat surface of the sample.

Before each experiment the sample was washed in distilled water, dried, anodically oxidized to a potential of 50V, and rinsed again in water to remove the oxide that was formed. This procedure was repeated several times to insure reproducibility. The sample was then transferred to the ellipsometer cell, and an oxide was formed galvanostatically to a preset potential. The sample was held potentiostatically at this potential for some time to measure the combined leakage and dissolution current. If after 30 min this current was less than 120 $\mu A/cm^2$, the oxide was dissolved in distilled water, the sample replaced in the ellipsometer cell, and an experiment was begun.

The cell used was a hollow equilateral triangular prism with windows mounted so that ellipsometer measurements could be taken at an angle of incidence of 60°. This cell was fitted with standard taper joints for the sample, a coiled platinum wire cathode, a platinum wire reference electrode, and a gas dispersion tube. All experiments were done at room temperature.

The electrolyte used was similar to that first reported by Keil and Salomon (5) and appears to be the only electrolyte that will sustain the formation of a vanadium oxide film. Since the anodic oxide of vanadium dissolves in water and also, more slowly, in this electrolyte which contains a small amount of water, we chose to modify the recipe of Keil and Salomon by reducing the water content of the solution. The solution used contained 19g of $Na_2B_4O_7 \cdot 10\ H_2O$, 10.6 ml of water, and enough acetic acid to make 1.0 liter of solution. This electrolyte has a higher resistivity than the usual electrolyte used for the anodic oxidation of vanadium, but it reduces the effects of oxide dissolution. The resistivity of the solution was not high enough to influence the uniformity of thickness of the oxide over the electrode surface for the current densities used here. The solution was bubbled with argon both prior to and during the experiments. The index of refraction of this solution is 1.3707 at a wavelength of 6328Å.

The electrical circuitry used is identical to that described by De Smet and Hopper (10). Voltage *vs.* time curves were recorded using a Hewlett-Packard Model 7004 x-ray recorder. All potentials are mea-

* Electrochemical Society Active Member.
Key words: ellipsometry, conversion, film, refractive index.

sured relative to the platinum wire reference electrode and are uncorrected for factors such as *IR* drop across the electrolyte. Current densities were calculated by dividing the applied current by the macroscopic surface area of the sample.

The automatic ellipsometer used in these experiments was constructed in this laboratory based on a design described by Ord (11-12). The instrument operates by alternately locating the null settings of the polarizer and analyzer with typical nulling times of about 4 sec for the experiments presented here. The polarizer and analyzer are Glan-Thompson prisms driven in 0.01° steps by stepping motors. The compensator is a quarter-wave plate with its fast axis fixed at −45° situated between the polarizer and the sample. The light source is a low-powered HeNe laser which operates at a wavelength of 6328Å. A 1P21 photomultiplier tube is used as the detector. Polarizer and analyzer settings and the potential of the electrode were recorded on a digital printer at the end of each nulling sequence. The ellipsometric data are reported in this work directly as the polarizer and analyzer settings at null.

Results

We begin by recalling the behavior of a vanadium electrode under constant-current conditions. Vanadium differs in some respects from most of the other valve metals in that there is a transition region which occurs prior to the commencement of oxide film growth, and in this transition region vanadium ions go into solution (4). In fact, growth of the anodic oxide could not be initiated using the current densities we were interested in, consequently a current density of 1.5 mA/cm^2 was used to initiate growth. Upon attaining steady-state growth conditions, the current density was lowered to 275 $\mu A/cm^2$.

Figure 1 shows the ellipsometric data for steady-state growth with an applied current density of 275 $\mu A/cm^2$. Before the current was applied the ellipsometer null settings give the starting point. As the film grew, the ellipsometric data traced out a curve in a clockwise direction. The null settings of the ellipsometer for the first loop of data are shown in this figure as open circles. Since during the experiment our ellipsometer recorded more than 1200 data points for this loop, only representative data points are plotted. The gap between the clean surface point and the next data point represents the transition region where oxide growth was initiated; we did not attempt to record data in this region.

As growth proceeds, this first loop closes upon itself, approximately, and a second loop, represented by a few squares, is traced out. The second loop does not exactly coincide with the first loop because during growth the vanadium oxide film exhibits a small amount of field-induced optical anisotropy similar to that reported for the anodic oxides of tantalum and niobium (13-15). This effect will be treated in more detail in another study and is small enough that it can be ignored here.

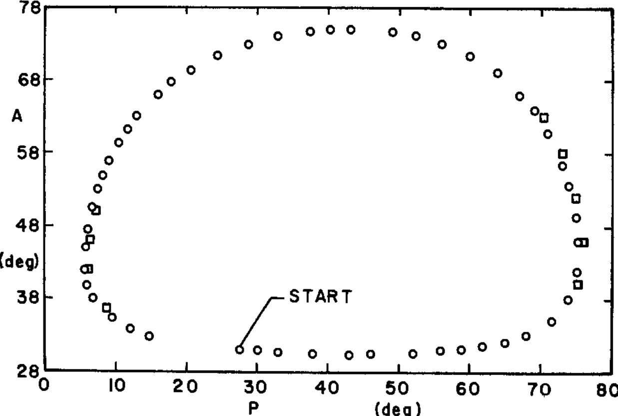

Fig. 1. Ellipsometer null settings for the growth of an anodic oxide film on vanadium at a current density of 275 $\mu A/cm^2$. Open circles, first loop; open squares, second loop.

The data in Fig. 1 can be fitted by a curve representing the growth of a uniform film of index 2.392 on a substrate of index 4.346 − 3.744i, and the film thickness at each point of the *P-A* curve can be calculated. Figure 2 shows a plot of the calculated film thickness *vs.* the electrode potential during film growth. The slope of this line gives a value for the electric field in the film of 2.63×10^6 V/cm for a current density of 275 $\mu A/cm^2$.

Let us now turn our attention to what occurs when an anodically grown film is subjected to an applied cathodic current. Figure 3 shows a typical potential *vs.* time curve for a portion of the anodic growth, the cathodic conversion, and subsequent anodic reconversion of a film formed on a vanadium electrode. The portion of the curve labeled A-B represents anodic oxidation. At point B the current was reversed so that the current density was −275 $\mu A/cm^2$. For this applied cathodic current the potential-time curve traced out the section of the curve labeled C-D-E; the length of time necessary to reach point D depended on the thickness of the oxide at point B. At point E the current was switched back to the anodic direction. We have assumed that at point E the conversion was complete. With an anodic current again flowing the potential traced out F-G-H, with steady-state growth condi-

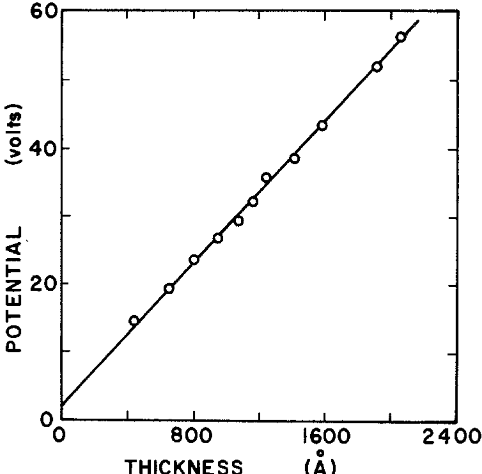

Fig. 2. Potential *vs.* thickness for the anodic oxidation of vanadium at a current density of 275 $\mu A/cm^2$. Thicknesses were calculated from the data in Fig. 1.

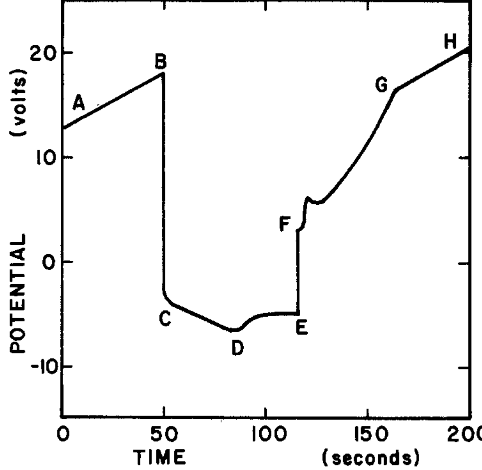

Fig. 3. Potential *vs.* time for a portion of the anodic oxidation (A-B), the cathodic conversion (B-C-D-E), and anodic reconversion (E-F-G) of the film formed on vanadium. At point B the current density was changed from +275 $\mu A/cm^2$ to −275 $\mu A/cm^2$. At point E the current density was changed back to +275 $\mu A/cm^2$.

tions being reattained at point G and anodic oxidation recommencing along G-H. This process of conversion and reconversion can be repeated any number of times using different values of the starting anodic potential (point B in Fig. 3) and consequently different values of the thickness of the anodic oxide when the conversion process was initiated.

The automatic ellipsometer was used to monitor optical changes of the electrode which occurred during a conversion process. We first present ellipsometric data for the points at which the conversion process was initiated and the points at which the conversion process was completed for conversions started at several different thicknesses. Note that the point where the conversion was complete is not well determined by electrical data; we determined the point where the conversion is complete in terms of the ellipsometer settings. When the changes in null settings of the ellipsometer became small (a few hundredths of a degree per null), conversion was considered to be completed and the applied current was switched back to the anodic direction.

Figure 4 shows the *P* and *A* null settings for the anodically formed film and for the film after cathodic conversion is completed. The open symbols are the data points for the anodic film and are the *P-A* settings measured at points similar to B in the voltage-time curve in Fig. 3. The closed symbols are the data points for the cathodically converted film; they are the *P-A* settings that are obtained for the film at points similar to E in Fig. 3. Open circles on the anodic *P-A* curve correspond to closed circles on the cathodic curve, etc. The points are numbered in order of increasing film thickness; the conversion process begins on a particular unprimed numbered point and ends at the point with the same primed number. The entire collection of *P-A* points represent ellipsometric data obtained for a sequence of successive voltage-time curves similar to those shown in Fig. 3. These were acquired during a single experiment without removing the sample from the cell.

The solid line through the open symbols in Fig. 4 is a theoretical curve for the growth of a film with refractive index 2.392 on a substrate of refractive index 4.346 − 3.743i, and the solid line through the closed symbols is a curve representing a film with a constant refractive index 2.013 − 0.046i and increasing thickness on the same substrate. The starting point is also indicated. These two lines fit the two sets of data points quite well. Thus we conclude that the application of a cathodic current to a vanadium electrode covered by an anodic oxide film converts this film in some manner from a film of refractive index 2.392 to a film of refractive index 2.013 − 0.046i.

We can also determine the thickness of the film for each of the data points in Fig. 3 using these refractive

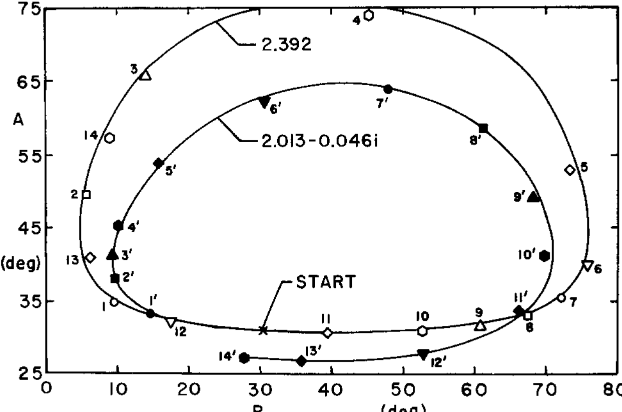

Fig. 4. Ellipsometer null settings for points at which the cathodic conversion process was initiated (open symbols) and points at which the conversion process was complete (closed symbols). The solid lines represent calculated null settings for films of refractive index 2.392 and 2.013 — 0.046i.

Table I. Calculated thicknesses for the points where the conversion process was initiated, D_a, and the points where the conversion process was complete, D_c. The conversion numbers correspond to the numbers in Fig. 4.

Conversion number	Anodic thickness, D_a (Å)	Cathodic thickness, D_c (Å)	Conversion ratio, D_c/D_a
1	303	295	0.973
2	498	483	0.970
3	582	560	0.962
4	646	622	0.963
5	757	724	0.956
6	869	826	0.950
7	957	900	0.940
8	1040	973	0.936
9	1138	1067	0.938
10	1246	1175	0.943
11	1412	1358	0.962
12	1684	1614	0.958
13	1938	1866	0.963
14	2068	1991	0.963
		Average	0.956
		Standard deviation	0.012

indices. The thickness at each point was determined by finding the thickness for the point on the theoretical *P-A* curve that was closest to the actual experimental point. For the anodic points the index of the film used was 2.392 and for the cathodic points the index of the film was 2.013 − 0.046i. The values of the thicknesses obtained in this manner are given in Table I. As can be seen from the numbers in the table, the conversion ratio, defined as D_c/D_a, is approximately constant and independent of the thickness of the anodic oxide prior to conversion. The average value of D_c/D_a is 0.956 with a standard deviation of 0.012.

We have thus far determined that a conversion of the anodic film takes place, but we have not said anything about how it takes place. We mentioned earlier that the entire conversion process was monitored using the ellipsometer. In order to answer the question of how the conversion process occurs, we must propose possible models for the process, examine the ellipsometric curves predicted by these models, and compare these predicted curves with the actual experimental data.

Figure 5 shows, schematically, three possible models for the conversion process. We have selected these models because we believe that they are the three simplest hypotheses that might describe the manner in which the film changes. In each of the models an initial film of refractive index n_i and thickness D_i is replaced by a film of refractive index n_f and thickness D_f. For the conversion process we use n_i = 2.392, n_f = 2.013 − 0.046i, and the appropriate thicknesses are listed in Table I.

In the first model, labeled I in Fig. 5, we assume that the conversion process begins at the oxide/electrolyte interface and proceeds inward toward the metal. At any intermediate point during the conver-

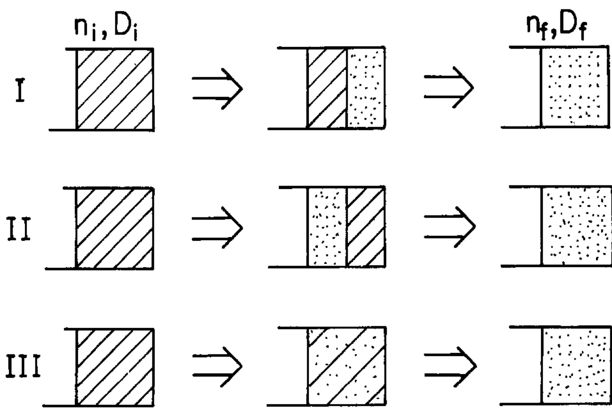

Fig. 5. Schematic of three possible models that can describe the conversion of a film with an initial refractive index n_i and initial thickness D_i to a film with a final refractive index n_f and final thickness D_f.

sion process there are two layers on the electrode, an inner layer of refractive index n_i and an outer layer of refractive index n_f. The boundary between the two layers is assumed to be sharp. The second model, labeled II, is similar to model I except that here we assume that the conversion process begins at the metal/oxide interface and proceeds outward. At an intermediate point during conversion the film will consist of two layers, an inner layer of refractive index n_f and an outer layer of refractive index n_i. In model III we assume that the conversion occurs uniformly throughout the film and that the film remains homogenous at any instant. In addition, we assume that all changes in the film proceed in a linear manner; that is, the fractional change in the real and imaginary parts of the refractive index and the fractional change in the thickness at any instant are the same.

It should be emphasized that the predicted ellipsometric curve for each model depends only on the thickness and index of refraction of the initial film and the thickness and refractive index of the converted film. These values have already been determined using the data in Fig. 4. There are no additional adjustable parameters included in any of the models so we are not curve fitting here; we only seek to determine if any of the models predict the experimental data adequately.

Figure 6 shows the experimental data, plotted as open circles for the conversion of an anodic oxide film with an initial thickness of 757Å. This particular conversion begins at point number 5 on the anodic curve and ends at point number 5′ on the curve for the converted film. The letters in Fig. 6 label the *P-A* data points that correspond to similarly lettered points in the potential *vs.* time curve in Fig. 3. The conversion begins at point B and is complete at point E. Not all data points obtained during the conversion process are shown, in particular the density of the experimental points near the point E is much greater than illustrated. Also shown in the figure are the predicted curves for the three proposed models; the number under each curve corresponds to the number of the model shown in Fig. 5.

It is evident from this figure that model I seems to describe the experimental data best. There is some deviation of the data points from curve I in the upper right-hand corner of the figure, but in this region the experimental null settings were changing rapidly and the amount of time required to determine a null becomes important. If we were to correct for the nulling time of our instrument these points would more closely approximate curve I.

In order to demonstrate that Fig. 6 does not represent an unusual set of circumstances that only accidentally show agreement between the experiment and model I, we present two additional conversion curves in Fig. 7 and 8. Again the experimental points are represented by open circles and again the *P-A* curves for the three models are shown for comparison. These are conversion numbers 12 and 13 of Fig. 4. We see that in these cases model I also best accounts for the experimental data. The agreement is surprisingly good considering that the curves for the model are calculated using only the parameters found for the starting point and the end point for the conversion process. The agreement of model I with the data over a wide range of initial thicknesses indicates that this is the correct model to describe the process.

Thus far we have said little about the reconversion of the film in region F-G-H of Fig. 3. We have mentioned that in this region a reconversion of the cathodic back to the original anodic film occurs, at least to the extent that in region G-H the film is indistinguishable from an anodically formed oxide. The ellipsometric data for a typical reconversion are shown in Fig. 9, along with calculated curves for the three models presented previously. The solid line through the data points is not a calculated curve, but has been added as an aid in following the sequence of data points. The curves based on the three models, represented by dashed curves, are labeled with the appropriate model numbers. The models for reconversion differ from the conversion models in that here we assume that the initial film has a refractive index of 2.013 − 0.046i and the final film has a refractive index of 2.392. The initial thickness for the reconversion models was taken to be the thickness of the appropriate cathodic layer in Table I. The final thickness for the reconverted layer was computed using the *P-A* point at which the reconversion curve returned to the curve

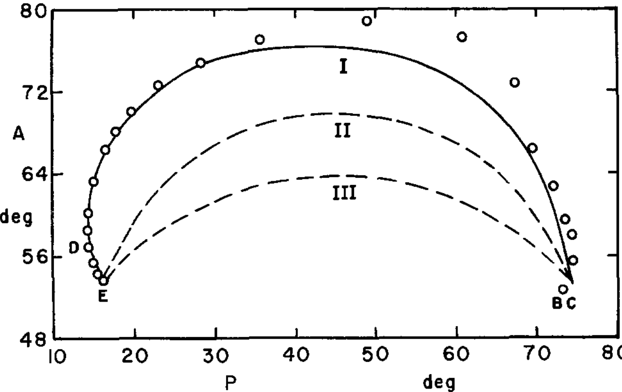

Fig. 6. Ellipsometer null settings, represented by open circles, recorded for the conversion of an anodic film with an initial thickness of 757Å to a cathodic film with a thickness of 724Å. for anodic growth. This thickness was always found to be smaller than the thickness at which the process was initiated; *i.e.*, in Fig. 3 the thickness of the oxide at point G is always less than at point B.

Figure 10 shows another reconversion beginning at a different initial thickness. As can be seen from Fig. 9 and 10, none of the models fits the experimental data particularly well. Therefore, the process of reconversion must differ in some way from the processes assumed in the models. Nevertheless, if we must select one of these models as a first approximation to the actual process, we would choose model I. While model I does not always give the best fit to the experimental data, it does always approximate the shape of the data. In Fig. 10, it is the only model that gives the same direction of curvature as the experimental points. Choosing model I as a reasonable first approximation to the actual process is not completely meaningless. As was stated above, the thickness of the anodic oxide after a complete conversion-reconversion cycle was less than at the beginning of such a cycle. Using model I, we can account for this by proposing that as the anodic layer is reestablished at the film/electrolyte interface it also slowly dissolves.

Discussion

By using an automatic ellipsometer to follow the changes in optical properties of a vanadium electrode, we have found that an anodically formed film on the electrode undergoes a change in refractive index and thickness when a cathodic current is applied. The

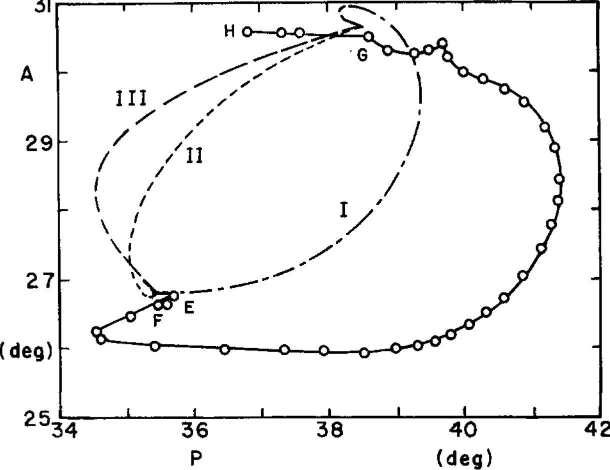

Fig. 10. Ellipsometric null settings for the reconversion of a cathodic film with an initial thickness of 1866Å. Other features are the same as in Fig. 9.

anodic oxide on vanadium was found to have a refractive index of 2.392, whereas the cathodically converted film had a refractive index of 2.013 − 0.046i. The ratio of the thickness of the anodic oxide to the thickness of the cathodic film was found to be almost constant, independent of the thickness of the anodic oxide when the conversion process was initiated. Further, the conversion can be accounted for by a model in which the conversion begins at the oxide/electrolyte interface and proceeds inward.

We propose that the reconversion of the film can be approximated by a similar model. While the predicted ellipsometer null settings for such a model do not fit the experimental data particularly well, they at least show approximately the same shape as the experimental data. In fact we are not entirely surprised at this lack of fit. The model assumes that a sharp interface exists between the two films present on the electrode during reconversion, whereas there is no obvious physical reason to make this happen.

The fact that the anodic film is much more soluble in water than the cathodically converted film provides another method of distinguishing between the two types of film. We can examine the results of a few simple experiments in which the solubility is tested by noting how rapidly the interference color of the film changes, thus indicating how quickly the film is being dissolved.

Using Fig. 3 as a guide, if we open the circuit in the region A-B, remove the sample from the cell, and place it in water, the oxide is found to completely dissolve in a matter of seconds. If, on the other hand, we form a cathodic film in the region D-E, remove the sample from the cell, and place it in water, there is no apparent color change in the interference color of the film over a period of a few minutes. This merely demonstrates the degree of difference in the solubilities of the two types of film.

We can also perform slightly more complicated experiments. For example, if an anodic film is formed and then a cathodic current is applied for only a short time, the film does not change its interference color when placed in water. This is exactly what we would expect using our proposed model for the conversion process. The cathodic current has caused the outer portion of the film to convert, and this outer film prevents the dissolution of the inner anodic oxide that has yet been converted.

Furthermore, if a film which has been cathodically converted is subjected to an anodic current for a short time and then placed in water, we find that the interference color changes rapidly for a few seconds and then stops changing, leaving some film on the surface. This is consistent with a model in which the reconverted anodic oxide is formed on the outside and the portion which is formed is dissolved away, leaving only the cathodic film. In fact, the film can be removed from the surface in a controlled manner by carefully controlling the amount of time that the anodic current is applied to a cathodically converted film.

Finally, we believe that by applying a carefully controlled series of anodic and cathodic currents to an anodically oxidized vanadium electrode, a series of layers can be produced within the film. For example, if we partially convert an anodic oxide by applying a cathodic current for a short time and then reconvert part of the converted layer, we would produce a film that consisted of three layers: an anodic oxide next to the metal, a cathodically converted layer on top of this, and another anodic oxide layer on the outer surface of the film.

We do not choose here to propose a detailed mechanism for the conversion process. We do not believe that we have sufficient information to present a meaningful picture at the present time. In particular, the chemical composition of the films was not measured in this work. This information is probably essential to a detailed description of this process. Even less can be said with certainty concerning the reconversion of a

cathodically treated layer. The reconversion process cannot be simply the reverse of the conversion process; if it were it would have to proceed from the metal/film interface outward. Despite the lack of close agreement between the data and the models for reconversion, we can definitely tell from our data that the cathodically treated film is not simply reconverted to an anodic film beginning at the metal/film interface proceeding outward. Any detailed explanation of the conversion and reconversion would have to account for this general behavior.

ABSTRACT

In connection with studies of the greater corrosion rates of metals in natural sea water as compared to equivalent saline solutions, a study of the influence of organic constituents has been initiated. This paper describes polarization resistance measurements, at low overvoltages, of copper corrosion in aerated aqueous solutions containing a series of ten α-amino acids. The data were analyzed by a novel computer program called CORFIT. The solutions were brought to a constant ionic strength of 0.7M with KNO_3 and maintained at pH 7. The amino acids were all found to accelerate the corrosion by a mechanism in which their anionic forms adsorb on the surface and form complex ions of lower than normal stoichiometry with Cu(II). The corrosion reactions were under anionic control and involved oxidation of copper to Cu^{2+}. Use of constant ionic strength eliminated changes in transfer coefficient due to changing ligand concentration and simplified the kinetic analysis of the corrosion data. The results open up a new procedure for studying the role of organic constituents of natural water systems in electrode adsorption and corrosion processes. A novel parameter to characterize quantitatively corrosion accelerators of this type is suggested.

Numerous publications have appeared dealing with corrosion of copper under a wide variety of conditions, mostly in acidic or basic solutions containing copper ion initially and excluding dissolved oxygen (1). Few authors have carried out fundamental electrochemical studies in solutions free of copper initially (2) or related to natural water systems (3). It has been reported (4, 5) that the corrosion of copper in natural sea water is greater than in synthetic sea water or in sodium chloride solution. It seems reasonable to attribute this increase in corrosion to the organic constituents which are known to be present in natural sea water. Results are reported herein for a number of α-amino acids which occur in natural sea water at concentrations of the order of 10^{-7}M (6) and which form stable complexes with Cu(II) ion (7).

A polarization resistance method (8) was used at low overvoltages and in solutions of pH 7-9 whose ionic strength was kept constant at the sea-water value of 0.7M by addition of the indifferent electrolyte KNO_3. The data were analyzed by means of a novel computer program called CORFIT, kindly furnished to us prior to its publication by Mansfeld (9).

The results were analyzed by means of the well-known equation employing standard symbols (10)

$$i = i_{corr}[\exp(2.3\eta/b_a) - \exp(-2.3\eta/b_c] \quad [1]$$

* Electrochemical Society Student Member.

Key words: copper, corrosion, amino acids, polarization resistance, cupric complexes.

where the anodic and cathodic Tafel slopes are defined as

$$b_a = 2.3RT/\overleftarrow{\alpha}n\mathbf{F} \text{ and } b_c = 2.3RT/\overrightarrow{\alpha}n\mathbf{F}$$

and $\overleftarrow{\alpha}$, $\overrightarrow{\alpha}$ are the anodic and cathodic transfer coefficients, respectively.

The derivation of this equation requires the assumption that the corrosion reactions are activation controlled.

The present research uses polarization resistance measurements at low overvoltages and currents. This technique has been described by Wagner and Traud (11) and by Stern *et al.* (12, 13). From Eq. [1]

$$(di/d\phi)_{\eta=0} = 2.3\, i_{corr}[(b_a + b_c)/b_a b_c] \quad [2]$$

or

$$i_{corr} = (1/2.3\, R_p)[b_a b_c/(b_a + b_c)] \quad [3]$$

where $R_p = (d\phi/di)_{\eta=0}$ is the polarization resistance.

The polarization resistance technique utilizes the i *vs.* η data which are taken at small values of η where the net measured current is comprised of both the partial anodic and partial cathodic currents. This offers the advantage that the observed currents are so low that the surface of the corroding electrode has not been altered. In the past the method has suffered from the fact that the measurements have only given values for R_p at much greater current densities. However, an analysis using the CORFIT program (8, 9, 14) allows values for R_p, b_a, b_c, and i_{corr} using Eq. [3], to be calculated from a single set of i *vs.* η data. The Tafel slopes are thus obtained from the mixed current region where $\eta < RT/n\mathbf{F}$ and no Tafel lines are observed.

Experimental

A tubular internal flow electrode was used (15). This was constructed from a 2.5 cm length of 0.635 cm ID commercial copper tubing. Emission spectrographic analysis showed 99.95% copper with the major impurities silver, nickel, zinc, and iron each present at less than 0.01%. Various methods of electroplating and electropolishing (16) the internal surface of the copper tube were tried. Scanning electron microscope study at 5000× showed that the following procedure gave the best surface, uniformly smooth and relatively free of pits and extrusion lines. The electrode was placed into a line of plastic tubing and 85% H_3PO_4 pumped through it at 600 cm³/min. A constant anodic current of 45 mA/cm² was passed using an axial copper wire for the cathode. The polishing was continued for several minutes after the potential had stabilized at 2.7 ± 0.2V. The electrode was then rinsed with water and methanol to remove the last traces of phosphate (17) and transferred immediately into the corrosion apparatus.

This apparatus was based on the 1 liter Greene six-neck polarization cell (18). The working electrode was mounted in a line of polyethylene tubing in such a manner that solution in the cell could be circulated through it with a noncontaminating Varistaltic pump. Surge tanks made from polyethylene bottles smoothed out the flow whose rate was measured with a calibrated rotameter. The auxiliary electrode was a platinum wire sealed through a T-shaped polyethylene tube and held axially in the working electrode by means of polyethylene spacers. The reference electrode was an Orion 90-02 double junction electrode which was calibrated before each run with a Beckman SCE. The reference electrode and a Corning Model 500 *p*H electrode entered the polarization cell through side necks. The cell also contained a thermometer and a sintered glass diffuser for purging with gas. The three-electrode system was connected to a Wenking 70-TS-1 potentiostat.

All runs were made with solutions which were brought to the sea water ionic strength of 0.7M by addition of KNO_3. The *p*H was controlled to ±0.1 units by addition of NaOH or HNO_3. The solutions were saturated and continually purged with a slow stream of air. No difference was observed between air from a cylinder or from an aeration pump. Temperature was constant at the ambient laboratory value of 24.5° ± 0.5°C. After equilibration for about 10 min (with the solution circulating) until a stable rest potential was attained, the working electrode potential was incremented in steps of 4 mV and the current read after 30 sec. The potential sweep was from an initial cathodic overpotential of −20 to +20 mV. The overvoltage-current data were then read into the CORFIT computer program.

All the polarization data were obtained at a flow rate which gave a linear velocity of 26 cm/sec for solution passing the inner surface of the TIFE. This velocity is well into the region of turbulent flow, the turbulence parameter (10) exceeding the critical value of 1 by a factor of 1830. Most data were collected with polarization current densities not exceeding 10 μA/cm². In a few cases, the maximum was 20 μA/cm².

About 10 independent runs were made at each concentration. The Tafel slopes were found to be independent of the concentration. The best values for i_{corr} were obtained by using in Eq. [3] a value for each Tafel slope averaged over all of the runs with amino acids, irrespective of the concentration. ϕ_{corr} was obtained from the i *vs.* η data (9).

Results and Discussion

The values of i_{corr} and of ϕ_{corr} determined in the low current linear polarization region were found to be independent of flow velocities ranging from 10 to 50 cm/sec. Thus, the electrode processes in the range studied were under activation control (19, 20).

Glycine was used as a prototype for the α-amino acids and was studied in some detail. Table I presents the results obtained for the corrosion parameters for glycine solutions. It is seen that with increasing amino acid concentration at constant *p*H, the corrosion rate increases, while the corrosion potential becomes more negative. Both b_a and b_c remain constant at 50 and 60 mV, respectively. Reference to a standard Evans diagram shows that the copper is corroding under anodic control (10), that is, the amino acid is influencing the rate of the anodic dissolution of the copper metal.

Glycine exists predominantly in three forms in aqueous solution, the concentrations being determined by the *p*H.

$$\underset{\text{cation}}{^{+}H_3NCH_2COOH} \underset{}{\overset{pK_1 = 2.3}{\rightleftharpoons}} \underset{\text{zwitterion}}{^{+}H_3NCH_2COO^-} \overset{pK_2 = 9.8}{\rightleftharpoons} \underset{\text{anion}}{H_2NCH_2COO^-}$$

The relative concentrations of these ions are given by the relation

$$pH_{soln} - pK = \log[(\text{basic form})/(\text{acidic form})]$$

The values for *p*K were taken from the literature for zero ionic strength (20, 21). The values at 0.7M are not available, but for the amino acids where *p*K is reported as a function of ionic strength the differences are of the same order as variations between the different authors. The concentrations of the forms can thus be calculated for various values of *p*H and total glycine concentration.

A study of i_{corr} values as a function of glycine concentration and *p*H makes it possible to determine that only the anion participates in the anodic dissolution of copper. It is seen that for constant total glycine, the corrosion rate increases significantly with *p*H and so does the concentration of the anion. Concentration of the cation decreases by orders of magnitude and of the zwitterion remains essentially constant. For entries where the concentration of the anion is

Table I. Effect of pH on corrosion rate with glycine

Total glycine (M)	pH	ϕ_{corr} (mV *vs.* SCE)	i_{corr} ($\mu A/cm^2$)	Cation (M)	Zwitterion (M)	Anion (M)
0.0010	7.0	-101 ± 8	0.40	2.0×10^{-8}	9.98×10^{-4}	1.6×10^{-6}
0.0100	7.0	-168 ± 7	1.18	2.0×10^{-7}	9.98×10^{-3}	1.6×10^{-5}
0.1000	7.0	-218 ± 10	2.44	2.0×10^{-6}	9.98×10^{-2}	1.6×10^{-4}
0.0010	8.0	-102 ± 2	1.51	2.0×10^{-9}	9.84×10^{-4}	1.6×10^{-5}
0.0100	8.0	-187 ± 3	2.64	2.0×10^{-8}	9.84×10^{-3}	1.6×10^{-4}
0.0001	9.0	-151 ± 4	1.39	1.7×10^{-11}	8.62×10^{-5}	1.4×10^{-5}
0.0010	9.0	-161 ± 1	2.57	1.7×10^{-10}	8.62×10^{-4}	1.4×10^{-4}

essentially constant at $1.4\text{-}1.6 \times 10^{-5}$M, the corrosion current is also constant within experimental error within the range 1.18-1.51 $\mu A/cm^2$. Similarly, when the anion concentration is constant in the range $1.4\text{-}1.6 \times 10^{-4}$M, the current is constant at 2.44-2.64 $\mu A/cm^2$. For the two constant corrosion current ranges just mentioned, the concentrations of cation and zwitterion change by four and two orders of magnitude, respectively.

The corrosion parameters for copper with a series of α-amino acids in solutions whose ionic strength was brought to 0.7M by adding KNO_3 were next measured at pH 7.0. The acids are listed in Table II with their structure, pK_2 values, and Tafel constants which were independent of concentration. By analogy with glycine it was assumed that the anionic form was corrosion active and the concentrations of this species were calculated as before. The corrosion currents and potentials are given in Table III.

The amino acids all accelerate the corrosion of copper and it has been shown that the reactions are all under anodic control. Table II shows that the anodic Tafel slopes lie in the range $35 \leq b_a \leq 61$ mV. If the reasonable assumption is made that the anodic reaction mechanism involves the same number of electrons for the oxidation of copper in the presence of each of the amino acids, then this value must equal 2. This follows because $b_a = 2.3\ RT/\overleftarrow{\alpha}n\mathbf{F} = 59.2/\overleftarrow{\alpha}n$ at 25° and in principle $\overleftarrow{\alpha}$ must be bounded by $0 \leq \overleftarrow{\alpha} \leq 1$. The range of observed b_a values can therefore only be accommodated with a common integral n by the values $n = 2$ and $0.49 \leq \overleftarrow{\alpha} \leq 0.85$.

The conclusion that $n = 2$ is of course reinforced by the known fact that amino acids stabilize Cu^{2+} ion in aqueous solution and form soluble complexes with it (7). The proposed anodic reaction for corrosion of copper in the presence of amino acids at pH 7 is therefore

$$Cu + pL^- \rightarrow CuL_p^{2-p} + 2e^-$$

where L^- is the amino acid anion and the copper in the complex ion product is Cu(II). Evaluation of the electrochemical reaction order p is discussed later.

When the corrosion current is plotted against the logarithm of the amino acid concentration, as in Fig. 1, very interesting results are obtained. The amino acids fall on three distinctly grouped lines. The groups correlate beautifully with the expected adsorption properties of the acids. Referring to the structures of the acids given in Table III, it is seen that in Fig. 1

glycine which has only a hydrogen atom as a substituent on the basic α-amino acid structure, is by itself on line 1. The corrosion current shows the least concentration dependence on this weakly adsorbed species. On line 2 in a second group are alanine, phenylalanine, and butyrine. These three have aliphatic and aromatic substituents which can be expected to increase the van der Waals surface adsorption. Members of this group increase the corrosion current appreciably. The remaining acids belong to a third group and increase the corrosion current strikingly as shown by line 3. The substituents on these acids

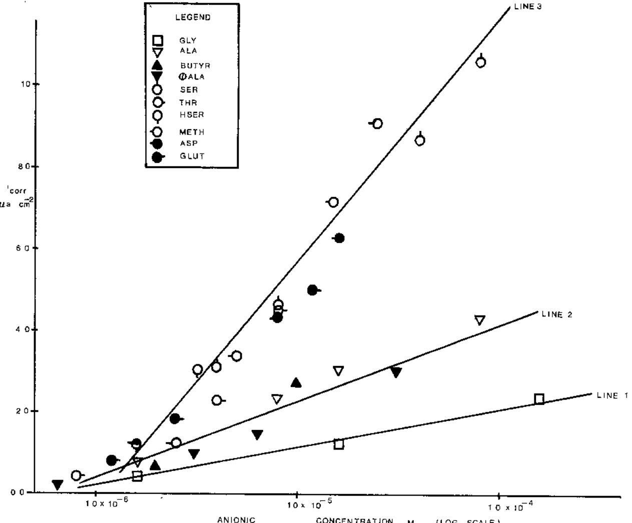

Fig. 1. Corrosion current density as a function of α-amino acid anion concentration.

contain the polar groups OH, COO^-, and SH which involve electronegative Group VI elements. These would be expected to enhance adsorption since the corroding electrode is positive to the point of zero charge (10).

Convenient corrosion acceleration parameters may be developed by fitting least square analytical expressions of the form

$$i_{corr} = a + b \log (L^-)$$

to the lines in Fig. 1. Table IV gives the results. The intercept a may be termed the standard-state corrosion current density since it refers to the state where $(L^-) = 1$. It should serve as a useful quantitative parameter to characterize corrosion accelerators.

The electrochemical kinetic order of this corrosion reaction (10) is defined as

$$p = (d \log \overleftarrow{i}_a / d \log C_{AA})_\phi \quad [4]$$

where C_{AA} is the amino acid concentration.

This quantity may be obtained from data of Table I at various arbitrarily chosen constant values of ϕ by graphing $\overleftarrow{i}_a$ against ϕ using the known Tafel slope b_a and the fact that $\overleftarrow{i}_a = i_{corr}$ at $\phi = \phi_{corr}$. Alternatively, using Eq. [1] to [3], it can be shown that the reaction order is also equal to

$$(d \log i_{corr}/d \log C_{AA})_{\eta=0} - (1/b_a)(d\phi_{corr}/d \log C_{AA}) \quad [5]$$

The initial results indicated that all the bidentate ligands (the first 8 in Table II) gave an order of 1.5 $\pm$ 0.3 while the tridentate ligands (aspartic and glutamic acids) gave a value near 1.0. Since the data in the present paper indicate unequivocally that complex ion formation involving amino acid ligands plays a part in anodic copper corrosion in these systems, it is tempting to speculate that the above reaction orders give information about the composition of the transition state complexes involved in the rate-determining anodic step. Thus the apparent order of 1.5 for the bidentate ligands might be taken to indicate that a complex involving three ligands bound to every two copper atoms plays a role. One of the ligands might bridge the copper atoms in a bidentate manner while each of the other two was chelated entirely to one of these atoms. The apparent order of one for the tridentate ligands would indicate a completely chelated complex involving one ligand per copper atom.

The above view is further enhanced by the observation that the product of the apparent reaction order times the number of chelating groups on the ligand for both bidentate and tridentate species is equal to the same value three. Thus the activated complex in both cases would have the same characteristic in the respect that three bonds between organic ligand and each copper ion are required. The normal stoichiometry of Cu(II)-amino acid complexes in solution is CuL_2 (7) involving four bonds per Cu. The distorted version is required by the steric hindrance of the surface and by the surface adsorption forces which undoubtedly play a role in the process as shown by the correlations in Fig. 1 and the attendant discussion above. If the activated complex energy barrier lies close to the metal surface, as it would for a charge-transfer reaction involving complexation, then the normal solution stoichiometry would not be expected due to the steric impossibility of formation of the square planar cupric-amino acid anion chelate where the octahedral cupric species has Jahn Teller stretched axial positions that are occupied by solvent molecules in the normal solution configuration. After the activation barrier to the corrosion process has been surmounted, the complex would of course disproportionate to its normal stoichiometry on passage into solution.

Table IV. Corrosion acceleration parameters

Amino acid group	Intercept a (μA)	Slope b ($\mu A/cm^2$)	Standard deviation σ
I	6.1	1.0	0.11
II	12.7	2.0	0.30
III	33.1	5.5	0.63

Some Aspects of the Electrochemical Behavior of Zinc in the Presence of Acrylate and Methacrylate Anions

P. F. Hutchison and J. Turner

Timex Corporation, Washington NE37 3HW, Tyne and Wear, England

ABSTRACT

The influence of acrylate and methacrylate anions on the anodic behavior of zinc in concentrated sodium hydroxide solution at ambient temperature and under quiescent conditions has been studied using cyclic linear sweep voltammetry. The effect that these additives have on the corrosion rate of the zinc electrode, and on hydrogen evolution in particular, is examined. Experiments show that although the organic species exhibit a marked over-all catalytic effect on both zinc dissolution and hydrogen evolution, the corrosion rate is little affected. Despite an apparent deleterious effect on passivation, results suggest that the additives improve the solubility of the anodic product in the electrolyte. A mechanism is tentatively suggested for the catalytic evolution of hydrogen.

It has been shown (1) that acrylate and methacrylate ions, present in solution to the extent of 0.1% by weight, lower the double layer capacitance (Cdl) of the Zn-KOH interphase. This effect, seemingly limited to high KOH concentrations (≧30% by weight), probably reflects adsorption of the organic anions at the electrode surface.

In view of the possible use of such additives in zinc-alkali cells it was decided to examine any influence they might have on the passivation and corrosion behavior of the zinc electrode. Zinc deposition was not considered since we were primarily interested in the application of the organic additives to primary cells, following information (2) of experimental evidence to suggest that such anions might improve the efficiency of the zinc anode on discharge.

Experimental

A diagram of the three electrode Pyrex cell is given in Fig. 1. Zinc foil, thickness 0.15 mm, purity 99.995+%, Goodfellow Metals Limited, was blanked into 2.54 cm diam disks which were given a 1 sec dip in 3*N* nitric acid, followed by thorough rinsing in triply distilled water prior to incorporation into the cell. The working electrode was positioned horizontally facing upwards so as to eliminate all but local convection at the zinc surface.

Key words: zinc, corrosion, passivation, acrylic anions.

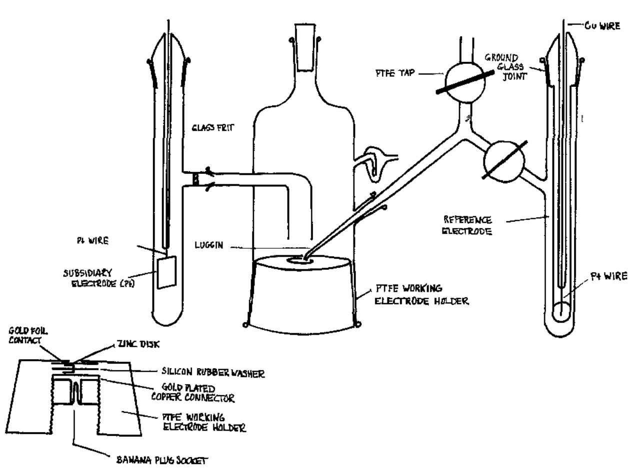

Fig. 1. Cell diagram

Experiments were performed using electrolyte deoxygenated by passage of nitrogen (BOC, white spot grade) for 1 hr, and the cell was assembled under a nitrogen atmosphere in a glove box. 10*N* solutions were made up from BDH 'AnalaR' sodium hydroxide pellets using triply distilled water, and the organic anions were added in the form of the acids, *viz.*

acrylic acid	Koch-light, puriss.	0.1 volume per cent (v/o) (0.015M)
methacrylic acid	Koch-light, puriss.	0.1 v/o (0.012M)

A cyclic linear potential sweep was applied to the zinc electrode *via* a Chemical Electronics TR40/3A potentiostat in conjunction with a linear sweep unit; cyclic voltammograms were recorded on a Bryans X-Y plotter Type 26000A4, and the potential of the working electrode, with respect to the Hg-HgO reference electrode, was also measured on a Solartron LM1620 D.V.M. The cathodic excursion always preceded the anodic excursion.

The corrosion rate of the zinc was also determined volumetrically by monitoring the volume of hydrogen evolved when one gram of granular zinc (particle size 125-250 μm, Berk Limited) was exposed to 20 ml of 10*N* NaOH in the apparatus shown in Fig. 2. The 100 ml volumetric flask was immersed in an oil bath maintained at 50°C. After addition of the alkali to the zinc, the mixture in the flask was evacuated in a desiccator

for 1 hr to remove any entrapped air prior to commencement of the experiment.

Results and Discussion

The form of the anodic portion of the voltammogram obtained under quiescent conditions in the absence of additives can be seen from Fig. 3. It seems fairly certain (3-6) that the first peak in the anodic sweep corresponds to the formation of a porous film of ZnO by a dissolution-precipitation mechanism and the active-passive transition to a low porosity film forming directly on the metal surface, the sharp peak obtained on the return sweep corresponding to reduction of the latter film.

The influence of the various additives on the corrosion parameters and passivation behavior of the zinc is summarized in Tables I and II, respectively. Their effect on the corrosion rate is only slight, as confirmed by the gassing test results presented in Fig. 4. Conversely, the anions appear to have a marked effect on anodic behavior; a typical voltammogram for methacrylate is presented in Fig. 3. Similar results were obtained for acrylate.

It can be seen that adsorbed anions have a pronounced over-all kinetic effect, both zinc dissolution, and hydrogen evolution at overpotentials > -550 mV, occurring more readily; conversely, inhibition appears to occur in the case of H_2 evolution for the overpotential range $-400 \text{ mV} < \eta < -550$ mV.

Representative Tafel plots for zinc dissolution and hydrogen evolution are presented in the form of an Evans diagram, constructed from the experimentally obtained voltammograms, in Fig. 5. Although hydrogen evolution is suppressed in the vicinity of the corrosion

potential, the increase in the zinc dissoluton rate results in a slight increase in the corrosion current with a corresponding displacement of the corrosion potential towards the equilibrium potential of Zn/Zn^{II} electrode.

Since the H_2-H^+ exchange reaction involves the adsorption of reactive species, anionic adsorption would be expected to have at least three kinetic effects: (*i*) variation of ϕ_2 the potential at the outer Helmholtz plane (OHP), (*ii*) variation of $\Delta G°$ for hydrogen adsorption, and (*iii*) decrease of area available for hydrogen adsorption. The influence of anionic adsorption on the overvoltage in the absence of adsorption of reactants and products follows from the Butler-Volmer relationship which implies that, at constant current, the change of overvoltage ($\Delta\eta$) resulting from a vari-

* All potentials quoted in mV with respect to Zn-Zn^{2+}.

ation $\Delta\phi_2$ is given by

$$\Delta\eta = \left(1 - \frac{z}{\alpha n}\right)\Delta\phi_2 \quad [1]$$

The quantities $\Delta\eta$ and $\Delta\phi_2$ have the same sign for $z/\alpha n < 1$ and opposite signs for $z/\alpha n > 1$, and thus $\Delta\eta$ has the same sign in the reduction of anions and the opposite sign to $\Delta\phi_2$ in the reduction of cations ($z \geqq n$) and $0 < \alpha < 1$). The specific adsorption of anions makes ϕ_2 more negative (7), and therefore $\Delta\eta$ more positive for the reduction of H^+; hence (*i*) would be expected to exert a catalytic influence on the H_2 evolution reaction. (*ii*) and (*iii*) would have the opposite effect, and it would therefore appear that (*ii*) and (*iii*) dominate at low overpotential; this situation, however, would probably pertain over the entire potential range for which the organic adsorbed, and the very marked catalysis at overpotentials > -550 mV must consequently arise from factors not mentioned in the foregoing discussion. The above equation and considerations apply strictly only to the case of mercury and dilute amalgams and it is not suggested that they afford a formal description of the situation at a solid electrode where the double layer structure is less well known. However, it is suggested that the treatment will have some qualitative significance and give some insight into the situation prevailing at the electrode surface, particularly since it can be supposed that the rate determining step of the over-all process is still hydrogen ion discharge resulting in the formation of an adsorbed hydrogen atom [(*cf.* mercury and dilute amalgams (8)].

As the potential of the zinc is made more negative during the cathodic excursion the pH of the electrolyte in the vicinity of the cathode decreases, in the following fashion: the variation of $[H_3O^+]$ and $[OH^-]$ close to the electrode surface obeys the Boltzmann distribution

$$[H_3O^+]_s = [H_3O^+]_b \exp(-\phi_2\mathbf{F}/RT) \quad [2]$$

$$[OH^-]_s = [OH^-]_b \exp(-\phi_2\mathbf{F}/RT) \quad [3]$$

where the indices *s* and *b* define concentrations close to the electrode surface (interphasial region up to and including the OHP) and in the bulk of the solution, respectively. For an acid-base system

$$H^+ + OH^- \rightleftharpoons H_2O$$

or

$$H_2O + H^+ \rightleftharpoons H_3O^+$$

Thus

$$\left(\frac{[H_2O]}{[OH^-]}\right)_s : \left(\frac{[H_2O]}{[OH^-]}\right)_b = \left(\frac{[H_3O^+]}{[H_2O]}\right)_s : \left(\frac{[H_3O^+]}{[H_2O]}\right)_b$$

$$= \frac{[H^+]_s}{[H^+]_b}$$

$$= \exp(-\phi_2\mathbf{F}/RT)$$

where it has been assumed that the surface and bulk concentrations of water are equal; this will only be approximately true for the polar water molecules but will suffice for the present analysis. Thus as the electrode potential becomes more negative, the pH will decrease. The ratio $[H^+]_s/[H^+]_b$ can amount to several orders of magnitude (9).

It is conceivable that the following equilibrium may be established between the specifically adsorbed organic anions (at the IHP) and the protonic species populating the OHP

$$R^- + H_3O^+ \underset{}{\overset{\text{rapid}}{\rightleftharpoons}} RH + H_2O$$

followed by electron transfer thus

$$RH + e^- \rightarrow R^- + H$$

with subsequent hydrogen evolution

$$H + H \rightarrow H_2$$

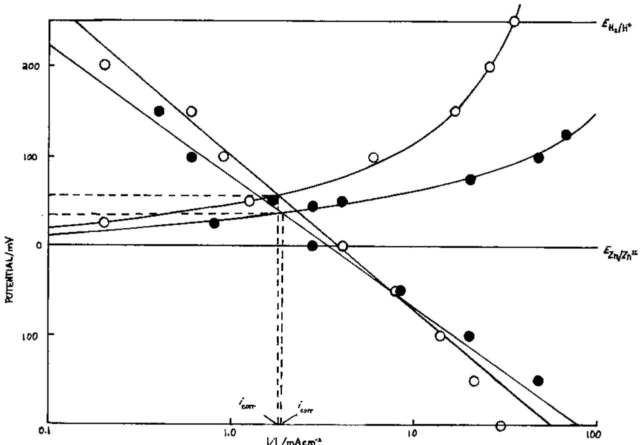

Fig. 5. Evans diagram. ○ = 10M NaOH, ● = 10M NaOH/0.1 v/o methacrylic acid, Y-axis: potential/mV, X-axis: $|i|$/mA cm^{-2}.

It follows from the above that the equilibrium between R^- and H_3O^+ would be extremely potential dependent; the over-all process would correspond to the catalytic action of certain organics on hydrogen evolution cited in the literature (9) and could be an explanation for the observed pronounced increase in the rate of hydrogen evolution with increase in potential.

The anions appear also to catalyze the dissolution of zinc, a direct consequence of which is the earlier saturation of the diffusion layer in the anodic potential scan with the resulting marked cathodic displacement of peak I. The similar displacement in the active-passive transition presumably arises from a variation in the texture and composition of the film formed in the presence of the adsorbed species to that formed in pure electrolyte (4). It is possible that the anions serve as impurity centers for film nucleation. The multiple-peak effect observed probably arises from the organic anions adsorbing onto certain preferred sites on the zinc surface, as a result of which the film formed might be expected to vary in composition and thickness over the surface area of the electrode. Similar experimental work on the influence of $SiO_3^=$ (4) where optical photomicroscopy was employed has shown that the film formed in the presence of the anion does in fact reduce in stages, giving rise to several reduction peaks on the cathodic going sweep of the anodic excursion. It is suggested that a similar effect is being observed in the case of the organic species. In contrast to $SiO_3^=$, the current maximum of peak I in the presence of the acrylic anions is much greater than in the pure electrolyte, suggesting that in the latter case the solubility of the zinc oxide-zinc hydroxide is substantially improved in the presence of these additives. It is possible that the anions stabilize micelles of ZnO-Zn$(OH)_2$ by provision of a better-developed hydration sheath. Such a mechanism has been proposed (10-12) for the stabilization of electrolytically generated zincate solutions.

Conclusions

Although the acrylic type anions have been shown to have a detrimental effect on the passivation of zinc in alkaline solution, results suggest that they could act as extenders for the zinc electrode at very low current drain. The influence of such additives on the corrosion rate of the zinc is only minimal.

The addition of these organics to the electrolyte of secondary zinc-silver oxide cells has been correlated (1) with an increase in cycle life, a phenomenon possibly related to a change in morphology of the electrodeposited zinc resulting from adsorption of the anions at the zinc-alkali interphase. In respect of rechargeable systems, the apparent catalytic influence which the ions have on hydrogen evolution is of interest, since such an effect could be a distinct disadvantage in high rate secondary cell applications.

Analysis of the Air-Formed Oxide Film on a Series of Iron-Chromium Alloys by Ion-Scattering Spectrometry

R. P. Frankenthal* and D. L. Malm

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Low energy ion-scattering spectrometry has been used to obtain the composition-depth profiles of air-formed oxide films on a series of iron-chromium alloys. By using iron, chromium, Fe_2O_3, Cr_2O_3, and $Fe_{1.5}Cr_{0.5}O_3$ as standards, the atom composition ratios Cr/Fe and O/M (M = Fe + Cr) have been obtained quantitatively as a function of sputtering time. The air/oxide interface appears to be oxygen-rich or metal-deficient. The Cr/Fe ratio is low at this interface but increases and peaks a few angstroms inside it. This ratio then diminishes continuously to its value in the alloy at the oxide/metal interface. The O/M ratio diminishes continuously from the air/oxide to the oxide/metal interface and appears to be independent of alloy composition. There is no region of constant concentration of any of the components. The average Cr content of the oxide varies linearly with alloy composition but exceeds the Cr content of the alloy. This may be associated with the method of surface preparation. Based on differences in the shape of the composition profiles, it is speculated that the distribution and bonding of cations in the oxide phase, not their concentration, differentiate the stainless from the nonstainless alloys.

There have been numerous studies of the composition of oxide films on austenitic stainless steels, *e.g.*, Ref. (1-6). There have been relatively few studies on ferritic stainless steels or on the Fe-Cr binary system, and in particular of the effect of chromium content of the alloy on the composition of the oxide film. Yearian *et al.* (7) measured the lattice parameters of iron-chromium spinels. McBee and Kruger (8) measured the lattice parameters of the anodically formed passivating film on a series of iron-chromium alloys by transmission electron diffraction. The oxides on the alloys with relatively low chromium content are spinel-like, while the oxide on an Fe24Cr [Fe-24 weight per cent (w/o) Cr] alloy gave no diffraction pattern. They concluded that the films tend to become amorphous as the chromium content of the alloy is increased. Holliday and Frankenthal (9) characterized by soft x-ray spectrometry the anodically formed passivating film on the same alloys examined by McBee and Kruger (8) and interpreted their data to indicate that substantial changes occurred in film thickness and composition (Cr/Fe ratio) at an alloy Cr content of about 12%, the composition that separates the stainless from the nonstainless steels; this technique averages the composition across the film. Neither the atomic composition of the oxide film nor its variation with position from the air/oxide to the oxide/metal interface has been established.

Surface analysis techniques, such as photoelectron, Auger-electron, ion-scattering, and secondary-ion mass spectrometry, when combined with inert gas ion sputtering, are well suited for depth profiling thin oxide films. To make these techniques quantitative, however, it is necesary to have suitable calibration standards, to establish the variation of the sensitivities of the different elements with changes in the composition of the matrix, and to show that preferential enrichment of an element does not occur in any of the phases during sputtering.

In the present study, low energy ion-scattering spectrometry was used to obtain in a quantitative manner the composition profiles as a function of depth of the oxide film formed in air at room temperature on the same series of iron-chromium alloys used previously (8, 9), as well as on iron and on chromium. Low energy ion-scattering spectrometry (ISS), introduced by Smith (10, 11), has recently been reviewed by Buck and Poate (12). ISS is unique among the family of surface analysis techniques that have been introduced in recent years in that it examines only the outermost atomic layer of the surface. For surface analysis, a low energy (1-3 keV) monoenergetic beam of inert gas ions, *e.g.*, He^+ or Ne^+, of mass M_1 and energy E_0 is directed at the surface atoms of mass M_2. A fraction of the incident ions will experience an elastic binary collision with the surface atoms; of these, another fraction will be reflected through a laboratory angle of 90° and have a reduced energy E_1. Providing the mass of the surface

Table I. Composition of alloys (a/o)

Nominal	Fe5Cr	Fe10Cr	Fe12Cr	Fe14Cr	Fe24Cr
Cr content	5.1	10.2	12.7	15.1	25.0

atom (M_2) is greater than that of the incident ion (M_1), the following relation is obeyed for these ions

$$\frac{E_1}{E_0} = \frac{M_2 - M_1}{M_2 + M_1} \quad [1]$$

Thus, for a well-collimated, monoenergetic, incident ion beam, the ion energy distribution of the scattered fraction collected at 90° will consist of a peak or series of peaks corresponding to each element on the surface, the height of which is proportional to the surface concentration of the element. The incident ion beam also sputters the surface, so that a series of spectra obtained as a function of sputtering time give a depth profile through the surface layer.

In addition to determining the composition profiles of the oxide films, the merits and limitations of ISS and of the spectrometer used in these studies are discussed in the context of the present study.

Experimental

The materials studied were iron, chromium, and a series of iron-chromium alloys, the compositions [atom per cent (a/o)] of which are given in Table I. The oxide films on most of these alloys have been studied previously (8, 9).[1]

Each specimen was mechanically polished with a suspension of 1 μm alumina particles in water, rinsed in distilled water, in methanol, dried in a stream of nitrogen, and stored in a plastic box at room temperature and humidity for at least 24 hr before analysis.

Films of α-Fe_2O_3 and Cr_2O_3 several hundred angstroms thick were grown by the oxidation of iron and of chromium at 417°C (13) and 700° C (14), respectively. Their identity was confirmed by low angle reflection electron diffraction. The oxide $Fe_{1.5}Cr_{0.5}O_3$ was prepared by heating measured quantities of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ and $CrNH_4(SO_4)_2 \cdot 12H_2O$ in a porcelain crucible with a gas burner until the H_2O and NH_3 had been expelled and then firing the residue at 1000 °C for several hours. Chemical analysis indicated Fe-53.1 w/o, and Cr-16.2 w/o, giving an atom ratio Fe/Cr = 3.05. The balance, 3.07 w/o, is close to the desired O content of 30.4 w/o.

All spectra were obtained with a 3M Company Model 520 ion-scattering spectrometer. This instrument measures the scattered ion energy distribution only at 90° to the incident ion beam. Spectra were obtained both with ^{20}Ne and with ^{3}He as incident ions. In the ^{20}Ne spectra, the peaks for Fe and Cr are well resolved; however, an O peak is not measured since it is lighter than the incident ion (Eq. [1]). When ^{3}He is used as the incident ion, the O peak and the metal (M) peak are observed, but the Fe and Cr peaks are not resolved. All spectra were obtained with a noble ion gas pressure of 2×10^{-5} Torr, an incident ion energy of 2.5 keV, an ion beam current density of 1 $\mu A/cm^2$, and an ion beam diameter of 0.32 cm at half-maximum intensity. The best vacuum obtained with this spectrometer before introduction of the inert gas was in the low 10^{-8} Torr range, even after bake-out. A major fraction of the residual gas is H_2O, as determined with a quadrupole mass spectrometer.

Results and Discussion

For iron, chromium, and each alloy a series of ^{20}Ne spectra and a series of ^{3}He spectra were recorded for different sputtering times (Fig. 1-3). In the initial spectra the desired peaks were generally masked by adsorbed surface impurities; however, after sputter etching approximately a monolayer, well-defined peaks were obtained. Corrections were made for the overlapping of the spectra (Fig. 1) by calculating the fractional contribution of the overlapping spectrum to the sum of the spectra at the energy corresponding to the peak and weighting this for the relative concentrations of Fe and Cr. Correction for the background was made by drawing base lines as shown (Fig. 2 and 3). All results are expressed as peak height ratios, which are relatively insensitive to the manner in which the base lines are drawn.

From each ^{20}Ne spectrum the Cr/Fe peak height ratio was calculated and plotted as a function of sputtering time (Fig. 4). The bell-shaped part of the curve represents the composition profile through the oxide from the air/oxide interface ($t = 0$) to the oxide/alloy interface. The horizontal segment represents sputtering through the alloy. From each ^{3}He spectrum the O/M (M = Fe + Cr) peak height ratio was calculated and plotted as a function of sputtering time (Fig. 5). The oxygen peak does not vanish, hence the O/M ratio never approaches zero even after hours of sputtering. This is due to the continuous partial reoxidation of the active metal surface by the residual water vapor in the vacuum system when sputtering with ^{3}He.

To interpret the data quantitatively, the relative sensitivity of each atomic species and its variation from metal to alloy to oxide must be determined, and the absence of preferential sputtering of any element from

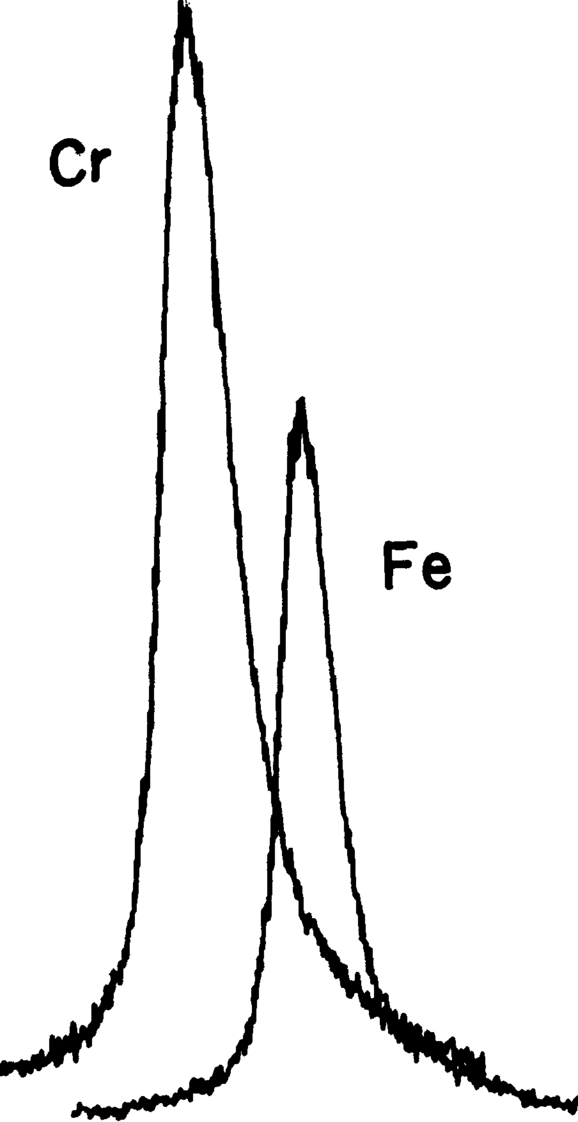

Fig. 1. ^{20}Ne spectra of iron and of chromium metal after sputter etching the oxide films. Spectrum of each metal recorded on same graph to show relative position and overlap. Chromium sensitivity is 1.5 times that of iron.

[1] The analyses given for these alloys in Ref. (8) and (9) are in weight per cent.

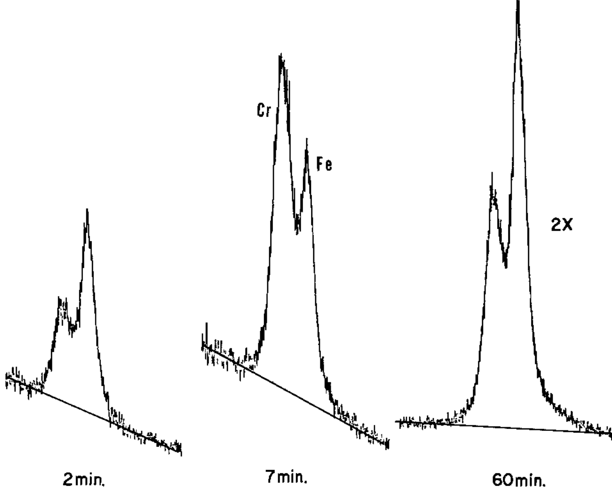

Fig. 2. ^{20}Ne spectra of an Fe24Cr alloy at different sputtering times. Cr peak is at left and Fe peak is at right in each spectrum. Note change in relative peak heights of Fe and Cr with sputtering time. First two spectra are within the oxide; last is from the alloy.

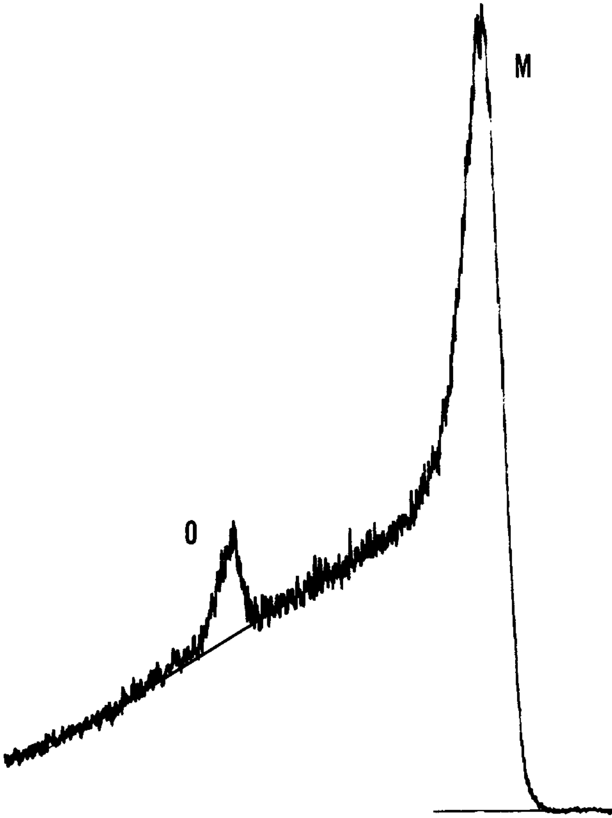

Fig. 3. ^{3}He spectrum of an Fe24Cr alloy after sputtering for 5 min. Note low sensitivity of O peak (left) relative to M peak (right). Fe and Cr cannot be resolved with ^{3}He.

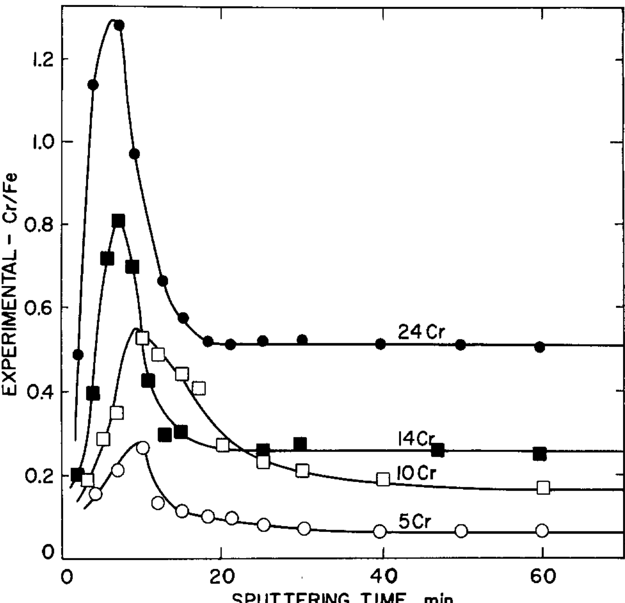

Fig. 4. Experimentally measured Cr/Fe peak height ratio as function of sputtering time with ^{20}Ne for four iron-chromium alloys. Cr content of alloy is shown on each curve. Bell-shaped part of curve is composition profile through oxide, horizontal part is the bulk alloy.

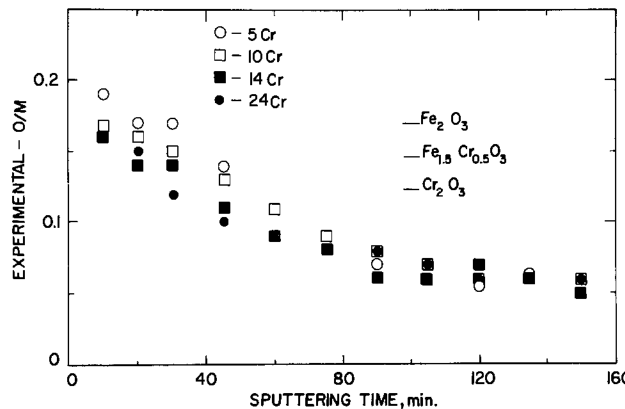

Fig. 5. Experimentally measured O/M peak height ratio as function of sputtering time with ^{3}He for different alloys. Ratios for three oxide standards are also shown.

the alloy or from the oxide surface must be established. From the ^{20}Ne spectra of iron and of chromium (Fig. 1), obtained after the oxides had been sputter etched, the relative sensitivity of the two metals, *i.e.*, the peak height ratio Cr/Fe, was 1.5 ± 0.1; the limits represent the extremes from many measurements taken after various sputtering times and on different days. When the experimental Cr/Fe peak height ratio for each alloy is corrected for the relative sensitivity of the two metals, good agreement is observed between the corrected ratio and that obtained from chemical analysis of the alloy (Fig. 6). In ^{20}Ne spectra obtained from a pellet of the oxide $Fe_{1.5}Cr_{0.5}O_3$, the average peak height ratio Cr/Fe was 0.52 in 15 measurements over a sputtering period of 180 min; the average deviation was 0.02 and the maximum deviation was 0.03. Correcting this peak height ratio for the relative concentration of Fe and Cr in the oxide gives a relative sensitivity Cr/Fe of 1.58, in agreement with that obtained from the metals.

From the ^{3}He spectra of the oxides Fe_2O_3 and Cr_2O_3, the peak height ratios O/Fe = 0.17 and O/Cr = 0.12 were obtained. Dividing the former by the latter gives a relative sensitivity Cr/Fe of 1.4, again in agreement with that found for the metals and the mixed oxide. The low sensitivity of oxygen, evidenced by the O/Fe and the O/Cr ratios, clearly limits the accuracy and precision of this result, as well as others calculated from O/M peak height ratios. The O/Fe and O/Cr sensitivities are obtained by dividing the above ratios by 3/2 to correct for the atomic composition of the oxides; this gives relative sensitivities of O/Fe = 0.11 and O/Cr = 0.08.

All the above results are explicable if (*a*) the relative sensitivity Cr/Fe = 1.5 ± 0.1 is the same for the metals, the alloys, and the oxides, (*b*) the sensitivity of O is independent of the oxide composition, and (*c*) preferential sputtering does not occur, within the detection limits of the spectrometer. While other explanations of the results may be postulated, they require compensating effects that appear to be unreasonable. For example, the agreement between the ISS data and

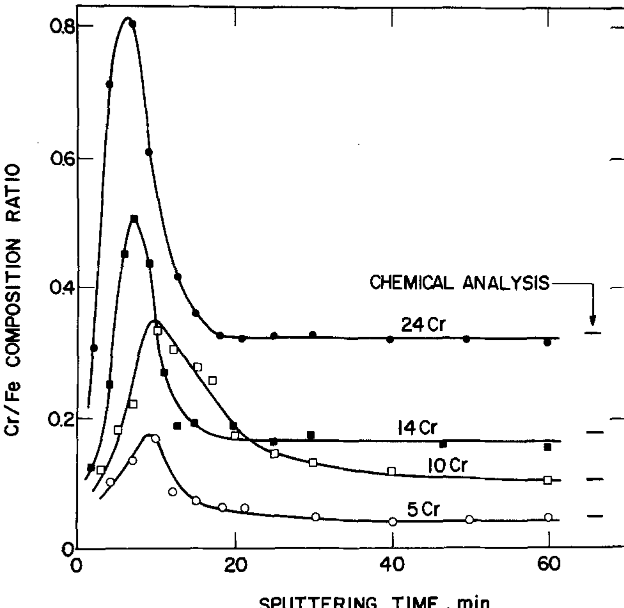

Fig. 6. Cr/Fe atom composition ratio as function of sputtering time for four iron-chromium alloys. Curves obtained after correcting experimental data for relative sensitivities of Fe and Cr in the oxides and in the alloys. Ratio for each alloy determined by chemical analysis is shown to right of each curve.

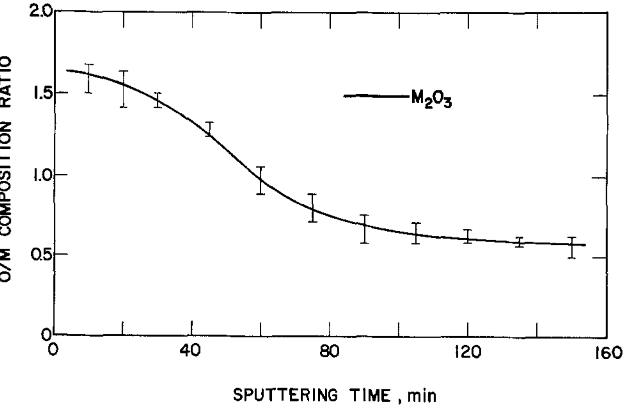

Fig. 7. O/M atom composition ratio as a function of sputtering time for five alloys and iron after correcting for relative sensitivities and relative sputtering rates with ^3He and ^{20}Ne. Ratio corresponding to M_2O_3 is also shown.

chemical analysis of the alloys (Fig. 6) could result from the preferential sputtering of one component compensating for changes in the relative sensitivities of Cr and Fe with changes in alloy composition; alternatively, the O sensitivity could be dependent on oxide composition but changes in a manner that is compensated for by changes in the sensitivity of Cr or Fe and/or by preferential sputtering of one of the elements. Since there is no evidence for any of these effects, the simpler explanation given above is preferred.

Having established that the relative sensitivity Cr/Fe is independent of phase, the data of Fig. 4 were corrected for the relative sensitivity to give the atomic composition ratios through the oxides and into the alloys (Fig. 6). The curve for the Fe12Cr alloy (not shown) lies between those for the Fe10Cr and Fe14Cr alloys.

The atom composition ratio O/M is now calculated. The data of Wehner and co-workers (15, 16) and of Oechsner (17) indicate that the sputtering rates for helium and neon are approximately proportional to their masses, all other conditions being the same. Assuming then that the sputtering rate for ^{20}Ne is 20/3 times that for ^3He, the abscissas in Fig. 5 and 6, *i.e.*, the sputtering times, can be related. Thus one obtains from Fig. 6 the Cr/Fe atom composition ratio corresponding to the O/M ratio at any given time in Fig. 5. From this and from the relative sensitivities of the elements, the atom composition ratio O/M was calculated as a function of sputtering time (Fig. 7). The data include all the alloys and iron. The error bars indicate extremes and are within experimental error, which is $\pm$ 0.1. The data for chromium fall on the initial part of the curve, but at later times the points lie slightly above those shown. This may be due to the greater affinity of chromium for oxygen,[2] which makes it a better getter for the residual water vapor in the vacuum system. The lack of dependence of the O/M ratio on alloy composition, unless accidental, confirms the assumption that the sputtering rates are proportional to the masses of the sputtering ions.

The sputtering rates were not measured. They may be estimated from (19)

$$S = 0.2Y\overline{V}I_p{}^+d^{-2}(\text{Å/hr}) \quad [2]$$

in which S is the rate, Y is the sputtering yield, $\overline{V}$ is the average atomic volume in $Å^3$, $I_p{}^+$ is the ion beam current in nA, and d is the ion beam width at half-maximum intensity in mm. The yield of iron sputtered with 2.5 keV Ne ions is estimated to be 2 atoms/ion by extrapolating the data of Wehner and co-workers (15, 16). The other factors in the above equation are known, so that a sputtering rate of approximately 300-400 Å/hr is calculated for iron. The rate for chromium is similar. It has been estimated (20) that chromium is sputtered 5 to 10 times faster than Cr_2O_3. Assuming that iron and the alloys also sputter 5 to 10 times faster than their oxides, we estimate the sputtering rate of the oxides to be 60 $\pm$ 20 Å/hr with ^{20}Ne. The sputtering rate of the oxides with ^3He is of the order of 10 Å/hr. From Fig. 6 and assuming a sputtering rate of 60 Å/hr with ^{20}Ne, the oxide thicknesses are estimated to be 20Å for the high-Cr alloys (Cr $>$ 12%) and 30-40Å for the low-Cr ones (Cr $<$ 12%), in agreement with previous results (9). These differences in thickness are masked during sputtering with ^3He (Fig. 7) by the continuous reoxidation of the surface by the residual water vapor.

Each point on the composition profiles is an average over all crystallographic planes, grain boundaries, and surface defects. Nonuniform sputtering and mixing due to knock-on effects have not been considered. These would smear out compositional variations. Thus sharp changes in composition over a distance of a few angstroms may be lost, and the true peak in the Cr/Fe composition ratio in the oxides may be somewhat greater.

From the composition profiles (Fig. 6 and 7) it appears that the composition of the oxide film changes continuously with depth. At the air/oxide interface the film appears to be an oxygen-rich or metal-deficient M_2O_3 with a low Cr content for all the alloys. Immediately beneath the surface layer the Cr content rises sharply, peaks, and then decays to its level in the bulk alloy. At its maximum the Cr content is two to three times that in the alloy. However, even for the Fe24Cr alloy the maximum observed Cr/Fe ratio is only about 0.8. The interface between the oxide and the alloy appears quite sharp, although less so for the low-Cr alloys. This is evident in Fig. 6 but not in Fig. 7, probably because of the inability to attain an oxygen-free surface. There is no region of constant O/M composition ratio, indicating that there is no layer of finite thickness in which an oxide of constant composition exists.

The average Cr/Fe composition ratio in the oxide film is given by

$$\left(\frac{\text{Cr}}{\text{Fe}}\right)_{\text{avg}} = \frac{1}{t_{o/a}}\int_o^{t_{o/a}} \left(\frac{\text{Cr}}{\text{Fe}}\right) dt \quad [3]$$

in which t is the sputtering time and $t_{o/a}$ is the time

[2] Standard free energies of formation for Cr_2O_3, Fe_2O_3, and Fe_3O_4 are −167, −118, and −121 kcal/mol O_2, respectively (18).

to sputter to the oxide/alloy interface. $(Cr/Fe)_{avg}$ may be obtained by integrating the area under each curve in Fig. 6. Then the average fraction of metal or cations in the film that is Cr is given by

$$\left(\frac{Cr}{Cr + Fe}\right)_{avg} = \frac{(Cr/Fe)_{avg}}{1 + (Cr/Fe)_{avg}} \quad [4]$$

This is plotted as a function of alloy composition in Fig. 8. The dashed line in this figure shows the result that would be obtained if these were equal. It is seen that there is an excess of Cr in the oxide over that in the alloy. The excess increases with increasing alloy Cr content. The slope of the plot is 1.35. No change in slope is observed around the alloy composition of 12Cr, as had previously been suggested (9). The reason for this difference between the two studies may be associated with the different means of surface and oxide film preparation or with the different analytical techniques. In the earlier x-ray study, the films were produced by anodic oxidation; also, this technique measures a signal that emanates from the bulk of the oxide, not only from the surface as with ISS. This latter point will be further discussed below.

The excess chromium in the film indicates a loss of iron. Since the profiles do not show an excess of iron at the oxide/alloy interface, it must have been lost during the mechanical polishing operation. This may be due to one of the following: (*i*) The rate of chromium metal dissolution under the polishing conditions is slower than that of iron, (*ii*) chromium passivates more readily than iron under these conditions, or (*iii*) the iron oxides or hydroxides formed are more soluble than the chromium ones. Since this result appears to have been affected by the technique of surface preparation, it is not clear whether the result is relevant to our understanding of the mechanism of passivation. However, it may be relevant technologically since similar techniques are in common use.

Despite these considerations, it is well known that the corrosion resistance of steels in most environments is governed more by the Cr content of the steel than by the means of surface preparation. The effect of alloy Cr content on the electrochemical and corrosion properties of steels is greatest around 12% (21, 22), leading to the hypothesis that a major change in film composition may occur at this alloy composition. This is not evident from Fig. 8 or from the variation of the peak Cr/Fe ratio in Fig. 6 as a function of alloy composition. An examination of the data in Fig. 6 does show some differences between the low-Cr and the high-Cr steels. First, the high-Cr alloys have a thinner oxide than the low-Cr ones. Second, the distribution of Cr in the low-Cr alloys is more skewed than in the high-Cr ones. Third, the maximum in the Cr/Fe composition ratio appears at a sputtering time of 6 ± 1 min for the high-Cr alloys and at 10 ± 1 min for the low-Cr ones. The corresponding times on the curve of Fig. 7, *i.e.*, the times to sputter to the same depth with ^3He, are 40 and 70 min; the O/M atom composition ratios for these times are 1.3 and 0.8, respectively.

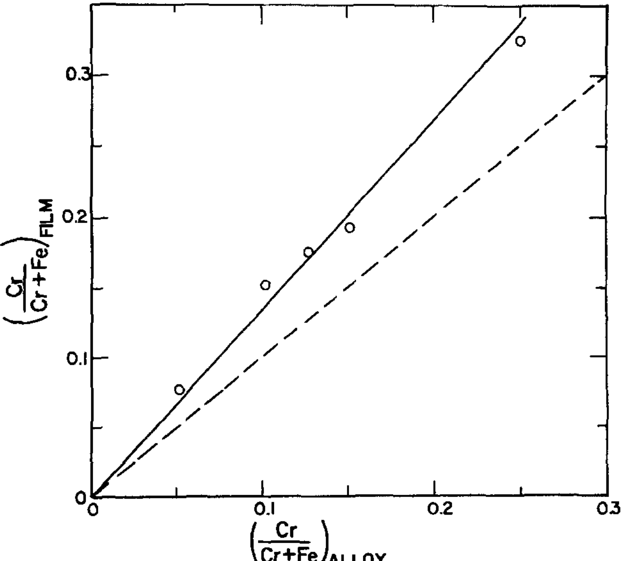

Fig. 8. Average oxide film Cr content vs. alloy Cr content, showing a linear relation from 0 to 25% Cr in the alloy. Dashed line represents equal concentrations in the oxide and alloy.

From this we speculate that the "stainless" behavior may not be associated with the quantity of chromium in the film but with the distribution, the defect structure, and the bonding of the cations. For the stainless alloys, the Cr content of the oxide is greatest when the O/M atom composition ratio is in a range corresponding to M_2O_3 or M_3O_4. But for the nonstainless alloys, the maximum Cr content of the oxide occurs in a region which is highly oxygen deficient, O/M < 1 or MO_{1-x}. Thus the shift in the position of the maximum in the Cr/Fe composition ratio between the stainless and the nonstainless alloys is accompanied by a change in the proportions in which the oxygen is bonded to Cr and Fe and hence in the valence states of the cations. Unfortunately, ISS gives no information on the valence state. However, since the free energy of formation of Cr_2O_3 is about 50 kcal/mol more negative than that of Fe_2O_3 or Fe_3O_4 (18), it appears likely that the average valence state of Fe decreases more rapidly with distance into the oxide than that of Cr.

Comparison of ISS and soft x-ray spectrometry data.—Both techniques have shown that the oxide film on the low-Cr alloys is thicker than that on the high-Cr ones. However, the data from the soft x-ray study (9) suggested that the Cr content of the oxide increased more sharply between the 10Cr and the 14Cr alloys than is expected on the basis of the change in alloy composition. This was not found in the ISS study. This discrepancy probably results from the different resolving powers of the two techniques. ISS resolves each atomic layer, while soft x-ray spectrometry obtains its signal from throughout the oxide. For the latter technique, the signal from beneath the surface is attenuated exponentially with depth according to Beer's law. The maximum in the Cr/Fe composition ratio occurs at 6 min for the high-Cr alloys and at 10 min for the low-Cr ones (Fig. 6). Thus the Cr x-ray signal from the oxide on the low-Cr alloys is attenuated more than that from the high-Cr ones, resulting in a greater difference in the signal intensity than dictated by the average Cr content of the oxide.

Summary

Composition-depth profiles have been obtained for the oxides on a series of iron-chromium alloys ranging in composition from 0 to 25 a/o Cr. From the spectra of a series of standards, it was determined that the relative sensitivities of the oxide components are independent of alloy or oxide composition and phase. No preferential sputtering of any component is observed, within the resolution of the spectrometer. The profiles show there is no region of constant concentration of any component within the oxide. The O content diminishes continuously from the air/oxide to the oxide/alloy interface. The Cr content is low at the air/oxide interface but then rises sharply and peaks a few angstroms inside that interface; it then decreases continuously to its value in the alloy at the oxide/alloy interface. The average Cr content of the oxide varies linearly with alloy composition and exceeds the Cr content of the alloy. This may be associated with the method of surface preparation. It is speculated that differences in distribution and bonding of the cations within the oxide phase distinguish the stainless from the nonstainless alloys.

Acknowledgments

We wish to thank Mrs. I. D. Payne for recording many of the ISS spectra, G. W. Kammlott for the elec-

tron diffraction data, and M. Robbins for help in preparing the iron-chromium oxide standard.

Anodic Oxide Films on Nickel in Acid Solutions

B. MacDougall* and M. Cohen*

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

The formation and removal of steady-state oxide films on nickel electrodes anodized in Na_2SO_4 solutions of pH 8.4-2.0 have been examined. Surface activity measurements showed that complete removal of all of these oxide films was possible in solutions of pH $\leq$ 2.8 with moderate cathodic treatments. Instability of the pH in the vicinity of the electrode was the probable cause of oxide nonreducibility at pH $>$ 2.8. The oxide was removed cathodically by a galvanostatic charging technique in pH 2.8 and a relative measure of the amount of oxide remaining at any time during the cathodic pulse could be obtained by subsequent application of an anodic potential step. No significant chemical dissolution of the oxide occurred during cathodic charging, in contrast to the situation on open circuit. However, the quantity of oxide on anodized nickel could not be determined from the total cathodic charge passed in its removal because of simultaneous massive hydrogen evolution. This was not the case with the oxide on electropolished nickel where galvanostatic charging techniques could be used to accurately determine the oxide thickness.

In a previous paper (1), electropolished nickel was shown to have a thin (6-8Å) film of NiO of somewhat expanded lattice parameter (by ca. 2%) which could be reduced with sufficient cathodic polarization in pH 8.4 Na_2SO_4. In contrast, the steady-state oxide on nickel electrodes anodized in pH 8.4 Na_2SO_4 was a 9-12Å film of NiO, with normal lattice parameter, which could not be cathodically reduced in the neutral solution. Consequently, cathodic coulometry in neutral solution could not be used to determine film thickness of the anodically formed oxide. While x-ray emission and anodic potential step techniques provided alternative methods for measuring steady-state nickel oxide coverages in neutral solution, they could not be used for accurate determination of very small oxide coverages (*e.g.*, less than a monolayer). A sensitive *in situ* cathodic treatment in an electrolyte where oxide reduction is possible, *e.g.*, a more acid solution, should provide a method for accurately determining small oxide coverages and also for characterizing and comparing the steady-state oxides formed at different potentials.

* Electrochemical Society Active Member.

Key words: passivity, nickel oxide, cathodic reduction, chemical dissolution.

There have been suggestions in the literature (2-7) that the oxide film formed on anodized nickel in acid solutions is also susceptible to cathodic removal in these acid solutions. However, little quantitative work has been done in either determining the extent of oxide removal at various pH's or in characterizing the nickel oxides formed. The present work involves an investigation in the pH range 8.4-2.0 of the cathodic reduction behavior of the steady-state oxide film on anodized nickel electrodes. The oxides formed at different pH's are compared with regard to both electrochemical and electron-optical properties. At the lower pH values investigated, the usefulness of the cathodic galvanostatic charging technique for determining oxide thicknesses on both anodized and electropolished nickel is examined. While mainly steady-state films are discussed here, the investigation provides a basis for further work dealing with the early and intermediate stages of nickel oxidation in solution.

Experimental

Specimen preparation.—Polycrystalline specimens, 1 × 2.5 cm, were prepared from zone-refined nickel

sheet of 99.996% purity as described elsewhere (1). They were degreased with benzene, chemically polished (1), electropolished for 2 min at 23°C in a 57% sulfuric acid solution at *ca.* 0.5 $A\text{-}cm^{-2}$ and then annealed at 800°C in a vacuum of 10^{-8} Torr. The specimens were electropolished again immediately before use in an experiment. A (111) nickel single crystal was used to obtain information regarding the lattice parameters of nickel oxides.

Reference electrode.—Potentials quoted in this paper are referred to the Hg_2SO_4 electrode in 0.15*N* Na_2SO_4 (+0.665V[1] with respect to the standard reversible hydrogen electrode).

Solution.—Deaerated solutions of 0.15*N* Na_2SO_4 had their *p*H's adjusted to various values in the range 8.4-2.0. Experiments were conducted at 25°C.

Apparatus.—A Princeton Applied Research Model 175 universal programmer was used in conjunction with a Wenking fast-rise potentiostat to obtain the potentiodynamic sweep profiles. These profiles and the galvanostatic cathodic charging curves were recorded on a Hewlett-Packard Model 7004B X-Y recorder. A high-speed Brush recorder was used to follow the initial rapid decrease of current after an anodic potential step treatment. Two types of electrochemical cell were used, one having the counter and recording electrodes in the same compartment and the other having them in different compartments separated by a glass frit and stopcock. The former cell was used for potential step experiments since large, initial current surges were involved. Both cells contained 50 ml of electrolyte and gave similar potentiodynamic sweep and galvanostatic charging results.

Electrochemical procedure.—After electropolishing, the electrodes were immersed in deaerated Na_2SO_4 solutions of various *p*H's under cathodic polarization sufficient to remove the prior 6-8Å film of NiO. The oxide-free electrodes were then anodized using either the potentiodynamic sweep or potential step methods, the latter being most frequently used. Unless specified otherwise, it is to be assumed that the potential step method was employed. An anodization time of 1 hr was used to establish the steady-state condition of oxide coverage (1). The effect of various cathodic treatments on the anodized electrodes was analyzed in terms of the charge under the anodic peak on a subsequent anodic sweep. Electrochemical transfer experiments were carried out by anodizing for 1 hr at one *p*H, then immediately transferring through the air to a fresh, deaerated solution of another *p*H where the anodized specimen was given a cathodic reduction. The effect of this air exposure on the steady-state oxide films was investigated by comparing, in *p*H 2.8 solutions, the open-circuit potential-time curves for anodized nickel with and without the air exposure. The similarity of results indicated that the brief air exposure did not significantly alter the steady-state oxide on anodized nickel.

Cathodic charging curves were obtained on both electropolished and anodized nickel electrodes in *p*H 2.8 Na_2SO_4, the electropolished specimens being immersed in the solution under cathodic polarization. At any time during this reduction, the relative degree of activity of the electrode could be obtained by interrupting the cathodic charging with an anodic potential step and measuring the anodic charge passed. The anodic potential step technique was also used to study chemical dissolution of the steady-state oxide in the more acid solutions. In this case, the relative activity of anodized nickel electrodes was determined after various times on open circuit. If the solution was to be analyzed for nickel, after either the open-circuit or cathodic charging experiments, the nickel electrodes were transferred to a fresh electrolyte after anodization.

[1] This potential was measured against both a saturated calomel electrode and hydrogen reference electrode. The hydrogen reference was used with a 0.15*N* Na_2SO_4 solution acidified to *p*H 2.8 with H_2SO_4, and there was thus no liquid junction potential.

Results

Reduction of nickel oxide in acid solutions.—Figure 1 shows anodic potentiodynamic *i-V* profiles obtained on nickel electrodes at *p*H of 4.0 and 2.8 with a sweep rate of 10 $mV\text{-}sec^{-1}$. The cathodic currents have been omitted for simplicity and the sweep limits have been adjusted to take account of the 60 mV shift of the nickel oxide formation potential with unit *p*H change. Profiles 1 and 3 were obtained on electropolished nickel electrodes, after a prior cathodic treatment of 2 min at −1.2 and −1.27V at *p*H 2.8 and 4.0, respectively. At both *p*H values, cathodic treatment of electropolished nickel at more negative potentials and/or for longer periods of time did not lead to any increase in the charge under the anodic peaks, *i.e.*, the quantity of nickel dissolved remained the same.[2] Profiles 2 and 4 are the second anodic sweeps after anodic cycling to 0 and −0.07V and cathodic cycling to −1.0 and −1.07V in *p*H 2.8 and 4.0, respectively. The very small difference in anodic peak charges at *p*H 2.8 (profiles 1 and 2) disappeared and the sweeps became identical with a slightly more vigorous cathodic treatment of the anodized nickel. At *p*H 4.0 the difference between the first and successive sweeps remained large even after a vigorous cathodic treatment of the anodized nickel electrode. This is shown by profile 5 which is the anodic sweep on the anodized electrode after a prior cathodic treatment of 10 min at −1.37V. It should be noted that the anodic treatments specified in Fig. 1 probably did

[2] Cf. Ref. (1, 8) where solution analysis by atomic absorption spectroscopy showed that almost all the charge under the anodic peak is accounted for by Ni^{2+} in solution.

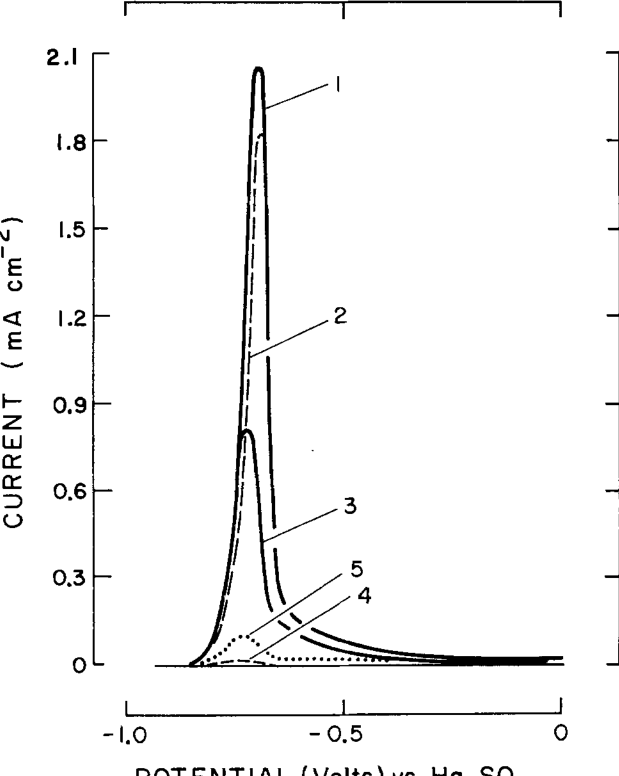

Fig. 1. Anodic potentiodynamic current-potential profiles for nickel electrodes at 10 $mV\text{-}sec^{-1}$ at *p*H 2.8 (profiles 1 and 2) and *p*H 4.0 (profiles 3 to 5) under various electrode conditions: (profiles 1 and 3) after a cathodic reduction of electropolished nickel sufficient for removal of the prior oxide (see text); (profiles 2 and 4) second anodic sweep after initially cycling to 0 and −0.07V at 10 $mV\text{-}sec^{-1}$ and then cathodic cycling −1.0 and −1.07V, respectively; profile 5 anodic sweep on anodized nickel in *p*H 4.0 after cathodic reduction at −1.37V for 10 min.

not give steady-state oxide films on nickel because of the transient nature of the sweep technique. However, the same principles apply in the situation where anodic holding is used to produce an equilibrium oxide film.

The surface activity of a nickel electrode at any pH will be defined here as the ratio of the anodic peak charge during a potentiodynamic sweep on that electrode to the charge obtained on an oxide-free nickel surface with a similar sweep (*e.g.*, curve 1, Fig. 1). Figure 2 shows the dependence of electrode surface activity on solution pH after a standard anodic and cathodic treatment. Since this work was concerned with the steady-state oxide on anodized nickel, the anodic treatment employed in Fig. 2 was 1 hr at $V_a = \{0.17V - (0.06V)(pH)\}$, *i.e.*, $V_a = 0V$ at $pH = 2.8$. This anodization potential was well within the passive region (Fig. 1) and the 1 hr anodization time allowed the current to fall to $<2 \times 10^{-7}$ A-cm^{-2} with little further decrease of current with time. A standard cathodic treatment of 3 min at $V_c = \{-1.03V - (0.06V)(pH)\}$, *i.e.*, $V_c = -1.2V$ at $pH = 2.8$, completely removed the oxide on anodized nickel only in solution of $pH \leq 2.8$. At $pH > 2.8$, the amount of surface activity which could be recovered was highly dependent on solution stirring by bubbling N_2 through the cell during the cathodic treatment; this was not the case at $pH \leq 2.8$. Also shown in Fig. 2 is the effect of a more severe cathodic treatment, *i.e.*, 10 min at $V_c = \{-1.33V - (0.06V)(pH)\}$, *i.e.*, $V_c = -1.5V$ at pH 2.8, on nickel surfaces given the same anodic treatment as described above. Even with this more intense cathodic polarization, little surface reactivation was observed above a pH of *ca.* 4.0. Measurement of the solution pH showed that the variation during a run was less than 0.1 pH unit over the range examined (2.0-5.0).

Figure 3 shows the effect of cathodic reduction potential at pH 2.8 on surface activity of a nickel electrode previously anodized for 1 hr at 0V in the same solution. Using a 3 min polarization time, the minimum cathodic potential required for complete activation of the anodized nickel electrode in pH 2.8 is seen to be close to $-1.05V$.

Oxide characterization as a function of pH.—The oxide thickness was determined by x-ray emission spectroscopy at solution pH values of 8.4, 4.5, and 2.8. The anodic treatment was that used in Fig. 2, *i.e.*, 1 hr for all pH's at an equivalent NiO formation potential. The

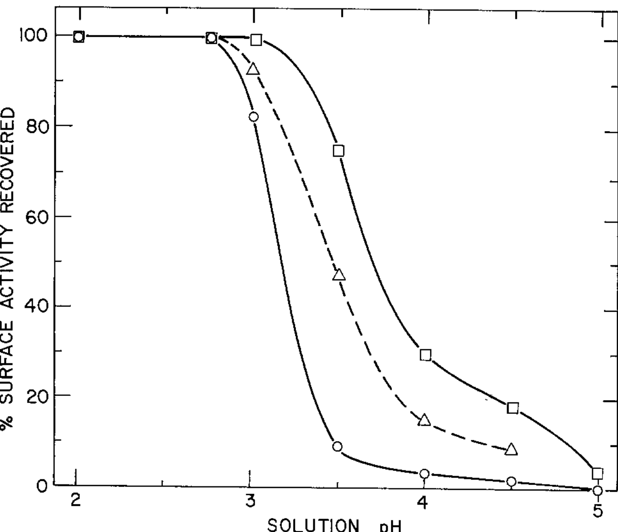

Fig. 2. Variation of surface activity with pH of solution in which standard anodic and cathodic treatment is applied. The prior anodization is for 1 hr at $V_a = \{0.17V - (0.06V)(pH)\}$ with the subsequent cathodic treatment being: △, 3 min at $V_c = \{-1.03V - (0.06V)(pH)\}$ with N_2 bubbling during treatment; ○, as in △ but without N_2 bubbling; □, 10 min at $V_c = \{-1.33V - (0.06V)(pH)\}$ with N_2 bubbling during treatment.

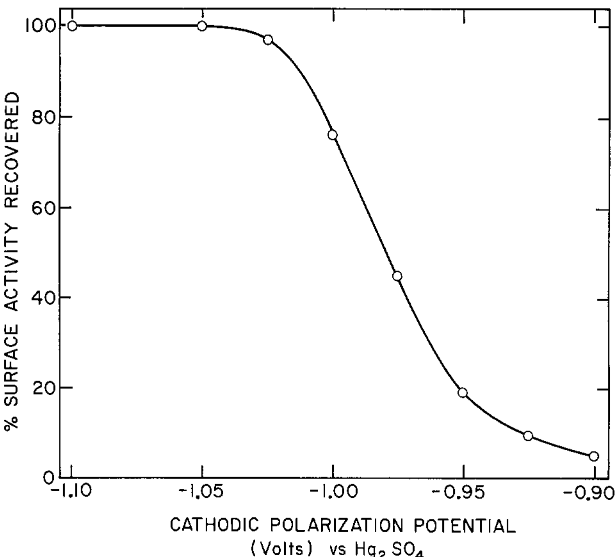

Fig. 3. Dependence of surface activity of a nickel electrode previously anodized for 1 hr at 0V in pH 2.8 on the cathodic potential at which the electrode is polarized for 3 min in the same solution.

oxide thickness was the same within experimental error, *i.e.*, 9-12Å, at each pH investigated. At pH 2.8, this oxide thickness was independent of anodization potential over the range -0.4 to $+0.3V$, similar to results in pH 8.4 (1). Reflection electron diffraction patterns were taken of a (111) nickel crystal surface given the above anodic treatment at $pH = 8.4$, 4.5, and 2.8. All patterns were those of NiO and were similar with regard to (*i*) measured lattice parameter (which was closer to stoichiometric NiO than that on electropolished nickel), (*ii*) oxide epitaxy, and (*iii*) grain size (1).

To check on the electrochemical properties of oxides formed at different pH values, a nickel electrode was anodized at $-0.34V$ for 1 hr in pH 8.4 Na_2SO_4 and then transferred to a cell with a pH 2.8 solution. The anodized electrode was given a cathodic treatment in the pH 2.8 solution which is just sufficient for removal of the oxide formed at 0V for 1 hr in the same solution, *i.e.*, 3 min at $-1.05V$ (see Fig. 3). This treatment gave a total reactivation of the surface toward nickel dissolution on a subsequent anodic sweep indicating complete removal of the oxide formed in neutral solution. The same experiment was also performed in the reverse direction, *i.e.*, the steady-state anodization was done in pH 2.8 at 0V for 1 hr with the cathodic reduction in pH 8.4 (for 10 min at $-1.45V$). The surface activity on the following anodic sweep in the same pH 8.4 solution was very low, the oxide formed in pH 2.8 being as nonreducible in pH 8.4 as the oxide formed in pH 8.4 itself.

Determination of oxide coverage.—Figure 4a shows the cathodic galvanostatic charging curves at 20 μA-cm^{-2} in pH 2.8 for nickel electrodes which had been given a prior anodization at 0V for 15 sec, 1 min, and 1 hr in the same solution. Also shown is the charging curve obtained upon immersion of a freshly electropolished nickel electrode into a pH 2.8 Na_2SO_4 solution. Figure 4b shows the charging curves for electropolished and anodized nickel electrodes with a more sensitive time base. The eventual, steady cathodic potential at 20 μA-cm^{-2} (Fig. 4a) was the same in all cases except for an anodization of 1 hr at 0V. In this case, the potential was still positive by 0.12V to that expected for an oxide-free surface after 1 hr of cathodic polarization. This situation persisted even after an intervening potentiostatic cathodic reduction of 10 min at $-1.3V$, a treatment which should have removed any remaining oxide (Fig. 3). No detectable roughening of the surfaces was observed by either electron diffraction or

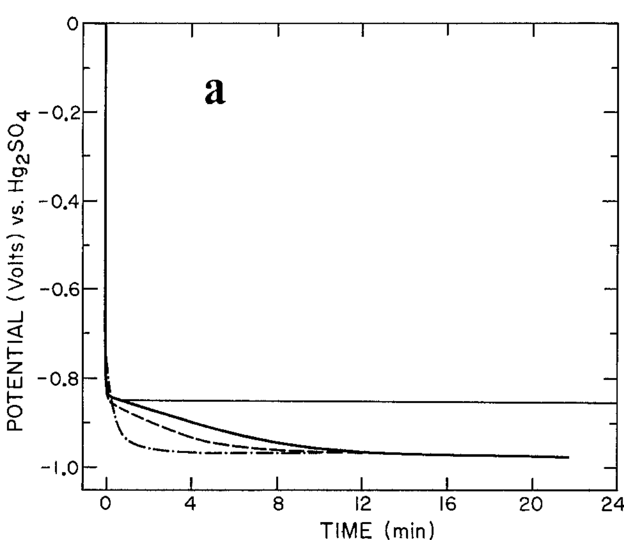

Fig. 4a. Cathodic galvanostatic charging curves, at 20 μA-cm^{-2}, of nickel electrodes in various electrochemical states in pH 2.8 Na_2SO_4: —●—●, electropolished nickel; – – –, anodized at 0V for 15 sec; ▬▬ , anodized at 0V for 1 min; ———, anodized at 0V for 1 hr.

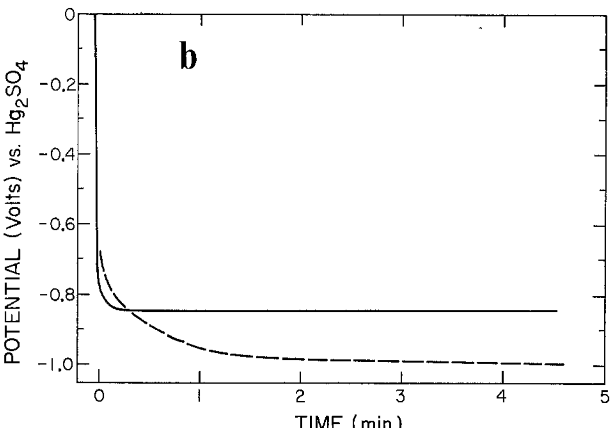

Fig. 4b. As in (a) but with a more sensitive time base: – – –, electropolished nickel; ———, anodized at 0V for 1 hr.

replica electron microscopy after any of the electrochemical treatments referred to in Fig. 4a, eliminating this as a possible explanation.

The surface activity of the electrode can be determined at any time during the cathodic charging by stepping the potential back to 0V and comparing the anodic charge passed with that obtained from a known oxide-free surface (*i.e.*, cathodically reduced electropolished nickel). Figure 5 shows the results obtained when this technique was applied to electrodes which had been anodized at 0V for either 1 min or 1 hr and then cathodically charged at 20 μA-cm^{-2}. As expected, the rate of surface reactivation was more rapid after the 1 min anodization than the 1 hr anodization. It is also seen that the steady potential at a cathodic current of 20 μA-cm^{-2} can vary with the prior anodization treatment of the electrode even if the surface becomes oxide free.

To determine whether possible changes in the electrolyte composition are responsible for this potential shift, two experiments were carried out. First, a freshly electropolished nickel electrode was immersed with cathodic polarization into the "used" Na_2SO_4 solution which had given the charging curve in Fig. 4a after 1 hr at 0V. The potential rapidly adjusted itself to the correct value expected for an oxide-free surface (*i.e.*, *ca.* −1.0V). Second, an electrode which had been anodized for 1 hr at 0V was transferred to a fresh *p*H 2.8

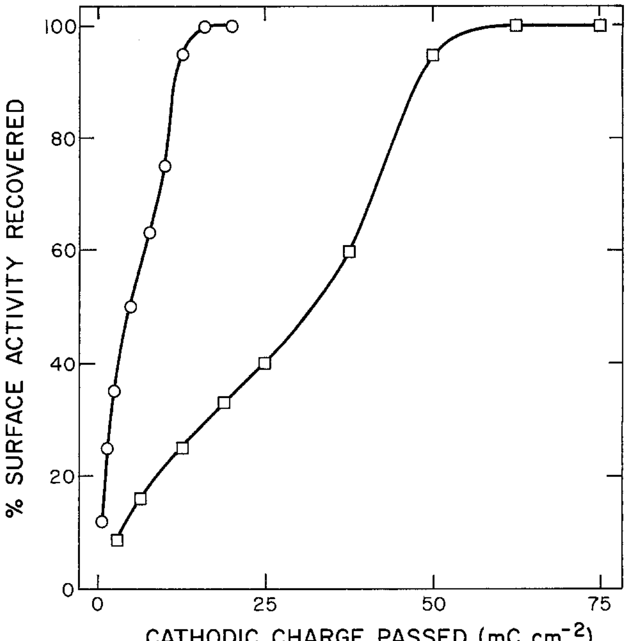

Fig. 5. Dependence of percentage of surface activity recovered on the charge passed during cathodic galvanostatic charging at 20 μA-cm^{-2} of nickel electrodes anodized at 0V for either 1 min (○) or 1 hr (□). pH of anodization and reduction was 2.8 .0.47 mC-cm^{-2} corresponds to one oxygen atom per surface nickel; 1 mC-cm^{-2} = 6.9Å NiO.

solution and cathodically polarized at 20 μA-cm^{-2}. The resulting steady potential was still 0.12V positive to that expected for the oxide-free surface. These results indicate that possible changes in the electrolyte during the 1 hr anodization at 0V were not responsible for the 0.12V anodic shift in the steady potential for hydrogen evolution at 20 μA-cm^{-2}.

The anodic potential step technique was thus used in conjunction with cathodic charging curves to determine the time (and charge) required for complete removal of the oxide formed after either 1 min or 1 hr at 0V. From Fig. 4 and 5 the charges are seen to be *ca.* 15 mC-cm^{-2} for the 1 min film and 65 mC-cm^{-2} for the 1 hr film formed at 0V. These charges correspond to 85 and 370Å of NiO. In comparison with the x-ray emission data which indicates a steady-state film thickness of 9-12Å, these values are much too high and indicate that cathodic side reactions were playing a major role during oxide reduction of anodized nickel.

To investigate the possibility of Ni^{2+} reduction contributing to the cathodic charges given in Fig. 5, solutions were analyzed for Ni^{2+} at times of 1 min and 1 hr after stepping the potential of an initially oxide-free electrode to 0V. The quantities of Ni^{2+} removed from the electrode surface were 1.8 and 2.4 μg-cm^{-2}, respectively. Galvanostatic cathodic charging curves were obtained after prior anodizations at 0V for 1 min and 1 hr in solutions containing 9 and 12 μg-cm^{-2} of dissolved Ni^{2+}, *i.e.*, concentrations five times more than are found after a single anodization. The results were not altered by the increased concentrations of Ni^{2+}. Further experiments were conducted to check the influence of solution agitation during the anodization at 0V on the cathodic charges consumed in the subsequent galvanostatic reactivation of the surface. No effect was observed with the anodization times employed, these being 1 sec, 1 min, and 1 hr at 0V.

The cathodic charging curve obtained after 1 hr anodization at 0V did not show the arrest structure expected for oxide reduction. With a more sensitive potential scale (not shown here), a slight increase of voltage with time was observed during the first 50 min of polarization. It was, however, insignificant when compared with the definite arrest structures evident on electrodes given a short anodization at 0V (15 sec and

1 min) and on electropolished nickel (Fig. 4a and b). The structure within the charging curve of electropolished nickel was only resolved when the sensitivity of the time base was increased considerably (Fig. 4). The arrest charge indicates an NiO thickness of *ca.* 7Å on electropolished nickel, in excellent agreement with the x-ray emission results.

Role of chemical dissolution in oxide removal.—In order to determine the stability of the steady-state oxide on anodized nickel toward chemical dissolution in the pH 2.8 solution, previously anodized electrodes were left in the solution on open circuit for various times. The effect of this treatment on the NiO coverage could be determined by subsequent initiation of an anodic potential step back to the anodization potential. Figure 6 shows the effect of time on open circuit on the potential and surface activity of a nickel electrode which was previously anodized at 0V for 1 hr in the same solution. Identical results were obtained with anodized nickel electrodes which were transferred to a fresh pH 2.8 solution with brief exposure to air during the transfer. For times on open circuit of less than *ca.* 50 min, very little surface reactivation was observed. However, at longer times the activity increased very rapidly with complete surface reactivation occurring within 110 min. The beginning of the significant increase in surface activity is seen to correspond with the abrupt change in the open-circuit potential to *ca.* −0.75V. Table I gives the corresponding quantities of nickel in solution for various times on open circuit in a fresh pH 2.8 solution. Also given is the amount of nickel in solution after surface reactivation has been achieved by cathodic charging, *i.e.*, after 50 min at −20 μA-cm^{-2} (see Fig. 5).

Discussion

In a previous paper (1) it was shown that the steady-state oxide on anodized nickel electrodes could not be cathodically reduced in the pH 8.4 Na_2SO_4 solution. Cathodic characterization of the oxide was thus impossible and electropolishing in sulfuric acid before cathodic reduction was required for reactivation of the nickel surface after anodization. The present investigation was undertaken to determine whether the oxide film on anodized nickel electrodes is susceptible to complete cathodic removal at pH more acidic than 8.4. The results were positive and an "optimum" pH was established at which to investigate the anodization of nickel electrodes by cathodic reduction techniques.

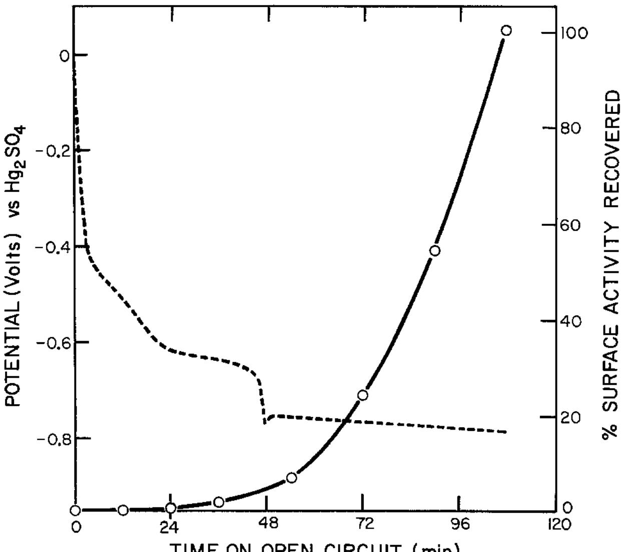

Fig. 6. Dependence of percentage of surface activity recovered on the time at open circuit in pH 2.8 after a previous anodization for 1 hr at 0V in pH 2.8 (○). Also shown is the corresponding variation of open-circuit potential with time (— — —).

Table I. Quantity of Ni^{2+} dissolved in pH 2.8 solutions after various treatments of nickel electrodes which have been previously anodized at 0V for 1 hr in a separate pH 2.8 solution

Treatment of anodized nickel	Ni^{2+} dissolved* (μg-cm^{-2} of electrode)
30 min on open circuit	<0.5
60 min on open circuit	1.3
75 min on open circuit	2.0
110 min on open circuit	3.5
50 min at −20 μA-cm^{-2}	<0.5

* The amount of Ni^{2+} in 12A of NiO is 0.6 μg-cm^{-2}.

The first part of the present work consisted of producing and characterizing an oxide-free surface as a reference. From the work in neutral solution (1), it is known that the oxide film on a freshly electropolished nickel electrode can be reduced with a moderate cathodic treatment and the same approach was adopted here (Fig. 1). When the charge under the current peak on a subsequent anodic sweep is a maximum, *i.e.*, not increased by further cathodic treatment of the electropolished nickel, the surface is defined as being free of oxide and having a surface activity of 100%. Conversely, any diminution of this maximum charge is taken to indicate the presence of oxide on the surface. Development of detailed relationships between surface activity and oxide coverage will be discussed in a later paper. However, the present results indicate that the steady-state oxide formed on nickel electrodes anodized in the passive (potential) region can be completely removed at pH $\leqq$ 2.8 with a moderate cathodic treatment. At pH > 2.8, oxide removal became more difficult with increasing pH and at pH 5.0 even vigorous cathodic treatments (Fig. 2) did not lead to any substantial surface reactivation. For further experimental work, a pH of 2.8 was chosen rather than a lower pH because of the smaller amount of anodic nickel dissolution and correspondingly lower degree of surface roughening at the higher pH.

The difference in cathodic reduction behavior of anodized nickel at different pH's may be due to a combination of two factors: (*i*) The oxide formed at lower pH (2.8) is different from that formed at higher pH (4.5 or 8.4), *i.e.*, the former is more easily reducible; and/or (*ii*) the cathodic reduction reaction is possible at lower pH but not at higher pH. There were several important results which indicate that the oxide formed in the steady state at pH 2.8 was similar to that formed under the same conditions at pH 4.5 or 8.4. First, the oxide thickness as determined by x-ray emission spectroscopy (1) was the same at pH = 8.4, 4.5, and 2.8, *i.e.*, 9-12Å, a thickness which has been shown to be independent of anodization potential within experimental error at pH 2.8 and 8.4. Second, the electron diffraction patterns of a (111) nickel crystal surface anodized at pH 8.4, 4.5, or 2.8 were similar with regard to measured lattice parameters, epitxay, and grain size of the oxide. Third, the electrochemical transfer experiments indicated that the oxide formed at pH 2.8 was nonreducible in pH 8.4 electrolyte, exactly like the oxide formed at pH 8.4; they also showed that in the pH 2.8 solution, the oxide formed at pH 8.4 was as easily removed as that formed at pH 2.8. These various results indicate that in the pH range 8.4-2.8 the characteristics of the oxide formed on anodized nickel in the steady state are not a function of the pH of anodic formation. The variation of extent of oxide removal with pH must therefore be associated with the cathodic reduction reaction. The pH dependence of this reaction ($NiO + 2H^+ + 2e = Ni + H_2O$) is the most probable cause of the present results even though the bulk solution pH did not change significantly over the range examined. The pH instability in the vicinity of the electrode during the cathodic treatment as a result of accompanying molecular hydrogen evolution is indi-

cated by the increased extent of surface reactivation with N_2 bubbling at $pH \geq 3.0$ (Fig. 2).

In neutral solution, cathodic coulometry could not be used to determine oxide thickness because of the stability of the oxide in *p*H 8.4. Alternatively, the anodic potential step technique, with the total anodic charge corrected for that portion associated with Ni^{2+} dissolution, provided an accurate method of evaluating the oxide thickness. In the more acidic solutions (*e.g.*, *p*H 2.8) the portion of the anodic charge associated with oxide formation was smaller in comparison with that due to nickel dissolution and accurate thickness determinations by the potential step technique were not possible. Since cathodic reduction in the *p*H 2.8 Na_2SO_4 solution resulted in complete removal of the steady-state oxide on anodized nickel, the possibility of making accurate *in situ* oxide thickness measurements seemed to exist. There were, however, two potential sources of error associated with: (*i*) chemical dissolution of the oxide in the *p*H 2.8 solution, and (*ii*) parallel cathodic side reactions. Chemical dissolution of the oxide during its galvanostatic removal would, in the absence of cathodic side reactions, lead to the estimated oxide coverage being less than the true value. In fact, the estimated coverage was much larger than the true oxide coverage, indicating that (*ii*) must play a major role but still saying nothing about (*i*). To obtain information on the possible role of (*i*), the open-circuit experiments must be correlated with the cathodic charging result.

The open-circuit experiments showed (Fig. 6) that the rate of recovery of surface activity was slow for times corresponding to those required for cathodic galvanostatic removal of the oxide at 20 μA-cm^{-2} (*i.e.*, 50 min). After the 50 min induction period the rate of recovery of surface activity was very rapid. These results can be explained in terms of a nonuniform chemical attack of the oxide film [*e.g.*, see Ref. (9-14)] with subsequent exposure of localized areas of the nickel surface. This could explain the abrupt change in open-circuit potential after *ca.* 40 min exposure (Fig. 6). Nickel dissolution can occur by a corrosion mechanism from those oxide-free areas on open-circuit and cause undermining of the remaining oxide on the surface. The 40 min induction period would thus be the time required for localized chemical attack to bare enough nickel surface for oxide undermining and subsequent rapid surface reactivation to occur. When the anodized nickel electrode is given a cathodic galvanostatic polarization, the rate of surface reactivation does not change abruptly after a certain percentage of activity is recovered (Fig. 5). This is due to the absence of oxide undermining in this latter situation since the electrode is being cathodically protected, with respect to nickel dissolution, by the applied cathodic current. These conclusions are supported by the observation that while considerable nickel is found in solutions after surface reactivation has been achieved by open-circuit dissolution, very little dissolved nickel is found in solution after surface reactivation by cathodic charging (Table I). The results thus indicate that chemical dissolution of the oxide did not play a significant role during cathodic galvanostatic charging, eliminating the first potential source of error associated with oxide thickness measurements.

From the number of coulombs passed during cathodic charging, the thickness of the steady-state oxide on anodized nickel was calculated to be *ca.* 45 times greater than that determined by the x-ray method. Hence, cathodic side reactions played a major role during cathodic galvanostatic removal of the oxide on anodized nickel. The most probable cathodic side reactions are hydrogen evolution and Ni^{2+} deposition from solution. Parallel Ni^{2+} deposition did not appear to play a significant role since the galvanostatic cathodic charges, which were highly dependent on the time of prior anodization at 0V, were independent of $[Ni^{2+}]$ in solution. The diffusion-limited current can be calculated for Ni^{2+} deposition from the solution containing 0.24 μg-ml^{-1} (*i.e.*, 4×10^{-6}M Ni^{2+}) dissolved during 1 hr anodization at 0V with solution agitation to give a uniform concentration. The corresponding maximum charge for $Ni^{2+} + 2e \rightarrow Ni$ during a 50 min cathodic reduction in a static solution is 0.7 mC-cm^{-2}. This charge is insignificant when compared with the 65 mC-cm^{-2} actually passed (Fig. 5). Another confirmatory observation was that the cathodic charges passed in galvanostatic reactivation of the surface (Fig. 4a and 5) were independent of solution agitation during the 1 sec, 1 min, and 1 hr anodizations at 0V. This last result can be due to either of the following: (*i*) The Ni^{2+} concentration near the electrode does not affect the measured cathodic charge, since it is probable that this concentration will be lower with solution agitation (this should be especially true after only 1 sec at 0V because of the short time available for diffusion of Ni^{2+} to the bulk of the solution), or (*ii*) these times at 0V were sufficient for establishment of a more uniform concentration distribution even in the static solutions. This second possibility was the assumption made when calculating the diffusion-limited current; hence the same conclusions concerning the role of Ni^{2+} apply. The above observations thus eliminate the possibility of both Ni^{2+} near the electrode and in the bulk of the solution contributing to the measured cathodic charge. In a paper to be published, it will be shown that the Ni^{2+} deposition only plays a significant role at much more cathodic potentials (*ca.* -1.3V), giving rise to a diffusion-controlled current peak on a cathodic potentiodynamic sweep.

The above conclusions leave hydrogen evolution as the cathodic side reaction responsible for the low current efficiency of NiO reduction. Indeed, it was shown earlier (1) that the rate of hydrogen evolution is 250% higher on anodized nickel than oxide-free nickel in *p*H 8.4, *i.e.*, the oxide on anodized nickel (almost stoichiometric NiO) is an excellent catalyst for hydrogen evolution. With the exception of the 1 hr anodization at 0V, the results in Fig. 4a can be interpreted in relation to an increase in the overpotential for hydrogen evolution as the oxide is slowly removed by cathodic reduction at 20 μA-cm^{-2}. The cathodic potential reaches a maximum when the nickel surface becomes oxide free. After a 1 hr anodization at 0V, the situation is more complex with the cathodic potential appearing to reach its steady value very rapidly after initiation of the cathodic polarization (Fig. 4a and b). With a more sensitive potential axis, a very small potential arrest can be observed during the 50 min reactivation of the surface. However, the steady cathodic potential on the oxide-free surface at 20 μA-cm^{-2} is *ca.* 0.12V more anodic after the 1 hr at 0V than after either the shorter anodizations or the electropolishing. This anomalous result was not due to changes in either composition of the electrolyte or roughness of the nickel surface during the 1 hr at 0V. The possible explanations remaining are: (*i*) Some other property of the nickel surface, *e.g.*, distribution of active sites or hydride formation, is influenced by the 1 hr at 0V and subsequent cathodic reduction; (*ii*) the nickel surface was not completely free of oxide after the 50 min of cathodic charging. With regard to (*ii*), the anodic potential step, used to determine surface activity, may have: (*a*) been insensitive to the remaining oxide; or (*b*) helped to remove it physically by undermining. If remaining oxide on the surface is the explanation, then it is a very difficult species to reduce since more severe cathodic polarization at -1.3V after 1 hr anodization at 0V did not lead to any change in the 0.12V shift. Such an oxide species (or coverage) would be able to lower significantly the overpotential for hydrogen evolution and also not have a detectable influence on the extent of nickel dissolution with subsequent anodization. The present investigation does not allow a resolution of these various possibilities.

As a consequence of the results presented in this paper, it appears that the x-ray emission technique must be used to determine equilibrium oxide thicknesses (*i.e.*, 9-12Å) on anodized nickel in the pH 2.8 solutions. On the other hand, the oxide on electropolished nickel (of somewhat expanded NiO lattice) is removed readily with a high current efficiency, the determined oxide coverage value being in agreement with that from x-ray analysis.

Summary

1. The oxide formed by steady-state oxidation of nickel at pH 8.4 had the same electrochemical and electron-optical characteristics as that formed under similar conditions at pH 4.5 or 2.8.

2. While this oxide was not susceptible to cathodic reduction at pH 8.4, it could be removed at pH 2.8 with the appropriate cathodic treatment.

3. The oxide films formed by the steady-state oxidation at pH 2.8 were 9-12Å in thickness. In this thickness range, *in situ* cathodic reduction could not be used to measure the thickness due to the very large charge contribution from parallel hydrogen evolution.

4. The oxide films are removed only slowly on open circuit and dissolve by a combination of local attack and undermining.

Acknowledgment

The authors thank Dr. D. Mitchell for the x-ray determination of oxygen content on nickel.

The Theory of Rate Limitation

M. A. Fullenwider*

RKP Industries, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

The theory of rate limitation is reviewed, and two possible cases are further distinguished. Mathematical expressions are developed for one case where gaussian behavior is simulated. Recent experimental results are taken to be evidence in favor of a strong interstitial-phonon interaction at the surface. Situations are discussed where rate limitation may be misinterpreted as concentration-dependent diffusion.

The theory of rate limitation in diffused systems was treated by Miller and Smits (1) in the 1950's. Since then, experimental results with the hydrogen-palladium system (2) have pointed to a type of rate limitation not treated by these authors. It is the purpose of this paper: (*i*) to further distinguish the two cases, (*ii*) to propose a mechanism for the second case, (*iii*) to develop mathematical expressions for the second case that pertain to the situation where it simulates the gaussian profile, and (*iv*) to bring out some points concerning the implications of rate limitation in the physical theory of diffused systems.

Physical Rate Limitation

As brought out previously (3), in the formation of semiconductor junctions by solid-state diffusion there is the possibility of two types of rate limitation. The type discussed by Miller and Smits (1) and corresponding to the radiation boundary condition of Carslaw and Jaeger (4) we will call here "physical rate limitation." The reason for this terminology is that the radiation boundary condition in the theory of heat transfer (in the absence of convection) corresponds to the passage of heat into a substrate covered with a thin "skin" of a poorly conducting substance. In the theory of diffusion the skin must then be composed of a material with a smaller diffusion coefficient than that of the substrate, *e.g.*, an oxide coating of some sort. Figure 1 illustrates the potential energy profile for such a situation. In Fig. 1 the skin is between $-\delta$ and $x = 0$. Here the potential

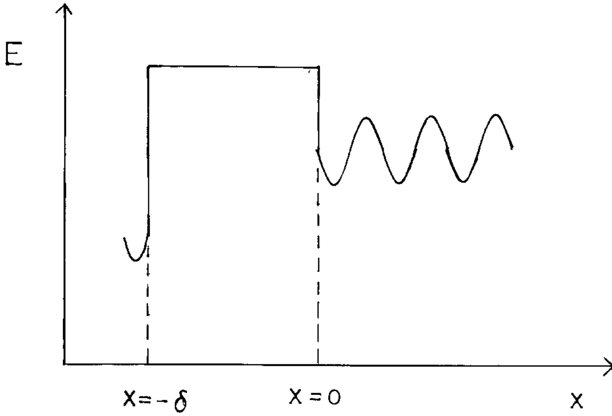

Fig. 1. Potential energy profile corresponding to the radiation boundary condition.

* Electrochemical Society Active Member.

Key words: semiconductor diffusion, rate limitation, concentration-dependent diffusion, hydrogen in metals.

hump at the surface has a square configuration because the skin must be supposed to have some finite thickness larger than the interatomic distance of the substrate.

Physical rate limitation derives from the boundary condition at the surface ($x = 0$)

$$[c_e - c(0, t)]K = - D[\partial c(x, t)/\partial x]_{x=0} \quad [1]$$

where x is distance into the semi-infinite substrate, c_e is the final equilibrium concentration at $x = 0$ as time becomes infinite, D is the diffusion coefficient, and K is a constant analogous to an electrical conductance in that a region of small size and small diffusivity may be the equal of a large region of larger diffusivity. If a more detailed knowledge for a particular system, *i.e.*, of the thickness and diffusivity of the skin, were available, then, of course, it would be possible to construct a better model, but this information is not usually known. In the mathematical treatment of the physical case the boundary condition, Eq. [1], remains the same for the two cases corresponding to (*a*) the error function complement profile and (*b*) the gaussian profile. In case (*b*) the quantity c_e is simply set equal to zero (5), since the final equilibrium concentration of a unit instantaneous point source must be zero at large times. The mathematical expressions are, case (*a*)

$$c(x, t) = c_e \left\{ \mathrm{erfc}\,[x/2(Dt)^{1/2}] - \exp[(Kx - K^2t)/D]\,\mathrm{erfc}\left[\frac{x}{2(Dt)^{1/2}} + K(t/D)^{1/2}\right]\right\} \quad [2]$$

and case (*b*)

$$c(x, t) = [a/(\pi Dt)^{1/2}] \exp(- x^2/4Dt) \times \left\{1 - K(\pi t/D)^{1/2} \exp\left[\frac{x}{2(Dt)^{1/2}} + K(t/D)^{1/2}\right]^2\right\} \times \mathrm{erfc}\left[\frac{x}{2(Dt)^{1/2}} + K(t/D)^{1/2}\right] \quad [3]$$

where a is the quantity of substance at the surface initially in moles-cm^{-2}.

Chemical Rate Limitation

An endothermic potential energy profile representing the situation for what we will call here "chemical rate limitation" is shown in Fig. 2. Here the potential step at the surface has the usual chemical shape, and its thickness is roughly the same as the interstitial spacings of the substrate. The expression corresponding to the error function complement profile, representing a strong interstitial-phonon interaction at the surface (to be discussed), derives from the constant flux boundary condition

$$j = - D[\partial c(x, t)/\partial x]_{x=0} \quad [4]$$

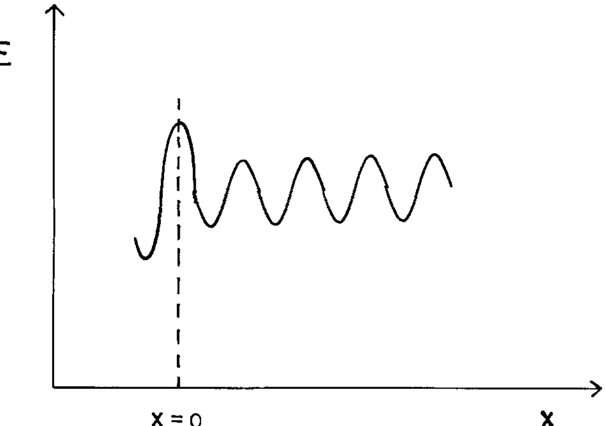

Fig. 2. Potential energy profile for chemical rate limitation

where both sides of the equation are taken, in this particular case, to be constant, since, in the absence of mechanical deformation or temperature change of the substrate, the phonon flux to and from the surface can be assumed to be constant and the interaction to proceed by a process of apertures slightly larger than available otherwise being created in the surface structure adjacent to the adsorbed interstitials as the phonons arrive at the surface and the interstitials then "falling" into these openings. Once inside the substrate the interstitials may then be imagined to go on about the usual random diffusional process.

The expression is (3)

$$c(x, t) = 2j(t/D)^{1/2}\, \mathrm{i\,erfc}[x/2(Dt)^{1/2}] \quad [5]$$

or

$$c(x, t)/c_o = \exp(- x^2/4Dt) - x(\pi/4Dt)^{1/2}\, \mathrm{erfc}[x/2(Dt)^{1/2}] \quad [6]$$

where c_o now varies as a function of time. Equations [5] and [6] correspond to Eq. [2] in that they both have the possibility of applying in the infinite surface source situation, *i.e.*, where the error function complement profile might reasonably be expected to apply in the absence of rate limitation.

Now moving on to the case corresponding to the gaussian profile we are led to consider the general expression for a chemical process

$$\mathrm{Rate} = k \prod^{n} c_n^{x_n} \quad [7]$$

where k is a rate constant, the remainder of the expression is a product of powers and concentrations, and the sum of the x_n is the order of the reaction. Taking the interstitial-phonon interaction to be strong and assuming: (*a*) the interaction is nonspecific, *i.e.*, that a single, isolated, adsorbed solute atom has no more chance of interaction than one closely oriented with respect to other adsorbed atoms, and (*b*) the interaction is of first order in the concentration of the adsorbed species at the surface, then we have for the rate

$$dc_T/dt = k_1(a - c_T) \quad [8]$$

where c_T is the total amount of adsorbed species which has interacted at time t and crossed the surface potential into the bulk substrate in moles-cm^{-2}, k_1 is the first-order rate constant, and a has the same meaning as in Eq. [3]. Integrating Eq. [8], with the condition $c_T = 0$ at $t = 0$, we get

$$c_T = a[1 - \exp(- k_1t)] \quad [9]$$

and since c_T is the total amount of solute atoms present in the substrate at time t, we can write the following boundary conditions to be solved in conjunction with the diffusion equation

$$c(x, t) = 0, \quad x \to \infty \quad [10]$$

$$c(x, t) = 0, \quad t = 0 \quad [11]$$

and from Eq. [9]

$$\int_0^\infty c(x, t)\, dx = a[1 - \exp(- k_1t)] \quad [12]$$

Using the Laplace transformation method, we have for $c(x, t)$

$$c(x, t) = [a/(\pi Dt)^{1/2}] \left[\exp(- x^2/4Dt) + 4(D^3t/\pi)^{1/2} \int_0^\infty \frac{4v^2 \exp(- 4Dv^2t)}{k_1 - 4Dv^2} \cos(2vx)\, dv\right] \quad [13]$$

Equation [13] has the following limits

$$\lim_{k_1 \to \infty} c(x, t) = [a/(\pi Dt)^{1/2}] \exp(- x^2/4Dt) \quad [14]$$

the regular gaussian profile, and

$$\lim_{k_1 \to 0} c(x, t) = 0 \quad [15]$$

Thus when k_1 is large, gaussian behavior will result, and when small, there will be no diffusion.

Also, just inside the surface (neglecting a small term, higher by a degree in k_1)

$$c(0, t) = c_o = [a/(\pi D t)^{1/2}] \text{erf}(k_1 t)^{1/2} \quad [16]$$

and

$$\lim_{t \to 0} c_o = 0 \quad [17]$$

Equation [16] is plotted for various values of k_1 in Fig. 3. It can be seen that in the limit as t becomes large, c_o will always approach the gaussian values for even small k_1. However, the profile can be expected to deviate more from the gaussian shape as k_1 becomes smaller, see the Discussion section.

From Eq. [3] we get the following relation for c_o to be compared with Eq. [16]

$$c_o = [a/(\pi D t)^{1/2}] \times [1 - K(\pi t/D)^{1/2} \exp(K^2 t/D)] \times \text{erfc}[K(t/D)^{1/2}] \quad [18]$$

Discussion

There has long been something lacking in thoughts about diffused systems. The usual boundary condition, corresponding to an infinite surface source, partially superseded by Miller and Smit's Eq. [1], was the simple

$$c(0, t) = c_o = \text{const}, \quad t > 0 \quad [19]$$

Now Eq. [19] implies a certain passivity to the nature of the effect of the surface on the diffusion process occurring.

At the same time diffusion has been experimentally observed many times in substrates that are strongly endothermic absorbers of the diffusing species, *e.g.*, hydrogen in iron, nickel, and platinum. In fact enough hydrogen goes into the bulk of these metals that it causes embrittlement. For these systems one might well ask the question, "How does the hydrogen ever get in there at all, if it is so difficult energetically?" At one time it was thought that hydrogen entered these metals only under circumstances of high equivalent pressure (6, 7). Recently, however, it was shown experimentally that at atmospheric pressure enough hydrogen penetrates, at least iron, to cause embrittlement (8). The exact mechanism of this process is still not clear (9, 10). In any case, the passive type of surface depicted by Eq. [19] would seem unlikely, and it would appear that the strong interstitial-phonon interaction referred to earlier in the text and previously considered as a possibility (11) is more probable. In this context the surface can be thought of as having the positive influence of acting as an interstitial "pump."

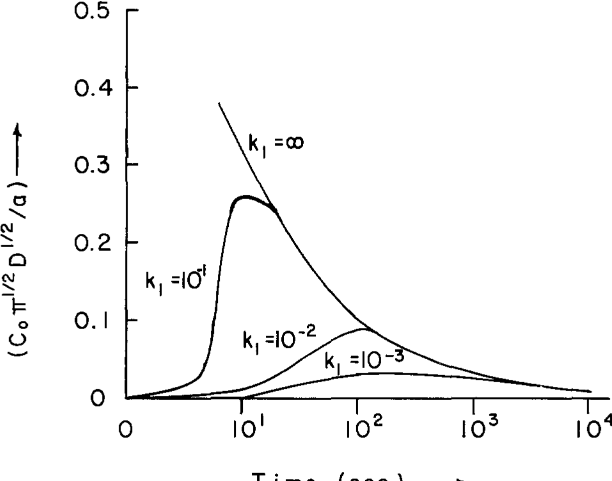

Fig. 3. c_o for various values of k_1 as a function of time

Both types of rate limitation have been observed experimentally. Ghoshtagore (12) has reported the physical case in the diffusion of boron and phosphorus into silicon. The previously referred to experiments with the hydrogen-palladium system (2) exhibited rate limitation of the chemical type. It might be argued that since the hydrogen was introduced electrochemically in the experiments the constant flux might have been simulated by some chemical process outside the surface. However, in contrast to most other work done with the bi-electrode technique where hydrogen is generated at the input side galvanostatically and in the overvoltage region, these experiments were performed in the undervoltage region and utilized the potentiostatic technique in introducing the hydrogen, and there is no doubt that the infinite surface source situation would obtain under these circumstances.

Possibly a more important topic involves the possibility of rate limitation being misinterpreted as concentration-dependent diffusion. The physical case is rather specialized, and here there seems to be no chance of error. In the chemical case the whole matter hinges upon the rate of attainment of the equilibrium concentration just beneath the input surface, and unfortunately some of the solutions of the diffusion equation, involving the use of Eq. [6] and [13] as initial conditions, are not easily accessible analytically. If equilibrium is attained rapidly with respect to the total diffusion time, then the classical cases of gaussian and error function complement profiles will result. However, if this time is finite, then, in general, the diffusion coefficient will appear to increase with time after equilibrium is reached if one tries to fit data with the classical profiles.

As mentioned in a previous note (3) in the case of slow equilibrium, infinite surface source type situations can be approximated by an equation of the type

$$c(x, t) = c_o \,\text{erfc}\,\{x/2[D(t + t_1)]^{1/2}\} \quad [20]$$

after equilibrium has been established, where c_o is now a constant, t is the time after equilibrium, t_1 is a fitting parameter such that Eq. [20] fits Eq. [5] at $t = 0$ [the shape of the curves are very similar (3)], and Eq. [20], of course, is not a true solution to the diffusion equation.

In the case of a finite surface source there two nongaussian possibilities: (*i*) slow time to equilibrium and saturation not being reached, and (*ii*) the same except that saturation is reached before the maxima in Fig. 3, causing the curve to have a flat portion. In the first case Eq. [13] gives an exact solution, and the second is more complicated. Both cases will exhibit the same apparent increase in diffusion coefficient after equilibrium (or saturation) if attempts are made to fit them to the gaussian profile.

In summary, it would appear reasonable that a strong interstitial-phonon interaction at least initiates most diffusion processes. The classical gaussian and error function complement profiles hold true only if the time to equilibrium is short, and if this time is not short more complicated behavior will result which in many cases may be misinterpreted as concentration-dependent diffusion.

Behavior of Pure and Platinum-Doped Sodium Tungsten Bronze Electrodes in Oxygen-Saturated Phosphoric Acid

A. J. Appleby[*,1] **and C. Van Drunen**

Institute of Gas Technology, Chicago, Illinois 60616

ABSTRACT

Platinum-doped tungsten bronze electrodes of composition $Na_{0.7}WO_3$ have been examined for the reduction of oxygen in 0.1*N* H_2SO_4 and $HClO_4$, together with orthophosphoric acid at various concentrations up to 14.5*N* (85 weight per cent). Whereas good activities of aged electrodes were shown in H_2SO_4 and $HClO_4$, those in H_3PO_4 were poor. This is attributed to the formation of phosphotungstate. It is concluded that such compounds are unsuitable for use as catalysts in phosphoric acid fuel cells.

Tungsten bronzes have been shown to possess catalytic activity for a number of reactions, in particular for certain organic processes (1, 2). Sodium bronzes were examined by Sepa *et al.* (3) for electrocatalytic oxygen reduction. They concluded that these materials were about as active as platinum in dilute sulfuric acid. As a result of this work, the tungsten bronzes were examined by a number of workers for electrocatalytic hydrogen and CO oxidation (4-6) and oxygen reduction (5-8). The oxygen-reduction activity was shown by Fishman *et al.* (7, 9) to be due to the presence of traces of noble metals, in particular platinum. This result has been more recently confirmed by Bockris and McHardy (10), who have examined the synergistic effect of the bronze on platinum for oxygen reduction.

More recent work has tended to examine more specific aspects of the electrochemistry of tungsten bronzes. For example, the electrochemistry of bronze formation (11) has been studied, together with the effects of bronze structure on hydrogen evolution (12, 13). The effect of anodization bronzes in sulfuric acid solution has also been investigated (14).

In the present paper, work on oxygen electrode processes on undoped and platinum-doped sodium tungsten bronzes is reported.

Experimental

Preparation of tungsten bronze single crystals.—Large single crystals (about 1 cm cubes) of tungsten bronze of composition approximating to $Na_{0.7}WO_3$ were prepared by the electrolytic technique from a fused 2:1 Na_2WO_4:WO_3 mixture by the method described by Lovrecek, McHardy, and Bockris (15). Specimens were grown around seed crystals tied by fine gold wires. A current density of 20 mA/cm^2 was used. The undoped samples described in this work were prepared at the Institute of Gas Technology, whereas the doped crystals (0.05% Pt) were prepared at the University of Pennsylvania. The electrolytic cell in the latter case used a two-electrode technique with a potential divider and a subsidiary platinum anode (15). The total (apparent) geometrical area of the electrode was calculated from the crystal dimensions and was used for current-density determinations.

Results and Discussion

Oxygen electrode reactions on Pt-doped tungsten bronze: dilute H_2SO_4 and $HClO_4$.—Initial experiments were conducted at room temperature in dilute (0.1*N*) sulfuric acid to check the reproducibility of data with that reported by previous workers (10). A three-compartment cell with hydrogen reference electrode was used for all experiments. The sulfuric acid solutions (together with all the solutions reported below) were made up from triple-distilled water (all-silica still) and analytical reagent grade acid. They were preelectrolyzed for at least 15 hr at a total current of 50 mA, using platinum black fuel-cell electrodes (Allis-Chalmers) before experiments were started. Electrodes were hung in the solutions on their gold suspension wires, and were previously placed above the solution during preelectrolysis. Initial open-circuit potentials noted for the bronze crystals in oxygen-saturated electrolyte were high: about 850 mV/HRE.

Galvanostatic plots for the anodic process under steady-state conditions were first obtained after a preliminary anodization of the bronze crystal. The object of this anodization was to produce a reproducible surface for oxygen evolution. Anodic plots from high to low current densities were first carried out. At current densities above about 10^{-6} A/cm^2 these initial plots were similar to those shown as plot 2 on Fig. 1. At lower current densities, potential values recorded were lower than those shown above, and in addition a time dependence of potential was noted. For example, at a current density of 2×10^{-8} A/cm^2, the potential fell from an initial value of 1340 mV to a value of 1200 mV *vs.* H_2 after 1.5 hr, after which the series of plots given in Fig. 1 was obtained.

At low current densities, the potential values recorded were essentially time independent (*i.e.*, in the potential range up to 1500-1600 mV). At higher potentials, results became time dependent: Points shown on

Key words: oxygen reduction, fuel cells, electrocatalysis.

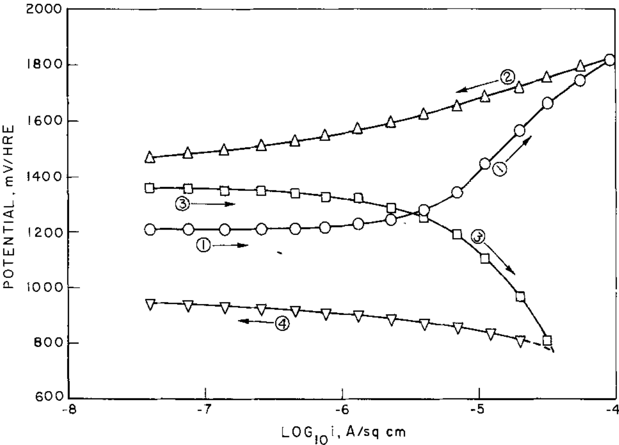

Fig. 1. V-$\log_{10} i$ plots on preanodized Pt-doped tungsten bronze: oxygen-saturated 0.1N H_2SO_4, 25°C. Arrows show plotting direction.

Fig. 1, curve 1 were taken after 2 min polarization. The hysteresis effect even after preliminary anodization is very marked. This implies a reanodization of the electrode surface after the decay of the original anodized state [cf. Ref. (14)].

After such treatment, cathodic behavior shown on plot 3, Fig. 1, was typically obtained. Most of the cathodic current in such plots is evidently used in restoring the bronze surface to its original condition, rather than for oxygen reduction. A typical return plot after this treatment is shown as plot 4, Fig. 1. If we conclude that the electrode surface is in a stable state after this treatment (as in the anodic case), then the activity of the electrode for the only other possible cathodic process (reduction of oxygen) is on the same order as that for platinum under these conditions, as observed by Bockris and McHardy (10) for "aged" electrodes (*i.e.*, electrodes that had either been anodized or exposed to lower positive potentials for long periods).

A different series of experiments, using the same steady-state technique, was conducted on nonanodized electrodes (fresh electrodes, or those that had had previous cathodic pretreatment of the types shown as curves 3 and 4 in Fig. 1). Results obtained in 0.1N H_2SO_4 and 0.1N $HClO_4$ were essentially superposable, showing that the anion had little or no effect in these cases. Results obtained in the latter solution are shown in Fig. 2. Hysteresis is very much less marked than in Fig. 1, and the anodic plots occur at much lower potentials than on preanodized electrodes. The cathodic plots are at lower potentials than the final plot on Fig. 1 (plot 4) and probably correspond to the plots observed by Bockris and McHardy (10) on fresh electrodes. In all cases, the points observed were unstable, and the values shown on Fig. 2 correspond to a time interval of 2 min between current densities.

Oxygen electrode reactions in 85% orthophosphoric acid (Pt-doped tungsten bronze).—Solution.—The acid was purified by hydrogen peroxide treatment as in previous work (16).

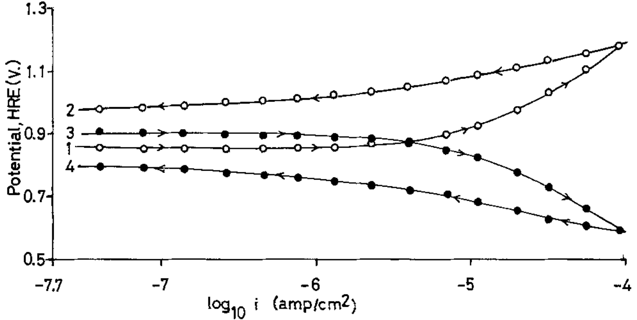

Fig. 2. V-$\log_{10} i$ plots as Fig. 1, 0.1N $HClO_4$. Nonpreanodized crystal.

Table I. Extrapolated rates at the reversible oxygen potential, $1/\alpha$ values, and Tafel slopes for anodic and cathodic processes as a function of temperature in oxygen-saturated 85% orthophosphoric acid; Pt-doped tungsten bronze crystals

	Temperature, °C	Extrapolated rate (A/cm²)	$1/\alpha$	Tafel slope (mV/decade)
Anodic process	51.0	9.0×10^{-7}	4.07	263
	68.0	2.3×10^{-6}	3.77	255
	100.0	2.4×10^{-5}	3.58	265
	118.0	5.8×10^{-5}	3.87	300
Cathodic process	53.0	2.1×10^{-14}	1.66	107
	68.0	7.5×10^{-13}	1.82	123
	81.0	2.9×10^{-12}	1.78	125
	100.0	9.5×10^{-12}	1.72	127
	118.0	10^{-11}	1.48	120

Anodic processes.—Anodic Tafel plots on 0.05% Pt-doped $Na_{0.7}WO_3$ single crystal electrodes were obtained, starting at the rest potential in oxygen-saturated solution. This was consistently about 100 mV lower than in dilute sulfuric or perchloric acids for fresh electrodes.

The points in Fig. 3 were obtained on preanodized electrodes (cf. Fig. 1 for dilute sulfuric acid) and correspond to the steady-state condition for oxygen evolution (less than 1 mV change in 2 min). Tafel behavior was obtained at each temperature, but the slopes were extremely high ($\sim 4RT/\mathbf{F}$), and the apparent α-values were temperature dependent (see Table I).

Cycling data.—A plot of the same type as in Fig. 2 (for fresh electrodes, 2 min between points) was obtained in oxygen-saturated orthophosphoric acid at 25°C (Fig. 4). Hysteresis was much greater than in sulfuric or perchloric acid, and the level of activity indicated in the final plot (Fig. 1, plot 4) for oxygen reduction was very low. No Tafel slope as such was observed: The final cathodic plot (descending current densities) was almost horizontal. Overpotentials increased slowly with time (see below). The electrode was extremely sluggish on changing the current density compared with the corresponding case in H_2SO_4.

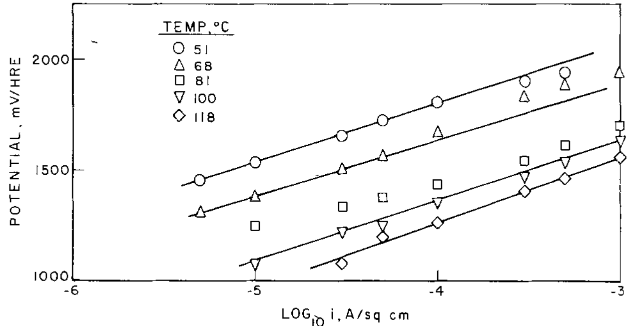

Fig. 3. Anodic Tafel plots in oxygen-saturated 85% H_3PO_4 as a function of temperature, Pt-doped tungsten bronze (steady-state data).

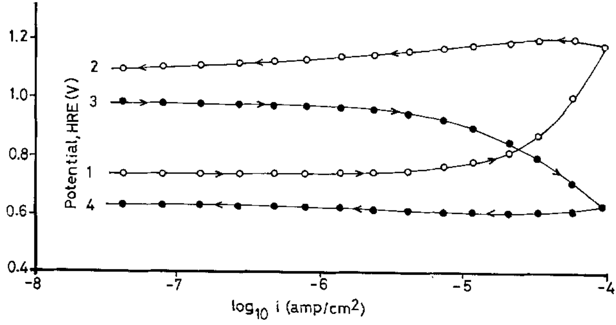

Fig. 4. V-$\log_{10} i$ plots as Fig. 1 and 2: 85% H_3PO_4. Nonpreanodized crystal.

Cathodic reduction of oxygen.—Descending galvanostatic plots, taken after the electrode had reached its rest potential in oxygen-saturated solution, are shown in Fig. 5 as a function of temperature. Again, great sluggishness was observed on changing current density, and several hours were required between points at low current densities. In each case, a Tafel slope was observed. However, α was strongly temperature dependent: The observed Tafel slopes were almost independent of temperature.

Values of the Tafel slope and α-values are given as a function of temperature in Table I. The Tafel plots were extrapolated back to the theoretical reversible oxygen potentials in each case. Values of the apparent i_o value for oxygen reduction, assuming this to be the major process involved, are also given in Table I. It is clear that the values obtained are several orders of magnitude less than the values for the initial anodic process extrapolated from the data given in Fig. 3 to the reversible oxygen potentials. This argues that the anodic process observed is attributable to anodization of the surface rather than to oxygen evolution.

Effect of phosphoric acid concentration on cathodic plots.—Crystals were examined in solutions of different H_3PO_4 concentration in the range 0.1-5M at 25°C. Solutions were in each case preelectrolyzed for 15 hr before testing was conducted, electrodes being hung above the solution during preparation in the manner described above. Open-circuit potentials were found not to depend significantly on the acid concentration; they were far below (~200 mV) those registered in dilute sulfuric (or perchloric) acids for fresh electrodes. Descending galvanostatic Tafel plots were obtained at each acid concentration, allowing sufficient time to reach equilibrium in each case. Results are shown in Fig. 6. In every case the Tafel slope was close to 100 mV/decade, and the overpotential was essentially independent of the acid concentration: A variation in overpotential of only about 15 mV was observed in the concentration range studied.

The results obtained suggest that the phosphate ion inhibits the crystal surface for the oxygen-reduction reaction.

Studies on Pt-doped tungsten bronzes previously aged in orthophosphoric acid.—In view of the reduced activity of crystals in orthophosphoric acid (Fig. 4-6) for the cathodic process compared with that in dilute sulfuric acid (aged electrodes, Fig. 1) a test was effected to determine the state of the surface after exposure to orthophosphoric acid.

Figures 7 and 8 show the effect of anodic and cathodic polarization, respectively, in 0.1*N* sulfuric acid after crystals had been used to obtain cathodic data in 85% orthophosphoric acid (Fig. 5). After the tests in orthophosphoric acid, the crystals were simply rinsed with distilled water and placed in oxygen-saturated preelectrolyzed sulfuric acid solution. The anodic and cathodic galvanostatic plots were then conducted.

Figure 7 (anodic data) shows that the orthophosphoric acid treatment appears to be equivalent to the anodizing treatment illustrated in Fig. 1. The curve on Fig. 7 represents the descending current density plot under the same conditions as Fig. 2 (ascending and descending current densities from the open-circuit potential, 2 min between points). No prolonged anodization was conducted, yet results were very similar to those shown in Fig. 1.

In Fig. 8 cathodic data is shown, taken at ascending current densities from the open-circuit potential on a new crystal directly after phosphoric acid treatment. Data for aged electrodes in dilute sulfuric acid (curve 4, Fig. 1) are also shown for comparison. A marked increase in activity after phosphoric acid treatment occurs.

There is thus no evidence of permanent deactivation of the surface of the Pt-doped bronze crystal by exposure to 85% orthophosphoric acid: On the contrary, this material has appeared to have activated its surface. The treatment perhaps corresponds to the marked aging phenomenon described by Bockris and McHardy (10) after continued polarization.

Oxygen electrode reactions on undoped tungsten bronzes in orthophosphoric acid solutions.—Data similar to those shown in Fig. 2 and 4 were obtained in 85% orthophosphoric acid using undoped bronze crystals of composition $Na_{0.7}WO_3$. The experimental method was the same as previously described; the temperature of the measurements shown in Fig. 9 was 55°C, but results

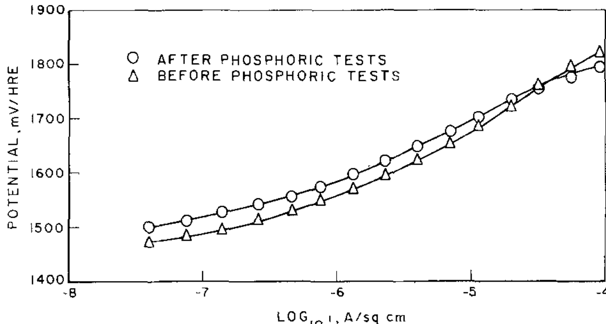

Fig. 7. Anodic V-$\log_{10} i$ plots on Pt-doped tungsten bronze in oxygen-saturated 0.1*N* H_2SO_4, 25°C, after exposure to cathodic polarization in 85% H_3PO_4.

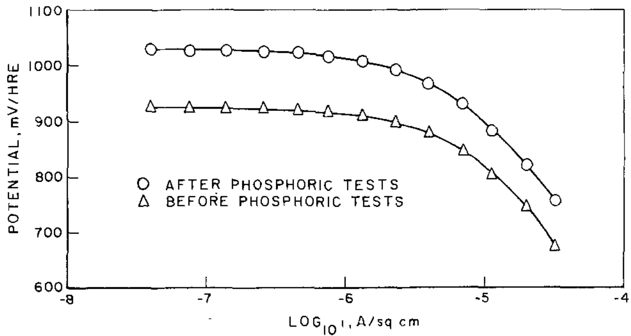

Fig. 8. Cathodic V-$\log_{10} i$ plots, conditions as Fig. 7

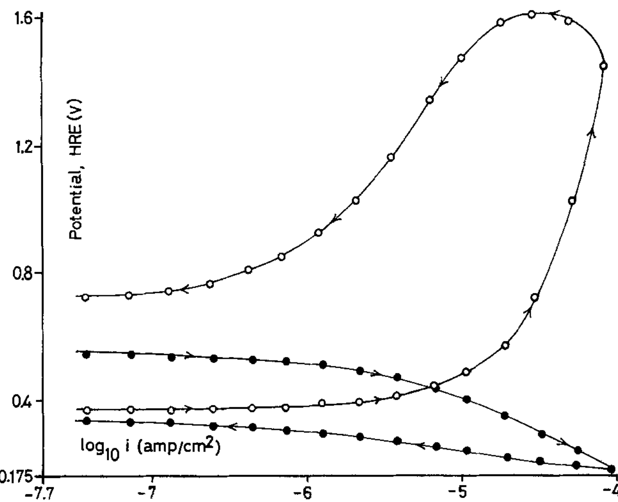

Fig. 9. V-$\log_{10}$ *i* plots as Fig. 4: 85% H_3PO_4, 55°C, undoped tungsten bronze crystals.

were similar at lower temperatures (25°C). The most noteworthy differences between the results obtained on undoped and doped crystals are as follows:

(*a*) Open-circuit potentials were very much lower. A value close to 340 mV was registered at 55°C on undoped crystals. At 25°C, the values were ~150 mV lower.

(*b*) On anodic polarization, potential remains essentially steady for current densities up to $5 \cdot 10^{-6}$ A/cm^{-2}, then rises extremely rapidly, to give values that are comparable with those registered on Pt-doped crystals at current densities of about $8 \cdot 10^{-5}$ A/cm^{-2} (Fig. 4). On reversing the anodic plotting direction, the current density falls rapidly, giving a final rest potential of about 700 mV. This decays after an interval of 2-3 hr by about 100 mV. The final curve of the cathodic cycle indicates much lower activity than that in the case of the doped crystal. This confirms that the first (ascending current density) anodic cycles in Fig. 1 and 2 are due to anodization of the surface rather than to oxygen evolution.

To investigate the effect of the concentration of orthophosphoric acid, a similar plot was conducted in 2M H_3PO_4 at 25°C (Fig. 10). Under these conditions, higher current densities are required to anodize the bronze surface, and much less hysteresis is observed.

Conclusions

The present results confirm those obtained by Bockris and McHardy (10) on Pt-doped tungsten bronzes for the oxygen electrode reaction in sulfuric acid medium. In general, fresh crystals, or those subjected to cathode treatment after anodizing or aging, show poor activity for oxygen reduction. Initial anodic treatment of fresh crystal surfaces involves a change of the condition of the surface, probably due to sodium ion loss. After this treatment (aged condition) the crystals appear to show activity for oxygen reduction comparable to that for platinum. Behavior is dominated by the state of the surface and the history of pretreatment.

In phosphoric acid these effects are much more exaggerated, and cathodic activity is very much less than in sulfuric or perchloric acid at all phosphoric acid

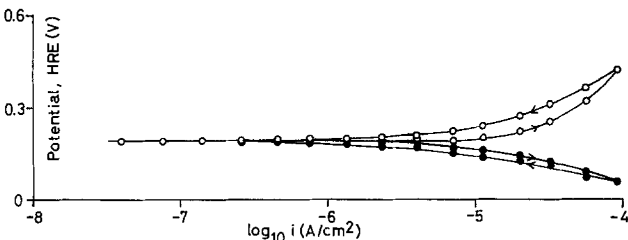

Fig. 10. V-$\log_{10}$ *i* plots as Fig. 9: 2M H_3PO_4, 25°C, undoped tungsten bronze crystals.

concentrations studied. This deactivation is not permanent: After washing, crystals show activity in sulfuric acid similar to that of aged crystals, and much less hysteresis. We suggest that the deactivation is due to the formation of phosphotungstates at the bronze surface. We conclude that tungsten bronzes of the composition used here, whether undoped or doped with platinum, are unusable as oxygen-electrode catalysts in conventional phosphoric acid fuel cells.

Electrochemical Semipermeability and the Electrode Microsystem in Solid Oxide Electrolyte Cells

J. Fouletier, P. Fabry, and M. Kleitz*

E.N.S. d'Electrochimie et d'Electrometallurgie de Grenoble, Domaine Universitaire, 38401 Saint Martin d'Hères, France

ABSTRACT

New evidence is put forward within the framework of a recently introduced model. The electrodes are viewed as measuring the oxygen chemical potential in a "microsystem" which exchanges oxygen at a finite rate with the surrounding gas being analyzed. In high temperature oxygen gauges, the oxygen flux resulting from the electrochemical oxygen semipermeability of the electrolyte can have two effects other than reducing the theoretical emf by the factor $(1 - \bar{t}_e)$ which appears to induce error of second order only. The oxygen semipermeability can obviously modify the oxygen content of the gas analyzed and also can disturb the equilibrium between the electrode microsystem and the analyzed gas. A special experimental setup was assembled to study both phenomena. The results showed that the second is generally far from being negligible and may lead to noticeable measurement error. A new arrangement with a zirconia point electrode is proposed to eliminate this source of error in oxygen gauges working at very high temperatures. The new arrangement was utilized to measure accurately the oxygen semipermeability of a ZrO_2-Y_2O_3 [9 mole per cent (m/o)] electrolyte at temperatures up to 1650°C. The semipermeability was found to be proportional to $(P'_3{}^{1/4} - P'_2{}^{1/4})$, where P'_3 and P'_2 are the equivalent oxygen pressures in the layers of oxygen adsorbed on both bases of the pellet. The activation energy of the electronic conductivity equaled 2.02 eV.

In several papers dealing with different phenomena such as the oxygen electrode overpotential (1), the time lag of the oxygen gauge electrode (2), and the kinetics of point-electrode oxidation (3), it was established that a solid electrode on stabilized zirconia does not directly measure the oxygen pressure in the surrounding atmosphere. The proposed phenomenological description of the over-all oxygen electrode process is sketched in Fig. 1. The electrode formed by the contact between the metal and the solid electrolyte is viewed as measuring the oxygen activity in a microsystem which more or less easily exchanges oxygen with the surrounding gas. It was first suggested that the microsystem was formed by a layer of adsorbed oxygen on zirconia (4). Mogab (5) also admitted the existence of an intermediary step of oxygen adsorption on zirconia in oxygen gauges. A recent systematic study (6) of the influence of the metal and the electrolyte seemed to indicate that they both contribute to determining the oxygen capacity of the microsystem.

In an oxygen gauge, the oxygen pressure over the reference electrode is generally different from that of the measuring electrode, resulting in an oxygen semipermeability flow through the electrolyte. (The characteristics of this phenomenon are recalled later on.) The relevant local oxygen flux must be taken into account in the oxygen balance of the microsystem. If the oxygen exchange rate with the surrounding gas is slow, as is the case under low oxygen pressure, this flux can make the microsystem deviate from its equilibrium with the gas. The importance of the induced error was recently investigated with a special differential assemblage of two gauges (7). The error can be significant even if the oxygen semipermeability flux is not high enough to alter the oxygen pressure in the gas being measured. Quantitatively, with the commonly used zirconia tubes and with air as a reference gas, the oxygen semipermeability flux is high enough above 1150°K to induce changes greater than 1 ppm in the oxygen content of the analyzed gas. Between 900° and 1050°K the tubes can be sufficiently impervious so that no change is noticed on a 0.1 ppm scale, but the oxygen semipermeability flux is still high enough to significantly disturb the equilibrium between the microsystem and the gas. We will report here on a more detailed investigation of these phenomena.

Experimental Setup

The measurements were carried out with the cell and the gas circuit schematically depicted in Fig. 2 and 3.

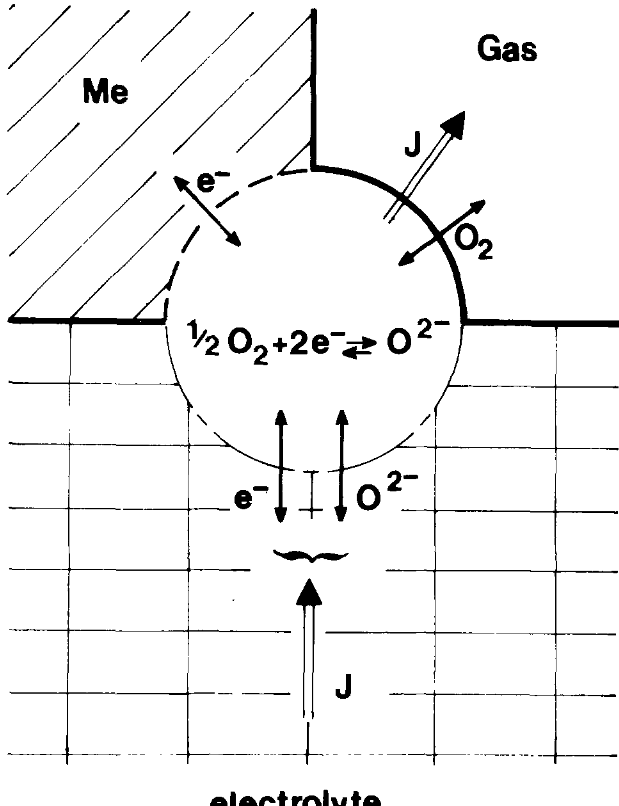

Fig. 1. Oxygen electrode microsystem; Me: inert metal, J: local oxygen semipermeability flux.

* Electrochemical Society Active Member.

Key words: oxygen gauge, electrode potential, zirconia, electronic conductivity, oxygen permeation.

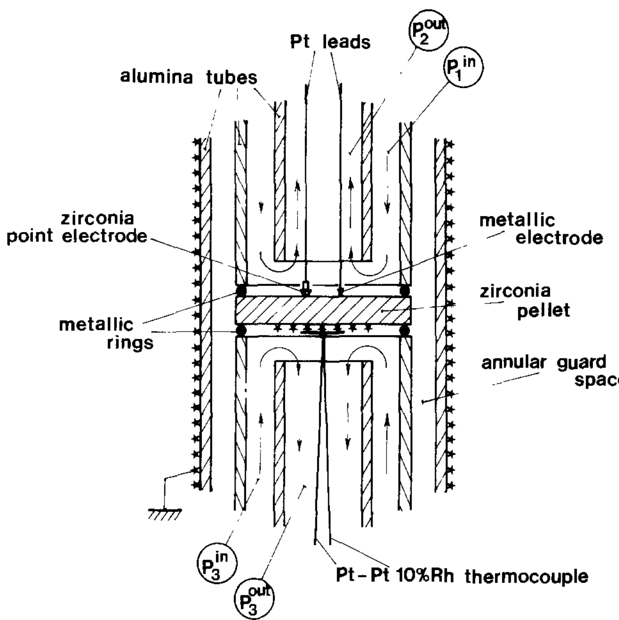

Fig. 2. Experimental cell

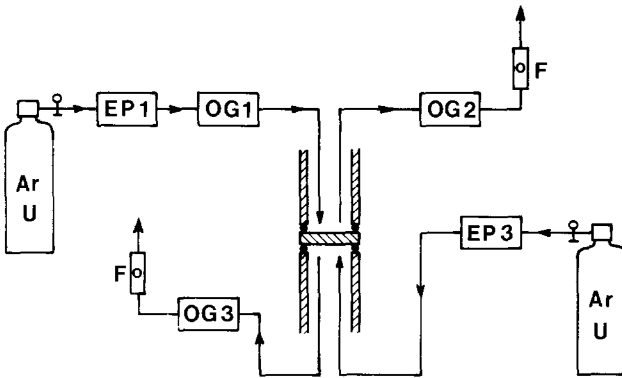

Fig. 3. Gas circuit; EP: electrochemical oxygen pump, OG: differential oxygen gauge, F: accurate displacement flowmeter.

The essential part of the cell which has already been described in other papers (3, 8) comprised a pellet of stabilized zirconia pressed between two alumina tubes and two metallic rings of gold or platinum. Such metallic seals were studied in detail by de Bruin *et al.* (9-11). They were also used by Takahashi *et al.* (12) and more recently by Zador *et al.* (13), Jakes (14), and Guillot *et al.* (15). The gas tightness thus ensured can be very good up to 1900°K. A vacuum of about 10^{-2} Torr is furthermore maintained in the annular guard space (Fig. 2). Among other advantages, this is the best way to minimize the effects of the local cell action by the local electrodes formed on both sides of the metallic ring. Under such conditions, variations of the order of a tenth of a ppm in the oxygen content of the gas streaming in the upper part of the cell could be measured as a function of the oxygen content in the gas in the lower part.

When the oxygen semipermeability of a solid electrolyte is studied, such a cell has the great advantage of yielding data relevant to an isothermal sample which is not the case with the more commonly used tubular cells.

The reference electrode of the electrochemical cell was formed by a layer of porous painted platinum (Degussa No. 308 A). The measuring electrode was a simple point electrode. At least as far as potentiometric measurements are concerned, such electrodes respond as large-surface porous electrodes (16).

Two samples of ZrO_2-Y_2O_3 9 m/o electrolyte were studied. The starting materials were the pure oxides [ZrO_2 (Nobel Bozel, and Merck) and Y_2O_3 (Pechiney)] which were ground to diameters less than 40 μm in a Linatex mill with zirconia balls. The samples were prepared by dry mixing the oxide powders, pressing under 1 tcm^{-2}, and firing at 2300°K for 1 hr [for more details see Ref. (17)]. Their measured lattice parameters were 5.139 and 5.140Å, respectively, and their densities equaled 91% of the theoretical value. Up to 1300°K, they appeared perfectly impervious in our experiments; on varying the oxygen pressure in the lower part of the cell, no change was detected within 0.1 ppm in the oxygen content of the gas streaming on the other side of the pellet. Their analyses and sizes are given in Table I.

The metals used for preparing the point electrodes were nominally pure metals purchased from Caplain St. Andre.

As first proposed by Moebius (18), the working gas circuit (Fig. 3) was based on the utilization of solid oxide electrolyte cells. It was formed of an argon cylinder (Argon U Air Liquide), a pressure expansion valve and an accurate needle valve which maintained the gas flux strictly constant, an electrochemical pump EP1, an oxygen gauge OG1, the cell proper, a second oxygen gauge OG2, and an accurate flowmeter. The apparatus was connected by stainless steel tubes and Viton O-ring seals. The gauges were differential assemblages (7) working at about 900°K. Such gauges can accurately measure oxygen content higher than a few 10^{-2} ppm. When no contamination occurred in the cell, the agreement between the oxygen measurements by the two gauges OG1 and OG2 was always better than 10% of the measured values over the 1-10^6 ppm range. Furthermore, the stability of the gauge voltages was such that for any given experiment, variation of the order of 1% in oxygen content could be measured for any oxygen content greater than a few ppm.

The accurate displacement flowmeter connected at the end of the gas circuit allowed us to use the Faraday law test (7). The verification of this law with the help of an oxygen pump and an accurate flowmeter was shown to be the best test to verify the good performances of an oxygen gauge.

As shown in Fig. 3, the reference gas circuit was very similar. Sometimes air was also used as a reference gas. A typical gas flow rate in both circuits was 10 liter/hr.

When working with oxygen contents of the order of a few ppm or less, about half a day was required for the surfaces of the whole circuit to be in equilibrium with the gas. The measurements were always performed when equilibrium was reached. This point was

Table I. Analysis and sizes of the two samples studied

Sample	Main impurities which could influence the electronic conductivity			Main impurities which could form segregated phases at the grain boundaries			Size	
	Cu (ppm)	Fe (ppm)	Mn (ppm)	Si (ppm)	Mg (ppm)	Al (ppm)	Effective permeation area (cm^2)	l (mm)
A ZrO_2-Nobel Bozel Y_2O_3-Pechiney	3	270	~10	100-500	50-100	200	2.27	3.3
B ZrO_2-Merck Y_2O_3-Pechiney	5	250	~10	100-500	50-100	250	2.27	3.6

checked by verifying that the voltages were stable to 1 mV over several hours.

The oxygen pressures measured by the gauges OG1, OG2, and OG3 will be called P_1, P_2, and P_3, respectively. The pressure P_3 was the reference oxygen pressure in the cell (*cf.* Fig. 2). The pressure P_1 was the oxygen pressure in the working gas arriving in the cell, and P_2 after passing in the cell. The difference

$$\Delta P = P_2 - P_1 \quad [1]$$

resulted from the oxygen semipermeability flow through the sample and its measurement was used to determine the corresponding flux.

An Oxygen Gauge with a Zirconia Point Electrode

The first set of measurements was devoted to verifying an assumption which derives from the model proposed in Fig. 1. Within the framework of this model, the departure of an electrode from its equilibrium potential results from the oxygen semipermeability flow arriving at its triple contact. If the cell geometry is designed in such a way that the oxygen flow does not reach the electrode, the measured potential must equal the theoretically expected value, which takes into account the usual $(1 - \bar{t}_e)$ factor.

The cell geometry which was investigated is sketched in Fig. 4. The electrochemical cell is formed by the reference electrode deposited on the pellet; the electrolyte composed of the pellet and a small point "electrode" of the same composition as the pellet and simply put in contact with it; and the measuring electrode coated on the top of the probe.

In another work (44) it has been shown that two blocks of stabilized zirconia simply put in contact, behave as a massive sintered pellet as regards the ohmic resistance.

The whole zirconia point electrode, apart from the small contact area, is surrounded by the same atmosphere. Thus, there is no oxygen activity gradient through the material. Should the oxygen activity on the contact surface be very different, it would be reasonable to assume that the resulting oxygen flow would be directed toward the closest free surface, as shown in the magnified part of Fig. 4. For these reasons, no oxygen flow emerges in the area of the measuring electrode which therefore must remain in equilibrium with the surrounding gas. Under these conditions the oxygen gauge sketched in Fig. 4 must correctly measure the oxygen pressure in the gas streaming over the zirconia point electrode whatever the oxygen semipermeability flow through the pellet.

This point was first verified by using the Faraday law test. This was done with air as a reference gas.

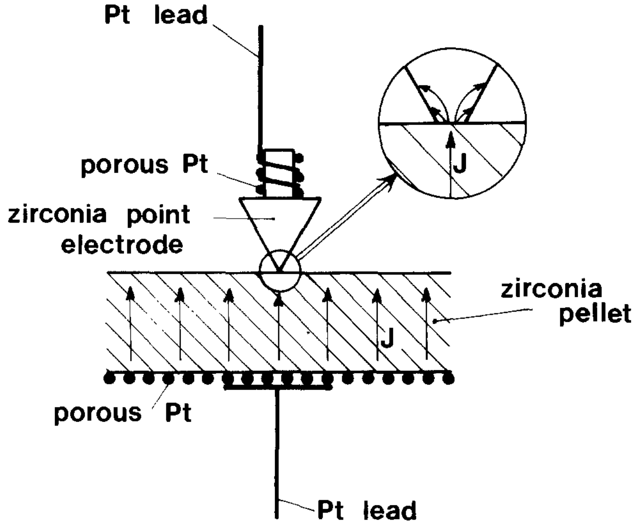

Fig. 4. Oxygen gauge with a zirconia point electrode; *J*: oxygen semipermeability flux.

Under these conditions, the reference electrode remained in equilibrium with the gas (see Fig. 7-9). Figure 5 gives a typical result. The current shown in abscissa is that which passed in the pump EP1, and the oxygen pressure is that deduced from the voltage of the gauge with the zirconia point electrode. The theoretical slope indicated was calculated according to the Faraday law [*cf.* Ref. (7)] by using an accurate measurement of the gas flow rate.

This point was again verified by comparing the zirconia point electrode gauge voltage to the theoretical value, E_{th}

$$E_{th} = \frac{RT}{4F} \ln \frac{P_2}{P_3} \quad [2]$$

This comparison was made several times at temperatures up to 1800°K. Each time the oxygen pressure in the reference gas was sufficiently high so that the reference electrode was in equilibrium, the agreement was within the experimental scatter: the oxygen pressure deduced from the zirconia point electrode potential was always equal to P_2 (1-10^6 ppm) to within 10%.

From a practical standpoint the arrangement with a zirconia point electrode is therefore an easy way to avoid the disturbing effect of the oxygen semipermeability on the measuring electrode. This could be particularly useful in gauges working at very high temperatures. A small difficulty in using such an arrangement has, however, been noted. It seems that sometimes a small spurious emf of a few millivolts is added to the gauge voltage. No obvious explanation was found for this phenomenon. This point should be investigated. It appeared in contradiction with the paper by Yushina *et al.* (19) where it was reported that no voltage drop was observed at a contact between two zirconia-based electrolytes.

Obviously such an arrangement can only eliminate the errors due to the disturbing effect on the electrode equilibrium but not the bulk effect which is usually

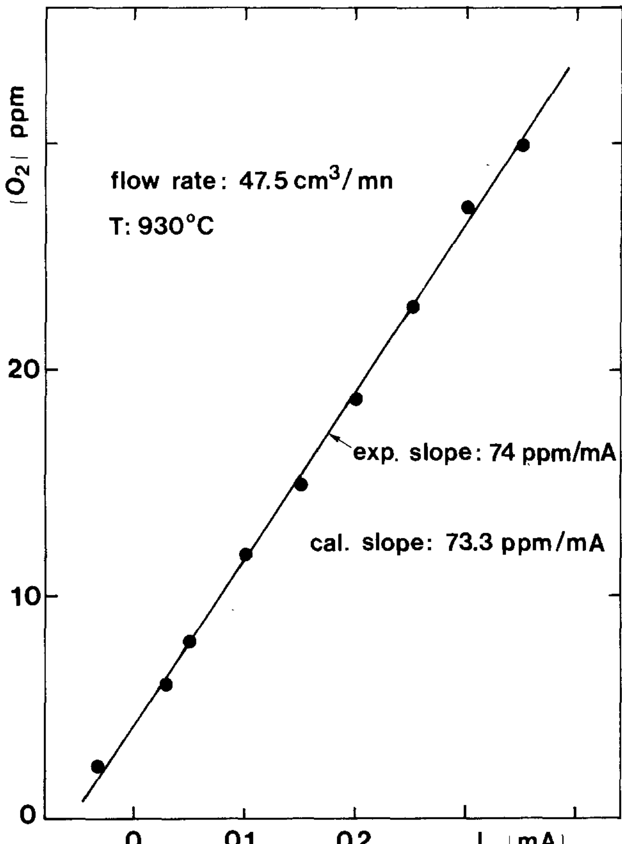

Fig. 5. Verification of the Faraday law with a zirconia point electrode; *I*: current passing through the upstream oxygen pump.

expressed by the factor $(1 - \bar{t}_e)$ in the relation

$$E = (1 - \bar{t}_e)E_{th} \quad [3]$$

Using an average value of the published data for the ionic conductivity of the ZrO_2-Y_2O_3 9 m/o electrolyte and the results presented later on, the semipermeability parameters and the relevant electronic conductivity, t_e, could be calculated and was found to be 6.10^{-4} at 1250°K and 2.10^{-3} at 1725°K under air. The error expressed by the factor $(1 - \bar{t}_e)$ is very small when compared to the other effects and will be neglected hereafter.

Measurements

The zirconia point electrode previously described was included in our cell. It provided a second "reference" electrode. Figure 6 is a sketch of the electrochemical cell which was investigated. We have represented adsorbed oxygen layers as definite phases. We furthermore formally characterize the oxygen activity in the adsorbed layers by their equivalent oxygen pressures P' which are equal to that in the gas which would be in equilibrium with the considered adsorbed layer. The change in the adsorbed oxygen level in the vicinity of the metals (Fig. 6) is a schematic way of representing the contribution of the metal to the modification of the amount of oxygen locally retained. This will represent the microsystem of the corresponding electrode.

The potentials of the metal and the zirconia probe as compared to the reference electrode will be called E_{Me} and E_Z, respectively. We can write

$$E_{Me} = \frac{RT}{4F} \ln \frac{P'_2}{P'_3} \quad [4]$$

$$E_Z = \frac{RT}{4F} \ln \frac{P_2}{P'_3} \quad [5]$$

According to our analysis, the error of measurement made with regular gauges working at high temperature results mostly from:

(*i*) the alteration of the pressure P_1 in the gas being analyzed to a pressure P_2. This alteration will be characterized by the parameter

$$\Delta P = P_2 - P_1 \quad [6]$$

(*ii*) the difference between the measured voltage E_{Me} (Eq. [4]) and the theoretical value E_{th} (Eq. [2]). This difference may result from a disturbance of the equilibrium of the measuring and the reference electrode, *i.e*, P'_2 being different from P_2, and P'_3 from P_3. These two possible contributions can be characterized by the parameters

$$\Delta E = \frac{RT}{4F} \ln \frac{P'_2}{P_2} \quad [7]$$

$$\Delta E_{Ref} = \frac{RT}{4F} \ln \frac{P'_3}{P_3} \quad [8]$$

which can be simply measured or calculated according to the formulae

$$\Delta E = E_{Me} - E_Z \quad [9]$$

$$\Delta E_{Ref} = E_Z - E_{th} \quad [10]$$

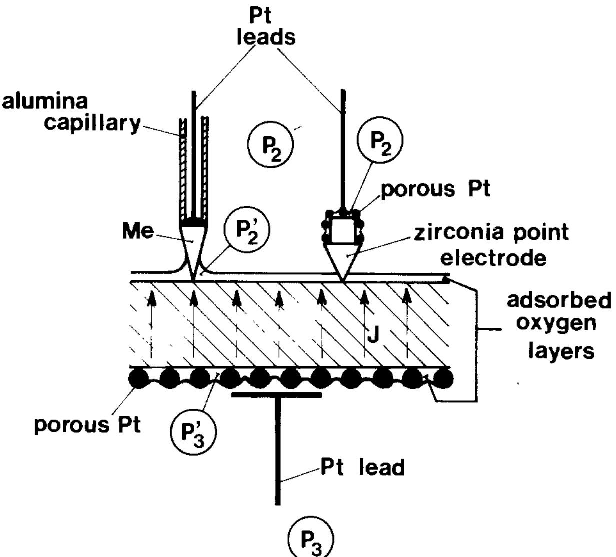

Fig. 6. Schematic representation of the investigated electrochemical cell showing oxygen adsorbed layers on the zirconia surfaces of interest.

Figures 7-9 show typical measurements of the parameters ΔP, ΔE, and ΔE_{Ref} as functions of the oxygen reference pressure P_3. Before analyzing these results, several qualitative obervations must be mentioned:

(*i*) At 1410°K, the alteration ΔP of the oxygen content was always smaller than 1 ppm. Below this temperature no alteration of the utilized gas was observed; in spite of this, a large departure from the theoretical voltage E_{th} was measured. This confirmed the results previously recalled: the error made with the gauges does not solely result from the alteration of the oxygen content in the analyzed gas. Further, the variation ΔE does not arise merely from a diffusion profile in the gas phase. The effect of a gaseous diffusion was observed (16) to be noticeable only with high oxygen flux through the electrolyte. Such effects were also reported (25) in the case of gauges working at very high temperature where the electrochemical semipermeability was very large.

In our experiments the deviations ΔE were smaller the higher the temperature. This does not mean that ΔE is inherently a decreasing function of the temperature. It results mostly from an increase in P_2 through ΔP due to an enhancement of the electrolyte semipermeability, the error ΔE being a decreasing function of P_2.

(*ii*) The measurements reported in Fig. 10 were carried out with the electrolyte sample B and a zirconia point electrode from the same bath as sample A. As shown in Fig. 10, a spurious increment of about 5 mV is measured for the zirconia point electrode (see above).

(*iii*) The great difference between the results obtained with samples A and B with a platinum electrode (compare Fig. 10 and 11) indicates that the error made by a zirconia gauge may vary greatly from one electrolyte to the other. We were unable to put forward a determinant parameter. The analysis showed no significant impurity-content differences which could account for the observed results. With regard to this point, with regular commercial tubes the alteration of the oxygen pressure in the analyzed gas is usually observed, on a 1 ppm scale, above 1100°K; with our sample this only occurs above 1400°K.

(*iv*) Figure 11 shows that the error can be noticeable for oxygen content much higher than 1 ppm.

(*v*) The existence of a noticeable error ΔE_{Ref} for the reference electrode confirms, at least qualitatively, that the errors reported here are not a specific property of the metallic point electrode.

(*vi*) The results reported in Fig. 10 confirm that the nature of the metal contributes to determining the characteristics of the electrode microsystem. From a practical viewpoint, silver should be a better electrode in a gauge working at medium temperature. Another work (2) has shown, furthermore, that the electrode time lag is much shorter with silver than with platinum, especially at a temperature around 900°K.

(*vii*) Silver and gold electrodes seem to behave quite similarly in spite of the very different properties of the corresponding metal-oxygen systems. The large devia-

tion when rhodium is used as an electrode could indicate that the formation of surface oxides, which is well known for platinum and rhodium, might play a part in the errors we have measured.

Oxygen Semipermeability

The primary cause of all the observed deviations ΔP, ΔE, and ΔE_{Ref} is the oxygen semipermeability of the electrolyte which has been frequently observed and studied (5, 7, 18, 20-36). The papers dealing with this phenomenon agree on its interpretation: under high or medium oxygen pressure, it results from a diffusion of holes, $h^{\cdot}$, electrically compensated by a diffusion of oxide ions O^{2-}. The flux of the former species is rate limiting. The hole concentration depends on the oxygen pressure in equilibrium with the material according to the reaction

$$\frac{1}{2} O_2 + V_o^{\cdot\cdot} \rightleftarrows O_o^* + 2h^{\cdot} \quad [11]$$

and the resulting relation

$$[h^{\cdot}] = \frac{a \cdot [V_o^{\cdot\cdot}]^{1/2} \cdot P_{O_2}^{1/4}}{[O_o^*]^{1/2}} \quad [12]$$

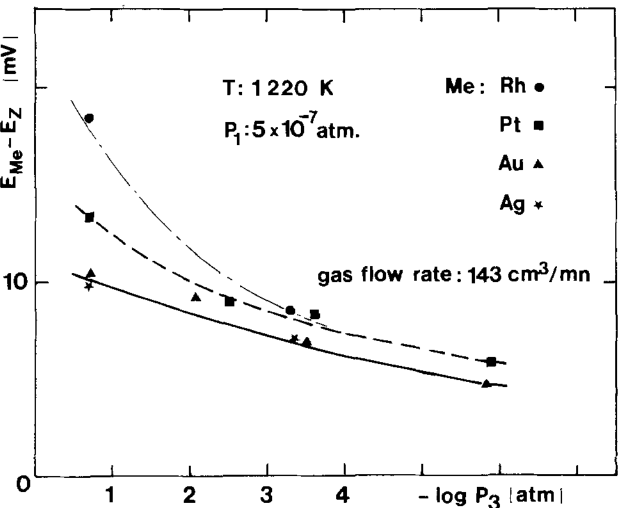

Fig. 10. Influence of the nature of the metal (Me) forming the metallic point electrode on the error ΔE.

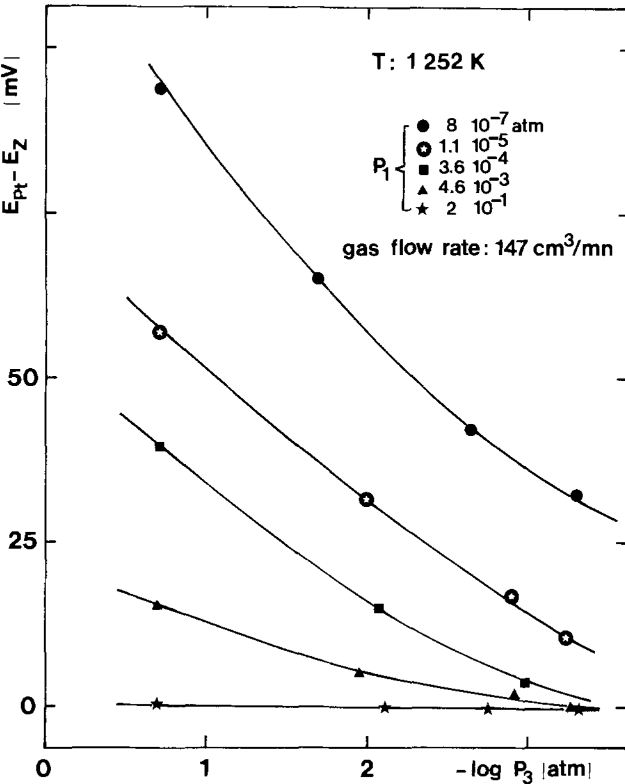

Fig. 11. Variations of the error ΔE in ranges where the oxygen semipermeability flux is negligible as far as alteration of the oxygen content of the analyzed gas is concerned.

or more simply

$$[h^\cdot] = A \cdot P_{O_2}{}^{1/4} \quad [13]$$

the oxide-ion and oxide-ion-vacancy concentrations being essentially constant.

Under these conditions the hole flux through a square centimeter of a zirconia pellet can be calculated within the framework of the Wagner theory (20, 22, 28, 38) or, more simply, as follows. Under high or medium oxygen pressures the $V_o^{\cdot\cdot}$ concentration is essentially constant, there is no chemical potential gradient for this species and the current density carried by the O^{2-} ions (or the corresponding vacancies) is simply given by the relation

$$I_{ion} = \frac{\sigma_{ion}}{l} \Delta V \quad [14]$$

where σ_{ion} is the ionic conductivity of the material, l the length of the conduction path, and ΔV the variation in electrostatic potential. The current carried by the holes can be expressed as

$$I_h = \frac{\bar{\sigma}_h}{l \cdot \mathbf{F}} \cdot \Delta\tilde{\mu}_h \quad [15]$$

where $\bar{\sigma}_h$ is the average hole conductivity and $\Delta\tilde{\mu}_h$ the variation of the hole electrochemical potential.

Under stationary conditions at open circuit there is no net current passing through the electrolyte and I_{ion} is equal to I_h. Then, combining Eq. [14] and [15] gives

$$\Delta V = \frac{\bar{\sigma}_h}{\sigma_{ion}} \cdot \frac{\Delta\tilde{\mu}_h}{\mathbf{F}} \quad [16]$$

The conductivity ratio is roughly of the order of 10^{-2}, and $\Delta\tilde{\mu}_h \cdot \mathbf{F}^{-1}$ which is equal to the cell voltage is smaller than 400 mV; therefore ΔV is smaller than a few millivolts and can be considered in a first approximation as zero.

Under these conditions, the hole flux J is due only to a chemical diffusion and can be expressed as

$$J = -U_h[h^\cdot] \operatorname{grad} \mu_h \quad [17]$$

where U_h is the mobility of the holes, $[h^\cdot]$ their local concentration, and μ_h their chemical potential. If μ_h can be expressed as

$$\mu_h = RT \ln [h^\cdot] \quad [18]$$

the flux, in a one-dimension geometry, is simply

$$J = -RTU_h \frac{d[h^\cdot]}{dx} \quad [19]$$

Under steady-state conditions, there is no local accumulation of holes (no change in the stoichiometry) and J is a constant through the material. Therefore the derivative of $[h^\cdot]$ is a constant, $[h^\cdot]$ is a linear function of x, and J is equal to

$$J = RTU_h \left\{ \frac{[h^\cdot]_3 - [h^\cdot]_2}{l} \right\} \quad [20]$$

where $[h^\cdot]_3$ and $[h^\cdot]_2$ are the local hole concentrations on the surfaces of the pellet.

According to formula [13], J can be expressed as a function of the oxygen pressures surrounding these surfaces as

$$J = \frac{A \cdot RTU_h}{l} (P_3{}^{1/4} - P_2{}^{1/4}) \quad [21]$$

or more simply

$$J = \frac{\rho}{l} \cdot (P_3{}^{1/4} - P_2{}^{1/4}) \quad [22]$$

In the literature, this flux is frequently written as

$$J = \frac{\pi^*}{l} \quad [23]$$

The parameters are related by the expression

$$\pi^* = \rho(P_3{}^{1/4} - P_2{}^{1/4}) \quad [24]$$

If we take the model of Fig. 6 into account, the oxygen activity in the adsorbed phases, *i.e.*, the equivalent pressures P'_3 and P'_2, must be substituted for the gas pressures P_3 and P_2

$$J = \frac{\rho}{l} (P'_3{}^{1/4} - P'_2{}^{1/4}) \quad [25]$$

We will neglect here the local modifications of these equivalent oxygen pressures due to the influence of the metal. Insofar as the semipermeability is concerned, they appeared as a second order cause of error.

In Fig. 12 we have compared the measured values of J as functions of the measured pressures according to formulae [22] and [25]. The flux J was simply deduced from ΔP using the measured values of the working gas flow rate and the sample surface. The comparison seems to indicate that formula [25] better fits the experimental results. The experimental results obtained at the other working temperatures yield similar plots.

In order to have a good determination of the parameter ρ for sample A, we carried out measurements over a wide temperature range, up to 1900°K. This was done with air as a reference gas and a working gas containing 0.5 ppm of oxygen initially. The pressure change ΔP, the voltages E_Z, E_{Pt}, and the gauge voltages were measured at various temperatures. The parameter ρ was calculated according to formula [25].

The results are reported in Fig. 13 together with the values representing the slope of the straight lines obeying relation [25] (*cf.* Fig. 12). The data fit well an Arrhenius law with an activation energy of 2.02 eV. This value is compared with the published data together with other parameters in Table II.

The scatter observed in the low temperature range results from the uncertainty of the measurements; in this range, the fluxes were determined by variations in oxygen content of the gas lower than 1 ppm. Taking into account the good fit in the range where the measurements were accurate enough, we have assumed that

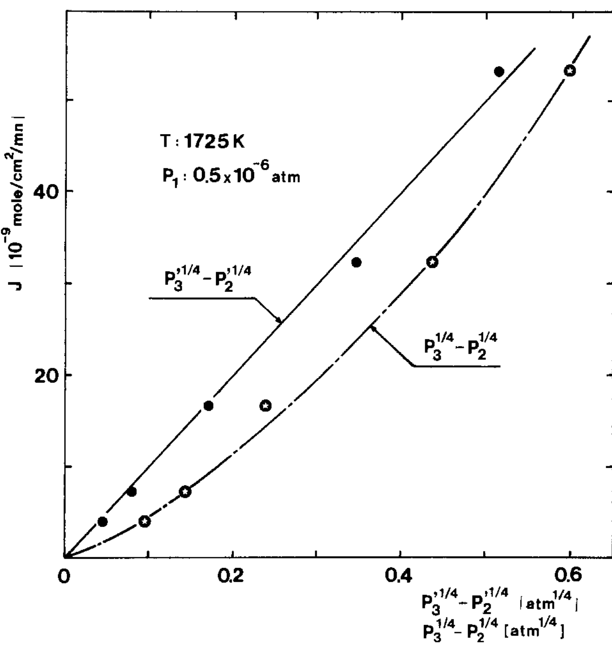

Fig. 12. Oxygen electrochemical semipermeability flux expressed as a function of the oxygen pressures P_2 and P_3 in the gases or the equivalent oxygen pressures P'_2 and P'_3 in the adsorbed layers.

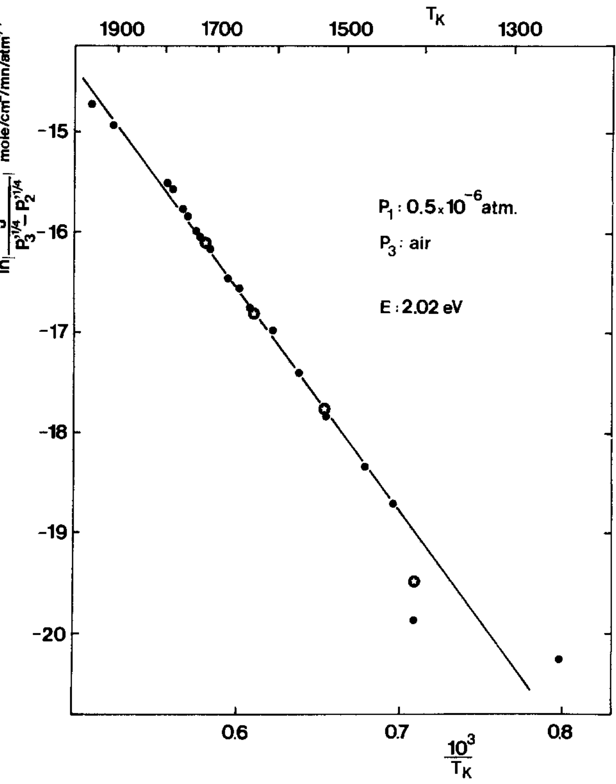

Fig. 13. Variation of the electrochemical semipermeability coefficient as a function of temperature. Stars: points representing the slope of the straight lines obeying relation [25].

the Arrhenius law represented by the straight line in Fig. 13 and Eq. [25] accurately determines the parameter ρ/l over the whole investigated range. In what follows, we will sometimes refer to these data and calculate the oxygen fluxes according to the relevant equations when the measurements were not accurate or sensitive enough.

Departure from Equilibrium Between the Electrode and the Gas

The oxygen semipermeability flux is determined by the electronic current through the electrolyte. The oxide ion flux, which is the oxygen semipermeability flux, simply compensates this current electrically. If the electronic current should pass in an external circuit, the oxide ion flux would be the same. This latter situation corresponds to electrode overpotential measurements. The "error" ΔE is then called the overpotential η and the oxide ion flux is simply the current I. From the similarity of these two situations it can be inferred that the relation between the error ΔE and the semipermeability flux J must be similar to that between the overpotential η and the current I. The influence of the nature of the metal is qualitatively the same in both cases. It was shown (16) that the overpotential of a platinum electrode is higher than that of a silver electrode and that rhodium enhances the overpotential even more. The results just reported (cf. Fig. 10) are the same.

The overpotential η was found (4, 6, 16) to be related to the current I by the equation

$$\eta = \frac{RT}{z\mathbf{F}} \ln \frac{I_1 - I}{I_1} \quad [26]$$

With platinum, z was found (4, 16) to equal 2, and I_1 is a parameter which appeared (6) to be proportional to the square root of the oxygen pressure P_{O_2} in the surrounding gas under oxygen pressures higher than about 10^{-4} atm and to $P_{O_2}{}^{2/3}$ under lower pressures.

According to the similarity previously mentioned, the error ΔE should therefore be related to the oxygen semipermeability flux J by the equation

$$\Delta E = \frac{RT}{2\mathbf{F}} \ln \frac{I_1 - J \cdot \mathbf{F}}{I_1} \quad [27]$$

or after transformation

$$J \cdot \mathbf{F} = -I_1 \left(\exp \frac{2\mathbf{F}\Delta E}{RT} - 1 \right) \quad [28]$$

To check the validity of this equation we plotted J as a function of ($\exp 2\mathbf{F}\Delta E/RT - 1$) under such conditions that I_1 could be considered as constant, that is to say, under a constant oxygen pressure. Under these conditions we could obviously not measure experimentally the flux J which is determined by the variations of the oxygen pressure. We used instead a calculation based on Eq. [25] and on the Arrhenius law shown in Fig. 13. Figure 14 and 15 give two examples of such plots obtained with the point electrode.

We also studied the variations of $I_1 \cdot \mathbf{F}^{-1}$ which is equal to $J(\exp 2\mathbf{F}\Delta E/RT - 1)^{-1}$ as a function of the oxygen pressure in the surrounding gas. Figures 16 and 17 show two plots of these variations which confirm that the $P_{O_2}{}^{1/2}$ and $P_{O_2}{}^{2/3}$ laws are approximately obeyed in the medium and low oxygen pressure ranges. In fact, some of our experimental results do not fit these laws so well, the exponent in the observed $P_{O_2}{}^{m}$ ranging from 0.5 to 0.75.

It was also shown (6) that the proportionality coefficients $B_{1/2}$ and $B_{2/3}$ between I_1 and $P_{O_2}{}^{1/2}$ or $P_{O_2}{}^{2/3}$

$$I_1 = B_{1/2} P_{O_2}{}^{1/2} \quad [29]$$

$$I_1 = B_{2/3} P_{O_2}{}^{2/3} \quad [30]$$

are activated with activation energies of 1.15 eV for $B_{1/2}$ and 1.10 for $B_{2/3}$. The results obtained with the large surface electrode and under medium oxygen pressures give an activation energy of approximately 1.0 eV which is in rather good agreement with that just recalled. The results obtained with the point electrode and under low oxygen pressure are unfortunately totally different; the activation energy is equal to 1.9 eV. No obvious explanation was found for this difference. Several suggestions could be made: (*i*) the investigated temperature ranges are different: 1050°-1480°K for the overpotential measurements, 1250°-1900°K for the measurements reported here; (*ii*) the similarity on which our derivation is based holds only for a macroscopic approach. On a microscopic scale the dominant elementary step of the over-all phenomenon would be different. In the semipermeability experiments the gradients of chemical potential are regularly directed from one surface of the electrolyte to the other. In the overpotential experiments, in the close vicinity of the electrode, the electrochemical potential gradients are certainly directed toward the

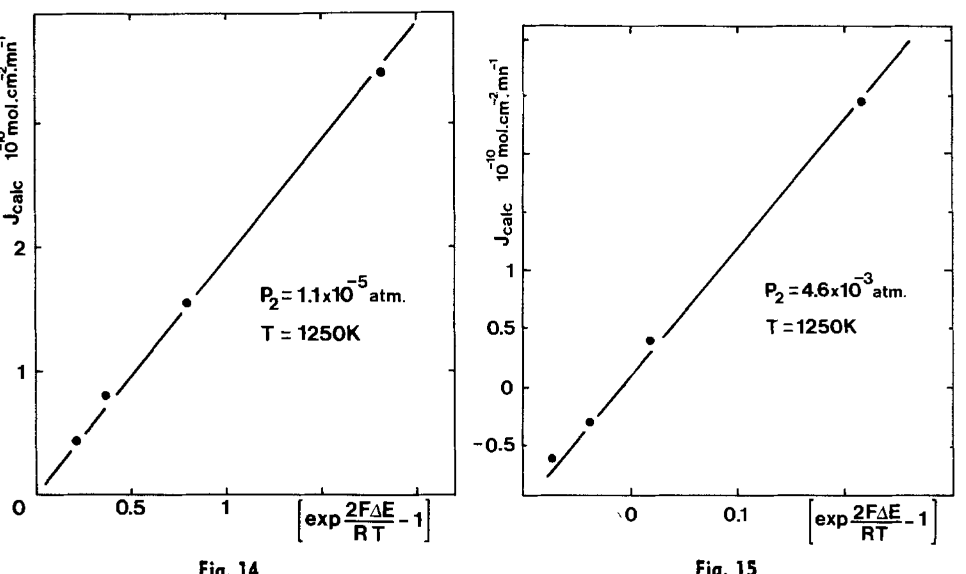

Fig. 14, 15. Verification of Eq. [28] expressing the similarity between the error ΔE and a conventional overpotential.

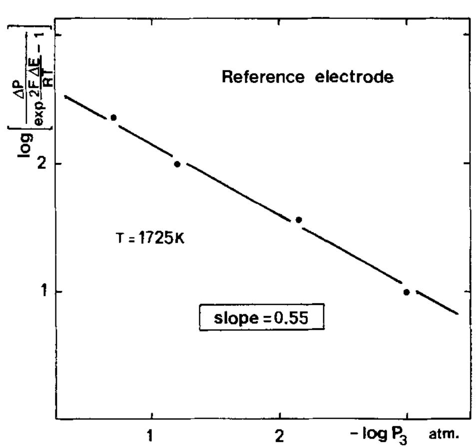

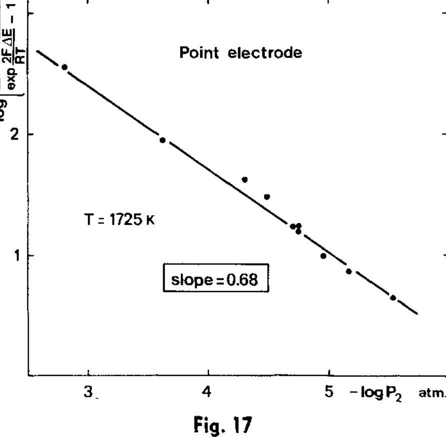

Fig. 16, 17. Variation of the parameter I_1 as a function of the oxygen pressure.

triple contact of the electrode. This could cause diffusion on the surface of the sample, for example.

Conclusions

Whatever the physical description of the microsystem, it seems well established that it constitutes a necessary intermediate stage between the electrode and the gas. Furthermore, the oxygen exchange rate between the microsystem and the gas has a finite value which is not always sufficient to maintain the equilibrium. From this simple statement several practical conclusions must be drawn. When making a gauge, it is of interest to select not only the electrolyte having the smallest semipermeability coefficient ρ, but also the electrode materials leading to the smallest overpotential of the electrode.

A gauge voltage E can be written

$$E = \frac{RT}{4F} \ln P - \frac{RT}{4F} \ln P_{Ref} \quad [31]$$

As previously shown, the error made in ascribing the first term to the oxygen pressure being measured can be decomposed into two components, ΔP and ΔE. Although not recognized so far, the error ΔE may have been very frequent. For instance, the experimental results recently reported by Cherkasov *et al.* (25) and Alcock *et al.* (33) where the departures from the theoretical emf were much larger than that predicted by the $(1 - \bar{t}_e)$ coefficient, were likely to result from a noticeable value for the error ΔE.

Increasing the gas flow rate, as it is frequently suggested (37), until the gauge voltage no longer depends on it only reduces the error ΔP to a very negligible value but not necessarily ΔE. (In fact, in such an experiment ΔE increases as ΔP decreases.) The results reported here have shown that ΔE can be very large even when ΔP is zero. In fact, all the experiments we have done so far indicate that, with oxygen contents smaller than roughly 50 ppm and air as a reference gas, it is necessary to operate the gauge at a temperature at least 200° lower than that where the semipermeability flux becomes noticeable on a 1 ppm scale to have any chance of observing a negligible ΔE value.

The properties previously described are not specific to oxygen; they were also observed with CO-CO_2 mixtures and are likely to hold with the H_2-H_2O system. In any cell where the electrode potentials are fixed by gaseous systems, the errors previously described may be found. That means, in particular, that we may make errors in measuring an electronic transport number by the emf method using gaseous systems. The errors are especially likely when the oxygen flux through the sample, that is to say its electronic conductivity, is large and also when the buffer effect of the gases is weak (argon with low oxygen content, CO-CO_2 mixtures with small content of either CO or CO_2, etc.). This point was verified experimentally (3) by comparing the results obtained under these conditions on a ZrO_2-Y_2O_3-CeO_2 sample to those obtained with metal-metal oxide electrodes. They have shown that the error may be very large.

In transient phenomena like those described by Heyne (32), for instance, the electrode microsystems are likely to play an important part in the measurement of the time lag of the oxygen permeation.

Referring to the results obtained with the zirconia point electrode, another remark can be made regarding the solid bielectrolyte cells which were used for instance by Tretyakov *et al.* (36), Fender *et al.* (41), and Salzano *et al.* (42), and which were criticized by Shores and Rapp (43). According to the arguments raised in the last paper and our results, the only positive way of using such cells is to insure the contact between the two electrolytes by coarse grains of a conveniently selected electrolyte surrounded by a gas having an oxygen activity close to that surrounding the less reversible electrode of the cell. This has the advantage of stopping the semipermeability flux in the intermediate space and then preventing this flux from reaching the considered electrode and disturbing its equilibrium. This obviously does not in principle reduce the errors which are usually described by the $(1 - \bar{t}_e)$ factor. On the other hand, insuring the contact between the two electrolytes by a metal such as platinum doubles the sources of error by doubling the number of electrode microsystems which can be disturbed. This point is well substantiated by the results which were obtained with the differential gauges (7).

Acknowledgments

The authors are greatly indebted to Mr. Hénault and Mr. Dessart for the preparation of the samples.

Energy Curves for the Hydrogen Evolution Reaction: Case of the Discharge Step

C. M. Marschoff* and P. J. Aragón*,[1]

Departamento de Química, Universidad de los Andes, Mérida, Venezuela

ABSTRACT

Using the Gomer-Swanson approximation and the results from Smith *et al.* (46), the potential energy curves for the discharge step of the hydrogen evolution reaction (HER) on several metals are obtained as a function of bond order. Using a modified BEBO method the classical activation energy is calculated in each case considered. "True" activation energies and enthalpy changes are estimated. Previous work is reviewed.

Although they are of undisputable importance in the study of rate processes, the calculation and experimental determination of activation energies have been only seldomly performed in the case of electrode processes. Even less have they been used in theoretical interpretation or prediction of reaction mechanisms. There are, indeed, powerful reasons for this being so: (*i*) in the experimental determination of activation energies there exists a thermal effect on the potential measurements that cannot be avoided (1) and that is due to the arbitrariness of the zero definition in the potential scale; (*ii*) the theoretical calculations of potential energy curves as a function of distance to the electrode must include image interactions, whose values are not well known for points located at very short distances from the metallic surface (2-4).

Nevertheless, any effort directed to the development of a theoretical approach to electrode processes must be recognized as worthwhile, and this should include, in a natural way, use and interpretation of activation energies. Up to now this has been approached by two main routes, namely, the so-called electrostatic theories and the model and methods based on the absolute rate theory.

The electrostatic approach developed chiefly by Marcus (5-10) and Levich, Dogonadze, and co-workers (11-16) has been recently reviewed by Lamy (17). However, application of these models to real cases is difficult, and accord with experiment is far from good (18) due to oversimplifying assumptions of the theory; particularly, the dielectric continuum hypothesis (19) and the lack of specific consideration of the metallic surface (20) must be pointed out.

On the other hand, typical transition state theories (21, 22) are known to be unreliable (23), and the modifications proposed to account for electrode processes (24-27) have shown inconsistencies, specially regarding vibrational characteristics and bond orders during the activation process (28). Besides, these models, as those based on the electrostatic approach, also dismiss the influence of the metallic surface through image effects.

As the exact solution of the many-body problem corresponding to the situation at an electrode-solution interface is far beyond actual computer facilities, it seems reasonable to look for empirical or semiempirical methods in order to attack some of the questions already unsolved in electrode processes. Considering the simplest electrode process, *i.e.*, the hydrogen evolution reaction when discharge is rate determining, Salomon, Enke, and Conway (3) have proposed that the bond energy-bond order (BEBO) method developed by Johnston and co-workers (29-31) for proton transfer might be used. Calculations based on the BEBO method have not been further pursued and even the attempt by Salomon *et al.* is only rarely mentioned in the literature (18, 28).

In this paper, some considerations on the use of the BEBO method for electrode processes are given, and a new way of calculating activation energies for the discharge step in HER is presented.

The BEBO Method in Electrode Processes

The BEBO method was developed as an empirical tool for calculating activation energies of proton transfer reactions that proceed in the gas phase. The basic assumption of the method is that, since bonds involving a hydrogen atom have energies of about 100 kcal/mole or more, and activation energies for processes of the type

$$R\text{-}H + X \rightarrow R + H\text{-}X \quad [1]$$

Key words: proton transfer, image forces, BEBO method, "jellium" model for surfaces, Gomer-Swanson approximation.

are always below 20 kcal/mole, the activation step of such reactions should proceed through gradual destruction of the R-H bond and simultaneous gradual building up of the H-X bond. Considering bond order as a measure of bond existence the above argument is resumed in the postulate of total bond order conservation (31)

$$n + m = 1 \qquad [2]$$

where, refering to reaction [1], n is the bond order for the R-H molecule and m is the H-X bond order. Bond order is defined as a function of bond length through the following equation, due to Pauling (32)

$$R = R_s - 0.26 \ln n \qquad [3]$$

where R is the bond length at bond order n and R_s is the nonperturbed bond length, *i.e.*, bond length when n is 1. Besides, bond energy and bond order are linked through the following equation (31)

$$D = D_s n^p \qquad [4]$$

where D is the bond energy at bond order n, D_s is the bond energy for the nonperturbed bond and p is a characteristic index that depends on the row of the Periodic Table in which the atoms forming the bond are located.

Considering the activated complex corresponding to reaction [1] as

$$R \overset{R_1}{-----} H \overset{R_2}{-----} X \qquad [5]$$

Eq. [4], together with condition [2], permits the calculation of D_1 and D_2, the bond energies for R-H and H-X bonds respectively, as a function of bond order. Nevertheless, in order to obtain the total energy for the whole system, the triplet repulsion between R and X must be taken into account. The expression proposed by Johnston and Parr (31), based on an anti-Morse function is

$$V = \frac{D_{3s} \exp(-a\Delta R_s) \cdot (nm)^{0.26a}}{2} \cdot \frac{1 + \exp(-a\Delta R_s)(nm)^{0.26a}}{2} \qquad [6]$$

where V is the triplet energy, D_{3s} is the bond energy for the R-X molecule, a is the Morse constant for the same bond and ΔR_s is

$$\Delta R_s = R_{1s} + R_{2s} - R_{3s} \qquad [7]$$

the R_{1s} being the equilibrium distances for the corresponding bonds.

The total energy for the system is obtained, defining the energy zero for the configuration consisting of the R-H molecule at infinite distance from X, as

$$E = D_{1s}(1 - n^p) - D_{2s}(1 - n)^q + V \qquad [8]$$

where q is the analog of p for the H-X bond. The maximum of this function should give the classical activation energy; so, differentiating Eq. 8 with respect to n and equating to zero, the bond orders at the activated complex configuration are obtained. Using these values in Eq. [8], one may calculate the activation energy.

As it has been said, the value thus obtained corresponds to the classical activation energy, E_c. If the "true" activation energy, E_o is wanted, the vibrational frequencies of the activated state should be known. Johnston and Parr suggest a way of calculating these frequencies through the determination of the force constants along the reaction coordinate and along the direction perpendicular to the reaction coordinate. The first of these force constants, F_ρ, is obtained by twice differentiating Eq. [8] with respect to ρ, the reaction coordinate. The second, F_σ, is calculated assuming that it follows a Badger-like rule (30, 33)

$$F_\sigma = \frac{F_{1s} n^3 + F_{2s} m^3 + F_{3s}(nm)^{0.26a} \exp(-a\Delta R_s)}{n^2 + m^2} \qquad [9]$$

From the knowledge of F_ρ and F_σ it is possible to obtain the force constants along the internal coordinates F_{11}, F_{22}, and F_{12}. Then, using Wilson's method, the frequencies in the activated state are calculated.

Considering that the HER on Hg has the discharge step as rate determining (34, 35) and accepting Conway and Salomon's suggestion that the rate-determining event in this case is the adiabatic transfer of a proton followed by nonadiabatic electron neutralization (36-38), Salomon *et al.* (3) used the BEBO method for the calculation of some fundamental parameters (activation energy, absolute electrode potential) of this electrode reaction. It will prove convenient for this presentation to describe, at least roughly, this calculation. According to the absolute rate theory (39), the exchange current may be expressed as a function of the classical activation energy, the vibrational frequencies of the activated complex, the absolute electrode potential corresponding to the electron reaction under study and a set of experimentally available data such as the electrochemical transfer coefficient for the particular reaction, the potential at the outer Helmholtz plane [obtainable for Hg from Grahame's data (40, 41)], partition functions for the hydroxonium ion, etc. Using these values and the experimentally determined exchange current, the following equations were obtained for a 0.1N HCl solution (3)

$$\exp(\beta\phi_r F/RT) = 1.31 \times 10^{22} \prod^{3} (2 \sinh u\#)^{-1} \exp(-E_c/RT) \qquad [10]$$

at 25°C and

$$\exp(\beta\phi_r F/RT) = 4.45 \times 10^{19} \prod^{3} (2 \sinh u\#)^{-1} \exp(-E_c/RT) \qquad [11]$$

for 85°C. In these expressions β is the transfer coefficient, ϕ_r is the absolute electrode potential, E_c is the classical activation energy, and u is defined as $hc\omega/2kT$ being ω the frequency in cm^{-1}. The vibrational frequencies at the activated state may be obtained through the BEBO method if the necessary data are known. However, D_{2s}, the bond energy for the proton-metal bond is not experimentally accessible; hence, in Salomon *et al.*'s calculation this quantity is taken as an adjustable parameter. The corresponding absolute electrode potential is obtained for each D_{2s} value, both at 25°C and at 85°C. Then, using the Gibbs-Helmholtz equation, ΔS and ΔH are calculated for the electrode reaction. Once ΔH is known, the experimentally accessible activation energy may be calculated through the relation

$$E_{exp} = E_o + RT - \beta\Delta H \qquad [12]$$

where E_o is obtained through the well-known equation

$$E_o = E_c - \tfrac{1}{2} hc \Sigma (\omega_{H^+} - \omega\#) \qquad [13]$$

The value of D_{2s} that makes the calculated E_{exp} fit the observed value is considered to be the correct energy for the proton-metal bond.

Although the present authors think that electrode processes involving proton transfer may be reasonably considered within the basic ideas underlying the BEBO method, there are several observations that must be made on the calculation carried out by Salomon *et al.* In the first place, it must be said that, although the electrostatic energy arising as a consequence of image effects is somehow considered when the energy of the metal-proton bond is fitted to the observed value of the activation energy, image effects are absolutely dismissed in the initial state. In this case, the total energy of the system is considered to be simply that of the nonperturbed hydrogen oxygen bond, D_{1s}. Now, the image interaction will exist not only when the proton-

metal bond is formed, but also in the initial state, since the hydroxonium ion carries an electric charge and is in close vicinity to the metallic surface. In consequence, the bare use of D_{1s} should not be acceptable. On the other hand, the way in which image effects are taken into account when the system is in the final state is also not correct. This is so because being due to long range forces, image interactions will depend on the metal-proton distance in a different way than that proposed by Johnston and Parr for chemical bonds; hence, the energy contribution due to electrostatic image effects should be included as a separate term in the expression that relates the total energy of the system with distances between atoms or, considering Pauling's relation, with bond orders.

Second, a word must be said with respect to the use of the equation linking bond length and bond order. Pauling's original relation, Eq. [3], was obtained for simple bonds between atoms or groups in cases in which no external fields were acting on the system. The situation when a proton approaches a metallic surface is very different: electric fields (due to image effects) appear, and the bond is not a bond between two free atoms or groups of atoms but between a free ion (the proton) and a metal atom that, being part of a lattice, has lost its translational freedom degrees and is subject to strong interactions with its neighbors. In consequence, it seems reasonable to assume that the original equation relating bond length and bond order should be modified to take into account the presence of the surface and the different nature of the bond established.

Third, it should be pointed out that the expression used by Salomon *et al.* for the triplet repulsion energy is not correct. They consider

$$V = D_{3s} \exp(-a\Delta R_s) nm^{0.26a}(1 + nm^{0.26a})/2 \quad [14]$$

instead of the correct expression, Eq. [6]. The omission of the brackets in the latter equation is due to a misprint in the original paper by Johnston and Parr [*cf.* Eq. (22) and (23) in Ref. (31)]. This mistake has little consequence on the absolute value of the total energy of the system since triplet terms are very small (20); however, since bond orders at the activated state are obtained by differentiation of the total energy with respect to n, the omission becomes significant, as is shown in Table I, where the bond order values that maximize both the correct form of the total energy and that used by Salomon *et al.* are listed, as well as the activation energies and absolute electrode potentials that result in each case if the calculation proposed by these authors is carried out.

Finally, there remains the question of the accuracy of the method. In reference to this, there are two facts that should be considered: (*i*) Two differentiations must be made on expressions that are ultimately empirical or semiempirical. The first one is performed in order to obtain the bond orders at the activated complex; the second differentiation is made when the Gibbs-Helmholtz equation is employed in order to determine the ΔH value for the electrode reaction. Differentiating an empirical expression will introduce a larger error than that contained in the original equation, and this will be particularly true in the case of the Gibbs-Helmholtz equation since it is performed assuming linear behavior between 25° and 85°C. (*ii*) The vibrational characteristics of the activated complex are not reliable, since the value of the force constant on the direction perpendicular to the reaction coordinate, F_σ, is of dubious validity because this force constant is obtained through an expression proposed by similarity with an empirical rule for diatomic molecules, due to Badger (30, 33). The use of this definition, as one of the present authors has shown (20, 42) leads to some contradictions in the bond order values at the activated complex.

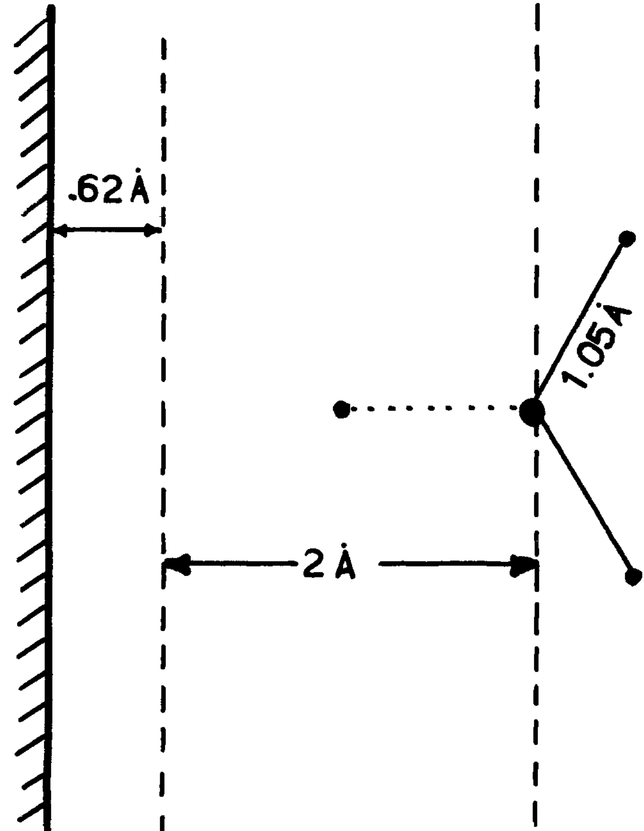

Fig. 1. Model for the system at the initial state. The screening length is that of Hg.

In consequence, if the BEBO method or its basic ideas are to be applied to the HER, these points should be kept in mind. As we shall see, when they are considered it will be necessary to restate some of Johnston's considerations in order to deal with electrode processes.

Model for the Activation Event

In view of Conway and Salomon's arguments (36-38) and considering that the binding energy of a proton to a water molecule is about 180 kcal/mole (43, 44), compared to a total ionic hydration energy of about 245 kcal/mole (45), the hypothesis of an adiabatic proton transfer as rate-determining event will be accepted. Also, the description given in Ref. (3) of the activated complex will be retained with a few extra considerations. The initial situation will be depicted as a planar hydroxonium ion located at the inner Helmholtz plane (accessible for instance by a Grotthuss mechanism) with its oxygen atom at about 2Å from the metallic surface (considered as a plane) as shown in Fig. 1. As in Ref. (3), the nonreacting O-H bonds will be considered to remain unmodified during the activation process carrying the system from the initial to the

Table I. Obtained values for bond order of the O-H bond in the activated state ($n^{\#}$) and for energetic parameters using the method proposed by Salomon *et al.* (3) with Eq. [13] for the triplet repulsion (first row) and using the correct form, Eq. [6] (second row).

D_{2s}, kcal/mole	$n^{\#}$	E_c, kcal/mole	E_o, kcal/mole	ϕ_{25}, mV	ϕ_{85}, mV	ΔH, kcal/mole	E_{exp}, kcal/mole
155	0.20	29.1	25.5	−225	−185	10.9	20.1
155	0.15	30.6	28.3	−386	−208	−11.4	34.6

activated state. The final state will be considered as a proton adsorbed onto the metallic surface.

It is convenient here to point out that the configuration assumed for the final state does not consider the fact of electron transfer from the metal to the proton. In consequence, this state need not have actual existence and in the case of HER is, almost surely, hypothetical. This may be considered so, if the activation energy is going to be obtained through the drawing of potential energy curves for the initial and "final" states, because the rate-determining event takes place before the electron is transferred.

The adopted model for the activation process and the activation complex allows treating the problem as if it were a three "particle" system composed of the OH_2 group (assumed to be invariant during the activation process), the proton, and the metallic surface. The zero point energy will be defined for the configuration in which all the three entities lie infinitely apart from each other. The bond length for the nonreacting O-H groups will be considered to be 1.05Å (43) and the equilibrium proton-metal distance will be taken to be 0.6Å according to calculations made by Smith, Ying, and Kohn (46).

Image Effects and Energy Calculations for Two Specific Configurations

As pointed out previously electrostatic effects due to image interactions should be included at every stage of the process as a different term than those corresponding to bond energies. Of course, the electrostatic energy resulting from image interactions between atoms and the metal should not be considered as a modification to the bond energy of a particular bond but, rather, as a contribution to the total energy of the system that may be written, for any configuration, as

$$E = U_{\text{elect}} + U_{\text{nonel}} \quad [15]$$

where U_{elect} represents the contribution of the coulombic interactions and U_{nonel} accounts for the energy of the system if image effects do not exist. In our case, U_{nonel} will be considered to correspond to the bond energies between atoms and groups of atoms.

Our problem, now, is to determine how these two terms are to be calculated for any value of the reaction coordinate. As a first step we will make an estimate of the total energy for the system in the initial and the "final" states and afterwards, using these results, a method of building up the corresponding potential energy curves will be presented.

The energy of the initial state.—Classically, a point charge q at a distance r from the surface of a perfect conductor produces an extra field equivalent, in vacuum, to that of a charge $-q$ at the image point with respect to the plane of the conductor. Hence, in the absence of external fields, the energy of such a charge would be

$$U = -q^2/4r \quad [16]$$

As is well known, the classical image potential gives interaction energies that are too high when the distance to the surface becomes small, being the deviation due to the screening effect of the metal. To account for this screening capability the linearized Thomas-Fermi approximation (TFA) may be used (47).

The TFA is developed for cases in which the screening length of the metal (λ^{-1}) is much bigger than the Fermi wavelength (λ_F). Actually, most metals do not satisfy this ideality condition; nevertheless, calculations going beyond the TFA are cumbersome and there exist doubts whether the boundary conditions have been properly considered in these refined approximations (48-50). For this reason, and on account of its simplicity, the TFA will be maintained.

The response of a metallic surface to an external point charge within the TFA has been derived by Newns (50) who obtained, for the electrostatic energy of a charge q, a definite integral that depends on r and λ^{-1}. This integral may be calculated by numerical methods and it is seen that when $r > \lambda^{-1}$ its value is well approximated by the Gomer-Swanson equation that considers a classical energy but with the surface recessed in λ^{-1} (51)

$$U = -q^2/4(r + \lambda^{-1}) \quad [17]$$

Considering the initial state, the distances between the metallic surface and the atoms in the hydroxonium ion are larger than the screening length; therefore, the Gomer-Swanson approximation (GSA) may be used in calculating the coulombic energy of this state. To do this, each atom in the hydroxonium ion will be considered to carry an electric charge. Contribution of terms depending on atomic polarizabilities may be disregarded within the distance range in which we are working, as is shown by the results of Antoniewicz (52).

Using reported charge densities for the planar configuration of the hydroxonium ion (43), the total energy at the initial state was calculated for Hg, Cu, Ni, and Au. Charge densities are 0.359 e_0 for the oxygen atom and -0.453 e_0 for each hydrogen atom, where e_0 is the electronic charge. Screening lengths for the different metals were obtained through the equation (53)

$$\lambda^{-1} = (E_F/6\pi n_0 e_0^2)^{1/2} \quad [18]$$

where E_F is the Fermi energy and n_0 is the electron density per cubic centimeter, calculated under the consideration that the number of free electrons per atom is given by the number of the corresponding group in the Periodic Table.

The chemical energy for the proton-oxygen bond at the initial state is considered to be 180 kcal/mole (3, 43, 44). The results obtained for the metals under consideration are shown in Table II.

The energy for the system metal-proton.—If the total energy of the system formed by a proton adsorbed onto a metallic surface is to be calculated, one must be aware that at distances near the equilibrium bond length of the metal-proton system the TFA will not be reliable and, of course, the GSA will not be valid (54). A possible breakthrough for this problem is the use of results obtained from the "jellium" model (54, 55). This model considers a metal as a lattice of point positive charges immersed in an "electron gas," *i.e.*, a negative charge continuum. When surface effects are to be considered the inhomogeneity introduced by the presence of the surface is taken into account within the jellium model by assuming a negative charge distribution outside the plane of the metal. After calculating the energy of a free electron gas that corresponds to this model (56, 57), the influence of the positive ion lattice is included by considering the additional constraint that Poisson's equation must be satisfied point by point (46, 57). The energy arising when a proton approaches a metallic surface may also be calculated with this additional condition using the jellium model, and numerical results have been obtained for the case of a tungsten surface (46).

If the hypotheses of the jellium approach are considered, it is clear that this model will account basically for electrostatic interactions, since jellium does not consider surface states, nor represents the localized electron densities arising when chemical bonding exists.

Table II. Energy values for the initial state obtained considering the electrostatic term by the Gomer-Swanson approximation. The chemical bond for O-H in hydroxonium was taken to be 180 kcal/mole. Net charges on the ion atoms were taken from Ref. (43).

Metal	λ^{-1}, Å	$E_{n=1}$, kcal/mole
Hg	0.62	212
Cu	0.55	213
Ni	0.77	210
Au	0.59	212

For the same reason, potential energy curves for metal-proton systems obtained by the jellium model will only slightly vary in shape from metal to metal and the equilibrium energy will be basically modified according to work function differences. In consequence, the electrostatic energy arising when a proton interacts with a metallic surface will be considered as given by a potential energy curve of the same shape as that obtained for tungsten (46) but with its equilibrium energy modified by the corresponding work function difference

The chemical interaction that arises when a proton approaches a metallic surface is of a different kind and may be linked to hydride formation (58). Data for MH^+ hydrides should be preferred in this case to those corresponding to neutral monohydrides. However, except for a few cases (Zn, Cd, Hg, Al, Mg), MH^+ bond energies have not been determined (59); so, neutral monohydrides bond energies will be used as a first approximation, being aware that the value used will be smaller, in modulus, than that corresponding to the charged hydride. Nevertheless, this difference will be much less in the cases of Cu, Ni, and Au than that observed for Zn, Cd, and Hg for which values of the bond energy vary by a factor of 10 from MH^+ to MH, because in the latter metals the *s*-orbital and the *d*-orbital are filled. Energy values for monohydrides were taken from Herzberg's tables (60). Work functions from the critical recompilation made by Trasatti (61) were used. The obtained results for the four metals under study are listed in Table III.

The Classical Activation Energy for the Discharge Step Using Potential Energy Curves

In order to build up potential energy curves for the discharge step, it will be necessary to obtain the relation between the total energy of the system and some reaction coordinate for both the initial and "final" states. This reaction coordinate was implicitly defined in the original BEBO method by the hypothesis that total bond order is conserved all along the activation process. The particular conditions prevailing in an electrode reaction make necessary the revision of this fundamental postulate of the method.

Effectively, in stating this basic assumption of the method, Johnston extended the intuitive idea that reacting bonds should sum up a complete bond in the activated state. This extension was allowable on the basis that activation energies for proton-transfer reactions are five or more times less than bond energies involved in the process. Now, the explicit inclusion of electrostatic effects through calculations based on the jellium model shows that the activation energy for the backward reaction (*i.e.,* desorption of a proton bonded to the metallic surface and its combination with an OH_2 group near the surface) is not as small as it should be; hence, Johnston's consideration will not apply in the case of the discharge step.

The fact that the final state and, in consequence, the backward reaction are hypothetical does not invalidate this argument. This is so because, the rate-determining event being the adiabatic transfer of the proton, what matters in the determination of the activation energy are the initial and final states of the adiabatic process, regardless of the fact that a nonadiabatic electron transfer takes place before the "final" state is effectively attained.

Table III. Energy values for metal-proton systems. U_{elect} is determined by analogy with the tungsten-proton system for which the work function is 4.55 eV and U_{elect} is 205 kcal/mole.

Metal	Work function, eV	U_{elect}, kcal/mole	U_{nonel}, kcal/mole	$E_{n=0}$, kcal/mole
Hg	4.50	204	53	257
Cu	4.70	209	67	276
Ni	5.25	222	71	293
Au	4.78	210	71	281

These considerations show that in the case of the HER the assumption of total bond order conservation during the complete adiabatic transference of the proton is not valid. Nevertheless, in the case of the forward reaction the activation energy is far less than the total energy for the three "particle" system and, also, than the O-H bond energy. This fact suggests that as long as the system is in a configuration between the initial state and the activated complex, total bond order may be considered to be constant. However, once the activated complex has been attained, the great energy difference from it to the final state will not permit the conservation of bond order. This amounts to saying that, due to the energy difference between the initial and final states of the adiabatic process, the breaking of the first bond should be accompanied by a corresponding gradual buildup of the proton-metal bond, but once the configuration of the activated complex is achieved the great increase in electrostatic energy determines that the chemical link between the proton and the oxygen atom is rapidly lost and the OH_2 group may eventually leave the metal-proton system.

With these considerations, the potential energy curve describing the evolution of the system for the adiabatic process will be obtained by superimposing the curve corresponding to the gradual destruction of the proton-oxygen bond and simultaneous appearance of the proton-metal bond with that corresponding to the metal-proton system. Since it is considered that total bond order in the activated complex is one, it is convenient to draw these potential energy curves as a function of bond order instead of bond length, thus defining a reaction coordinate.

Energy curve for the initial state.—According to the BEBO method the nonelectrostatic part of the total energy will be given by

$$U_{nonel} = D_{HO}n^p + D_{HM}(1 - n)^q \qquad [19]$$

where, as before, D_{HO} = 180 kcal/mole and D_{HM} is obtained from Herzberg's data for the neutral monohydrides of Cu, Ni, and Au, and the positive monohydride in the case of Hg. The electrostatic energy is calculated from the GSA according to the geometry of Fig. 1 and considering that the charge density on each atom varies linearly with bond order (20)

$$\delta_i = \delta_i^f + (\delta_i^f - \delta_i^o)n \qquad [20]$$

where δ_i is the charge density of atom *i*, δ_i^o is the charge density of atom *i* when the system is in the initial configuration, and δ_i^f is the same quantity in the final state. Values for δ_i^o are those from Conway (43); δ_i^f is considered to be $-e_o$ for the transferring proton and 0.53 e_o for the oxygen atom. The final charge density on the oxygen atom was obtained considering a polarized water molecule at 2Å from the surface.

Since in the initial state the hydroxonium ion is not bonded to the metal, Pauling's relation between bond length and bond order, Eq. [3], will be considered to be valid for the proton-oxygen bond.

Potential energy curve for the final state.—In this case, as was described before, the electrostatic energy is obtained using the potential energy curve resulting for tungsten through application of the jellium model (46), taking into account the work function difference between tungsten and the metal in consideration. The nonelectrostatic interaction is taken into account by building the corresponding Morse curve for the monohydride from the data tabulated by Herzberg (60).

In order to build up the energy curve for the proton-metal system as a function of bond order, the objections presented to the direct use of Pauling's relation between bond length and bond order must be recalled. According to them, the original relation, Eq. [3], should be modified in order to account for the presence of the metallic surface. In doing so, it must be remembered

that when the ion is relatively far from the metallic surface the GSA will hold as a first order correction to the classical point of view. This means that, in this case, the effective distance may be written as

$$R_{\text{eff}} = R_{\text{geom}} + \lambda^{-1} \quad [21]$$

where R_{eff} is the effective distance and R_{geom} the geometric or actual distance from the ion to the surface. Also, it must be considered that when bond order tends to zero, the effective distance will tend to the GSA and the relation between bond length and bond order should tend to Pauling's equation. With this basis, the following expression, valid at relatively low values of m (bond order for the proton-metal bond) is proposed (62)

$$R = R_s + \lambda^{-1}(1 - m) - 0.26 \ln m \quad [22]$$

In Fig. 2, the curves obtained for Hg are shown. Similar curves are obtained for the other three metals and from them classical activation energies are determined. Numerical results for the four metals under consideration are presented in Table IV.

Conclusions

If calculated E_c data are compared with experimentally determined activation energies (Table IV), qualitative agreement is apparent since both magnitudes follow the sequence

$$\text{Hg} > \text{Cu} > \text{Ni} \sim \text{Au}$$

If these two activation energies are to be compared quantitatively, it is necessary to estimate a value for the "true" activation energy, E_o, in order to apply Eq. [12].

As has been pointed out before, the estimation of the "true" activation energy requires the vibrational analysis of the activated complex. This analysis cannot be carried out within the limits of the method presented in this paper because there does not exist an analytical function representing the energy curve of the systems in terms of bond order. Use of the vibrational analysis described by Johnston and Parr (31) cannot be made because of the observations made on the applicability of the method to electrode processes and because of the inaccuracies existing in the F_σ definition. We will, in consequence, limit ourselves to determining upper and lower limits for the "true" activation energies.

In order to make this determination, the fact that vibrational frequencies of reacting bonds are lower in the activated state than in the free molecules will be

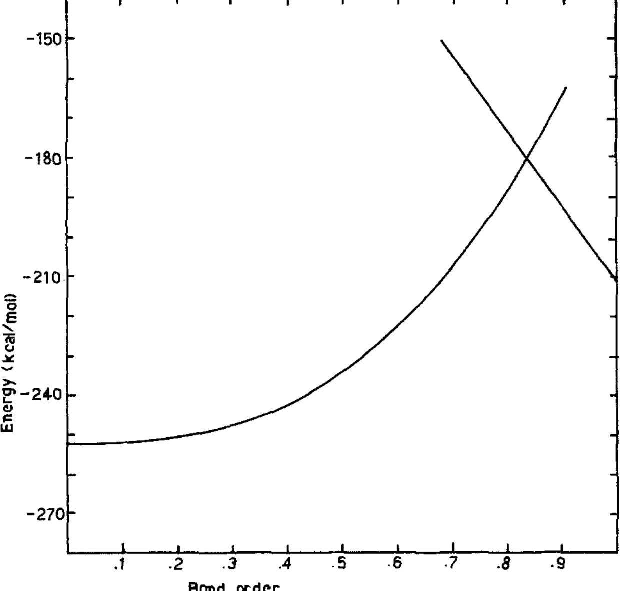

Fig. 2. Potential energy curves for $(H\text{-}OH_2)^+$ and for $Hg^-\text{-}H^+$ as a function of H-O bond order.

Table IV. Obtained E_c values and estimated "true" activation energies and enthalpy changes.

Metal	E_c, kcal/mole	E_o, kcal/mole	E_{exp}, kcal/mole	ΔH, kcal/mole
Hg	30	25-30	21 (63)*	8-18
Cu	21	16-21	11 (32)	10-20
Ni	18	13-18	9 (32)	8-18
Au	18	13-18	9 (64)	8-18

* Numbers in parentheses indicate references.

recalled. In consequence, since the O-H bonds that do not intervene directly in the reaction are considered to remain unmodified during the process, the lower limit for E_o will be given by

$$E_o = E_c - \tfrac{1}{2} hc\omega_{H^+}$$

where ω_{H^+} refers to the initial frequency of the reacting bond and where it is considered, as a limited case, that the vibrational frequencies in the activated state are zero. Taking for the stretching frequency of the proton-oxygen bond a value about 3500 cm^{-1} (63), the correction term would be about 5 kcal/mole. The upper limit will be considered that for which the vibrational contribution in the activated state equals that of the reagents, *i.e.*, $E_o = E_c$. Possible ranges for E_o and for ΔH are shown in Table IV.

The obtained results may also be considered from a mechanistic point of view. The energy values for HER on Hg suggest that, in this case, the discharge step is rate determining, in good accordance with experiment. In the cases of Cu, Ni, and Au the values calculated for activation energies do not permit a definite statement about the rate-determining step on these metals. Nevertheless, if it is recalled that MH bond energies were used instead of data for MH^+ hydrides, it follows that calculated E_c and E_o values are higher than those that would result if the appropriate data were available. This would be in accordance with most experimental data suggesting that the discharge step is not rate determining in these metals (34, 64, 65).

The method compares favorably with the presentation by Salomon *et al.* (3) regarding both its reliability and capability of being improved. The first assertion arises from the fact that there is no need of explicit differentiation of empirical expressions. The improvement capability of the method is a consequence of the more rigorous way of considering the problem through theoretically defined models for the surface and the explicit recognition of image effects, as well as from the fact that all the experimental data that are necessary for the calculations come from fields different from electrochemistry and, thus, calculated values and experimental results are not interdependent.

Extension of the method to nonaqueous solvents as well as the study of the vibrational characteristics of the system as a function of bond order are currently being considered.

Acknowledgments

This work is part of the requirements to be fulfilled by one of us (CMM) in order to obtain the Ph.D. degree. The authors gratefully recognize financial support for this investigation through Grant 31.26-S1-0335 of the Consejo de Investigaciones Científicas y Técnicas and from the Consejo de Desarrollo Científico y Humanística (U.L.A.), Project C-24. Discussions with Dr. N. V. Joshi on surface properties and with Dr. B. Fontal on vibrational characteristics of the activated complex are warmly acknowledged.

Technical Note

Cathodic Characteristics of a CuS Electrode in Liquid Ammonia

Yoshiharu Matsuda,* Hiroaki Ueyama, and Yoshio Takasu

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755, Yamaguchi, Japan

In the course of the investigation and the development of batteries whose electrolytes are nonaqueous solvents, a few papers (1-4) have presented the possibility of liquid ammonia as the electrolyte of high energy batteries. This solvent, liquid ammonia, is possible for use as the electrolyte at low temperatures and will contribute to the improvement of new batteries. On the other hand, a CuS cathode has often been used in organic electrolytes (5-11), but it has never been used in an electrolyte of liquid ammonia.

In this study, we examined some properties of liquid ammonia as the electrolyte and the cathodic performance of cupric sulfide (CuS) electrode in this electrolyte. The results revealed that this cathode showed excellent polarization characteristics and a possibility of stable discharge for a long time, and that it was changed to Cu in the discharge process.

Experimental

Figure 1 shows a schematic diagram of the equipment. This system consists of pressure bottles and a temperature-controlled electrolytic cell (500 ml) composed of special glass for use under 20 atmospheric pressure. After the system was evacuated, ammonia was introduced into a pressure bottle of 300 ml cooled with a mixture of Dry Ice and organic solvent. Next, ammonia was distilled and transferred into another bottle containing solid sodium. Then it was transferred into the electrolytic cell containing thiocyanates and ammonium chloride. Conductivity measurements were made with two platinum plate electrodes whose dimensions were 1×1 cm^2. A test electrode was prepared by pressing the mixture of pure commercial CuS, graphite, and polyethylene powders. This electrode, whose area was 1.33 cm^2, was mounted at the bottom of a glass tube with a glass diaphragm, and graphite powder and a carbon rod were used to make electrical contact. The counterelectrode was a platinum plate whose dimension was 2×3 cm^2. The reference electrode was a Ag/AgCl/Cl$^-$.

Results and Discussion

Relations between specific conductivity of liquid ammonia with 4 mole/l of thiocyanates and temperature are shown in Fig. 2. Measurements were made with an a-c bridge at a frequency of 1 kHz and the order of the conductivity was $NH_4SCN > KSCN > NaSCN$. In Fig. 3, relations between equivalent conductivities of liquid ammonia with NH_4SCN and the square root of its concentration are shown. This figure suggests that the solutions are strong electrolytes.

Polarization characteristics of a CuS cathode are shown in Fig. 4. The composition of the electrode was 80 weight per cent (w/o) CuS, 5 w/o polyethylene, and 15 w/o graphite, and the electrolyte was liquid ammonia containing 4 mole/l NH_4SCN and 0.5 mole/l NH_4Cl. The current density was 42.8 mA/cm^2 at the electrode potential of -1.00V (*vs.* Ag/AgCl/Cl$^-$) at 25°C. At -65°C, the open-circuit voltage was -0.20V and the current density was 9.39 mA/cm^2 at the electrode potential of -1.00V. The cathodic polarization characteristics of the CuS electrode were improved by elevating temperature. As shown in Fig. 4, linear relations between the current densities and the electrode potentials were found on the low polarization ranges, and these results suggest that the electrochemical process should be controlled by *IR* loss on these ranges.

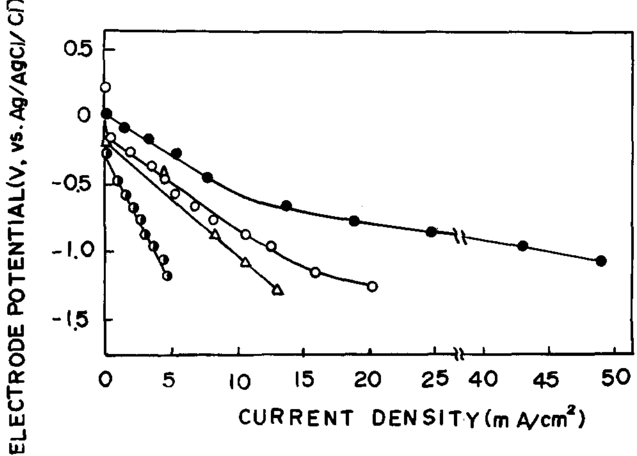

Fig. 4. Cathodic polarization curves for a CuS electrode. Electrode composition: CuS 80%, polyethylene 5%, graphite 15%. Solute: 4 mole/l NH_4SCN + 0.5 mole/l NH_4Cl. Temperature: ○ = 25°C, ● = 0°C, △ = −65°C, ◑ = −75°C.

Figure 5 shows the results of the continuous discharge of this electrode. The measurements were made at 0°C, and currents applied were 5 and 10 mA. The efficiencies of the CuS electrode utilized were over 65% on the basis of a mechanism of two electrons per mole. Similar results were obtained in the measurements using electrode composed of 65 w/o CuS, 5 w/o polyethylene, and 30 w/o graphite. X-ray diffraction patterns from the cathode material are shown in Fig. 6. Curve 1 is the pattern before discharge and curve 2 is the pattern after discharge at 5 mA/1.33 cm^2 for 20 hr. These patterns suggested that CuS was reduced to Cu during cathodic discharge. Since the polarization curves of the constant discharge gave plateaus and no evidence of Cu_2S was found in x-ray diffraction patterns, the discharge of the electrode involved two electron processes.

Consequently, CuS was revealed to be a favorable material for a cathode in liquid ammonia. On the cathodic discharge of CuS electrode, the performance was stable and the utilization of reactant was over 65%.

Brief Communication

Thin Film Deposition of Solid Electrolyte $Ag_{19}I_{15}P_2O_7$

M. R. Arora* and J. Childs

Unican Electrochemical Products Limited, Montreal, Quebec, Canada

During the last few years, a considerable amount of work has been carried out on silver iodide based solid electrolytes such as $RbAg_4I_5$, Ag_3SI, $Ag_{19}I_{15}P_2O_7$, etc. All these materials are known to exhibit high ionic conductivity for silver at ambient temperatures. Pellets of these solid electrolytes, with suitable electrodes applied to them, have already been used successfully in the fabrication of devices such as coulometers, timers, batteries, etc. However, such devices tend to have high internal resistances and polarization losses due to poor solid-solid contacts. These problems can be overcome by the use of thin films since very small film thicknesses and excellent contacts between electrodes are possible. Recognizing this, Yamamoto and Takahashi (1), Vouros and Masters (2), Kennedy *et al.* (3, 4), Butherus and Broadhead (5), Takahashi *et al.* (6), and Fraser and Krishna (7) have prepared thin films of Ag_3SI, AgBr, and $RbAg_4I_5$, but no literature is yet available on the thin films of oxy-anion substituted silver iodide solid electrolytes. The purpose of this communication is to describe our work on the thin films of $Ag_{19}I_{15}P_2O_7$.

The solid electrolyte $Ag_{19}I_{15}P_2O_7$ was prepared in our laboratory by vacuum fusion by mixing the powders of AgI and $Ag_4P_2O_7$ in a molar ratio of 15 to 1 with subsequent heating at 250°C for 20 hr under a reduced pressure following the method of Takahashi *et al.* (8). This product was then ground and sieved and only the particle sizes between mesh Tyler screens 40 and 70 for flash evaporation, and finer than 200 for rf sputtering, were used in all the experiments.

Our initial experiments using flash evaporation of $Ag_{19}I_{15}P_2O_7$ resulted in films whose room temperature conductivity was rather low, being about 10^{-5}-10^{-6} (ohm-cm)$^{-1}$. To understand the problems involved in this process, use was made of a Micromass (Model Q8) mass spectrometer during the flash evaporation to monitor the vapor species, and the films formed were subsequently characterized using x-ray diffraction and scanning electron microscopy. It was found that the films which exhibited low conductivity were nonstoichiometric in nature, generally containing more iodine than required by stoichiometry.

After a large number of experiments, it was found that the film deposition parameters have to be strictly controlled within rather narrow limits in order to obtain films of high conductivity at room temperature. The main requirement is that the temperature of the evaporation source be greater than about 1250°C. But as the film deposition continues, the nozzle of the vibratory feeder steadily heats up due to its close proximity to the hot source and tends to get clogged up. Therefore, the nozzle must be kept at a distance of at least about 4 cm from the hot source to reduce its heating. (Greater distances result in the particles spraying all over the vacuum chamber rather than going into the source itself.) Therefore, the experimental conditions used for all subsequent flash evaporation of $Ag_{19}I_{15}P_2O_7$ were: an initial vacuum of about 10^{-6} Torr, source temperature exceeding about 1250°C, distance between the feeder nozzle and the baffle-type evaporation source of about 4 cm, distance between the revolving substrate holder and the source of about 25 cm, and a film formation rate of about 20-60 Å/sec.

Rf sputtering of $Ag_{19}I_{15}P_2O_7$ proved to be somewhat simpler than flash evaporation though the experimental parameters still had to be kept within narrow limits in order to consistently obtain films of high conductivity. The conditions used in this method were: argon gas pressure = 4 mTorr, spacing between target and the substrate = 4 cm, potential across the electrodes = 700-900V, and rate of film deposition = 15-60 Å/sec.

The conductivity of these films, measured using a Wayne Kerr Universal Bridge B221, was found to be quite satisfactory, being about 0.02-0.03 (ohm-cm)$^{-1}$ for flash evaporation and about 5×10^{-3} (ohm-cm)$^{-1}$ for rf sputtering. These values of conductivity compare well with 0.09 (ohm-cm)$^{-1}$, the conductivity of bulk $Ag_{19}I_{15}P_2O_7$. On storage, the conductivity of these films decreased during the first few hours but then remained essentially constant at about half of their initial value over a period of more than five weeks.

Sandwich-type cells of the type $Ag/Ag_{19}I_{15}P_2O_7/Au$ were vacuum evaporated on glass slides to study their coulometric characteristics. The procedure employed in the fabrication of these cells has been described previously (7) and is essentially similar to that of Kennedy and Chen (3). Other crucial details of these cells are as follows:

Material	Film thickness, A	Surface area, cm²
Au	1,500	0.13
$Ag_{19}I_{15}P_2O_7$	25,000-50,000	0.30
Ag	3,000	0.16

Currents of 5 and 10 μA (40-80 μA/cm^2 at the gold electrode) were used and charges of up to 4000 μcoulombs were employed in testing a large number of cells. Some of the results are summarized in Table I and a typical charging-discharging plot is given in Fig. 1. The charging and stripping of the cells were carried out using constant currents and the charges recovered were generally well within 2% when the stripping was carried out immediately after charging. However, when the charged cells were stored for vari-

* A and B represent two different depositions each containing eleven cells.

ous time intervals, the loss of charge became somewhat greater, approaching about 10% after one day, though the rate of charge loss slowed down considerably after greater storage time intervals, with total charge loss approaching about 15-18% after over two weeks. These results are similar in nature to those observed by Kennedy *et al.* for AgBr and $RbAg_4I_5$ (3, 4).

All these results are only preliminary in nature and more detailed work is now underway where attempts are being made to improve the characteristics of these films. Similar work is also being extended to other solid electrolytes such as $Ag_7I_4PO_4$, $Ag_7I_4VO_4$, and $Ag_6I_4WO_4$, etc.

ABSTRACT

Quantitative microsegregation analysis was carried out on Sb-doped silicon crystal pulled from the melt. Interference by thermal convection in the melt, invariably present in silicon growth at commonly used rates of pulling and seed rotation, was eliminated by introducing severe thermal asymmetry in the growth system. Interface demarcation was employed for the determination of the microscopic growth rates and spreading resistance measurements for obtaining composition profiles. For growth under forced convection conditions it was shown that the microsegregation behavior is controlled by the microscopic growth rate and is adequately accounted for by the Burton, Prim, and Slichter (BPS) model based on steady-state segregation. The small deviations from steady-state segregation were manifested as solute redistribution transients associated with the periodic growth rate variations (slight phase shift between dopant concentration and microscopic growth rate). For growth under thermal convection conditions, the microscopic growth rate is modulated by convective temperature fluctuations in the melt, but it does not control the microsegregation behavior because under these conditions the diffusion boundary layer thickness undergoes significant fluctuations. Accordingly, the BPS model, which assumes a constant diffusion boundary layer thickness, was found to be inapplicable to microsegregation in silicon grown under thermal convection.

Quantitative analysis of microsegregation associated with silicon growth by the Czochralski technique, at the generally employed rates of seed rotation (1), presents serious difficulties because of pronounced interference by thermal convection at the growth interface. Random compositional fluctuations invariably present in the silicon crystals (2) impair the systematic study of the relationship between the microscopic growth rate, the characteristics of the diffusion boundary layer, and the microsegregation behavior. It was reported recently (3), however, that during Czochralski growth, random compositional fluctuations in silicon, for aspect ratios (diameter over height of melt) greater than a critical value (*i.e.*, 2.5), are eliminated by introducing pronounced thermal asymmetry; under this thermal configuration the interference by thermal convection was eliminated, and forced convection conditions were achieved at commonly used rates of seed rotation.

In this communication a quantitative investigation of microsegregation in silicon is presented; the above thermal configuration is utilized and the interface demarcation technique is employed (4); spreading resistance measurements are used for dopant concentration microprofiling (5).

Experimental

Apparatus.—A resistance-heated Czochralski puller was employed in this study. The main features of the puller and the modification which established the thermal configuration making possible silicon growth under forced convection conditions have been described elsewhere (3).

Electrical contact with the seed for transmitting current pulses across the growth interface (interface demarcation technique) was made through the pulling shaft as in previously reported studies (4). Since the silicon melt is contained in an electrically insulating quartz linear and reacts with all available electrical conductors, a special technique was developed for achieving contact with the melt; molybdenum wire (0.5 mm in diameter) was inserted into a quartz capillary, one end of which was then sealed; one end of the wire was positioned a few millimeters inside the open end of the capillary and the other end was brought into contact with the power supply via the pedestal of the crucible; the open end of the capillary was inserted into the melt which rose into the tube and established electrical contact with the wire, a small portion of which it dissolved.

Procedures.—The samples employed in this study (about 20 × 20 × 2 mm) were cut in longitudinal segments along the rotational axis of (111) single crystals (about 2 cm in diameter and 10 cm long) pulled from melts doped with antimony (1.22×10^{20} atoms/cm^3). During pulling, current pulses (18A) of 0.05 sec duration at intervals of 0.5 or 1 sec were transmitted across the growth interface. Spreading resistance measurements at 5 μm intervals were used for obtaining the microscopic dopant concentration

* Electrochemical Society Active Member.

Key words: silicon, segregation analysis, Czochralski growth.

profiles, as described elsewhere (5); the spreading resistance measurements were reduced to dopant concentrations employing silicon standards whose carrier concentration was determined by Hall effect measurements; the dopant concentration was taken equal to the carrier concentration.

The following surface preparation procedure was developed and adopted for carrying out spreading resistance measurements and microscopic rate determinations directly on the same surface; the samples were cleaned in CP4 (5 parts HNO_3 + 3HF + $3CH_3COOH$) rinsed with distilled water, and dried in a stream of nitrogen; they were then ultrasonically soldered onto brass disks with a 50 weight per cent (w/o) Pb: 50 w/o Sn alloy to obtain large ohmic contacts. Subsequently, the surface of each sample was polished with Syton-HT 30 and etched with Sirtl etchant (6): 1 part HF + 1 part (50 w/o aqueous solution) CrO_3; optimum definition of the interface demarcation lines (intercepts of the periodically delineated growth interface with the surface) and of the dopant striations was obtained by about 12 successive immersions in the etchant; each immersion was of about 5 sec duration. For reproducible spreading resistance measurements it was found necessary to swab-clean the etched surface successively with HNO_3, hot water, and 1 part H_2O_2 + 1 part (saturated aqueous solution) KOH; this cleaning sequence was repeated a few times (7).

Employing interface demarcation, the microscopic growth rate is obtained from the known frequency of the current pulses and the separation of the resulting interface demarcation lines (rate striations) (4). These values are the average growth rates for the regions between successive striations. In order to obtain rate values at any instant in time, the microscopic growth rate was taken as a Taylor (time) expansion series about a fixed origin in terms of its higher order derivatives. Thus, the rates were determined for the specific instants in time corresponding to the application of the individual current pulses (rather than for the time intervals between current pulses). Growth rate values corresponding to the concentration measurements at locations between successive rate striations were determined by means of parabolic time interpolation. In this interpolation it is taken into consideration that for a given time interval the fraction grown (distance) is proportional to the growth rate.

Results and Discussion

General remarks.—A longitudinal cross section of a typical silicon crystal grown under severe thermal asymmetry with a pulling rate of 11 μm/sec and a seed rotation of 5 rpm is shown in Fig. 1. It is seen that the initial segment of the crystal (upper part of figure) exhibits well-defined periodic dopant striations with a period identical to that of the seed rotation (rotational striation); random dopant inhomogeneities are not present in this segment; these segregation characteristics indicate that forced convection conditions prevail during growth. The transition from growth under forced convection to growth under thermal convection (3) is abrupt and clearly visible. The dopant inhomogeneities in the segment grown under thermal convection exhibit no periodicity and are randomly distributed; such segregation behavior is invariably observed in silicon crystals pulled at the standard rates of seed rotation.

A detailed analysis of the prevailing thermohydrodynamics of the silicon melt in the present case has not been pursued. It appears, however, that for a specific range of melt aspect ratios, severe thermal asymmetry gives rise to a mode of convection leading to laminar flow at the growth interface, for seed rotation rates as low as 3 rpm. Without seed rotation, it was found that thermal convection at the growth interface (giving rise to nonrotational inhomogeneities) prevails for all aspect ratios of the melt.

Segregation under forced convection conditions.—Since pronounced thermal asymmetry was present during growth, backmelting occurred at the periphery of the crystal during each rotational cycle. Typical off-core segments grown without backmelting and with backmelting will be analyzed individually. No analysis of the on-core region will be presented.

No backmelting.—The photomicrograph in Fig. 2 shows a portion of the crystal segment grown under forced convection conditions at 9.5 μm/sec and with a seed rotation of 5 rpm. Rotational striations spaced approximately 120 μm from each other, rate striations introduced by the interface demarcation technique at 1 sec intervals, and the impact traces of the spreading resistance probe at a constant spacing of 5 μm can be identified. The microscopic growth rates, and the corresponding dopant concentrations, are also shown in Fig. 2. It is seen that the growth rate varies periodically. The rotational striations coincide with the dopant concentration minima. The microscopic growth rate minima and maxima occur slightly in advance of the corresponding concentration minima and maxima. (This displacement is more pronounced in the backmelting case, see below.)

A direct analysis of the relationship between the dopant concentration in silicon pulled from the melt and the microscopic growth rates can now be performed. In the present analysis the theoretical model of Burton, Prim, and Slichter (8) (BPS) is employed which relates the dopant concentration in the crystal,

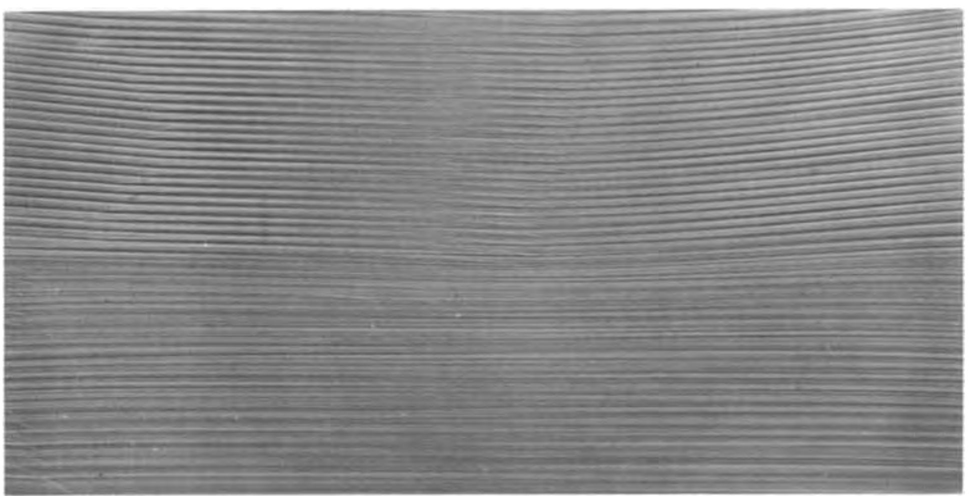

Fig. 1. Longitudinal cross section of silicon crystal pulled at 11 μm/sec with a seed rotation of 5 rpm. In the upper portion of the crystal segment shown growth took place under forced convection; periodic (rotational) striations are clearly defined; their period is the same as the period of rotation; pronounced backmelting is associated with the rotational striations at the outer parts of the crystal, no random inhomogeneities are present. The abrupt transition to growth under interference by thermal convection is visible near the middle of the figure; the lower portion grown under these conditions exhibits nonperiodic (random) inhomogeneities typical of silicon crystals pulled at commonly employed rates of rotation. Magnification 12X.

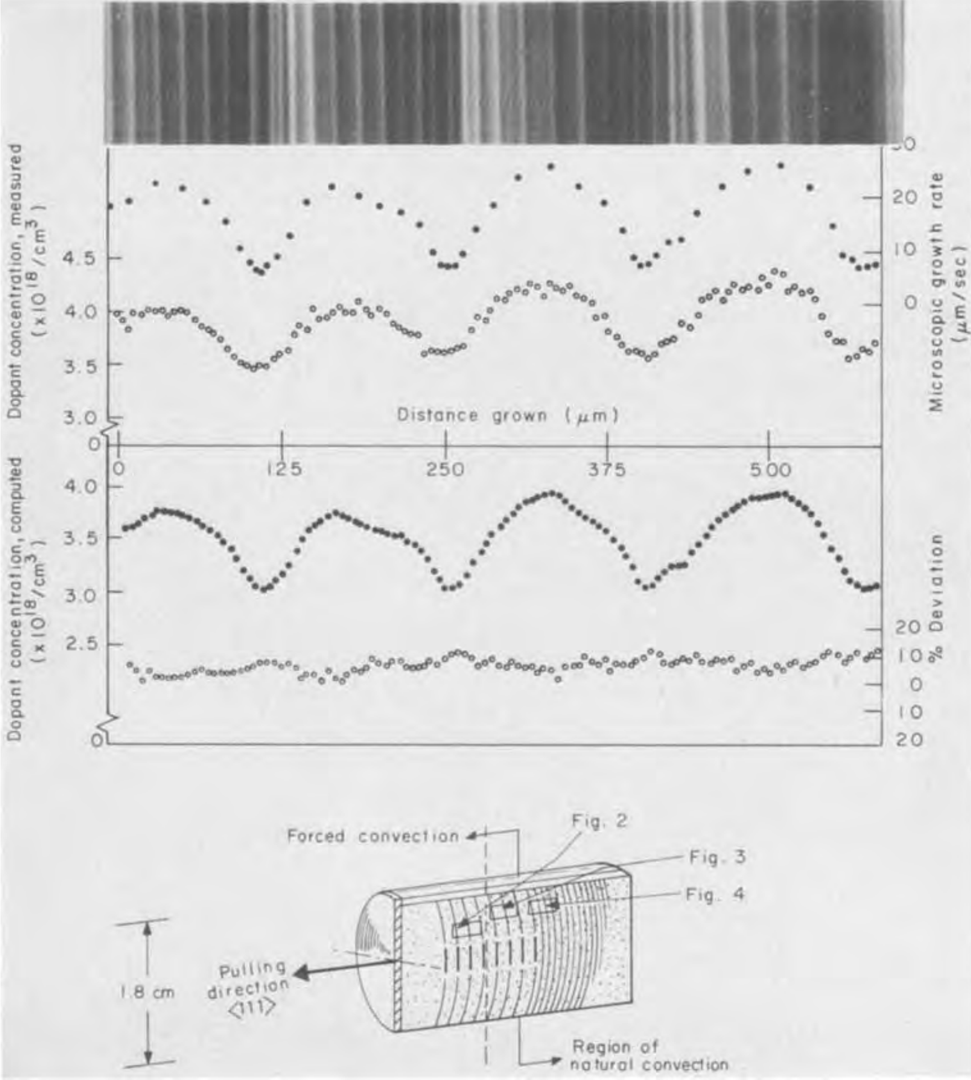

Fig. 2. Microsegregation analysis of a differentially etched portion of the crystal (see sketch at bottom of figure) pulled at 9.5 μm/sec and with a seed rotation rate of 5 rpm; no backmelting took place during its growth; rate striations and the impact traces of the spreading resistance probe are visible; the uppermost curve (black dots) is the microscopic growth rate plot as a function of distance grown; the second curve from the top is the corresponding dopant concentration plot. The theoretical dopant concentration computed on the basis of the BPS model (black dots) and the deviation between the experimental and the theoretical dopant concentration, $[(C_{exp} - C_{theor})100/C_{exp}]$ are shown in the lower part of the figure (see text). The positions of all portions of the crystal analyzed in this paper are shown in the sketch; the segment on the left-hand side of the vertical dotted line in the sketch was grown at 9.5 μm/sec and the segment on the right-hand side was grown at 11 μm/sec.

C_S, to the growth rate, assuming diffusion controlled steady-state segregation

$$C_S = \frac{C_L k_o}{k_o + (1 - k_o)\exp(-V\delta/D)} \qquad [1]$$

where C_L is the dopant concentration in the bulk of the melt, k_o is the equilibrium distribution coefficient, V is the (microscopic) growth rate, δ is the diffusion boundary layer thickness, and D is the diffusion coefficient of the dopant in the melt.

From the above relationship the dopant concentration in the crystal, C_S, was computed as follows: The experimental growth rate values were used; the value for C_L was obtained from experimental parameters using the normal freezing relationship

$$C_L = C_L^o(1 - g)^{(k_{eff} - 1)} \qquad [2]$$

where C_L^o is the original concentration of the dopant in the melt prior to solidification, g is the fraction solidified, and k_{eff} is the effective distribution coefficient; C_L^o was determined from the amount of dopant (Sb) initially added to a known weight of silicon melt. This value of $1.22 \times 10^{20}/cm^3$ was found to be in good agreement with the value determined from the concentration in the silicon immediately adjacent to the original growth interface ($C_S^{o+} = 2.64 \times 10^{18}/cm^3$) and the equilibrium distribution coefficient ($k_o = 0.023$), *i.e.*, $C_L^o = C_S^{o+}/k_o = 1.15 \times 10^{20}/cm^3$. k_{eff} was obtained from the average dopant concentration in the crystal segment first to solidify ($C_S = 3.8 \times 10^{18}/cm^3$) and the value of C_L^o. For δ/D, which is required to be constant in the BPS model, a value of 133.3 sec/cm was determined, by trial and error, so that both the amplitude of the dopant variation and the mean dopant concentration obtained from Eq. [1] are as close as possible to those determined by spreading resistance measurements.

The dopant concentration thus computed from Eq. [1] is shown in Fig. 2. Since the experimental measurements of the dopant concentration were carried out at 5 μm intervals the computation of the concentration was also carried out for 5 μm intervals; the required growth rate values for points between successive rate striations were determined by parabolic interpolation as pointed out earlier. The deviation between experimental and theoretical concentrations is also shown in Fig. 2; it is seen that most of the theoretical values deviate by less than 10% from the experimental ones.

From the value of $\delta/D = 133.3$ cm/sec (found to give the best agreement of the experimental results with the BPS model) a thickness for the diffusion boundary layer $\delta = 0.0266$ cm is found, taking $D = 2 \times 10^{-4}$ cm²/sec (9). Using Cochran's analysis (10) for the employed seed rotation (5 rpm) a value of $\delta = 0.044$ cm is obtained. An assessment of the difference between these two values will not be attempted at this time; it should be pointed out, however, that there are uncertainties associated with the precision of the diffusion constant D and the kinematic viscosity, ν, in Cochran's relationship.

An inspection of the two concentration plots in Fig. 2 shows that the positions of the maxima and minima do not coincide and that the maxima and minima of the experimental plot are slightly lagging; *i.e.*, the

microscopic rate maxima and minima occur somewhat in advance of the corresponding (experimental) concentration maxima and minima. This phase shift is associated with the slow (diffusion controlled) redistribution of the solute at the interface. Thus, within each rotational cycle, and in the absence of fluctuations in diffusion boundary layer thickness, the dopant concentration at the interface remains higher than required by steady-state segregation (11). Accordingly, the mean concentration in the solid must be higher than that expected for steady-state concentration. Indeed, the mean dopant concentration determined from the measured values shown in Fig. 2 is $3.81 \times 10^{18}/cm^3$ as compared to $3.45 \times 10^{18}/cm^3$ obtained from the computed values.

The analysis of microsegregation in silicon taking into consideration solute redistribution kinetics, is being quantitatively pursued and will be presented in a future communication.

Periodic backmelting.—The photomicrograph in Fig. 3 shows another portion from the same crystal segment used for the above segregation analysis (see sketch in Fig. 2). This portion was grown at a pulling rate of 11.0 μm/sec with a seed rotation of 5 rpm. Here also the period of the rotational striations (broad lines) is the same as the period of seed rotation; the rate striations (narrow lines) were introduced at intervals of 0.5 sec. In this portion (located closer to the periphery of the crystal than the portion shown in Fig. 2) pronounced backmelting is associated with the rotational striations. Since the time interval between successive rotational striations is 12 sec (period of rotation) and since only about 10 rate striations of a period of 0.5 sec are visible between rotational striations, an apparent backmelting, for at most 7 sec, is associated with each rotational striation. It is seen that the rotational striations coincide with the concentration minima. The transition from the concentration maxima to the concentration minima is typical for rotational backmelt striations.

As in the case presented in Fig. 2, here also the theoretical dopant concentration was computed from the experimental microscopic growth rates employing the BPS model by determining a value of δ/D so that the theoretically computed mean concentration and the amplitude of the concentration fluctuations were as close to the experimentally determined values as possible; Eq. [2] was used for determining the value of C_L, the fraction solidified being 0.15. As in Fig. 2, here also it can be seen that the dopant concentration maxima are displaced with respect to the growth rate maxima. The deviation between the experimentally determined and theoretically computed dopant concentrations is also shown in Fig. 3. It is, thus, seen that the dopant segregation is essentially controlled by the microscopic rate and that the BPS model accounts quite satisfactorily for the prevailing segregation conditions, although not as well as in the absence of backmelting.

It is of interest to point out that the dopant concentration in the segments first to solidify after backmelting is about 22% higher than if the concentration at the interface were C_L. This behavior indicates that the dopant concentration gradient at the original interface position does not vanish during backmelting.

The value of δ/D which gave the best agreement between the computed dopant concentrations and the experimentally determined ones is 166.6 sec/cm as compared to 133.3 sec/cm found in the case of Fig. 2. The apparent increase of δ/D in the present case (although the rate of seed rotation was the same for both cases) reflects the fact that, following backmelting, the dopant concentration at the growth interface at the onset of regrowth is higher than the value of C_L used in the present analysis.

Thermal convection conditions.—A crystal portion grown after the transition from forced convection to thermal convection conditions (see sketch in Fig. 2) is shown in the photomicrograph of Fig. 4. This portion was grown at a pulling rate of 11 μm/sec with a seed

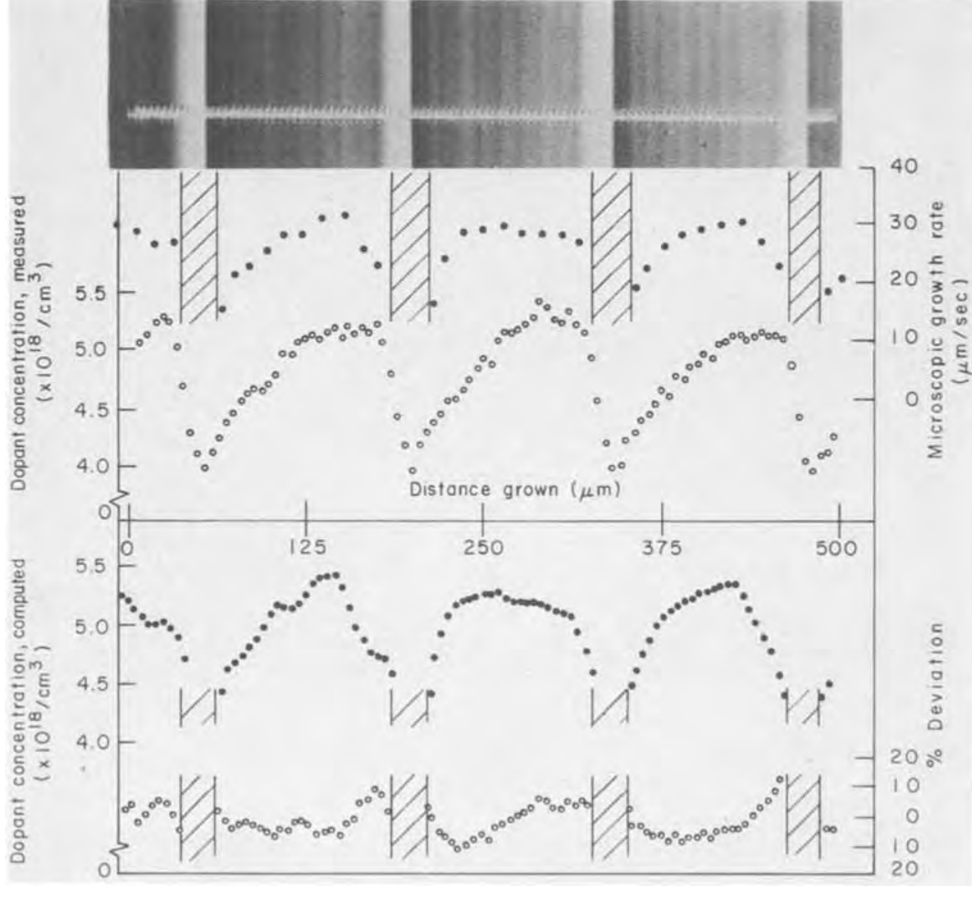

Fig. 3. Microsegregation analysis of a differentially etched portion of the crystal (see sketch in Fig. 2); backmelting is associated with the rotational striations (broad lines); the rate striations (fine lines) and the impact traces of the spreading resistance microprobe are visible (the apparent overlapping of the impact traces resulted from reetching the surface for photomicrography after the spreading resistance measurements were made). The microscopic growth rates are shown on the top plot of the figure (dark dots); no measurements could be made in the regions of the broad striations. The measured dopant concentrations are shown on the second plot (from the top) in the figure. The theoretical dopant concentration (dark dots) and the deviation between experimental and theoretical values are shown in the lower part of the figure (see text).

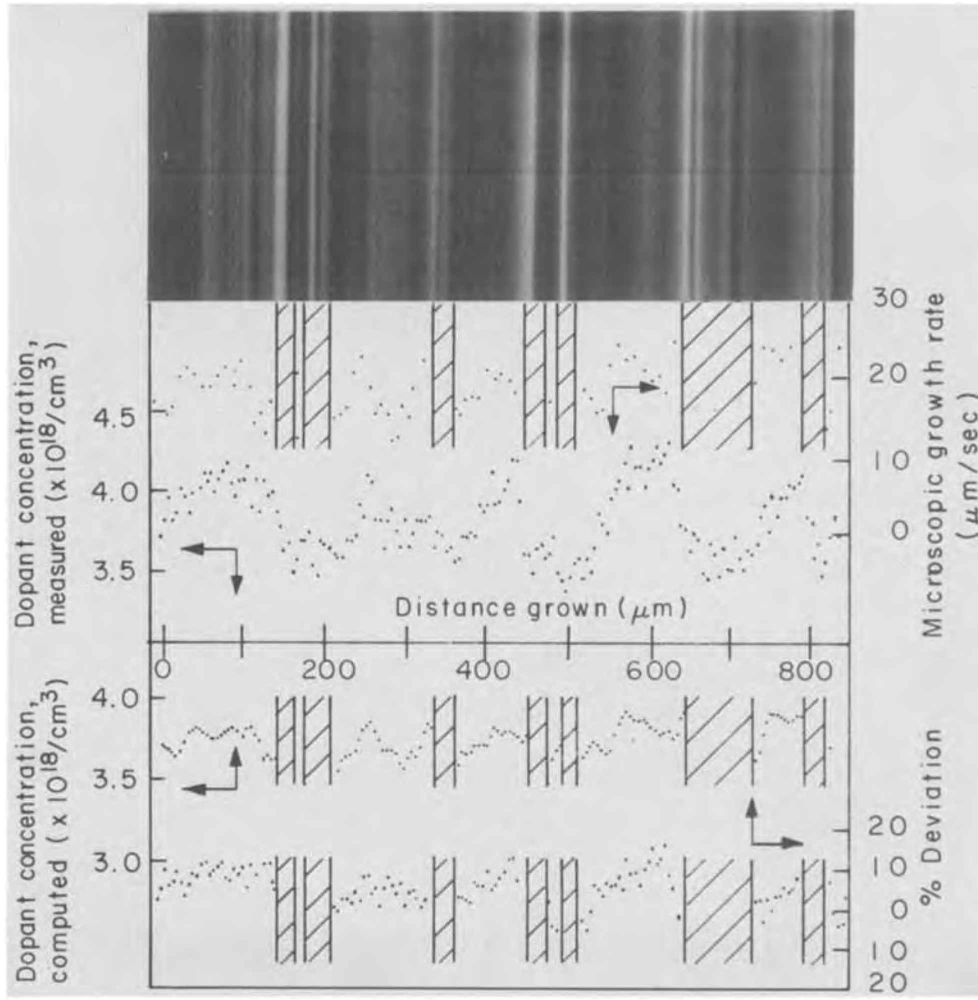

Fig. 4. Microsegregation analysis of a differentially etched portion of the crystal grown under thermal convection (see sketch in Fig. 2). A periodic pattern of dopant inhomogeneities is not apparent; rate striations can be identified in some parts of the portion shown. The microscopic growth rate, the measured dopant concentration, the theoretical dopant concentration, and the deviation (between the theoretical and experimental concentration) plots are shown in that order from top to bottom (see text).

rotation rate of 5 rpm. Current pulses for interface demarcation were transmitted at intervals of 0.5 sec. It is seen that the dopant inhomogeneities do not exhibit a well-defined periodic pattern. The rate striations (fine lines) can be identified in some areas of the crystal portion shown, but not throughout, because of interference by random dopant inhomogeneities; a comprehensive microsegregation analysis is not possible in this case. Nevertheless, from the dopant concentration profiles and from the best possible determination of the microscopic growth rates (using the identifiable rate striations), a comparison can be made with the microsegregation under forced convection conditions.

As seen in Fig. 4, there is no consistent correlation between the dopant concentration and the microscopic growth rate; nor is there a constant correspondence between dopant striations and the growth rate maxima or minima. Thus, the variation of the dopant concentration is not controlled solely by the variations in the microscopic growth rate, but also by variations in the diffusion boundary layer characteristics (thickness and compositional profile); the effects of these variations cannot be quantitatively isolated. Figures 3 and 4 show that fluctuations of the dopant concentration are smaller under thermal convection.

For a comparison with the previous two cases the BPS model was employed; an effective value of $\delta/D =$ 80 sec/cm was determined (by trial and error) so that the computed mean dopant concentration value best matches the experimentally determined one. As seen in Fig. 4, the amplitude of the dopant fluctuations in the computed plot is generally smaller (up to approximately a factor of two) than in the experimental plot. Furthermore, the details in the pattern of the dopant fluctuations differ in the computed and the experimental plots. It is, thus, seen that on the basis of this analysis the diffusion boundary layer thickness is not constant and fluctuates toward smaller values than that required for steady-state segregation. Consistent with this analysis the mean dopant concentration decreased abruptly, *i.e.*, the mean k_{eff} decreased from 0.033 to 0.026, in going from forced convection to thermal convection conditions. Furthermore, due to the decrease in the diffusion boundary layer thickness the amplitude of the dopant fluctuation in this crystal portion is smaller than in the crystal portion grown at the same pulling rate and at the same distance from the periphery of the crystal but under forced convection (Fig. 3). It is thus clear that the BPS model is not applicable to segregation under thermal convection because in addition to the microscopic growth rate, the diffusion boundary layer thickness also undergoes significant fluctuations.

It is of interest to note that as in periodic backmelting here also the dopant concentration in the parts of the segment first to solidify after backmelting is higher (by about 18%) than k_oC_L, but less than the corresponding value in the periodic backmelting case; this result indicates again that the mean diffusion boundary layer thickness is smaller in the presence of thermal convection than under forced convection conditions. Under thermal convection, however, backmelting is on occasions sufficiently extensive so that the initial diffusion boundary layer vanishes and the concentration in the portion first to solidify is smaller than k_oC_L, indicating that the concentration at the interface becomes less than C_L due to backmelting of a relatively large crystal portion with a dopant concentration ($k_{eff}C_L$) appreciably less than C_L.

Summary

Forced convection conditions (laminar flow at the growth interface) were attained for silicon growth at

seed rotation rates above 3 rpm by introducing severe thermal asymmetry into a standard Czochralski-type apparatus. Crystal segments grown under these conditions exhibited only periodic rotational striations rather than random compositional inhomogeneities, which are invariably present in silicon crystals pulled at commonly employed rates of seed rotation. An abrupt transition from growth under forced convection conditions to growth under convective interference was found to occur at a critical aspect ratio of the melt.

The elimination of convective interference made possible the quantitative microsegregation analysis in silicon. Employing the BPS model it was shown that near steady-state microsegregation takes place under these conditions (with and without periodic backmelting). The observed deviation between the experimental results and the BPS model was manifested as solute redistribution transients associated with the variations in the microscopic growth rate (phase shift between dopant concentration and microscopic growth rates). The agreement of the experimental results with the BPS model was found to be better in the case of silicon than in the case of germanium growth reported earlier (5); this finding is not surprising since steady-state conditions should be more readily attainable for silicon growth (in the absence of convective interference) because of the significantly higher dopant difficulties in silicon melts.

It was shown that thermal convection (invariably present under the commonly employed conditions in silicon crystal pulling) leads to random fluctuations, not only of the microscopic growth rate but also of the diffusion boundary layer thickness; furthermore, under these conditions the mean diffusion boundary layer thickness decreases. Consequently, the effective distribution coefficient as well as the amplitude of the dopant concentration fluctuations are smaller in silicon growth under thermal convection than in silicon grown under forced convection. Because of the concurrent fluctuations of the microscopic growth rate and the diffusion boundary layer thickness, the BPS model is not applicable to the microsegregation in silicon pulled under thermal convective interference. Detailed studies of various aspects of microsegregation (including solute redistribution during growth rate transients and radial concentration gradients) in silicon crystals pulled from the melt are being pursued employing the presently reported experimental approach.

Sulfidation Kinetics of Iron and Ferritic Iron-Cobalt Alloys

D. J. Young* and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Pure Fe and ferritic Fe-Co alloys react with H_2S/H_2 atmospheres in the range $8 \times 10^{-8} \leq p_{S_2} \leq 6 \times 10^{-5}$ atm at temperatures of 533°-700°C to form a solid single-phase scale of $(FeCo)_{1-\delta}S$. Parabolic scaling kinetics are observed in all cases, the magnitude of the rate constant, its activation energy, and its p_{S_2} dependence being independent of alloy composition. The sulfidation of iron is shown to be controlled by lattice diffusion of iron through the sulfide and the quantitative applicability of Wagner's parabolic scaling theory is verified.

A preliminary investigation (1) of the reaction between Fe-Co alloys and H_2S/H_2 atmospheres at 700°C showed that scales of a single-phase solid-solution monosulfide $(FeCo)_{1-\delta}S$ grew by parabolic kinetics on two ferritic alloys. It was argued then that in view of the close similarities in thermodynamics and structure of the binary sulfides $Fe_{1-\delta}S$ and $Co_{1-\delta}S$, both of which possess metal deficit NiAs structures, that the scaling kinetics observed for the alloys should be amenable to analysis from the standpoint of ternary diffusion theory.

Prior to attempting such an analysis it is necessary to quantify the reaction kinetics as a function of alloy composition, ambient sulfur partial pressure, and temperature. As the behavior of the alloys is compared to that of pure Fe, it is important to establish the mechanism of the iron-sulfur reaction.

Considerable evidence already exists (2-6) that the sulfidation of iron is controlled by solid-state diffu-

* Electrochemical Society Active Member.

Key words: diffusion, Fe-Co alloys, sulfidation kinetics, (FeCo)S scales.

sion and accordingly that the reaction is described by Wagner's theory (7) for scaling of pure metals. The recent publication (8) of accurate tracer diffusivity data for $Fe_{1-\delta}S$ as a function of (δ, T) together with existing information (9) on the variation of δ with (p_{S_2}, T) and the electrical properties of $Fe_{1-\delta}S$ (10) makes possible the quantitative verification of Wagner's treatment. Such a test is of interest as the degree of nonstoichiometry in $Fe_{1-\delta}S$ is large, ranging up to $\delta \simeq 0.25$.

No diffusivity data is available for $Co_{1-\delta}S$ although qualitative evidence can be found from sulfidation studies. Marker experiments (11, 2) show that in both $Co_{1-\delta}S$ and $Fe_{1-\delta}S$ the metal is much more mobile than sulfur, and it may be assumed that this is the case also in the ternary sulfide. The variation of δ in $Co_{1-\delta}S$ has been measured (12) as a function of (p_{S_2}, T). Comparison of this data with analogous data for $Fe_{1-\delta}S$ shows that in a wide range of p_{S_2}, T values, both $Co_{1-\delta}S$ and $Fe_{1-\delta}S$ are the stable binary sulfides. Experimental conditions employed in this work fall within this range.

Experimental

Single-phase ferritic alloys containing 0.00, 10.0, 19.9, 30.7, 40.0, 50.1, and 61.4 weight per cent (w/o) Co were fabricated from iron (>99.975 w/o pure) and cobalt (>99.997 w/o pure). They were sulfidized in H_2S/H_2 atmospheres corresponding to $8 \times 10^{-8} \leq p_{S_2} \leq 6 \times 10^{-5}$ atm at temperatures of 533°, 600°, 657°, and 700°C and the kinetics measured thermogravimetrically. Experimental details have been previously described (1).

Results

Reaction kinetics were parabolic and examples are shown in Fig. 1. The straight lines in this figure represent the result of linear regression to the rate equation

$$\Delta W/A + W' = (k_p t)^{1/2} \quad [1]$$

where $\Delta W/A$ is the weight change per unit area measured after time, t. This form of the parabolic rate equation was chosen to allow for the initial, unobserved period of reaction.

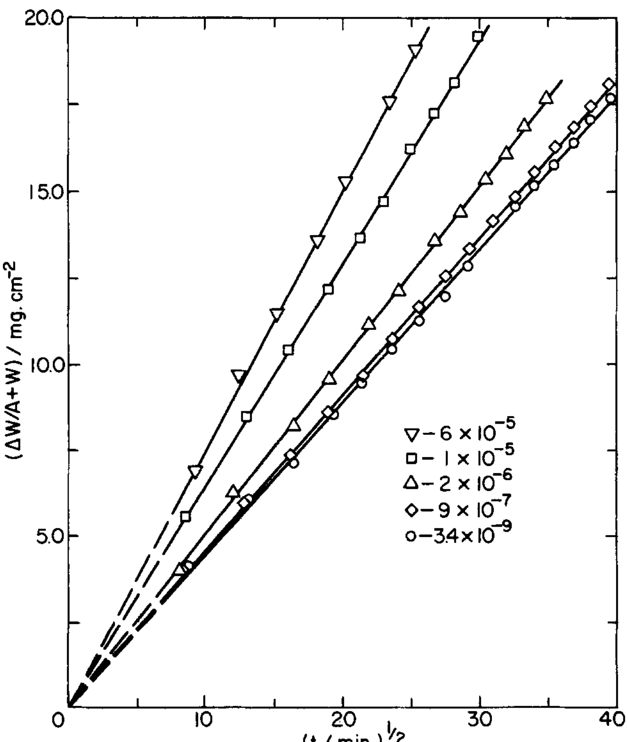

Fig. 1. Sulfidation kinetics of Fe-40 w/o Co at 700°C and several sulfur partial pressures. Continuous lines are regression lines found from Eq. [1].

The sulfur pressure dependence of the parabolic rate constant was determined for each of the alloys at 700°C and the results are displayed in Fig. 2. Linear regression of the data to the equation

$$\log k_p = \frac{1}{n} \log p_{S_2} + \text{constant} \quad [2]$$

yields a value for n of 5.6 ± 0.5. Values of n for the various alloys do not differ at a 0.05 level of significance. The p_{S_2} dependence of k_p was also determined at 600°C for Fe-40 Co and pure Fe. The results are shown in Fig. 3 and yield $n = 5.5 \pm 0.3$. The influence

of temperature on the sulfidation rate of each alloy at $p_{S_2} = 2 \times 10^{-6}$ atm was determined. Arrhenius plots of the results are shown in Fig. 4 which also gives the deduced activation energies, E_A. The relatively large error in E_A is a consequence of the small temperature range employed.

The effect of alloy composition on the parabolic rate constant was determined at $p_{S_2} = 2 \times 10^{-6}$ atm and the results are shown in Fig. 5. Inspection of the error bars on this figure reveals that no statistically significant variation of reaction rate with alloy composition is found at any of the temperatures employed.

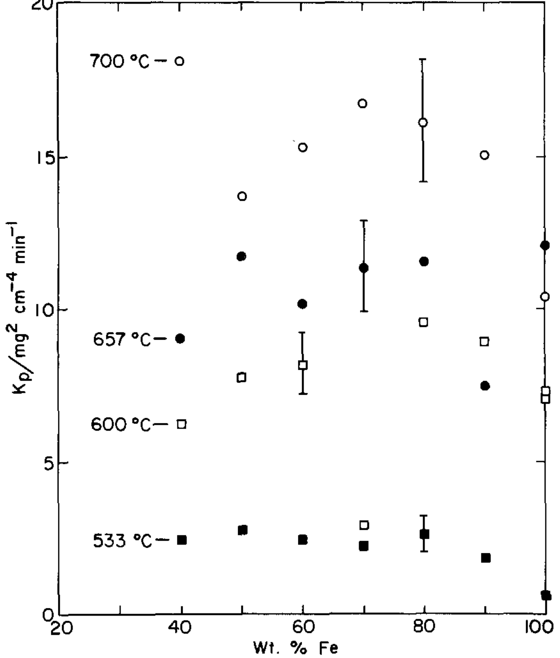

Fig. 5. Variation of parabolic rate constant with alloy composition at $p_{S_2} = 2 \times 10^{-6}$ atm and various temperatures.

The appearance of the sulfide scales formed is typified by the micrographs in Fig. 6. The scales are seen to be compact, tightly adherent to the metal surface, and of very large grain size. As was reported earlier (1) the sulfidation product was the monosulfide $(FeCo)_{1-\delta}S$ which, when sufficiently rich is Co, decomposed upon cooling via a eutectoid reaction (12) to yield $(CoFe)_9S_8$ and $(CoFe)_3S_4$.

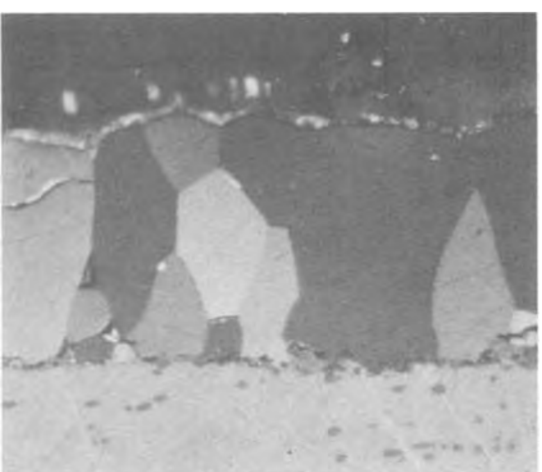
In order to investigate the applicability of Wagner's theory (7) for growth of a reaction product layer, the composition of the scale formed on pure iron was determined by microprobe analysis as a function of position within the scale. The results are shown in Fig. 7.

Discussion

Sulfidation of pure iron.—The formation of a compact sulfide scale in a reaction which follows parabolic kinetics suggests that the process is controlled by solid-state diffusion. Is this case, the theory of Wagner (7) should describe the reaction rate as a function of T and p_{S_2}. On the assumptions that only metal cations and electronic species are mobile in $Fe_{1-\delta}S$ and that local equilibrium is attained, the theory predicts for the flux of metal through the scale

$$J_{Fe} = C_{Fe}D_{Fe}\frac{Z_{Fe}}{2|Z_S|}\frac{d\ln}{dx}p_{S_2} \quad [3]$$

where J is the flux, C the concentration, D the self-



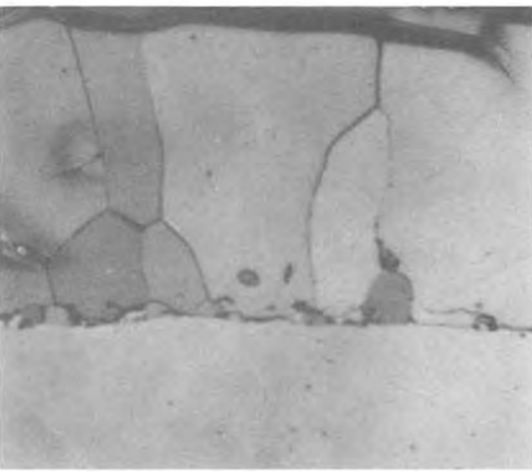


Fig. 6. Cross sections of sulfidized samples. Upper micrograph: pure Fe reacted at 700°C with $p_{S_2} = 8 \times 10^{-8}$ atm for 22.5 min, magnification 380X. Lower micrograph Fe-40 w/o Co reacted at 600°C with $p_{S_2} = 2 \times 10^{-6}$ atm for 39.3 min, magnification 380X.

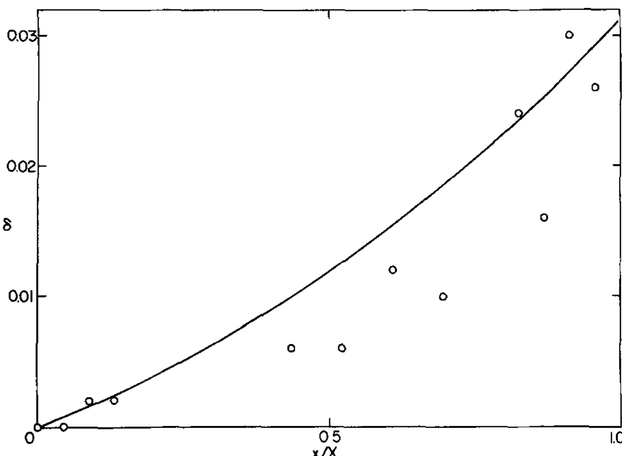

Fig. 7. Variation of stoichiometry with position in an $Fe_{1-\delta}S$ scale formed on Fe at 700°C and $p_{S_2} = 8 \times 10^{-8}$ atm. Continuous line calculated on the basis of divergence-free flux and local thermodynamic equilibrium; circles represent experimental measurements obtained on an electron microprobe.

diffusion coefficient, Z the effective valence, and x the position coordinate within the growing scale. Use has been made of the fact (10) that the electronic transport number $\simeq 1$. The value for $|Z_S|$ is taken as 2 and, therefore, $Z_{Fe} = 2/(1 - \delta)$. If the flux is assumed position independent, Eq. [3] integrates to yield the parabolic rate law with the rational rate constant expressed as

$$2k_r = c_{eq} \int_{p'_{S_2}}^{p''_{S_2}} \frac{Z_{Fe}}{|Z_S|} D_{Fe} d \ln p_{S_2} \quad [4]$$

where c_{eq} is the average concentration, in equivalents, of sulfide in the scale; p'_{S_2}, p''_{S_2} are the sulfur partial pressures at the metal-scale and scale-gas interfaces.

The fundamental assumptions of the theory are: that local thermodynamic equilibrium is obtained; that the mechanism of mass transport is diffusion; and, finally, that the flux of matter within the scale is position independent. Both the flux equation [3] and the rate equation [4] are employed to investigate these assumptions.

The self-diffusion of S is very much slower (8) than that of Fe in $Fe_{1-\delta}S$ and may be neglected. It follows then that if the deviation from stoichiometry in $Fe_{1-\delta}S$ is small, the deviation from a constant value of J_{Fe} within the scale is also small. If Eq. [3] applies, then the quantity $(D_{Fe} d \ln p_{S_2}/dx)$ should also be nearly independent of position. The variation of tracer-diffusion coefficient, D^T_{Fe}, with stoichiometry has been measured (8) in single crystal $Fe_{1-\delta}S$ as

$$D^T_{Fe} = D_o \delta \exp[-(19.4 + 20.1\delta)/RT] \quad [5]$$

and thus D^T_{Fe}, and hence D_{Fe}, is dependent upon composition for δ small but practically constant for larger values. It follows therefore from [3] that the gradient $d \ln p_{S_2}/dx$ in the FeS scale also is approximately position independent under these conditions. If the further assumption of local equilibrium is correct, it is possible from a knowledge of the composition of $Fe_{1-\delta}S$ as a function of p_{S_2} to calculate the compositional gradients in a scale which is growing by solid-state diffusion. Many authors have measured δ as a function of T and p_{S_2} and the data of Toulmin and Barton (9) has been employed in performing the present calculation. The results are compared with experimental measurements on a scale grown at 700°C in Fig. 7. Agreement is seen to be excellent except very near the metal-scale interface where δ approaches zero and D_{Fe} is composition dependent.

Narita and Nishida (6) measured the elemental distributions within a $Fe_{1-\delta}S$ scale grown at 700°C and found compositional gradients near the scale interfaces but an almost flat concentration profile in the interior of the scale. This result was taken to imply a much higher value for D_{Fe} in the region of the very small gradient. Metallographic examination revealed that this interior region of the scale was cracked and porous, thereby providing an explanation for the enhanced diffusion. In the present case, the scales are nonporous (Fig. 6) and Eq. [3] is directly applicable with values for D_{Fe} characteristic of single crystal $Fe_{1-\delta}S$.

Table I. Scaling constant for sulfidation of iron

T/K	p_{S_2}/atm	k_r/equiv., cm^{-1}-sec^{-1} Measured	Predicted
973	8×10^{-8}	2.0×10^{-9}	6.3×10^{-9}
	3×10^{-7}	2.2×10^{-9}	1.0×10^{-8}
	2×10^{-6}	3.2×10^{-9}	1.3×10^{-8}
	1×10^{-5}	3.9×10^{-9}	1.6×10^{-8}
	6×10^{-5}	6.5×10^{-9}	2.0×10^{-8}
973	2×10^{-6}	3.2×10^{-9}	1.3×10^{-8}
930		3.8×10^{-9}	8.3×10^{-9}
873		2.3×10^{-9}	4.7×10^{-9}
806		6.9×10^{-10}	2.2×10^{-9}

As the assumption of a position-independent flux, which is necessary for the integration of Eq. [3], is apparently a viable approximation, the utility of the integrated form [4] is now examined. The parabolic rate constant, as measured in g^2-cm^{-4}-sec^{-1}, is related to the rational rate constant, expressed in equivalent cm^{-1}-sec^{-1}, by the expression

$$k_r = \frac{1}{2} V_{eq} k_p / A^2 \quad [6]$$

where V_{eq} is the equivalent volume of $Fe_{1-\delta}S$ and A is the atomic weight of S. Equation [4] was integrated numerically using the data of Toulmin and Barton (9) for the variation of Z_{Fe} with p_{S_2} and Eq. [5] for the variation of D_{Fe} with δ and hence with p_{S_2}, on the assumption that $D_{Fe} = D^T_{Fe}$. The diffusion of Fe in $Fe_{1-\delta}S$ is in fact anisotropic with $D_c \simeq 1.8 D_a$ (8), where a and c refer to the basal and prismatic directions, respectively. An average value of $D_o = 2.35$ cm^2-sec^{-1} in Eq. [5] was employed. Values of V_{eq} taken from Meussner and Birchenall (2) were employed in Eq. [6] to compare the predicted and measured rate constants. The results are summarized in Table I and shown as functions of p_{S_2} and T in Fig. 8 and 9.

The predicted and measured rate constants recorded in Table I are within half an order of magnitude, which is remarkably good agreement for the type of measurement involved. However, the error is nonrandom, the measured rates being consistently lower than those predicted. A possible reason for this discrepancy is that diffusion has been assumed uncorrelated in calculating D_{Fe} from the tracer diffusion coefficient, D^T_{Fe}. In fact $D_{Fe} = f D^T_{Fe}$ where f, the correlation co-

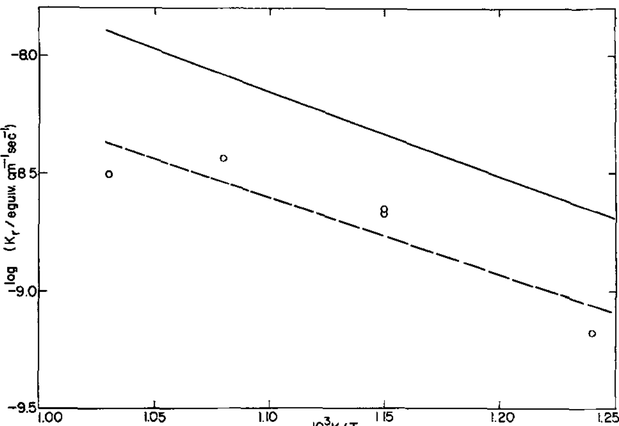

Fig. 8. Measured temperature dependence of iron sulfidation rates at $p_{S_2} = 2 \times 10^{-6}$ atm compared with prediction of Wagner's theory (continuous line).

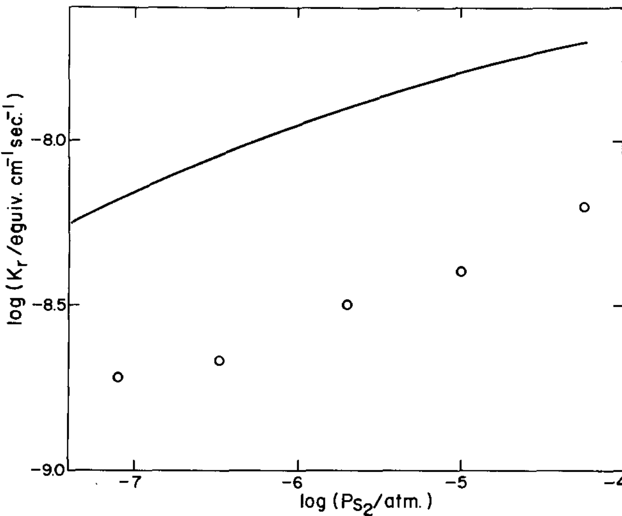

Fig. 9. Measured p_{S_2} dependence of iron sulfidation rates at 700°C compared with predictions of Wagner's theory (continuous line).

efficient, is unknown for $Fe_{1-\delta}S$ but is certainly less than one for noninterstitial diffusion. It is emphasized that the errors in the original determinations of D^T_{Fe} and of $\delta = f(p_{S_2})$ are large enough to account for the discrepancy between the measured and calculated values.

The predicted rate dependence on p_{S_2} and T are closely obeyed. The activation energy for reaction at $p_{S_2} = 2 \times 10^{-6}$ atm is 15.1 kcal whereas the activation energy for the tracer diffusion (8) of Fe in $Fe_{1-\delta}S$ is $(19.4 + 20.1\delta)$ kcal. The difference arises through the temperature dependence of both p'_{S_2} and the functional relationship between Z_{Fe} and p_{S_2}. Since $D_{Fe} \simeq \overline{D}_{Fe} \neq f(p_{S_2})$, then from [4]

$$k_r \simeq C_{eq}\overline{D}_{Fe} \int_{p'_{S_2}}^{p''_{S_2}} \frac{Z_{Fe}}{|Z_S|} d \ln p_{S_2}$$

The temperature coefficient of the above integral can be evaluated numerically from the data of Toulmin and Barton (9) to yield, for $p''_{S_2} = 2 \times 10^{-6}$ atm

$$\frac{d \ln (\text{Integral})}{d(1/T)} = +5.4 \text{ kcal}$$

Hence it can be deduced from the kinetic activation energy for iron sulfidation that the activation energy of $\overline{D}_{Fe}$ is 20.5 kcal, in excellent agreement with the tracer diffusion results which yield an average activation energy of 20.2 kcal for $p_{S_2} = 2 \times 10^{-6}$ atm.

Self-diffusion activation energies have been estimated from the sulfidation reaction by other authors, by further approximating the integrated rate equation as

$$k_r = \frac{C_{eq}\overline{D}_{Fe}}{|Z_S|} [Z''_{Fe} \ln p''_{S_2} - Z'_{Fe} \ln p'_{S_2}]$$

This procedure can lead to substantial error. Meussner and Birchenall (2) deduced as average value of 20.6 kcal for $0.12 < \delta < 0.25$ whereas the actual self-diffusion activation energy, Q, is $22 < Q < 24.4$ in this region of nonstoichiometry (8). Turkdogan (4) deduced a value of 26.4 kcal for $\delta \simeq 0.13$ compared to $Q = 22.0$ kcal, and a value of 20 kcal for $\delta = 0.008$ which compares well with $Q = 19.6$ kcal. Thus the above approximation of the integrated rate equation is viable only as δ approaches zero.

The pressure dependence of the parabolic rate constant may be described empirically by Eq. [2] with $n = 5.7$ at 700°C. Previous studies, carried out at higher values of p_{S_2}, yielded $n = 5.7$ (5), $n = 6$ (2, 4), and $n = 7$ (3). At 500°C a value of 7.8 was found (13) for n. A value for n of 6 has in the past been ascribed to rate control by diffusion of doubly ionized vacancies. Such a model is based on the proposed gas solid equilibrium

$$\frac{1}{2} S_2(g) \rightleftarrows S^x{}_S + V''_{Fe} + 2h^{\bullet} \quad [7]$$

and the approximate formulation of charge balance

$$2[V''] = [h^{\bullet}] \quad [8]$$

where the point defect notation of Kroger and Vink (14) has been employed. With the further assumption of ideal or Henrian solution behavior, Eq. [7] and [8] yield

$$[V''] = (K/4)^{1/3} p_{S_2}{}^{1/6} \quad [9]$$

where K is the equilibrium constant for the process [7]. However it has been shown (9, 12) that the solution behavior of $Fe_{1-\delta}S$ is not ideal nor Henrian, and as a consequence (8) the Wagner equation predicts a pressure dependence which is strong for small δ but which decreases as δ increases. The observation of a particular pressure dependence is therefore an insufficient basis for the deduction of a particular point defect mechanism.

Independent evidence exists (10) that the electronic conductivity, σ, of $Fe_{1-\delta}S$ is metallic in type, and obeys the relation

$$\sigma = \text{const } p_{S_2}{}^{1/30}$$

Both observations appear to be inconsistent with the defect model posed above. The conductivity is however related to both the concentration and the mobility of the free carriers. It is conceivable that the mobility is dictated largely by the stoichiometry of the solid (*e.g.*, through the existence of specific scattering centers whose concentration is stoichiometry dependent) and hence that the conductivity experiments and the defect model are possibly reconcilable. Kinetic studies of the Fe-S reaction, accordingly, do not resolve the question of the defect model for $Fe_{1-\delta}S$.

It is concluded that, under the present experimental conditions, the sulfidation of pure iron is controlled by lattice diffusion of Fe through the growing scale for the following reasons. The distribution of components within the sulfide scale is in accord with the known thermodynamic and diffusion properties of $Fe_{1-\delta}S$ and with the assumption of a position-independent flux. The functional form of the kinetics and the magnitude of the rate constants are as predicted by Wagner's theory of scale growth. The magnitude and temperature dependence of the deduced value for D_{Fe} are in good agreement with independent measurements, in single crystal $Fe_{1-\delta}S$, of D^T_{Fe}. Finally, the pressure effect on the reaction rate constant is consistent with independent measurements of the thermodynamics of $Fe_{1-\delta}S$.

Sulfidation of the alloys.—The sulfidation properties of the alloys are in all respects closely similar to those of pure iron. Again parabolic kinetics and compact, large-grain sulfide scales were observed. The parabolic rate constants of pure Fe and the different alloys under given experimental conditions were the same within 95% confidence limits (Fig. 5). Similarly, the p_{S_2} and T dependencies of the rate constant (Fig. 1-4) were independent of alloy cobalt content at a 0.10 level of significance. These results imply that sulfidation of the alloys is also solid-state diffusion controlled and that the self-diffusion coefficients of Co and Fe are very similar in magnitude, in T dependence and in p_{S_2} dependence.

Resistivity-Temperature Characteristics of Boron- and Antimony-Doped Tin Oxide Films

J. P. Marton

and D. A. Lepic[1]

McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Freshly deposited films are found to exhibit irreversible changes in resistivity when cycled in the range of $-60°$ to $+175°C$, but the resistivity may be stabilized by heat-treatment for a few hours at 200°C. Reversible changes in resistivity of stable films with temperature are found to depend in a unique way on the concentration of the dopants and the film thickness. An empirical relation has been developed to describe the resistivity-temperature relation of films as a function of doping concentration. Practical applications include the possibility of electrical resistors with controlled temperature coefficient of resistance in the range of near zero to +500 ppm/°C at room temperature.

SnO_2 single crystals and films have been investigated extensively because of the unique combination[2] of their useful electrical and optical properties. The electrical properties of single crystals (1, 2) are understood reasonably well, but the mechanism of conduction in films (3, 4) remains obscure. The latter depends strongly on the method of preparation, subsequent heat-treatments in various ambients, and the nature and concentration of dopants introduced.

Tin dioxide in its pure form is an n-type wide band-gap semiconductor with conduction electron concentration of about 10^{17} cm^{-3} at room temperature. This may be increased near metallic densities by doping with elements from Group V of the Periodic Table (*e.g.,* Sb). Doping tin dioxide with Group III elements (*e.g.,* In or B) also changes the carrier concentration and at high levels renders the host p-type.

The study of SnO_2 films is complicated in a twofold manner. First, the process of film deposition is such that it renders the film oxygen deficient (5) and it introduces chlorine (4) into the film. Second, the films are polycrystalline with film thickness dependent on degrees of disorder. The first set of defects acts as dopants and may or may not be thermally stable, while the second class of disorders influences the electrical conductivity through carrier scattering which may also be thermally unstable. However, if samples are prepared carefully and are thermally stabilized after film deposition, the effects of donor and acceptor doping and film thickness on the electrical resistivity and its temperature dependence may be studied. The present work is such a study aimed at characterizing thermally stable SnO_2 films doped with antimony and boron.

Experimental

Samples were prepared by high temperature hydrolysis of $SnCl_4$ in a H_2O and HCl atmosphere using the reaction $SnCl_4 + 2H_2O \rightleftarrows SnO_2 + 4HCl$ (endothermic). High alumina cylindrical ceramic substrates, with a submicron surface roughness, ¼ in. diameter by 1 in. long were heated in a furnace to 800°C and were passed through the deposition zone. The latter was a chamber through which a vaporized firing solution[3] was passed. The solution was vaporized by passing the liquid through a quartz capillary heated to 200°C.

Doping was done by mixing the chlorides of antimony and boron in the $SnCl_4$ solution in various quantities. In this work we refer to doping in terms of mole per cent of SnO_2. A 4% B and 0.6% Sb doping means that the firing solution contained 0.04 moles of B and 0.006 moles of Sb for every mole of SnO_2 assumed to be formed. As all constituents appeared in the vapor at the same proportion as they had been

[1] Present address: Computing Devices Limited, Ottawa, Ontario, Canada.

Key words: doped tin oxide films, electrical conduction.

[2] The resistivity of SnO_2 may be made to approach that of alloys (viz., be as low as 1000 μohm-cm) and, in its undoped form, it is optically transparent in the visible range of wavelengths.

[3] The firing solution used in the experiments was made up of $SnCl_4$ (351 cm^3), H_2O (108 cm^3), HCl (250 cm^3), H_3BO_3 (variable), $SbCl_5$ (variable).

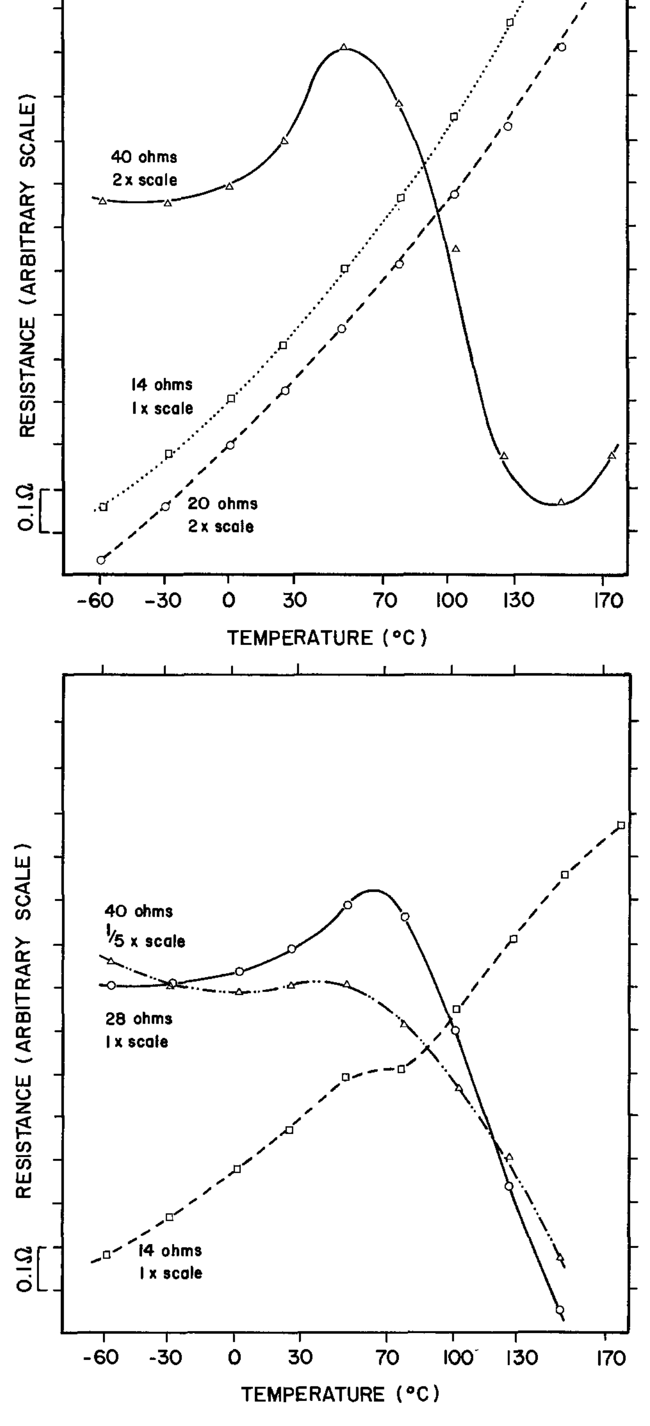
introduced into the firing solution, it was assumed that the concentration of B and Sb in the SnO_2 films was proportional to their concentration in the firing solution. The doping of films was then varied by the amount of B and Sb in the firing solution.

Films were deposited with a large number of firing solutions containing different amounts of dopants, each group divided into four subgroups with room temperature resistances of 14, 20, 28, and 40 ohms. The resistance was controlled by the thickness of the films which in turn was adjusted by the deposition time. The film thickness ranged from 1.5 to 3μ and the deposition time was adjusted between 5 and 10 sec. The rate of deposition was kept constant for all groups of samples at 3000 Å/sec by a suitable adjustment of the firing solution vapor flow rate. For all samples, other deposition conditions, *i.e.*, temperature, pressure, substrate feed rate, etc., were kept constant.

After deposition, the samples were allowed to come to room temperature in the normal laboratory atmosphere without attempts to anneal them in any special way. The samples were then provided with terminals and their resistance was measured between $-60°$ and $+175°C$. Stabilization followed at 200°C for 5 hr and the resistance was measured again in the same range of temperatures.

The resistivity of film material was calculated from the resistance and film dimensions. Film thickness was measured by weighing the samples, removing the film by chemical means, and reweighing the bare substrates again. The differential weight and bulk density of SnO_2 was used to obtain the film thickness.

In Table I, some typical groups used in the experiments are listed, along with their approximate volume resistivity and film thickness.



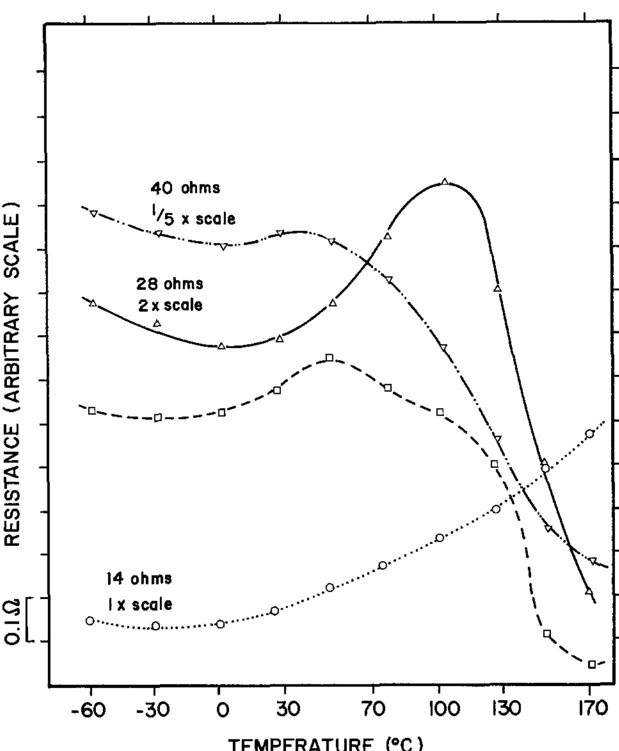


Fig. 1. Resistance vs. temperature of samples having three different doping levels (a, above left) 4.0% B, 0.27% Sb, (b, above right) 6.0% B, 0.4% Sb, and (c, left) 9.0% B, 0.9% Sb. Lower resistance films appear to behave similar to elemental semiconductors. Higher resistance films show anomalous behavior above 50°C. The anomaly extends to lower resistances for higher doping levels. The notes 1x and 2x etc. mean resistance divisions to be read as 0.1 and 0.2 ohm, respectively.

9.0% B, 1.35% Sb-40 ohms	0.0131

Results and Discussions

Irreversible effects.—The characteristic temperature dependence of resistance of as-deposited films depends on the doping level and on the film thickness. $R(T)$ curves of lightly doped thick films appear characteristic of elemental semiconductors, but at higher doping levels and for thinner films there appears an anomalous decrease of resistance with increasing temperatures above 50°C.

Typical curves are shown in Fig. 1 where the doping concentrations for Fig. 1a, b, and c are, respectively, 4.0% B, 0.27% Sb; 6.0% B, 0.4% Sb; and 9.0% B, 0.9% Sb. The anomalous decrease was measured for several samples, and activation energies for the decrease were calculated in the linear region. The results are listed in Table II, and a typical log $1/R$ *vs.* $1/T$ plot is shown in Fig. 2.

From the results, an average activation energy of 0.013 eV could be assigned to the resistance decrease, which was assumed to be associated with annealing of defects (6) in the film. These defects may be grain boundaries, which are known to occur at high densities in deposited films having a film thickness dependence. When annealed, the number of grain boundaries would decrease which would manifest itself in a decreasing resistance. In order to test this assumption, samples were cycled between −60° and +175°C and the resistance was monitored. Irreversible changes in resistance were indeed detected and their degree was found to depend on the doping concentration and film thickness. Typical results are shown for samples doped with 9% B, 1.35% Sb in Fig. 3 where the curves in 3a

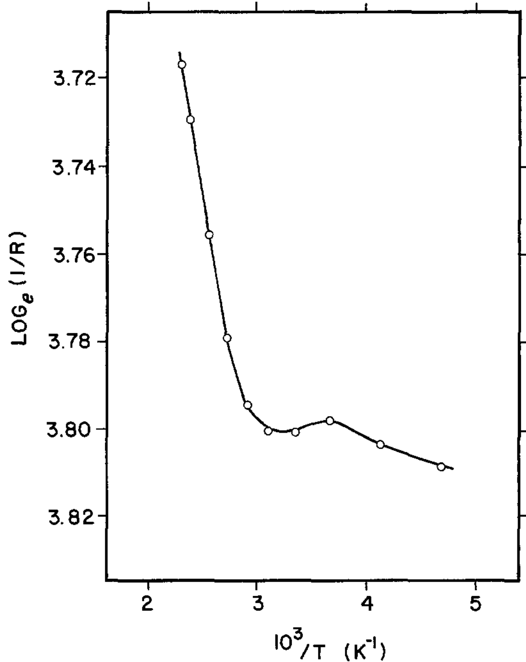

Fig. 2. Activation energy determination of the anomalous resistance decrease for films with 9.0% B, 0.9% Sb doping.

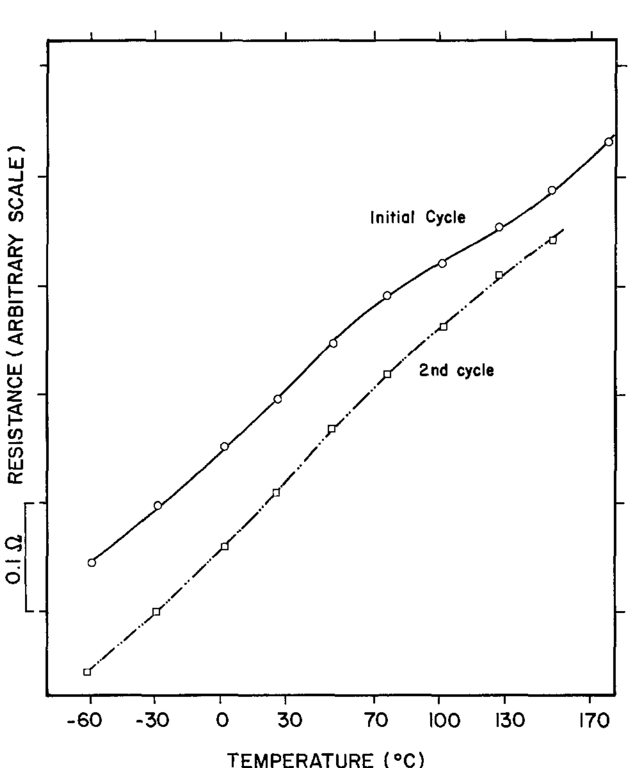

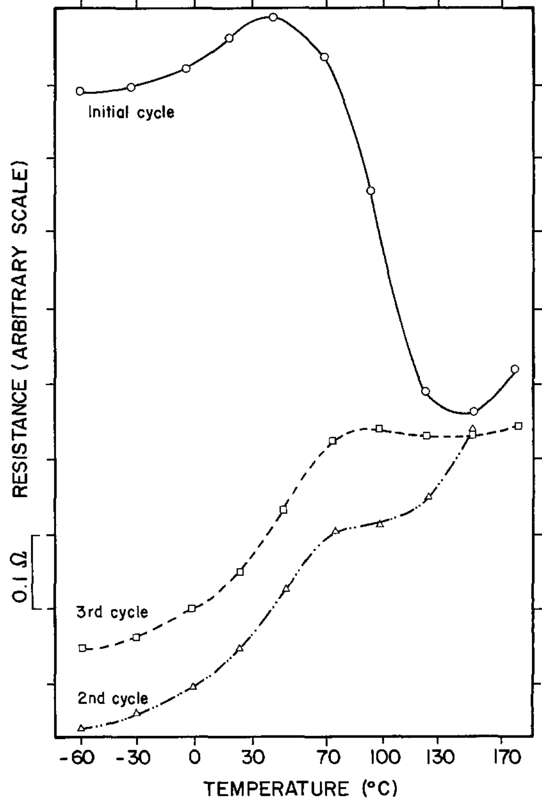

Fig. 3. Hysteresis of resistance on thermal cycling of films doped 9.0% B, 1.35% Sb. (a, above left) 14 ohm group (b, above right) 28 ohm group.

and b were measured on 14 and 28 ohm sample groups, respectively. For lighter doping levels and for lower resistances (thicker films) the irreversible changes are less than those for higher doping levels and thinner films.

In Fig. 3b we may note that the $R(T)$ curve after the third cycle is above that measured after the second cycle. This was due to a slow cooling in cycle two, which annealed defects, and a fast cooling in cycle three, which reintroduced defects. The same behavior was observed for several other sample groups.

Structural (thin film) effects.—The volume resistivity ρ_v of freshly deposited films was measured in an attempt to determine whether any orderly film thickness dependence of resistivity exists at the different doping concentrations used. The thickness of films and their resistivity were obtained by differential weighing and by measuring the width and length of films. It was assumed that the density of SnO_2 films was that of the bulk crystal.

Typical results are shown in Fig. 4 where the bulk resistivity is plotted against the reciprocal film thickness for several different doping levels. Although the plots are linear, a numerical comparison of the experimental values with the Fuchs theory (7) for thick films

$$\rho_v/\rho_{vo} = 1 + (3l/8d) \quad [1]$$

yields unreasonable values of several microns for the mean free paths of carriers. In the above expression, ρ_{vo} is the bulk resistivity of the crystal, l is the carrier mean free path, and d is the film thickness.

From the results we may speculate that the film thickness dependence of resistivity does not come about by film boundary scattering of carriers as predicted by the Fuchs theory, but rather by defect and grain boundary scattering of carriers. The density of defects and grain boundaries are known to depend on film thickness of films with a given concentration of impurities and a given thermal history; thus it may be the density of defects which causes the film thickness-dependent resistivity.

This idea conforms to the observed irreversible changes in resistance of freshly deposited films discussed above as defects and grain boundaries may be decreased (or increased) by heat-treatment.

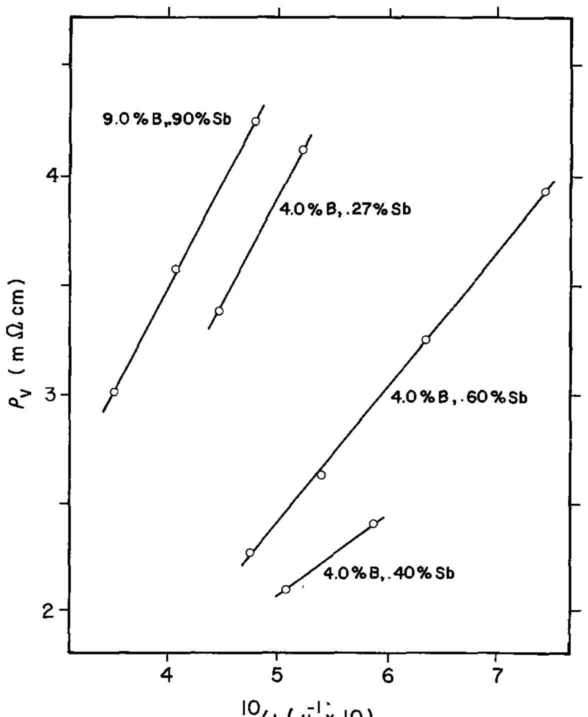

Fig. 4. Volume resistivity ρ_v plotted against inverse film thickness d for various doping levels to illustrate film thickness dependence of resistivity.

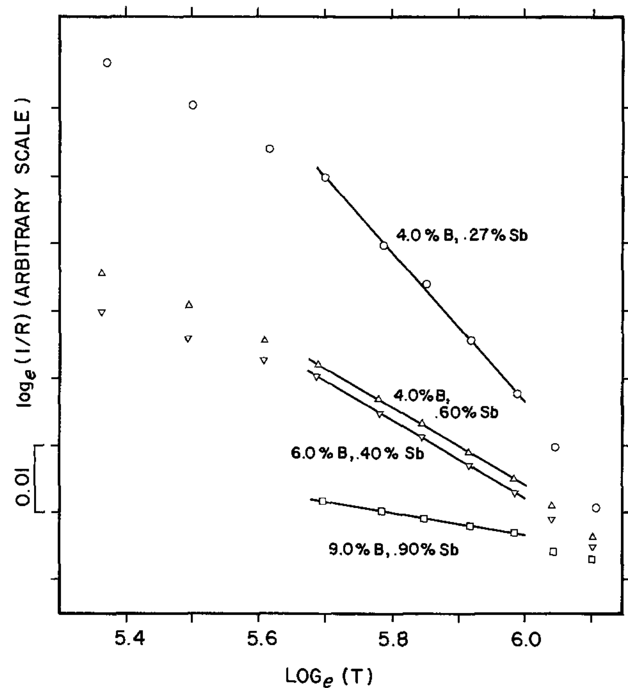

Fig. 5. Stable resistance vs. temperature of 20 ohm films with different doping levels. The slope of the curves decreases with increasing doping level.

Effect of doping.—The effect of doping on the resistivity and its temperature dependence was measured on films that were stabilized at 200°C for several hours. In Fig. 5 log 1/R is plotted against log T for 20 ohm films in order to isolate a power law relation. In the region of interest where solid lines are drawn through the data points, the $R(T)$ relation may be written as

$$R(T) = R_0 T^x \quad [2]$$

where R_0 is the resistance at the reference temperature and where x appears to be some function of doping. T is the absolute temperature.

Measurements on a large number of 14 and 20 ohm samples yielded fairly reliable values for x at different doping concentrations. The results are listed in Table III and are plotted in Fig. 6. The plot is x *vs.* the reciprocal of the product of B and Sb concentration in mole per cent. The film thickness dependence of x is also contained in the figure, with the 14 and 20 ohm groups representing thicker and thinner films, respectively.

It is apparent from Fig. 6 that increasing doping levels decrease x and that this decrease saturates at some moderate doping concentration. It is also apparent that it is the product of B and Sb concentrations that controls x. In fact, we see from Table III that samples with 6% B, 0.4% Sb and 4% B, 0.6% Sb have the same x value. A lower limit for x appears to exist for both

Table III. Temperature exponent vs. doping level

Doping	Temperature exponent x	
	14 ohms	20 ohms
2.7% B, 0.90% Sb	0.101	—
4.0% B, 0.27% Sb	0.163	0.118
4.0% B, 0.40% Sb	—	0.097
4.0% B, 0.60% Sb	—	0.063
6.0% B, 0.27% Sb	—	0.086
6.0% B, 0.40% Sb	—	0.063
6.0% B, 0.60% Sb	0.069	0.035
6.0% B, 0.90% Sb	0.073	—
9.0% B, 0.40% Sb	—	0.035
9.0% B, 0.90% Sb	0.055	0.018
9.9% B, 1.35% Sb	0.038	0.021

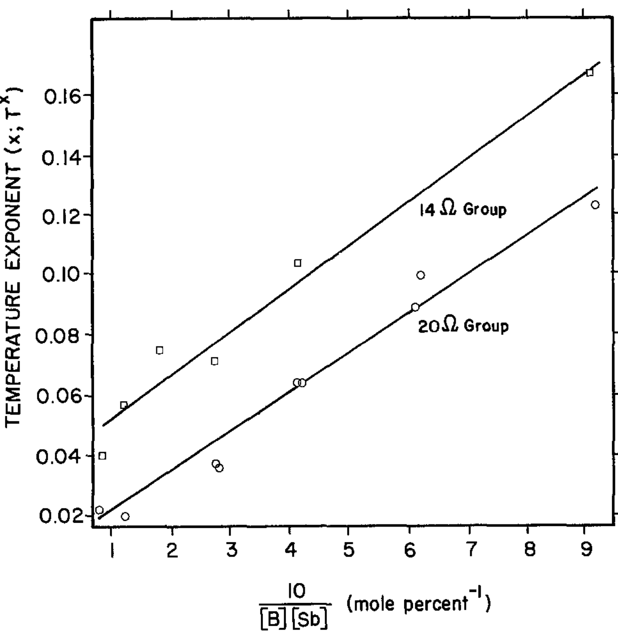

Fig. 6. Temperature exponent in Eq. [2] plotted against inverse doping concentration for 14 and 20 ohm groups of films.

resistance groups measured. For the 14 and 20 ohm group they are, respectively, 0.038 and 0.015.

Finally, we note that the slope of both curves in Fig. 6 is the same; thus we may write a final expression for $R(T)$ in the temperature range of 25°-125°C as

$$R = R_0 T^{F(d)} T^{G(B,Sb)} \quad [3]$$

where F and G are functions of film thickness and doping concentration, respectively. For our specific case

$F(d) = 0.015$ for the 20 ohm group
$= 0.038$ for the 14 ohm group
$G(B, Sb) = 0.118/([B][Sb])$

This expression provides a "recipe" to fabricate electrical resistors with a desired temperature coefficient of resistance in the temperature range 25°-125°C. The TCR defined as

$$\frac{1}{R_0}\frac{\partial R(T)}{\partial T}$$

may be calculated from Eq. [3] to range from near zero to 500 ppm/°C for typical samples used in this work. The $R(T)$ relationship can not be predicted by Eq. [3] however, outside this temperature range.

Conclusions

The thermal instability of freshly deposited SnO_2 films doped with B and Sb was found to depend on film thickness and doping level. Irreversible changes in resistance were found to be greater for thinner films and for those with a higher concentration of dopants. These instabilities were suggested to be due to defect and grain boundary annealing.

It has been found that freshly deposited films may be stabilized by heating them at 200°C for several hours and then cooling them slowly to room temperature. Reversible $R(T)$ characteristics of stabilized films showed a unique film thickness and doping concentration dependence in the temperature range 25°-125°C, and it was possible to write an empirical expression describing this relationship.

It was suggested that the results of this work may be used to design electrical resistors with a desired temperature coefficient of resistance in the present temperature range of interest.

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

When SiO_2 is deposited from the SiH_4-CO_2-HCl-H_2 system at ~1000°C, the resulting films are equivalent to or better than dry O_2 grown SiO_2 in electrical properties. The addition of HCl to the SiH_4-CO_2-H_2 system reduces the Q_{ox}. This is believed to be due to the reaction of unbonded Si with HCl, which prevents the incorporation of unbonded Si in the depositing SiO_2 matrix. The investigated properties, such as mobile charge density, index of refraction, etch rate, and density, were not affected by the presence of HCl. Postdeposition anneal (1050°C for 15 min in N_2) deteriorates the films by causing an increase in fixed oxide charge level and in fast surface-state density.

Chemical vapor deposited (CVD) oxides find extensive applications in planar semiconductor device processing. These applications have been discussed elsewhere (1-7). The use of CVD oxides in the gate region of a field effect transistor (FET), however, is almost unknown. The high fixed-charge level (1-7) ($Q_{ox} = 1 - 20 \times 10^{11}$) as determined at flatband condition, by

Key words: deposition rates, flatband charge, annealing, fast surface-state density.

the usual C-V technique (8, 9), is one factor that has inhibited the use of CVD oxides for the above application. The mobile ions in these oxides are not a problem, since they can be reduced by increasing the deposition temperature (3, 7). In fact, at a deposition temperature of 1000°C, "as-deposited" oxide films from the $SiH_4 + CO_2 + H_2$ system (6) show a low mobile charge density of 2.7 (±0.5) × 10^{10} cm^{-2}. Again it was shown (6) that the fast surface-state density (N_{FS}) is 1.5 (±0.5) × 10^{10} cm^{-2} eV^{-1} for CVD oxides deposited at 1000°C. The low mobile charge and the fast surface-state density, coupled with other physical and electrical properties, show that it is possible to deposit CVD oxides superior or equivalent in all respects, except the fixed-charge level, to the thermal oxides grown from dry oxygen.

Deal *et al.* (9) have hypothesized that the cause of fixed charges in the thermal oxides is excess ionic silicon, present at the Si-SiO_2 interface during oxidation, waiting to react with the oxidizing species that has to diffuse through the already-grown oxide. This hypothesis does not explain either the source of ionic silicon or any other cause of high charge levels in CVD oxides.

It is postulated here that the ionic silicon comes from the pyrolysis or reduction of silicon-bearing compounds used for the CVD oxide deposition. For example, in the SiH_4-CO_2-H_2 system, SiH_4 oxidation reaction must proceed simultaneously and in parallel with the decomposition of SiH_4. We feel that the latter reaction is responsible for free silicon in CVD oxides.

If, by some means, the rate of decomposition of SiH_4 could be reduced or silicon formed by this means eliminated, then the fixed charge level in the CVD oxides would also be reduced. One way of reducing the free silicon is to add small amounts of HCl in the gas phase during the CVD deposition (10) so that the following reaction can occur

$$Si + HCl \rightarrow SiH_xCl_y \uparrow \quad [1]$$

The result may be a reduction of the fixed (*i.e.*, flat-band) charge level in CVD oxides. As will be seen later, the experimental results met the above expectation.

This paper deals with the deposition rate of SiO_2 from the $SiH_4 + CO_2 + HCl + H_2$ system and with the physical and electrical properties of the oxides so deposited.

Experimental

Equipment.—The equipment used for the entire experimental investigation was a vertical, cold-wall, barrel-type, induction-heated reactor (11). The silicon "wafers" were placed on an SiC-coated graphite susceptor. Figure 1 gives a schematic cross-sectional view of the reactor. The fused-quartz chamber is 18 in. (~45 cm) long, with an internal diameter of 9 in. (~23 cm). The susceptor is placed in the chamber so that its leading edge is ~5 in. (12.7 cm) from the molybdenum distributor. The susceptor is hexagonal and is divided into three tiers, or "rings." Each of the six faces of the susceptor makes an angle of ~3 degrees with the central vertical axis. The susceptor is placed on a fused-quartz plate, which in turn is supported by a fused-quartz pedestal. The susceptor, approximately 8.25 in. (21 cm) long, was rotated at about 8 rpm throughout this experimental work. The volume of the annulus between the susceptor and the chamber (*i.e.*, the volume of the deposition zone) is ~5 liters. The surface area of the susceptor is ~1.1 × 10^2 cm^2.

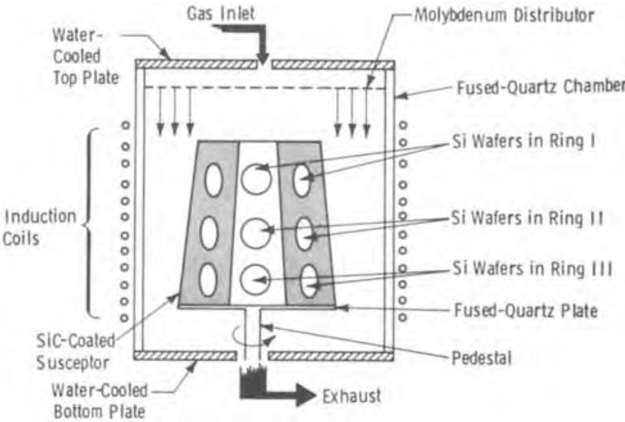

Fig. 1. Schematic cross-sectional view of reactor

The temperature was measured with an optical pyrometer.[2] All temperatures reported were corrected for system transmission losses and for emissivity (12). The reacting and carrier gases were introduced from the top of the reactor after each had been separately metered. All gases, except SiH_4, were metered through calibrated rotometers. The SiH_4 (5% mixture in hydrogen) was controlled by a mass-flow controller.

Typical deposition conditions and measurement technique.—Three 2¼ in. (5.7-cm) Si, 11-25 ohm-cm, p-type, <100> wafers were processed in each experimental run, unless otherwise indicated. One wafer each was placed in rings 1, 2, and 3, at a predetermined fixed position. The remaining positions on the susceptor were filled with dummy wafers. Before loading in the reactor, wafers were cleaned ultrasonically in hot (85°C) deionized water (for 5 min), followed by H_2SO_4/HNO_3 (3:1, at 120°C) cleaning (for 10 min), followed by a 10:1 dilute HF dip (for 10 sec). The wafers were then rinsed in running deionized water (for 5 min) and subsequently spin-dried. The wafer surface was hydrophobic after this cleaning.

During the experimental work, the H_2 flow rate, typically, was 110 liters/min; the SiH_4 flow rate (5% in H_2) was varied between 60 and 1000 cm^3/min. The CO_2:SiH_4 ratio was changed between 15:1 and 250:1. The deposition temperature range was 850°-1050°C; the deposition time was never less than 5 or greater than 25 min. The HCl volume percentage was varied between 0.1% and ~1%. Without exception, HCl gas was introduced at the start of deposition and its flow terminated within 30 sec of the end of deposition.

The resulting SiO_2 film thicknesses were measured by CARIS[3] and by ellipsometry. In most cases, one thickness measurement per wafer was taken because the typical within-a-wafer thickness uniformity was ≤2%. The typical within-a-run deposition uniformity was ≤ ±5% at 1000°C, at a total flow rate of ~110 liters/min; the worst-cast within-a-run uniformity at any temperature and flow (within the experimental range) was ~ ±15%. The deposition rates used in this report are therefore averaged deposition rates over three rings, and thus, as a first approximation, we neglected the SiH_4 concentration variations along the susceptor length.

The electrical properties of the resulting oxides were investigated by means of MOS capacitors. These capacitors were formed by evaporating 20-mil (~0.05 cm) Al dots from a resistance heat source. Blanket Al was evaporated on the back side of these wafers to facilitate electrical contact. Following Al evaporation, all wafers were annealed for a half-hour in N_2 at 400°C.

Results

Deposition rates.—The parameters whose effect on the deposition rate of SiO_2 was investigated are HCl mole fraction, SiH_4 mole fraction, deposition temperature, CO_2:SiH_4 ratio, and H_2 flow rate.

Deposition rate vs. HCl mole fraction.—Figure 2 shows the effect on the SiO_2 deposition rate of increasing the HCl mole fraction at a constant deposition temperature (*i.e.*, 1000°C) and at two SiH_4 mole fractions, 3.8 ×

[2] The temperature along the susceptor length is ± 10°C of any reported value.
[3] Constant angle reflection interference spectroscopy.

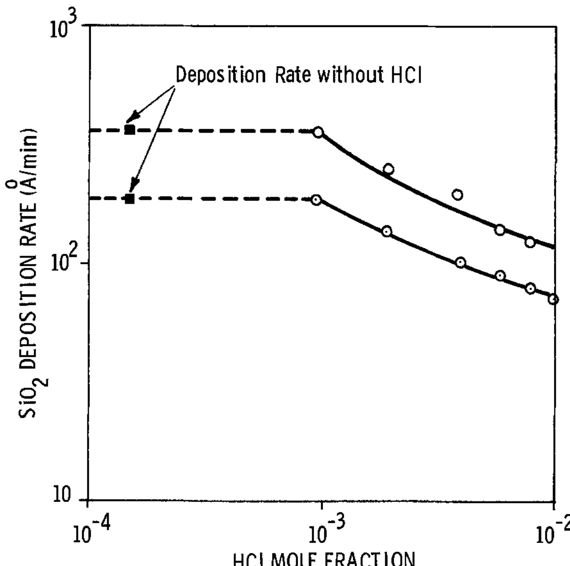

Fig. 2. Deposition rate of SiO_2 as a function of HCl mole fraction at two SiH_4 mole fractions: ⊙, 1.9×10^{-4}; ○, 3.8×10^{-4}. Deposition temperature, H_2 flow rate, and CO_2 mole fraction are constant at 1000°C, 110 liters/min, and 1.14×10^{-2}, respectively.

10^{-4} and 1.9×10^{-4}. The deposition rate for SiO_2 in the absence of HCl is also given for both SiH_4 mole fractions. Note that (*i*) at low HCl mole fractions, *i.e.*, $\sim 9.55 \times 10^{-4}$, there is no measurable change in deposition rate of SiO_2 when compared with the deposition rate of SiO_2 in the absence of HCl, and (*ii*) the deposition rate begins to decrease with increasing HCl concentration and continues even at an HCl:SiH_4 ratio of 50:1, though there is a slight evidence of leveling off.

This slight indication of saturation can be best seen in Fig. 3, where Δd_{SiO_2}, the difference in SiO_2 deposition rate with and without HCl, is plotted against the HCl mole fraction for two silane concentrations. Note that, as the HCl mole fraction is increased beyond $\sim 4 \times 10^{-3}$, the slope of the curve is reduced from 0.85 to 0.42.

Deposition rate vs. SiH_4 mole fraction.—Figure 4 shows the effect of SiH_4 concentration on SiO_2 deposition rate at three HCl mole fractions. Deposition rates without HCl are also given. Note that (*i*) at low HCl mole fractions, *i.e.*, 9.55×10^{-4}, there is no measurable difference in deposition rate with and without HCl for any silane concentration within experimental range; (*ii*) all curves in Fig. 4 have been drawn with a slope of 1, the experimental points closely approximating these slopes, indicating that the reaction responsible for SiO_2 deposition is still a first-order reaction with respect to SiH_4 (6); and (*iii*) the drop in deposition rate is a function of SiH_4 concentration, *i.e.*, when the drop in deposition rate does occur, the higher the SiH_4 concentration, the larger the drop for a fixed HCl concentration. This is shown in Fig. 5, where Δd_{SiO_2} is plotted for varying SiH_4 concentration, with the HCl mole fraction as a parameter.

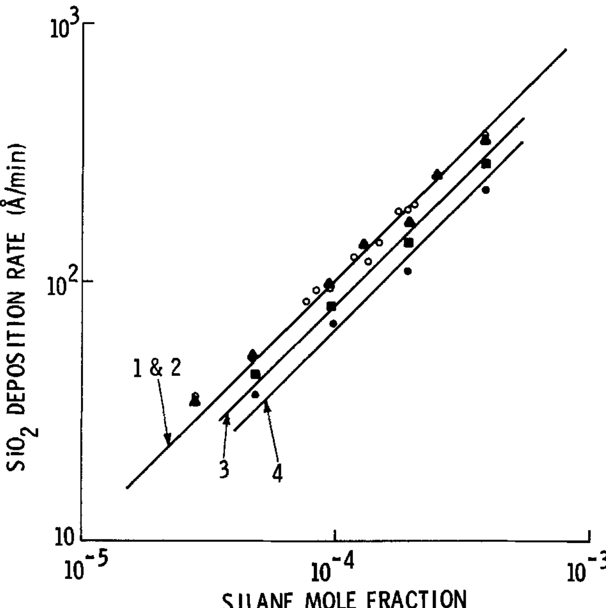

Fig. 4. Deposition rate of SiO_2 as a function of SiH_4 mole fraction, with HCl mole fraction as parameter. HCl mole fraction: ○, zero (curve 1); ▲, 9.55×10^{-4} (curve 2); ■, 1.91×10^{-3} (curve 3); ●, 3.82×10^{-3} (curve 4). Other deposition conditions same as Fig. 2.

Deposition rate vs. deposition temperature.—The reduction of SiO_2 deposition rate in the presence of HCl is a

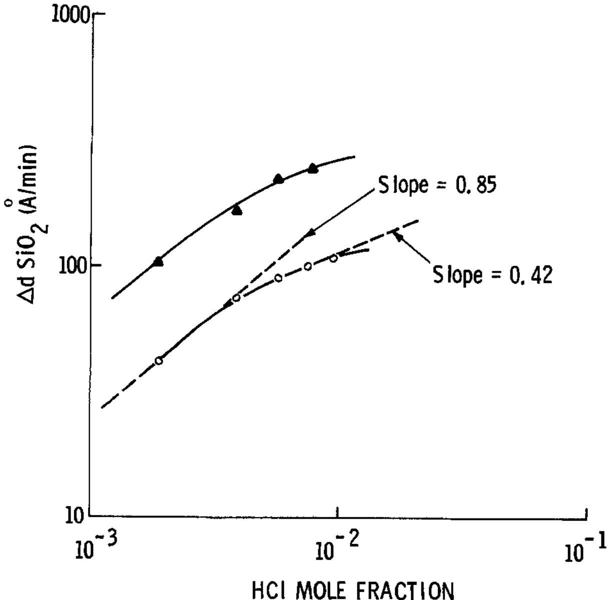

Fig. 3. Change in deposition rate of SiO_2 with and without HCl (*i.e.*, Δd_{SiO_2}) as a function of HCl mole fraction; two SiH_4 mole fractions: ▲, 3.8×10^{-4}; ○, 1.9×10^{-4}. Other deposition conditions same as Fig. 2.

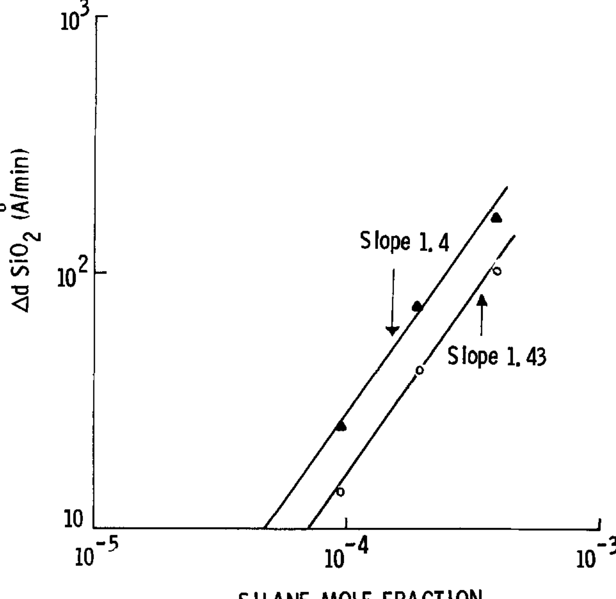

Fig. 5. Δd_{SiO_2} as a function of SiH_4 mole fraction at two HCl mole fractions: ▲, 3.82×10^{-3}; ○, 1.91×10^{-3}. Other deposition conditions same as Fig. 2.

very temperature-sensitive phenomenon. This can readily be seen in Fig. 6, where the log of deposition rate is plotted as a function of the inverse of absolute temperature. The data for Fig. 6 were generated at a constant H_2 flow rate of 110 liters/min and with constant SiH_4 and HCl mole fractions, *i.e.*, 1.9×10^{-4} and 1.91×10^{-3}, respectively. The CO_2:SiH_4 ratio was kept constant at 40:1. The curve for SiO_2 deposition rate without HCl is also provided for comparison. Note that (*i*) at ~925°C, deposition rate reduction ceases, and (*ii*) the reduction in deposition rate is a strong function of temperature, as shown in Fig. 7, where Δd_{SiO_2} is plotted against $1/T$. The activation energy value for the deposition rate reduction phenomenon is ~65 kcal/g mole as calculated from Fig. 7.

Deposition rate vs. CO_2:SiH_4 ratio.—At a constant H_2 flow rate (110 liters/min), deposition temperature of 1000°C, SiH_4 mole fraction of 1.9×10^{-4}, and HCl mole fraction of 1.91×10^{-3}, the CO_2:SiH_4 ratio was varied from 15:1 to 250:1 by varying the CO_2 flow rate. The deposition rate was a constant within the experimental error and run-to-run reproducibility (~ ±4%). Similar observations were made when no HCl was used (6).

Deposition rate vs. H_2 flow rate.—In this experiment, the SiH_4, HCl, and CO_2 mole fractions were kept constant. The deposition temperature was also a constant at 1000°C. The H_2 flow rate was varied from 60 to 130 liters/min. The deposition rate was found to be independent of H_2 flow rate variation within this experimental range. Similar results were obtained without HCl (6). This experiment showed that the deposition rate of SiO_2 is limited by surface chemical reaction, both with and without HCl. These results are consistent with the fact that the calculated mass transfer coefficient [estimated using Pohlhausen's approximation for isothermal flow (13)] for both SiH_4 and HCl are

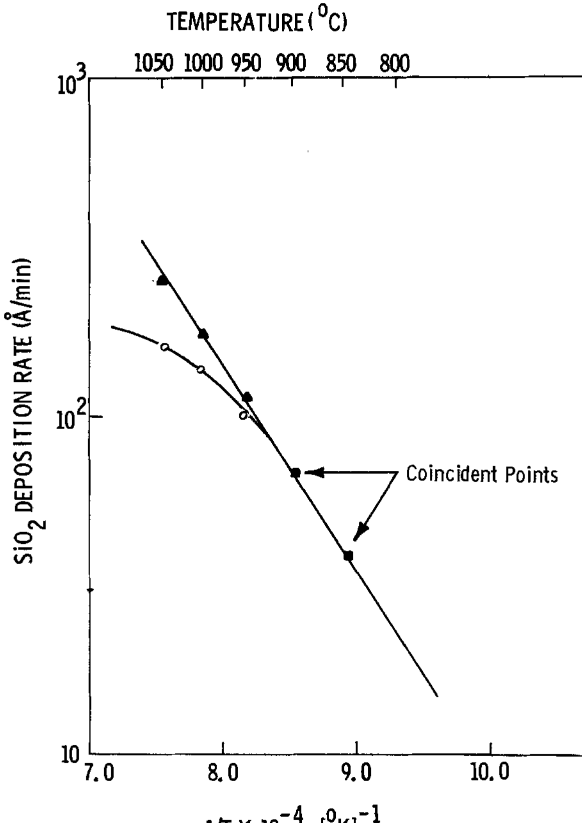

Fig. 6. Deposition rate of SiO_2 as a function of deposition temperature: ▲, without HCl; ○, HCl mole fraction of 1.91×10^{-3}; ■, coincident points. SiH_4 mole fraction, H_2 flow rate, and CO_2 mole fraction are constant at 1.9×10^{-4}, 110 liters/min, and 7.64×10^{-3}.

~ four orders of magnitude larger than the surface chemical rate constant for SiO_2 deposition with and without HCl at 1000°C, and at flows within the experimental range.

To summarize the effect of HCl on the deposition rate of SiO_2: (*i*) the presence of HCl, in general, reduces the deposition rate of SiO_2; (*ii*) the exception to this occurs when low mole fractions of HCl and SiH_4 are used; (*iii*) the drop in deposition rate due to the addition of HCl is highly temperature-sensitive (at ~925°C, the drop in SiO_2 deposition rate is no longer discernible); and (*iv*) the presence of HCl does not alter the fundamental nature of the reaction which results in SiO_2 deposition, *i.e.*, the SiO_2 deposition rate is still first order with respect to SiH_4, independent of CO_2:SiH_4 ratio and H_2 flow rate.

Physical properties.—No significant difference was found in refractive index, etch rate, density, pin-hole density, and infrared absorption spectra between oxides deposited with and oxides deposited without HCl. As an example, Table I presents the index of refraction for selected samples deposited at 1000°C. For all the samples, the refractive index lay between 1.45 and 1.46, irrespective of various levels of processing variables considered in this paper. The physical properties without HCl are discussed in detail in Ref. (6).

Table I. Index of refraction as a function of HCl mole fraction CVD oxides deposited at 1000°C

CO_2:SiH_4 ratio	HCl mole fraction $\times 10^{-3}$	Index of refraction at 5460Å	Sample thickness (Å)
20	0	1.458	1142
20	0.955	1.454	1090
50	1.91	1.455	980
250	3.82	1.453	1080
60	5.73	1.460	1361
60	7.8	1.454	1200
60	9.55	1.459	1048

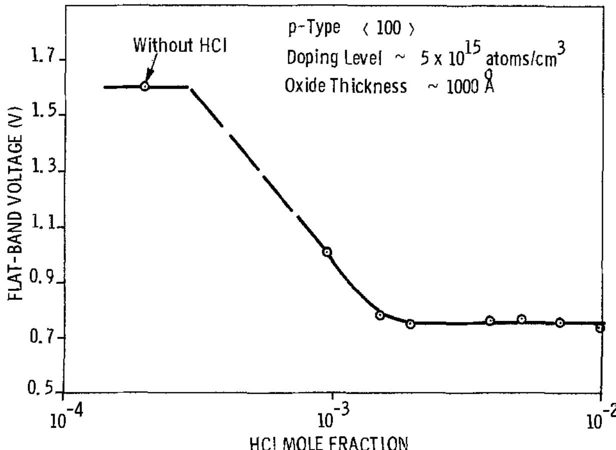

Fig. 8. Flatband voltage as a function of HCl mole fraction for oxide thickness of ~ 1000Å on p-type <100> Si. Doping level of silicon ~ 5 × 10^{15} atoms/cm^3. Flatband voltage without HCl, but for otherwise identical deposition conditions, also provided for comparison.

Electrical Properties.—The electrical properties were studied using MOS capacitors formed by the procedure outlined in the experimental section. It should be noted that, in general, these oxides were not exposed to any higher temperature anneal after deposition unless stated otherwise.

Changes in flatband voltage as a function of HCl mole fraction (1000°C deposition).—The flatband voltage was measured by the usual C-V technique (8, 9). The change in flatband voltage as a function of increasing HCl concentration and at a constant SiH_4 concentration (1.9 × 10^{-4}) is shown in Fig. 8. The oxide thickness was kept constant at ~1000Å. Though Fig. 8 shows data for p-type <100> Si substrates, similar results were obtained on n-type <100> Si substrates. Note that the flatband voltage first reduces very rapidly and then saturates at a value approximately equal to the ϕ_{MS} value. These results are consistent with the hypothesis presented in the introduction.

Flatband charge (Q_{ox}) as a function of HCl mole fraction (1000°C deposition).—Table II presents Q_{ox} as a function of increasing HCl mole fraction at a constant SiH_4 concentration. The oxide thickness is a variable between ~600 and 2600Å. Note once again that, as HCl concentration increases for a fixed SiH_4 mole fraction, the Q_{ox} decreases. In fact, at high HCl mole fractions, the Q_{ox} appears to be negative, *i.e.*, the flatband voltage is less negative than the ϕ_{MS} value. This is most likely due to the uncertainty of the ϕ_{MS} value. The Q_{ox} values in Table II are average values obtained from both p- and n-type <100> Si substrates. The last column of Table II shows whether there is a drop in the SiO_2 deposition rate at that HCl concentration, when compared with the SiO_2 deposition rate without HCl. At HCl mole fraction of 9.55 × 10^{-4}, there is no drop in deposition rate and yet there is a significant reduction (factor of 4) in Q_{ox}. This is consistent with the hypothesis.

Table II. Effect of increasing HCl concentration on Q_{ox} and deposition rate

HCl mole fraction × 10^{-3}	Q_{ox} (cm^{-2}) × 10^{10} [a,b]	Drop in deposition rate
0	28 (±2)	—
0.955	7 (±2)	No
1.91	1.3 (±0.3)	Yes
3.82	1.2 (±0.2)	Yes
5.73	−2.5 (±1)	Yes
7.64	−1.5 (±0.5)	Yes

1. Results are average of n- and p-type <100> silicon.
2. SiH_4 mole fraction is constant at 1.9 × 10^{-4}.
3. Oxide thickness is variable, 625-2580Å.
4. Deposition temperature is constant at 1000°C.

[a] The ϕ_{MS} value in volts used to determine the Q_{ox} was calculated from the relationship −0.4 ± ϕ_B, where −0.4V is the Al silicon work function for intrinsic silicon (16) and ϕ_B is the potential difference between the fermi level and the mid bandgap for doped silicon.

[b] Numbers in parentheses are twice the standard deviation.

Flatband charge Q_{ox} vs. SiH_4 mole fraction (1000°C deposition).—From the hypothesis it was expected that for a constant HCl mole fraction, if the SiH_4 concentration in the gas phase were increased, the Q_{ox} would increase. Table III presents the results of such an experiment, where the HCl mole fraction is kept constant at 0.955 × 10^{-3} and SiH_4 is increased. The thickness is variable from ~600 to 2300Å. The results of Table III are consistent with the hypothesis.

Flatband charge (Q_{ox}) vs. HCl:SiH_4 ratio (1000°C deposition).—It has been shown that HCl and SiH_4 concentrations, when considered independently, had a marked effect on Q_{ox} (Table II and III). The question next was whether maintaining a certain ratio of HCl:SiH_4 was a sufficient condition for obtaining reproducibly low Q_{ox} values. Table IV shows the results of such an experiment, with HCl:SiH_4 kept at approximately 10:1 but at varying levels of SiH_4 and HCl concentrations. Even though the HCl:SiH_4 ratio is nearly constant, markedly different Q_{ox} values result. Thus, the HCl: SiH_4 ratio is not an important parameter to control Q_{ox} values.

Mobile charge (Q_m) (1000°C deposition).—Mobile charges were measured by applying ±2 × 10^6 V/cm for 10 min at 200°C. This technique is similar to the one used by Kriegler *et al.* (14). The shift in flatband under positive bias was converted into mobile charge. For 1000°C deposited samples, the shift in the flatband under negative bias was not taken into account, because, in all cases, the flatband shift was negligible (*i.e.*, ≤10 mV). This also means that the mobile charges were present at the metal/SiO_2 interface.

The mobile charges were investigated as a function of SiH_4 and HCl concentration variations. The SiH_4 mole fraction was varied from 0.28 to 3.8 × 10^{-4}; the HCl mole fraction, from 0 to 7.64 × 10^{-3}. No systematic variation of Q_m was found as a function of either SiH_4 or HCl mole fraction. The mobile charge for all samples can be adequately represented as ~2.5 × 10^{10} charges/cm^2. The sample-to-sample variations were from ≤1

Table III. Effect of increasing SiH_4 concentration on Q_{ox} at fixed HCl mole fraction

SiH_4 mole fraction × 10^{-4}	Q_{ox} (cm^{-2}) × 10^{10} [a,b]
0.475	<1
0.95	6.5 (±1)
1.91	7.0 (±2.0)
3.82	5.5 (±2)

1. Results are an average of n- and p-type <100> silicon.
2. HCl mole fraction is constant at 0.955 × 10^{-3}.
3. Oxide thickness is variable 585-2340Å.
4. Deposition temperature is constant at 1000°C.

[b] See footnote [b] in Table II.

$\times 10^{10}$ to 4×10^{10}. These variations were most likely due to run-to-run variations of Al evaporation. Thermal-oxide monitor wafers from each metallization run were also checked, and they showed a similar variation in mobile charge.

The inability of HCl to affect the mobile charge is in total contradiction to the observations reported with HCl-grown thermal oxides (14). This contradiction is not surprising, however, for two reasons: (*i*) the CVD oxides deposited from SiH_4-CO_2-H_2 at 1000°C have very low mobile-charge levels, as reported earlier (6) and verified during these experiments, and (*ii*) the HCl concentration, in our case, is very small, *i.e.*, $<<1\%$. Our experiments with HCl thermal oxidation show that comparable low HCl concentration does not significantly improve mobile charges in thermal oxide, either, for 1000°C oxidation, especially when the mobile-charge levels are low without HCl.

Fast surface-state density (N_{FS}) (1000°C deposition).—Fast surface-state density was measured by the quasi-static technique of Khun (15), modified after Castrange (16) and Kerr (17). The modifications involve the use of high-frequency C-V trace as the ideal.

The fast surface-state densities at mid bandgap were measured on samples with oxide thickness between 800 and 1200Å. The value of the fast surface-state density at mid bandgap was unaffected by either SiH_4 or HCl concentration variations and can be adequately represented by $\sim 1.5 \times 10^{10}$ charges cm^{-2} eV^{-1}. The SiH_4 mole fraction was varied from 0.28 to 3.8×10^{-4}, and the HCl mole fraction from 0 to 7.64×10^{-3}. We attribute these low N_{FS} values to the use of H_2 during deposition.

The lack of relationship between Q_{ox} and the fast surface-state density (N_{FS}) is shown in Fig. 9 for these CVD oxides. Note that the Q_{ox} varies by larger than one order of magnitude and the N_{FS} shows only sample-to-sample variations. It is important here to recall that these samples were not exposed to high-temperature anneal after deposition. This behavior is in contradiction to that of thermal oxides, where the N_{FS} is usually proportional to Q_{ox} (18). Figure 9 also shows that at least for these CVD oxides the causes for Q_{ox} and N_{FS} may be unrelated.

Effect of deposition temperature on Q_{ox}, Q_m, and N_{FS}.—Table V presents an overview of the effect of deposition temperature on various charges. These oxides were not exposed to high-temperature postdeposition anneal, the SiH_4 and HCl mole fractions were kept constant, and the deposition time was adjusted to obtain ~1000Å of SiO_2. Note that, as the deposition temperature is dropped below 1000°C, the Q_{ox} increases as a step function. This is consistent with the hypothesis.

During the measurement of mobile charges, it became evident that the shift in flatband was significant (*i.e.*, 50-100 mV) at 200°C and -2×10^6 V/cm for oxides deposited below 1000°C. This shift, which was

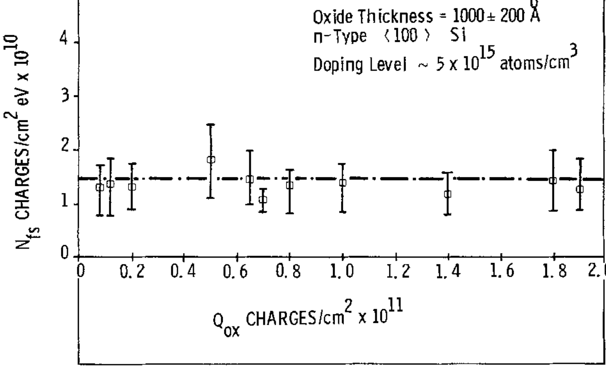

Fig. 9. Lack of dependence of fast surface-state density at mid bandgap on Q_{ox} in as-deposited CVD oxides. Oxide thickness was 1000 ± 200Å on n-type <100> Si; doping level of silicon ~ 5×10^{15} atoms/cm^3.

Table V. Effect of deposition temperature on electrical properties

Deposition temperature (°C)	Q_{ox} (cm^{-2}) $\times 10^{10}$ [a,b]	Q_m (cm^{-2}) $\times 10^{10}$ [b]	N_{FS} (cm^{-2} eV^{-1}) $\times 10^{10}$ [b]
1050	<1	3.0 (±0.5)	1.1 (±0.5)
1000	1.3 (±0.3)	2.1 (±0.5)	1.0 (±0.5)
950	7.0 (±2)	4.0 (±0.2)	1.2 (± 0.2)
900	7.0 (±3)	4.2 (±0.5)	1.5 (±0.5)
850	4.5 (±1)	2.8 (±0.2)	3.0 (±1)

1. Results are average of n- and p-type <100> silicon.
2. SiH_4 mole fraction is constant at 1.9×10^{-4}.
3. HCl mole fraction is constant at 1.91×10^{-3}.
4. Sample thickness is ~1000Å.

[a] See footnote [a] in Table II.
[b] See footnote [b] in Table II.

taken into account in the mobile-charge data presented in Table V, also implies that at least part of the mobile charges (~33%) are distributed in the bulk of the oxides when the oxides are deposited below 1000°C.

The deposition temperature also appears to affect the fast surface-state density at mid bandgap. For example, the 850°C deposited samples showed very nearly the highest fast surface-state density measured during this experimental work. The value of N_{FS} for 850°C samples is 2-3 times the value of N_{FS} for 1000°C samples.

Effect of annealing.—The effect of postdeposition high-temperature anneal (1050°C) for 15 min in N_2 is shown in Table VI. As-deposited wafers were divided into halves: one half was annealed at high temperature (1050°C in N_2 for 15 min); subsequently, both halves were metallized (Al) and annealed at 400°C for a half-hour in N_2. Note that the Q_{ox} and the fast surface-state density at mid bandgap are consistently higher in high-temperature annealed samples. The detrimental effect of annealing on V_{FB} stability when the MOS capacitors are exposed to $\pm 2 \times 10^6$ V/cm at 200°C for 50 hr is discussed in the section about electrical stability. Mobile charges appear to be unaffected. There is also 2-4% densification, as shown in the T_{ox} (oxide thickness) column. The breakdown field (E_B) [4] does not appear to be a strong function of annealing. The distribution of E_B was extremely tight, without any early failures (0 out of 400 capacitors tested). A comparison between MOS capacitors made with CVD oxide and those made with dry O_2 grown thermal oxide showed that the standard deviation of E_B in the latter case was larger (5-10 times), and that 2-5% of capacitors, also in the latter case, showed early breakdown (as much as 50% below the mean value). Osborne (19) reported similar wide distribution of E_B for MOS capacitors made with dry O_2 grown oxides.

It is pertinent here to point out that HCl does not affect the E_B distribution for CVD oxides. Similar tight distributions were observed when CVD oxides were deposited without HCl, under otherwise identical conditions (6).

Dielectric constant.—A comparison of the oxide thickness measurements by ellipsometry and capacitance measurements agreed within ±3% in almost all cases. Thus, the dielectric constant lies between 3.8 and 4.0, indicating that the presence of HCl during deposition did not affect the dielectric constant of CVD oxides.

Electrical stability.—It was our aim to investigate the effect of three variables on electrical stability (*i.e.*, flatband voltage stability): (*i*) high-temperature postdeposition anneal, (*ii*) HCl mole-fraction variation, and (*iii*) SiH_4 mole-fraction variation. Selected samples ~1000Å thick were therefore stressed with $\pm 2 \times 10^6$ V/cm at 200°C for ~50 hr.

Figure 10 shows the results of a sample deposited with low SiH_4 and HCl mole fractions, 2.8×10^{-5} and 1.44×10^{-3}, respectively, and at a deposition temperature of 1000°C. After deposition, the wafer was broken

[4] The procedure for measuring breakdown field is described in Ref. (6).

Table VII. Fast surface states as a function of temperature bias stress and postdeposition high-temperature anneal (1050°C, 15 min, N_2) with and without HCl

Deposition condition	Sample	N_{FS} cm^{-2} eV^{-1} (at mid bandgap) $\times 10^{10}$[a] Initial	After 20 hr of $+2 \times 10^6$ V/cm	After 20 hr of -2×10^6 V/cm and 200°C
Without HCl	As-deposited	1.2 (±0.3)	1.3 (±0.3)	2.5 (±0.3)
	Annealed	1.7 (±0.2)	3.2 (±0.5)	6.6 (±0.7)
With HCl	As-deposited	1.3 (±0.5)	1.3 (±0.5)	2.1 (±0.5)
	Annealed	2.2 (±0.5)	2.8 (±0.8)	4.2 (±1)

[a] Numbers in parentheses are twice the standard deviation.

in half, and one half was annealed at 1050°C for 15 min in N_2. Both halves were then metallized. As shown in Fig. 10, the behavior of the annealed half is markedly different from the unannealed half under negative bias. The electrical-stability behavior of CVD oxides deposited without HCl is identically affected by high-temperature anneal (6). Note that under positive bias the flatband shifts by ~75 mV within the first hour, with subsequent rapid leveling off. This shift is consistent with the mobile charge in the sample.

Negative shift of flatband under negative bias in thermal oxide is attributed to an increase of Q_{ox} (18) and/or of N_{FS} (18, 20). To see whether the fast surface states, in fact, showed a larger increase in the annealed half of the sample after negative-bias stress, several MOS capacitors from both halves of the wafer were stressed for 20 hr at 200°C under a bias of $\pm 2 \times 10^6$ V/cm. The fast surface states were measured before and after the stress. The results are presented in Table VII. The results of similar experiments on CVD oxides deposited without HCl, but with otherwise identical conditions, are also presented. Note that the annealed half of the wafer, when compared with the as-deposited half, irrespective of whether the oxides are deposited with or without HCl, shows larger (~2 times) N_{FS} after 20 hr of stress at -2×10^{-6} V/cm. Thus, negative-bias instability is directly related to high-temperature postdeposition anneal.

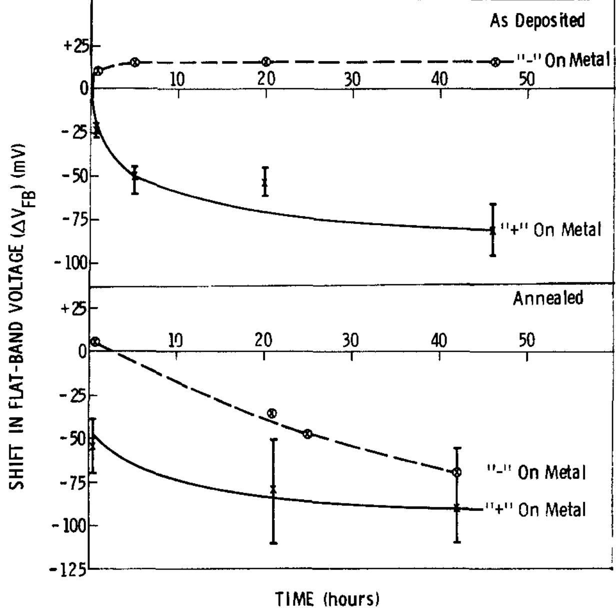

Fig. 10. Results of temperature (200°C) bias $\pm 2 \times 10^6$ V/cm stress on flatband voltage stability. Shown is the effect of high-temperature (1050°C, 15 min, in N_2) postdeposition anneal. Samples deposited at SiH_4 and HCl mole fractions of 2.8×10^{-5} and 1.44×10^{-3}, respectively. Deposition temperature was 1000°C; sample thickness, 850Å on n-type <100> Si.

To verify the results of Fig. 10 and to investigate the impact on stability of doubling the HCl mole fraction, a sample was prepared at SiH_4 and HCl mole fractions of 2.8×10^{-5} and 2.88×10^{-3}, respectively, at a deposition temperature of 1000°C. The rest of the sample preparation was identical with the sample of Fig. 10. The results of the stability test are presented in Fig. 11. Once again, the annealed half of the sample behaves like thermal oxides, whereas the nonannealed sample appears to characterize CVD oxides. Note also that changing the HCl mole fraction had no significant effect.

Several additional samples (all unannealed) were subjected to the stability test. In these samples, the SiH_4 mole fraction was varied from 0.28×10^{-4} to 3.8×10^{-4}, and the HCl mole fraction was kept constant at 3.82×10^{-3}. Data from two of these samples (SiH_4 mole fractions 1.9 and 3.82×10^{-4}, respectively) are presented as an example in Fig. 12. Note that the change in SiH_4 mole fraction does not significantly affect the behavior of these oxides; the same is true for threefold variations in HCl (compare nonannealed data from Fig. 10, 11, and 12).

Discussion

In the introductory section, two points were made in the hypothesis outlined: (*i*) adding HCl in the gas phase during the CVD deposition of SiO_2 reduces the fixed charges; (*ii*) the fixed charges are reduced because HCl reacts with unbonded Si atoms and thus prevents their incorporation in the depositing layers of SiO_2. Implicit in these two statements is the hy-

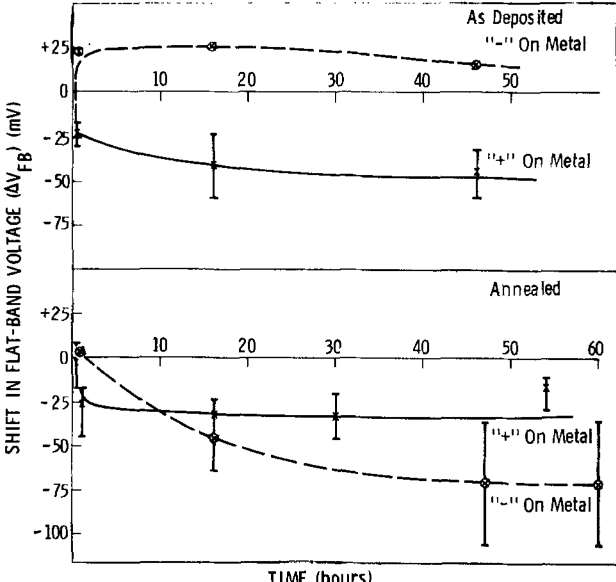

Fig. 11. Same as Fig. 10, except sample deposited with 2.88 × 10^{-3} mole fraction HCl. Sample thickness was 1100Å.

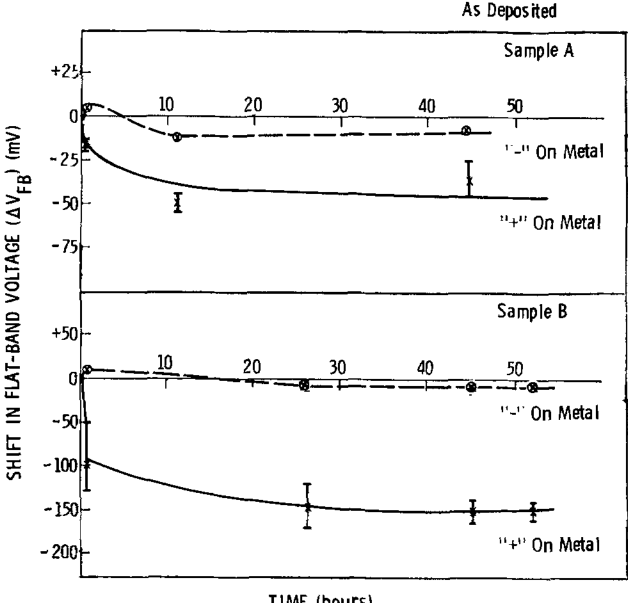

Fig. 12. Results of temperature (200°C) bias ± 2 × 10^6 V/cm stress on flatband voltage stability. Sample A was deposited at SiH_4 and HCl mole fractions of 1.9 × 10^{-4} and 3.82 × 10^{-3} and deposition temperature of 1000°C. Sample B preparation was identical with sample A except SiH_4 mole fraction was 3.82. Sample A and B thicknesses were 950 and 1150Å on n-type <100> Si.

pothesis, after Deal *et al.* (9), that free silicon is the major cause of fixed charges in SiO_2. Our experimental results prove the first point without doubt. It should also be obvious that we cannot prove point (*ii*) of the hypothesis by the present experimental work; we can merely show consistency.

The drop in the SiO_2 deposition rate in the presence of HCl was unexpected. We questioned whether perhaps a drop in deposition rate was necessary to reduce Q_{ox}, but found many combinations of SiH_4 and HCl concentrations where there was no measurable drop in deposition rate and yet the Q_{ox} was very small (for example, see Table VI, lines 1, 3, and 7). Low SiH_4 and/or low HCl mole fractions generally produce the results described above. Thus, the experimental data, where there is no drop in deposition rate of SiO_2 because of HCl and low value of Q_{ox}, are consistent with point 2 of the hypothesis. The consistency of the experimental results presented in Tables II-V with the hypothesis has already been shown.

We are uncertain as to the precise cause of the decrease in the SiO_2 deposition rate in the presence of HCl. However, since Δd_{SiO_2} is a quantitative function of SiH_4 and HCl concentration (Fig. 3 and 5) and is temperature-dependent (Fig. 7), the drop in deposition rate is probably due to SiH_4-HCl reaction, resulting in a compound whose reaction rate with CO_2 is small, in the experimental temperature range, to deposit SiO_2. Other equally probable and complex causes could also explain the decrease in deposition rate.

Some of the electrical properties of CVD oxides deposited from SiH_4-CO_2-HCl-H_2, though not unexpected, are different from thermal oxides. For example, it is accepted that N_{FS} is proportional to Q_{ox} (18) in thermal oxides. In these CVD oxides, an order-of-magnitude variation in Q_{ox} showed no significant variation in N_{FS} (Fig. 9), *i.e.*, for as-deposited samples, the Q_{ox} and N_{FS} are unrelated. These results, we believe, are due to the high deposition temperature and H_2 used during the deposition of these oxides. The increase in N_{FS} upon postdeposition high-temperature annealing (Table VI), however, has been reported for thermal oxides (18). The phenomenon of an increase in Q_{ox} as a result of high-temperature postdeposition anneal is also known in thermal oxides (18), *i.e.*, > 60 min at 1200°C in an inert ambient. It is important to note here, however, that we saw an increase in Q_{ox} after only a 15 min anneal at 1050°C in N_2 (Table VI). This high sensitivity to annealing in an N_2 ambient could be due to the fact that these oxides in as-deposited condition had a small charge. Again, from the data of Fig. 10, 11, and 12, it is clear that the phenomenon of "drift VI" (18) is almost nonexistent in as-deposited CVD oxides. However, upon annealing, these CVD oxides behave much like thermal oxides as far as drift VI phenomenon is concerned (Fig. 10 and 11). Thus, from the point of view of CVD oxides, high-temperature postdeposition annealing causes drift VI.

Finally, we have clearly demonstrated that the effect of HCl in the case of CVD oxides is to reduce Q_{ox} (Fig. 8), unlike thermal oxides, where the presence of HCl reduces mobile charge. The lack of impact by HCl on mobile charge in these oxides was not unexpected, for two reasons: (*i*) CVD oxides deposited ~1000°C without HCl in our reactor have low mobile charges ($\leq 3 \times 10^{10}$) and (*ii*) the HCl concentration in the gas phase is small (usually <<1%). It is therefore possible that a small quantity of HCl in the gas phase may not be sufficient to reduce the already low level of mobile charges present in these CVD oxides.

Conclusion

We have demonstrated the effect of HCl on deposition rates (*i.e.*, deposition rate reduction) and on the properties of CVD oxides deposited from SiH_4-CO_2-H_2 in the temperature range of 850°-1050°C. In marked contrast to thermal oxides, the presence of HCl during CVD oxide deposition affects Q_{ox}. There is no detectable effect of HCl on mobile charges in these CVD oxides; however, the mobile-charge levels were low without HCl ($\leq 3 \times 10^{10}$ cm^{-2}).

We have reported some significant differences in the electrical properties of CVD oxides and thermal oxides, such as a lack of relationship of Q_{ox} and N_{FS} (Fig. 9), the effect of high-temperature postdeposition anneal on Q_{ox} and N_{FS} (Table VI), and the lack of drift VI (18) in as-deposited CVD oxides (Fig. 10, 11, and 12). It is our hope that these differences in the electrical properties of thermal and CVD oxides will enhance the understanding of Si/SiO_2 interface and associated charges.

We have not shown the location of Q_{ox} in these CVD oxides, that not being our purpose. Our interest was to produce CVD oxides with very nearly ideal flatband voltages, irrespective of the location of charge. We have done this, though with a somewhat limited range of oxide thickness (~600-2600Å).

We have also shown the consistency of our experimental results with the hypothesis that the cause of Q_{ox} is unbonded silicon in SiO_2 matrix.

Finally, the CVD oxides deposited from SiH_4-CO_2-HCl-H_2 at ~1000°C are eminently suitable for application in the gate region of FET's.

Acknowledgments

We are deeply indebted to Messrs. A. Kozul and T. Williams for preparing the test samples.

$YVO_4:Eu^{3+}$ + SiO_2, A Diluted Phosphor System

A. Wachtel*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Combinations of $YVO_4:Eu^{3+}$ with SiO_2 can display fluorescence intensity which is higher than predicted on the basis of phosphor concentration. The effect is observed when the phosphor particles are encapsulated by vitreous SiO_2 and is due to increased optical efficiency of excitation.

A diluted phosphor system may be defined as a combination between a phosphor and an optically transparent diluent in which the absorption and emission of a given amount of phosphor, excited by a given radiation density of diffuse u.v., can be higher than it would be in the absence of the diluent. Relatively few diluted phosphor systems have been reported in the past; one is the $Zn_3(VO_4)_2$-ZnO system described by Bernikov and Zelikin (1) in which the authors speak of a "microphase" of $Zn_3(VO_4)_2$ dispersed in ZnO, and another is the heterogeneous halide-silica system recently published by Lehmann (2). The present system is based on original observations by Corth (3).

Experimental

Samples were prepared by coprecipitating $Y_{0.93}Eu_{0.07}VO_4$ by known methods (4, 5) followed by filtration and washing. Aliquots of the moist filter cake were then slurried with the appropriate amounts of flux and silicic acid prior to drying and firing, usually at 1150°C 2 × 1 hr in air. Fired phosphors were ground and washed with dilute HCl to remove traces of unreacted matter.

Fluorescence was measured under 254 nm excitation, using three types of targets: (*i*) conventional powder plaques, (*ii*) conventional lehred layers prepared on 1½ in. × 90° sections of T-12 fluorescent lamp tubing, and (*iii*) single-particle layers deposited on microscope slides coated with a pressure-sensitive adhesive. Measurements of the latter two were taken from the side opposite to that of excitation. Reflectance of 254 nm u.v. was measured by the method of Thornton (6).

Results

Preliminary observations showed that the plaque output of silica containing compositions is increased by the presence of a flux during firing. Suitable fluxes are alkali halides, borates, or carbonates. Most of the compositions in this study were prepared with 10 mole silica/1 mole phosphor and Fig. 1 shows the fluorescence

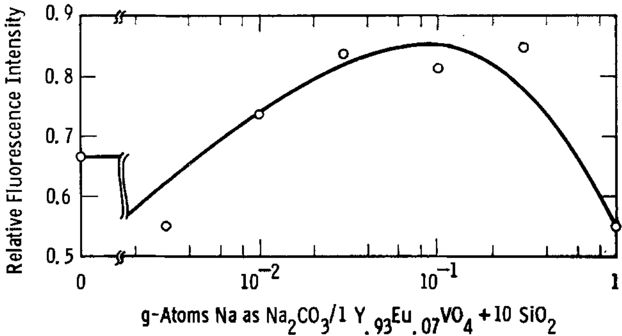

Fig. 1. Fluorescence intensity of YVO_4:Eu + 10 SiO_2 as a function of Na_2CO_3 flux.

* Electrochemical Society Active Member.

Key words: $YVO_4:Eu^{3+}$, excitation, powder optics.

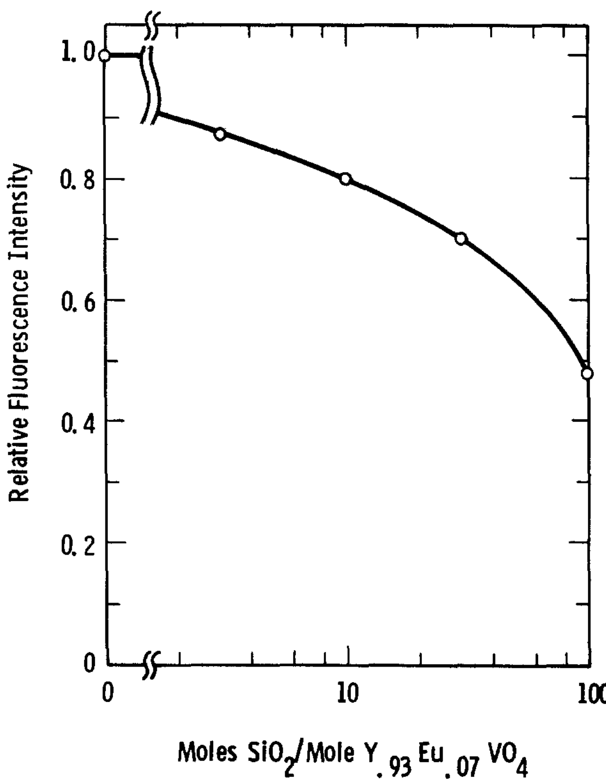

Fig. 2. Fluorescence intensity of YVO_4:Eu as a function of SiO_2 $Na_2CO_3 = 0.003 \times SiO_2$.

obtained with this as a function of Na_2CO_3 added, based on the fluorescence of undiluted phosphor. In general, optimum flux amounted to 0.1 alkali metal/1 $YVO_4:Eu^{3+}$ + 10 SiO_2.

Figure 2 shows the fluorescence in plaques over the range of 0-100 SiO_2/1 $YVO_4:Eu^{3+}$ where the flux addition consisted of 0.03 Na_2CO_3/1 SiO_2. At the 1 to 10 molar ratio of phosphor to silica, the concentration of $YVO_4:Eu^{3+}$ is about 12% by volume, yet the fluorescence is still about 80% of that of undiluted phosphor and more highly optimized samples with this SiO_2 concentration ranged as high as 96% (Table I). At the 1 to 100 molar ratio, the corresponding figures are 1.6% $YVO_4:Eu^{3+}$ and 48% fluorescence intensity. Phosphate containing preparations behaved similarly.

Figure 3 shows the effect of flux on the morphology of pure phosphors and aliquots of the same precipitates fired with silica. Unfluxed $YVO_4:Eu^{3+}$ (a) obtains in particles which are only 0.2-0.4μ in size. In the presence of SiO_2 (b) it can be seen that the phosphor particles form a dense layer over the SiO_2. The magnification here was reduced so as to show more than one coated particle of silica. Fluxed $YVO_4:Eu^{3+}$ (c) forms rather well-faceted crystals which are typically 0.5-1.5μ in size, while in the presence of silica and flux (d) these are no longer evident while the silica shows signs of fusion which resulted in encapsulation of the phosphor.

Table I summarizes the optical properties of these materials which, for convenience, are also identified with the appropriate letter of Fig. 3. In order to compare the effect of the physical arrangement between phosphor and silica with that of simple dilution, additional samples were prepared by mechanically mixing portions of the pure phosphors (a, c) with separately fired silica in the same ratio. These are indicated under "mixed." SEM of these were considered impractical because of the likelihood of segregation during settling of the suspensions on the copper blocks. We note, for instance, that the u.v. absorption ($1 - R_{254}$) of the mechanical mixtures is appreciably lower than that of the undiluted phosphors, as is expected. On the other hand, the absorption of the fired combinations is only slightly lower. Considering the measured fluorescence intensities, we note that the unfluxed phosphor (a) performs normally in deep plaques but decreases in output with decreasing layer thickness. In combination with silica (b) fluorescence is drastically reduced in plaques, but the relative reduction decreases with decreasing layer thickness. This is seen in the ascending values of the ratios shown in the right-hand side of the table. In particular, we note that the performance of (b) equals that of (a) in single-particle layers. The mechanical mixture performs relatively well in plaques and lehred layers[1] in spite of the lower u.v. absorption.

The fluxed phosphor (c) is typical of normal production type YVO_4:Eu; hence, the fluorescence is similar to the standard in all cases. In combination with silica (d), the plaque performance is very high but rapidly decreases with layer thickness. In contrast to the unfluxed preparation (b), this decrease is due to the silica (dilution) as seen by the descending values of ratio shown in the right-hand side of the table. The mechanical mixture performs much more poorly and, again in contrast to the previous case, drops to a very low value in single particle layers. In general, the data show that the effect of encapsulation as compared to random distribution of phosphor and silica particles increases with decreasing layer thickness.

Discussion

The decreased fluorescence intensity of unfluxed $YVO_4:Eu^{3+}$ in the single-particle layer is easily explained by the small particle size which limits the total amount of phosphor on the target. Since, however, the addition of silica caused no further reduction and resulted in a fluorescence intensity of 53.0 (Table I) which is actually higher than that of the fluxed system (49.5), it would seem that an enhancement effect was obtained in both cases. That this is not so is seen by reference to Fig. 3 which shows that a single particle layer of (b) contains approximately twice as much phosphor as a single particle layer of (a). The "dilution" of (b), while real in bulk, consists in this case merely of the separation of the phosphor layers by the silica particles and is optically of no consequence. On

[1] Since fluorescence output through lehred layers is a function of layer thickness, and optimum thickness depends on phosphor particle size and shape [phosphor (a) is much smaller than the SiO_2], "comparable" layers are difficult to prepare. Thus, the value of 68.3 for (a) + SiO_2 compared to 64.7 for pure (a) is due such complications and all data for lehred layers should be considered to be very approximate.

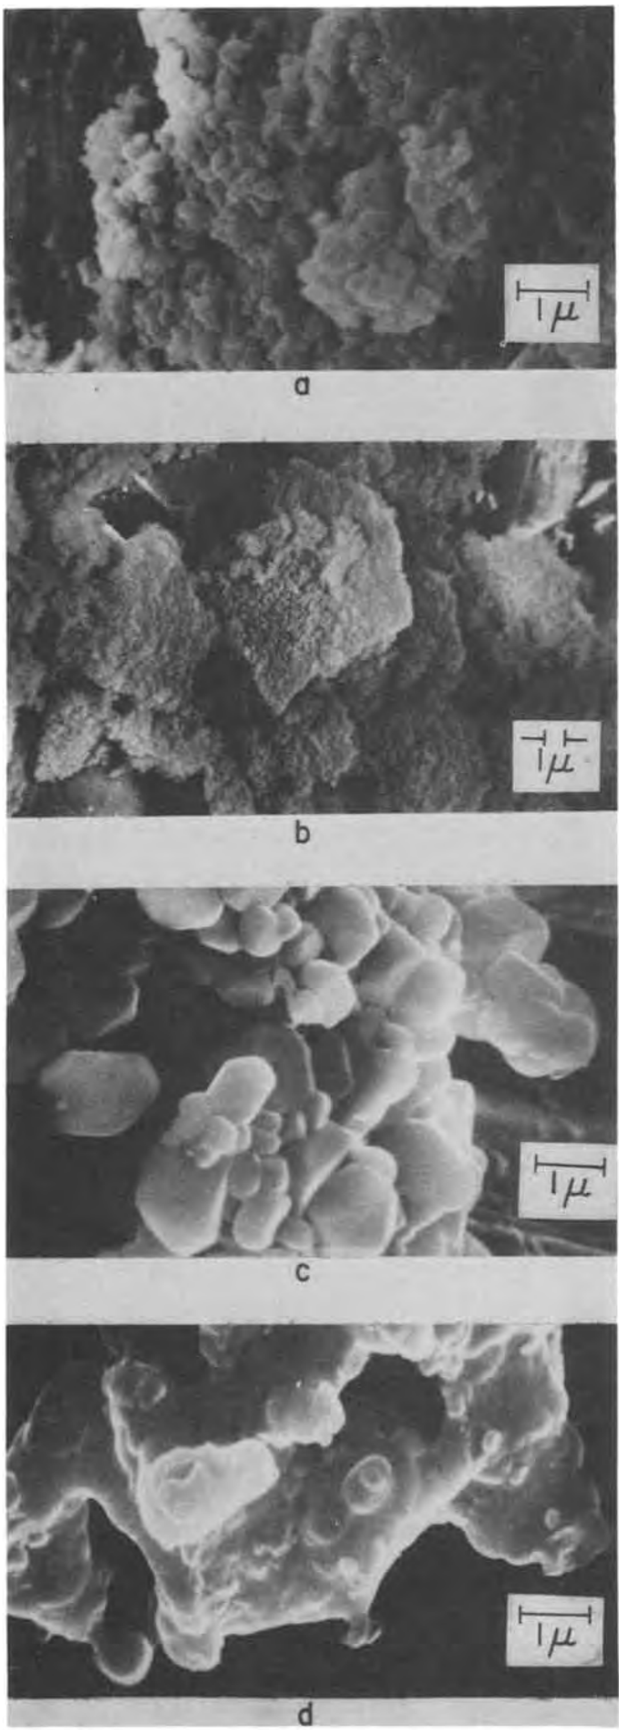

Fig. 3. Scanning electronphotomicrographs of compositions: a = YVO_4:Eu, unfluxed; b = YVO_4:Eu + 10 SiO_2, unfluxed; c = YVO_4:Eu, fluxed; d = YVO_4:Eu + 10 SiO_2, fluxed. Magnification: a, c, d = 10,000X; b = 3000X.

the other hand, a single particle layer of (d) still contains only the proportion of phosphor which is present

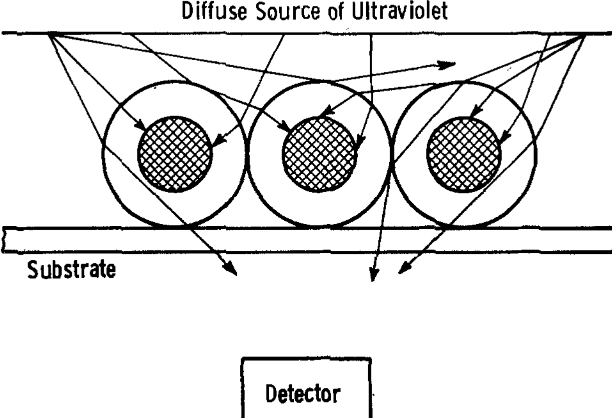

Fig. 4. Schematic representation of some optical paths in the excitation of fluxed YVO_4:Eu + 10 SiO_2.

in bulk, *i.e.*, 0.12 by volume. Since the phosphor particles are randomly oriented, their surface exposed to the exciting source equals $0.12^{2/3} = 0.243$ of the total surface. One would therefore expect this layer to display 0.243 of the fluorescence intensity of the layer of undiluted phosphor. The measured intensity ratio of 0.495 shows that there exists enhancement by a factor of $0.495/0.243 = 2.04$. Owing to the complexity of the system (irregularly shaped particles with random inclusions whose morphology and distribution depend on numerous experimental details), this figure should serve only as an indication that the effect exists and, in the present system, has about this order of magnitude.

The process which seems to be primarily responsible for the observed effect is indicated in Fig. 4 which shows an array of particles which are idealized in the form of concentric spheres of phosphor and silica. As shown, the ratio of diameters is 0.5 to 1 which roughly corresponds to 12 volume per cent (v/o) phosphor ($0.12^{1/3} = 0.493$). The linear magnification of a concentric sphere equals the refractive index of the shell which is 1.51 for vitreous silica at 254 nm. The total area of phosphor seen by the exciting source is therefore $1.51^2 = 2.28$ times greater for all angles of incidence except grazing where shadowing of particles by their neighbors occurs and the magnification decreases towards the linear value of 1.51. The figure indicates the optical path of a number of rays, several of which contact the phosphor cores only by virtue of refraction at the silica surfaces. In real (irregular) silica particles each containing a number of randomly dispersed phosphor inclusions, the process is likely to be less efficient but fundamentally no different because all angles of incidence are equally represented.

It is possible that a small additional contribution obtains from the effect of the silica as a low refractive index coating which may decrease reflection losses of the exciting and emitted radiations. No efforts were made to evaluate it.

In layers of practical thickness, there is, of course, the additional effect in which the diluent serves to involve a greater depth of the layer in efficient absorption and emission. Although Table I shows that high ratios of fluorescence intensity of mechanical mixtures of fine particle size phosphor and silica compared to pure phosphor (a) are obtainable, the actual fluorescence intensities are relatively low. In the encapsulated system (d), on the other hand, the fluorescence can become quite high in lehred layers and be almost undiminished in plaques.

Acknowledgments

The author wishes to thank Miss I. Walinski for sample preparations, Dr. W. A. Thornton for reflectance measurements, and Drs. F. M. Ryan, W. Lehmann, and N. T. Melamed for helpful discussions.

Manuscript submitted Sept. 10, 1975; revised manuscript received Oct. 24, 1975. This was Paper 203 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by the Westinghouse Electric Corporation.

Zn Diffusion in GaAs under Constant As Pressure

A. Luque, J. Martín, and G. L. Araújo

Laboratorio de Semiconductores de la E.T.S.I. de Telecomunicación, Universidad Politécnica de Madrid, Madrid, Spain

ABSTRACT

Zn diffusion at different temperatures has been performed in GaAs keeping the arsenic pressure at the same value for all the temperatures. The effective diffusion coefficient and the surface concentration obtained under those conditions are temperature dependent and temperature independent, respectively. A generalization of the interstitial-substitutional model is presented to account for these facts.

It is a well-known fact that the diffusion coefficient of Zn in GaAs increases with the zinc concentration, which gives steeper diffusion profiles than the erfc profile appearing when the diffusion coefficient is a constant.

Allen and Cunnell (1, 2) proposed a model in which the zinc diffuses simultaneously in neutral and ionized forms. This model leads to a smaller variation of the diffusion coefficient, D, with zinc concentration than the observed one. Kendall and Jones (3) suggested that D is proportional to the concentration of positively ionized gallium vacancies; though this model shows a concentration dependence of D near that observed, it predicts the increase of D with the vacancy concentration and therefore with the arsenic vapor pressure, which is in disagreement with the experimental results of Rupprecht and Le May (4).

To date, the most widely accepted model is the so-called interstitial-substitutional model proposed by Longini (5) in 1962. This model assumes that the interstitial zinc diffuses much faster than the substitutional zinc, which becomes interstitial zinc on leaving a neutral gallium vacancy; the diffusion is therefore mainly controlled by the rate of production of interstitial zinc.

In the following, we first consider the dependence of the diffusion coefficient with Zn concentration and As pressure established by the interstitial-substitutional model. Then we study the diffusion conditions which allow As pressure to be kept under control in order to perform experiments of constant As pressure. Finally, the experimental results are interpreted on basis of a generalization of the interstitial-substitutional model.

The Interstitial-Substitutional Model

In this model two forms of zinc impurities are assumed to be present; substitutional zinc and interstitial zinc. The two forms diffuse with different diffusion coefficients D_s and D_i, D_i being much higher than D_s. However the most abundant form is the substitutional one. The diffusion process is therefore limited by the rate of production of interstitial zinc, which diffuses very rapidly.

The interstitial zinc reacts with a neutral gallium vacancy to produce substitutional zinc according to the equation

$$Zn_s^- + h^+ \rightleftarrows V^\circ_{Ga} + Zn_i^{r+} + re^- \qquad [1]$$

Key words: Zn diffusion, GaAs, compound semiconductors, semiconductor technology, interstitial-substitutional model.

Well-established evidence exists that the substitutional zinc is a single acceptor. However it is not clear if the interstitial zinc has to be considered as a single donor (6) or as a double donor (7).

Using k_o as the equilibrium constant of Eq. [1] with the relationships $np = n_i^2$ and $p = [Zn_s^-]$ we may write

$$[Zn_i^{r+}] = \frac{k_o}{n_i^{2r}} \frac{[Zn_s^-]^{r+2}}{[V^\circ_{Ga}]} \qquad [2]$$

Fick's laws for this diffusion process establish that

$$\frac{\partial}{\partial x}\left(D_s \frac{\partial [Zn_s^-]}{\partial x} + D_i \frac{\partial [Zn_i^{r+}]}{\partial x} \right) = \frac{\partial}{\partial t}\left([Zn_s^-] + [Zn_i^{r+}]\right) \qquad [3]$$

Considering $[Zn_i^{r+}] << [Zn_s^-]$

$$\frac{\partial}{\partial x}\left[\left(D_s + D_i \frac{\partial [Zn_i^{r+}]}{\partial [Zn_s^-]} \right) \frac{\partial [Zn_s^-]}{\partial x} \right] = \frac{\partial [Zn_s^-]}{\partial t} \qquad [4]$$

An effective diffusion coefficient appears as

$$D = D_s + D_i \frac{\partial [Zn_i^{r+}]}{\partial [Zn_s^-]} \qquad [5]$$

and considering Eq. [2] we obtain

$$D = D_s + D_i (r+2) \frac{k_o}{n_i^{2r}} \frac{[Zn_s^-]^{r+1}}{[V^\circ_{Ga}]} \qquad [6]$$

Unless the $[Zn_s^-]$ is very small, the dominant term in Eq. [6] is the second one. So the process is limited by the diffusion rate of interstitial zinc that decreases with increasing neutral gallium vacancy concentration.

The dependence of D on $[V^\circ_{Ga}]$ implies its dependence on the partial arsenic pressure p_{As} within the diffusion ampul. The generation of arsenic and gallium vacancies are regulated by the following equations

$$Ga(s) \rightleftarrows V^\circ_{Ga} + Ga(g) \qquad [7]$$

$$As(s) \rightleftarrows V^\circ_{As} + \frac{1}{4} As_4(g) \qquad [8]$$

$$GaAs(s) \rightleftarrows \frac{1}{4} As_4(g) + Ga(g) \quad [9]$$

The mass-action law relationships for these equations are

$$k_1 = p_{Ga} [V^\circ_{Ga}] \quad [10]$$

$$k_2 = p_{As_4}^{1/4} [V^\circ_{As}] \quad [11]$$

$$k_3 = p_{As_4}^{1/4} p_{Ga} \quad [12]$$

From [10] and [12] we obtain

$$[V^\circ_{Ga}] = \frac{k_1}{k_3} p_{As_4}^{1/4} \quad [13]$$

Thus the result is that D decreases with increasing arsenic pressure for high zinc concentrations ($\sim 10^{19}$) in good agreement with the experimental evidence reported by Rupprecht and Le May (4). For these concentrations and taking Eq. [13] into account, Eq. [6] can be written as

$$D = D_s + D_i \frac{k_0 k_3}{k_1} \frac{r+2}{n_i^{2r}} \frac{1}{p_{As_4}^{1/4}} [Zn_s^-]^{r+1} \quad [14]$$

Diffusion Source

$ZnAs_2$ has been used as a zinc diffusion source to provide a controlled arsenic pressure in addition to the zinc pressure. This arsenic pressure must be high enough to prevent As evaporation from the GaAs wafer which would damage the surface and produce anomalous diffusion fronts for shallow diffusions. Since $ZnAs_2$ dissociates after the reaction

$$ZnAs_2 \rightleftarrows \frac{1}{3} Zn_3As_2 + \frac{1}{3} As_4 \quad [15]$$

for temperatures below 744°C (the ternary eutectic temperature of the system $ZnAs_2$-Zn_3As_2-GaAs), Zn_3As_2 and GaAs are present in equilibrium with As_4, Zn, and Ga vapors. This equilibrium is provided by the reactions

$$ZnAs_2(s) \rightleftarrows Zn(g) + \frac{1}{2} As_4(g) \quad [16]$$

$$Zn_3As_2(s) \rightleftarrows 3Zn(g) + \frac{1}{2} As_4(g) \quad [17]$$

$$GaAs(s) \rightleftarrows \frac{1}{4} As_4(g) + Ga(g) \quad [9]$$

The mass-action law relationships for these equations are

$$k_6 = p_{Zn} p_{As_4}^{1/2} \quad [18]$$

$$k_7 = p_{Zn}^3 p_{As_4}^{1/2} \quad [19]$$

$$k_3 = p_{As_4}^{1/4} p_{Ga} \quad [12]$$

Equations [18] and [19] give the As_4 equilibrium vapor pressure; this pressure is the same for the ternary system and for the binary system $ZnAs_2$-Zn_3As_2, because relations [18] and [19] hold for both systems. Figure 1 shows the As equilibrium vapor pressure *vs.* $1/T$ reported by Lyons (8) for the binary system.

Using $ZnAs_2$ as a diffusion source almost all the arsenic in the vapor phase is supplied through reaction [15] by this compound, which is much more volatile than the GaAs. The amount of $ZnAs_2$ per unit volume of the diffusion ampul to obtain a certain arsenic vapor pressure, p_{As_4}, is given by

$$m_{ZnAs_2} = \frac{10.35}{T(^\circ K)} p_{As_4}(\text{Torr})\,\text{mg/cm}^3 \quad [20]$$

taking into account reaction [15] and assuming that As_4 behaves as a perfect gas. The maximum vapor pressure that can be obtained is the ternary system equilibrium pressure and formula [20] will give the minimum amount of $ZnAs_2$ necessary to reach this pressure. The variation with temperature of the equilibrium vapor pressure and the minimum amount of $ZnAs_2$ is shown in Fig. 2.

For temperatures over 744°C and below 1015°C (melting point of Zn_3As_2) an invariant ternary liquidus richer in zinc than the $ZnAs_2$ is formed in equilibrium with the GaAs and the Zn_3As_2. Again, in this case, if the amount of $ZnAs_2$ is small enough the ternary equilibrium is not reached and the arsenic vapor pressure is given by [20].

The minimum amount of $ZnAs_2$ to supply the arsenic vapor pressure that avoids the surface damage produced by the arsenic evaporation from the GaAs surface is much smaller and can be obtained also by using [20] together with the equilibrium p_{As_4} value for GaAs, given by Fig. 2.

Experimental

To study the zinc diffusion into GaAs, 30 diffusions were performed using the sealed ampul technique. The

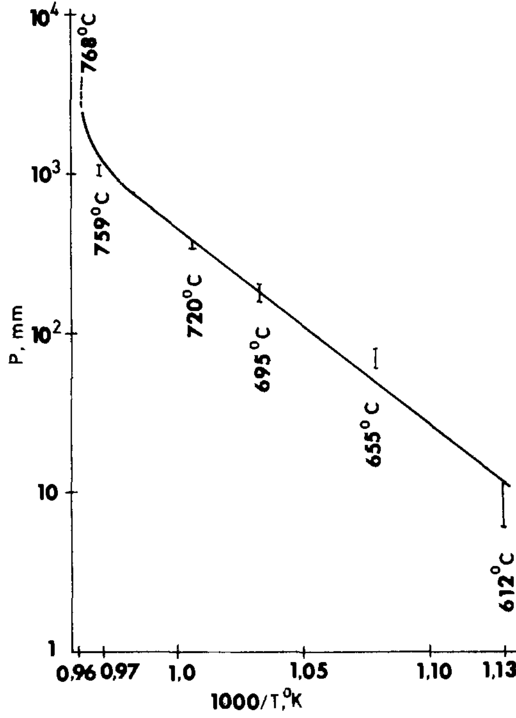

Fig. 1. As equilibrium vapor pressure [after Lyons (8)]

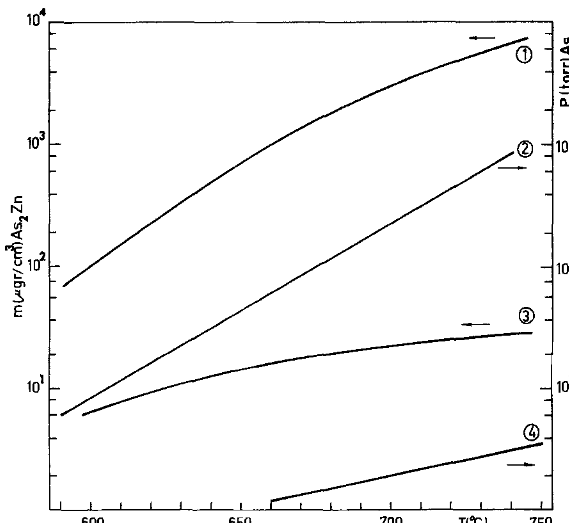

Fig. 2. As pressure *vs.* temperature in equilibrium with $ZnAs_2$ (plot 2) (8) and with GaAs (plot 4) (18) and minimum amount of $ZnAs_2$ *vs.* temperature to reach the As equilibrium vapor pressure with $ZnAs_2$ (plot 1) and with GaAs (plot 3).

temperature was varied between 700° and 875°C and the diffusion time between ½ and 16 hr.

Selenium-doped wafers from Wacker-Chemitronic, grown in the (111) direction, were used. The resistivity for these wafers ranged from 3.1×10^{-3} to 1.6×10^{-3} ohm·cm and the mobility from 3320 to 2560 cm^2/V-sec corresponding to a concentration between 6×10^{17} and 1.5×10^{18} cm^{-3}. In each experiment a 6 × 10 mm specimen of wafer was used.

The amounts of $ZnAs_2$ put as a dopant source in each ampul were lower than the minimum necessary to reach the equilibrium with a ternary system. Therefore, the diffusions were performed only in the presence of Zn_3As_2 and GaAs under an arsenic vapor pressure given by

$$p_{As_4}(\text{Torr}) = \frac{T(^\circ\text{K}) \cdot m_{ZnAs_2}(\text{mg/cm}^3)}{10.35} \qquad [21]$$

The ampul volume was about 2.5 cm^3 in each case, varying due to the handling of the glass during the sealing process. For this reason it was not important to use an exact amount of $ZnAs_2$. Table I shows the amount used in each case.

The value of p_{As_4} obtained from formula [21] is 610 ± 10% mm considering the spreading of m_{ZnAs_2} and the variation of T. Therefore the experiments can be considered as performed under a constant arsenic pressure.

After each diffusion process, x_j and V/I were measured and the results are presented in Table I. To measure x_j the grooving cylinder technique was used for the shallower diffusions and the beveling technique for the deeper ones. The staining solution (100g of $CuSO_4$ and 5 cm^3 of FH 49% in a liter of water) was used under an intensive illumination.

The V/I was measured by the four-point technique. The average resistivity, $\bar{\rho}$, can be obtained from the V/I and x_j data by using the formula

$$\bar{\rho} = K(V/I)x_j \qquad [22]$$

where K depends on the size of the specimen. In our case the value of K is 4.49 as obtained from the data reported by Logan (9).

Results

The partial differential equation of diffusion

$$\frac{\partial}{\partial x}\left[D\frac{\partial C}{\partial x}\right] = \frac{\partial C}{\partial t} \qquad [23]$$

can be changed into an ordinary differential equation using the Boltzmann transformation

$$y = \frac{x}{2\sqrt{D_{surf}\, t}} \qquad [23a]$$

and a solution of $C(y)$ can be found provided D depends only on C and C_{surf} is time independent during the diffusion process.

Therefore, if these conditions hold in our case, a proportionality will exist between x_j and $\sqrt{t}$.

In Fig. 3 the experimental values of x_j *vs.* $\sqrt{t}$ for the different diffusion temperatures are plotted. As can be seen the linear relationship theoretically predicted is experimentally found for each temperature. We can conclude that an equilibrium of vacancies is reached during the diffusion process causing D and C_{surf} to be time independent.

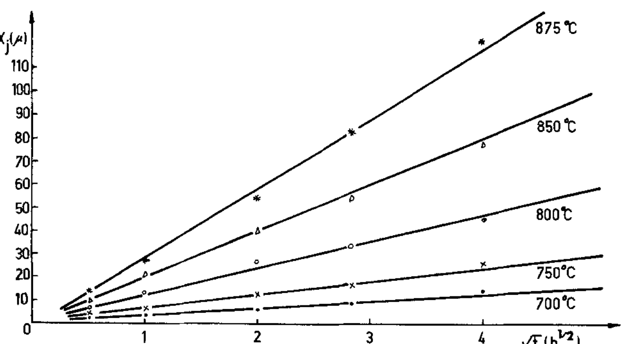

Fig. 3. Measured values of the junction depth as a function of the square root of the diffusion time.

Recently irregularities in diffusion profiles have been interpreted (10) as coming from nonequilibrium sources of gallium vacancies of the surface and inside the bulk. In our experiments these nonequilibrium conditions were not observed perhaps because our diffusions were shallower.

Weisberg and Blanc (6) solved the diffusion equation for diffusion coefficients of the form

$$D = D_{surf}\,(C/C_{surf})^m \qquad [24]$$

for $m = 1$, 2, and 3, using the Boltzmann variable transformation (11). Since the profiles are very steep and the bulk concentration C_B is much lower than C_{surf}, the function position is independent of C_B and corresponds to

$$y_j = \frac{x_j}{2\sqrt{D_{surf}\, t}} \qquad [25]$$

where $y_j = 0.808$ for $m = 1$, $y_j = 0.546$ for $m = 2$, and $y_j = 0.436$ for $m = 3$ as obtained by Weisberg and Blanc (6).

D_{surf} can be obtained from relationship [25]

$$D_{surf} = \frac{1}{4y_j^2}\left(\frac{x_j}{\sqrt{t}}\right)^2 \qquad [26]$$

$x_j/\sqrt{t}$ being the slope of the lines plotted in Fig. 3. The values of D_{surf} calculated in this way for the different temperatures are presented in Table II for $m = 2$ and 3. A new value for $m = 2.5$ is estimated by interpolation.

C_{surf} can be obtained from the experimental values of V/I and x_j, which allows $\bar{\rho}$ to be computed using Eq. [22] and considering that

$$\frac{1}{\bar{\rho}} = \frac{1}{x_j}\int_0^{x_j}\frac{dx}{\rho} \qquad [27]$$

where the expression for ρ is that reported by Gardner (12).

$$\rho(\text{ohm·cm}) = 9.85 \times 10^{11}\, C^{-0.744}\ (\text{cm}^{-3}) \qquad [28]$$

Table II. D_{surf} ($cm^2 \cdot sec^{-1}$) for different temperatures and different values of m

Temp, °C	$m = 2$	$m = 2.5$	$m = 3$
700	5.26×10^{-11}	7.10×10^{-11}	8.25×10^{-11}
750	9.83×10^{-11}	1.33×10^{-10}	1.54×10^{-10}
800	2.82×10^{-10}	3.80×10^{-10}	4.42×10^{-10}
850	7.65×10^{-10}	1.03×10^{-9}	1.20×10^{-9}
875	1.60×10^{-9}	2.17×10^{-9}	2.52×10^{-9}

Table III. y_j, $I = (1/y_j) \int_0^{y_j} (C/C_{surf})^{0.744}\, dy$, and C_{surf} values for different values of m

	$m = 2$	$m = 2.5$	$m = 3$
y_j	0.546	0.470	0.436
I	0.407	0.380	0.352
C_{surf}	1.75×10^{20} cm^{-3}	1.57×10^{20} cm^{-3}	1.57×10^{20} cm^{-3}

The expression for C_{surf} is thus

$$C_{surf} = \left[\frac{9.85 \times 10^{11}\, (I/V)/x_j}{K(1/y_j) \int_0^{y_j} (C/C_{surf})^{0.744}\, dy} \right]^{1/0.744} \quad [29]$$

Equation [29] shows that I/V must be proportional to x_j for diffusion processes performed at the same temperature and different diffusion times.

Figure 4 shows I/V *vs.* x_j. As can be observed all the experimental points can be joined by a single straight line implying that not only the surface concentration is time independent but is temperature independent too.

To obtain the value of C_{surf} the integral

$$\frac{1}{y_j} \int_0^{y_j} (C/C_{surf})^{0.744}\, dy$$

has been computed for $m = 1$, 2, and 3 from the data of Ref. [6]. A new value for $m = 2.5$ has been also estimated by interpolation. The value of $(I/V)/x_j$ is obtained from the slope of the straight line of Fig. 4. Data corresponding to $m = 2$, 2.5, and 3 is presented in Table III.

The diffusion coefficients *vs.* concentration, as reported by several authors, are plotted in Fig. 5. The values of the exponent m, deduced from the slope of the straight lines, range from 2 to 3.3. The graphic representation of Eq. [24] has also been drawn in this figure for $m = 2.5$ and $T = 850$°C using the values of C_{surf} and D_{surf} obtained in the present paper (Table IV). As can be seen curve 8 lies between the Rupprecht and Kendall curves. Since Rupprecht diffusion experiments were performed with a greater arsenic pressure than in ours and the Kendal diffusion was carried out with a lower arsenic pressure, it can be concluded that the diffusion coefficient is strongly dependent on the arsenic vapor pressure and that this parameter has to be kept under control in order to obtain good repeatability.

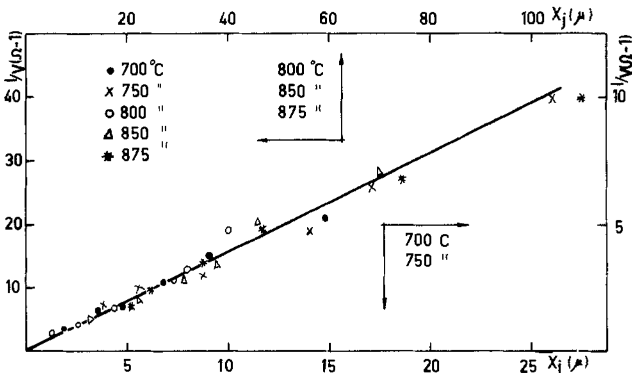

Fig. 4. Measured values of the sheet conductance as a function of the junction depth.

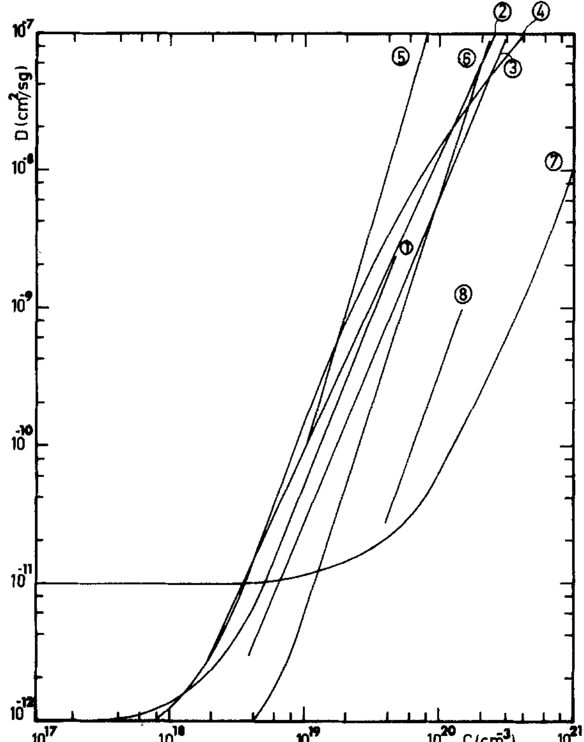

Fig. 5. Effective diffusion coefficient of Zn in GaAs after different authors: plot 1, Tuck (15); plot 2, y; plot 3, Kadhin and Tuck (16); plot 4, Chang and Pearson (7); plot 5, Pearson (17) and Kendall (3); plot 6, Kendall (3); plot 7, Rupprecht (4); and plot 8, present article. The diffusion temperatures and logarithmic slopes appear in Table IV.

Since the surface concentration is temperature independent the variation of D_{surf} (C_{surf}, T) can only be attributed to the temperature variation. This result is not in agreement with other previously reported results [13], which may be attributed to the fact that these other results were obtained under a temperature variable arsenic pressure. D_{surf} *vs.* $1000/T$ is plotted in Fig. 6 for three different values of m.

Discussion

The incorporation reaction of zinc atoms in the vapor state to solid substitutional zinc is

$$Zn(g) + V_{Ga} \rightleftarrows Zn_s^- + h^+ \quad [30]$$

The action-mass law for this reaction is

$$\frac{[Zn_s^-]p}{p_{Zn}[V^o{}_{Ga}]} = k_5 \quad [31]$$

with $p = [Zn_s^-]$, we obtain from Eq. [13] and [31]

$$[Zn_s^-] = \left(\frac{k_1 k_5}{k_3} \right)^{1/2} p_{Zn}{}^{1/2} p_{As_4}{}^{1/8} \quad [32]$$

During the diffusion process an equilibrium state exists between the zinc and arsenic vapors and the solid Zn_3As_2, so that, considering Eq. [19], Eq. [32] becomes

$$[Zn_s^-] = \left(\frac{k_1 k_5}{k_3} \right)^{1/2} k_7{}^{1/6} p_{As_4}{}^{1/24} \quad [33]$$

Table IV. Diffusion temperatures and logarithmic slopes in Fig. 5

Plot number	1	2	3	4	5	6	7	8

Slope	2.3	2.2	2.2	2.5	2.9	3.4	2.0	2.5

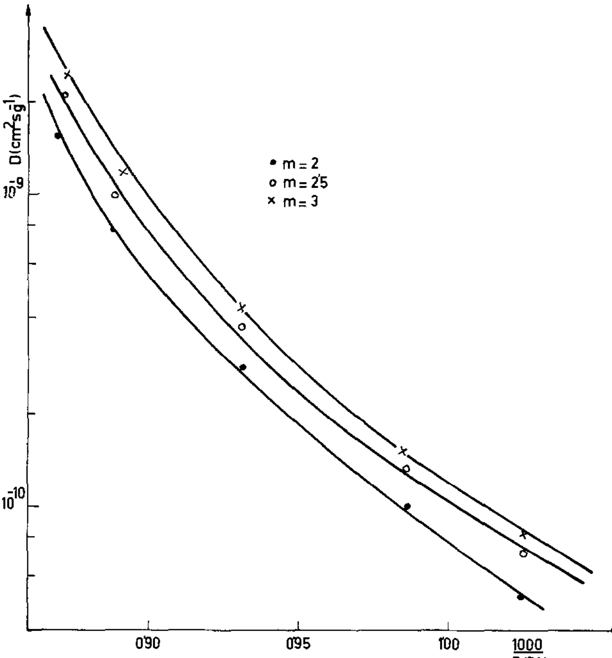

Fig. 6. Effective diffusion coefficients of Zn in GaAs vs. temperature for different values of *m*.

From this equation we observe that $[Zn_s^-]$ varies very slowly with p_{As_4}. Therefore the lack of accuracy in the arsenic pressure referred to earlier, is not important when considering Eq. [33] as the relative error is reduced by 1/24.

Since a mass-action law constant k is of the form (14)

$$k = \exp\left(-\frac{\Delta G}{kT}\right) = \exp\left(\frac{\Delta S}{k}\right) \cdot \exp\left(-\frac{\Delta H}{kT}\right) \quad [34]$$

The main dependence of k on T is given by exp $(-\Delta H/kT)$. ΔG, ΔS, and ΔH are, respectively, the increments of free energy, entropy, and enthalpy during the reaction.

Therefore the constants of Eq. [33] are (see Eq. [7], [9], [30], and [17])

$$k_1 \propto \exp\left[-\frac{H_{Ga}(g) + H_{V^oGa}}{kT}\right] \quad [35]$$

where $H_{Ga}(g)$, is the enthalpy necessary to remove a Ga atom from the GaAs surface and $H_{V_{Ga}}$ is the enthalpy necessary to generate a gallium vacancy, the value about half the Ga-As bonding energy.

$$k_3 \propto \exp\left[-\frac{H_{As_4}(g) + H_{Ga}(g)}{kT}\right] \quad [36]$$

$H_{As_4}(g)$ is the enthalpy necessary to remove an As atom from the GaAs surface and form an As_4 molecule.

$$k_5 \propto \exp\left[\frac{H_{Zn_s}(g)}{kT}\right] \quad [37]$$

where $H_{Zn_s}(g)$ is the enthalpy necessary to remove a substitutional zinc atom from a gallium site.

$$k_7 \propto \exp\left[\frac{-H_{Zn_3As_2}}{kT}\right] \quad [38]$$

$H_{Zn_3As_2}$ is the formation enthalpy of Zn_3As_2.

Substituting [35], [36], [37], and [38] in Eq. [33] we may write

$$[Zn_s^-] \propto p_{As_4}{}^{1/24} \exp \left[\frac{H_{As_4}(g) + H_{Zn_s}(g) - H_{V^oGa} - 1/3 H_{Zn_3As_2}}{2kT}\right] \quad [39]$$

Although the values of the enthalpies in expression [39] are not known, the fact that two of them are positive and the other two negative could give a very small value of the exponent in [39]. This would explain the temperature independence of $[Zn_s^-]$ experimentally observed.

As shown in Fig. 6 the diffusion coefficient increases with temperature. Regardless of the value of m, the activation energy of D increases with temperature between 1.3 and 2.6 eV, approximately, for temperatures ranging from 700° to 875°C. This variation could be explained if we consider that the interstitial zinc can simultaneously exist in single and double ionized forms. In this case the effective diffusion coefficient could be written, using a straightforward generalization of Eq. [6], as

$$D = D_s + \frac{3k_o{}^+}{n_i{}^2}\frac{[Zn_s^-]^2}{[V^o{}_{Ga}]}D_i{}^+ + \frac{4k_o{}^{++}}{n_i{}^4} \cdot \frac{[Zn_s^-]^3}{[V^o{}_{Ga}]}D_i{}^{++} \quad [40]$$

where $D_i{}^+$ and $D_i{}^{++}$ are, respectively, the diffusion coefficients of the single and double ionized forms and $k_o{}^+$ and $k_o{}^{++}$ are action-mass law constants of reaction [1] for $r = 1$ and $r = 2$, respectively. The temperature dependence of these constants are

$$k_o{}^+ \propto \exp\left[-\frac{H_{Zn_i}{}^+}{kT}\right] \quad [41]$$

and

$$k_o{}^{++} \propto \exp\left[-\frac{H_{Zn_i}{}^{++}}{kT}\right] \quad [42]$$

$H_{Zn_i}{}^+$ and $H_{Zn_i}{}^{++}$ being the increment of enthalpy in the corresponding reactions.

The difference in activation energy of the second and third terms of Eq. [40] is

$$-\Delta E_a = -E_g + (H_{Zn_i}{}^{++} - H_{Zn_i}{}^+) + (E_i{}^{++} - E_i{}^+) \quad [43]$$

where the temperature independence of $[Zn_s^-]$ has been considered and $E_i{}^+$ and $E_i{}^{++}$ are the activation energies of $D_i{}^+$ and $D_i{}^{++}$, respectively.

Since the differences in parenthesis in Eq. [43] are probably small, ΔE_a must differ very little from E_g, which in GaAs at 700°C is 1.1 eV. This value is in reasonable agreement with the experimentally found value of 1.3 eV.

Conclusions

A set of diffusions was performed at a constant arsenic vapor pressure. It was found that the junction depth increased linearly with $\sqrt{t}$ and that I/V increased linearly with x_j for each temperature implying that an equilibrium of vacancies exists in the diffusion process.

Using for the diffusion coefficient a law of the form $D = D_{surf}(T)\ [C/C_{surf}(T)]^m$, $D_{surf}(T)$ and $C_{surf}(T)$ were obtained from experimental data. $C_{surf}(T)$ was found to be temperature independent and this fact is discussed in terms of the interstitial-substitutional model. On the other hand $D_{surf}(T)$ increases exponentially with $1/T$ through an activation energy which varies between 1.3 and 2.6 eV for temperatures ranging from 700° to 875°C.

The behavior of D_{surf} *vs.* T can be attributed to a diffusion of interstitial zinc mainly in its doubly ionized form for the lower temperatures and in its singly ionized form for the higher ones. Therefore the exponent m changes from 3 to 2 when the temperature increases.

LIST OF SYMBOLS

D	effective diffusion coefficient
D_i	diffusion coefficient of interstitial zinc
D_s	diffusion coefficient of substitutional zinc
D_{surf}	effective surface diffusion coefficient
k_i	mass-action law constants
$[Zn_s^-]$	substitutional zinc concentration
p_{As4}	partial arsenic pressure, mm Hg
m_{ZnAs2}	amount of $ZnAs_2$ per unit of volume to obtain a given partial arsenic pressure, mg/cm^3
C	impurity concentration
C_{surf}	impurity surface concentration
$H_{Ga}(g)$	enthalpy to remove a Ga atom from the GaAs surface
$H_{V_{Ga}}$	enthalpy to generate a gallium vacancy
$H_{As4}(g)$	enthalpy to remove an arsenic atom from the GaAs surface
$H_{Zn_s}(g)$	enthalpy to remove a substitutional zinc atom from a gallium site
$H_{As_2Zn_3}$	formation enthalpy of As_2Zn_3
D_i^+	diffusion coefficient of single ionized zinc
D_i^{++}	diffusion coefficient of double ionized zinc
$H_{Zn_i}^+$	incremental enthalpy of Eq. [1] for $r = 1$
$H_{Zn_i}^{++}$	incremental enthalpy of Eq. [1] for $r = 2$
ΔE_a	incremental activation energy
E_i^{++}	activation energy of D_i^{++}
E_i^+	activation energy of D_i^+

Raman Scattering Spectroscopy Applied to the Study of Chemical Vapor Deposition Systems

T. O. Sedgwick* and J. E. Smith, Jr.

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Gas phase Raman scattering spectroscopy is being used as a new tool to study chemical processes taking place at high temperatures in chemical vapor deposition (CVD) systems. This technique allows measurement of changes in species concentration as well as gas temperature with spatial resolution of 0.1-0.5 mm without perturbing the CVD system. Studies of the decomposition of NH_3 and SiH_4 in a typical CVD system are presented as an example of the application of this technique. Measurements of NH_3 concentration profiles, both normal and parallel to an rf-heated susceptor in H_2-N_2 gas mixtures, are presented. Attempts to measure SiH_4 concentration profiles were thwarted by fluorescence from a trace impurity in the same spectral region.

Detailed understanding of gas phase chemical reactions important in CVD systems has been severely hampered by the lack of a technique for the detection of molecular vapor species, and measurement of their concentration and their concentration gradients in the heated zone of a CVD reactor. Similarly, until recently there has been no satisfactory technique for the measurement of temperature in a highly nonisothermal situation such as occurs in an rf-heated CVD reactor. Deposition rate and mass balance measurements combined with equilibrium thermodynamic calculations can sometimes give enough information to allow characterization of an over-all reaction as input mass transport or kinetically limited. However, because of the lack of local concentration and temperature information, little is known about the details of the chemical reactions taking place. The existence of intermediate reaction products, the understanding of the variation of deposition rate as a function of position in the reactor, and the acquisition of quantitative kinetic and mass transport data depend in part upon being able to measure concentration and temperature profiles within a reactor.

The recent application of mass spectrometry to sample gases at elevated temperatures is beginning to yield important information about the species present in open tube CVD systems operated at atmospheric pressure (1). However, the mass spectrometric technique requires the use of a capillary-like sampling probe. The probe itself disturbs the flow of gases locally in a laminar flow reactor and the necessary expansion of the gas within the probe gives rise to some uncertainty as to whether the molecules reaching the spectrometer are representative of the gas composition in the reactor. U.V. and infrared absorption spectroscopy have been used to measure chemical equilibria at elevated

Key words: light scattering, Si deposition, NH_3, $SiCl_4$, gas phase chemical reaction.

temperatures, but the inability to sample a small, well-defined sample volume as a function of position in the reactor, which may have a very nonhomogeneous chemical composition, limits the utility of these techniques. Possible excitation of the gas molecules in u.v. spectroscopy and the interference of the furnace infrared radiation in infrared spectroscopy are also problems. Temperature profiles in a CVD reactor measured by thermocouples have not been reported on in detail presumably because, once again, the probe (thermocouple) disturbs the local gas flow, and because radiation and conduction effects may be large and are difficult to evaluate.

Raman scattering has unique advantages for the study of gases and has developed rapidly in the last few years with the advent of the laser. It has been used primarily for molecular structure and bonding studies at room temperature (2, 3). However, it has also been used for molecular structure studies at high temperature, and for qualitative studies of chemical equilibria in an isothermal cell up to 1000°C (4-7). The use of Raman scattering as an analytical tool for species identification in gas mixtures and concentration measurements for process control, pollution monitoring, or atmospheric composition has been proposed, and some preliminary data is available (8-13). Similarly, the use of Raman scattering to measure gas temperature has been proposed, but until recently (13-14) no substantial use of the technique has been reported. In the present study we have used Raman scattering to determine species concentration and temperature as a function of position in a CVD reactor. In order to achieve the sensitivity and resolution needed it has been necessary to use more elaborate equipment than has been used in the above-cited studies. We will describe this apparatus below.

The properties of Raman scattering which may be used to advantage in the detection of molecules in the hot gas of a CVD reactor are:

(*i*) The Raman spectrum is unique for a molecular species and is usually composed of several narrow ($<< 50$ cm^{-1} wide) peaks.

(*ii*) A sample volume of gas is analyzed *in situ* at operating temperature and pressure.

(*iii*) Positioning of the detector at right angles to the laser beam allows the sampling of a small volume ($\sim$ 1 mm^3 is easily achieved) which can be moved throughout the reactor volume.

(*iv*) Gas temperature can be measured simultaneously by a Raman technique.

(*v*) The Raman spectrum is detected in a spectral region away from the peak of the black-body radiation emitted by the reactor, reducing interference from this source.

In this paper, data will be presented showing concentration profiles of NH_3 in a H_2-N_2 carrier, and attempts to measure SiH_4 concentration profiles in various reacting environments will be discussed.

Raman Scattering

The Raman effect (15) is the inelastic scattering of light. Photons are scattered with energy shifted from that of the incident photons, and the energy difference is taken up by quantum transitions of the scattering system. In this paper, where the light is Raman scattered by a molecular gas, the transitions measured are between quantized molecular vibrational states. (The discussion could equally well be applied to transitions between rotational or mixed rotational-vibrational states, but the vibrational transitions have proved more useful in the applications we have made of the technique.)

The intensity, I, of Raman scattered light is given by the expression

$$I = K\,(\omega_L \pm \omega_V)^4\, I_L \rho_i \sigma_i(\omega_V)\, G_\pm(\omega_V, T) \qquad [1]$$

where ω_L is the frequency of the incident light, ρ_i the number density of the gas, $\sigma_i(\omega_V)$ the Raman cross section for the vibrational transition of energy ω_V of molecules of type identified by the subscript i, I_L is the incident light intensity, K is a proportionality constant dependent upon measurement system geometry and response, and $G_\pm$ (ω_V, T) is a statistical factor described below. Although the scattered light is shifted both down (Stokes scattering) and up (anti-Stokes scattering) in energy, we have used only Stokes scattering for concentration measurements, and anti-Stokes scattering will not be considered further here. For Stokes scattering, the minus sign is appropriate in the factor $(\omega_L \pm \omega_V)^4$ and G_- is

$$G_-(\omega_V, T) = 1 + \frac{1}{e^{\hbar\omega_V/kT} - 1} \qquad [2]$$

where $\hbar$ is Planck's constant, k Boltzmann's constant, and T is temperature.

Several qualitative statements can be made about Raman scattering based on these equations. Raman cross sections are very small, so in order to produce an easily detectable signal intensity, I, it is desirable to excite a Raman spectrum with the most intense light source possible, a laser. For the same reason the factor $(\omega_L \pm \omega_V)^4$ in Eq. [1] dictates the use of the highest frequency laser possible. (In general, $\omega_L >> \omega_V$.) More precisely, the factor $I_L(\omega_L \pm \omega_V)^4$ should be maximized, since there is a trade-off between I_L and ω_L in the choice of a suitable laser. An argon ion laser operating at wavelength of 4880Å (a deep blue light) seems to be the best available choice at this time.

The Raman scattered light is scattered in all directions relative to the exciting laser beam, with only a slow, smooth dependence on relative direction. The optical detection system is located on a line normal to the laser beam, so it is possible to define a small, easily located volume for measurement. This feature makes it possible to make gradient measurements on a fine spatial scale. It also enables measurements to be made in the hot part of a reactor, without being affected by temperatures or concentrations near the walls.

The Raman cross section is generally independent of exciting wavelength. The exception to this is when either the incident or scattered photons are in resonance with (equal in energy to) one of the allowed electronic transitions of the molecule under study. This is called resonance Raman scattering or resonance fluorescence scattering. In this case the cross section can be enhanced by five or six orders of magnitude with a resulting rise in sensitivity of the measurement. Resonance light scattering is not important for most gases of interest, since the allowed transitions lie above the range of energies covered by usefully powerful lasers. However, resonance fluorescence has been observed in the Si-Cl system (13) and is due to a high temperature Si-Cl compound, probably $SiCl_2$. In the present work we have observed a similar signal which is associated with the presence of a trace impurity in the SiH_4. This will be discussed below.

The Raman cross section for most molecules is very small and does not vary by more than an order of magnitude for most common gases. Table I shows the absolute cross section for N_2 and the relative cross section and scattered energy shift for the most useful vibrational transitions of some common gases. Raman scattering is roughly equally sensitive for most common gases. In the present system, described below, the detection sensitivity for gases at room temperature at 1 atm total pressure is about 10-100 ppm. Since spectral peaks are < 50 cm^{-1} wide, it is easy to see from Table I that at least several species can be detected simultaneously.

In order to obtain chemical composition data in a reacting system with a temperature gradient, we have reduced the raw data in the following manner. The number density, ρ, of a molecular reactant or product species is obtained directly from the Raman spectrum using Eq. [1]. In a system with a temperature gradient,

Table I. The Raman scattering cross sections of various gases relative to that of N_2. The incident light of 5145Å was vertically polarized. The Raman scattered light was measured at 90° in the horidontal plane, and was not analyzed for its polarization (15).*

the density will change as a function of temperature variation according to the ideal gas law even in the absence of chemical reactions. Therefore, in a non-isothermal system it is useful to obtain a measure of gas composition or relative concentration, such as mole fraction or partial pressure, which is independent of temperature or ideal gas law effects for use in mass transport or kinetic calculations. The composition of a gas mixture is obtained by dividing the number densities of its constituent gases by the density of a constituent whose relative concentration in the mixture does not change, but whose number density is governed by the ideal gas law.

The mole fraction, X_A, of species A in a gas mixture containing a component B whose relative concentration in the mixture does not change can be approximated, in the limit $X_A << X_B$, by

$$X_A(T) = G' \frac{I_A(T)}{I_B(T)} \frac{I_B(T_o)}{I_A(T_o)} X_A(T_o) ,$$

$$G' = \frac{G_-(\omega_{VB}, T)}{G_-(\omega_{VA}, T)} \frac{G_-(\omega_{VA}, T_o)}{G_-(\omega_{VB}, T_o)} \quad [3]$$

where I_A and I_B are the measured Raman scattering intensities of species A and B, and must be measured at the desired point in space both at temperature T and at some convenient reference temperature T_o. T_o is usually room temperature, but may be any temperature below which the gases do not react and change composition from the known input value $X_A(T_o)$. The factor G' is easily calculated knowing the measured ω_{VA}, ω_{VB}, T, and T_o values. For many cases of relatively low temperature and large ω_V, the term $e^{\hbar\omega V/kT} >> 1$, and the functions G_- and hence G' may be approximately 1. By using Eq. [3] to obtain the relative concentration, errors due to variations in window transmission are also eliminated.

Experimental Apparatus and Procedures

Optical equipment and measuring technique.—A schematic diagram of our experimental apparatus is shown in Fig. 1. The laser is a Spectra Physics Model 170 argon ion laser operating at a peak intensity, feedback stabilized, of 9W with photon energy of 20,492 cm^{-1} (wavelength 4880Å). This is chopped at a frequency of 108 Hz. The scattered light is collected with a f/1.5, 135 mm focal length Soligor lens located about 20 cm from the beam with its axis normal to the beam. The lens images a segment of the laser beam into the entrance slit of a Spex Model 1301 f/7 double monochromator with 1200 groove/mm gratings blazed at 5000Å. The monochromator is operated with slits 300-500 μm wide, corresponding to an instrumental resolution of 11-21 cm^{-1}.

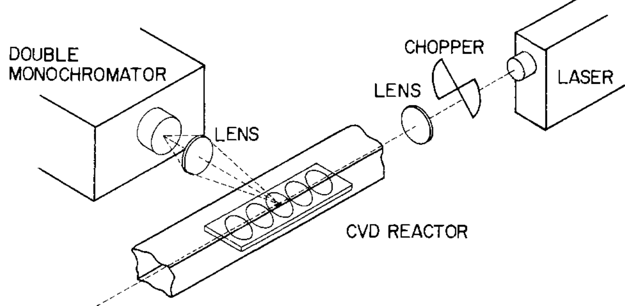

Fig. 1. Schematic of Raman scattering ana chemical vapor deposition apparatus.

Light from the monochromator is focused on the cathode of a RCA C31034 photomultiplier tube (PMT) operated at −20°C. The signal from the PMT is analyzed by photon counting techniques with a SSR Model 1110 digital synchronous computer. This instrument also functions as a digital lock-in amplifier operating synchronously with the laser chopper, accumulating signal plus noise during the time the laser is on and noise (*i.e.*, black-body radiation, PMT dark count, stray room light, etc.) during the "off" periods; the difference is computed by the instrument and recorded on a strip chart recorder.

To measure the concentrations of SiH_4 and NH_3, the Raman intensity, I, was measured by scanning through the principal scattering peak and integrating the signal to get the peak area. From this area was subtracted a a background which was obtained from an identical scan, where the gas in question was not flowing in the reactor. Only at the lower concentrations was the background a significant fraction of the total signal. Table II shows the principal peak position, typical scan ranges, and counting times used for a slit width of 500μ. The reference gas used in the concentration measurement and designated as B in Eq. [3] was N_2; the amount of N_2 produced by decomposition of NH_3 was assumed negligible compared with the N_2 in the carrier gas.

CVD reactor and gas flow conditions.—The reactor, shown in Fig. 2, is a horizontal open tube of cross section 3.5 × 3.5 cm with a flat, rf-heated, graphite susceptor 1.1 × 3.4 × 17.0 cm in the bottom of the tube serving as the heat source. The system is open in the sense that a dilute mixture of SiH_4 and/or NH_3 in a carrier gas of N_2 or a H_2-N_2 mixture is constantly flowing through the tube. The total flow of gas is 3.9 liter/min through the tube which has 8.4 cm^2 of unobstructed cross section, resulting in a room temperature average gas velocity of 7.7 cm/sec. Flow visualization experiments using TiO_2 "smoke" in the tube showed that H_2 gives a very smooth laminar flow, while N_2 results in a rather unstable flow due to thermal convection. Because we wanted a relatively large concentration of both H_2 (to promote laminar flow) and N_2 (to use as reference gas) we chose a carrier gas mixture of 50% H_2-50% N_2 in all but one experiment. This mixture gives a relatively smooth laminar flow with only a slight flutter in the stream lines appearing over the last half of the susceptor.

The NH_3 and SiH_4 were obtained from Matheson. The SiH_4 was a 5% mixture in N_2 (Fig. 5, data only), or a 10% mixture in H_2 with a trace impurity of $SiCl_4$ as

Table II. Experimental parameters for composition measurements

Species	Raman shift (cm^{-1})	Scan range (cm^{-1})	Scan time (min)
N_2	2327	40	6.67
NH_3	3332	60	10
SiH_4	2187	60	10

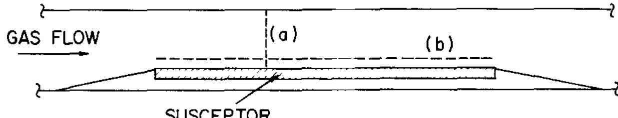

Fig. 2. Schematic of reactor. Data shown in Fig. 3-6 were taken at positions along dashed lines (a) 5.3 cm from front of susceptor, and (b) 0.25 cm above susceptor. Ramps are located at the leading and trailing ends of the susceptor to encourage the smoothest possible flow.

measured by Raman scattering. The N_2 was boil-off from liquid N_2.

The susceptor was graphite and became coated with polycrystalline Si or silicon nitride during the experiments. The walls of the reactor tended to become coated with deposit after running several hours, depending on the input concentration of SiH_4, the gas composition, and the flow rate. Under some experimental conditions where SiH_4 was present, it was found that the laser beam was made visible in a region over the susceptor by highly scattering particles, presumably consisting of polycrystalline Si or silicon-nitrogen compounds.

The concentration gradients in Fig. 3-6 were measured along the dashed lines as indicated in Fig. 2. The temperatures referred to in the figures and in the text were obtained with an optical pyrometer calibrated at the melting point of Ge and always refer to the temperature of the susceptor surface at the position (a), (in Fig. 2, 5.3 cm from the front of the susceptor). Gas temperature gradients have been measured by the Raman technique for this same reactor and have been published elsewhere (14).

Results and Discussion

Ammonia decomposition.—Figure 3 shows the measured NH_3 mole fraction as a function of vertical position [dashed line (a) in Fig. 2] above the susceptor. The input gas was 46% H_2, 46% N_2, and 8% NH_3 at a susceptor temperature of 750° and 950°C. The relative concentration of N_2 was assumed constant for the calculations in Fig. 3. The decrease in NH_3 mole fraction as the susceptor is approached at both temperatures is presumed due to the decomposition of NH_3 according to

$$NH_3 \rightleftarrows 3/2H_2 + 1/2N_2 \quad [4]$$

The logarithms of the equilibrium constants for Eq. [4] at 1200° and 1000°K are 3.233 and 3.716, respectively, and so at thermal equilibrium in the temperature range studied (17) essentially complete decomposition of NH_3 is expected. In fact, only slight decomposition of NH_3 at 750°C is observed, indicating that the reaction is kinetically limited. The 950°C data show, however, complete decomposition at the susceptor surface. Without more information it cannot be determined whether the decomposition takes place in the gas phase or at the surface or both. Thus, the shape of this curve could be determined by both mass transport and kinetic factors. Unlike the 750°C case, the curve at 950°C does not extrapolate to the indicated input concentration of 8.2% mole fraction NH_3. Although the difference is within the observed scatter of the data, it is expected that there will be some depletion of NH_3 far above the susceptor along its length.

Figure 4 shows the concentration of ammonia as a function of distance along the susceptor [dashed line (b) in Fig. 2]. The susceptor surface was at 950°C in the center, but it exhibited a considerable decrease in temperature at each end, particularly the front or gas inlet end. The decrease in concentration of NH_3 as a function of distance indicates a depletion of reactant as would be expected from the comments on Fig. 3 above. It should be mentioned, however, that the Raman measurements give some evidence, not shown here in detail, that reactant concentrations and temperatures are effected by subtle changes in reactor geometry, wall cooling rates, or possibly even changing catalytic properties of the susceptor surface. For example, the NH_3 concentration at the intersection point (5.3 cm along and 0.25 cm above the susceptor) of the two curves, Fig. 3 and Fig. 4, are not the same. This may have been due to the fact that different reactors and susceptors were used in these two experiments.

Silane decomposition.—Silane was observed to decompose rapidly above 500°C in a carrier gas of pure N_2 as indicated by polycrystalline deposits of Si on the susceptor and quartz tube walls. Figure 5 shows the apparent mole fraction SiH_4, calculated from Eq. [3], as a function of vertical position above the susceptor at about 650°C. However, the apparent increase in SiH_4 mole fraction, as the susceptor is approached, occurred at the same time as a qualitative change in the spectrum indicating the presence of a new gas species. At first we thought the new species to be disilane because of the similarity of the new spectrum with that of disilane in the 2140-2220 cm^{-1} region. Subsequent measurements on the Si-Cl and Si-Cl-H systems, however, revealed a Si-Cl compound (probably $SiCl_2$) which has a spectrum very similar to the presently observed species throughout the spectral range studied (13). $SiCl_2$ is observed to fluoresce rather than Raman scat-

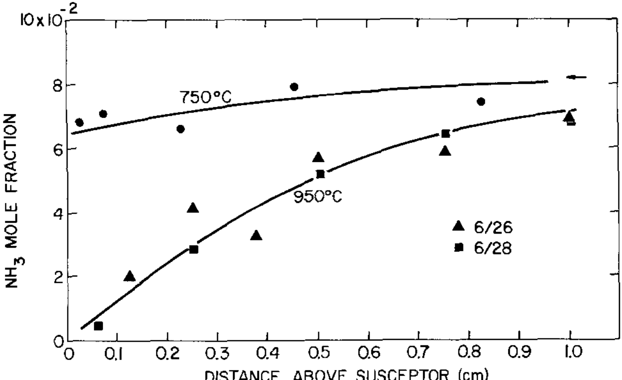

Fig. 3. NH_3 concentration *vs.* distance above susceptor (Fig. 2, line a) at 750° and 950°C.

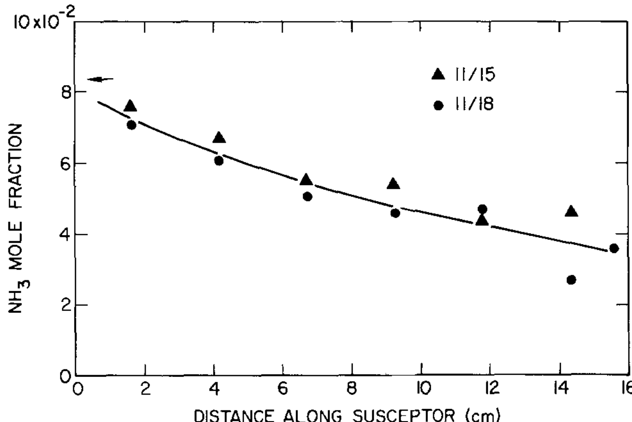

Fig. 4. NH_3 concentration *vs.* distance along susceptor (Fig. 2, line b).

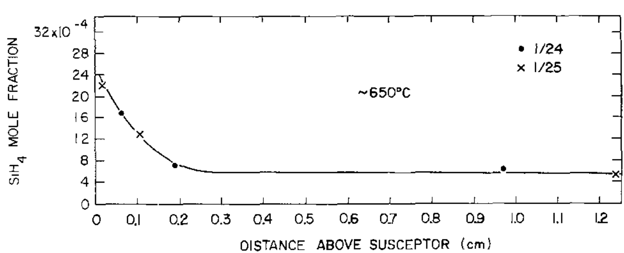

Fig. 5. Apparent SiH_4 concentration *vs.* distaance above susceptor (Fig. 2, line a) in a N_2 ambient at ~ 650°C

ter, and therefore can be seen with at least a factor of 10^3 greater sensitivity than a Raman scattering molecule. Although there was no intentional introduction of Cl into the present system, there is an impurity of $SiCl_4$ as well as possibly other Si-Cl-H compounds in commercial SiH_4. Thus, $SiCl_2$ is apparently produced from the $SiCl_4$ impurity in the hot gas and, because it fluoresces, it dominates the spectrum and makes concentration measurements of SiH_4 impossible in its presence. The apparent increase in signal as the susceptor is approached occurs because of the strong fluorescence.

Reaction of SiH_4 + NH_3 in H_2-N_2.—Figure 6 shows the mole fraction of SiH_4 in a 46% H_2, 46% N_2, 8% NH_3 mixture as a function of position above the susceptor for three different temperatures. This is a gas mixture which is commonly used to grow silicon nitride films. At both 750° and 850°C the observed mole fraction of SiH_4 corresponds to the input concentration 0.065%, and does not change right up to the susceptor. Thus H_2, and we suspect also NH_3, suppresses formation of $SiCl_2$ as well as the decomposition of SiH_4 at least up to 850°C.

At 950°C the "hump" in the mole fraction SiH_4 curve from 0.1 to 0.6 cm again correlates with the appearance of the $SiCl_2$ fluorescence spectrum. The data curve decreases to zero at the susceptor surface, indicating that the $SiCl_2$ is produced in the gas phase by a homogeneous gas reaction. Apparently both the $SiCl_2$ as well as the SiH_4 concentration is reduced to very small values as the susceptor is closely approached. The slightly higher-than-input level of the signal above 0.6 cm is presumably caused by the diffusion of $SiCl_2$ out into the bulk gas.

Conclusions

For the first time data is presented on chemical concentration gradients in a CVD reactor. These results, along with previously reported Raman gas temperature measurements (14), demonstrate the value of Raman spectroscopy for the detailed characterization of CVD systems. The results on SiH_4 and NH_3 decomposition in various ambients are preliminary, but they do show that it is possible to observe a chemical-kinetic limited reaction (NH_3 decomposition), and detect a reaction intermediate (a Si-Cl compound formed by the reduction of the trace contaminant $SiCl_4$). Clearly the possibility of sensing a fluorescing molecule, in this case the Si-Cl compound which is probably $SiCl_2$, makes the detection of the other major gas species more difficult. At the same time, the great sensitivity for detecting a fluorescing species will make this technique potentially very powerful for probing systems where the fluorescing species is the main species of interest.

The technique is limited whenever reactions deposit opaque films on the viewing window. Data acquisition is relatively slow, requiring 5-20 min per point, and measurements above 1000°-1100°C will require either longer counting times, changes in reactor design, or improvement in the optical equipment. Because the system must be at steady state for data acquisition, a stable laminar flow is necessary.

In conclusion it appears that Raman scattering offers considerable potential for the study of high temperature CVD and other chemical reactions.

Electrolytic Etching of Boron Phosphide

T. L. Chu,* M. Gill,† and Shirley S. Chu

Institute of Technology, Southern Methodist University, Dallas, Texas 75275

ABSTRACT

The electrolytic etching of boron phosphide in various electrolytes was investigated. Conditions to polish p-type boron phosphide were determined, but an insoluble film tended to form on the surface of n-type material. For electrode potentials near and above 1V, the removal of p-type material proceeded at a rate more than 100 times faster than the removal rate of n-type material. This difference in the etch rates allows selective removal of material, and mesa-type p-n homojunction and boron phosphide-silicon carbide heterojunction structures were fabricated.

Etching and polishing techniques are important processes for the study of semiconductors and for semiconductor device fabrication. For elemental semiconductors and some of the compound semiconductors, convenient chemical etchants are available for surface preparation and for certain types of selective etching. However, there are materials which are either inert to ordinary chemical etchants or are attacked very irregularly. In the case of boron phosphide, the only known etchants are fused alkalis at 400°-500°C and hydrogen chloride near 1100°C. The former etchant attacks boron phosphide very nonuniformly, and with the latter etchant, the decomposition of material at 1100°C is a problem. As a consequence, electrolytic etching may be the most useful etching technique for boron phosphide.

The purpose of this paper is to describe the experimental results obtained from an investigation of electrolytic etching of boron phosphide. Both p-type and n-type materials were studied, although more extensive data were obtained from p-type boron phosphide. The difference in the etching behavior of (111) and ($\bar{1}\bar{1}\bar{1}$) faces was investigated. Also, electrolytic etching was used as a selective etching process in the fabrication of junction devices.

Experimental

Electrolytic etching studies were carried out with both n-type and p-type boron phosphide platelets, which were grown by recrystallization from a nickel phosphide solution (1). Boron phosphide crystals up to $7 \times 4 \times 3$ mm have been obtained recently (2) by the accelerated container rotation technique (3,4). The main faces of the platelets have a (111) orientation; usually one face is smooth and the other face is rough. The two faces could also be distinguished by chemical etching in a 3:1 molten mixture of sodium hydroxide and sodium peroxide at 400°-500°C. Dislocation etch pits were observed on the smooth face and not on the other. It is well established that the chemical etching of other III-V compound semiconductors produces etch pits on the Group III face and not on the Group V face (5). If the etching behavior of boron phosphide is similar to that of other III-V compound semiconductors, then the face which developed dislocation etch pits on the boron phosphide crystals is the boron, or the (111), face. The room temperature carrier concentration of the solution-grown boron phosphide crystals, determined by measurements on Schottky barrier diodes, was on the order of 10^{18} cm^{-3} or above (6).

Prior to electrolytic etching, rough faces of the boron phosphide platelets were polished with 0.3 μm alumina abrasive; the as-grown smooth faces were etched without mechanical polishing. Because of the high carrier concentration in solution-grown crystals, ohmic contact to the back side of the boron phosphide crystals was readily made by electroless nickel plating followed by an annealing in hydrogen or argon at 800°-850°C for 1 hr. For the etching process, Apiezon W wax was used as a mask so that only the desired region of the crystal surface was exposed to the electrolyte. Silicon monoxide and silicon dioxide were also used for masking purposes and were found to be more reliable than Apiezon W wax for controlling small area geometries in the fabrication of mesa structures.

A schematic of the electrolytic cell used for the etching and polishing of boron phosphide is shown in Fig. 1. The current density-potential relationships were determined, and the crystal-electrolyte potential difference was measured relative to a calomel reference electrode. Measurements were made both in the dark and with illumination. The solution was continuously agitated by nitrogen bubbled into the electrolyte near the anode. A uniform removal of material without undercutting of etching masks was obtained with the boron phosphide platelets near the axis of a cylindrical molybdenum cathode, as shown in Fig. 1. A simple parallel plane electrode configuration was used for some of the basic measurements. The electrolytes investigated were aqueous solutions of common alkalis and acids, and a few chemical etchants previously used for other III-V semiconductors. With these techniques, mesa-type heteroepitaxial boron phosphide-silicon carbide junction and boron phosphide p-n junction structures were isolated.

Results

Typical current density-potential relationships and rest potential values for p-type and n-type boron phosphide crystals in a 10% sodium hydroxide solution at room temperature in the dark are shown in Fig. 2.

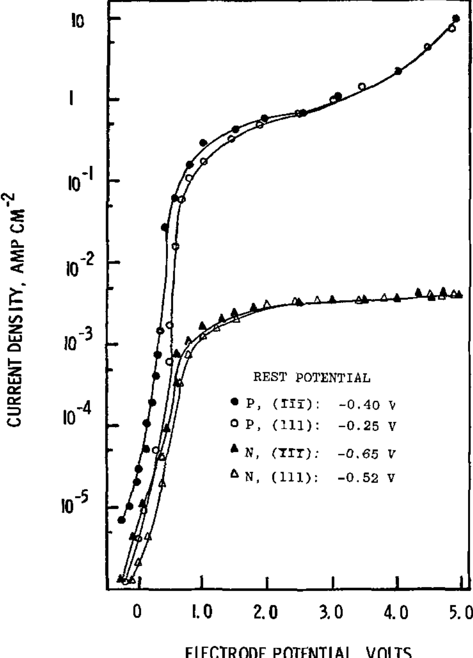

Fig. 2. Current density *vs.* electrode potential for (111) and ($\bar{1}\bar{1}\bar{1}$) faces of n-type and p-type boron phosphide in a 10% NaOH solution in the dark.

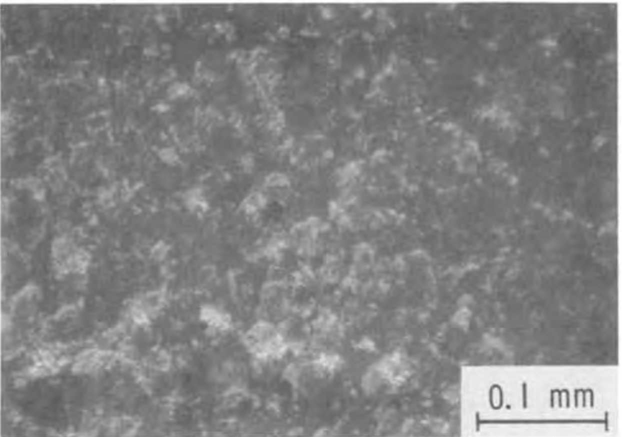
As expected, current saturation was observed in all of the experiments with n-type boron phosphide crystals. The p-type material was readily dissolved, and it drew much larger currents than n-type material. At low anode potentials, the ($\bar{1}\bar{1}\bar{1}$) face of both n-type and p-type boron phosphide drew larger current densities at a particular electrode potential than did the (111) face. At anode potentials higher than about 1V, the difference between the currents drawn by the (111) faces and the ($\bar{1}\bar{1}\bar{1}$) faces is very small.

The rest potentials of n-type and p-type boron phosphide were measured in a number of electrolytes in addition to sodium hydroxide, and the rest potential for n-type crystals was always more negative than the rest potential for p-type crystals. A similar relationship was reported for gallium phosphide rest potentials (7). For both n-type and p-type boron phosphide, the rest potential was more positive for the (111) face. This polarity effect has also been observed for a number of other III-V compound semiconductors, and the Group III element face was reported to have a more positive rest potential (5, 7, 8). This observation agrees, therefore, with the tentative assignment of the smooth (111) face of the crystals to the boron face.

The following observations were made specifically from the etching of p-type boron phosphide. Twin lines and other gross crystallographic defects were revealed with current densities of 0.01 A/cm^2 or lower. For current densities between 0.01 and about 0.2 A/cm^2, etch pits formed on the faces. At larger current densities, above about 0.5 A/cm^2, the (111) and ($\bar{1}\bar{1}\bar{1}$) faces had different etching characteristics. On the (111) face, a film tended to form; this film was, however, easily removed by rinsing with water. The texture of the etched (111) face was rough as shown in Fig. 3a. On the ($\bar{1}\bar{1}\bar{1}$) face, however, there was no evidence of film formation, and a smooth, mirrorlike surface finish shown in Fig. 3b was produced. These observations are very similar to the results reported for gallium phosphide (7); at high current densities, the gallium face developed a rough texture and the phosphorus face became smooth. A few experiments were carried out with other electrolytes, and the etching characteristics of p-type boron phosphide in potassium hydroxide solutions and common acids were found to be similar to the characteristics obtained with the use of sodium hydroxide solutions.



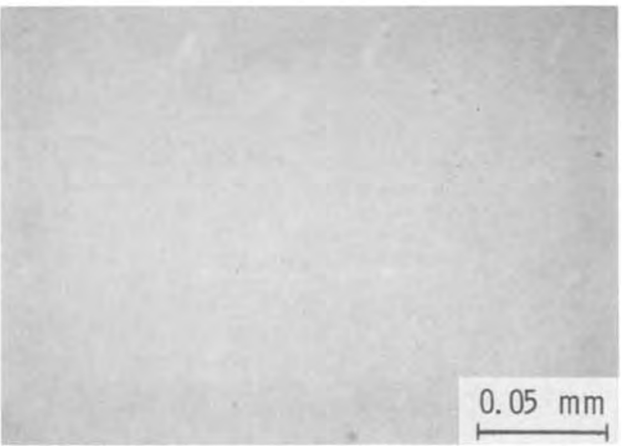


Fig. 3. Electrolytically etched surfaces of p-type boron phosphide with a current density of 0.5 A/cm^2: (a, top), (111) face; (b, bottom), ($\bar{1}\bar{1}\bar{1}$) face.

In contrast to the etching of p-type boron phosphide, the etching of n-type boron phosphide was complicated by the formation of surface films at current densities higher than about 10^{-3} A/cm^2. At this current density, a film was observed with a 15 min etching period; with higher current densities, the film grew faster. The film could not be completely removed from the surface of the crystal even with ultrasonic agitation during etching, and the film was not soluble in hot alkali mixtures. X-ray measurements indicated that the films were predominantly boron phosphate (BPO_4).

With current densities above 1 A/cm^2 through n-type boron phosphide, a porous, brittle, fiberlike film formed on the surface. Reflection electron diffraction examination showed that these films were monocrystalline boron phosphide of (111) orientation. It was concluded, therefore, that anodic disintegration of n-type boron phosphide at high current densities occurred preferentially in <111> directions, and a surface layer which is a skeleton of the original crystal remained. Similar results were obtained from an etching study of gallium arsenide (9).

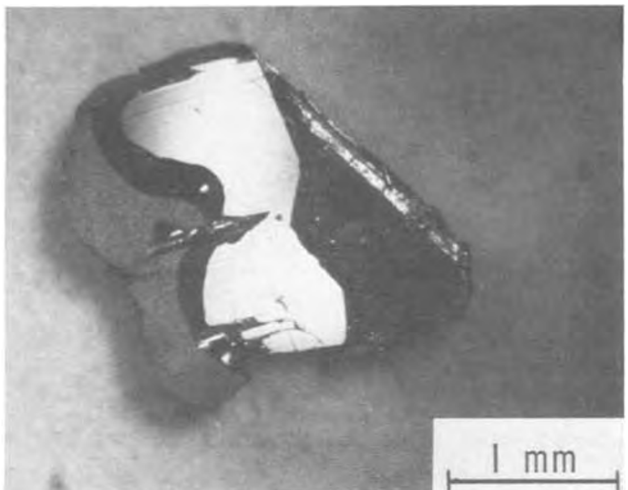
Various approaches were investigated to determine the conditions for the electrolytic polishing of n-type boron phosphide. A variety of electrolytes in addition to sodium hydroxide were used without success; an insoluble film formed in all cases. The effect of illumination on the etching of n-type boron phosphide was also investigated. A 650W incandescent lamp with a color temperature of 3400°K was used as the light source, so that a significant portion of the lamp output had an energy greater than the bandgap of boron

phosphide. A negative shift of about 0.2V or more of the rest potentials was observed with illumination, but very little difference in the cell currents was found. Consequently, the anodic dissolution behavior was not significantly affected by the illumination. N-type boron phosphide was successfully etched without film formation only under one condition: the n-type material exposed to the electrolyte was one side of a shallow, forward biased p-n junction. This observation supports the well-known fact that a supply of holes is required for electrolytic etching (10,11).

Selective Etching

It can be seen from Fig. 2 that the current density at, for example, 3V is about 300 times higher for p-type boron phosphide than for n-type material. This current density ratio corresponds approximately to the etch rate ratio between p-type and n-type boron phosphide, suggesting the possibility of selective removal of p-type material from boron phosphide p-n structures. The preferential etching of p-type material was initially investigated with a number of solution-grown boron phosphide crystals with built-in p-n junctions on a crystal face. Selective removal of p-type boron phosphide was obtained with current densities between 0.1 and 10 A/cm^2. To prevent the formation of a surface film on the n-type regions, either very low current densities with a long etching time or very high currents for a very short time were used. Figure 4 shows one solution-grown crystal which was selectively etched; the p-type region developed a mirror-like finish, and no removal of n-type material was observed. With low current densities and short etching times, electrolytic etching was also used to delineate thin epitaxially grown p-n junctions in boron phosphide.

Since electrolytic etching is selective, it can be used to produce mesa junction structures in boron phosphide. Mesa diodes were formed with both homoepitaxially and heteroepitaxially grown junctions. Both n-type and p-type layers of boron phosphide were deposited on solution-grown boron phosphide crystals and on hexagonal silicon carbide platelets by the thermal reduction of a boron tribromide-phosphorus trichloride mixture (12). To isolate the mesas, either silicon dioxide or silicon monoxide was used to define the mesa pattern, and the exposed boron phosphide was electrolytically removed. In the preparation of the boron phosphide-silicon carbide heterojunctions, a sharp decrease in the current indicated the complete removal of the boron phosphide layer exposed to the electrolyte. At that stage, the electrolyte was replaced by a 1*N* solution of hydrofluoric acid, and a slight anodic etching of the silicon carbide was carried out. This latter step improved the characteristics of the mesa junctions. The removal of n-type boron phosphide on silicon carbide occasionally required mechanical means to remove a surface film near the edge of the mesa. Figure 5 shows photomicrographs of two mesa junctions fabricated by anodic dissolution of boron phosphide. Figure 5a shows a homojunction made by selective removal of a portion of an n-type



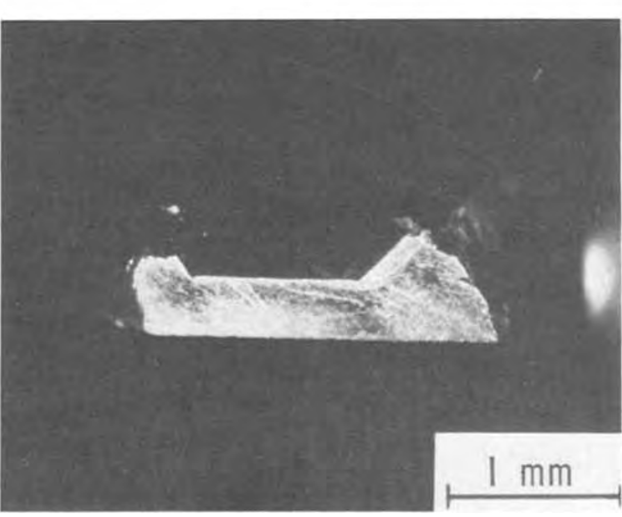


Fig. 4. Photomicrographs of an electrolytically etched boron phosphide crystal which has both n-type and p-type regions. Etching was done at 10 A/cm^2 for 10 sec: (a, top), top view; (b, bottom), cross-sectional view.

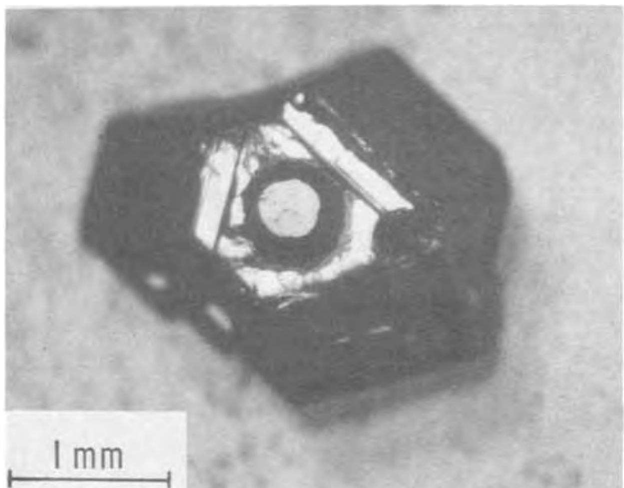

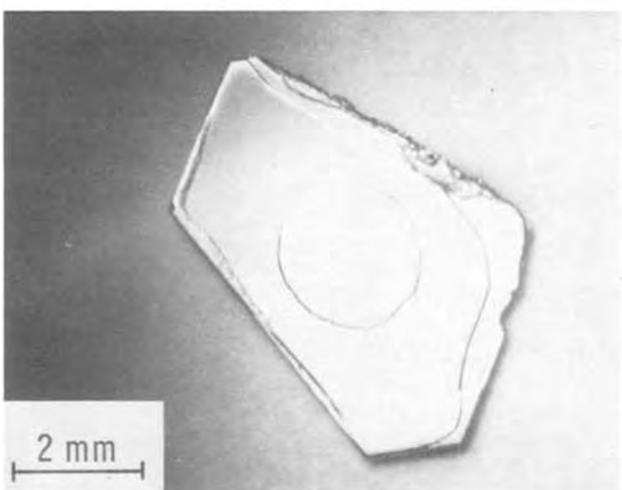

Fig. 5. Two mesa structures fabricated by electrolytic etching: (a, top) boron phosphide p-n homojunction; (b, bottom) boron phosphide-silicon carbide heterojunction.

epitaxial layer on a p-type substrate, and Fig. 5b shows a p-type boron phosphide mesa on n-type silicon carbide. These devices have rectifying characteristics, and easily visible, red, p-n junction electroluminescence was observed in some of the homojunction and heterojunction structures (13).

Summary

Electrolytic etching of boron phosphide was investigated for device applications, since there is no suitable chemical etchant for this material. A technique was developed to etch and polish p-type boron phosphide. In contrast, an insoluble film tended to form on n-type boron phosphide, and material removal was very slow. Due to a large differential etch rate ratio between p-type and n-type material, boron phosphide p-n junction interfaces were delineated by electrolytic etching. Electrolytic etching was also applied to the fabrication of mesa-type boron phosphide p-n junctions and boron phosphide-silicon carbide heterojunction structures. Because of the inert nature of boron phosphide, electrolytic etching is the most suitable means available to remove p-type material and to isolate mesa-type junctions.

Fabrication and Thermal Stability of W-Si Ohmic Contacts

V. Kumar

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

W-Si ohmic contacts have been fabricated using rf-sputtered W and bulk-doped n- and p-type Si. The investigated doping range is $\sim 5.5 \times 10^{18}$-$\sim 1.2 \times 10^{20}/cm^3$ for B (p-type) and $\sim 4.5 \times 10^{18}$-$\sim 8 \times 10^{19}/cm^3$ for As (n-type); with corresponding contact resistance ranging as 1.5×10^{-4}-5×10^{-7} ohm-cm^2 and 1.2×10^{-5}-8×10^{-7} ohm-cm^2, respectively. Steam-grown and deposited oxide (SiO_2) were used as the mask to study the effect of impurity redistribution during steam oxidation on contact resistance. Chemical (100:1 buffered HF) and sputter etch cleaning were used to remove the native oxide from contact windows before W deposition. Metallurgical and electrical stability of these contacts was studied up to $\sim$830°C. The unannealed contacts (using steam oxide mask) are ohmic if the Si has $>10^{19}/cm^3$ As but the minimum B needed is $\sim 10^{20}/cm^3$. This difference stems from two reasons: (*i*) B is lost from Si during steam oxidation whereas As concentrates in Si; (*ii*) the native oxide growing on p-Si seems to be electrically quite different from that on n-Si. Contacts improve with anealing up to $\sim$800°C (1 hr treatments), but if higher temperatures are used high resistance or "opens" may occur. Sputter etching is found to be more effective in cleaning the contact windows than the chemical cleaning.

Tungsten has been extensively studied for use as a refractory gate material for a new MOS-LSI technology (1). Some of the important reasons for selecting W as the first level metallization are (*i*) high melting temperature which is essential if the IC chip is to withstand the high temperature CVD (chemical vapor deposition) steps of intermediate insulator and/or the Si_3N_4 encapsulation, (*ii*) good adhesion to both SiO_2 and Si, (*iii*) the best (of all metals) matching of thermal expansion with Si, (*iv*) no low temperature melting eutectic with Si, (*v*) low electrical resistivity (only about 2.5 times that of Au in bulk), and (*vi*) its ability to act as a good mask during ion implantation for self-aligned structures.

Key words: ohmic contacts, metal-Si contacts, W metallization, dopant redistribution, WSi_2 (tungsten disilicide).

It is therefore desirable to be able to form W-Si ohmic contacts while keeping the number of processing steps to a minimum. The beam lead technology utilizing a trilayer metallization, Ti-Pt (or Pd)-Au, uses PtSi at the contact sites to obtain ohmic contacts to both p- and n-type Si. Quite a number of workers (2-8) have experimentally investigated the PtSi-Si contacts and used the metal-semiconductor barrier contact as the theoretical model. For low resistance ohmic contacts this model requires a low and/or thin potential barrier. Although the barrier height is fixed for a given metal-Si pair, the width of the barrier (the depletion layer) can be progressively decreased by increasing the doping level of Si. W-Si Schottky barrier diodes have been fabricated in the past (16, 18) and the reported barrier height for W-(n)Si is intermediate between

Table I. Schottky barrier heights to Si at 300°K (data from forward I-V characteristics)

Material	Silicon type	ϕ_B (eV)	Reference
PtSi	n	0.85	(2)
PtSi	p	0.25	(2)

W	n	(0.59-0.68)*	(16)

* WSi_2 formation at the interface was detected in samples with ϕ_B greater than 0.65.

that for PtSi-(n)Si and PtSi-(p)Si as shown in Table I. Thus the extension of the barrier model suggests the feasibility of W-Si ohmic contacts without the use of an intermediate contact material like PtSi. Furthermore, the W-PtSi-Si system has been found to be not very stable at high temperatures (>750°C) (9).

This work was undertaken to evaluate the possibility of fabricating W-Si ohmic contacts and their metallurgical and electrical stability under various high temperature treatments including the encapsulation by CVD-Si_3N_4.

Experimental

Sample preparation.—

(i) Substrates.—Bulk-doped, (As, 4.5 × 10^{18}-1.2 × 10^{20}/cm^3 and B, 5.5 × 10^{18}-2 × 10^{20}/cm^3), (100) Si wafers were used for the investigation in order to ensure a well-known surface dopant-concentration for the W-Si contact.

(ii) Oxide masking.—It is known that when B-doped Si is thermally oxidized to cover the wafer with a masking oxide, the B concentration in Si at the interface is reduced considerably because of preferential B accumulation in the growing oxide. On the other hand, there is an enrichment in As which is preferentially retained in the Si (21) during oxide growth. Thus if steam oxide is used as a mask, the contact resistance data obtained would not correspond to the respective bulk dopant concentrations. However, an enhanced carrier concentration in Si at the interface is beneficial for making a contact ohmic and so As-doped (n-type) Si does not pose a problem for contacts opened through a steam oxide mask. The redistribution problem is absent if windows are opened through a vapor-deposited oxide. In view of the above, both a steam-grown and a deposited oxide were used as masks for opening contact windows. Contact windows were opened through the oxide mask using standard photolithography.

(iii) Cleaning and W deposition.—A free Si surface exposed to air (or any oxidizing ambient) for any length of time becomes covered with native oxide. Experiments have shown that the nature (refractive index, etc.) and growth rate of this oxide depend greatly on the Si surface (orientation, dopant type and concentration, and also the mode of doping). In general, doped Si shows a greater growth rate than the undoped and the rate is greater if the dopant has been introduced by diffusion rather than by addition to the melt. This thin native oxide has been observed to control the extent of reaction between Si and W (10). An insulating interlayer of silicon oxide between W and Si is obviously undesirable for a good contact. It is thus essential that steps be taken to remove the native oxide before W is deposited. Two schemes were used to remove this oxide before carrying out the next step of rf sputtering ~3000Å W.

In the first scheme the samples were given a 100:1 buffered HF clean for 2 min, spin dried, and loaded in the vacuum system for W deposition. Toward the end of the investigation, a water spray test (11) which tests the cleanliness of Si through hydrophobicity was used to monitor the slices before W deposition. The test setup is shown in Fig. 1 and the test results on Si and SiO_2 surfaces in Fig. 2. This test turned out to be quite useful and some wafers were detected which had to be given extra cleaning (more time in 100:1 HF) before they were loaded for W deposition.

In the second scheme the oxide from the windows was sputter etched following which ~3000Å W was sputter deposited in the same system. Only the samples with steam oxide mask were used in this case. *In situ* sputter etching has the advantage of the Si surface not being exposed to an oxidizing ambient before W deposition but it can also cause damage to the exposed Si surface, the effects of which on a contact are not known. Wafers for the two cleaning methods were taken from the same crystal in order to have identical bulk doping.

After the W deposition, the test pattern shown in Fig. 3 was etched out using standard photolithography. Following a thorough clean, contact resistance measurements were made as described below. The measurements were repeated after various heat-treatments. The treatments consisted of 1 hr anneals in dry H_2 or in vacuum (~10^{-7} Torr) between 600°-830°C. Each treatment was preceded by a thorough clean. Some samples were processed for a CVD Si-nitride encapsulation (680°C, 30 min) followed by removal of the cap in phosphoric acid for measurements. Metallurgical changes in the contact windows were followed with optical microscopy, SEM, and x-ray diffraction. The

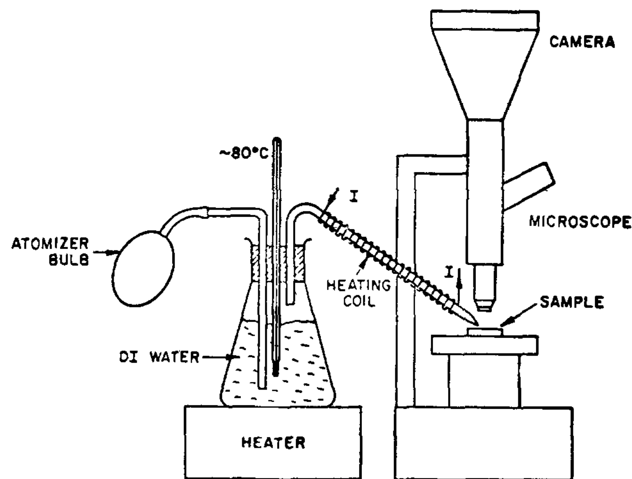

Fig. 1. Spray test setup

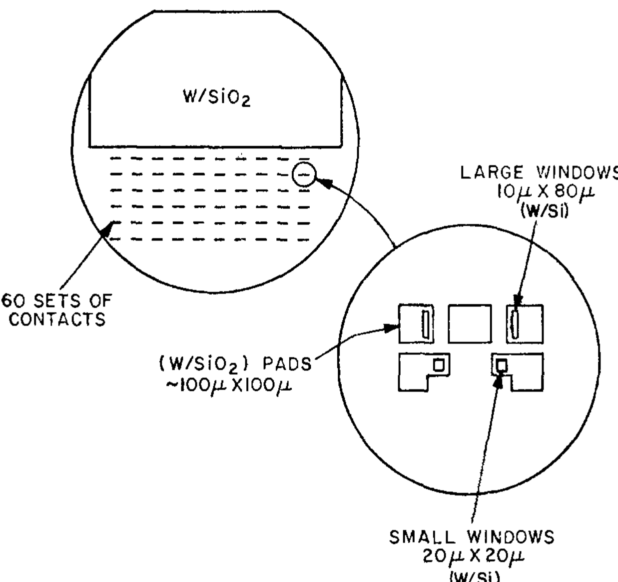

Fig. 3. Tested pattern

large W/SiO_2 area was used to monitor changes in the sheet resistivity of the W film as a result of heat-treatments.

Measurement procedure.—Contact resistance was estimated by taking the difference between resistance values obtained in a two-probe measurement on two sizes of contact windows. Each sample has 60 sets of two small ($20 \times 20\ \mu^2$) and two large ($10 \times 80\ \mu^2$) contact windows, with the connecting pads ($\sim 100 \times 100\ \mu^2$) in the pattern shown in Fig. 3. In a two-probe measurement, the voltage developed across the probes (in mV) when a current of 1 mA is flowing in the circuit will be expressed by

$$V_L = 2R_{CL} + 2R_W + 2R_P + R_{SL}$$

for large area contacts and

$$V_{Sm} = 2R_{CSm} + 2R_W + 2R_P + R_{SSm}$$

for small contacts. Here R_C is the resistance of the contact, *i.e.*, of the W-Si interface, R_W that of the W pad, R_P that of the probe, and R_S is the resistance of Si between the two contacts including the spreading term from each contact.

Probe tips were placed near the edges of the contact windows to minimize the R_W term, and R_P for the two cases was adjusted (by the probe-pressure adjustment) to be nearly equal. Taking the difference of the two voltages we get

$$\Delta V \cong 2(R_{CSm} - R_{CL}) + \Delta R_S$$

ΔR_S being close to the difference in the spreading resistance for the two cases.

Spreading resistance at an isolated contact is expressed as

$$R_{SP} = K \frac{\rho_s}{l}$$

where ρ_s is the substrate resistivity, l is a linear dimension of the contact, and K is a geometrical factor for the shape of the contact. For a circular contact of diameter D, $R_{SP} = \rho_s/2D$. This is also roughly true for a square contact (L^2) if we use $D = L\ (4/\pi)^{1/2}$. For the rectangular ($10 \times 80\mu$) contact, the value of K turns out to be such that (12)

$$(R_{SP})_{Sm} \cong 2(R_{SP})_L$$

where the small contact is ($20 \times 20\mu$). The contact resistance is expressed as

$$R_C = \frac{\rho_c}{\text{Area}}$$

where ρ_c is the specific contact resistance in ohm-cm^2. Since the contact areas are $400\mu^2$ (small) and $800\mu^2$ (large)

$$R_{CSm} = 2R_{CL}$$

and therefore

$$2(R_{CSm} - R_{CL}) = R_{CSm} = \rho_c/4 \times 10^{-6}\ \text{ohm}$$

Keeping in mind the spreading contribution, we can write that as an upper limit

$$\rho_c \lesssim \Delta V \times 4 \times 10^{-6}\ \text{ohm-cm}^2$$

All reported values therefore include a spreading contribution.

The two-probe method itself places a lower limit on the determined ρ_C. Since a metal-Si contact is generally asymmetrical, the two-probe method measures the greater of the two resistances, because one of the two contacts is in reverse bias. However, at the high dopant concentrations and low currents involved, there is no asymmetry in the forward and reverse characteristics. This was confirmed by measuring forward and reverse characteristics of a single contact by using a thin Al film on the back of the slice (providing a large area back contact with very small ohmic resistance), with currents up to 10 mA. Contact resistance of a sample ($3.5 \times 10^{19}/\text{cm}^3$ B, ~900Å PtSi, metallized with W) when measured with this two-probe technique was calculated to be 3.4×10^{-6} ohm-cm^2. The value obtained by using the "single front contact to large area back contact" method (13) on the same sample was 3.7×10^{-6} ohm-cm^2. The results are essentially the same, considering the variation generally observed in ρ_C measured with different techniques (14). Before doing the actual measurements, a scan of about 30 contact pairs was taken in the form of a multiple exposure I-V trace to assess the uniformity and ohmicity of the contacts.

Results and Discussion

Measured ρ_C values are summarized in Tables II and III for chemically cleaned and sputter etch cleaned samples, respectively. It is noticed that as-deposited contacts for n- and p-type silicon are quite different. W-(n)Si contacts are nearly always ohmic, whereas W-(p)Si contacts are not and especially so when the masking oxide is steam grown and the bulk B concentration less than $10^{20}/\text{cm}^3$. Also, for the p-type samples sputter etching leads to better contacts. In all cases the contacts improve with annealing. I-V traces of contacts from two samples with substrates from the same crystal ($\sim 10^{19}/\text{cm}^3$ B) but cleaned chemically (1BP; F-2) and by sputter etching (1BP; J-2) are shown in Fig. 4. The sputter cleaned sample shows better contacts (lower resistance and less spread) even though the annealing temperature is 50° lower while the anneal time is the same (1 hr). One sample (chemical window clean) showed nonohmic contacts up to a 730°C anneal. Even after the 780°C anneal (Fig. 4), this sample showed a large number of contacts which were nonohmic and had high resistance (a set of I-V curves very close to the V axis).

Chemical cleaning is found to be ineffective in cleaning the contact windows uniformly. Entire windows are left covered with the thin native oxide in some wafers. 1BP; F-series ($\sim 1.5 \times 10^{19}/\text{cm}^3$, B) of samples show this effect quite well. All contacts on these samples were nonohmic and had high resistance (5-10K ohm at 1 mA) as deposited. However, after a 730°C (1 hr, H_2) anneal, some contacts became ohmic (R ~ 100 ohm) while the rest remained high and nonohmic. There was an indication (from optical microscopy at magnifications of 100× or less so that depth of focus was appropriate) of an incipient reaction in the windows where the contacts had become ohmic, but on

the surface these contacts were still covered with W and no reaction product appeared over the W. Etching away the W from these contacts revealed that there was formation of granular WSi_2 (structure confirmed by x-ray diffraction) in the contact area. As shown in Fig. 5, only parts of the contact area have reacted. This confirms the nonuniformity of chemical cleaning (native oxide removal) within a window. In contrast, the reaction in the 1BP series of samples cleaned by sputter etching was uniform over the entire sample and also within each contact window. Figure 6(a) shows one such window before the W was removed and the reacted area (made up of WSi_2/Si) is shown in Fig. 6(b); W and the surrounding SiO_2 having been etched off.

A further anneal of 1BP; F-samples for 1 hr at 780°C caused more reaction at the already reacted contacts and started it at some previously unreacted. Electrically, the freshly reacted and the previously reacted contacts were identical (R ~ 7 ohm). At this stage one of the samples (out of four) showed reaction at all contacts while on another sample there were many contacts without reaction which were nonohmic and had a high resistance. One such pair of neighboring sets on this sample is shown in Fig. 7. Figure 8 shows these two types of contacts as seen with a SEM. A layer

of interfacial oxide is evidently responsible for both the absence of reaction and a good electrical contact. An attempt to cause reaction at more contacts by further annealing (one more hour) at 780°C resulted in more reaction (without any resistance change) at the reacted contacts but none at all in the unreacted ones. A cleaved section through a reacted contact at this stage showed it to be continuous as shown in Fig. 9. Even an anneal at 830°C (1 hr, H_2) could not induce any reaction in the unreacted contacts. However, the reacted contacts experienced even more severe reaction and most of these actually "opened up" due to cracks as shown in Fig. 10.

As can be seen from a comparison of Fig. 6 and 7, the native oxide removal (which is also necessary for W-Si reaction) is more complete and uniform in back-sputter-cleaned samples. As-deposited contacts in the sputter-cleaned samples ($\sim 1.2 \times 10^{20}/cm^3$ B) are nearly ohmic ($R_C \sim 10$ ohm). Annealing (1 hr, H_2) at temperatures from 600°-730°C, progressively reduces this value (down to ~1 ohm). The distribution of the measured contact resistivity over 60 sets after each treatment is shown in Fig. 11 for one of these samples.

Figure 11 includes the distribution obtained after Si_3N_4 encapsulation (CVD at 680°C, 30 min, ~2000Å thick film) and removal. It is clear that no significant degradation of contacts occurs as a result of this process.

The effect of impurity redistribution during steam oxidation on contact resistance is clearly seen in Table II. Since the barrier width is determined by the dopant concentration at (or near) the Si surface, the depletion of B from the Si surface in p-type samples leads to a thicker barrier compared to that expected for the bulk concentration. The reverse happens for the As-doped samples. This effect is not present when the oxide is a deposited one. Thus as-deposited contacts to $\sim 4 \times 10^{19}$ B/cm^3 Si are ohmic for CVD oxide mask and nonohmic for steam oxide whereas for $\sim 2 \times 10^{19}$ As/cm^3 the situation is reversed. One of the reasons that the so far discussed 1BP; F-samples ($\sim 10^{19}$ B/cm^3) show such an improvement with annealing and WSi_2 formation is probably the fact that during the W-Si reaction the Si layer with reduced ($<10^{19}$) B concentration is consumed and deeper Si with higher B level ($\sim 10^{19}$) comes into contact with the metallic WSi_2. Boron diffusion in Si is too small ($\sim 3 \times 10^{-17}$ cm^2/sec) at these temperatures to lead to any appreciable flux from the

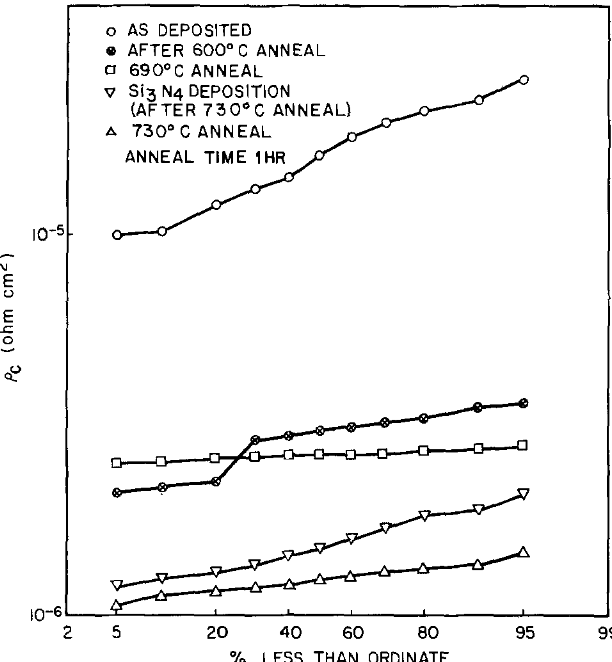

Fig. 11. Distribution of ρ_C over 60 contacts in 2BP; J-3 at various stages of heat-treatment.

bulk to the depleted surface. However, it can be seen from Table III that sputter etching of a 4×10^{19} B/cm^3 substrate leads to ohmic contacts (as deposited) even though the masking oxide is steam grown. It was argued and confirmed that in addition to the native oxide, sputter etching also removed some Si from the surface, thus exposing the Si with higher B concentration and improving the as-deposited contacts. The amount of Si removed by sputter etching was found to depend on the doping type. p^+-Si sputtered at a faster rate ($\sim$1.2 times) compared to n^+-Si. Since both the boron concentration profile in Si following the oxidation and the sputter etch depth will determine the concentration at the W-Si interface, the sputter etching does not always lead to a good contact. The lower the bulk concentration, the greater the etch depth required for a "good" contact provided the bulk concentration is high enough to yield an ohmic contact. Samples with $\sim 1.5 \times 10^{19}$/cm^3 B formed good W-Si contacts using chemical clean and CVD oxide mask but failed to give good contacts with sputter etch clean (steam oxide mask) until after annealing at 750°C (1 hr).

There seems to be no difficulty in making ohmic contacts to n-type Si by either of the cleaning processes and the thermal stability is excellent for up to one hour exposures to H_2 at 730°C. The contacts are not too stable above 800°C, when excessive WSi_2 formation can result in cracking or lifting up of W in the contact windows leading to "opens" or very high resistance. In contrast with the p-type samples which required a 100:1 HF clean not more than $\sim$5 min before loading, an n-type sample (8×10^{19}/cm^3 As, steam oxide) when loaded in the W-deposition system after being exposed to air for over a week after the 100:1 HF clean (but kept in a plastic container for cleanliness) showed ohmic contacts in the "as-deposited" condition with a resistance value only slightly greater than the corresponding value in Table III. This indicates that the effectiveness of the native oxide whose thickness was measured to be only $\sim$15Å for p-type samples 5 min after clean and $\sim$22Å for n-Si after a week as a barrier to conduction is quite different for the two types of Si (B- or As-doped). It is possible that the redistribution of impurities between Si and oxide at the interface is responsible for this effect. However, removal of the native oxide by one of the methods (just prior to W deposition) was found to be essential for making ohmic contacts to n-Si with As less than $\sim 4 \times 10^{19}$/cm^3.

Measured values from all samples are summarized in Fig. 12. Here ρ_C, which includes the spreading contribution, is plotted against the dopant concentration. Since the dominant transport mechanism at high dopant concentration is tunneling (15), the calculated theoretical curves for a tunneling controlled contact are also shown. These curves have been obtained by using the expression (2)

$$\rho_C = g_o^{-1}$$

where

$$g_o = 10^{-4} \left(\frac{e}{h}\right)^2 \frac{\sqrt{2em^*\phi_o}}{\omega} \exp \left(-\frac{4\pi\omega}{h}\sqrt{2em^*\phi_o} \right) \text{(mho/cm}^2\text{)}$$

in which e is the electronic charge, m^* is the carrier effective mass, ω is the width of the barrier (depletion layer), and $\phi_o = 1/2\ \sqrt{\phi_B}$, where ϕ_B is the barrier height.

Due to absence of available data on the carrier effective masses in heavily doped (100) Si, values of (0.19)m for n-Si and (0.17)m for p-Si have been used. Since effective mass increases with doping, the real curves for calculated ρ_C lie lower than those shown in Fig. 12. In any case, the agreement with theoretical calculations based on tunneling alone is poor, especially in terms of the slope of $\rho_C - N_{D,A}$ curve; theory predicts a much steeper slope. Strictly speaking, the influence of the thin native oxide barrier should also be included in the above expression. But as the experiments show, the electrical properties of the oxide are

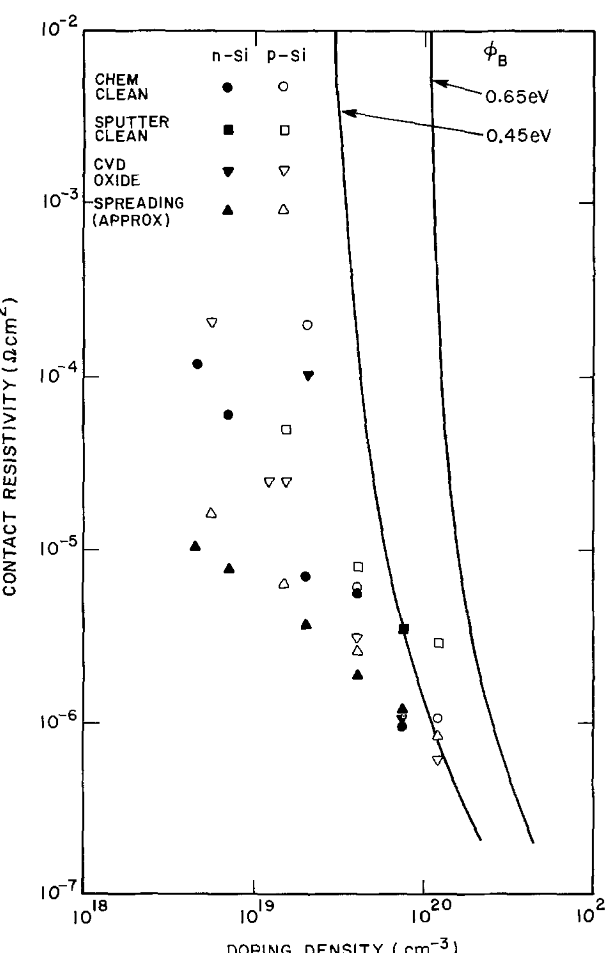

Fig. 12. Results of ρ_C variation with doping density. Two curves show the theoretical values expected for tunneling dominated contacts.

dependent on the substrate and the quantitative introduction of such an effect is impossible. Figure 12 also shows the approximate (geometric factor K is unknown) values of corresponding spreading resistance for each sample.

Figure 13 shows similar experimental data and theoretical curves for PtSi contacts (13). W-Si experimental data points are also shown in Fig. 13. In view of the fact that W-Si and PtSi-Si contact data are closer to one another and deviate from theory very sharply, it is believed that the measured ρ_C has a significant contribution from the spreading resistance. Spreading resistance depends only on the contact size (and shape) and substrate resistivity and is independent of the resistance of the interface. However, since the interface resistance (true contact resistance) and the spreading resistance are in series it suggests that the true contact resistance is probably smaller than measured. Experiments where contact windows were opened using electron beam lithography indicate that for contacts larger than on the order of a few square microns, the spreading term is indeed dominant (20). An additional argument for the interface not controlling the total resistance is the fact that on n-type Si, the resistance goes down even after the formation of WSi_2 which has a higher barrier height to n-Si than W.

Conclusions

1. W-Si ohmic contacts can be made by using rf-sputtered W on n-type as well as p-type Si.
2. The lowest measured contact resistivity to B-doped Si (5.5×10^{18}-$1.2 \times 10^{20}/cm^3$) ranges from 1.5×10^{-4} to 5×10^{-7} ohm-cm² and for As-doped Si (4.5×10^{18}-$8 \times 10^{19}/cm^3$) from 1.2×10^{-5} to 8×10^{-7} ohm-cm².
3. The measured values include a large contribution from the spreading resistance.
4. Contact resistance decreases with annealing (1 hr, H_2) from 600°C up to 800°C. This heat-treatment causes W and Si to react to form WSi_2.
5. In order to form a contact the thin layer of native oxide on Si has to be removed before depositing W. This can be accomplished by a simple chemical clean (100:1 HF for 1 min) or by sputter etching the oxide. The latter is found to be more effective.
6. Steam oxidation for obtaining oxide mask prior to contact formation has opposite effects for p-type (B) and n-type (As) Si. Boron tends to concentrate in the oxide thus reducing its concentration in Si and leading to higher contact resistance as deposited. The opposite happens for As-doped Si. This effect is confirmed by using deposited and steam-grown oxide on similar substrates.
7. The native oxide growing on n-Si seems to be electrically different from that on p-Si. This difference may also be a result of the redistribution at Si-oxide interface.

Chemical Vapor Deposition of Antimony-Doped Tin Oxide Films Formed from Dibutyl Tin Diacetate

James Kane and H.P. Schweizer

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

A CVD process for the preparation of transparent conducting layers of antimony-doped tin oxide has been developed utilizing dibutyl tin diacetate, antimony pentachloride, O_2, H_2O, and N_2 as carrier gas at a substrate temperature of 400°-550°C. It was designed to fulfill a need for more highly conducting coatings than those obtainable without doping, in the sheet resistance range 50-100 ohm/square, but still possessing an optical transmission in excess of 80% throughout the visible spectrum. Coatings to this specification are used extensively for a variety of electro-optic devices. A set of optimized deposition conditions is presented together with important optical, electrical, structural, and chemical properties of the films. Typical SnO_2:Sb films have film thicknesses ranging from 1500-3600Å with a sheet resistance of 50-150 ohm/square, a specific resistivity of 0.0015-0.0032 ohm-cm, an n-type carrier concentration of 1.2×10^{20} cm^{-3}, and a Hall mobility of 23 cm^2/V-sec. They exhibit a light transmission of 85-91% net, and have an optimum dopant concentration within the range of 0.6-2.7 atomic per cent of antimony. The films are free of volatile chlorine, are chemically inert, and may be heated in air for prolonged periods without noticeable deterioration. Samples on sapphire substrates were heated in air to 1000°C for several hours without change in the sheet resistance.

Transparent, electrically conducting thin films are required in many modern opto-electronic devices. Numerous materials, prepared by a variety of physical and chemical techniques (1,2), have been reported but in practice only two materials, tin oxide doped with antimony and indium oxide doped with tin, are widely used. Antimony-doped tin oxide coatings are conventionally prepared by spray hydrolysis of tin tetrachloride-antimony chloride mixtures (1-16), but for the high quality coatings required in electronic devices more sophisticated deposition techniques are needed. Sputtering techniques (1, 2, 17-20) have been used with better success. Chemical vapor deposition (21-22) could offer economic advantages of lower equipment cost and simpler processing.

A chemical vapor deposition process for the preparation of transparent conducting coatings of nonstoichiometric tin oxide has been described in a previous paper (22). The subject of the present investigation is an important modification of this basic process by which a controlled quantity of an antimony dopant, which greatly increases the conductivity of the film, is introduced into the tin oxide. A full description of the apparatus and the proposed advantages of the CVD technique over spray hydrolysis were presented in the previous paper (22). Also given were extensive literature references on undoped tin oxide films; references in the present paper are therefore confined essentially to antimony-doped tin oxide films.

In addition to lower conductivity, a second disadvantage of the undoped tin oxide is that it is nonstoichiometric and is therefore only a metastable phase. If it is subjected to any high temperature processing after deposition the conductivity is usually decreased. Prolonged heat-treatments eventually produce a high resistivity form of tin oxide. In contrast, antimony-doped tin oxide remains highly conducting and, provided that the substrate material is inert, it does not deteriorate even after prolonged heating in nonreducing ambients. Several samples deposited on sapphire were heated to 1000°C in air for several hours and there was no apparent deterioration in either the film quality or the conductivity. The material is more thermally stable in air than most of the substrates with which it is normally employed.

On quartz substrates heat-treatments in excess of 750°C produce a rapid deterioration in the sheet resistance due to chemical interaction of the tin oxide with the silicon dioxide substrate. On alkali-containing glass substrates the coatings deteriorate rapidly when heated above 500°C, due to the diffusion of alkali metal ions from the glass into the tin oxide.

Film Deposition

Choice of dopant compound.—In preliminary experiments attempts were made to use various halide-free organometallic antimony compounds as dopant sources. This approach is attractive since it eliminates the possibility of halide contamination of the tin oxide; however, these doping experiments were only partially successful. The main disadvantage of antimony organometallic compounds is that they are too thermally stable and therefore are not entirely decomposed within the reaction chamber.

Antimony trichloride was examined but found to be troublesome because this compound is a solid at room temperature. Difficulties arise due to the accumulation of nonvolatile impurities on the surface of the melted $SbCl_3$, thus lowering its effective vapor pressure. In addition, due to poor thermal contact between the solid and the walls of the container, the effective vapor pressure of the solid is not constant.

It was eventually decided to optimize the process using antimony pentachloride ($SbCl_5$) as the dopant source. This compound has a number of advantages over the other materials that were considered. Since it is a volatile liquid it can be transported at room temperature in a stream of inert gas; this transport can be achieved conveniently and in a reproducible manner by bubbling nitrogen through the liquid. Antimony

Key words: doped tin oxide, CVD, transparent conductors, thin films, semiconductors.

pentachloride is a corrosive and highly reactive material which is readily hydrolyzed by water. The ease of hydrolysis is, to a certain extent, an advantage since it ensures that the compound is entirely decomposed within the reaction chamber. Water vapor was introduced by passing nitrogen through a water bubbler, as indicated in Table I. A certain amount of water vapor is present during the reaction even without its extraneous addition since considerable quantities of water are generated in the vapor phase combustion of the organic constituents from the tin compound; complete exclusion of water is therefore not readily possible. The addition of water vapor was merely to ensure that excess was present in the reaction chamber. If proper handling precautions are observed, such as minimal exposure to air, this compound has proved to be a very convenient dopant source. Its one disadvantage is that it introduces chloride contamination into the tin oxide, but this seems to have no derogatory effects. Furthermore, we proved by very careful measurements that no chlorine or chlorides are given off from the films during heating in reduced pressure.

Study of deposition parameters.—The effects of the deposition variables were systematically explored to define the optimum processing conditions for the preparation of antimony-doped tin oxide coatings, with a sheet resistance of less than 200 ohm/square and an optical transmission in excess of 80% throughout the visible spectrum. The deposition parameters affecting the deposition rate and uniformity had already been investigated at length in previous work with the undoped tin oxide (22). The present study was required primarily to determine the optimum antimony concentration in the reactant gas stream and the effect of other parameters, such as substrate temperature, on the incorporation of this dopant into the tin oxide. The optimum quantity of antimony dopant was defined empirically as the maximum quantity which could be introduced into the chamber without producing any discoloration of the films. If this optimum concentration was exceeded the films became light blue in color and there was a consequent loss in optical transmission. After these optimum conditions for preparing doped coatings on an inert substrate had been defined, additional experiments were then undertaken to determine what changes were necessary to process borosilicate-type glasses and whether coating of soda lime glass would be feasible. Due to the rapid thermal diffusion of alkali ions at temperatures approaching the deposition temperature, these substrate materials are not chemically inert and this places additional constraints on the deposition process.

Table I. Materials and typical conditions for CVD of antimony-doped tin oxide films

1.	Substrate material	Glass plates
2.	Tin source material	Dibutyl tin diacetate
3.	Tin source temperature	98°C
4.	Organotin carrier flow rate	6750 cm³ N_2/min
5.	Antimony source material	$SbCl_5$
6.	Antimony source temperature	25°C
7.	Antimony carrier flow rate	420-850 cm³ N_2/min
8.	H_2O source temperature	25°C
9.	H_2O carrier flow rate	2100 cm³ N_2/min
10.	Oxidant flow rate	380 cm³ $O_2(H_2O)$/min
11.	Substrate temperature	450°-475°C
12.	Thermal equilibration	5 min
13.	Deposition time	15-20 min
14.	Postdeposition purge	0.5 min N_2

Deposition apparatus.—The deposition system used in the present study was basically the same as that described for the preparation of undoped tin oxide coatings (22). A number of modifications in the construction of the apparatus were necessary to obtain satisfactory incorporation of the antimony dopant. Specifically the points of entry of the organometallic tin compound and the oxygen were repositioned and separated in order to avoid homogeneous gas phase nucleation with the consequent formation of hazed films containing particulate defects. A schematic diagram of the modified deposition system is shown in Fig. 1 and typical deposition conditions are summarized in Table I.

Substrates for film deposition.—Plates of polished vitreous (fused) quartz served as inert standard substrates on which to optimize the deposition parameters. They were later used as standards with which to compare other substrate materials. To establish the optimum antimony content and to determine which trace impurities are present in the system, representative deposits were prepared on high resistivity, (100)-oriented, and polished silicon wafers. These samples were then analyzed by mass spectroscopy, infrared spectroscopy, and ellipsometric measurements.

To demonstrate the high temperature stability of the antimony-doped tin oxide, coatings were prepared on several polished sapphire substrates of various crystallographic orientations. When annealed at 1000°C in air for several hours the tin oxide crystallized, but there was no apparent deterioration in either the optical or electrical properties of the coatings. X-ray examination revealed a high degree of preferred orientation in the annealed samples. This phenomenon is considered in more detail later.

In contrast to these substrate materials, soda lime glass substrates are not chemically inert at the temperatures required for chemical vapor deposition. To

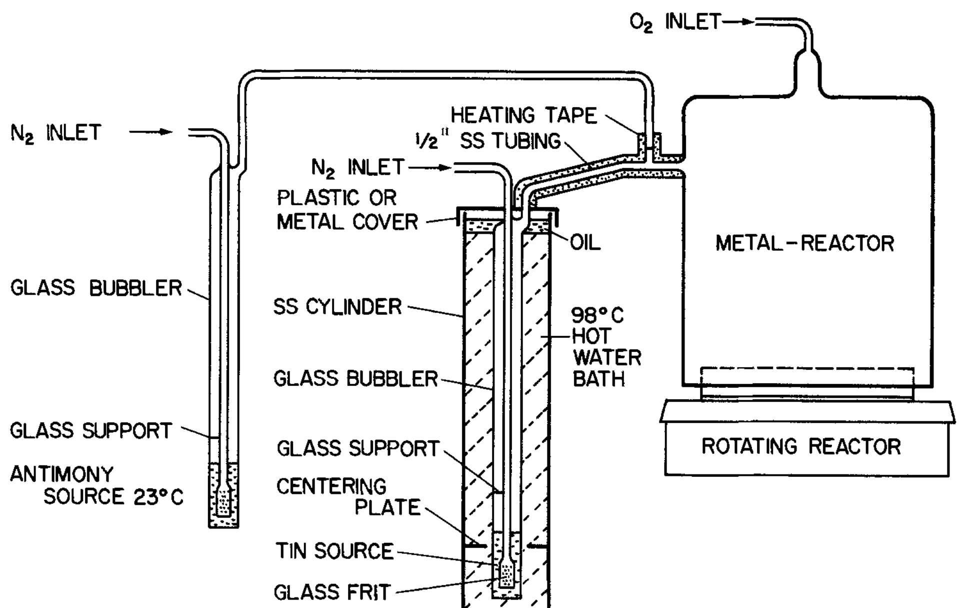

Fig. 1. Schematic representation of the modified CVD system used for preparing antimony-doped tin oxide films.

process glass substrates the optimum conditions must therefore be reestablished. The problem is caused by the diffusion of the highly mobile alkali metal ions out of the glass and into the growing tin oxide layer. The alkali metals apparently act as p-type doping agents in the n-type tin oxide, thus neutralizing some of the charge carriers. An even more unacceptable result of alkali impurities is hazing of the films, which makes them unsatisfactory for optical applications. Borosilicate glasses have usually a sufficiently low alkali metal content so that there is generally no difficulty in processing this type of substrate.

Soda lime glasses have a high alkali content and without special prior surface treatment it was not possible to prepare satisfactory coatings on this material. Several approaches were examined, as discussed in the following section.

Surface treatment of soda lime substrate glasses.— For commercial applications it is desirable to use soda lime float glass as substrates since this material is cheap and readily available. Float glass is also flat as prepared, requiring no surface polishing. This eliminates one of the major cost factors in the preparation of Pyrex glass or vitreous quartz substrates.

The rate of film deposition was found to be dependent on the substrate material. It is believed to be due to impairment or differences in initial film nucleation of the oxide layer rather than in a difference in the subsequent growth rate once full coverage is attained. For some substrate materials, notably untreated soda lime glass, the inability of the oxide to uniformly nucleate sometimes results in patchy deposition with large areas of the substrate remaining uncoated. If the soda lime glass is untreated prior to the tin oxide deposition, a hazy, highly resistive tin oxide coating is also formed due to the out-diffusion of alkali metal ions from the glass. Removal of the alkali metal ions from the surface of the glass is therefore necessary if high quality tin oxide coatings are to be prepared. This is especially true for high temperature CVD processing as the rate of diffusion is temperature dependent.

Two different surface treatments of the glass were evaluated, viz., surface ion depletion (SID) and acid leaching. Of the two treatments, surface ion depletion (23) was found to be the more effective.

It was found that the SID treated glass behaved in a similar manner to vitreous quartz with respect to the rate of tin oxide deposition and the electrical and optical properties of the resulting coatings. The sheet resistances were up to 30% higher than comparable layers on fused quartz, but were better (lower) than those achieved on polished borosilicate glasses with a low alkali metal content. The layers were haze free and the optical transmission was identical to that on quartz. The substrates could be processed at temperatures approaching the softening point of the glass without hazing.

Leaching of the alkali from the surface of the glass with a mineral acid is also a useful treatment. For this to be effective the glass substrates required boiling in 1:1 diluted hydrochloric or sulfuric acid for periods of at least 1 hr. The removal of the surface ions is not permanent or as deep as in the SID treatment, so that the substrates require close control of the deposition process to obtain the best results. The substrate temperature is especially critical, the optimum processing temperature being 475°C. Above this temperature the rate of alkali diffusion is increased and the electrical and optical properties of the coatings deteriorate. Below 475°C the sheet resistance gradually increases due to incomplete incorporation of the antimony dopant. Low sheet resistances can be obtained but the control of the deposition parameters becomes critical. For the preparation of SnO_2:Sb films on soda lime glass, having a sheet resistance of about 100 ohm/square, the SID treatment is recommended. The deposition parameters are less critical in this case since higher surface temperatures do not result in the diffusion of alkali ions to the surface.

A comparison of film properties resulting from using fused quartz and variously acid-leached soda lime glass substrates is presented in Table II. The data show that the sheet resistance of the quartz continued to decrease at temperatures above 475°C, while there is a drastic increase in the sheet resistance of the soda lime glass. This is accompanied by hazing and a consequent decrease in optical transmission, resulting in films of unacceptable quality. Quartz is, therefore, a consistently better substrate material than either acid-leached or SID soda lime glass.

Film Properties

Electrical and compositional properties.—The electrical resistance of the films was measured with a conventional four-point probe. The point separation of the probe was 10 mil. In order to calculate the specific resistivity, measurements of film thickness were made using a Sloan "Dektak," equipped with a 25 μm stylus. For this measurement a step was etched in the layer with HCl/Zn powder slurry.

The optimum concentration of the antimony dopant was determined from resistivity data recorded in three series of experiments. In the first series the antimony concentration was increased from zero to a level at which the layers became blue in appearance. The sheet resistance decreased with increasing antimony content until a blue coloration appeared. At this point a further increase in the antimony content produced a rapid deterioration in the optical transmission, with no further decrease in resistivity. The optimum doping level of antimony was taken to be the concentration which yielded films of minimum specific resistivity and maximum light transmission.

The second series of experiments was designed to determine the influence of substrate temperature on the effective incorporation of the antimony dopant. In this series the antimony dopant concentration was set within the previously determined range of values and the substrate temperature was varied from 350° to 550°C.

** Blue-grayish coloration of high light absorbance.
CVD conditions as stated in Table I except for temperature; films on quartz and glass substrates were codeposited.

In a third series of tests, further refinements in the CVD conditions weres examined for different substrate materials.

Representative data from the first two series of experiments are recorded in Table III. Plates of vitreous fused quartz and surface-treated soda lime glass were used as substrate materials in 15 min deposition periods. The chemical composition of the SnO_2:Sb films is expressed as atom ratio Sb/Sn and was determined by x-ray fluorescence analysis described in a later section. The measured sheet resistances of the films obtained at 425°, 450°, and 475°C are plotted as a function of the antimony dopant input (gas flow rate Sb-N_2 cm^3/min) in Fig. 2. The sheet resistance is seen to decrease as the dopant input increases, and also as the temperature increases. This type of graph is useful in practical applications where sheet resistance is specified regardless of film thickness. However, part of these resistance changes are caused by differences in the film thickness which varies for the various CVD conditions. The same data are therefore plotted in Fig. 3 in terms of specific resistivity to eliminate effects of film thickness.

The effect of the dopant input on the Sb/Sn atom ratio of SnO_2:Sb films on quartz for the 425°, 450°, and 475°C samples from Table III is shown graphically in Fig. 4. It is seen that the Sb/Sn ratio increases nearly exponentially with the dopant carrier gas (Sb-N_2) flow rate over the range studied. Apart from the wide spread of two of the 450°C data, which we cannot explain, there is little difference in the Sb/Sn ratios between the low and high temperature films.

The lowest resistivity (2-3 $\times$ 10^{-3} ohm-cm) with highest light transmission (>85% net) was obtained with films deposited at 450°C with intermediate doping level. The best film had a Sb/Sn ratio of 0.0075

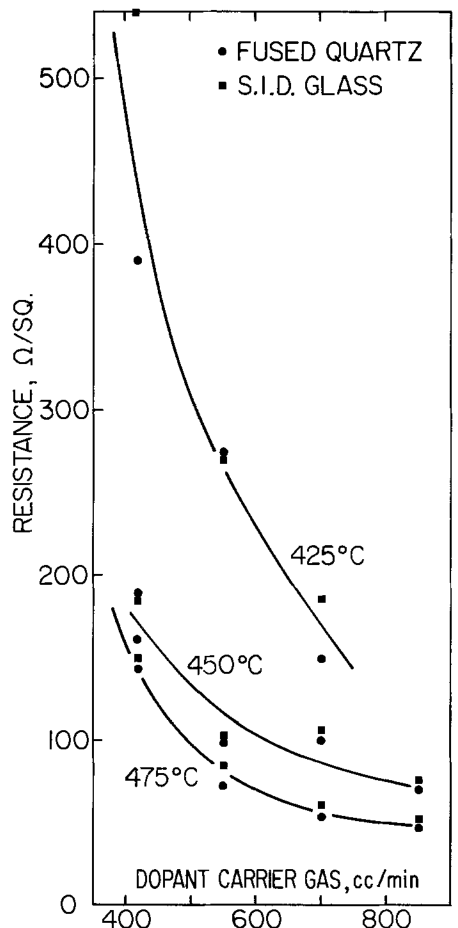

Fig. 2. Sheet resistance of SnO_2:Sb films on two substrate materials as a function of antimony dopant input (Sb-N_2 flow rate) for three different deposition temperatures. (Film thicknesses vary as shown in Table III.)

which corresponds to about 0.6 atomic per cent (a/o) Sb in SnO_2: Sb.

In Table IV several physical properties of coatings prepared under optimum conditions on a number of different substrate materials are recorded. The Sb/Sn atomic ratios, determined by x-ray fluoresence analysis, were in the range 0.025-0.034 (2.0-2.7 a/o Sb in SnO_2:Sb). These values are considerably higher than was expected from the results listed in Table III, but values in the same range were also obtained by electron probe microanalysis (Table V). The reason for the difference in dopant concentration is not understood, but it may have been due to minor modifications to the gas inlet system. Although the results in Tables IV and V are mutually consistent they can therefore not be strictly compared with those in Table III. The values of specific resistivity for this series (in Table IV) are in the range 1.1×10^{-3} to 1.8×10^{-3} ohm-cm, the lowest being for a film on a sapphire substrate. For comparison, values cited in the literature for SnO_2:Sb films prepared by various methods range typically from 7×10^{-4} to 6×10^{-3} ohm-cm (5, 13, 15, 19, 20, 24, 25).

Hall measurements were performed at room temperature using the standard Van der Pauw technique. The magnetic field employed was 16 kG. The layers examined were deposited under optimum conditions on quartz substrates and had a measured thickness of 2800Å. The layers were found to be n-type with a carrier concentration of 1.2×10^{20} cm^{-3} and a mobility of 23 cm^2/V-sec. For comparison, undoped layers were also n-type but had a carrier concentration of 9.0×10^{18} cm^{-3} and a Hall mobility of 10 cm^2/V-sec.

Optical properties.—The index of refraction and thickness of a single sample on silicon were determined by ellipsometry. The thickness of the sample was measured to be 2013Å and the refractive index at a wavelength of 5461Å was 1.8912, within the experimental limits 1.8855-1.8969. The refractive index of the tin oxide is to a large extent dependent on the deposition conditions, especially the presence of water vapor in the reaction gas stream which produces films of lower index (22).

In thin layers the thickness and uniformity of tin oxide coatings could be readily estimated simply by observing their color in reflection. This is a very sensitive technique for comparing run-to-run uniformity or for determining variations in the deposit thickness across the deposition zone. The reflection color which corresponds to a given thickness depends on the substrate material and the refractive index of the film. With experience and a set of calibrated samples one can determine the thickness quite accurately by observing the color in reflection, providing one knows or ascertains the order of interference. This technique is especially useful since the thickness range in which it is most sensitive corresponds to thicknesses of tin oxide films used in practical devices. For example, the films in the thickness range of 2200-2500Å listed in Table IV exhibit a blue-violet interference color.

The visible light transmission was measured throughout the range of 4000-7200Å. The transmission data is recorded in Table IV as per cent transmittance measured with an uncoated substrate in the reference beam. Due to interference effects the light transmission can be peaked at any given wavelength in the visible by a correct choice of film thickness. In Fig. 5 the transmission and reflectance spectra of a 2800Å thick layer on quartz is shown. This figure illustrates the variations in transmission produced by interference effects.

The introduction of the antimony dopant had no measurable effect on the optical transmission [as compared to undoped tin oxide (22)] until a certain threshold concentration was exceeded. At this value, which varies with CVD conditions employed (Table III), the films became blue in appearance and there was a consequent decrease in optical transmission. Further increases in the dopant concentration produced a very rapid deterioration in the optical transmission.

To record the infrared spectrum of the antimony-doped tin oxide, a coating was prepared on an infrared transparent silicon wafer. The observed Sn-O band structure was very weak in the lattice band region near 600 cm^{-1}. The Sb-O band structure which

occurs in the same spectral region was also weak. Since the Sn-O bandgap transition occurs in the near u.v. (approximately 4 eV), the absorption occurring in the region 4000-2000 cm^{-1} was free carrier absorption due to doping of the SnO_2 film. Absorption in the 4000 cm^{-1} region as related to doping has been studied by Summitt and Borrelli (26).

Surface morphology.—The general features of the tin oxide surfaces were established by visual examination and by low power optical microscopy, including Nomarski differential interference contrast. Samples deposited under optimum conditions exhibited very smooth, structureless surfaces. Details of the surface morphology were studied at magnifications up to 20,000× by scanning electron microscopy in the secondary electron emissive mode with a Cambridge Stereoscan. The photographs in Fig. 6 for films deposited on SID glass and acid leached glass exhibit a fine-grained surface with few defects. No pretreatment of the specimens was required, since the SEM image is generated by secondary electrons emitted from the surface being scanned.

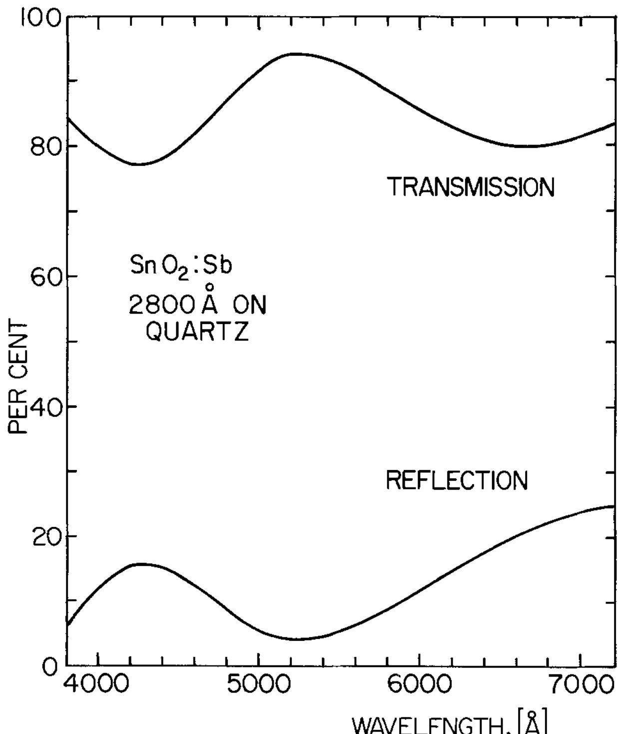

Fig. 5. Transmission and reflectance spectra of a 2800Å thick layer of SnO_2:Sb deposited on fused quartz.

Under certain gas flow or deposition temperature conditions where homogeneous gas phase nucleation was appreciable, hazy tin oxide films were obtained. These coatings were similar in appearance to those obtained on untreated soda lime glass substrates. The films also exhibited an excessive number of particulate defects. Hazed tin oxide coatings are unacceptable for most applications; therefore, considerable effort was devoted to ascertaining the cause of the haze and defining deposition conditions which minimized this effect.

X-ray and electron diffraction studies.—Samples from doped tin oxide layers deposited on fused quartz plates at substrate temperatures in the range 425°-500°C were destructively removed from the substrate by scraping with a diamond stylus and were

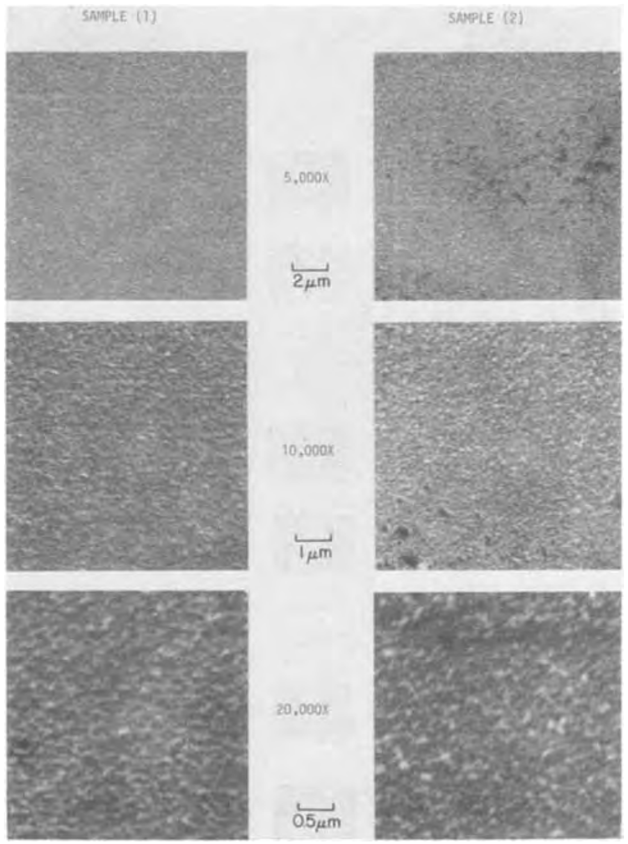

Fig. 6. Scanning electron micrographs of antimony-doped tin oxide films deposited at 450°C on two different substrate materials: sample 1, SID glass and sample 2, acid-treated soda lime glass. (Samples from Table IV.)

examined by x-ray diffraction. The x-ray powder patterns obtained were essentially the same for all samples. They showed that the layers were crystalline and composed almost entirely of tegragonal tin oxide (SnO_2), similar to the results for undoped films reported by us (22) and also noted in the literature for undoped SnO_2 films deposited from $SnCl_4$(27).

Surface examination of the same samples by electron diffraction confirmed this result for the films deposited at 500°C; these were identified as polycrystalline tin oxide with azimuthal ordering about the (200)-axis. All other samples showed complex patterns which were most closely identifiable as polycrystalline antimony oxide (Sb_2O_4) with azimuthal ordering about the (200)-axis. In addition, some unidentified second phase appeared to be present. The electron diffraction studies revealed the tin oxide to have a high degree of preferred orientation.

A number of attempts were made to produce epitaxial transparent conducting layers of tin oxide on single crystal substrate materials. Of all the materials examined sapphire appears to be the most promising. The tin oxide layers in thicknesses up to 1 μm were deposited on sapphire under the conditions described in Table I. They were subsequently annealed in air at 1000°C for 1 hr. On the inert sapphire substrates the optical and electrical properties of the tin oxide are not significantly changed by this treatment. Two orientations of sapphire (0001 and $\bar{1}102$) were used in this investigation. Epitaxial growth was not achieved on either orientation but there were strong indications that given the correct choice of sapphire orientation epitaxial growth should be possible. Two typical Laue photographs for these sapphire orientations are presented in Fig. 7 for illustration.

On the $\bar{1}102$ orientation the tin oxide was single-crystal-like in a direction perpendicular to the wafer face. The tin oxide <101> coincided with the perpendicular to the {$\bar{1}102$} of the sapphire. The tin oxide "a" axis was in the plane of the wafer and parallel to the sapphire $11\bar{2}0$ axis. This results in two different tin oxide domains since the "a" axis of the tin oxide can align itself positive or negative with respect to the sapphire "a" axis. On the sample examined the two domains were not present in equal numbers; they were in a ratio of approximately 6 : 1. This observation would lead one to believe that it might be possible to misorient the substrate so as to bias the growth of a single domain and produce epitaxy.

The tin oxide layer on the 0001 sapphire orientation was also single-crystal-like in a direction perpendicular to the wafer face. In this case the tin oxide "a" <100> axis was aligned in the plane of the wafer with the sapphire "a" axis. Since there are three different sapphire "a" axes in the plane of the wafer this results in three different tin oxide domains each having a <100> axis perpendicular to the wafer face. In this case misorientation of the wafer might also favor the growth of a single domain and produce epitaxy.

X-ray fluorescence analysis.—The concentration of the antimony dopant in the tin oxide was monitored by x-ray fluorescence spectroscopy. Since the elements antimony and tin are adjoining in the Periodic Table and have no interfering absorption edges, the relative intensities of spectroscopic lines should correspond closely to the relative concentrations of the elements. This was later confirmed by mass spectrographic analysis discussed in the section on trace impurity analysis.

For x-ray fluorescence spectroscopic analysis the type of substrate material was found to be critical. Earlier attempts to analyze doped tin oxide layers deposited on glass were unsuccessful due to the interference of strong x-ray fluorescence from calcium and potassium present in the glass. These samples on glass substrates were subsequently analyzed by electron probe microanalysis (see next section). Samples suitable for analysis by x-ray fluorescence were obtained by depositing the tin oxide on quartz substrates. The analytical results reported in Table III for films codeposited on quartz and surface-treated soda lime glass were obtained by x-ray fluorescence analysis of the films on quartz. The film composition ranged from an atomic ratio Sb/Sn of 0.002-0.11.

Electron-probe microanalysis.—A number of samples of variously antimony-doped tin oxide coatings on glass and quartz deposited at various temperatures to different thicknesses were examined by electron-probe microanalysis for the reasons pointed out above. The results obtained were consistent with those obtained by x-ray fluorescence. The results are summarized in Table V, together with deposition parameters and other physical properties of the coatings. The antimony dopant concentration is expressed as the intensity ratio

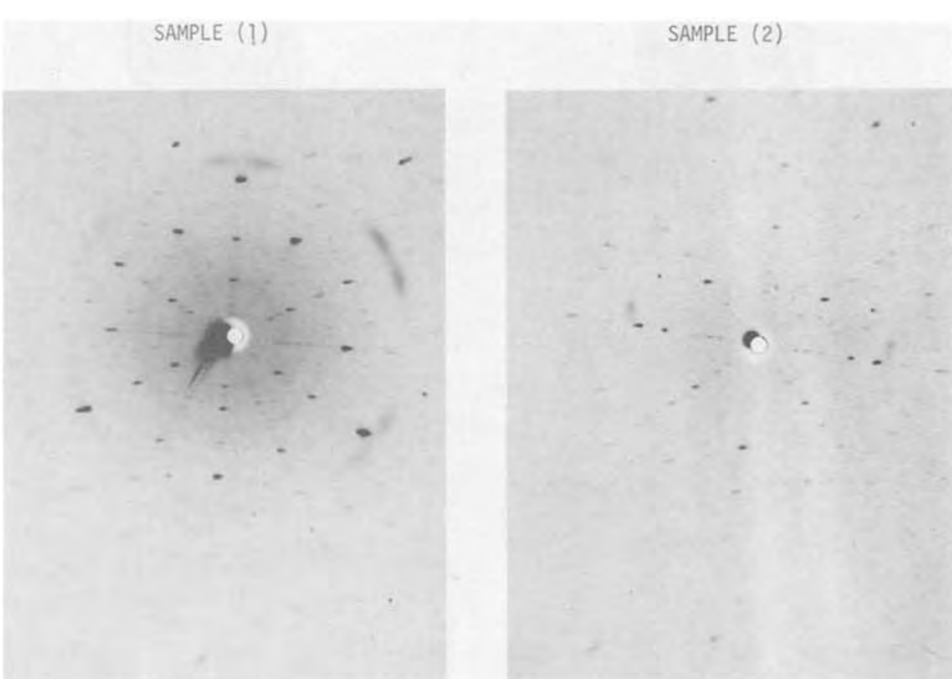

Fig. 7. Laue photographs of SnO_2:Sb coatings on single crystal sapphire substrates: sample 1, 0001 orientation and sample 2, $\bar{1}102$ orientation.

(SbLα₁)/(SnLα₁), which was assumed to correspond closely to atomic ratio. For Lα₁ lines of elements of consecutive atom number in this region of the Periodic Table, net intensity ratio should be substantially equivalent to mass concentration ratio. Several samples on quartz were analyzed by both x-ray fluorescence and electron-probe microanalysis to verify this assumption; the results obtained by the two analytical methods are in good agreement.

Trace impurity analysis.—One typical antimony-doped tin oxide layer, deposited on a polished wafer of 100 ohm-cm high purity silicon at a substrate temperature of 475°C under optimum conditions, was examined by spark source solids mass spectroscopy to identify and quantitize any chemical impurities. Besides the high concentration of antimony which was intentionally added to the tin oxide, the only other major impurity found was chlorine at a concentration of 0.05 a/o.

Other impurities identified were minor concentrations of transition metals (Zn 19, Fe 8.4, and Cu 1.3 ppma). The origin of these impurities is not known, but since only reagent quality chemicals were employed it was not entirely unexpected.

For many applications the presence of volatile impurities in the tin oxide is undesirable. To ascertain the nature and quantity of these impurities, several tin oxide coatings on glass were analyzed by means of an AEI MS-10 gas mass spectrometer. The samples were heated in an evacuated stainless steel container to temperatures up to 140°C and the gases evolved examined in the mass spectrometer. The experimental data showed that the bulk of the outgassing products was derived from the substrate material and not from the tin oxide coating. The principal gases evolved were carbon dioxide and water, but in no case were chlorine or chlorine-containing species present.

Conclusions

It has been established that highly conducting antimony-doped tin oxide coatings can be prepared at deposition temperatures as low as 425°C by modifying the CVD process based on dibutyl tin diacetate, O_2, H_2O, and N_2 as carrier gas (22). This is accomplished by introduction of antimony as dopant in the form of $SbCl_5$ vapor.

The antimony concentrations measured in the films that were deposited under widely varying temperature and reactant flow conditions ranged from 0.002 to 0.11 atomic ratio Sb/Sn. The optimum dopant concentration was found to be within the range of 0.6-2.7 a/o (or mol per cent) Sb in SnO_2:Sb.

Typical samples are 1500-3600Å thick with sheet resistance values of 50-150 ohm/square, and have a specific resistivity in the range 1.5×10^{-3} to 3.2×10^{-3} ohm-cm. Light transmission in the visible region of the spectrum ranges from 85 to 91% net. The films are free of volatile chlorine or chlorides. Coatings are thermally stable in air up to 1000°C, provided that the underlying substrate material is inert. Coatings prepared on single crystal sapphire did not deteriorate when heated to 1000°C in air for several hours. When heated in hydrogen the coatings were rapidly destroyed due to reduction of the oxide, as expected.

The films can be readily, reproducibly and uniformly deposited on different types of substrate material. Substrate plates of fused quartz, borosilicate glass, and treated soda lime glass have been used successfully. Surface ion depletion of soda lime glass by application of an electric field to the glass effected sufficient alkali ion depletion to yield film resistivities comparable to those of quartz. Provided that the substrates are treated by a less effective boiling acid leaching prior to the tin oxide deposition and the deposition temperature does not exceed 475°C, the coatings can be applied even to glass substrates with a high alkali content.

Chemical Vapor Deposition of Amorphous Boron on Massive Substrates

L. Vandenbulcke and G. Vuillard

Centre de Recherches sur la Chimie de la Combustion et des Hautes Températures, C.N.R.S., 45045 Orleans, Cèdex, France

ABSTRACT

Compact coatings of amorphous boron were deposited on the smooth surface of substrates such as graphite, refractory metals, iron, and stainless steel using the reduction of boron trichloride by hydrogen. With a constant surface temperature and a low deposition efficiency, a constant thickness is obtained if transport limitations are avoided at all points of the surface. Extension of the results is proposed for a deposition on larger surfaces and substrates of complex shape. The rate of deposition was studied at temperatures ranging from 950° to 1200°C. The apparent activation energy was found equal to 31.4 kcal/mole. Adherence and absence of cracks are a function of the specific nature of the substrate. The most satisfactory coatings were obtained on graphite, refractory metals of Group Vb, iron, and stainless steel. On iron and stainless steel, a diffusion barrier was first deposited by pack cementation, which avoids the transport of the metals and slows down the boron diffusion. Boron morphology regularity is shown to be a function of nucleation.

The rate at which a substance is deposited from chemically reactive vapors can be governed by either chemical kinetics or mass transport of reactants and products. The relative rate of transport to and from the reaction surface and the rate of chemical conversion in turn determine local concentrations and supersaturation which may influence deposit morphology. The relative importance of the diffusional and kinetic factors during chemical vapor deposition of boron by hydrogen reduction of boron trichloride on a hot filament was studied in detail by P. E. Gruber (1) and H. E. Carlton *et al.* (2). Generally a horizontal resistance heated wire is used. In this case, mass transport in the vapor phase is important whatever the geometry of the deposition cell. It is always equal to or greater than the mass transport by natural convection, and up to 1050°-1100°C, the deposition rate is governed by chemical kinetics (1-3).

On a massive substrate, the rate of deposition is generally limited by mass transport at these temperatures and crystals of boron nucleate very rapidly (4). To avoid this crystallization, a deposition cell was built to produce a stream of reactants flowing at high velocity normal to the center of the substrate, then flowing at high velocity in a parallel direction. In this case, it is very difficult to specify mass transport properties, but it was possible to increase experimentally the mass transfer by increasing the mass flow rate. The rate of mass flow was determined by the rate of reactants metered with flowmeters and by the shape and size of the deposition cell. In all cases where the deposition rate is governed by chemical kinetics at all points of the substrate, uniform coatings of "amorphous" boron are produced.

Experimental Techniques

The experimental set up is shown in Fig. 1. The details of the deposition cell are shown in Fig. 2. The apparatus is made of Pyrex glass except for the reactor which is made of silica. The desired flow rates of BCl_3 and H_2 are adjusted by metering valves, and metered by flowmeters. The mixing gas is introduced in the reactor or bypassed outside through a valve. This valve provides for a flow of He introduced in the reactor and for a flow of the reactants bypassed outside, and vice versa. The stream of either He or the reactants is introduced at a high velocity normal to the substrate in a 0.8 cm diam cylindrical nozzle. The substrate is a disk of 2 to 3 cm diam, 0.5 to 1 cm thick. It is heated by a high frequency generator regulated by a thermocouple fitted at 0.05 cm under the surface to be coated. The surface temperature of the substrate is measured by this thermocouple. The maximum temperature fluctuations are ± 2°C.

The experimental procedure is as follows: the desired flow rates of BCl_3, H_2, and He metered by rotameters are set and the power supply adjusted to a predetermined value for the desired temperature. The substrate

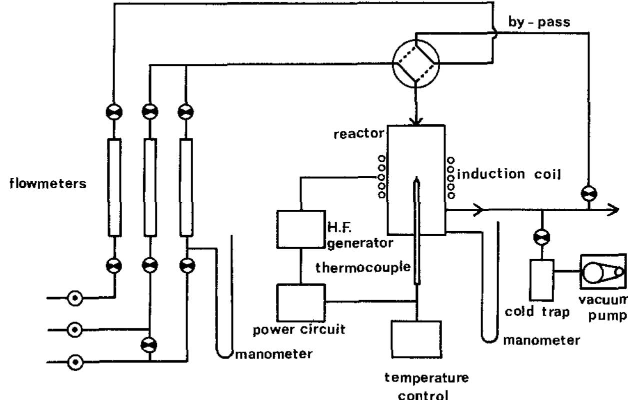

Fig. 1. Schematic diagram of experimental apparatus

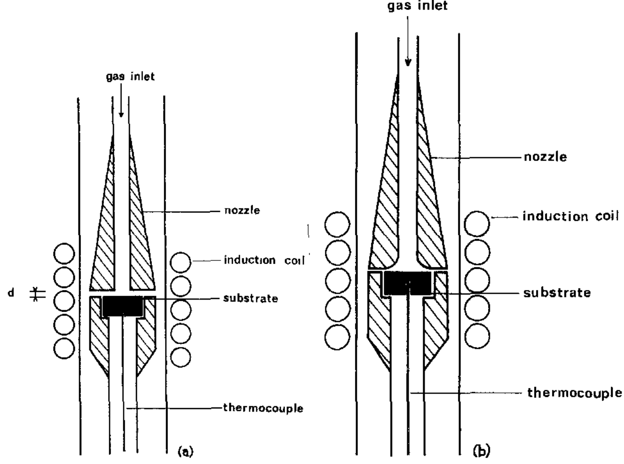

Fig. 2. Details of deposition cell showing high velocity nozzles

Key words: mass transport, kinetic, refractory metals, steel morphology.

is heated to the desired temperature in helium. Timing of the experiment is started with the reactants flow in the reactor. The volume measured between the bypass valve and the substrate is about 10 cm^3 and is flushed during a very small time (<1 sec in our experimental conditions). Timing of the experiment is stopped when the helium flow is turned into the reactor. The substrate and the boron deposited are cooled in helium. The helium flow rate is determined in order to avoid temperature fluctuations larger than during deposition at the start and the end of the experiment.

In all experiments, the ratio of $BCl_3:H_2$ is equal to 2:3 without any addition of inert gas and the pressure is 1 atm. Hydrogen used in these experiments is of 99.995% by volume purity. CP-grade boron trichloride, 99.9% pure (manufacturer's specification) was used. The experimental apparatus is flushed before and after each reaction with helium of 99.995% pure by volume. The substrates used are: fine-texture prepolished graphite of average density 1.75, cleaned in alcohol in an ultrasonic device and dried; the refractory metals titanium, zirconium, niobium, tantalum, molybdenum, and tungsten of 99.9% purity (all surfaces are prepolished, in some cases optically polished and/or annealed); iron (99.95% purity), and stainless steel with average composition ($C < 0.03$, $Cr = 18$, $Ni = 10\%$). In the case of iron and stainless steel it was necessary to first deposit a film to act as a diffusion barrier for boron. This was obtained by diffusion of tantalum produced by a pack-cementation process.

Influence of Mass Transport and Chemical Kinetics: Experiment and Discussion

The effect of flow rate, position of the substrate, and temperature on deposition rate were studied on a graphite substrate. Thickness of boron deposits was measured with an optical microscope on the prepolished vertical plane of the disk.

Figure 3 shows the thickness of boron deposits as a function of the radial distance on the disk with varying flow rates of reactants ($H_2 + BCl_3$). Figure 2a shows the nozzle that was employed and the distance d between the nozzle and the deposition surface ($d = 0.3$ cm). The reaction time was always 120 sec and the temperature 1100°C. Figure 3 shows that the thickness is constant in the center of the substrate in front of the nozzle. When the flow rate is equal to or greater than 40 cm^3/sec (0.14 g/cm^2 · sec of BCl_3), it does not influence the boron-deposited thickness in the center of the substrate. At smaller flow rates the thickness is a function of the flow rate. The deposition rate is limited in one case by chemical kinetics, and by mass transfer in the vapor phase in the other. When the distance from the center of the substrate is greater than 0.4 cm, mass transfer in the vapor phase is small and the thickness falls quickly.

Figure 4 shows the thickness of boron deposits as a function of the diametral distance on the dish with varying distance d (Fig. 2a). The effect of d is very small over the range investigated, the flow of reactants remaining normal to the deposition surface. In the center of the substrate, the deposition rate is only limited by chemical kinetics.

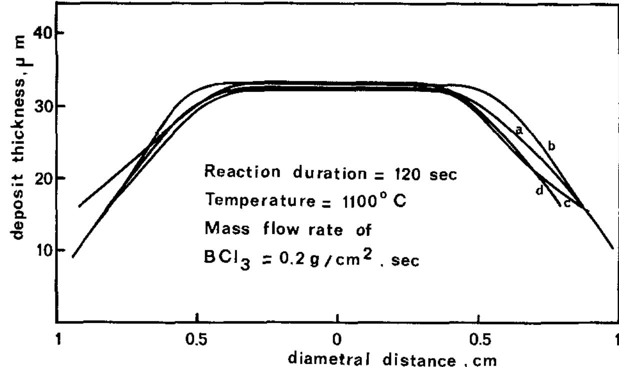

Fig. 4. Effect of d on deposit thickness along the sample diameter: a = 0.3, b = 1, c = 2, d = 3 cm.

The above studies show that the deposition rate is only limited by chemical kinetics when the stream of reactants is flowing at a rate equal to or greater than 80 cm/sec normal to the deposition surface at a temperature of 1100°C. However, the diameter of the nozzle cannot be increased extensively since in that case mass flow becomes considerable. It is possible to increase the rate of reactants flowing in a parallel direction to the substrate by reducing the distance d ($d < 0.05$ cm), but the boron deposit is always scaled off at a distance of 0.4 cm from the center of the deposition surface (circumference of the nozzle). Another nozzle type (Fig. 2b) was constructed to avoid this scaling. Figure 5 shows the boron-deposited thickness as a function of the diametral distance on two different substrates, graphite and molybdenum. The distance d is smaller than 0.5 mm, but our apparatus was not accurate enough to adjust d at a fixed value ±0.1 mm and to position the substrate in a horizontal plane. The reaction time was 120 sec, the temperature 1100°C, and the flow rate 100 cm/sec. Line a in Fig. 5 shows that the deposit thickness is slightly smaller at the periphery of the deposition surface; d was too large. Line b shows that the substrate surface was slightly at an angle and the mass transfer in the vapor phase was too small on one side of the substrate. The higher circumference thickness was produced by the temperature being higher at the periphery than in the center of the substrate which was cooled by the stream flow of the reactants. The two effects, mass transfer too low and temperature too high, can be a way to obtain constant thickness deposits. The deposition efficiency is very low (generally 0.2%) and it is not necessary to take the production of hydrogen chloride into account. Then, it is easier to pre-

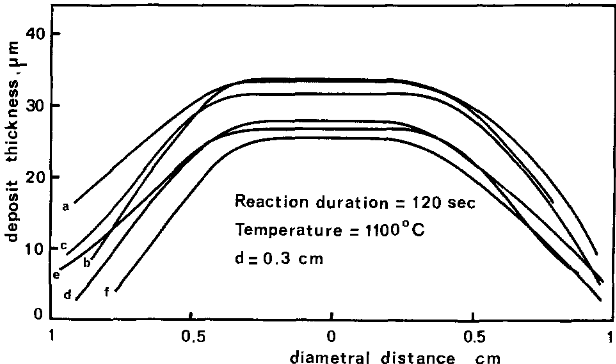

Fig. 3. Effect of flow rates of reactants on deposit thickness along the sample diameter: a = 50, b = 40, c = 34, d = 28, f = 16 cm^3/sec.

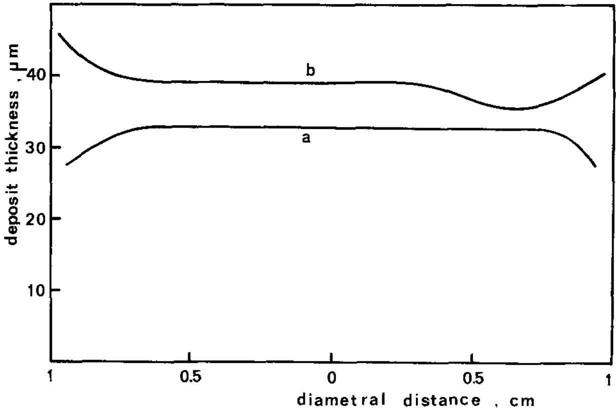

Fig. 5. Deposit thickness along the sample diameter with the nozzle of Fig. 2b: a = graphite, b = Mo.

heat the reactants and to deposit boron on a constant temperature substrate if the stream of reactants flows at a normal rate, then parallel to the substrate as high to produce a chemical kinetics limited deposition rate and without any pressure increase. It becomes obvious that amorphous boron could be deposited on a more complex shape if we adapt each deposition cell to each shape.

The effect of temperature on deposition rate is shown in Fig. 6, with a constant flow rate of 50 cm^3/sec, 0.2 g/cm^2 · sec of BCl_3. The final thickness of the boron deposit is observed to be directly proportional to the reaction time, except for 1200°C when the reaction time is greater than 180 sec. We can explain the shifting of the zero of the straight line by the nucleation occurring at a rate which is a function of the temperature. The apparent activation energy determined from the slope of the line in Fig. 7 is about 31.4 kcal/mole in the range of 950°-1100°C. Above 1100°C, the deposition rate is limited by the mass transfer in the vapor phase. Up to 1150°C, the boron deposit is amorphous during the first minutes of reaction. At 1200°C boron crystallizes very quickly (in the first minute).

Deposition on Metallic Substrates

Boron was deposited on two types of metallic substrate: first, the refractory metals of the Groups IVb, Vb, and VIb where the interaction of the deposition reaction with the substrate is only a diffusion of boron in the metal; second, metals or alloys like iron and stainless steel where there is an interaction of H_2/BCl_3 compositions with Cr and Fe which are transported as $CrCl_2$ along with the deposition of boron. In these cases, it was necessary to first deposit a barrier to avoid partially or entirely the transport of the metals and to reduce the diffusion rate of boron in the substrate. This barrier was of tantalum diffused into the substrate by a pack-cementation process which will be explained in detail elsewhere (5). On iron, the diffused tantalum formed an intermediate phase Ta_3Fe_7 as determind by x-ray diffractometry and electron microprobe analysis. The thickness of this layer was 10-60μ and constituted a new substrate. On stainless steel the structure of the layer is TaC(n) type. It is a very thin layer (0.4μ)

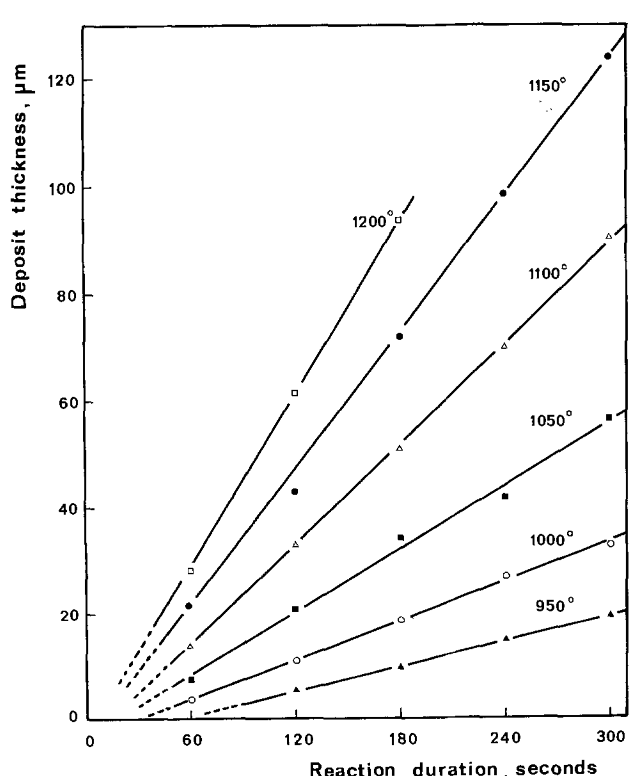

Fig. 6. Effect of temperature on deposition rate

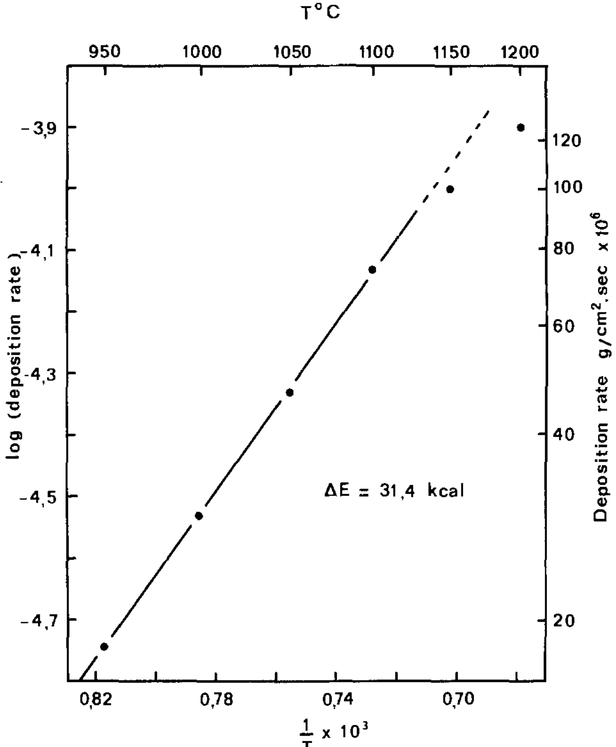

Fig. 7. Arrhenius plot of the boron deposition

which prevents the transport of metals as chlorides and slows down the boron diffusion in steel.

Coatings were studied by x-ray diffraction directly on the substrate coated with boron. The boron has a very small absorption coefficient and the different borides were identified as TiB_2, ZrB_2, NbB_2, TaB_2, Mo_2B_5, and W_2B_5. We have never obtained lines for other borides and pure metals. With molybdenum and tungsten as substrate, two layers of borides are identified by optical microscopy on a cross section. Studies of the inner layers by electron microprobe analysis show that presumably they are MoB and WB, the precision of the analysis, however, is unsatisfactory (Fig. 8). Optical studies did not reveal other borides of the other metals Ti, Zr, Ta, and Nb. The observed boride layers formed under the same conditions of time and

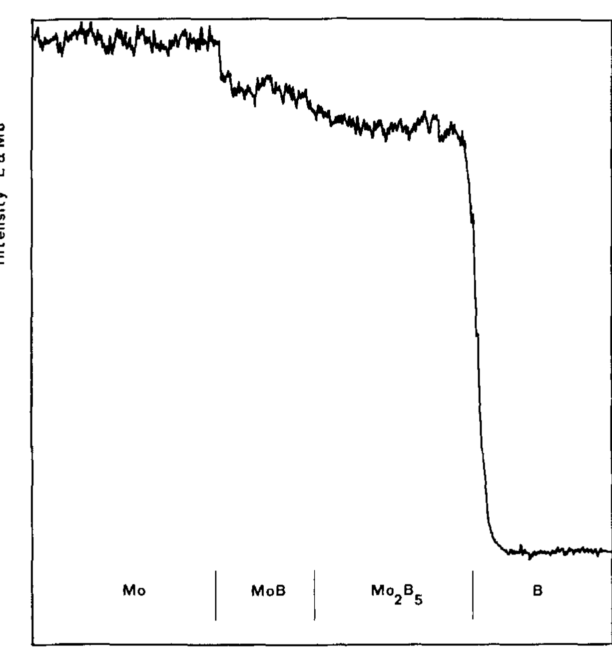

Fig. 8. Electron microprobe scan across a B coating on Mo

temperature show that the rate of boriding increases when going from the metals of Group IV to those of Group VI. These results are in agreement with the results of Epik (6). On tantalumized iron, the diffusion of boron forms two mixed borides of tantalum and iron. The x-ray lines of the borides are very close to those of TaB and TaB_2. This shows that iron is certainly inserted in the lattice. Figure 9 is a scanning of iron on a cross section of boron deposited on tantalumized iron which successively shows the different layers: boron, the two borides, Ta_3Fe_7, and pure iron. On stainless steel, there was boriding of the tantalumized layer and of the inner steel. The x-ray studies show a small displacement of the cementation layer lines and the formation of a complex boride of iron, chromium, and nickel. The EMA studies confirmed the boriding of steel through the cementation layer. Figures 10 and 11 show the diffusion being slowed down. All these results will be developed elsewhere (5).

The precipitation of borides at the interface is an important fact which regulates the adherence of boron to the substrate. It is essentially a diffusion of the small atoms of boron with a very slow diffusion of the metallic atoms in the opposite direction. This rapid one-way diffusion of boron fairly often produces an accumulation of vacancies which creates porosities in the interface proximity. These porosities increase when going from the metals of Group IV to those of Group VI (Fig. 12b-e). The deposits of boron on tantalumized iron do not show porosities when the deposition surface is strictly prepared. In the case of iron, the opposite diffusion of iron in boron is important as seen on iron scanning of Fig. 9. The deposits on tantalum stainless steel never show porosities (Fig. 12f and g).

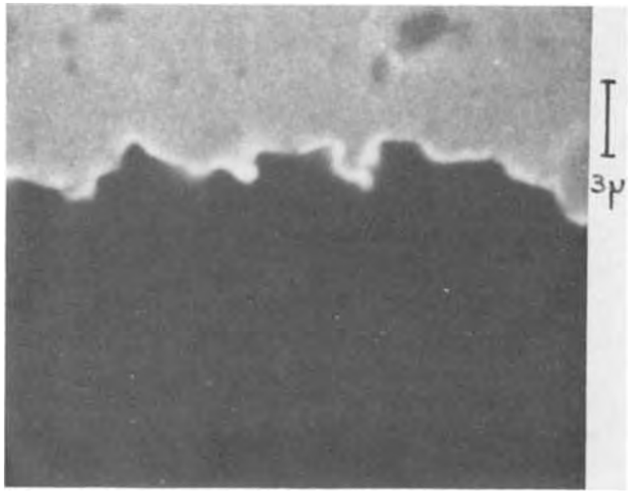

Fig. 11. Backscattered image

Another important aspect of the defects lies in the cracks that are produced normal to the deposit surface during the cooling of the sample. These cracks were observed with titanium or zirconium substrates which present a martensitic transformation which causes deep striation of the metal by itself (Fig. 12b). When the substrate was niobium or tantalum no cracks were

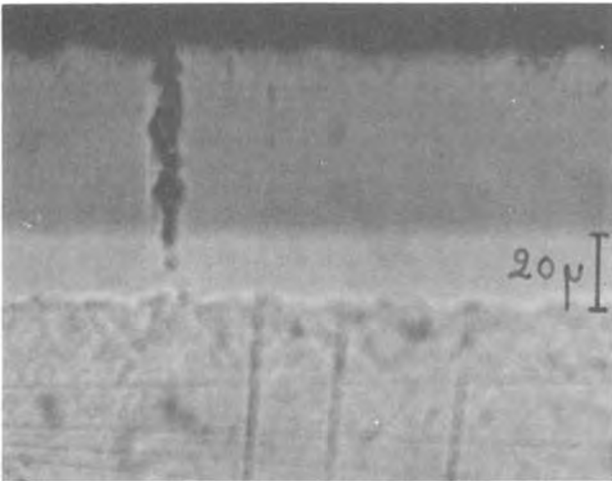

Fig. 12e. B coating on W

observed, but the metal does not present any transformation and the diffusion of boron forms only one boride (NbB_2 and TaB_2), the thermal expansion coefficient of which is of the same order as those of the pure metal and the amorphous boron ($6.5\text{-}8.5 \times 10^{-6}/°C$) (Fig. 12c).When boron is deposited on molybdenum and tungsten, the diffusion of boron forms two borides, and the cracks could arise from the difference between thermal expansion coefficients (Fig. 12d and e). In all cases, cracks cross over the boron cones (Fig. 13).

Complete breakage of the boron deposit can arise during cooling down of the sample when the substrate-like carbides have a low ductility. So, boron deposited on steel coated with layers of carbide ($\geq 5\mu$) presented an explosive splintering during cooling, although the thermal expansion coefficient is of the same order.

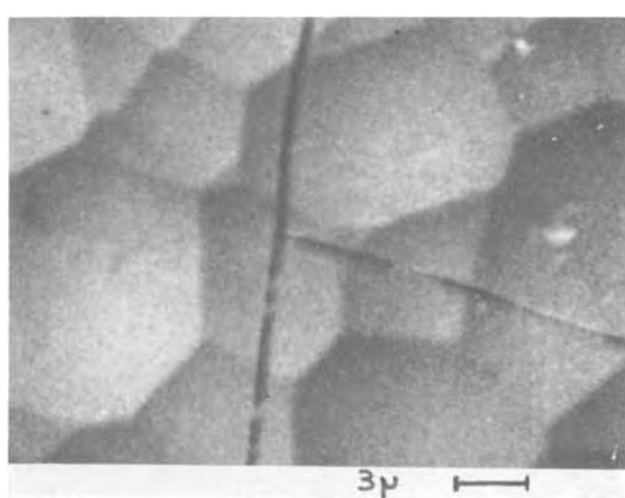

Fig. 13. Morphology of B coating on Mo

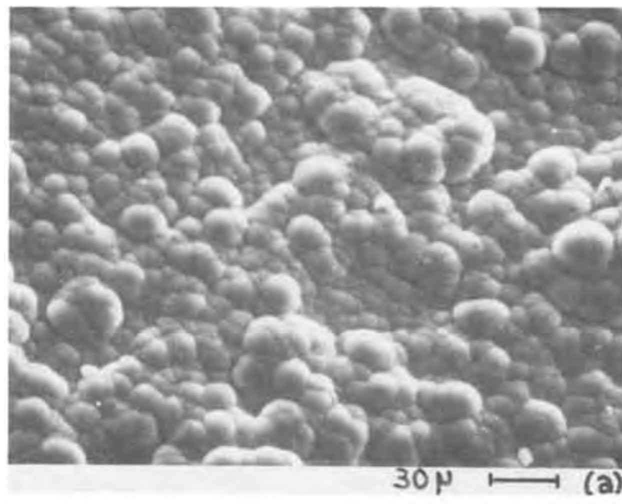
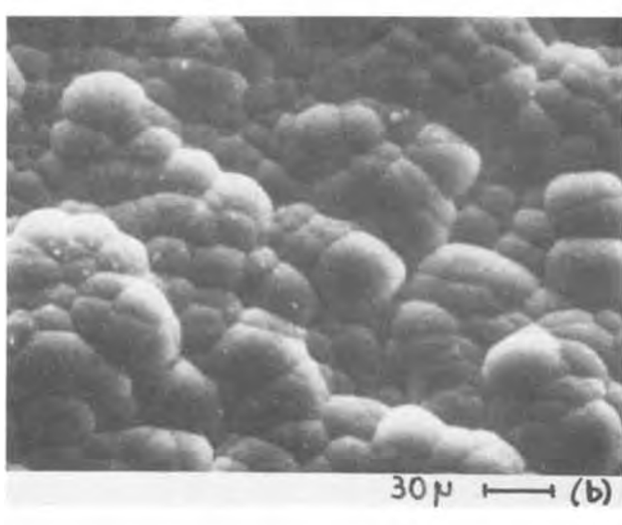
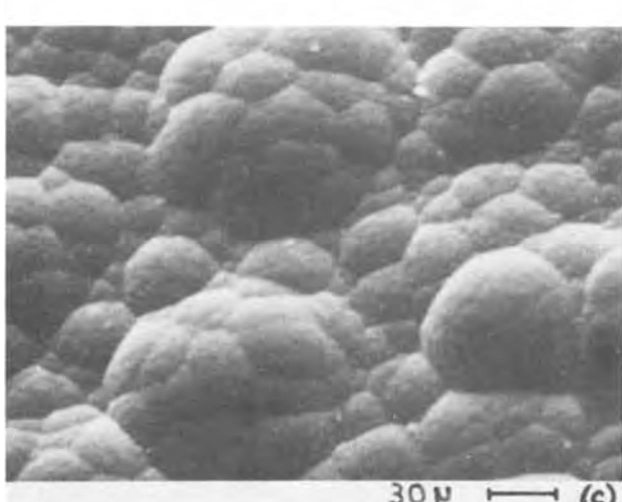
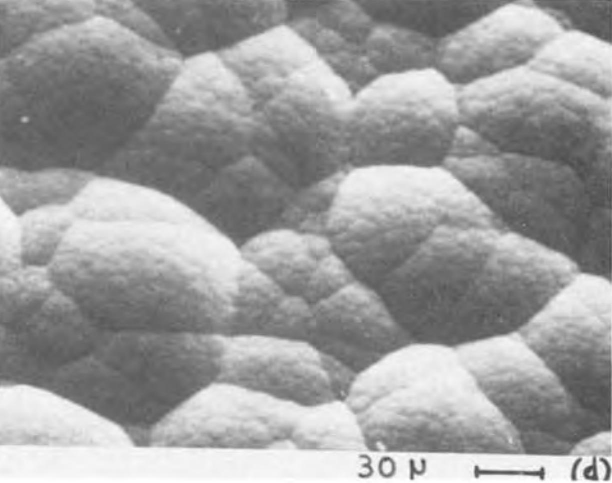
Complete scaling arises when crystallized boron is deposited on iron and steel.

The surface morphology of the boron deposits depends upon a number of factors connected to the substrate characteristics and the thickness of boron deposited. Figure 14 shows the surface morphology of amorphous boron deposited on tantalumized iron as a function of the deposition time. We shall show elsewhere (7) that amorphous boron presents a mononucleated morphology with growing cones. It is clear that the deposit morphology depends upon the physical aspect of the surface and is more regular on polished surfaces. Figure 15 shows the boron deposited on different substrates under the same conditions. Deposits are more regular when nucleation occurs on nonprivileged sites or when these sites are distributed statistically. Since the nucleation occurs faster on privileged sites another important factor is the recrystallized state of the metals. On an optically polished metal, these sites are essentially the grain boundaries. When the average grain size of the metal is of the same order as the size of the boron nucleus, the boron deposit is regular (Fig.









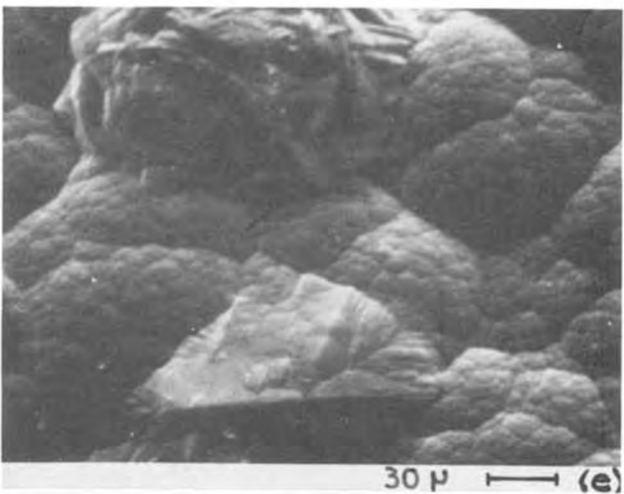


Fig. 14. Morphology of B deposited on Fe (Ta): (a) during 60 sec, (b) during 180 sec, (c) during 300 sec, (d) during 420 sec, (e) during 600 sec.

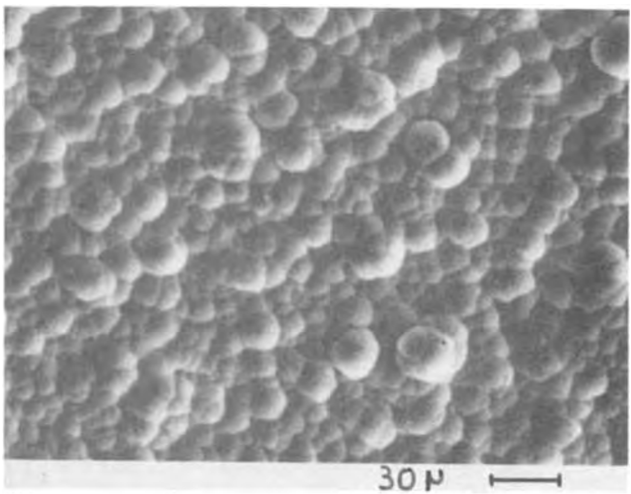

Fig. 15a. Morphology of B deposited in 120 sec at 1000°C on graphite.

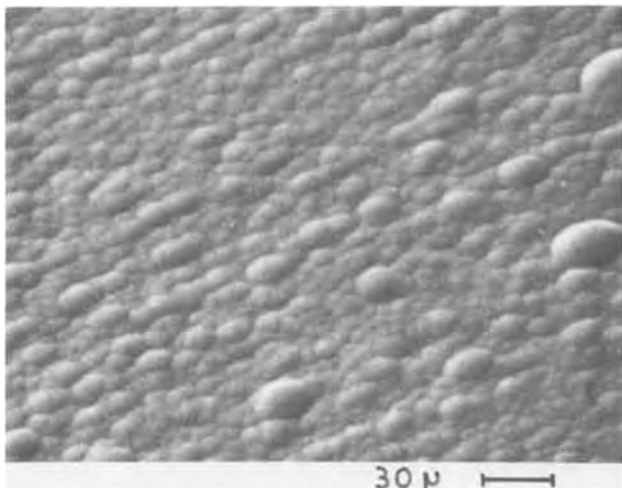

Fig. 15b. Morphology of B deposited in 120 sec at 1000°C on prepolished Nb.

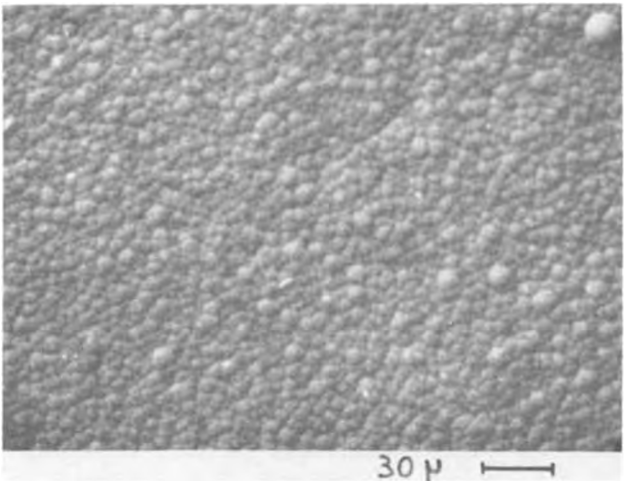

Fig. 15c. Morphology of B deposited in 120 sec at 1000°C on optically polished Ta.

16). When the average grain size is greater than the size of boron nucleus, the boron deposit is irregular. This effect occurred with annealed metals (Fig. 17). The nucleation occurs first on the grain boundary, then on the grain surfaces as a function of the crystalline orientation of the grains. The final boron thickness was

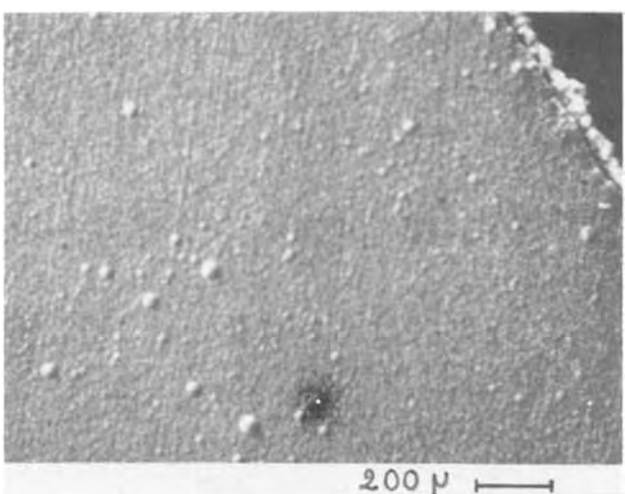

Fig. 16. B coating on a prepolished Mo sample

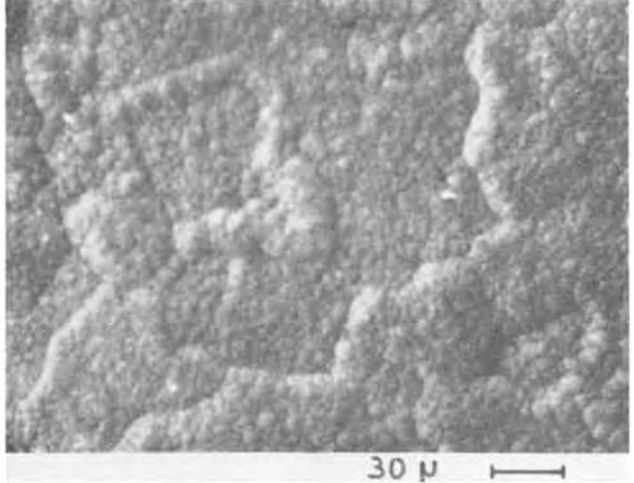

Fig. 17. B coating on a polished and annealed Mo sample

accordingly greater on the boundary layer and on some grains.

The microhardness of amorphous boron was measured on the cross section of the layers deposited on various substrates with thickness greater than 50μ. The Knoop microhardness values found were 3350 ± 50 (kg · mm^2) with a 100g load.

Conclusion

Mass transport limitations can be avoided in the deposition of boron from boron trichloride reduction by hydrogen on a massive substrate when the deposition cell provides for a stream of reactants flowing at high velocity normal to the substrate, subsequently flowing at a higher velocity in a parallel direction. Under these conditions deposition of amorphous boron occurs during a time that is a function of the temperature, and constant thickness of the deposit is achieved in all points of constant temperature if deposition efficiency is low. Then amorphous boron could be deposited on a complex-shaped substrate if one adapts each deposition cell to each shape. The deposition rate of boron increases sharply with the temperature. The apparent activation energy is about 31.4 kcal/mole.

Good coatings are achieved on graphite. On refractory metals, the best deposits, without cracks, are obtained with the metals of Group Vb. On iron and stainless steel, it is necessary to first deposit a barrier to avoid the transport of the metals and to reduce the diffusion rate of boron. It is a diffusion of tantalum produced by a pack-cementation process. Good coatings without any cracks and interfacial porosities are achieved on iron and stainless steel under strictly reproducible conditions for the preparation of the deposition surface. Complete scaling of the deposits occurs on hard substrates or hard layers such as carbides except when the hard layer is very thin.

The regularity of the deposit morphology is a function of the nucleation. Statistical nucleation arises when the surface does not present physical or structural privileged sites, or when these sites are statistically distributed at small distances, of the order of the size of one nucleus.

Coating of Cemented Carbide Cutting Tools with Alumina by Chemical Vapor Deposition

R. Funk, H. Schachner, C. Triquet,[1] M. Kornmann, and B. Lux

Battelle, Geneva Research Centre, 7, Route de Drize, CH-1227 Carouge-Genève, Switzerland

ABSTRACT

Alpha-Al_2O_3 has been chosen as the coating material for cemented carbide cutting tool inserts. The coatings have been prepared by chemical vapor deposition via hydrolysis of $AlCl_3$. The hard, dense and adherent alumina layers consisted of α-Al_2O_3 when deposited at temperatures above 850°C. Depending on the choice of the deposition parameters, the layer growth rate varied between a few tenths to 20 μm/hr. Machining tests carried out with cast iron and steel have shown that the presence of the alumina coating considerably increases the lifetime of the tool insert, reduces the number and the size of "cutting microholes" on the work piece, and decreases the amount of heat generated.

The quality of the cutting tool is of particular importance for the productivity of the metal cutting operation. Failure of tools used for cutting at high speeds is due to wear, plastic deformation, or rupture of the tool (1).

Wear of the surface of the tool is related to abrasion and adhesion processes taking place at the interface between the tool and the chip. In the case of cutting tools of cobalt-bonded tungsten carbide which are used for machining steel, diffusion of iron from the chip into the cobalt binder and of cobalt from the tool into the chip is particularly important in degrading the tool resistance (2). Furthermore, brittle and low melting carbides of tungsten and iron are sometimes formed at the tool/chip interface (3).

Plastic deformation (cratering) of the tool as well as the above-mentioned diffusion processes are accelerated by an increased temperature of the tool.

Rupture of the tool is mainly caused by mechanical shocks or vibrations.

Taking these factors into account, high performance from a cutting tool can be expected if: (*i*) The bulk of the tool has a high compressive strength, a high Young's modulus, a high creep resistance, and a high toughness. and (*ii*) the surface of the tool has good chemical resistance against the material to be machined, has a high hardness, and minimizes the absorption of heat by the tool.

A single material cannot combine the optimum values required for both the surface and the bulk of the tool. Cemented carbides satisfy the conditions required of the bulk but not those demanded of the surface of the tool. Therefore, an increased performance can be expected for tools made of cemented carbide, the surface of which is covered with a suitable coating. Titanium carbide and titanium nitride coatings produced by CVD have already found industrial application.

Applying the above criteria for the choice of an efficient coating (see the comparisons given in Table I) α-Al_2O_3 appears as a very promising coating, especially for the machining of steel at high temperatures, *i.e.*, at high cutting speed. This choice is supported by the fact that massive alumina tools are already used in industry and that the low wear of tools when machining steels that have been deoxidized with aluminum seems to be related to a thin layer of alumina formed at the surface of the tool during the cutting operation (5).

Experimental

Deposition procedure.—Alumina layers have been deposited on cemented carbide tools by chemical vapor deposition in a flow-type laboratory reactor which is shown schematically in Fig. 1, using one of the following reactions

$$2AlCl_3 + 3H_2O = Al_2O_3 + 6HCl \quad [1]$$

$$2AlCl_3 + 3CO_2 + 3H_2 = Al_2O_3 + 3CO + 6HCl \quad [2]$$

The feed rates of the gases participating in the process (H_2, CO_2, CO, and HCl) were metered at atmospheric pressure and room temperature. The $AlCl_3$ vapor was produced by conversion of HCl over aluminum chips heated to about 250°C. The water vapor required for reaction [1] was introduced by bubbling H_2 as carrier gas through a saturator held at a constant temperature. Heating of the substrate was carried out by high frequency induction. The temperature was measured with a thermocouple and an optical pyrometer.

The substrates were commercial tool inserts of grade ISO P30 (S4) produced by SANDVIK AB (chip face 1.61 cm²), total surface 4.5 cm²). Experiments were also carried out with inserts precoated with layers of TiC, TiN, and Cr. Before coating the tool inserts were ultra-

1100°C		0.099	0.11	0.063	0.013	0.014	0.0056

sonically cleaned, followed by vapor degreasing with Freon TF solvent or isopropyl alcohol.

Heating up and cooling down in the CVD reactor was carried out under hydrogen.

The values of the experimental parameters of the deposition runs are given in the figures and tables which summarize the results.

Examination of coated samples.—The difference in weight of the insert before and after coating permitted an estimation of the average layer thickness (1 mg $\approx$ 1 μm). It corresponds reasonably well to the values measured directly on polished sections. The coating thickness is not completely uniform and increases toward the edge of the chip face (Fig. 2, 3).

Comparative wear tests were carried out with uncoated, TiC-coated, and Al_2O_3-coated tool inserts.

Influence of Deposition Parameters upon Layer Growth Rate and Structure

Reaction 1 (H_2O process).—Figure 4 shows the deposition rate, expressed as the weight increase in mg · hr^{-1}, as a function of the substrate temperature in the interval of 600°-1000°C. The decrease in the deposition rate with temperature might be related to an increasing degree of formation of Al_2O_3 in the vapor phase. At higher total pressures (20 and 50 Torr) the deposition rate at a substrate temperature of 1000°C was negligible. These results are in agreement with observations made when Al_2O_3 was deposited on aluminum at lower temperatures (400°-600°C) by the same process (6).

Reaction 2 (H_2O-CO_2 process).—Substrate temperature.—For the CO_2-H_2 process the deposition rate increases rapidly with temperature (Fig. 5) which indicates that it is controlled mainly by a chemical reaction step. The "activation energy," calculated according to the Arrhenius equation is about 40 kcal/mole.

Total pressure.—The deposition rate as a function of total pressure in the deposition chamber presents a maximum between 50 and 100 Torr (Fig. 6). The experiments were carried out at constant mass flow rate.

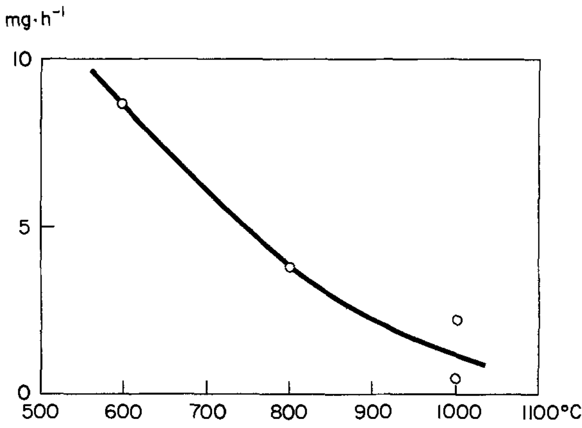

Fig. 4. H_2O process. Deposition rate as a function of substrate temperature. (Substrate, ISO P30. Total pressure, 5 Torr. Partial pressures: $AlCl_3$, 0.02; H_2O, 0.06; and H_2, 4.92 Torr. Linear gas velocity at 200°C, 9.4 cm · sec^{-1}.)

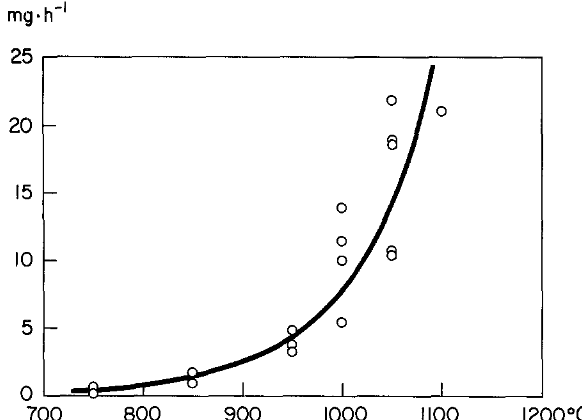

Fig. 5. H_2-CO_2 process. Deposition rate as a function of substrate temperature. (Substrate, ISO P30. Total pressure, 50 Torr. Partial pressures: $AlCl_3$, 0.2; CO_2, 24.9; and H_2, 24.9 Torr. Linear gas velocity at 200°C, 9.4 cm · sec^{-1}.)

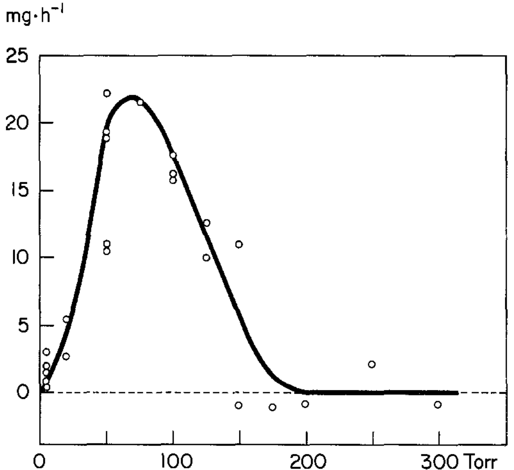

Fig. 6. H_2-CO_2 process. Deposition rate as a function of total pressure at constant mass flow rate. (Substrate, ISO P30. Substrate temperature, 1050°C. Gas composition: $AlCl_3$, 0.4%; CO_2, 49.8%; and H_2, 49.8%. Linear gas velocity at 50 Torr and 200°C, 9.4 cm · sec^{-1}.)

The decreasing deposition rate at higher pressure might be due to undesirable homogeneous reactions which lead to powder formation. These reactions are favored by the residence time of the reactants in the hot zone and the occurrence of free convective currents, the importance of which increases with pressure, *i.e.*, with decreasing flow velocity.

Sparrow *et al.* (7) derive the ratio Gr/Re^2, ratio of buoyancy forces to inertial forces, as the criterion for judging the nature of gas flow over a hot surface

$$Gr/Re^2 = \frac{gH(T_1 - T_0)}{4T_0v^2}$$

with Gr the Grashof number; Re the Reynolds number; g the gravity; H the length dimension: distance between substrate and reactor wall, according to Curtis and Dismukes (8); T_1 the substrate temperature; T_0 the wall temperature; and v the gas velocity.

Gr/Re^2 increases with pressure. For pure forced convection this value should be less than 0.3 or 0.06 according to the criteria which are chosen (7). Furthermore, in the present experiments, for which the buoyancy force has a component opposite to the free stream velocity ("opposing flow"), a separation of flow occurs if Gr/Re^2 is >1; near the surface the gas flow is then upward and no longer downward (7). Gr/Re^2 is calculated to be about 0.4 for a pressure of 100 Torr and about 1.6 for 200 Torr. If the average gas flow is directed upward there is no separation of flow due to buoyancy, and the decrease of the deposition rate with pressure is lower. An experiment at 300 Torr, with upward flow under the conditions indicated in Fig. 6, gave a deposition rate of 11.3 mg · hr^{-1}.

Table II. Deposition of Al_2O_3 on cemented carbide cutting tools (ISO P30): Deposition rate as a function of gas composition (substrate temperature, 1000°C; total pressure, 50 Torr; gas entrance temperature, 200°C; linear gas velocity at 200°C, 9.4 cm · sec^{-1}

* Mean value of four experiments.

Gas composition.—Table II summarizes the deposition experiments carried out with different partial pressures of the constituents of the vapor phase, but with an almost constant total pressure of 50 Torr and a substrate temperature of 1000°C. The deposition rate decreases slightly with p_{AlCl_3} (No. 1-4) and p_{H_2} (No. 5-7). Within the limits of reproducibility of the experiments, however, the measured values fall. The deposition rate increases approximately proportionally with p_{CO_2} (No. 8-11). Figure 7 shows deposition rates as functions of $p_{CO_2}:p_{H_2}$ and $p_{H_2}:p_{CO_2}$. Addition of CO or HCl to the feed mixture reduces the deposition rate as shown in three experiments (No. 12-14) in which identical amounts of Ar, CO, and HCl were added.

Structure of the coatings.—The columnar growth structure of the Al_2O_3 layers is shown in the metallographic section of Fig. 2. The coatings contained α-Al_2O_3 over the range of substrate temperatures from 850° to 1100°C. In most cases no noticeable change of the substrate occurred and only the initial phases of the cemented carbide (monocarbides and Co) have been detected by x-ray diffraction in addition to the α-Al_2O_3 of the coating. In a few cases only, the presence of η-carbides has been determined.

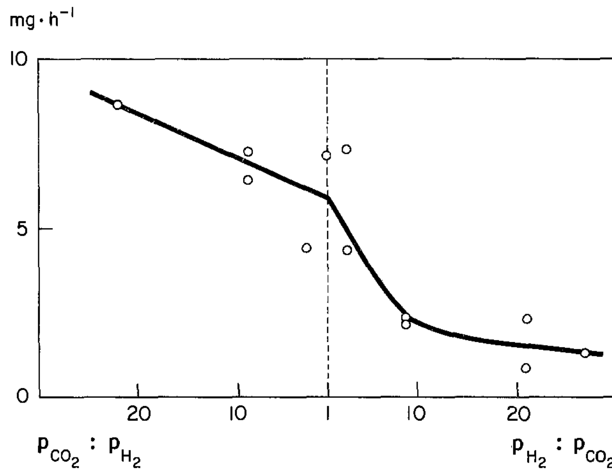

Fig. 7. Deposition rate as a function of $p_{CO_2}:p_{H_2}$ and $p_{H_2}:p_{CO_2}$. (Substrate, ISO P30. Substrate temperature, 1000°C. Total pressure, 50 Torr. p_{AlCl_3}, 1.5 Torr. Linear gas velocity at 200°C, 9.4 cm · sec^{-1}.)

Deposition of Al_2O_3 on WC, Co, and Precoated Tool Inserts

Deposition experiments have been carried out separately on the constituents of cemented carbides (WC and Co) as well as on inserts precoated with intermediate layers of TiC (Fig. 3), TiN, and Cr.

Very adherent layers of α-Al_2O_3 have been obtained on WC whereas on Co the formation of loose deposits was observed. TiC and TiN as intermediate layers were found to favor the adherence of the Al_2O_3 coating, while on Cr nonadherent deposits were formed. The nonadherence on Co and Cr could be explained by substrate attack, possibly by HCl, and hence disturbance of the nucleation and layer growth. This view would agree with observations made by Bryant and Meier (9) in the case of other CVD reactions involving chlorides.

Observations concerning the nucleation of Al_2O_3 coatings on TiC-coated and uncoated cemented carbide substrates have been reported earlier (10).

Table III. Machining condition for cast iron and high carbon steel

Materials machined	Lamellar gray cast iron	SANDVIK high carbon steel (C-0.96, Si-0.27, Mn-0.25, P-0.019, S-0.015, Cr-0.15%)
Dry cutting		
Advance	0.1 mm/rev	0.3-0.4 mm/rev
Depth of cut	0.5 mm	2.0 mm
Initial diameter of bars	40 mm	144 mm
Speed of first pass	190 m/min	140-200 m/min

Results of Machining Tests

Comparative cutting tests have been carried out with Al_2O_3-coated, TiC-coated and uncoated tools; cast iron and high carbon steel have been machined mainly under the conditions given in Table III.

The main results of machining tests are the following: The wear of uncoated or TiC-coated tools is greater than that of the Al_2O_3-coated tools tested under the same conditions. This result is obtained both with high carbon steel and with lamellar gray cast iron (Fig. 8 and 9).

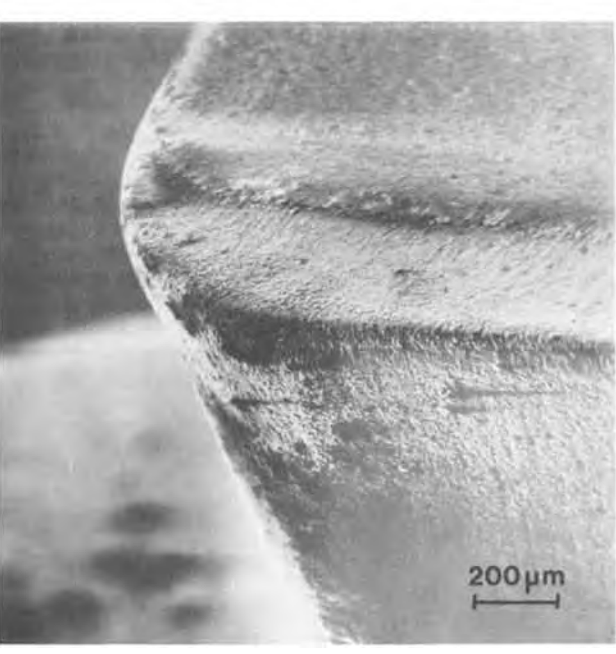

Fig. 8. Comparison of wear of Al_2O_3- and TiC-coated tools after cutting high carbon steel at 180 m/min for a duration of 10 min. (a, top) TiC-coated tool, (b, bottom) Al_2O_3-coated tool.

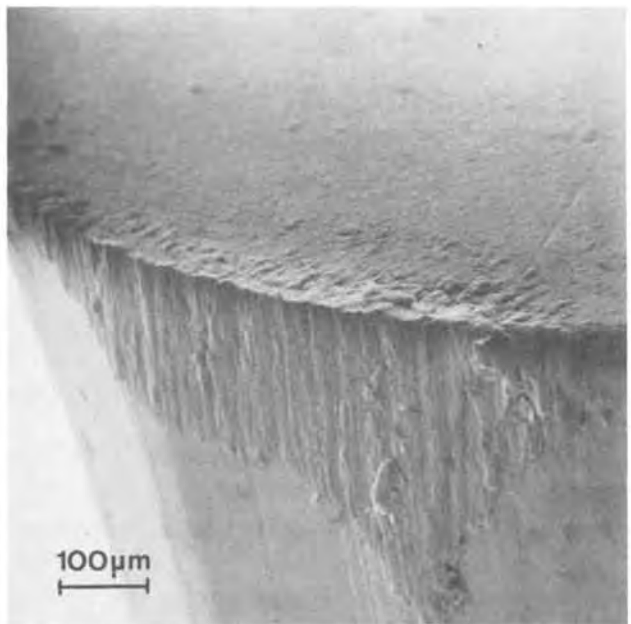

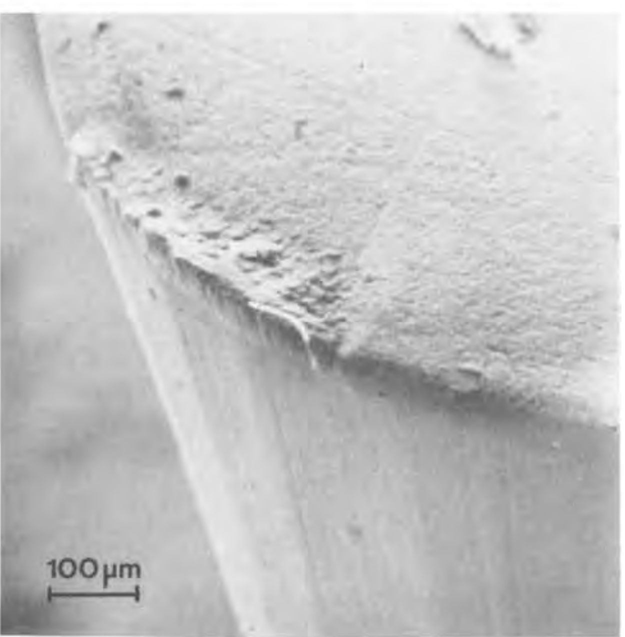

Fig. 9. Cutting edges of (a, top) uncoated and (b, bottom) Al_2O_3-coated (1 μm) carbide tool after cutting cast iron for a duration of 1 min.

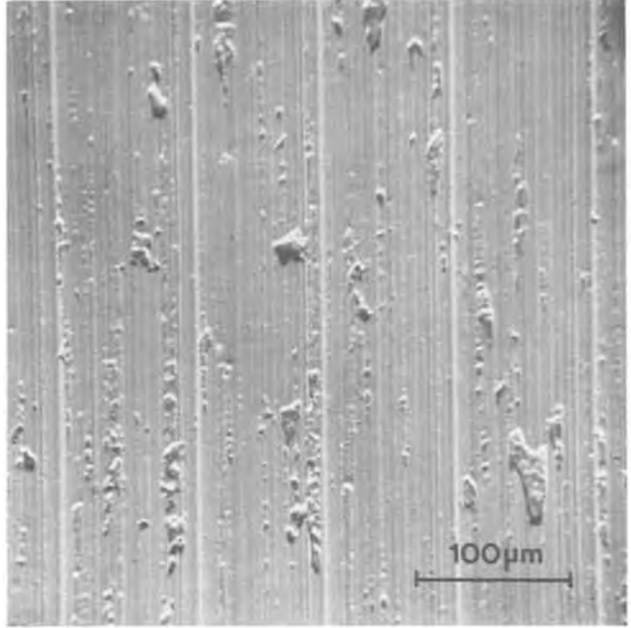

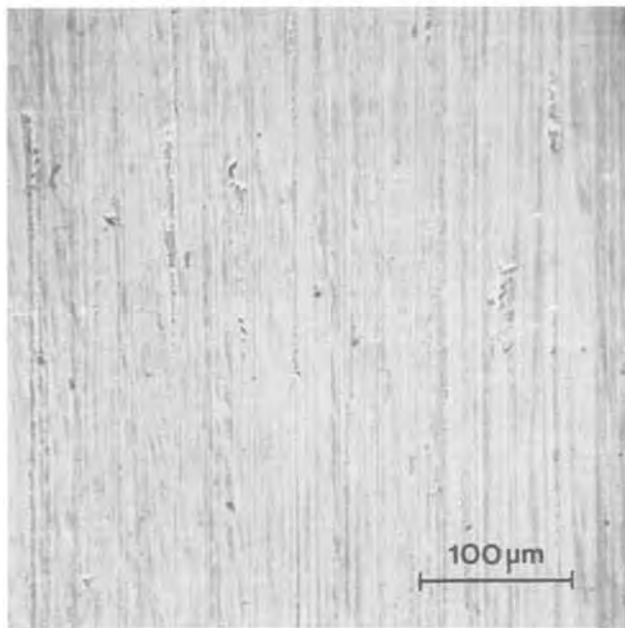

Fig. 10. Surface of high carbon steel workpieces cut with (a, top) an uncoated carbide tool and (b, bottom) an Al_2O_3-coated carbide tool.

For example, in machining tests with high carbon steel carried out at a speed of 140 m/min the lifetime of the Al_2O_3-coated tool insert was about twice that of a TiC-coated one and more than 10 times as long as that of an uncoated tool insert.

Al_2O_3 coatings with a thickness as low as 1 μm have been effective (Fig. 9).

When cutting steel, the α-Al_2O_3 coating on the tool reduces the number and the size of "cutting microholes" on the work-pieces (Fig. 10). This effect is more marked at high cutting speeds (*e.g.*, 180 m/min) than at lower speeds (*e.g.*, 145 m/min).

ABSTRACT

Well-formed hexagonal whiskers of TiP (5-10 mm in length and 0.5-25 μm in diameter) were obtained by chemical vapor deposition on a quartz substrate at 850°-1150°C using Au metal as an impurity to promote crystal growth, whereas platelet crystals were obtained at 1250°C using Pd or Pt. The effects of temperature, gas composition, and the kind of impurities on the growth rates were examined. Electrical resistivity and thermoelectric power of whiskers and platelet crystals indicated anisotropy. The tensile strength of whiskers was found to be about 1000 kg/mm^2 for 1 μm samples. The whiskers showed a considerable oxidation resistance in air below 1000°C, probably because of the formation of TiP_2O_7 and TiO_2 layers.

A number of compounds of borides, carbides, and nitrides of transition metals have been extensively investigated during the past decades. However, only a few studies on the phosphides have been performed, although some of the phosphides are of much interest in view of their physical and chemical properties.

Previously it was reported that the reactions of titanium metal with red phosphorus (1-2), phosphine (3-6), and calcium phosphide (7), or of titanium hydride with phosphine (2) at elevated temperatures gave titanium phosphides with various compositions depending on the reaction conditions used: TiP_2, TiP, Ti_2P, Ti_3P, Ti_3P_2, etc.

Titanium monophosphide, TiP, is very stable to heat without appreciable vaporization of phosphorus even at 1100°C (1), is highly resistant to oxidation (3, 5), and is metallic in conduction. Its space group (8) is $P6_3/mmc$ and the unit cell dimensions are a = 3.499Å and c = 11.700Å.

However, there is no work reported in the literature on single crystal growth of TiP, much less about the preparation of whiskers from the vapor phase. In this paper, with the objective of obtaining the well-formed and long whiskers of TiP from a gas mixture of $TiCl_4$, PCl_3, and H_2, the reaction conditions were examined, and some physical and chemical properties of the crystals were investigated in some detail.

Experimental

Materials.—Commercial reagent grade titanium tetrachloride and phosphorus trichloride were used without further purification. Argon was purified by passing over titanium sponge kept at 800°C, and hydrogen was refined by passing through concentrated sulfuric acid and phosphorus pentoxide, sequentially.

Preparation of TiP.—The apparatus is shown in Fig. 1. A quartz tube 7, (8 mm OD and 65 mm in length), in which a SiC heater was inserted, was placed as a substrate in the center of the reaction tube (quartz of 19 mm ID). The substrate was heated at 900°-1250°C. Hydrogen was bubbled into a titanium tetrachloride evaporator, 1, and was flowed through a condenser, 2. The temperature of coolant in the condenser was regarded as the saturating temperature. Phosphorus trichloride was also carried into the reaction tube by passing hydrogen through a saturator, 3. Argon was used for cleaning the reaction system before each experiment.

The surface temperature of the substrate was measured by an optical pyrometer through a window and the ambient temperature inside the reaction tube was monitored by a Chromel-Alumel thermocouple.

Aqueous solutions of $MnSO_4 \cdot 4H_2O$, $Fe_2(SO_4)_3 \cdot 9H_2O$, $CoCl_2$, $NiCl_2$, $RhCl_3 \cdot 4H_2O$, $PdCl_2$, H_2PtCl_6, $HAuCl_4$, etc. were used as the source of various impurities to promote crystal growth, and these were painted on a substrate scratched by abrasives, followed by decomposition or reduction into corresponding metals inside the reactor at a temperature below that used for the TiP crystal growth.

The range of the whisker length reported in this paper refers to that measured under 150× magnification of about twenty of the longest samples obtained in any one growth experiment.

Observation and analysis of deposits.—The deposits were examined by x-ray diffraction, scanning electron microscopy, and x-ray microanalysis. Quantitative analysis of titanium in the deposits was carried out by back titration of cupric ion with EDTA using pyridylazo-naphthol as an indicator (9).

Electrical resistivity.—The four-point probe method was applied where each probe was separated by 0.5 mm from the other, and the crystal was contacted with probes by silver paint. Voltage of 10V from a d-c Wheatstone bridge was applied between the outer two probes and the voltage drop between inner two probes was measured by a microvoltmeter.

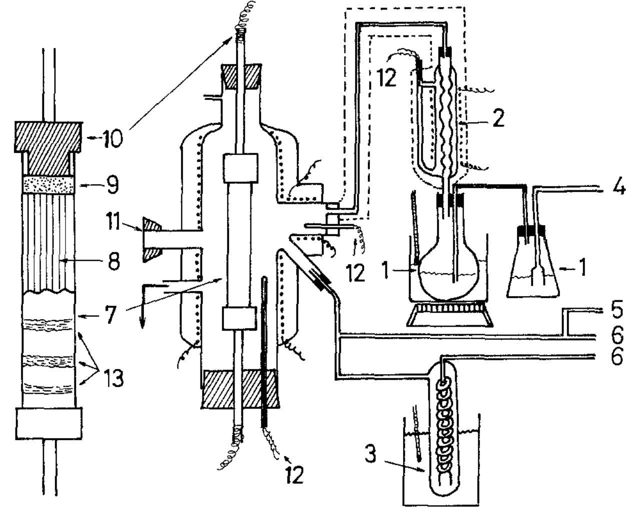

Fig. 1. Experimental apparatus. 1, $TiCl_4$ evaporator; 2, $TiCl_4$ condenser; 3, PCl_3 saturator; 4, H_2; 5, Ar; 6, H_2; 7, quartz substrate; 8, SiC heater; 9, graphite powder; 10, graphite conductor; 11, window; 12, thermocouple; 13, impurity painted zone.

Key words: CVD (chemical vapor deposition), whisker, VLS (vapor-liquid-solid) growth.

Thermoelectric power.—The crystal was bridged between two copper plates (3 × 5 mm), which were separated by 2 mm from each other and one of which was heated by a Nichrome heater, and was contacted using silver conducting paint on the plates. The temperature difference of the two sides of crystal was measured by a 100 μm diameter iron-Chromel thermocouple. Thermoelectric power was measured in an argon atmosphere, and the temperature difference across the specimen was held at 1°-1.5°C.

Tensile strength.—Measurements of the tensile strength of the whiskers were carried out by a spring-type apparatus at room temperature.

Stability for oxidation.—A gravimetric method was adopted to check the progress of the oxidation reaction. TiP whiskers of about 100 mg (w) were heated at a given temperature in a flow of air (about 2 cm^3/sec) during which weight change (Δw) was measured at every time interval. The results were expressed in terms of $\Delta w/w$.

Results and Discussion

Identification of products and impurity effect.—In a preliminary experiment, polycrystals or whiskers were observed in the absence or presence of gold impurity, respectively, at 1050°C. In the presence of palladium, however, platelet crystals were obtained at 1250°C. X-ray diffraction peaks of polycrystals or whiskers as grown, shown in Fig. 2A, were consistent with those reported by Schönberg (3) for pulverized TiP (Fig. 2D), and no other peaks were observed. Chemical analysis of titanium in the TiP crystals showed the atomic ratio of Ti/P to be 0.99. The whiskers were also identified as TiP by x-ray diffraction (Fig. 2B) which was conducted by placing a collection of whiskers on a holder plate along the growth direction and perpendicular to the x-ray beam. The growth direction was found to be parallel to the c-axis. A Laue photograph with the x-ray beam perpendicular to a face of the platelet crystal showed six-fold symmetry, and the diffraction peaks obtained from the platelet crystal attached on a holder plate keeping the face parallel to the plate face are shown in Fig. 2C. From these results, the face of the platelet crystal was assigned as the (001) plane.

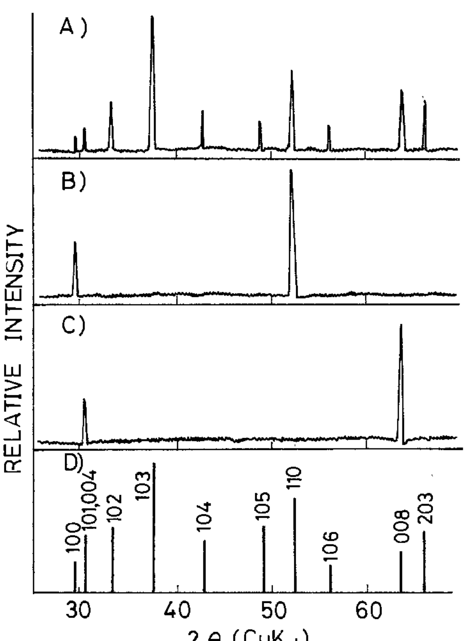

Fig. 2. X-ray diffraction profiles. A, As-grown whiskers; B, whisker aligned along the growth direction; C, platelet crystal keeping the face perpendicular to the x-ray beam; and D, TiP data from Schönberg (3).

Table I. Impurity effects.

Reaction conditions: temperature 1040°C; $PCl_3/TiCl_4/H_2$ = 0.013/0.13/1.86 (cm^3/sec); reaction time 15 min.
* (−) No effects. (+) Weak positive effects (up to 3 mm long). (+ +) Strong positive effects (longer than 3 mm).
** Atomic per cent of titanium or phosphorus at each eutectic point is shown in parenthesis.
† Peritectic temperature.

The variations of reaction temperature of 850°-1250°C and of the ratio $PCl_3/(PCl_3 + TiCl_4)$ of 0.1-0.9 did not result in other products than TiP. In the absence of an impurity, no whiskers or platelet crystals were formed at any condition, indicating the essential role of the impurity in crystal growth.

In Table I, the effect of various metal impurities on whisker growth is shown together with the eutectic temperature of the corresponding binary alloys (10-11). Chromium, iron, cobalt, nickel, copper, and neodymium resulted in no effect on whisker growth, and deposition took place in a form of uniform coatings or polycrystals. On the other hand, manganese, rhodium, gold, and antimony showed a strongly positive effect, giving straight and thin whiskers (up to 3 mm in length), gold was particularly effective giving well-formed whiskers (above 5 mm in length).

Palladium and platinum exhibited a weak effect on whisker growth at 1040°C, but a strong effect at 1150°C; however, runs at 1250°C gave thin platelet crystals of longer than 3 mm in diagonal. The role of an impurity on the growth mechanism of crystals is discussed in a later section.

Gold was used hereafter unless otherwise indicated because of the convenience in handling. Although the concentration of gold may play a role in whisker growth the surface concentration of gold was fixed at about 50 $\mu g/cm^2$ of substrate area in this experiment.

Whiskers grown at 1040°C are shown in Fig. 3A and platelet crystals grown at 1250°C with the use of Pd impurity are shown in Fig. 3B. It can be seen that the whiskers and platelet crystals grow only on the impurity-painted zone and their growth direction tends to be vertical to the substrate surface. In Fig. 4, photomicrographs of a typical whisker obtained at 1040°C and the cross section are shown. They have the appearance of regular hexagonal pillars with an average size of 5-10 mm in length and 0.5-20 μm in diameter. Sometimes rectangular pillar crystals were also observed, and the growth direction may be judged from their appearance to be vertical to the c-axis.

The effect of substrate temperature.—Substrate temperature exhibited a strong effect on whisker growth. An average length of 5-6.5 mm was observed at 1020°-1050°C, and at higher or lower temperatures than 1020°-1050°C the length decreased abruptly. Above the optimum temperature, crystals grew in radial directions resulting in considerable branching. Sometimes platelets crystals of 1 ~ 3 × 0.5 ~ 2 mm, 0.5 ~ 5 μm thick were grown mixed with whiskers above the optimum temperature. At a temperature higher than 1100°C, they are apt to grow thick and have continuous growth steps (Fig. 5). Figure 5C shows a regular hexagonal pyramid frequently formed on the platelet crystals, on the tip of which a deposit is observed.

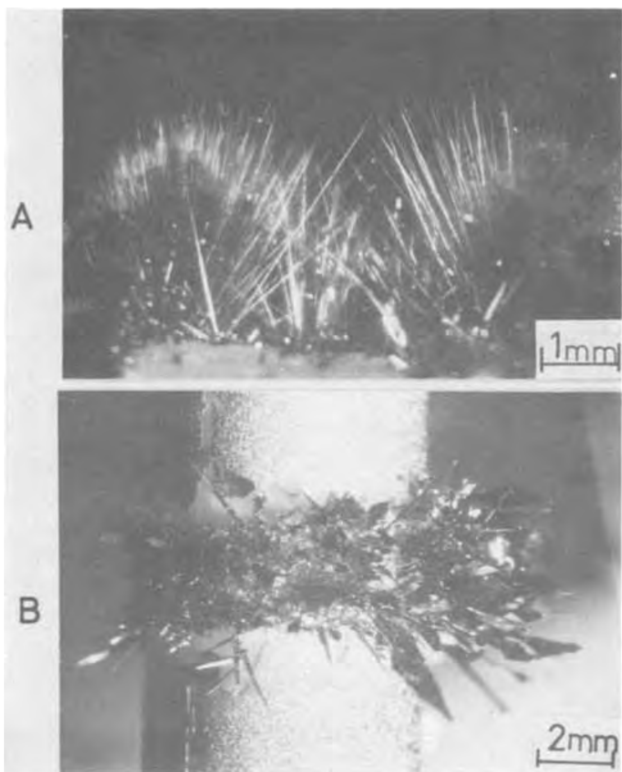

Fig. 3. Appearance of whiskers and platelet crystals. A, Whiskers, reaction temperature 1040°C; reaction time 15 min; $PCl_3/TiCl_4/H_2$ = 0.015/0.12/2.0 (cm^3/sec), impurity Au. B, Platelet crystals, reaction temperature 1250°; reaction time 30 min; $PCl_3/TiCl_4/H_2$ = 0.02/0.2/2.2 (cm^3/sec), impurity Pd.

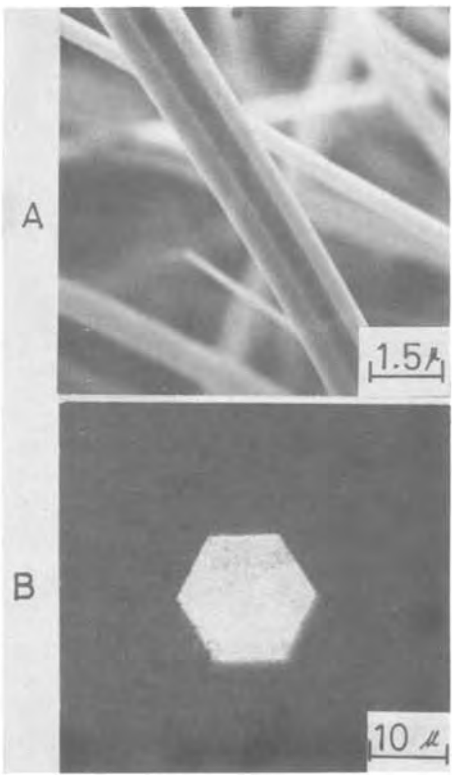

Fig. 4. A whisker of hexagonal pillar and its cross section. Reaction temperature 1050°C, reaction time 20 min, $PCl_3/TiCl_4/H_2$ = 0.03/0.2/2.0 (cm^3/sec), impurity Au. A, Appearance of whisker; B, its cross section.

The lowest temperature for the growth of TiP whiskers was approximately 850°C when gold was used as an impurity. In the case of palladium and platinum, the lowest temperature for the whisker growth was found to be 1050°C, and the optimum temperature was in the range of 1100°-1150°C; on the other hand, platelet crystals were mainly obtained at a temperature higher than 1200°C. Although the system Au-Ti-P, Pd-Ti-P, or Pt-Ti-P have not been reported, the difference of the lowest or optimum temperature for the whisker growth among the impurities may be attributed to the eutectic temperature in the expected ternary system, impurity-titanium-phosphorus.

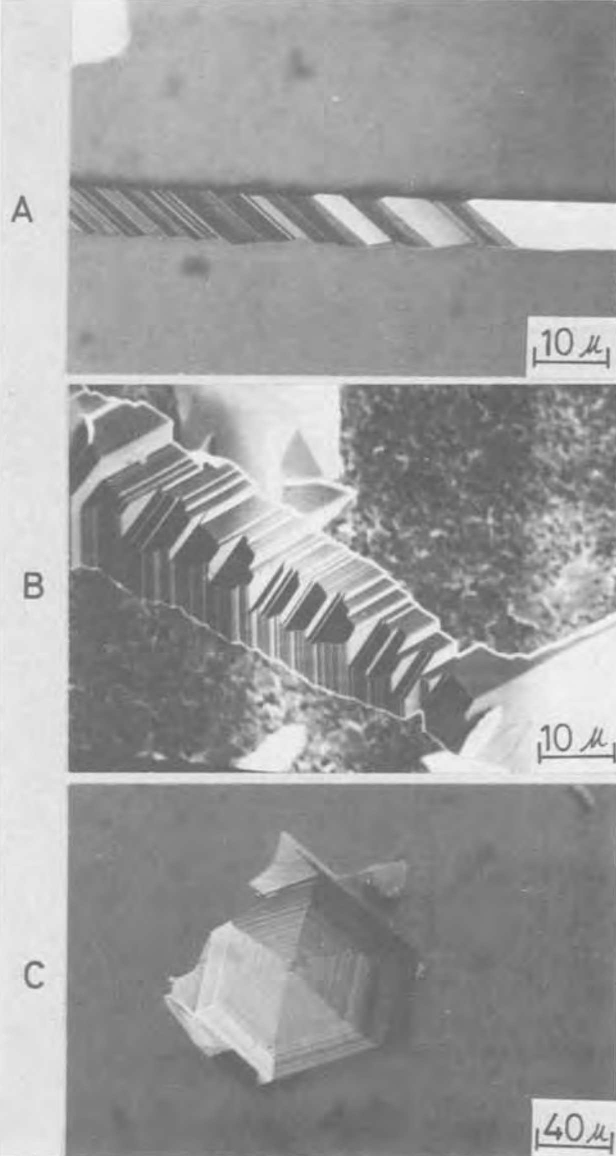

Fig. 5. Growth steps. A, Rectangular pillar, reaction temperature 1130°C, $PCl_3/TiCl_4/H_2$ = 0.03/0.15/2.3 (cm^3/sec). B, Hexagonal pillar, reaction temperature 1130°C, $PCl_3/TiCl_4/H_2$ = 0.03/0.15/2.0 (cm^3/sec). C, Hexagonal pyramid deposited on a platelet crystal, reaction temperature 1100°C, $PCl_3/TiCl_4/H_2$ = 0.03/0.13/2.2 (cm^3/sec).

Effects of gas composition and flow rate on whisker growth.—The effect of the concentration of PCl_3 and $TiCl_4$ on whisker growth (solid line) and polycrystalline growth (broken line) are shown in Fig. 6, where the total chloride flow rate was fixed at 0.25 cm^3/sec. The longest whiskers were not obtained at the ratio of $PCl_3/(PCl_3 + TiCl_4) = 0.5$, which corresponds to the stoichiometric ratio of the reactions, $PCl_3 + TiCl_4 + 7/2\ H_2 = TiP + 7HCl$, but at $PCl_3/(PCl_3 + TiCl_4) =$ 0.08-0.11.

Such a tendency for phosphide whiskers to grow from a gas mixture having a poorer PCl_3 composition

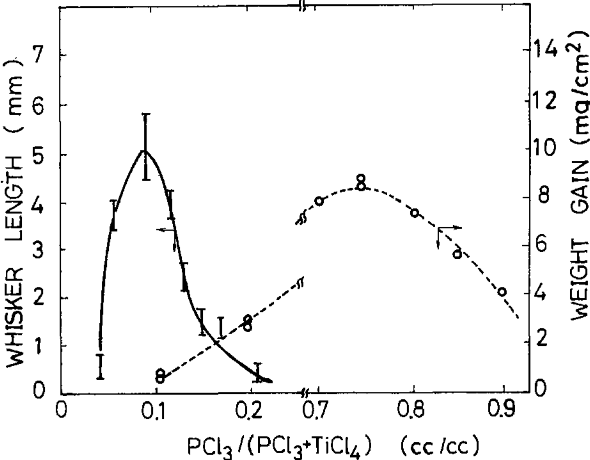

Fig. 6. Influence of PCl_3 and $TiCl_4$ composition on whisker and polycrystalline growth. ——, Whisker (with Au), reaction temperature 1050°C, reaction time 15 min, $PCl_3 + TiCl_4 = 0.25$ cm³/sec, $H_2 = 2.25$ cm³/sec. - - - -, Polycrystalline (without Au), reaction temperature 1050°C, reaction time 15 min, $PCl_3 + TiCl_4 = 0.2$ cm³/sec, $H_2 = 2.2$ cm³/sec.

than expected from stoichiometry has been found in the cases of ZrP (12) and BP (13) in the systems $ZrCl_4 + PCl_3 + H_2$ and $BCl_3 + PCl_3 + H_2$, respectively. When no impurity was used, on the other hand, maximum growth rate of polycrystalline films was observed at $PCl_3/(PCl_3 + TiCl_4) = 0.7$-$0.8$, that is, in a PCl_3-rich region. The fast growth of polycrystalline films may require the ratio $PCl_3/(PCl_3 + TiCl_4)$ of 0.5 in gaseous layer over the growing surface. However, PCl_3 is easily reduced to the element of phosphorus which deposits on the inner wall of the reaction tube. Therefore, a ratio of $PCl_3/(PCl_3 + TiCl_4)$ of larger than 0.5 is reasonable in the flow system. On the contrary, the small value of the ratio for optimum condition to whisker growth suggests the phosphorus transport to be rate determining in whisker growth at least in its early stage of growth.

The total chloride flow rate also exhibited a pronounced effect on whisker growth, where the ratio of PCl_3 and $TiCl_4$ was fixed at $PCl_3/TiCl_4 = 0.1$. An average length of 8-10 mm was obtained at $PCl_3 + TiCl_4 = 0.12$-0.15 cm³/sec (linear velocity $\simeq 0.27$ cm/sec at 1040°C), and at a ratio higher or lower than this the length decreased abruptly below 2 mm and curled or woolly whiskers were obtained.

Growth rates of woolly whiskers were determined at about 2-3 mm/min, which is a considerably larger value than that of the pillar whisker of 0.2-0.6 mm/min.

The influence of total gas flow rate on whisker growth was also examined, where the flow ratio of the relevant gases was fixed at $PCl_3/TiCl_4/H_2 = 0.0065/0.065/1$. Whiskers grew to an average length of 6.5-7.5 mm at a flow rate of 1.8-2.2 cm³/sec (linear velocity is roughly estimated as 3.7-4.5 cm/sec at 1040°C).

Mechanism of whisker growth.—In order to clarify the role of the impurity, its location on the growing crystals is very important, since one of the indications for the tip vapor-liquid-solid (VLS) mechanism (14) is the existence of drops of impurity on their tips.

The tip part of most whiskers had a shape of a long hexagonal pyramid, and a droplike solid was seldom found on the tip, suggesting that a tip VLS mechanism does not take part in the growth, although a rapid VLS growth followed by slow VS growth in a radial direction cannot be ruled out at this time.

Similar appearances of the tip were also observed in the case of ZrP whisker growth (12) in which the tip was a clear-cut square or tetragonal pyramid.

Photomicrographs of the cross section of a base of a whisker display the presence of a thick and continuous layer, from which the whisker emerged. A result of x-ray microanalysis on this layer is shown in Fig. 7, indicating that the layer consists of a uniform composition of titanium-phosphorus-gold.

This observation suggests a growth mechanism by a center axial screw dislocation proposed by Frank *et al.* (15). However, as mentioned above, the present result can also be explained by the VLS mechanism (16), at least during the initial stage of growth.

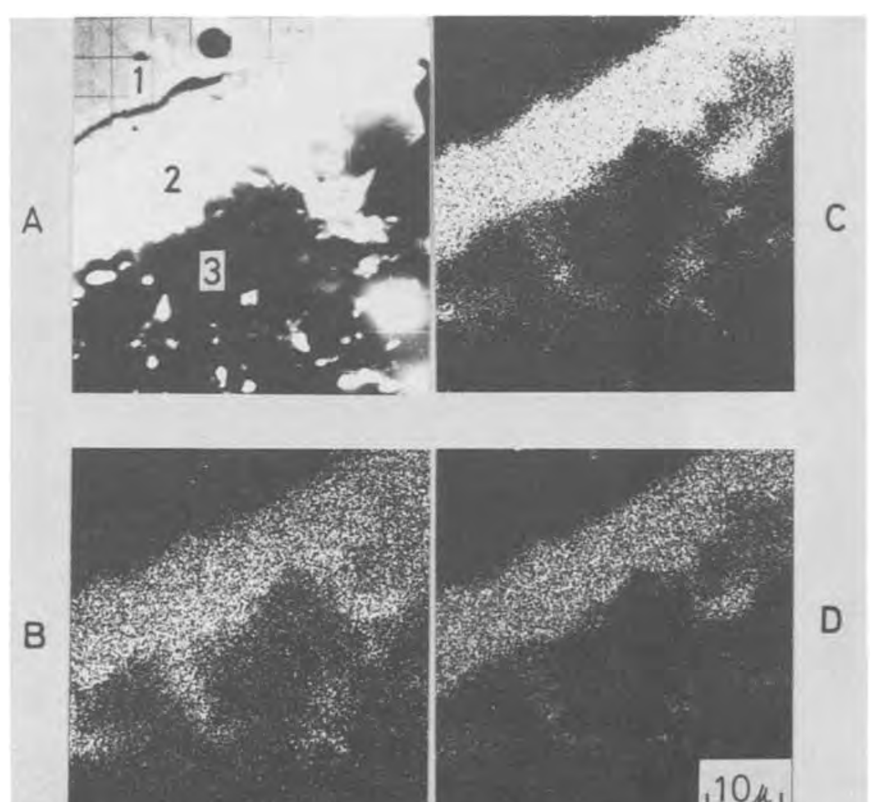

Fig. 7. Profiles of x-ray microanalysis. A: 1, Quartz substrate; 2, TiP layer; 3, whisker part molded in resin. X-ray: B, PKα; C, TiKα; D, AuMα.

Properties of TiP crystals.—Electrical resistivity.— The resistivities of well-formed whiskers of hexagonal pillar (5-10 mm in length and about 10 μm in diameter) and platelet crystals (3 $\sim$ 6 $\times$ 2 $\sim$ 5 mm, 2 $\sim$ 5 μm thick) are shown in Fig. 8, where the direction chosen for measurements of electrical resistivity and thermoelectric force (see next section) of crystal plates is in some direction within (001) plane of the plate. Although the measurements were carried out on three crystals of each type, the results were characteristic of each type within experimental error. In Fig. 8, the resistivity increases linearly with the temperature, characteristic of metallic conduction, and the whisker and the platelet crystals have resistivities of 2.5×10^{-4} and 3.5×10^{-5} ohm · cm at room temperature, respectively. The activation energies are also estimated as 0.65 and 0.83 eV, respectively.

Thermoelectric power.—The thermoelectric power of the crystals are shown in Fig. 9. The thermoelectric power of whiskers relative to copper increased with temperature and showed 18 and 30 μV/°C at 25° and 200°C, respectively. These values are similar to those of TiP_2 (17). On the other hand, the thermoelectric power of platelet crystals was independent of temperature and showed 8 μV/°C.

Tensile strength.—The tensile strength of hexagonal pillar whiskers was measured at room temperature as shown in Fig. 10, which indicates that the tensile strength increases with decrease of diameter and has values of 100 and 1000 kg/mm² for whiskers of 20 and 1 μm in diameter, respectively.

Stability for oxidation in air.—Figure 11 shows the change of weight ratio with time at various temperatures between 400° and 1000°C. The weight ratio increased with increasing temperature above 400°C, and at each temperature studied, the ratio quickly increased to a limiting value and remained constant with time. For example, at 1000°C, the ratio increased steeply to 0.56 after 5 min, and remained unchanged after 90 min.

The ratio of weight increase expected by the reaction

$$4TiP + 9\,O_2 = 4TiO_2 + P_4O_{10} \qquad [1]$$

is as small as 1.0 weight per cent if phosphorus pentoxide is lost into the gaseous phase. Therefore, the real weight increase cannot be explained by the above reaction.

X-ray diffraction profiles of the products obtained at 1000°C for 30 min are assigned to both TiP_2O_7 and TiO_2, indicating that the products consist mainly of TiP_2O_7 and TiO_2 in separate phases. But the x-ray pattern indicates little TiP remained at this temperature. It is reasonable to assume that TiP is susceptible to air oxidation at elevated temperatures according to the reaction

$$2TiP + 9/2\,O_2 = TiP_2O_7 + TiO_2 \qquad [2]$$

but a tight double layer of TiP_2O_7 and TiO_2 formed on the surface of crystals protects the bulk from further oxidation.

The oxidation product of ZrP, an analogous phosphide of TiP, was solely ZrO_2 (12), probably due to the difference in the stability of the respective pyrophosphates.

Conclusions

1. Titanium monophosphide single crystals were obtained by chemical vapor deposition from a system, $TiCl_4$, PCl_3, and H_2 on a quartz substrate at 850°-1250°C.
2. Manganese, rhodium, gold, and antimony had a beneficial effect on whisker growth at 1040°C. In the case of gold, whiskers with an average length of 5-10 mm and a diameter of 0.5-25 μm and with well-formed hexagonal cross section were obtained in the temperature range of 1020°-1050°C in 15 min. Palladium promoted platelet crystal growth at 1250°C.
3. The growth direction of whisker was the c-axis and the face of platelet crystals was assigned as the (001) plane.
4. The longest whisker was obtained at a substrate temperature of 1020°-1050°C, $PCl_3/(PCl_3 + TiCl_4)$ ratio of 0.08-0.11, total flow rate of $PCl_3 + TiCl_4$ of 0.12-0.15 cm³/sec, and a total gas flow rate (mainly H_2) of 1.8-2.2 cm³/sec.
5. A droplike solid was seldom found on the tip part of most whiskers, and layers with uniform Ti-P-Au compositions were observed in the bottom part of whiskers. It is presumed that a screw dislocation or a bottom site VLS mechanism is responsible for the growth of TiP whiskers rather than a tip VLS mechanism.
6. The whisker and platelet crystals had 2.5×10^{-4} and 3.5×10^{-5} ohm · cm resistivity at room temperature along the direction of the growth axis and some direction in (001) plane, respectively.
7. The whisker and platelet crystal had 18 and 8 μV/°C thermoelectric power at room temperature along the direction as above, respectively.
8. The whiskers of 20 and 1 μm in diameter had tensile strengths of 100 and 1000 kg/mm², respectively.
9. TiP crystal was inert in air below 400°C, but oxidized at higher temperature. A layer of titanium pyrophosphate and titanium oxide formed in an early stage of oxidation prevented further oxidation and gave a high temperature stability up to about 1000°C in air. But the x-ray pattern indicates little TiP remained at this temperature.
10. TiP whiskers 5-10 mm long could be easily obtained by the CVD method using a gold impurity. Furthermore, they have a high stability to oxidation at elevated temperatures. Therefore, TiP whiskers are expected to be one of the interesting materials for high temperature composite.

Low Temperature Migration of Gold Through Thin Films of Silicon Monoxide

D. V. Morgan, M. J. Howes, and C. J. Madams

Department of Electrical and Electronic Engineering, The University of Leeds, Leeds LS2 9JT, England

ABSTRACT

A study of gold migration in silicon monoxide in the temperature range 200°-600°C has been carried out using the Rutherford scattering technique. It has been found that for plane sources, diffusion occurs which can be characterized by the normal Arrhenius form. For thick gold sources this temperature relation is followed until the silicon-gold eutectic temperature is exceeded at which point a rapid migration of the gold occurs and a high concentration is established in the film.

This investigation was initiated with a view to characterizing some of the less well investigated properties of the material commonly referred to as "silicon monoxide," and which has been used extensively as the amorphous material in the investigation of electrical switching phenomena in amorphous oxide films (1).

Key words: silicon monoxide, thin films, gold migration.

As the properties of silicon monoxide depend markedly on its method of preparation we have restricted our investigation to the study of the migratory behavior of gold in films which have been vacuum deposited from an electrically heated boat source. As silicon monoxide thus prepared is nonstoichiometric, we will refer to it as SiO_x, where the x refers to the material stoichiom-

etry and which is given an experimentally determined value where appropriate.

Experimental Techniques

Films of SiO_x, of thickness ranging from 200 to 500 nm, were prepared by the thermal deposition (10^{-6} Torr, 1-2 nm/sec) of solid silicon monoxide lumps from a boat source onto polished vitreous carbon substrates. It was found necessary to heat the substrate to 200°C to promote adhesion and to eliminate the stress cracking which occurs when deposited films cool to room temperature after deposition onto a cold substrate.

To facilitate depth profiling by Rutherford scattering, measurements of film density were made by including a clean microscope slide in the vacuum system and exposing this to the SiO_x flux during the evaporation. Microbalance and Talysurf thickness measurements on the slide enabled the density of the deposited oxide to be determined to an accuracy of 4%.

After the substrates had cooled to room temperature a gold evaporation was carried out through a mask containing 5 mm diameter holes to produce circular areas of gold on the surface of the deposited SiO_x layer. The resulting gold layers were of two thicknesses, ~3 and 30 nm, as determined by a crystal film thickness monitor. The specimens were then annealed in an open tube, nitrogen gas ambient, furnace at temperatures in the range 200°-600°C and for periods in the range 200-0.25 hr.

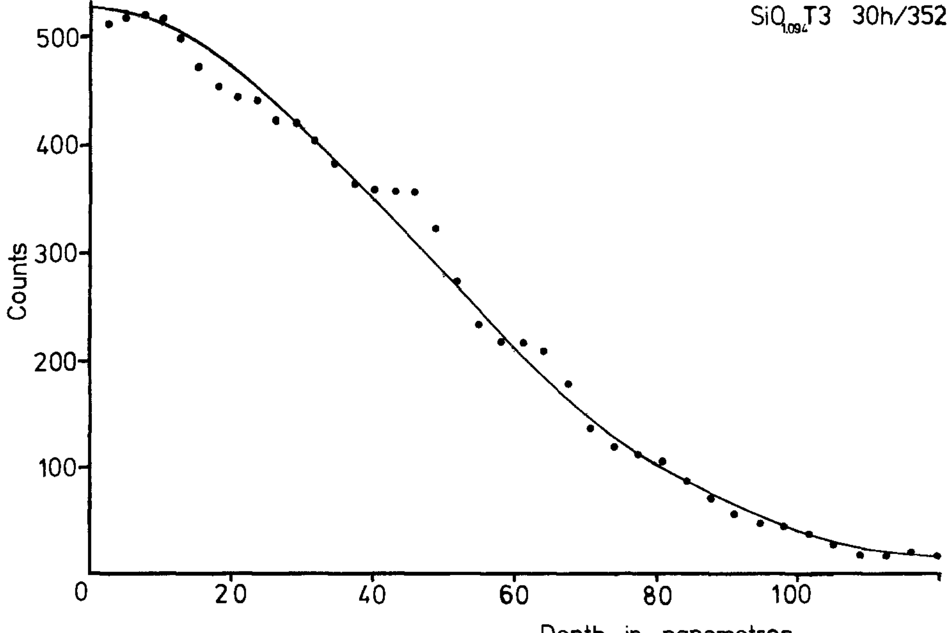
Methods of Analysis

Thin gold layer.—A thin diffusion source approximates to a perfect plane source of zero thickness providing certain conditions are fulfilled (1). In general these conditions will be met if the resulting diffusion depth is large compared to the original source thickness. If the diffusion mechanism can be described by Fick's law then the resulting diffusion profile will have a half-Gaussian form. This particular case is extremely simple to analyze using the Rutherford scattering technique as the concentration of the diffusing species does not contribute significantly to the over-all stopping power of the substrate material and the concentration of substrate atoms can be assumed constant with depth. The over-all stopping power of the SiO_x film can be determined by Bragg's rule (2) (3) from tabulated data, and a check on the validity of the rule made against the known thickness of the SiO_x film.

If we consider the initial high energy side of a diffusion profile in a Rutherford scattering spectrum and assumes depth/energy linearity then a simple calculation enables the contribution of the analyzing system to the FWHM of the profile to be calculated. For a diffusion profile FWHM greater than a factor of five times the detector and system FWHM the contribution from the measuring system is less than 2% of the profile FWHM. This is only true if the surface broadening, which is due solely to the system resolution, is removed. This may be accomplished by adding complementary channels about the surface half maximum point on the profile. For our results, our system resolution of 14 keV contributes less than 0.28 keV to the FWHM's of the profiles under these conditions. After this initial correction, the resulting data points were smoothed by truncating their Fourier transforms (4, 5) and the smoothed diffusion profiles extracted by iteratively computing channel depths (Fig. 1). A plot of log counts *vs.* channel depth squared, results in a graph whose slope yields the value of the diffusion coefficient. The values thus obtained may then be plotted against reciprocal temperature to obtain the diffusion parameter D_o cm²/sec (Fig. 2). This procedure was checked by comparing the diffusion coefficients of gold in silicon as obtained from Rutherford scattering, with those obtained from the extrapolation of known data (6). We find that there is satisfactory agreement between the different results (see Table I).

Thick gold source.—For the thick gold source case the analysis is not as simple, and we have been unable to make quantitative measurements on the migration of the gold into the SiO_x layer. Previous authors (7) have relied on existing knowledge of compound densities in determining the stopping power of alloy formations at interfaces. However these generally imply a semi-infinite substrate and the question of the growth direction of the interfacial layer does not arise. When dealing with film thickness of only 500 nm it becomes important, when analyzing the data, to determine whether material is moving out from the film into the surface layers or vice versa and whether the over-all specimen thickness remains constant. Unfortunately it is rarely possible to determine this from the Rutherford scattering spectrum. Nevertheless it is possible to draw some qualitative conclusions from the Rutherford scattering results.

The method of smoothing data by the truncation of its Fourier transform is only useful when applied to individual peaks on a Rutherford scattering spectrum. The spectra obtained from the thick film specimens were smoothed by a least squares, (fourth difference) curve fit applied to the entire spectrum.



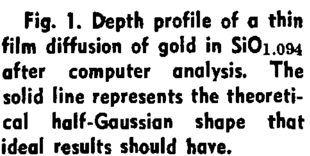


Fig. 1. Depth profile of a thin film diffusion of gold in $SiO_{1.094}$ after computer analysis. The solid line represents the theoretical half-Gaussian shape that ideal results should have.

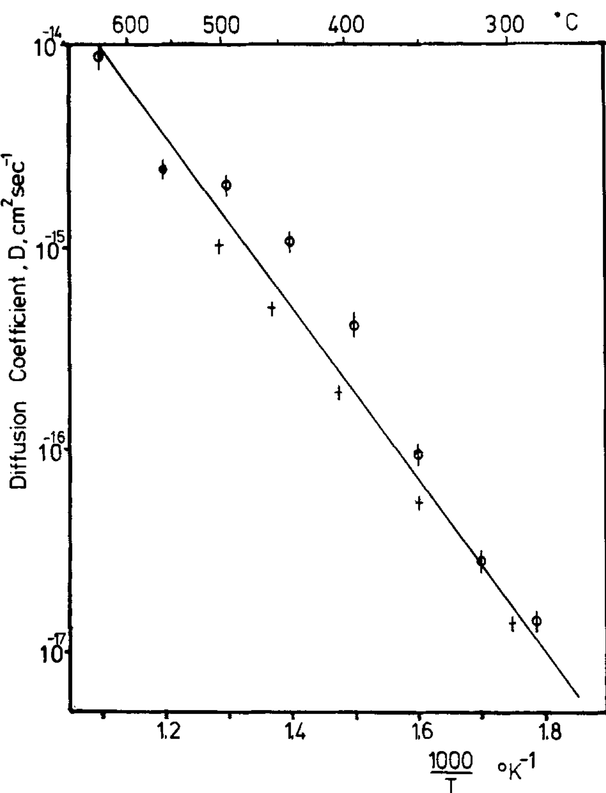

Fig. 2. Low temperature plane source diffusion coefficients of gold in SiO_x. The points ϕ are from data obtained with a film of stoichiometric proportions of $SiO_{1.096}$ and density 2.08 g/cm^3, those points + refer to films of stoichiometry $SiO_{1.192}$ and density 2.13 g/cm^3.

Results

Thin gold source.—We have obtained data from several sets of thin gold film specimens prepared at different times and which have different densities and stoichiometries. However, it is stressed that these results apply to films prepared by thermal deposition and with stoichiometric proportions near to SiO. These results should not be extrapolated to all values of stoichiometry up to SiO_2. [We have, however, observed significant gold diffusion in rf sputtered silicon dioxide (stoichiometrically $SiO_{1.8}$) at 390°C after 16 hr.]

Our measured values of the diffusion parameters for SiO_x

Table I. Comparison of calculated gold in silicon diffusion parameters

	D_o cm^2 sec^{-1}	ΔE eV
Determined from plane source diffusions analyzed by Rutherford scattering (200°-600°C)	1.4 10^{-3}	1.23
Radiotracer determination by sectioning (6) (800°-1200°C)	1.1 10^{-3}	1.12

$$D_o = 5\ 10^{-10}\ \text{cm}^2/\text{sec}, \quad \Delta E = 0.85\ \text{eV}\ [200°\text{-}600°\text{C}]$$

differ markedly from those obtained for SiO_2 by Badalov and Shuman (8)

$$D_o = 8.5\ 10^{-5}\ \text{cm}^2/\text{sec}, \quad \Delta E = 3.7\ \text{eV}\ [850°\text{-}1000°\text{C}]$$

albeit over a different temperature range. Optical and scanning electron microscopy examinations of the gold deposition areas after annealing showed that within instrumental resolution, the gold penetration occurred uniformly over the surface and no regions of irregularity (pinholes, etc.) could be detected.

All of the SiO_x films were deposited from either molybdenum boats covered with stainless steel mesh or from a tantalum boat which had a cover, also of tantalum, with a single 5 mm diameter hole. The tantalum boat was designed to minimize "spitting" of the silicon monoxide source material due to uneven heating. In general good quality films were produced by both types of boat.

No significant differences in the results on the thin gold source specimens deposited under the conditions described could be attributed to the different types of boat used, but there is some evidence that this is not the case with some of the thick gold film structures.

Thick gold source.—Devices fabricated with thick gold sources (~30 nm) exhibited a similar type of diffusion to that of the thin gold source devices up to temperatures of about 370°C. Above this temperature a rapid migration of the gold occurs with a nearly rectangular depth distribution. The leading edges of the silicon and oxygen peaks in the Rutherford scattering spectrum have moved to an energy corresponding to surface scattering (Fig. 3). As is illustrated in Fig. 3, once this initial penetration has occurred the "normal" mode diffusion process continues until eventually total film penetration results (Fig. 4) and a high gold concentration, estimated at approximately 10^{22} atoms cm^{-3} is established within the film.

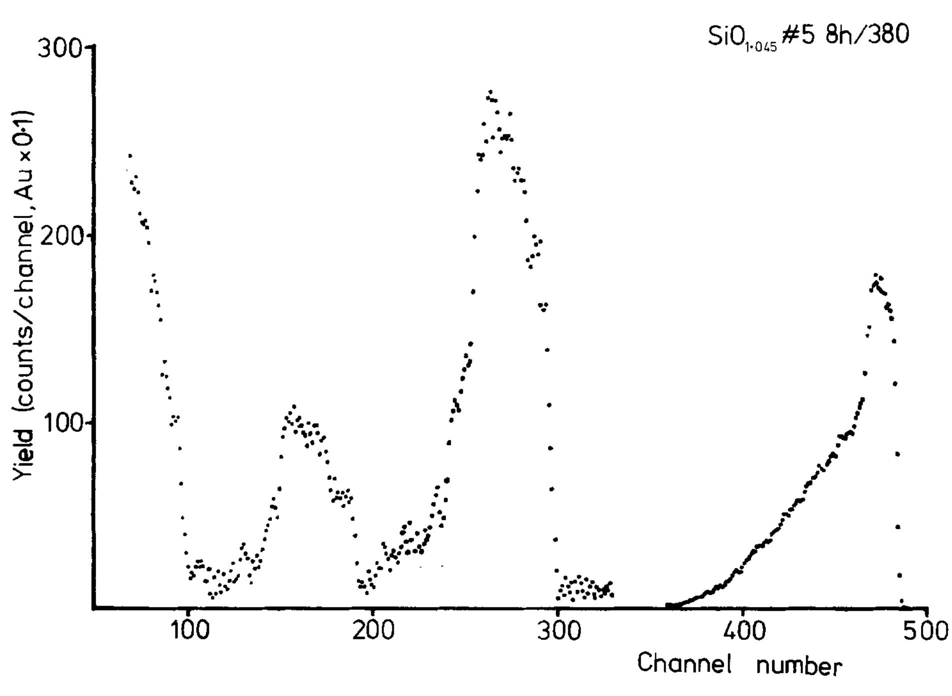

Fig. 3. Rutherford scattering spectrum, θ = 16°, E_0 = 2 MeV, of thick gold source specimen after annealing for 8 hr at 385°C showing initial penetration and subsequent diffusion of the gold.

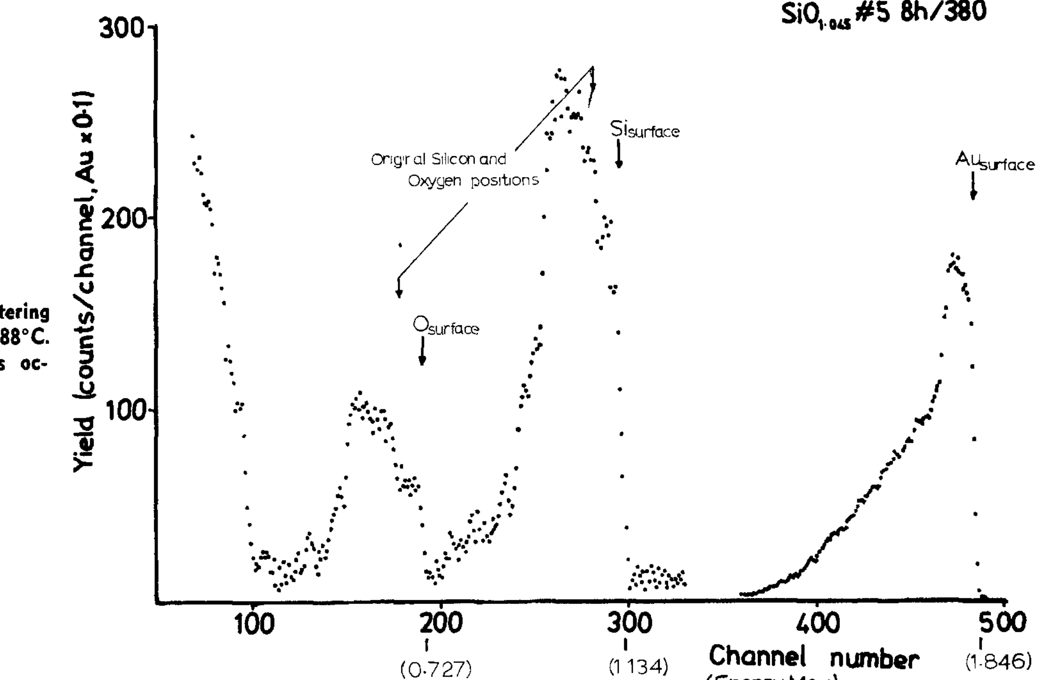

Fig. 4. Rutherford scattering spectrum after 16 hr at 388°C. Total film penetration has occurred.

The depth of this initial penetration depends on the original source thickness, but the rate at which the reaction occurs appears to vary with density and/or stoichiometry. However we have been unable to resolve whether it is the density or the stoichiometry of the SiO_x which plays the more significant role although we suspect it may be the latter.

As qualitative results are based largely on a visual interpretation of Rutherford scattering spectra we should consider possible sources of error in our interpretations.

It is known that surface irregularities can occur when thin metal films are annealed. The metal can withdraw into globules under the influence of surface tension resulting in a highly irregular surface. Although the absolute size of the surface irregularity may vary it is generally difficult to detect these by microscopy. The Rutherford scattering spectrum from such a specimen is ambiguous since it may show an apparent "profile" which is identical to that obtained when strong interpenetration has occurred.

Gold films 50 nm thick which were deposited as stripes across both the SiO_x layer and the vitreous carbon surface showed "island" formation after 10 min anneals at 500° and 600°C. Optical examination with an interferometer clearly showed the "islands" to be thick (300 nm) regions of gold and the Rutherford scattering spectra shows "profiles" which are almost twice as thick as the SiO_x film itself. Had a thinner gold film or a thicker SiO_x layer been used one might have erroneously assumed that significant penetration had occurred.

Annealing the thick gold source specimens below 500°C produced no evidence of the surface agglomeration as judged by optical microscopic examination.

As a further check that the Rutherford scattering data was correctly interpreted a theoretical spectrum to simulate surface agglomeration of the gold was computed for scattering from an SiO_x film which had 50% of its surface covered with a 50 nm gold film. Ignoring straggling effect (which was assumed to be minimal) but including the detector and system resolution (14 keV) a comparison may be made between the shape of the silicon peak of Fig. 3 and the computed silicon peak of Fig. 5. As there are no points of similarity between the two figures it is concluded that the spectrum in Fig. 3 does not result from surface accumulation.

Silicon oxide (SiO_x) films deposited in a similar manner but with a slow evaporation rate (0.2 nm/sec) and a higher background pressure (10^{-5} Torr) show heavy contamination from the boat source. The stoichiometry of these films is $SiO_{1.15}Mo_{0.02}$. Although the normal diffusion process may be observed in these films the expected rapid gold migration above 370°C did not occur. Above 500°C surface agglomeration of the gold was evident both over the SiO_x and carbon substrate and penetration which occurred was masked in the Rutherford scattering spectrum by the pseudoprofile from the surface agglomeration.

Electrical measurements.—Some simple electrical measurements were performed on devices made by depositing 100 nm of gold onto 500 nm of SiO_x on a carbon substrate.

The electroforming (1), of such thick SiO_x films, was unsuccessful and resulted only in dielectric breakdown. After annealing for 2 hr at 500°C, devices were found to electroform and exhibited voltage controlled negative resistance and bistable switching.

A few devices annealed for 8 hr at 390°C were found to be irreversibly in a short-circuit condition implying complete gold penetration of the SiO_x film.

Conclusions

We have shown that for thermally deposited SiO_x, over a restricted range of stoichiometries, the plane

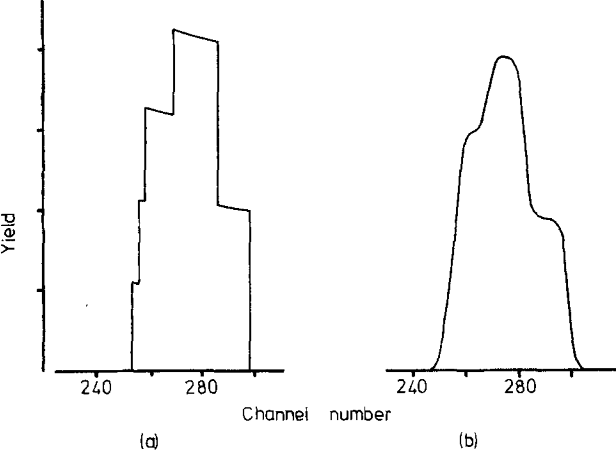

Fig. 5. Calculated shape of the backscattered spectrum from silicon in 200 nm $SiO_{1.14}$ film with 50% of the analyzed surface covered with a 50 nm gold film. $\theta = 168°$, 2 MeV alphas. (a) Assuming perfect detection system and negligible straggling. (b) Incorporating a 14 keV FWHM detection resolution.

source diffusivity of gold may be expressed as

$$D = 5.10^{-5} \exp(-0.85/KT) \text{ cm}^2/\text{sec} \qquad (200°\text{-}600°C)$$

Increasing the available source concentration, by increasing the gold layer thickness, has no effect on the diffusivity until the anneal temperature exceeds 370°C. This is the gold-silicon eutectic point (11), and the resultant rapid migration of the gold into the SiO_x may be described as a form of alloying of the gold with free silicon (12, 13) in the SiO_x. This results in a more rapid penetration of the SiO_x than would be the case if the gold migration was diffusion limited.

High concentrations of molybdenum, from the molybdenum boat source, in the SiO_x film appear to inhibit this alloying behavior, possibly by modifying the structure of the SiO_x (14).

The high electrical conductivity of the SiO_x observed after gold penetration has occurred is similar to that observed when thin film devices are switched into their low resistance state. The Bistable memory switching of SiO_x films in air has been reported by Manhart. The high conductivity state results from electrode migration along a high temperature region which has been initiated by thermal runaway.

It has previously been considered that in these amorphous oxide devices a high temperature (1000°C) (16) must be established, under conditions of thermal runaway or avalanche ionization, for structural changes to occur in either the insulating film or the electrodes. Our results have shown that, for gold on SiO_x, rapid migration can occur at a markedly lower temperature than this and, considering that the metal counterelectrodes used in these devices are biased positively (10, 15) the migration may also be enhanced by the applied field if the metal ionizes under extreme conditions such as avalanching.

Technical Notes

Monolithic Studs as Interlevel Connectors in Planar Multilevel LSI

G. C. Schwartz* and V. Platter

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

Planar aluminum and aluminum alloy interconnection metallization for multilevel integrated circuits was first made possible by the substitution of anodic conversion for subtractive etching (1-3). The anodic process results in a planar structure of interconnection metallization embedded in anodic oxide; there are no metal edges which subsequently must be covered by the interlevel insulator. Therefore the interlevel insulation can be significantly thinner than that required when standard processing is used. Nevertheless, a step is formed when the via holes are etched, so that the resultant structure is no longer completely planar.

A method for complete planarization was proposed by Sato *et al.* (4). They described a scheme which uses "bumps" as interlevel connectors and polyimide as a planarizing insulator to cover the conventionally etched metal. However, this excellent idea requires three separate metal depositions to form a two-level structure, five to form three levels, etc. This introduces additional vacuum steps, but more important, it introduces additional interfaces. It is well known that aluminum rapidly grows an oxide film as soon as it is exposed to air; this thin insulating layer adds to the interlevel resistance.

Anodic processing can be used to form the interconnection metallization pattern and the interlevel "bumps" or "studs" from a single metal film as described below.

Step 1.—The appropriate metal film is deposited upon the semiconductor substrate. A hafnium underlay is used when the metallization pattern includes electrically "floating" conductors (5). When the metal used for the interconnection pattern is not pure aluminum, an appropriate alloy is deposited between the underlay and the aluminum cap (3). The composite metal film which is shown in Fig. 1a is deposited sequentially in a single evaporation in a multisource system.

Step 2.—A thin porous anodic oxide layer is formed on the surface of the aluminum, in oxalic acid, to insure adhesion of the photoresist layer which is then applied. Using standard photolithography, openings are made in the photoresist layer at the location of the studs, as shown in Fig. 1b.

Step 3.—A barrier layer is formed to about 75V in ammonium borate in ethylene glycol; the photoresist layer is removed by ashing; the structure in Fig. 1c results.

Step 4.—The barrier layer protects the area it covers from subsequent anodization in oxalic acid (1). The rest of the film is anodized in oxalic acid so that a thickness of aluminum equal to the thickness of the required interlevel insulator is anodized, producing the structure in Fig. 1d.

Step 5.—The anodic oxide is removed in an etch which dissolves the oxide without attacking the underlying aluminum (3), leaving the stud as shown in Fig. 1e.

Step 6.—A thin porous anodic oxide is formed again for resist adhesion, and a photoresist mask which leaves the interconnection metallization pattern areas uncovered (which include the previously formed studs is produced. A barrier layer is formed to about 75V in the exposed regions; the stud is completely encapsulated in barrier layer, as shown in Fig. 1f.

Step 7.—The resist is removed and the exposed

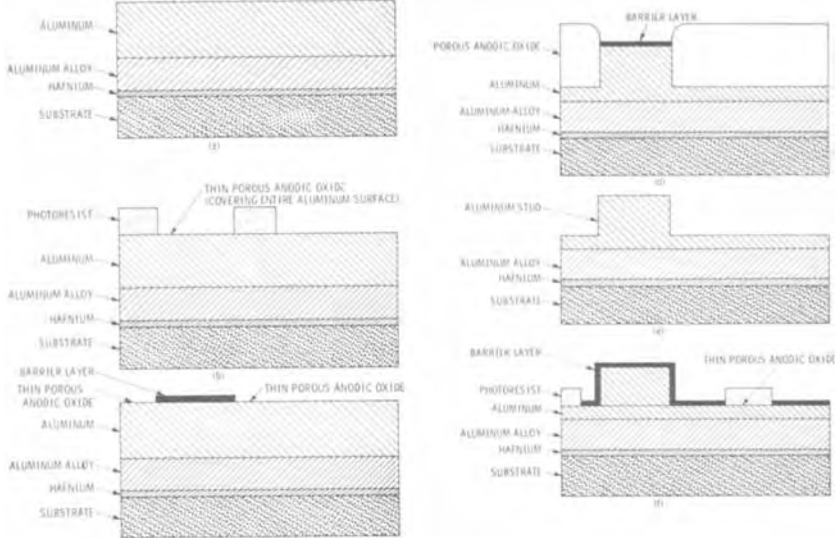

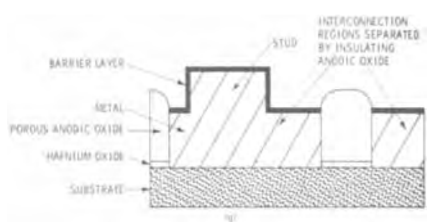

Fig. 1. The process for forming monolithic studs shown schematically: (a) composite metal film, Step 1; (b) step 2; (c) step 3; (d) step 4; (e) step 5; (f) step 6; (g) monolithic stud structure; step 7.

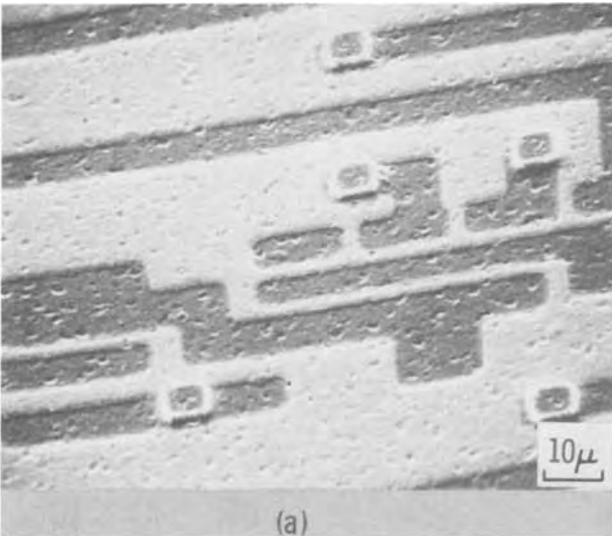
aluminum and aluminum alloy are completely anodized as described previously (3) and the hafnium underlay is converted to an insulating layer by anodization followed by steam oxidations (5). At the temperature of the steam oxidation, the aluminum (aluminum alloy) and hafnium interdiffuse, so that there is no longer a discrete layer of hafnium at the substrate interface (5). Also it is unlikely that a sharp boundary still exists between the aluminum cap and the underlying alloy. If the hafnium underlay is required on upper levels, its oxidation temperature may have to be reduced (and the time increased) to be compatible with the underlying polyimide. The final structure is shown schematically in Fig. 1g.



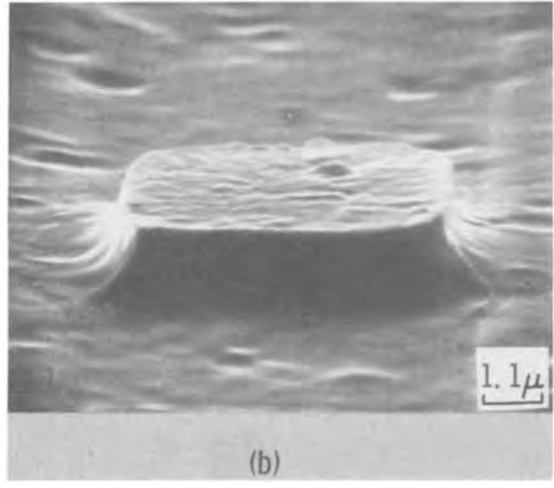


Fig. 2 (a) Scanning electron micrograph of a monolithic stud and interconnection metallization pattern formed by anodic processing. (b) Scanning electron micrograph of a stud only; higher magnification.

The polyimide is applied after the completion of the composite structure. It is then etched uniformly using rf reactive ion etching at high pressure (6) followed by a short rf sputter clean at the appropriate argon pressure to remove the anodic oxide which had protected the top of the stud during the processing.

The interconnection metallization is not completely planar since the barrier layer process of Tsunemitsu and Shiba (1) was used. However, this process was chosen because the barrier layer provides the best protection for the tall, narrow stud. Moreover, it is not the planarizing capability of the anodic processing that is important in this application; it is the ability to form the structure from a single metal film. However, an added dividend of anodic processing is the increased cross-sectional area of the conductors thus formed (compared to subtractive etch) with the attendant increase in current carrying capability (3).

A scanning electron micrograph of a stud formed by this process is shown in Fig. 2. It can be seen that some undercutting has occurred during the formation of the stud, but it is substantially less than that which results from subtractive etching.

Conclusion

A description has been given of an anodic process by which it is possible to form both the interconnection metallization pattern and the interlevel connectors ("studs") from a single (composite) metal layer.

Influence of Trichloroethylene on Room Temperature Flatband Voltages of MOS Capacitors

D. L. Heald, R. M. Das, and R. P. Khosla[1]

University of California, Department of Electrical Engineering and Computer Science, Santa Barbara, California 93106

The ever increasing interest in growing high quality SiO_2 is well documented by the large number of recent papers in this area (1). Although the stabilization of the thermally grown SiO_2 can be achieved by a film of phosphosilicate glass (PSG), the use of HCl (2, 3) during the oxidation process has gained considerable attention.

This process provides a reduction in the instabilities due to the presence of mobile ions in the oxide. It also improves the dielectric breakdown characteristics of the oxide, reduces the surface-state density at the Si-SiO_2 interface, and increases the minority carrier lifetime in the silicon surface.

Most of these improvements are attributed to the presence of chlorine in HCl and are well substantiated by recent work of Van der Meulen *et al.* (4). It is believed that some chlorine is always incorporated in the oxide near the Si interface, which helps in neutralizing and immobilizing the sodium ions that are drifted toward the interface under an electric field at an elevated temperature. Since HCl is very corrosive and dangerous to handle, attempts have been made to use other compounds that contain chlorine and are easy to handle.

Chen and Hile (5) and Declerck *et al.* (6) have investigated the effects of trichloroethylene (TCE) on the characteristics of MOS devices subjected to bias-temperature stress. Van der Meulen *et al.* (4) noted that oxides grown in Cl_2 were electrically unstable at room temperature and that oxides grown in HCl exhibited flatband voltage shifts after room-temperature bias stress. It is the purpose of this paper to report on the room-temperature stability of oxides grown in TCE.

MOS capacitors were fabricated on n-type (100) Si substrates having 2-5 ohm-cm resistivity. The wafers were cleaned in a sulfuric acid-hydrogen peroxide solution, followed by an HF dip and DI H_2O rinse. The furnace tube was cleaned and acclimatized with TCE and O_2 for a period of 10 hr.[2] All the wafers were oxidized at 1060°C, using the following sequence: (*i*) 1000 cm^3/min of dry O_2 for 5 min; (*ii*) TCE/He at 0-105 cm^3/min and dry O_2 at 1000 cm^3/min for 60 min; (*iii*) 1000 cm^3/min dry O_2 for 15 min; (*iv*) N_2 anneal for 15 min prior to removal of wafers. Thus the total oxidation time for each wafer was 80 min. The TCE bubbler was kept at room temperature, 23°C [Declerck *et al.* (6) kept the TCE bubbler at 34°C]. Immediately after removal, 30-mil aluminum dots for the metal gates were evaporated from tungsten filaments through a metal mask. Then oxide from part of the wafers was carefully etched in HF to allow contact to the substrate. Photoresist steps were completely avoided. The wafers were annealed for 15 min at 525° in N_2. Conventional *C-V* measurements were made with and without room-temperature bias stress.

Figure 1 shows a plot of oxide thickness *vs.* TCE/He flow. The increased rate of the growth of SiO_2 is consistent with the observations reported both in the presence of HCl (3) as well as TCE (6). The growth rate of SiO_2 increased as the flow rate increased but saturated beyond 70 cm^3/min. The oxide thickness varied from 900 to 1650Å. The initial values of the flatband voltage, V_{FB}, *vs.* TCE/He flow prior to any bias stress is shown in Fig. 2 (solid line). It was found that the optimum region of this curve occurs between 37-42 cm^3/min of TCE/He, which is consistent with results of Van der Meulen *et al.* (4) and Declerck *et al.* (6) for high quality halogen-grown oxides. The improvement in flatband voltage afforded by low TCE/He flow rates is most probably a result of the compensation of positive oxide charge.

At the highest flow rate, 105 cm^3/min of TCE/He, the C-V plots exhibit a small degree of low frequency behavior, indicative of increased recombination/generation activity. This is in general agreement with the reduced storage time for large percentages of TCE observed by Declerck *et al.* (6). The increased magnitude of the flatband voltage at the higher TCE/He flow rates has not previously been reported and is probably caused by an increase in positive charge density or a decrease in negative charge density in the oxide. It should be noted that for higher concentrations of TCE, Declerck *et al.* (6) did observe an increase in surface-state density.

The gates on the MOS capacitors were subjected to a negative bias at room temperature for times up to 20

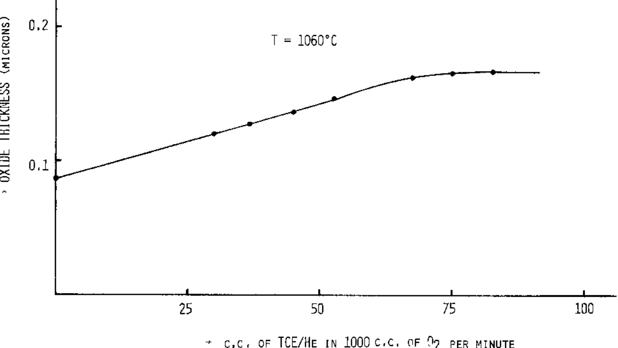

Fig. 1. Oxide thickness vs. TCE flow rate

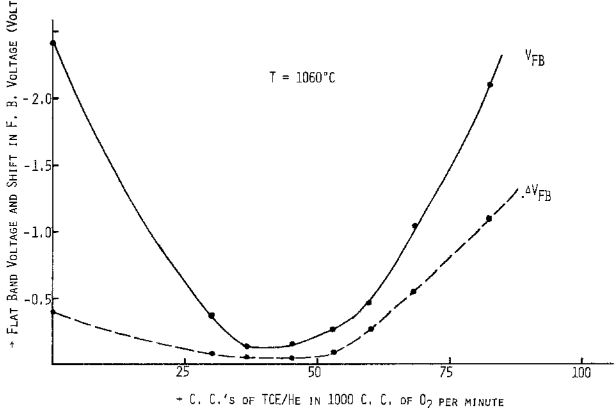

Fig. 2. Flatband voltage and shift in flatband voltage vs. TCE flow rate. Bias of +15V was applied for 5 min at room temperature, measurements were made as soon as possible.

[1] Visiting Scholar from Kodak Research Laboratories, Eastman Kodak Company, Rochester, New York 14650.

[2] At the early stages of the experiments carbon deposition in the furnace tube was frequently observed, even at low concentrations of TCE. But after substantial use we were unable to reproduce the conditions resulting in carbon deposition.

Key words: halogen oxidation, chlorine incorporation, flatband voltage shifts.

hr and fields up to 6 × 10^6 V/cm. For a 15 min bias stress of 10^6 V/cm. no flatband voltage shifts could be detected except for the sample corresponding to 105 cm^3/min of TCE/He, in which a positive shift of 0.55V was observed. It would be consistent with the initial flatband measurements if this shift were due to the motion of mobile charge acquired in the sample oxidized with the high TCE/He flow rate. The ions H^+ or H_3O^+ which are mobile at room temperature (7) are possible candidates. The actual role and fate of the hydrogen contained in the TCE has not been established. Van der Meulen *et al.* (4) have indicated that some sodium may be mobile at room temperature.

For extremely high fields (6 × 10^6 V/cm) and negative gate bias, the samples oxidized with 105 cm^3/min of TCE/He exhibited a transient flatband instability similar to that observed by Van der Meulen *et al.* (4) for Cl_2-grown oxides, although the instability was less pronounced. The flatband voltage first shifted in the positive direction and then for long times (on the order of 10 hr) shifted slightly in the negative direction, the flatband voltage never changing sign, however. A positive bias stress of 10^6 V/cm inhibited this negative bias instability completely. At field strengths normally encountered in device operation, the oxides were more stable.

Next the effects of positive bias stress were investigated. The resulting shift in flatband voltage is shown in Fig. 2 (dashed line). The minimum shift in the flatband voltage ΔV_{FB} is 0.062V for samples which were grown with flow rates of 40-50 cm^3/min of TCE/He. At flow rates below this minimum, both the reduction in flatband voltage and the reduction in flatband voltage shift can most easily be explained by the neutralization and trapping of mobile oxide charge. Introducing trap

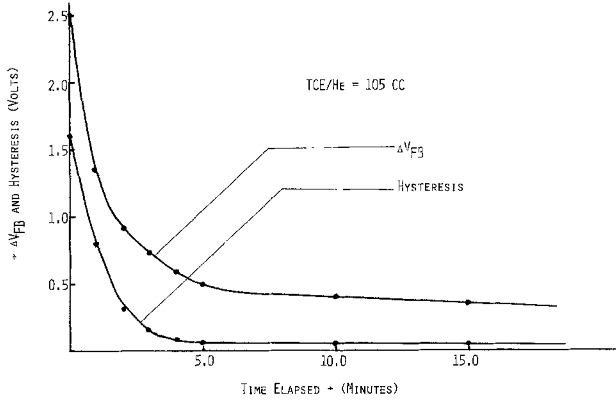

Fig. 3. Shift in flatband voltage and hysteresis vs. time elapsed after the bias of 15V was applied at room temperature for 5 min.

sites for electrons in the oxide will not account for this behavior. A flatband shift of 0.062V corresponds to a mobile charge density of about 5 × 10^9 charges/cm^3.

For higher flow rates of TCE/He the flatband shift increases. At a concentration of 105 cm^3/min of TCE/He, not shown in Fig. 2, the shift was about 2.5V (corresponding to a mobile charge concentration of 2.85 × 10^{11}/cm^2), and substantial hysteresis appears in the *C-V* characteristics. Figure 3 shows the recovery of this shift with time and the observed hysteresis. (No hysteresis was observed for samples oxidized with low concentrations of TCE.) The dramatic increase in V_{FB} and ΔV_{FB} implies high concentrations of mobile oxide charges or donor-like oxide traps, either of which could also cause the observed hysteresis.

In summary we have shown that TCE can be effectively used to lower oxide charge mobile at room temperature (mostly H^+ or H_3O^+ and perhaps some alkali ions) to values as small as 5 × 10^9/cm^2. Because of ease of handling, TCE may be a good substitute for HCl in growing high quality oxides. For extremely high fields (larger than those normally encountered in device operation) the TCE-grown oxides exhibited a room-temperature instability similar to that observed in Cl_2-grown oxides. For high quality oxides there is an optimum flow rate of TCE during oxidation of about 4-5%. Above this point, the introduction of additional positive mobile charge or donor-like traps in the oxide degrade the *C-V* characteristics. The incidence of low frequency behavior for large TCE flow rates indicates increased recombination/generation activity at the interface or bulk silicon near the surface.

The Effect of Substrate Bias on the Properties of Reactively Sputtered Silicon Nitride

A. W. Stephens,[1] J. L. Vossen,* and W. Kern*

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

There have been several reports (1-13) on the properties of sputtered silicon nitride films. In most cases optimum film properties have been achieved by reactive sputtering using high-purity Si targets rather than direct sputtering of hot-pressed Si_3N_4. Most of the reported work has been done by rf sputtering without direct control over the substrate bias. In general, the results of others indicate that optimum film properties (low etch rate, good barrier to alkali ions, etc.) are achieved when the deposition rate is high and the

* Electrochemical Society Active Member.

[1] Present address: 95 Meadow Drive, Hightstown, New Jersey 08520.

Key words: silicon nitride films, bias sputtering, reactive sputtering, thin films.

discharge gas pressure is low. These sputtering conditions are known to lead to relatively high substrate bias voltages (14). With electrically floating substrates, it has been found (2, 6, 12) that films of high quality could not be produced at discharge pressures greater than about 15 mTorr, and the suggestion has been made that a high, negative self-bias is responsible for the improved film properties because of an increase in film density. Such an increase in film density could arise from two mechanisms: (*i*) enhanced surface mobility of depositing atoms and (*ii*) resputtering of weakly bound deposited species (12, 14).

In this note, we report direct evidence for improvement of the properties of rf reactively sputtered Si_3N_4 using a sputtering system in which the substrate bias can be controlled, independent of the other rf glow discharge conditions.

Experimental

The system for rf sputtering with controlled rf-induced substrate bias has been described in detail elsewhere (15). Briefly, there are two identical rf sputtering targets (~20 cm diameter) mounted concentrically in the top and bottom of the vacuum chamber. The separation between the targets was 2.85 cm. The lower target serves as a substrate platform. Both targets were 99.999+% cast Si. The voltage on each target can be controlled independently of the other, and of other discharge conditions (*e.g.*, pressure). The vacuum chamber is cylindrical (65 cm diameter by 16.5 cm high), and is pumped with a liquid-nitrogen-baffled oil diffusion pump/mechanical pump combination that was ordinarily pumped to 2×10^{-7} Torr prior to all deposition runs. The substrates (Si) were not thermally attached to the lower target. Substrate temperature was monitored with an infrared pyrometer calibrated for the emissivity of the Si_3N_4 surface and for losses from absorption and reflection in the optical path. The substrate temperature did not vary much with differing deposition conditions and averaged 130° ± 30°C.

The upper (deposition) target voltage was held constant at 1500V (d-c sheath potential) and the discharge parameters that were varied were substrate bias voltage, partial pressure of N_2 in Ar, and total gas pressure. The etch rate of the films in buffered HF was used as an indicator of the quality of the films.

Figure 1 illustrates the variation in etch rate with substrate bias. The etch rate decreases by about two orders of magnitude as the bias is increased from 0 to −50V, and then remains nearly constant for higher bias voltage. Under the conditions shown in Fig. 1, the deposition rate varies from about 200 Å/min at 0V to 150 Å/min at −300V. The other varied parameters (partial pressure of N_2 in Ar, Fig. 2; and total gas pressure, Fig. 3) had a very much smaller influence on the etch rate of the films. The over-all trend was toward lower etch rates at higher deposition rates. The etch rate could be lowered by a factor of about 2-3 by heat-treating the films in N_2 at 1000°C for 15-20 min, indicating that the films were not completely dense as deposited.

Electron diffraction analyses indicated that the films were amorphous. Infrared analysis showed a typical Si_3N_4 spectrum with no evidence of oxygen. However, Auger electron spectroscopic analysis showed about 1% oxygen content. The only other film impurities observed were Ar and C. The carbon content was about 3.5 a/o. No Auger calibration for Ar was available, but the amount incorporated was probably high. The infrared absorption spectrum of the as-deposited films show, in addition to the typical Si_3N_4 absorption bands, a very weak band near 2100 cm^{-1}, suggesting the as-deposited films contain Si-H functional groups. After heat-treatment in N_2 at 1000°C, there is a slight change in the refractive index and/or the film thickness. The Si-N band at 850 cm^{-1} narrows slightly, but the band

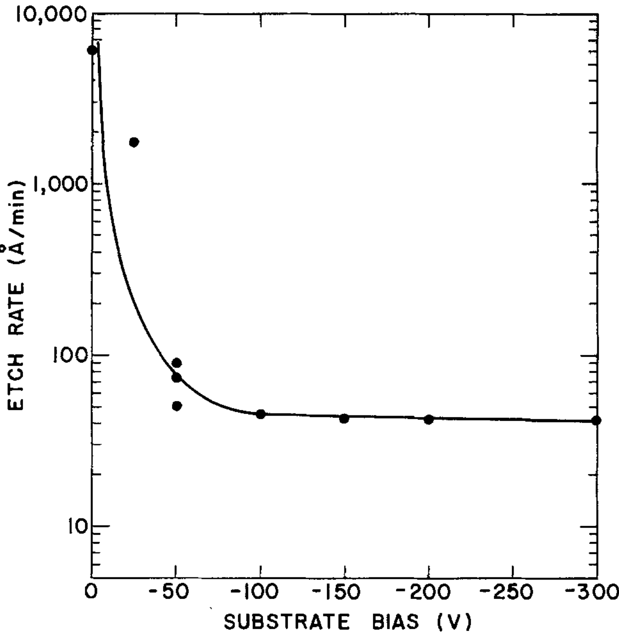

Fig. 1. Etch rate (buffered HF)[2] *vs.* substrate bias (total pressure = 48 mTorr; 6.5% N_2).

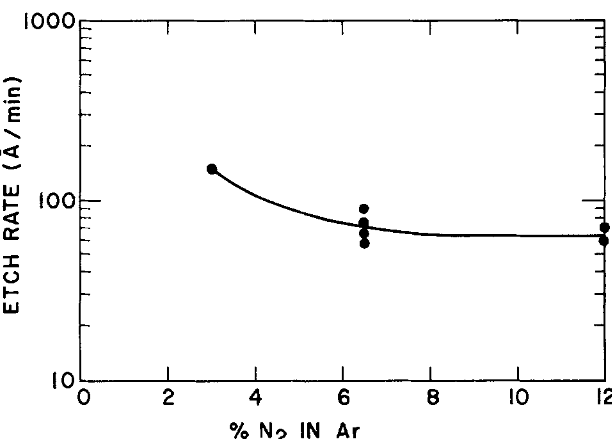

Fig. 2. Etch rate (buffered HF)[2] *vs.* per cent N_2 in Ar (total pressure = 48 mTorr; substrate bias = −50V).

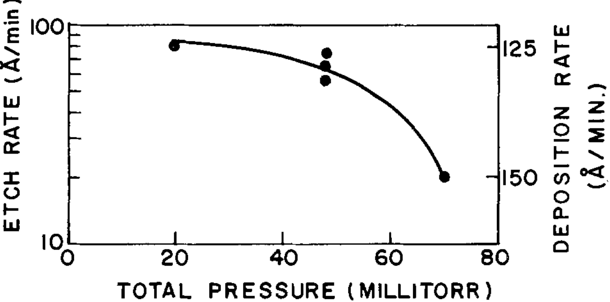

Fig. 3. Etch rate (buffered HF)[2] *vs.* total gas pressure (6.5% N_2; bias voltage = −50V).

[2] Composition of buffered HF: 1 part by weight 48-49% HF plus 5.75 parts by weight of 39-40% NH_4F solution.

center does not shift. Si-H absorption is not observed after the heat-treatment.

Ellipsometric measurements of the refractive index of the films yielded values ranging from 1.55 to 2.18 depending on the substrate bias and deposition rate. For bias voltages greater than 50V and deposition rates in excess of 200 Å/min, the refractive index was 2.165 ± 0.025, which is somewhat higher than the bulk value of 1.98.

Stress was measured by beam bending (unclamped Si beam). Films were deposited to a thickness of 2 μm

under conditions that yielded moderately low etch rates. The total stress measured was 3.4 × 10^9 dyne/cm^2 (compressive).

Discussion and Conclusions

The data presented here clearly indicate that the major determinant of rf reactively sputtered Si_3N_4 film quality is the substrate bias, as was earlier hypothesized. The use of controlled substrate bias allows good quality films to be deposited with a wide range of gas pressures, whereas self-bias of the magnitude required (> −50V) can only be achieved at low gas pressures. [It should be noted that the bias voltages quoted are measured with respect to ground. As has been pointed out (16, 17) there is a systematic error involved in these measurements because the plasma potential is somewhat positive with respect to ground.] The data tend to indicate that increased film deposition rate improves the film properties, but, by comparison to the substrate bias, it is a second order effect.

Acknowledgments

We are grateful for the help of several of our colleagues, R. Vibronek for many of the etch rate measurements, M. D. Coutts for electron diffraction analyses, D. G. Fisher for Auger electron spectroscopic analyses, P. Zanzucchi for some of the infrared analyses, and G. L. Schnable for several helpful discussions and review of the manuscript.

A Comparison of the Process-Induced Gettering of Atomic Platinum and Gold in Silicon

K. P. Lisiak*[,1] and A. G. Milnes**

Department of Electrical Engineering, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

Platinum has recently been shown (1) to have two active sites in Si. One of these sites, the Pt_{II} acceptor, has been found (2) to be a good lifetime controller. Based on energy position, the Pt levels can be expected to have less generation leakage for a given lifetime reduction than gold (2, 3). Also, Pt-doped diodes have lower forward volt drop than gold-doped diodes, at equal lifetime values (3). Since Pt is apparently a more promising lifetime controller than gold, a significant question is whether Pt suffers unintentional gettering during processing cycles.

Impurity gettering has been studied along two basic lines. One approach attempts to remove all deep impurities introduced into the silicon crystal in the growth and diffusion process (4-8). Techniques for this purpose use either some form of available chlorine in a gas flow during heat soaking or a phosphorous diffusion into the back surface. Studies of gold doping in Si, for example, have shown atomic gold to pile up in n^+ regions (9, 10). A second approach (11, 12) has been to study the unintentional loss of desired lifetime-controlling impurity species during subsequent device processing steps or by aging processes at operating temperatures or higher (13, 14).

Key words: silicon, gettering, platinum, gold.

Using neutron activation analysis, platinum has been studied here for its resistance to unintentional gettering by processing cycles accompanying its introduction into the silicon lattice. Distribution of atomic Pt within the various layers and loss of atomic Pt from the bulk are both monitored by this technique.

Adamic and McNamara (11) and Nakamura *et al.* (12) have conducted neutron activation studies of gold loss by phosphorous and boron glass getters. They used the Au^{198} radioactive isotope as a tracer by irradiating samples of pure gold as the source material for Au deposition and saturation diffusions. For our work with Pt, the use of preirradiated metal in diffusions was not convenient. The most prevalent Pt isotopes, Pt^{197} and Pt^{199}, have half-lives of 18.5 hr and 31 min, respectively. These isotopes are produced in lower concentrations than is Au^{198} from Au^{197}. Also, the shorter half-lives of the Pt isotopes make elapsed time more critical. The Au^{199} isotope which forms from the decay of Pt^{199} has a sufficiently long half-life; however, if used in diffusion it would presumably behave as gold and not as platinum. To use this longer (3.15 day) half-life isotope in Pt work it is thus necessary to irradiate samples at the completion of all high temperature processing steps.

Processing was done in sealed Spectrosil ampuls. The initial experiment used Pt- and Au-saturated silicon which is subjected to diffusion using 3000-4000Å of

the Emulsitone products phosphorosilica film ($P\text{-}SiO_2$), borosilica film I ($B\text{-}SiO_2$), and silica film ($E\text{-}SiO_2$). These films have been shown useful in Si device processing (15) and allow the use of closed-tube processing. This experiment models the situation where the Pt (or Au) must be inserted prior to the last high temperature cycle. Subsequent experiments compared the behavior of Pt and Au when diffused for a short time (15 min) in the presence of doped oxides and heavily doped diffused Si layers. This models the introduction of the deep impurity into the p-n junction regions as the last diffusion step.

Silica Film Gettering

Samples of silicon saturated with platinum (48 hr, 900°C diffusion and quench) were cleaned of all surface alloys by etching and lapping to remove 1-2 mil per side. One slice received a phosphorosilica film layer on each side, another received borosilica film, and a third was coated with undoped silica film. The films were densified at 250°C and then each slice was sealed into a Spectrosil ampul. As a further control on the gettering process, a Pt-saturated slice was sealed into an ampul without any silica coating. The ampuls were then heat-soaked for 1 hr at 1100°C and quenched in a water bath. A second group of silica slices, saturated with gold, were gettered in a similar fashion.

The ampuls were then neutron irradiated, along with standards containing known amounts of Pt and Au. Nonheat-treated slices containing Pt or Au were also included for comparison. Following irradiation, each slice was counted in the Ge(Li) detector and the weight and concentration of Pt or Au determined from counts of the standard ampuls.

The doped silica films were then removed by etching in buffered HF. The Pt or Au concentration in the etched layer was determined from the differences of the successive slice weighings and the gamma count of the etch bath. An aqua regia etching (20 min, hot, 3:1 of $HCl:HNO_3$) and count step was used to determine the presence of interface metal layers. Surface (p^+ or n^+) region concentrations were investigated by successive etching of the slice in freshly made CP4.

Samples, diffused at 900°C to yield 1.5×10^{15} cm^{-3} Pt and 1.2×10^{15} cm^{-3} Au, were gettered at 1100°C for 1 hr in sealed ampuls with $P\text{-}SiO_2$, $B\text{-}SiO_2$, or $E\text{-}SiO_2$. For this experiment a low concentration of Pt or Au was used so that surface (or bulk) impurity depletion might be noticeable if extreme gettering was encountered.

The results show that Pt is not gettered by the spin-on oxide films. Figure 1 shows the concentration of Pt in each slice (solid symbols) after surface etching to be comparable to the concentration in the heat-treated control. The concentrations of Pt in the $P\text{-}SiO_2$ and $E\text{-}SiO_2$ oxide etches show no significant gettering by these oxides. Only the $B\text{-}SiO_2$ gettered slice showed a significant amount of Pt concentrated near the surface. However, as Fig. 1 shows, this slice had twice the initial Pt concentration of the other Pt samples in this run. Since all Pt samples were initially diffused together until saturated with Pt, this decrepancy indicates some undissolved Pt was present on or in the sample. This excess Pt was then removed in subsequent etching of the gettered slice and was not gettered by the $B\text{-}SiO_2$ film.

All the Pt samples which received the 1100°C gettering cycle ($P\text{-}SiO_2$, $B\text{-}SiO_2$, $E\text{-}SiO_2$, and heat-soaked control) showed some excess Pt in the first Si slice etch. This is apparently due to a tendency to form a layer of heavily Pt-doped Si at a damaged surface. These samples were not mirror-smooth polished or etched to strain relieve the surface. O'Shaughnessy *et al.* (9) showed that Au similarly accumulates at a lapped surface in their experiments. The close agreement of the Pt concentrations in the etch bath of the control slices with the etch baths of the $P\text{-}SiO_2$ or $B\text{-}SiO_2$ slices

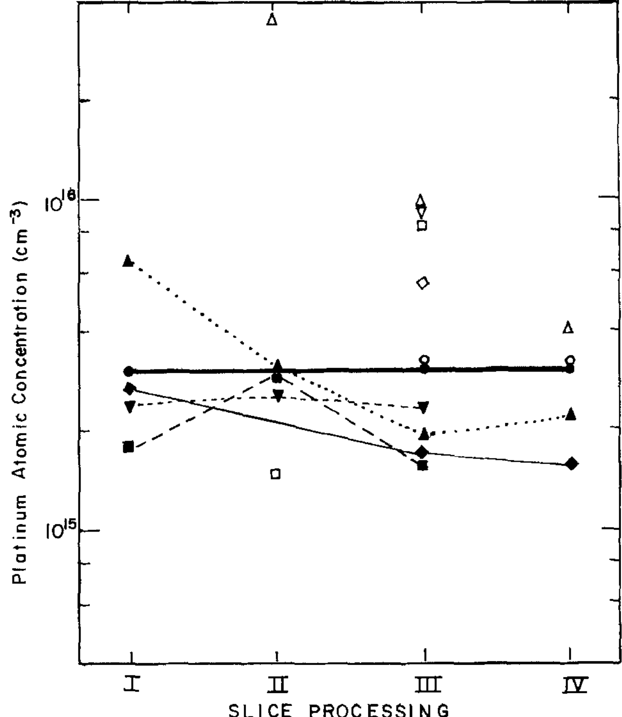

Fig. 1. Neutron activation results for gettering of Pt by Emulsitone film diffusions. Solid symbols are the average concentrations of platinum in each slice following a particular step in the etching sequence. The hollow symbols represent the concentration determined for the layer removed by the etch. Key: □■ phosphorosilica film I, △▲ borosilica film, ▽▼ silica film, ◇◆ heat-treatment only, ○● untreated control, (I) as irradiated, (II) oxide removed by HF, (III) first Si etch (about 6 μm pe, face), (IV) second Si etch (about 8 μm per face).

(shown by the hollow symbols in Fig. 1 column III) suggests that no significant Pt gettering is caused by the p^+ or n^+ doping but that a damaged Si surface will getter Pt to some extent.

Au is gettered into $P\text{-}SiO_2$ layers and tends to form an interface layer between the $B\text{-}SiO_2$ layer and the silicon. While the oxides constituted less than 1% of sample weight, nearly 10% of Au in the $P\text{-}SiO_2$ sample was found in the oxide and 15% of Au in the $B\text{-}SiO_2$ sample was at the interface. These Au results agree qualitatively with the findings of Adamic and McNamara (11) and Nakamura *et al.* (12). Backscattering studies (10) have failed to find Au gettering into diffusion source phosphor glasses. Presumably this is because the sensitivity of backscattering techniques (10^{18} cm^{-3}) does not match that of neutron activation studies, which for Au is capable of reaching 10^{12} cm^{-3} and for Pt, 10^{13}-10^{14} cm^{-3}.

Thermal Oxide Gettering

Another experiment was performed to observe the uniformity of Pt diffusion in the presence of the thermal oxides P_2O_5, B_2O_3, and SiO_2. Similar specimens were diffused with Au to provide a direct comparison. For this experiment, chemically polished Si slices were cleaned by the H_2O_2 process (16) and one group was oxidized at 1150°C by wet O_2 for 60 min to grow 1 μm of SiO_2. A second group was placed in a furnace at 1150°C in a flow of O_2 over $POCl_3$ to grow P_2O_5 until the n^+ layer was 2-4 μm deep. The third group was coated with B_2O_3 at 1100°C from the decomposition of BBr_3 to form 2-4 μm of p^+ Si.

Slices which were to be Pt or Au diffused had the oxide and diffused layer removed from the back by lapping. These slices were recleaned by the H_2O_2 process and the backs were covered with Au or Pt from spin-on solutions. Following bakeout of the films, the slices of each metal-oxide pair were sealed into sepa-

Table I. Gettering results of Pt and Au by thermal oxides during a 15 min 1100°C diffusion

Treatment (15 min 1100°C)	Concentration after alloy removal (cm^{-3})	Concentration after oxide removed from front surface by HF* (cm^{-3})	Concentration after first etch of front in CP4 ($-4\mu m$) (cm^{-3})	Concentration after second etch of front in CP4 ($-4\mu m$) (cm^{-3})	Concentration after third etch in CP4 ($-8\mu m$) (cm^{-3})
Pt + P_2O_5	2.48×10^{16}	2.96×10^{16}	2.79×10^{16}	1.90×10^{16}	1.78×10^{16}
Pt + B_2O_3	2.50×10^{16}	3.02×10^{16}	2.79×10^{16}	2.69×10^{16}	2.53×10^{16}
Pt + SiO_2	2.72×10^{16}	2.72×10^{16}	2.74×10^{16}	2.68×10^{16}	2.78×10^{16}
Au + P_2O_5	2.84×10^{16}	2.95×10^{16}	9.9×10^{15}	—	—
Au + B_2O_3	2.05×10^{16}	9.16×10^{15}	9.22×10^{15}	—	—
Au + SiO_2	1.61×10^{16}	1.65×10^{16}	1.60×10^{16}	—	—

* The B_2O_3 oxide was removed by hot H_2SO_4HCl; HNO_3:H_2O of 1:2:4:20. The results shown are the slice concentrations, after each particular etch step, as the volume average of the atomic Pt detected in the slice. Steps not shown were not performed. Variations of 10% are not statistically significant.

rate Spectrosil ampuls. One oxidized slice from the same group was also included without a metal film. These controls served to check contamination and to indicate the amount of metal that could be vapor transported from the oxide surface. After a 15 min diffusion at 1100°C, the samples were removed to a water-bath quench. The ampuls were then opened and the metal-diffused slices were lapped on their backs (reducing one thickness by 1-2 mil) and trimmed along the edges to remove all alloyed Si. The results for the Pt- and Au-diffused experimental specimens are listed in Table I.

The Pt-diffused specimens all show an initial average concentration of Pt that is in good agreement with the 1100°C solubility of Pt (1). The final average concentration of the Pt + P_2O_5 sample does show that there has been some loss of Pt to the n^+ surface layer. This is confirmed by the counts of the etch baths which show excess Pt in the n^+ Si. The variation in the Pt + B_2O_3 concentration appears to be a statistical fluctuation since only slightly more Pt is found in the oxide etch of this sample than in that of the Pt + SiO_2 slice. This suggests that Pt diffusion produces a uniform Pt concentration profile in the presence of n^+- or p^+-doped material and that P_2O_5 and B_2O_3 do not significantly getter Pt.

The gold slices again show accumulation of gold into the front surface regions. Since the gold (and platinum) were diffused in the presence of the oxides and p^+ or n^+ regions, the initial concentrations are not fixed to the bulk solubility as in the previous run. Initially, the Au + P_2O_5 and Au + B_2O_3 slices show a higher average concentration than the Au + SiO_2 slice whose concentration agrees with the 1100°C solubility of gold (17). Subsequent etching showed the gold in the bulk of the Au + P_2O_5 and Au + B_2O_3 slices to be slightly lower than in the Au + SiO_2 sample. The gamma counts of the respective etch baths confirm this gold was present in the oxide and surface layers. Thus, Au diffusion produces a markedly nonuniform Au concentration profile in the presence of n^+ Si and is gettered by P_2O_5 and B_2O_3 glasses.

Control slices showed the processing to be sufficiently clean. Au in the control samples included with Pt samples was about 10^{12} cm^{-3}. Pt in these control samples approached the detectibility limit of Pt(10^{14} cm^{-3}). Some Au was found in the Au control specimens, caused by the vapor transport of gold.

The possible solubility enhancement of Pt in p^+ or n^+ Si was more closely examined in a final experiment. Slices of very low resistivity n^+ and p^+ Si were saturated with Pt at 1150° for 24 hr and irradiated. Following the removal of surface alloys by trimming, lapping, and etching, both slices show a somewhat larger Pt concentration than previous 1150°C diffusions. An n^+ Si slice with 10^{19} cm^{-3} phosphorous showed 1.6×10^{17} cm^{-3} Pt and a p^+ Si slice with 10^{19} cm^{-3} boron showed 1.3×10^{17} cm^{-3} Pt. Although this is approximately twice the concentration of Pt found in diffusions into higher resistivity Si, some slight solubility enhancement is expected since lattice strains in low resistivity material and increased dislocations may cause precipitates to form in the Si material. These Pt results can be contrasted with the 10^2-10^3 solubility enhancement reported for gold in heavily doped n-type Si (11, 12).

Conclusions

Pt was not gettered by phosphorosilica film or silica film layers on Pt-saturated Si during a 1 hr soak. The result for borosilica film was inconclusive because excess Pt was present on that sample. Gold was clearly gettered by the phosphorosilica film and formed an interface layer under borosilica film. These gold results agree qualitatively with measurements of gold gettered by thermal oxides. The tendency of Pt to self-getter at a lapped surface is noted; however, the effect on the bulk is not significant for $N_{Pt} = 3 \times 10^{15}$ cm^{-3}.

Pt diffusion was not found to be affected by the presence of P_2O_5, B_2O_3, or thermal SiO_2 in a 15 min cycle. The measurements show no significant oxide gettering and only a factor of two enhancement of N_{Pt} for p^+ or n^+ Si over p or n Si. A 15 min diffusion cycle has also been shown to be as practical a means for insertion of Pt at 1100°C as it is for Au. Au diffusion is affected by the presence of P_2O_5 or B_2O_3 and the nonuniform profile confirms the gettering of Au noted in the literature. Thus, evidence presented, which is limited to observation of atomic (total) concentrations, suggests that Pt can be inserted in Si more reliably than can Au. This, together with related work on the recombination role of Pt in Si (2), suggests that Pt may be more effective than Au as a lifetime controller in silicon.

Chemical Vapor Deposition of NbB_2 and TaB_2 through Heating by Concentration of Solar Radiation

B. Armas, C. Combescure, and F. Trombe

Laboratoire de l'Energie Solaire, C.N.R.S., Odeillo, 66120 Font-Romeu, France

According to some authors (1) molybdenum, tungsten, niobium, and tantalum borides cannot be produced in a suitable manner if hydrogen is used to reduce a mixture of a metal halide and a boron halide. The metal halide would be reduced first at rather low temperature. In that case one observes no reaction or only an incomplete one between boron and the metal. This procedure often leads to a mixture of boron and free metal or to some powdery deposits.

An alternative method is a direct thermal decomposition of mixtures of appropriate halides in the absence of hydrogen. Thermodynamic considerations have led us to use those halides which have the same dissociation domain (2). Since the hexagonal NbB_2 and TaB_2 structures have a domain of homogeneity, they are the easiest compounds to prepare. We attempted to prepare niobium and tantalum borides by the following reactions

$$2BBr_3 + NbBr_5 \rightarrow NbB_2 + x\ (Br_2 \text{ or } Br) \quad [1]$$

$$2BBr_3 + TaBr_5 \rightarrow TaB_2 + y\ (Br_2 \text{ or } Br) \quad [2]$$

Apparatus

A solar furnace was used for heating. A flat mirror following the apparent sun motion receives the incident rays and reflects them parallel to the axis of a fixed parabolic mirror, 2m diameter and 0.85m focal length, which concentrates the solar radiation in its focus. In practice the total energy (1600W) lies inside of a 16 mm diameter circle. The representation of energy distribution in the focal plane is given by a bell-shaped curve which decreases rapidly and shows symmetry relative to the optical axis. The vapor deposition apparatus is shown in Fig. 1. The samples used were 12 mm diameter cylinders, 1 mm thick, placed in the focal plane. The temperature is measured with a micro-optical pyrometer "Pyro." The system can measure up to 3000°C but lower temperatures can be determined if desired by adjusting the luminous flux with two shutters.

Experimental

The gas phase effect.—Experimental conditions were: temperature (T) = 1500°C, pressure (P) = 2.10^{-1} Torr, gas flow (D) = 400 $cm^3 \cdot hr^{-1} \cdot cm^{-2}$. The composition of the gas phase is given by the ratio ρ = boron halide weight to metal halide weight. The theoretical ratios are $\rho_1 = 1.015$ for NbB_2 and $\rho_2 = 0.86$ for TaB_2. An x-ray diffraction analysis shows that a metal-boron diagram can be derived by modifying the gas phase composition.

Key words: niobium, tantalum, halides, borides.

Pressure and temperature effect.—The NbB_2 case.— $D = 400\ cm^3 \cdot hr^{-1} \cdot cm^{-2}$, $\rho_1 = 1.015$, T = variable temperature. Curves plotting efficiency *vs.* temperature are given in Fig. 2. To determine the efficiency curves a slightly different but more practical device for systematic experiments was used. Heating was obtained through high frequency induction as was described in a previous paper (3). Curve 1 ($P = 2.10^{-1}$) and curve 2 ($P = 2.5 \cdot 10^{-2}$) show efficiency increasing with temperature. But, on both sides of T = 1040°C, the variation of the efficiency with the pressure is inverted. Furthermore, above 1300°C the efficiency does not depend on the temperature. Moreover, the deposit composition is a strong function of the temperature: three types of deposits are obtained.

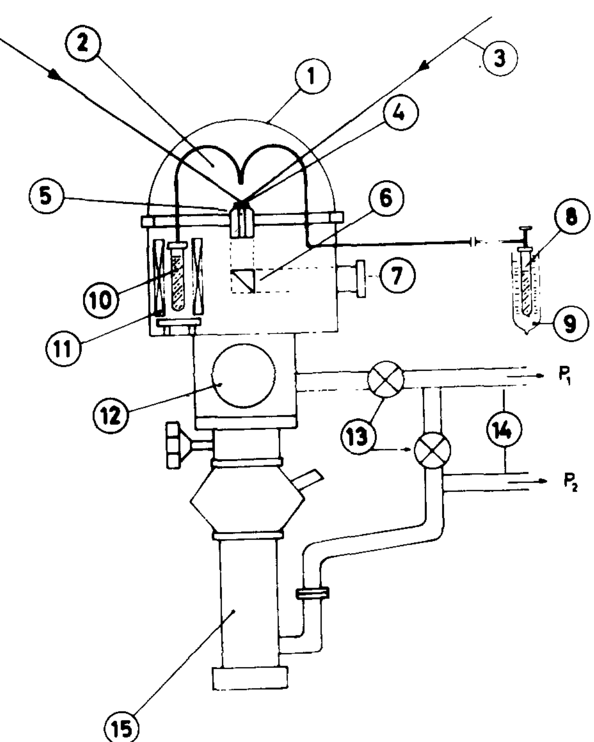

Fig. 1. Experimental apparatus used: (1) Pyrex cover, (2) reaction vessel, (3) solar radiation, (4) substrates, (5) water jacket, (6) prism, (7) observation window, (8) boron halide, (9) cooled condenser, (10) metallic halide vaporizer, (11) furnace, (12) cool trap for halides, (13) valves, (14) vacuum pumps, (15) diffusion vacuum pump.

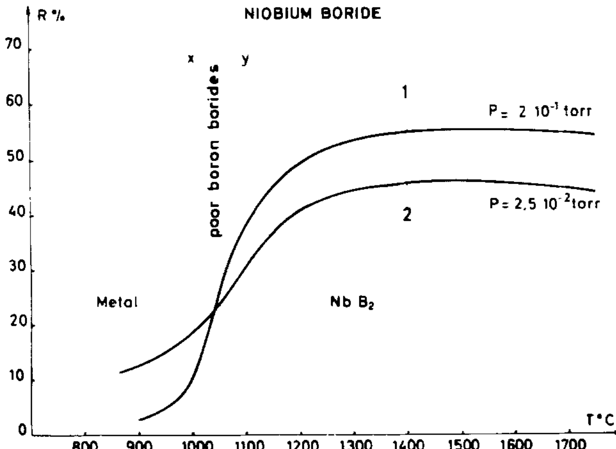

Fig. 2. Experimental efficiency curves. *R%* is the ratio of the weight of the deposited boride to the maximum weight of boride available from the input gas mixture.

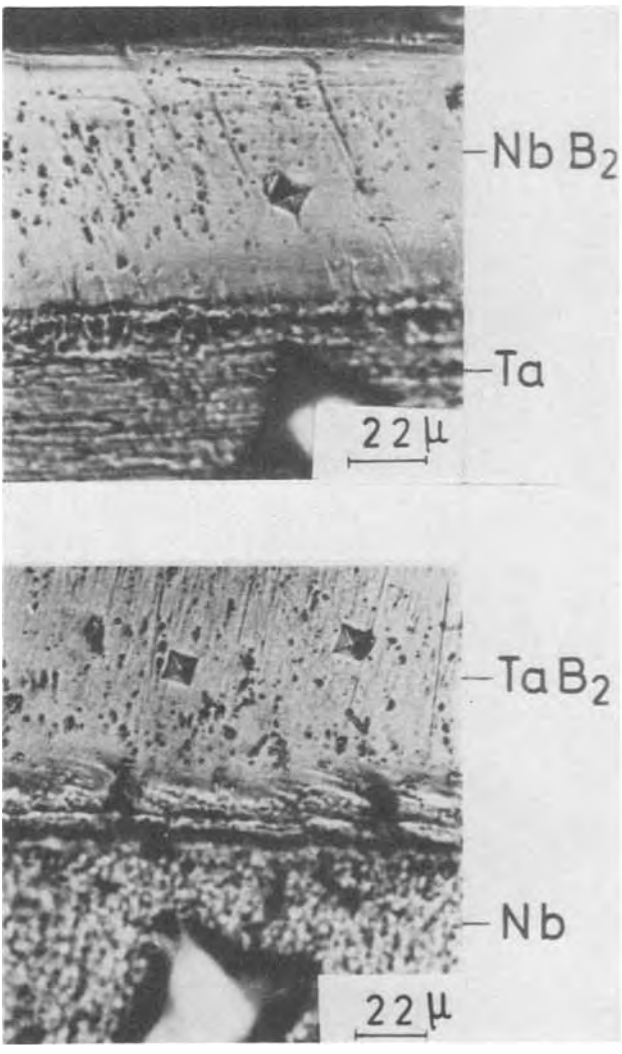

Fig. 3. (a, top) NbB_2 deposit on Ta, $P = 1.5 \cdot 10^{-1}$ Torr, $T = 1500°C$, $D = 400$ $cm^3 \cdot hr^{-1} \cdot cm^{-2}$, $\rho_1 = 1.015$, Vickers microhardness 2200 kg/mm². (b, bottom) TaB_2 deposit on Nb, $P = 1.5 \cdot 10^{-1}$ Torr, $T = 1500°C$, $D = 400$ $cm^3 \cdot hr^{-1} \cdot cm^{-2}$, $\rho_2 = 0.26$, Vickers microhardness 2600 kg/mm².

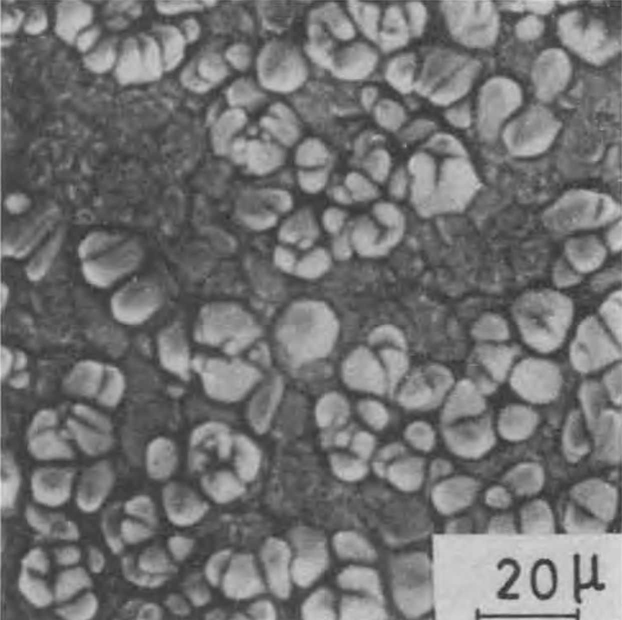
In the high frequency heating method, the substrates we used presented a 50°C difference of temperature between the center and the border of the sample. An inference from curves 1 and 2 is that we should operate between 1300° and 1600°C in order to obtain uniformity in deposit thickness. In this temperature range, one can master the deposit composition by bringing the gas phase composition under absolute control. Stoichiometrical borides were obtained under the various conditons of temperature and pressure that were the best.



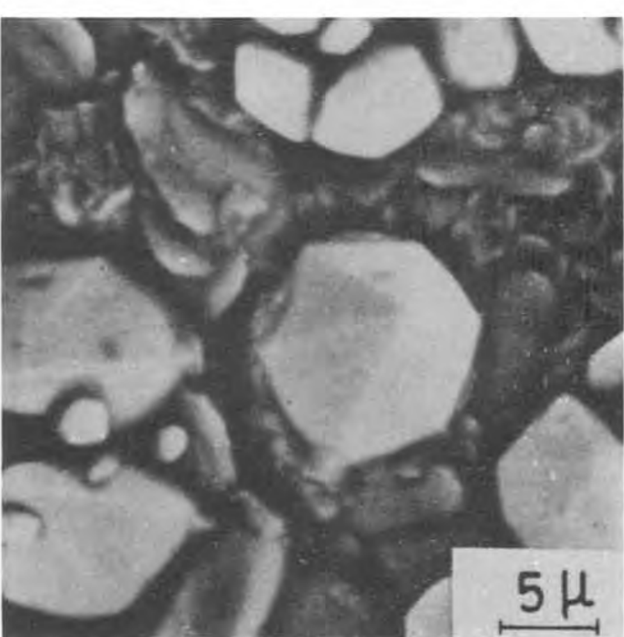


Fig. 4. (a, top) TaB_2 deposit on Nb, $P = 2.5 \cdot 10^{-2}$ Torr, $T = 1400°C$, $D = 150$ $cm^3 \cdot hr^{-1} \cdot cm^{-2}$, $\rho_2 = 0.86$. (b, bottom) Same conditions of deposition as (a).

The TaB_2 case.—The corresponding curves presented the same form as the NbB_2 case, but the dissociation temperature was higher. This was consistent with our thermodynamic study.

The halide flow effect.—Efficiency remains constant if the flow is less than 400 $cm^3 \cdot hr^{-1} \cdot cm^{-2}$ and decreases regularly with flow up to 700 $cm^3 \cdot hr^{-1} \cdot cm^{-2}$. The decrease becomes faster with higher flows.

Deposit Characterization

NbB_2 deposition was performed on Ta substrates and, conversely, TaB_2 was deposited upon Nb.

Compact deposits.—Compact and adhesive deposits are shown on the micrographs Fig. 3. Deposit compact-

ness is destroyed when conditions referred to in the legend of Fig. 3 are not respected. As the flow increases, the deposit gets more porous. As the temperature increases, very strong deposit-substrate interactions occur. At temperatures higher than 1700° and 1860°C for NbB_2 and TaB_2, respectively, brilliant particles appeared in the gas jet denoting powder formation.

Oriented deposits.—Under the experimental conditions $T = 1500°C$, $D = 400$ cm$^3 \cdot$ hr$^{-1} \cdot$ cm^{-2}, $\rho_1 = 1.015$ and $\rho_2 = 0.86$ but with a lower pressure, porosities became visible on a line perpendicular to the substrates. With $P = 2.5 \cdot 10^{-2}$ Torr, we got a basaltic deposit oriented in the C axis direction. These borides were not very adhesive and showed a cleavage plane parallel to the deposition surface. With the same value of P but with reduced gas flow we observed isolated nuclei shaped like small hexagonal-based pyramids. An attempt was undertaken to develop some of these nuclei and to study their behavior during the initial phase of the deposition process.

In these experiments, the halide flow was reduced to 150 cm$^3 \cdot$ hr$^{-1} \cdot$ cm^{-2}. We found that surface microcrystals can be observed if first a polycrystalline deposit is used which is oriented in no preferential direction and which is not amorphous. This particular feature is contrary to some cases of boride deposition (4). These small surface crystals are shown in Fig. 4(a); they are sometimes very distorted by their neighbors. Figure 4(b) presents one of them much more enlarged. Hexagonal symmetry can be clearly observed.

Therefore, development of well-defined microcrystals can be easily performed by reducing the halide concentration at the substrate level. However, their development is limited in the horizontal plane due to the large number of nuclei. The microcrystals rarely measure more than 15 or 20μ. The bigger ones come into contact with their neighbors and become distorted. Derivation of bigger monocrystals seems unlikely under the indicated operating conditions. One would probably need to use an amorphous substrate and decrease the total concentration of halides (5) to reduce the number of nuclei.

Under the previous operating conditions, the deposition temperature seems to have a slight effect on the crystals' characteristics. On the other hand, interactions with the substrates increase rapidly with the temperature of deposition.

Leclanché Electrolyte Compositional Studies for Thin Film Batteries

Alf M. Bredland

ESB Incorporated, Ray-O-Vac Division, Madison, Wisconsin 53711

and Michael N. Hull*

ESB Incorporated, Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

The effect of zinc oxide dissolution and pH rise on the crystallization behavior of a series of Leclanché electrolytes has been determined with reference to their use in thin film batteries such as the ESB-P70. An electrolyte (2725) consisting of 27% ammonium chloride and 25% zinc chloride was identified as exhibiting increased solubility of zinc oxide, increased resistance to both pH rise and harmful crystal formation when compared to the presently employed 2210 composition.

Within the last five years, research and development of thin film batteries have accelerated in many parts of the battery industry. ESB has developed a thin film Leclanché battery for use in the Polaroid SX-70 cameras (1-5). In this particular battery, a small volume of 22:10 (22% NH_4Cl and 10% $ZnCl_2$) electrolyte is exposed to a large surface area of the active materials. It would be anticipated that under these conditions, the electrolyte would be highly susceptible to changes in both composition and pH because of the chemical and electrochemical interaction between the electrolyte and the electrodes under open- or closed-circuit conditions. The question which arises is whether or not 22:10 is the most suitable electrolyte composition for use in a thin film format.

In the round cell configuration, experience has shown that 22:10 combines good conductivity with a tolerable corrosion rate of the anode and although crystals of $Zn(NH_3)_2Cl_2$ are known to form on stand, such crystals in this configuration are relatively harmless (6-9). In the thin film format, however, conductivity may not be of prime importance due to the close proximity of the opposing electrodes while the formation of elongated crystals of $Zn(NH_3)_2Cl_2$ could damage the separator. Again, in the round cell design, the zinc oxide content of the zinc can constitute a very small percentage of the total anode weight, while in the thin film case, the zinc oxide content of the zinc powder can have a typical value of the order of 5%. Furthermore, this zinc oxide is in intimate contact with the small volume of electrolyte and has a tendency to dissolve into it. Thus, in this latter case, both the pH and zinc ion composition of the electrolyte will be altered and it is therefore necessary that an initial electrolyte composition be chosen which can dissolve a substantial proportion of the zinc oxide from the anode without undergoing a large pH increase and without precipitating zinc diammine crystals throughout the limited volume of electrolyte. In addition, the electrolyte should have a conductivity equal to or greater than the standard 22:10 composition.

It was decided to investigate the effect of electrolyte composition on each of the following factors: (*a*) pH rise and buffering capacity on the addition of NH_4OH, (*b*) type of crystal formation, (*c*) pH rise and type of crystal formation on the addition of ZnO. On the results of this information, one could then adjust the Leclanché electrolyte composition to give the best discharge performance for the particular configuration and cell materials employed.

Experimental

As a starting point, electrolyte compositions along the iso-pH curve of 4.7 shown in Fig. 1 were investigated (6). For several of these compositions, the relative molar concentrations of each of the ions in solution is given in Table I and in particular, attention should be drawn to the $NH_4^+:Zn^{++}$ ratio. This is an important parameter, since the solubility of ZnO would be expected to increase with increase in the concentration of NH_4^+ species due to the formation of the soluble complex species $Zn(NH_3)_4^{++}$. Again, the relative tendency of $Zn(NH_3)_2Cl_2$ crystals to be formed in preference to $ZnCl_2 \cdot 4Zn(OH)_2$ should be more favored in the compositions having the higher $NH_4^+:Zn^{++}$ ratio, all other conditions being equal.

The titration of 13:00, 22:10, and 00:25 electrolytes with 29.4% NH_4OH is shown in Fig. 2. As expected, the 13:00 electrolyte shows an immediate rise into the alkaline region with the addition of NH_4OH. No precipitation products are produced and further additions of NH_4OH result only in a gradual increase of the solution pH. On the other hand, electrolyte 00:25 forms an immediate dense, white precipitate at point D [reported to be $ZnCl_2 \cdot 4Zn(OH)_2$] (6) and by continuously precipitating with further additions of NH_4OH, buffers

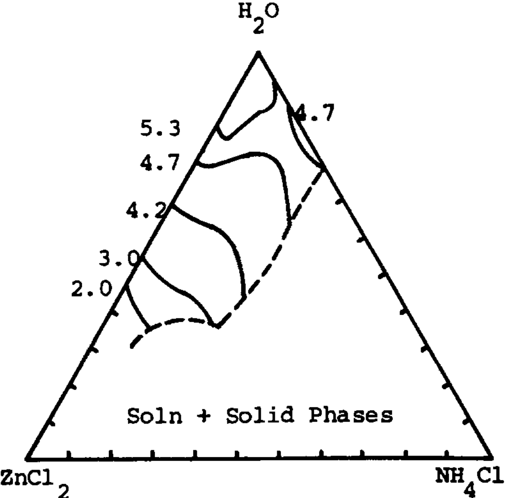

Fig. 1. Phase diagram for the system $ZnCl_2$-NH_4Cl-H_2O showing iso-pH lines from pH 2 to pH 5.3 at 25°C.

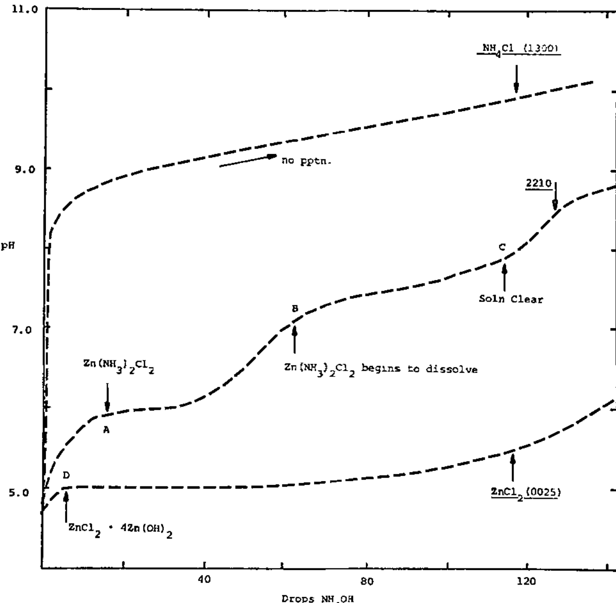

Fig. 2. pH variation of 20 ml amounts of 13% NH_4Cl, 22:10 and 25% $ZnCl_2$ on the addition of 0.05 ml drops of 29.4% NH_4OH. pH measurements were recorded three days after the addition of hydroxide to allow time for equilibrium to be established.

the solution at a pH of approximately 5.0. Addition of NH_4OH to 22:10 causes the pH to rise slowly and at approximately pH 5.9, (point A), the solution is buffered by the precipitation of $Zn(NH_3)_2Cl_2$. After the addition of approximately 40 drops, precipitation is complete and the pH rises to a second buffered region (at B) where redissolution of the $Zn(NH_3)_2Cl_2$ as $Zn(NH_3)_4^{++}$ occurs. Complete redissolution has occurred at point C in the figure.

With change of the electrolyte composition from that of 22:10, having an NH_4^+:Zn^{++} ratio of 5:58, to lower values of this ratio, one finds that there is a transition point at a composition between 12:13 (2:36) and 11:14 (2:01) below which formation of the $ZnCl_2 \cdot 4Zn(OH)_2$ is favored over that of the $Zn(NH_3)_2Cl_2$. This is illustrated in Fig. 3 where two compositions on each side of this transition point are shown. It is seen that with 15:10 (3:82) and 10:15 (1:70), both the crystalline (diammine) and the amorphous (zinc hydroxy chloride) precipitates can be distinguished both by the regions of inflection in the pH curves and by visual inspection of the solutions. With 15:10, formation of the crystalline precipitate precedes that of the amorphous while the reverse is true with 10:15. Figure 4 summarizes the relationship between the amount of NH_4OH required to form each type of precipitate and the initial NH_4^+:Zn^{++} ratio for each of the nine electrolyte compositions examined. The NH_4^+:Zn^{++} ratio is that of the solution prior to the NH_4OH addition. It is evident that there is an extremely rapid rise in the amount of NH_4OH required for precipitation of the diammine crystals for electrolyte compositions having an initial ratio $<2:5$. However, at these low NH_4^+:Zn^{++} ratios, the amorphous precipitate is readily formed and buffering of the electrolyte occurs at pH values somewhat below that when the diammine salt is the first precipitate formed (as in 22:10).

Table I. Molar concentration of each of the ions and the NH_4^+:Zn^{++} ratios for each of the electrolytes investigated along the 4.7 iso-pH curve

Electrolyte*	$[NH_4^+]$†	$[Zn^{++}]$†	$[Cl^-]$†	$[NH_4^+]:[Zn^{++}]$
13:00	2.53	—	2.53	—

† Concentrations are given in moles/liter.

It would appear, therefore, from Fig. 4 that, if it is desirable to have a Leclanché electrolyte with an initial pH of 4.7 and maximum resistance to the formation of precipitated salts, the composition 11:14 should be chosen. However, one must choose the electrolyte composition by considering what the final NH_4^+:Zn^{++} ratio will be at the onset of precipitation. Reconsidering the 11:14 electrolyte from Fig. 4, it is evident that 21 drops of 29.4% NH_4OH were necessary for precipitation.

Now, 29.4% NH_4OH contains 15.43 moles/liter.

Hence, 21 drops (of 0.05 ml each) contain 0.016 mole.

This was added to 20 cm^3 of 11:14 electrolyte.

Thus the increase in the NH_4^+ concentration of 11:14 was 0.8 mole.

In 11:14 $[Zn^{++}] = 1.18$ moles/liter
$[NH_4^+] = 2.37$ moles/liter
and $[NH_4^+]:[Zn^{++}] = 2.01$.

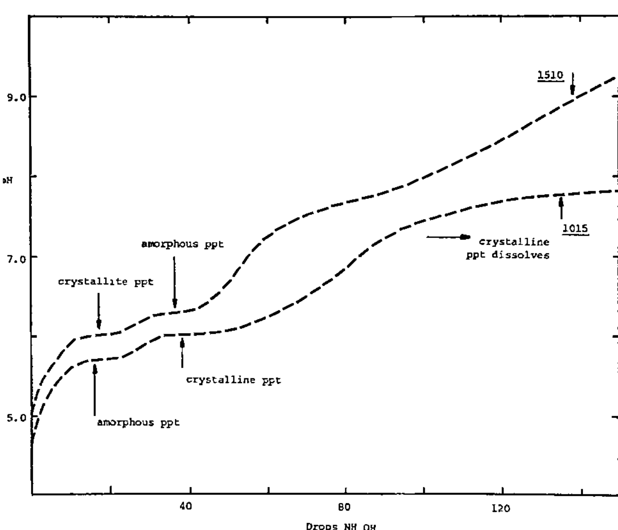

Fig. 3. Titration of 15:10 and 10:15 electrolytes under conditions identical to those of Fig. 2.

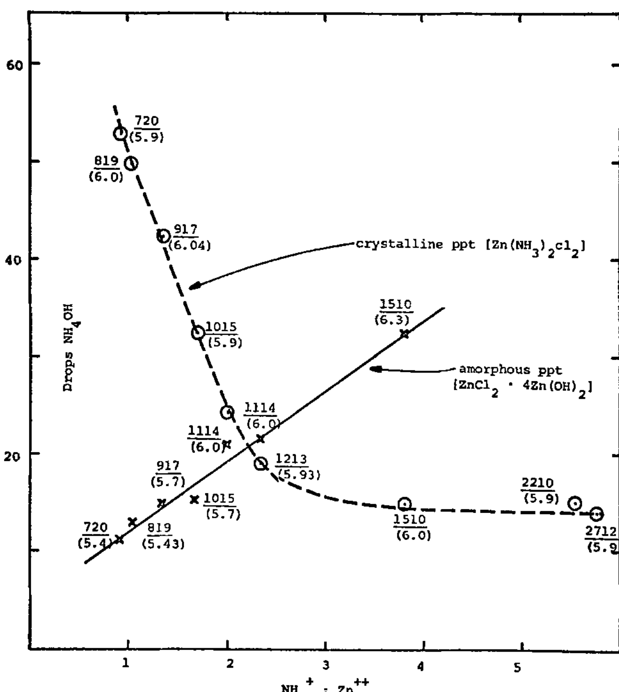

Fig. 4. Volume of NH_4OH as a function of the NH_4^+:Zn^{++} ratio required to precipitate $Zn(NH_3)Cl_2$ and $ZnCl_2 \cdot 4Zn(OH)_2$ from 20 cm^3 aliquots of Leclanché electrolytes along the iso-pH line 4.7. Each drop ~0.05 ml. Figures beside points give electrolyte composition while figures in brackets refer to solution pH at point of precipitation.

After addition of 0.80 mole NH_4^+, the ratio now becomes (2.37 + 0.80)/1.18 = 2.69. This means that an electrolyte with an initial *p*H of 4.7 and having an NH_4^+:Zn^{++} ratio of approximately this final value, can best resist the formation of precipitates.

Considering, now, the effect on the solution *p*H of the addition of zinc oxide to Leclanché electrolytes along the 4.7 iso-*p*H curve, one finds that there is a gradual rise in *p*H of each electrolyte as ZnO is added (Fig. 5 shows two examples) until an amorphous or a crystalline deposit is formed beyond which point the *p*H will remain constant. Figure 6 shows the variation in grams of ZnO as a function of the initial NH_4^+:Zn^{++} ratio required to just form a precipitate in the solution. As the initial NH_4^+:Zn^{++} ratio rises, the amount of ZnO

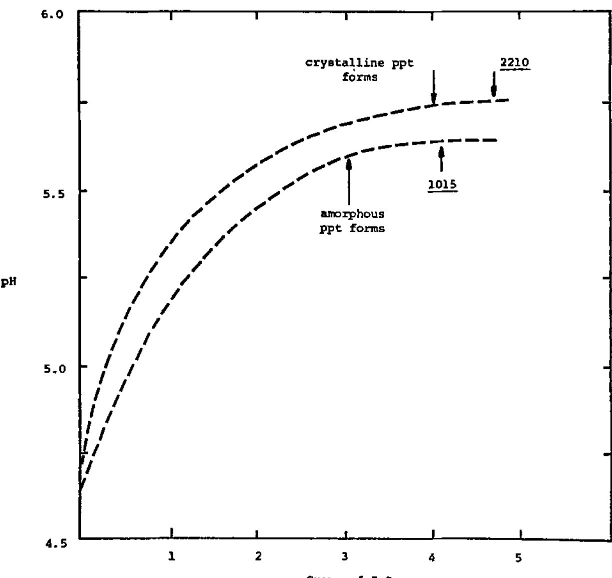

Fig. 5. Variation in the *p*H of 200 cm^3 amounts of 22:10 and 10:15 electrolytes with the addition of zinc oxide.

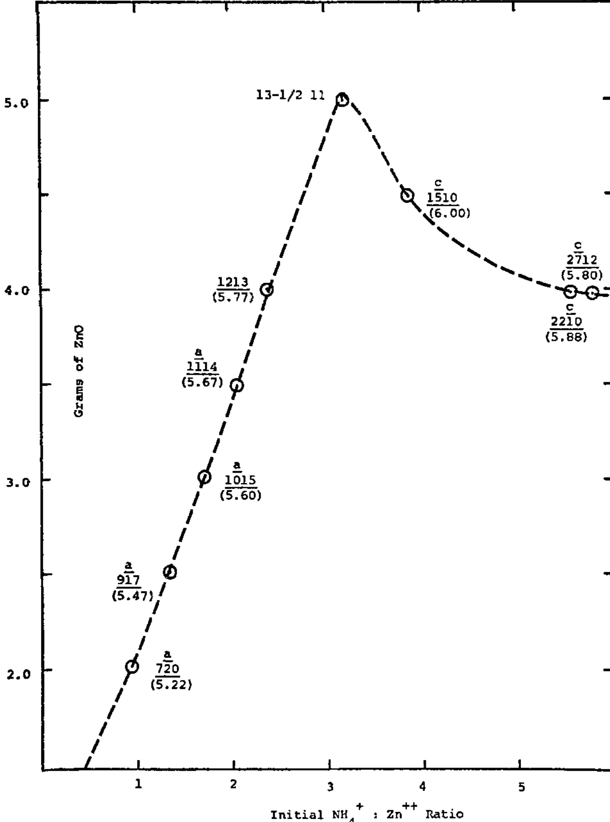

Fig. 6. Minimum amount of zinc oxide, plotted as a function of the NH_4^+:Zn^{++} ratio, which is required to cause permanent precipitation in 200 cm^3 of various electrolytes along the 4.7 iso-*p*H curve. Letter gives type of precipitate: a = amorphous, c = crystalline. Figures in brackets refers to solution *p*H at point of precipitation.

which can be accepted by the electrolyte also rises and passes through a maximum of 13½:11. ZnO is known to increase in solubility as the concentration of NH_4^+ in the solution is increased, so a rise to 13½:11 in the apparent solubility of ZnO is not unexpected. Above an NH_4^+:Zn^{++} initial ratio of ~ 3, the solubility appears to decline. This is due to the fact that at these ratios sufficient ZnO is soluble to raise the *p*H to the value at which $Zn(NH_3)_2Cl_2$ is precipitated and further addition of ZnO causes further precipitation of this diammine.

Once again, if one calculates the final NH_4^+:Zn^{++} ratio after the addition of the required amount of ZnO to 13½:11 for precipitation, one obtains the following:

5g of ZnO in 200 cm^3 of 13½:11 raise the electrolyte composition to approximately 13:13
Specific gravity of 13:13 is 1.14

In 1000g of 13:13, there are 130g NH_4Cl and 130g $ZnCl_2$

1000g of 13:13 have a volume of 877 cm^3

therefore

1000 cm^3 of 13:13 contains 148.2g NH_4Cl and 148.23g $ZnCl_2$

Thus $[NH_4^+] = 2.77M$
$[Zn^{++}] = 1.09M$

and $NH_4^+:Zn^{++} = 2.54$

It is seen that the final NH_4^+:Zn^{++} ratio is close to that observed for minimum crystallization tendency on the addition of NH_4OH.

For electrolytes with an initial *p*H of 4.7, the composition 13½:11 will show the least salt formation if a substantial amount of the ZnO present in a powdered

Table II. Molar concentration of each of the ions and the NH_4^+:Zn^{++} ratios for the electrolytes having a fixed NH_4^+ concentration of 27%

Electrolyte	$[NH_4^+]$	$[Zn^{++}]$	$[Cl^-]$	$[NH_4^+]:[Zn^{++}]$
27:05	5.61	0.41	6.43	13.68
27:08	5.74	0.67	7.07	8.57
27:12	5.85	1.02	7.89	5.74
27:15	5.97	1.30	8.57	4.59
27:25	6.53	2.37	11.27	2.76

zinc anode is dissolving in the electrolyte. However, the lower conductivity of this electrolyte compared to 22:10 (~ 30% less) outweighs its advantages over 22:10 in respect to crystal formation and hence its utility as an alternative thin film battery electrolyte would appear to be limited for those applications requiring high drain rates.

Since there is normally an appreciable amount of ZnO present in a powdered zinc anode which will cause the electrolyte *p*H to rise rapidly after cells are constructed, it was considered unnecessary to restrict the initial electrolyte *p*H to that of 22:10 since the important parameter is the final electrolyte *p*H after the battery has had time to equilibrate. Hence, a series of electrolyte compositions were investigated keeping the NH_4^+ concentration fixed and as high as possible (27%) while varying the Zn^{++} concentration and thus the NH_4^+:Zn^{++} ratio. In this case, the initial *p*H of the electrolyte is lowered as the Zn^{++} concentration is increased but the final electrolyte *p*H is determined by the ZnO content of the final equilibrated electrolyte.

The electrolyte compositions investigated are given in Table II with the corresponding NH_4^+:Zn^{++} ratios. Figure 7 gives the *p*H titration curves of the three compositions 27:05, 27:10, and 27:25 with the addition of 29.4% NH_3. With 27:05 and 27:10, two plateaus are observed in which the first reflects buffering of the electrolyte by formation of $Zn(NH_3)_2Cl_2$ and the second by dissolution of the $Zn(NH_3)_2Cl_2$ as $Zn(NH_3)_4Cl_2$. With 27:25, the point of dissolution of the $Zn(NH_3)_2Cl_2$ is not reached within the limits of the amount of ammonium hydroxide added in this experiment. Two main points should be noted from Fig. 7: (*a*) the buffering action begins at an increasingly higher *p*H as the NH_4^+:Zn^{++} ratio goes up, and (*b*) the buffering capacity due to formation of $Zn(NH_3)_2Cl_2$ decreases as the NH_4^+:Zn^{++} ratio goes up. Note also that a greater addition of alkali is required as the ratio goes down before diammine formation is observed. These observations mean that fewer diammine crystals will be formed in a 27:05 electrolyte than in 27:25 before the electrolyte *p*H will rise to the second plateau and dissolution of the crystals will begin. However, during the period when the buffering action is operative, the cathode discharge performance will be better with the 27:25 electrolyte in view of the lower *p*H value.

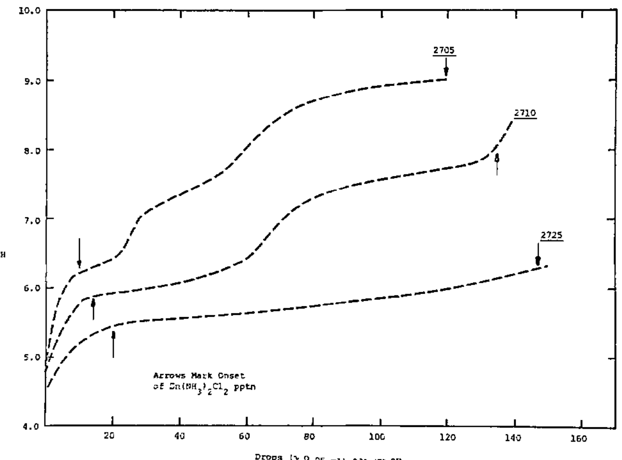

Fig. 7. Titration of 27:05, 27:10, and 27:25 electrolytes under conditions identical to those of Fig. 2 and 3.

Figure 8 shows the minimum amount of ZnO required to form a precipitate of $Zn(NH_3)_2Cl_2$ for each of the five compositions and gives the *p*H of the solution at the point of precipitation. A similar trend is seen for the iso-*p*H 4.7 electrolytes presented in Fig. 6, in that, as the NH_4^+:Zn^{++} ratio goes down, the amount of zinc oxide which can be taken up by the electrolyte before diammine formation occurs, goes up. As further points it may be noted that the buffered electrolyte *p*H is lowest with the lowest NH_4^+:Zn^{++} ratio and that the average crystal length of the precipitating diammine increases by about one order of magnitude between the electrolyte composition of 27:25 and that of 27:05. The longest and hence potentially more detrimental crystals are observed in the 27:05 electrolyte.

With a 22:10 electrolyte, 4g of ZnO per 200 cm^3 of electrolyte will cause diammine formation. This ratio of ZnO weight to electrolyte volume is approximately the same as that in the ESB P-70 thin film cell assuming 5% ZnO in the anode. Hence such an anode with 22:10 in the P-70 electrolyte will rapidly establish an electrolyte *p*H of approximately 5.9 and slow formation of diammine will have commenced. With 27:25, however, 4.0g of ZnO in 200 cm^3 electrolyte is insufficient for diammine formation and even at a level of 7.5g per 200 cm^3, the *p*H cannot rise above ~ 5.4. Hence it may be advantageous when using a 27:25 electrolyte to allow the ZnO present in the anode to remain rather than attempt to remove it in order that the initially low *p*H value of 27:25 would be pulled up rapidly to 5.4 and thus anode corrosion be kept at a minimum. Compared to 22:10, however, the 27:25 electrolyte will always operate at least one-half of a *p*H unit lower than 22:10 and should thus give better discharge performance of the MnO_2.

Conclusions

The main conclusion to be drawn from this work is that when a specific composition of Leclanché electrolyte is used, it should be tailored to fit the battery configuration, internal chemistry, and drain rate of that

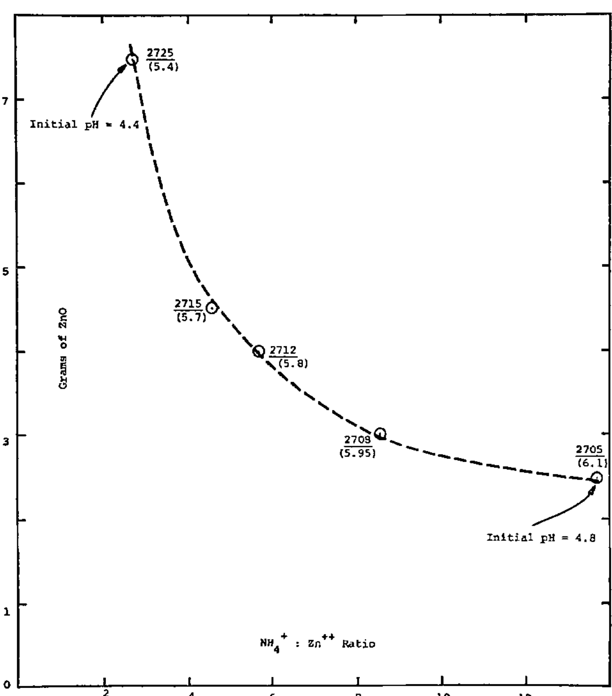

Fig. 8. Minimum amount of ZnO required for precipitation of the electrolytes having fixed NH_4^+ concentration of 27%. Conditions identical to those of Fig. 6.

particular system in which it is employed. Clearly, an important consideration is not the initial composition of the electrolyte, but rather what the composition will be after equilibration with the active cell materials. Further, this equilibrated composition must have the correct pH for good anode stability and MnO_2 discharge performance. In addition, one needs to consider how susceptible the electrolyte will be toward diammine crystal formation and if such crystals are formed, is the configuration such that rapid cell failure will result?

In the particular case of the ESB P-70 system in which diammine formation is undesirable and in which the zinc oxide content of the anode is relatively high, it appears that a composition of 27% NH_4Cl and 25% $ZnCl_2$ constitutes the most suitable electrolyte.

The Role of Ternary Phases in Cathode Reactions

M. Stanley Whittingham*

Exxon Research and Engineering Company, Corporate Research Laboratories, Linden, New Jersey 07036

ABSTRACT

The cell reactions between lithium and several transition metal oxides and sulfides have been found to produce ternary phases and not the formation of lithium oxide or sulfide as previously proposed. These reactions, at 25°C, take place with essential retention of the crystalline lattice, thus facilitating secondary cathodic behavior. It is found that cell reversibility is optimized when no chemical bonds are broken during discharge, that is, where ternary phases are formed by an intercalation reaction and where a broad range of nonstoichiometry exists as in the system Li/TiS_2. Where some chemical bonds are broken as for V_2O_5 and TiS_3 partial or difficult reversibility is found, but when all the bonds are broken as for example in CuS, the cell only exhibits primary characteristics.

There has been much recent work in ambient temperature batteries using lithium anodes and cathodes comprising metallic compounds of the halides, oxides, and chalcogenides. Very little is known concerning the mechanism of cathodic reduction of such materials or even of the products of reaction. Thus frequently the observed emf's bear little, if any, relation to those calculated for simple reduction reactions. For V_2O_5 reduction to VO_2, an emf of 2.4V is expected (1) but the observed cell emf is 3.5V (2, 3), for $(CF)_n$ going to graphite and LiF the free energy change corresponds to 4.6V and yet only 2.8V is observed experimentally (4, 5), and for MoO_3 giving MoO_2 and Li_2S the values are 2.2 (1) and 2.8V (2, 6). In the case of cupric sulfide the cell emf is that expected for the formation of Li_2S and Cu, 2.3V (7), and in many cases there is no discrepancy for the halides.

At low temperatures reactions in the solid state tend to go by the easiest route, that is, by the one involving minimal structural change. Thus in the reduction of tungsten trioxide by hydrogen at ambient temperatures hydrogen is incorporated into the lattice without any significant structural changes giving a hydrogen tungsten bronze, H_xWO_3 (8). At temperatures, ~350°C, above the stability limit of the bronze, reduction occurs by abstraction of oxygen along discrete planes with the formation of shear planes at definite intervals (9, 10). The remainder of the crystalline structure remains unchanged during this process, so here again there is no bulk rearrangement of atoms. Further reduction occurs directly to tungsten metal and no evidence is found for the presence of any intermediate oxides, which have very different crystalline structures although many are known. Thus where such simple structural changes cannot occur, the lattice will react by complete destruction to the metal. On the discharge of MnO_2 (11) and V_2O_5 (12) cathodes in aqueous solution it has been proposed that hydrogen atoms are incorporated into the lattice forming nonstoichiometric compounds analogous to H_xWO_3. It is therefore proposed that many of the cathode discharge reactions in lithium cells are governed by the same structural considerations. Such considerations are expected to dominate whenever the cathode material is insoluble in the electrolyte medium, that is, where liquid dissolution recrystallization processes cannot occur.

This paper describes the evidence for the formation of ternary phases during the reduction by lithium of a number of oxides and sulfides, and of their formation by topochemical reactions. The important role of topology in solid-state reactions has recently been reviewed by Thomas (13) and its important role in electrochemical reactions has also been suggested (2, 14).

Experimental

The oxides and sulfides were obtained from Alfa Inorganics or were prepared by direct reaction of the

* Electrochemical Society Active Member.
Key words: cathode, secondary battery, sulfide, oxide, nonaqueous cell, lithium, ternary phases, nonstoichiometry.

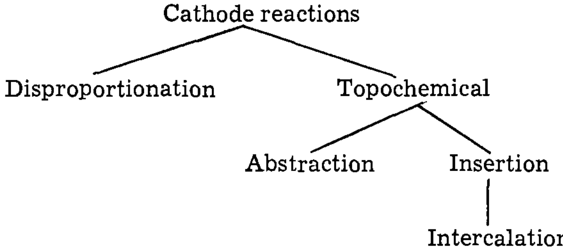
elements. They were then pressed into expanded metal screens using Teflon as a binder and with the addition of some graphite powder as conductor for those materials that are electronic insulators in the pure state. Lithium foil was used as the anode. The electrochemical experiments were performed using a Princeton Applied Research potentiostat, coulometer, and programmer. Open-circuit potentials were recorded only after at least an overnight stand under zero current flow. The lithium content of the cathode was changed by coulometric titration, and x-ray analysis was made at periodic intervals.

A major part of the structural analysis was performed on samples lithiated chemically using n-butyl lithium (15, 16). This technique has a number of advantages over the electrochemical method. It is much simpler and therefore quicker and there is no possibility of any side reactions due to the presence of graphite or of a polar solvent.

Samples were prepared for x-ray analysis in a helium glove box and were protected from reaction with air or moisture by a film of Mylar as described elsewhere (17). All the x-ray patterns were taken on a Philips diffractometer using CuKα radiation, and the lattice parameters were calculated with the aid of a PDP 8E computer.

Results and Discussion

The possible cathode reactions can be classified as follows:



A disproportionation reaction here is one such as is found with the copper halides

$$CuF_2 + 2Li \rightarrow 2LiF + Cu$$

where the crystalline structure of the cathode is completely broken down. A topochemical reaction is one in which the structure of the product bears a close relationship to that of the reactant, and in which any atomic rearrangements can be accomplished by simple transformations. The shear structures, described above, are an example of such a structural change as are also the dehydration reactions of the molybdenum oxide hydrates which are shown schematically in Fig. 1. In the first step of this reaction water is simply lost from between the layers, which are built up by bonding between ($MoO_5 \cdot OH_2$) octahedron; in the second step the water in the bonding octahedra themselves is lost and a double layer of MoO_6 octahedra are formed (18). A feature of these topochemical reactions is the frequent obtaining of good x-ray patterns, often closely related to that of the reactant; in contrast disproportionation reactions at ambient temperatures tend to give products amorphous to x-rays. In addition there is usually an increase in the BET surface area in the latter case due to the breakdown of the crystal, whereas for topochemical reactions the crystallites maintain their integrity and hence the BET areas usually remain constant (10). For lithium reactions, there may be two subsets, one in which anions are abstracted from the crystalline lattice and the other where lithium is inserted into the structure. In the former two binary phases are formed whereas in the latter a ternary phase is found

$$x\text{Li} + MO_z \rightarrow x/2\, Li_2O + MO_{z-x/2}$$
$$x\text{Li} + MO_z \rightarrow Li_xMO_z$$

These reactions do not necessarily have to involve stoichiometric ratios of reactants, as the products can be nonstoichiometric phases such as the well-known sodium tungsten bronzes, Na_xWO_3 where $0 \leq x \leq 1$ (19).

Intercalation reactions are a special case of a ternary insertion process in which the reactant has a layered structure and where lattice expansion occurs perpendicular to the basal planes to allow the insertion of the intercalate. In a true intercalation compound, where the host structure remains unchanged during formation, the reaction should be reversible. Graphite is perhaps the best known example of a lamellar material that can form such intercalation complexes, it is amphoteric in nature, forming compounds with both electron donors, such as potassium, and electron acceptors, such as bromine. Many of the dichalcogenides of the group IVB, VB, and VIB transition metals also form layer compounds in which anion layers are held together by weak Van der Waals forces and between which many electron donors can be intercalated including metals such as lithium and many organic nitrogen compounds, *e.g.*, pyridine (16, 17, 20, 21).

As the intercalation reaction is the simplest to visualize, an example of it is described first. Although the layered disulfides were described as being electrochemically inactive and were merely used as inert substrates for electrochemically active materials such as iodine (22), titanium disulfide has recently been proposed as an active cathode material in both lithium (23, 24) and sodium cells (25). This could react with lithium in the following ways

$$Li + TiS_2 \rightarrow \tfrac{1}{2}\, Ti_2S_3 + \tfrac{1}{2}\, Li_2S \qquad [1]$$

$$Li + \tfrac{1}{2}\, TiS_2 \rightarrow \tfrac{1}{2}\, TiS + \tfrac{1}{2}\, Li_2S \qquad [2]$$

$$Li + \tfrac{1}{4}\, TiS_2 \rightarrow \tfrac{1}{4}\, Ti + \tfrac{1}{2}\, Li_2S \qquad [3]$$

$$Li + TiS_2 \rightarrow LiTiS_2 \qquad [4]$$

$$Li + \frac{1}{x} TiS_2 \rightarrow \frac{1}{x} Li_xTiS_2 \qquad [5]$$

The associated calculated cells emf's for reactions [1] through [3] are 2.24, 1.87, and 1.38V, respectively (1). The experimentally determined values are given in Fig. 2. These were determined using as electrolyte a solution of lithium hexafluorophosphate in propylene carbonate, but were found to be independent of both salt and solvent. Clearly these cell potentials do not fit the calculated values for reactions [1], [2], or [3]. They are higher in all cases as observed for the oxides of vanadium and molybdenum. The variation with lithium content suggests the formation of a single compound with a continuously changing composition such as in Li_xTiS_2 where $0 \leq x \leq 1$, as proposed in reaction [5]; reaction [4] would give a cell potential independent of state of reaction as TiS_2 and $LiTiS_2$ are in equilibrium with one another until the reaction is completed. This thermodynamic data thus suggests the formation of a ternary nonstoichiometric phase analogous to the well known sodium tungsten bronzes, Na_xWO_3.

An x-ray study of titanium disulfide before and after reaction with lithium shows little change as is shown in Fig. 3. The diffraction lines for $LiTiS_2$ have

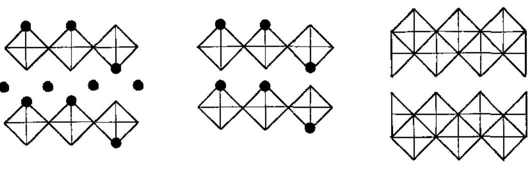


Fig. 1. The topotactic dehydration of molybdenum trioxide dihydrate, $MoO_3 \cdot 2H_2O$. ⊠ MoO_6 or $MoO_5 \cdot OH_2$ octahedra; ● H_2O.

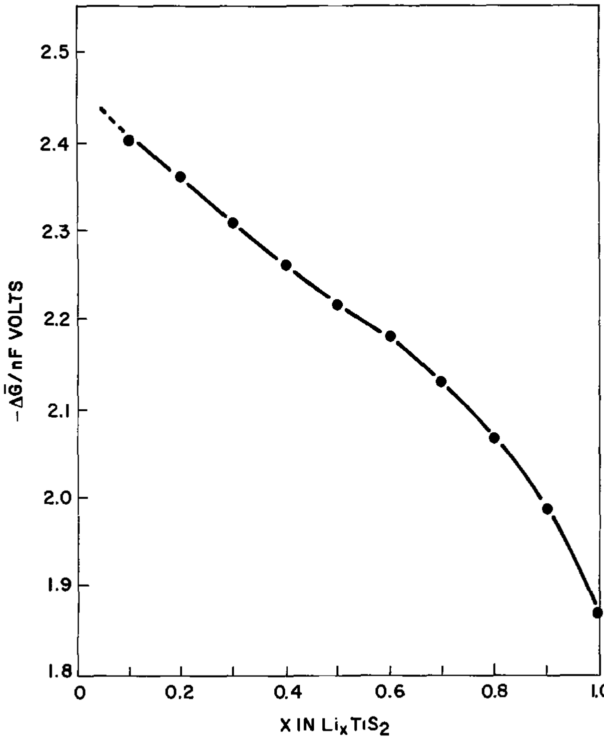

Fig. 2. Partial molar free energy of formation of Li_xTiS_2

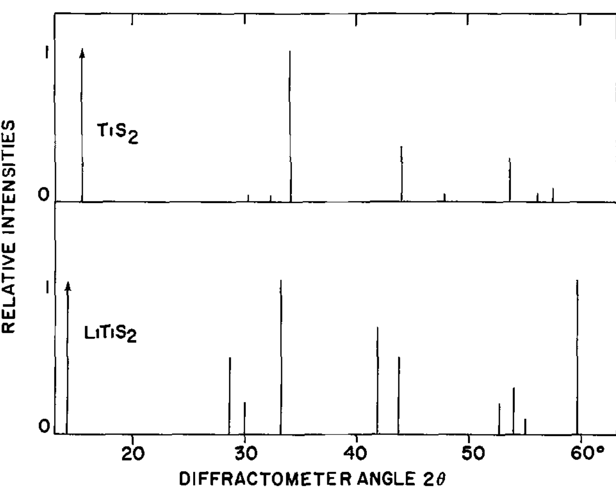

Fig. 3. Schematic of x-ray diffractograms of TiS_2 and $LiTiS_2$

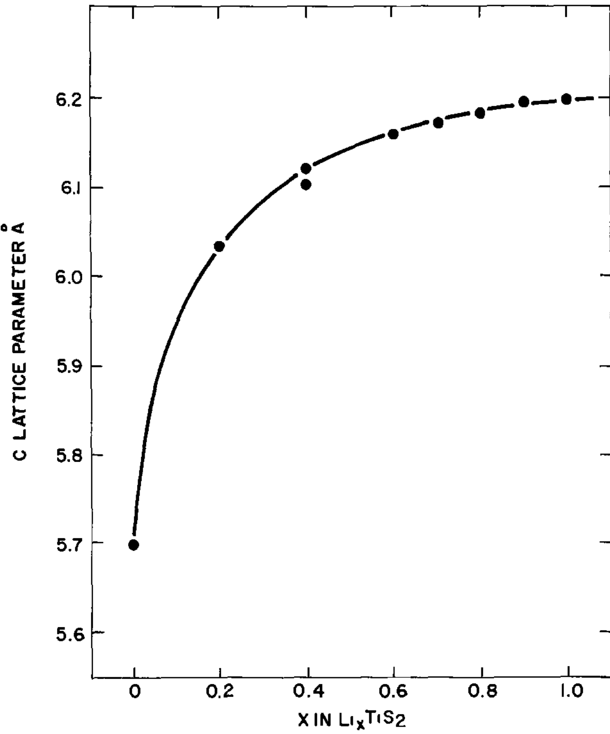

Fig. 4. Variation of c-lattice parameter with x in Li_xTiS_2

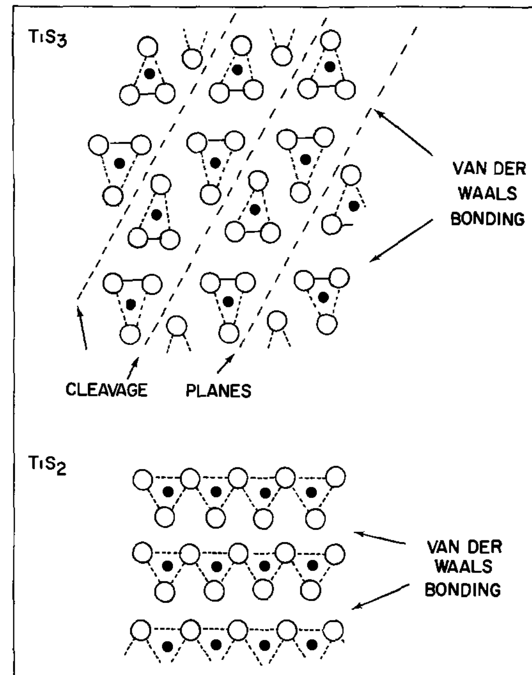

Fig. 5. Comparison of the structures of TiS_3 and TiS_2 looking down the b-axis. ○, Sulfur; ●, titanium. The atoms are not all in the same plane.

shifted to slightly lower angles, 2θ values, indicating a fractional increase in the hexagonal lattice parameters. Thus for TiS_2 itself, $a_o = 3.407Å$ and $c_o = 5.697Å$, whereas for $LiTiS_2$, $a_o = 3.455Å$ and $c_o = 6.195Å$ (17), an increase of about 10% in the c-direction. These x-ray results were found to be identical for TiS_2 reacted in an electrochemical cell and for the sulfide reacted with n-butyl lithium. Care had however to be taken in both cases. In the former the solvent could also intercalate the structure along with the lithium, causing a substantial lattice expansion, up to 18, 19, and 24Å in the case of propylene carbonate. In the latter, because the n-butyl lithium reaction is not reversible, lengthy reaction times were necessary to ensure equilibration of the lithium throughout the solid for x-values less than unity. Figure 4 shows the continuous variation of the c-lattice parameter with lithium content. This is consistent with the cell emf data and again shows the formation of a single ternary phase of formula Li_xTiS_2 for all x-values. This variation in lattice parameters is in agreement with previous qualitative x-ray data (26).

Inspection of the crystal structure (Fig. 5) shows how this reaction can take place. Between the sulfur-titanium-sulfur sandwiches there is no chemical bonding, just weak Van der Waals bonding, so that the lithium ions can be rather readily inserted between these layers without radically altering the over-all structure. The lithium and titanium ions occupy octahedral interstices (17) in the close-packed sulfur lattice. Although these holes are sufficiently large, ~0.7Å radius, to accommodate lithium ions, 0.7Å radius, without any expansion of the lattice, an expansion is, nonetheless, observed. This is probably related to a fractionally decreasing ionicity of the lithium with increasing x; thus for x tending to zero the lithium is probably completely ionized whereas for x close to unity the ionization drops about 10% (assuming a linear change in the lithium volume with change of

ionicity). Li^7 nuclear magnetic resonance studies (27) of Li_xTiS_2 as a function of lithium content also indicate a decreasing ionicity of the lithium with increasing x. The Knight shift and quadrupole coupling constant both increased almost linearly with x.

Clearly in the case of titanium disulfide, lithium reacts in an electrochemical cell by forming a ternary phase which is nonstoichiometric. In addition the crystalline structure of the initial material determines the final structure, that is, the material's topology is critical. This type of cell reaction is not restricted to lithium but has been shown by the author (21) and others (28, 29) to be general. Thus organics, such as pyridine and trimethylamine, as well as metals such as copper and silver, can be readily electrointercalated into these layered dichalcogenides. However, the existence of such a layered structure does not necessarily mean that the reaction will be thermodynamically allowed; thus, for example, tungsten disulfide is reduced directly to metallic tungsten (17) by lithium.

Titanium forms a trisulfide as well as the disulfide discussed previously. The trisulfide has the formula TiS(S-S), *i.e.*, it contains one sulfide sulfur and one polysulfide group (30). Its structure, which superficially resembles the disulfide, is shown in Fig. 5. The Van der Waals layer is lined with polysulfide groups rather than the sulfide ions found in TiS_2. In addition the titanium atoms are in distorted trigonal prismatic sites as contrasted with octahedral sites of TiS_2. The trigonal prisms in the two rows between the Van der Waals gap are displaced perpendicular to the plane of the figure by half their height so that there is weak bonding between the sulfide, $S^=$, ion in one prism with the titanium in the adjacent prism. This weak bonding creates additional cleavage planes which cause the crystals to grow as fibers rather than the platelets of TiS_2; thus the only strong bonding is along the axis of the trigonal prisms. This one-dimensional structure of TiS_3 is compared with the two-dimensional structure of TiS_2 in Fig. 5.

The reaction of titanium trisulfide and niobium triselenide with lithium has been proposed as the basis of a secondary lithium battery (22, 31) and to be

$$NbSe_3 + 2(1+x)Li \rightarrow NbSe_{2-x} + (1+x)Li_2Se$$

with x approaching 0.5. Such a disproportionation reaction is unlikely to be reversible and moreover is unlikely to occur at ambient temperatures for the reasons discussed at the beginning of this paper. An electrochemical discharge of TiS_3 gave an open-circuit emf, of 2.17V, almost independent of lithium content up to two lithium with a gradual fall-off as a third was added. This is consistent with the two reactions

$$TiS_3 + 2Li \rightarrow Li_2TiS_3$$
$$Li_2TiS_3 + xLi \rightarrow Li_{2+x}TiS_3 \text{ for } 0 < x \leq 1$$

In the first reaction the lithium reacts by insertion into the structure forming a ternary compound and breaks the polysulfide bond. X-ray analysis of TiS_3 cathodes after reaction showed an expansion of ~0.4Å from 8.73Å to 9.11Å of the crystalline lattice perpendicular to the Van der Waals layer. A complete study of the reaction of titanium trisulfide with n-butyl lithium (32, 33) using x-ray and infrared techniques has clearly shown that ternary phases are formed and that the polysulfide bond is broken on reaction. A continuing x-ray analysis program (34) indicates that the chains of trigonal prisms are probably distorting toward the more stable octahedral coordination of the sulfur around the titanium. This formation of ternary phases has been independently ascertained (35).

Contrary to the original reports (31), our studies on titanium trisulfide indicate that it is only marginally rechargeable. At most one of the three lithium in Li_3TiS_3 can be recovered and then only at very low current densities, for example under trickle charge. Clearly the lithium that causes the breakage of the polysulfide bond cannot be reclaimed; this is probably related to a conversion of the titanium coordination polyhedron from a trigonal prism to the more stable octahedron. Thus in titanium trisulfide where a ternary phase is formed by a topochemical reaction in which some chemical bonds are irreversibly broken, secondary cathodic behavior is marginal. In contrast our electrochemical tests on niobium triselenide indicate that in this case complete reversibility for three lithium is found in agreement with prior work (31). The Se-Se bond in $NbSe_3$ is variable in length and longer than that normally associated with the polychalcogenide bond (36), so that little disruption probably occurs on breakage. More important, however, is that niobium atoms do not have any preference for octahedral over trigonal prismatic sites (37), so that the initial breaking of the Se-Se bond does not lead to subsequent reorganization of the host structure as in TiS_3. These results on the trichalcogenides indicate that ternary phase formation in itself is not a sufficient criterion for reversibility.

Like the sulfides discussed above, we have found that many transition metal oxides also form ternary phases with lithium in electrochemical cells. Vanadium pentoxide has been extensively studied as the cathode in primary lithium cells (3) and recently has been shown to be rechargeable (38). The open-circuit emf on the Li/V_2O_5 cell is almost constant for one lithium at ~3.4V (2) and then falls abruptly to ~2.5V for a second lithium. The x-ray pattern of the reaction product of V_2O_5 and 1 mole of n-butyl lithium is compared in Fig. 6 with the x-ray patterns of V_2O_5 and LiV_2O_5 formed at 600°C by a solid-state reaction. This pattern bears a close resemblance to both known compounds, and the strong 001 reflection decreasing and the weak 200 reflection increasing in 2θ on reaction, but not as far as at high temperatures.

Figure 7 shows the structure of V_2O_5. The vanadium resides in a highly distorted octahedron of oxygen and much closer to one of the oxygen so that the bond to this oxygen is essentially of the type V = O. This allows for ready cleavage of the structure in the plane of these bonds permitting the inclusion of alkali and other metals. Thus for small amounts of lithium, $x < 0.13$, and sodium, $x < 0.02$, this structure is maintained as shown in Fig. 7b (39); these are the α-alkali vanadium bronze phases, $M_xV_2O_5$. In the case of sodium, the compound NaV_2O_5 has the same structure (Fig. 7c) but for the high temperature formed LiV_2O_5, the VO_5 distorted square pyramids have a different orientation to that found in V_2O_5 itself. Thus

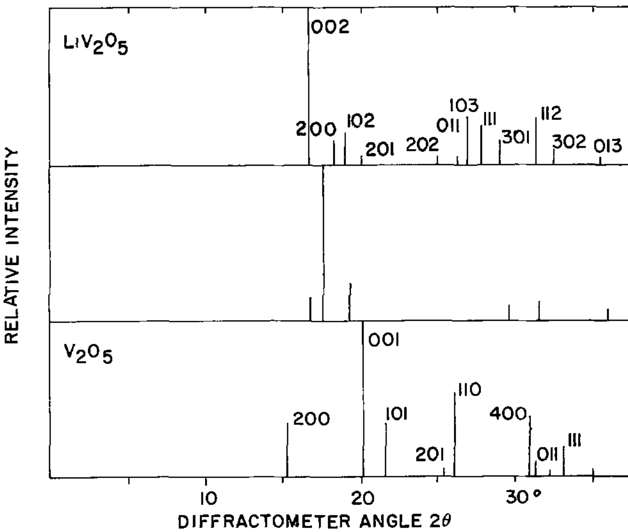

Fig. 6. Schematic of x-ray diffractograms of LiV_2O_5, V_2O_5, and ambient temperature formed LiV_2O_5.

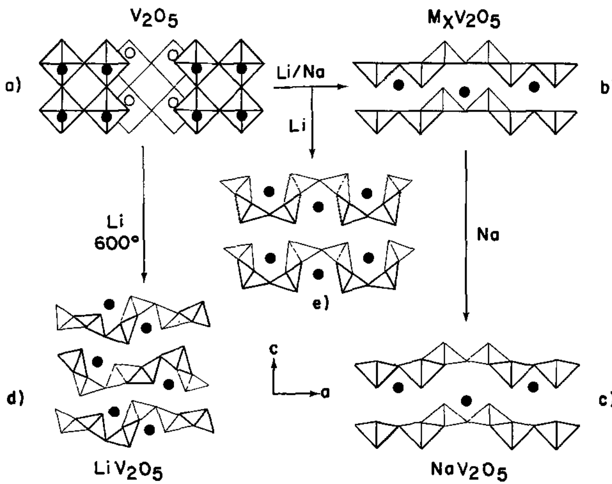

Fig. 7. Structures of vanadium pentoxides looking down the b-axis. (a) V_2O_5; (b) $M_xV_2O_5$ for low x values; (c) NaV_2O_5 formed at high temperature; (d) LiV_2O_5 formed at high temperature; and (e) LiV_2O_5 formed at ambient temperature.

in LiV_2O_5 the base of the pyramids alternate up and down singly, whereas in V_2O_5 itself they alternate up and down in pairs. Although at high temperatures this change can readily take place, it is unlikely that it can occur at ambient temperatures. Therefore, it is proposed that on discharge in a lithium cell, vanadium pentoxide tends toward this same structure but maintains its pair alternation giving the structure shown in Fig. 7e. This structure has a c-parameter smaller than that of LiV_2O_5 but larger than that of V_2O_5, and the converse for the a-cell parameter in agreement with the x-ray data of Fig. 6. Heating of this phase at 600°C converts it to the high temperature form of LiV_2O_5.

In the reaction of the alkalis with vanadium pentoxide the vanadium is reduced from the +5 valent state to the +4 state, with the electron localized on the vanadium (19) as the V = O bond is presumably broken. So here as for TiS_3 bond breaking occurs, followed by structural distortion, and recharging is difficult, though it has been accomplished recently at low discharge depths, ~0.25 Li (38). An added complication in this case is the decomposition of the organic electrolyte that occurs at the emf's, $>$ 3.5V, necessary for recharge so that the degree of reversibility cannot be determined for certain.

Molybdenum trioxide reacts readily with lithium forming ternary phases, as expected from its layered structure which is shown in Fig. 1. However, we have found at least two well-defined discharge products from the x-ray data which are different, but similar, to the known high temperature Li_2MoO_3 (40) as found in the case of V_2O_5. Their structures are now being analyzed. The existence of two discharge plateaus, consistent with the above x-ray data, has been previously reported (41), but the suggestion that a primary reaction product reacts further with MoO_3 to form polymolybdates, as originally proposed in a high temperature molten salt environment (42), is extremely unlikely. As discussed earlier such reactions are not likely to occur at low temperatures unless the reactants are at least partially soluble in the electrolyte. We have found similar x-ray evidence for ternary phase formation for MnO_2 and TiO_2. The high emf found for the so-called CrO_3 intercalate of graphite, 3.9V for sodium (15) and lithium cells (measured by us on "Seloxcette" obtained from Alfa Chemicals) is probably due to the formation of a ternary complex. This might be $LiCr_3O_8$ as "Seloxcette" has been claimed to be merely a mixture of graphite and Cr_3O_8 (43). To determine the exact reaction paths of these ternary oxides will require x-ray analysis of single crystals because of the complexities of their structures.

A number of metal compounds react with the formation of the metal and the simple lithium salt. Cupric sulfide apparently reacts with lithium in a one-step reduction step giving copper metal and lithium sulfide (44), the calculated and observed cell emf's, 2.3V, are in good agreement. This class of reaction in which all the chemical bonds are broken is not normally reversible unless a partial solubility of the reactants in the electrolyte occurs. Thus NiS and CuS cells have been found to be irreversible and this was associated with the insolubility of Li_2S in the electrolyte (45).

Conclusions

For some time now it has been postulated that the reversibility of alkali metal based cells should be enhanced if the crystalline structure of the cathode material is maintained during discharge and the subsequent charging (15, 46, 47). That the alkali metal tungsten and vanadium oxides bronzes, M_xWO_3 and $M_xV_2O_5$ where $x < 1$, could be used as ionically reversible electrodes (48, 49) for the measurement of the conductivity of the data aluminas focused attention on them for initial studies. However, although their thermodynamic properties and nonstoichiometry requirements were ideal for cathodic use, the diffusion of the alkali ions was much too small to maintain any significant current density (2). Emphasis was then shifted away from these high temperature phases to lower temperature reactions.

This study of the ambient temperature reaction between lithium and transition metal oxides and sulfides indicates that in many cases ternary phases are formed rather than simpler lower oxides or sulfides and lithium oxide or sulfide as had been previously suggested. The structure of this ternary product is determined by the crystal lattice of the initial reactant and minimum structural change occurs for intercalation reactions. The reversibility of the discharge reaction is maximized when no chemical bonds are broken during discharge (intercalation reaction) and minimum when all the chemical bonds are broken, that is, where the structure is completely broken down as for example found in the case of CuS, CuF_2, and AgCl. When some but not all the chemical bonds are broken and the structure distorts as in TiS_3 and V_2O_5 partial and/or difficult rechargeability is found.

In many cases, such as for V_2O_5 and MoO_3, the phases formed in these cells are different from the phases formed at elevated temperatures and may be metastable.

If nonstoichiometric phases are formed on discharge, then the rate of reaction and reversibility are likely to be enhanced as it is unnecessary to nucleate new phases. Reversibility is thus optimized when a single ternary phase is formed which is nonstoichiometric and exists over the entire phase region from reactant to final product, as in Li_xTiS_2; the structure of this phase should remain essentially unchanged during reaction and no chemical bonds should be broken. These criteria become less important at higher temperatures. As the group VIA anions form such compounds much more often than the halides it is amongst the former that reversible ambient temperature cathodes are likely to be found. Naturally the existence of high electrical conductivity in many of these ternary phases is a strong asset from both discharge rate and reversibility considerations. Here an inert conductive matrix, such as carbon, which must make good contact with the electrochemically active material. need not be added.

Manuscript submitted July 7, 1975; revised manuscript received Oct. 10, 1975. This was Paper 40 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Structure and Anodic Discharge Behavior of Lithium-Boron Alloys in the LiCl-KCl Eutectic Melt

S. D. James* and L. E. DeVries

Electrochemistry Branch, Naval Surface Weapons Center, White Oak, Maryland 20910

ABSTRACT

Anodic discharge curves in the LiCl-KCl eutectic melt have been obtained for two lithium-boron alloys (70 and 80 weight per cent Li) between 673° and 873°K (400° and 600°C) and from 2-8 A/cm². The behavior of Li contained in wicks of porous Ni was also studied for comparison. Calculated Li contents for Li-B alloy anodes, at the main break in curvature of discharge curves, clustered closely around 0.67 mole fraction Li. We consider this strong evidence for the existence of a compound Li_2B in this alloy system. Between 748° and 873°K (475° and 600°C) and up to at least 8 A/cm², there is no diffusional limitation to the anodic extraction of Li from the Li-B alloys. The shape of discharge curves, the lack of anodic diffusional limitation, and the longer low-V plateaus of the alloy richer in Li, are consistent with the following picture of the discharge process. The discharging material behaves like a sponge of solid Li_2B compound containing a Li-rich, Li-B liquid alloy, probably a conjugate phase to the Li_2B compound. Lithium anodizes into the melt at constant V out of this liquid alloy until it is wholly transformed to solid Li_2B. This process constitutes the main plateau of alloy discharge curves. At this point (the main break in discharge curves) voltage rises to values where tighter-bound Li can be anodized out of the decomposing compound. The Li-B alloy electrodes are markedly superior to the Li-Ni wicks both in gravimetric coulombic capacity and in the ability to retain Li at high temperatures. Useful coulombic capacities of the Li-B alloys ranged up to 7700 coulombs/g of (Li + B) at about 3V *vs.* a chlorine reference electrode.

Presently used molten salt batteries yield only a small proportion of their theoretical energy. This is often due to failure of their Ca or Mg anodes. Calcium anodes react chemically with the electrolyte and both Ca and Mg anodes are passivated at high drains, becoming coated with resistive films of solid salt (1). Lithium, the most electronegative and one of the lightest of the elements, is a prime anode material. It does not react extensively with the LiCl-KCl melt and does not readily passivate in it. However, at the temperatures of these melts lithium is a highly corrosive liquid. This presents severe materials problems which may be mitigated by using a lithium alloy with a high melting point, as for example the LiAl compound (2). Of particular interest in the present work is the behavior of some alloys of lithium and boron which remain solid at high temperatures yet can be easily shaped by machining or pressing at room temperature. Their anodic behavior has been studied by obtaining discharge curves in the LiCl-KCl eutectic melt as a function of alloy composition, melt temperature, and discharge rate. Data were obtained between 673° and 873°K (400° and 600°C) for two alloy compositions [70 and 80 weight per cent (w/o) Li corresponding to 78.4 and 86.2 atomic per cent (a/o) Li] and three discharge current densities (2, 4, and 8 A/cm²). The behavior of Li contained in Ni Feltmetal wicks was also studied for comparison.

Experimental

Preparation of test electrodes.—Lithium-boron alloys.—All the manipulations described below relating to Li-containing materials were done in high-purity He-atmosphere glove boxes. Alloy ingots were made using lithium of 99.9% purity from Foote Mineral Company, and boron, "Crystalline Lump, 99.9%, D1263" from Atomergics Chemetals Company. Alloy electrodes were prepared by pressing the alloy into the cylindrical hole of a steel cup (stainless steel Type 303) called the electrode holder. Alloy disks were pressed into the electrode holder as shown in Fig. 1a. During pressing, the alloy filled the 8 mm diameter by 6 mm deep hole in the electrode holder and excess material extruded up through the 1 mm hole in the form of 0.04-0.1g of "spaghetti," This spaghetti was retained, weighed, and chemically analyzed for its Li content. Thus we arrived at an Li content of the alloy in that part of the ingot immediately adjacent to each individual sample to be discharged. Weighing the electrode holder before and after gave the mass of alloy in each test electrode. This averaged about 0.25g with the 70% alloy and 0.21g with the 80% alloy.

Li wick electrodes.—These were made as shown in Fig. 1b. From a 1 in. thick sheet of Ni Feltmetal (Brunswick Corporation, "Grade FM131, 18% dense" average pore size 50 μm) were machined cylindrical plugs slightly oversize (by 0.001-0.002 in.) in diameter but within 0.001 in. of the correct length. These then were pressed into the same electrode holders used for displaying Li-B alloys and placed for 1 min in molten Li at 1073°K (800°C) as in the diagram. Weighing the electrode holder before and after gave the mass of Li taken up by the Ni wick. This generally ranged from 0.12-0.14g of Li.

Discharge cell and procedure.—Figure 2 shows the experimental setup for discharging test electrodes. This setup was contained in a Pyrex glass pot (not shown). An atmosphere of dry argon gas was maintained inside

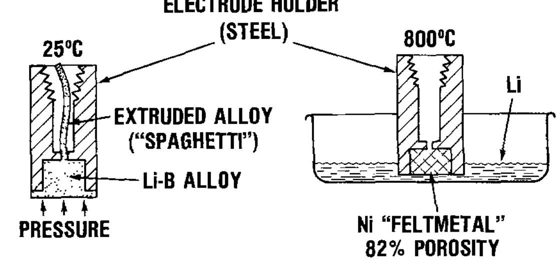

Fig. 1. Preparation of test electrodes

* Electrochemical Society Active Member.

Key words: anodes, electrodes, lithium, boron, molten salt batteries.

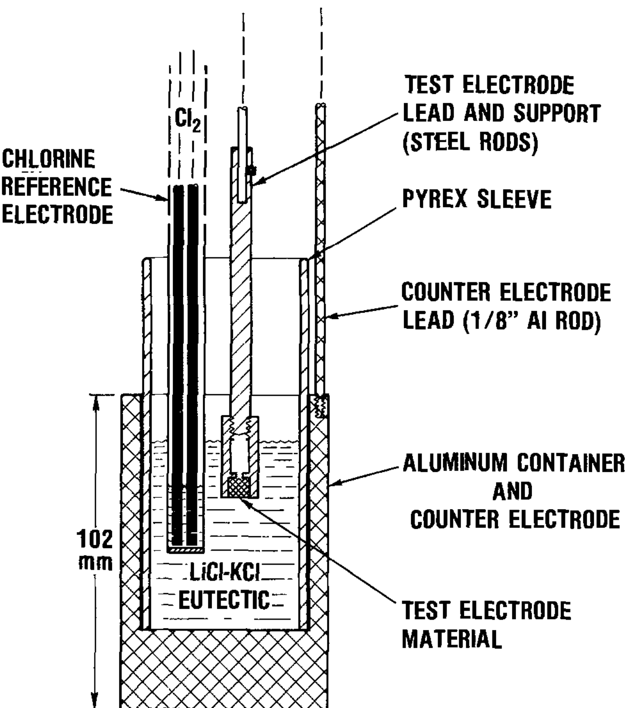

Fig. 2. Cell for discharging test electrodes. Drawing is to scale

the pot by flowing predried high purity (99.995%), water-pumped Ar through it. Before heating to the experimental temperature, the cell, containing powdered salt and reference electrode, was evacuated overnight at 553°K (280°C) to effect drying. A constant current (±0.1%) was driven between test and counterelectrodes so as to anodically dissolve test electrode material while its voltage was measured with a high-impedance recorder and voltmeter. The test electrode was contained in the electrode holder already described, held centrally in the cell by threaded steel connecting rods as shown. The melt container was an Al pot (Type 1100, 99+Al) which also served as counter-electrode, absorbing Li cathodically deposited on it during anodic discharge of the test electrode. The reference electrode was the chlorine electrode—the carbon/chlorine system inside a 8 mm fritted Pyrex tube. The Pyrex sleeve snugly fitting into the Al container served as an electrical insulator to restrict current to the bottom part only of the Al, thus favoring a uniform current density at the test electrode. After positioning the test electrodes in the melt it took from 20-40 min before steady temperature was recovered and discharge was begun. At the end of discharge the discharged electrode was normally withdrawn from the cell within 5 min for subsequent chemical analysis of its residual Li content.

Lithium contents were measured by extracting samples in aqueous solution and titrating the equivalent OH^- produced. After the run in which the Li wicks were discharged, cell materials were analyzed for Li by atomic absorption and acidimetry. Of the 1.783g of Li introduced into the cell in this run, 1.077g (60.4%) was found as lithium oxide or silicate in a black skin adhering to Pyrex glass surfaces. The Al pot contained 0.657g of Li (36.9%) and smaller amounts totaling 0.015g (0.8%) were found in the solidified melt and on cooler glass surfaces above the cell. Finally, 0.015g (0.8%) of residual Li was found in the 15 discharged wick electrodes. This left 0.0185g, only 1.0% of the introduced Li, unaccounted for.

The present article is based on interpretation of data from the discharge of 76 Li-B alloy electrodes and 16 Li-wick electrodes. These data were obtained over the course of seven runs, each employing a fresh charge of salt and a new Al container.

Results and Discussion

When discharged Li-B alloy electrodes were withdrawn from the experimental cell, it was apparent that a drastic shrinking of the sample had usually occurred. In extreme cases the shrinkage was from the initial 8 to 6.5 mm in diameter and from the initial 6 to 4 mm in length.

Shape of discharge curves.—Figure 3 shows discharge curves normalized by replotting the X-axis in terms of

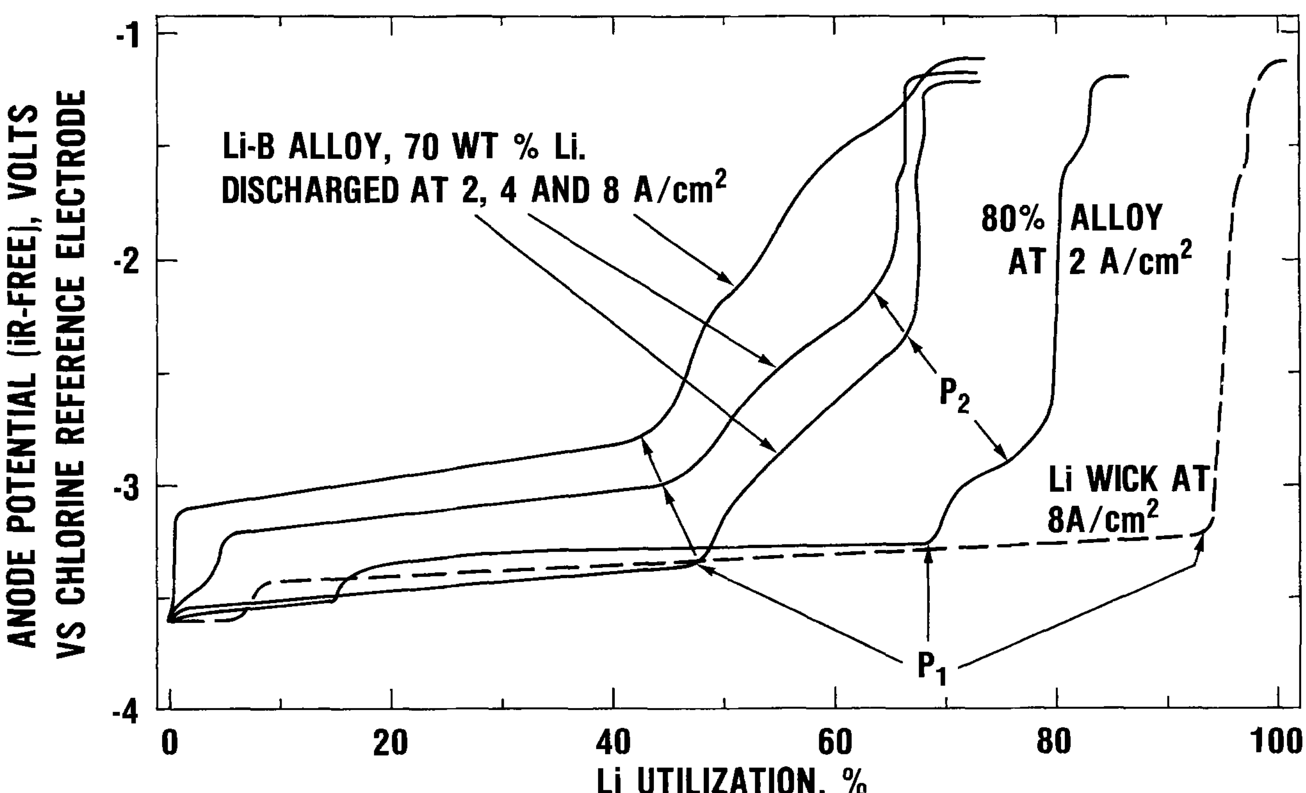

Fig. 3. Discharge curves normalized with respect to per cent utilization of the Li in each electrode. LiCl-KCl at 773°K (500°C)

per cent utilization of the Li in each electrode. The alloy discharge curves although referring mainly to the 70% alloy at 773°K (500°C) are actually typical of both alloys in the temperature range 723°-873°K (450°-600°C). Also shown for comparison is a typical Li-wick discharge curve. Current densities labeled on the curves are the ratio of current to the cross-sectional area of the mouth of the electrode holder (0.500 cm^2).

All of the Li-B alloy discharge curves have the same general shape as follows: (*i*) a relatively brief and rather flat plateau close to the Li potential, (*ii*) a long gently sloping plateau, (*iii*) an intermediate region where voltage rises faster and is heavily inflected, and (*iv*) a long and quite flat final plateau. The first plateau was present in only 62% of the samples discharged. There was no apparent correlation between its appearance and any pretreatment or composition factor. Its duration was usually quite brief as in Fig. 3 but on occasion it lengthened to be as long as the second region (*ii*). In view of its closeness in potential to pure Li, it is probably associated with the discharge of relatively small amounts of free Li, unalloyed with boron. The Li balance (accountability) data discussed below are consistent with the view that regions (*i*), (*ii*), and (*iii*) represent the discharge of Li only; anodic oxidation of boron does not contribute appreciably to the current over this voltage range. The final plateau is controlled by anodic dissolution of stainless steel (Type 303) of the electrode holder. This was shown by anodizing a Type 303 steel rod in the melt and duplicating the voltage of this final plateau (about -1V *vs.* the chlorine electrode). As Fig. 3 shows, even on this final plateau the 70% alloys still retained one third of their original Li. So a minor part of the current on this plateau could be due to the anodic dissolution of this residual Li.

Considering the three 70% alloy curves, it is apparent that Li utilization at P_1 and P_2, the two main breaks in curvature, falls only slightly with increasing current density with average values of about 45% for P_1 and 65% for P_2. With respect to the usefulness of these alloys as battery anodes, the Li utilized at low voltages (*i.e.*, prior to P_1) is of particular interest. If the main break at P_1 was caused by concentration polarization, then Li utilization at this point would vary inversely with current density. The minor effect of current density upon Li utilization at P_1 shows therefore that, up to 8 A/cm^2 there is essentially no diffusional limitation to the anodic extraction of this Li from the 70% alloy at 773°K (500°C). Table III shows that this statement holds true for both 70 and 80% alloys at 773° and 873°K (500° and 600°C). For the 80% alloy the low-voltage plateau is significantly longer, *i.e.*, a definitely larger proportion of the richer alloy's Li is utilizable at low voltage than is so for the 70% alloy. Again, Table III shows that this behavior is typical both at 773° and 873°K. Comparing the 8 A/cm^2 curve of the 70 w/o alloy with that of the Li wick shows the wick to utilize its Li twice as efficiently as the alloy and at about 0.5V lower voltage. However, as discussed below, the alloys are markedly superior to the wicks both in gravimetric coulombic capacity and in the ability to retain Li at high temperatures.

The Li-wick discharge curve presumably approximates that of free liquid Li. Thus the long low-voltage plateau in the alloy discharges corresponds closely with that of free Li at 2 A/cm^2 and parallels it with increasing overvoltage at the higher current densities. So this low-voltage part of the alloy's Li content is relatively loosely bound in the alloy. However, subsequent to P_1, the alloy's Li is discharged at much higher overvoltages from states of steadily stronger binding. The two inflections between the initial and final plateaus show the discharge process is not simple.

Escape of Li from anode materials.—Table I shows the results of our attempt to keep track of the Li content of our electrodes. This was done in terms of a "Li balance" defined in the table footnote. "Li residue" and "Li initial" were calculated from weighings and chemical analysis for Li. "Li anodized" was calculated from the quantity of electricity passed assuming it all involved merely $Li \rightarrow Li^+ + e^-$. If Li balance exceeds one then some other anodic process must be occurring in addition to $Li \rightarrow Li^+ + e^-$. An Li balance less than one means that Li is escaping from the electrode by some means other than anodic dissolution, *e.g.*, by dissolution in the melt. The fact that the data of Table I never exceeded unity for Li-B alloys supports our assumption that only Li (not B) is anodically dissolving in the voltage range of Fig. 3. However, some of the data were significantly less than one so anodic dissolution was not the only way that the Li-B alloys were losing Li. We see from the table that alloy composition has little or no effect on Li loss whereas there is a clear tendency for more Li to escape from alloys discharged in the hotter melts. Below 773°K (500°C), Li balances tend to unity. Data were obtained using two separate ingots of each alloy composition. These ingots behaved essentially the same with respect to Li loss. To aid wetting and thereby good electrical contact between alloy samples and the steel electrode holders, some electrodes were preheated in He for 2 min at 1023°K (750°C). Two correlations in the table on preheating effect show a big loss of Li for preheated 70% alloy but little or no loss for the 80% alloy. On the whole it is clear that significant amounts of Li escape from these Li-B alloys at the higher temperatures of this study.

The loss of Li from test electrodes, noted above for Li-B alloys, was even more noticeable in the case of the Li-wick electrodes. Table I shows that the wicks (like the alloys) suffered essentially no Li loss during the conditions of a 773°K discharge. However, at 873°K a very definite loss of Li occurred from the wicks. While there is no direct correlation in the table between wicks and alloys it is clear that Li escaped faster from the wicks; at 873°K Li balance for the wicks was 0.78 while it was 0.82 and 0.83 for the alloys even though the alloys were preheated while the wicks were not. Figure 4 shows the results of varying the time for which wick electrodes were kept at open circuit in the melt at 873°K before discharging at 2 A/cm^2. For a

Table I. Li balance[a,b] for Li-B alloy and Li wick electrodes

Anode material			Discharge temperature					
			673°-723°K (400°-450°C)		773°K (500°C)		873°K (600°C)	
			Preheat	No preheat	Preheat	No preheat	Preheat	No preheat
w/o of Li in Li-B alloy	70	Ingot 1		1.01	0.84	0.98		
		Ingot 2			0.89		0.82	
	80	Ingot 1		1.02	0.94	0.97		
		Ingot 2			0.90		0.83	
Li-Ni Feltmetal wicks						1.04		0.78

[a] Li balance = (Li anodized + Li residue) ÷ Li initial.
[b] Each datum is the average of results of from 2-8 similarly treated electrodes; mean deviations ranged from ±0.01 to ±0.07.

Fig. 4. Loss of Li from Ni Feltmetal wicks *vs.* soaking period in melt at 873°K (600°C) prior to discharge. Dischargeable Li is that per cent anodically extracted up to point P_1 of the 2 A/cm^2, 873°K discharge curves. Square data point: Li-B alloy electrode, 80 w/o Li (see text).

series of wicks, Li remaining in the electrodes (as calculated from the discharge curves) fell drastically and linearly with soaking period. Extrapolation showed all Li would be lost after about 130 min; in fact, one electrode soaked for 193 min had no dischargeable Li left. Chemical analysis of the Ni wicks of these discharged electrodes showed them to contain only 0.8% of their initial Li content, *i.e.*, no significant quantity of Li was being tied up in the form of an undischargeable Li-Ni alloy. The rate of Li loss from the wicks at 873°K is equivalent to a self-discharge current of about 400 mA/cm^2 of anode surface. We did not do a systematic study of Li escape from alloy electrodes comparable to that of Fig. 4, with the wicks. Alloys were routinely discharged about 30 min after dipping them into the melt. However, due to instrument-problems, one alloy electrode spent 105 min in a 873°K melt before discharge at 4 A/cm^2 and 873°K (in addition it spent 20 hr in the Ar stream above the discharge-cell at 643° ± 25°K). Figure 4 shows that, in spite of this protracted preheating, its dischargeable Li was 36% *vs.* an extrapolated 18% for the wicks. After escaping from test electrodes, Li dissolved in the melt and then reacted with the various Pyrex glass surfaces contacted by melt. At the end of each run these surfaces were found to be coated with an adherent black layer which was essentially elemental Si plus lithium oxide or silicate.

It was suggested by one of the referees that the low Li balances of Table I were caused by the reaction of Li in electrodes with K^+ in the melt to produce metallic K vaporizing out of the cell (3, 4). The equilibrium constant for reaction [1] based on data at 800°K (5) is 0.137

$$KCl(l) + Li(l) \rightarrow LiCl(l) + K(l) \quad [1]$$

Thus one might expect continuing reaction as K vapor is swept away from the melt by the stream of Ar cover gas. However the following data showed this was not the case. After a series of Li wicks had been discharged at 773° and 873°K, a detailed analysis for Li was done on the cell materials. Although the over-all Li balance for these discharges was 0.90, *i.e.*, 10% had escaped discharge, all but 1.0% was found in the cell. Furthermore we found no K (and very little Li) condensed on the cooler glass surfaces above our melt or in room-temperature traps in the effluent Ar stream. The lack of K generation in our system must be ascribed to the extensive surface of Pyrex glass that contacted our melt. Silica reacts rapidly with Li (6-11) according to reaction [2]

$$4Li(l) + 3SiO_2(c) \rightarrow 2Li_2SiO_3(c) + Si(c) \quad [2]$$

Potassium however forms a protective silicate film and reacts very slowly (7, 9). Furthermore in our temperature range Li reduces potassium oxides (5) and metasilicate (12). Thus it is reasonable to suppose that Pyrex glass would remove Li from the melt in preference to K and drive reaction [1] to the left. The melts of Ref. (4) and (5), where K generation was observed, were free from efficient getters of Li.

To sum up, the data indicate that under our discharge conditions, both Li-B alloys and Li wicks lose a significant proportion of their Li, only above 773°K. The results indicate that at 873°K the wicks lose Li about two or three times faster than the alloys.

Composition of alloy electrodes at points P_1 and P_2 of discharge curves.—It is reasonable to expect that well-defined breaks in the discharge curves may, in some cases, coincide with the arrival of the discharging alloy at a composition corresponding to some simple stoichiometric compound (since a compound has a well-defined free energy of decomposition, Li should discharge out of it at a characteristic voltage). This has been found to be true, *e.g.*, in the case of charge-discharge curves in the Li-Al system (2). Thus the analysis of discharge curves can give valuable information concerning compound formation in alloy systems. This assumes of course that the discharging alloy is very close to states of equilibrium. In this case, changes in alloy voltage correspond to changes in the equilibrium activity of the potential determining species in the alloy sample (in our case, Li). Equilibrium will strictly be followed only in an infinitely slow discharge when composition is precisely uniform throughout the system. In a faster discharge, concentration changes (of Li and Li^+) at the alloy/melt interface may themselves cause sudden large voltage steps which could be mistaken for those due to compounds. A distinction is possible however, because concentration polarization usually disappears after a few minutes at open circuit.

Our discharge curves generally had two quite well-defined breaks indicated as P_1 and P_2 on Fig. 4. It was invariably true that, within 2 min after opening the discharge circuit, the voltage had recovered and fallen below the value of P_2. Thus we must be careful of

Table II. Calculated Li atom-fraction[a] at points P_1 and P_2, the main breaks in curvature of alloy discharge curves.

	Initial composition, w/o Li	Discharge temperature 773°K (500°C) 2 A/cm²	4 A/cm²	8 A/cm²	873°K (600°C) 2 A/cm²	4 A/cm²	8 A/cm²
P_1	70	0.67	0.65	0.66	0.67	0.68	0.70
	80	0.67	0.67	—	0.70	0.71	0.74
P_2	70	0.54	0.50	0.50	0.55	0.55	0.56
	80	0.58	0.54	0.51	0.61	0.58	0.71

[a] Each datum is the average of results of from 2-5 similarly discharged electrodes. The deviations ranged from ±0.01 to ±0.05 at P_1 and ±0.001 to ±0.04 at P_2. The size of these mean deviations is paralleled by and probably arises from a heterogeneity in Li content of the Li-B ingots which was revealed by the "spaghetti" analyses. Due to this heterogeneity, spaghetti composition, in spite of being from material interfacial with the discharged sample, may differ slightly from it in Li content.

interpreting Li content at P_2 in terms of compounds; concentration polarization was certainly involved to some extent in this voltage step. However, voltage recovery subsequent to recovery of the P_2 value was much slower. For five samples, we followed the open-circuit voltage for an hour after discharge. In only one case did it reach the P_1 value, in the others it leveled out significantly above this value. Thus we are on much firmer ground in discussing Li content at P_1 than at P_2 in terms of compound formation.

For the two main breaks, we calculated the atom fraction of Li remaining in the sample by subtracting from the initial Li content the amount of Li taken out anodically. The calculated values at P_1 and P_2 are collected in Table II. Here, Li fraction at P_1 shows a definite clustering around the figure 0.67. This strongly suggests that a compound Li_2B is arrived at at this point on the discharge curves. Proof of such a compound's existence must of course await more direct structural studies such as x-ray spectroscopy on the material. There is no definite trend in Li fraction at P_1 as a function of current density or of composition of the starting material. There is a possibly significant rise in tabulated Li fractions at 873°K *vs.* those at 773°K. This may be associated with the tendency, already discussed, for the alloy to lose Li more readily in the hotter melt. Our calculations assumed the samples were losing Li only by anodic discharge so the real compositions would be smaller than the tabulated values if additional Li were escaping. At the second main break in curvature, P_2, calculated values of Li fraction show some tendency to group around 0.50 especially for samples discharged at 773°K. However, the divergences are much greater than those from the value 0.67 at P_1. The most we can say about P_2 is that, at this point in the discharge, there is the possibility of an LiB compound being arrived at. As with the P_1 data, calculated Li contents are generally higher for samples discharged at 873°K due probably to a greater loss of Li from electrodes in the hotter melt.

Open-circuit voltage (OCV) of various Li electrodes.—Figure 5 compares our data with other literature values. Our data includes the OCV of 76 Li-B alloy samples (673°-873°K), of 16 Li wick electrodes (773°-873°K) and of one electrode at 873°K where Li was cathodically deposited onto a steel rod dipped in the melt. Within ± 5 mV all of our data falls on the indicated line. The broken line in Fig. 5 shows Li voltages calculated from standard free energies of formation of LiCl(l) found in the JANAF compilation (5). These voltages were modified to the eutectic situation by equating salt activity to cation fraction. Also shown are the data of Anthony *et al.* (13) and Parassakis and Treadwell (14). These latter data seem definitely anomalous. This may be due to the presence in their cell of a porcelain membrane separating the electrodes. A bias potential across this membrane may have contributed to their OCV's.

It remains therefore to discuss the relatively small deviations among our data, Anthony's data, and the calculated (JANAF) Li OCV's. Our OCV's lie about 30 mV negative of the JANAF-derived Li line with Anthony's data in between. Differences of this order are not uncommon in measurements on reactive materials at high temperatures; they may arise through variation in experimental procedures and materials used by different groups of workers. Furthermore, the calculated values may be in error due to the assumption that the LiCl activity in the eutectic is equal to the Li^+ cation fraction.

Lithium utilization and nature of discharge process.—Table III collects together Li utilization data for the alloy and wick anodes and includes the lower temperature discharges. It shows the per cent Li utilization (coulombic discharge efficiency) for the anodes at two points on the discharge curves; firstly at P_1, the end of the main, low voltage plateau and secondly, in parenthesis, at an arbitrary value of 2V (*iR*-free) *vs.* the chlorine reference electrode.

Comparing Li utilization to P_1 for the two Li-B alloys, it is clear (except at 723°K) that a higher proportion of the 80% alloy's Li is utilizable at low voltage. In other words, as seen graphically in Fig. 3, the 80% alloy's extra Li (*vs.* the 70% alloy) goes towards extending the low voltage plateau. Current density has a relatively small effect on the utilization of Li in Li-B alloys. As noted before in discussing Fig. 3, there is a tendency for utilization to fall as current density rises. This effect is especially marked at the 2V point which usually occurs on the steeply rising part subsequent to P_2. However, even here the effect is much smaller than the inverse first power dependence associated with pure diffusion control. So above about 750°K, there is essentially no diffusional limitation to the anodic extraction of Li from these Li-B alloys (below 8 A/cm²).

Together with data discussed in the two previous sections this is consistent with the following view of alloy discharge curves. The discharging material behaves like a sponge of solid Li_2B compound containing a Li-rich, Li-B liquid alloy, probably a conjugate phase to the Li_2B compound. Lithium anodizes into the melt out of this liquid alloy at constant voltage until it is wholly transformed to solid Li_2B. This process con-

[a] Calculated from the ratio of coulombs obtained at the appropriate point to the theoretical coulomb equivalent of the mass of Li in each anode. Each datum is the average of results of from 2-5 similarly discharged electrodes. Mean deviations ranged up to ±0.06 at P_1 and up to ±0.10 at 2V.

stitutes the main plateau of alloy discharge curves. At this point (P_1, the main break in discharge curves) voltage rises to values where tighter bound Li can be anodized out of the decomposing compound. This view (of a Li-rich liquid alloy of constant composition wicking to the melt interface) explains the flatness of the main discharge plateau and the essential independence of Li utilization on discharge rate. It is consistent also with the appearance of the discharged alloy: a porous, hard, black and coke-like mass. We have recently obtained direct evidence for the essential plausibility of this picture. Alloy samples, 70 w/o in Li (78.4 a/o), surrounded with close-fitting mantles of Ni Feltmetal were heated to 973°K. At this temperature, substantial amounts of Li-rich, Li-B liquid alloy wicked from the solid Li-B alloy into the porous Ni. Work is continuing to establish the composition of solid and liquid phases in this alloy system. The slightly lowered activity of Li in the Li-B liquid alloy would account for the observed slower escape of Li from alloys compared with that from the Li-Ni wicks. At point P_2 it is possible that a second compound, Li-B, is arrived at. This over-all picture at present is a tentative one; it needs to be verified and supplemented by studies which probe structure more directly.

Table III shows that Li-B alloy anode performance falls off very sharply below about 723°K. At 673°K the alloys never gave more than about 10% of their capacity before voltage rose sharply to the final plateau value. A possible cause of this low temperature anode failure is a mass transport limitation either of Li^+ ions through melt away from the interface or of Li atoms through alloy toward the interface. However, the total lack of any rate dependence of Li utilization at 673°K argues against this view. Perhaps the Li-B liquid alloy, which was considered above to be the main source of dischargeable Li, solidifies between 723° and 673°K. More work is needed to clarify this point.

Li-B alloy anodes show great promise for use in high energy and power density, molten salt batteries. Table III shows that they consistently deliver between 50 and 70% of their theoretical coulombic capacity even up to 8 A/cm². This is in striking contrast to the presently used Ca and Mg anodes which cannot be used above about 0.1 A/cm² due to solidification of resistive salt films on their surface. Providing melt temperature is above about 748°K, the Li-B alloy anodes seem virtually immune to this problem. Table III shows the 80% alloy to be clearly superior to the 70% alloy to point P_1 of the discharge curves. However, to the 2V point, this superiority is much less marked; it is in fact roughly halved. Table III demonstrates that the Li wicks definitely outperform the Li-B alloys with respect to Li dischargeability. At 773°K the wicks utilize virtually 100% of their Li. At 873°K though still outdoing the alloys, performance of the wicks has fallen somewhat due to the accelerated escape of Li from wick anodes in the hotter melt. Nevertheless the

Table IV. Useful coulombic capacities and plateau voltages of Li anodes

		Lithium-boron alloys w/o of Li 70	80	Lithium wicks (in Ni-Feltmetal)
Coulombs/cm³ [a]		3900	5400	5500

[a] Coulombic capacity up to point P_1 of discharge curves [i.e., end of low-voltage plateau (see Fig. 3)]. Coulombs per cm³ or g of (Li + B) for alloys and of (Li + Ni) for wicks. Wick capacities at 600°C are about 10% smaller than tabulated values.
[b] Average voltage (*iR*-free) up to point P_1 of discharge curves *vs.* chlorine reference electrode.

wicks, although excellent at discharging their Li, cannot contain as much, nor grip it as tenaciously as the boron alloys do. Both the 70 and 80 w/o Li-B alloys contain about 0.56g of Li per cubic centimeter of alloy whereas only an average of 0.41g of Li was absorbed in 1 cm³ of our 82% porosity Ni Feltmetal wicks. On a weight basis a much bigger penalty is paid for using the wicks; they contain only about 0.19g of Li per gram of wick compared with 0.7 and 0.8g Li per gram of the two alloys. Furthermore, as shown earlier, Li escape from electrodes into the melt is about 2-3 times faster with wicks *vs.* alloys. Table IV compares briefly some of the battery aspects of alloy and wick performance.

The Kinetics of the Self-Discharge Reaction in a Sealed Lead-Acid Cell

Kathryn R. Bullock* and Donald H. McClelland*

The Gates Rubber Company, Denver, Colorado 80217

ABSTRACT

The kinetics and mechanism of the self-discharge reaction in a sealed, lead-acid cell have been investigated. The unique cell design and the purity of the materials used produce a slower rate of self-discharge and a different mechanism than the traditional lead-acid battery. Particular attention is given to the effects of expander composition and phosphoric acid concentration on the reaction. Rates of the reaction are determined for temperatures in the range of 35°-65°C.

A number of studies have been reported on the kinetics and mechanism of the self-discharge reaction in a vented, lead-acid cell (1-4). Particular emphasis has been placed on the effects of grid alloys (5-8), the electrolyte concentration (9), the presence of impurities (10), the formation temperature (11), and the storage temperature (12).

Although the self-discharge reaction in the lead-acid battery has been extensively studied, the unique construction of the Gates cell makes a reevaluation of this phenomenon necessary. There are three important differences between the Gates cell and the traditional lead-acid battery with respect to the self-discharge reaction. First, the grids in the Gates cell do not contain antimony. Therefore, the self-discharge mechanism which has been well established in the literature (1-8), whereby antimony is oxidized at the positive plate and reduced at the negative plate to form a local cell, cannot occur in the Gates cell. Secondly, the Gates cell is "dry," since all the electrolyte is absorbed either in the plates or in the porous glass separator. The capacity of the cell is thermodynamically limited by the volume and concentration of electrolyte in the cell. Thirdly, the Gates cell is sealed. Therefore, the possibility that gases given off during self-discharge are recombined within the cell must be considered.

The purpose of this study is twofold: (*i*) to examine the kinetics of the self-discharge reaction in a sealed cell at various temperatures, and (*ii*) to determine the effects of the expander composition and phosphoric acid concentration on the self-discharge reaction.

Experimental

A cross section of a standard Gates "X" cell is shown in Fig. 1. The wound plates and separator are sealed in a polypropylene liner which is encased in a metal can crimped around the edge of the plastic top. The cell is filled with electrolyte through the tube in the center, and this tube is then sealed with a Bunsen valve which will vent at approximately 50 psi.

The lead and lead oxides used in the grid, posts, and paste are at least 99.99% pure. The electrolyte is prepared from reagent grade acid and deionized water.

Voltage measurements were made as a function of time on standard Gates "X" and "D" cells and on experimental "D" cells at temperatures up to 65°C using a high impedance digital voltmeter. The data were analyzed using BASIC programs written for an IBM 370 computer.

Three sets of experimental "D" cells were constructed. In the first set, the quantities of phosphoric acid in the electrolyte and of lignin and barium sulfate in the negative plate expander were varied. These cells did not contain any carbon black in the expander. In the second set of cells, the amounts of carbon black and barium sulfate in the expander were varied, while the amount of lignin remained constant. In the third set of cells, the amount of phosphoric acid in the electrolyte was varied.

Measurements of the weights of the positive grid in the standard cells were made at several points in the self-discharge reaction. The positive active material was removed from the grids by slowly adding hydrazine to a hot solution of 5M ammonium acetate. After the positive active material was removed, the grids were washed in distilled water, blotted dry with a paper tissue, dried at 60°C for 15 min, and weighed.

Results and Discussion

The open-circuit voltage of a lead-acid cell is related to the activity of the electrolyte by the Nernst equation for the cell reaction

$$Pb + PbO_2 + 2H_2SO_4 = 2PbSO_4 + 2H_2O$$

$$E = E_o + \frac{RT}{\mathbf{F}} \ln \frac{a_a}{a_w}$$

where a_a is the activity of the sulfuric acid and a_w is the activity of the water.

* Electrochemical Society Active Member.

Key words: shelf-life, phosphoric acid, expander, first-order reaction, grid corrosion.

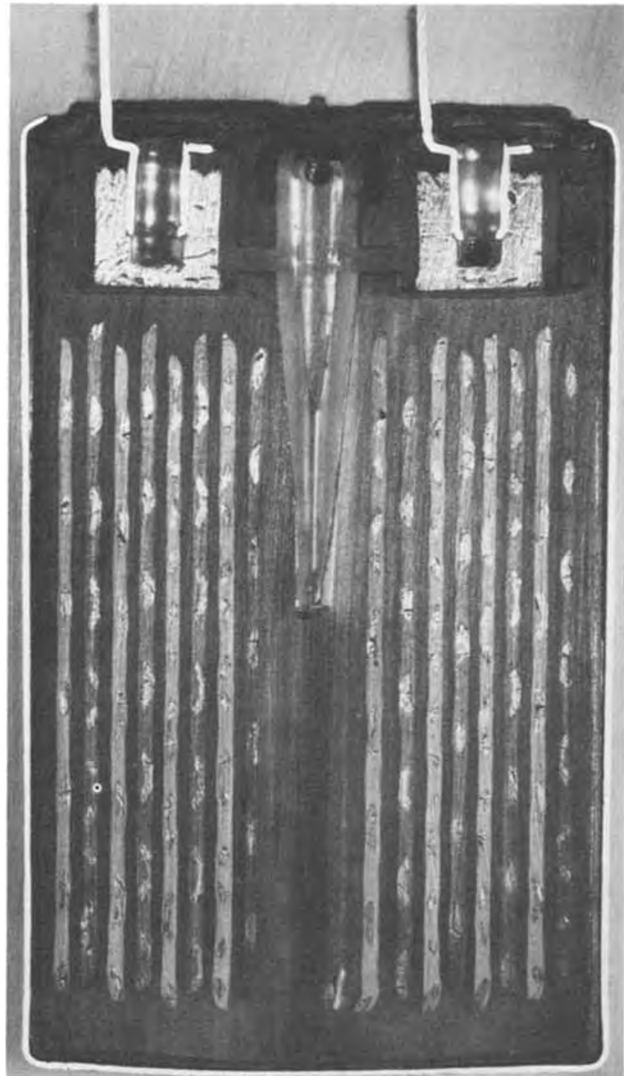

Fig. 1. Cross section of Gates "X" cell

If complete dissociation of the bisulfate ion is assumed, then $a_a = 4\ \gamma\pm^3\ m^3$ where $\gamma\pm$ is the mean ionic activity coefficient of sulfuric acid and m is the molality of the electrolyte. The values of a_a and a_w used in these calculations were calculated from the data of Harned and Hamer (13-15) at the temperatures specified.

In most of the self-discharge reactions which have been proposed (4) for the lead-acid battery, sulfuric acid reacts with a solid material such as lead or lead dioxide. Thus, it is reasonable to assume that the self-discharge reaction is pseudo-first-order with respect to sulfuric acid. The kinetic equation for such a reaction may be written as

$$\ln a_a - \ln (a_a)_o = -kt$$

where t is the time, k is the rate constant, a_a is the acid activity at time t, and $(a_a)_o$ is the initial acid activity.

Activities are used in this calculation instead of concentrations because of the high initial acid concentration and the wide concentration range covered during the shelf-life of the cell.

According to this equation, a plot of ln a_a *vs.* time should be linear with a slope of $-k$. Some typical examples of such plots are shown in Fig. 2 for Gates "X" cells stored at three different temperatures. Below an ln a_a value of about -3, which corresponds to an open-circuit voltage of about 2, the plots are linear. The self-discharge reaction, therefore, is first-

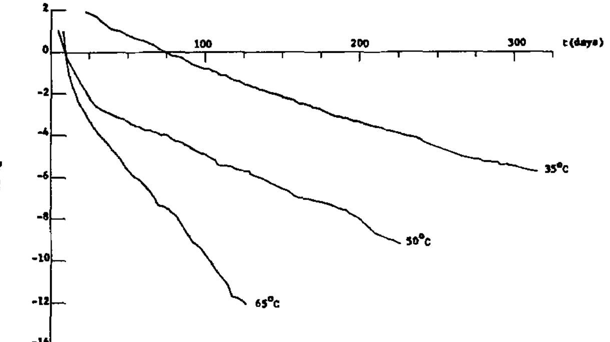

Fig. 2. Ln activity of sulfuric acid as a function of time at several temperatures.

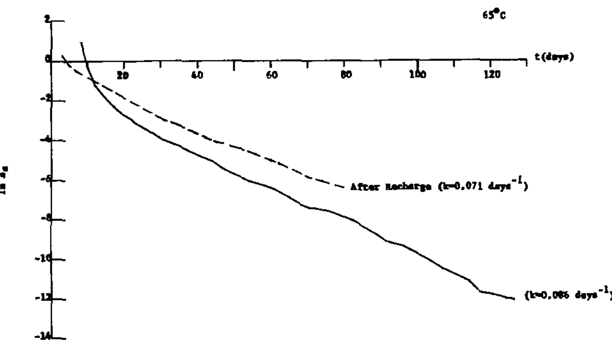

Fig. 3. Ln activity of sulfuric acid as a function of time before and after recharge.

order with respect to sulfuric acid below about 2V. The mechanism remains the same throughout the remaining shelf-life of the cell even though the concentration of the sulfuric acid changes by three orders of magnitude.

The slopes of the lines were evaluated by the method of least squares. Correlations were excellent, with beta coefficients varying between 0.996 and 0.999. The average rate constant and standard deviation for five cells at each temperature are shown in Table I.

In Fig. 3, the 65°C curve shown in Fig. 2 is plotted on an expanded scale so that the change in slope at a ln a_a value of about -3 is more apparent. The last point on the curve corresponds to an electrolyte molality of 0.04. After this deep self-discharge. the cell was recharged with a constant current of 100 mA for one week at room temperature and was again stored at 65°C. The dashed curve in the figure shows the self-discharge of the cell after this recharge. The initial part of the curve has now straightened out almost entirely and the slope of the line has decreased slightly. The rate constant is now 0.071 days^{-1} with a standard deviation of 0.001. A similar phenomenon was observed by Zachlin for cells with pure lead grids (7).

The fact that the cell is rechargeable after such an extreme self-discharge is in itself surprising. Figure 4 shows the capacity retention of a standard "X" cell which was allowed to self-discharge at 50°C to a voltage of 1.654 and was then recharged at 2.5V for 16 hr and cycled. A voltage of 1.654 at 50°C corresponds to an electrolyte molality of 0.014 and an ln a_a value of -13.8. The cell recovered capacity rela-

tively quickly and eventually delivered the full nominal capacity at the C/5 rate.

The results of the first set of tests on experimental cells are summarized in Fig. 5. A series of 57 "D" cells was constructed with concentrations of $BaSO_4$ and lignin ranging from 0.2 to 0.4% and from 0.4 to 0.8% of the dry, negative oxide weight, respectively, and with 0.1 or 0.8 weight per cent (w/o) phosphoric acid in the electrolyte. The cells were allowed to self-discharge at temperatures of 25°, 45°, 55°, and 65°C. Three standard "D" cells were discharged simultaneously at each of the four temperatures as controls. None of the experimental cells had any carbon black in the expander.

The upper curve in Fig. 5 represents the results from two cells. Both contained 0.1% phosphoric acid and 0.3% $BaSO_4$, but one contained only 0.4% lignin while the other contained 0.8% lignin. Since the self-discharge curves of the two cells are indistinguishable, doubling the amount of lignin in the expander has no observable effect. The two lower curves represent the results from cells containing 0.8% phosphoric acid. One cell contains 0.2% $BaSO_4$ and 0.4% lignin, while in the other cell these concentrations have been doubled. These self-discharge curves are also the same within experimental error. Thus, the concentrations of $BaSO_4$ and lignin have no apparent effect on the self-discharge reaction.

The difference between the two sets of self-discharge curves comes from the change in phosphoric acid concentration from 0.1 to 0.8%. Of particular interest is the change in the limiting slope of the curves, indicating that the phosphoric acid inhibits the self-discharge reaction. These trends were observed throughout the temperature and concentration ranges of the experiment.

Since none of these cells contained any carbon black in the expander, a second set of "D" cells was constructed which contained either 0 or 0.2% carbon black in the expander. One group of cells contained 0.4% $BaSO_4$ and 0.4% lignin, while the other group contained 0.2% $BaSO_4$ and 0.4% lignin. Standard Gates "D" cells were again used as controls. The cells were stored at 65°C. Varying the carbon black concentration in the expander had no effect on the self-discharge reaction within the limits of experimental error.

Further experiments were conducted at 50°, 60°, and 65°C on standard "D" cells which were filled with electrolyte containing 0, 0.1, and 0.8% phosphoric acid. Some results at 65°C are shown in Fig. 6. It is again apparent, from the limiting slopes of these curves, that the rate of the self-discharge reaction decreases as the phosphoric acid concentration is increased. Thus, phosphoric acid apparently inhibits the self-discharge reaction. The tests at the other two temperatures showed the same trend.

Table II summarizes the effect of phosphoric acid concentrations on the rate of the self-discharge reaction. The rate constants given at 50°, 60°, and 65°C are averages of the results from three "D" cells tested under each set of conditions. The data at 55°C are taken from the first set of experiments. The rate constants for cells containing 0.1 and 0.8% phosphoric

acid are averages for nine and six cells, respectively, with varying expander compositions.

The Arrhenius equation may be applied to these results in order to obtain the activation energy of the self-discharge reaction

$$\ln k = \ln A - \frac{E_a}{RT}$$

where A is the Arrhenius constant, E_a is the activation energy, and T is the absolute temperature.

An Arrhenius plot for standard "X" cells is shown in Fig. 7. The points are taken from the data given in Table I. The range of values obtained for the five cells tested at each temperature is also shown. The line shown was defined by the least-squares method. The data in Table II are plotted in the same manner in Fig. 8. The activation energy did not change significantly with the concentration of phosphoric acid in the electrolyte. Thus, it is apparent that phosphoric

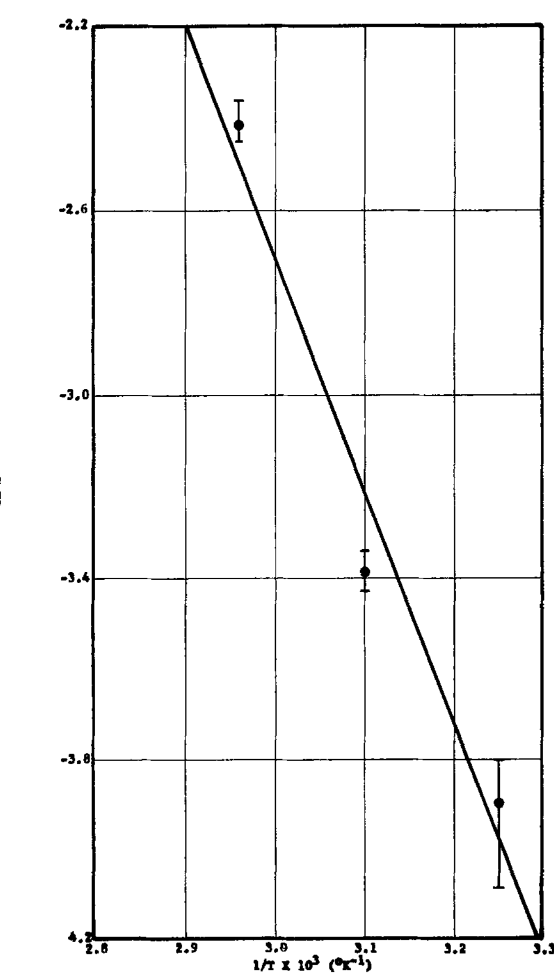

Fig. 7. Arrhenius plot for standard "X" cells

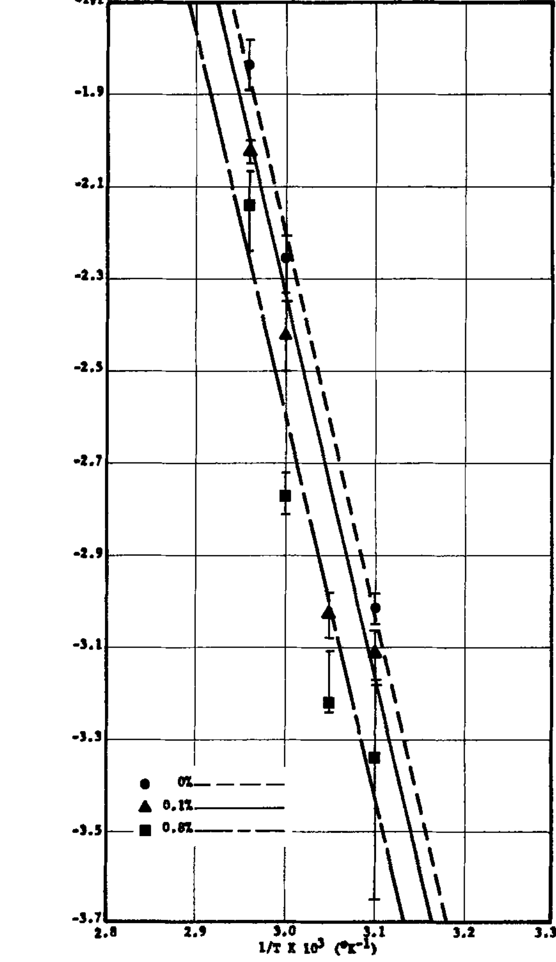

Fig. 8. Arrhenius plot for "D" cells with varying phosphoric acid concentrations.

acid decreases the rate of the self-discharge reaction but does not affect the reaction mechanism.

The activation energy obtained for all the cells tested is between 10 and 17 kcal/mole. More experiments are being done at lower temperatures in order to obtain more points and define this value more precisely. However, it will take a number of years for the cells to fully self-discharge at the lower temperatures.

There are three possible mechanisms for the self-discharge reaction in the Gates cell. These are:

Positive grid corrosion

$$Pb + PbO_2 + 2H_2SO_4 = 2PbSO_4 + 2H_2SO_4 \quad [1]$$

The oxygen cycle

$$PbO_2 + 2H^+ + SO_4 = PbSO_4 + H_2O + 1/2\ O_2 \quad [2a]$$

$$Pb + 1/2\ O_2 + H_2SO_4 = PbSO_4 + H_2O \quad [2b]$$

The hydrogen cycle

$$Pb + H_2SO_4 = PbSO_4 + H_2 \quad [3a]$$

$$PbO_2 + H_2 + H_2SO_4 = PbSO_4 + 2H_2O \quad [3b]$$

The over-all reaction for each of these three mechanisms is the double sulfate reaction. The oxidation of lignin at the positive electrode does not appear to be a significant part of the self-discharge reaction, since doubling the lignin concentration does not change the rate of the reaction (see Fig. 5).

Mahato, Weissman, and Laird (16) have recently shown that hydrogen and oxygen recombination (reactions [2b] and [3b]) proceed many times faster than the self-discharge reaction in a sealed cell. Therefore, the rate-limiting step in either the oxygen cycle or

the hydrogen cycle should be the gas-generating reaction (reactions [2a] and [3a]).

Values of activation energies which have been found in the literature range from about 8 to 18 kcal/mole for reaction [2a] (17-19), and from about 2 to 10.2 for reaction [3a] (17, 18, 20). Milner (18) has calculated an activation energy of 13.5 kcal/mole for reaction [1]. Thus, our value of 10-17 kcal/mole is in the right range for either reaction [1] or [2a].

In order to determine the influence of positive grid corrosion, positive grid weights were obtained on a series of 32 "D" cells from the same production lot. Twelve of these cells were stored at 65°C and allowed to self-discharge to an average voltage of 1.700 ($1\sigma = 0.088$) at room temperature. Eight of the cells were stored at 65°C to an average voltage of 1.989 ($1\sigma = 0.004$) at room temperature. The remaining 12 cells were stored at a cold temperature to minimize their self-discharge and had an average voltage of 2.144 ($1\sigma = 0.003$). The weights of the positive grids in the cells discharged to 1.989 and to 1.700V were approximately the same and were about 2.45g lighter than the positive grids from the cells with high open-circuit voltages. Similar results were obtained on a set of standard Gates "X" cells. Apparently, the grid corrosion that does take place occurs early in the shelf-life before the cell has discharged to about 2V. About 1/3 of the sulfuric acid which reacts before this voltage is reached would be required to corrode 2.45g of grid. This can, at least in part, account for the initial high rate of self-discharge (see Fig. 1). However, the corrosion reaction does not occur to a significant extent below 2V and should not affect either the rates of the reactions shown in Tables I and II or the activation energy determined from the Arrhenius equation. Therefore, oxygen evolution (reaction [2a]) seems to be the most likely choice for the rate-determining step of the self-discharge reaction below 2V.

It should also be noted that a newly formed cell may contain "apparent PbO" and/or α-PbO_2 in the positive plate (11, 21). These compounds are known to self-discharge at a higher rate than β-PbO_2 (22) and may also be part of the reason for the higher rate of self-discharge initially (23).

Summary

The results of this study may be summarized as follows:

1. The self-discharge reaction is first-order with respect to sulfuric acid in a sealed, lead-acid cell.
2. The rate of the reaction increases with temperature, as predicted by the Arrhenius equation. The activation energy of the self-discharge reaction is between 10 and 17 kcal/mole.
3. Positive grid corrosion is a significant part of the self-discharge reaction early in the shelf-life of the cell. Below about 2V, grid corrosion is not significant.
4. The cell can be recharged even after it has been completely self-discharged.
5. The composition of the negative expander does not affect the self-discharge reaction.
6. Phosphoric acid is an inhibitor of the self-discharge reaction.

Effect of Temperature on Electrode Kinetic Parameters for Hydrogen and Oxygen Evolution Reactions on Nickel Electrodes in Alkaline Solutions

M. H. Miles,*[,1] G. Kissel, P. W. T. Lu,*[,2] and S. Srinivasan*

Department of Applied Science, Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

The electrode kinetic parameters for hydrogen and oxygen evolution were determined at temperatures of 80°, 150°, 208°, and 264°C on nickel electrodes in 50 weight per cent KOH solutions. Improvements in the exchange current density with increasing temperature were more significant for the oxygen evolution reaction than for the hydrogen evolution reaction. A favorable change in the Tafel slope for the oxygen evolution reaction occurs between 150° and 264°C which corresponds to an increase in the transfer coefficient from 0.67 to 3.3. This result supports the concept that a change in the reaction mechanism occurs for the oxygen electrode reaction near the Neel temperature of nickel oxide. At the higher experimental temperatures, the Tafel slope for the hydrogen evolution reaction changes from $2RT/3\mathbf{F}$ at low overpotentials to about $2RT/\mathbf{F}$ at high overpotentials suggesting a slow electrochemical desorption mechanism. The present study indicates that significant reductions in cell voltage for water electrolysis can be obtained by higher operating temperatures. At temperatures of about 150°C, it should be possible to approach a 100% energy efficiency (based on ΔH) at current densities commonly used in commercial water electrolyzers.

Hydrogen has attracted considerable attention as a possible fuel for the future (1-3). It is hoped that with abundant nuclear power, water could be decomposed to provide hydrogen as a portable fuel (1, 4, 5). There is also interest in producing hydrogen by water electrolysis, storing it as a metal hydride, and converting it to electricity in a fuel cell for load leveling and peak shaving operations in electric utilities (2, 6). Most commercial water electrolyzers use nickel electrodes and are operated at 70°-90°C in 25-35 weight per cent (w/o) potassium hydroxide solutions (7, 8). Voltage efficiencies range from 65 to 75% at current densities of about 200 mA/cm^2. Increasing the operating temperature would obviously increase the efficiency of water electrolysis; however, quantitative information is unavailable since electrochemical studies of hydrogen and oxygen evolution reactions in alkali solutions at elevated temperatures are sparse (9). The objectives of the present study are to obtain fundamental kinetic parameters and to ascertain the efficiency gain at higher operating temperatures for water electrolysis. Tafel slopes, transfer coefficients, and exchange current densities are determined for both the hydrogen and oxygen evolution reactions on nickel electrodes in 50 w/o potassium hydroxide solutions at temperatures of 80°, 150°, 208°, and 264°C.

Experimental

Major problems in designing electrochemical cells for use with aqueous systems at high temperatures include provisions for insulated electrode assemblies which are pressure tight, minimizing corrosion of metal parts, and finding a reference electrode which can operate at high temperatures. The reference electrode selected for this study was the dynamic hydrogen electrode (DHE) as described by Giner (10).

The main features of the stainless steel pressure vessel used for these studies is shown in Fig. 1. A segment of 4 in. (ID) pipe was welded to a bottom plate 9 in. in diameter and 1¼ in. thick and to a top flange containing eight bolt holes. The cover was fabricated from 1¼ in. stainless steel with eight matching bolt holes and five experimental entry ports. Four entrance ports were tapped for ¼ in. pipe thread fittings. Three insulated electrical feed-throughs were made from ⅛ in. diameter nickel rods threaded at each end and stainless steel Swagelock fittings with Teflon and plastic plug insulators. The voids were filled with RTV 630 silicone rubber which was the actual pressure seal. The fourth entrance port was fitted with a stainless steel Swagelock tee so that purge gas (argon or hydrogen) could be admitted and removed, and with a pressure gauge to monitor the vapor pressure of the solution as a function of temperature. The fifth entrance port, tapped for ⅛ in. pipe thread fitting, was used for a 1/16 in. Chromel-Alumel thermocouple clad with stainless steel. This thermo-

Key words: cell voltage, exchange current density, Tafel slope, transfer coefficient, water electrolysis.

couple was fed through a Swagelock fitting and then clad also with shrink Teflon and platinum so that it could serve a dual role as a counterelectrode for the dynamic hydrogen reference. The pressure gauge and thermocouple are not shown in Fig. 1. Prior calibration of the thermocouple showed that the measured temperatures were accurate to within 2°C.

In setting up a run, the three electrodes (anode, cathode, and reference) were connected to the three insulated electrical feed-throughs and positioned to fit into a Teflon cell which contained 300 ml of electrolyte. The alkaline solution was prepared from Baker analyzed KOH, low in chloride, and doubly distilled water. The three-compartment Teflon cell is shown schematically in Fig. 2. Each compartment was provided with holes at the top for venting the evolved gases to the pressure vessel. The Teflon cell cover minimized contamination problems due to any refluxing action within the pressure vessel. About 10 ml of water were placed outside the cell to compensate for the loss of water to the vapor phase at high temperatures and to reduce changes in the activity of water with increase of temperature. When the three electrodes and thermocouple were properly positioned in the Teflon cell, the pressure vessel cover was fastened to the flange by ⅝ in. steel bolts fitted with two washers. The gas seal was made using a ¼ in. thick "O" ring positioned into a groove on an aluminum back-up plate. The walls of the vessel were heated with stainless steel encased Nichrome wire covered with asbestos, which in turn was insulated with a blanket of quartz wool about 1 in. thick. Magnetic stirring was used to agitate the KOH electrolyte during a run to reduce any temperature gradients within the cell, and the insulated magnetic stirring hot plate was used also to heat the bottom of the vessel. With 50 w/o KOH electrolyte, the pressure gauge reading increased from 0 psig at room temperature to about 210 psig at 264°C. Preliminary experiments using 30 w/o KOH were disbanded since vapor

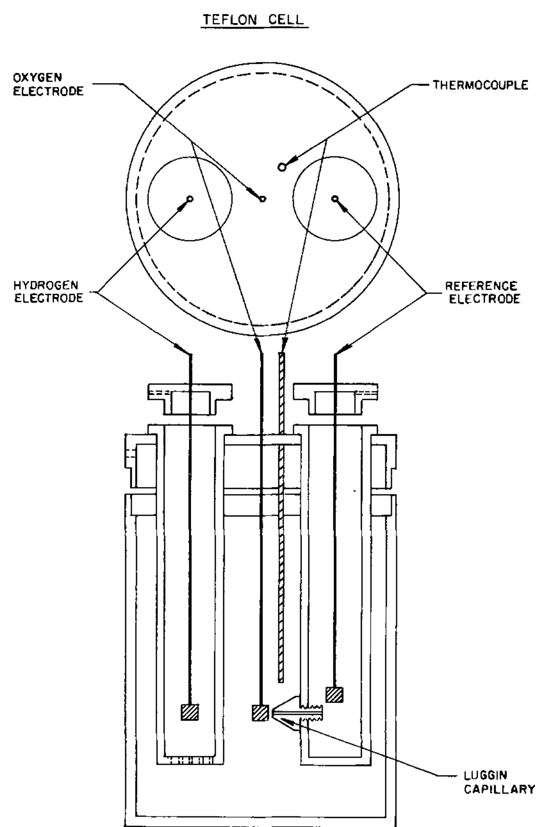

Fig. 2. Schematic diagram of the three compartment Teflon cell used in the pressure vessel.

pressure readings exceeded the safety limit of the vessel (about 300 psig).

Simultaneous studies of the hydrogen and oxygen evolution reactions were made by separately recording the current-potential relationships at the nickel electrodes. Each nickel electrode was mechanically polished using a series of emery papers followed by wet aluminum oxide powder polishing on a rotating felt wheel. The geometrical area of each electrode was 0.20 cm^2. The electrochemical measurements were made using a PAR Model 173 potentiostat coupled with a PAR Model 175 programmer. Current-potential relationships were determined by steady-state, potentiostatic measurements in the direction of high currents to low currents. Before each experiment, currents of about 1 A/cm^2 were passed for at least several minutes to form an oxide layer on the nickel anode. Slow potential sweep rate (1 mV/sec) studies were used to check the results and usually gave good agreement with the potentiostatic measurements.

The potential of the DHE reference electrode *vs.* the reversible hydrogen electrode (RHE) was measured directly in the pressure vessel at the four experimental temperatures. After placing a second platinized platinum electrode about ½ cm above the DHE reference and bubbling pure hydrogen through the KOH solution overnight at room temperature, the cell was brought to the desired temperature. The hydrogen generated by the DHE reference could then be used to establish the reversible hydrogen potential on the second electrode.

The *IR* drop between the DHE reference electrode and the nickel electrode was determined by the interrupter technique (11). Due to the positioning of the Luggin capillary close to the oxygen electrode (Fig. 2), the *IR* drop at this electrode was about a factor of three times smaller than the *IR* drop measured at the hydrogen electrode.

Results and Discussion

Three separate studies of the hydrogen and oxygen evolution reactions were made on the nickel electrodes in 50 w/o KOH solutions in the Teflon cell and pressure vessel described above. These results were generally in good agreement with earlier preliminary measurements using a Teflon beaker in place of the three-compartment cell.

Figure 3 shows the averaged results for the three separate studies of the hydrogen and oxygen evolution reactions at temperatures of 80°, 150°, 208°, and 264°C. The experimental potentials have been corrected for the *IR* drop.

From Fig. 3 it is readily apparent that the increase in temperature has a more striking effect on the oxygen evolution reaction than on the hydrogen evolution reaction. Each temperature increase produces an obvious shift in the experimental lines to lower potentials for the oxygen evolution reaction. This is due to the slow kinetics of the oxygen electrode reaction (9, 12, 13). For the hydrogen evolution reaction, only small shifts in potential are observed at temperatures above 150°C. Nevertheless, substantial overpotentials are found for the hydrogen evolution reaction on nickel electrodes in alkaline solutions at lower temperatures (8).

Distinct, linear Tafel regions were observed at each temperature for both the hydrogen and oxygen evolution reactions. Dual Tafel regions were found for the oxygen evolution reaction at 208°C and also for the hydrogen evolution reaction at each of the three higher temperatures.

The exchange current densities for the hydrogen and oxygen evolution reactions can be determined at each temperature from Fig. 3 if the reversible electrode potentials *vs.* the DHE reference are known. For the hydrogen electrode reaction, the reversible potential, E_{RHE}, is given by

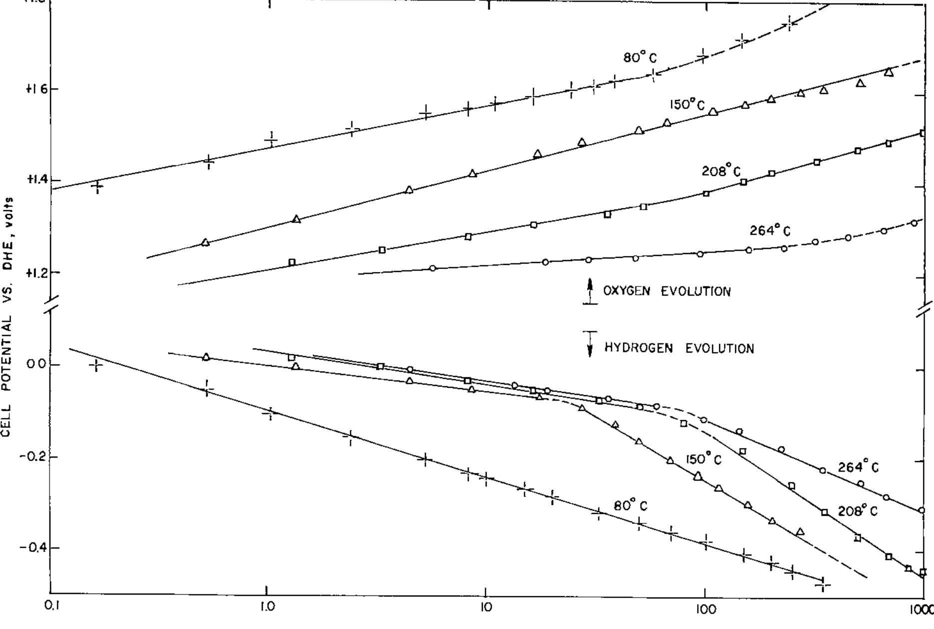

Fig. 3. Potential vs. current density relationships for hydrogen and oxygen evolution on polished nickel electrodes in 50 w/o KOH solutions at temperatures of 80°, 150°, 208°, and 264°C. Both nickel electrodes had a geometrical area of 0.20 cm^2.

$$E_{RHE} = |\eta_{DHE}| \quad [1]$$

where η_{DHE} represents the overpotential of the DHE reference electrode at 1 mA/cm^2 as measured *vs.* the RHE electrode. Experimetally determined η_{DHE} values at the four temperatures are given in Table I. Similar to the observations by Giner (10), the overpotential for the DHE reference in KOH solutions decreases only slightly with increasing temperature.

Considering the cell reaction

$$H_2O_{(l)} \rightleftarrows H_2(g) + \tfrac{1}{2}\, O_2(g) \quad [2]$$

the reversible potential for the oxygen evolution reaction, E_{ROE}, can be calculated from the expression

$$E_{ROE} = |\eta_{DHE}| + |E^o| + \frac{2.303RT}{2\mathbf{F}} \log \frac{P_{H_2} \cdot (P_{O_2})^{1/2}}{a_{H_2O}} \quad [3]$$

where P_{H_2} and P_{O_2} represent the partial pressures in atmospheres of the evolved gases at the electrode surfaces, and a_{H_2O} represents the activity of water in the KOH solution. Changes in the standard reversible cell potential, E^o, with temperature are given by

$$\left(\frac{\partial E^o}{\partial T}\right)_P = \frac{\Delta S^o}{2\mathbf{F}} \quad [4]$$

The minimum applied voltage needed to decompose water at standard conditions, decreases from 1.229V at 25°C to 1.027V at 264°C. Since hydrogen and oxygen will not be evolved until the partial pressures at the electrode surfaces equal the pressure above the solution, the experimental gauge pressure can be used to obtain the values for P_{H_2} and P_{O_2} needed in Eq. [3]. The gauge pressure can also be used to calculate the activity of water at high temperatures in 50 w/o KOH using the relationship

$$a_{H_2O} = P_{H_2O}/P^o_{H_2O} \quad [5]$$

where P_{H_2O} is the experimental vapor pressure for the solution at a given temperature and $P^o_{H_2O}$ is the vapor pressure of pure water at that same temperature. For the three higher temperatures where P_{H_2O} was more accurately measurable, the activity of water calculated using Eq. [5] was 0.3 ± 0.1. Results reported by Bro and Kang (14) indicate that the activity of water in 50 w/o KOH (13M) at 25°C is about 0.3 and that this activity changes little with temperature. Table I presents the calculated results for the various terms in Eq. [3] along with the end result for E_{ROE} *vs.* the DHE reference electrode.

The Tafel slopes, transfer coefficients, and exchange current densities at the four experimental temperatures are presented in Table II for the hydrogen evolution reaction and in Table III for the oxygen evolution reaction.

T(°C)	low η	high η	low η	high η	low η	high η
80	0.095		0.74		4.2×10^{-6}	
150	0.125		0.67		1.8×10^{-4}	
208	0.085	0.135	1.1	0.71	6.0×10^{-4}	3.5×10^{-3}
264	0.032		3.3		1.0×10^{-3}	

* Transfer coefficient = 2.303$RT/b\mathbf{F}$ where b is the Tafel slope.

tion reaction. Where two Tafel regions exist, results for both the low overvoltage and high overvoltage regions are listed.

For the hydrogen evolution reaction at 80°C, the transfer coefficient of $\alpha = 0.5$ indicates a rate-determining step involving an electron transfer such as the discharge step

$$H_2O + e^- \rightleftarrows H_{ads} + OH^- \quad [6]$$

or the electrochemical desorption step

$$H_2O + H_{ads} + e^- \rightleftarrows H_2 + OH^- \quad [7]$$

Previous studies suggest a slow discharge-fast recombination mechanism on nickel in alkaline solutions at room temperature (15, 16). The unusual Tafel slope of $2RT/3\mathbf{F}$, *i.e.*, $\alpha = 1.5$, observed at low overpotentials at the higher temperatures, indicates either a fast discharge-slow electrochemical desorption mechanism under conditions of low hydrogen coverage ($\theta \approx 0$) or a slow discharge-fast electrochemical desorption mechanism under conditions of high coverage ($\theta \approx 1$) (17). Either mechanism predicts that the Tafel slope will change from $2RT/3\mathbf{F}$ to $2RT/\mathbf{F}$, *i.e.*, $\alpha = 0.5$, at high overpotentials as observed experimentally. The coverage of adsorbed hydrogen on nickel at low overpotentials in 2M NaOH is reported to be small at room temperature (16). Since LeChatelier's principle predicts a decreasing equilibrium coverage of adsorbed hydrogen atoms with increasing temperature, the condition of low coverage at low overpotentials seems even more probable at the higher temperatures; hence a slow electrochemical desorption step is suggested.

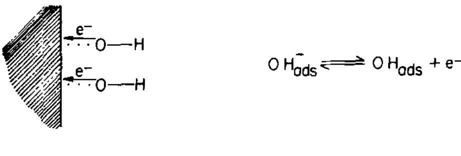
For the oxygen evolution reaction, the anodic transfer coefficient changes from 0.67 to 3.3 as the temperature increases from 150° to 264°C, suggesting a change in the reaction mechanism. Dual mechanisms which are influenced by the overpotential seem to operate at the intermediate temperature of 208°C. Although many mechanisms are possible for the oxygen evolution reaction (12, 13), the most generally accepted mechanisms on various electrodes involve steps such as

$$OH^-_{ads} \rightleftarrows OH_{ads} + e^- \quad [8]$$

$$OH^- + OH_{ads} \rightleftarrows O_{ads} + H_2O + e^- \quad [9]$$

$$O_{ads} + O_{ads} \rightleftarrows O_2 \quad [10]$$

where one of the electron-transfer steps is rate determining (12, 13, 18-20). Possible stages in the reaction mechanism are illustrated in Fig. 4. The observed transfer coefficient of about 0.7 at 80° and 150°C is



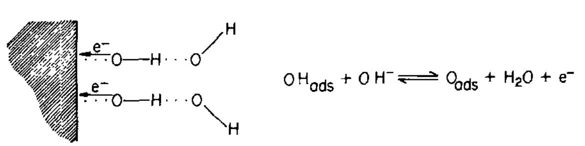


Fig. 4. Possible stages in the oxygen evolution reaction, $4\ OH^- \rightleftarrows O_2 + 2H_2O + 4e^-$, in alkaline solutions.

consistent with a slow electron-transfer step. If the recombination of adsorbed oxygen atoms becomes rate limiting at higher temperatures, an increase in the transfer coefficient to about 4 would be expected under Langmuirian adsorption conditions at low overpotentials. Considering the limitations of the theory and the experimental errors, the observed transfer coefficient of 3.3 at 264°C seems to support the slow recombination step rather than a slow electron-transfer step at high temperatures.

The change in mechanism for the oxygen evolution reaction may be related to the Neel temperature (T_N) for nickel oxide. At 250°C, nickel oxide undergoes a magnetic transition from antiferromagnetic to paramagnetic. A change in the mechanism of O_2 chemisorption occurs near T_N (21, 22), and Winter (22) has suggested that oxygen is dissociatively chemisorbed above T_N.

Stronger bonding of OH^-, OH, and O species with nickel oxide above T_N would increase the rates of the electron-transfer steps and decrease the rate of the recombination step. Studies of the electrochemical reduction of oxygen by Bevan and Tseung (23) suggest that above T_N oxygen is dissociatively adsorbed on nickel oxide and then reduced directly to hydroxide ions without forming the peroxide intermediate. Their proposed mechanism is similar to the one given above for the oxygen evolution reaction since the electron-transfer steps for both involve single oxygen atoms.

Due to the changes in reaction mechanism producing large changes in the Tafel slopes, it is difficult to compare the exchange current densities, i_o. However, the exchange current density for the oxygen evolution reaction increased by more than three orders of magnitude from 4.2×10^{-6} A/cm^2 at 80°C to 1.0×10^{-3} A/cm^2 at 264°C. For the hydrogen evolution reaction, a smaller increase is observed from 1.1×10^{-4} A/cm^2 at 80°C to 2.0×10^{-2} A/cm^2 at 264°C. Where there is no change in reaction mechanisms, a heat of activation, $\Delta H^{\ddagger}$, can be calculated from

$$\Delta H^{\ddagger} = -2.303R\ \partial \log i_o/\partial(1/T) \quad [11]$$

using the temperature dependency observed for i_o. From i_o values for the oxygen evolution reaction below the Neel temperature, $\Delta H^{\ddagger}$ is about 18 kcal/mole. From log i *vs.* reciprocal temperature plots at constant overvoltages of about 100 mV, an Arrhenius activation energy of approximately 15 kcal/mole is found. A break in the Arrhenius lines is observed when the data at 264°C are included, which again indicates a change in the reaction mechanism near this temperature. The change in log i_o with $1/T$ is not as linear for the hydrogen evolution reaction; however, $\Delta H^{\ddagger}$ can be estimated to be about 8 kcal/mole from the i_o values determined at low overpotentials and about 14 kcal/mole from i_o values extrapolated from high overpotentials.

The cell potentials for water electrolysis at any desired current density can be readily determined from Fig. 3. Table IV presents the experimental cell voltages at current densities of 20 and 200 mA/cm^2 for the four temperatures. Most commercial electrolyzers operate at current densities in the range of about 200 mA/cm^2 using electrodes with high surface roughness factors. As shown in Table IV, operating cell potentials can be significantly reduced by increasing the temperature.

Table IV. Experimental cell voltages and voltage efficiencies for water electrolysis using nickel electrodes in 50 w/o KOH

T (°C)	E_{cell} at 20 mA/cm^2(V)	% Efficiency*	E_{cell} at 200 mA/cm^2(V)	% Efficiency*
80	1.88	79%	2.17	68%
150	1.54	96%	1.92	77%
208	1.38	107%	1.66	89%
264	1.28	116%	1.43	103%

* The efficiency obtained on the basis of ΔH.

For water electrolysis to be competitive with other methods for hydrogen production, it is necessary to operate the cells at high current densities and at voltages close to the thermoneutral potential based on the enthalpy change for the cell reaction. This potential, E_H, is defined by the equation

$$E_H = -\Delta H/2\mathbf{F} \quad [12]$$

where ΔH is the enthalpy change for reaction [2] and $\mathbf{F}$ is the Faraday. This thermoneutral potential represents the operating voltage at which the electrical energy supplied is equal to the thermochemical energy required to decompose water; hence the cell can operate without producing any extraneous heating or cooling effects. Variation of the thermoneutral potential with temperature is very small, being $-1.48V$ at 25°C at standard conditions and about $-1.49V$ at 1000°C. Commercial water electrolyzers operate well above the thermoneutral potential; therefore, the excess electrical energy supplied appears as waste heat. When operating below E_H, the electrolysis cell would act as a refrigerator (24). This would be advantageous only if heat, such as waste heat from a nuclear reactor, is readily available to compensate for the cooling effect produced.

Assuming surface roughness factors in the range of 10-20 for nickel electrodes used in water electrolyzers as compared with the mechanically polished electrodes used in this study, Table IV suggests that voltage efficiencies of 100% (based on ΔH) are possible at current densities of 200-400 mA/cm² at temperatures as low as 150°C.

Conclusions

1. Effects of temperature on electrode kinetic parameters are greatest for the oxygen evolution reaction. The exchange current density for this reaction increases more than three orders of magnitude from 4.2×10^{-6} A/cm² at 80°C to about 1.0×10^{-3} A/cm² at 264°C.

2. The transfer coefficient for the oxygen evolution reaction changes from 0.7 at temperatures of 80°, 150°, and 208°C to 3.3 at 264°C. A change in reaction mechanism near the Neel temperature (250°C) for nickel oxide is suggested. Recombination of adsorbed oxygen atoms appears to be the rate-determining step at 264°C while electron-transfer steps are the likely slow steps at lower temperatures.

3. The dual Tafel slopes observed for the hydrogen evolution reaction suggest a slow electrochemical desorption step.

4. The efficiency of water electrolysis as a method for producing hydrogen can be greatly improved by increasing the temperature. At normal operating current densities, voltage efficiencies of about 100% based on ΔH are possible at temperatures as low as 150°C. The extra energy input for carrying out water electrolysis at this temperature is negligible. The biggest problem in designing and developing a large scale water electrolysis plant to operate at 150°C will be in finding a substitute for asbestos as the separator material (25).

Acknowledgments

The authors wish to thank Dr. R. H. Wiswall and Mr. F. J. Salzano for their interest and encouragement of this work. The assistance of Mr. Warren Johnson and his colleagues in the construction of the pressure vessel is also appreciated. One of us (M.H.M.) gratefully acknowledges two summer appointments as a Visiting Scientist provided by the Brookhaven National Laboratory.

Unique Transparent Film Deposited on Glass at Room Temperature

Charles B. Greenberg

PPG Industries, Incorporated, Glass Research Center, Pittsburgh, Pennsylvania 15238

ABSTRACT

Thin, transparent, essentially metallic films may be deposited on glass at room temperature by electroless reduction from solution. By partial chemical replacement of the electroless metal by another more noble metal, a new film is formed. In one very interesting case, using $S_2O_3^{-2}$ and NH_3 in solution, the film develops significant nonmetallic character and an unusually low reflectance from the glass-air interface. In addition to silver metal the film consists of Cu_2O and a sulfur-containing species, probably Cu_2S. The resulting film is atypical within the family of generally metallic films deposited chemically on glass for purposes of solar and thermal insulation in architectural construction. In the course of developing this film as a commercial product, experimental data have been generated which suggest an interesting oxidation reaction.

Metals are, in general, excellent reflectors of thermal radiation at room temperature. For silver, gold, aluminum, and copper deposited to opacity in vacuum, spectral reflectance values in excess of 0.98 have been reported from 3 μm to 20, 30, or 40 μm (1, 2). For a radiating source at 25°C, 73% of the total emissive power lies between 3-20 μm, 89% between 3-30 μm, and 94% between 3-40 μm (3). The bulk metals are of course also highly reflective in the spectral region of solar energy, about 99% of this energy being between 0.3-2.2 μm at sea level (4). When deposited in vacuum or by electroless deposition as thin, partially transmitting films on glass, they still exhibit high reflectance in both the thermal and solar regions of radiation. Properties such as these have contributed to the considerable interest in coated windows for insulation in architectural construction, where, in part for reasons of chemical and mechanical durability, the uncoated glass surface usually faces the sun, while the coating itself faces inward. A second sheet of glass encapsulates it.

An electrolessly deposited, transparent film containing copper and silver, for example, in a weight ratio of about 6:1 has been characterized spectrally (5). Data are shown schematically in Fig. 1. The reflectance of incident solar spectral energy, as viewed in Fig. 1 from the side of the glass substrate which does not become coated, is quite high relative to uncoated glass. The reflectance from the film-air interface at 9.7 μm, the peak of the spectral curve for thermal radiation incident at 25°C, is similarly high; the infrared reflectance is very much the same within at least the measured range of 2-15 μm. The reflectance for the uncoated glass surface is peaked at 9.7 μm, this wavelength corresponding to the Si-O-Si stretching band, but is elsewhere, within 2-15 μm, generally lower.

Essentially metallic films are easily deposited chemically at room temperature from aqueous solution by established methods for electroless deposition. There are, of course, some chemical and mechanical manipulations to achieving uniformity on a large area. Not heretofore reported, to this writer's knowledge, are thin, transparent films on glass prepared by partial chemical replacement of one metal already present in the film by another from solution. Similar galvanic reactions are known for replacement in bulk metals (6, 7). In one particular instance on glass an unusually rapid oxidation reaction occurs in air also, yielding a very interesting film. It is this oxidation which, although not fully understood, constitutes the thrust of the work to be described herein and the real novelty of the film.

Key words: thin film, sulfur-containing, replacement deposition, oxidation of copper.

Experimental Procedures

Replacement film preparation.—The usual sequence for film formation at room temperature, using aqueous solutions and intervening rinses, all with demineralized water, is as follows. A thin, electroless silver layer is deposited, from an ammoniated solution of silver nitrate and dextrose, on the glass surface after sensitizing in a dilute solution of stannous chloride. Only one surface about 25-60 cm^2 in area is coated while horizontal. This is done by applying each solution as a puddle on a leveled surface. The thickness of the silver layer has not been measured, but for practical purposes is monitored by measuring the luminous transmittance. The target value is 0.80. The layer of silver acts as a catalyst for deposition of copper to a luminous transmittance of about 0.24. Deposition is from a basic solution containing cupric sulfate, nickel sulfate, sodium potassium tartrate, and formaldehyde. Similar solutions are well known. The electroless film may or may not be dried with flowing air at this point. Thereafter, still working in the horizontal position, copper is partially replaced by silver in 50 sec, using a solution containing in one liter 1.0g $AgNO_3$, 1.0 cm^3 NH_4OH (28-30% NH_3), and 3.0g $Na_2S_2O_3 \cdot 5H_2O$. Both NH_3 and $S_2O_3^{-2}$ are complexers for Ag^+ and Cu^+ (8, 9). A more concentrated version of this formula is known for replacement of copper from the bulk (10). This particular diluted version has been used for subsequent data except where otherwise stated. In one

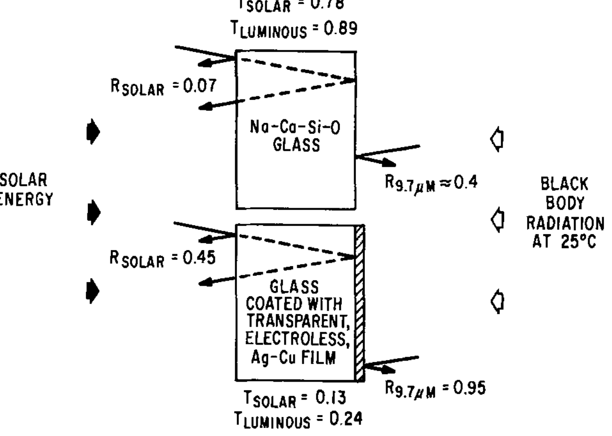

Fig. 1. Practical orientation of coated glass for architectural use. Reflectance (R) and transmittance (T) relative to uncoated glass.

case the replacement solution was further diluted 50% with demineralized water. The precursory electroless film was correspondingly thinner; luminous transmittance before replacement equal to 0.30 instead of 0.24. By dilution from the bulk concentration, the rate of replacement is more favorable for thin films. Replacement is terminated by rinsing followed by drying the film with pressurized air. Oxidation within the film occurs rapidly and spontaneously thereafter in the ambient air. In the broadest sense, it is continuing, having certainly begun in aqueous solution and during the brief final drying period (11).

In one instance oxidation was inhibited by following the otherwise final rinse with a passivating step. The film was exposed to an aqueous solution containing 0.13 g/liter of 3-amino-1H-1,2,4 triazole for 4 min at room temperature (12). This was followed by an additional rinse. Then the film was dried.

In two instances the usual procedure was altered by substituting for $S_2O_3^{-2}$ the disodium salt of $C_2O_4^{-2}$ or ethylenediamine tetraacetate. Replacement times were 30 sec at room temperature for data shown, but 15-60 sec have been used with similar results.

Observing the oxidation reaction.—Immediately after sample preparation, the reflectance from the uncoated glass-air interface was monitored while the opposite, coated surface was exposed to either the ambient air or a selected environment. In all cases but one, the Gardner Precision Glossmeter Model GG-9100 (precision ± 0.002) was used. For the passivated sample the Gardner Multi-Angle Glossmeter Model GG-9095 (precision ± 0.01) was used. Not more than about 15 sec passed between the final step in preparation and the initial data point at "zero" time. For the ambient environment, a typical condition was 30-60% relative humidity at 24°C. For the selected environments, a glass enclosure was used to contain the sample. This resulted in spurious reflections which had the net effect of decreasing all reflectance values by about 0.04. These data are therefore reported as relative reflectance values. Selected environments included N_2 and O_2, moistened in some instances by flowing over water at room temperature. It was not necessary to remove dissolved O_2 from the water.

Electroless copper samples.—In a few instances unreplaced electroless copper films were deposited on glass. Palladium activation was used. These were treated with $S_2O_3^{-2}$ or NH_3-$S_2O_3^{-2}$ solutions at room temperature prior to the final rinse and drying. Immediately thereafter the reflectance was monitored.

Identification of film constituents.—The usual replacement film and, for comparison, the precursory electroless film were analyzed quantitatively by atomic absorption spectroscopy to give the amounts of silver and copper present. Also, the replacement film was qualitatively compared to uncoated glass using a Norelco PW1212 automatic x-ray spectrometer to determine whether sulfur was present. As a second qualitative determination for sulfur, analysis was made by energy dispersive x-rays using a Princeton Gamma-Tech Model LS-30 attachment to a JSM-2 scanning electron microscope. Crystal phase analysis was by electron diffraction using a JEM-7 transmission electron microscope. For the latter two analyses it was necessary to facilitate sample preparation by deviating somewhat, but not importantly, from the usual procedure for sample preparation. Instead of beginning with a precursory, electroless copper film on glass, copper was deposited in vacuum on either collodion or carbon, supported on a mica substrate. This permitted the necessary easy release for collection on copper grids after treating in a puddle of the normal replacement solution. Samples were also exposed to aqueous solutions containing sodium thiosulfate alone. Rinsing in these instances was done essentially by diluting the puddle of replacement solution or $S_2O_3^{-2}$ with demineralized water within a confining tray.

Table I. Film analysis

	Cu (Units/cm²)	Ag (Units/cm²)	Ni (μg/cm²)
Electroless film, prior to replacement	18.8 μg	1.9 μg	<0.3
After replacement, 50 sec at room temperature	8.1 μg	15.9 μg	<0.3
Weight gain	−10.7 μg	+14.0 μg	—
Molar gain	−0.17 μm	+0.13 μm	—

Results and Discussion

Experimental evidence for replacement and oxidation in air.—For the usual aqueous solution described, partial replacement is confirmed by the atomic absorption data in Table I. Because nickel sulfate is present in the percursory electroless coppering solution, its content is also shown. In some way nickel sulfate promotes adherence, but it is not detectable within the film in measurable quantities. On a molar basis more copper has been removed from the film than silver deposited. That may be indicative of experimental error but side reactions are also likely. For the replacement film in Table I, the film thickness, by the method of Tolansky (13), is about 465Å. Partial oxidation within the film is implied by the curve with open data points in Fig. 2, although a less likely case for restructuring could be made. The reflectance for this unpassivated film decreased rapidly within the first 10 min and then decreased slowly. The film is relatively stable thereafter. Accompanying this change is a clear change in visual appearance by reflection, generally occurring within the brownish gray colors (14) by irradiation with illuminant C. A similar change did not occur when the film was chemically passivated with

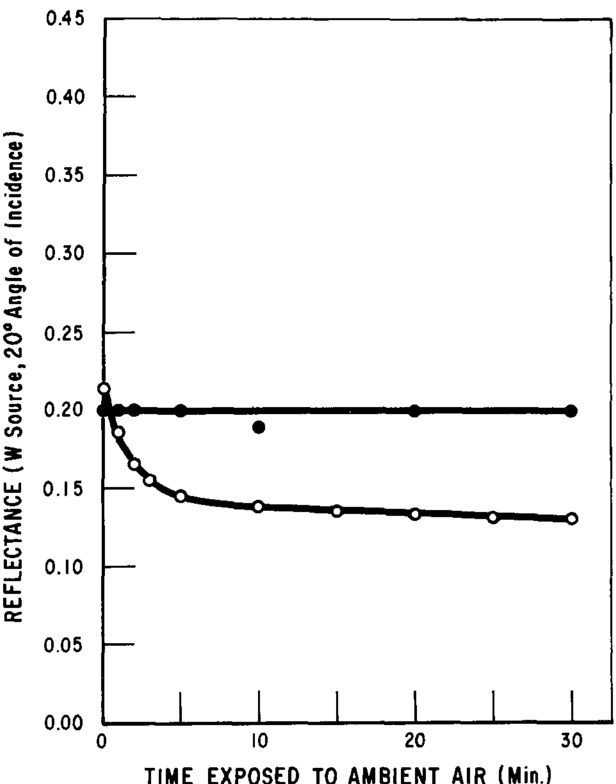

Fig. 2. Reflectance from the glass-air interface immediately after film deposition on one surface by electroless and replacement reactions: ○ film having partial replacement of electroless copper by silver from solution containing $S_2O_3^{-2}$; ● similar film passivated prior to drying.

the triazole solution, as indicated by the curve with solid data points in Fig. 2.

A decrease in reflectance is also inhibited generally at room temperature by maintaining the sample in either partial vacuum or nitrogen, dry or moist, while monitoring. The curve in Fig. 3 indicates film stability in partial vacuum and moist nitrogen. The initial decrease in reflectance in partial vacuum is relatively small and can be accounted for by allowing for some time to reach 0.2 atmospheres. In this instance the replacement solution was, by 50%, a diluted version of the usual. The reflectance decreased quickly once air was admitted into the system. Moist oxygen caused a similar sharp decrease when introduced instead of N_2; dry O_2 did not.

The prior work of Germer (15) and Campbell and Thomas (16) suggests that residual copper in the replacement film, were it purely metallic, should oxidize to only about 10-20Å within the first 30 min of exposure to the ambient environment. The metallic silver component should not oxidize to any noticeable extent. Thereafter, the replacement film should be relatively stable. An oxide film 10-20Å thick should not be visible to the unaided eye. In the unpassivated films of Fig. 2 and 3, therefore, oxidation in air beyond this minimal thickness has been presumed.

Phase analyses.—There is evidence that the $S_2O_3^{-2}$ replacement film contains Ag, Cu_2O, and probably Cu_2S. Vacuum-deposited copper exposed to the usual replacement solution for about 50 sec was shown qualitatively by electron diffraction to consist of at least crystalline silver and Cu_2O. There were no unidentified diffraction lines. By analysis with both energy dispersive x-rays and fluorescent x-rays, sulfur was detected qualitatively. Sulfur was only detected by electron diffraction after exposing another portion of the vacuum-deposited copper specimen to an aqueous solution of 3.0 g/liter $Na_2S_2O_3 \cdot 5H_2O$ for about 30 min. A faint pattern for Cu_2S was discerned in some instances, suggesting this may also be the sulfur-containing species in the normal replacement film. The structure of Cu_2S is probably too poorly defined for easy identification by electron diffraction.

Accelerated oxidation of Cu dependent on the presence of $S_2O_3^{-2}$.—In Fig. 4 it is shown that an electroless copper film once exposed to $S_2O_3^{-2}$ in the absence of a replacement reaction also suffers an exaggerated decrease in reflectance upon subsequent exposure to air. Its behavior is compared to that of similar copper films which were, as references, not exposed to $S_2O_3^{-2}$. Both references are relatively stable. In this way it has been demonstrated that supposedly enhanced oxidation within the replacement film can be explained in terms

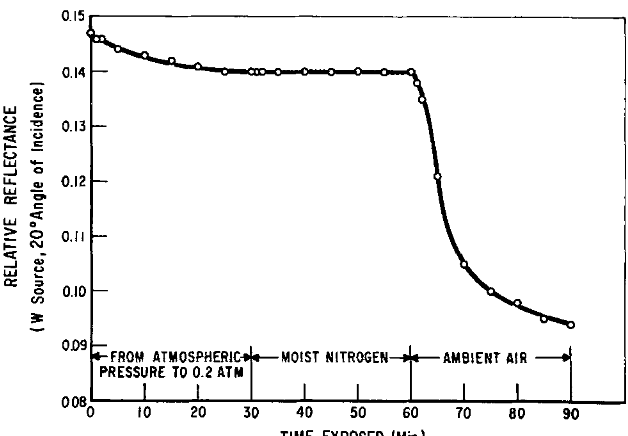

Fig. 3. Relative reflectance from the uncoated glass-air interface with an electroless-replacement film undergoing successive exposures to different environments. Electroless copper was partially replaced by silver from an aqueous solution containing $S_2O_3^{-2}$.

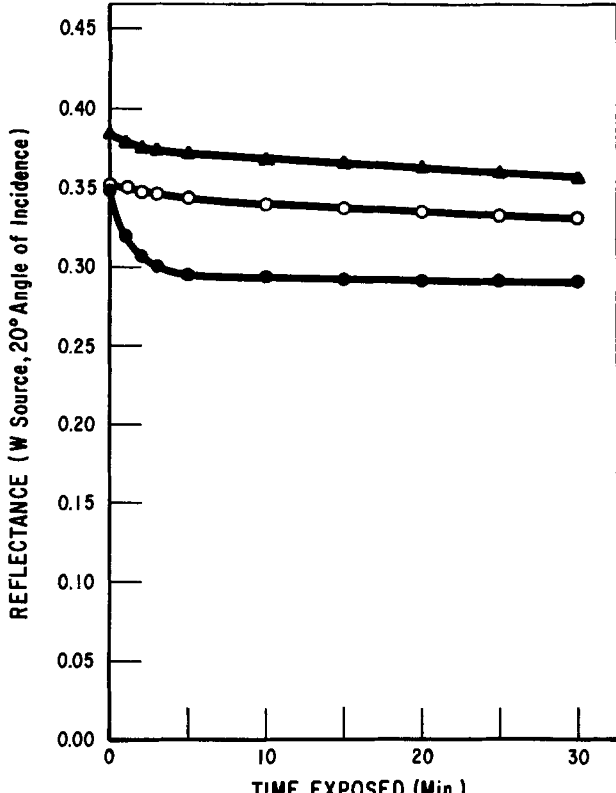

Fig. 4. Reflectance from the uncoated glass surface after deposition of electroless copper: ▲ fresh film exposed to oxygenated water at room temperature; ○ fresh film exposed to the ambient air; ● film exposed to ambient air immediately after treatment in an aqueous solution of 3.0 g/liter $Na_2S_2O_3 \cdot 5H_2O$ for 50 sec at room temperature.

of a reaction of copper or copper ions with $S_2O_3^{-2}$. In the case of electroless silver films deposited to approximately 150Å, no change in reflectance has been observed in air, with or without a pretreatment in aqueous solution containing $S_2O_3^{-2}$.

That the replacement reaction is favorable without the complexities of $S_2O_3^{-2}$ is suggested by the samples in Fig. 5. Partial replacement, in these typical instances, was facilitated in the absence of $S_2O_3^{-2}$ by known complexers for Cu^{+2}. There is no evidence for accelerated oxidation in air from the data in Fig. 5, further support for the special case with $S_2O_3^{-2}$.

An interesting parallel to the observed stability of copper in the replacement solutions of Fig. 5 is that stability can also be found with certain $S_2O_3^{-2}$-NH_3 solutions. This is shown by the curves in Fig. 6 for copper films exposed to two different $S_2O_3^{-2}$-NH_3 solutions. When the NH_4OH concentration was 1.25 cm^3/liter, as compared to being 0.25 cm^3 (or absent), there was no evidence of a sharp decrease in reflectance.

Possible reaction mechanism.—One explanation for the curves in Fig. 6 follows from assuming that NH_3 consumes copper ions as soluble complexes during the 50 sec of exposure to the $S_2O_3^{-2}$ solution. This would work against precipitation involving dissolving copper ions and $S_2O_3^{-2}$ by buffering copper ions. It would then be possible that with a low concentration of NH_4OH and a locally high concentration of dissolving Cu^+

$$2Cu^+ + S_2O_3^{-2} + H_2O \rightarrow Cu_2S + SO_4^{-2} + 2H^+ \quad [1]$$

The standard free energy of formation for Eq. [1] is −41 kcal (17). In the usual Ag^+-NH_3-$S_2O_3^{-2}$ replacement solution, about three-fourths of the available NH_3 could be consumed as $Ag(NH_3)^+_2$. Upon replacement $Cu(NH_3)^+_2$ could form. Further oxidation to $Cu(NH_3)_4^{+2}$ would consume NH_3. Notice that Eq. [1] does not appear to be in itself causing the sharp change in reflectance based on the results mentioned in con-

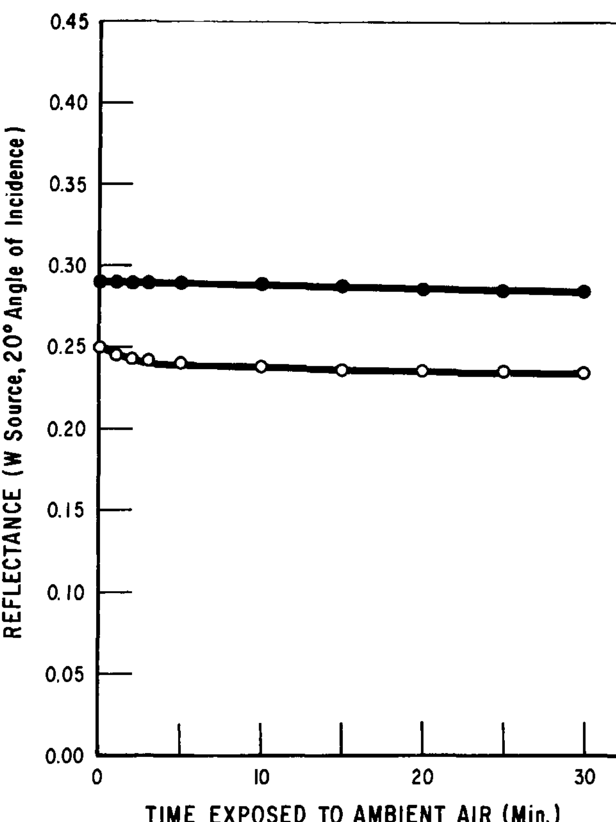

Fig. 5. Reflectance from the uncoated glass-air interface immediately after film deposition on one surface of glass by electroless and replacement reactions: ● 0.16 g/liter $Na_2C_2O_4$ instead of $Na_2S_2O_3 \cdot 5H_2O$; ○ 0.30 g/liter $Na_2C_{10}H_{14}O_8N_2 \cdot 2H_2O$. The luminous transmittance of the electroless precursor was 0.32-0.33.

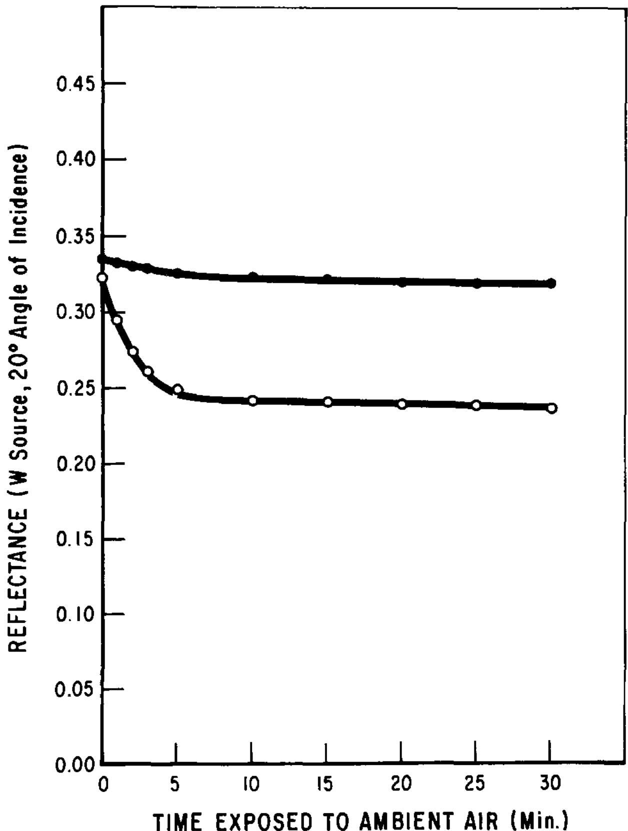

Fig. 6. Reflectance from the uncoated glass side with a deposit of electroless copper on one surface after the film was exposed at room temperature for 50 sec to an aqueous solution of 3.0 g/liter $Na_2S_2O_3 \cdot 5H_2O$ with 1.25 cm³/liter NH_4OH (●) or 0.25 cm³/liter NH_4OH (○).

nection with Fig. 3. Air or moist O_2 is necessary. Another thermodynamically favorable reaction is

$$2Cu + S_2O_3^{-2} \rightarrow Cu_2S + SO_3^{-2} \qquad [2]$$

but it is not obvious how this would depend on the concentration of NH_3.

With a precipitated sulfide present, accelerated oxidation in air is suggested by invoking the argument of an easy access for oxidation. The theory originally proposed by Cabrera and Mott (18), subsequently elaborated by many workers, characterizes slow logarithmic oxidation of pure copper by O_2 as taking place by migration of cations driven in the field developed initially by the fast place exchange of adsorbed oxygen. Cation migration is facilitated in a more loosely bound structure or in grain boundaries (19, 20). The cuprous sulfide may, in some way, provide easy access for oxidation of residual copper metal in the film. It would be preventing the formation of a more protective, continuous oxide film which would normally slow oxidation.

Summary

Using electroless copper films on glass as precursors, it has been possible to prepare new transparent films by partial chemical replacement with silver from aqueous solution at room temperature. Replacement solutions which were used contained NH_3 and $S_2O_3^{-2}$, $C_2O_4^{-2}$, or ethylenediamine tetraacetate, all complexing agents for silver and/or copper ions. An interesting secondary reaction, namely the apparently rapid oxidation of residual copper in air, occurred with some ammoniated $S_2O_3^{-2}$ solutions. The film constituents which have been identified in this case are Ag, Cu_2O, and a sulfur-containing species which may be Cu_2S. Consistent with the anticipated slow rate of oxidation of pure copper in oxygen and air at room temperature and with the data presented, a case can be made from prior literature for an easy access for oxidation by O_2. It may be that favorable structural defects and grain boundaries are formed by disruption of the growing Cu_2O lattice by sulfide in the presence of O_2 and H_2O. The source of sulfur is $S_2O_3^{-2}$ contained in the replacement solution. Among the various electroless and electroless-replacement films which have been prepared on glass at room temperature, the behavior in the presence of $S_2O_3^{-2}$ seems to be unique.

Phase Structure and Composition of Fe-W Alloy Electrodeposits

T. Omi, H. L. Glass,[1] and H. Yamamoto*

College of Engineering, University of Osaka Prefecture, Sakai, Japan 591

ABSTRACT

Parallel studies have been made of the phase structure, composition, and current-potential characteristics of iron-tungsten alloy electrodeposition from alkaline aqueous ammoniacal tartrate electrolytes. The presence of sodium, introduced with tungstate in the form of Na_2WO_4, was found to have profound effects on the deposition process. The deposits formed at low current densities consisted of a solid solution bcc phase containing a maximum of 13 atomic per cent (a/o) W. As the limiting current density for iron deposition was reached, an amorphous alloy phase, having a constant composition of 22.2 a/o W, began to form. This amorphous phase was identified as Fe_3W saturated with excess iron atoms and having a structure based on tetrahedral units. The initiation of amorphous phase deposition was correlated with the occurrence of multiple nucleation associated with increasing accumulation of sodium atoms at the electrode. When the cathode potential was made still more negative, further increase in sodium accumulation appeared to have been responsible for an observed decrease in the rate of deposition of the amorphous Fe_3W. However, an amorphous Fe_2W phase may have formed at extreme values of cathode potential. Such a phase was prepared by elevation of the electrolyte *p*H. From analysis of these results, a prescription is developed to account for the formation of homogeneous stoichiometric electrodeposits. This prescription, which may be applicable to many amorphous and crystalline alloy deposition systems, consists of three conditions which describe material balance and atomic interactions at the electrode surface.

For at least fifty years (1) it has been known that alloy electrodeposits may exhibit nonequilibrium structures. Two common examples of deviations from equilibrium are the formation of supersaturated solid solutions and phases which normally are produced only at elevated temperatures. It is also possible for alloy electrodeposits to exist in metastable phases which do not appear at all on the usual equilibrium phase diagrams. Although formation of nonequilibrium structures must be related to the kinetics of the electrodeposition process (2, 3), this relationship is not well understood.

The work described in this article deals with the electrodeposition of iron-tungsten alloys which can form a metastable amorphous phase having a fixed composition containing 22.2 a/o W. Parallel studies of structure, composition, and current-potential characteristics provide insight into certain electrodeposition mechanisms which appear to be responsible for initiating the amorphous phase. In addition, an earlier analysis of the origin of stoichiometry in amorphous Co-W electrodeposits (4) is generalized into a prescription which may be applicable to deposition in many alloy systems, both amorphous and crystalline.

Key words: amorphous alloy, stoichiometry, limiting current, sodium, cathode potential.

Experimental Procedure

Electrolytes were made up of special grade chemicals (Wako Pure Chemicals Industries, Limited) and deionized water. They were prepared in a nitrogen gas atmosphere in order to prevent oxidation of the ferrous complex (5). Unless otherwise stated, the *p*H of the electrolytes was kept constant at 8.50 by addition of ammonium hydroxide. Nitrogen was swept through the solution for at least 20 min prior to electrolysis.

Electrolysis was carried out at 80° ± 0.2°C without agitation. A 400 cm^3 Pyrex glass cell was used. The platinum anodes were separated from the cathode by glass disks in order to avoid contamination by anode products. Vertically held rectangular cold-rolled mild steel substrates with an area of 5.74 cm^2 were used as cathodes. These cathodes were prepared by mechanical polishing on 5/0 emery paper, electrolytic degreasing in warm aqueous alkaline solution, etching in sulfuric acid (diluted 1:20) for 30 sec, and then rinsing in flowing deionized water. A 0.3 mm (outside diameter) Luggin capillary with a tip cut at an obtuse angle and in light contact with the center of the cathode plane was used as the probe of the reference electrode, a saturated calomel electrode held at 25° ± 1°C. The potential drop due to the ohmic resistance between cathode and reference electrode was determined with the aid of a synchroscope by measuring the decay of

the electrode potential after cutting off the current (6).

Alloy deposition.—The solutions used for alloy deposition were made from $FeSO_4$, Na_2WO_4, and ammonium tartrate. The total Fe+W concentration was kept equal to the tartrate concentration at a constant value of 0.26 mole/liter.

Over most of the range of alloy deposition, the current density varies rapidly with cathode potential. Therefore, measurements were made under galvanostatic conditions with the cathode potential measured on a Shimazu 3P potentiometer after a quasi-static state had been attained. The time required to reach a quasi-static state ranged from about 1 min for high current densities to several minutes for low current densities. Over a range of very low current density, the potential varies quite slowly. In this range, potentiostatic conditions were employed with the quasi-static current measured on a Hokuto-Denko PS-500B potentiostat. The time dependence of cathode potentials or of cathode currents was recorded on a TOA Electronics stripchart recorder EPR-22A. This recorder has a high internal resistance (2 megohm) and fast response (above 500 mm/sec).

Wet gravimetric chemical analyses were carried out to determine the compositions of the deposits. Using deposits prepared under coulostatic and galvanostatic conditions (0.0198 A·hr/cm^2 and taking ionic valences of 2 for iron and 6 for tungsten, the partial currents due to deposition of metals and hydrogen were calculated from the measured compositions.

The structures of electrodeposits were studied by x-ray diffraction or by electron microscopy. Coulostatically (0.0198 A·hr/cm^2) formed alloys of about 10 μm thickness were examined. A Shimazu VD-1A scintillation counter diffractometer equipped with a step scanning mechanism, 1.2 kW cobalt target, and iron filter was used for x-ray diffraction. In order to irradiate the whole or a part of alloy deposits, suitable divergence slits were used. A JEM-200 electron microscope equipped with a JEM-AD3 high resolution electron diffraction attachment and operated at an accelerating voltage of 200 kV was used for electron microscopy. The electropolishing of alloy deposits for transmission electron microscopy was made after dissolving out the substrate in sulfuric acid (diluted 1:1). The deposits were then electropolished from both sides at a cell voltage of 7-13V using a large stainless steel cathode and ice-cold electrolyte of the composition 840 cm^3 CH_3OH, 150 cm^3 H_2SO_4, and 13 cm^3 HF.

Iron deposition.—Iron depositions were made from two different electrolytes. Both electrolytes were similar to those used for alloy deposition; however, in one case both sodium and tungstate were omitted and in the other case tungstate was omitted but sodium, in the form of sodium tartrate, was retained. The same apparatus and reagents of the same quality as employed for alloy deposition were used.

Deposition was carried out potentiostatically while the current was continuously recorded. The mean over-all current density as well as the current efficiency for deposition of iron was determined at each value of cathode potential from the recorded current and the weight gain of the samples. In a few cases the current exhibited a rapid increase with time. In these cases deposition was carried out for 10 min; otherwise longer deposition times were employed.

The surfaces of the deposits were analyzed by reflection electron diffraction using an accelerating voltage of 100 kV.

Results

Alloy deposition.—Figure 1 shows the current-potential curves during alloy electrodeposition. For presentation, the potential axis is displaced for each solution. In the determination of partial current-potential curves, at least two measurements were made of alloy composition and cathode current efficiency for each value of cathode current density. These determinations resulted in smooth dependences of partial currents on the over-all current density. These smooth dependences were used to draw the partial currents shown in Fig. 1. In this way the maximum for deposition of iron in curve 6 (41 mA/cm^2) was found and verified.

Under the galvanostatic conditions employed for alloy deposition, certain regions of the polarization curves exhibited a kind of bistable behavior. In these regions, shown by the horizontal lines in Fig. 1, the cathode potential spontaneously fluctuated between two values. Though irregular, the fluctuations had periods of about 10 sec. In regions of these fluctuations the thick curves in Fig. 1 are the time averages of the fluctuations which are described by the enveloping thin curves.

In general, the galvanostatic measurements of alloy deposition were reproducible to ± 4 mV. However, for solutions 3 and 4, the reproducibility at current densities above the bistable region was about ± 10 mV. This poorer reproducibility may be due to unresolved bistable behavior at these higher currents.

The scale of Fig. 1 has been chosen to display the general forms of the current-potential curves. At this scale, however, many detailed features of the original current-potential data are lost. In particular, the original data exhibited numerous characteristic breaks, defined as points where there is an abrupt change in slope. Only a few of these breaks are discernible in Fig. 1; however, the breaks are more fully described below and in Table I. Examination of the breaks leads to a division of the six sets of curves in Fig. 1 into two groups. The first group consists of curves 1 and 2, corresponding to tungsten mole fractions of 0.09 or less. The second group, consisting of the remaining curves 3-6, corresponds to tungsten mole fractions of 0.23 or greater.

For the first group, the values of cathode potential at which breaks occur appear to be independent of electrolyte composition. Thus, the breaks α, β, and γ which appear in curve set 1 at 930, 1010, and 1020 mV are also found in curve set 2 at the same values of cathode potential.

For the second group, the values of cathode potential at which breaks occur vary with electrolyte composition; however, the relative change in partial currents are very similar for all of these solutions. This similarity is brought out in Fig. 2 and Table I. Figure 2 is a set of schematic current-potential curves showing various breaks. Table I lists the values of cathode potential at which the breaks occurred for solutions 3-6. Also given in Table I are the relative changes in slope of the hydrogen, iron, and tungsten partial current curves; a + sign corresponding to an increase in slope and a − sign to a decrease. In general, the

relative changes in slope are the same for hydrogen and iron; the break H being an exception.

Alloy composition and structure.—The structures of the alloy deposits were studied in detail for the solutions in which the tungsten mole fraction was 0.23 or greater; curves 3-6 in Fig. 1. For these solutions, alloy deposition initiated at a cathode potential slightly more negative than the break B in Fig. 2 and in Table I. At potentials less negative than this, no deposition of metal or alloy was observed. This is in agreement with Kudo's work which involved radioactive tracer in a similar solution (7).

At potentials more negative than B, two different structures were found. One structure was crystalline and may be described as a solid solution of tungsten in bcc iron. The second structure was an amorphous W-Fe alloy. As will be explained in the Discussion, this amorphous alloy appears to be isomorphous with amorphous Co_3W (4) which possesses neither crystal symmetry nor translational invariance. The occurrence of these two structures was found to be a function of cathode potential. This is indicated in Fig. 2 where the amorphous phase, denoted by Am, is shown to form when the cathode potential is more negative than N while the crystalline phase, denoted by bcc, is shown to form when the cathode potential is more negative than B. There is a range of overlap where both phases can deposit. This range of overlap depends on the tungsten mole fraction of the electrolyte. For solutions 5 and 6, having tungsten mole fractions of 0.71 and 0.85, the range of overlap is small, with the bcc region extending only slightly beyond N. For solutions 3 and 4, having tungsten mole fractions of 0.23 and 0.41, the range of overlap is quite large, extending all the way to the break H as indicated by the bcc in parentheses.

The extended range of overlap for solutions 3 and 4 corresponds to the region in which the cathode potential was observed to fluctuate as was shown in Fig. 1. For each value of current density in this region, the bistable fluctuations between two values of cathode potential were found to correlate with the structure of the deposit which formed near the Luggin capillary. When deposition was terminated at the less negative value of cathode potential, the x-ray diffractogram showed this portion of the deposit to be crystalline. For termination at the more negative value, this portion was amorphous. The two phases could also be distinguished by their visual appearance.

In those regions of Fig. 1 where the thick time-average curves for solutions 3 and 4 lie close to the more negative (right hand) enveloping curves, the deposit consisted mainly of amorphous phase. The crystalline phase occurred as embedded thin platelets lying parallel to the surface near the center of the sample where the Luggin capillary was located. These platelets were up to 8 mm in diameter but only about 0.1 μm in thickness. The converse structure, with amorphous phase platelets embedded in a crystalline phase matrix, was observed where the time-average curve lies close to the less negative enveloping curve. Thus, Fig. 1 indicates that within the extended range of overlap, N-H of Fig. 2, the formation of bcc phase occurs primarily in the range from C to D or E.

Since the platelets formed in the two-phase region had relatively large lateral dimensions, it was possible to use x-ray diffraction to measure the spatial variation of lattice parameter in the crystalline regions. It was found that this lattice parameter attains its maximum value, 2.940Å, at the physical boundary where the crystalline and amorphous materials meet. This value of lattice parameter is found to correspond to a composition of 13 a/o W in bcc iron if one extrapolates the lattice parameter-composition relation obtained from deposits prepared in the single phase bcc region B-N of Fig. 2 where the tungsten content ranged from 3 to 9 a/o.

It is interesting to note that the maximum tungsten content of the electrodeposited bcc phase is the same as the maximum solubility of tungsten in bcc iron which is shown in the equilibrium phase diagram (8); however, this level of tungsten concentration is in equilibrium only at elevated temperatures. A similar relation was found for the maximum tungsten content in the crystalline phase of W-Co alloy electrodeposits (9).

Selected area diffraction in transmission electron microscopy yielded essentially identical patterns for the amorphous regions of two-phase samples and for the single phase amorphous samples. In the previously reported W-Co system (4, 9), the amorphous regions of two-phase deposits were found to contain small particles of the crystalline phase. These particles decreased in size and number as the cathode potential became more negative and as the over-all tungsten content of the deposits increased. In contrast to this behavior, selected area diffraction did not show any evidence of bcc particles in the amorphous regions of the two-phase W-Fe deposits.

Both the electron and x-ray diffraction patterns obtained from the amorphous W-Fe phase were nearly the same as the patterns from amorphous Co_3W (4). Actually, the so-called amorphous Co_3W was found to contain 22.2 a/o W (4) and should probably be viewed as a saturated solution of Co in Co_3W. Similarly, the chemical analyses of the single phase amorphous W-Fe electrodeposits revealed a tungsten content of 22.2 a/o.

As depicted in Fig. 2, the partial currents for iron and tungsten deposition are roughly parallel to each other in the ranges from N to C and from D or E to G; ranges where the deposits consisted mainly of the 22.2 a/o W amorphous phase. At G, however, the partial current curves begin to diverge, with the curve for tungsten dropping off. Beyond J, as seen for solution 6 in Fig. 1, the tungsten partial current rebounds and the ratio of the increase of tungsten current to that of iron is about 1:5. This suggests that it may be possible to form an alloy of approximate composition Fe_2W if the tungsten mole fraction is sufficiently high and if the cathode potential is sufficiently negative. To explore this possibility, electrolytes of higher *p*H were prepared, since the maximum tungsten content found with the *p*H 8.50 solutions was 22.2 a/o. Figure 3 presents the results of chemical analyses of samples deposited galvanostatically from solutions having *p*H 9.00 and various tungsten mole fractions. Similar results were obtained for electrolytes of *p*H 9.40. Although these results are not sufficient to prove that an amorphous Fe_2W phase can be deposited, they do give some support to such an interpretation. A crystalline Fe_2W phase is shown in the equilibrium phase diagram (8).

Iron deposit.—Figures 4 and 5 present the current-potential curves for electrolytes analogous to solution 5 of Fig. 1 which had a tungsten mole fraction of 0.71. For Fig. 4 the tungstate was omitted but sodium was retained. For Fig. 5 both sodium and tungstate

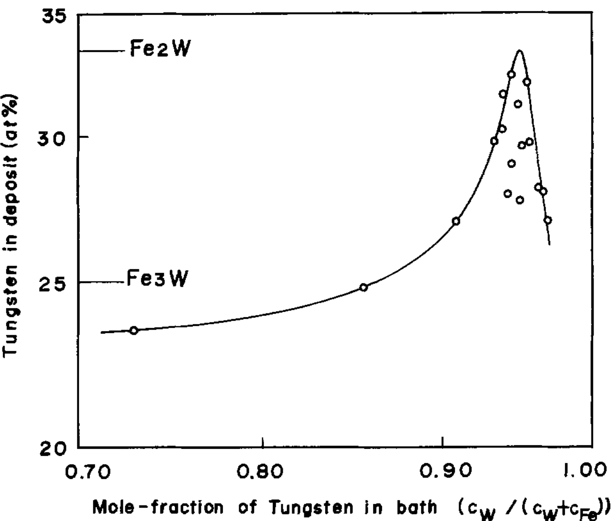

Fig. 3. Composition of deposits *vs.* tungsten mole fraction. 50 mA/cm²; pH = 9.00, elevated by addition of NH_4OH.

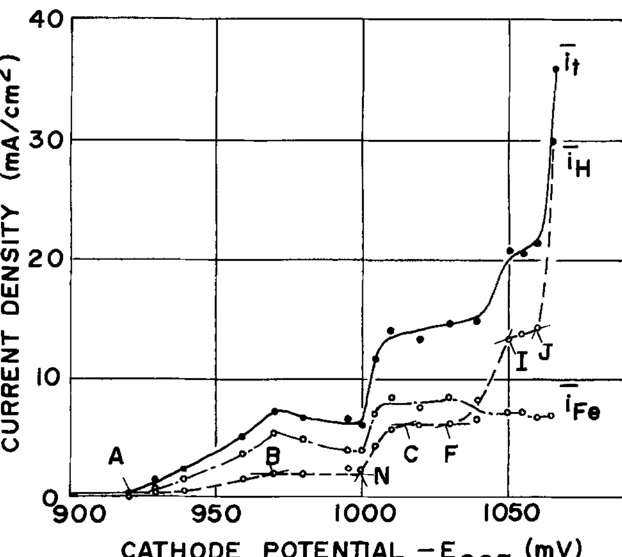

Fig. 4. Mean current-potential curves for deposition of iron in presence of sodium. $(NH_4)_2C_4O_6H_4$, 0.075 mole/liter; $Na_2C_4O_6H_4$, 0.185 mole/liter; $FeSO_4$, 0.075 mole/liter; pH = 8.50, 80°C.

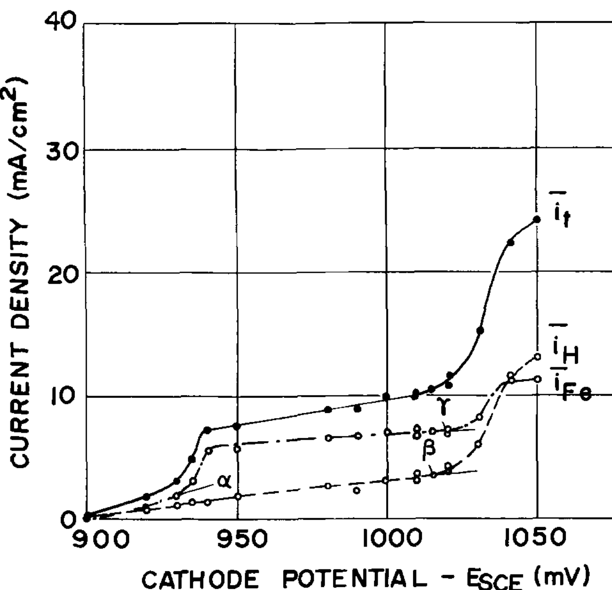

Fig. 5. Mean current-potential curves for deposition of iron in absence of sodium. $(NH_4)_2C_4O_6H_4$, 0.26 mole/liter; $FeSO_4$, 0.075 mole/liter; pH = 8.50, 80°C.

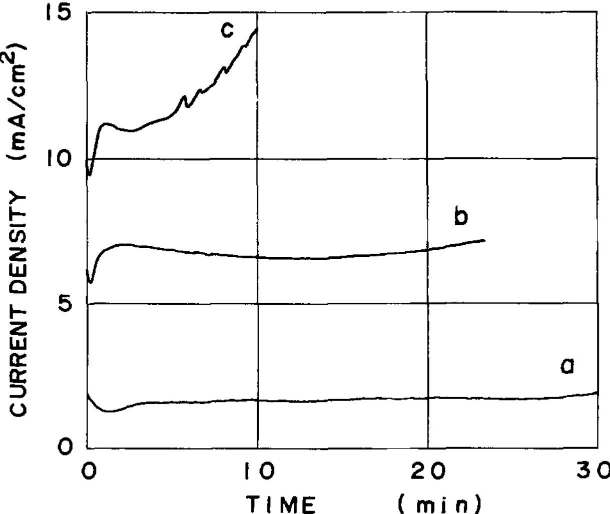

Fig. 7. Representative current-time behaviors observed during measurement of Fig. 4. a: behavior for the region −(920-940) mV_{SCE}, measured at −930 mV_{SCE} b: region −(960-995) mV_{SCE}, measured at −995 mV_{SCE} c: region −(1005-1055) mV_{SCE}, measured at 1005 mV_{SCE}.

were omitted. The values of current which were measured for these potentiostatic depositions were reproducible to ±5% for solutions containing sodium and to ±10% for solutions without sodium.

Figure 4, for which sodium was present, exhibits a series of breaks similar to those of the analogous alloy curve of Fig. 1. The values of cathode potential at which the breaks occur are very nearly the same for both the alloy and iron depositions. On the other hand, Fig. 5, for which sodium was absent, does not exhibit breaks like those of the analogous alloy curve. Instead, Fig. 5 is similar to curve 1 of Fig. 1 for which the tungsten mole fraction and, therefore, the sodium concentration were minimum.

The current-potential curves in Fig. 6 correspond to an electrolyte analogous to solution 3 of Fig. 1, which had a tungsten mole fraction of 0.23, but with the tungstate omitted. Although less striking than Fig. 4, there is again a series of breaks which occur at the same values of cathode potential as those of the analogous alloy curve; at least up to the break N.

Figure 7 shows examples, for three different ranges of cathode potential, of the time dependence of the

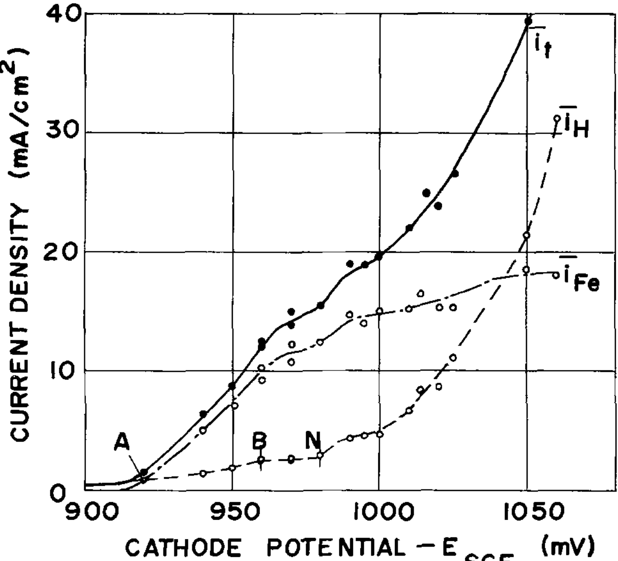

Fig. 6. Mean current-potential curves for deposition of iron in presence of sodium. $(NH)_4)_2C_4O_6H_4$, 0.200 mole/liter; $Na_2C_4O_6H_4$, 0.060 mole/liter; $FeSO_4$, 0.200 mole/liter; pH = 8.50, 80°C.

deposition current observed during measurement of Fig. 4. Curve c, for the range of cathode potential beyond N, exhibits the fairly rapid increase of current with time which was found to be characteristic of iron deposition in this range of cathode potential. Because quasi-static conditions could not be attained, the current-potential curves for this range were obtained by keeping the deposition time constant at 10 min and using the time-averaged over-all current density.

Although the deposition current increased with time in the range beyond N, the current efficiency for iron decreased with time. This effect was especially pronounced for cathode potentials beyond 1040 mV. Another effect which was observed for the range beyond N was that the deposits were black in appearance rather than metallic gray as was seen at less negative potentials. All of these features, the increasing current, the decreasing current efficiency, and the blackening of the deposits, were observed for the electrolyte of Fig. 6 as well as that of Fig. 4. However, these effects were not observed for the solution of Fig. 5, which did not contain sodium.

The reflection electron diffraction patterns of the iron deposits failed to show evidence of any substances which could be responsible for the observed blackening. In spite of the difference in appearance, both the gray and black deposits gave diffraction patterns which were characteristic of bcc iron with a (321) preferred orientation.

Discussion

Since cobalt and iron have nearly equal atomic scattering factors (for both x-ray and electron diffraction) and since the amorphous Fe-W alloys prepared in the range N-G in Fig. 2 and the amorphous Co_3W electrodeposits were both found to contain 22.2 a/o W, the close similarity of the diffraction patterns for the two amorphous alloy systems can be accounted for by the same atomic configuration. Therefore, adapting the configuration derived for amorphous Co_3W (4), the amorphous Fe-W electrodeposit may be described as a saturated solution of iron atoms in amorphous Fe_3W having as its basic structural unit a tetrahedron consisting of three iron atoms and one tungsten atom.

In the case of Co_3W, an equilibrium phase having an ordered crystalline structure is known. No corresponding Fe_3W phase appears in the equilibrium phase diagram for the Fe-W system (8). Nevertheless,

the generally close chemical similarity between cobalt and iron and the fact that the amorphous Fe_3W phase has a constant composition of 22.2 a/o W over a wide range of deposition conditions point to the existence of such a phase. Moreover, there is experimental evidence of a crystalline Fe_3W phase, isomorphous with crystalline Co_3W, localized at the surface of Fe-22.2 a/o W electrodeposits (10).

Because the amorphous deposits are nonequilibrium phases, their occurrence must be determined by the electrodeposition process. Several characteristics of this process are evident in the results of these experiments. First of all, it should be noted that the irregular fluctuations of cathode potential (Fig. 1) which were associated with transitions between crystalline and amorphous depositions are indicative of a diffusion-limited current density (6). From material balance considerations (11) and from the fact that the amorphous phase deposits at the negative end of the fluctuations, it follows that amorphous Fe_3W forms when the deposition of iron is diffusion controlled.

Additional information about the nature of the deposition process comes from a comparison of the iron deposition curves with the alloy curves. It is especially instructive to compare Fig. 4 for iron deposition in the presence of sodium and Fig. 5 for iron deposition in the absence of sodium with the results for the analogous alloy depositions from solution 5 in Fig. 1. Obviously, the essential form of the current-potential curves and the occurrence of most breaks are associated with the presence of sodium in the electrolyte. Further, on comparing Fig. 6, also for iron deposition in the presence of sodium, with its analog, solution 3 in Fig. 1, it is clearly seen that the values of cathode potential at which the breaks occur are controlled by the sodium and iron concentrations and are insensitive to the presence of tungstate.

While the form of the current-potential curve and the occurrence of breaks are associated with the presence of sodium, Fig. 2 and Table I show that there is a close correlation between the changes in hydrogen and iron partial currents at the breaks. The apparent connection between the presence of sodium and the deposition of hydrogen is expected to arise from the nature of the hydrogen electrode reaction which involves the deposition and accumulation of sodium atoms and their reaction with water molecules. The positive correlation between hydrogen and iron partial currents may be ascribed to convective effects associated with hydrogen evolution.

Both the hydrogen electrode reaction and the effects of hydrogen on iron deposition require elaboration. In this connection, the work of Matsuda and Notoya (12) on aqueous sodium hydroxide appears to be relevant. Their Fig. 8 in which the rate of sodium accumulation at a platinum electrode is plotted as a function of electrode potential, exhibits some interesting effects which seem to correspond to certain features of the Fe-W alloy deposition.

Matsuda and Notoya found that the accumulation of sodium atoms was initiated at a potential $-E_{SCE} \approx$ 780 mV. Similarly, preferential adsorption of tungsten (in some oxidation state) is known to occur on nonpolarized electrodes only for electrolytes for which the open-circuit potential is more negative than $-E_{SCE} \approx 780$ mV (10). This apparent connection between sodium accumulation and tungsten adsorption may be ascribed to the dissociation of the tungstate-tartrate complex brought about by the presence of sodium atoms at the electrode surface. The product tungstate then condenses.

Another feature noted by Matsuda and Notoya was a sharp maximum in the rate of sodium accumulation which occurred at $-E_{SCE} \approx 1040$ mV irrespective of sodium concentration or electrolyte pH. In Fe-W alloy deposition, the break H (Table I) occurred at a potential very near this value. At this break, the hydrogen partial current increased but the iron partial current exhibited a decrease in slope. This was the major exception to the observation that the relative changes in slope were the same for hydrogen and iron. The behavior at break H may be attributed, therefore, to a rapid increase in the number of sodium atoms at the electrode which results in an increase in hydrogen. The increased sodium at the electrode may obstruct iron deposition. The same mechanism would account for the pronounced decrease, with time, of the current efficiency of iron deposition which was observed beyond 1040 mV for those electrolytes which contained sodium but not tungstate. It should be remarked that an exact comparison with Matsuda and Notoya's results is hindered by the effects of concentration polarization and shielding by the Luggin capillary.

The effects of sodium appear to play a crucial role in establishing the amorphous alloy structure. Strong evidence for this was seen in the deposition of iron from those electrolytes which contained sodium, Fig. 4 and 6. In the range of cathode potentials beyond N the deposition current continually increased (Fig. 7) and the deposits became black in color; yet reflection electron diffraction showed no significant differences to account for the color change. These observations are consistent with the development of a more complex microprofile of the surface and an increase in defect density when the cathode potential exceeds N. These characteristics suggest the occurrence of multiple nucleation. However, the continued existence of crystallinity, as evidenced by the bcc electron diffraction patterns, implies a reasonably large particle size, probably no less than a few hundred atoms (13-15). It is not possible to determine whether this particle size arises directly through a nucleation and growth deposition process or by a rearangement of atoms after deposition. In any case, the blackening occurs in the presence of sodium when the cathode potential exceeds N. These are the same conditions under which the amorphous phase deposits. Moreover, a similar relation between initiation of amorphous alloy deposition and blackening of metal deposits was found in the study of the Co-W system (9, 16).

The amorphous alloy structure must arise either because the deposition process produces mutually incoherent particles which are too small for the crystalline configuration to be energetically favored (13-15) or because the atoms do not bond together in the arrangement required for crystalline long-range order (4, 17). The occurrence of multiple nucleation along with the obstructive effects of sodium atoms and hydrogen atoms appears to be responsible for the initiation of the amorphous structure in the electrodeposits. This structure will be retained in the deposits if the atoms are unable to rearrange themselves into crystalline configurations. This will largely be determined by thermal vibration. In fact, amorphous alloys generally consist of a metal and a metalloid for example Ni-P (18) or Fe-P-C (19), so that strong bonding reduces thermal vibration; or the alloys contain an element having a high intrinsic Debye temperature, as in the tungsten alloys described here.

An important feature of the amorphous alloys, both Co_3W and Fe_3W, is that the chemical composition is constant and essentially stoichiometric over a wide range of deposition conditions. While stoichiometry in an ordered crystal structure is not surprising, the origin of stoichiometry in an amorphous structure may require elaboration. Certainly, the existence of an ordered crystal structure implies a preference for a local atomic configuration (short-range order) which can also exist in an amorphous structure of the same composition. However, by generalizing the criteria which were used to derive the structural model for amorphous Co_3W (4), a prescription may be written by which the deposition process can lead to the formation of a

stoichiometric alloy whether the structure is amorphous or crystalline.

An alloy of composition A_nB will be deposited if the following three conditions are met: (*i*) an n-atom cluster of A atoms forms a unique site on which a B atom can deposit; (*ii*) m-atom clusters of A atoms ($m \geqq n$) can form; (*iii*) the concentration of B atoms at the surface is much greater than the concentration of A atoms. Conditions *i* and *iii* are equivalent to statements that the deposition of B is catalyzed by n-atom clusters of A and that B atoms are available for deposition. Condition *ii*, which will be discussed in detail below, essentially means that the necessary n-atom clusters of A actually are formed. At this point it is clear why the conditions are independent of the degree of crystallinity of the structure; the stoichiometry involves interactions among only small numbers of atoms while crystallinity involves interactions among large numbers of atoms extending over large distances.

To discuss condition *ii* it is convenient to review Walton's theory (20) for nucleation in monatomic vapor deposition. Walton derived the equilibrium distribution of cluster sizes. This distribution depends upon a complicated balance among several factors including rate of incidence, substrate temperature, and the activation energy for surface diffusion. He found that under given deposition conditions one size of cluster dominates. This is the size m in condition *ii*. Walton also found that m is generally small and that the predominance of a particular value of m (at least when m is indeed small) extends over a substantial range of deposition conditions. The predominant cluster size will tend to shift to a smaller value if the rate of incidence increases, the temperature decreases, or the activation energy for surface diffusion increases.

If a Walton-type theory describes the nucleation of A atoms in alloy electrodeposition, there will be some equilibrium number density of n-atom clusters of A. When conditions *i* and *iii* are satisfied, a B atom will deposit on each of these n-atom clusters forming A_nB structural units. Furthermore, the deposition of B atoms may stabilize these clusters, thus effectively removing them from the equilibrium process of cluster formation and dissociation. If $m = n$, the n-atom clusters of A will predominate and nearly all of the deposited A atoms will be associated with B atoms in A_nB units. It is unlikely that there will be any clusters of A atoms of a size larger than n, for such clusters would form through atom-by-atom additions to n-atom clusters; but condition *iii* makes the formation of A_nB more probable. This is the significance of the term $m \geqq n$ in condition *ii*.

When $m < n$, there are additional considerations. If the deposition is dominated by an ordinary nucleation-and-growth process, the m-atom clusters will either dissociate or grow through atom-by-atom addition. In the latter case condition *ii* is superfluous, since the growing clusters will pass through the n-atom stage and, by conditions *i* and *iii*, A_nB structural units will be formed. This, of course, describes the formation of ordered crystalline alloy deposits. On the other hand, when multiple nucleation dominates the deposition process, as in the formation of amorphous alloy deposits, some m-atom clusters will attain size n and form A_nB units; however, many clusters smaller than n would probably become entrapped. The resulting deposit would be nonstoichiometric because of the excess A. The composition would vary with the degree of entrapment and, therefore, with the deposition conditions. Although the actual Fe_3W and Co_3W amorphous deposits contain excess iron and cobalt atoms, the compositions are constant at 22.2 a/o W for a wide range of deposition conditions. Thus, the departure from exact stoichiometry is not attributed to $m < n$ effects; rather, the excess iron or cobalt is believed to be accommodated in sites which would otherwise be voids or clearances between the tetrahedral units (4).

The ranges of cathode potential in Fig. 2 can be described in terms of parameters m and n. In the range N-G, where amorphous Fe_3W deposits, $n = 3$. Beyond J it appears that Fe_2W is formed, so $n = 2$. To assign values of m to these ranges it is necessary to consider the partial currents. In the range N-G, where $n = 3$ and the tungsten current increases, $m = 3$ (or possibly $m > 3$). In the range G-J the tungsten current drops off although the iron current increases. This is also the range in which sodium and hydrogen deposition increases. The obstructive effects of these elements may be equivalent to an increase in the activation energy for surface diffusion which could lower the value of m. If $m = 2$, then tungsten deposition would be retarded because $m < n$. The resumed increase in tungsten partial current beyond J may now be accounted for by the deposition of Fe_2W with $n = 2$ so that condition *ii* is again satisfied. The fact that the Fe_2W composition was not actually attained in the *p*H 8.50 electrolytes may be ascribed to the violent agitation produced by hydrogen evolution at the high values of cathode potential in this range beyond J. With the higher *p*H solutions, as in Fig. 3, there was less agitation due to hydrogen and Fe_2W was obtained.

As described in the preceding paragraph, the adsorption of foreign substances is expected to lead to a small cluster size. Such effects would be common to many cases of deposition from solutions. Furthermore, small clusters are known to have catalytic effects (21, 22). Thus, in many cases of alloy deposition conditions *i* and *ii* will be satisfied and the occurrence of stoichiometry will be determined by condition *iii*. A factor which contributes to condition *iii* being satisfied for Fe_3W and Co_3W is that the stoichiometric alloy is deposited at the limiting current density for iron or cobalt. Under such circumstances the deposition of the A atoms (iron or cobalt) is diffusion limited and their concentration at the surface will be nearly zero; the concentration of the B atoms (tungsten) being finite at the surface leads to fulfillment of condition *iii*. Another system in which the three conditions seem to be met is Ag-Sn (23) in which the stoichiometric alloy Ag_3Sn forms under pulse electroplating at or near the limiting current density for Ag.

Tin (IV) Chloride Solution as a Sensitizer in Photoselective Metal Deposition

B. K. W. Baylis, A. Busuttil, N. E. Hedgecock, and M. Schlesinger*

Department of Physics, University of Windsor, Windsor, Ontario N9B 3P4, Canada

ABSTRACT

Experiments were conducted which show that Sn(IV) bound to a substrate is capable, in conjunction with Pd(II), of catalyzing Ni-P plating and that this effect can be inhibited by u.v. light. Some of the parameters affecting the quality of the plating and u.v. inhibition were determined. It was also found that in order for u.v. irradiation to inhibit Ni-P plating, the radiation must be applied after the Pd(II) activation step. In the case of copper, however, plating occurs only on the irradiated area of the catalyst. A mixture of Sn(IV) and Pd(II) was also found to catalyze Ni-P plating. The behavior of the catalyst deposited by this mixture was quite similar to that of the catalyst present after Pd(II) activation following Sn(IV) sensitization in the stepwise procedure.

The use of u.v. light to generate patterns in the catalytic surface of dielectric substrates has been well studied in recent years (1-4). The initial procedure was to immerse the substrate in a $SnCl_2$ solution (the sensitizer), to rinse, and then to irradiate with u.v. light through a quartz mask. After immersion in a $PdCl_2$ solution (the activator) and another rinse, the substrate was placed in a metallizing bath. Plating occurred wherever the u.v. light did not reach the catalyst.

The mechanism that has been proposed for the preparation of a catalytic layer by the conventional process is

$$\text{substrate} + \text{Sn(II)} \rightarrow \text{substrate}\cdot\text{Sn(II)} \quad [1]$$

$$\text{substrate}\cdot\text{Sn(II)} + \text{Pd(II)} \rightarrow \text{substrate}\cdot\text{Sn(IV)}\cdot\text{Pd(O)} \quad [2]$$

The palladium metal is then the catalyst for the metallizing bath. U.V. light has been presumed to cause oxidation of the Sn(II) to Sn(IV), preventing reaction [2] (formation of the Pd(O) catalyst) and hence preventing metallization (2, 4)

$$\text{substrate}\cdot\text{Sn(II)} + O_2 \xrightarrow{\text{u.v.}} \text{substrate}\cdot\text{Sn(IV)} \quad [3]$$

$$\text{substrate}\cdot\text{Sn(IV)} + \text{Pd(II)} \rightarrow \text{either}$$

$$(a)\ \text{no reaction} \quad [4]$$

$$\text{or}\ (b)\ \text{substrate}\cdot\text{Sn(IV)}\cdot\text{Pd(II)}\ \text{(which is noncatalytic)}$$

That this mechanism does not give the complete explanation was shown [1] when it was discovered that u.v. light could cause inhibition of the catalyst even when applied after the activation step. It was in order to further probe this mechanism that the following study was undertaken, involving use of acidic Sn(IV) solution as a sensitizing bath.

* Electrochemical Society Active Member.

Key words: electroless, sensitizer, tin (IV), photo selective.

Experimental

All chemicals were supplied by Fisher or Canlab, A.C.S. reagent grade, and were used without further purification.

Sensitizers.—The stock solution used in this work was made by dissolving 10g $SnCl_4\cdot 5H_2O$ in 10 ml concentrated HCl. To prepare a sensitizer bath, 2 ml of this stock solution were diluted to 200 ml using distilled water.

Substrate.—Glass slides were allowed to stand overnight in 10M NaOH, rinsed well with distilled water, dilute HCl, then distilled water and dried.

Activator.—1g $PdCl_2$ was dissolved in 10 ml concentrated HCl to make the stock solution. One ml of this was diluted to 200 ml for the activator bath.

Mixed Sn(IV)·Pd(II) bath.—One ml Sn(IV) stock solution plus 0.5 ml Pd(II) stock solution was diluted to 100 ml with distilled water.

Ni-P bath.—The nickel-plating bath consisted of 5.8g $NiSO_4\cdot 6H_2O$, 3.5g $NaH_2PO_2\cdot H_2O$, 2.9g disodium succinate, and 0.2g succinic acid dissolved in distilled water to make a 200 ml solution.

Cu bath.—Solution A consisted of 8g $CuSO_4\cdot 5H_2O$, 20g Rochelle's salt, and 5.6g NaOH dissolved in enough distilled water to make a 200 ml solution. Solution B consisted of 13g paraformaldehyde and 8.6g NaOH dissolved in enough distilled water to make a 200 ml solution. Two to three parts A were added to one part B to make the copper-plating bath.

Test for Sn(II).—A molybdate solution was prepared by dissolving 15g $(NH_4)_2MoO_4$ in 300 ml warm distilled water. The solution was cooled and 350 ml concentrated HCl was added. The cooled solution was diluted to 1 liter and stored in the dark.

A phosphate solution was prepared by dissolving 0.426g $(NH_4)_2HPO_4$ is distilled water and diluting to 1 liter.

For each test, 1-5 ml of tin(II) solution (ranging in concentration from 5 to 0.078 g/liter) was added to a freshly made mixture of 10 ml molybdate solution, 10 ml phosphate solution, and 20 ml distilled water. This solution was diluted to 50 ml, and a visible spectrum was recorded with a Cary-14 spectrophotometer as soon as possible. We were able to detect concentrations of Sn(II) as low as 3 mg/liter. This procedure is a slight modification of that described in Ref (5).

Exposure system.—The samples were exposed typically for 6 min to u.v. radiation from an Oriel low pressure mercury lamp Nr. C-13-61 at a distance of about 4 cm. Based on factory specifications, our luminance was calculated to be 1.17 mW/cm^2 at the $\lambda = 2537Å$ spectral line. This one is the dominant spectral component of the radiation from this particular light source. The masks used were Nichrome evaporated onto quartz, etched metal sheet, or simply opaque material supported over half the sample.

Procedure.—All solutions were used at room temperature. A slide was immersed in the sensitizer bath, the first distilled water rinse, and the activator bath for 2 min each. The slide was quickly dried in a hot airstream and irradiated with u.v. light for 6 min followed by a rinse in running distilled water. Times in the metallizing bath varied.

For some experiments, the drying and irradiation steps were performed either after the sensitizer bath, after the first rinse, or after the second (running water) rinse.

Results

Aging of Sn(II) sensitizer.—It has been observed that use of aged $SnCl_2$ solution as the sensitizer results in better plating (6). "Aging" involves oxidation of the Sn(II) to Sn(IV) by atmospheric oxygen and subsequent colloid formation (7, 8). Adding $SnCl_4$ to the sensitizer has also been tried (6, 9, 10) but no improvement results unless the $SnCl_4$ is itself aged (11-13).

It has been hypothesized that aged Sn(IV) forms a colloidal dispersion which entraps Sn(II) ions. The latter has been presumed to be the active agent in the sensitizing process. According to Feldstein (11-14), an aged Sn(IV) component is adsorbed onto the substrate, and the Sn(II) attaches to the Sn(IV).

It has been noted (4) that, at least in the case of copper plating, oxygen is a prerequisite for the deactivation of fresh sensitizer by u.v. light (see Eq. [3]) and that no plating is obtained with aged sensitizer unless there is still some Sn(II) present (8). However, we obtained good Ni-P plating using a Sn(II) solution which had been aged for three weeks and, therefore, presumably contained almost exclusively Sn(IV). Further, using the same sensitizer we were able to get u.v. inhibition of plating, resulting in a "positive" image, *i.e.*, a replica of the mask. In addition, we observed that u.v. deactivation of the catalyst even occurred in a pure nitrogen atmosphere. This means that our aged Sn(II) solution, which contains predominantly Sn(IV), was nevertheless still capable of interacting with Pd(II) to form a substance which catalyzes Ni-P plating. This substance is affected by u.v. irradiation, even in the absence of oxygen, in a way which destroys its ability to catalyze Ni-P plating.

Nickel plating with Sn(IV) sensitizer.—In order to clarify the role of Sn(IV) in the sensitizing procedure, we carried out a series of experiments using an acidic solution of $SnCl_4 \cdot 5H_2O$[1] as the sensitizer. From Table I it can be seen that a uniform deposit is obtained only if the age of the sensitizer solution is between 20 and 45 hr. This is evidently associated with better wetting of the substrate; for sensitizer ages outside this range, nonuniform plating due to uneven drying is observed. This observation is in agreement with that of Feldstein *et al.* (11) relating aging of Sn(IV) solution with better wetting.

[1] The test for Sn(II) described in the experimental section was employed to determine if any Sn(II) was present in the Sn(IV) solution or in our three-week-old Sn(II) solution. Both tests were negative, indicating that there was less than 3 mg/liter Sn(II) in both solutions.

Table I. Effect of aging Sn(IV) sensitizer on nickel plating

Appearance of sensitizer	Age of sens. ($T \sim 21°C$)	Quality of plating
Clear	0-1½ hr	Sometimes no plating. Otherwise nonuniform plating caused by uneven drying.
Clear	1½-11 hr	Nonuniform plating caused by uneven drying
Faintly hazy	12-21 hr	Transition to uniform
Opalescent	22-38 hr	Uniform plating
Cloudy	39-45 hr	Uniform plating
Cloudy to separating	After 45 hr	Nonuniform plating caused by uneven drying

The range in ages of the sensitizer during which uniform plating is observed is strongly affected by temperature. For example, if the room temperature is raised to 26°C, uniformity in plating is obtained for sensitizers 8-26 hr old. Lower temperatures have been observed to result in later times. Fortunately, higher temperatures also increase the rate of colloid formation, thus making the temperature effect quite visible. The appearance of the sensitizer bath is noted in Table I, because the correlation of the quality of plating with appearance of the sensitizer is better than that of the quality of plating with time, especially when fluctuations in room temperature are a problem.

When more stock solution was used in making the sensitizer bath, thus increasing not only the Sn(IV) but also the hydrochloric acid concentration, the evolution process shown in Table I was slowed. For instance, when the quantity of stock solution was increased by 30%, it required about 30% more time before smooth plating was observed.

Both the uniform and nonuniform plating are quite adherent to glass substrate. Once the samples are thoroughly dry, they are unaffected even by scrubbing with a brush.

U.V. inhibition of nickel plating.—If the substrate is dried and irradiated with u.v. light after the activation step or after the subsequent rinse, deposition of nickel is inhibited (see Table II). The effectiveness of the inhibition shows the same dependence on sensitizer age that the uniformity of plating does; that is, the most effective inhibition is obtained if the sensitizer is aged between 20 and 45 hr at an ambient temperature of 21°C. The sensitizer solutions appears faintly hazy to cloudy when it is capable of producing best "positive" images, *i.e.*, replication of the photomask.

If in preparing the sensitizer bath additional HCl is used, the period of optimum photo-imaging is postponed considerably. The colloid also takes longer to

Table II. Results of drying and u.v. irradiation at different stages of the stepwise procedure for electroless deposition

		Ni-P	Cu
Drying and irradiation after:			
Sensitizer Sn(IV) ~24 hr old			
	u.v.	Plating	No plating
	No u.v.	Plating	No plating
Rinse H_2O			
	u.v.	Plating	No plating
	No u.v.	Plating	No plating
Activator Pd(II)			
	u.v.	No plating	Plating
	No u.v.	Plating	No plating
Rinse H_2O			
	u.v.	No plating	Pating
	No u.v.	Plating	No plating

appear. Hence, the correlation between appearance of the solution and its ability to produce good positive images still holds. However, it should be stressed that even during the period of optimum performance of the sensitizer, no inhibition is observed if drying and irradiation occur following sensitization or following the subsequent rinse (see Table II).

Copper plating.—D'Amico and DeAngelo observed (8) in their work that appreciable amounts of Sn(IV) were deposited on their substrate after immersion in a Sn(IV) sensitizer. Nonetheless, after activation and immersion in a Cu-plating bath, they observed no metallization. We also observed that copper does not plate under these conditions. However, when hot air drying and irradiation follow either the Pd(II) activation step or the second rinse, we observed copper plating on the u.v. irradiated areas. That is, a perfect negative results (see Table II). These negatives are only observed when the sensitizer is of the right age to also give good Ni-P positive images. Again, under these circumstances, we find that no plating at all is observed if irradiation follows Sn(IV) sensitization or the first rinse.

Mixed sensitizer-activator.—An acidic solution containing the same amount of Sn(IV) as in the sensitizer and the same amount of Pd(II) as in the activator was prepared as described in the experimental section. The variation observed in quality of plating and in imaging as the sensitizer-activator solution aged was as would be expected for the Sn(IV) sensitizer alone, especially if allowance is made for the delaying effect of slightly increased acidity. That is, the presence of the Pd(II) does not seem to alter the aging process of the Sn(IV). We find that good Ni-P positive images and good Cu negative images are obtained when hot air drying and u.v. irradiation are applied following immersion in the sensitizer-activator solution which has been aged from 24 to 48 hr.

Discussion

Aging of Sn(IV) solutions.—$SnCl_4 \cdot 5H_2O$ is a covalent compound and requires a period of time before most or all the chlorine is present as chloride ions free in solution. This period of time has been known for about 70 years to be a function of many parameters, such as temperature, concentration, and hydrochloric acid concentration. The rate of the reaction is increased by increasing temperature, decreasing $SnCl_4 \cdot 5H_2O$ concentration, and decreasing hydrochloric acid concentration. It has already been noted here and in Ref. (11) that these parameters also affect the length of time required for onset of optimum performance of the sensitizer, and in the same way. Thus the photosensitive species which may also be the one responsible for good wetting (hence uniform plating) must be one of the products of the reaction of water with $SnCl_4 \cdot 5H_2O$.

The mechanism assumed for the hydrolysis of $SnCl_4 \cdot 5H_2O$ can be represented as (15)

$$SnCl_4 \cdot 2H_2O \underset{}{\overset{-H^+}{\rightleftharpoons}} SnCl_4(H_2O)OH^-$$

$$\overset{-Cl^-}{\rightleftharpoons} SnCl_3(H_2O)OH \overset{+H_2O}{\rightleftharpoons} SnCl_3(H_2O)_2OH$$

$$\overset{-H^+}{\rightleftharpoons} SnCl_3(H_2O)(OH)_2^- \ldots SnCl(OH)_4(H_2O)^-$$

$$\overset{-Cl^-}{\rightleftharpoons} Sn(OH)_4(H_2O) \overset{H_2O}{\rightleftharpoons} Sn(OH)_4(H_2O)_2$$

$$\searrow \qquad \swarrow$$

$$[Sn(OH)_4(H_2O)]_x$$

The species of interest is one toward the end of the hydrolysis reaction, as indicated by the fact that some colloidal polymeric species is present in the solution when good wetting is observed. The improved wetting observed by Feldstein *et al.* (11) with aged $SnCl_4$ solution was attributed to "a β-stannic acid," which would correspond to our $[Sn(OH)_4(H_2O)]_x$. They picture this species as $(HO)_3Sn[OSn(OH)_2]_nOH$, where n may be 1, 2, 3, etc.

Some background plating in the irradiated sections (indicating incomplete inhibition of Ni-P plating) and nonuniform plating both occur when the sensitizer solutions are very cloudy and beginning to separate. These facts suggest that the species that does not wet well and is not photosensitive is the polymeric $[Sn(OH)_4 \cdot H_2O]_x$, where x is relatively high. They also suggest that the species which does wet well and is perhaps also photosensitive could either be $SnCl(OH)_4(H_2O)^-$, $Sn(OH)_4 \cdot (1 \text{ or } 2)\ H_2O$, or $[Sn(OH)_4H_2O]_x$, where x is quite small. It is hoped that further study will clarify the nature of this species.

Activation chemistry.—As a result of the present work, we have been able to show that Sn(IV) can serve as an effective sensitizer for electroless plating. This we feel shows conclusively, as pointed out by us previously (1), that the effect of u.v. light cannot simply be explained by the mechanism shown in Eq. [3] and [4]. This mechanism requires that Sn(IV) which results from photo-oxidation of Sn(II) be incapable of interacting with Pd(II) to give a catalytic species. Our present experimental results indicate at the very least that the interaction between Sn(IV) bound to the substrate and Pd(II) results in a species that is catalytic for Ni-P plating.

Our present results also indicate that the activation stage cannot be accounted for simply in terms of the redox reaction between Sn(II) and Pd(II) (Eq. [2]). It is well known that some Sn(IV) is present in Sn(II) sensitizer solutions, and we have shown that this Sn(IV) is also capable of reacting with Pd(II) to form a catalyst for Ni-P. Recently Kelly and Vondeling (16) reported that the Pd(II) present on their TiO_2 bound to quartz was also capable of giving rise to metal plating "in certain cases." They suggest that the reducing agent in the metallizing bath reduces the Pd(II) to Pd(O), thus creating nucleation centers for plating. If this explanation is applicable to our case, it would appear from our results that the reducing agent, $H_2PO_2^-$, present in the Ni-P bath, is capable of reducing the bound Pd(II) to Pd(O), but formaldehyde, the reducing agent present in the copper bath, is not. It is also possible that there is a specific interaction between Ni(II) and the species resulting from the interaction between Sn(IV) and Pd(II), which might be designated substrate·Sn(IV)·Pd(II), that initiates the plating, and that Pd(O) is not necessary for catalyzing Ni-P plating.

Our work shows that the species substrate·Sn(IV)·Pd(II) must also be affected by u.v. light in such a way as to render it noncatalytic for Ni-P plating but still catalytic for Cu plating. Kelly and Vondeling further indicate that u.v. irradiation of TiO_2 renders it capable of reducing Pd(II) to Pd(O). The mechanism for this has been discussed by Mollers *et al.* (17). Kelly and Vondeling also note that copper will plate on these Pd(O) nuclei, but that Ni-P will do so only under very specific conditions, *i.e.*, if a wetting agent was present in the Pd(II) solution or if the irradiation time was "not too long." The similarities between our results and theirs suggest strongly that the role of SnO_2 in substrate·Sn(IV)·Pd(II) is very similar to that of TiO_2 in the system $TiO_2 \cdot Pd(II)$.

The work on TiO_2 suggests that the Pd(O) minimum coverage must be higher for Ni-P plating than for copper plating. Our previous work (1) on irradiation of the catalytic species present after the conventional activation step indicated that irradiation results in increased degree of crystallinity. It would appear from this and our present work that the more crystalline Pd-containing material is incapable of catalyzing

Ni-P plating. Thus it may be possible that the effect of u.v. radiation on the catalyst may be to reduce the Pd(II) to Pd(O)

$$\text{substrate}\cdot\text{Sn(IV)}\cdot\text{Pd(II)} \xrightarrow{\text{u.v.}} \text{substrate}\cdot\text{Sn(IV)Pd(O)} \quad [5]$$

In addition, it may decrease the density of noncrystalline Pd(O) sites below the threshold for Ni-P but not for Cu. It might also be possible that Pd(O) in this form is simply incapable of initiating Ni-P plating.

The above also suggests a reason that good wetting of the substrate correlates with photosensitivity. Good wetting means a uniform distribution of catalyst sites, making it possible for irradiation to decrease the density of noncrystalline Pd(O) sites below the Ni-P threshold. The Sn(IV) species giving good wetting could be, as discussed in the section on aging, either $SnCl(OH)_4(H_2O)^-$, $Sn(OH)_4\cdot$(1 or 2)H_2O, or polymeric $[Sn(OH)_4H_2O]_x$, where x is quite small.

Conclusion

Sensitization with acidic Sn(IV) solutions followed by activation with a Pd(II) solution has been shown to catalyze Ni-P plating but not copper plating. The redox mechanism (Eq. [2]) that has been proposed [see Ref. (18)] to describe the reaction between Sn(II) and Pd(II) in the conventional activation step presumably has as its product substrate·Sn(IV)·Pd(O). Our experiments show that substrate·Sn(IV)·Pd(II) catalyzes Ni-P plating, and it is well known that Sn(IV) is present in Sn(II) sensitizer baths. It is, therefore, obvious that Sn(IV)-containing species must also be included as active components in mechanisms for sensitization and activation of Ni-P plating. However, nonirradiated substrate·Sn(IV)·Pd(II) does not catalyze copper plating and, therefore, can be left out of mechanisms leading to copper plating.

The mechanism (Eq. [3] and [4]) proposed (2, 4) to explain the inhibiting effect of u.v. light when Sn(II) is the sensitizer implies that substrate·Sn(IV)·Pd(II) must be incapable of catalyzing metal plating. Our observation that substrate·Sn(IV)·Pd(II) does catalyze Ni-P plating seems to contradict this mechanism, at least in this simplified form. On the other hand, our copper plating results do not seem to contradict the mechanism in Eq [3] and [4].

Using a mixed Sn(IV) sensitizer-Pd(II) activator bath gives the same results as when these baths are separate. Drying and u.v. irradiation following immersion in this bath results in positive Ni-P images and negative Cu images.

Our experiments to date indicate the following procedure should be followed in order to obtain the best imaging with Ni-P plating using $SnCl_4\cdot5H_2O$ in the sensitizer bath. A clean, dry microscope slide is immersed first in an acidic (8.3×10^{-2}M HCl) tin (IV) chloride (2×10^{-2}M) solution that is between 20 and 45 hr old (for room temperature about 21°C). After the rinse and activation steps, the slide is dried in a hot airstream and irradiated with u.v. light through an appropriate mask. After a running water rinse and plating in a Ni-P metallizing bath, striking positives are obtained.

A Thermodynamic Study of the $PbO\text{-}Na_2O\text{-}SiO_2$ System

A. E. Grau and S. N. Flengas*

University of Toronto, Department of Metallurgy and Materials Science, Toronto, Ontario, Canada

ABSTRACT

The thermodynamic properties of PbO in the ternary melts $PbO\text{-}Na_2O\text{-}SiO_2$ have been investigated by using solid electrolyte galvanic cells of the type

$$\text{Ni, NiO} \left| \begin{matrix} ZrO_2 \\ CaO \end{matrix} \right| Pb_{(1)}, (PbO\text{-}Na_2O\text{-}SiO_2)_{(1)}$$

The results of this work, combined with those reported in previous publications from this laboratory (7, 23), cover the region of the ternary diagram lying between the $PbO\text{-}SiO_2$ side and the line joining the PbO corner with the sodium metasilicate compound. The results indicate that the addition of Na_2O to the melt produces a significant increase in the activity of PbO. This type of behavior has also been observed in other ternary silicate systems. The partial molar enthalpies of mixing of PbO show a marked tendency toward positive values for increasing contents of Na_2O in the solutions. This is interpreted as the presence of repulsive interactions between the PbO and Na_2O components. A comparison of the available activity data for various metal oxides dissolved in sodium disilicate is presented.

The experimental thermodynamic study of molten silicates is difficult. Because of the very high temperatures involved, the choice of techniques is drastically reduced, and the problem of finding a container which will not contaminate the slag becomes critical. The only binary systems for which activity data have been directly determined are the $FeO\text{-}SiO_2$ (1-3), $PbO\text{-}SiO_2$ (4-9), $MnO\text{-}SiO_2$ (10), and $CoO\text{-}SiO_2$ (11). In the last two cases, however, the activities of the metal oxide component have been referred to the solid oxide as the standard state, and their expressions with respect to the liquid oxide cannot be accurately recalculated because of the lack of data for both the enthalpies of fusion and the heat capacities of the liquid metal oxides. Activities of SnO in the $SnO\text{-}SiO_2$ system have been reported in three different publications (12-14), but the results are in total disagreement. Reliable data for the enthalpies and entropies of mixing in binary silicates are available for the $PbO\text{-}SiO_2$ system only (7, 15).

Regarding ternary silicate melts, activity data are available for the systems $FeO\text{-}CaO\text{-}SiO_2$ (16, 17, 18), $MnO\text{-}CaO\text{-}SiO_2$ (10), and $PbO\text{-}CaO\text{-}SiO_2$ (19). Other systems such as $NiO\text{-}Na_2O\text{-}SiO_2$ (20), $FeO\text{-}Na_2O\text{-}SiO_2$ (21), and $CoO\text{-}Na_2O\text{-}SiO_2$ (22) have been investigated only over very narrow composition ranges along the line joining the divalent metal oxide corner of the ternary diagram with the sodium disilicate compound. Systematic determinations of the enthalpies and entropies of mixing in ternary systems are unavailable in the literature.

In the present study, the thermodynamic properties of the $PbO\text{-}Na_2O\text{-}SiO_2$ system have been investigated by employing solid electrolyte galvanic cells of the type

$$\begin{matrix} (-) \\ \text{Ni, NiO} \end{matrix} \left| \begin{matrix} ZrO_2 \\ CaO \end{matrix} \right| \begin{matrix} (+) \\ Pb_{(1)}, (PbO\text{-}Na_2O\text{-}SiO_2)_{(1)} \end{matrix} \quad [1]$$

The cells were operated over a sufficiently wide temperature range in order to allow the calculation of not only the activities of PbO but also the partial molar enthalpies and entropies of solution of this component.

Experimental

The experimental electrochemical cell used in this investigation is shown in Fig. 1, and its design was very similar to that previously used in this laboratory for the investigation of the thermodynamic properties of a number of metal oxides (23).

The most important part of the cell was a 24 in. long tube of ZrO_2 stabilized with 5% CaO, commercially available from the Zirconium Corporation of America. The tube had one closed flat end, an inside diameter of 3/8 in., and an outside diameter of 1/2 in. Although the imperviousness of the tube is certified by the manufacturing company, it was subjected to helium leak detection tests in this laboratory using a Veeco Mass Spectrometer Leak Detector.

The reference electrode consisted of a mixture of Ni and NiO powders placed in a ceramic crucible at the bottom of the assembly. The electrical connection for this electrode consisted of several pieces of spectrographically pure nickel wire approximately 1¼ in. long.

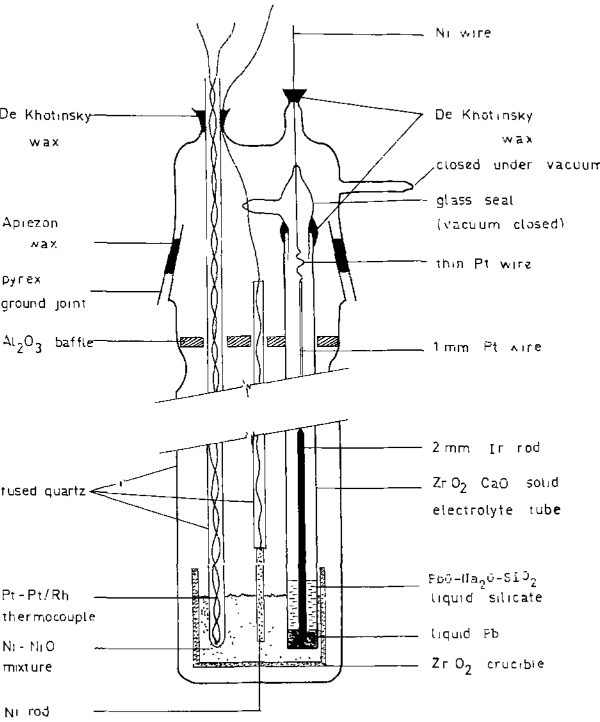

Fig. 1. Schematic diagram of "closed" solid electrolyte cell

* Electrochemical Society Active Member.

Key words: $PbO\text{-}Na_2O\text{-}SiO_2$ system, emf silicate melts, silicate thermodynamic data.

The nickel wire was welded to a platinum wire 0.020 in. in diameter which was insulated by means of an alumina tube and served as a lead wire to the potentiometer.

In some preliminary experiments, a $Pt,O_{2(1\ atm)}$ electrode was used as the reference. However, the large oxygen chemical potential difference created across the solid electrolyte appeared to cause the permeability of this membrane to non-ionic oxygen, especially at high temperatures. This nonelectrochemical transfer of oxygen should explain the observed time dependence of the cell emf's when such a reference electrode was used. This phenomenon has also been reported in other publications (24, 25). The effect of oxygen permeation was unnoticeable when the low oxygen partial pressure electrode Ni/NiO was introduced.

Lead of 99.999% purity and the crushed ternary silicate were loaded inside the ZrO_2-CaO tube. The electrical connection for this electrode was made by means of a 6 in. long iridium wire, 2 mm in diameter, partially immersed in the metal phase. Other metals like platinum or stainless steel were found to alloy with Pb. The iridium wire was welded to a platinum wire of 0.040 in. in diameter which was insulated with a fine alumina tube and brought to the upper part of the assembly to serve as the second lead wire to the potentiometer. The ZrO_2-CaO tube was evacuated to 10^{-5} atm and its open end closed under vacuum by means of a glass seal and "De Khotinsky" medium cement as indicated in Fig. 1.

Temperature measurements were made by means of a Pt/Pt-13% Rh thermocouple properly insulated and placed inside a 6 mm ID quartz tube closed at the lower end.

The entire cell was contained in a quartz tube of 45 mm ID with a closed flat end. A 50/60 quartz ground joint allowed the coupling of the quartz tube to the air-cooled Pyrex cap. This coupling was vacuum-sealed with Apiezon cement. The complete assembly was evacuated to 10^{-5} atm and sealed under vacuum.

The alumina disk shown in Fig. 1 served both as a spacer and as a radiation baffle.

The bottom of the cell was placed in the 2 in. long constant temperature zone of a vertical furnace. The temperature was controlled within $\pm 1°K$ by means of a Brown Pyr-O-Vane controller from Honeywell Instruments. A grounded Inconel sheath was placed between the cell wall and the furnace tube to eliminate induced currents from the a-c field of the furnace windings.

The emf's originating from the Pt/Pt-13% Rh thermocouple were measured with a Leeds and Northrup K-3 potentiometer with the same furnace and over-all geometric arrangement. Corrections had to be applied for the use of cold junctions (44°C). All thermocouples used were standardized with respect to a calibrated couple.

Cell emf's were registered by means of a Keithley digital multimeter, Model 160, with an accuracy of $\pm 0.1\%$ of recording. Polarization currents in such instruments are negligible. All cell emf readings were corrected for thermal emf's measured separately. Such corrections were of the order of 3 mV.

The main characteristic of the cell design described above is that the electrode compartments are completely isolated from each other, so that the only mass transfer which can take place between the electrodes is the electrochemical transfer of oxygen ions across the solid electrolyte. Since there is no gas diffusion from one electrode to the other, the oxygen partial pressure in each compartment reaches the equilibrium value, and both electrodes behave as closed thermodynamic systems. This type of cell is known as a "closed cell" and has been shown (23) to be free of mixed potential effects which are inherent in "open" type cells.

The system was systematically investigated along the three lines joining the PbO corner of the ternary diagram with the sodium metasilicate, sodium disilicate and sodium trisilicate compounds. The compositions investigated are shown in Fig. 2. The shadowed area indicates the part of the phase diagram covered by this work combined with the work of Charette and Flengas (7) for the $PbO-SiO_2$ binary system.

The method adopted for the preparation of the slag samples was to prepare first the pure sodium silicate and then melt it with the amounts of PbO corresponding to the desired ternary compositions.

Na_2O (in the form of Na_2CO_3 anhydrous) and SiO_2 (obtained by dehydrating H_4SiO_4 at 1250°-1300°K for 18-24 hr) were mixed in the proportions corresponding to the meta-, di-, and trisilicate. Each mixture was loaded into a large platinum crucible and heated slowly to about 1073°K in order to allow the decomposition of the carbonate. After a few hours, the temperature was raised to well above the melting point of the silicate and the sample left for 18 hr or so in order to assure its homogeneity. After this period of time, the crucible was removed from the furnace and cooled, with its contents, in a dessicator. When the presence of CO_2 bubbles or undissolved material was considerable, the silicate was ground and remelted in the same platinum crucible. The preparations obtained were finely ground and stored in a dessicator. Usually, about 50g of the sodium silicate was prepared at a time.

Both the sodium disilicate and sodium trisilicate formed colorless glasses while the metasilicate was obtained as a white nonglassy material.

For the preparation of the ternary slags, the sodium silicates were mixed with yellow PbO in the amounts corresponding to 10g samples. The mixtures were placed in small platinum crucibles provided with an alumina lid and introduced into a furnace preheated to about 1273°K where they were kept for 30 min.

After this time the slags were cooled, ground, and stored in a dessicator. The slags were homogeneous and yellow in color, the intensity of the color varying according to the PbO content. Some PbO volatization was evidenced by a very light yellow deposit on the alumina lid. most of which may have been produced before the PbO dissolved in the slag. As indicated in Fig. 2, most of the compositions formed clear glasses upon solidification.

Five different samples were analyzed for PbO by dissolving the silicates in concentrated H_2SO_4 and HF and evaporating to fumes to expel the silicon tetrafluoride. Pb was precipitated as $PbSO_4$, which was filtered, washed, dried at 120°C, and finally weighed. The results agreed very well with the compositions calculated on weighing.

The electrochemical cells were operated on temperature cycles to a maximum of about 1273°K. Cell emf's

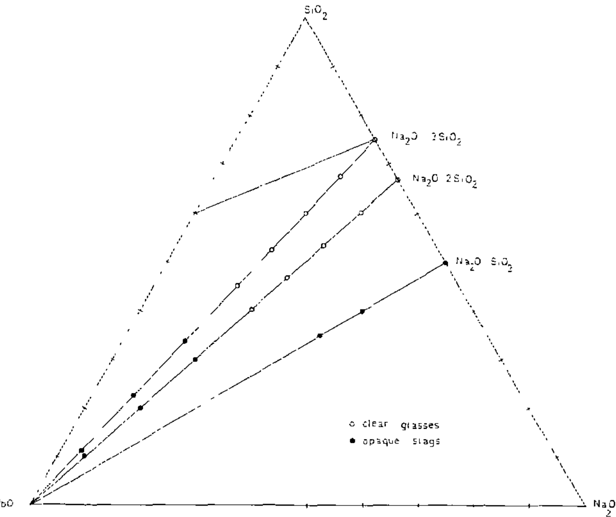

Fig. 2. Ternary compositions investigated

were read every 30° or 40°K and only when stable, so that the time between readings was usually 1-2 hr. The behavior of the cells may be described as follows:

(*a*) Cells containing PbO dissolved in either the sodium di- or trisilicate. They were run for period of at least 48 hr and in some cases up to 120 hr. The emf's were totally reproducible on repeated temperature cycling over an interval of about 250°K. After disassembling the cells, the following observations were always made: (*i*) The Ni-NiO mixture that served as the reference electrode formed a compact mass around the electrolyte tube and provided a very steady electrical contact. (*ii*) The Ir rod immersed in the silicate melt was unaffected by either Pb or the liquid slag. (*iii*) The ZrO_2-CaO solid electrolyte tube did not show any effect of a possible interaction with the silicate melt. A barely visible yellow deposit on the inner wall at the bottom of the tube indicated some slight volatility of the PbO.

(*b*) Cells containing PbO dissolved in sodium metasilicate. These cells produced stable emf's during a period of 4-6 hr, after which time the emf fell to very low and unstable values. When the cells were disassembled, the lower part of the ZrO_2 tube was totally cracked and the liquid silicate had leaked to the outside of the tube. It was evident that the attack on the electrolyte was due to the higher concentration (and therefore higher activity) of the Na_2O in the solution. Na_2O shows a tendency to escape from the metasilicate in the form of a vapor which later decomposes in Na atoms and oxygen molecules (26). The small atoms of Na may then diffuse into the solid electrolyte causing its weakness and the eventual cracking.

Results

The temperature dependence of the cell emf for all the slags investigated is shown in Fig. 3, 4, and 5. Figures 3 and 4 show the results obtained for compositions along the lines $PbO\text{-}Na_2O \cdot 3SiO_2$ and $PbO\text{-}Na_2O \cdot 2SiO_2$, respectively, while Fig. 5 refers to compositions along the line $PbO\text{-}Na_2O \cdot SiO_2$. In the last case because of the problem discussed above, only two compositions could be investigated. Other runs failed before producing any acceptable results.

According to the phase diagram for the $PbO\text{-}Na_2O\text{-}SiO_2$ system due to Krakau and co-workers (27), reproduced in Fig. 6, the compositions $X_{PbO} = 0.70$ and $X_{PbO} = 0.85$ on the line $PbO\text{-}Na_2O \cdot 3SiO_2$ and also the compositions $X_{PbO} = 0.70$ and $X_{PbO} = 0.85$ on the line $PbO\text{-}Na_2O \cdot 2SiO_2$ lie in the stability field of PbO. This means that PbO is the first solid to appear during the cooling of the solutions and should be found in thermodynamic equilibrium with the PbO remaining in solution. These characteristics of this portion of the phase

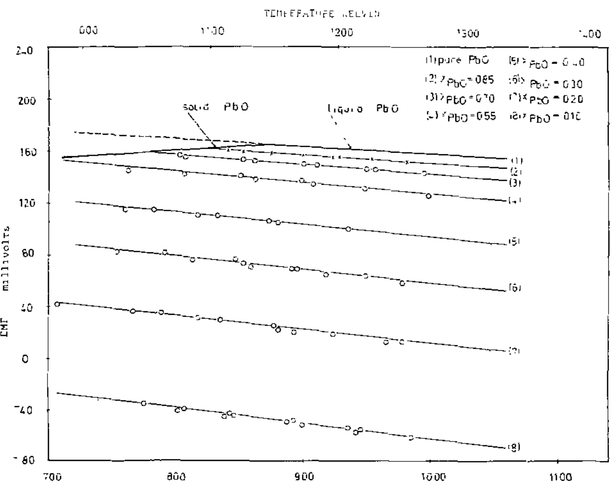

Fig. 3. Temperature dependence of emf for cell Ni, NiO/ZrO_2-CaO/Pb, $(PbO\text{-}Na_2O\text{-}SiO_2)_{Na_2O:SiO_2} = 1:3$.

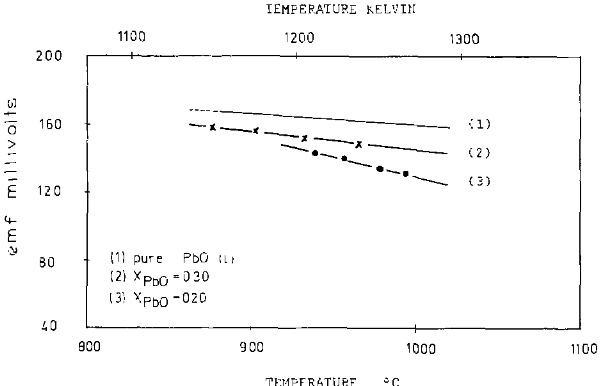

Fig. 5. Temperature dependence of emf for cell Ni, NiO/ZrO_2-CaO/Pb, $(PbO\text{-}Na_2O\text{-}SiO_2)_{Na_2O:SiO_2} = 1:1$.

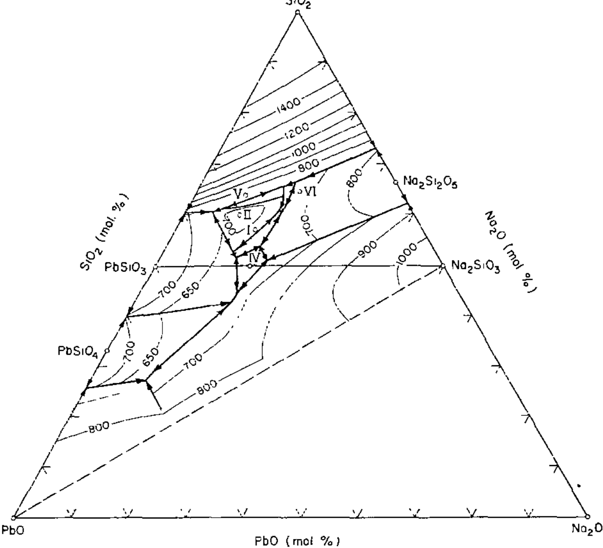

Fig. 6. Phase diagram of the $PbO\text{-}Na_2O\text{-}SiO_2$ system [Ref. (27)]

diagram should be reflected in the emf data obtained for the above-mentioned compositions in the following way: (*a*) The emf *vs.* temperature lines should intersect the pure solid PbO line at the freezing point, and (*b*) all emf measurements below the freezing point should be coincident with the line corresponding to solid PbO.

As may be seen in Fig. 7, this behavior was strictly followed by the experiments. The obtained freezing points are in good agreement with those indicated in

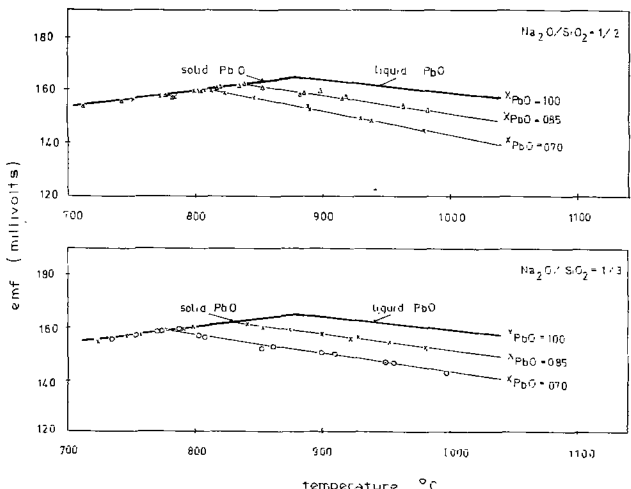

Fig. 7. Temperature dependence of emf for slags whose compositions lie in the stability field of PbO.

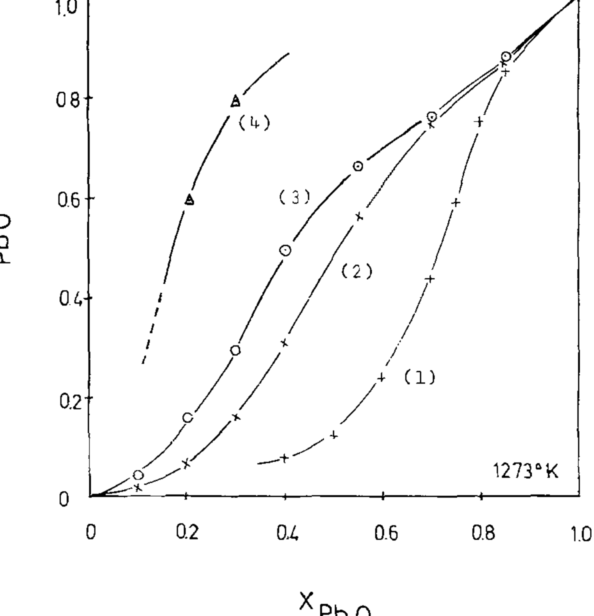

Fig. 8. Concentration dependence of the activities of PbO at 1273°K for various values of the ratio X_{Na_2O}/X_{SiO_2}.

Fig. 6, and the emf data for lower temperatures coincide almost exactly with the line for solid PbO. These facts were taken as an excellent test for the accuracy of the emf data.

Each set of results represented in Fig. 3, 4, and 5 was subjected to a least squares analysis using a standard computer program, and the resulting linear relationships between cell emf and temperature have been included in Table I together with their corresponding standard deviation.

Thermodynamic Calculations

Considering the polarity of the cells indicated in the schematical representation [1], the cell reaction may be written as

$$Ni_{(s)} + PbO_{(in\ slag)} \rightarrow NiO_{(s)} + Pb_{(l)} \quad [2]$$

and the activities of the PbO in the ternary melts (a_{PbO}) at T°K may be calculated from the equation

$$E = E° + \frac{RT}{2\mathbf{F}} \ln a_{PbO} \quad [3]$$

where R is the gas constant, $\mathbf{F}$ the Faraday constant, and E the measured cell voltage. $E°$ represents the emf of the cell in which the slag phase has been replaced by pure liquid PbO. $E°$ was calculated from the available emf data (23) for the cell reactions as

$$Ni_{(s)} + ½\ O_{2(1\ atm)} \rightarrow NiO_{(s)} \quad E°_{NiO} = 1210.8\text{-}0.4399T \text{ mV} \quad [4]$$

$$Pb_{(l)} + ½\ O_{2(1\ atm)} \rightarrow PbO_{(l)} \quad E°_{PbO} = 987.8\text{-}0.3894T \text{ mV} \quad [5]$$

$$Ni_{(s)} + PbO_{(l)} \rightarrow NiO_{(s)} + Pb_{(l)} \quad E° = 223.0\text{-}0.0505T \text{ mV} \quad [6]$$

Plots of the activity of PbO at 1273°K *vs.* the mole fraction of this oxide for different X_{Na_2O}/X_{SiO_2} ratios are shown in Fig. 8. It may be readily seen that, as the X_{Na_2O}/X_{SiO_2} ratio increases, the activity curves are consistently displaced toward more positive values. This observation follows the general rule for ternary silicate systems in the sense that the addition of a more basic metal oxide raises the activity of the other oxide in solution. The results plotted in Fig. 8 have also been used to obtain the isoactivity contours represented in Fig. 9 on an isothermal section of the ternary diagram at 1273°K.

From the analysis of the PbO activity data at different temperatures which are presented in Table II, it is readily concluded that the thermodynamic behavior of the solutions slowly approaches that of the ideal molecular model as the temperature increases. The knowledge of the temperature dependence of the activities of PbO was also used to calculate the partial molar enthalpies of mixing of liquid PbO, $\Delta \bar{H}_{PbO}$, by means of the van't Hoff equation

$$\frac{d(\ln a_{PbO})}{d(1/T)} = \frac{\Delta \bar{H}_{PbO}}{R} \quad [7]$$

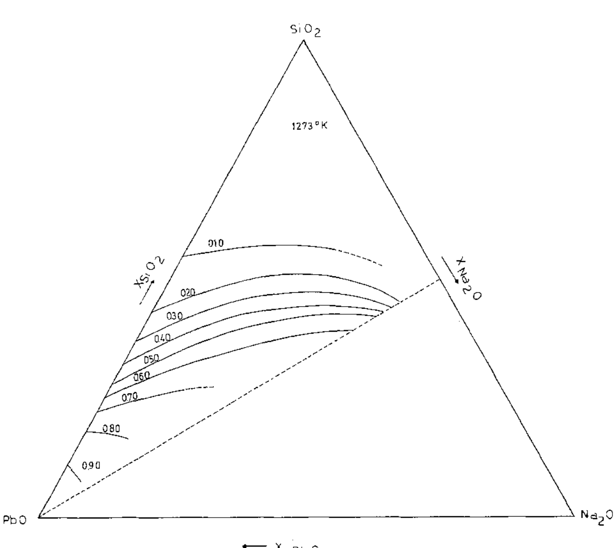

Fig. 9. PbO isoactivity lines at 1273°K

The concentration dependence of the partial molar enthalpies of mixing of liquid PbO dissolved in sodium silicates of different X_{Na_2O}/X_{SiO_2} ratios is shown in Fig. 10. It may be seen that the curves are of a rather unusual shape, going from negative to positive values and showing a minimum in the PbO-rich side of the diagram.

The partial molar entropies of mixing of liquid PbO, $\Delta\bar{S}_{PbO}$, were calculated from the standard expression

$$RT \ln a_{PbO} = \Delta\bar{H}_{PbO} - T\Delta\bar{S}_{PbO} \quad [8]$$

and the corresponding results are shown in Fig. 11. It may be noted that for the PbO-rich compositions, $\Delta\bar{S}_{PbO}$ increases as the silica content increases, and that this tendency is completely reversed as the PbO concentration decreases. In order to follow such a drastic change, the curve corresponding to the ratio $X_{Na_2O}/X_{SiO_2} = 1/2$, goes through a peak which is characteristic of the presence of important configurational contributions to the entropy of the system.

The numerical values for both the partial molar enthalpies and the partial molar entropies of mixing of liquid PbO have been included in Table III. Because of the experimental difficulties experienced with slags having the ratio $X_{Na_2O}/X_{SiO_2} = 1$, the results obtained in such cases should be taken only as approximated values. These values have not been reported in the plots presented in this paper.

Discussion

According to the general experimental evidence (10, 16-19), the addition of a more basic metal oxide $M_{II}O$ to a silicate solution containing a metal oxide M_IO,

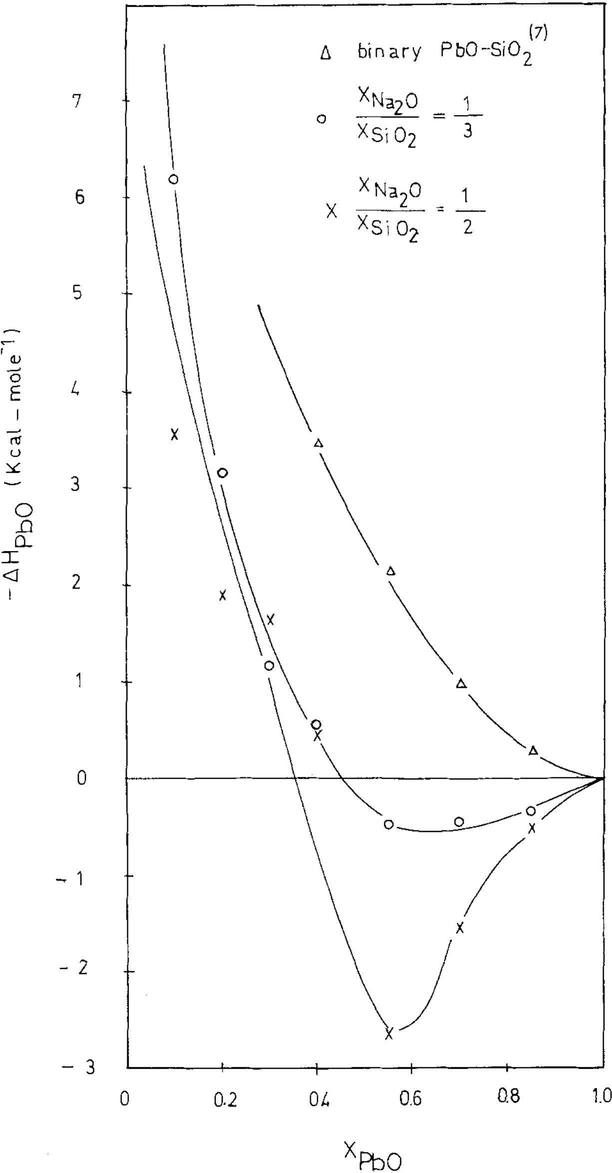

Fig. 10. Concentration dependence of the partial molar enthalpies of mixing of PbO for various values of the ratio X_{Na_2O}/X_{SiO_2}.

produces a rise in the activity of the latter. The explanation for this observation is that SiO_2 reacts with $M_{II}O$, so that the proportion of M_IO left "unreacted" is increased and its activity also increases. Accordingly, for a given temperature and composition of the ternary slag, the highest activity of M_IO is reached when the nature of the $M_{II}O$ component is such that it reacts completely with SiO_2. The phenomenon may be represented by the simplified reaction

$$\rightleftarrows O\text{—}Si\text{—}O \ldots M_{II} \ldots O\text{—}Si\text{—}O + M_IO \quad [9]$$

In the case of the $PbO-Na_2O-SiO_2$ system, it is seen in Fig. 8 that the activities of PbO show a significant in-

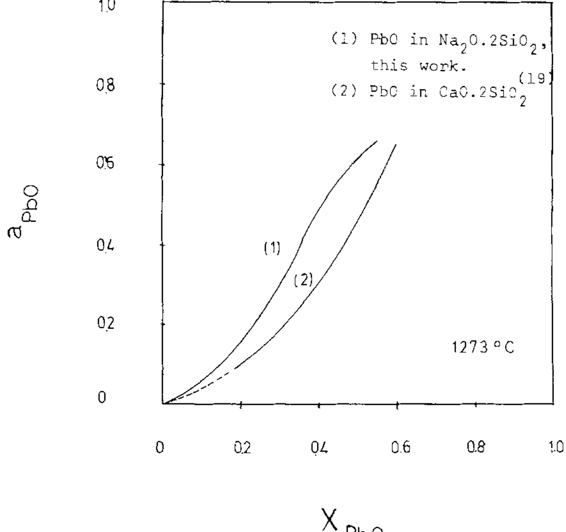

Fig. 12. Experimental concentration dependence of the activities of PbO dissolved in $Na_2O \cdot 2SiO_2$ and in $CaO \cdot 2SiO_2$ at 1000°C.

crease with increasing concentrations of Na_2O. Accordingly, the latter should be expected to behave as a highly reactive metal oxide with respect to silica. Since this characteristic is also a property of CaO, then the activities of PbO in the $PbO-Na_2O-SiO_2$ melts should not be dramatically changed by replacing the Na_2O component by CaO. The effect of this replacement is shown in Fig. 12, and it is interesting to note that Na_2O appears to be more efficient than CaO in raising the activity of PbO. This observation could be of some use in metallurgical processes involving slag-metal reactions and where the recovery of a metal from the slag is largely affected by the activity of the corresponding metal oxide in this phase. However, from the available experimental data, it is not clear that this observation can be extended to systems containing metal oxides other than PbO.

The high escaping tendency of PbO from the $PbO-Na_2O-SiO_2$ solutions seems to be partially caused by the existence of repulsive interactions between the PbO and Na_2O components. This interpretation is suggested by the marked tendency toward positive heats of mixing evidenced in Fig. 10 and is supported by the activity data for a number of metal oxides dissolved in sodium disilicate melts which have been summarized in Fig. 13. From the tendencies observed in binary silicate melts, these activities are expected to decrease in the order NiO-CoO-FeO-PbO. This sequence is respected by the oxides of the transition metals Ni, Co, and Fe. However, the activities of PbO are seen to be higher than those of CoO and FeO. It appears, therefore, that there exist strong interactions between PbO and Na_2O which are not comparable to similar interactions that may exist between the other metal oxides and Na_2O.

The activities of PbO in the PbO-Na_2O-SiO_2 system have also been measured by Esin and co-workers (28) by using an electrochemical cell of the type

$$\text{Pb, PbO} \mid \text{MgO} \mid \text{Pb, (PbO-Na}_2\text{O-SiO}_2) \quad [10]$$

where the electrical contact for the electrodes was provided by means of graphite rods. Their results, however, are in total disagreement with those reported in this paper. These authors found that the replacement of SiO_2 by Na_2O in the solutions (at constant mole fraction of PbO) results in a decrease of the activity of PbO. This is opposed to the behavior observed in the present work and in other thermodynamic investigations on ternary silicate melts (10, 16-19). Furthermore, the activities of PbO in the PbO-SiO_2 binary melts reported by Esin and co-workers (28) disagree completely with the well-established (4-9) concentration dependence of that property.

The reasons for the disagreement should be found in the experimental technique used by Esin. In the first place, it is now recognized that fused MgO is not a purely oxygen-ion conductor as it is in the case of the substitutional solid solutions ZrO_2-CaO, ThO_2-Y_2O_3, etc. Thus, the use of the MgO membrane may have introduced an important error in the measured cell emf's. The second source of error should be found in the use of graphite as the electrical connection for the electrodes, since this will result in a value of the oxygen partial pressure different from the equilibrium pressure that would coexist with pure liquid Pb and PbO in solution according to the reaction

$$Pb_{(l)} + \tfrac{1}{2} O_2 \rightleftarrows (PbO)_{\text{in slag}} \quad [11]$$

ABSTRACT

The apparatus and technique for making differential capacitance measurements on a dropping mercury electrode under computer control are described. Sample results for electrolyte solutions and for aliphatic alcohol solutions are presented. A comparison of interfacial tension and differential capacitance measurements, both under computer control, reveals a source of systematic error in differential capacitance measurements which has generally been ignored in the past. Theoretical and experimental results are used to argue that differential capacitance is not a suitable experimental route to electrosorption isotherms for organic compounds.

For many years it was generally believed that differential capacitance measurements at a dropping mercury electrode (DME) based on the a-c impedance bridge method originated in 1941 by Grahame (1) were inherently more accurate than electrocapillary measurements and were therefore the best source of reliable information about the structure of the electrical double layer. A few years ago, however, a computer-controlled capillary electrometer was developed in this laboratory (2, 3) which is much faster and easier to use than the manual a-c bridge, and which was shown to yield data which are quite comparable to the best which can be obtained from a bridge for simple salt solutions. In the case of organic compounds, this computer-controlled capillary electrometer yields superior data, one reason for which is the difficulty of properly correcting capacitance measurements for frequency dispersion (4-6). A careful recent study (7) has indeed shown that the 95% confidence limits of the interfacial tension measured by the computer-controlled capillary electrometer do not exceed 0.1 dyne cm^{-1} and are independent of electrode potential, which implies a relative precision of about 1 part in 4000. Nevertheless, it seemed to us that it was not really fair to compare capacitance measurements obtained with a manual a-c bridge with computer-controlled electrocapillary data. Therefore we have designed a computer-controlled differential capacitance measuring instrument. In this paper we report on the design and operation of this instrument, and we evaluate its performance by direct comparison of integrated differential capacitance curves with electrocapillary curves on the same solution obtained with the computer-controlled capillary electrometer. One result of this direct comparison is that we have found a source of systematic error in differential capacitance measurements which may be serious in certain cases and which has generally been ignored in the literature (8). This particular source of systematic error probably could not have been detected from manual bridge measurements, but it is easily made manifest when the measurements are computer controlled.

Experimental

Apparatus.—The a-c bridge was replaced by an operational amplifier potentiostat coupled with a phase sensitive current detector. This circuit was interfaced to a Digital Equipment Corporation (DEC) PDP-8/I minicomputer with 8K core and 32K fixed head disk. The potentiostat circuit was similar to that described by deLevie and Husovsky (9). The phase sensitive current detector consists of an operational amplifier current-to-voltage converter coupled to a commercially available phase-lock amplifier (Ithaco Model 353, with Type Dl display unit, Type Cl demodulator, Type Bl amplifier, and Type Hl oscillator). The 90° phase angle switch on the front panel of the Type Cl demodulator was replaced by a mercury-wetted relay operating under computer control. A block diagram of the complete apparatus is shown in Fig. 1.

The d-c potential signal is supplied to the potentiostat by a 12-bit D/A converter on software command. The potentiostat input has a standard adder configuration. In addition to the d-c signal from the D/A converter, a d-c bias supply can be connected to the potentiostat input to permit the d-c potential of the electrode to be offset. The low frequency a-c signal for the capacitance measurements is supplied from the Type H1 oscillator, and the input resistance is normally chosen so that the controlled a-c potential of the electrode has an amplitude of 5 mV peak-to-peak. This same a-c signal from the Type H1 oscillator is connected to the reference input of the Type C1 demodulator to serve as the phase reference signal for the phase-lock amplifier. A second, high frequency (10 kHz), a-c oscillator can be connected to the potentiostat input via a computer-controlled mercury-wetted relay. This 10 kHz signal is connected to the DME momentarily before natural drop fall. The resulting 10 kHz a-c current is input to a birth detector

Key words: electrosorption, surface excess, electrocapillarity, dropping mercury electrode.

circuit similar to that described for the computer-controlled capillary electrometer (2). The birth detector circuit produces a sharp voltage pulse when the drop falls. This voltage pulse, signalling the beginning of a new drop, is input to the computer interface to start the programmable real-time clock which is used for timing the capacitance measurements. During capacitance measurement, the 10 kHz signal is disconnected from the potentiostat input by opening the relay contacts. The a-c current resulting from the 5 mV peak-to-peak controlled a-c potential is detected by a current-to-voltage converter whose output is input to the Type B1 amplifier of the Model 353 phase-lock amplifier system. This lock-in amplifier can be set by software command to detect either the in-phase or the 90° out-of-phase (quadrature) component. The output of the phase-lock amplifier is passed through a 50 Hz third-order Butterworth low-pass filter (10) into a Philbrick Model 1700 chopper stabilized operational amplifier which scales the signal appropriately and passes it to the sample-and-hold amplifier of the 12-bit A/D converter of the computer interface.

The three-electrode potentiostat can be connected either to the electrochemical cell or to a dummy cell consisting of a standard resistor and standard capacitor in series. The dummy cell is used for initial phase adjustments on the demodulator to compensate for the natural phase shifts of the potentiostat and current amplifiers. It is also used to adjust the phase angle switching circuitry so that on computer command the phase can be switched from exactly in-phase to exactly 90° out-of-phase. Finally the dummy cell is used to determine the calibration constant which is stored in the memory of the computer and is used to calculate the series capacitance and series resistance of the electrochemical cell from the measured in-phase and quadrature components of the a-c cell current.

An x-y plotter (Hewlett Packard Model 7004A) is interfaced to the computer so that a graphical display of the differential capacitance curve may be obtained during measurements. The digital data are typed on the teletype and are also punched on high speed paper tape for subsequent data analysis.

Measurement procedure.—Each time the a-c frequency is changed it is necessary to adjust the phase compensation for the operational amplifiers and the 90° phase angle switching circuitry. In order to make these adjustments more exact and more convenient, two modifications were introduced into the Type C1 demodulator. First, the single-turn phase angle adjustment potentiometer on the front panel (resistor R1) was replaced by a 10-turn Helipot with Duodial. Second, the single-turn variable resistor in the 90° phase angle switching circuit (resistor R97) which was originally located on the printed circuit board of the C1 demodulator was replaced by a 25-turn trimpot on the front panel.

The demodulator is first adjusted to compensate for the natural phase shifts of the operational amplifier circuitry by using a purely resistive dummy cell. For this purpose the phase angle switch of the demodulator is set to detect the quadrature component which should be exactly zero for a purely resistive dummy cell, and the Helipot is adjusted until the A/D reading is exactly zero. Next a dummy cell is inserted with the series resistor and capacitor selected so that the phase angle for the chosen a-c frequency is exactly 45°. The in-phase and quadrature components for this cell should be equal. The computer switches the phase angle to read alternately both of these components, and the A/D readings are typed out on the teletype. If the two A/D readings are not equal, the 25-turn trimpot is adjusted until they are equal. Since there is an interaction between this adjustment and the phase compensation adjustment, the latter is rechecked. Usually after two or three trials the two adjustments can be set so that a purely resistive dummy cell gives a quadrature component which is exactly zero, and the dummy cell with 45° phase angle gives exactly equal in-phase and quadrature components. These two adjustments of the phase-lock circuitry, are vital for accurate differential capacitance measurements. They must be made every time the a-c frequency is changed, and even when one is operating at a single frequency they should be checked periodically.

The apparatus is calibrated using the same dummy cell with series standard resistance, R_{STD}, and standard capacitance, C_{STD}, so chosen that the phase angle is exactly 45°. For this purpose the computer first sets the phase angle switch of the demodulator to detect the current which is in-phase with the applied a-c potential and the voltage, V'_D, which corresponds to the in-phase dummy cell current is measured by the A/D converter. Then the computer switches the detected phase angle to exactly 90° out-of-phase and the corresponding voltage, V''_D, is read by the A/D converter. The calibration factor, K, for the measurements is then calculated from the values of V'_D and V''_D using the following formula which can be easily derived by standard a-c circuit analysis (11)

$$K = C_{STD}/[V''_D + (V'_D)^2/V''_D] = 1/(\omega R_{STD})[V'_D + (V''_D)^2/V'_D] \quad [1]$$

In Eq. [1] ω is the angular frequency of the applied a-c potential in radian sec^{-1}. In all experiments described here the a-c frequency was measured with a Monsanto Model 110B programmable counter-timer.

The measured series resistance, R_s, and series capacitance, C_s, of the electrochemical cell at any electrode potential and at any instantaneous time in the drop life of the DME can then be determined by the following equations

$$(1/R_s) = \omega K[V'_m + (V''_m)^2/V'_m] \quad [2]$$

$$C_s = K[V''_m + (V'_m)^2/V''_m] \quad [3]$$

In Eq. [2] and [3] V'_m and V''_m denote the instantaneous values of the voltages read by the A/D converter corresponding to the in-phase and quadrature components of the cell current, respectively. C_s in Eq. [3] is equal to the capacitance of the electrical double layer of the DME provided that the surface area of the DME is negligibly small in comparison with the area of the auxiliary electrode (1, 8). In the measurements reported here the DME was placed in the center of a platinized cylindrical platinum gauze auxiliary electrode whose surface area was much larger than that of the DME. The differential capacitance per unit area, C, of the double layer is obtained by dividing C_s by the corresponding instantaneous area of the DME.

The computer is programmed so that for each value of the d-c electrode potential the in-phase voltage, V'_m, and the 90° out-of-phase voltage, V''_m, are measured at any desired times in the drop life on each of two successive drops. The timing sequence of the measurements is illustrated schematically in Fig. 2. Just before natural drop fall, the programmable real-time clock is stopped and its counter is zeroed. The fall of the drop causes the birth detector to issue a pulse which starts the clock recording the time in the life of the next drop. The computer then disconnects the 10 kHz input to the potentiostat and switches the phase angle switch on the demodulator to read the quadrature component. After waiting a specified period of time (for example, 2 sec) which is controlled by software command, the value of V''_m is read any desired number of times determined by the programmable clock and stored in memory. Then the 10 kHz signal is reconnected to the input of the potentiostat, the clock is stopped, and its counter is zeroed. When

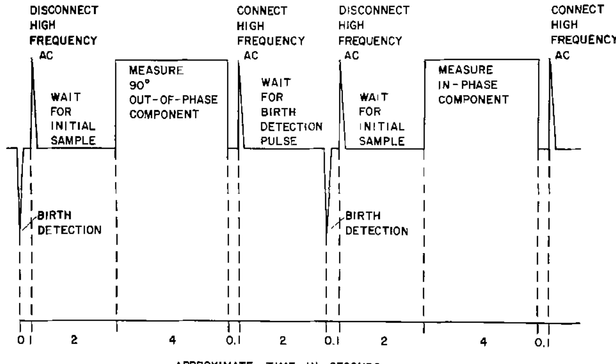

Fig. 2. Timing diagram for computer-controlled differential capacitance measurements.

the drop falls the clock is started again, the computer switches phase angle to in-phase, and after the same waiting period the value of V'_m is read at the same times in drop life as the V''_m readings, and the values are stored in memory. The d-c potential is then changed to the next value by the D/A converter, the 10 kHz a-c signal is connected again, and the sequence is repeated at the new electrode potential. After every two drops at a fixed d-c potential, the values of R_s and C_s are calculated for each of the times in drop life at which measurements were made by application of Eq. [2] and [3], and the differential capacitance, C, per unit area is calculated and plotted.

In the experiments described below the electrochemical cell and the calomel reference electrode were jacketed, and their temperatures were controlled at 25°C by pumping water from a thermostat through the jackets. The DME capillary was drawn from borosilicate glass to a fine tip, and the interior of the capillary was dewetted with the vapor of dichlorodimethvlsilane by the method described previously (3). After dewetting, the capillary tip was recut so that the end of the capillary was wet by water. The sodium sulfate was reagent grade and was used without further purification. The mercury was triple vacuum distilled. The water used to prepare solutions was distilled from alkaline permanganate and then redistilled to prevent carry-over of traces of permanganate. The 2-butanol was distilled, and its purity was verified by gas chromatography.

Results and Discussion

Electrolyte solutions.—It was decided that the best way to evaluate the performance of this instrument would be to compare directly the results of the capacitance measurements with electrocapillary measurements performed with the computer-controlled capillary electrometer on the same solution. Therefore we measured the differential capacitance of the DME in a solution of 0.05M sodium sulfate at 25°C. This solution is always used as the calibration solution for the capillary electrometer because an accurate, independent measurement by the sessile drop method of the interfacial tension of mercury at the electrocapillary maximum is available for it (12). Electrocapillary measurements were made on the same solution using the same reference electrode (a 0.1M KCl calomel electrode) employed in the capacitance measurements.

In the first experiments the computer was programmed to measure V'_m and V''_m at three different times 0.1 sec apart in the life of a drop, namely, 4.8, 4.9, and 5.0 sec. The area, A_{SPH}, of the electrode at each of these times was calculated, as in most published differential capacitance studies, by the following equation which assumes that the drop is spherical

$$A_{SPH} = (6m\sqrt{\pi}/d)^{2/3}t^{2/3} \quad [4]$$

In Eq. [4] m is the mass flow rate of the DME in g-sec^{-1}, d is the density of mercury at 25°C in g-cm^{-3}, and t is the time in seconds in the drop life of the measurement. The series capacitance, C_s, of the electrochemical cell, which is the same as the differential capacitance of the DME, was calculated by means of Eq. [3] and the corresponding value of the differential capacitance per unit area, C, was calculated by dividing C_s by A_{SPH}. The precision of the measurement appeared to be very good. At all electrode potentials the relative standard deviation of C determined from the measurements of C_s at the three different times was about 0.05%. The differential capacitance per unit area, C, was then doubly integrated as a function of electrode potential, E, to obtain the interfacial tension, γ, by application of the equation from the thermodynamic theory of electrocapillarity (13)

$$\gamma = -\int_{\gamma_{max}}^{\gamma}\int_{E_z}^{E} C\,dE\,dE + \gamma_{max} \quad [5]$$

where γ_{max} is the value of the interfacial tension at the electrocapillary maximum, and E_z is the potential of the electrocapillary maximum. The value of γ_{max} is 426.2 dyne cm^{-1} (12) at 25°C, and the value of E_z was determined by digital computer fitting of the directly measured electrocapillary curve using the previously published digital computer techniques (14, 15).

The results of this double integration, which are shown in Fig. 3, were disturbing. In this figure, the smooth curve is the double integral of the differential capacitance, and the points are the interfacial tensions measured directly with the computer-controlled capillary electrometer. Except for the electrocapillary maximum, where there is a forced fit, the double integral of the differential capacitance lies systematically above the directly measured values of γ, and the magnitude of this systematic error increases progressively as the potential differs more and more from E_z. In fact, it can be seen from Fig. 3 that on the far cathodic branch of the electrocapillary curve the systematic error approaches 2 dyne cm^{-1}, which is 20 times the 95% confidence limits of the direct measurements of γ with the computer-controlled cap-

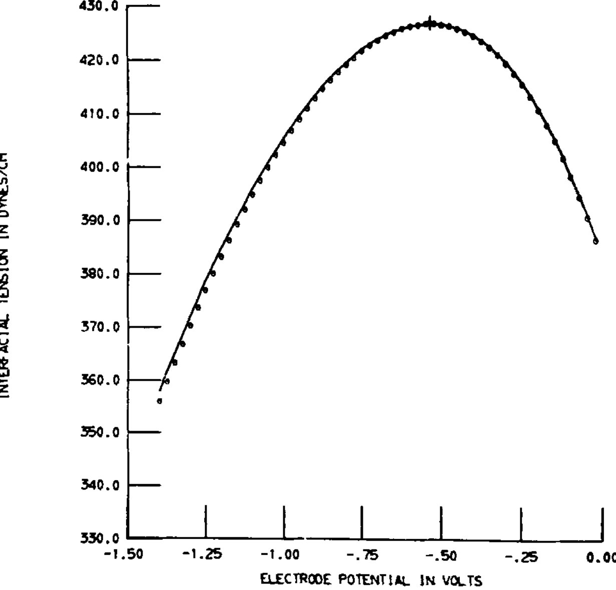

Fig. 3. Comparison of directly measured interfacial tension (circles) and doubly integrated differential capacitance (smooth curve) for 0.05M Na_2SO_4 at 25°C before correction for excluded area due to capillary orifice.

illary electrometer. Such large systematic errors, clearly, could lead to serious errors in determination of relative surface excesses from the slopes of plots of γ at constant electrode potential *vs.* chemical potential of adsorbate (13).

In searching for a source of this systematic error, we decided to try measurements of V'_m and V''_m at different times in the drop life. It was observed that when the time interval between measurements was increased the relative standard deviation of C, the differential capacitance per unit area, determined from three measurements on one drop, also increased. For example, when the interval was increased from 0.1 to 2.0 sec the relative standard deviation increased from about 0.05 to 1.0%. This fact led us to record the value of the apparent capacitance per unit area, C, separately for each time of measurement. It was found that the apparent value of C at any fixed electrode potential increased as the time of measurement, t, increased. Typical results are illustrated in Fig. 4. The top curve in this figure gives C for 7.0 sec, the middle curve is for 5.0 sec, and the lowest curve is for 3.0 sec in drop life. Since C must be independent of the actual area of the electrode, this result suggested that the difficulty might lie in our calculation of the area of the drop as a function of time.

In the literature (8), there are numerous discussions of two possible sources of error in determining the correct area of a DME. The first source of error is the variation with time of the flow rate of mercury, m, due to the back pressure resulting from the interfacial tension. The second source of error is nonspherical shape. According to Payne (8a), "The absolute accuracy of the capacity measurement may be no better than 1% because of these factors." However, there is one even more obvious source of error in the calculation of the area of the drop which apparently has never been seriously considered (8b). This third source of error is simply the fact that even if the drop is truly spherical in shape its true area cannot be the area of a sphere of the same radius, because at the place where the drop connects with the column of mercury, *i.e.*, at the orifice of the capillary, there is an excluded area not in contact with the solution. The true area, A_t, of the drop should therefore be given by the area of the sphere, A_{SPH}, minus the area of the orifice, A_o. Therefore, assuming that the mass flow rate of mercury may be taken as a constant

$$A_t = A_{SPH} - A_o = (6m\sqrt{\pi}/d)^{2/3}t^{2/3} - A_o \quad [6]$$

The measured series capacitance, C_s, will then be given by

$$C_s = C(6m\sqrt{\pi}/d)^{2/3}t^{2/3} - CA_o \quad [7]$$

where C is the true differential capacitance per unit area.

We therefore changed the computer program to take the data in a new way in conformity with Eq. [7]. On one drop the computer samples the value of V''_m at 128 different times. On the next drop it samples the value of V'_m at the same times. Then the series capacitance, C_s, for each of these 128 different times is calculated from Eq. [3], and C_s is fitted to a least squares straight line as a linear regression on $t^{2/3}$. Typical results are shown in Fig. 5. It was found that at all potentials such least squares fits were very good. The differential capacitance at each potential was then calculated according to Eq. [7] from the slope of the least squares straight line. Figure 6 shows the differential capacitance curve for 0.05M Na_2SO_4 at 25°C obtained by this new method. The value of C at any potential on this curve is higher than that calculated by the old method for any time in drop life (*cf.* Fig. 4) as it should be if Eq. [7] is correct.

The new differential capacitance curve was doubly integrated as a function of electrode potential and compared to the electrocapillary curve for the same solution directly measured by the computer-controlled capillary electrometer. The results are shown in Fig. 7. It can be seen from this figure that the agreement between the double integral of the capacitance and the directly measured electrocapillary curve is essentially perfect. In fact, the over-all difference between the two electrocapillary curves is within the 95% confidence limits (± 0.1 dyne cm^{-1}) of the directly measured interfacial tensions. Similar excellent agreement has been achieved with numerous other electrolyte solutions. We therefore believe that our new method of measuring the differential capacitance, tak-

ing account of the excluded area due to the capillary orifice according to Eq. [7], is the best way for obtaining thermodynamically meaningful differential capacitance curves. The excellence of the agreement between the doubly integrated capacitance and the directly measured electrocapillary curves seems to imply that the neglect of the excluded area of the orifice is the only serious error involved in obtaining the area of the drop as a function of time. Undoubtedly the back pressure effect and the nonsphericity effect are still present, but these must be second-order effects below the limits of error of the method of measurement. The fact that previously reported capacitance measurements using the manual a-c bridge have neglected this source of error now casts some doubt on the absolute thermodynamic validity of those measurements. It would obviously be very difficult and tedious to determine the area of the capillary orifice by manual measurements but we would strongly urge that an attempt should be made in future manual capacitance measurements. Otherwise, this systematic error is bound to be present. Since all thermodynamic methods for determination of ionic surface excesses from differential capacitance, for example, the method of Grahame and Soderberg (16), necessarily involve integration of the capacitance, such systematic errors will be accentuated in the thermodynamic results. Because integration accentuates systematic error while smoothing out random error, such a systematic error can be especially insidious.

Organic sorbates.—It is also possible to measure the differential capacitance of the DME in the presence of organic sorbates using this computer-controlled apparatus. A typical example is the differential capacitance curve shown in Fig. 8 for a solution of 0.3M 2-butanol in a sodium sulfate solution in which the mean ionic activity, $a_\pm = 0.07087$, one of the solutions used in a recent study of the electrosorption of 2-butanol (7, 17). The a-c frequency for this capacitance measurement was 102.4 Hz. This curve exhibits the typical shape which is usually observed for aliphatic compounds, *i.e.*, two adsorption-desorption peaks and a low capacitance in the region of strong adsorption between the peaks. Such capacitance curves can be very useful for qualitative study of organic electrosorption (18), and they are very quickly and easily measured with this computer-controlled apparatus. However, there are two serious complications involved in obtaining thermodynamic relative surface excesses of compounds from differential capacitance curves.

The first problem is that the differential capacitance which is actually measured (especially on the adsorption-desorption peaks) is frequency dependent, and the only capacitance which has thermodynamic significance is the limiting, zero frequency capacitance. Therefore, it is necessary to measure the capacitance at a series of frequencies and to extrapolate to zero frequency. This is simple enough if it is justifiable

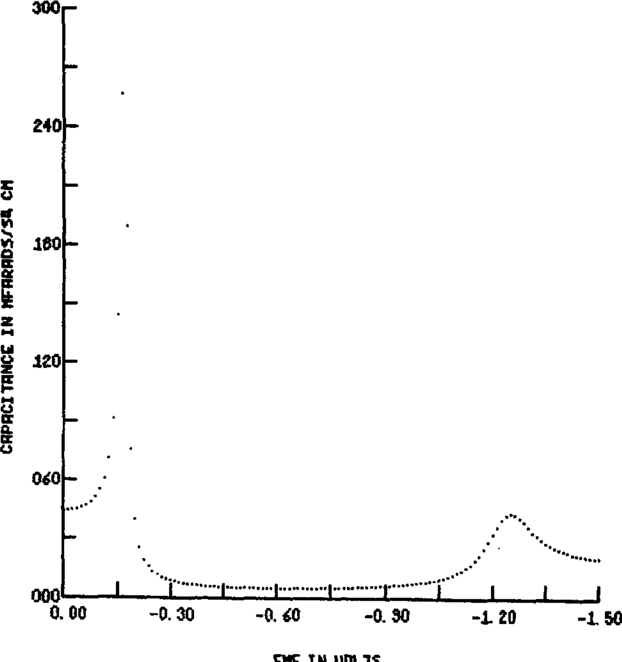

Fig. 8. Differential capacitance curve for 0.3M 2-butanol in Na_2SO_4 solution with mean ionic activity of 0.07087 at 25°C. Frequency of measurement = 102.4 Hz. Electrode potential measured vs. 0.1M KCl calomel electrodes.

to plot the measured capacitance *vs.* $\omega^{1/2}$ and take the intercept at $\omega = 0$ as the true zero frequency or thermodynamic capacitance (5). Unfortunately, such a procedure can be very dangerous because, as Doblhofer and Mohilner (4) showed, it is possible to obtain plots of C *vs.* $\omega^{1/2}$ which appear to be linear but which nevertheless yield too low values for the zero frequency capacitance. Therefore the only really safe method for extrapolating measured differential capacitance is the method of the Cole-Cole (19) plot as recommended by Armstrong *et al.* (6). This method requires that both the capacitance and the resistance due to the diffusion-controlled adsorption process be measured as a function of frequency at a sufficient number of frequencies to establish the Armstrong quarter-circle (6). Unfortunately, this requires a very accurate measurement of the series resistance of the cell as a function of time because the resistance due to the adsorption process is quite small and in series with the solution resistance. This means that in order to obtain the resistance due to the diffusion-controlled adsorption one must subtract two large numbers which are quite close to each other. We found that it was not possible to obtain the total cell resistance and the solution resistance with enough significant figures to yield, after subtraction, the resistance due to the diffusion-controlled adsorption with enough significant figures to permit a Cole-Cole analysis. It is possible that this problem might be overcome by adding a computer-controlled change in the amplification of the scaling amplifier which passes the output of the phase-lock amplifier to the A/D. However, we did not add this modification to the apparatus because it became clear that for any organic system the time required to take the capacitance and resistance data at enough different frequencies would be practically prohibitive. That is, the required electrosorption data for an organic system could certainly be obtained in so much less time with the computer-controlled capillary electrometer (3) that it would be impractical to try to obtain the same information from capacitance data. Moreover, there is a second complication involved in the study of organic electrosorption which has appeared as a result of a recent study carried out in this laboratory (7, 17, 20). We believe, in fact, that this second complication completely vitiates the idea of obtaining thermodynamic relative surface excesses of organic sorbates from differential capacitance measurements even if the frequency dispersion problem could be overcome.

Assuming that the proper zero frequency capacitances can be obtained, the only route (13) to thermodynamic relative surface excesses for the organic compound from differential capacitance data is still via the interfacial tension which can in turn only be obtained by double integration of the capacitance with respect to electrode potential. Such double integration requires prior knowledge of two integration constants, *i.e.*, the charge density, σ, and the interfacial tension, γ, at some electrode potential. Because E_z and γ_{max} change drastically with increase of concentration of an organic sorbate (*cf.* Fig. 9) it is not feasible to carry out this double integration from the point of zero charge as in Eq. [5], for this would require prior measurement of the electrocapillary curve for each solution in order to obtain the required integration constants. It has been commonly believed that at electrode potentials far from E_z, where there is complete desorption of the organic compound, the electrocapillary curves for all solutions containing the organic compound merge with the electrocapillary curve for the base electrolyte solution. If this were true, then one could double integrate the differential capacitance from any potential in the region of total desorption, and the only integration constants required could be obtained from the electrocapillary curve of the base electrolyte solution. However, this idea is actually incorrect both from a theoretical (13) and, as our recent study (7, 20) has shown, from a practical point of view.

According to the thermodynamic theory of electrocapillarity (13) the relative surface excess, Γ_{AW}, of the organic compound, A, with water, W, as the reference component is given by

$$\Gamma_{AW} = -(1/RT)(\partial\gamma/\partial \ln a_A)_{T,p,E,a_e} \quad [8]$$

where R is the gas constant, T is the absolute temperature, a_A is the bulk activity of the organic compound (21), and the subscripts T, p, E, and a_e indicate that the differentiation is carried out at constant temperature, pressure, electrode potential, and activity of the electrolyte (17) in the bulk solution. But Γ_{AW} is related to the true surface concentration of the organic compound, Γ_A, and of the adsorbed water, Γ_W, by the following equation (13)

$$\Gamma_{AW} = \Gamma_A - (x_A/x_W)\Gamma_W \quad [9]$$

where x_A and x_W are the bulk mole fractions of the organic compound and of the water, respectively. Now, clearly, if at some extreme electrode potential the organic compound is completely desorbed, *i.e.*, $\Gamma_A = 0$, it follows that $\Gamma_{AW} < 0$, since Γ_W will be positive. This implies that the interfacial tension will increase with increasing bulk activity of the organic compound. This means that in the potential region of total desorption of the organic compound the electrocapillary curve should rise progressively above the base electrolyte curve as the bulk activity of the organic compound is increased. This behavior is illustrated (7, 20) in Fig. 9 and 10 for the system 2-butanol in sodium sulfate solution. Figure 9 is the set of electrocapillary curves for the base electrolyte (0.1M Na_2SO_4) and for 25 solutions containing successively increasing activities (21) of 2-butanol in solutions in which the mean ionic activity is the same ($a_\pm = 0.07087$) as for the 0.1M Na_2SO_4 in pure water (17). Examination of Fig. 9 shows that in the potential region in which adsorption of the organic compound occurs, the interfacial tension is progressively lowered and the potential of the electrocapillary maximum is progressively shifted in the anodic direction as the

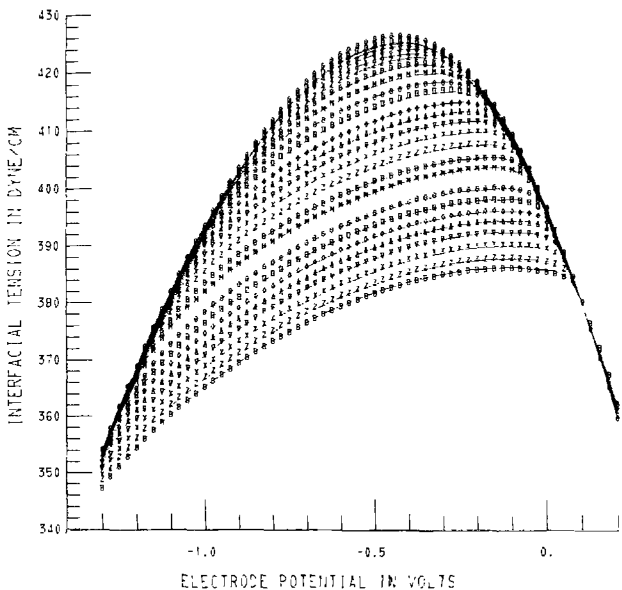

Fig. 9. Electrocapillary curves for 0.1M Na_2SO_4 and 25 different activities of 2-butanol in solutions in which mean ionic activity is constant at 0.07087. Top curve in middle section is for base electrolyte. Other curves are for progressively increasing activities of 2-butanol from top to bottom [for details see Ref. (7) and (20)]. Electrode potential is measured *vs.* a Corning NAS 11-18 sodium ion glass electrode in same solution.

bulk activity of the 2-butanol is increased. However, on the far anodic side ($E > +0.1$V) the 2-butanol is completely desorbed from the electrode surface. Since $\Gamma_A = 0$, $\Gamma_{AW} < 0$ and the interfacial tension rises at constant potential as the bulk activity of 2-butanol is increased. Simultaneously, the charge density at constant potential becomes less positive since the charge density, σ, is given by the Lippmann equation (13)

$$\sigma = -(\partial\gamma/\partial E)_{T,p,a_A,a_e} \qquad [10]$$

This means that there is no electrode potential in the region of complete desorption of the organic compound in which the two integration constants required for integration of the differential capacitance are the same as on the base electrolyte electrocapillary curve. This behavior can be seen more clearly in Fig. 10 which is an expanded view of the same set of 26 electrocapillary curves in the electrode potential range +0.1 to +0.2V. This result proves experimentally what was deduced above theoretically, that the old idea that the electrocapillary curves for the organic compound merge with the electrocapillary curve for the base electrolyte in the region of desorption is incorrect. Therefore the only way that the differential capacitance curves for the organic system can be integrated is to have a separate pair of integration constants for each concentration of the organic compound. This means that it would be necessary to have already measured the electrocapillary curves for every single solution.

The only other possible routes to organic electrosorption isotherms from differential capacitance measurements involve various nonthermodynamic assumptions including those of congruence of the isotherm with respect to either the electrode potential (22) or the charge density (23, 24). Since our studies of organic electrosorption (4, 7, 20) have indicated that organic electrosorption isotherms are congruent with respect to neither of these electrical variables, we believe such approaches are unlikely to lead to correct results. We therefore recommend that the attempt to obtain electrosorption isotherms for organic compounds from differential capacitance should be abandoned. The only valid route to such isotherms appears to be via interfacial tension measurements which can anyway be done more easily and more accurately using the computer-controlled capillary electrometer (3) than can zero frequency differential capacitance measurements.

Conclusions

A computer-controlled apparatus for measuring the differential capacitance of a dropping mercury electrode has been designed and evaluated. It was found that, provided account is taken of the excluded area due to the capillary orifice, the differential capacitance obtained with this instrument agrees with the electrocapillary curves obtained with a computer-controlled capillary electrometer within the confidence limits of the latter instrument. If account is not taken of the excluded area, serious systematic errors will occur. Such systematic errors must necessarily be present in most previously published differential capacitance measurements. This computer-controlled apparatus probably provides the easiest and most accurate method of obtaining differential capacitance curves for electrolyte solutions. An analysis of the problem involved in obtaining electrosorption isotherms for organic sorbates from differential capacitance curves is given. It is concluded that except for qualitative purposes, differential capacitance should be abandoned as a route to thermodynamic electrosorption isotherms for organic compounds. The best route to such isotherms is electrocapillary data obtained with a computer-controlled capillary electrometer.

Current Distribution on a Disk Electrode for Redox Reactions

Peter Pierini, Peter Appel,[1] and John Newman*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Current and concentration distributions on a rotating disk electrode are computed for general electrode reactions where the product concentrations must be included. The effect of migration on the surface concentration of the supporting electrolyte is also demonstrated.

Newman (1) introduced a method for the calculation of current and concentration profiles over the surface of a rotating disk electrode operated below the limiting current. The problem is complex, since the concentration variations near the electrode, the surface overpotential associated with the electrode reaction, and the ohmic potential drop in the bulk of the solution must be included in the analysis. The diffusion layer on a rotating disk electrode is thin compared with the characteristic dimensions of the electrochemical cells used in most experimental applications. This physical situation, in which the concentration changes rapidly in a region much smaller than the bulk of the solution where the potential continues to vary, was naturally formulated as a singular perturbation (6). Thus the potential in a large portion can be considered to satisfy Laplace's equation with the current density distribution on the boundaries matched to the mass flux entering the diffusion boundary layer. In the diffusion layer, the concentrations are determined from the appropriate mass transport equations with a mass flux at the electrode surface related by Faraday's law to the current density distribution on the electrodes, and with the concentrations approaching the bulk concentrations far from the electrode. The current distribution and concentrations at the electrode surface are further specified by the overpotential computed as the difference of the applied voltage, the equilibrium potential, and the ohmic drop in the solution (2). Marathe and Newman (3) experimentally proved the soundness of the theory by plating copper from a cupric sulfate-sulfuric acid solution and then measuring the thickness of the deposit. The potential mapping experiments of Miller and Bellavance (4) also agree quantitatively with theoretical predictions. Other verification exists in the work of Miller and Bruckenstein (11), and Smyrl and Newman (9, 12).

In an attempt to keep the treatment of the problem from being a quagmire of computational detail, common experimental situations were evaluated, and assumptions were made that would permit the broadest application of the theory. The flow was considered fully developed and laminar. The disk was designed to minimize edge effects. The mass transfer boundary layer must lie well within the hydrodynamic boundary layer; thus the Schmidt number must be large. Radial diffusion was neglected over the entire surface of the electrode, even at the outer edge. A mathematically convenient cell utilized a centered disk, embedded in an infinite insulating plane, and placed the counterelectrode at infinity. Actual cells must be carefully devised to approximate the condition of infinite dimension, or a correction to the potential description is necessary. Any electrochemical reaction may be studied except those evolving gas, but attention was restricted to metal deposition from a single salt solution and to an electrode reaction with an excess of supporting electrolyte, having a zero transference number and no dependence upon the product concentration.

Copper plating from a cupric sulfate solution is an example of the single salt reaction while the addition of enough sulfuric acid to suppress migration effects on the reactants illustrates the second type. Since the product does not remain in solution, it may be validly ignored. Any electrode reaction that involves only electron transfer usually requires that the effect of the product concentration be included. Redox couples and organic syntheses are in this class of reactions.

The alternating current response of a disk electrode has been investigated by Newman (13), but the effect of concentration variation was not included. Variations of double layer effects can be computed only if the concentrations of all the ionic species are known at the electrode surface. The supporting electrolyte does not participate in the surface reaction, but migration causes the surface concentration to deviate from the bulk solution. A future objective to treat the alternating current response more completely requires the knowledge of the local value of each component in solution.

We shall extend here the original perturbation scheme to general electrode reactions depending on both reactant and product concentrations and will de-

Key words: current distribution, product dependent, supporting electrolyte concentration.

velop a procedure for determining the concentration of the supporting electrolyte. [See also Ref. (14).]

Overpotential

The major departure from the formulation that omits the product dependence (1) lies in the treatment of the overpotential expressions and the variation of the exchange current density i_o. The necessary reaction parameters are conveniently introduced by the general electrode reaction

$$\sum_i s_i M_i^{z_i} \rightarrow ne^- \quad [1]$$

where s_i is the stoichiometric coefficient, M_i is the symbol for the chemical species, z_i is the species charge number, and n is the number of electrons participating in the reaction. The total voltage V applied to the cell is decomposed into the equilibrium potential U, ohmic drop Φ_o, the concentration overpotential η_c, and the surface overpotential η_s

$$V = U + \Phi_o + \eta_c + \eta_s \quad [2]$$

The surface overpotential is defined by the Butler-Volmer expression

$$i = i_o \left[\exp\left(\frac{\alpha Z\mathbf{F}}{RT} \eta_s \right) - \exp\left(-\frac{\beta Z\mathbf{F}}{RT} \eta_s \right) \right] \quad [3]$$

The local value of the exchange current density i_o can be related to the concentrations of the reactants and products at the electrode surface by

$$i_o = i_{o,\infty} \Pi \left(\frac{c_{i,o}}{c_{i,\infty}} \right)^{\gamma_i} \quad [4]$$

where $i_{o,\infty}$ is a constant determined by the reaction properties and the constituents of the bulk solution, and Z is equal to $-n$. The kinetics parameters α, β, and γ_i are associated with the type of reaction occurring. The parameters of Eq. [3] and [4] may be measured experimentally; Newman (5) suggests rules for the evaluation of the exponents γ_i.

The concentration overpotential depends upon the variation of concentration through the diffusion layer in a complicated way. A relatively high electric conductivity which can be considered constant and enough supporting electrolyte to suppress the effect of migration on the reactants and products allow concentration dependent potential effects to be adequately represented by (6)

$$\eta_c = \frac{RT}{n\mathbf{F}} \sum_i s_i \ln \left(\frac{c_{i,\infty}}{c_{i,o}} \right) \quad [5]$$

Although no formal arguments about the order of the perturbation approach have been given, Eq. [5] may be considered a first approximation which is justified by the small variation in electrical conductivity through the diffusion layer.

Potential Distribution in the Bulk of the Solution Outside the Diffusion Layer

The potential distribution in the bulk of the solution outside the diffusion layer, where the concentrations are uniform, satisfies Laplace's equation. Rotational elliptic coordinates have proven both natural and convenient for the representation of the ohmic effects of rotating disk electrodes (1, 7). The expression for the potential at the surface of the electrode is

$$\Phi_o = \frac{RT}{-n\mathbf{F}} \sum_{m=0} B_m P_{2m}(\eta) \quad [6]$$

$P_{2m}(\eta)$ is the Legendre polynomial of order 2m and $\eta = \sqrt{1 - (r/r_o)^2}$ at the surface. The constants B_m are evaluated by taking the normal derivative of the potential distribution, then making use of the orthogonal properties of Legendre polynomials and the current matching condition between the diffusion layer and the bulk solution.

The Diffusion Layer

The mass balance is

$$v \cdot \nabla c_i = D_i \nabla^2 c_i + z_i u_i \mathbf{F} \nabla \cdot (c_i \nabla \Phi) \quad [7]$$

Levich (8) advanced the idea of investigating the concentration distribution of all components in the solution by a perturbation technique. The method has been successfully applied to show the effect of ionic migration on the supporting electrolyte at the limiting current (15). For a solution that contains minor species and a binary indifferent electrolyte, the zero approximation omits the minor species. The potential and concentration profile associated with the supporting ions are then found to be constants, since the major species do not participate in the electrode reaction. Therefore, no current is passed, and the solution is the bulk concentration of the supporting ions, $c_1^{(0)} = c_{1,\infty}$ and $c_2^{(0)}$ is specified by electroneutrality. The first order approximation is

$$c_1 = c_1^{(0)} + c_1^{(1)}$$

$$c_2 = c_2^{(0)} + c_2^{(1)}$$

$$c_i = c_i^{(1)} \text{ where } i > 2 \quad [8]$$

Equation [8] is substituted into Eq. [7], and second order terms are dropped, which gives

$$v \cdot \nabla c_i^{(1)} = D_i \nabla^2 c_i^{(1)} \text{ for } i > 2 \quad [9]$$

$$v \cdot \nabla c_1^{(1)} = D_e \nabla^2 c_1^{(1)} + \sum_{i=3} \frac{z_i u_1 (D_2 - D_i)}{z_1 u_1 - z_2 u_2} \nabla^2 c_i^{(1)} \quad [10]$$

The physical parameter D_e is the diffusion coefficient of the binary electrolyte

$$D_e \equiv \frac{z_1 u_1 D_2 - z_2 u_2 D_1}{z_1 u_1 - z_2 u_2} \quad [11]$$

The potential is eliminated between the two equations for the ions of the supporting electrolyte; then the electroneutrality condition is used to eliminate $c_2^{(1)}$.

The minor components are found by solving Eq. [9], the equation of convective diffusion that applies when the effect of migration can be ignored. Smyrl and Newman (9) have worked out a formal solution to Eq. [9] that can be applied to diffusion layers in laminar forced convection at high Schmidt numbers on axisymmetric bodies. The concentration derivative at the electrode surface, as a function of the surface concentration, is

$$\left. \frac{\partial c_i}{\partial \zeta} \right|_{\zeta=0} = \frac{-r}{\Gamma(4/3)} \int_0^r \left. \frac{dc_{i,o}}{dr} \right|_{r=r'} \frac{dr'}{(r^3 - r'^3)^{1/3}} \quad [12]$$

and Eq. [12] can be inverted

$$c_{i,o} - c_{i,\infty} = \frac{-1}{\Gamma(2/3)} \int_0^r \left. \frac{\partial c_{i,o}}{\partial \zeta} \right|_{\substack{\zeta=0 \\ r=r'}} \frac{r'dr'}{(r^3 - r'^3)^{2/3}} \quad [13]$$

where the dimensionless distance from the surface is

$$\zeta = y(a\nu/3D_i)^{1/3}(\Omega/\nu)^{1/2} \quad [14]$$

All of the minor ionic species are either a reactant or a product in the general electrode reaction Eq. [1] which combined with Eq. [13] provides the relationship

$$\frac{c_{i,o} - c_{i,\infty}}{c_{j,o} - c_{j,\infty}} = \frac{s_i}{s_j} \left(\frac{D_j}{D_i} \right)^{2/3} \quad [15]$$

A great economy in computation can be achieved by using Eq. [15] to find the concentrations of all reaction species except for one, which must be determined from Eq. [12]. The reference ion will be taken to be the third species, and this can be conveniently regarded as the limiting reactant. The quantity D_i in Eq. [14] is now conveniently specified to be D_3.

Eq. [10] is solved subject to the boundary conditions

$$c_1^{(1)} \rightarrow c_{1,\infty}^{(1)} \text{ as } \zeta \rightarrow \infty \quad [16]$$

and zero flux of the supporting ions at the electrode surface. The Nernst-Einstein equation can be used to eliminate the mobilities from Eq. [10], which in terms of the Lighthill transformation becomes

$$\frac{d^2c_1^{(1)}}{d\zeta^2} + 3\zeta^2 \frac{D_3}{D_e} \frac{dc_1^{(1)}}{d\zeta} = \frac{1}{z_2 - z_1} \sum_{i=3} z_i \left(1 - \frac{D_i}{D_2}\right) \frac{d^2c_i^{(1)}}{d\zeta^2} \quad [17]$$

with the boundary condition

$$\left.\frac{dc_1^{(1)}}{d\zeta}\right|_{\zeta=0} = \sum_{i=3} \frac{z_i}{z_2 - z_1} \frac{dc_i}{d\zeta} \quad [18]$$

The solution to Eq. [17] is first sought for the case of a constant surface concentration, $c_{i,0}^{(1)}$. The concentration derivatives of the minor species are expressed in terms of the reference ion concentration utilizing the solutions of Eq. [9] for a constant surface concentration (15) and Eq. [1]

$$\frac{d^2c_1^{(1)}}{d\zeta^2} + 3\zeta^2 \frac{D_3}{D_e} \frac{dc_1^{(1)}}{d\zeta} = \frac{-3\zeta^2 (c_{3,\infty}^{(1)} - c_{3,0}^{(1)})}{\Gamma(4/3)(z_2 - z_1)} \sum_{i=3} z_i \frac{D_3}{D_i} \left(\frac{D_3}{D_i} - \frac{D_3}{D_2}\right) \frac{s_i}{s_3} e^{-\frac{D_3}{D_i}\zeta^3} \quad [19]$$

The solution to Eq. [19] is

$$\frac{c_1^{(1)} - c_{1,\infty}^{(1)}}{c_{3,\infty}^{(1)} - c_{3,0}^{(1)}} = \frac{1}{\Gamma(4/3)} \left[\left(\frac{D_3}{D_e} - \frac{D_3}{D_2}\right) \sum_{i=3} \frac{z_i}{z_2 - z_1} \frac{1}{\left(\frac{D_i}{D_e} - 1\right)} \int_\infty^\zeta e^{-\frac{D_3}{D_e}x^3} dx + \sum_{i=3} \frac{z_i}{z_2 - z_1} \frac{s_i}{s_3} \frac{D_3}{D_i} \frac{\left(\frac{D_i}{D_3} - 1\right)}{\left(\frac{D_i}{D_e} - 1\right)} \int_\infty^\zeta e^{-\frac{D_3}{D_i}x^3} dx \right] \quad [20]$$

which at $\zeta = 0$ becomes

$$\frac{c_{1,0}^{(1)} - c_{1,\infty}^{(1)}}{c_{3,\infty}^{(1)} - c_{3,0}^{(1)}} = -\sum_{i=3} \frac{z_i}{z_2 - z_1} \left[\frac{\frac{D_i}{D_2} - 1}{\frac{D_i}{D_e} - 1} \left(1 - \left(\frac{D_e}{D_i}\right)^{1/3}\right) + \left(\frac{D_e}{D_i}\right)^{1/3} \right] \left(\frac{D_3}{D_i}\right)^{2/3} \quad [21]$$

Since the differential equations are linear, the solutions for the constant surface concentration may be extended by a superposition integral (16) to the situation where $c_{3,0}^{(1)}$ varies arbitrarily. The superposition integral reduces to Eq. [21], thus simply relating the two concentrations. The remaining concentration, $c_2^{(1)}$, is calculated from the condition of electroneutrality.

Numerical Example

For a numerical example, a fast redox reaction equimolar in the bulk concentrations of minor species, such as the ferro-ferricyanide couple with sodium fluoride as the supporting electrolyte, was chosen for a system that would exhibit significant differences between a product dependent and a product independent treatment. Many other systems would serve just as well. The dimensionless groups that characterize the solutions are (1, 10)

$$N = -\Gamma(4/3) \frac{n\mathbf{F}r_o i_{\lim}}{RT\kappa_\infty} \quad [22]$$

and

$$J = \frac{i_{o,\infty} r_o n\mathbf{F}}{RT\kappa_\infty} \quad [23]$$

The basic solution procedure for the set of equations is similar to that of Parrish and Newman (10) with the addition of Eq. [5] for the concentration of the product and Eq. [18] for the concentration of the supporting electrolyte.

Concentration and current distributions are calculated with a given average current rather than a specified fraction of the limiting current at the center of the disk, by adding an extra loop (3) to the basic iteration (1). The parametric dependence of the computations on the dimensionless stirring rate N is thus clearly emphasized in Fig. 1 and 2. Increasing N produces larger differences between the product dependent and independent approaches. The concentration of the supporting electrolyte cation differs from the bulk value as shown in Fig. 3. The effect is small, but it must be taken into account for alternating current impedance calculations or double layer investigations.

Figure 2 for the reactant concentration is related to Fig. 1 for the current distribution by means of Eq. [12] or Eq. [13]. The product concentration $c_{4,0}$ would be higher than the bulk concentration by an amount proportional to the depletion of the reactant in Fig. 2, and could be computed through Eq. [15]. The supporting cation in Fig. 3 reflects the current distribution also, but this is through the reactant and product concentrations according to Eq. [21].

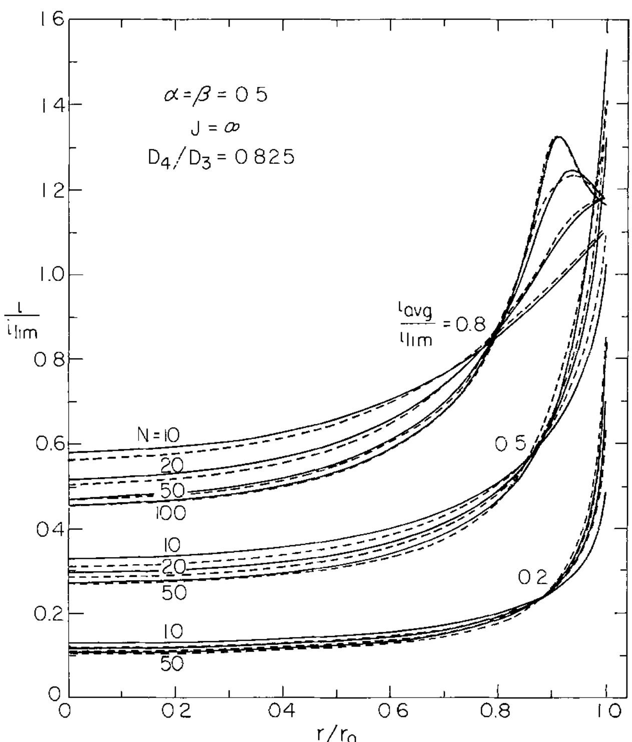

Fig. 1. Current distribution: dashed lines represent the product-independent reaction and solid lines are for the product-dependent reaction (reduction of ferricyanide with equal bulk concentrations of ferricyanide and ferrocyanide). D_4/D_3 is the ratio at infinite dilution.

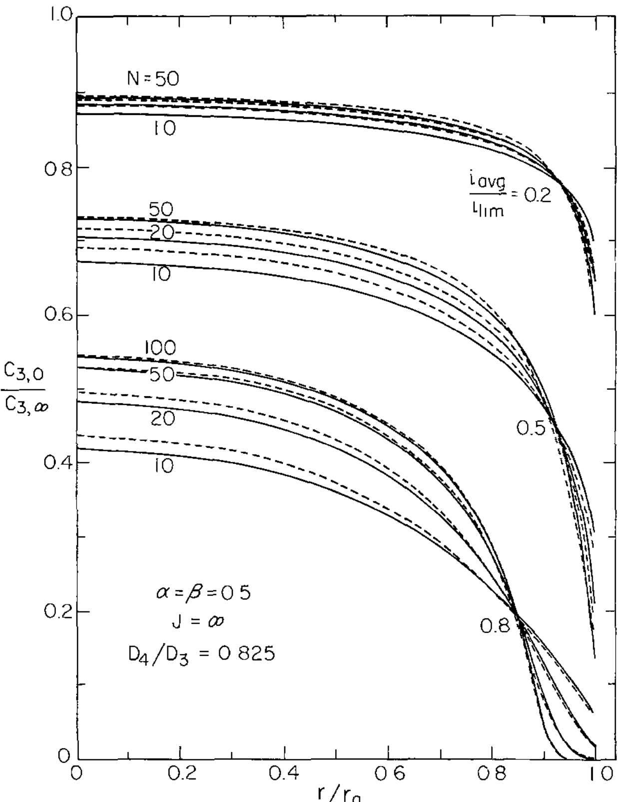

Fig. 2. Concentration distribution: dashed lines represent the product-independent reaction and the solid lines are for the product-dependent reaction.

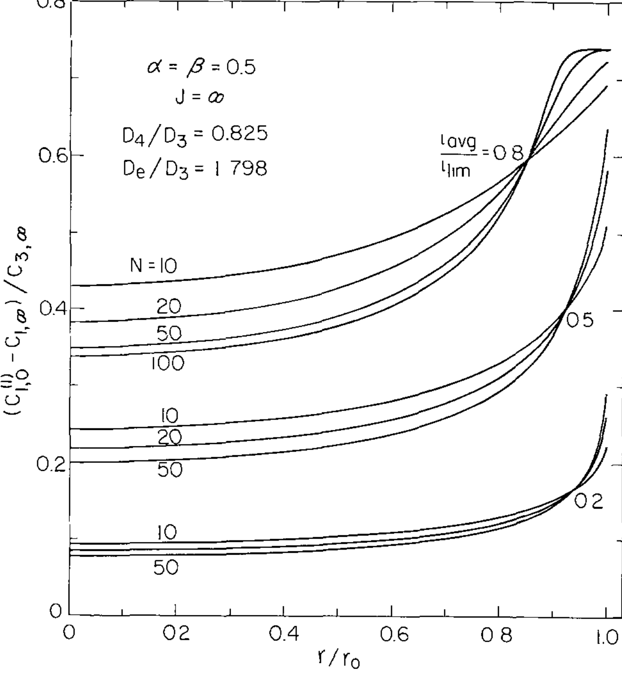

Fig. 3. Concentration distribution of the cation of the uni-univalent supporting electrolyte for the product- and reactant-dependent reaction. D_e/D_3 is the ratio at infinite dilution.

Ion Exchange Capacity of Cellulose Acetate Membranes

H.-U. Demisch and W. Pusch

Max-Planck-Institut für Biophysik, 6 Frankfurt am Main, Germany

ABSTRACT

The fixed charge concentration of asymmetric cellulose acetate membranes caused by a small amount of carboxyl groups of the cellulose acetate was determined by titrating the corresponding H^+ ions using the method of Heymann and Rabinov. The fixed charge concentration, $C^o_{X^-}$, was thus estimated to be $3.4 \cdot 10^{-3}$ mequiv/g wet membrane. This value is compared with the effective fixed charge concentration determined by means of streaming potential measurements using NaCl solutions and asymmetric cellulose acetate membranes annealed at 82.5°C. Furthermore, the effect of the *p*H of the outside solution on the effective fixed charge concentration of the asymmetric cellulose acetate membrane is theoretically discussed assuming a dissociation equilibrium for the carboxyl groups. Thus, it is shown that the effective fixed charge concentration, C_{X^-}, of weak ion exchangers depends strongly on the *p*H as well as on the electrolyte concentration of the outside solution, and on the valency of the counterions. Since the theoretical treatment of the influence of *p*H on the effective fixed charge concentration is based on approximations, only a semiquantitative agreement between experimental findings and theoretical results is obtained.

During the late fifties Reid and Breton (1) proved homogeneous cellulose acetate membranes to be highly impermeable to salts but quite permeable to water. Parallel to these investigations with homogeneous cellulose acetate membranes, Loeb and Sourirajan (2) developed so-called modified or asymmetric cellulose acetate membranes possessing the same high salt rejection as the homogeneous ones but a much larger water permeability at nearly the same over-all thickness of the membranes. This difference in the water permeability was proved by Merten *et al.* (3, 4) to be due to the asymmetric structure of the modified membranes. Because of their essentially larger water permeability, these asymmetric cellulose acetate membranes became very important in the field of brackish and sea water desalination. Since the transport behavior of these membranes was investigated primarily with brine solutions of larger electrolyte concentrations, and the resulting salt rejection explained by a solution-diffusion mechanism (5), these membranes were believed not to be permselective (6). Only recently, Spiegler and Minning (7) as well as Pusch (8) reported that asymmetric cellulose acetate membranes possess a low fixed charge concentration and behave, therefore, as cation exchange membranes at very low electrolyte concentrations ($< 10^{-2}$ mol/liter). These conclusions were drawn from streaming and membrane potential measurements. Because of these experimental findings, it was desirable to get further support of the cation exchange properties of these membranes as well as to get a more accurate value for the fixed charge concentration in lieu of the approximation which is obtained primarily from membrane potential measurements. Thus, we determined the fixed charge concentration by analytical methods and by means of "streaming potential" measurements.

Experimental

The following experiments were performed with asymmetric cellulose acetate membranes annealed at 82.5°C. The membranes were prepared from Cellit K 700 cellulose acetate (39.1% acetyl) produced by Bayer AG of Leverkusen, Germany, according to the procedure of Manjikian, Loeb, and McCutchan (9). First, the fixed charge concentration, $C^o_{X^-}$, of these membranes was determined using the method of Heymann and Rabinov (10). For this reason, a suitable membrane sample was imbibed in distilled water for several days. Thereafter, the sample was treated with 0.1*N* HCl to remove any cation other than H^+ ions from the membrane. Then, the membrane sample was washed with distilled water until the rinse water was neutral (checked by methyl orange) and free from any chloride. The final rinse water was stored in order to be used later for the determination of a blank value of titration. This wet membrane sample was put in a 0.1M calcium acetate solution and kept in a closed Erlenmeyer flask for about 2 hr. During this time the Erlenmeyer flask, surrounded by an ice-water bath, was stored in a refrigerator. After this treatment, the membrane sample was squeezed and repeatedly washed, collecting all wash water in a suitable container. The collected rinse water was then titrated using 0.01M $Ba(OH)_2$ solution with an automatic burette, carefully excluding CO_2. The last rinse water was also titrated in the same way. The difference in the amounts of $Ba(OH)_2$ solution consumed in both cases results in the fixed charge concentration of the membrane. A series of determinations yielded the following mean value for the fixed charge concentration of the membrane with an error of ±10%

$$C^o_{X^-} = 3.4 \cdot 10^{-3} \text{ mequiv/g wet membrane}$$

or

$$C^o_{X^-} = 5.0 \cdot 10^{-3} \text{ equiv/liter pore volume}$$

using a water content of the entire asymmetric membrane of 0.68 cm³/g wet membrane.

It should be mentioned that one obtains a fixed charge concentration which is only one-half of the one obtained if the membrane sample is not treated with 0.1*N* HCl.

In addition, three transport coefficients of the phenomenological relationships of thermodynamics of irreversible processes (11) were determined, which allow the estimation of the fixed charge concentration by means of the Schmid relationship (12), relating the electro-osmotic coefficient, l_{ep}, to the effective fixed charge concentration, C_{X^-}, the mechanical permeability, L_P, and the electrical resistance, R_e, of the membrane by the following relationship

$$l_{ep} \equiv (L_{EP}/L_E) = -\mathbf{F} \cdot \omega \cdot C_{X^-} \cdot L_P \cdot R_e \qquad [1]$$

where $l_{ep} = -(\Delta E/\Delta P)_{I=0}$ = measured "streaming potential coefficient" under the boundary condition of zero electrical current (mV/atm); L_{EP} = electro-osmotic coefficient which relates an electrical current

Key words: streaming potential, membrane resistance, electro-osmotic coefficients, pH effect, asymmetric cellulose acetate membranes.

across the membrane to a pressure difference (mA/atm); L_E = electrical conductivity of the membrane ($ohm^{-1}\ cm^{-2}$); $R_e = 1/L_E = (\Delta E/i)_{\Delta P=0}$ = electrical membrane resistance (ohm-cm²); $L_P = (q/\Delta P)_{\Delta E=0}$ = mechanical or hydrodynamical permeability of the membrane (cm/sec·atm) under the boundary condition $\Delta E = 0$; q = volume flux through the membrane (g/cm²·sec or cm/sec); i = electrical current density across membrane (mA/cm²); ΔE = electrical potential difference across membrane measured by reversible electrodes such as Ag/AgCl electrodes in the presence of chloride ions in the outside solutions (mV); ΔP = hydrostatic pressure difference across membrane (atm); $\omega = +1$ or -1 for anion or cation exchange membranes, respectively; C_{X^-} = effective fixed charge concentration (mol/liter pore volume); $\mathbf{F}$ = Faraday number (As/equiv).

Rearranging Eq. [1] and using the definition of l_{ep} and the approximation $q \simeq L_P \Delta P$ (15), which was proved to be valid for asymmetric cellulose acetate membranes, the following relationship is obtained

$$(\Delta E)_{i=0} = \mathbf{F} \cdot \omega \cdot C_{X^-} \cdot R_e \cdot (q)_{i=0} \qquad [2]$$

As can be seen from Eq. [2], the so-called "streaming potential," ΔE, depends on the product $C_{X^-} \cdot R_e \cdot q$ and not only on the effective fixed charge concentration, C_{X^-}. Therefore, the "streaming potential" of high fixed charge ion exchange capacity membranes is of the same order of magnitude as the "streaming potential" of the asymmetric cellulose acetate membranes, although the fixed charge concentration of ion exchange membranes with high capacity is about 1000 times larger than the fixed charge concentration of cellulose acetate membranes. On the other hand, the hydrodynamic permeability (volume flux) and the electrical resistance of common ion exchange membranes are much lower than those for asymmetric cellulose acetate membranes.

Since the Schmid relationship is only valid at low electrolyte concentrations, a salt concentration of 0.02M NaCl was chosen for measuring the electroosmotic coefficient, l_{ep}, the mechanical permeability, L_P, and the electrical resistance, R_e. This electrolyte concentration is also very convenient for an accurate measurement of the over-all ohmic resistance of the membrane assembly plus salt solution by means of conductivity bridges such as a Weyne-Kerr bridge. In addition, it should be mentioned that the pH of the NaCl solutions was always 5.8 because of the presence of CO_2.

Using a dialysis cell described in detail elsewhere (13-15), with salt solutions of equal concentrations on both sides of the membrane, the mechanical permeability, L_P, was measured at 25°C by means of volume flow measurements (16, 17). The following procedure was used to measure the streaming potential coefficient, l_{ep}, under the boundary condition $i = 0$. A pressure difference, ΔP, was established across the membrane and the resulting electrical potential difference, ΔE, was measured as a function of time, t, with Ag/AgCl electrodes by means of a compensation recorder. The desired electrical potential difference, ΔE, was then obtained from the difference of the two measured steady-state values $\Delta E(q) - \Delta E(q = 0)$, where $q = 0$ corresponds to $\Delta P = 0$ thus, eliminating asymmetry potentials. Plotting this potential difference as a function of ΔP, a straight line is obtained as is shown in Fig. 1. The slope of this straight line yields the streaming potential coefficient, l_{ep}.

In other experiments, the electrical resistance, R_e, of the asymmetric cellulose acetate membrane was determined by a difference method (18-20) using so-called Luggin capillaries (Pt/Ag/AgCl electrodes with a suitable salt bridge). On each side of the membrane a Luggin capillary was arranged at a distance, d, from the corresponding membrane surface, and the capillary endings were adjusted in such a way that they touched

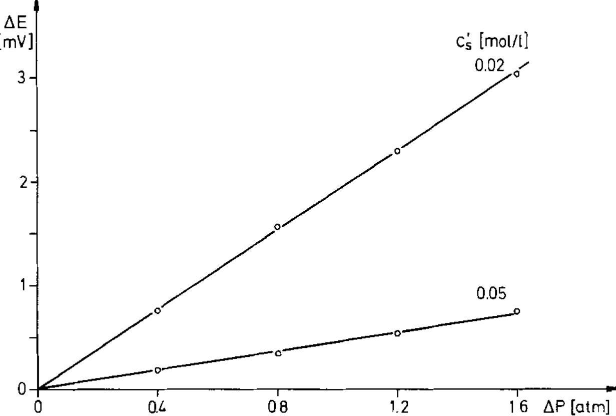

Fig. 1. "Streaming potential," ΔE, as a function of the hydrostatic pressure difference, ΔP, with the boundary condition $c'_s = c''_s$ at 25°C using an asymmetric cellulose acetate membrane annealed at 82.5°C.

the corresponding membrane surface at $d = 0$. Adjusting a constant electrical current across the membrane by means of the Ag/AgCl electrodes, the resistance between the two capillary endings was measured as a function of the distance, d. Now, the measured resistance is composed of the membrane resistance, $\rho_m \delta$, and the resistance of the solution between the capillary end and the corresponding membrane surface, $\rho_s d$. Thus the measured over-all resistance is related to these resistance components as follows

$$R = (1/A)(2\rho_s d + \rho_m \delta) \qquad [3]$$

where R = measured over-all resistance (ohm); A = effective membrane area (cm²); ρ_s = specific resistance of salt solution (ohm-cm); ρ_m = specific resistance of the membrane (ohm-cm); d = distance between capillary ending and membrane surface (cm); δ = membrane thickness (cm).

Plotting the measured resistance, R, as a function of d, a straight line is obtained for distances, d, larger than the diameter of the capillary end. At distances smaller than the capillary diameter deviations from the straight line are observed in agreement with similar experimental findings by Guillou *et al.* (21). Extrapolating the straight line obtained for larger distances to $d = 0$ yields the membrane resistance, $R_e = \rho_m \delta$. With a 0.02M NaCl solution the following experimental results have been obtained

$$L_P = 2.83 \cdot 10^{-4}\ cm^4/V\ As^2 = 2.77 \cdot 10^{-5}\ cm/sec \cdot atm$$

$$l_{ep} = 1.89 \cdot 10^{-2}\ cm^3/As = 1.85\ mV/atm$$

$$R_e = 325 \pm 26\ ohm\text{-}cm^2$$

$$\omega = -1$$

Substituting these values into Eq. [1], the following effective fixed charge concentration results

$$C_{X^-} = 2.3 \cdot 10^{-3}\ equiv/liter\ pore\ volume$$

Taking into account the different methods of determination of the fixed charge concentration, one can conclude that there is reasonable agreement between the two values obtained for the fixed charge concentration of an asymmetric cellulose acetate membrane. In this connection, one must consider the influence of the electrolyte concentration and the pH of the outside solution on the effective fixed charge concentration, C_{X^-}, which is discussed later in more detail. In addition, it should also be pointed out that with the underlying model, the counterions in the membrane are assumed to move with the same velocity as the water. But, as Spiegler (22) has reported, this assumption is not completely valid because of the interaction of the counterions and fixed charges. This interaction can be

taken into account by a so-called conductivity factor, f_λ, in Eq. [1] and [2]. This conductivity factor can be assumed to be about 0.5, implying that the fixed charge concentration obtained from Eq. [1] has to be doubled in order to yield a more certain value. This correction results in a much better agreement between the two values obtained for the fixed charge concentration of the asymmetric cellulose acetate membrane.

Effective Fixed Charge Concentration of Weak Ion Exchangers

As Rabek (23) reported and reviewed, potentiometric titration curves of weak acidic or basic ion exchange materials are a good tool for the investigation of the reactive groups and a conformation analysis of an ion exchange material. These titration curves are often used in order to characterize the range of action of these ion exchange materials which is understandably different, depending on the activity of the ion exchange groups. It is well known that these titration curves are strongly affected by electrolytes which are present during titration (24). Whereas many theoretical investigations on the uptake of ions by ion exchange materials, in the presence of complexing agents, have been performed (24), no theoretical analysis of the effect of pH and electrolyte concentration on the effective capacity of weak ion exchange materials has been reported, as far as the authors are aware. Therefore, such an analysis is given below.

Assuming a dissociation equilibrium for the acidic active groups, such as COO^- groups of weak ion exchange materials, with an acidity constant, K_a, the following relationship between the effective fixed charge concentration, C_{X^-}, and the fixed charge concentration at complete dissociation, $C^o_{X^-}$, as well as the pH or H^+ ion concentration, C_H, of the surrounding solution in the ion exchange phase is obtained

$$C_{X^-} = (K_a C^o_{X^-})/(K_a + C_H) \quad [4]$$

Using the well-known Donnan relationship (25) for the distribution of the ions between outside solution and membrane phase without taking into account individual distribution coefficients of the ions, the electroneutrality condition within the membrane phase, and the ion product of water, the following four additional equations are obtained if an univalent acid, HA, and an x-valent metal salt, MeA_x, of this acid are considered

$$C_H \cdot C_A = c_H(c_a + xc_e) \quad [5]$$

$$C_{Me} = (c_e/c^x_H) \cdot C^x_H \quad [6]$$

$$C_{OH} = K_w/C_H \quad [7]$$

$$xC_{Me} + C_H = C_{OH} + C_A + C_{X^-} \quad [8]$$

where c_a = concentration of acid, HA, in the outside solution (mol/liter); c_H = concentration of H^+ ions in the outside solution (mol/liter). Because of the electroneutrality condition in the outside solution, c_H and c_a are not independent but correlated to each other by the following relation: $c_H = c_a + K_w/c_H$; c_e = concentration of metal salt MeA_x in the outside solution (mol/liter); x = valency of metal ion; K_a = acidity constant of active groups of membrane (mol/liter); K_w = ion product of water (mol²/liter²); C_H, C_{OH}, C_{Me}, C_A, and C_{X^-} are the H^+, OH^-, Me^{x+}, A^-, and fixed charge concentration, respectively, within the membrane phase (mol/liter pore volume).

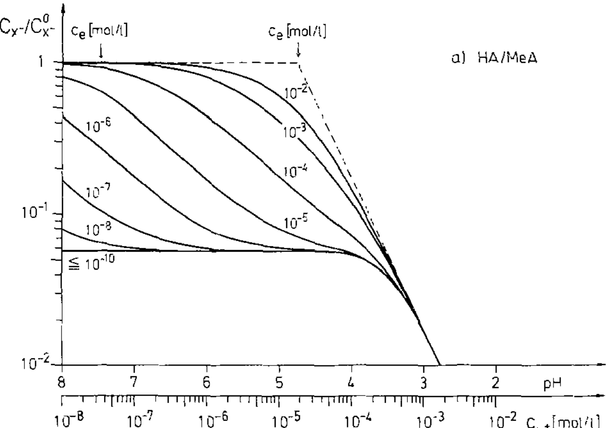
Substituting Eq. [4], [5], [6], and [7] into the electroneutrality condition [8] and rearranging, the following polynomial equation for C_H is obtained

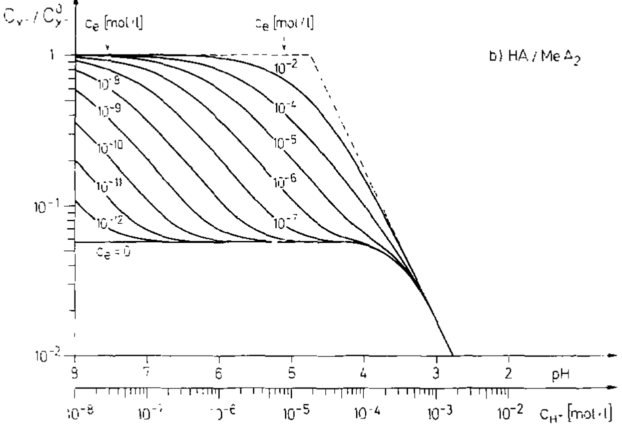
$$\{C^{x+2}_H + K_aC^{x+1}_H\} \cdot (xc_e/c^x_H) + C^3_H + K_aC^2_H - \{K_aC^o_{X^-} + K_w + c_H(c_a + xc_e)\} \cdot C_H - \{K_w + c_H(c_a + xc_e)\} \cdot K_a = 0 \quad [9]^1$$

[1] Equation [9] is valid for $pH \leq 7$. At $7 < pH \leq 14$ one has to add $Me(OH)_x$ instead of HA. This leads to a somewhat different equation which is not considered here.

This equation yields a cubic equation for $x = 1$, a fourth degree polynomial equation for $x = 2$, and a fifth degree polynomial equation for $x = 3$, as well as the same cubic equation for every x in the case $c_e = 0$. All these polynomial equations can easily be solved by means of a calculator such as the HP 65, for instance, with the corresponding programs. Assuming a suitable value for K_a of $1.78 \cdot 10^{-5}$ mol/liter, the theoretical results presented graphically in Fig. 2a, b, and c were obtained. There, the ratio of the effective fixed charge concentration over the fixed charge concentration at complete dissociation, $C_{X^-}/C^o_{X^-}$, is plotted as a function of the pH of the outside solution using different parameter values of the metal salt concentration, c_e.

The following points should be noted. (i) Activity coefficients have been assumed to be unity replacing thermodynamic activities by concentrations. This as-





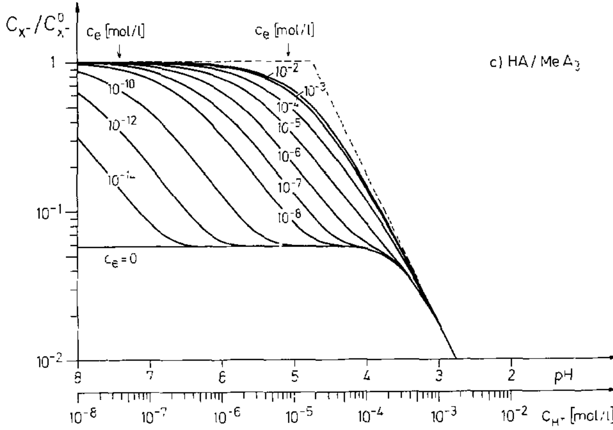


Fig. 2. Ratio of effective to total fixed charge concentration of a weak cation-exchange membrane as a function of pH in the presence of a monovalent acid and a monovalent (a), a divalent (b), and a trivalent (c) salt as calculated from Eq. [9] using an acidity constant $K_a = 1.78 \cdot 10^{-5}$ mol/liter.

sumption will become increasingly invalid at higher solute concentration. (*ii*) No individual distribution coefficients for the ions have been taken into account. But, this could easily be done further for the metal salt by using an effective metal salt concentration $K_s c_e$ of the outside solution with the distribution coefficient, K_s, of the salt.

As can be seen from Fig. 2a, b, and c, there exists a strong effect of the pH and the electrolyte concentration of the outside solution on the effective fixed charge concentration of the membrane. On the other hand, if no electrolyte, other than the acid, is present in the outside solution ($c_e = 0$), the effective fixed charge concentration is strongly lowered ($C_{X^-}/C^o_{X^-} \simeq 0.06$), but independent of the pH up to a pH value which corresponds to about the pK_a value of the active groups of the membrane. This theoretical result can easily be understood by a brief calculation. When no additional electrolyte is present except the acid, the only counterion which can balance the fixed charges is the H^+ ion. Thus the concentration C_H within the membrane has always to be equal to the effective fixed charge concentration, C_{X^-}, if the small amount of OH^- ions is neglected. With this condition, Eq. [4] yields $C_{X^-}/C^o_{X^-}$ directly without further calculations. The square root of the corresponding quadratic equation yields the effective fixed charge concentration for the case $c_e = 0$ at $pH < pK_a$.

From Fig. 2a, b, and c it can also be seen that there exists only a small effect of the pH on the effective fixed charge concentration, C_{X^-}, at electrolyte concentrations larger than 10^{-2} mol/liter or even 10^{-3} mol/liter, depending on the valency of the corresponding cation. Furthermore, the change of the effective fixed charge concentration with increasing pH becomes more pronounced with increasing valency of the metal ion. At the same outside electrolyte concentration, the effective fixed charge concentration is lower at lower pH values in the presence of higher valency metal ions, whereas the opposite is true at larger pH values. On the other hand, the effective salt concentration, which determines the effective fixed charge concentration, is always lower than the salt concentration of the surrounding solution because of a distribution coefficient, K_s, for the salt, which is less than unity. Therefore, there will exist a strong dependence of the effective fixed charge concentration on the pH of the outside solution even at salt concentrations exceeding 10^{-3} mol/liter. Thus, determining fixed charge concentrations of weak ion exchange membranes by methods other than analytical, will yield values for the effective fixed charge concentration which depend strongly on the composition of the outside solution. Also, every transport property of a weak ion exchange membrane, which is influenced by the effective fixed charge concentration, is affected by the pH of the outside solution. This was recently demonstrated by de Körösy (26) and Vacik *et al.* (28), for instance, by measuring electrical resistances of an amphoteric membrane as a function of the pH of the outside solution and formerly by Ohki (29) measuring the resistance of lipid bilayers which contained zwitterionic groups.

Finally, some remarks should be made on the use of the Schmid relationship for the determination of the fixed charge concentration of asymmetric cellulose acetate membranes. With the experimental setup and the corresponding boundary conditions used to measure C_{X^-}, it is assumed that there exist no electrical potentials other than the streaming potential in the membrane. But this assumption is no longer valid for asymmetric membranes, as was shown recently (8). Because of the concentration gradient within the porous sublayer of an asymmetric cellulose acetate membrane (14), there exist two diffusion potentials and additional Donnan potentials within the membrane, even when the electrolyte concentrations on both sides of the membrane are equal (27). The two diffusion potentials may possess opposite signs, depending on the ratio D_+/D_- in the active layer and the porous sublayer of the asymmetric cellulose acetate membrane (D_+, D_- = diffusion coefficient of the cation and anion, respectively, within the active layer or porous sublayer). A detailed analysis indicates (15) that the two diffusion potentials of opposite sign and the resulting Donnan potentials nearly cancel for an asymmetric cellulose acetate membrane annealed at 82.5°C, using a salt concentration of 0.02M NaCl on both sides of the membrane. Thus, this detailed analysis of the electrical potential situation across an asymmetric cellulose acetate membrane leads to the conclusion that the Schmid relationship may be used for the determination of effective fixed charge concentrations of asymmetric membranes, if special boundary conditions are chosen. Under such special boundary conditions, the over-all membrane potential of an asymmetric membrane corresponds nearly to a pure streaming potential within the error of measurement. These assumptions are supported by further detailed analyses of the potential situation in asymmetric cellulose acetate membranes.

Summarizing, it should be stated that a comparison of fixed charge concentrations of weak ion exchange membranes, determined on the one hand by analytical methods such as titration, and on the other hand by measuring transport coefficients and/or streaming potentials, may fail since the former analysis leads to the total amount of fixed charges, whereas in the latter case, only an effective fixed charge concentration is delineated. The effective fixed charge concentration may differ strongly from the total fixed charge concentration due to the effect of pH and electrolyte concentration of the outside solutions on the amount of dissociated active groups of the membrane material. The pH of the 0.02M NaCl solutions used was always around 5.8. This means that the effective fixed charge concentration, C_{X^-}, must be smaller than the fixed charge concentration, $C^o_{X^-}$, determined by titration. Our experimental results are in qualitative agreement with this requirement, when all necessary semiquantitative corrections have been made.

Furthermore, it is, in principle, impossible to measure pure streaming potentials using asymmetric membranes with the corresponding experimental setup because of the additional diffusion and Donnan potentials which are present, even at equal electrolyte concentrations on both sides of the membrane. Thus, the effective fixed charge concentration can only be compared to the total fixed charge concentration if a detailed analysis of all additional electrical potential effects is conducted. With regard to the experimental findings reported here, this detailed analysis was performed yielding reasonable agreement between total and effective fixed charge concentration of an asymmetric cellulose acetate membrane.

Acknowledgments

The authors are indebted to Professor R. Schlögl for his interest in this work and some stimulating discussions. The authors would also like to thank Mr. R. Gröpl for preparing the asymmetric cellulose acetate membranes and Mr. R. McKinney for reading the proofs. The work was financially supported by the Bundesminister für Forschung und Technologie, Bonn, Germany.

Manuscript submitted June 24, 1975; revised manuscript received Oct. 27, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1976 JOURNAL. All discussions for the December 1976 Discussion Section should be submitted by Aug. 1, 1976.

Publication costs of this article were partially assisted by Max-Planck-Institut für Biophysik.

ABSTRACT

The kinetics of oxygen evolution reaction at platinum anodes in acid solutions with different pH's is examined, and possible reaction mechanisms are discussed. The activity of the reaction at initially prereduced electrodes brought to a constant potential, or kept at a constant current density, decreases with time. Only at the electrodes initially subjected for a given time either to a high potential, or to a high anodic current density, it is possible to observe in "run down," or subsequent "run up" experiments a linear V-log i relationship for over several decades of current density with a slope close to 115 mV. The positions, but not the slopes of Tafel lines, are affected by time or conditions of pretreatments of electrodes (various V or i). The decrease in the activity is attributed to the increase in average thickness of anodically formed surface oxide films. Only when it is assured that the film thickness remains practically unaltered during the i-V measurements, meaningful kinetic parameters for the oxygen evolution reaction are obtained. The reaction order with respect to H^+ is then found to be negative and fractional according to the over-all rate equation

$$i = kc^{-1/2} \exp\left(\frac{F\Delta V}{2RT}\right)$$

A model is suggested according to which a surface oxide film forms a barrier to charge transfer in series with the double-layer barrier. The fractional reaction order is accounted for with this model. A chemical step that follows a charge transfer step is rate determining. It is suggested that oxygen atoms in the surface oxide films participate in the oxygen evolution reaction.

The rate of oxygen reduction at potentials below 1.0V *vs.* hydrogen electrode (HE) is significantly lower at anodically preoxidized than at prereduced noble metal electrodes (1-3). This decrease in catalytic activity has been attributed to the presence of a thin oxide film over the surface of an anodically oxidized metal (1-4). Meyer (5) has suggested that the surface

oxide films at zirconium electrodes form a potential barrier for charge transfer in oxygen reduction. The barrier is in series with the double layer barrier and with the latter controls the over-all rate of oxygen reduction. The same concept has been used by MacDonald and Conway (6) to account for the unusually high Tafel slopes for oxygen evolution reaction at gold, palladium, and gold palladium alloy electrodes. In most of the studies of the kinetics and mechanisms of oxygen evolution reaction at platinum, little attention has been paid to the presence of thin surface oxide films that form (7-13) anodically over the metal surface. The presence of the films, and in particular the film thickness, which varies with time and experimental conditions (9, 10, 13), is expected to affect kinetic parameters (12, 14). Any analysis of the reaction mechanism may be invalid if the effect of film thickness on the kinetics is not taken into account.

In order to assess the importance of the surface oxide films at platinum electrodes, the kinetics of the oxygen evolution reaction in sulfuric acid solutions of different pH's is reexamined at conditions of controlled electrode pretreatment. A mechanism for the reaction is sought that would take into account the presence of oxide films at electrodes.

Experimental

An all glass, three compartment cell used for most of the present experiments is similar to those already described (2, 15). A large platinized platinum gauze in a separate vessel attached to the cell was used to purify solutions (16). For additional pH measurements, another two compartment cell was made. Both the test and reference compartments of this cell are connected to two solution reservoirs each. Solutions in the first two reservoirs were saturated with O_2 and in the other two with oxygen. With this arrangement it has been possible to replace in a few seconds solutions in both compartments with a solution of different pH.

Platinum (stated purity 99.998%) wire (diam = 0.5 mm) electrodes with geometrical areas of 1 cm^2 were "sealed" into Pyrex tubes fitting the true bore inlets in the test compartment. Electrodes were washed with sulfuric acid and quadruply distilled water. The cell and electrodes were finally washed *in situ* with water redistilled directly into the cell.

Solutions are prepared from quadruply distilled water, including distillation from permanganate and bichromate solutions, and analyzed reagents H_2SO_4. Water is distilled directly into the cell. A required amount of sulfuric acid is introduced into the cell from a burette attached to the counterelectrode compartment. Solutions are finally purified by adsorption of residual impurities at a large platinized platinum gauze (16) kept at 0.3V. Oxygen, nitrogen (or argon), and hydrogen are purified by passing through systems of columns each with specific purification function (17).

Prior to an experiment the test electrode was anodically polarized at 1.9V for 1 min and then kept at 0.5V for 5 min (prereduced electrodes). Roughness factor of such electrodes has previously been found (18, 19) to be about 1.7. Current density data are scaled here with this roughness factor. Unless otherwise stated, all potentials refer to the reversible hydrogen electrode in the same solution (HE).
