In cyclic voltammetry, the effects of scan rate on the voltammogram are shown in Fig. 5. On the cathodic sweep, where ruthenate is reduced, the peak current, $i_p/\sqrt{v}$, either increases or decreases as the scan rate increases, depending on the concentration of ruthenate. The effect of scan rate on the cathodic peak current is shown in Fig. 6. It can be observed that for low ruthenate concentrations, the peak current, $i_p/\sqrt{v}$, decreases as the scan rate increases, while at higher concentrations the reverse trend is observed. The pattern shown indicates a chemical reaction is involved following the electron transfer (15). The chemical reaction is irreversible but shows some limited reversible characteristics for ruthenate concentrations of greater than 4×10^{-4}M. It was also noticed that aged solutions showed increasing irreversibility for the reaction. A gradual shift of the curves in Fig. 6 into the shape of curve A was observed. The negative slope of the curves became steeper and started at a slower scan rate. At the same time, solutions of low ruthenate concentration showed increasing visible signs of decomposition. (Stock solutions can be stored for months without deterioration.)

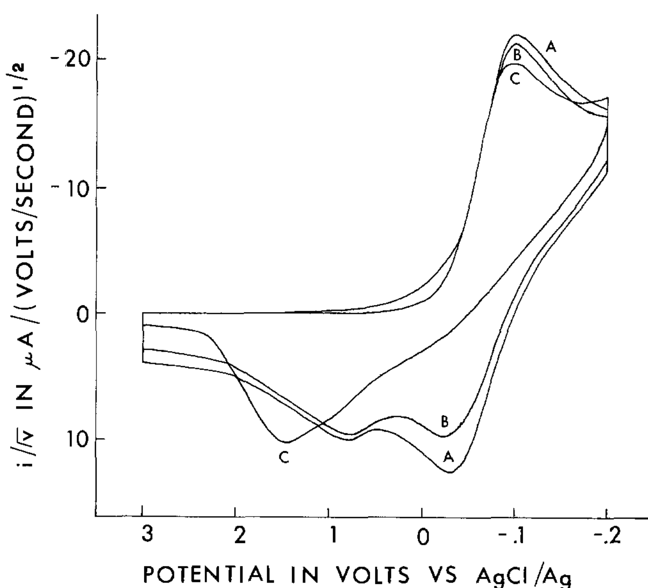

Fig. 5. Cyclic voltammograms of ruthenate reduction showing the effect of scan rate. Ruthenate concentration was 2.0×10^{-4}M in 1M NaOH. Scan rate was: A, 100 mV/sec; B, 50 mV/sec; C, 5 mV/sec.

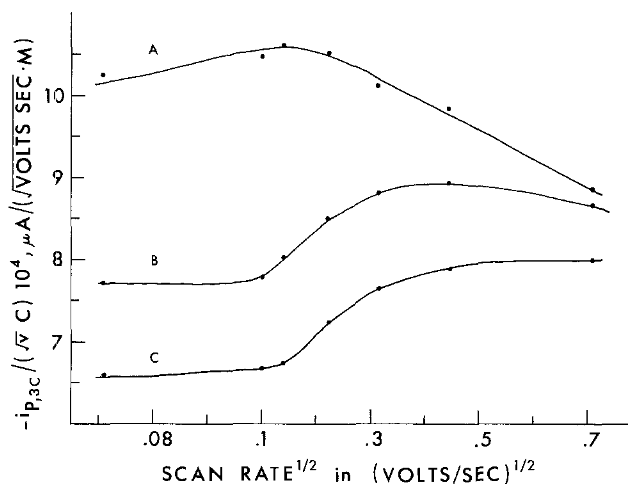

Fig. 6. Effect of scan rate on the cathodic peak current of ruthenate reduction. Ruthenate concentration was: A, 1.0×10^{-4}M in 1M NaOH; B, 4.0×10^{-4}M; C, 6.0×10^{-4}M.

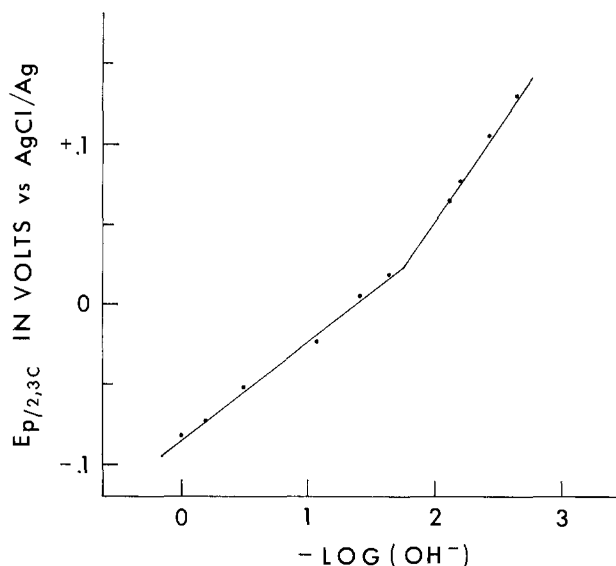

Fig. 7. Effect of hydroxide concentration on the cathodic half-peak potential of ruthenate reduction. Ruthenate concentration was 1.7×10^{-4}M. Scan rate was 50 mV/sec.

The effect of the hydroxide concentration on the voltammogram is shown in Fig. 8. The reduction wave shifts cathodically on increasing the hydroxide concentration, and a corresponding slight increase in peak current is observed. (For low hydroxide concentrations, the peak current also increases very slightly.) The shift of the cathodic peak or half-peak potentials as a function of hydroxide concentration is shown in Fig. 7. Two slopes are observed. For low hydroxide concentrations (below $\sim 1 \times 10^{-2}$M), the shift is approximately -120 mV per decade increase in hydroxide concentration, while at higher concentrations, the average of the least squares slopes of four sets of experiments is -60 ± 1.5 mV/decade. Though the reproducibility of the least-square slope is good, the reproducibility of the peak or half-peak potentials for the same hydroxide concentration from one set of experiments to another is rather poor. A 10 mV shift of the plot along the potential axis is not uncommon. This poor reproducibility was probably due to changes in the electrode surface conditions and, more importantly, the different degree of deteriorations of the ruthenate solutions. Nevertheless, the plot indicates that at high hydroxide concentrations the ratio of $(OH^-)/(e^-)$ is unity, while at low concentrations the ratio is two.

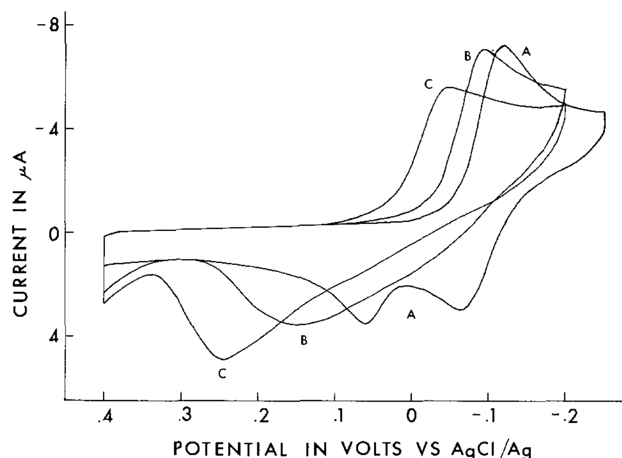

Fig. 8. Cyclic voltammograms of ruthenate reduction showing the effect of hydroxide concentration. Ruthenate concentration was 2.3×10^{-4}M. Scan rate was 50 mV/sec. Hydroxide concentration was: A, 4.0M; B, 0.6M; C, 0.1M.

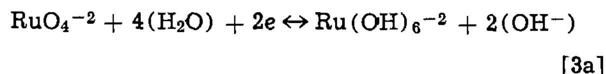
From the above coulometric and cathodic sweep results, the reaction scheme for ruthenate reduction may be written as



$$RuO_4^{-2} + 4(H_2O) + 2e \leftrightarrow Ru(OH)_6^{-2} + 2(OH^-) \quad [3a]$$

$$Ru(OH)_6^{-2} \rightarrow RuO_2 + 2(OH^-) + 2H_2O \quad [3b]$$

The proposed reaction scheme is further supported by the anodic waves of the cyclic voltammograms. Two peaks, instead of one, are observed. This confirms that two electroactive products are produced as the result of the reduction. The more cathodic (negative) peak appears only at higher scan rates as shown in Fig. 5. (This anodic peak together with the cathodic composes the normal cyclic voltammogram for a chemical reaction following the electron transfer when the chemical reaction does not further produce an electroactive product.) The appearance of the peak also depends on the concentration of hydroxide and ruthenate. These effects are shown in Fig. 8 and 9 and are in accord with the proposed reaction. The more positive peak, however, appears under any conditions but is comparatively very small when the ruthenate concentration is small and the scan rate is fast. The shift of the peak potential as a function of hydroxide concentration is -125 ± 3 mV/log(OH) for four sets of determinations. The peak shows all signs such as the sharpness of the peak and the noisy characteristics of the current of a deposit on a solid electrode being reoxidized. The reaction for this peak is thus

$$RuO_2 + 4(OH^-) \rightarrow RuO_4^{-2} + 2H_2O + 2e^- \quad [3c]$$

Only the above two-electron transfer (no one-electron reaction) was detected. Though it has been claimed (17) that a ruthenium (V) species, Na_3RuO_4, can be produced chemically, attempts to reproduce the experiment thus far in this laboratory have failed and no Na_3RuO_4 has ever been found.

Peak IV.—The last pair of peaks was usually obscured by a huge platinum oxide peak occurring immediately before it. To observe the cathodic peak, a reduced platinum electrode must be used.

Coulometric reduction of ruthenate solutions gave charge-time curves with a sloping plateau after an initial rise. Baselines drawn parallel to the plateaus gave the number of electrons as 2.8 ± 0.15 for four determinations. The forms of the electrolysis products are similar to the previous case (reduction to ruthenium dioxide). The film deposited on the electrode can be dissolved in hydrochloric or nitric acid solutions but not in sulfuric acid. Coulometric oxidation of the film or the light green solution back to ruthenate gave the number of electrons between 3.2 and 3.4. The results were high due to the oxidation of the platinum electrode itself, uncertainty in measuring the small absorbance values of the resulting ruthenate solutions, and the relatively large initial charging current. Thus, the number of electrons involved in the over-all reaction is three and the oxidation state of ruthenium in the electrolysis product is III or slightly higher.[1] The u.v.-visible spectrum of the light green solution is shown in Fig. 4, curve D. The spectrum shows that the solution contains a new species besides Ru(IV). The products are susceptible to air oxidation since the solution, upon standing for a couple of days, gave a spectrum similar to curve C.

In cyclic voltammetric experiments, the peak is rather broad and usually seems to have a shoulder on the rising portion of the wave even though the platinum electrode had already been reduced and no platinum oxide peaks should occur. This shoulder can be diminished to an undetectable level if a fast scan rate is used and the voltammogram recorded immediately after a previous sweep. To examine whether this is a composite peak of two or more waves, a slower scan rate was used and the solutions were stirred to enhance the shoulder even more. [These were the conditions used by a previous investigator (7) who first observed the shoulder wave.] The cyclic voltammograms for a stirred and a quiescent solution are shown in Fig. 10. The reproducibility of this shoulder wave is extremely poor and no correlation with the other peaks or any trend in experimental parameters could be detected. However the magnitude of the wave does increase with increasing stirring rate or ruthenate concentration. The same enhancement effect can also be observed if the initial potential is slightly more positive or in other words when the electrode is partially oxidized. The voltammogram recorded with a partially oxidized electrode is shown in Fig. 11 where the shoulder wave is seen to merge with peak IV. This merging of the shoulder wave with peak IV is gradual with a positive increment of the initial electrode potential from +0.1V. This huge composite peak IV was the one observed by another investigator (8) who used a rotating electrode. The same huge wave can also be observed if a high ruthenate concentration (1×10^{-3}M) is used even though the initial potential starts at a more negative value than +0.1V. Thus, all indi-

[1] In a paper by Trojanek (18), which appeared during the preparation of this manuscript, the author compared the areas of peaks IIIa and IVa and found that they were in the ratio of 2:1. Hence, the author concluded that the final product of ruthenate reduction probably has a +III oxidation state.

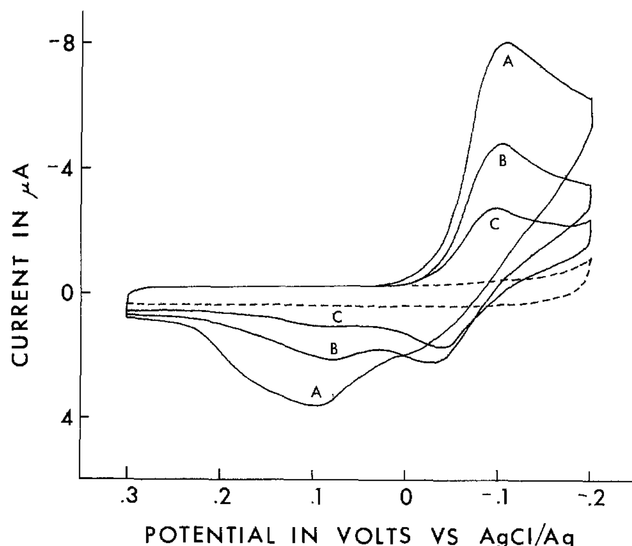


Fig. 9. Cyclic voltammograms of ruthenate reduction showing the effect of ruthenate concentration. Scan rate was 50 mV/sec. Ruthenate concentration was: A, 4.0 × 10^{-4}M in 1M NaOH; B, 2.0 × 10^{-4}M; C, 1.0 × 10^{-4}M. --- blank, 1M NaOH.

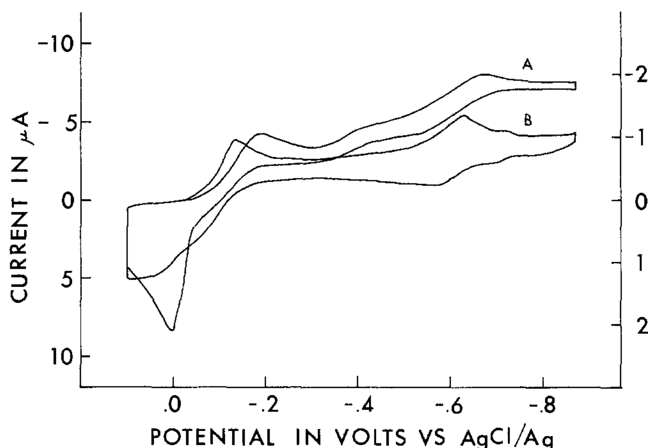

Fig. 10. Cyclic voltammograms of ruthenate reduction showing the ruthenium dioxide reduction peaks. Sweep began at + 0.1V. Ruthenate concentration was 2.0 × 10^{-4}M in 1M NaOH. Scan rate was 2 mV/sec. A, solution was stirred; current scale is on the left. B, solution was quiet; current scale is on the right.

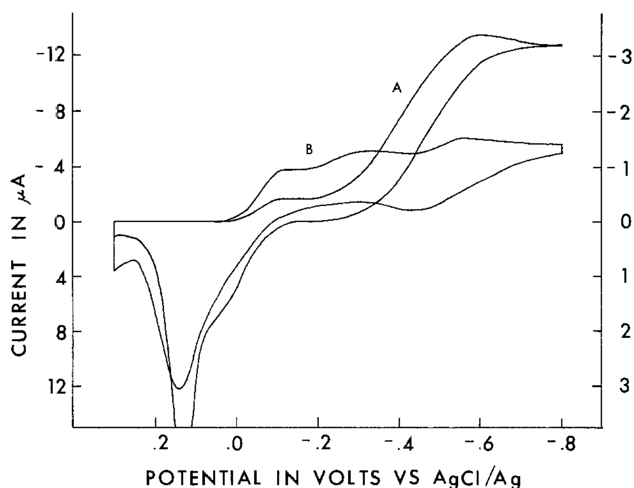

Fig. 11. Cyclic voltammograms of ruthenate reduction showing the ruthenium dioxide reduction peaks. Sweep began at + 0.3V. Other parameters were the same as in Fig. 12.

cations point to the possibility that ruthenate in the solution oxidizes the platinum electrode which in turn produces the platinum oxide peak. Oxidation of the platinum electrode by electroactive species is not uncommon. In the present case, the reduction of ruthenate to ruthenium dioxide occurs at a potential slightly more positive than the oxidation wave of the platinum electrode and thus the possibility of the oxidation of the electrode by ruthenate cannot be discarded.

Figure 12 shows that the platinum electrode is indeed oxidized by ruthenate. Curves A and B in Fig. 12 are, respectively, cyclic voltammograms for an oxidized and a reduced platinum electrode. It can be seen that for the reduced electrode, no sign of the platinum oxide peak is observed. Curve C is also a voltammogram of a reduced electrode, but immediately after reducing the electrode was soaked in a quiet 1×10^{-3}M ruthenate solution for about 2 min and then the electrode was washed with distilled water before recording the voltammogram. In this voltammogram the platinum oxide peak reappears. Thus, the experimental results strongly suggest that the shoulder on peak IV is due to the reduction of platinum oxide. To further confirm this, voltammograms were recorded from an electrolytically plated ruthenium dioxide electrode in sodium hydroxide solutions. The solutions were thoroughly deaerated with nitrogen to avoid further adsorption of oxygen on the electrode [a process favored by ruthenium dioxide (16)]. The resulting voltammograms showed no sign of the shoulder wave.

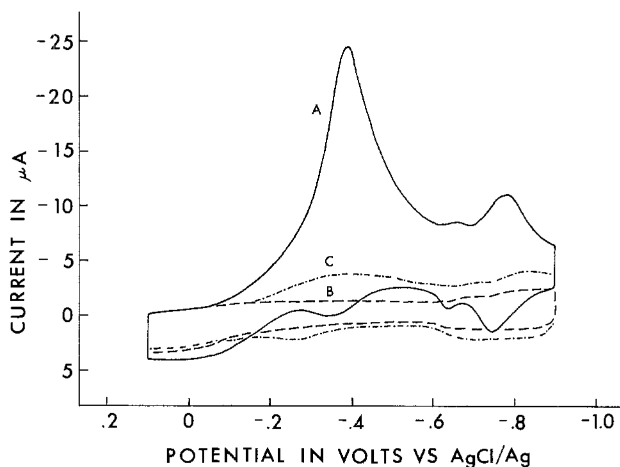

Fig. 12. Cyclic voltammograms of platinum electrode in 1M NaOH. Scan rate was 50 mV/sec. A, electrode was oxidized at + 0.8V before sweep; B, electrode was reduced at —0.9V before sweep; C, same as B but the reduced electrode was soaked in 1×10^{-3}M ruthenate for ~ 2 min and then washed in distilled water before sweep.

The various experimental parameters which affect the peak current are not discussed here since the theory for consecutive reactions starting from solution to solid, then from solid to solid (or a theory simply from solid to solid) has not been developed. However, the effect of hydroxide concentration on the peak potential can be observed easily. The average least-squares slope for plots of both the cathodic and anodic peak potential *vs.* log(OH) is 59 ± 2 mV for three sets of experiments using a platinum electrode, a chemically prepared ruthenium dioxide electrode in hydroxide solution and in ruthenate solution. The measurement of the peak potentials was in fact not very accurate due to the somewhat rounded nature of the peak especially when the ruthenium dioxide electrode was used. The plots, similar to the previous system for peak III, shift 10-15 mV along the potential axis from one to another. The reproducibility of the slope was surprisingly good and the result indicates that the ratio of OH^-/e^- is one. From the above coulometric and voltammetric observations, the over-all reaction responsible for peak IV is postulated as

$$2RuO_2 + H_2O + 2e \leftrightarrow Ru_2O_3 + 2(OH^-) \quad [4]$$

Ruthenium dioxide electrode.—Ruthenium dioxide electrodes freshly prepared by chemical methods give very ill-defined voltammograms (Fig. 13, curve B) except for a pair of prominent peaks immediately following the anodic limit. Slightly deteriorated electrodes, however, provide more defined voltammograms. This was also noticed by previous investigators (1, 2) who ran the electrode in acidic media. The slightly deteriorated condition can be achieved by sweeping or holding the electrode potential past the cathodic limit where the electrode on prolonged standing can collapse very easily. However, the best voltammograms obtained were not very well defined. On the other hand, running the electrode in a ruthenate solution enhances all the ill-defined waves so that they can be observed with ease (Fig. 13, curve A). These waves or peaks coincide exactly with those discussed above for the oxidation and reduction of ruthenate. The first pair of peaks following the anodic limit corresponds to the redox reaction of the $RuO_4^-/RuO_4^=$ couple. The second pair corresponds to that of RuO_4^{-2}/RuO_2 and the third or the most cathodic pair corresponds to RuO_2/Ru_2O_3.

Once these waves have been identified, their behavior can be followed as was shown in the discussion of the RuO_2/Ru_2O_3 reaction above. The behavior of the most positive pair is almost exactly the same as the RuO_4^-/RuO_4^{-2} couple even though it can only be observed qualitatively due to its close proximity to the

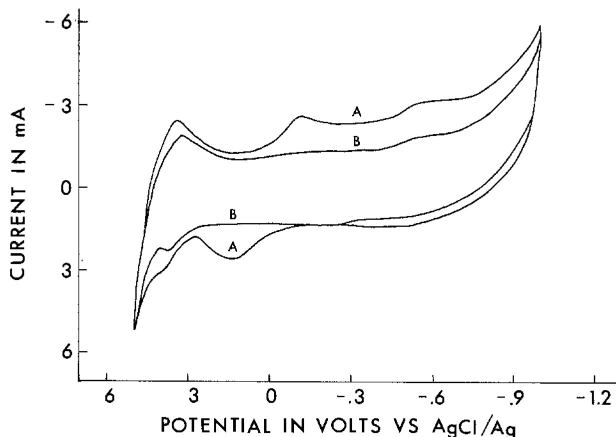

Fig. 13. Cyclic voltammogram of ruthenium dioxide electrode. The scan rate was 50 mV/sec. The solution was: A, 5.4×10^{-4}M ruthenate in 1M NaOH; B, 1M NaOH.

oxygen evolution limit. The only difference between this pair and that of the ruthenate oxidation reaction is in the shift of the average of the cathodic and anodic peak potentials with the hydroxide concentration. For the ruthenium dioxide electrode, the shift is in the cathodic direction with increasing hydroxide concentrations, while in the ruthenate solutions, the shift is in the opposite direction (these effects will be discussed in another paper on the detailed mechanism of ruthenate oxidation). The difference in this behavior is probably due to the nature of the surface as opposed to solution phenomena, since adsorbed oxygen may have been involved in the oxidation of ruthenium dioxide. Nevertheless, the rate of shifts for both, but not their sign, are approximately the same (they differ by ~3 mV). At low hydroxide concentration, however, the anodic peak may possibly be the composite of the oxidation of ruthenium dioxide to ruthenate and then to perruthenate since in voltammograms obtained with a platinum electrode in ruthenate solutions having low hydroxide concentrations, the ruthenium dioxide oxidation peak actually overshadows the ruthenate oxidation wave (Fig. 14). The wave for the RuO_4^{-2}/RuO_2 couple is rather flat and broad, and when freshly prepared electrodes are used it often blends with that of the RuO_2/Ru_2O_3 couple such that one continuous wave is observed. A few sweeps passing the anodic or cathodic limit distinguishes the two waves in that the magnitude for the RuO_2/Ru_2O_3 wave increases while the RuO_4^{-2}/RuO_2 wave remains the same. This, together with the observation that the electrode can withstand several sweeps past the anodic limit, indicates that it can resist oxidation or dissolution much

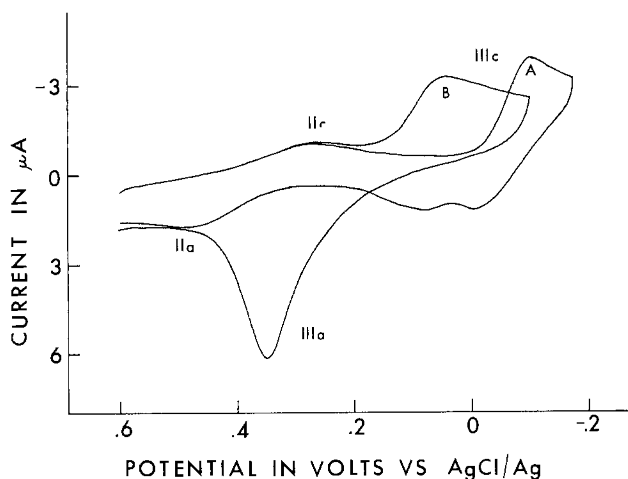

Fig. 14. Cyclic voltammograms showing the overlap of the ruthenium dioxide and ruthenate oxidation peaks. The scan rate was 50 mV/sec. The solution was 1.7×10^{-4}M ruthenate in A, 0.32M NaOH; B, 3.8×10^{-3}M NaOH. The ion strength of the solution was 1M by adding sodium perchlorate.

better than reduction or rearrangement of the crystal lattice, providing the electrode with corrosion resistant characteristics.

During the course of the investigation it was observed that hydrated ruthenium dioxide can undergo partial air oxidation to ruthenate in high hydroxide concentration solutions (> 1M). It is also known that in low hydroxide concentrations, ruthenate decomposes to ruthenium dioxide. Thus, without complexation reactions, the electrode should perform longer in lower pH media.

Some Electrocapillary-Type Behaviors of Gold Electrode

Kaung-Far Lin

Department of Industrial Chemistry and Chemical Engineering, National Tsing Hua University, Taiwan, China

ABSTRACT

The effect of activity on potential of interfacial tension maximum in aqueous solutions of I^-, Br^-, and Cl^- is investigated for gold electrodes. It is seen that the potential decreases with ion concentration at a rate of $-0.1V$/decade in activity for I^- and Br^-. Electrocapillary-type curves for $0.1N$ $N(CH_3)_4OH$ is found to almost coincide with that for $0.1N$ KOH. Change in interfacial tension for I^- and Br^- is of the same magnitude in methanol solution as in aqueous solution.

The electrocapillary behavior of mercury is very well known in the literature. However, much less data is available for solid metals. Electrocapillary-type curves (interfacial tension *vs.* potential) for solid metals have been recently reported by Bockris *et al.* (1, 2) and Beck *et al.* (3, 4). A rather thorough study of the electrocapillary-type phenomena on gold electrode has been made by Lin *et al.* (5). Information about gold electrode is complemented in this study by showing the effect of activity (or concentration) on the observed potential of electrocapillary maximum and comparing interfacial tension curves in organic solution and aqueous solution.

Experimental

Gold ribbon ($0.000127 \times 0.318 \times 50$ cm) with purity 99.99% is used. The interfacial tension is measured by an extensometer. The design and characteristics of the extensometer have been presented previously (3-5). The experimental procedure is the same as those in the previous reports. The potential is relative to standard hydrogen electrode (V_{she}). The potential span is limited in the range that there is no appreciable faradaic current and Joule heating. For small value of linear strain ($\Delta L/L < 10^{-7}$), bulk and surface elastic moduli can be regarded as a constant. Thus a linear relationship between interfacial tension and length of gold ribbon is valid.

Results and Discussion

Activity effect of anions.—It was observed that the surface active anions I^-, Br^-, and Cl^- shift the potential of interfacial tension maximum in a negative direction for gold (5). A series of electrocapillary-type curves are measured for these ions in various concentrations in a small potential span around the interfacial tension maximum and the potential of interfacial tension maximum is thus determined. Figures 1, 2, and 3 show the original electrocapillary-type curves for 4, 1, 0.1, 0.01, and 0.001M aqueous solutions of KI, KBr, and KCl.[1] The activity coefficients of potassium salts in aqueous solution are available in the literature (6). The effect of activity of anions on the potential of interfacial tension maximum is shown in Fig. 4. It can be seen that the potential of interfacial tension maximum changes with activity at a rate of -0.1 V/decade for strongly adsorbed I^- and Br^-, like that observed on mercury (7). However, the potential of interfacial tension maximum for Cl^- decreases with activity nonlinearly on a semilog scale.

Bode *et al.* obtained slopes of lines of -0.050, -0.045, -0.040 V/decade in activity for I^-, Br^-, and Cl^- by open-circuit scrape method for gold electrode (8). The potentials of interfacial tension maximum in Fig. 1 are generally more negative than other reported values (8-10). This trend is also observed for $SO_4^{=}$, ClO_4^-, and NO_3^- though measured change in interfacial tension and charge density is in agreement with the Lippmann equation in electric double layer region (5). The reason for this discrepancy is not exactly known.

Cation adsorption.—It was known that tetra-alkylammonium cations are specifically adsorbed on mercury (11). A tetra-alkylammonium ion would be ex-

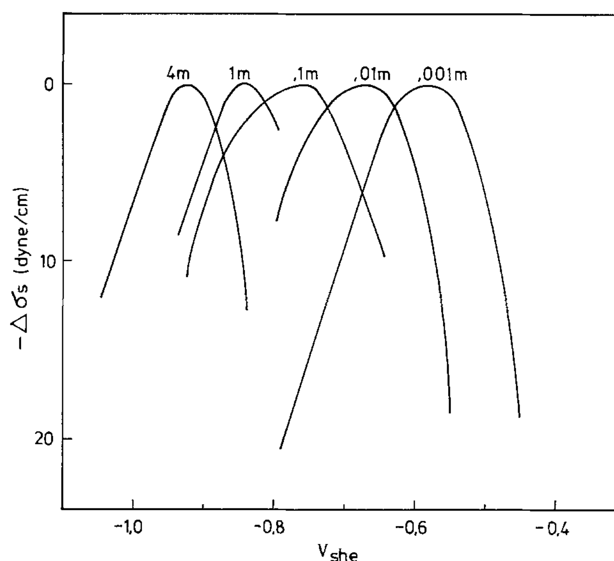

Fig. 1. Electrocapillary-type curves for 4, 1, 0.1, 0.01, and 0.001M aqueous solutions of KI.

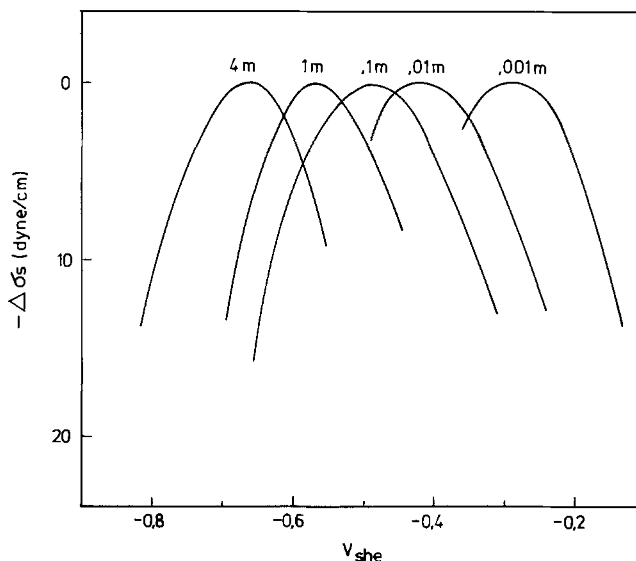

Fig. 2. Electrocapillary-type curves for 4, 1, 0.1, 0.01, and 0.001M aqueous solutions of KBr.

Key words: electrode, capacitance, stress-strain.

[1] The extensometer can measure the change in interfacial tension, not the absolute value. In Fig. 1, 2, and 3, interfacial tension values are arbitrarily set at zero for interfacial tension maximum in various solutions.

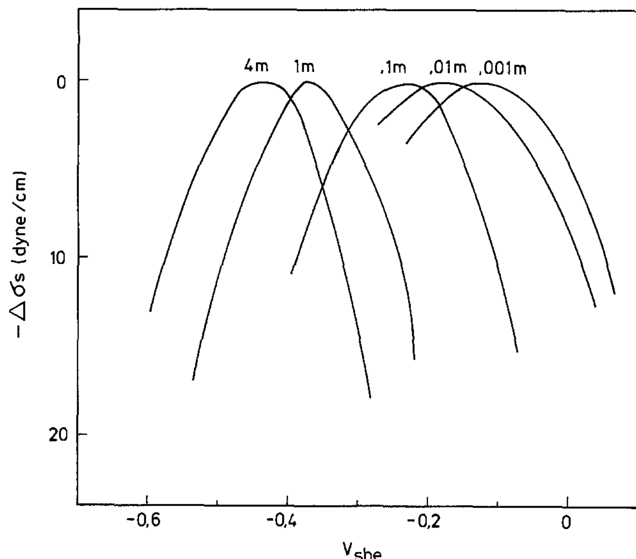

Fig. 3. Electrocapillary-type curves for 4, 1, 0.1, 0.01, and 0.001M aqueous solutions for KCl.

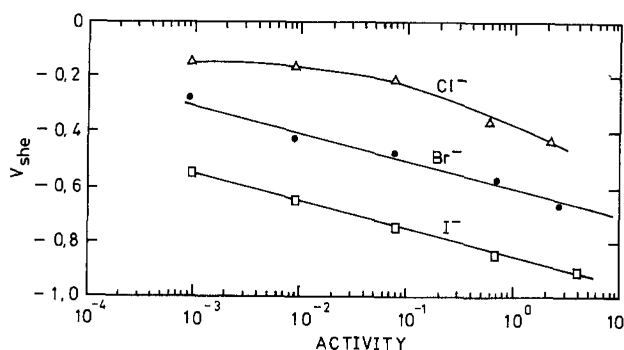

Fig. 4. Effect of activity on potential of interfacial tension maximum in potassium salt.

pected to shift the potential of interfacial tension maximum anodically if it is specifically adsorbed on gold electrode. However, experimental interfacial tension curves for 0.1*N* KOH and 0.1*N* $N(CH_3)_4OH$ almost coincide in Fig. 5. This anomaly can be explained by the fact that, for gold electrodes, adsorption of an anion is enhanced by the large tetramethyl ammonium cation and the metal-anion interaction is stronger than the metal-cation interaction. Thus the anion is nearer to the metal than the cation and a metal-anion-cation bridge is formed. The over-all effect is that there is not much difference in interfacial tension curve for 0.1*N*

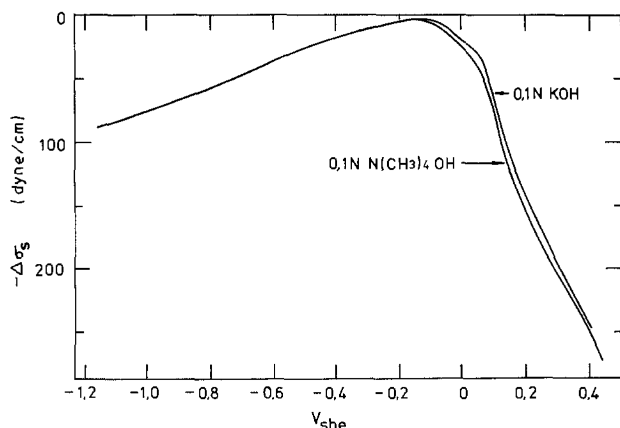

Fig. 5. Interfacial tension curve for aqueous 0.1*N* KOH and 0.1*N* $N(CH_3)_4OH$.

KOH and 0.1*N* $N(CH_3)_4OH$, just like there is not much difference in potentials of zero charge for NaOH and $N(CH_3)_4OH$ in different concentrations (12). The enhancement of anion adsorption by tetra-alkylammonium ion and the formation of metal-anion-cation bridges have been invoked in explaining observed peak potential for gold and silver electrodes (12) and some kinetic processes (13).

Organic solvent.—Interfacial tension curves for 0.1*N* NaI and 0.1*N* NaBr in methanol (ACS reagent grade) are shown in Fig. 6. (The two curves are matched at the negative potential side). It is seen that I^- is more strongly adsorbed on gold than Br^-, with potential of interfacial tension maximum at -0.96 V_{she} and -0.31 V_{she}, respectively. The shift in potential of interfacial tension maximum is thus 0.65V, as compared to 0.2V for 1*N* I^- and Br^- in methanol on mercury (14). For a gold electrode, change in interfacial tension with potential in methanol is of the same magnitude as that in aqueous solution, but shift in potential of interfacial tension maximum for I^- and Br^- is 0.28V in an aqueous solution (5).

A Detailed Treatment of the Reaction Zone for Electron-Transfer Chemiluminescence

J. Lee Morris, Jr., and Larry R. Faulkner*

Department of Chemistry, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Techniques of digital simulation have been used to model the reaction zone yielding chemiluminescence in conventional double or triple potential step experiments. Each simulation describes the steady state achieved within a fixed volume into which the reactant radical ions are injected at a constant rate. Thus each simulation depicts a single point along the luminescence decay curve. Other points are examined via simulations involving different rates of reactant injection. Radical ion annihilation, triplet-triplet annihilation, first-order triplet decay, and triplet quenching by the radical ions are all modeled directly. Problems associated with the simulation of a steady state are discussed in detail. The results of simulations for various sets of realistic rate parameters are compared with the predictions of a simplified treatment of the reaction zone as a homogeneous region of constant width. The impact of quenching by radical ions is evaluated quantitatively for the first time. The results show that one can usually expect triplet lifetimes to be controlled by these species at times early in the light pulse. The importance of this conclusion to the usual interpretation of magnetic effects is discussed.

Light transients produced in electrochemical step experiments have been carefully studied since Feldberg first recognized the value of their shapes for mechanistic diagnosis (1, 2). In these experiments (3, 4), two high energy reactants (*e.g.*, the anion and cation radicals of an aromatic precursor) are generated sequentially at a planar microelectrode in a quiescent solution at diffusion-controlled rates. The first reactant is deposited in the diffusion layer during the forward step, which lasts for a period t_f. Light arises during the reversal step, when the second reactant is produced at the electrode, diffuses outward, and meets the first reactant in a reaction zone located within the diffusion layer. If energy permits, the emitting state can be produced directly by the reactant annihilation (S route). Alternatively, the chemistry may yield triplet intermediates, which can themselves annihilate to produce emitting singlets (T route).

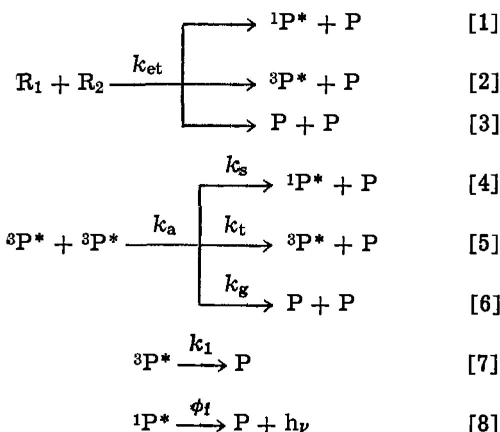
Feldberg noted that these two mechanisms could be distinguished from the form of the light decay, as reflected in the slope of a linear plot of log I *vs.* $(t_r/t_f)^{1/2}$, where I is light intensity and t_r is time measured into the second step from its start (2). The predicted slope for an S-route system requires no model of the reaction zone and is well defined by diffusion. The T mechanism is much more complex, and predictions of the corresponding decay function require a model of the reaction zone. Feldberg took this zone as a small region of fixed thickness into which the reactants are injected at a rate controlled by diffusion (2). Triplets were regarded as being uniformly distributed over the zone, and their concentration was assumed to be at a virtual steady state. This basis simplifies the problem greatly, and the intensity decay is readily defined within its framework. The slope magnitude of a Feldberg plot was expected to exceed that for an S-route case, but it should never be larger than twice that lower limit. Later work by others sought to develop quantitative techniques for extracting mechanistic information from the light transients (3-7).

Finding experimental systems that are explicable in terms of the theory has proved very difficult, despite the fact that the electrochemical features are often quite well behaved (8, 9). Feldberg slopes are frequently 4-6 times larger than the S-route value, and only rarely are T-route shape functions followed over a wide time range, even when reaction energy dictates a T mechanism (10-12). Part of the problem is that Feldberg plots are linear only for $t_r/t_f \geqq 0.2$, when most of the light pulse has passed, and the reactant levels are easily perturbed by side reactions (13). Another aspect is that the simplifications introduced in the Feldberg model may be too restrictive to allow an accurate prediction of decay functions, except in special cases.

In this paper, we present a technique for obtaining detailed models of the reaction zone. Calculations for realistic experimental situations allow an evaluation of the assumptions underlying the simplified model. In addition, they provide rationale for a number of anomalous observations, and they yield insight into the fundamentals of important experimental methods.

The Simplified Model

We consider only the case in which the two reactant ions are produced from the same precursor, P. The reaction scheme is given by [1]-[8]



where R_1 and R_2 are the reactants and $^1P^*$ and $^3P^*$ are excited singlet and triplet precursors. The parameter k_1 is the first-order rate constant for triplet decay, and ϕ_f is the fluorescence efficiency of $^1P^*$.

Reactions [1]-[3] take place at a rate controlled by diffusion of R_1 and R_2 into the reaction zone (2, 5). That rate is N (moles per second), and the reaction zone volume is V_r. The kinetics of triplet formation by [2] and decay by [4]-[7] leads to an analytical expression for the triplet concentration, *viz.*

* Electrochemical Society Active Member.

Key words: chemiluminescence, diffusion, kinetics, simulation.

$$[^3P^*] = \frac{-1 + [1 + 8\,k_a(1-g)\tau^2 L/V_r]^{1/2}}{4\,k_a(1-g)\tau} \quad [9]$$

The steady-state approximation for $^3P^*$ has been invoked, and the reaction zone has been taken as homogeneous. The various symbols in [9] are defined as follows: $k_a = k_s + k_t + k_g$, $\tau = 1/k_1$, $g = k_t/2k_a$, $L = \phi_t N$. The parameter ϕ_t is the triplet yield of radical ion annihilation. Using the additional relationships [10] and [11]

$$I = \phi_f \phi_{tt} k_a [^3P^*]^2 V_r \quad [10]$$

$$V_r = fA(Dt_f)^{1/2} \quad [11]$$

one can develop a relationship for the T-route intensity in dimensionless terms

$$\omega_i = \beta[1 - (1 + \alpha\omega_n/\beta)^{1/2}] + 0.5\,\alpha\omega_n \quad [12]$$

Here ϕ_{tt} is the singlet production efficiency of triplet-triplet annihilation k_s/k_a, D is the diffusion coefficient, and A is the electrode area. Equation [11] essentially defines f as a dimensionless reaction zone thickness, which is taken as a constant throughout the experiment. In [12], $\omega_i = It_f^{1/2}/AD^{1/2}C_P^*$ and is the dimensionless intensity; $\omega_n = Nt_f^{1/2}/AD^{1/2}C_P^*$ and is the dimensionless ion annihilation rate; $\alpha = \phi_t\phi_{tt}\phi_f/(1 - g)$; $\beta = ft_f\phi_f\phi_{tt}/8k_a\tau^2C_P^*(1 - g)^2$; and C_P^* is the bulk precursor concentration. Since ω_i can be determined experimentally and ω_n can be readily calculated theoretically, the simplified treatment allows the evaluation of α and β from real data, in principle. Estimates of the triplet yield ϕ_t could be obtained from reliable α's.

There are at least three important deficiencies in the treatment: (*i*) Time-dependent triplet quenching by radical ions is not considered. (*ii*) The reaction zone thickness is assumed to remain constant throughout the experiment. (*iii*) The reaction zone is taken as a homogeneous region.

The presence of radical ions in and around the reaction zone bears importantly on all three of these issues. These species have been shown to deactivate triplets readily (14, 15), and a detailed treatment must implicate kinetics reflecting this activity. If radical ion quenching has a large influence on the triplet lifetime, then that lifetime will show a time dependence as the radical ion concentrations decrease during the course of the experiment. Since the triplet lifetime partially determines the size of the reaction zone, it is evident that the radical ion concentrations will also play a role in controlling the thickness of the zone, f, along the dimensionless diffusion axis. A time-dependent lifetime would imply a time-dependent f. Finally, we note that the relative competitiveness of quenching by radical ions and triplet-triplet annihilation changes across the reaction zone, because both triplets and radical ions are inhomogeneously distributed. One of our goals here is to use a detailed model to evaluate the practical impact of these factors on the light decay.

Formulation of the Problem

Most aspects of the computer program developed to model the reaction zone involve well-known digital simulation techniques (16, 17) and need not be discussed. Most of the notation used here corresponds to common practice in dealing with electrochemiluminescence (ECL). There are, however, several features of this particular simulation that are unique and require amplification. These include: (*i*) the basic spatial features of the reaction zone, (*ii*) the means of ascertaining the stopping point for the simulation, and (*iii*) the methods for evaluating the rates of ion and triplet annihilation.

Any consideration of the reaction zone begins with the concentration profiles of the radical ions during the second step of the experiment. Figure 1 shows a typical case. The reaction zone is the region where

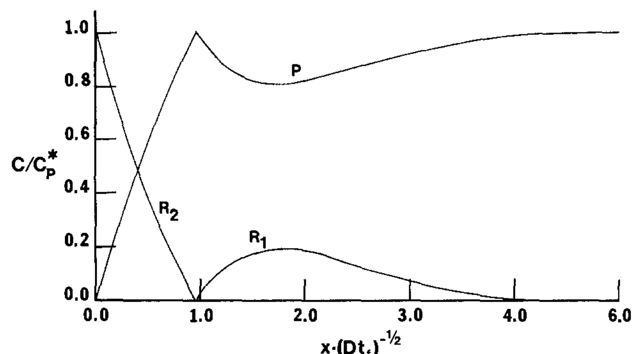


Fig. 1. Concentration profiles in the diffusion layer at $t_r/t_f = 0.4$

the profiles for R_1 and R_2 meet. This region is very thin compared to the thickness of the whole diffusion layer, hence the rate of ion injection into the reaction zone is dictated by the slopes of the essentially linear profiles on either side (13). The time scale over which the profiles evolve is much longer than those of the steps in reaction scheme [1]-[8], hence a steady-state condition essentially prevails within the zone (7). The rate of ion injection, therefore, equals the rate of ion annihilation N (or ω_n, in dimensionless format). This parameter is determined only by basic considerations of diffusion and is readily calculated (13). For any time t_r/t_f, there is a corresponding ω_n value.

Thus, the problem is to model the steady-state condition for a reaction zone into which reactants are injected from opposite sides at a fixed rate. The digital arrays representing various species are initialized arbitrarily, then they are manipulated according to the dynamic laws until a steady condition is reached.

Initialization.—The starting concentration profiles of the reactants R_1 and R_2 are chosen to be linear functions. Their concentrations are largest at opposite sides of the zone and decrease to zero at the center The concentration of the precursor P is chosen such that the sum of all fractional concentrations ($f_i \equiv C_i/C_P^*$, where i is any species) in any box is unity. This relationship always holds for the present case, in which all species have the same diffusion coefficient (13).

Since the radical ion annihilation rate changes over a long time scale, a simulation at steady state yields a picture of the system for essentially a single experimental time. A series of simulations for discrete values of ω_n must be carried out to cover a wide time range. Once one sets ω_n for a given simulation, one has fixed the injection rates of R_1 and R_2 and, thus, the gradient in their concentrations at the two boundaries. This gradient is the slope used for the initial linear profiles. It allows one to fix the initial difference in fractional concentration between adjacent boxes in the simulation, if one first determines the size of the zone to be considered and the number of boxes in that zone.

We have chosen to define the reaction zone size in terms of the rates of diffusion and electron transfer. Thus the actual zone width, d, along the diffusion axis is given by

$$d \equiv v\left(\frac{D}{k_{et}C_P^*}\right)^{1/2} \quad [13]$$

where D is the diffusion coefficient, k_{et} is the over-all rate constant for electron transfer, and v is a scale factor to be optimized. It is easy to see that $(k_{et}C_P^*)^{-1}$ has the units of time and defines a time scale for the electron transfer reaction. Therefore, the value of v is the size of the reaction zone in terms of diffusion lengths on this time scale. This parameter is a simulation variable and can be selected at will, but it must be large enough to accommodate all of the reaction events of interest. Ideally, it is no larger. Using this definition, that of the model diffusion co-

efficient, D_M

$$D_M \equiv \frac{D\Delta t}{\Delta x^2} \quad [14]$$

and the dimensionless redox rate constant κ

$$\kappa = k_{et} t_f C_P{}^* \quad [15]$$

we arrive at useful expressions for the space and time increments, Δx and Δt, that characterize the simulation

$$\Delta x = \frac{v}{(j_{max} - 1)} \left(\frac{Dt_f}{\kappa} \right)^{1/2} \quad [16]$$

$$\Delta t = \frac{v^2 D_M t_f}{\kappa (j_{max} - 1)^2} \quad [17]$$

Here, it is understood that the distance d is represented by boxes numbered from 1 to j_{max}, so that $d = (j_{max} - 1)\Delta x$.

The value of J, the difference in fractional concentrations between adjacent boxes in the initial linear concentration profiles of R_1 and R_2, can now be determined to be

$$J = \frac{\omega_n v}{\kappa^{1/2}(j_{max} - 1)} \quad [18]$$

See the Appendix for details. This relation provides the means for initializing the simulation.

Let us note a few differences between the simulation technique presented here and that which is utilized in the more familiar case of semi-infinite linear diffusion. In the latter case, the time resolution is specified by the number of iterations corresponding to some experimental period (16, 17), whereas the number of boxes required for spatial representation is not directly controlled. Therefore, the over-all size of the region to be described is initially unknown. In the steady-state case presented here, the over-all size of the reaction region and the number of boxes representing it are specified at the start, thus the spatial resolution is initially defined in direct terms. Time resolution is defined indirectly through D_M, and the number of iterations required to achieve steady state is completely unknown. Whereas the number of iterations is the chief simulation variable in the semi-infinite case, the reaction zone scaler is the chief variable for the present model. Since the number of iterations cannot be preset in this case, some other indicator must be devised for stopping the simulation when steady state is reached.

Boundary conditions.—The key constraint on the model is that the two radicals are injected from opposite sides at steady rates corresponding to the value of ω_n chosen for the simulation. This condition is enforced for R_2 by maintaining its fractional concentrations in boxes 1 and 2 at the constant difference J. After each iteration, the fractional concentration in box 1 is adjusted appropriately. For species R_1, the boundary condition is enforced in boxes $j_{max} - 1$ and j_{max} in exactly the same way. The zone width parameter v is always sufficiently large that radical ions do not diffuse through the zone and triplets do not diffuse out of it.

Dynamics.—The chemical reactions that must be considered in the reaction zone are (*i*) electron transfer, (*ii*) triplet-triplet annihilation, (*iii*) first-order triplet decay, and (*iv*) quenching of triplets by radical ions. The expressions used to determine the changes in the various fractional concentrations in each box during each iteration are listed below. They are derived by conventional techniques for treating homogeneous processes (16, 17)

$$-\Delta f_{R_1} = -\Delta f_{R_2} = \Delta f_T/\phi_t = \Delta f_P/(2 - \phi_t) = \frac{v^2 D_M f_{R_1} f_{R_2}}{(j_{max} - 1)^2} \quad \text{electron transfer} \quad [19]$$

$$-\Delta f_T = \Delta f_P = \frac{2v^2 D_M}{(j_{max} - 1)^2}(1 - g)\left(\frac{k_a}{k_{et}}\right) f_T{}^2 \quad \text{triplet-triplet annihilation} \quad [20]$$

$$-\Delta f_T = \Delta f_P = \frac{v^2 D_M}{(j_{max} - 1)^2}\left(\frac{k_1}{k_{et} C_P{}^*}\right) f_T \quad \text{first-order triplet decay} \quad [21]$$

$$-\Delta f_T = \Delta f_P = \frac{v^2 D_M}{(j_{max} - 1)^2}\left(\frac{k_q}{k_{et}}\right) f_T f_Q \quad \text{radical-ion quenching} \quad [22]$$

Here, the f_i's are fractional concentrations of species denoted by the subscripts, where T signifies the triplet $^3P^*$, and Q stands for both radical quenchers R_1 and R_2, which are assumed to destroy triplets equally effectively by rate constant k_q, *i.e.*

$$^3P^* + Q \xrightarrow{k_q} P + Q \quad [23]$$

Thus, $f_Q = f_{R_1} + f_{R_2}$. The singlet $^1P^*$ is not specifically modeled because its lifetime is too short to permit significant concentrations at steady state. These reactions are allowed to occur sequentially in the simulation at the end of each iteration, just after diffusion of all species.

Steady-state criterion.—The simulation is stopped at the earliest point where the values of the total radical ion reaction rate and the total triplet-triplet annihilation rate cease to change significantly in successive iterations. The total electron transfer rate is given by ω_n, and the total triplet-triplet annihilation rate is given in dimensionless terms by an analogous parameter ω_t, which for a T-route system is directly proportional to ω_i

$$\omega_t = \omega_i/\phi_f \phi_{tt} \quad [24]$$

Both ω_i and ω_t can be determined from the input parameters for the simulation and the concentration profiles at the end of each iteration. It was necessary to monitor both functions, because they approached steady state at different rates. Their values can be calculated at any time from the following expressions, which are derived in the Appendix

$$\omega_n = \frac{v\kappa^{1/2}}{(j_{max} - 1)}\left[\sum_j f_{R_1}(j) f_{R_2}(j) + \frac{(j_{max} - 1)^2}{v^2 D_M} \sum_k f_l(k)\right] \quad [25]$$

$$\omega_t = \left(\frac{k_a}{k_{et}}\right)\left[\frac{v\kappa^{1/2}}{(j_{max} - 1)}\right] \sum_j f_T{}^2(j) \quad [26]$$

The second term in [25] is introduced to account for those boxes in which the extent of the redox reaction is limited by the concentration of R_1 or R_2. The fractional concentration f_l refers to the limiting value f_{R_1} or f_{R_2}. The summation in the first term runs over all boxes j where a limiting reagent is not found. The summation in [26] runs over all boxes in the zone.

The validity of using ω_t and ω_n to determine the steady state was tested by monitoring the ratio of ω_t to ω_n for a special case. In the absence of triplet decay and radical ion quenching, all triplets must undergo triplet-triplet annihilation, and one obtains simply from stoichiometric factors

$$\frac{\omega_t}{\omega_n} = \frac{0.5\alpha}{\phi_f \phi_{tt}} = \frac{0.5\,\phi_t}{(1 - g)} \quad [27]$$

For the simulations considered here, where $\phi_t = 1$ and $g = 0.37$, Eq. [27] produces the numeric ratio $\omega_t/\omega_n = 0.794$. A valid simulation must predict this result. In addition, the value of ω_n calculated from

[25] ought to agree with the assigned value used to fix the injection rates of R_1 and R_2.

In general, we found that the ratio ω_t/ω_n was quite independent of model variables and was very close to 0.794. However, the individual values of ω_t and ω_n were significantly sensitive to the spatial resolution of the simulation. This effect is illustrated by the results in Table I. The reasons behind it are not fully understood. In part, it seems to stem from the ordered manner in which diffusion and the chemical processes are effected in the model. The sequential handling of processes that are actually concurrent may lead to a slightly erroneous steady state. Still, the important ratio ω_t/ω_n is reliably predicted, and the zone width parameter can be optimized so that the assigned and calculated values of ω_n agree very closely. The zone width scaler values listed in Table II for various values of ω_n yield agreement within 1% for a 51 box simulation. These values of v were used to obtain results reported below. They increase as ω_n falls, because the reaction zone expands as the concentrations and the gradients of the radicals decline.

Results and Discussion

The simplified view of the ECL reaction zone as a homogeneous region of light emission is a good first approximation for the case of (*i*) an infinitely fast ion annihilation rate, (*ii*) a very short triplet lifetime, and (*iii*) no triplet quenching by radical ions. However, the results of the simulations reported below indicate that this treatment cannot be extended to cases with realistic reaction parameters. In our work, we have assumed that the electron transfer rate constant is on the order of 10^{10} M^{-1} sec^{-1}. This figure accords with the few available experimental measurements (6, 18). For $t_f = 1$ sec, and $C_P^* = 10^{-3}M$, we arrive at $\kappa = 10^7$, which is a constant for all simulations. The rate constants k_a and k_q are probably significantly smaller than k_{et} (14, 19-25), hence we have used ratios (k_a/k_{et}) and (k_q/k_{et}) equal to 0.1 in our simulations. It is important to recognize that the values of κ, (k_a/k_{et}), and (k_q/k_{et}) must lie fairly near our choices, because the rate constants determining them are diffusion controlled (or nearly so) and should not vary much from system to system. In contrast, the rate constant for first-order triplet decay, k_1, has wide latitude. In carefully deaerated solutions, it probably corresponds to a lifetime $\tau_{max} = 1/k_1$ of perhaps 100 μsec. Under more favorable conditions, τ_{max} could approach or exceed 1 msec. Poor purity could produce a value as short as 1 μsec.

Table I. Dependence of simulation performance on zone width*

v	ω_n	ω_t	ω_t/ω_n
50	29.08	23.23	0.799

90	28.23	22.65	0.802
100	26.34	21.21	0.805

* $\omega_n = 30$ (assigned), $j_{max} = 51$, $\kappa = 10^7$, $(k_1/k_{et}C_P^*) = 0$, $(k_a/k_{et}) = 10$, $(k_qk_{et}) = 0$, $\phi_t = 1$, $g = 0.37$, $D_M = 0.45$.
† Optimal v.

Table II. Optimal values of the zone width scaler*

Assigned ω_n	Optimized v
30	76
15	92
10	107
5	129
1	179
0.1	291

* $j_{max} = 51$, $\kappa = 10^7$, $(k_1/k_{et}C_P^*) = 0$, $(k_a/k_{et}) = 10$, $(k_q/k_{et}) = 0$, $\phi_t = 1$, $g = 0.37$, $D_M = 0.45$.

Shorter values would probably lead to complete loss of T-route emission and are not of interest. In all of our simulations, we assume that the electron transfer reaction produces triplets with efficiency $\phi_t = 1$.

Structure of the reaction zone.—Figures 2a and 2b illustrate the inhomogeneity of the reaction zone under realistic conditions. The radical ion profiles overlap considerably in the light emitting region, and the total radical ion concentration at the center is sizable. The illustrated case is for $\omega_n = 30$ and would apply at a point just earlier than $t_r/t_f = 0.001$. These results indicate that for a typical ECL experiment, where the bulk precursor is present at a 1 mmole level, the radical ion concentration is near $5 \times 10^{-5}M$ in the very early part of the light transient. Such a concentration is large enough to completely overshadow first-order decay, unless k_1 provides for triplet lifetimes less than 10 μsec.

This conclusion is very important for its bearing on the interpretation of magnetic effects. The rationale now offered for the magnetic enhancements that are universally seen for energy deficient systems rests on the assumption that triplet disappearance (aside from annihilation) is almost totally controlled by the radical ions (3, 4, 14, 15, 26, 27). Our present results strongly support the validity of that assumption, at least for the earliest experimental times, where magnetic measurements have usually been made.

At later times, when ω_n falls, the mean radical concentration across the light emitting region also declines, and first-order processes may regain control of triplet decay. For example, $\omega_n = 1$ yields a mean concentration near $5 \times 10^{-6}M$. This level would dominate triplet deactivation only in systems with τ_{max}

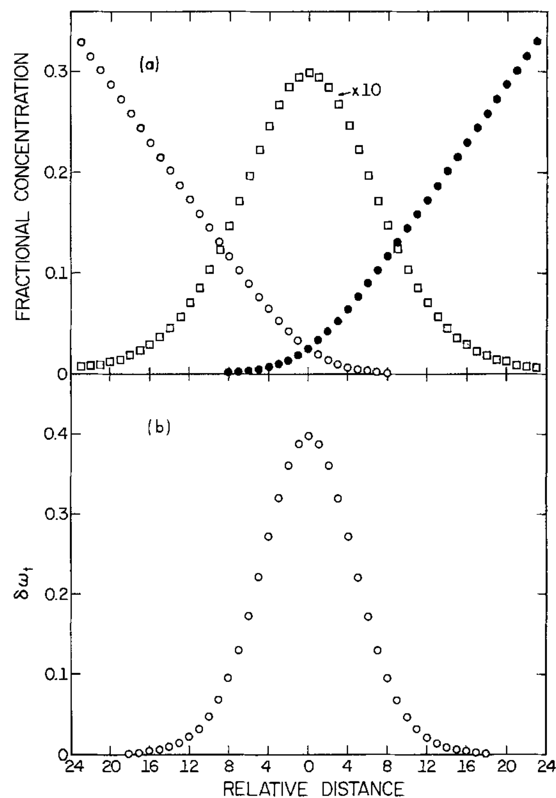

Fig. 2. Distributions across the reaction zone. (a) Concentration profiles: filled circles, R_1; open circles, R_2; squares, triplets. (b) Triplet-triplet annihilation rate; each point represents the contribution to ω_t made in a single box. Parameters: $\phi_t = 1$, $\kappa = 10^7$, $(k_a/k_{et}) = 0.1$, $(k_q/k_{et}) = 0.1$, $(k_1/k_{et}C_P^*) = 10^{-3}$, $j_{max} = 51$, $D_M = 0.45$, $g = 0.37$, $\omega_n = 30$. Distance axis is relative to the center of the reaction zone and is in units of Δx. For $t_f = 1$ sec, $C_P^* = 10^{-3}M$, and $k_{et} = 10^{10}$ M^{-1} sec^{-1}, this simulation corresponds to $t_r \sim 1$ msec and a first-order triplet lifetime of 100 μsec.

$= 1/k_1 \lesssim 100$ μsec. The corresponding experimental time is $t_r/t_f = 0.236$.

Also of interest is the distribution of light emission, which for a T-route system is directly proportional to the rate of triplet-triplet annihilation. The distribution for that process is shown in Fig. 2b. It is significantly narrower than the over-all reaction zone, because there is a square dependence on $[^3P^*]$, and because triplet-triplet annihilation becomes uncompetitive in the wings of the triplet distribution. For the conditions applicable to Fig. 2b, the width of the distribution at half-height is on the order of $10(D/k_{et}C_P^*)^{1/2}$, which amounts to about 10^{-5} cm for typical values of D, k_{et}, and C_P^*. At later times, the zone widens considerably, as one sees in Fig. 3, which gives the distribution of intensity with distance from the center. To facilitate comparisons of breadth, the curves in the figure have been normalized to unit height. Of course, the absolute intensity decreases with time, due to the steadily decreasing availability of R_1.

In general, the broadening of the emitting region results from three effects. The first of these is the increased overlap in the profiles of R_1 and R_2 as time proceeds. With decreasing ω_n, the concentrations of the radicals in the reaction region fall, hence the two reactants can penetrate their opposing profiles to greater distances before annihilation is assured.

A second factor reflects an interplay between the first-order lifetime τ_{max} and the rate of triplet-triplet annihilation. Since the latter factor depends on the square of the triplet concentration, its effect decreases with time as ω_n and the triplet concentration fall off. Triplet-triplet annihilation in these systems is often competitive with first-order decay; thus, the triplets live longer as the experiment proceeds and are able to diffuse further before deactivation.

The third effect leading to a broadening of the intensity distribution is the time dependence of triplet quenching by radical ions. This process also controls the actual triplet lifetime to a significant degree. Since the ion concentrations decrease steadily during the experiment, the triplet lifetime again increases monotonically, and the emission zone widens.

The triplet concentrations shown in Fig. 2a approach the highest that can be achieved, because ω_n is very large, and ϕ_t has been set to unity. The calculated level is on the same order as that of the radical ions and shows that triplet-triplet annihilation can indeed be competitive with other processes for deactivating triplets, particularly at early times. Annihilation efficiencies near 50% seem possible. At later times, the competitiveness of annihilation always declines, hence light from the T route must decay faster than ω_n does.

Effective width of the reaction zone.—The curves depicted in Fig. 4-6 illustrate the effect of triplet lifetime on the effective size of the emitting region. The circles in each figure represent simulations in which triplet quenching by radical ions is deleted; *i.e.*, $(k_q/k_{et}) = 0$. In those cases, the triplet lifetimes are constant with time, aside from the effect of annihilation, and the simplified treatment can be tested by direct comparison with the simulations.

Our test of the adequacy of that treatment is to examine the time dependence of the effective zone width parameter f, which is defined in [11]. It is

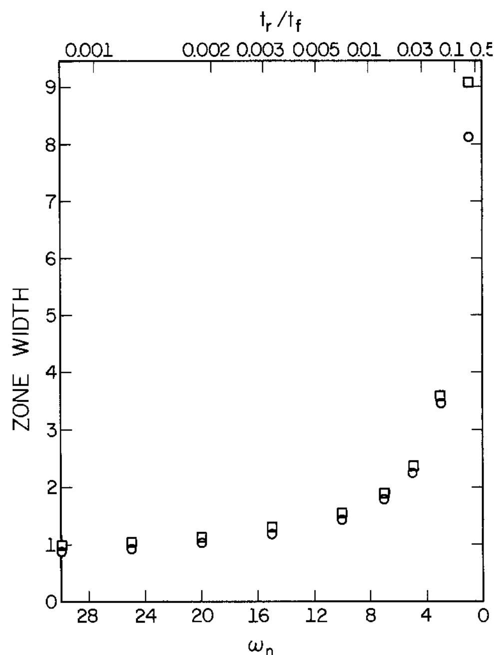

Fig. 4. Variation of effective zone width with ω_n. Circles show f vs. ω_n for $(k_q/k_{et}) = 0$. Squares show $f(\tau_{max}/\tau)^2$ vs. ω_n for $(k_q/k_{et}) = 0.1$. Both curves have ordinates multiplied by 100. All unspecified parameters are the same as for Fig. 2, except $(k_1/k_{et}C_P^*) = 0.1$. For $t_f = 1$ sec, $C_P^* = 10^{-3}$M, and $k_{et} = 10^{10}$ M^{-1} sec^{-1}, these curves correspond to $\tau_{max} = 1$ μsec.

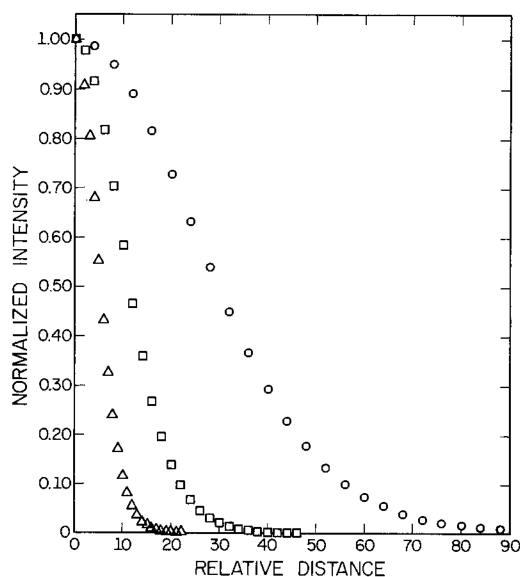

Fig. 3. Normalized intensity distributions as a function of ω_n. Same conditions as for Fig. 2. Circles, $\omega_n = 0.1$; squares, $\omega_n = 3$; triangles, $\omega_n = 30$.

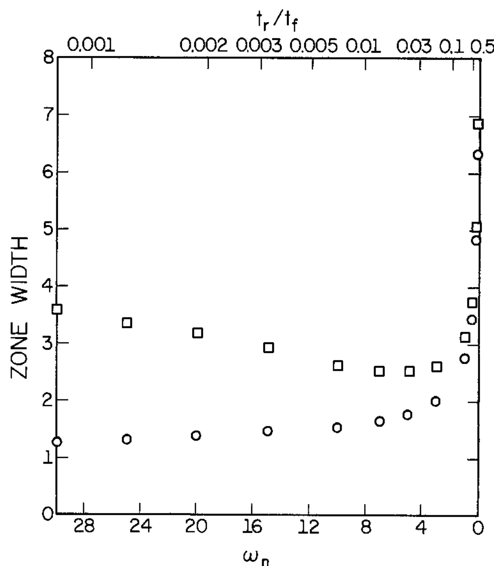

Fig. 5. Variation of effective zone width vs. ω_n. All details are the same as for Fig. 4, except $(k_1/k_{et}C_P^*) = 10^{-2}$. For $t_f = 1$ sec, $C_P^* = 10^{-3}$M, and $k_{et} = 10^{10}$ M^{-1} sec^{-1}, these curves correspond to $\tau_{max} = 10$ μsec.

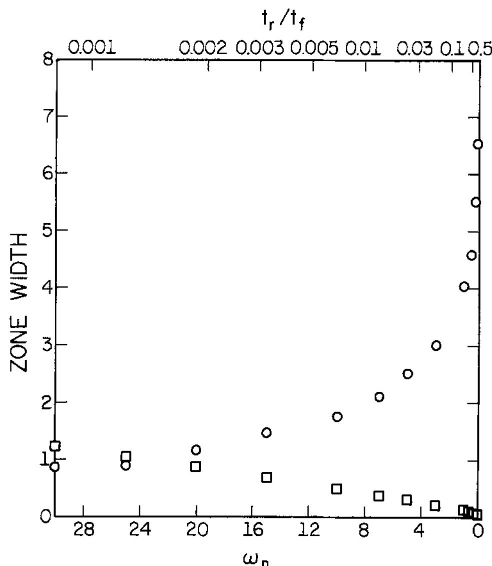

Fig. 6. Variation of effective zone width vs. ω_n. All details are the same as for Fig. 4, except $(k_1/k_{et}C_P^*) = 10^{-3}$. For $t_f = 1$ sec, $C_P^* = 10^{-3}$M, and $k_{et} = 10^{10}$ M^{-1} sec^{-1}, these curves correspond to $\tau_{max} = 100$ μsec. The squares have not been scaled upward, hence their true ordinates are ~100 times larger than those of the circles.

easy to obtain the value of f for any given reaction situation. The simulation yields ω_t for a particular set of dynamic parameters and a single defined value of ω_n. Equations [12] and [14] link ω_t and ω_n in an explicit manner for any set of dynamic conditions. Only f is freely adjustable. One can, therefore, calculate it from the simulated ω_t corresponding to any ω_n. This job is readily accomplished by the Newton-Raphson technique. The time dependence of f is important, because an assumption that it is constant underlies every proposed scheme for evaluating dynamic parameters from T-route decay curves.

The figures indicate that, in the absence of triplet quenching by radical ions, the effective size of the zone is strongly time dependent. It remains constant within a factor of two until ω_n reaches a value near 5 ($t_r/t_f \cong 0.02$). Smaller values of ω_n, applicable at later times, lead to drastic increases in effective zone size. This result in itself precludes the use of Feldberg plots for extracting dynamic parameters, because the plots utilize data only for values in the range $0.2 \leq t_r/t_f \leq 1.0$, where f changes most rapidly. The frequent experimental observation of Feldberg slopes steeper than -2.90 may manifest the expanding f. We shall address that aspect in more detail below.

It is interesting that changing the triplet lifetime τ_{max} from 1 to 100 μsec has little effect on the f function. This result suggests that the main determinant of effective zone thickness is not triplet diffusion, but overlap of the reactant profiles, unless τ_{max} is very long. The details of the f curve change from case to case, because the competitiveness of triplet-triplet annihilation varies in a complex way across the zone, and f must accommodate these spatial aspects.

The squares in Fig. 4-6 correspond to simulations in which the triplets are quenched by the radicals with $(k_q/k_{et}) = 0.1$. Simulated ω_t values were obtained for various sets of conditions in a straightforward manner, but comparisons with [12] and [24] were complicated by the fact that the triplet lifetime τ (which appears in β) varies across the reaction zone in a complex fashion. Our approach was to treat the aggregate $f(\tau_{max}/\tau)^2$ as an adjustable parameter that can be used to bring the simulated results and the simplified treatment into agreement. Applications of the simplified approach demand only that this aggregate be reasonably constant, and that is our concern here. The value of $f(\tau_{max}/\tau)^2$ is readily calculated for any set of conditions by the Newton-Raphson method.

The behavior of this function depends markedly on the value of the first-order lifetime τ_{max}. For very short τ_{max} (Fig. 4), radical ions are not competitive quenchers, hence $(\tau_{max}/\tau) \to 1$, and one obtains the f function defined earlier without quenching by radical ions.

For intermediate τ_{max} (Fig. 5), the radical ions are effective quenchers at early times. Thus $(\tau_{max}/\tau) > 1$, and $f(\tau_{max}/\tau)^2$ lies well above the f curve obtained without quenching by radicals. At later times, the concentrations of R_1 and R_2 decline, and they become less effective quenchers. The value of (τ_{max}/τ) then approaches unity, and the plot of $f(\tau_{max}/\tau)^2$ converges on that of f. Figure 5 is especially clear in showing that the effect of triplet quenching by the ions is greatest in the early part of the experiment. This point bears significantly on the interpretation of magnetic effects, as we have noted above. Since the intensity enhancement, according to current interpretation, is dependent on the degree of triplet quenching by the reactant ions, the largest positive field effect ought to occur on the height of the light pulse.

Figure 6 shows that triplets with long τ_{max} will be dominated in an ECL experiment by the radical ions. Since $(\tau_{max}/\tau) >> 1$, $f(\tau_{max}/\tau)^2$ lies far above the f curve obtained without quenching by radicals. (Note that the squares have been scaled down, relative to the circles, by a factor of 100.) As time proceeds, (τ_{max}/τ) becomes smaller, because the radical concentrations fall, and the curve of $f(\tau_{max}/\tau)^2$ approaches that of f. Even so, the rightmost square lies slightly above the corresponding circle.

Treatment of experimental data.—The results of the previous section show clearly that one cannot expect $f(\tau_{max}/\tau)^2$ to remain constant with time in any experiment. Thus, Eq. [12] does not straightforwardly describe the decay of emission from the T route, and treatments based on it can generally be expected to give only roughly approximate quantitative results. This statement is especially valid when a wide range of t_r/t_f is to be considered. Figures 4-6 suggest that reasonably good behavior might be encountered for times earlier than perhaps $(t_r/t_f) = 0.1$.

In the region used for Feldberg plots ($0.2 \leq t_r/t_f \leq 1.0$), $f(\tau_{max}/\tau)^2$ generally changes rather rapidly, and β changes in the same manner. One can expect to see nonlinear plots or plots with slopes steeper than the predicted upper limit of -2.90. Complications from side reactions may exacerbate these effects (13).

We propose to replace the Feldberg slope, as a diagnostic criterion, with a plot of ω_i/ω_n *vs.* t_r/t_f. Since ω_i/ω_n is the instantaneous chemiluminescence efficiency, it should start at some finite value and decay to zero at long times, if light arises via the T route. For an S-route process, however, ω_i/ω_n should be constant throughout the experiment. If a mixed ST process is encountered, ω_i/ω_n ought to decay to a constant, nonzero value that represents the S-route component.

In general, reliable quantitative efficiencies for the S route should be readily accessible from these plots. Useful estimates of T-route parameters might be obtained from the extrapolated intercepts at $t_r = 0$, but a theoretical basis for that operation would have to be established beforehand.

APPENDIX

Derivation of Eq. [18].—The radical ion reaction rate N can be expressed as the product of the area of the diffusion field A and the flux of R_1 at the outer edge of the reaction zone

$$N = \frac{AD}{\Delta x}[C_{R_1}(j_{max}) - C_{R_1}(j_{max} - 1)]$$

$$= \frac{ADC_P^*}{\Delta x}[f_{R_1}(j_{max}) - f_{R_1}(j_{max} - 1)] \quad \text{[A-1]}$$

Substituting for Δx and defining $J = f_{R_1}(j_{max}) - f_{R_1}(j_{max} - 1)$ one has

$$N = \frac{AD^{1/2}C_P^*\kappa^{1/2}J(j_{max} - 1)}{vt_f^{1/2}} \quad \text{[A-2]}$$

Rearrangement of [A-2] and substitution according to the definition of ω_n yields [18].

Derivation of Eq. [25].—The total reaction rate N is given by the sum of the reaction rates in the boxes of the zone. The reaction rate in a given box is given by the product of the volume of the box and the conventional reaction rate (moles per second) within the box. This relationship is expressed

$$N = \Delta x A\left[\sum_j k_{et}C_{R_1}(j)C_{R_2}(j) + \sum_k C_l(k)/\Delta t\right] \quad \text{[A-3]}$$

The first summation in [A-3] accounts for all boxes within the zone in which the extent of reaction is rate limited. In some boxes, however, the extent of reaction is limited by one of the radicals whose concentration is less than the product $k_{et}C_{R_1}(k)C_{R_2}(k)\Delta t$. For these cases, the second summation is required, where C_l is the concentration of the limiting radical and the index k runs only over pertinent boxes. Equation [A-3] can be rearranged, with appropriate substitutions, to

$$N = \frac{vt_f^{1/2}AD^{1/2}C_P^*}{(j_{max} - 1)\kappa^{1/2}}\left[\sum_j k_{et}C_P^*f_{R_1}(j)f_{R_2}(j) + \sum_k \frac{f_l(k)\kappa(j_{max} - 1)^2}{v^2D_Mt_f}\right] \quad \text{[A-4]}$$

Rearrangement to give ω_n yields [25].

Derivation of Eq. [26].—Since only the T route to emission is considered here, the intensity of emitted light is given by

$$I = \Delta x A\phi_{tt}\phi_f \sum_j k_aC_T^2(j) \quad \text{[A-5]}$$

which can be expanded to

$$I = \frac{vt_f^{1/2}AD^{1/2}C_P^{*2}\phi_{tt}\phi_f k_a}{(j_{max} - 1)\kappa^{1/2}} \sum_j f_T^2(j) \quad \text{[A-6]}$$

Following the same procedure as above for simplification and rearrangement, we arrive at [26], which is written in terms of $\omega_t \equiv It_f^{1/2}/(AD^{1/2}C_P^*\phi_{tt}\phi_f)$.

Hole Reactions from d-Energy Bands of Layer Type Group VI Transition Metal Dichalcogenides: New Perspectives for Electrochemical Solar Energy Conversion

Helmut Tributsch

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin, Germany

ABSTRACT

Holes, photogenerated in d-energy bands of covalent semiconducting layer-type group VI-transition metal dichalcogenides react electrochemically differently from holes generated in semiconductors with valence bands based on p-orbitals (*e.g.*, CdS, ZnO, CdSe, GaAs). They do not constitute broken crystal bonds and do therefore not lead directly to an anodic photodecomposition of the electrode. The chemical character of these holes as missing d-electrons, on the other hand, gives rise to very specific electrochemical surface reactions with electron donors such as I^-, Br^-, and even OH^-, for example. The specific nature of the interfacial charge transfer complexes formed, their advantageous effect on the potential distribution in the electrode surface, and their favorable oxidation potential (in the case of the photoreaction with OH^- ions), respectively, may be the clue to a promising new approach to several unaccomplished goals of photoelectrochemical research, among them the construction of stable regenerative electrochemical solar cells and the oxidation of water with visible light. Photoelectrochemical measurements performed with $MoSe_2$ single crystals as well as experiments on solar energy conversion and photoelectrochemical reactions with water induced by visible and near infrared light are described as experimental evidence in support of this finding.

Recently, there have been considerable efforts to improve chemical stability of compound semiconductor electrodes (CdS, CdSe, CdTe, GaAs, GaP) for solar energy conversion in semiconductor liquid junction cells (1-9). Sulfide-polysulfides, telluride-polytellurides, or selenide-polyselenides (7,8) in the electrolyte or ultrathin noble-metal layers deposited onto the semiconductor electrode (6) have, with some success (7), been applied to reduce photocorrosion of the electrode surface.

The author's approach to the problem of light-induced photodecomposition was based on an entirely different idea; instead of trying to reestablish bonds broken by electron excitation in metal chalcogenides of considerable polar character or to prevent transport of reaction products, a search was initiated for new substrates which should provide favorable optical transitions between nonbonding orbitals which would therefore not affect the original bonding situation in the semiconductor surface. Such a property of a photoelectrode would not only appear to be interesting for continuously operating redox-photoelements but also for solar cells aimed at a photoelectrochemical dissociation of water for the purpose of generation of fuel.

A detailed theoretical analysis, mostly based on energetic and kinetic considerations, focused attention to $d \rightarrow d$ electron excitation in transition metal compounds and an approximation procedure to identify compounds with suitable energetically low-lying d-bands led to a simple criterion: to screen transition metal dichalcogenides for those with the smallest metal-metal distances (10). The analysis of 70 compounds showed that suitable target substrates had to be searched for among largely covalent layer-type compounds and not among more polar compounds of pyrite structure. As theoretically most promising layer compounds, WS_2 and MoS_2, and second in the line, $MoSe_2$ and WSe_2 were identified.

The experimental investigation of MoS_2 confirmed good photoelectrochemical activity. As expected, electrochemical hole reactions from d-bands of layer-dichalcogenides belonging to nonbonding orbitals of the transition metal were different as compared to hole reactions from anion p-bands in semiconductors of more polar bonding character (CdS, CdSe, PbS, GaAs). Instead of an anodic photodecomposition into metal ions and the chalcogenide in molecular form, upon illumination with visible light between 400 and 715 nm, MoS_2 reacts with water. The main reaction product is sulfate (11), however, at low anodic potentials the liberation of small quantities of oxygen could be traced by polarographic techniques (10). Evidence was given, that the mechanism leading to the photoelectrochemical oxidation of water is initiated by a hole-mediated transition of molybdenum from the four-valent to the five-valent state. An additional bonding possibility for OH^- ions is thus created from which electrons can subsequently be transferred to recombine with holes in the low lying d_z2-band of MoS_2 (10). Since the flatband potential of MoS_2 is found remarkably far in the anodic range, it became possible to construct a regenerative solar cell, in which p-MoS_2 is operating as a photocathode at which a suitable oxidizing agent of a redox couple is reduced (12).

The present paper extends investigations to $MoSe_2$. The basic scientific objective is an attempt to generalize and test the derived theoretical considerations on photoelectrochemical hole reactions from low-lying d-bands of transition metal compounds (10), the attempt to construct a regenerative solar cell with n-type MoSe as well as an investigation of whether light quanta of only 1.4 eV corresponding to infrared light of up to approximately 900 nm would be sufficient to initiate an oxidative reaction with water.

Experimental Methods and Materials

$MoSe_2$ crystals, grown by iodine-transport from the gas phase were obtained from the Kristallographisches Institut of the University of Freiburg (Prof. R. Nitsche). The surface dimensions of the thin layer crystals $d \lesssim 2 \times 10^{-1}$ mm were between 5 and 50

mm^2. Their appearance was similar to that of MoS_2, gray and metallic bright. They were contacted and embedded into a Teflon mounting according to a procedure described in Ref. (11). The surface preparation occurred through mechanical cleavage of the crystals by means of an affixed and subsequently pulled off adhesive tape or through a method especially elaborated for layer crystals, which is based on the abrasive action of a controlled water jet (11). The experiments were performed in a standard three electrode electrochemical glass cell with a saturated calomel reference electrode in water (0.1M KCl) as an electrolyte and an Ag/0.01M $AgClO_4$ reference electrode in acetonitrile (0.1M $LiClO_4$). Electrochemical measurements were made with a potentiostat and current-voltage curves plotted dynamically with a scanning speed of 4 mV/sec. Capacitive phase shift measurements were made with the lock-in technique. The light source was a xenon XBO-150W lamp. For the infrared portion of the photocurrent spectrum a 100W tungsten halogen lamp was used. The monochromator was a Bausch and Lomb high intensity model with interchangeable blazes for the visible and the infrared region.

Solid-State Properties of $MoSe_2$

Transition metal dichalcogenides with two-dimensional layer structures have received much attention from solid-state physicists (13-20). However, only partial experimental information is available for $MoSe_2$ (20-23). The basic structural unit of this compound is a sandwich of three planes: selenium-molybdenum-selenium. Within the planes the atomic alignment is in hexagonal packing. The Se-Mo-Se sandwiches are only loosely bound together through van der Waals forces. The most abundant hexagonal 2 H-polytype has two sandwiches per unit cell along the c-axis. The bonding character of $MoSe_2$ is mainly covalent and indicated by short Mo-Se and Se-Se distances. Hall measurements yielded electron mobilities of the order of 100 $cm^2\ V^{-1}\ sec^{-1}$ (16). Electrical measurements have been reported by several authors. P-type conduction (doping with Nb) as well as n-type conduction (doping with Re) have been shown to exist (13, 21). As in other layered transition metal dichalcogenides there is a pronounced anisotropy of electrical conduction. It is considerably (two to three orders of magnitude) larger parallel to the planes. Perpendicular to the planes, conduction occurs by a hopping mechanism (13).

Detailed band calculations apparently do not yet exist for $MoSe_2$. Sufficiently reliable information can, however, be deduced from theoretical work on MoS_2 (20, 24, 25) and from spectroscopic data on $MoSe_2$ (13). In MoS_2 the conduction band is approximately 3 eV wide and based on four of the six Mo 4d orbitals ($4d_{xy}$, $4d_{x2-y2}$), with antibonding admixtures of S 3p orbitals (Fig. 1). Separated by a hybridization gap (20) and approximately 1.75 eV below (as determined from the anodic photocurrent spectrum measured in the electrochemical cell arrangement) there is the energy band derived from the nonbonding Mo $4d_{z2}$ orbital holding two electrons per MoS_2. It is approximately 1 eV wide (electrons in this energy band do not contribute to the transition metal-dichalcogene bonding; however, the width of the band indicates that there is some bonding interaction among transition metal atoms). Below and slightly overlapping (0.1 eV) with the Mo d_2-band is the principal 3p valence band. Optical excitation in the visible spectral range consequently involves d → d transitions, a fact which has also been confirmed experimentally by parametric resonance measurements of holes (26). Transitions from the sulfur 3p to the unoccupied molybdenum 4d bands are only expected to occur in the near ultraviolet region (20). A series of details on excitons and electron-transitions are known for MoS_2 (13) which are not considered here for reasons of simplicity.

The main difference between the energy scheme of MoS_2 and $MoSe_2$ is that the d-hydbridization gap in $MoSe_2$ will be decreased to approximately 1.4 eV [a value determined from the electrochemical photocurrent spectrum and somewhat larger than a value of 1.1 eV deduced from solid-state measurements (23)] and the Mo d_{z2} band is more narrow due to weaker atomic interactions. This is shown in Fig. 1 together with the energetic position of redox couples in an aqueous electrolyte which is in contact with these molybdenum compounds as determined electrochemically by electron transfer studies in the dark and during illumination (investigated redox couples were H^+/H_2, I^-/I_2, $Fe(CN)_6{}^{-3/-4}$, Quinhydrone, $Fe^{2+/3+}$, Br^-/Br^2, $Ce^{3+/4+}$). Photoreactions in the near infrared and in the red region of the $MoSe_2$ spectrum have therefore to be expected to arise essentially from molybdenum d → d transitions. Light of shorter wavelength will in addition involve electron excitation from Se 4p orbitals. Holes generated in $MoSe_2$ electrodes will be available for surface reactions near the upper edge of the Mo 4 $d_z{}^2$ band and consequently do not represent missing chemical bonds such as, for example, holes in CdSe.

Experimental Results

The current voltage dependence of covalent $MoSe_2$ crystals is characterized by a behavior which is qualitatively different from that obtained for well-investigated semiconductor electrodes with valence bands derived from p-orbitals of the electronegative component such as ZnO, CdS, or GaAs (Fig. 2). The observed pronounced anodic photoeffect would appear to be typical for n-type semiconductors. However, when compared with the cathodic electrode behavior, there is no characteristic limiting behavior in the anodic region. In addition there is a slow and small photoeffect in the cathodic region. Capacitive phase-shift measurements (because of the difficulty of determining a reliable representative electrical circuit, no attempt has been made to specify the absolute capacitance) also lead to results which are not consistent with the experience from well-investigated semiconductors of similar bandgap since $MoSe_2$ electrodes like MoS_2 electrodes produce a pronounced capacitive minimum (Fig. 2). It is difficult to imagine an inversion of the space-charge layer within a narrow potential range in a semiconductor with a 1.4 eV bandgap. It is therefore suggested that kinetic phenomena and space-charge effects are jointly responsible for these capacitive properties. The clue to this peculiar electrochemical behavior of $MoSe_2$ are hole reactions from Mo-4 $d_z{}^2$ bands with water. They are clearly manifested by the

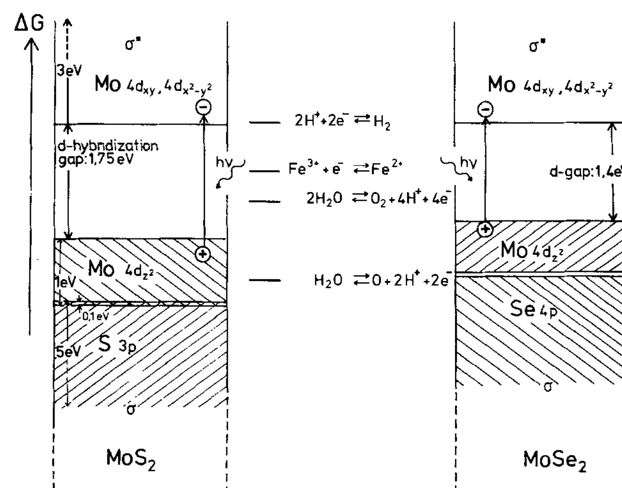

Fig. 1. Simplified energy schemes of MoS_2 and $MoSe_2$ as compared with the energetic position of redox couples in an aqueous electrolyte (acid solution, pH 1).

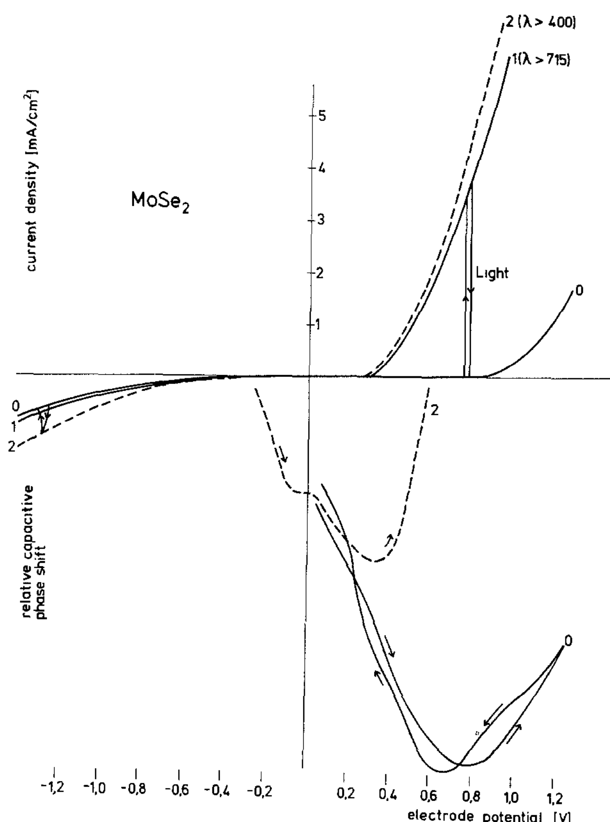

Fig. 2. Dynamic current voltage curves and relative capacitive phase shift (500 Hz) of $MoSe_2$-electrodes 0, dark effect; 1, illumination with $\lambda > 715$ nm (150W xenon lamp); 2, illumination with $\lambda > 400$ nm. Electrolyte, citrate buffer, pH 2/0.1M KCl. Potential sweep: 4 mV/sec.

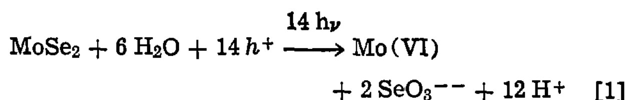
kind of electrochemical reaction products which are obtained from the anodic reaction as well as evident from the current voltage behavior of $MoSe_2$. When a $MoSe_2$ electrode was illuminated with visible and near infrared light (xenon lamp, $\lambda > 400$ nm) and a photocurrent drawn at a potential of 0.6V (Fig. 2) for a prolonged time to yield a turnover of 26C of electric charge, only traces of elemental selenium were found on the electrode surface. However, there was an accumulation of soluble selenium in the electrolyte (citrate/HCl-buffer, pH 2; 0.1M KCl) in the form of selenic acid and a red deposit of elemental selenium formed on the Pt counterelectrode. The latter was found to be the result of an electrochemical reduction of selenic acid from the electrolyte to elemental selenium. A quantitative analysis confirmed the following anodic photoelectrochemical reaction as predominant reaction path (h^+ = holes)



$$MoSe_2 + 6\,H_2O + 14\,h^+ \xrightarrow{14\,h\nu} Mo(VI) + 2\,SeO_3^{--} + 12\,H^+ \quad [1]$$

Of 3.13 mg originally crystal bound selenium, 1.83 mg were subsequently found in soluble form in the electrolyte and slightly more than 1 mg as elemental selenium on the counterelectrode. (Mo and soluble Se were measured photometrically with thiocyanate complex and diaminobenzidine, respectively.) The involvement of water in the anodic hole reaction was thus confirmed for $MoSe_2$. In addition, the anodic liberation of soluble SeO_3^{--} and its subsequent cathodic reduction to elemental selenium was recognized as the mechanism essentially responsible for the small and relatively slow cathodic photoeffect, observed during the cyclic plot of current-voltage characteristics (Fig. 2); it results from a thin p-conducting deposit of selenium with an approximate absorption edge of 1.9 eV. It could be confirmed, that, with respect to the photoeffect of $MoSe_2$ (bandgap = 1.4 eV), its spectral response was shifted toward shorter wavelengths and the cathodic photocurrent could be clearly increased by adding SeO_3^{--} to the electrolyte. The mechanism of the anodic photoreaction of $MoSe_2$ with water is especially interesting, since it can proceed even with near infrared light up to 900 nm.

Figure 3 shows the spectral dependence of the anodic photocurrents of $MoSe_2$ on the wavelength of the incident light and compares it with the corresponding photocurrent spectrum of MoS_2. With both systems the photocurrent output gradually drops toward the u.v. region although the light absorption in the bulk continues to increase (13). It is suggested that the photocurrents of these layer crystals essentially arise from d → d phototransitions (compare Fig. 1 and 3) and are for some unknown reasons suppressed if sulfur p-orbitals are involved. In order to get some insight into the mechanism which enables holes from a d-band to react with OH^- ions at energy levels close to the thermodynamic 2-electron transfer oxidation potential of water (1.23V) and considerably more negative than the 1-electron transfer potential ($\sim$ 2V) (Fig. 1), some experiments have been performed with organic electrolytes. If $MoSe_2$ is in contact with acetonitrile (0.1M $LiClO_4$) the anodic photocurrents are very small and can be attributed to traces of water in the organic solvent. They systematically decrease with increasing purification from water (molecular sieve).

The photocurrents can be made to increase if a suitable reducing agent such as hydroquinone is added to the acetonitrile (Fig. 4b). Photocurrents consequently only pass the interface if electrons are transferred into the electrode to recombine with holes which cannot leave the electrode surface by means of liberating ions from the solid. If instead of a typical reducing agent water is added to the organic electrolyte, photocurrents are produced in the same way (Fig. 4a). With photogenerated d-holes it apparently reacts efficiently as an electron donor. This behavior has not been observed with nonlayered semiconductor electrodes until now. CdS, for example, the valence bandedge of which is situated at much more positive redox potentials than that of $MoSe_2$ [its energy band scheme approximately corresponds to that of $MoSe_2$ (Fig. 1) without the low-lying 4 d_{z^2} band] does not react photoelectrochemically with water. Anodic photocurrents which result from a photodecomposition of CdS continue to flow in presence of oxidation resistant organic electrolytes in contrast to the situation with d-band conductors such as MoS_2 or $MoSe_2$. Here it is necessary that a hole oxidizes an OH^- ion or water (or another oxidizable

agent) in the electrolyte to produce charge transfer across the layer crystal-electrolyte interface. The oxidation of OH^- ions or water molecules has therefore to be considered the primary step of the mechanism leading to the generation of anodic photocurrents, although the principal oxidation product is not oxygen, but selenic acid (compare reaction [1]). It is therefore justified to conclude that holes in energy bands derived from d-orbitals are reacting electrochemically differently from holes in energy bands derived from p-orbitals. Support for this conclusion may also be found in the observation that $ZrSe_2$ and $HfSe_2$, which have the same layer structure as $MoSe_2$ but an empty d_{z^2}-band (compare Fig. 1) and consequently hole reactions from Se p-bands, do anodically produce elemental selenium and not selenic acid. The peculiarity of hole reactions from d-bands is also evident from the interaction of redox couples of less positive redox potential with the $MoSe_2$-electrode. If an anodic potential is applied to an illuminated n-type semiconductor and if suitable electron donors are available in the electrolyte, the migration of holes, generated in the space charge layer, to the electrode surface should be the rate-limiting process controlling the onset of anodic photocurrents. With $MoSe_2$ the onset of anodic photocurrents is, however, strongly dependent on the type of redox couple added to the electrolyte. Redox couples, the oxidation potential of which is more positive than that of water, generally shift the onset of photocurrents and dark currents toward more negative electrode potentials. Figures 5 and 6 demonstrate the effect of hydroquinone, Br^- and I^-. They shift the photocurrent onset up to approximately 0.4, 0.25, and 0.6V, respectively. Figure 6 shows how additions of I^- ions gradually suppress the photocurrent resulting from the oxidation of water and build up new photo and dark currents arising from the oxidation

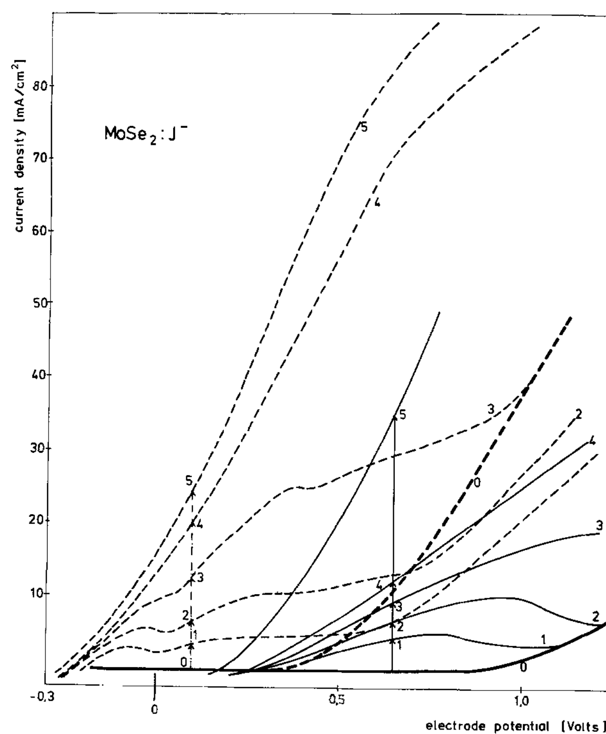

Fig. 6. Influence of I^- on the anodic dark currents and photocurrents (broken lines) of $MoSe_2$ (in order to keep the redox potential constant, I_2 was also added at a concentration ten times smaller than that of I^-). 0, 0.5M Na_2SO_4, no KI; 1, 10^{-1}M KI; 2, 2 $\times$ 10^{-1}M KI; 3, 5 $\times$ 10^{-1}M KI; 4, 1M KI; 5, sat. solution of KI. Illumination, 150W xenon, $\lambda > 615$ nm. Scanning (4 mV/sec) in direction of increasing positive electrode potential.

of iodide. Most remarkably the onset of the new dark current which leads to the formation of iodine is finally more negative than the original photocurrent arising from the oxidative reaction with water.

The fact that certain redox couples produce large photocurrents through $MoSe_2$ electrodes at potentials which they also would produce at a metal electrode, the standard redox potential of I^-/I_2 in aqueous solution which adjusts itself at the metal counterelectrode is, for example, + 0.293V against a SCE (compare Fig. 6), indicates that this effect could be used to drive regenerative electrochemical solar cells. Since the photoreaction with water only starts at more positive electrode potentials and since it is, in addition, suppressed in the presence of a suitable redox couple (*e.g.*, I^-/I_2) there is also a good chance that $MoSe_2$ photoelectrodes would be corrosion resistant. Solar cells, based on d → d electron transitions in combination with anodic electron transfer from Fe^{2+} and I^- respectively have actually been put into operation and are described elsewhere in more detail (27). With the $MoSe_2$:I^-/I_2 solar cell (current-voltage behavior in Fig. 6) photocurrent densities of 23 mA/cm^2 and photopotentials of 0.55V were produced. At moderate light intensities (21 mW/cm^2) energy conversion efficiencies between 4-5% were found for illumination with red and near infrared light. Longtime experiments actually suggest an apparently corrosion-free operation of the cell: Photocurrent densities between 10 and 12 mA/cm^2 were drawn over a load resistance of 100Ω over a period of more than 120 days without any visible deterioration of the performance of the approximately 1/10 of a mm thick $MoSe_2$ electrode (Fig. 7). It seems that only electrons and no ions are passing the $MoSe_2$/electrolyte + I^-/I_2 interface.

An important problem (it is the clue to the anodic stability of the $MoSe_2$ electrochemical solar cell) is the question, why reducing agents such as I^- or Fe^{2+} are photo-oxidized at more negative potentials than OH^- ions although all three systems should energetically be placed above the Mo 4 d_{z^2} "valence"-band and the oxidation controlled by the availability of holes which reach the electrode surface. An investigation of capacitive phase shifts at $MoSe_2$ electrodes [measurement of $U = (2U_m/\pi) \cos\phi \approx (2U_m/\pi)\phi$ with lock in technique] has provided some interesting insight into this phenomenon (Fig. 8). When they are in contact with neutral 0.5M KCl or Na_2SO_4 solution a pronounced minimum is found between +0.5 and +0.6V. When I^-/I_2 is added, this minimum is gradually, with increasing concentration of the redox couple, shifted toward more negative potentials. At a concentration of

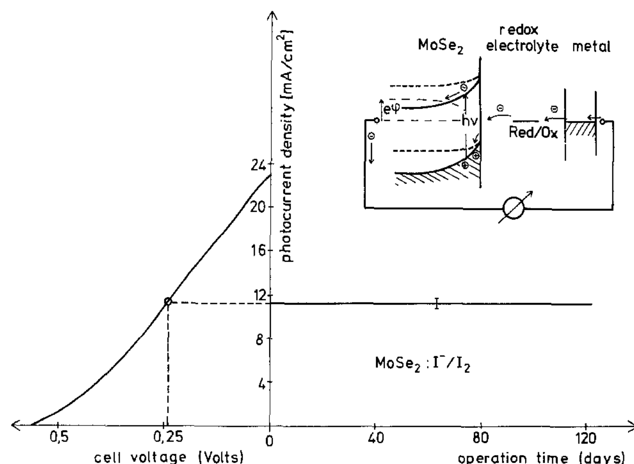

Fig. 7. Operation mode, power characteristic, and stability of $MoSe_2$: I^-/I_2 solar cell. Electrolyte, 1M I^-, 10^{-1}M I_2 (water); work resistance, 100Ω; access of air, no stirring; 150W xenon lamp, λ > 615 nm.

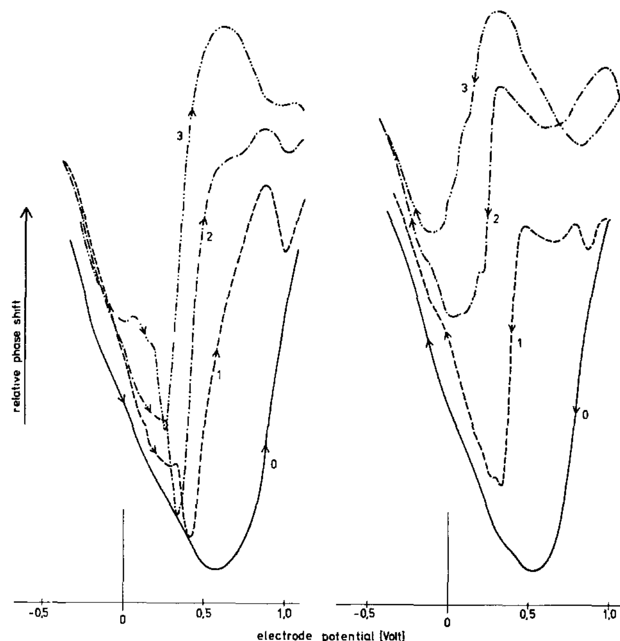

Fig. 8. Dependence of the capacitive phase-shift minimum of $MoSe_2$ on additions of the I^-/I_2 redox system for scanning in opposite potential directions. Potential sweep: 15 mV/sec. Frequency 500 Hz, N_2-bubbling. 0, 0.5M Na_2SO_4; 1, 1.3 × 10^{-3}M KI, 1.3 × 10^{-4}M I_2; 2, 8 × 10^{-3}M KI, 8 × 10^{-4}M I_2; 3, 10^{-1}M KI, 10^{-2}M I_2.

10^{-1}M KI and 10^{-2}M I_2 it is found at +0.25 (for the curve plotted in anodic direction) and at −0.1V (for the curve plotted in cathodic direction). Concurrently same major changes of the shape of the curve occur and finally an additional, smaller minimum appears on the positive potential side (Fig. 8). It was originally not entirely evident why an n-type semiconductor with a forbidden bandgap as large as 1.4 eV can have such a pronounced capacitive phase shift minimum. This would presuppose that the charge in the space-charge layer can be inverted within a surprisingly narrow potential range. Since this is not easily possible through thermal activation across a 1.4 eV gap from the Mo 4 d_{z^2} to the Mo 4 d_{xy,x^2-y^2} conducting band, it has to be examined whether the minimum is obtained by the combination of a space charge effect and a kinetic phenomenon on the electrode surface. Such a situation is actually confirmed experimentally. The capacitive phase shift-branch at more negative potentials may be considered relatively stable, while the position of the positive branch is strongly dependent on the presence of the reducing agent (iodide) in the electrolyte so that the minimum is not only shifted but also becoming more narrow with increasing concentration of I^- (compare Fig. 8). The positive branch of the capacitive phase shift may therefore be regarded a consequence of the reaction of an oxidizable agent (*e.g.*, OH^-, I^-) with the electrode surface. A support for this conclusion is also the fact that the capacitive phase shift minimum is to be found near the onset of anodic oxidation currents and correspondingly shifted with increasing concentration of the electron donor (compare Fig. 6 and 8). Additional evidence may also be deduced from the observation that illumination, in absence of I^-/I_2, shifts the capacitive minimum to negative potentials (Fig. 2) and that anodic polarization of the electrode in presence of I^-/I_2 is followed by a similar negative shift of the capacitive minimum (compare scanning of capacitive curves into positive and negative potential directions in Fig. 8). The information content of the phase-shift measurements is, as presented, somewhat ambiguous. At the moment, it is not possible to deduce the real interface capacitance due to the lack of information needed to design a representative electrical

circuit for layer crystal interfaces. Necessary measurements of frequency behavior and the influence of redox agents are presently being performed.

Several additional experimental observations seem worth mentioning. The reducible components of the redox couples investigated (I_2, Br_2, quinone, Fe^{3+}) always produce cathodic dark currents at the $MoSe_2$ electrode. They are generally overlapping the potential range in which photocurrents are produced and, especially with I^-/I_2 and Br^-/Br_2 they directly pass over into the anodic dark current which arises from the oxidation of I^- and Br^-, respectively (*e.g.*, Fig. 5a, curve 2). Cathodic dark currents and anodic photocurrents are therefore superposed on each other. If I_2 or Br_2 is absent from the electrolyte and the electrode illumination switched off, a cathodic dark current, arising from the reduction of anodically formed I_2 or Br_2 will flow for a short time. There is also some photoenhancement of the cathodic reduction current in form of a very slow photo or temperature effect (observed with Br^-/Br_2). The superposition of anodic and cathodic reactions occurring in the same potential region makes the systems kinetically relatively complicated. An indication for intricate reactions is also the occurrence of electrochemical current oscillations which have frequently been observed with the $MoSe_2$: I^-/I_2 system in the potential range between + 0.5 and + 1.0V. They are a definite sign of proceeding autocatalytic surface reactions.

Discussion

The experimental observation that near infrared light leads to an anodic photoreaction of $MoSe_2$ in presence of water but not in presence of acetonitrile, and the fact that selenic acid is found to be the main reaction product leaves practically no doubt that the formation of a chemical bond between the illuminated semiconductor and water (OH^-) is involved in this reaction. Additional arguments against a following reaction of water with a hypothetical photodissolution product of $MoSe_2$ are that (*i*) photocorrosion does not occur if the oxidation reaction involves a reducing agent (*e.g.*, I^-) which does not form a soluble compound with selenium (compare long time experiment of Fig. 7), (*ii*) the oxidation product (H_2SeO_3) does not form with CdSe although this compound photocorrodes, and (*iii*) that elemental selenium, not selenic acid is found anodically at $HfSe_2$ and $ZrSe_2$ electrodes which have the same structure as $MoSe_2$ but in which hole reactions occur from p-bands below the empty d_{z^2} band (compare Fig. 1). A bond formation between illuminated $MoSe_2$ and OH^- ions is the only mechanism explaining the energetic feasibility of a reaction with water without having to postulate a theoretically ideal one-step 2-electron transfer reaction near its thermodynamic standard redox potential (+ 1.23V). A chemical bonding as an intermediate step also explains why a transition from MoS_2 to $MoSe_2$, corresponding to a shift of the Mo 4 d_{z^2} bandedge toward negative redox potentials by approximately 0.35 eV (compare also Fig. 3) is not reflected in a significant change of the semiconductors photooxidative reactivity with water. In both cases, with MoS_2 as well as with $MoSe_2$, there is apparently sufficient interaction energy to discharge OH^- ions: The chemical interaction of an OH^- ion with a surface hole in the d-band will result in the formation of a complex which is apparently characterized by an occupied electronic state situated above the edge of the 4 d_{z^2} energy band. It can be further oxidized by an additional hole in the d-band. Why is there a formation of a chemical bond when a d-hole reaches the semiconductor surface? Is it possible that missing d-electrons convert a layer crystal surface which only exhibits van der Waals interactions into a surface forming chemical bonds with molecules capable of donating electrons? Previous studies performed to analyze the photoelectrochemical reaction of water with MoS_2 electrodes (10) have yielded a reasonable qualitative explanation. In contrast to holes in energy bands derived from p-orbitals (*e.g.*, CdS, ZnO), which represent broken polar bonds, holes in d-bands of molybdenum dichalcogenides mean an increase of the valence state of molybdenum. A transition from Mo(IV) to $Mo(V)^+$ in the electrode surface, however, would be paralleled by a reorganization of electron densities leading to changes in the crystal geometry and to the liberation of an additional bond. OH^- ions would interact with it to produce a Mo(V)-(OH) complex. The corresponding electronic level rises above the edge of the Mo 4 d_{z^2} band and will serve as trap for holes which further oxidize the complex (Fig. 9). The finding of this investigation that reducing agents such as I^-, Br^-, hydroquinone, $Fe(CN)_6^{4-}$, or Fe^{2+} shift the anodic onset of $MoSe_2$ photocurrents (in the presence of water) and induce dramatic changes in the potential structure of the double layer (as measured with the I^-/I_2 redox couple) provides convincing additional support for the formation of complexes between electron donors and surface states produced by d-holes. OH^- ions are included in the list of complexing electron donors. Experimental consequences are a *p*H dependent onset of anodic photocurrents and a *p*H and water-dependent capacitive behavior. The peculiarity of individual complexes explains the observations that potential shifts in the current voltage behavior do not reflect a simple relation with redox potentials and their specific importance as transition states for photoactivated electron transfer makes it understandable why high photocurrents can pass the electrode surface for a long time without leading to inhibition phenomena, typical for many electrochemical processes: If the Mo(V)-Red (Red = reducing agent) surface complex is oxidized by holes from the lower Mo 4 d_{z^2} energy band (Fig. 9), the bond of the original electron donor is simply broken and the oxidized reactant desorbed. (It is presently not yet known to what extent half crystalline sites are favored in this complex formation). It is also relatively easy to understand why the presence of a reducing agent such as I^- suppresses the photoreaction of $MoSe_2$ with OH^- ions. The potential drop, which the complex-formation of I^- with the surface produces, generates a relative shift between energy levels in the electrode surface and in the electrolyte (Fig. 9c). Electron transfer from OH^- is thus suppressed while transfer from I^- is still possible and the generation of photocurrent is considerably facili-

tated through the induced positive charge in the space-charge layer.

These arguments provided for a complex formation between reducing agents and vacant d-states in transition metal-dichalcogenide layer crystals receive substantial support from the remarkable crystal-chemical property of these compounds. They belong to a class of lamellar hosts capable of intercalating organic compounds between the composite sheets of their chalcogenide-transition metal-chalcogenide sandwiches (15, 28-34). A most interesting detail is that the guest molecules have to be Lewis bases (*e.g.*, ammonia, pyridine) or electron donating species (such as alkali metals) and another one that the intercalate formation with organic molecules works well with layer crystals belonging to Group V transition metals (TaS_2, NbS_2), in which the low energy d-bands are only half filled, giving them metallic character, but not with those belonging to Group VI transition metals (MoS_2, WS_2) which are semiconductors with full d-bands (29). The experimental observation that the ability to form organic intercalation complexes disappears with the filling of the low energy d-band (29) and the finding that the interaction responsible for intercalation involves a donation of electron charge from the nitrogen of the organic or from the inorganic electron donor to the layer crystal (29, 33) leaves no doubt that vacant low lying d-orbitals play a crucial role as electron acceptors during complex formation. Since holes photogenerated or anodically formed in molybdenum dichalcogenide electrodes would create the necessary preconditions for this complex formation with electron donating compounds it may be concluded that the complex-formation described in our photoelectrochemical study is deducible to the same kind of electronic interaction which is responsible for intercalate formation. A detailed molecular understanding of the electronic structure of these transition complexes will therefore go parallel with a better understanding of intercalate formation which is still very fragmentary. An obvious conclusion, which has already been successfully tested experimentally, is that electrochemical studies of the reaction of transition metal dichalcogenide layer crystal electrodes with intercalating compounds will be most instructive for a better comprehension of the mechanism of intercalation.

The finding that photogenerated holes from d-bands of Group VI transition metal layer-semiconductors react with oxidizable agents by way of formation of charge transfer-transition complexes could have major consequences for future developments in photoelectrochemistry and photoelectrochemical energy conversion. One important conclusion is that photoassisted or photopowered oxidation of water with visible light or even near infrared light may be an achievable goal with suitable hole reactions from d-bands. Experimental studies performed with MoS_2 have demonstrated photoelectrochemical oxygen evolution from water, although it is only a subordinate process and in the long run most of the light energy is channeled into sulfate formation because of the reactive intermediate's attack on crystal bound sulfur (10). Once the energetically efficient d-band mechanism of photoelectrochemical oxidation of water is thoroughly understood, it may be tried to produce favorable d-bands for hole reactions in more oxidation resistant electrodes or it may be tried to improve oxygen evolution catalytically. Attempts in this direction have already been started with MoS_2 (10). It is interesting to note that a d-hole mediated valence increase of a transition metal compound to yield a transition metal hydroxide which can further be oxidized to liberate molecular oxygen might not be a newly discovered mechanism but applied in one of the most basic processes of life. Why exactly are holes from reaction centers in photosynthetic systems channeled into an oxidation complex for water which is based on a transition metal (manganese) which is apparently being oxidized (35) (necessarily by an extraction of d-electrons) as intermediate step toward oxygen evolution?

Experiments with the photooxidation of water at MoS_2 and $MoSe_2$ electrodes suggest that such a mechanism is kinetically or energetically reproducible with hole reactions from d-bands of a semiconductor provided a secondary destructive oxidation by reactive intermediate compounds is avoided by appropriate chemical bonding in the neighborhood of the transition metal reaction center.

The inability of holes in an energy band derived from nonbonding d-orbitals to initiate anodic photocorrosion, in combination with their specific charge transfer interaction with reducing agents have finally provided a basis for regenerative electrochemical solar cells which seem to be sufficiently stable to be developed for practical use (27). The experimental evidence suggests that it is much more reasonable not to break chemical bonds in a photoelectrode surface at all than to try to repair them by complicated successive chemical reactions from the electrolyte.

From theoretical points of view tungsten dichalcogenides will photoelectrochemically behave very similarly to molybdenum dichalcogenides and interesting additional experience on d-band electrochemistry will be obtained from Group IV and V transition metal layer crystals. Preliminary studies of several among the latter compounds have confirmed unusual electrochemical mechanism also there. For example, anodic photocurrents in the mA/cm^2 range have been observed with $2H\text{-}TaS_2$ (and NbS_2) although its solid-state behavior is typically metallic with hole concentrations exceeding 10^{22} cm^{-3}. Mixed layer compounds which would permit a gradual filling of d-bands should be promising substrates for research into d-hole reactions as well.

There is one important circumstance to be considered, when dealing with d-hole reactions in which the formation of specific surface complexes is involved. It will not be admissible to apply the simplified theoretical concepts developed for electron transfer between semiconductor electrodes and redox couples in the electrolyte which neglect chemisorption of the reactants. The closest approach to the problem of d-hole reactions may be a theoretical model which has been discussed as a special reaction type of electrocatalysis (36). It is the case of surface states on an electrode which strongly interact with both the electronic bulk of the electrode and the redox couple in the electrolyte.

X-Ray Photoelectron Spectroscopic Studies of RuO_2-Based Film Electrodes

Jan Augustynski, Lucette Balsenc, and Jean Hinden

Département de Chimie Minérale, Analytique et Appliquée, Université de Genève, Geneva, Switzerland

ABSTRACT

The nature and relative amounts of the different species present in the surface region of RuO_2 and RuO_2-TiO_2 film electrodes, before and after an anodic polarization in 4M aq NaCl solution, have been determined by means of x-ray photoelectron spectroscopy. The existence of a surface defect structure of RuO_3, analogous to that found on RuO_2 powder, has been confirmed for both the RuO_2 and RuO_2-TiO_2 electrodes. Two different chlorine species, identified as chloride ions and adsorbed atomic chlorine, have been shown to be present on the surface of the electrodes used as anodes for the chlorine evolution.

Successful industrial application of the dimensionally stable anodes (DSA) in chlor-alkali cells during recent years (1-3) has attracted considerable interest to the electrocatalytic properties of transition metal oxides, especially those exhibiting metallic conductivity as RuO_2 or IrO_2. A number of authors have studied the kinetics of chlorine evolution on RuO_2-based electrodes (4-10). The low-slope linear Tafel behavior up to very high anodic current densities has been generally reported for the latter reaction on pure RuO_2 film electrodes as well as on mixed RuO_2-TiO_2 electrodes containing at least 20 mole percent (m/o) of RuO_2 (7). However, apparently, some disagreement exists about the mechanism of this reaction and the nature of the rate-determining step (8, 10).

In the present paper, recent results obtained by x-ray photoelectron spectroscopy (XPS) concerning the chemical constitution of the surface region of RuO_2 film electrodes are discussed. Data are given for both pure RuO_2 and mixed oxide RuO_2-TiO_2 films prepared by thermal decomposition in air of $RuCl_3$ and $TiCl_3$ on metallic titanium supports. Spectra have been obtained for freshly prepared RuO_2 and RuO_2-TiO_2 electrodes and for electrodes being employed as anodes in the electrolysis of 4M aq NaCl solution. Distinct changes in the composition of the 20-30Å outermost layer of the electrodes, subsequent to the polarization at anodic potentials and chlorine evolution, are to be expected. These changes could affect the oxidation state of ruthenium atoms, the degree of hydration, and the adsorption of chloride-chlorine species.

Key words: anodes, chlorine evolution, surface analysis.

The results of this study are, thus, likely to permit a better understanding of the peculiar features of RuO_2-based electrode materials, *i.e.*, of their low overpotential for chlorine evolution and excellent corrosion resistance to anodic potentials. The latter have been tentatively assigned (4) to the nonstoichiometric character of the thermally deposited oxide films and also to chloride ion adsorption which is supposed to prevent the surface oxidation of the electrode.

Experimental

The photoelectron spectra were obtained with a Varian IEE spectrometer using $MgK\alpha_{1,2}$ x-rays at 1253.6 eV. Basic pressure in the sample chamber was 10^{-6}-10^{-7} Torr. Binding energies were referred to the carbon ls electron peak due to residual pump oil on the sample surface and are given relative to the zero kinetic energy level, taking 290.0 eV as the C ls binding

energy in vacuo (11). The deconvolutions of the multiple signals were performed graphically with gaussian peak shapes (12). The relative concentrations of the various species were calculated from the corresponding XPS peak intensities. The relative photoelectron line sensitivities referred to the fluorine 1s signal (13, 14) were used for this purpose. Measured concentrations were reproducible within 15%.

The electrodes were prepared by depositing a thin film of RuO_2 or RuO_2-TiO_2 on cylindrical titanium samples of about 6.5 cm^2 area. Commercial 99.5% Ti rods were used. All electrodes were first etched in 20% hydrochloric acid at 100°C for 60 min, then washed with distilled water, and dried. Coatings were applied using a brush, layer by layer, from solutions of the corresponding chlorides. The solution of $RuCl_3$ was prepared by dissolving first $RuCl_3$ aq (Fluka) in 20% HCl aq and evaporating to dryness by gentle heating. The residue was then dissolved in isopropanol. The solution containing both ruthenium and titanium chlorides was obtained by adding to the $RuCl_3$ solution a solution of 15% $TiCl_3$ in HCl (Analar grade, Merck) and a few drops of H_2O_2. The individual layers were first dried at 60°C and then fired at 450°C for 10 min in an oven with forced air circulation. The whole electrode, coated with 6 layers and having a thickness of about 5 μm, was finally annealed at the same temperature for 60 min.

The electrolyses were carried out in a two-compartment cell containing an acidified (pH 2) 4M NaCl solution. Analar grade NaCl and triply distilled water were used. The electrodes were polarized anodically at 200 mA ($\sim$30 mA cm^{-2}) for 4 hr at 20°C. After being removed from the cell, the electrodes were carefully washed with distilled water and dried in a desiccator for at least 24 hr.

Barium ruthenate $BaRuO_4 \cdot H_2O$ was synthesized as described in (15). All ruthenium compounds submitted to XPS analysis were first characterized using x-ray diffraction.

Results

In their XPS study of the surface chemistry of a series of ruthenium-oxygen compounds Kim and Winograd (16) have reported the existence on the surface of RuO_2 (both powder and single crystal) of an additional, higher valency ruthenium compound identified as RuO_3. Their observation has been confirmed by the present authors (17) in the case of RuO_2 and RuO_2-TiO_2 coatings on titanium metal. Figure 1 shows the photoelectron spectra of Ru 3p region for RuO_2 powder (Koch-Light) and RuO_2 coating on titanium obtained by thermal decomposition of $RuCl_3$ in air. Both spectra (a and b) are quite similar, each of them being apparently composed of double signals. The corresponding O 1s electron spectra are even more complex (Fig. 2) showing, besides two larger peaks associated with two Ru compounds, two smaller signals due to water and adsorbed gases as are discussed later. By comparing the relative concentrations of the Ru and O species (Table I) a Ru/O atomic ratio of about 1:2 (corresponding to RuO_2) is obtained for the largest signals, while the Ru/O ratio for Ru and O signals shifted to higher binding energies agrees reasonably well with the formula of RuO_3.

To ascertain further the nature of multiple Ru signals in the RuO_2 spectra we have examined by means of XPS a well-defined compound of Ru(VI)-$BaRuO_4$. As shown in Table II, the position of the smaller Ru peak in the RuO_2 spectra corresponds indeed quite well, for various electron levels, to the binding energy of Ru(VI) in $BaRuO_4$.

Thus, the analysis of XPS spectra strongly suggests that the surface region of freshly prepared RuO_2 film electrode contains, in an analogous manner to RuO_2 powder, an appreciable amount of RuO_3. Assuming the XPS effective depth in the range of 20-30Å, the Ru(VI)/Ru(IV) atomic ratio of about 1:2 could be tentatively interpreted[1] in terms of a 7-10Å outermost surface layer of RuO_3. This situation, therefore, would be similar to that of some noble metals covered with thin oxide films, with the difference that, in the present case (of RuO_2), the metal is substituted by the electronically conducting oxide.

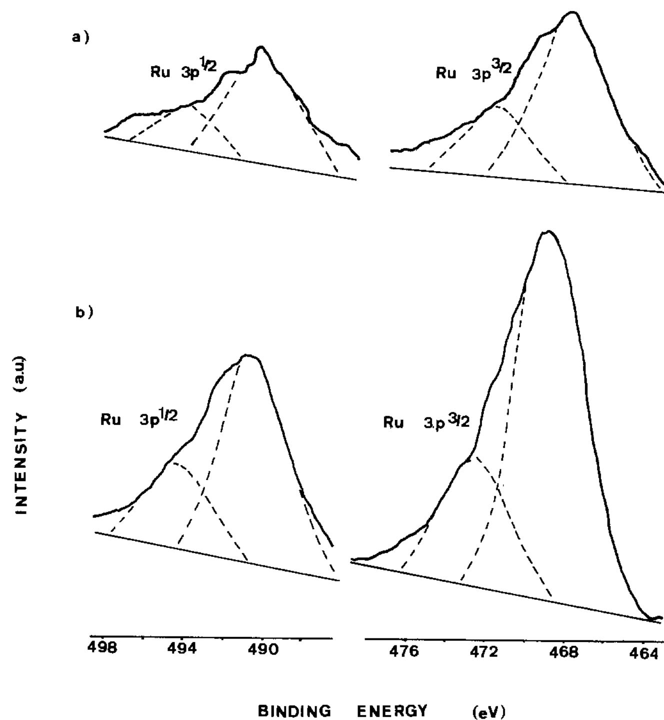

Fig. 1. X-ray photoelectron spectra of Ru 3p region of (a) RuO_2 powder, and (b) RuO_2 deposit on titanium.

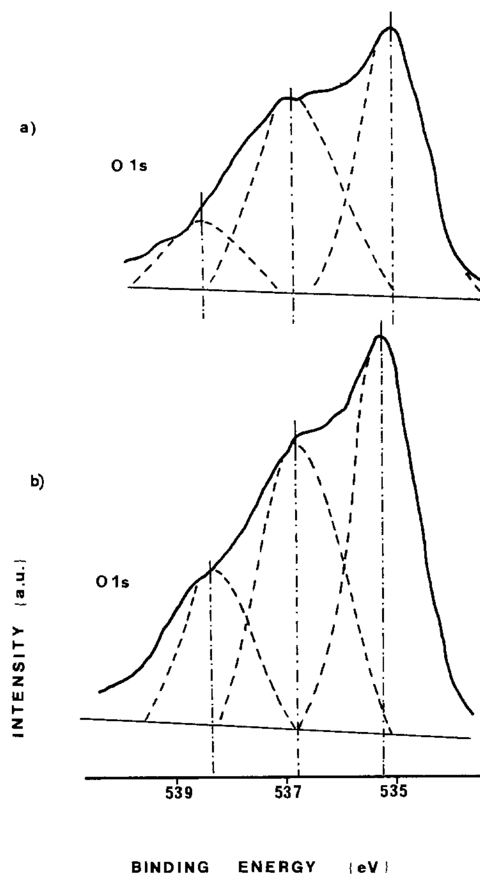

Fig. 2. Oxygen 1s photoelectron signals for (a) RuO_2 powder, and (b) RuO_2 deposit on titanium.

[1] Another possibility is that RuO_3 exists on the surface in a mixture with RuO_2.

Table I. Relative amounts of different Ru and O species identified on the surface of RuO_2 powder and RuO_2 deposit on titanium

	Ru(VI)/Ru(IV)	O/Ru
RuO_2 powder	0.47	2 (largest signals) 3.13 (smaller signals)
RuO_2 deposit on Ti	0.49	2 (largest signals) 3.06 (smaller signals)

Since in industrial applications the so-called RuO_2 electrode consists most frequently of a mixed oxide RuO_2-TiO_2 film on Ti, it was also interesting to characterize Ru species in TiO_2 environment. The mixed RuO_2-TiO_2 deposit, containing about 22 atomic percent (a/o) of Ru as a metal and prepared in the same manner as RuO_2 films, was first examined by x-ray diffraction. As shown in Table III, the principal diffraction lines for the RuO_2-TiO_2 sample are placed between the values relative to RuO_2 and those of rutile form of TiO_2 indicating that the deposit is constituted[2] by the solid solution of both oxides. As in the case of pure RuO_2, various Ru levels in the XPS spectra of mixed RuO_2-TiO_2 deposit are composed of double signals assigned above to RuO_2 and RuO_3. In comparison with the spectra of pure RuO_2 film we observed neither detectable shift in the positions of Ru peaks (Table II) nor a significant change in the Ru(VI)/Ru(IV) ratio.[3] It must be noted that the Ru(total)/Ti atomic ratio obtained from the photoelectron peak intensities (about 0.15) is appreciably lower than the corresponding mean film composition (0.28). This result implies that some preferential diffusion processes have probably taken place during final heat-treatment of the electrodes.

The oxygen 1s electron signal for mixed RuO_2-TiO_2 film (Fig. 3a), appears to be less complex than that of pure RuO_2 and can be resolved into two peaks. From comparison with the spectra of pure TiO_2 and RuO_2 the larger O 1s peak is assigned to oxygen species associated with Ti(IV) and Ru(IV), the corresponding binding energies being practically the same. The smaller O 1s signal,[4] the position of which agrees well with that of the hydration water peak in the TiO_2 spectrum, is shifted about 2 eV to lower binding energies with respect to the O 1s peak attributed to water in the RuO_2 spectrum (Table II).

The photoelectron spectra obtained with RuO_2 and RuO_2-TiO_2 deposits on Ti used as electrodes for anodic chlorine evolution show some significant differences with respect to those of freshly prepared samples.

[2] In addition to the rutile-type RuO_2-TiO_2 solid solution we have also found some nontransformed TiO_2-anatase.
[3] Also the Ti 2p electron spectra from pure TiO_2 (rutile) and from Ti species in the RuO_2-TiO_2 electrode were fairly identical.
[4] Due to the small relative concentration of Ru(VI), the oxygen associated with these species cannot be distinguished from the oxygen of water.

Table III. Principal x-ray diffraction lines for RuO_2, TiO_2-rutile, TiO_2-anatase, and RuO_2-TiO_2 mixed oxide

RuO_2	RuO_2/TiO_2 mixed deposit	TiO_2 rutile	TiO_2 anatase
3.17	3.23	3.25	3.52
2.55	2.50	2.487	2.378
2.243	2.28	2.297	2.332
1.685	1.687	1.6874	1.892
1.586	1.615	1.6237	1.666
1.349	1.355	1.360	1.481

These differences essentially concern the spectra of oxygen and chlorine levels, the Ru binding energies and the Ru(VI)/Ru(IV) and Ru/Ti ratios remaining practically unchanged. As could be expected, the O 1s signals assigned to water and adsorbed oxygen are clearly enhanced for both RuO_2 and RuO_2-TiO_2 electrodes (Fig. 3b).

On account of exceptional characteristics of RuO_2 electrode with regard to the anodic chlorine evolution, it was, of course, important to obtain some more detailed information about the nature and the relative concentrations of chlorine species present on the film surface. In this connection it must be mentioned that the freshly prepared RuO_2 deposit already contains a certain quantity of chlorine (18, 19) resulting from incomplete decomposition of $RuCl_3$ during the heating at 450°C. As a matter of fact, the photoelectron spectrum of Cl 2p level for freshly prepared RuO_2 film (Fig. 4a) clearly shows the presence of two different chlorine species. Since the chlorine 2p electron spectrum consists normally of two signals, due to spin-orbit splitting, the larger $2p^{3/2}$ and the smaller $2p^{1/2}$ placed at higher binding energies, the middle (largest) peak at Fig. 4a must result from the superposition of the $2p^{1/2}$ signal arising from first Cl species and the $2p^{3/2}$ signal characteristic of second Cl species. According to the generally observed tendencies, the binding energy for a given electron level increases together with the oxidation state of the element. Consequently, the lower binding energy Cl $2p^{3/2}$ peak originates, in our opinion, from the chloride ions[5] in RuO_2 crystal lattice, whereas the second Cl $2p^{3/2}$ peak is assigned to adsorbed (atomic) chlorine.[6] This is supported by the fact that the higher binding energy Cl $2p^{3/2}$ peak strongly increases after the RuO_2 electrode has been polarized in the region of the chlorine evolution potential (Fig. 4b). While the amount of adsorbed atomic chlorine rises from about 3 a/o[7] before electrolysis to near 15 a/o[7] after electrolysis, the chloride content changes only from 4 to 6 a/o[7] (Table IV) under the same conditions.

[5] The assignment of this peak is based on the comparison with the binding energies obtained for Cl^- species incorporated into the oxide films on titanium or aluminum.
[6] In the Discussion section we propose an alternative assignment of this peak.
[7] Values reported to Ru(IV).

Table II. Ru and O binding energies of various ruthenium-oxygen compounds

Compound	Binding energy (eV) ±0.2 eV			
	Ru $3d^{5/2}$	Ru $3p^{3/2}$	Ru $3p^{1/2}$	O 1s
RuO_2 powder	286.3 and 287.9	468.1 and 471.5	490.1 and 493.4	535.0, 536.8, and 538.4
RuO_2 deposit on Ti	286.5 and 288.1	468.4 and 471.9	490.5 and 493.9	535.25, 536.8, and 538.35

* Values reported to Ru(IV).
** Values reported to the sum of Ti(IV) and Ru(IV).

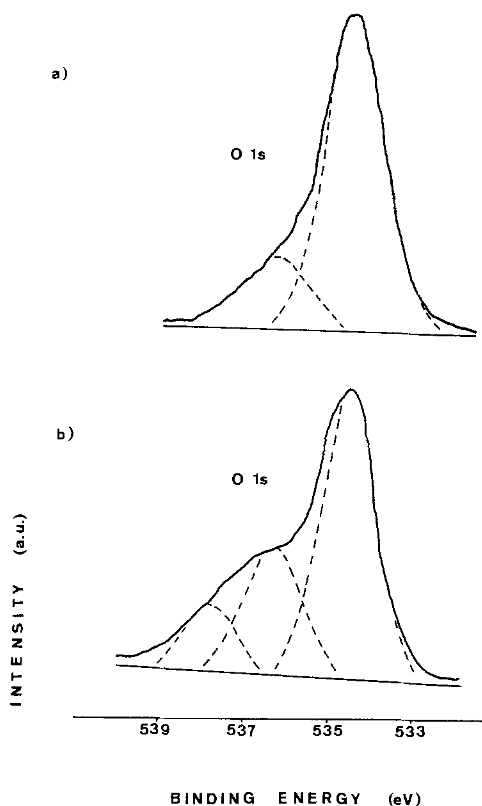

Fig. 3. Oxygen 1s photoelectron signals for RuO_2-TiO_2 deposit on titanium: (a) as prepared, (b) after electrolysis in 4M NaCl solution.

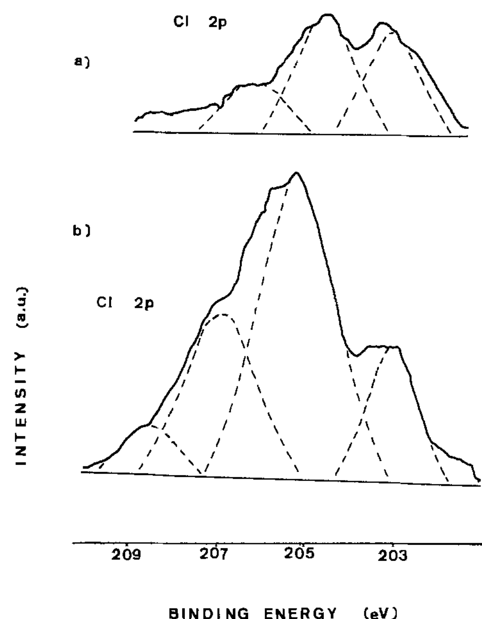

Fig. 4. X-ray photoelectron spectra of Cl 2p region for RuO_2 deposit on titanium: (a) as prepared, (b) used as an anode for chlorine evolution.

The Cl 2p electron spectrum of a freshly prepared RuO_2-TiO_2 deposit shows the presence of a single chlorine species (Fig. 5a), which is characterized by the same binding energy as the one assigned to chlorides in RuO_2 (Table IV). It is interesting to note that the relative concentration of the residual chlorides in RuO_2-TiO_2 coating, calculated with respect to the sum of Ti(IV) and Ru(IV) concentrations, is equal to that found for pure RuO_2 films (4 a/o). This result suggests that the degree of chloride doping in the RuO_2-TiO_2 coatings obtained by thermal decomposition of $RuCl_3$ and $TiCl_3$ rather depends on the annealing temperature than on the ruthenium content.

After using the RuO_2-TiO_2-coated electrode as an anode for the chlorine evolution from 4M NaCl solu-

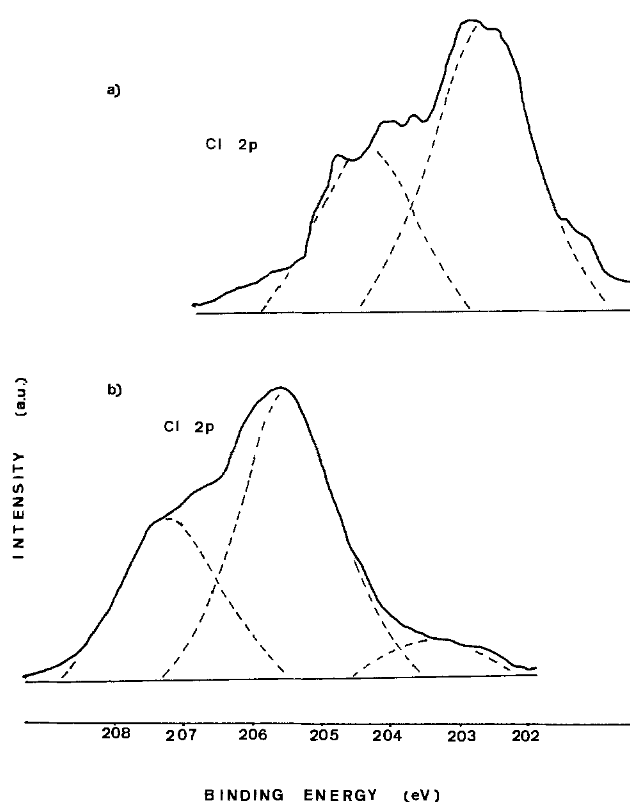

Fig. 5, X-ray photoelectron spectra of Cl 2p region for RuO_2-TiO_2 deposit on titanium: (a) as prepared, (b) used as an anode for chlorine evolution.

tion, a strong additional signal appears in the photoelectron spectrum; this is due to adsorbed atomic chlorine[8] (Fig. 5b). Rather surprisingly, the extent of Cl adsorption found on the RuO_2-TiO_2 electrode is higher than that on the RuO_2 electrode: 32 a/o compared with 15 a/o.

Discussion

Notwithstanding the fact that the XPS analysis is performed outside an electrochemical cell, under high vacuum conditions, the existence of a RuO_3 defect structure on the surface of RuO_2-based film electrodes seems to be definitely established. As a matter of fact, the Ru(VI) species have been detected on the surface of all the kinds of RuO_2 examined by photoelectron spectroscopy; *i.e.*, single crystal of RuO_2 (16), commercially obtained or freshly prepared RuO_2 powder (16, 17), and RuO_2 film electrode. The Ru(VI) species have been equally identified on the surface of the mixed oxide RuO_2-TiO_2 film electrode, wherein RuO_2 forms a solid solution with TiO_2. Moreover, the relative amounts of RuO_3 to RuO_2 do not appear to be significantly influenced by such experimental conditions as the pressure in the sample chamber of the spectrometer (16, 20) and the duration of x-ray irradiation. Finally, the same Ru(VI) species are still present on the surface of RuO_2 and RuO_2-TiO_2 film electrodes which have been used as anodes for the chlorine evolution.

All these results suggest that RuO_3 may be the species responsible for the good stability of RuO_2 electrodes at anodic potentials where, according to the thermodynamic data (21),[9] formation of RuO_4 should take place.

Another significant point in relation to the specific properties of thermally deposited RuO_2 electrodes is the substantial chemical shift of the O 1s signal assigned to water in RuO_2 with respect to the corresponding signals for TiO_2 and for other hydrated ox-

[8] As shown in Table IV, this signal is placed at the same binding energy as in the case of RuO_2 electrode.

[9] It must be noted, however, that the known thermodynamic data concern actually a hydrated ruthenium dioxide $RuO_2 \cdot 2H_2O$.

ides such as $Al_2O_3 \cdot xH_2O$.[10] This shift may be interpreted in terms of a particularly weak bonding (*i.e.*, of a nondissociative adsorption) of water by the oxide.

The photoelectron spectra of Cl 2p level for the RuO_2 and RuO_2-TiO_2 electrodes polarized anodically in 4M NaCl show the presence of a large amount of Cl species which have been assigned to adsorbed atomic chlorine. As a matter of fact, the relative concentrations of these species given in Table IV seem to indicate that the degree of surface coverage by Cl_{ads} must be roughly equal to unity ($\theta \approx 1$), assuming one Cl atom per Ru or (and) Ti atom. It is interesting to consider this result in connection with the postulated mechanisms of the $Cl^- - e = \frac{1}{2} Cl_2$ reaction at RuO_2 and RuO_2-TiO_2. According to Ref. (4) and (10), the observed low Tafel slopes ($b = dV/d \ln i = RT/2F$ to $2\,RT/3F$) are consistent with the

$$Cl^- \leftrightarrows Cl_{ads} + e \quad [1]$$

$$2Cl_{ads} \rightarrow Cl_2(\text{rds}) \quad [2]$$

reaction pathway, the second step being the rate-determining step (rds). In the case of radical recombination controlled kinetics (Eq. [2]), $dV/d \ln i = RT/2F$ corresponds to moderate surface coverage conditions, while for $\theta \rightarrow 1$ a transition of Tafel slope to ∞ (the limiting anodic current) is expected. The above mechanism (4) has been refuted by Erenburg *et al.* (8) on the basis of the observed dependence of the overpotential on the chloride concentration and of the anodic reaction order with respect to Cl^- ions equal to +1. After detailed analysis of various possible reaction schemes these authors have proposed an alternative three-step mechanism

$$Cl^- \rightleftarrows Cl_{ads} + e \quad [3]$$

$$Cl_{ads} \rightarrow Cl^{(+I)} + e(\text{rds}) \quad [4]$$

$$Cl^{(+I)} + Cl^- \rightleftarrows Cl_2 \quad [5]$$

with the second charge-transfer step (Eq. [4]) as rate controlling. The rds is assumed barrierless at low overvoltages, corresponding to $\alpha = 1$ with $b = dV/d \ln i = RT/(\alpha + 1)F$, where α is the true transfer coefficient. At higher overvoltages, where a transition to normal process is expected, a Tafel slope of about $2RT/3F$ was obtained (9) in agreement with $b = RT/(\alpha + 1)F$ for $\alpha = 0.5$. However, the reaction mechanism suggested by Erenburg *et al.* clearly implies $\theta << 1$, *i.e.*, very low coverage by atomic chlorine on the electrode, which is in disagreement with our results. In this connection it must be pointed out that certain points of measurements carried out by the latter authors are subject to criticism. In particular, sulfuric acid added in excess to chloride solutions, in order to suppress secondary double layer ionic distribution effects in the determination of the reaction order, can hardly be considered in this case as a nonspecifically adsorbing supporting electrolyte. Indeed, as shown by preliminary XPS analyses, SO_4^{2-} ions strongly interact with both RuO_2 and TiO_2.

In any case, further experimental information is needed before definite mechanistic conclusions can be made. These must involve the examination of a possible role which Ru(VI) species could play in the chlorine evolution process, *e.g.*, through the following reaction sequence

$$2Cl^- + RuO_3 + 2H_3O^+ \rightarrow (RuO_2)2Cl_{ads} + 3H_2O \quad [6]$$

and

$$RuO_2 + 3H_2O \rightarrow RuO_3 + 2H_3O^+ + 2e \quad [7]$$

Finally, the possibility that the chlorine species detected by our XPS measurements are not Cl_{ads} atoms but adsorbed ClO^- ions cannot be completely excluded. These species could be produced in a secondary chemical reaction or originate (as intermediates) from a reaction pathway of the kind

$$Cl^- + RuO_3 \rightarrow (RuO_2)ClO_{ads}^- \quad [8]$$

Eq. [7] and

$$ClO_{ads}^- + Cl_{ads}^- \text{ (or } Cl_{aq}^-) + 2H_3O^+ \rightarrow Cl_2 + 3H_2O \quad [9]$$

Reaction [9] presents an analogy with the third step (Eq. [5]) in the mechanism postulated by Erenburg *et al.*

[10] In the case of other oxide films analyzed in our laboratory (TiO_2, Al_2O_3, Cr_2O_3, and MoO_{2+x}) the binding energies (BE) attributed to adsorbed H_2O species were comprised between 536 and 537 eV; consequently the value of O 1s BE for H_2O_{ads} on the RuO_2 electrode (538.4 eV) may be considered as anomalously high.

A Rotating Ring-Disk Electrode Study of the Underpotential Deposition of Mercury on Gold

W. G. Sherwood*,[1] and Stanley Bruckenstein*

Department of Chemistry, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

The isotherm for the underpotential deposition (UPD) of mercury from $0.2M$ H_2SO_4 solutions of mercurous or mercuric ions is the same. At the equilibrium potential of a liquid mercury electrode in either of the solutions, the surface coverage of mercury species is 1.9×10^{-9} g·atom/cm^2. However, only faradaic charge sufficient to deposit 1.7×10^{-9} g·atm/cm^2 of Hg(O) is consumed and $\sim 2 \times 10^{10}$ g·atm/cm^2 of $(Hg(I))_2$ appear to be adsorbed along with the UPD Hg(O).

Underpotential deposition (UPD) involves the deposition of a metal ion on a foreign metal substrate at potentials anodic to the equilibrium potential of the metal/metal ion couple. UPD is usually observed for the first few atom-layers of the metal (adatom) deposited on the electrode (1-28), and the process is sometimes accompanied by the adsorption of submonolayer quantities of the metal ion (adion) (9, 10, 18, 26-28). Some authors prefer to consider the deposition process to produce a single species carrying a partial charge rather than a mixture of adatoms and adions. Neither view can be distinguished from the other by electrochemical methods.

We report here the results of a study of the UPD of Hg on Au from dilute $(Hg(I))_2$ or Hg(II) in $0.2M$ H_2SO_4 solutions. The issues to which our study were directed were the determination of (*i*) the mercury coverage at the Nernst potential for the $(Hg(I))_2$/Hg couple, (*ii*) the UPD isotherm in $(Hg(I))_2$ and Hg(II) solutions, and (*iii*) the net charge of the adsorbed species as a function of deposition potential.

Experimental

Circuitry and electrodes.—The electrochemical equipment and supporting circuitry used have been described elsewhere (29). Additional circuitry was added to the standard four-electrode potentiostat in order to perform deposition experiments at 0.1 mV anodic to the Nernst potential (Fig. 1). Using a saturated calomel reference electrode, ten monolayers of Hg were deposited on a gold electrode, and then the current was set equal to zero by disconnecting the auxiliary electrode. After the Hg-coated electrode reached equilibrium, potentiometer P was adjusted until the output of inverter I was -10.0 mV. The output of follower F_2 was then injected through a 10^4 Ω resistor into the input of amplifier CA by closing switch S. The auxiliary electrode was connected in order to deposit Hg on a rotating disk electrode at 0.1 mV anodic of the Nernst potential.

The data reported here were obtained using a rotating gold disk-gold ring electrode RRDE. Its dimensions were $r_1 = 0.379$ cm, $r_2 = 0.402$ cm, and $r_3 = 0.484$ cm, $N = 0.34$ and $S = 0.63$. All potentials are reported with respect to the saturated calomel electrode (SCE).

The surface roughness of the gold disk was calculated by the method of Brummer and Makrides (30), which gives the charge required to oxidize a 1.00 cm^2 gold surface at 1.2V.

Mercury surface coverage was calculated by assuming that one monolayer of mercury on gold requires 336 μC/cm^2 to be oxidized to soluble Hg(II). This assumption is justified in the Results and Discussion section.

[1] Present address: AMAX, Incorporated, Extractive Metallurgy Laboratory, Golden, Colorado 80401

Experimental procedure.—The potential sequence used to obtain the data reported is given in Table I. Digital data acquisition and control techniques are given elsewhere (29). Data acquisition was initiated at step 6 and the rotation speed, ω, set to zero at step 5 if stationary anodic stripping data were desired. The disk potential scan was performed at $\omega = 0$ if only disk electrode data were desired. The stationary disk electrode potential scans were performed to minimize the steady-state background current associated with the oxidation of $(Hg(I))_2$ during the anodic potential scan. Step 8 resets the digital sequencer to step 1, allowing signal averaged data acquisition, when this is required. Data for the potential-charge curves were obtained at 0.1V intervals near the anodic limit of the underpotential region, and at smaller potential intervals near the cathodic limit of the underpotential region. The 5 min time interval allowed for underpotential deposition was sufficient to achieve equilibrium coverage of Hg on Au at the deposition potential of interest.

Results and Discussion

Determination of the Nernst potential.—The Nernst potential for the Hg(I)/Hg couple in $2 \times 10^{-5}M$ $(Hg(I))_2$ $-0.2M$ H_2SO_4 solution was determined using the gold disk of the RRDE. First, the Au disk was potentiostated at 0.0V and $\omega = 2500$ rpm, where the reduction of $(Hg(I))_2$ to Hg(O) occurs under convective diffusion control. After deposition of more than 10 layers of Hg(O), the disk current, i_D, was set equal to zero and the disk potential was monitored. The rest potential attained by the gold disk is the equilibrium potential for the Hg(I)/Hg couple, *i.e.*, 0.398V in $2.0 \times 10^{-5}M$ $(Hg(I))_2$ $-$ $0.2M$ H_2SO_4 for our particular SCE.

In order to verify that on the gold disk mercury coverages greater than 10 layers behave as metallic mercury for the time of each experiment, a mercury

Fig. 1. Circuit for UPD at 0.1 mV anodic to Nernst potential

Table I. Sequence for underpotential deposition and stripping of Hg

Step No.	Disk potential (V)	Purpose of step	Ring potential (V)	Purpose of step	Time
1	1.20	Pretreat $\omega = 0$ rpm	1.20	Pretreat	1 min
2	0.00	Reduce Au $\omega = 0$ rpm	1.20	Pretreat	3 sec
3	E_{DEP}	Deposit Hg $\omega = 2500$ rpm	1.20	Pretreat	4 min
4	E_{DEP}	Deposit Hg $\omega = 2500$ rpm	0.0 or 1.0	Stabilize for coll.	1 min
5	E_{DEP}	Deposit Hg $\omega = 2500$ rpm	0.0 or 1.0	Set rotation	5 sec
6	Scan anodic	Data acq. $\omega = 0$ or 2500 rpm	0.0 or 1.0	Collect products	As required
7	1.60	Clean $\omega = 2500$ rpm	1.60	Clean	2 min
8	Reset	Sig. avg.	Reset	Sig. avg.	1 msec

pool was substituted for the SCE reference electrode, and the potential of the mercury coated gold electrode was measured *vs.* the mercury pool. The potential measured in this experiment was 0.0 mV.

Hg(O) layer thickness at the Nernst potential.—Anodic stripping method.—The gold disk of the RRDE was potentiostated 0.1 mV anodic to the Nernst potential for 5, 10, and 120 min. Then the amount of mercury deposited for each time was determined by anodic stripping. No time dependent increase in stripping charge was noted, and all data agreed within 2% of the value obtained after 5 min, 340 $\mu C/cm^2$ (1.76×10^{-9} g·atom/cm^2 of mercury).

The only time effect found at the above potential was that the stripping potential shifted 30 mV more anodic after a 120 min wait. The time stability of mercury in the gold surface demonstrates the large interaction energy of the UPD process, an energy which exceeds that for bulk amalgam formation.

Deposition at potentials 1.0 mV cathodic of the Nernst potential produced time dependent anodic charges under the stripping peaks, as would be expected for ordinary metal deposition.

The charge corresponding to electrooxidizing one atom layer of mercury on gold as Hg(II) was calculated by assuming that the zero-valent mercury atoms form a close-packed array on the gold surface. Thus the maximum coverage for one layer of Hg atoms is proportional to the ratio of the square of the radii of Hg and Au. The atomic radius of Au is 1.44Å. However, the reported radii for Hg vary somewhat between 1.50 and 1.73Å (23), and the best value of r_{Hg} cannot be selected on the basis of these data.

Bowles (25) presented evidence that mercury deposits on Pt in a square lattice. Using this assumption, Hassan, Untereker, and Bruckenstein (19) showed that if the $r_{Hg} = 1.57$Å, the charge calculated for stripping one geometric monolayer of mercury from a platinum electrode coincides with the amount of mercury required to inhibit all hydrogen adsorption on the same platinum electrode. Therefore, it is assumed here that 1.57Å is also the correct value for the radius of UPD Hg on Au and that a monolayer is 1.74×10^{-9} g·atom/cm^2. We calculate, then, that the charge required to strip one monolayer of mercury on gold as Hg(II) is 336 $\mu C/cm^2$. This value coincides, within experimental error, with the amount found above for the quantity of Hg(II) stripped after UPD 0.1 mV anodic of the Nernst potential. This remarkable result indicates that one atom layer of mercury on a gold substrate behaves as if it were bulk mercury in a potentiometric experiment.

$(Hg(I))_2$ direct reduction method.—When an oxidized gold disk electrode is reduced at 0.0V and $\omega = 0$ rpm and the potential subsequently stepped to 0.40V at $\omega = 2500$ rpm in solution of $2.0 \times 10^{-5}M$ $(Hg(I))_2$ and 0.2*M* H_2SO_4, the disk current, i_D, *vs.* time, *t*, curve of

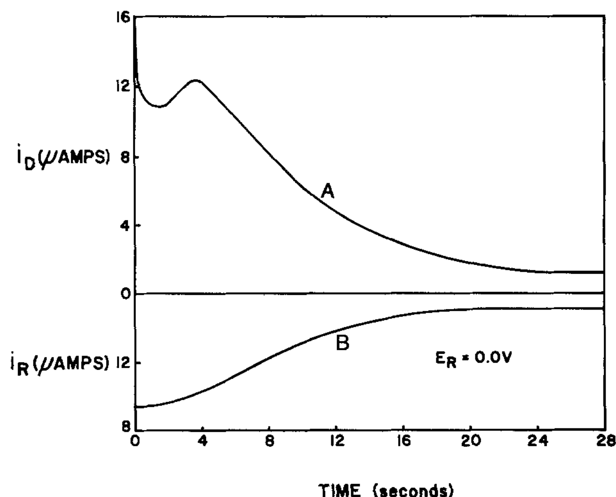

Fig. 2. RRDE-current-time responses during UPD of Hg. Curve A, disk; curve B, ring. Disk potential = 0.40V; ring potential = 0.0V; ω = 2500 rpm; $C_{H_2SO_4}$ = 0.2*M*; and $C_{Hg(I)}$ = $2.0 \times 10^{-5}M$.

Fig. 2, Curve A, results. The time required to obtain 99% of the equilibrium coverage of Hg is approximately 30 sec. After 300 sec, i_D had diminished to 7 nA. Integration of the area under the i_D *vs.* *t* curve, yields an apparent charge density of 164 $\mu C/cm^2$ for reaction [1], *i.e.*, 1.70×10^{-9} g·atom/cm^2 of Hg were deposited.

$$(Hg(I))_2 + 2e \rightleftarrows 2Hg(O)_{UPD} \qquad [1]$$

However, during the initial 3 sec waiting period at the start of the experiment when $\omega = 0$ (step 2 in Table I), we calculate that 0.12×10^{-9} g·atom/cm^2 of $Hg(O)_{UPD}$ forms as a result of semi-infinite linear diffusion to the stationary disk electrode. Thus the total $Hg(O)_{UPD}$ formed is 1.82×10^{-9} g·atm/cm^2. This coverage agrees well with that calculated using Eq. [2] to interpret the anodic stripping of the underpotential deposit produced potentiostatically at 0.399V. Equation [2] is shown below to describe the anodic stripping process.

$$Hg(O)_{UPD} \rightleftarrows Hg(II) + 2e \qquad [2]$$

Ring shielding method.—The ring current, i_R, *vs.* *t* response of a rotating ring disk electrode corresponding to the i_D *vs.* *t* experiment described above is shown in Fig. 2, Curve B. The ring electrode was potentiostated at 0.0V during this experiment, and the consumption of $(Hg(I))_2$ via reaction [1] was monitored. The ring electrode remains partially shielded for the first 15 sec, after which the ring electrode current approaches the limiting value for the reduction of $(Hg(I))_2$. The integral of the i_R *vs.* *t* curve, when divided by *N*, yields a value of 184 $\mu C/cm^2$ for the amount of $(Hg(I))_2$ consumed on the gold disk of the RRDE, only in fair agreement with the anodic stripping and the direct reduction experiments. This experiment indicates 1.91×10^{-9} g·atom/cm^2 of mercury species has been consumed at the gold disk.

Figure 3 shows both i_D *vs.* *t* and $-i_R/N$ *vs.* *t* curves for the experiment described above. In the absence of adsorption or other phenomena that consume $(Hg(I))_2$ at the disk electrode via a nonfaradaic mechanism, the two curves of Fig. 3 should superimpose. However, the ring electrode shielding observed during the first 16 sec indicates that a nonfaradaic process is consuming $(Hg(I))_2$ at the disk electrode. The charge density under the shaded region of Fig. 3, Q_{ads}, equals (368 − 328) or 40 $\mu C/cm^2$. Evidence is given below that this difference can be represented as the adsorption of 2.1×10^{-10} g·atom/cm^2 $(Hg(I))_2$ that occurs on a reduced Au electrode simultaneously with the underpotential deposition of Hg.

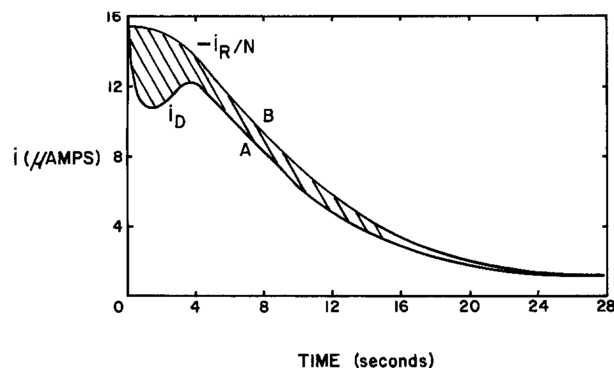

Fig. 3. Comparison of time dependence of the disk current and flux of $(Hg(I))_2$ removed at the disk. Data of Fig. 2. Curve A, disk current; Curve B, current equivalent to flux removed at disk electrode calculated from $-i_R/N$.

UPD in $(Hg(I))_2$ solutions.—Anodic stripping charge. —To obtain the relationship between charge and potential in the underpotential region, mercury was deposited on various potentials, E_{DEP}, ($1.00V \geqq E_{DEP} \geqq 0.398V$), and subsequently oxidized from the electrode via a linear anodic potential sweep. In these experiments, the rotator was turned off prior to stripping the UPD deposit to avoid interference due to the steady-state oxidation of $(Hg(I))_2$, since the latter process occurs simultaneously with the oxidation of Hg(O) from the Au electrode. Figure 4 shows a typical *i-E* curve obtained following deposition at 0.42V. The anodic stripping charges obtained following deposition at various potentials in the underpotential region are summarized in column 2 of Table II and are plotted in curve A of Fig. 5. Values obtained in this manner are termed "$Q_{D,\omega=0}$."

If, following deposition, the initial potential scan was made in the cathodic direction, a peak (Fig. 4, peak "P") was observed at 0.2V. The charge under this peak (Q_{ads}^P) increased with increasingly cathodic deposition potentials (column 6, Table II). RRDE experiments showed that the disk reduction process associated with the cathodic peak does not consume or produce any oxidizable or reducible species. This result again suggested the presence of an adsorbed species on the electrode surface, such as $(Hg(I))_2$ (or Hg(II)), and further RRDE anodic stripping experiments were conducted.

Ring collection. The anodic stripping experiments described in the preceding section were repeated at ω = 2500 rpm, and both the i_D-E_D and i_R-E_D responses were recorded first at E_R = 0.0V and then at 0.80V. These data are shown in Fig. 6 and 7. The disk electrode stripping curves for deposition potentials of 0.60 and 0.45V, and the corresponding ring electrode responses at 0.0 and 1.0V demonstrated that Hg(II) was the sole product of the electrooxidation of underpotential mercury.

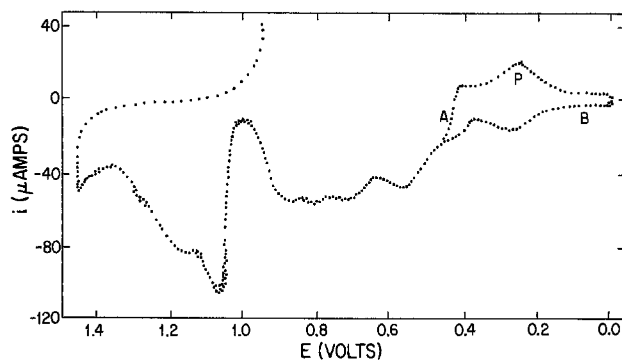

Fig. 4. Current-potential curves at a stationary gold disk electrode following UPD of Hg at 0.42V. dE/dt = 50 mV/sec. $C_{H_2SO_4}$ = 0.2*M* and $C_{Hg(I)} = 2.0 \times 10^{-5}M$.

[a] $Q_{D,\omega=0}$: Disk electrode anodic stripping charge obtained at ω = 0 rpm.
[b] $Q_{D,\omega=2500}$: Disk electrode anodic stripping charge obtained at ω = 2500 rpm.
[c] Q_R^*: Ring electrode collection data (divided by the RRDE collection efficiency, *N*) obtained for disk electrode anodic stripping experiments at ω = 2500 rpm.
[d] $Q_R^* - Q_{D,\omega=2500}$: The difference between the ring electrode and disk electrode charge density values for a given E_{DEP} corresponds to the charge equivalent to adsorbed $(Hg(I))_2$ or Hg(II).
[e] Q_{ads}^P: The charge corresponding to peak "P" in Fig. 4; agreement with column 5 data indicates the peak results from reduction of adsorbed Hg(I) or Hg(II).

The disk and ring electrode charges for similar experiments at various deposition potentials are summarized, respectively, in columns 3 and 4 of Table II. $Q_{D,\omega=2500}$ is used to designate disk electrode data obtained in the above experiments, and Q_R^* designates the corresponding ring electrode data, divided by the RRDE collection efficiency (Q_R/N). The ring electrode data are plotted in curve B of Fig. 5.

Values of Q_R^* are all larger than $Q_{D,\omega=2500}$. This difference indicates the collection at the ring electrode of a reducible species that has been desorbed from the disk electrode via a nonfaradaic mechanism. This inference is consistent with the conclusion drawn earlier that either $(Hg(I))_2$ or Hg(II) is adsorbed on the reduced gold electrode during the UPD process. Two possible adsorption reactions are given by Eq. [3] and [4].

$$(Hg(I))_2 \rightleftarrows (Hg(I))_{2ads} \quad [3]$$

$$(Hg(I)_2)_2 \rightleftarrows (Hg(II))_{ads} + Hg(O)_{UPD} \quad [4]$$

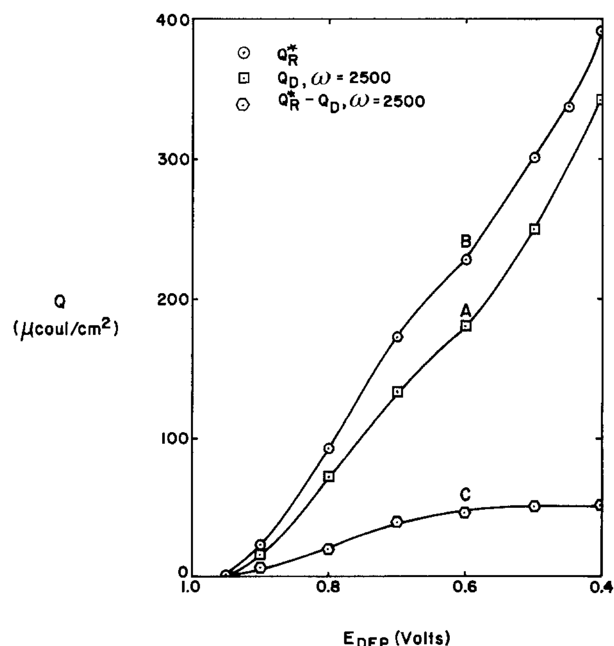

Fig. 5. Potential dependence of charge density at gold disk of RRDE. Curve A, ring collection data divided by *N*, Q_R^*; curve B, disk stripping data, $Q_{D,\omega=2500}$; curve C, charge equivalent to adsorbed mercury species, $Q_R^* - Q_{D,\omega=2500}$.

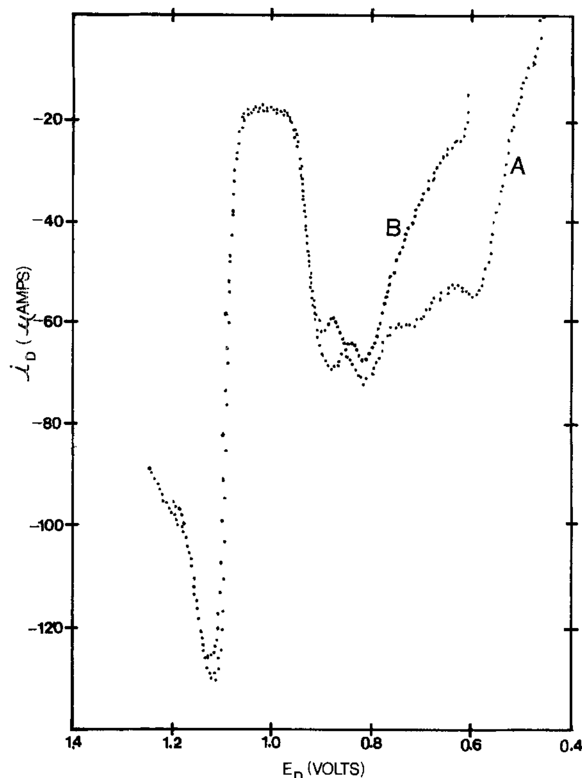

Fig. 6. Rotating disk electrode anodic stripping curves. Curve A, $E_{DEP} = 0.45V$; Curve B, $E_{DEP} = 0.60V$. $\omega = 2500$ rpm, $dE/dt = 50$ mV/sec, $C_{H_2SO_4} = 0.2M$ and $C_{Hg(I)} = 2.0 \times 10^{-5}M$.

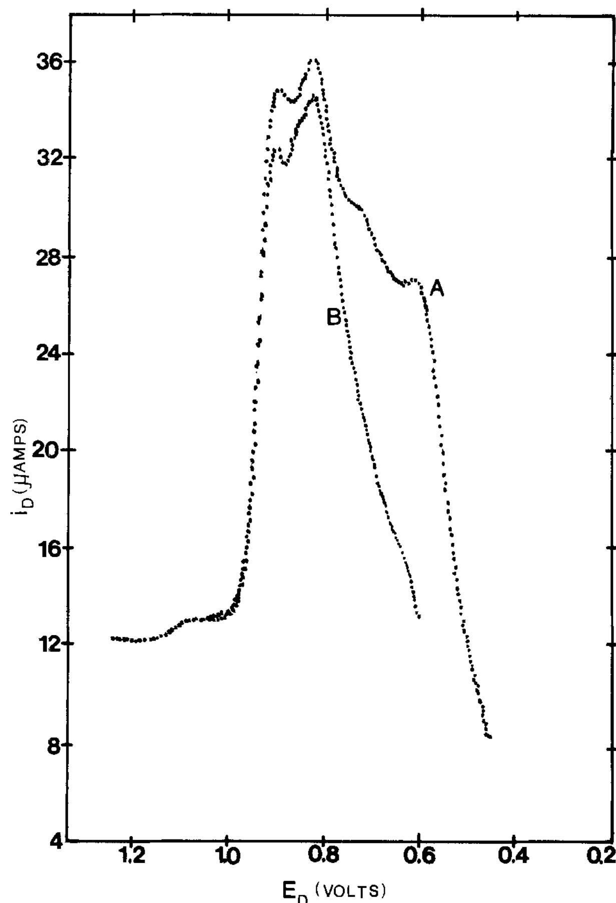

Fig. 7. Ring electrode collection curves of disk of RRDE used in Fig. 6. Curves A and B as in Fig. 6. $E_R = 0.0V$.

These are indistinguishable on the basis of the existing data, as is the possible existence of a partially discharged Hg species produced during the UPD process

$$(Hg(I)_2)_2 + (2 - 2a)e \rightleftarrows 2Hg^{a+} \quad [5]$$

The desorption path is the reverse of the adsorption path. If the charge associated with peak "P" ($Q_{ads}{}^P$) of Fig. 4 is that required to reduce the adsorbed mercury species, and the difference between the ring and disk electrode charges measured in the above experiments ($Q_R{}^* - Q_{D,\omega=2500}$) is attributed to the desorption of the same mercury species, then the relationship

$$Q_R{}^* - Q_{D,\omega=2500} = Q_{ads}{}^P \quad [6]$$

should hold at each deposition potential. Comparison of the above difference (column 5, Table II and curve C, Fig. 5) with the $Q_{ads}{}^P$ (column 6, Table II), indicates that Eq. [6] is obeyed over the entire underpotential deposition range. Again, the results do not permit distinguishing between the various mechanisms, although the existence of peak "P" is suggestive of a surface species undergoing charge transfer, rather than some double layer process.

An excellent method for visualizing the potential region over which the adsorbed mercury species desorbs is to compare I_D-E_D curves with i_R/N-E_D curves obtained simultaneously during the anodic stripping of the underpotentially deposited Hg. Typical curves for deposition at 0.45V are shown in Fig. 8. The shaded area between the curves represents the charge associated with the adsorbed mercury species present on the reduced gold electrode.

UPD Hg(II) solutions.—Experiments identical to those described in the previous sections for $(Hg(I))_2$ were also performed using $2.0 \times 10^{-5}M$ Hg(II). The zero-current rest potential was determined to be 0.399V using the methods described in the section dealing with the establishment of the Nernst potential in $(Hg(I))_2$ solution. Here, as in the $(Hg(I))_2$ case the rest potential was independent of the electrode rotation rate over the range 400-4900 rpm. Since the potential in $(Hg(I))_2$ and Hg(II) solutions are identical for practical purposes in our experiments, the reaction

$$(Hg(I))_2 \rightleftarrows Hg(II) + Hg(O)_{UPD}$$

must be very fast at the electrode surface, and lie far to the right. This conclusion has been confirmed by coulostatic experiments reported elsewhere (31).

Anodic stripping and ring collection curves obtained after potentiostating the disk electrode in the UPD region are essentially indistinguishable from those obtained in $(Hg(I))_2$ solutions. Note that the stripping data obtained at $\omega = 2500$ rpm are not complicated by the background oxidation of $(Hg(I))_2$ that was present in the previous experiments. Peak "P" (Fig. 4) is also

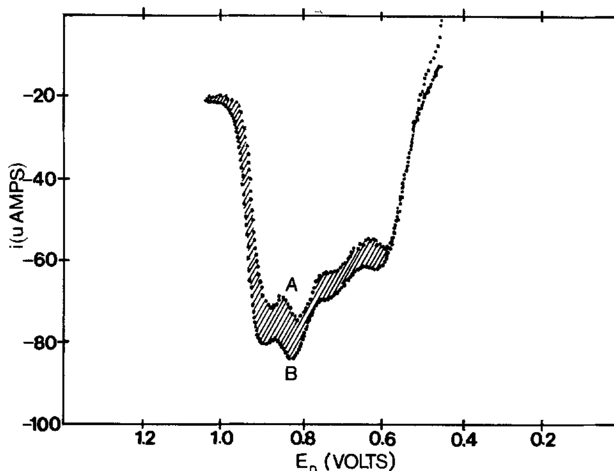

Fig. 8. Comparison of potential dependence of disk current and flux of $(Hg(I))_2$ removed at the disk. Data of Fig. 6 and 7. Curve A, disk current; curve B, current equivalent to flux removed at disk electrode calculated from i_R/N.

[a] Q_D is disk electrode anodic stripping data obtained at ω = 2500 rpm; all other charge values are as defined in Table II.

observed during stationary cathodic scans following the deposition of Hg(O) at underpotential from Hg(II) solutions.

The potential-charge data for the Hg(II) experiments are tabulated in Table III. The similarity between these data and corresponding $(Hg(I))_2$ data again suggest that deposition and adsorption from Hg(II) solutions proceed through a common intermediate.

Conclusions

Just anodic of the Nernst potential, one monolayer of Hg deposits on gold at underpotential from mercurous or mercuric solutions. UPD mercury does not diffuse into the bulk of the gold electrode because of the strong interactions between mercury and surface gold atoms. $(Hg(I))_2$ (or Hg(II)) coadsorb with $Hg(O)_{UPD}$ on a reduced gold electrode in 0.2*M* H_2SO_4 over a wide potential range, $1.0V \geqq E_{DEP} \geqq 0.40V$. This adsorption increases at more cathodic deposition potentials, and it reaches a maximum of 54 $\mu C/cm^2$ at the Nernst potential.

Electrooxidation of Hg(O) in the underpotential region produces Hg(II) in four overlapping stripping peaks. Deposition of bulk Hg does not occur until potentials cathodic of the Nernst potential, and then only after one monolayer of $Hg(O)_{UPD}$ has been deposited.

The Kinetics of the Oxygen Reduction Reaction on Gold in Alkaline Solution

R. W. Zurilla,*,[1] R. K. Sen,* and E. Yeager**

Case Laboratories for Electrochemical Studies and the Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

ABSTRACT

The kinetics of the O_2 cathode have been examined on Au in alkaline electrolytes using the rotating ring-disk method. Only the series mechanism is operative. The cathodic and anodic kinetic data for the O_2/HO_2^- couple support the mechanism

$$O_2 + e^- \rightarrow O_2^-(\text{ads})$$

$$2\,O_2^-(\text{ads}) + H_2O \rightarrow HO_2^- + O_2 + OH^-$$

The further reduction of HO_2^- to OH^- is first order in HO_2^- and involves a rate-controlling step with very little potential dependence.

Several studies (1-4) indicate that O_2 reduction on Au in alkaline solutions proceeds only by the series mechanism with HO_2^- (ads) as an intermediate in the reduction process. Some questions persist, however, regarding the mechanism involved in the reduction process to peroxide (1-4) as well as the peroxide elimination step. To resolve some of these questions the present study has involved kinetic measurements of O_2 reduction on Au in alkaline solution of high purity.

Experimental

The experiments were carried out in an all-Teflon cell, using a Au rotating ring-disk electrode, the details of which are available elsewhere (5). The gold was obtained from Alfa Products Division of the Ventron Corporation and had a purity of 99.999% according to the supplier. The Au disk (0.5 cm diam, 0.196 cm^2 area) and ring (0.89 cm OD, 0.62 cm ID, 0.32 cm^2 area) electrodes were mechanically polished in successive stages with the following materials: (*i*) silicon carbide paper, 600 grit (3M Company); (*ii*) crocus cloth (Behr-Manning Company); (*iii*) AB alumina, 600 grit (Buehler Limited); (*iv*) AB alpha alumina, 0.3μ (Buehler Limited); and (*v*) AB gamma alumina, 0.05μ (Buehler Limited). When the electrodes attained a mirror finish, they were soaked in 6*M* NaOH (16 hr), 1:1 H_2SO_4-HNO_3 (16 hr), 1:1 HNO_3-H_2O (12 hr), and then washed and stored in triply distilled water. The electrodes thus prepared are probably in a slightly oxidized state. Therefore, prior to the electrochemical measurements the Au disk electrode was cycled several times between +0.9 and +0.25V *vs.* RHE at a sweep rate of 1 V/min. Such treatment yields an electrode surface which is in the reduced state. Linear sweep voltammetry for Au over a sufficiently wide potential range in alkaline solutions indicates that the anodic film is reduced at ~0.85V *vs.* RHE. Diaphragm-type β Pd-H electrodes, fed from the rear with H_2, were used as the reference and counterelectrodes. Unless otherwise indicated all potentials are expressed relative to the β Pd-H electrode, which exhibits the reversible hydrogen electrode (RHE) potential.

A 50% stock solution of NaOH was prepared from special low carbonate NaOH pellets (J. T. Baker). The solubility and hence maximum concentration of Na_2CO_3 in this solution is very low ($10^{-4}M$). Over a period of several months the 50% solution was decanted several times to remove the precipitated Na_2CO_3. The 0.1*M* NaOH solution used in the present study was prepared from this stock solution with care to avoid recontamination with CO_2.

Preelectrolysis of the 0.1*M* NaOH solution was carried out with two interconnected Au foil cathodes (total area ~45 cm^2) in the main compartment of the cell. The maximum current density during preelectrolysis was 10 μA/cm^2. In prior studies many workers have used Pt for the preelectrolysis electrodes. Under anodic conditions, however, even in alkaline solutions Pt may be introduced in the solution and subsequently redeposited on the working electrode during electrochemical measurements. To check on this, various metals were used as preelectrolysis anodes, namely Pt, Au, Ni, and β Pd-H (H_2 fed from the rear). In all instances preelectrolysis was carried out for a minimum of 40 hr with purified He bubbling through the solution. The two preelectrolysis cathodes were usually maintained at −0.40V, whereas the corresponding anode potentials were for Pt ~1.5V *vs.* the β Pd-H reference, Au ~1.7V, Ni ~1.8V, and β Pd-H ~0.0V. In addition two unbiased Au foil electrodes (~22 cm^2 each) were introduced in the main compartment of the cell at a rest potential of +0.9V during preelectrolysis to adsorb impurities.

O_2 reduction was then studied with the solutions preelectrolyzed in the presence of the various anodes. The Tafel plots diffusion corrected are as shown[2] in Fig. 1. The current i_1 indicated in Fig. 1 is that portion of the disk current that results in the formation of adsorbed HO_2^- and i_D is the diffusion-limited current for this process. The method of calculation and significance of i_1 are discussed later. The use of Pt as the preelectrolysis anode yields different results. This is attributed to Pt contamination of the solution. For all further results presented in this article, only β Pd-H anodes were used during preelectrolysis.

Results

O_2 reduction.—The disk and ring currents as a function of the disk potential for O_2 reduction on Au in 0.1*M* NaOH at 2500 rpm are shown in Fig. 2. The ring was held at +1.05V where prior measurements indicate that H_2O_2 oxidation is diffusion controlled. A small residual ring current (<5 μA) was observed with the disk in the potential range 0.93-0.89V, even though the disk current was essentially zero. This residual ring current was rotation dependent and amounted only to a few percent of the ring current in the current-potential plateau region for the disk. This background ring current is probably due to traces of HO_2^- in solution and was subtracted from the observed ring currents in the data shown in Fig. 2.

[2] Cathodic currents are taken as positive.

Fig. 1. Tafel plots for O_2 reduction on Au measured at 2500 rpm and 2 V/min in O_2-saturated 0.1*M* NaOH preelectrolyzed with β Pd-H (○), Au (●), Ni (△), and Pt (□) anodes with Au cathodes. Disk area, 0.196 cm^2; temperature, 26°C; i_D = 0.66 mA.

Fig. 2. Comparison of disk and ring currents with calculated current (i_1) for O_2 reduction to HO_2^- for Au disk electrode at various potentials in O_2-saturated 0.1*M* NaOH at 26°C. Rotation rate, 2500 rpm; sweep rate, 1 V/min; *N*, 0.43; disk electrode area, 0.196 cm^2.

The hysteresis in the disk polarization curves was negligible between the cathodic and anodic voltage sweeps. The collection efficiency *N* for the disk-ring electrode system was calculated to be $N = 0.43$ from the geometry of the disk and ring electrodes, using the treatment of Albery and Bruckenstein (6).

If the series mechanism is assumed to be operative for O_2 reduction on Au in alkaline media, the reaction sequence can be represented as

$$\begin{array}{lccccc} \text{electrode surface} & O_2 & \xrightarrow{i_1} & HO_2^-\ (\text{ads}) & \xrightarrow{i_2} & \text{products} \\ & \uparrow & & i_4 \downarrow \uparrow i_5 & & \\ & & & (HO_2^-)_e & & \\ & & & \downarrow i_R/N & & \\ \text{bulk solution} & O_2 & & HO_2^- & & \end{array}$$

where i_2 is the current associated with the electrochemical reduction of HO_2^-, i_R is the ring current, i_4 and i_5 are the rates of desorption and adsorption of HO_2^- expressed as currents, and HO_2^- and $(HO_2^-)_e$ correspond to solution phase peroxide in the bulk and at the electrode surface, respectively. This reaction scheme predicts the relationship (5)

$$\frac{i}{i_R} = \frac{(2k_2/k_4) + 1}{N} + \frac{2k_2k_5(1.61\nu^{1/6})}{k_4ND_p^{2/3}\omega^{1/2}} \quad [1]$$

where i is the experimentally measured disk current, D_p is the diffusion coefficient of HO_2^-, ν is the kinematic viscosity of the electrolyte, ω is the electrode rotation rate, *N* is the collection efficiency, and the *k*'s are the rate constants of the steps indicated by the subscripts.

Equation [1] predicts a linear relationship between i/i_R and $\omega^{-1/2}$ for a given potential and the intercept can be greater than $1/N$ depending on the rate constants for steps 2 and 4. Damjanovic *et al.* (4) have stated that i/i_R *vs.* $\omega^{-1/2}$ plots having intercepts greater than $1/N$ are proof that the parallel mechanism is operative. This analysis shows that such is not a proof. Recently Tarasevich *et al.* (2) and Wroblowa *et al.* (3) have also arrived at the same conclusion regarding the analysis of Damjanovic *et al.* (4).

If $2k_2/k_4 << 1$, then Eq. [1] rearranges to

$$\frac{i}{i_R} = \frac{1}{N} + \frac{2\overline{k_2}(1.61\nu^{1/6})}{ND_p^{2/3}\omega^{1/2}} \quad [2]$$

where $\overline{k_2} = k_2k_5/k_4$.

A plot of i/i_R *vs.* $\omega^{-1/2}$ obtained from the experimental data of the present study is shown in Fig. 3. The extrapolations of the linear plots in Fig. 3 to $\omega^{-1/2} = 0$ yields an intercept which is independent of the disk potential and its magnitude (2.2) approximately equals $1/N$. Since this behavior fits Eq. [2], the O_2 reduction on Au in 0.1*M* NaOH appears to proceed via the series mechanism. Furthermore it confirms that $k_4 >> k_2$.

Fig. 3. Ratio of the disk to ring currents obtained for O_2 reduction for Au electrodes at various disk potentials in O_2-saturated 0.1*M* NaOH plotted against $\omega^{-1/2}$. Disk area, 0.196 cm^2; sweep rate, 1 V/min; temperature, 26°C; ring potential, 1.05V.

The expressions for i_1 and i_2 obtained from the reaction scheme presented above are

$$i_1 = \frac{i + (i_R/N)}{2} \quad [3a]$$

and

$$i_2 = i - i_1 \quad [3b]$$

With the disk-ring data obtained in the present study, i_1 can be calculated at various potentials for a particular rotation rate. The results of such calculations at 2500 rpm are shown in Fig. 2 and indicate that at all cathodic potentials the experimental disk currents are larger than the calculated i_1 values. The difference is due to the further reduction of HO_2^- (i_2).

If the kinetics are first order with respect to dissolved O_2, the corrected disk current i_1 is related (7) to rotation rate ω by the equation

$$\frac{1}{i_1} = \frac{1}{(i_1)_k} + \frac{1}{B\sqrt{\omega}} \quad [4]$$

where $(i_1)_k$ is the kinetic limiting current for O_2 reduction to HO_2^- and $i_D = B\sqrt{\omega}$ is the corresponding diffusion limiting current. Figure 4 shows a plot of $1/i_1$ *vs.* $\omega^{-1/2}$ obtained from the present experimental data. The linearity of the plot indicates that O_2 reduction is first order with respect to dissolved O_2. The experimental value of B obtained from Fig. 4 is 0.013 mA $(rpm)^{-1/2}$ which compares favorably with the calculated value of 0.014 mA $(rpm)^{-1/2}$ using Newman's (8) expression for B and the data of Gubbins and Walker (9) for the solubility and diffusion coefficient of O_2 in 0.1*M* NaOH.

If the experimentally measured disk currents are used directly to construct Tafel plots, the slope turns out to be a function of the rotation rate. This apparent change of Tafel slope with rotation rate is caused by a failure to consider the contribution made to the disk current by HO_2^- reduction. When the corrected disk current (i_1) is used, the Tafel slope is independent of rotation rate and has a value of −120 mV/decade as shown in Fig. 5. The values of i_D for these plots were calculated from the B value obtained from Fig. 4 and

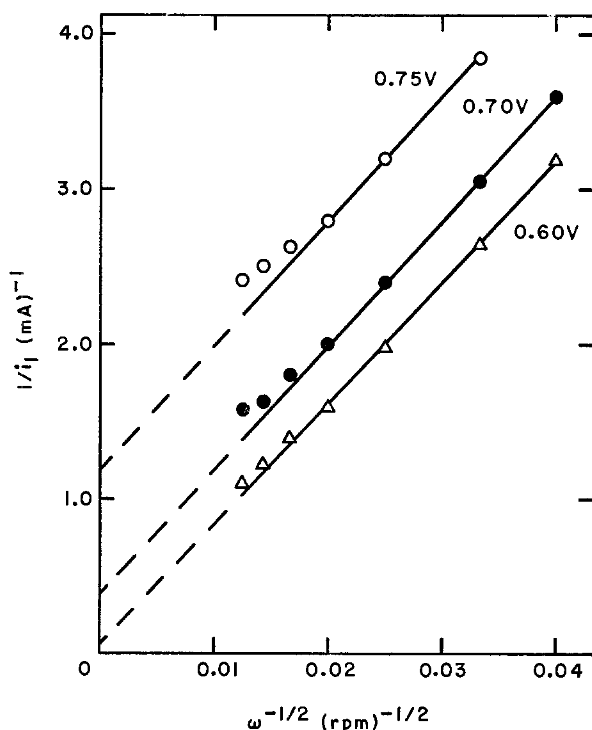

Fig. 4. Plot of $1/i_1$ vs. $\omega^{-1/2}$ for the reduction of O_2 on Au at various disk potentials in O_2-saturated 0.1*M* NaOH. Electrode area, 0.196 cm^2; sweep rate, 1 V/min; temperature, 26°C.

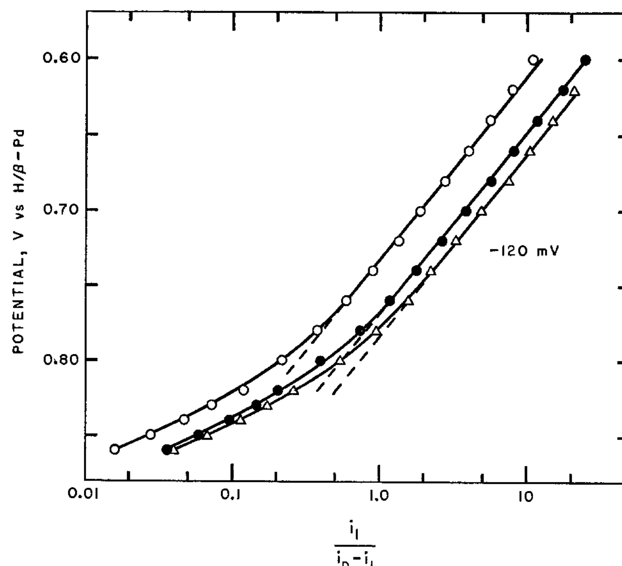

Fig. 5. Tafel plots constructed from corrected disk currents (i_1) for O_2 reduction on Au in O_2-saturated 0.1*M* NaOH at 26°C. Disk area, 0.196 cm^2; sweep rate, 1 V/min, ○, 6400 rpm; i_D = 1.04 mA. ●, 1600 rpm; i_D = 0.52 mA. △, 900 rpm; i_D = 0.39 mA.

the rotation rate. Deviations from Tafel linearity begin at a potential of +0.77V. These deviations are caused most likely by a contribution to the disk current by the back-reaction of HO_2^- to O_2, which decreases the net observed cathodic current. The observed −120 mV/decade Tafel slope implies rate control by an initial one-electron transfer step.

Investigations of 0.1*M* NaOH solutions containing O_2 and $8.8 \times 10^{-4}M$ HO_2^- were carried out to detect possible coupling of the O_2 and HO_2^- reduction processes and any inhibition effects of the O_2 reduction reaction caused by the presence of HO_2^- in the bulk solution. The Tafel plots for O_2 reduction obtained in this case superimpose with the ones obtained in the absence of any HO_2^- in the Tafel linear range. Therefore, the rotating disk-ring data do not indicate any kinetic coupling.

The experiments with peroxide added to the solution were also used to evaluate the stoichiometric number ν with the help of the equation

$$\left(\frac{\partial \eta_a}{\partial i_1}\right)_o = \frac{-RT}{n\mathbf{F}} \cdot \frac{\nu}{(i_o)_a} \quad [5]$$

where $(\partial\eta_a/\partial i_1)_o$ is the activation polarization resistance evaluated at $\eta = 0$ for O_2/HO_2^- couple, $(i_o)_a$ is the apparent exchange current for this couple evaluated from the Tafel slope, and n is the over-all number of electrons transferred per mole of O_2 ($n = 2$). The activation polarization resistance was determined by correcting the experimentally determined over-all polarization resistance $(\partial\eta/\partial i_1)_o$ for mass transport by the equation

$$\left(\frac{\partial \eta_a}{\partial i_1}\right)_o = \left(\frac{\partial \eta}{\partial i_1}\right)_o - \left(\frac{\partial \eta_d}{\partial i_1}\right)_o \quad [6]$$

The mass transport resistance $(\partial\eta_d/\partial i_1)_o$ is defined by

$$\left(\frac{\partial \eta_d}{\partial i_1}\right)_o = \frac{RT}{n\mathbf{F}}\left[\frac{1}{i_D} + \frac{1}{i_d}\right] \quad [7]$$

where i_D and i_d are the diffusion-limiting currents for O_2 reduction and HO_2^- oxidation. The over-all polarization resistance $(\partial\eta/\partial i_1)_o$ was determined from a plot of η *vs.* i_1 at small η with i_1 calculated from the disk-ring data. This procedure for the evaluation of $(\partial\eta/\partial i_1)_o$ was used to eliminate contributions to the disk current from HO_2^- reduction.

Table I. Parameters for the evaluation of the apparent stoichiometric number (ν) for the reduction of O_2 on Au in O_2-saturated 0.1*M* NaOH containing $8.8 \times 10^{-4}M$ HO_2^- at 26°C. Electrode area, 0.196 cm².

rpm	900	2500	4900
i_D (mA)	0.40	0.66	0.93
i_d (mA)	0.20	0.33	0.47
$(i_o)_a$ (mA)	0.18	0.17	0.18
$\left(\frac{\partial\eta}{\partial i_1}\right)_o \left(\frac{V}{mA}\right)$	−0.24	−0.21	−0.17
$\left(\frac{\partial\eta_d}{\partial i_1}\right)_o \left(\frac{V}{mA}\right)$	−0.10	−0.06	−0.04
$\left(\frac{\partial\eta_a}{\partial i_1}\right)_o \left(\frac{V}{mA}\right)$	−0.14	−0.15	−0.13
Apparent ν	2.0	2.0	1.8

Values of the stoichiometric number calculated by use of the above equations are listed in Table I together with values for the various parameters involved in the computations. These results indicate an apparent stoichiometric number of 2 for the O_2/HO_2^- couple.

The *p*H dependence of the O_2 reduction was examined in the range 11.5-12.7 by adding $HClO_4$ to the 0.1*M* NaOH. At constant electrode potential, the disk current was essentially independent of *p*H in this range and hence the O_2 reduction to peroxide is considered to be zero order with respect to OH^-.

HO_2^- oxidation.—The oxidation of HO_2^- on Au in He-saturated 0.1*M* NaOH containing $1.34 \times 10^{-2}M$ HO_2^- exhibits a well-defined limiting current. Figure 6 shows experimental current-potential curves for HO_2^- oxidation at various rotation rates. Hysteresis was negligible between the curves measured with increasing and decreasing anodic potentials, provided the maximum potential did not exceed 1.1V. The rotation dependence of the potential corresponding to $i = 0$ is attributed to the heterogeneous decomposition of HO_2^- according to the reactions

$$HO_2^- + OH^- \rightarrow O_2 + H_2O + 2e^- \quad [8]$$

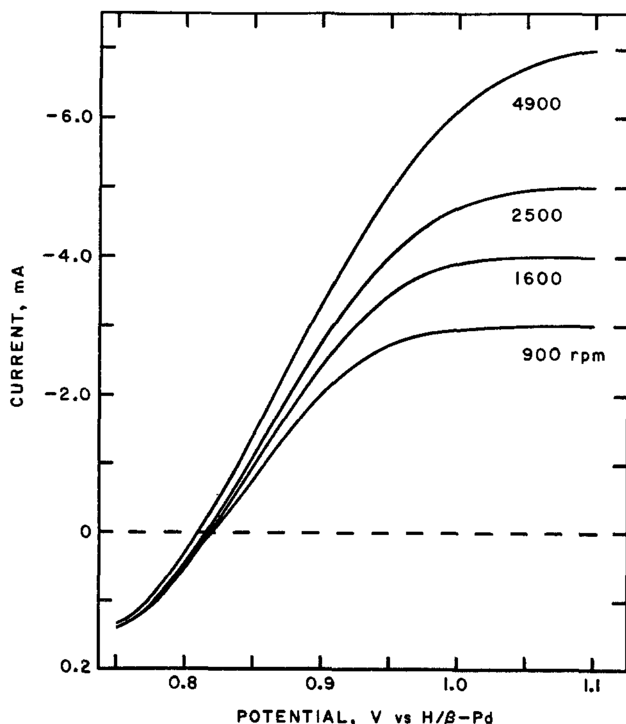

Fig. 6. Oxidation of HO_2 at various rotation rates (rpm) on Au in He-saturated 0.1*M* NaOH containing $1.34 \times 10^{-2}M$ HO_2^- at 26°C. Electrode area, 0.196 cm²; sweep rate, 1 V/min².

$$HO_2^- + H_2O + 2e^- \rightarrow 3\,OH^- \quad [9]$$

or the total reaction

$$2HO_2^- \rightarrow O_2 + 2\,OH^- \quad [10]$$

When the back-reaction for HO_2^- oxidation is negligible, the kinetics at constant *p*H and potential follow the relationship

$$i = -k[HO_2^-]_e^m \quad [11]$$

where *k* is the rate constant and *i* the current for HO_2^- oxidation, *m* is the reaction order, $[HO_2^-]_e$ is the concentration of HO_2^- at the electrode surface. With the use of the relation

$$\frac{[HO_2^-]_e}{[HO_2^-]} = \frac{i_d - i}{i_d} \quad [12]$$

where $[HO_2^-]$ is the bulk concentration of HO_2^-, Eq. [11] becomes

$$i = k[HO_2^-]^m \left[\frac{i_d - i}{i_d}\right]^m \quad [13]$$

By plotting log (*i*) *vs.* log $[(i_d - i)/i_d]$ at different rotation rates and constant potential, the slope *m* can be determined. Such plots are shown in Fig. 7 for the oxidation of HO_2^- on Au in He-saturated $1.34 \times 10^{-2}M$ HO_2^- + 0.1*M* NaOH. The plots for 0.95 and 1.00V indicate a reaction order of ~½ while that at 0.90V indicates ~1. The most likely explanation for this apparent discrepancy is that at 0.90V the HO_2^- is undergoing reduction to OH^- according to Eq. [9], and O_2 formed at the electrode by the oxidation of HO_2^- is contributing a cathodic current.

If the oxidation of HO_2^- is one-half order with respect to HO_2^-, the disk current at a given potential is related to the rotation rate (7) by

$$\frac{1}{i^2} = \frac{1}{(i_k)^2} + \frac{1}{B\,i\sqrt{\omega}} \quad [14]$$

where i_k is the kinetic limiting current for HO_2^- oxidation and $B = \overline{B}/[HO_2^-]$. Plots of $1/i^2$ *vs.* $1/i\sqrt{\omega}$ for various potentials are given in Fig. 8 for the same set of experimental data. The linearity and parallel slopes at 0.95 and 1.00V provide further evidence of $m = ½$ at these potentials. While the plot is linear also at 0.90V, the slope deviates from that at more anodic potentials. This deviation in slope at 0.90V is not surprising in view of the difference found also in Fig. 7 at this potential. The values of $\overline{B}$ calculated from the plots in Fig. 8 are 7.7 and 7.8 in mA^{-1} $(rpm)^{-1/2}$ for 0.95 and 1.00V as compared with a value of 7.6 determined under conditions of pure diffusion HO_2^- control from a plot of $1/i$ *vs.* $1/\sqrt{\omega}$ for a $2.5 \times 10^{-3}M$ HO_2^- + 0.1*M* NaOH at 1.05V. The value of $\overline{B}$ calculated from Fig. 8 for 0.90V, however, is 6.1 which deviates substantially from the expected value.

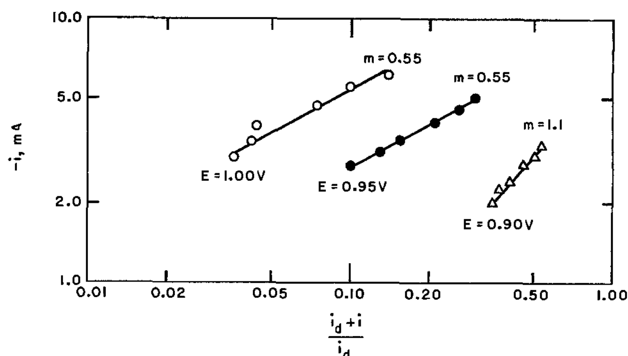

Fig. 7. Reaction order (*m*) for oxidation of HO_2^- on Au in He-saturated 0.1*M* NaOH containing $1.34 \times 10^{-2}M$ HO_2^-. Electrode area, 0.196 cm²; temperature, 26°C; sweep rate, 1 V/min.

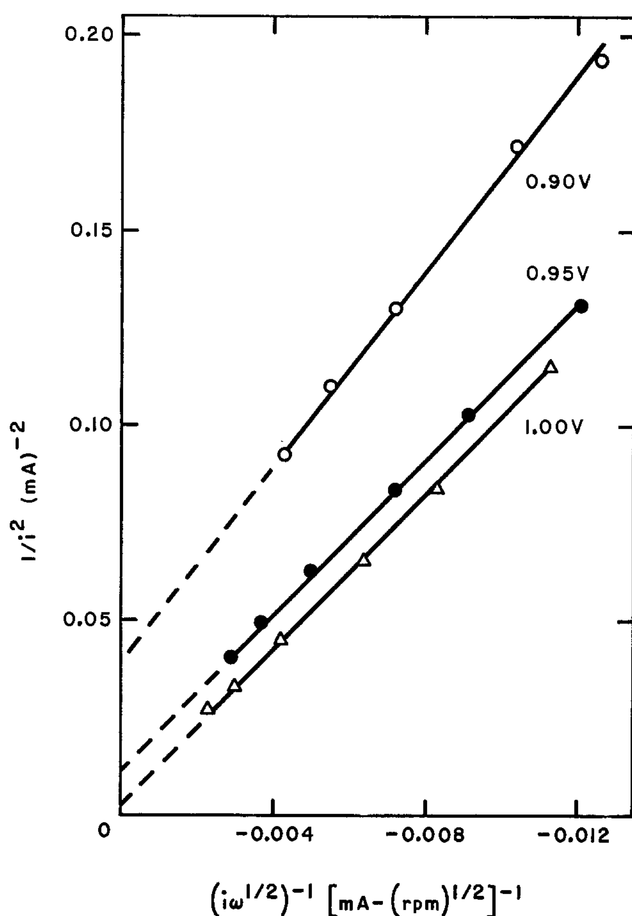

Fig. 8. Plot of $1/i^2$ vs. $(i\omega^{1/2})^{-1}$ for the oxidation of HO_2^- on Au at various potentials in He-saturated 0.1*M* NaOH containing 1.34 × 10^{-2}*M* HO_2^- at 26°C. Electrode area, 0.196 cm^2; sweep rate, 1 V/min.

It is unfortunate that the reaction orders can be examined for the HO_2^- oxidation step only relatively close to the HO_2^- diffusion-limiting current using the rotating disk data. This makes it difficult to obtain accurate values for m by this approach. Even so, the reaction order data in Fig. 7 and 8 support a value of $m = ½$ with respect to HO_2^-. In the later discussion of mechanism it is shown that a HO_2^- reaction order of one-half is compatible with the stoichiometric number of 2 evaluated from the combined rotating disk-ring data whereas a HO_2^- reaction order of 1 is not.

The pH dependence of the HO_2^- oxidation was also examined over the range 11-12.7 at 0.95 and 1.00V by adding varying amounts of concentrated $HClO_4$ to an O_2 saturated 0.1*M* NaOH + 7.8 × 10^{-4}*M* HO_2^-. The results are shown in Fig. 9 in terms of a function of the current density i and the limiting current densities i_D and i_d corresponding to the values for O_2 and HO_2^- transport, respectively. The use of this function is prompted by mechanistic considerations discussed later. The OH^- reaction order corresponds to the slope in the log-log plot and is ~½. Measurements at lower pH's than 11 gave erratic results probably because of OH^- transport problems. The pK of H_2O_2 is ~12, which also can lead to complications at pH less than this value.

HO_2^- reduction.—Investigations of the reduction of HO_2^- on Au were conducted in He-saturated 0.1*M* NaOH. Reproducible results were difficult to obtain due to the decomposition of HO_2^- which introduced O_2 into the solution. Nonetheless, reliable results for HO_2^- reduction on Au were obtained by performing the experiments in reasonably short time. The results obtained in 0.1*M* NaOH solutions plus 2.5 × 10^{-3}*M* HO_2^- are shown in Fig. 10 and 11.

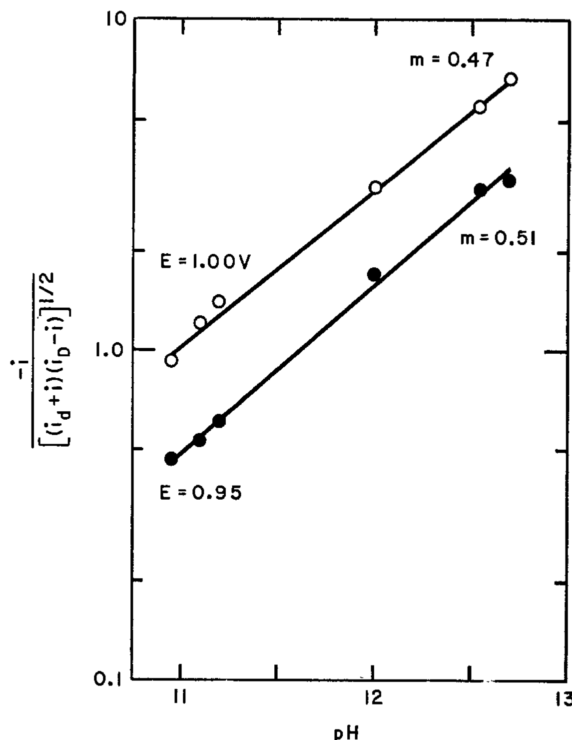

Fig. 9. Dependence of oxidation of HO_2^- on pH for Au electrode in O_2-saturated 0.1*M* NaOH and small amounts of 70% $HClO_4$ + 7.8 × 10^{-4} HO_2^-. Electrode area, 0.196 cm^2; rotation rate, 2500 rpm; temperature, 26°C.

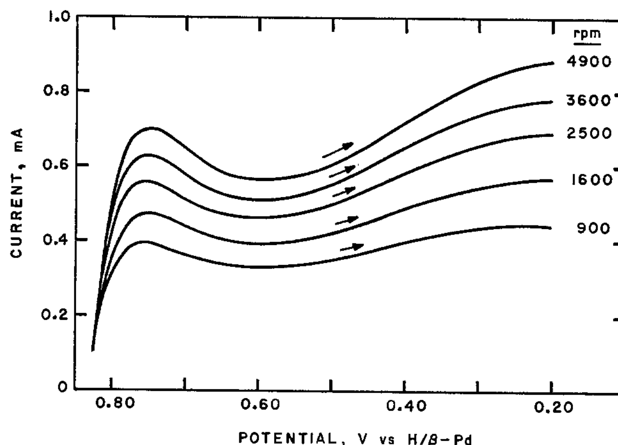

Fig. 10. Reduction of HO_2^- in He-saturated 0.1*M* NaOH containing 2.5 × 10^{-3}*M* HO_2^- at 26°C. Electrode area, 0.196 cm^2; sweep rate, 4 V/min.

The i vs. E plots in Fig. 10 have a rather strange shape. The $1/i$ vs. $1/\sqrt{\omega}$ plot in Fig. 11 indicates that the current even at the most cathodic potentials examined is still under combined kinetic and diffusion control. The kinetic currents $(i_2)_K$ obtained from the intercepts in Fig. 11 have very little potential dependence over a wide range of potentials (0.2-0.75V) and correspond to a value of $k_2 \cong 0.01$ cm/sec. The lack of potential dependence of k_2 suggests that the rate-controlling step and any step preceding it do not involve electron transfer.

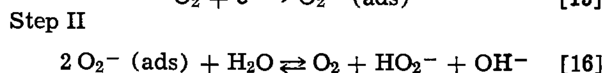
Mechanistic Considerations

The kinetic data for O_2 reduction and HO_2^- oxidation on Au in alkaline solution are compatible with the following mechanism

Step I

$$O_2 + e^- \rightarrow O_2^- \text{ (ads)} \quad [15]$$

Step II



$$2\,O_2^- \text{ (ads)} + H_2O \rightleftarrows O_2 + HO_2^- + OH^- \quad [16]$$

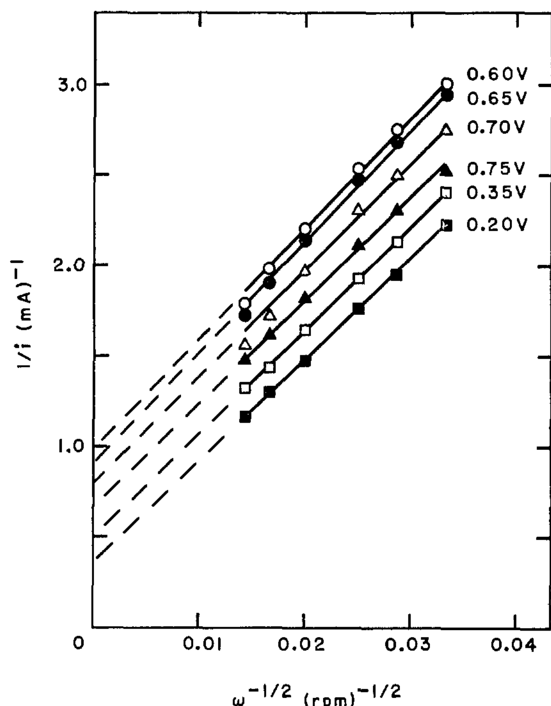


Fig. 11. $1/i$ vs. $\omega^{-1/2}$ plots for the reduction of HO_2^- on Au at various potentials in He-saturated 0.1M NaOH containing $2.5 \times 10^{-3}M$ HO_2^- at 26°C. Electrode area, 0.196 cm²; sweep rate, 4 V/min.

This mechanism satisfies the requirement of a Tafel slope of −120 mV/decade, a stoichiometric number of 2, and the observed reaction orders with respect to O_2 ($m = 1$), OH^- ($m = 0$) for the reduction, and HO_2^- ($m = 1/2$) and OH^- ($m = 1/2$) for the peroxide oxidation. Further it does not involve the cleavage of the O-O bond prior to the formation of HO_2^-. Isotopic experiments on various surfaces (10, 2) provide strong evidence that all of the peroxide oxygen originates from the O_2 and not H_2O or OH^- and that the O-O bond is not ruptured.

The dismutation step II is rather surprising. Since the rate of the reverse of step I is negligible, step II is not just the simple electrochemical oxidation of the superoxide $O_2^{\overline{\cdot}}$ coupled with its further reductions. Further, it is unlikely that step II proceeds by the desorption of $O_2^{\overline{\cdot}}$, followed by the second-order homogeneous reaction

$$2\,O_2^{\overline{\cdot}} + H_2O \rightarrow HO_2^- + O_2 + OH^- \quad [17]$$

The slopes of the $1/i_l$ vs. $1/\sqrt{\omega}$ plots in Fig. 4 correspond to those of $2e^-$ per O_2 transported through the Nernst layer. Consequently if Eq. [17] contributes significantly to the HO_2^- formation this reaction must proceed sufficiently fast to be essentially complete within a distance small compared to the Nernst diffusion layer thickness. Thermodynamics imposes an upper limit on the $O_2^{\overline{\cdot}}$ concentration adjacent to the electrode. Recent estimates (11, 12) of the standard reduction potential for the reaction

$$O_2 + e^- \rightarrow O_2^{\overline{\cdot}} \quad [18]$$

indicate $E° = -0.28V$ vs. SHE or $+0.55V$ vs. β Pd-H. At a potential of, for example, 0.75V vs. β Pd-H (see Fig. 4), the upper limit for the $O_2^{\overline{\cdot}}$ concentration (calculated from the Nernst equation) is $\sim 10^{-3}M$. The upper limit for the second-order rate constant for Eq. [17], however, has been shown (13) to be 100 M^{-1} sec^{-1}. Assuming that the reaction must occur in an electrolyte layer of $X = 10^{-3}$ cm thickness, the upper limit on the rate of Eq. [17] expressed in units of current density is

$$i = 2\mathbf{F}k(C_{O_2^{\overline{\cdot}}})^2 V = 2 \times 10^{-5}\ \text{A/cm}^2 \quad [19]$$

where $\mathbf{F}$ is the Faraday, $k = 10^2$ M^{-1} sec^{-1}, $C_{O_2^{\overline{\cdot}}} = 10^{-3}M$, and $V = (10^{-3}$ cm$)(1$ cm$^2) = 10^{-6}$ liters. The observed current density i_l at this potential and a rotation rate of 2500 rpm is 1.8×10^{-3} A/cm² or two orders of magnitude greater. Thus it appears that step II is definitely a surface process involving the direct interaction of two $O_2^{\overline{\cdot}}$ adsorbed radicals.

With step I slow and step II fast, the current for O_2 reduction is

$$i = (i_o)_I \left[\frac{i_D - i}{i_D} \exp \frac{-\alpha_I \mathbf{F} \eta}{RT} - \left(\frac{i_d + i}{i_d} \cdot \frac{i_D - i}{i_D} \right)^{1/2} \exp \frac{(1-\alpha_I)\mathbf{F}\eta}{RT} \right] \quad [20]$$

where $(i_o)_I$ and α_I are the apparent exchange current density and transfer coefficient for step I, i_D and i_d are the diffusion limiting current densities for O_2 reduction and HO_2^- oxidation involving the over-all transfer of two electrons, and $\eta = E - E_r$, with E_r the reversible potential of the O_2/HO_2^- couple. For Eq. [20] the current density i is negative for net oxidation currents and positive for the reduction currents. Equation [20] also assumes that the surface coverage of O_2^-(ads) is small.

For ease in testing the proposed reaction scheme Eq. [20] is rearranged to the following form

$$\eta = \frac{2.3RT}{\alpha_I \mathbf{F}} \log \frac{(i_o)_I}{i_D} - \frac{2.3RT}{\alpha_I \mathbf{F}} \log X \quad [21]$$

where

$$X = \frac{i/(i_D - i)}{1 - \left[\frac{i_D(i_d + i)}{i_d(i_D - i)} \right]^{1/2} \cdot \exp \frac{\mathbf{F}\eta}{RT}} \quad [21a]$$

Thus a plot of η vs. log X should be linear over the whole potential range in which anodic and cathodic currents are observed and the linear plot should have a slope of $-(2.3\,RT/\alpha_I\mathbf{F}) = -120$ mV when $\alpha_I = 0.5$.

Plots of η vs. log X are given in Fig. 12 for the polarization curves measured at 900, 2500, and 4900 rpm for the oxidation of HO_2^- and reduction of O_2 on Au in O_2-saturated 0.1M NaOH containing $8.8 \times 10^{-4}M$ HO_2^-. The cathodic disk currents were corrected for HO_2^- reduction using the ring current data and the appropriate equation. The linear plots in Fig. 12 show the expected translation with rotation rate in the ratio of the diffusion currents i_D and have a slope of ~ -120 mV/decade which corresponds to $\alpha_I = 0.5$. The plots in Fig. 12, therefore, are a good verification of the reaction mechanism represented by Eq. [15] and [16]. The exchange current density $(i_o)_I$ calculated from Fig. 12 is ~ 0.9 mA/cm² for the O_2-saturated $8.8 \times 10^{-4}M$ HO_2^- + 0.1M NaOH solution at 26°C.

The observed pH dependence of the anodic oxidation of HO_2^- to O_2 (Fig. 9) can also be explained on the basis of steps I and II. The oxidation current is related to the molar concentrations of O_2, HO_2^-, and OH^- at the electrode surface by the equation

$$i = -2\mathbf{F}\overleftarrow{k}_I K_{II}^{-1/2}[O_2]_e^{1/2}[HO_2^-]_e^{1/2}[OH^-]_e^{1/2} \quad [22]$$

where $\overleftarrow{k}_I$ is the reverse rate constant for step I and K_{II} the equilibrium constant for step II. Correcting for diffusion of HO_2^- and O_2, Eq. [22] becomes

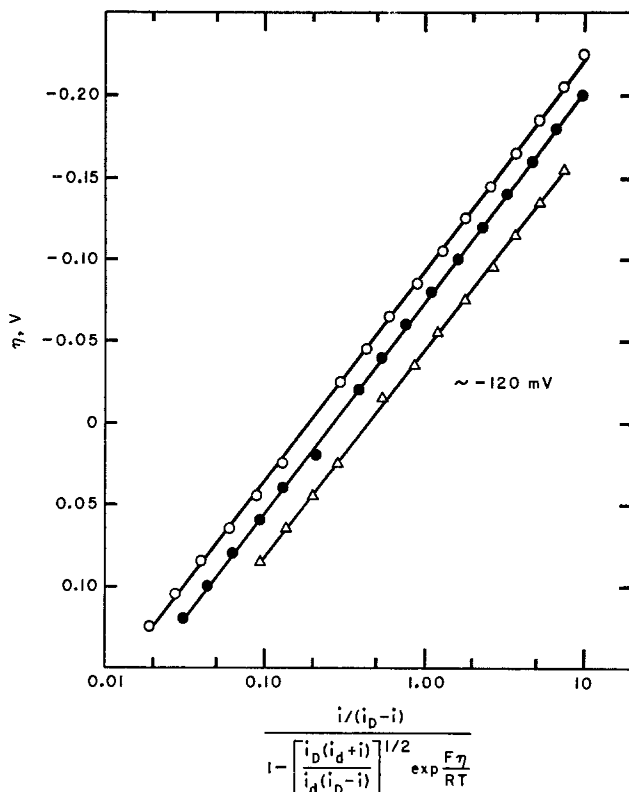

Fig. 12. Oxidation of HO_2^- and reduction of O_2 on Au in O_2-saturated 0.1M NaOH containing $8.8 \times 10^{-4}M$ HO_2^- at 26°C. Electrode area, 0.196 cm^2; sweep rate, 2 V/min; $E_r = 0.83V$. ○, 4900 rpm; $i_D = 0.93$; $i_d = 0.47$. ●, 2500 rpm; $i_D = 0.66$; $i_d = 0.34$. △, 900 rpm; $i_D = 0.40$; $i_d = 0.20$ mA.

$$\frac{i}{[(i_d + i)(i_D - i)]^{1/2}} = \overleftarrow{k}_I K_{II}^{-1/2}(i_d \cdot i_D)^{1/2}[O_2]^{1/2}[HO_2^-]^{1/2}[OH]^{1/2} \quad [23]$$

where $[O_2]$, $[HO_2^-]$, and $[OH^-]$ are the bulk concentrations. The plot in Fig. 9 verifies the one-half order dependence on $[OH^-]$. Equation [20] also predicts a one-half order dependence on O_2 for the oxidation of HO_2^-. This reaction order was not checked in the present work.

Only the reduction process could be studied for the HO_2^-/OH^- couple. The process is first order with respect to HO_2^-. A surprising result is that even at very cathodic potentials (0.2V) the process is still under partial kinetic control. The rate constant for the process has a very small potential dependence. This suggests that a chemical step proceeding the electron transfer is rate controlling. Such a step might be

$$HO_2^- + H_2O \rightarrow 2\,OH(ads) + OH^- \quad [24]$$

The small variation of the rate constant with potential may be just secondary changes due to the potential dependence of the state of adsorption of anions and other features of the surface.

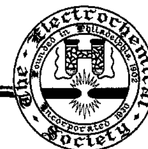
Technical Note



A Practical Electrochemical Transport Equation for Concentrated Solutions

Aharon S. Roy*,[1]

Energy and Metals and Ceramics Divisions, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

Most electrochemical energy-related processes employ concentrated electrolytic solutions or fused salts. Notable are storage batteries and fuel cells. Analysis of the transport behavior of the various species of the liquids involved is useful for optimizing the system. However, the conventional transport equations in the literature for nondilute solutions, either of the linear phenomenological or the friction-coefficients form, require thermodynamic data which is often difficult to obtain. When the conventional Stefan-Maxwell form is used, an additional difficulty is involved when transport with respect to stationary axes is needed as the mathematical inversion required is quite complicated with multicomponent liquids (1-4). It would be very helpful if a practical, simplified transport model could be devised which would relate to gradients of concentrations and to the gradient of the electrical potential as the driving forces and which would give directly a flux expression with respect to stationary axes. This is the purpose of the present work. This approach (5, 6) constitutes a marked deviation from the conventional ones in the field.

Diffusional Fluxes, Velocities, and Transport Coefficients

For simplicity, the molar system (5, 6) is depicted for the present work. For isothermal and isobaric conditions, the total electrochemical transport $\mathbf{N}_i$ (mole/cm^2-sec) of component i will be the sum of three fluxes of i. One is by virtue of the bulk (molar-average) velocity $\mathbf{v}^*$ (cm/sec) and the other two are diffusion fluxes (relative to $\mathbf{v}^*$): migration, $\mathbf{J}_i^{*(E)}$ and ordinary, $\mathbf{J}_i^{*(x)}$, diffusion fluxes

$$\mathbf{N}_i = c_i\mathbf{v}^* + \mathbf{J}_i^{*(E)} + \mathbf{J}_i^{*(x)} \quad [1]$$

where c_i is the concentration of component i (mole/cm^3). The following relations hold (1-8)

$$\mathbf{v}^* = \Sigma_k x_k \mathbf{v}_k \quad [2]$$

$$\mathbf{J}_i^{*(E)} = c_i\mathbf{w}_i^{*(E)} = -cx_i u_i^* \nabla\phi \quad [3]$$

$$\mathbf{J}_i^{*(x)} = c_i\mathbf{w}_i^{*(x)} = c\Sigma D_i{}^*{}_k{}' \nabla x_k \quad k = 3, 4, \ldots, n) \quad [4]$$

where x_k is the molar fraction, $\mathbf{v}_k$ the velocity of component k, $c = \Sigma_k c_k$, and Σ_k stands for summation for all components (k = 1, 2, . . ., n). $\mathbf{N}_i$, $\mathbf{v}^*$, and $\mathbf{v}_k$ are measurable with respect to a fixed frame of reference (*e.g.*, the porous disk of Fig. 1). $\mathbf{w}_i^{*(E)}$ is the migration diffusion velocity of i, measurable, in absence of concentration gradients, by

$$\mathbf{w}_i^{*(E)} = \mathbf{v}_i - \mathbf{v}^* \quad [5]$$

which, with the electrostatic potential gradient [or (−) field], $\nabla\phi$, as driving force, defines the mobility of i, u_i^*. $\mathbf{w}_i^{*(x)}$ is the ordinary-diffusion velocity of i, measurable in the absence of electric field by

$$\mathbf{w}_i^{*(x)} = \mathbf{v}_i - \mathbf{v}^* \quad [6]$$

which, with the concentration gradient, ∇x_k, as driving force, defines the ordinary diffusivities $D_i{}^*{}_k{}'$.

Including the practical transport coefficients u_i^* and $D_i{}^*{}_k{}'$, Eq. [1] takes the form of a practical electrochemical transport equation

$$\mathbf{N}_i = c_i\mathbf{v}^* + c\Sigma D_i{}^*{}_k{}' \nabla x_k - c_i u_i^* \nabla\Phi, \quad (k = 3, 4, \ldots, n) \quad [7]$$

Note that only one driving force is used for defining mobilities for all components, whereas many driving forces exist for the ordinary diffusion of each component. For migration, an n-component liquid (6) gives rise to n mobilities u_i, of which $n - 1$ are independent. This is because of the constraint resulting from the definition of diffusion by which the summation of the diffusional fluxes for all components is zero. For instance, for a 4-component liquid, the constraint is (by Eq. [3], [5], and [2])

$$\Sigma_k x_k u_k^* = x_1u_1^* + x_2u_2^* + x_3u_3^* + x_4u_4^* = 0 \quad [8]$$

For ordinary diffusion the concentration gradient of any component is a driving force for all components. This leads to multicomponent or cross-term diffusivities, $D_i{}^*{}_k{}'$, of which a certain number are necessary in order to define the transport system (8-10). n^2 diffusivities may be written of which $(n-2)^2$ are independent [$(n-1)^2$ for nonelectrolytes (10)]. For instance, consider a four-component fused-salt solution composed of the components M, X, N, and Y, where M and N are, say, monovalent metals and X and Y are halogens. Indexing these components consecutively by 1, 2, 3, and 4, one may write an ordinary diffusion flux equation including four multicomponent ordinary diffusivities for the total ordinary diffusion flux of component 1

$$\mathbf{J}_1^{*(x)} = c(D_1{}^*{}_1{}')\nabla x_1 + c(D_1{}^*{}_2{}')\nabla x_2 + c(D_1{}^*{}_3{}')\nabla x_3 + c(D_1{}^*{}_4{}')\nabla x_4 \quad [9]$$

With similar equations also for fluxes of components 2, 3, and 4, sixteen diffusivities are thus written. However, two restricting relationships reduce the number of the independent gradients by two, so that the number of diffusivities decrease to eight [$n(n-2)$]. One relationship is by definition of concentration and their gradients: with n components there are only $n-1$ independent concentration gradients (summation of mole-fractions is unity, the gradient of which is zero)

$$\Sigma_k \nabla x_k = \nabla x_1 + \nabla x_2 + \nabla x_3 + \nabla x_4 = 0 \quad [10]$$

The other is the condition of electroneutrality which leads to ($z_1 = z_3 = 1$; $z_2 = z_4 = -1$)

$$\Sigma_k z_k \nabla x_k = \nabla x_1 - \nabla x_2 + \nabla x_3 - \nabla x_4 = 0 \quad [11]$$

Key words: electrolyte, cell, diffusion.

Altogether, only $(n - 2)$ gradients are independent. For our example, Eq. [10] and [11] yield

$$\nabla x_3 = -\nabla x_1 \quad \text{and} \quad \nabla x_4 = -\nabla x_2 \qquad [12]$$

Consequently, the total ordinary diffusion flux of component 1 is now represented by only two diffusivities (which bear explicit relationships to those of Eq. [9])

$$J_1^{*(x)} = cD_1{}^*{}_1{}'\nabla x_1 + cD_1{}^*{}_2{}'\nabla x_2 \qquad [13]$$

Similar equations hold also for the fluxes of components 2, 3, and 4. Of the resulting eight diffusivities only four $[(n - 2)^2$ in general] are independent due to two additional restrictions (Eq. [19], [22]). The cross-term diffusivities are not equal in general to the binary-solution diffusivities of the respective components.

The transport coefficients u_i^* and $D_i{}^*{}_k{}'$ are a function of state (composition and temperature) (8-11), *i.e.*, they are not a function of the magnitude of the gradients for most practical purposes (for fields up to about 10,000 V/cm and concentration gradients of virtually no limitation). The property of being a function of state holds equally well independently of how the gradients are defined (11), whether in terms of thermodynamic activities, molar or mass concentrations, or fractions of them, etc. It is this very property of being a function of state which is responsible for the additivity of the diffusion fluxes and their measurability independently of each other, a property that can be utilized for devising methods for measuring the transport coefficients.

A Method for Measuring Mobilities

An experimental measurement may follow one of the conventional methods for measuring migration transport of which the Hittorf method is typical. However, a special treatment of the experimental results is necessary (Eq. [16]) in order to adapt them for use with the practical transport equation. Figure 1 illustrates the principle of the Hittorf method. With uniform liquid composition (all $\nabla c_i = 0$) at the measuring zone (the porous disk) to enable compliance with Eq. [5], the transport of all components i under an electrical field (imposed by the two electrolysis electrodes shown) gives expression to measurable migration fluxes. The electrical field is defined by the potential difference across the disk as is measurable by two equal reference electrodes (12).

However, due to volume changes occurring in the two compartments across the disk during the transport experiment, the measured velocity of any component i across the disk will include also a hydrodynamic part (which depends on experimental conditions). Because this part is equally imposed on all components, it is possible to get rid of it (and thus obtain a transport coefficient which is a function of state) by resorting to relative migration-velocities (and mobilities) with respect to an arbitrarily chosen reference component s of the liquid

$$\mathbf{w}_{k/s}{}^{*(E)} = \mathbf{w}_k{}^{*(E)} - \mathbf{w}_s{}^{*(E)} \qquad [14]$$

Only $\mathbf{w}_{k/s}{}^{*(E)}$ is known from experiment. $\mathbf{w}_k{}^{*(E)}$ is still unknown. The latter can be derived by use of the relation

$$\Sigma_k x_k \mathbf{w}_k{}^{*(E)} = 0 \qquad [15]$$

(by definition of diffusion, Eq. [2] and [5]) with the function

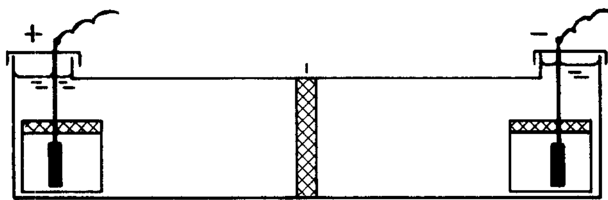

Fig. 1. A schematic representation of a migration cell

$$\mathbf{w}_i{}^{*(E)} = \Sigma x_k(\mathbf{w}_i{}^{*(E)} - \mathbf{w}_k{}^{*(E)})$$
$$= \Sigma x_k(\mathbf{w}_{i/s}{}^{*(E)} - \mathbf{w}_{k/s}{}^{*(E)} \qquad [16]$$

From Eq. [16] $u_i{}^{*(E)}$ is directly obtained by use of Eq. [3] ($\nabla\Phi$ across the disk and c_i are known).

One transport experiment yields n migration fluxes, (velocities and mobilities), of which $n - 1$ are independent, due to Eq. [15]. Being a function of state the mobilities found in an experiment with a uniform composition and in a particular electrical field will be applicable for a wide range of electrical fields and also usable within a very wide range of concentration gradients for a defined state. Similar considerations hold also for diffusivities.

A Method for Measuring Diffusivities

A possible method follows a typical conventional technique, *e.g.*, the diffusion cell with a porous disk. Here, too a special new treatment of the experimental results will render them applicable for use with the practical transport equation. Figure 2 represents a schematic of the diffusion cell. The two compartments on the two sides of the disk contain liquids with a defined difference in their composition and maintain a controlled concentration gradient across the disk. Each compartment is kept mixed at a nearly uniform composition and the fluxes across the disk during a certain period are measured by a material balance and chemical analysis. The concentration gradients for our example system are illustrated in Fig. 3. For the purpose of defining the state to which the diffusivity is assigned, the choice of the average composition of the gradient is fair enough, as is illustrated by point 0. The plane shown in the middle of the gradient lines thus specifies the state.

Each experiment is performed with only one independent concentration gradient existing. For our example, ∇x_1 $(= -\nabla x_3)$ is the only nonzero gradient $(\nabla x_2 = \nabla x_4 = 0)$. There are no electrolysis electrodes in the two compartments and there is no net electric current crossing the disk (electroneutrality forbids continuous accumulation of substantial electric charge in any macroscopic liquid volume), namely an over-all electrical field $-\nabla\Phi$ of zero value.

The electrical field $(-\nabla\Phi)$ of our consideration (for use in Eq. [7]) is defined by the addition of electric potential difference over the cell emf (13, 14)

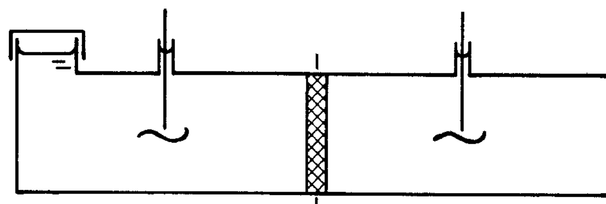

Fig. 2. A schematic representation of an ordinary diffusion cell

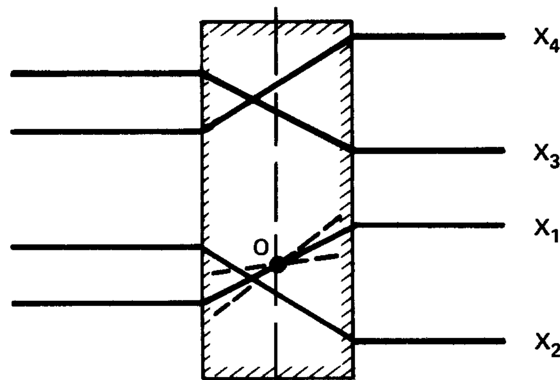

Fig. 3. A schematic representation of molar fraction gradients inside the porous disk (expanded) of the diffusion cell.

[measured by reference electrodes (12)] due to the passage of net electric current density **i** via two electrolysis electrodes. Both electric current and potential difference are externally measured.

As with the case of mobility measurement, here too the observed velocity of component i across the disk includes an undesirable hydrodynamic part due to volume changes which usually accompany any transport process. Again, this part is eliminated by recording only relative velocities with respect to a reference component s

$$\mathbf{w}_{k/s}^{*(x)} = \mathbf{w}_k^{*(x)} - \mathbf{w}_s^{*(x)} \quad [17]$$

Similarly to Eq. [14]-[16], the ordinary diffusion velocity is derived by the appropriate summation function based on the relative transport data

$$\mathbf{w}_i^{*(x)} = \Sigma x_k (\mathbf{w}_{i/s}^{*(x)} - \mathbf{w}_{k/s}^{*(x)}) \quad [18]$$

Each experiment for $\nabla x_k \neq 0$ yields n (i = 1, 2, ..., n) $D_i{}^*{}_k{}'$ diffusivities of which $n - 2$ are independent, due to two restrictive relationships. In our first experiment for example, with ∇x_1 as the only nonzero gradient, only the first term on the right of Eq. [13] is nonzero and thus the measured flux $\mathbf{J}_1^{*(x)}$ yields $D_1{}^*{}_1{}'$. Similarly, a measured $\mathbf{J}_2^{*(x)}$ will yield $D_2{}^*{}_1{}'$, etc. As the summation of all these diffusion fluxes is zero, the resulting restrictive relationship between the derived diffusivities is

$$D_1{}^*{}_1{}' + D_2{}^*{}_1{}' + D_3{}^*{}_1{}' + D_4{}^*{}_1{}' = 0 \quad [19]$$

Another restrictive relationship is obtained from the constraint that no net electric current occurs

$$\Sigma z_i \mathbf{J}_i^{*(x)} = 0 \quad [20]$$

$$z_1 D_1{}^*{}_1{}' + z_2 D_2{}^*{}_1{}' + z_3 D_3{}^*{}_1{}' + z_4 D_4{}^*{}_1{}' = 0 \quad [21]$$

which, for the numerical values of z from our example, gives

$$D_1{}^*{}_1{}' - D_2{}^*{}_1{}' + D_3{}^*{}_1{}' - D_4{}^*{}_1{}' = 0 \quad [22]$$

From Eq. [19] and [22] it follows (compare Eq. [12]) that

$$\text{(a) } D_3{}^*{}_1{}' = -D_1{}^*{}_1{}' \quad \text{(b) } D_4{}^*{}_1{}' = -D_2{}^*{}_1{}' \quad [23]$$

This reduces the array of independent diffusivities from eight to four (now only two equations of the type of Eq. [13] are independent) requiring only two ordinary diffusion experiments in our example. In general this means $(n - 2)^2$ independent diffusivities and $n - 2$ experiments. Altogether, the number of experiments required for obtaining both the mobilities and the diffusivities for each state point is $1 + n - 2 = n - 1$. As functions of state the diffusivities are not function of the magnitude of the gradients under which they were measured and therefore they are applicable for any mixed gradients condition.

Conclusion

Experience shows that transport coefficients are generally not supposed to depend on the magnitude of the fluxes and of the forces within very wide ranges. Irreversible thermodynamics, which heavily depends on this concept, do not necessarily require the use of chemical or electrochemical potentials or friction coefficients for all purposes. Separate transport coefficients for different driving forces, such as concentration and electrostatic potential gradients, can be arbitrary functions of state variables (9, 11). This enables both definition and planning of measurement of coefficients, one type at a time, as demonstrated above.

When we have all the independently measured data concerning $u_i{}^*$, which are $n - 1$ in number, and on $D_i{}^*{}_k{}'$, which are $(n - 2)^2$ in number, the general transport equation (Eq. [7]) becomes usable with all its necessary transport coefficients known. Other systems may be analyzed easily by following the pattern used in our example of the M, X, N, Y system. The number of experiments required and the number of independently measurable transport coefficients for several systems are demonstrated in Table I.

Table I. The number of independently measurable transport coefficients for several systems

System	Global number of components n	Number of independent mobilities* $n - 1$	Number of independent diffusivities $(n - 2)^2$	Thermodynamic min. (Onsager) number of independent diffusivities $(n - 1)(n - 2)/2$
M,X	2	1	0	0
M,N,X	3	2	1	1
M,N,X,Y	4	3	4	3
M,N,P,X,Y	5	4	9	6
M,N,P,X,Y,Z	6	5	16	10

* This column also indicates the total number of transport experiments necessary for each state point.

The last column on the right of Table I gives the minimum number of independent diffusivities which can be arrived at by the use of Onsager's symmetrical reciprocal law, applicable when appropriate thermodynamic driving forces are used. Though a smaller number of coefficients is obtained by this method, the effort required in attempting to obtain thermodynamic data far exceeds that involved in obtaining a few more simple experimental data, as shown above for the practical model. The inapplicability of Onsager's symmetrical reciprocal law to the practical transport coefficients is not a real disadvantage when it is realized how difficult it is, if at all possible, to measure chemical or electrochemical potentials for most nondilute systems. This may explain the limited application of the symmetrical-coefficients approach for solving practical problems in concentrated solutions for many years (15). It seems that both conceptual and experimental difficulties prevent their wide use (15).

The practical electrochemical transport equation has potential advantages at least for some particular systems. It is considerably simplified as compared to some other formalisms. It is related to single component concentrations, it is relatively less dependent on the complications involving both the definition and the elaborate measurements of many ionic activities, its coefficients are relatively readily measurable, it is directly expressed with respect to stationary axes, and it clearly reflects the different contributions of the different driving forces to the transport phenomena.

Erratum

In reference to the paper "Preparative Electrolyses at Graphite Paste Electrodes," by K. D. Wolter and J. T. Stock, which appeared on pp. 531-533 in the April 1978 JOURNAL, Vol. 125, No. 4, several things should be noted.

First, the authors overlooked the fact that a paper based on Colaruotolo's Ph.D. dissertation (Ref. 2) had actually appeared in *This Journal*, **120**, 773 (1973).

Second, it should have been stressed that Colaruotolo and co-workers were the first to show the feasibility of graphite paste as a material for preparative-scale electrolytes.

Finally, a paper by Bobbitt, Colaruotolo, and Huang [*This Journal*, **120**, 773 (1973)] should be added as Ref. (2a). This 1973 paper clearly shows for the first time that graphite paste can be used as electrode material for preparative-scale electrolyses and gives examples of actual products that were obtained at such electrodes.

Interaction of NO_x and Cu at Various Relative Humidities

Rudolf Schubert

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

It has been shown that NO_2 (2 ppm) in air at room temperature does not react (<1%) with Cu at relative humidities $\lesssim$ 65%. At RH $\gtrsim$ 65% the Cu appears to act as a catalyst to reduce NO_2 to NO. The maximum activity occurs at 100% RH with ~70% of the NO_2 being reduced. It is further shown that at 65% $\lesssim$ RH $\lesssim$ 100%, NO (0-1.3 ppm) and Cu do not interact in air. At the RH generally found in air-conditioned electronic equipment areas, NO_2 and NO should not cause any significant deterioration of exposed Cu.

If one reduces the thickness of the electroplated gold over copper on electrical connector contacts, more Cu is exposed to the atmosphere through pores in the Au electroplate and by diffusion through the Au (1). The exposed Cu may interact with oxides of nitrogen and water vapor from the atmosphere. The combination of these compounds might be expected to form nitric acid and hence insulating corrosion deposits on connector contacts over a multiyear life span. The reaction of exposed Cu through porous Au to concentrated HNO_3 vapor is well known from the nitric acid porosity test (2). In this test the Cu reacts through the Au pores and leaves a visible insulating product, providing a measure of Au porosity. This test is a highly accelerated condition as compared to the field situation, and the test in all likelihood does not reflect field performance.

This paper reports the investigation of the interaction of NO_2, H_2O vapor, and Cu filings in air. Oxides of nitrogen at the ppm level were continuously monitored after passing over Cu particles at various relative humidity (RH) levels. The reduction of NO_2 to NO as a function of RH with no copper nitrate formation is reported. These data, known RH data in air-conditioned electronic equipment locations, and estimated vapor pressure of HNO_3 over copper nitrates are taken to indicate a negligible rate of formation of copper nitrates in air-conditioned electronic equipment areas.

Experimental

The apparatus consisted of a Bendix oxides of nitrogen analyzer, Model No. 8101-B, and a gas flow system. The detector measures the chemiluminescence occurring during the reaction of NO and instrument-generated ozone. Different oxides of nitrogen are measured by alternately analyzing the gas stream for NO and then a sample in which all the NO_2 has been reduced; a difference measurement then determines the amount of NO_2 in the sample. Figure 1 is a schematic of the system.

To minimize gas-system interactions, glass and Teflon tubing were the primary components in the flow system. However, there were stainless steel fittings on the flowmeters and detector. Connections between the glass and Teflon were made by using Tygon tubing clamped over a glass-Teflon butt joint such that a minimum of Tygon tubing was exposed to the gas.

Key words: environment, metals, connectors, catalysis, corrosion.

Oxygen used in the ozone generator of the photometric detector was 99.95% pure. Laboratory room air was used to calibrate the zero point of the detector. Linde zero-grade air ($\leq$ 1 ppm total hydrocarbons, $\leq$ 3 ppm H_2O) doped with ~ 1.8 ppm NO_2 was used to investigate the interaction between NO_2 and Cu. This concentration was determined by maximizing the detector reading on the 5 ppm full scale mode with the tank gas flowing directly into the detector. Although the absolute value is somewhat arbitrary since no full-scale calibration standard was available, it is believed to be accurate to within a factor of 2 with the relative values being accurate to within ± 5% of the full-scale reading. Relative humidity in the NO_2/air mixture was varied by adjusting the percentage of the mixture passing through a fritted glass water bubbler. Direct RH measurements were deemed unnecessary and the percentages of RH listed below should be approximately correct. With 100% of the test atmosphere passing through the H_2O bubbler a slight fogging of the tubing occurred, indicating saturated water vapor. Other RH percentages were calculated as a proportion

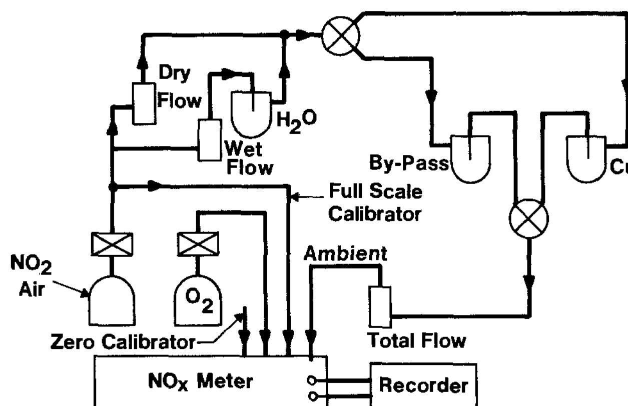

Fig. 1. Schematic of flow system. Dry flow and wet flow are gas flow meters. The by-pass section of the apparatus is to insure that the apparatus is not altering the doped gas before the exposure to the Cu filings.

of the dry-to-saturated air. As expected, no loss of NO_2 was detected when bubbling the doped air through the water.

Interaction of the test atmosphere and Cu was achieved by placing 2.6g of fresh Cu filings in the base of a fritted glass bubbler tube (~ 5 mm diam) and passing the gas up through the Cu at a flow rate of 250 ml/min. No attempt was made to prevent the Cu from oxidizing before the experiment began since the experiment was being carried out in air. The total Cu surface area is calculated to be well in excess of 2×10^3 cm^2 from particle size determination by microscope photographs of samples of the powder.

Data were taken in the following order: 0, 50, 100, 75, 84, and 100% RH on the same Cu sample. At each of these RH's several cycles were carried out; all cycles were at 1.8 ppm NO_2. A cycle consisted of setting the meter zero with room air; setting the full scale span adjustment with dry NO_2/air; measuring the NO and NO_2 values passing through the system at a given RH; and finally measuring the NO and NO_2 values passing through the equivalent system with Cu particles. Typically 2-3 days were used for one complete cycle. All data were recorded dynamically on a strip chart recorder. Measurements reported herein are after steady state was established, approximately 2 hr after any change in the cycle.

Results and Discussion

NO_2 levels measured in doped air were 1.8 ppm when fed directly from the cylinder to the detector. The same level of NO_2 was found after the gas stream had been bubbled through the water and through the bypass system without Cu. No NO was detected ([NO] < 0.02 ppm) in the NO_2-doped air at all RH's used.

NO_2-doped air was found to react with OFHC Cu particles at a rate which is very humidity dependent. NO_2 did not react at 0 and 50% RH as indicated by a constant [NO_2] of 1.8 ppm. Nor was NO (< 0.02 ppm) detected at these RH's. At 100% RH more than 70% of the NO_2 has interacted with the Cu to form NO. Both the increase in [NO] and the decrease in [NO_2] as a function of RH are plotted in Fig. 2. Before interacting with the Cu, 1.8 ppm NO_2 was present, and after the interaction 0.53 ppm NO_2 and 1.3 ppm NO were present at 100% RH. Thus the sum of NO_x molecules appears to have been conserved in the gas phase within the limits of our instrumentation.

Upon inspection, the Cu particles appeared to have oxidized, as would be expected from exposure to moist air. They were slightly brown in color but no trace of blue could be seen, which is the color of $Cu(NO_3)_2 \cdot n\,H_2O$. Tests with 1, 2, 4 phenol bisulfonic acid, which is a specific nitrate test, indicated no nitrate.[1] The vapor pressure of HNO_3 over $Cu(NO_3)_2 \cdot 3H_2O$ is estimated from vapor pressures of other organic and inorganic compounds with similar mass and boiling point to be of the order of 500 ppm at room temperature.[2] Thus, at the low partial pressures of our experiment it is expected that if a copper nitrate is formed it would also rapidly dissociate. Therefore, it appears that in this case virtually no copper nitrate is formed.

The interaction of NO_2 and H_2O is described by

$$3NO_2 + H_2O \rightarrow 2HNO_3 + NO \quad [1]$$

This reaction is very slow, if one assumes an ideal gas, since its rate is proportional to the cube of the [NO_2]. It could have been observed in this experiment at 5% of the [NO_2] by looking for an increase in the NO

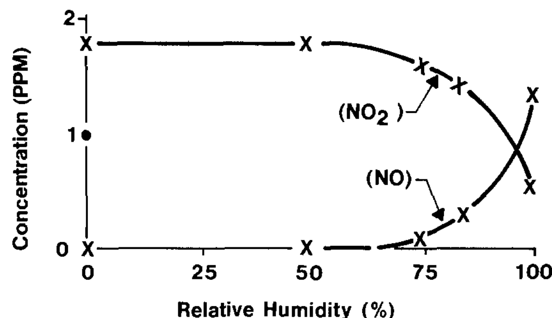

Fig. 2. Plot of concentration of NO and NO_2 (ppm) in zero-grade air vs. relative humidity when it is passed over OFHC Cu particles.

concentration. An increase in [NO] was not seen before exposure to Cu and is in agreement with the other results of trying to remove NO_2 from stack gases by scrubbing (5).

The reaction between Cu and nitric acid fumes in the solid-gas case is

$$3Cu + 8HNO_3 \leftrightarrow 2NO\uparrow 3Cu\,(NO_3)_2 + 4H_2O\uparrow \quad [2]$$

In solution at low concentration, the reaction proceeds slowly but as (3)

$$8H^+ + 2NO_3^- + 3Cu = 3Cu^{++} + 2NO\uparrow + 4H_2O \quad [3]$$

At the low partial pressures of our experiments it is not known whether the Cu is simply acting as a catalyst in the NO_2 reduction or if the Cu is being oxidized by reaction [3].

It is difficult to distinguish between reactions [2] and [3]. In both cases NO is liberated. The fact that no copper nitrate was seen does not rule out reaction [2] since the concentration of NO_2 and HNO_3 is much less than the dissociation vapor pressure of HNO_3 from copper nitrate (~ 500 ppm). Thus, it is concluded that either the solid-gas reaction or the quasisurface solution-solid reaction can explain our results.

A small fraction of the evolved NO may be lost in the air before the detector by

$$2NO + O_2 \leftrightarrow 2NO_2 \quad [4]$$

This is believed to be negligible due to the short time path between evolution and detection, as well as a rate dependence on the square of the [NO], assuming ideal gases.

The interaction of $NO_2/Cu/H_2O$ is amply demonstrated in Fig. 2. The importance of RH affecting corrosion rates has been known to some extent for a long period of time (6), however, the published literature for low concentrations is scarce and generally on slightly different systems. Aziz and Godard (7) find that SO_2 interacts with Cu to cause corrosion at RH $>$ 63%. Vernon (8) indicates that even with the inclusion of particles minimal corrosions occurred at RH $<$ 60%. Abbott *et al.* (9) also find RH an important component of corrosion tests. Thus RH is an important consideration for control of sensitive electronic equipment corrosion.

Recent studies of RH in eight locations which were air conditioned to handle large amounts of electronic equipment show that the RH was $<$60% RH for $>$90% of the time over a one year cycle (10). This RH data coupled with Fig. 2 would seem to indicate that NO_2 would not be a problem as far as Cu surfaces are concerned. This is reinforced by noting from Fig. 2 that, rather than copper nitrate forming, the Cu acts as a catalyst in reducing NO_2 to NO.

Conclusions

It is shown that NO_2 (1.8 ppm) does not interact with Cu surfaces at RH $\lesssim$ 65%. Furthermore, even at higher RH the NO_2 is reduced to NO without appreciable formation of $Cu(NO_3)_2 \cdot n\,H_2O$. At the RH gen-

[1] The 1, 2, 4 phenol bisulfonic test is capable of detection ~2 μg of $Cu(NO_3)_2 \cdot n\,H_2O$. Thus for our flow conditions we would have been able to see a test reaction if only 0.1% of the gas had reacted when using a test sample of Cu of 40 mg.

[2] If one plots the vapor pressure *vs.* temperature for N_2O_4, N_2O_5, NH_2OH, C_2H_5NO, and H_2SO_4 the slopes are between 2 and 4. At 170°C the vapor pressure of HNO_3 over $Cu(NO_3)_2 \cdot 3H_2O$ is one atmosphere. Using the above slopes and extrapolating to room temperature, the vapor pressure of interest is between 100 and 1000 ppm. In all cases the vapor pressure of HNO_3 over $Cu(NO_3)_2 \cdot 3H_20$ is much greater than the 1.8 ppm [NO_2] (4).

erally found in air-conditioned electronic equipment locations NO_2, up to several ppm, should not cause any significant deterioration of exposed Cu surfaces over what is normally found in pure air. It is also shown at RH > 65% that NO does not interact with Cu in any readily detectable amounts.

The Criterion for the Onset of Internal Oxidation Beneath the External Scales on Binary Alloys

W. W. Smeltzer*[,1] and D. P. Whittle

Department of Metallurgy and Materials Science, University of Liverpool, Liverpool L69 3BX, England

ABSTRACT

Ternary diffusion theory is used to establish a criterion for the onset of an internal oxidation zone beneath the external scale when oxidizing conditions favor formation of the oxide of the less noble metal in a binary alloy. The problem is posed in terms of ternary solution thermodynamics and diffusion and is correlated to the locus of the virtual diffusion path on the ternary alloy-oxygen isotherm. External scale formation alone occurs when the virtual diffusion path in the alloy phase contacts the oxygen solubility curve for the alloy. External scale formation accompanied by internal oxidation occurs when the virtual diffusion path for the alloy leads to oxygen supersaturation and oxide precipitation by cutting into and across the two-phase alloy/oxide field. These assertions can be used to define a limiting bulk atom fraction of the selectively oxidized solute, $N_A{}^{O*}$, in the alloy above which internal oxidation does not occur: $N_A{}^{O*}$ satisfies

$$\epsilon_O{}^A(N_A{}^{O*})^2 + \left\{ \frac{1-F(u)}{F(u)}\left[1+\left(\frac{D_{OO}}{D_{AA}}\right)^{1/2}\frac{u}{\nu}\pi^{1/2}\right] - \epsilon_O{}^A[1+F(u)] \right\}$$

$$(N_A{}^{O*}) + \left\{ \epsilon_O{}^A F(u) - (1-F(u)) - \left(\frac{D_{OO}}{D_{AA}}\right)^{1/2}\frac{1-F(u)}{F(u)}\frac{u}{\nu}\pi^{1/2} \right\} = 0$$

where $\epsilon_O{}^A$ is the Wagner interaction coefficient between oxygen and A in the alloy, D_{AA} and D_{OO} are the direct diffusion coefficients of A and oxygen in the alloy, ν is the atomic ratio of oxygen to A in the oxide AO_ν, $F(u)$ is an auxiliary function

$$F(u) = \pi^{1/2}u \exp(u^2) \operatorname{erfc}(u)$$

and u replaces $(k/2D_{AA})^{1/2}$ with k as the corrosion constant for the parabolic rate of recession of the alloy/surface scale interface. Typical ranges of parameters applicable to a variety of alloy systems are used to show the effects of the diffusion coefficients, scaling constants, and interaction parameters on the limiting value $N_A{}^{O*}$.

A limiting condition has been determined by Wagner (1) from an analysis of the diffusion processes for the onset of an internal oxidation zone beneath the external scale when oxidizing conditions favor the formation of the oxide of the less noble metal in a binary alloy. In this treatment, he assumed that metal and oxygen diffuse down their own individual gradients established by the formation of the pure binary oxide and that both metal and oxygen exhibit ideal solution behavior in the alloy. The criterion for defining the onset of internal oxidation is when conditions exist at the alloy side of the scale/alloy interface for the product of the metal and oxygen concentrations to exceed the solubility product of the binary oxide. By this means a minimum composition of the less noble metal in the binary alloy, above which internal oxidation will not occur, can be ascertained in terms of the

Key words: oxidation, alloys.

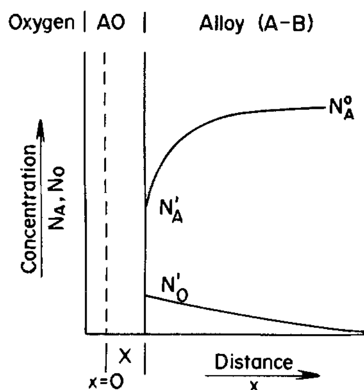
metal and oxygen diffusivities in the alloy and the parabolic rate constant for external scale growth.

The purpose of this paper is to expand this analysis by treating the binary alloy plus oxygen as a true ternary system, since Whittle *et al.* (2) have shown recently that the oxygen flux into the alloy under these circumstances can readily arise from either or both the oxygen and metal gradients in the alloy, and depending on the thermodynamic properties of the alloy solid solution, the latter can be the more significant. Thus the problem is posed in terms of the underlying ternary solution thermodynamics and diffusion, and using appropriate approximations, equations are then derived for the onset of internal oxidation based on the following two assertions relating the locus of the virtual diffusion path on the ternary alloy-oxygen isotherm: (*i*) External scale formation alone occurs when the virtual diffusion path in the alloy phase contacts the oxygen solubility curve for the alloy. In this case, the virtual path corresponds to the actual diffusion path during the oxidation reaction. (*ii*) External scale formation accompanied by internal oxidation occurs when the virtual diffusion path for the alloy cuts into and across the two-phase alloy-oxide field. This path leads to oxygen supersaturation and oxide precipitation, and, as a consequence, the virtual diffusion path does not correspond to the actual path followed during the oxidation reaction.

The Wagner Criterion for Internal Oxidation

The parabolic growth by metal transport of a scale AO_ν on an alloy A-B with concurrent diffusion of oxygen into the alloy is shown schematically in Fig. 1a. The concentration profiles in the alloy phase are described by the appropriate solutions of Fick's second law, under the assumption of concentration-independent diffusivities

$$N_A = N_A^\circ - (N_A^\circ - N_A')\frac{\operatorname{erfc} x/2\sqrt{D_{AB}t}}{\operatorname{erfc}\sqrt{k/2D_{AB}}}; \quad x \geq X \quad [1]$$



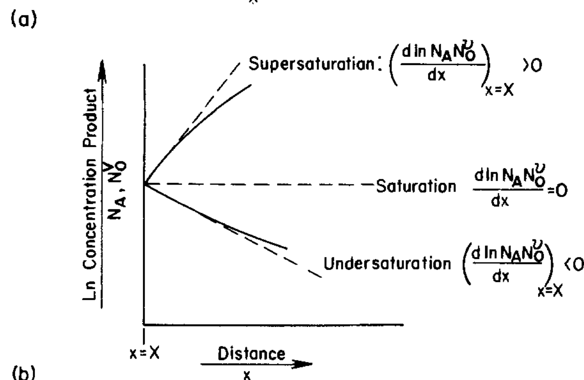


Fig. 1. The oxide scale/alloy model with symbols corresponding to those in the text. (a) Cross-section showing concentrations of solute A and oxygen in the underlying alloy. (b) The product $N_A N_O^\nu$ as a function of distance in the underlying alloy demonstrating the three possibilities.

$$N_O = N_O'\frac{\operatorname{erfc} x/2\sqrt{D_O t}}{\operatorname{erfc}\sqrt{k/2D_O}}; \quad x \geq X \quad [2]$$

where N_A°, N_A', and N_A are the atom fractions of A in the bulk alloy, at the alloy/scale interface, and locally at distance x and time t, respectively, where position x is measured from the original alloy surface. N_O' and N_O are the corresponding atom fractions of oxygen. D_{AB} and D_O are the interdiffusion coefficient and the oxygen diffusion coefficient in the alloy, respectively. The position of the actual alloy surface X at any time is related to the corrosion constant, k, by

$$X = \sqrt{2kt} \quad [3]$$

Since pure oxide, AO_ν, is assumed to form, a mass balance at the alloy/scale interface leads to

$$\frac{1}{V_M}\frac{dX}{dt} = \frac{N_A'}{V_M} - \frac{D_{AB}}{V_M}\frac{\partial N_A}{\partial x}\Bigg|_{x=X} \quad [4]$$

where V_M is the molar volume of the alloy. Substitution of [1] and [3] into [4] gives

$$N_A' = \frac{N_A^\circ - F(u)}{1 - F(u)} \quad [5]$$

where u replaces $\sqrt{k/2D_{AB}}$ and the auxiliary function $F(u)$ is given by

$$F(u) = \sqrt{\pi}\, u \exp u^2 \operatorname{erfc} u \quad [6]$$

The following equilibrium defines the relationship between the oxide and alloy components at the alloy/oxide interface

$$AO_\nu = A\,(\text{alloy}) + \nu O\,(\text{alloy}) \quad [7]$$

enabling a solubility constant K to be defined such that

$$K = N_A' \cdot N_O'^\nu \text{ at } x = X \quad [8]$$

Accordingly, the criterion for internal oxidation then becomes whether the product $N_A \cdot N_O^\nu$ exceeds the solubility constant at positions within the alloy, away from the interface. Thus, the value of $\frac{\partial}{\partial x}(N_A \cdot N_O^\nu)$ at $x = X$ is examined. Using [1], [2], [3], [6], and [8]

$$\left[\frac{\partial}{\partial x}(N_A \cdot N_O^\nu)\right]_{x=X} = \frac{2}{\sqrt{\pi}}\frac{1}{2\sqrt{D_{AB}t}}K\left[\frac{N_A^\circ - N_A'}{N_A'}\frac{\exp(-k/2D_{AB})}{\operatorname{erfc}\sqrt{k/2D_{AB}}} - \nu\left(\frac{D_{AB}}{D_O}\right)^{1/2}\frac{\exp(-k/2D_O)}{\operatorname{erfc}\sqrt{k/2D_O}}\right] \quad [9]$$

If $[\partial/\partial x(N_A \cdot N_O^\nu)]_{x=X} < 0$: the alloy is unsaturated and there is no internal oxidation.

If $[\partial/\partial x(N_A \cdot N_O^\nu)]_{x=X} = 0$: the alloy is saturated and at the limit for internal oxidation.

If $[\partial/\partial x(N_A \cdot N_O^\nu)]_{x=X} > 0$: the alloy is supersaturated directly behind the scale/alloy interface and internal oxidation is possible.

These three possibilities are shown schematically in Fig. 1b.

Equation [9] may be simplified further since in most systems

$$D_O >> k \text{ and } D_{AB} \quad [10]$$

and thus

$$\operatorname{erfc}(\sqrt{k/2D_O}) \cdot \exp\left(\frac{k}{2D_O}\right) \simeq 1 \quad [11]$$

The criterion for internal oxidation therefore becomes

$$\frac{N_A^\circ - N_A'}{\nu N_A'}\left(\frac{D_O}{D_{AB}}\right)^{1/2}\frac{\exp(-k/2D_{AB})}{\operatorname{erfc}\sqrt{k/2D_{AB}}} > 1 \quad \text{(internal oxidation)} \quad [12]$$

Equation [12] may be utilized to define the limiting atom for mole fraction of solute A above which internal oxidation would not occur. Upon the use of [5] and [6] to define N_A' and the auxiliary function $F(u)$ with u replacing $\sqrt{k/2D_{AB}}$, Eq. [12] becomes

$$N_A^{\circ} \geq \frac{F(u) + \frac{1}{\nu}\left(\frac{D_O}{D_{AB}}\right)^{1/2} u\pi^{1/2}}{1 + \frac{1}{\nu}\left(\frac{D_O}{D_{AB}}\right)^{1/2} u\pi^{1/2}} \quad \text{(no internal oxidation)} \quad [13]$$

The Ternary Representation of the Wagner Criterion for Internal Oxidation

The oxidation model considered by Wagner can be placed into a ternary thermodynamic and diffusion formalism using the A-B-O ternary isotherm and the placement of the representative diffusion paths on this isotherm. The previously discussed oxidation model corresponds to the phase diagram shown in Fig. 2. Diffusion path (Fig. 2, 1) corresponds to the formation of an external AO_ν scale only. In this case, the virtual diffusion path is constructed as tangenting the oxygen solubility curve in the alloy which is assumed to increase in slope with increasing B content of the alloy in accord with Eq. [8]. Here the virtual diffusion path corresponds to the actual diffusion profile in an alloy sample oxidizing by parabolic kinetics. Path (2, Fig. 2) corresponds to the case for external scale formation accompanied by internal oxidation. Here, the virtual diffusion path cuts into the two-phase AO_ν + alloy field leading to oxygen supersaturation. The relief of this supersaturation causes formation of internal oxide precipitates in the alloy beneath the external scale. Consequently, the criterion of Wagner for the presence or absence of internal oxidation based on the concentration gradients of metal and oxygen and their relationships to oxygen supersaturation now becomes a relationship between the diffusional composition path and the oxygen solubility curve in the ternary A-B-O isotherm.

The equivalence of the Wagner approach to that described by a limiting application of ternary diffusion theory is now demonstrated. The slope of the solubility curve at the composition corresponding to the alloy/surface scale interface (N_A', N_O') is obtained from Eq. [8]

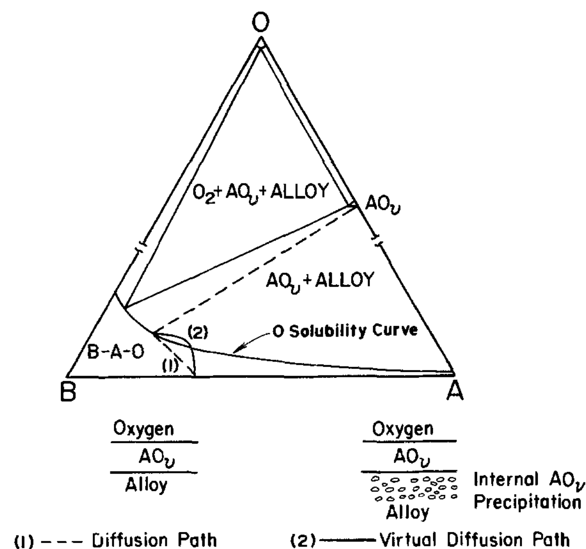

Fig. 2. The diffusion path for metal and oxygen superimposed on the A-B-O ternary isotherm. Diffusion path labeled (1) corresponds to the formation of an external AO_ν scale only. Path labeled (2) corresponds to the case of external scale formation accompanied by internal oxidation.

$$\left(\frac{dN_O}{dN_A}\right)^{\text{Sol.}}_{x=X} = -\frac{N_O'}{\nu N_A'} \quad [14]$$

In addition, the gradient of the virtual diffusion path (DP) at the alloy/scale interface

$$\left(\frac{dN_O}{dN_A}\right)^{\text{DP}}_{x=X} \quad [15]$$

can also be calculated to determine the manner in which DP contacts the solubility curve at the interfacial composition

$$\left(\frac{dN_O}{dN_A}\right)^{\text{DP}}_{x=X} = \left(\frac{\partial N_O}{\partial x} \bigg/ \frac{\partial N_A}{\partial x}\right)_{x=X} \quad [16]$$

and using Eq. [1]-[3] along with the approximation introduced as Eq. [11]

$$\left(\frac{dN_O}{dN_A}\right)^{\text{DP}}_{x=X} = -\frac{N_O'}{N_A^{\circ} - N_A'}\left(\frac{D_{AB}}{D_O}\right)^{1/2} \frac{\text{erfc}\,(k/2D_{AB})^{1/2}}{\exp -k/2D_{AB}} \quad [17]$$

These two gradients, Eq. [14] and [17] can now be compared to define the conditions of oxidation. Thus, for internal oxidation to occur

$$\left(\frac{dN_O}{dN_A}\right)^{\text{DP}}_{x=X} \geq \left(\frac{dN_O}{dN_A}\right)^{\text{Sol.}}_{x=X} \quad [18]$$

or substituting Eq. [15] and [17]

$$\frac{N_O'}{\nu N_A'} \geq \frac{N_O'}{N_A^{\circ} - N_A'}\left(\frac{D_{AB}}{D_O}\right)^{1/2} \frac{\text{erfc}\,(k/2D_{AB})^{1/2}}{\exp -k/2D_{AB}} \quad [19]$$

Rearrangement of [19] shows it is identical to the Wagner criterion as given in [13].

Although both approaches arrive at the same result, it will now be shown that the ternary analysis is more appropriate for interpreting less restrictive models.

Ternary Diffusional Analysis of the Transition from Internal Oxidation to External Scale Formation

As has been emphasized, external scale formation accompanied by a zone of internal oxidation will occur when the calculated virtual diffusion paths cuts into and across the two-phase alloy-oxide field. On the other hand, external scale growth only occurs when the virtual diffusion path for the alloy phase contacts the oxygen solubility curve and in the limit becomes a tangent to it. Accordingly, in formulating more general expressions for this criterion, particularly where nonideal thermodynamic behavior prevails, two aspects are involved: firstly, the thermodynamics of oxygen solubility in the alloy, and especially the magnitude of the solubility and its variation with composition, and secondly, the effects of thermodynamic interaction on the diffusion profiles in the alloy, and hence on the shape of the diffusion path. These two calculations on oxygen solubility and ternary diffusion are then coupled to describe internal oxidation and scale growth.

Oxygen solubility in a binary alloy involving ternary interaction.—Liquid binary alloys, in which one element is selectively oxidized from the solvent metal often exhibit a minimum in the oxygen solubility curve. Using the Wagner formalism for solution thermodynamics involving ternary interaction, St. Pierre and Blackburn (3) and Feldman and Kirkaldy (4) have derived solubility relations to interpret the experimental oxygen solubility curves in iron melts. A similar formalism is used here to interpret the oxygen solubility curves in solid binary alloys.

Expressions derived from the Gibbs-Duhem relationship, or from the equilibrium constant of the oxide with oxygen dissolved in the alloy describe the variation of the oxygen solubility curve with alloy compo-

sition. The latter method is used here as interest focuses on formation of an oxide containing negligible concentration of the solvent metal. The oxide-alloy equilibrium may therefore be written as

$$A_{1-\delta}B_\delta O_\nu = (1 - \delta)\,A + \delta B + \nu O \qquad [20]$$

where A, B, and O refer to alloy compositions and B is the solvent metal such that its concentration in the oxide is small ($\delta << 1$). Accordingly for a constant activity of the oxide $A_{1-\delta}B_\delta O_\gamma$

$$\ln K = \ln a_A^{1-\delta} a_B^{\delta} a_O^{\nu} = \ln N_A^{1-\delta} N_B^{\delta} N_O^{\nu} + \ln \gamma_A^{1-\delta}\gamma_B^{\delta}\gamma_O^{\nu} \qquad [21]$$

where K is the equilibrium constant. The oxygen solubility curve for the alloy is then defined by

$$\frac{d \ln K}{dN_A} = 0 \qquad [22]$$

If the dissolved oxygen concentration in the solvent metal B is very small, the activity coefficients in [21] can be expressed according to the Wagner formalism

$$\ln \gamma_A = \ln \gamma_A^\circ + \epsilon_A^O N_O + \epsilon_A^A N_A \qquad [23]$$

$$\ln \gamma_O = \ln \gamma_O^\circ + \epsilon_O^O N_O + \epsilon_O^A N_A \qquad [24]$$

$$\ln \gamma_B = 0; \quad N_B \simeq 1 - N_A \qquad [25]$$

Substituting [23]-[25] in [22] using [21] and remembering that $\epsilon_O^A = \epsilon_A^O$, gives

$$\left\{ \frac{1-\delta}{N_A} - \frac{\delta}{1-N_A} + (1-\delta)\epsilon_A^A + \nu\epsilon_O^A \right\} + \left\{ \frac{\nu}{N_O} + (1-\delta)\epsilon_O^A + \nu\epsilon_O^O \right\} \frac{dN_O}{dN_A} = 0 \qquad [26]$$

It follows then, that the gradient of this solubility curve can be calculated at $x = X$, the interface between alloy and growing surface scale. Under the restrictions that $\delta << 1$ and $N_A' << 1$, Eq. [26] becomes

$$\left(\frac{dN_O}{dN_A} \right)^{\text{Sol.}}_{x=X} - \frac{N_O'}{N_A'} \left(\frac{1 + N_A'\epsilon_A^A + \nu N_A'\epsilon_O^A}{\nu + N_O'\epsilon_O^A + \nu N_O'\epsilon_O^O} \right) \qquad [26a]$$

[26a] reduces to [14] earlier if ϵ_A^A, ϵ_O^O, and ϵ_O^A are zero.

Equation [26] can be utilized to define the minimum in the oxygen solubility curve since at this point dN_O/dN_A will be zero. Thus, again with $\delta << 1$

$$N_A^* = -\frac{1}{\nu\epsilon_O^A + \epsilon_A^A} \qquad [27]$$

where N_A^* is the atom fraction of A at the minimum in the solubility curve (3, 4). When A and B are neighboring transition metals in the periodic table they often exhibit Henrian solution behavior, and $\epsilon_A^A = 0$, thereby simplifying [27] to

$$N_A^* \simeq \frac{1}{\nu\epsilon_O^A} \qquad [28]$$

Oxygen solubility in a binary alloy involving Henrian and non-Henrian solution behavior.—A distinction between Henrian and non-Henrian solution behavior is essential when coupling thermodynamic and diffusional parameters to interpret reaction kinetics. It is only for the latter case of non-Henrian behavior that the slope of the oxygen solubility curve and the coupling of diffusion fluxes on the two independent compositional profiles become significant. Equation [28] has demonstrated the role of a non-Henrian interaction parameter ϵ_O^A in determining the existence of a minimum in the oxygen solubility curve, and it is appropriate here to compare Henrian and non-Henrian oxygen solubility.

Equation [21] for the oxide equilibrium reaction assuming the oxide to be essentially pure AO_ν becomes for Henrian (H) and non-Henrian (NH) behavior

$$\ln K = \ln(\gamma_A^\circ N_A)_H (\gamma_O^\circ N_O)^{\nu}{}_H \qquad [29]$$

$$\ln K = \ln(\gamma_A^\circ N_A)_{NH} (\gamma_O^\circ N_O)^{\nu}{}_{NH} + (\epsilon_A^A + \nu\epsilon_O^A) N_A + (\epsilon_O^A + \nu\epsilon_O^O) N_O \qquad [29a]$$

where the activity coefficients were defined in [23]-[25]. Because the oxygen solubility is very small ($\sim$ 10-1000 ppm), $N_O << 1$ and also the solute element (A) in the binary alloy has been regarded as exhibiting Henrian behavior ($\epsilon_A^A = 0$), [29] and [29a] yield

$$\frac{(N_O)_{NH}}{(N_O)_H} = \exp(-\epsilon_O^A N_A) \qquad [30]$$

If the Henrian activity coefficients were known, an equilibrium constant could be defined

$$K_H = \frac{K}{\gamma_A^\circ (\gamma_O^\circ)^\nu} \qquad [31]$$

such that

$$(N_O)_{NH} = \left(\frac{K_H}{N_A} \right)^{1/\nu} \exp(-\epsilon_O^A N_A) \qquad [32]$$

Expressions [31] and [32] allow, in principle, the oxygen solubilities for Henrian and non-Henrian solution behavior of oxygen in a binary alloy to be compared.

A similar shape of oxygen solubility curve is obtained for Henrian solution behavior since values of the activity coefficients remain constant irrespective of the composition of the alloy solid solution. Figure 3a presents the ratio of the non-Henrian oxygen solubility to that of Henrian oxygen solubility as given by Eq. 30. In this case component A is the less-noble alloying element in the solid solvent B. As can be seen, positive values of the interaction coefficient ϵ_O^A decrease the solubility, the decrease being more pronounced, the larger the interaction coefficient. The

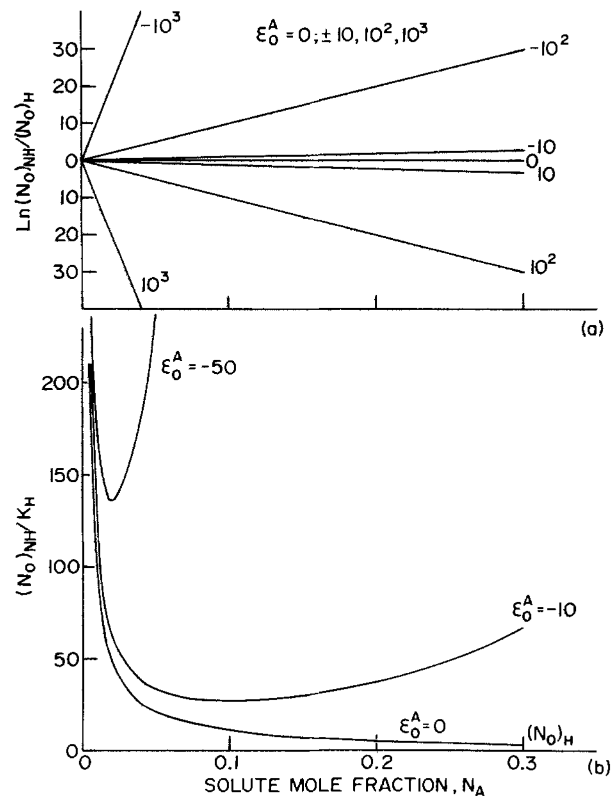

Fig. 3(a) The ratio of non-Henrian oxygen solubility to that of Henrian oxygen solubility as a function of alloy composition for different Wagner interaction parameters according to Eq. [30]. (b) The shape of the oxygen solubility curve for nonideal behavior as a function of the Wagner interaction parameter according to Eq. [32] and $\nu = 1$.

converse is found when $\epsilon_O^A < 0$, oxygen solubility increasing with larger negative values of the interaction coefficient. Figure 3b illustrates the variation and shape of the oxygen solubility curves for different negative values of ϵ_O^A. These solubility curves exhibit minima of larger oxygen concentrations which occur at smaller values of N_A with larger negative values of ϵ_O^A. The absolute slopes of the curves on either side of the minima also markedly increase as ϵ_O^A increases in negative value.

The Ternary Oxidation Model

The relatively simple diffusion model, similar to that considered by Wagner (1) is shown schematically in Fig. 4: The ternary oxide $A_{1-\delta}B_\delta O_\nu$ is assumed to correspond closely with the composition of the binary oxide ($\delta << 1$) and the oxygen solubility curve may exhibit a minimum.

Oxygen is the only component which is regarded as diffusing on both its own and the metal gradient. This assumption is realistic in that its concentration is small, and it diffuses interstitially at a rate much more rapid than the metallic species by substitutional vacancy mechanisms. Accordingly

$$D_{OO} >> D_{AA} \text{ and } |\partial N_O/\partial x| << |\partial N_A/\partial x| \quad [33]$$

and the flux equations describing diffusion in the alloy may be written as

$$j_A = -D_{AA}\frac{\partial N_A}{\partial x} \quad [34]$$

$$j_O = -D_{OO}\frac{\partial N_O}{\partial x} - D_{OA}\frac{\partial N_A}{\partial x} = -D_{OO}\left(\frac{\partial N_O}{\partial x} + \epsilon_O^A N_O \frac{\partial N_A}{\partial x}\right) \quad [35]$$

where the dilute solution approximation has been substituted for the off-diagonal diffusion coefficient D_{OA} (5)

$$D_{OA} = D_{OO}\epsilon_O^A N_O \quad [36]$$

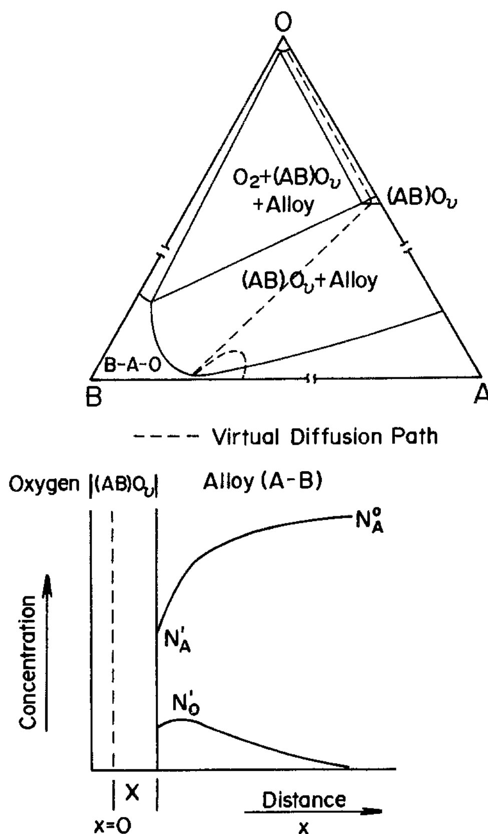

Fig. 4. The ternary oxidation model

The divergence of the fluxes may be written

$$\frac{\partial N_A}{\partial t} = \frac{\partial}{\partial x}\left(D_{AA}\frac{\partial N_A}{\partial x}\right) = D_{AA}\frac{\partial^2 N_A}{\partial x^2} \quad [37]$$

$$\frac{\partial N_O}{\partial t} = \frac{\partial}{\partial x}\left| D_{OO}\left(\frac{\partial N_O}{\partial x} + \epsilon_O^A N_O\frac{\partial N_A}{\partial x}\right)\right| = D_{OO}\frac{\partial^2 N_O}{\partial x^2} + D_{OO}\epsilon_O^A\frac{\partial}{\partial x}\left(N_O\frac{\partial N_A}{\partial x}\right) \quad [38]$$

where it has been assumed that D_{AA} and D_{OO} are independent of composition.

Since ternary interactions have been assumed not to influence the diffusion of A, the solution of [37] is that due to Wagner (1) given earlier in Eq. [1], with Eq. [5] giving N_A', the mole fraction of A at the alloy/scale interface, $x = X = (2kt)^{1/2}$. The solution of [38] gives the oxygen profile in the alloy. A modification of a solution presented by Bolze *et al.* (6), which assumes that the off-diagonal coefficient, D_{OA}, and the direct coefficient, D_{OO}, are constant, gives

$$N_O = \frac{D_{OA}}{D_{OO}}(N_A^o - N_A')\frac{\text{erfc}(x/2\sqrt{D_{AA}t})}{\text{erfc}(k/2D_{AA})^{1/2}} + N_O'\frac{\text{erfc}(x/2\sqrt{D_{OO}t})}{\text{erfc}(k/2D_{OO})^{1/2}} - \frac{D_{OA}}{D_{OO}}(N_A^o - N_A')\frac{\text{erfc}(x/2\sqrt{D_{OO}t})}{\text{erfc}(k/2D_{OO})^{1/2}} \quad [39]$$

N_O' is the mole fraction of oxygen at the alloy/scale interface, which is also the oxygen solubility limit for an alloy of composition N_A'. Equation [39] can be used to give the gradient of the oxygen profile at this interface, $x = X$

$$\left(\frac{\partial N_O}{\partial x}\right)_{x=X} = \frac{N_A^o - N_A'}{(\pi D_{OO}t)^{1/2}}\left\{\frac{D_{OA}}{D_{OO}} - \frac{D_{OA}}{(D_{OO}D_{AA})^{1/2}}\frac{\exp(-k/2D_{AA})}{\text{erfc}(k/2D_{AA})^{1/2}} - \frac{N_O'}{N_A^o - N_A'}\right\} \quad [40]$$

where the approximation given in [11] has been used. The gradient of the metal profile at $x = X$ is obtained from [1], and combining this with [40] provides an expression for the slope of the virtual diffusion path in the alloy at the point where it contacts the surface scale

$$\left(\frac{dN_O}{dN_A}\right)^{DP}_{x=X} = \left(\frac{D_{AA}}{D_{OO}}\right)^{1/2}\frac{\text{erfc}(k/2D_{AA})^{1/2}}{\exp(-k/2D_{AA})}\left\{-\frac{D_{OA}}{D_{OO}} - \frac{D_{OA}}{(D_{OO}D_{AA})^{1/2}}\frac{\exp(-k/2D_{AA})}{\text{erfc}(k/2D_{AA})^{1/2}} - \frac{N_O'}{N_A^o - N_A'}\right\} \quad [41]$$

If ternary interaction were negligible, and $D_{OA} = 0$, [41] reduces to [15] given earlier, with D_{AA} equivalent to D_{AB}, the interdiffusion coefficient in the binary alloy.

Upon substitution of [36] for the constant off-diagonal coefficient, at the specific value corresponding to N_O', the atom fraction of oxygen at the alloy/scale interface, [41] becomes

$$\left(\frac{dN_O}{dN_A}\right)^{DP}_{x=X} = -N_O'\left(\frac{D_{AA}}{D_{OO}}\right)^{1/2}\frac{\text{erfc}(k/2D_{AA})^{1/2}}{\exp(-k/2D_{AA}}\left\{\frac{1}{N_A^o - N_A'} + \epsilon_O^A\left(\frac{D_{OO}}{D_{AA}}\right)^{1/2}\frac{\exp(-k/2D_{AA})}{\text{erfc}(k/2D_{AA})^{1/2}} - \epsilon_O^A\right\} \quad [42]$$

This tangent to the compositional profile of the virtual diffusion path has to be compared to the tangent to the solubility curve at the composition of the alloy/scale interface (N_A', N_O') as given by [26a]. Equation [42] then provides the limiting criterion for transition from external scale formation accompanied with internal oxidation, to external scale formation only. Thus, for internal oxidation to occur, condition [18] must be satisfied, irrespective of the composition N_A' on the solubility curve: N_A' can be ahead of the oxygen minimum solubility, at this minimum, or on the ascending curve. Substitution of [42] and [26a] into [18] gives

$$\frac{N_A^o - N_A'}{N_A'}\left(\frac{1 + N_A'\epsilon_A^A + \nu N_A'\epsilon_O^A}{\nu + N_O'\epsilon_O^A + \nu N_O'\epsilon_O^O}\right)\left(\frac{D_{OO}}{D_{AA}}\right)^{1/2}\frac{\exp(-k/2D_{AA})}{\operatorname{erfc}(k/2D_{AA})^{1/2}} \left\{\frac{1}{1 + (N_A^o - N_A')\,\epsilon_O^A\left[\left(\frac{D_{OO}}{D_{AA}}\right)^{1/2}\frac{\exp(-k/2D_{AA})}{\operatorname{erfc}(k/2D_{AA})^{1/2}} - 1\right]}\right\} > 1 \quad [43]$$

Equation [43] may be utilized to define the limiting atom fraction of solute A above which internal oxidation of the alloy would not occur, using [5] and [32], respectively, to define N_A' and N_O'. However, first it is appropriate to introduce the following simplification, since ϵ_A^A and ϵ_O^O are generally much less than ϵ_O^A, $N_O' << N_A'$

$$\frac{1 + \epsilon_A^A N_A' + \nu\epsilon_O^A N_A'}{\nu + \epsilon_O^A N_O' + \nu\epsilon_O^O N_O'} \simeq \frac{1 + \nu\epsilon_O^A N_A'}{\nu} \quad [44]$$

Thus rearrangement of Eq. [43] gives

$$\frac{N_A^o - F(u)}{1 - N_A^o} \geq \frac{\sqrt{\pi}}{\nu}u\sqrt{\frac{D_{OO}}{D_{AA}}}\left\{\frac{1 + \nu\epsilon_O^A N_A^o - F(u)[1 + \nu\epsilon_O^A]}{1 + \sqrt{\pi}u\epsilon_O^A\sqrt{\frac{D_{OO}}{D_{AA}}}(1 - N_A^o) - F(u)[\epsilon_O^A(1 - N_A^o) + 1]}\right\} \quad [45]$$

where the auxiliary function $F(u)$ is defined by [6] and as earlier, u replaces $\sqrt{k/2D_{AA}}$. In the case of ideal behavior, when $\epsilon_O^A = 0$, [45] reduces to [13] earlier; that given by Wagner (1).

Oxygen flux into the alloy.—It is appropriate here to compare the fluxes of oxygen into the alloy in the two limiting cases in which oxygen is free from, or includes ternary interaction. The metal concentration gradient has been assumed to be identical in each case. The oxygen fluxes are as follows:

No interaction

$$j_O = D_{OO}(\partial N_O/\partial x)_{x=X} \quad [46]$$

Including ternary interaction

$$j_O = -D_{OO}\left(\frac{\partial N_O}{\partial x} + \epsilon_O^A N_O'\frac{\partial N_A}{\partial x}\right)_{x=X} \quad [47]$$

Using the approximation in Eq. [11], together with Eq. [2], [40,] and [1]

$$\left(\frac{\partial N_O}{\partial x}\right)_{x=X}[\text{no interaction}] = -(N_O')_H/(\pi D_O t)^{1/2} \quad [48]$$

$$\left(\frac{\partial N_O}{\partial x}\right)_{x=X}[\text{interaction}] = -\frac{(N_O')_{NH}}{(\pi D_{OO}t)^{1/2}}\left\{1 + \epsilon_O^A(N_A^o - N_A')\left[\left(\frac{D_{OO}}{D_{AA}}\right)^{1/2}\frac{\exp - k/2D_{AA}}{\operatorname{erfc}(k/2D_{AA})^{1/2}} - 1\right]\right\} \quad [49]$$

$$\left(\frac{\partial N_A}{\partial x}\right)_{x=X} = \frac{N_A^o - N_A'}{(\pi D_{AA}t)^{1/2}}\frac{\exp - k/2D_{AA}}{\operatorname{erfc}(k/2D_{AA})^{1/2}} \quad [50]$$

where $(N_O')_H$ and $(N_O')_{NH}$ are the oxygen solubilities at the particular metal concentration existing at the alloy/scale interface corresponding to Henrian and non-Henrian thermodynamic behavior, respectively. Thus

$$\frac{j_O(\text{no interaction})}{j_O(\text{interaction})} = \frac{(N_O')_H}{(N_O')_{NH}}\frac{1}{[1 - \epsilon_O^A(N_A^o - N_A')]} \quad [51]$$

When ternary interactions are considered, the total oxygen flux, as given by Eq. [47], consists of two parts: that along the oxygen gradient itself, j_O^O, and that along the metal gradient, j_O^M

$$j_O(\text{interaction}) = j_O^O + j_O^M \quad [52]$$

$$j_O^O = -D_{OO}(\partial N_O/\partial x)_{x=X} \quad [53]$$

$$j_O^M = -D_{OO}\epsilon_O^A(N_O')_{NH}(\partial N_A/\partial x)_{x=X} \quad [54]$$

The latter contribution to the flux, of course, does not exist in the case of Henrian or noninteractive behavior. However, in the former, the flux of oxygen along its own gradient has also been modified from that of Henrian behavior due to the ternary interaction since the oxygen concentration gradients are different in the two cases. Equations [48] and [49] give these gradients for Henrian and non-Henrian behavior, respectively; an increasingly negative interaction parameter ϵ_O^A causes the oxygen gradient to become more positive and thus retards the inward diffusion of oxygen. The contributions to the total oxygen flux by the oxygen and metal gradients can be compared for the ternary oxidation model

$$\frac{j_O^O}{j_O^M} = -\left\{1 + \left(\frac{D_{AA}}{D_{OO}}\right)^{1/2}\frac{\operatorname{erfc}(k/2D_{AA})^{1/2}}{\exp - k/2D_{AA}}\left[\frac{1}{\epsilon_O^A(N_A^o - N_A')} - 1\right]\right\} \quad [55]$$

A comparison of Eq. [53] to [54] demonstrates that the above flux ratio is negative when the influence of the interaction causes the oxygen gradient at the alloy/scale interface to become positive. Moreover, the oxygen flux along the metal gradient is always greater in magnitude than that along the oxygen gradient (the absolute value of the ratio in Eq. [55] is always less than 1), and so the net oxygen flux is always into the alloy.

In our earlier paper (2) oxygen diffusion under the influence of its own gradient was neglected, and the oxygen flux into the alloy under Henrian behavior, Eq. [46], was compared with that under interactive conditions along the metal gradient only, j_O^M in Eq. [54]. This comparison upon using Eq. [48] and [50] becomes

$$\frac{j_O(\text{no interaction})}{j_O^M(\text{interaction})} = -\frac{(N_O')_H}{(N_O')_{NH}}\left(\frac{D_{AA}}{D_{OO}}\right)^{1/2}\frac{1}{\epsilon_O^A(N_A^o - N_A')}\frac{\operatorname{erfc}(k/2D_{AA})^{1/2}}{\exp - k/2D_{AA}} \quad [56]$$

This is identical to the expression in our earlier paper (2) for the special case when $(N_O')_H \simeq (N_O')_{NH}$ and $k/2D_{AA}$ is relatively small

$$\text{erfc}(k/2D_{AA})^{1/2} \exp(k/2D_{AA}) \simeq 1$$

Discussion

An extreme limitation in attempts to apply conclusions from the preceding analysis to practical systems is the lack of data on oxygen solubilities in solid binary alloys and of ternary interaction parameters. Limited data are available for liquid iron alloys and Table I summarizes these from Ref. (4): Ranges of values are given in some instances, and these represent either experimental values [refer to Ref. (4) for the original reference] or values calculated theoretically from oxygen solubility curves.

Table I and the value $\epsilon_O{}^O = -13.9$ indicate that the neglect of $\epsilon_A{}^A N_O'$, $\epsilon_O{}^A N_O'$ and $\nu\epsilon_O{}^O N_O'$ in arriving at Eq. [45]-[44] is justified, particularly in view of the very low value of N_O', the atom fraction of oxygen at the alloy/scale interface. $\epsilon_O{}^A$, the interaction coefficient for oxygen with the alloying additions which would be selectively oxidized from transition metal alloys can have high negative values, even at 1600°C; extrapolation of known values demonstrates that these become even more negative with decreasing temperature.

The criterion then which determines whether the virtual diffusion path contacts the oxygen solubility curve for the alloy at a tangent or cuts into and across the two-phase alloy-oxide field is given in Eq. [45]. This condition can be used to define a limiting bulk atom fraction of the selectively oxidized solute, A, in the alloy above which internal oxidation would not occur. Equation [45] can be rearranged as a quadratic in $N_A{}^{o*}$, the critical atom fraction

$$\epsilon_O{}^A (N_A{}^{o*})^2 + \left\{ \frac{1-F(u)}{F(u)} \left[1 + \frac{u}{\nu}\left(\frac{\pi D_{OO}}{D_{AA}}\right)^{1/2} \right] - \epsilon_O{}^A[1+F(u)] \right\} (N_A{}^{o*}) + \left\{ \epsilon_A{}^O F(u) - [1-F(u)] - \frac{u}{\nu}\left(\frac{\pi D_{OO}}{D_{AA}}\right)^{1/2} \frac{1-F(u)}{F(u)} \right\} = 0 \quad [57]$$

where as before u replaces $(k/2D_{AA})^{1/2}$ and $F(u)$ represents the auxiliary function defined in Eq. [6]. Although exact calculation of Eq. [57] is not possible at this stage, it is nevertheless appropriate to carry out order of magnitude calculations to examine the influence of the various parameters involved. Clearly $N_A{}^{o*}$ depends on the interaction parameter $\epsilon_O{}^A$, the two diffusion coefficients D_{AA} and D_{OO}, and alloy/oxide interface recession rate constant k, which in turn is directly related to the diffusion coefficient of the ionic species responsible for scale growth.

It is appropriate then to consider the ranges of values which these parameters can take. Primarily, concern is with binary alloys composed of metals which have widely different affinities for oxygen: Fe, Ni, and Co-base alloys with solute additions of Cr or Al which tend to form Cr_2O_3 or Al_2O_3 protective scales. The growth rates of these latter two oxides depend marginally on the particular alloy involved: However, typical parabolic rate constants at 1000°C may be taken as 1×10^{-10} and 8×10^{-14} g^2 cm^{-4} sec^{-1}, respectively (7). These parabolic rate constants in terms of weight increase per unit surface area, the conventional k_p, are related to the alloy recession rate constant through

$$k = (2V_A/\nu M_O)^2 k_p \quad [58]$$

where V_A is the molar volume of the alloy, M_O the gram molecular weight of oxygen, and ν the ratio of oxygen ions to metal cations in the oxide AO_ν. Thus, the rate constant k has values of approximately 8.0×10^{-12} and 6.4×10^{-15} cm^2 sec^{-1} for Cr_2O_3 and Al_2O_3 growth at 1000°C, respectively.

Alloy interdiffusion coefficients, which are essentially equivalent to D_{AA}, are summarized in Table II along with the appropriate oxygen diffusivities: Again the data are at 1000°C and are only intended to represent order of magnitude values.

Thus, approximate values of the ratios k/D_{AA} and D_{OO}/D_{AA} pertinent to the Cr_2O_3 and Al_2O_3-forming systems are given in Table III.

As was seen in Table I, the interaction parameter $\epsilon_O{}^A$ is likely to lie in the range -10 to -500. Positive values need not be considered since these would correspond to noble metals, with low oxygen affinities, and thus unlikely to be selectively oxidized.

Wagner (15) and Whittle (16) have derived the following relationship to define the limiting bulk mole fraction of A required to form the surface scale AO_ν

$$N_A{}^{o*} = F[(\tfrac{1}{2}k/D_{AA})^{1/2}] \quad [59]$$

upon assuming that oxygen diffusion in the alloy can be ignored. Equation [57] also leads to Eq. [59] when $\epsilon_O{}^A = 0$ and D_{OO}/D_{AA} is ignored. Only the diffusion of the selectively oxidized solute is involved, and the condition represents the criterion that the concentration of the solute at the alloy/scale interface must not fall below the value at which the oxide AO_ν becomes thermodynamically unstable. In practice, where there is a wide difference in stability between the oxides of the various components, this concentration at the alloy/scale interface is virtually zero. The limiting condition defined by Eq. [59] is shown as one of the curves in Fig. 5 where $N_A{}^{o*}$ is plotted as a function of k/D_{AA} for different ratios of D_{OO}/D_{AA}. For this limiting case, $D_{OO}/D_{AA} = 0$, and with increasing values of k/D_{AA}, that is, either the scaling rate increases or the diffusion rate in the alloy decreases, the limiting bulk concentration increases.

One may develop a more realistic model by considering finite oxygen diffusivities in the alloy but with no interaction. Equation [57] then reduces to Eq. [13] earlier: This is Wagner's pseudobinary model. $N_A{}^{o*}$ is shown as a function of k/D_{AA} and D_{OO}/D_{AA} for this condition in Fig. 5. As would be expected, increase in the relative rate of oxygen diffusion in the alloy to that of the alloying element increases the critical bulk atom fraction of A required for exclusive external oxidation.

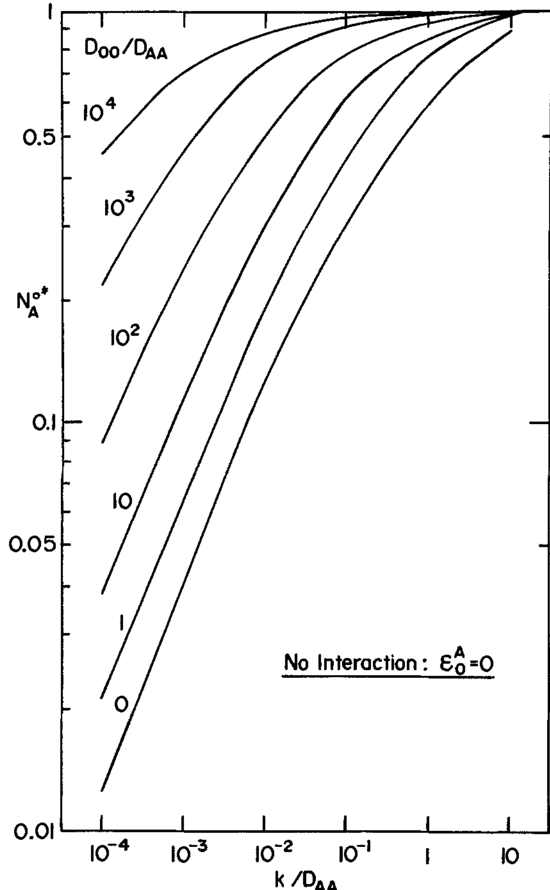

Fig. 5. The critical atom fraction of A in the alloy, N_A^{o*}, for exclusive external oxidation as a function of k/D_{AA} and D_{OO}/D_{AA}: no interaction.

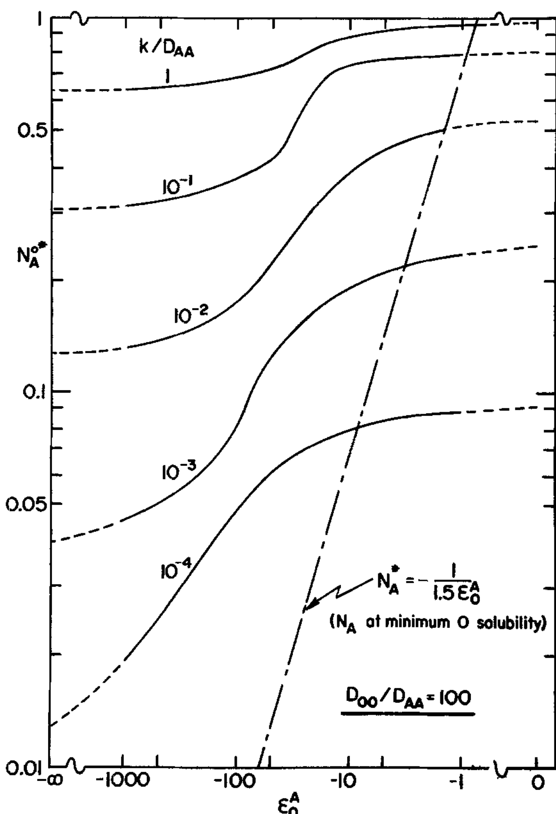

Fig. 6. The critical atom fraction of A in the alloy, N_A^{o*}, for exclusive external oxidation as a function of k/D_{AA} and the interaction parameter ϵ_O^A. $D_{OO}/D_{AA} = 100$.

Finally the ternary model involving non-Henrian interaction: Fig. 6 shows N_A^{o*} as a function of ϵ_O^A and k/D_{AA} at a value of $D_{OO}/D_{AA} = 100$. The critical atom fraction N_A^{o*} lies on each calculated curve between two limiting values depending on ϵ_O^A: The upper value at $\epsilon_O^A = 0$ corresponds to Henrian thermodynamic behavior, the lower limiting value at $\epsilon_O^A = -\infty$ is identical to Eq. [59] above. However, this is not because oxygen diffusion in the alloy becomes insignificant but with large negative values of ϵ_O^A the minimum in the oxygen solubility curve decreases to lower alloy solute concentrations as shown in Fig. 6, and the solubility rises more sharply after this minimum (Fig. 3b). Thus, although the diffusional flux of oxygen into the alloy may be substantial, the oxygen solubility curve is very steep and the alloy does not become saturated with respect to AO_ν because the diffusion path does not cut into the two-phase alloy and oxide field.

Within the reasonable range of interaction coefficients, ϵ_O^A, referred to earlier, -500 to -10, the critical mole fraction of solute for exclusive external scale formation, N_A^{o*}, is most affected by non-Henrian behavior. Furthermore, as soon as oxygen diffusion in the alloy becomes significant, particularly when the alloy diffusion coefficient is small and relatively large depletions exist, the interaction between dissolved oxygen and the solute must be significant, otherwise only alloys rich in the solute A would be able to form exclusively an external scale. The two upper curves in Fig. 6 may not be particularly significant because the simple model of thermodynamic behavior based on Wagner interaction coefficients is not expected to remain valid at solute concentrations exceeding about 30 atomic percent. However, the alloy composition near the alloy/scale interface is more important in determining whether a dilute solution approximation can be used. This is shown in Fig. 7 for the cases where the bulk atom fraction is the critical value to prevent internal oxidation, N_A^{o*} as shown in Fig. 6. The critical concentrations at the alloy/scale interface, N_A', are calculated as a function of the ratio k/D_{AA} and ϵ_O^A with $D_{OO}/D_{AA} = 100$, using Eq. [5]. Thus, the simple interactive solution model is probably valid for

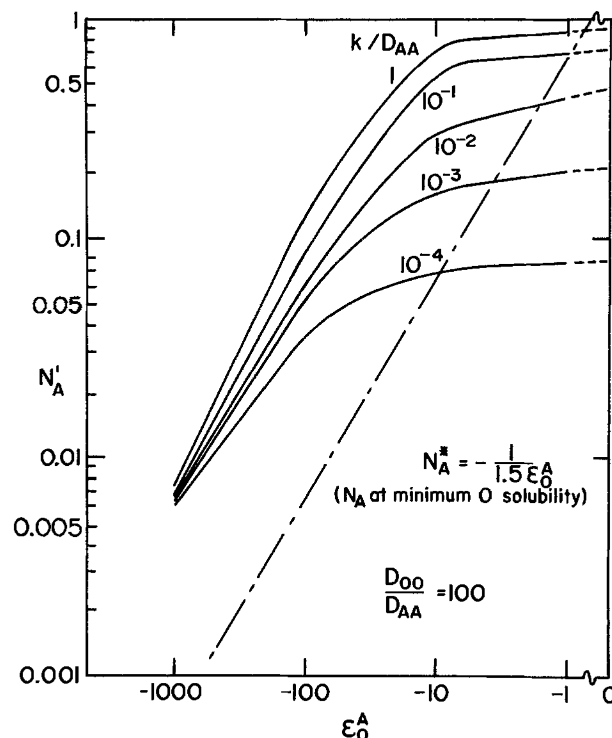

Fig. 7. The atom fraction of A at the alloy/scale interface, N_A', corresponding to the transition from internal to external scale formation as a function of $k/2D_{AA}$ and the interaction parameter ϵ_O^A. $D_{OO}/D_{AA} = 100$.

all the situations other than where k/D_{AA} is relatively large, and the interaction is weak corresponding to small negative values of ϵ_O^A. Figrue 7 also indicates that in most instances the critical concentration corresponds to a point on the solubility curve to the right of the oxygen solubility minimum, that is, on the ascending part of the solubility curve.

The distinction between Henrian and non-Henrian thermodynamic behavior of oxygen in the alloy on both the oxygen solubility curve and the diffusion path is demonstrated in Fig. 8. The oxygen solubility curves have been calculated according to Eq. [32] for different values of the interaction parameter, ϵ_O^A, using a value for the Henrian solubility product, K_H, (defined in Eq. [31]) of 10^{-12}. As was pointed out earlier, the solubility curves exhibit minima of larger oxygen concentrations and at smaller base metal concentrations as ϵ_O^A becomes more negative. The absolute slopes of the curves behind the minima also markedly increase as ϵ_O^A increases in negative value. The curve for Henrian behavior, $\epsilon_O^A = 0$, shows no minimum. Diffusion paths are also included in Fig. 8. These have been calculated using Eq. [39] and [1] to give the oxygen and metal concentration profiles, respectively, and then eliminating the variable $x/\sqrt{t}$ from the two expressions; the following values of the diffusion parameters were used: $k = 10^{-12}$, $D_{AA} = 10^{-10}$, $D_{OO} = 10^{-8}$, and $\nu = 1.5$. The diffusion cofficients and the alloy recession rate constant all have the same units. The diffusion paths correspond to a bulk alloy compostion, $N_A°$, of 0.178 which is the critical value necessary to prevent internal oxidation under these conditions when ϵ_O^A has a value of -100: This is shown in Fig. 6. At small negative values of the interaction coefficient, this particular alloy composition is not sufficient to prevent internal oxidation and the slope of the diffusion path is greater than that of the solubility curve at the point corresponding to the alloy/scale interface. Thus, the diffusion path cuts into the two-phase alloy and oxide phase field as shown in Fig. 8. Increase in the negative value of the interaction parameter increases the slopes of both the diffusion path and the oxygen solubility curve and it is the interplay between these two factors which governs the critical atom fraction of solute in the alloy necessary to prevent internal oxidation.

Of course, it must be remembered that internal oxide and a surface scale are formed when the virtual diffusion path cuts into the alloy and oxide phase field. This internal oxide precipitation confines the actual diffusion path along the solubility curve in the alloy. The effective removal of a fraction of the solute A diffusing to the alloy/scale interface to form the surface scale must then be taken into account. Certainly, this modified diffusion path leads to a reduced concentration of A at the alloy/scale interface. However, it may not necessarily be reduced such that other less stable oxides of the solvent metal are formed. It is not possible to proceed further and calculate actual diffusion paths for these limiting cases without detailed knowledge of the alloy-oxygen solubility curves.

Equation [51] compares the flux of oxygen into the alloy from the alloy/scale interface under the assumption of Henrian and non-Henrian thermodynamic behavior. Figure 9 shows this ratio, j_O^H/j_O^{NH}, as a function of the interaction parameter, ϵ_O^A, with various values of k/D_{AA}. The value of k/D_{AA} determines the metal concentration profile in the alloy and, in particular, the concentration of A at the alloy/scale interface for a given bulk alloy content of A, $N_A°$. The curves in Fig. 9 have been calculated for $N_A° = 0.2$: this alloy content is sufficient to prevent internal oxidation under these conditions ($k/D_{AA} = 10^{-2}$, $D_{OO}/D_{AA} = 10^2$) only when ϵ_O^A is less than a certain value, as indicated by the arrows in Fig. 9 for the various ratios of k/D_{AA}.

The concentration of A at the alloy/scale interface, N_A', is independent of ϵ_O^A; N_O', however, the concentration of oxygen, is strongly dependent on ϵ_O^A increasing markedly with increasing negative values of ϵ_O^A as shown in Fig. 8. Thus, there are two factors contributing to the decreased flux of oxygen into the

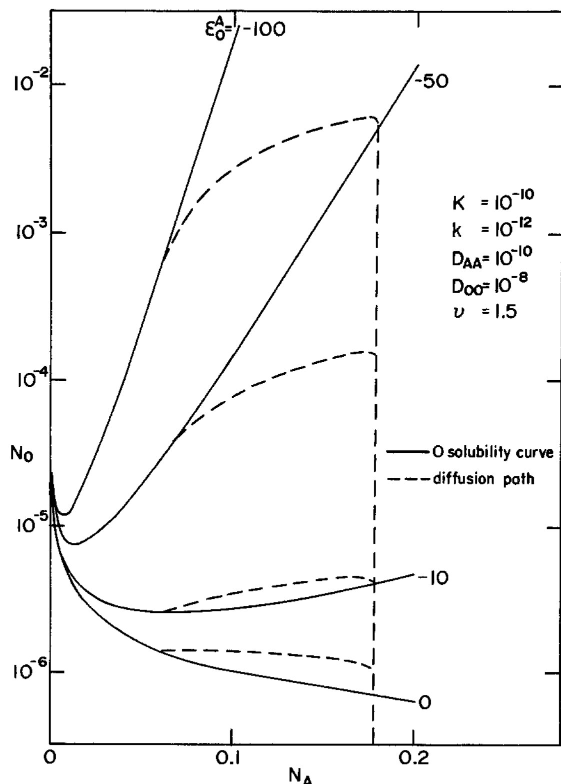

Fig. 8. The oxygen solubility curve according to Eq. [32] with $k = 10^{-10}$ and $\nu = 1.5$ with diffusion paths superimposed for an alloy of $N_A° = 0.178$: $k = 10^{-12}$, $D_{AA} = 10^{-10}$, $D_{OO} = 10^{-8}$.

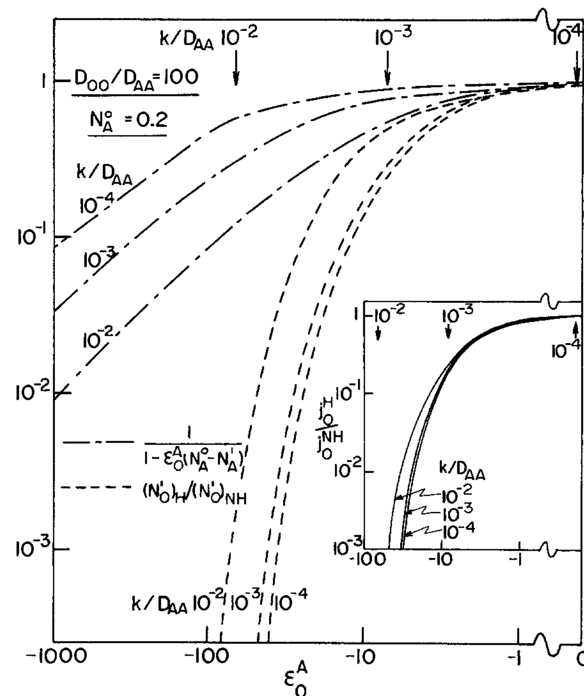

Fig. 9. The ratio of oxygen flux at the alloy/scale interface with Henrian thermodynamic behavior to that with non-Henrian behavior for an alloy of $N_A° = 0.2$. The ratio of solubilities and the effective diffusion coefficient are also shown. Conditions to the left of the vertical arrows correspond to exclusive surface scale formation, and to the right, combined internal and external oxidation for the indicated ratio of k/D_{AA}. $D_{OO}/D_{AA} = 100$.

alloy under Henrian behavior $(j_O^H/j_O^{NH}) < 1$: the decreased oxygen solubility in the alloy as represnted by the term, $(N_O')_H/(N_O')_{NH}$, and a decreased effective diffusion coefficient because under Henrian behavior the only driving force for oxygen diffusion inward is its own concentration. These two factors are shown separately in Fig. 9. The former, relating to the change in oxygen solubility, is the more important term: It decreases as k/D_{AA} decreases since as the metal gradient decreases the diffusion path contacts the oxygen solubility curve at higher oxygen concentrations. In contrast, the effective diffusion parameter, $1/1 - \epsilon_A{}^o(N_A{}^o - N_A')$, increases as k/D_{AA} decreases since the reduced metal gradients correspond to a reduced driving force for oxygen inward. For $\epsilon_O{}^A$ values in the range of interest, -10 to -100, the oxygen flux under interactive conditions is always very much larger than when Henrian solution of oxygen in the alloy prevails.

An extreme limitation in trying to apply the conclusion of the preceding analysis is the lack of oxygen solubility data in binary alloys and of ternary interaction parameters: Suitable thermodynamic models of solution behavior have also not been developed to permit order of magnitude calculations. The measured oxygen solubilities in pure metals whose oxides grow by cation transport are exceedingly small, of the order of parts per million, and consequently experimental determination is extremely difficult, particularly since the variation of this solubility as a function of the solute alloying element content is required. However, measurement of oxygen activities in saturated binary alloys may be sufficient. Ternary A-B-O phase diagrams can be readily related to oxygen activity/alloy diagrams in which log a_o is shown as a function of the atom fractions of metal in all the possible phases. Moreover, diffusion paths can readily be superimposed on these diagrams, in the same way as on phase diagrams referred to earlier. Several of these diagrams for transition metal alloys-oxygen are already available (17), for example: Fe-Ni-O, Fe-Cr-O, and Ni-Cr-O, having been determined by electrochemical and gas equilibration methods.

Defining the oxygen activity, $a_O{}^S$, on the oxygen solubility curve, accordng to the Wagner formalism

$$\ln a_O{}^S = \ln N_O{}^S + \ln \gamma_O{}^S$$

$$= \ln N_O{}^S + \ln \gamma_O{}^o + \epsilon_O{}^O N_O{}^S + \epsilon_O{}^A N_A{}^S \quad [60]$$

the slope of the solubility curve is given by

$$\left(\frac{dN_O}{dN_A}\right)^{\text{Sol.}} = \left[\frac{1}{a_O{}^S}\left(\frac{da_O{}^S}{dN_A}\right) - \epsilon_O{}^A\right]\frac{N_O{}^S}{1 + \epsilon_O{}^O N_O{}^S}$$

$$\simeq \left[\frac{1}{a_O{}^S}\left(\frac{da_O{}^S}{dN_A}\right) - \epsilon_O{}^A\right] N_O{}^S \text{ for } \epsilon_O{}^O N_O{}^S << 1 \quad [61]$$

Thus, the limiting criterion separating the transition from exclusive external oxidation to combined internal and external oxidation as given in Eq. [18] using Eq. [42] for the gradient of the diffusion path, and Eq. [61] in place of [26a] for the gradient of the solubility curve, may be written as

$$-\left(\frac{D_{AA}}{D_{OO}}\right)^{1/2} \frac{\operatorname{erfc} u}{\exp - u^2} \left\{ \frac{1}{N_A{}^o - N_A'} + \epsilon_O{}^A \left(\frac{D_{OO}}{D_{AA}}\right)^{1/2} \frac{\exp - u^2}{\operatorname{erfc} u} - \epsilon_A{}^O \right\}$$

$$\geqq \left[\frac{1}{a_O{}^S}\left(\frac{da_O{}^S}{dN_A}\right) - \epsilon_O{}^A\right] \quad [62]$$

u represents the ratio $(k/2D_{AA})^{1/2}$ as earlier. The differential term, $1/a_O{}^S\ (da_O{}^S/dN_A)$ can be determined from the ln a_O as a functiion of N_A data referred to earlier. The interaction parameter, $\epsilon_O{}^A$, can be obtained if the alloy composition at the minimum oxygen solubility is known. At the minimum, $(dN_O/dN_A) = 0$ and thus Eq. [61] gives

$$\epsilon_O{}^A = 1/a_O{}^S \left(\frac{da_O{}^S}{dN_A}\right)_{(N_O)\min.} \quad [63]$$

Accordingly, it is not necessary to know the absolute value of the minimum oxygen solubility, but only the atom fraction, N_A, at which this minimum occurs. Possibly, electrochemical thermodynamic and coulometric techniques using solid electrolytes could be used to determine these parameters.

The concepts outlined in this paper may be extended to the oxidation of ternary alloys. For example, it has been known for several decades that the addition of an alloying element which forms an oxide preferentially to the solvent metal often prevents the internal oxidation of the alloying element in a binary alloy which forms the most stable oxide .The addition of Cr to Fe-, Ni-, or Co-Al alloys leads to the formation of Al_2O_3 solely as an external scale at Al concentrations much less than required in the binary alloys. Following a suggestion by Wagner (18) this phenomenon has usually been described as due to a gettering action by the element whose oxide is of intermediate stability, even though only Al_2O_3 is formed during steady-state oxidation. The function of the additional element according to our diffusional analysis is to ensure that the diffusion path only contacts or in the limit tangents the oxygen solubility surface at an area where Al_2O_3 exists in equilibrium with the alloy.

Summary

The pseudobinary model considered by Wagner for the onset of internal oxidation beneath the external scale based on the criterion that conditions must exist at the alloy side of the scale/alloy for the product of the selectively oxidized metal and oxygen concentrations to exceed the solubility of the binary oxide has been expanded into a ternary thermodynamic and diffusional formalism using the A-B-O isotherm and the placement of the representative diffusion paths on this isotherm. The Wagner formalism for interaction coefficients was utilized to interpret the ternary solution thermodynamics and the Fickian type diffusion. It was possible to demonstrate, firstly, that external scale formation accompanied by internal oxidation occurs when the virtual diffusion path for the alloy cuts into and across the two phase alloy-oxide field and, secondly, that a limiting atom fraction of the selectively oxidized solute alloying element for external scale formation alone can be defined by the diffusion path in the alloy which tangents the oxygen solubility curve for the alloy. Typical ranges of interaction parameters applicable to cobalt, iron, and nickel-base alloys were used to show the effects of the diffusion coefficients, scaling constants, and interaction parameters on this limiting solute alloying element concentration. In the case of non-Henrian solution behavior of oxygen, this critical alloy composition corresponds generally to a point on the solubility curve to the right of the oxygen solubility minimum, that is, on the ascending part of the solubility curve.

Chemical Mechanisms in Photoresist Systems

Part II. Thermal Reactions of a Bisazide Resist

Shigeki Shimizu[1]

School of Chemistry, Rutgers, The State University of New Jersey, New Brunswick, New Jersey 08903

ABSTRACT

We have investigated the thermal reaction of a negative photoresist (cyclized polyisoprene + bis(4-azidobenzal)cyclohexanone) by infrared spectroscopy. Two major thermal crosslinking reactions were observed, one is the oxidative polymerization of cyclized polyisoprene and the other is the decomposition of bisazide. At 100°C, the oxidative crosslinking in air proceeds about three times faster than the bisazide crosslinking. The activation energies of these reactions were determined as 32 and 23 kcal/mole, respectively. Extensive crosslinking of cyclized polyisoprene tends to retard the bisazide decomposition reaction. This retardation is attributed to a cage effect of the increasing rigid matrix.

Thermal fog stands in the way of any organic imaging systems (1). In photoresists thermal fog may become a problem, especially in the process of prebaking. Prebaking is generally thought necessary to get hard films and good adhesion of polymer to the Si wafer, but it can also cause thermal fog at higher temperature or longer prebaking times. DeForest (2) shows allowable prebaking times for several types of commercial photoresists at different prebaking conditions. Nakane (3) did a more quantitative study on a positive-type resist, observing u.v. absorption and thermal decomposition of quinone diazide. Working with a negative photoresist, Moreau *et al.* (4) studied photo crosslinking of bisazide-cyclized polyisoprene and reported enhanced sensitivity at higher temperatures.

We have conducted a mechanistic study on thermal reactions of a related negative resist (bis(4-azidobenzal)-cyclohexanone + cyclized polyisoprene) by infrared spectroscopy, thus gaining some information on the rate of removal of bisazide and the rate of polymer immobilization by the thermal reactions. The decreased importance of direct bisazide crosslinking in the over-all thermal reactions in air is explored in detail.

Results and Discussion

Comparison of crosslinking efficiency between the thermal reactions and the photoreactions of bisazide resist.—When equal amounts of bisazide are decomposed thermally and photochemically, we might at first assume that they form equal amounts of bisamine-crosslink in a negative photoresist. We can obtain the information on the extent of the crosslinking reaction by comparing the film thickness of photoresist before and after development (dissolve in benzene for 3 min).

Figure 1 shows the percentage of polymer retention after development) *vs.* the percentage of decomposed bisazide. There is a great difference between thermal

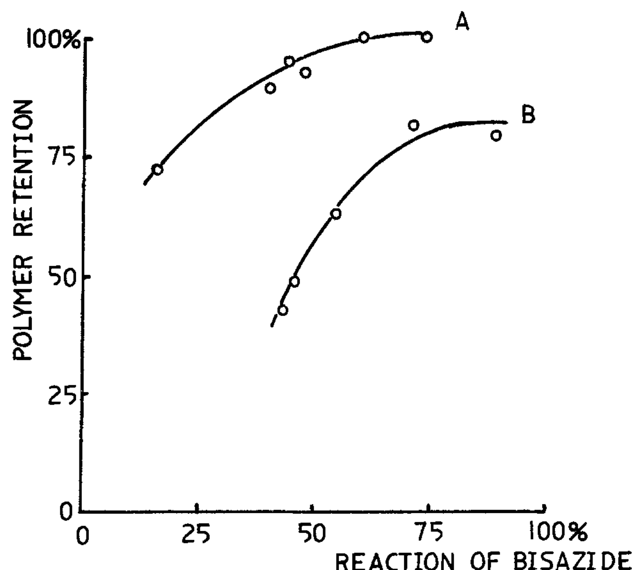

Fig. 1. Crosslinking *vs.* reacted bisazide in photo and thermal reactions of photoresist. Photoresist: 3% bisazide, 1.2 μm coating on Si. A:thermal reaction at 100°C in air; B:photoreaction by 365 nm dosing at 25°C at 3.6 mJ/cm^2 min under N_2.

[1] Present address: Mitsubishi Chemical Industries, Research Laboratory, 1000 Kamoshida, Midori-ku, Yokohama, Japan.

Key words: film, infrared, oxidation, polymerization.

and photoreaction. At 100°C in air and with no exposure, about 70% of the cyclized polyisoprene is retained after only 15% decomposition of bisazide. The retention of 70% of polymer, after thermal reactions have decomposed only 15% of the bisazide, clearly indicates that at least one additional thermal crosslinking reaction is operating independent of the bisazide. To retain this fraction of the polymer by room temperature photocrosslinking under N_2 requires 55% reaction of bisazide (at 3%/wt. loading).

Thermal crosslinking of cyclized polyisoprene.—We made several coatings of cyclized polyisoprene (no bisazide added) on Si wafers and observed their crosslinking by comparing film thickness before and after development. Figure 2 shows the percentage of polymer retention (after development) at different temperatures and heating times. It shows that cyclized polyisoprene crosslinks thermally without the aid of bisazide. This is the main reason why the thermal crosslinking in Fig. 1 proceeds further than the photo crosslinking when identical amounts of bisazide are decomposed. The small difference between 80% polymer retention in film 2C (no bisazide) *vs.* 97% retention in film 2D (3% bisazide) on the time-independent retention plateau at 5 hr (100°C) is assigned to the effect of bisazide crosslinking.

We observed *IR* spectra of cyclized polyisoprene upon heating. When a film is heated at 100°C in air for 24 hr, the *IR* spectrum shows a tremendous change, indicating the formation of OH groups (3500 cm^{-1}), isolated C=O groups (1720 cm^{-1}) and conjugated C=O groups (1670 cm^{-1}), as in Fig. 3. The formation of these groups can be explained as the termination products of oxidative radical reactions that are initiated by the thermal decomposition of peroxide. The peroxides are unstable and their *IR* absorption cannot be identified in Fig. 3. It is well known that oxygen reacts with polyolefins to form peroxide, which initiates radical crosslinking upon heating (5).

Both crosslinking and chain scission reactions are reported to occur in the oxidative heating of unsaturated polyolefins, the former leading to gels and the latter decreasing the viscosity (5). In the case of cyclized polyisoprene, oxidative crosslinking apparently predominates over oxidative chain scission since heating in air does immobilize the polymer instead of increasing its solubility.

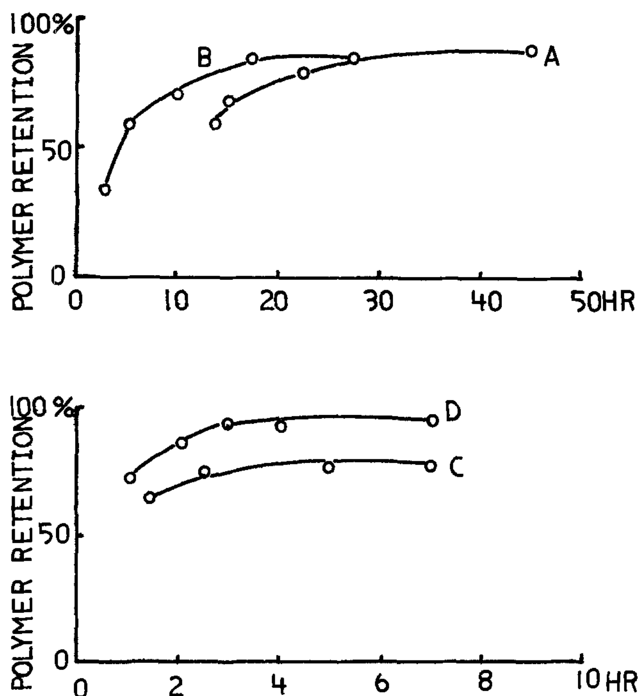

Fig. 2. Thermal crosslinking of cyclized polyisoprene in air as observed in terms of percent polymer retention on development with benzene for 3 min. A = 82°C, 0% bisazide, 1.0 μm coating on Si; B = 90°C, 0% bisazide, 1.0 μm coating on Si; C = 100°C, 0% bisazide, 1.0 μm coating on Si; D = 100°C, 3% bisazide, 1.2 μm coating on Si.

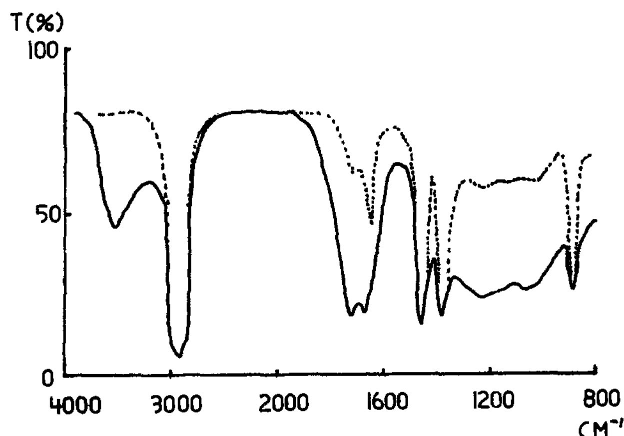

Fig. 3. *IR* spectra of cyclized polyisoprene film on NaCl. ——— 100°C, in air, 24 hr; - - - - - control, no thermal treatment.

The crosslinking of cyclized polyisoprene also proceeds in vacuum, though at a slower rate than in air.[2] This crosslinking can be attributed to the small amount of residual catalyst for the cyclization (p-toluene sulfonic acid), which might initiate the intermolecular reaction analogous to the intramolecular cyclization (10). The crosslinking in vacuum can be reduced to one-fourth by washing the polymer solution (15% in xylene) in 0.1*N* NaOH aqueous solution for 3 hr.

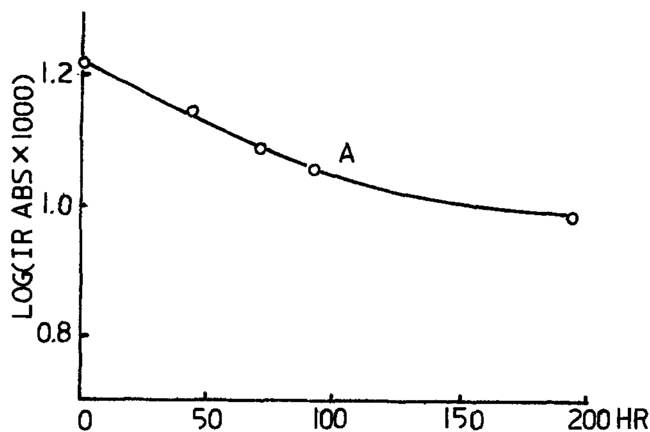
There is also a report that polycyclized polyisoprene is formed when polyisoprene is heated in vacuum between 200° and 300°C (6). This polycyclized polyisoprene shows no vinylidene absorption like that which is observed in partially cyclized polyisoprene (7). The *IR* spectra of our films of cyclized polyisoprene show no decrease of the vinylidene absorption (875 cm^{-1}) after heating in vacuum at 110°C for 72 hr, indicating no further intramolecular cyclization around this temperature.

Thermal decomposition of bisazide in photoresists.—Figure 4 shows the plot of the logarithm of *IR* azido absorbance *vs.* time of heating in air. The decrease of azido absorbance shows a retardation as the thermal reaction proceeds somewhat similar to that observed in the photoreaction (8).

Making several coatings with different azide concentrations, we compared azide decomposition characteristics between thermal and photoreaction. In Fig. 5A, two coatings (I *vs.* II) with different azide concentration show different retardation characteristics upon exposure. Films coated with higher azide concentration show more retardation because of greater generation of bis-amine (reacted bisazide) which works as an energy acceptor for photoexcited bisazide and lowers the quantum yield of bisazide photodecomposition. In thermal reaction (Fig. 5B), two coatings at different azide concentrations showed the same characteristic retardation curve (I *vs.* II), in great contrast with the photoreaction. It can be concluded immediately that the energy transfer, characteristic of the photoreaction, is not operating in the thermal decomposition retardation.

We made extended observations on the retardation of bisazide decomposition at 90° and 100°C in air and compared these with the data on oxidative polymerization of cyclized polyisoprene. At 90°C, the retardation of azide decomposition becomes constant on the log (absorbance) *vs.* time plot after 17 hr (Fig. 6A), a

[2] We estimate that the reaction rate of normal, unwashed polymer for crosslinking in vacuum is about one-fifth the rate for oxidative crosslinking in air. The measurement was difficult to perform in vacuum since the oven developed thermal gradients in the absence of a circulating atmosphere, and film temperature was poorly controlled.



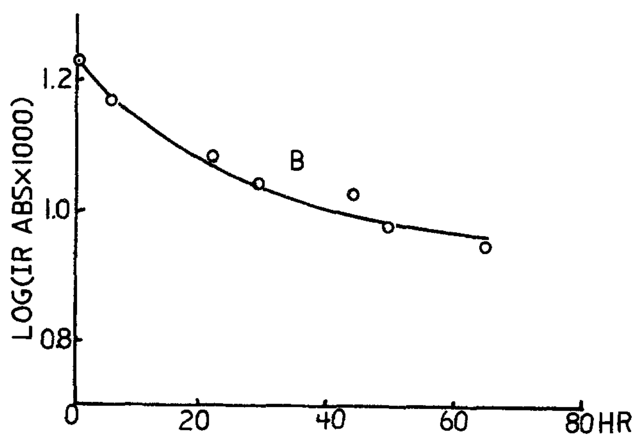


Fig. 4. Thermal decomposition characteristics of bisazide in photoresists. Photoresist = 3% bisazide, 1.2 μm coating on Si. A = 60°C in air; B = 80°C in air. The infrared absorbance is observed at 2110 cm^{-1}, the well-isolated and sharp band of the bisazide.

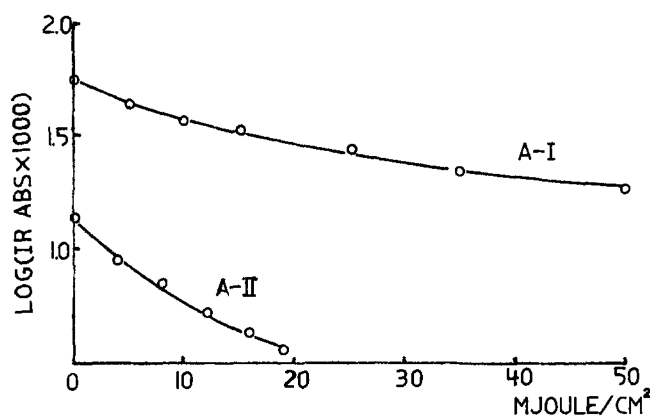

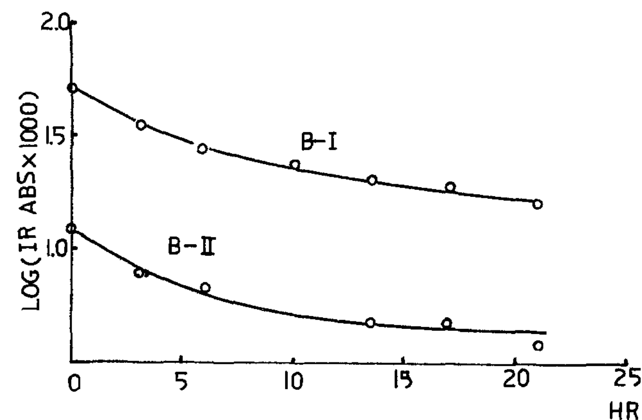

Fig. 5. Comparison of the concentration dependence of photo and thermal decomposition of bisazide in photoresists. A:photoreaction at 365 nm at 25°C, 5.0 mJ/cm^2 min; B:thermal reaction at 100°C in air; I:4.6% bisazide, 2.7 μm coating on Si; II:0.9% bisazide, 2.7 μm coating on Si.

time corresponding to the time when the percentage of polymer retention after development reaches its saturation value (Fig. 2B). This same correlation can also be observed at 100°C after 3 hr by comparing the retardation of azide decomposition in Fig. 6B with the oxidative crosslinking in Fig. 2C.

Thus this retardation can well be explained by the cage effect of crosslinked polyisoprene. The cage effect is an inhibition of a dissociation reaction by a relatively rigid solvent or polymer medium which prevents that degree of nuclear motion necessary to accomplish bondbreaking. It is a familiar effect in studies of photodissociation in glassy matrixes. Crosslinking makes the polymer matrix more rigid and does seem to make the thermal decomposition of bisazide increasingly difficult.

Activation energy of thermal reactions.—By assuming that the same amount of thermal and photodecomposition of bisazide produce the same amount of bisamine crosslinks we can compare the crosslinking reaction rates by bisazide decomposition and oxidative polymerization.

Figure 1-B shows that 48% bisazide photodecomposition causes 60% (after development) polymer retention when the azide concentration is 3% based on polymer. Oxidative thermal polymerization of cyclized polyisoprene can be neglected at room temperature over the elapsed time of the experiment. From the initial slope of thermal decomposition of bisazide in Fig. 4 and 6 we can obtain the reaction times that are required for 48% decomposition of bisazide.

The corresponding time for 60% polymer retention (after development) by oxidative polymerization of azide-free polyisoprene can also be obtained from Fig. 2.

The reciprocals of these times for 60% retention of polymer can be interpreted as solid-state reaction rate constants, and by plotting the logarithm of rate constants *vs.* (1) temperature we obtain the activation energies of bisazide decomposition and oxidative self-polymerization of cyclized polyisoprene. In Fig. 7 the two reaction rate constants cross around 65°C, indicating that oxidative crosslinking causes more "thermal fog" than bisazide decomposition at the normal prebaking temperature (80°C) and at the normal azide concentration (3%).

The activation energy of bisazide decomposition is 23 kcal/mole, whereas that of oxidative self-polymerization is 32 kcal/mole.[3] The activation energy of bisazide looks very low, but it is in accord with the previous work (9) on substituted 2-azidobiphenyls whose activation energies can be as low as 25.5 kcal/mole when the azido group is conjugated with various electron donating groups in para-position. This low activation energy is presumed to be the energy for rupture of a single azide bond. (If two groups could be broken directly with 23 kcal of energy, a gross instability of the bisazide molecule would be implied.) This low value can also be used indirectly to support the observed single photon simultaneous cleavage of bisazide molecules (8). The input of 80 kcal of optical energy plus the actual exothermal bond-breaking of the first azido group can be considered as producing an energy-rich azidonitrene whose azide group is cleaved before vibrational deactivation can occur. Our photochemi-

[3] This oxidation crosslinking also includes the slower nonoxidative acid crosslinking mentioned above. Measured activation energies for the nonoxidative crosslinking fluctuated between 27 and 35 kcal/mole because of the difficulty of maintaining precise temperature control in vacuum. Since this is a minority reaction with an activation energy comparable to the oxidative crosslinking reaction, no correction was introduced in determining the energy of 32 kcal. Any such correction should have a trivial effect.

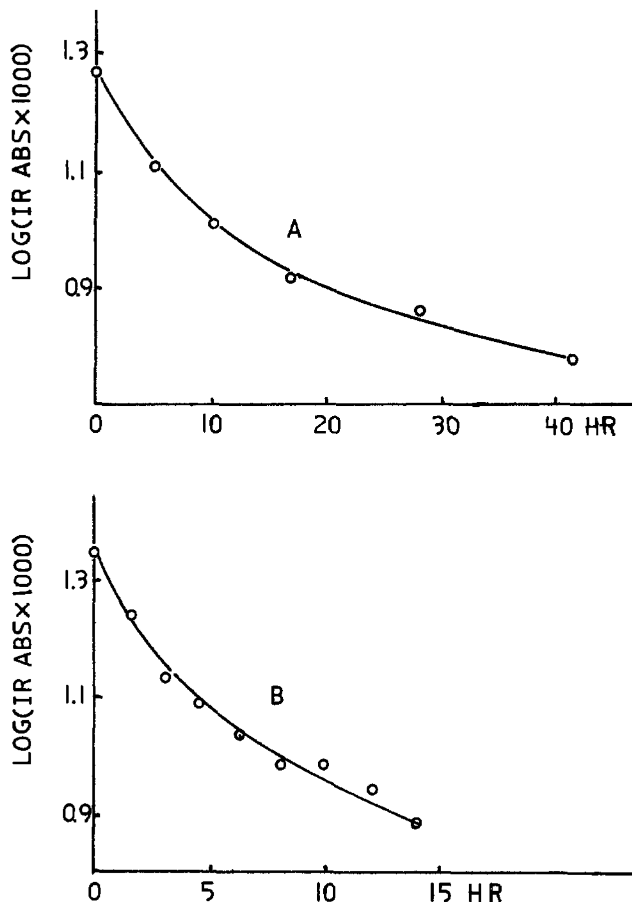

Fig. 6. Thermal decomposition characteristics of bisazide in photoresist showing retardation of the reaction as crosslinking becomes extensive:compare with Fig. 2. Photoresist:3% bisazide, 1.2 μm coating on Si. A:90°C in air; B:100°C in air.

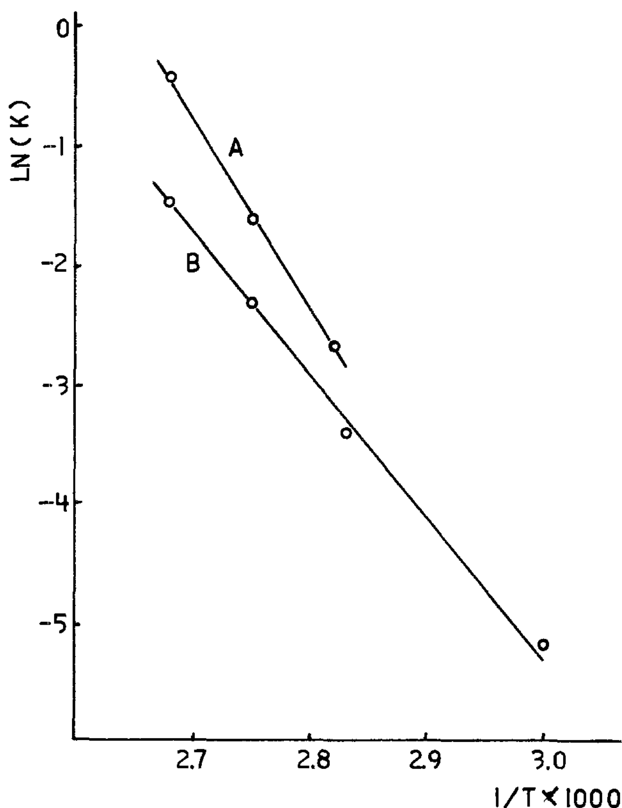

Fig. 7. Thermal reaction rate constants as calculated from reciprocal times for retention of 60% of polymer film on development. A:oxidative polymerization of cyclized polyisoprene; B:bisazide decomposition.

cally inclined friends all seem to be uneasy with the concept of a truly simultaneous cleavage, but are quite at home with a triggered second cleavage which is experimentally indistinguishable from a simultaneous bisazide photochemical cleavage (8).

We conducted further studies of the thermal decomposition mechanism of bisazide to confirm whether both azido groups decompose in concert or stepwisely. However, the self-crosslinking of cyclized polyisoprene made the extraction of low molecular weight azido compound much more difficult (8) and we could not obtain a clear answer. *IR* azido absorption (2110 cm^{-1}) showed no shift in the course of thermal decomposition of bisazide and we find no information supporting the stepwise mechanism.

Experimental

The same materials and chemicals (photoresist, Si wafer), the same analytical methods (*IR* expansion, u.v. specular reflectance) and the same exposing apparatus (Hg lamp, filter, photomultiplier) were used as the previous work (8). Thermal reaction was conducted in a steel box (11 × 14.5 × 20 cm) with heater (300W), fan, wafer holder, quartz window, and thermistor (Yellow Spring Company, Model-621). By combining thermistor controller (Yellow Spring Company, Model-63RC) and variac, precise temperature control (± 0.1°C) was obtained.

Two methods of optical thickness gauging were used. The first was measurement of the interference fringes of the cast film on the Si wafer, as measured in a Cary Model 14 spectrophotometer with integrating sphere attachment operating in the total reflectance mode. With the peak reflection wavelengths converted to reciprocal wavelengths (cm^{-1}), successive interference maxima are separated by $\Delta\tilde{\nu} = (2nt)^{-1}$ where n is the refractive index of the film and t is the thickness in centimeters. The refractive index of partially cyclized polyisoprene was taken to be 1.541 for this measurement. Reflectance maxima should be measured at the longest convenient wavelengths to minimize errors from optical phase shifts at the silicon surface. These same interference maxima can be observed from films coated on NaCl, though with much reduced amplitude.

The reflectance method was used to calibrate the intensity of the CH absorption as measured by the Perkin-Elmer Model 521 spectrometer at a frequency of 2929 cm^{-1}. The attenuation constant obtained was $k = 1.18 \cdot 10^3$ cm^{-1} from the equation $\log_{10}(I_o/I) = kt$. Note that this value is subject to change as polyisoprenes of different cyclicity are examined. When the polymer film has been coated on a silicon wafer, a zero-absorption baseline must be constructed between 3300 and 2500 cm^{-1} to compensate for the low transmission of silicon in the near infrared. Routine thickness measurements were made by the infrared method, and are considered accurate to ±3% relative, to ±5% absolute.

Conclusion

From the *IR* study on the thermal reaction of bisazide-cyclized polyisoprene photoresist, we obtained the following conclusions.

1. Two major kinds of thermal reaction are observed in this photoresist, one is oxidative self-polymerization of cyclized polyisoprene and the other is the expected bisazide reaction.

2. The activation energies of these two reactions are 32 and 23 kcal/mole, respectively, and at the prebaking conditions of photoresist preparation, oxidative crosslinking predominates over bisazide crosslinking.

3. The thermal decomposition reaction of bisazide is retarded in the later stage of reaction, and this can be explained as a cage effect of crosslinked polyisoprene.

Luminescence of Rare Earth-Activated Tellurate Perovskites

R. R. Neurgaonkar,* L. E. Cross, and William B. White*

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

$M_2^{2+}R^{2+}TeO_6$, where M^{2+} = Ba, Sr, Ca, or Cd and R^{2+} = Ba, Sr, Ca, Cd, Mg, or Zn, crystallize with ordered (Fm3m) or ordered-distorted ($P2_1$) perovskite structures, and can be used as hosts for rare earth activated luminescence. Rare earths (Ln^{3+}) were introduced according to the substitution $2R^{2+} \rightarrow Ln^{3+} + Na^+$, $Ln^{3+} = Eu^{3+}, Tb^{3+}, Dy^{3+}$, or Er^{3+}. The Eu^{3+} emission depends strongly on the ordering of the perovskite structure. The $^5D_0 \rightarrow {}^7F_1$ transition is dominant when Eu^{3+} occupies a site with symmetry O_h in the Fm3m ordered perovskite, whereas the Eu^{3+} emission is the $^5D_0 \rightarrow {}^7F_2$ transition in the ordered-distorted perovskite structure. Only Ca_2MgTeO_6 is an effective host for Tb^{3+}-, Dy^{3+}-, and Er^{3+}-activated luminescence.

The first report of the substitution of Te^{6+} in perovskite was by Merz (1) in 1956. He synthesized Ba_3TeO_6 and Sr_3TeO_6 and reported that they are isotypic with Ba_3UO_6. Subsequently, Bayer (2-5) prepared the Te^{6+}-containing $M_2^{2+}R^{2+}TeO_6$ compounds where M = Ba, Pb, or Sr and R = Mg, Cd, Ca, etc., and it was he who put forward the idea that some of these compounds are ferroelectrics. Sleight and Ward (6) also reported the synthesis of Ba_2CaTeO_6 and Ba_2MgTeO_6 types of perovskites. More recently, Politova and Venevstev (7) reinvestigated the crystal structure and dielectric properties of the Te^{6+}-containing perovskite compounds with compositions $M_2^{2+}R^{2+}TeO_6$, $(M^{3+}M^{2+})R^+TeO_6$, and $(M^{1+}M^{3+})R^{2+}TeO_6$, where M^{2+} = Ba, Pb, Sr, Ca, or Cd, M^{3+} = Bi or La, M^{1+} = Na, R^+ = Na or Li, R^{2+} = Mn, Mg, Co, Zn, Cd, or Ca. Their investigations show that all of these compounds belong either to ordered (Fm3m) or ordered-distorted ($P2_1$) perovskite structures. Further, they confirmed that most of these compounds exhibit phase transitions at high temperatures, some of which have large dielectric anomalies.

Blasse and Bril (8) reported the luminescence of tungsten-activated tellurates. Corsmit *et al.* (9) also used the vibrational spectra to characterize the ordering schemes in these compounds.

This paper reports on the fluorescence of Eu^{3+}-, Tb^{3+}-, Dy^{3+}-, and Er^{3+}-activated $M_2^{2+}R^{2+}TeO_6$, where M = Ba, Sr, Ca, or Cd and R = Ba, Sr, Ca, Cd, Zn, or Mg. The objective is to examine the effects of the two ordering schemes on the luminescent emission of rare earth ions, especially Eu^{3+}.

Experimental

The rare earth activated $M_2^{2+}R^{2+}TeO_6$ compounds were prepared by solid-state reactions as described by Bayer (2). Compositions were first fired in air at 800°C to oxidize the tellurium to Te^{6+}. To avoid tellurium loss, the final firings were made in sealed silica tubes at 1000°-1150°C. Each preparation was checked for phase identification and phase purity by x-ray powder diffraction methods. In all cases the powder patterns were in good agreement with the literature (1-7).

The luminescent emission spectra were measured using powder plaques excited by the 253.7 nm line of a 150W mercury lamp. The emission spectrometer was a 1m Jarrell-Ash scanning monochromator with an RCA 31034 photomultiplier cooled to −40°C. The photomultiplier has a fairly flat response over the spectral range examined and no corrections for photomultiplier response were made. The spectra that appear in the figures are direct tracings from strip-chart records of the photomultiplier current. Spectrometer slit widths were in the range of 30-60 μm.

Several exceptions to the findings reported in the literature were uncovered in the course of synthesis of the phosphors. Sr_2MgTeO_6 has been reported to crystallize in space group Fm3m. The results of the present work showed that the attempted synthesis of this compound with or without Eu^{3+} and Na^+ resulted in a mixture of two phases. There is some disagreement over the structure of Sr_3TeO_6 with earlier literature (1, 10, 11) assigning it to space group $P2_1$, whereas a recent paper by Politova and Venevtsev (7) claims it belongs to Fm3m. The results of the present x-ray analysis indicate that Sr_3TeO_6 with or without Eu^{3+} + Na^+ prepared at 1100°C could only be indexed on space group $P2_1$.

Complete replacement of the octahedral cation by a combination of Eu^{3+} + Na^+ was successful in $M_2^{2+}R^{2+}TeO_6$, M = Ba or Sr. Both the $Ba_2[Eu_{.50}Na_{.60}]TeO_6$ and $Sr_2[Eu_{.50}Na_{.50}]TeO_6$ phases crystallized in the space group Fm3m.

Luminescence of Eu^{3+}-Activated Phosphors

The $M_2^{2+}R^{2+}TeO_6:Eu^{3+}$ compounds are luminescent under 253.7 nm excitation. Both Fm3m and $P2_1$ forms are luminescent, but with considerable differences in luminescence behavior. The results for the compounds investigated are summarized in Table I.

Figure 1 shows spectral energy distribution of the emission of Eu^{3+}-activated $Ba_2R^{2+}TeO_6$ (R = Ca or Mg) and Sr_2CaTeO_6. The spectra of Eu^{3+} contain lines which can be attributed to the transitions $^5D_0 \rightarrow {}^7F_J$, where J = 0, 1, 2, 3, and 4. The $^5D_0 \rightarrow {}^7F_1$ magnetic dipole transition is unsplit and very intense. The transitions corresponding to $^5D_0 \rightarrow {}^7F_4$, $^5D_0 \rightarrow {}^7F_3$, $^5D_0 \rightarrow {}^7F_2$, and $^5D_0 \rightarrow {}^7F_0$ are all weak and broad.

The spectral energy distributions of Eu^{3+} in $Sr_2[Eu_{0.5}Na_{0.5}]TeO_6$ and $Ba_2[Eu_{0.5}Na_{0.5}]TeO_6$ are given in Fig. 2. It can be seen that the magnetic dipole transition is dominant for both the phases.

The spectra of the ordered-distorted perovskite structures are entirely different from the spectra of the ordered compounds. The spectral energy distribution of the emission of $M_3^{2+}TeO_6:Eu^{3+}$ (M = Ba, Sr or Ca), $M_2^{2+}MgTeO_6:Eu^{3+}$ (M = Ca or Cd) and

Fig. 1. Emission spectra of Eu^{3+} in $Ba_2R^{2+}TeO_6$ (R = Ca or Mg) and Sr_2CaTeO_6.

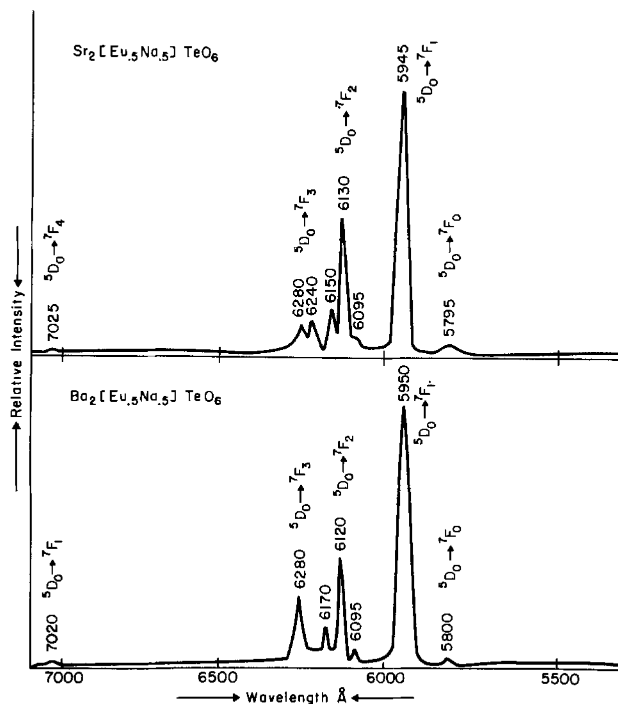

Fig. 2. Emission spectra of Eu^{3+} in $M_2^{2+}[Eu_{0.5}Na_{0.5}]TeO_6$. M = Ba or Sr.

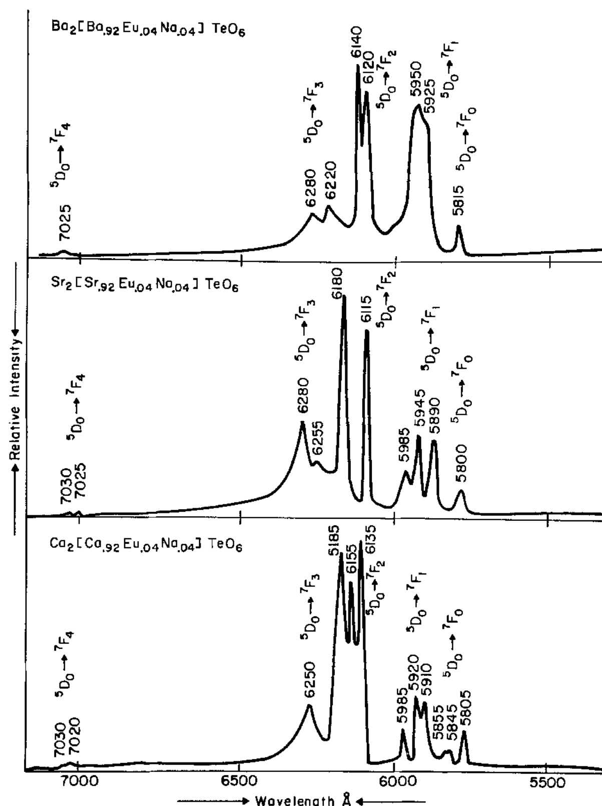

Fig. 3. Emission spectra of Eu^{3+} in $M_3^{2+}TeO_6$. M = Ba, Sr, or Ca.

$Sr_2ZnTeO_6:Eu^{3+}$ are given in Fig. 3 and 4. Since emission spectra of $Ca_3TeO_6:Eu^{3+}$ and $Cd_3TeO_6:Eu^{3+}$ are similar, no separate figure is given for the latter compound. The strong Eu^{3+} emission that appears from all compounds is the forced electric dipole transition $^5D_0 \rightarrow {}^7F_2$ as expected from the distorted structure. The transitions $^5D_0 \rightarrow {}^7F_4$, $^5D_0 \rightarrow {}^7F_3$, and $^5D_0 \rightarrow {}^7F_0$ are weak in both the systems and are not affected by the changes in crystal symmetry.

The spectroscopic results confirm the x-ray findings concerning the structure of Sr_3TeO_6. The similarity of the Eu^{3+} emission in this host to that of the other

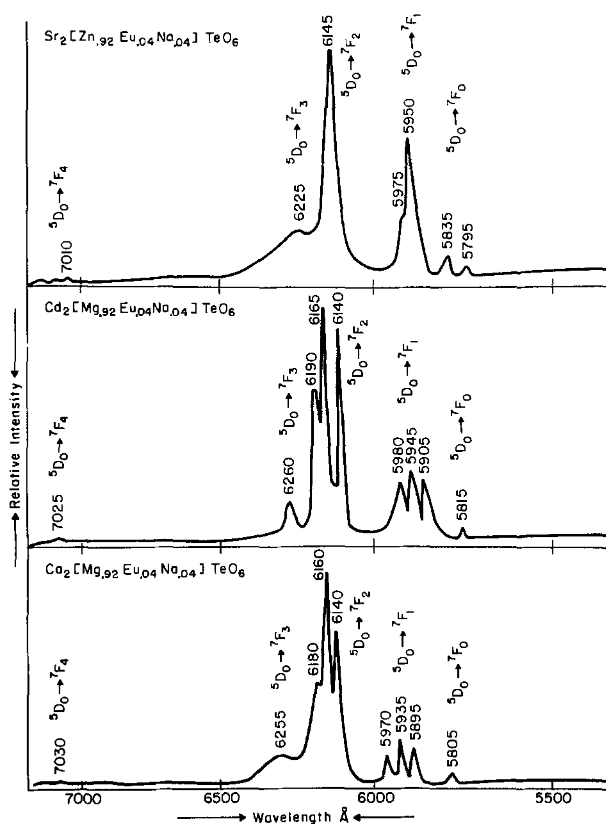

Fig. 4. Emission spectra of Eu^{3+} in $M_2^{2+}MgTeO_6$ and Sr_2ZnTeO_6. M = Ca or Cd.

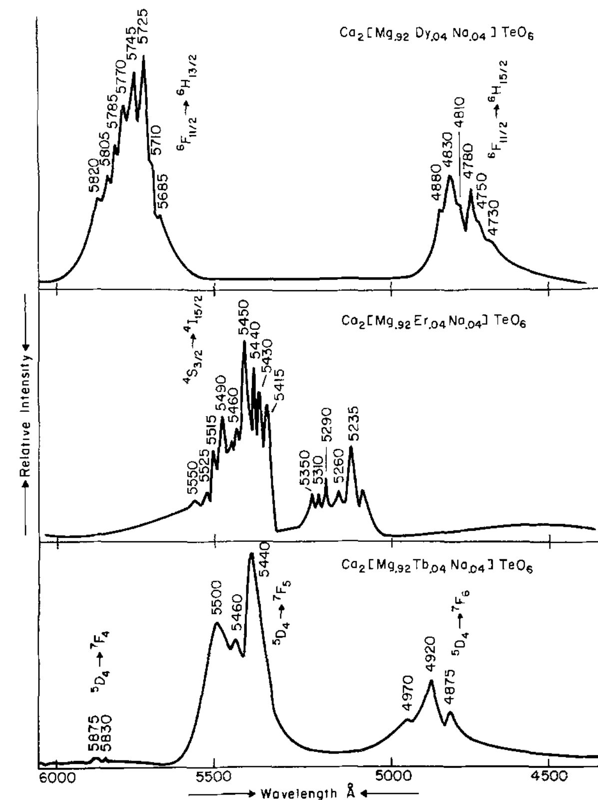

Fig. 5. Emission spectra of Tb^{3+}, Dy^{3+}, and Er^{3+} in Ca_2MgTeO_6.

ordered-distorted perovskites leaves little doubt that the space group is $P2_1$ rather than Fm3m.

Luminescence from Other Rare Earth Activators

Table II summarizes compositions and luminescence color for Tb^{3+}-, Dy^{3+}-, and Er^{3+}-activated $M_2^{2+}R^{2+}TeO_6$ (M^{2+} = Ba^{2+}, Sr^{2+}, Cd^{2+} or Ca; R^{2+} = Mg^{2+} or Ca^{2+}). The Dy^{3+}- and Er^{3+}-activated phases showed luminescence under 365 nm excitation.

Ca_2MgTeO_6 was found to be the only effective host for Tb^{3+}-, Dy^{3+}-, and Er^{3+}-activated luminescence. Dy^{3+}-activated Cd_2MgTeO_6 showed typical yellow luminescence. Although a very feeble green luminescence was noted for Tb^{3+}- or Er^{3+}-activated Sr_2CaTeO_6, the compounds belonging to the space group Fm3m do not exhibit intense luminescence when activated with Tb^{3+}, Dy^{3+}, or Er^{3+}.

Figure 5 shows the spectral energy distribution of Tb^{3+}-, Er^{3+}-, and Dy^{3+}-activated Ca_2MgTeO_6. The Tb^{3+} spectra consist of the transitions $^5D_4 \rightarrow {}^7F_J$, J = 6, 5, 4, and 3. The transition $^5D_4 \rightarrow {}^7F_5$ is stronger, while $^5D_4 \rightarrow {}^7F_6$, $^5D_4 \rightarrow {}^7F_4$, and $^5D_4 \rightarrow {}^7F_3$ transitions are weak. The transition $^5D_4 \rightarrow {}^7F_3$ is not shown in Fig. 5 since it is very weak and can be seen only at much higher sensitivity settings of the spectrometer. The Dy^{3+} spectra arise from the two transitions corresponding to $^6F_{11/2} \rightarrow {}^6H_{13/2}$ and $^6F_{11/2} \rightarrow {}^6H_{15/2}$. The Er^{3+} luminescence spectra appear in the green region. All lines indicated in the region 5400-5550Å were identified as the transition from $^4S_{3/2} \rightarrow {}^4I_{15/2}$. Ozawa (12) also noted similar spectra for Er^{3+}-activated $BaYb_2F_8$ under infrared excitation.

Table II. Luminescence of Tb^{3+}, Dy^{3+}, and Er^{3+} in $M_2^{2+}R^{2+}TeO_6$

Composition	Space group	Luminescence	Main emission peak
$Ba_2Ca_{1-2x}Tb_xNa_xTeO_6$	Fm3m	No luminescence	—
$Ba_2Ca_{1-2x}Dy_xNa_xTeO_6$	Fm3m	No luminescence	—
$Ba_2Ca_{1-2x}Er_xNa_xTeO_6$	Fm3m	No luminescence	—
$Sr_2Ca_{1-2x}Tb_xNa_xTeO_6$	Fm3m	Green (VW)	—

x = 1-10 m/o, VW = very weak, M = medium, S = strong.

Discussion and Conclusions

The discussion that follows deals with the Eu^{3+}-activated compounds, since only for these phosphors are systematic data available.

The cubic compounds are a superstructure built on the perovskite structure by the ordering of the octahedral cations. As a result of the ordering, the point symmetry of the 12-fold coordinated cations becomes $\bar{4}3m$. Although the 12 nearest-neighbor anions still form a symmetric array, the next-nearest neighbor cations are alternately Te^{6+} and the R^{2+} cation. The resulting configuration is that of two interpenetrating cation tetrahedra, and the center of symmetry is lost on the 12-fold site. The octahedral site retains symmetry m3m and thus is strictly centrosymmetric both with respect to the anion octahedron and with respect to the array of M^{2+} next-nearest-neighbor cations. The spectra of Eu^{3+} in these structures is dominated by the magnetic dipole line which usually appears only when Eu^{3+} occupies a centrosymmetric site. It can be concluded, therefore, that the Eu^{3+} activator enters these structures preferentially on the octahedral site. The relative intensities of the $^7F_1$ and $^7F_2$ transitions are known to be hypersensitive to the environment of the Eu^{3+} ion (13). The possibility that Eu^{3+} might be on the 12-fold site and exhibit only the $^7F_1$ magnetic dipole line because of the regular oxygen array can be excluded by the observations of Blasse (14) who showed that the next-nearest-neighbor cation symmetry also profoundly affects the relative intensities when the cations have large differences in charge.

Substitution of the rare earths in the six fold coordinated site of $Ba_2R^{3+}M^{5+}O_6$, R = rare-earths, M = Nb, Ta, Re, etc., ordered perovskite structure is known

and reported by several workers (15-18). Blasse *et al.* (19) also reported the magnetic dipole transition for Eu^{3+}-activated Ba_2GdNbO_6 ordered perovskite phase, indicating that Eu^{3+} replaces the octahedrally coordinated Gd^{3+} ion. The line corresponding to the transition $^5D_0 \rightarrow {}^7F_1$ does not split in Oh symmetry. The results of the present investigation are in excellent agreement with earlier findings.

The spectra of the monoclinic structures are more diverse than the cubic structures. In all compounds the forced electric dipole transition is dominant. In four of the compounds, Sr_3TeO_6, Ca_3TeO_6, Ca_2MgTeO_6, and Cd_2MgTeO_6, the $^7F_2$ level appears as a cluster of sharp crystal field lines. The $^7F_1$ level is separated into three components, the maximum that may appear. Detailed structure determinations are not available for the tellurate compounds, but the octahedral site in the isostructural alkaline earth uranates (10) is known to be quite distorted. In Ba_3TeO_6 the magnetic dipole line is much stronger in proportion to the other compounds and appears as a broad band. The monoclinic structures were originally described as pseudocubic and the barium compound is perhaps more nearly isometric than the others. In two of the compounds, Ca_3TeO_6 and Sr_2ZnTeO_6, the nondegenerate $^7F_0$ line appears in at least two components. This can only be accounted for if Eu^{3+} appears on more than one site in these structures. Finally, the emission spectrum of Sr_2ZnTeO_6 is distinctly different from the other compounds. The separation of the crystal field levels is much smaller, and the individual J-multiplets appear as roughly single rather broad lines. It is tempting to argue that Eu^{3+} is partitioned onto the 12-fold site in this structure with the intensity of the forced electric dipole line derived from distortion of the site.

These phosphors provide a useful demonstration of the importance of next-nearest-neighbor effects and the effects of structural order on luminescence behavior. They also show that the Eu^{3+} ion shows a pronounced site preference for 6 coordinated sites in these structures.

Investigation of Luminescence in Ge-Doped Sodalite Powders

Lee T. Todd, Jr.

Department of Electrical Engineering, University of Kentucky, Lexington, Kentucky 40506

ABSTRACT

A new class of cathodochromic materials, germanium-doped sodalite: Br, are described. They exhibit both a bright luminescence at room temperature and a long lifetime, high contrast coloration mode. The effect of hydrogen annealing on the initial reflectance, luminescent intensity, and FB location are studied. The FB energy is shown to initially increase with increasing germanium concentration up to 9% and then to decrease with higher germanium concentration. A technique is outlined for determining the luminescence generated within a powdered sample that possesses an absorption band. This technique is used to determine the effect of electron beam coloration on the luminescent centers. It is shown that the formation of thermally erasable F centers quenches luminescent centers while the formation of optically erasable F centers does not.

The coloration properties of sodalite and the luminescent properties of doped synthetic sodalites have been extensively studied (1-11). Sulfur (3-9), oxygen (7, 8, 10), manganese (7, 10), and iron (7, 10, 11) are the most common dopants investigated. This paper discusses germanium-doped sodalite powders (12, 13) which emit a bright green luminescence under ultraviolet radiation and exhibit a long lifetime, high contrast, and thermally erasable coloration. Figure 1 shows excitation and emission spectra of the luminescence. The effect of material preparation on the initial reflectance, luminescence intensity, and position of the FB peak absorption is presented. A method of obtaining the luminescence intensity generated within colored powders using observed luminescence intensity measurements is outlined and employed to determine the effect of FB coloration on generated luminescence.

Key words: cathodochromism, emission spectra, reflectance spectra, F centers.

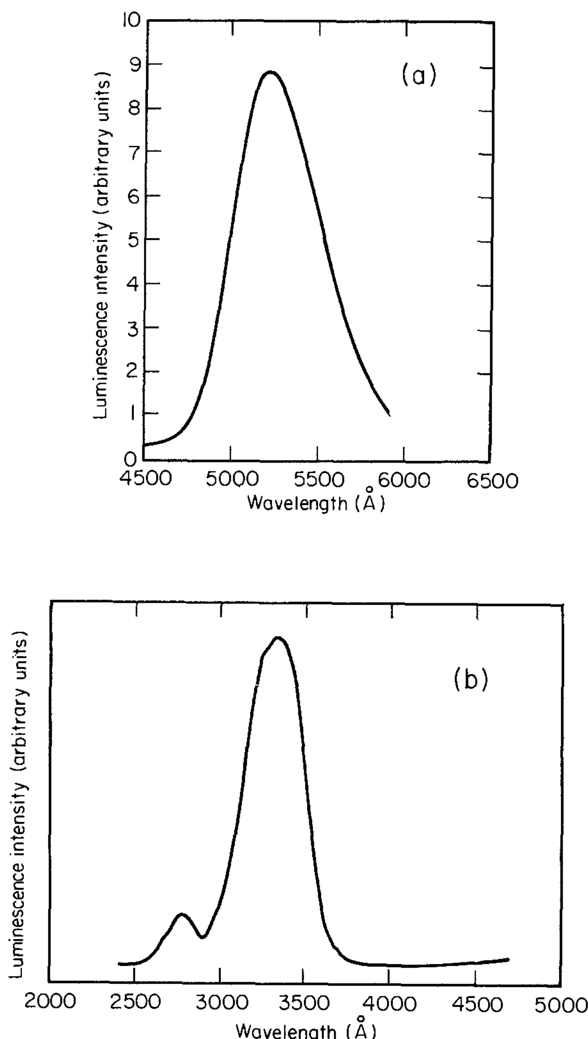

Fig. 1. Luminescence (a) and excitation (b) spectra of Ge-doped sodalite:Br.

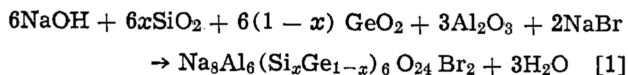
Experimental

Material preparation and measurement techniques.—Using a hydrothermal method (14, 15), sodalite materials were grown by combining chemicals according to the equation



$$6NaOH + 6xSiO_2 + 6(1-x)\ GeO_2 + 3Al_2O_3 + 2NaBr \rightarrow Na_8Al_6(Si_xGe_{1-x})_6\,O_{24}\,Br_2 + 3H_2O \quad [1]$$

where x is the atomic percent (a/o) silicon. The sodium bromide and sodium hydroxide were reagent grade, while the SiO_2, GeO_2, and Al_2O_3 were three nines pure. The powders were identified as sodalite by x-ray powder diffraction; the amount of germanium in each sample was determined with an electron microprobe (15). Materials were grown containing 0, 1, 2, 3, 9, 28, and 64 a/o germanium substituted for silicon. Annealing in a hydrogen atmosphere sensitized the powders to permit both coloration and luminescence.

Samples made by depositing the sodalite powders onto aluminum slides [using conventional powder settling techniques (16)], were colored by electron beam exposure in a demountable CRT system and u.v. light. Diffuse reflectance spectra were measured with a Cary-14 spectrophotometer equipped with a diffuse reflectance integrating sphere: Typical luminescent and excitation spectra, measured with equipment described by Jenssen (17), are shown in Fig. 1. The excitation source was a 1000W Xenon lamp and a Bausch and Lomb high intensity monochromator. The detection system included a 400 Hz chopper, a McPherson 0.3 meter Model 218 Grating Monochromator, and an RCA C7164R photomultiplier.

Determination of generated luminescence.—The F-center absorption band for the materials studied was about 1000Å wide and was centered at approximately 5550Å. Therefore, the absorption band overlapped the luminescent emission band and caused the observed, or measured, emission to be less than the emission generated by the luminescent centers. Melamed's (18) theory of luminescent powders was used to determine the generated luminescence from experimental measurements of diffuse reflectance and luminescent spectra.

If the exciting radiation is very strongly absorbed, one may assume that the excitation is consumed in a single layer. For this case, Melamed shows that the observed luminescent intensity $J(E)$, can be corrected to give the intensity of the generated luminescence, $J'(E)$, by applying the formula

$$J'(E) = J(E)\,\frac{(1-2xm_e)_E}{(R_1-2xm_e)_E} \quad [2]$$

where R_1 is the diffuse reflectance from the first layer of particles and the subscript E denotes that the quantity in parenthesis is measured at the energy of the emission. The value of m_e depends on the index of refraction and is 0.10 for sodalite:Br, $n = 1.485$. The parameter x is given by

$$x = \frac{x_u}{1-(1-2x_u)T} \quad [3]$$

where T is the percent transmission through a particle and x_u is a geometrical factor that depends on the characteristics of the powder particles. Faughnan *et al.* (19) have determined a value of $x_u = 0.143$ for settled screens of sodalite: Br. The general formula for R_1 calculated by Melamed is

$$R_1 = 2xm_e + \frac{x(1-2xm_e)T(1-m_eR)}{(1-m_eR)-(1-x)(1-m_e)TR} \quad [4]$$

where R is the diffuse reflectance for all layers beneath the first. Because the maximum value of x is one-half and because m_e is small, Eq. [4] can be reduced, with only a small error, to

$$R_1 = \frac{xT}{1-(1-x)TR} \quad [5]$$

For an uncolored sample, $R_1 = R$ but $R_1 < R$ when the sample is colored. From Eq. [3] and [5] and the value $x_u = 0.143$, an equation for T in terms R_1 and R can be obtained

$$T = \frac{1+6RR_1+5R_1}{10RR_1} - \sqrt{\left[\frac{1+6RR_1+5R_1}{10RR_1}\right]^2 - \frac{7}{5R}} \quad [6]$$

Using the measured values of R, R_1, and $J(E)$ in Eq. [2], [3], and [4], the value of generated luminescence intensity, even in the presence of an absorption band, can be obtained. Considering the accuracy with which the luminescence intensity and the diffuse reflectance can be measured, the generated luminescence is determined within ±1%.

Results

Effect of hydrogen annealing on initial reflectance.—Although undoped sodalite powders remain highly reflective if annealed at 200°C above an optimum value for maximum coloration efficiency of about 700°C, germanium-doped powders turn dark at relatively low annealing temperatures. The degree of discoloration depends on the annealing temperature and the amount of germanium in the sample. Figure 2a shows the diffuse reflectance at 5000Å for five sodalite: Br samples, containing different percents of germanium annealed in hydrogen at various temperatures for 15 min. De-

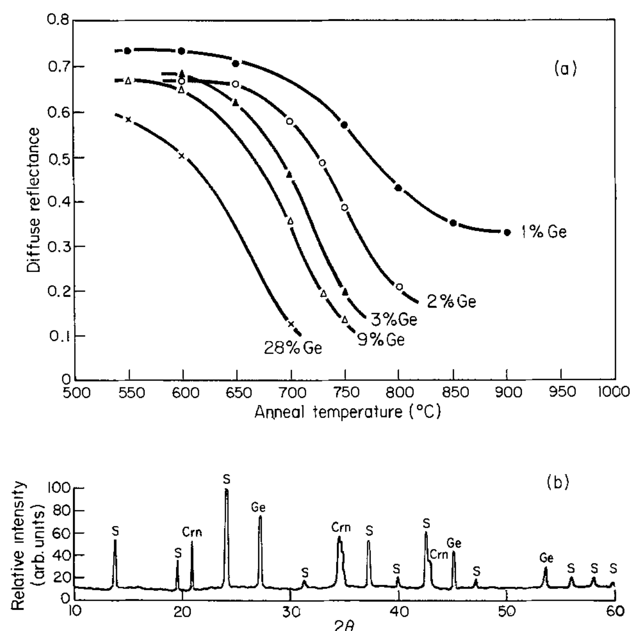


Fig. 2. Initial reflectance of Ge-doped sodalite:Br as a function of Ge concentration and anneal temperature for an annealing time of 15 min (a), and x-ray powder pattern of sample annealed at 800°C for 15 min (b).

creased reflectance is caused by the powder darkening as the annealing temperature increases. That is, the higher the germanium content, the lower the reflectance at a given annealing temperature. This reduction is also influenced by the lattice parameter increasing with germanium concentration (15) which affects diffusion rates and, therefore, the sensitizing properties of the material. Improved sensitization can be achieved by annealing for a longer time at a temperature below the break in the reflectance curves of Fig. 2a. This improvement is limited, however, because the initial reflectance also decreases with increasing anneal time at a fixed temperature.

Black coloration of over-annealed powders is due to the precipitation of germanium metal. Figure 2b is an x-ray powder pattern of $Na_6Al_6(Si_{0.91}Ge_{0.09})_6O_{24} \cdot 2NaBr$ annealed in hydrogen at 800°C for 15 min. In addition to the strong sodalite peaks, denoted by S, there are six other lines. The three lines, Ge, at 27.3° ($d = 3.280Å$), 45.2° (2.006Å), and 53.7 (1.708Å) are due to germanium metal as indicated by the excellent agreement between the observed lines and the standard lines for germanium. Another strong line, Crn, is shown in Fig. 2b at 20.9° ($d = 4.230Å$). This coincides very closely with the location of the strongest peak of high carnegieite (17, 18). It is believed that this phase occurs because of excessive loss of NaBr at high annealing temperatures.

Effects of hydrogen annealing on luminescence intensity.—The hydrogen annealing process also strongly affects the intensity of the luminescence emission. Figure 3 summarizes the results of an experiment in which materials with the composition $Na_6Al_6(Si_{0.97}Ge_{0.03})_6O_{24} \cdot 2NaBr$ were annealed at various temperatures for 15 min. The luminescence intensity is negligible for anneal temperatures less than 600°C, but increases rapidly with increasing anneal temperature. The observed emission must be corrected for reabsorption since Ge precipitation occurs upon annealing, causing the material to darken. Once corrected, the peak emission occurs at 750°C, 20° above the peak of the observed intensity. This correction explains the spectrum shift in Fig. 3. The observed intensity begins to decrease at 730°C even though new luminescent centers are being created due to reabsorption caused by germanium precipitation, while the corrected luminescence curve increases between these temperatures because the ef-

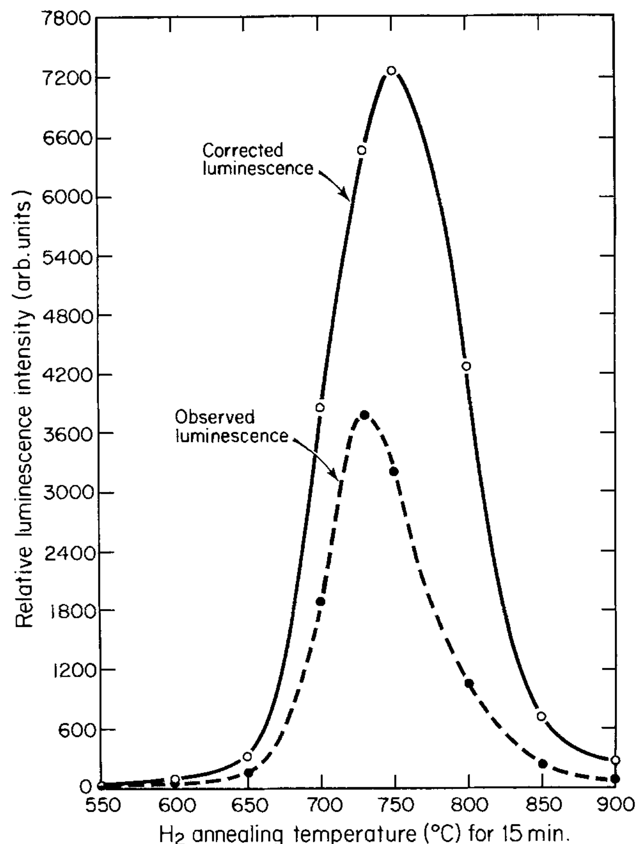

Fig. 3. Luminescence intensity of $Na_6Al_6(Si_{0.97}Ge_{0.03})_6O_{24} \cdot 2NaBr$ as a function of H_2 anneal temperature for an annealing time of 15 min.

fect of reabsorption has been removed. Above 750°C, the corrected luminescence also begins to decrease. It is believed that this is caused by the conversion of the sodalite structure into either nepheline or high carnegieite (14, 21). High carnegieite, $Na_4Al_4Si_4O_{16}$, has the same chemical formula as nepheline but is cubic while nepheline is hexagonal.

Luminescence intensity is also affected by hydrogen annealing time at a given temperature. Figure 4 shows the luminescence intensity of the powder discussed above at various annealing times at 700°C. The emission increases almost linearly between 0 and 25 min and then saturates. It appears that annealing times above 45 min causes a decrease in the emission. Figures 3 and 4 show that the annealing temperature, not the annealing time, determines the maximum luminescence intensity because annealing at 730°C for only 15 min results in a higher emission than obtained when annealing at 700°C for times much longer than 15 min.

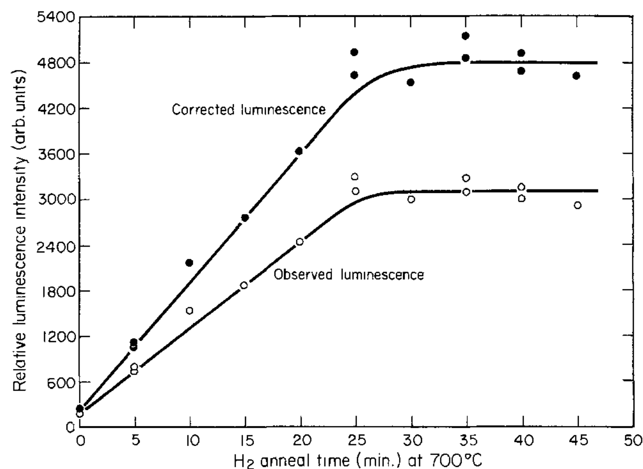

Fig. 4. Luminescence intensity of $Na_6Al_6(Si_{0.97}Ge_{0.03})_6O_{24}$ $2NaBr$ as a function of H_2 anneal time at 700°C.

The best luminescent materials contained less than 9% germanium substituted for silicon. The strongest emission was observed using a material containing 3% germanium which was annealed in hydrogen at 730°C for 30 min. When excited by a 20W ultraviolet lamp, this material exhibits a 14 f-L emission. Samples containing 28 and 54% germanium are difficult to sensitize because the material darkens at very low annealing temperatures and the luminescence intensity observed with these samples was almost negligible.

Effect of Ge concentration on F band absorption peak.—Though the positions of the excitation and emission bands are unaffected by germanium concentration, the location of the F band is strongly affected by the germanium concentration. A study of the effect of germanium substitution in bromine sodalite on the location of the F band peak is complicated by the fact that the F band position is also a function of the hydrogen annealing temperature and time. Figure 5 shows that the wavelength of the peak absorption for a bromine sodalite sample containing no germanium varies from 5400 to 6300Å when the annealing temperature is varied from 600° to 800°C. Therefore, there is not a unique F band peak wavelength for each germanium composition, but a range of values. To avoid this problem and obtain an F band peak wavelength characteristic of the germanium content, the samples used in this part of the investigation were annealed for 15 min at 600°C to minimize the shift of the peak due to annealing. The F band locations were determined from diffuse reflectance spectra of settled screen samples. The results are presented in Table I. These data indicate that the incorporation of Ge causes the lattice parameter to increase almost linearly starting from zero Ge concentration (15). One would expect that this lattice expansion would cause the F center potential well to expand and hence E_F to decrease. However, the data in Table I show that E_F first increases and then decreases as germanium is added. Rizzo (22) observed this same behavior when using ESR to measure the effect of germanium substitution on the hyperfine constant of the trapped electron. He found that the interaction of the trapped electron with its surrounding sodium nuclei increased and then decreased as germanium was added. Therefore, at low

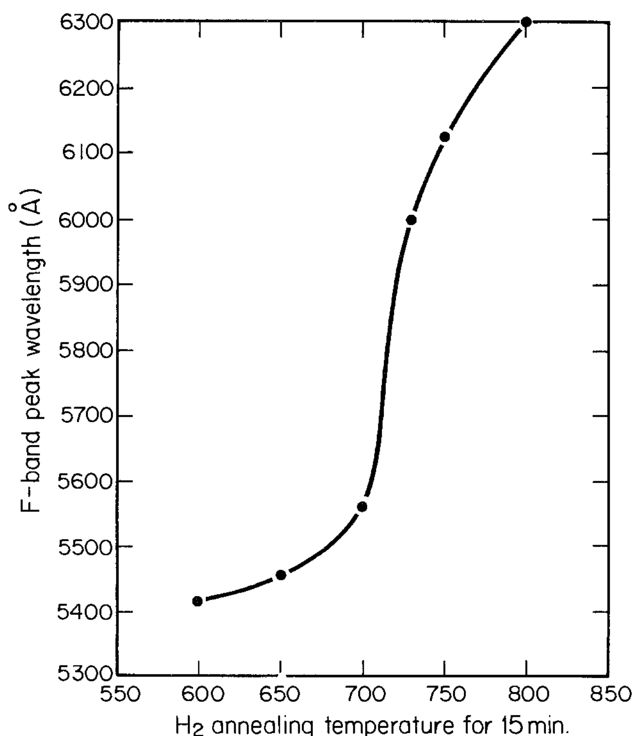

Fig. 5. Sodalite:Br F band peak wavelength as a function of H_2 annealing temperature.

Table I. F band peak location as a function of Ge concentration

A/o Ge	a_0 (Å)[12]	λ_{peak} (Å)	E_F (eV) $= \frac{hc}{\lambda_{peak}}$
0	8.914	5420	2.294
1	8.919	5400	2.302
3	8.921	5375	2.313
9	8.932	5365	2.317
28	8.973	5515	2.253
54	9.042	5800	2.143

Ge concentrations another effect must be occurring to produce the energy shift in the opposite direction from the lattice expansion shift. This effect could, for example, be a perturbation of the F center wavefunctions which could cause a shift in the absorption band. The perturbation may be less significant at higher Ge concentrations where E_F decreases with lattice expansion. The data in Table I show that E_F begins decreasing at a germanium concentration of nine atomic percent. The logarithm of the energy of the trapped electron, $E_F = hc/\lambda_{peak}$, is plotted in Fig. 6 *vs.* the lattice parameter to show the exponential dependence of E_F on a_0. Above 9% Ge, E_F can be represented by

$$E_F = (2.37 \times 10^6)\, a_0^{-6.32} \quad [7]$$

The exponential dependence in Eq. [7] is much stronger than that observed in the alkali halides which is represented by the Mollwo-Ivey relation

$$E_F = 17.7\, a_0^{-1.84} \quad [8]$$

However, the exponential dependence in Eq. [7] is less than that observed for sodalite when substitutions are made into the halogen site. From the data of Taylor *et al.* (6), one can calculate for this case

$$E_F = (7.15 \times 10^9)\, a_0^{-10} \quad [9]$$

Therefore, substituting into the cage framework rather than into the center of the cage produces a more subtle effect on the position of the F band peak.

Effect of F band coloration on luminescent intensity.—Coloration of these materials greatly quenches the observed luminescence. Some quenching was expected because the F band and emission band overlap, but the reduction in intensity was larger than that due merely to reabsorption. To determine the cause of this reduction, luminescence intensity as a function of F band absorption was measured. First, initial reflectance and luminescence spectra of the uncolored slide were measured. The slide was then lightly colored with ultraviolet light and the resulting reflectance and lumin-

* The value of R used in Eq. [6].

escence spectra determined. This procedure was continued by increasing the sample coloration and measuring the spectra after each exposure until the contrast saturated. Darker coloration was obtained by electron beam exposure. Table II lists the parameters used to calculate the corrected luminescence and the F band absorption along with a few sample calculations. The luminescence peak occurred at 5250Å while the F band peak was at 5450Å. Figure 7 shows both the observed and corrected luminescence intensities as a function of F band absorption. The observed luminescence decreases almost linearly with increased coloration. The corrected intensity is essentially constant for low F band absorption, however, and then decreases almost linearly with increasing absorption. The region in which the corrected luminescence intensity remains constant coincides with the region of photoerasable coloration, *i.e.*, that portion of the coloration that can be erased by light, while the decrease in corrected intensity coincides with the region of thermally erasable coloration. This correlation was confirmed by repeating the above experiment but, in addition, thoroughly optically bleaching the sample after each exposure and before measuring the luminescence and diffuse reflectance spectra. The results of this experiment are shown in Fig. 8. In this case, the corrected luminescence decreases over the entire range of coloration. These two experiments indicate that the reduction in observed luminescence due to photoerasable coloration results entirely from partial reabsorption of the generated emission by the F centers. Thermally erasable coloration causes the observed luminescence to decrease not only due to reabsorption, but also as a result of an additional quenching mechanism. For example, in zero ambient light and under ultraviolet excitation, a sample with an emission of 14 f-L from an uncolored area emitted only about 0.1 f-L in a colored area giving a contrast ratio of approximately 140:1. This sample exhibits a reflective contrast ratio of 15:1 in high ambient light.

Summary

Germanium-doped, sodalite:Br powders were prepared and shown to exhibit luminescence at 5250Å with an excitation band at 3465Å. The materials also possess a long lifetime, high contrast, cathodochromic coloration mode. The luminescent intensity depends strongly on both the hydrogen-annealing temperature and duration. The luminescence initially increases with increasing annealing temperature and then decreases at higher temperatures due to structural collapse. The sample with the highest luminescent intensity, *i.e.*, 14

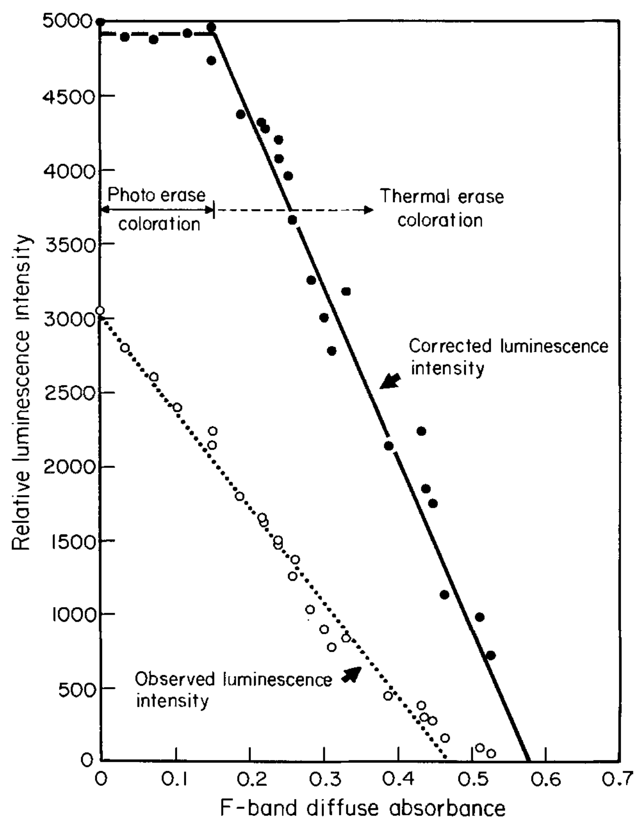

Fig. 7. Luminescence intensity as a function of F band absorption for $Na_6Al_6(Si_{0.99}Ge_{0.01})_6O_{24} \cdot 2NaBr$ annealed at 700°C for 30 min.

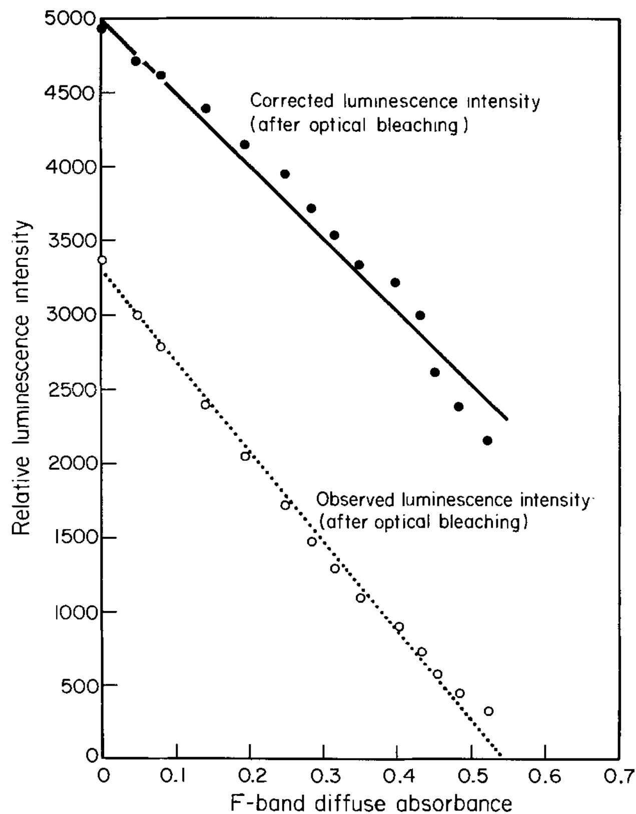

Fig. 8. Luminescence intensity as a function of F band absorption (after optical bleaching) for $Na_6Al_6(Si_{0.99}Ge_{0.01})_6O_{24} \cdot 2NaBr$ annealed at 700°C for 30 min.

f-L, contained 3% germanium and was annealed at 730°C for 30 min.

The sensitizing of germanium-doped powders is complicated by the precipitation of germanium at relatively low anneal temperatures. This causes the powder to appear black and reduces the initial reflectance. This effect becomes more pronounced with higher germanium concentrations. Samples containing less than 9% Ge have very good luminescent and cathodochromic properties while those above 9% are very difficult to sensitize.

The F band energy was shown to increase with increasing germanium concentration up to 9% and then to decrease with higher concentrations. Above 9% germanium, the F band energy was shown to obey the relationship

$$E_F = (2.37 \times 10^6)\, a_0^{-6.32} \qquad [10]$$

Electron beam coloration of these materials greatly reduces the observed luminescence. While some of this reduction results from absorption of the generated luminescence by F centers, a further reduction results from the quenching of luminescent centers. It was shown that the formation of thermally erasable F centers results in the quenching of luminescent centers while the formation of optically erasable F centers does not.

Experiments are being conducted to measure the effect of electron beam coloration on the intensity of an absorption band that is attributed to the luminescent center. Other experiments are being considered to determine a model for the luminescent mechanism.

Passivating CVD Molybdenum Films Against Infrared Reflection Losses Caused by Oxidation

G. E. Carver, H. S. Gurev,* and B. O. Seraphin

Optical Sciences Center, University of Arizona, Tucson, Arizona 85721

ABSTRACT

Thin film reflectors of molybdenum deposited by CVD can be passivated against oxidation by overcoating them with either a thin film of aluminum oxide (500Å) or silicon nitride (300Å). A set of such molybdenum films were exposed to open air at 500°C for 160 min without measurable deterioration of their infrared reflectance. This demonstrates the feasibility of using refractory metal reflectors in high temperature photothermal converters without risking reflectance losses caused by oxidation. It also established the possibility of integrating the refractory metal reflector into the deposition sequence of converter fabrication by CVD.

The spectral selectivity required for photothermal solar energy converters can be provided by a sequence of thin films. Antireflection coating and thin film absorbers operating in the visible range, covering a thin film reflector operating in the infrared are the major components of a converter. Previous work has demonstrated the feasibility of fabricating these thin

* Electrochemical Society Active Member.

Key words: refractory metal reflector, photothermal conversion, high temperature anneals.

film stacks by CVD (1). The method is economically particularly attractive for solar technology since it proceeds at atmospheric pressure, thereby facilitating large scale flow-through operation without the restrictions and costs of vacuum-based techniques. In addition, fabrication by CVD requires exposure of the growing stack to temperatures in excess of 700°C. As a consequence, the final system is well suited for long-term operation at temperatures of 500°C. However, the high temperatures of fabrication and operation present difficulties. If highly reflective noble metals such as silver are used, the reflective film tends to agglomerate during fabrication, resulting in reduced infrared reflectance. As an alternative, refractory metals of superior thermal stability can serve as reflectors. In contrast to films prepared by physical vapor deposition, thin films of molybdenum deposited by CVD compete in their infrared reflectance with the high reflectance of the bulk material (2). Having profited from the thermal and optical properties of molybdenum, problems still arose concerning the strong oxidation tendency of this refractory metal, especially at the temperatures of converter operation. We consequently studied methods of passivating CVD molybdenum thin films with respect to preserving their infrared reflectance. The results of tests in which a set of passivated molybdenum films was exposed to open air at 500°C for 160 min is reported. Within reflectometer accuracy, the infrared reflectance of the passivated films remained unchanged throughout this period of time. Two typical samples were further heated and failed to determine a lifetime limit.

Sample Set

Twenty-one samples were deposited by thermal decomposition of molybdenum carbonyl [$Mo(CO)_6$]. An important aspect of this process is the possibility of incorporating traces of oxide and carbide phases within the molybdenum matrix. Anticipating that these oxides and carbides could alter metallurgical interactions between the metallic film, passivator, and atmosphere, we included deposits of differing impurity content within our sample set. This was done by varying the deposition temperature of the metallic films, as it is known that the end products of the thermal decomposition of $Mo(CO)_6$ are a function of temperature (3). Films were deposited at temperatures ranging from 200° to 350°C. All samples were deposited on fused silica and range in thickness from 600-1800Å. As explained below, four different methods of passivation were tested. Sample subsets were assembled for use with each passivator, along with an additional subset which was not passivated for reasons of comparison. Each subset includes samples of different deposition temperature. The top two rows of the figure summarizes this information. In addition to variations of the purity amongst the sample set, the large surface-

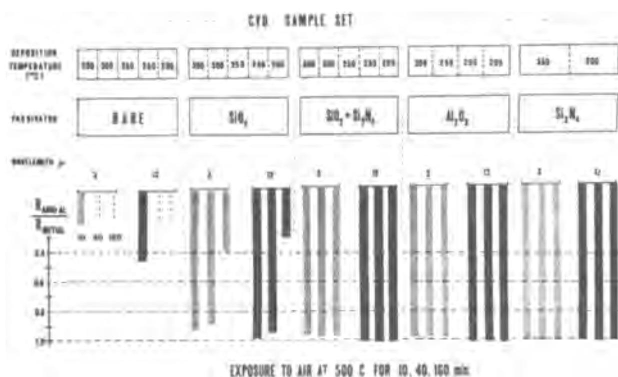

Fig. 1. Ratios of the reflectance of passivated, annealed CVD molybdenum films to as-deposited reflectance values at 3 and 12 μm for samples which have been annealed in air at 500°C for 10, 40, and 160 min using different passivators.

to-thickness ratio of a thin film can force structural differences from the bulk. In order to study the influence of these parameters on the passivation, we included in our test samples of bulk molybdenum which were polished to a specular finish.

Choice of Passivators

For purposes other than the stabilization of the optical properties, passivation of molybdenum is routinely accomplished with a few thousandths of an inch of molybdenum silicides when structural strength, impact resistance, and/or thermal shock resistance of the object to be passivated is of interest (4). The fact that our application requires preservation of the high infrared reflectance of the passivated films places more stringent requirements on the passivators. The high infrared emittance, ranging from 0.4-0.8 (5), of these silicide layers precludes their use as passivators in solar applications. However, the mechanism by which the silicides operate suggests a passivator for our application. During heating, the silicide reacts with oxygen to form a thin layer of SiO_2 on the outer surface which acts as the protective layer (6). Thus we coated one subset of our molybdenum films with 500Å of SiO_2 by evaporation. These layers are thin enough to render the infrared reflectance of the metal unaltered by the passivator. Other subsets were passivated with 500Å of Al_2O_3 which was also deposited by evaporation. In addition, a passivating layer of 300Å thickness of Si_3N_4 was applied to a sample subset by chemical vapor deposition from a $SiH_4/NH_3/He$ gas mixture at a temperature of 750°C. It is remarkable that the reflectance of the Mo films thus coated did not change in the CVD process, indicating that the absence of oxygen in the reaction chamber permitted heating of the Mo films up to temperatures above 700°C without adverse effects. In order to guarantee the survival of the Mo films during Si_3N_4 deposition, we applied 500Å of SiO_2 to a subset of metal films before the CVD step. As mentioned above, bulk molybdenum samples were also passivated. Similar Al_2O_3 and SiO_2 layers were used on the bulk samples.

Testing Procedures

Using a PE 137 spectrophotometer, we measured the near-normal incidence specular reflectance of all samples, (*i*) after deposition of the metal; (*ii*) after passivation; and (*iii*) after each step of the lifetime test. Concerning the vertical scale of the figure, $R_{initial}$ refers to the reflectance before application of the passivating layer, and R_{anneal} to the reflectance after annealing the sample for the times given. The quotient is therefore indicative of conservation or deterioration of the infrared reflectance. All samples were heated in air in a furnace of near-constant temperature profile varying only from 502° to 504°C over the area utilized. Reflectances were measured after exposure to this condition for 10, 40, and 160 min, respectively.

Results

All results for the metallic films are summarized in the figure where light and dark bars indicate values of R_{anneal} over $R_{initial}$ at 3 and 12 μm, respectively, for each sample subset after each of the three anneal periods. Each bar represents an average calculated over all samples in each subset, each sample being characterized by deposition temperature, and consequently by impurity content. Changes in reflectance varied only slightly among samples within each subset. Therefore, variations of impurity content within the metallic films due to different deposition temperatures are seen to be of little consequence concerning passivation.

One sample subset and the bulk molybdenum sample were passivated by 500Å of SiO_2. They deteriorated in their reflectance after 40 min of anneal in open air at 500°C. In addition, measurements of reflectance of these samples in the visible and near infrared indicate

a shift of the first interference fringe to longer wavelengths during exposure. This indicates an increase in the optical thickness of the dielectric layer above the metallic surface. It can be assumed that the fringe shift is caused by a growth of molybdenum oxide at the metal-dielectric interface which in turn eventually consumes the metal and destroys the reflectance. Incomplete densification (7) of the silicon dioxide layers may explain the partial failure of these samples.

Similar fringe shifts are seen after 40 min of exposure in the reflectance measurements on unpassivated bulk molybdenum. In this case, the shifts result from an oxide growth on the outer metallic surface. As the dielectric thickness increases, fringe minima shift towards the infrared and reduce reflectance values. Oxide absorption bands also contribute to infrared reflectance losses for these unprotected bulk molybdenum surfaces. It can be assumed that the unpassivated subset of molybdenum films was consumed by oxide growth resulting in complete reflectance loss within 10 min of exposure.

The Al_2O_3 and Si_3N_4 passivators protected their respective subsets through at least 160 min in air at 500°C without loss of infrared reflectance. Aluminum oxide preserves the reflectance of bulk molybdenum under the same conditions. No lifetime limit was found as two typical samples were tested for an additional 6 hr without reflectance degradation. Reflectance measurements in the visible range indicated that the dielectric layer overcoating these samples did not change in thickness as the first order fringe minima remained at the same wavelength throughout all tests. In some cases reflectance values increased slightly after the first anneal, indicating a possible outgassing and/or structural improvement of the film caused by heating.

Conclusions

Both thin layers of Al_2O_3 and Si_3N_4 can passivate thin molybdenum films deposited from the vapor phase without degrading their infrared reflectance against exposure to air at 500°C for 160 min. Thin layers of SiO_2 preserved the reflectance for nearly 40 min at 500°C. These results establish the possibility of integrating refractory metal reflectors into the deposition sequence of photothermal converter fabrication by CVD. In addition, in the event of accidental exposure of a photothermal converter to air during operation, the metallic reflectors would easily survive the ensuing cooldown period prior to enclosure repair without suffering oxidation induced reflectance losses.

Thickness Uniformity of GaAs Layers Grown by Electroepitaxy

L. Jastrzebski, Y. Imamura,[1] and H. C. Gatos*

Department of Materials Science and Engineering,

Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The thickness profiles of GaAs layers grown by electroepitaxy (current-controlled liquid phase epitaxy) were investigated in conjunction with experimental growth parameters. It was found that defective electrical contacts to the substrate and variations in the dissolution depth of the substrate by the gallium contact layer lead to random fluctuations in the epitaxial layers. Convective flow in the solution due to horizontal gradients in the solution caused by joule heating leads to systematic variations in the thickness of the epilayers. Experimental procedures are presented for minimizing or essentially eliminating both types of thickness variations.

Current-controlled liquid phase epitaxy, referred to from here on as electroepitaxy, of semiconductors and other compounds utilizes current flow through the growth interface while the temperature of the system is maintained constant (1). Growth of semiconductors such as InSb (1), GaAs (2-6), InP (7), and GaAlAs (8-10) as well as garnet layers (11) has been successfully achieved by electroepitaxy. Furthermore, electro-

Key words: GaAs, LPE, electroepitaxy, layer thickness, uniformity.

epitaxy has been employed for the study of growth kinetics of GaAs layers and Si segregation from Si-doped solutions; in these studies the amphoteric doping behavior of Si has been elucidated and attributed to the formation of As-Si-Ga complexes in solution from which Si can be incorporated into Ga or As sites during growth depending on temperature (6). The electrical properties of GaAs layers and p-n junctions grown by electroepitaxy (*i.e.*, mobility, minority carrier diffusion length, and *I-V* characteristics) were found to be as good as in layers (or p-n junctions) grown under the same conditions by thermal cooling (5); similarly, parameters of DH GaAlAs layers were found to be comparable to those prepared by classical methods (10).

During electroepitaxy it has been found that joule heating can play a significant role and that a.c. must be applied prior to the direct current for successful growth (8). Other investigators, on the other hand, have not encountered any interference from joule heating (2). Furthermore, convection in the solution was found to be very significant in some experiments (12); however, its origin has not been clarified.

It was the purpose of the present work to study in detail the extent of joule heating and its effects on the thermal gradients in the growth cell and on convection in the solution; it was also the purpose of this work to study the thickness uniformity of the epitaxial layers as affected by joule heating and other experimental parameters.

Apparatus and Procedure

The apparatus employed in the present study is shown schematically in Fig. 1. The growth cell, operated in a furnace with a cylindrical gold reflector, is a modified version of that commonly employed in LPE to permit a controlled flow of electric current through the growth interface. Thus, two stainless steel electrodes are threaded, one each into the top and bottom graphite segments; the two segments are electrically isolated with boron nitride and current can flow only when the seed is brought into contact with the solution by means of a boron nitride slide. Monitoring thermocouples are positioned 1 mm from the seed and the solution. During growth the controlled thermocouple can be either in position C near the seed or in position B near the heating element for reasons to be discussed below.

GaAs substrates (1.2×1.2 cm) with the (100) orientation were employed; their thickness varied from 200 to 300 μm; they were Cr doped (semi-insulating at room temperature). A uniform electrical contact on one side of the substrate was established with a 150 μm thick gallium layer[2] (details on this contact are discussed later). Depending on the dimensions of the solution well, the growth area was 1.4, 1.0, 0.5, and 0.2 cm^2. The layers were Ge doped (p-type) to a level of about 1.0×10^{18}; other dopants such as Te, Sn, and Si led to similar results. The height of the solution was varied from 0.2 to 2 cm.

In a typical growth experiment the cell was brought to the desired temperature (from 800° to 1000°C) and the solution was equilibrated over a dummy substrate for a period ranging from 2 to 5 hr depending on the height of the melt. The substrate was then brought into contact with the melt and electric current was passed through the growth interface at a density of 0.3-60 A/cm^2; the substrate had a positive polarity with respect to the solution.

Interface demarcation (13) (for the determination of the microscopic growth rate) was introduced by passing through the growth interface 40A current pulses of 0.5 sec duration; depending on the growth rate, the pulse frequency was varied for optimum resolution. Growth was terminated by switching the current off and the substrate was isolated from the solution by moving the slide. The epitaxial layer ranged in thickness from 1 to 150 μm and the growth time from a few minutes to a few hours.

After growth the layers were cleaved along the diameter parallel to the horizontal direction of the cell, etched in AB etchant, and studied by interference contrast microscopy.

The total electrical resistance of the system at 900°C (including stainless steel electrodes, graphite segments, solution, and substrate) for a number of runs was found to range from 0.19 to 0.25Ω. Upon removing the substrate and allowing the solution to make electrical contact between the two graphite segments, no change in resistance was observed; the resistivity of the

[2] Electrical contacts made by evaporating metals such as Pt, Au, Ag, and Pb or by soldering In and Sn did not give satisfactory results.

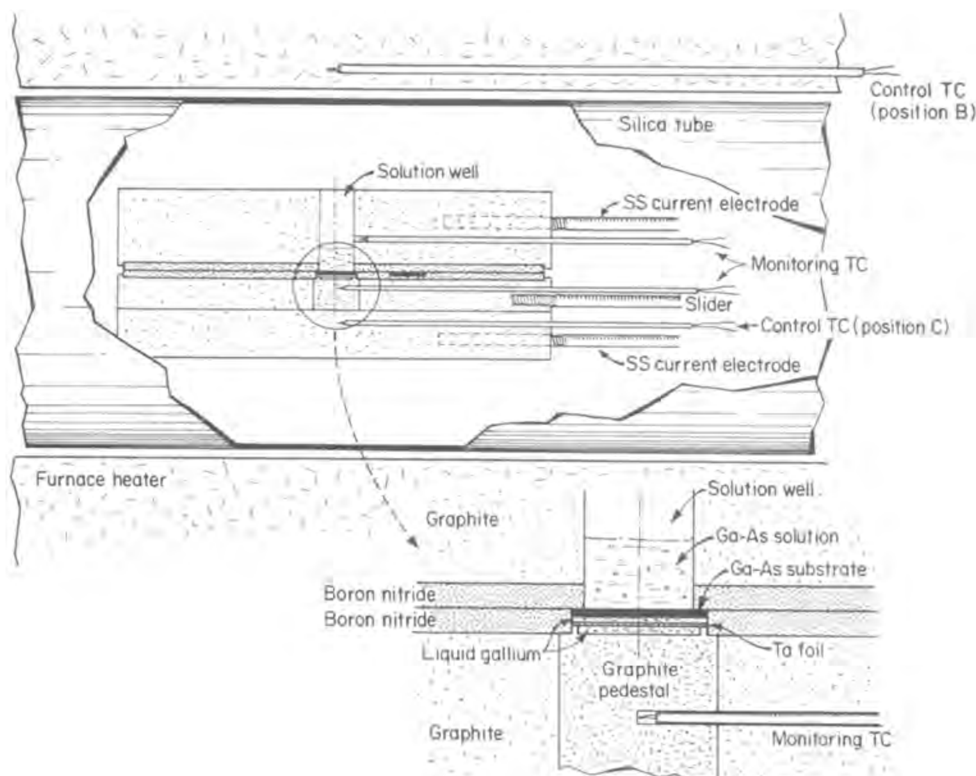

Fig. 1. Schematic diagram of the electroepitaxy apparatus.

graphite segments was estimated to be a few milliohms, taking the resistivity of the graphite to be 10^{-3} Ω-cm; the resistance of stainless steel electrodes was found to be 0.07-0.09Ω. Thus, there is resistance of about 0.1-0.16Ω unaccounted for which must be attributed to the stainless steel-graphite contacts. As is discussed below, this resistance leads to localized joule heating on the right-hand side of the growth cell.

Experimental Results and Discussion

Thermal effects associated with electroepitaxy.—Effect of joule heating on the temperature profile.—Temperature measurements, after thermal equilibration of the growth apparatus, were carried out along a horizontal line 2 mm below the substrate employing a thermocouple as indicated in Fig. 1. The results in the absence and presence of current flow (20A) are plotted in Fig. 2. It is seen that the temperature profile (curve A) is significantly changed in the presence of current flow (curves B and C).

In the absence of current flow the location of the control thermocouple (position B or C indicated in Fig. 1) does not affect the equilibrium temperature profile. However, in the presence of current flow the location of the control thermocouple plays an important role. In the presence of current flow (20A) and with the control thermocouple in position B, near the heating element, (curve B in Fig. 2) the substrate temperature increases by about 8°C and the thermal gradients on either side of the temperature maximum become steeper; furthermore, the temperature maximum is shifted to the right. This shift and the fact that the gradient to the left-hand side of the temperature maximum is greater than that to the right-hand side of the maximum indicate that joule heating is concentrated in the graphite segments of the growth cell on the right-hand side of the substrate. Thus, the joule heating appears to be associated with the stainless steel electrode-graphite contacts which represent half of the electrical resistance of the entire growth system, as pointed out above.

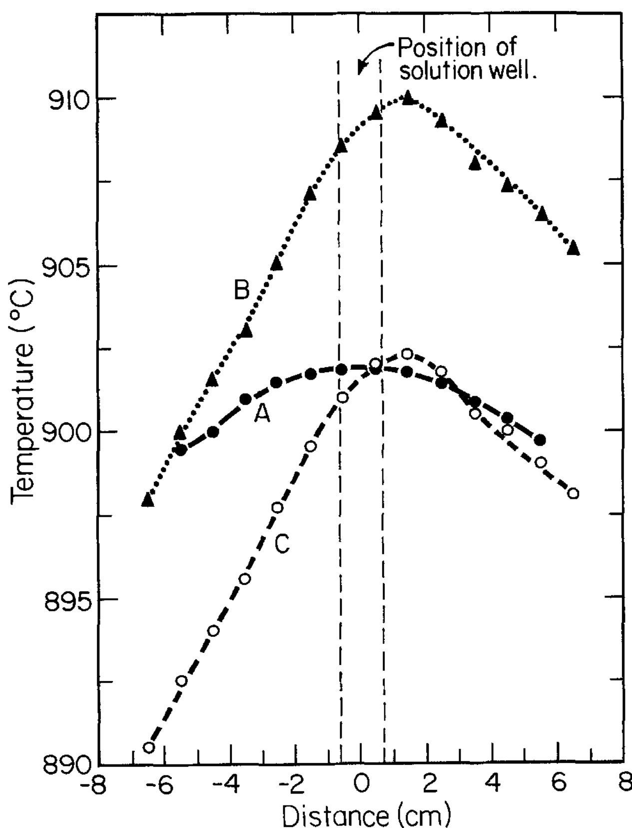

Fig. 2. Horizontal temperature profile in growth cell. Curve A temperature profile in the absence of current; curve B and C temperature profiles during current flow (20A) with the controlled thermocouple in positions B and C, respectively from Fig. 1.

With the control thermocouple in position C near the substrate (Fig. 1), the thermal profile after equilibration in the presence of current flow (curve C, Fig. 2) indicates also significant joule heating at the stainless steel electrode-graphite contacts (different thermal gradients about the maximum). However, the substrate and solution temperature is changed to a relatively small extent. The same curves as in Fig. 2 were obtained 4 mm above the solution (having a height of 0.5 cm) by traversing a monitoring thermocouple through a graphite plug resting on the solution.

It is, thus, shown that joule heating in electroepitaxy establishes a new thermal equilibrium characterized by steeper thermal gradients than the thermal equilibrium prior to the flow of electric current. The new thermal equilibrium is established in about 5 min after the current flow is initiated, as shown in Fig. 3 for an initial temperature of 902°C and a current of 20A.

In the present growth system the thermal gradients, after thermal equilibration, were found to be a function of the electric power. The measured thermal gradient across the solution as a function of electric power (resistance of the system 0.25Ω) is shown in Fig. 4. This horizontal thermal gradient is a potential cause of thermal instability in the solution and could lead to convective flow. The effects of such flow on the uniformity of the epitaxial layers are discussed below.

Effect of the joule heating on the growth process.—As was shown in Fig. 2, with the controlled thermocouple near the heating element (position B in Fig. 1) the temperature of the substrate and the solution increases by about 8°C during flow of 20A. Accordingly, in this case, it was possible to carry out electroepitaxy only after alternating current (a.c.) was passed through the system prior to direct current (d.c.) consistent with results reported previously (8). During a-c flow substrate dissolution took place and the As concentration in the solution reached a new equilibrium value, corresponding to the increased temperature brought about by joule heating (910°C for a current of 20A). Thus, after substituting d.c. for a.c., electroepitaxy was carried out at 910°C, *i.e.*, 8°C higher than set by the temperature controller. When the control thermocouple was near the substrate (position C in Fig. 1) the temperature of the solution and the substrate did not change during current flow as the control thermocouple sensed the joule heating and thus reduced the power to the heating element. Thus, in this

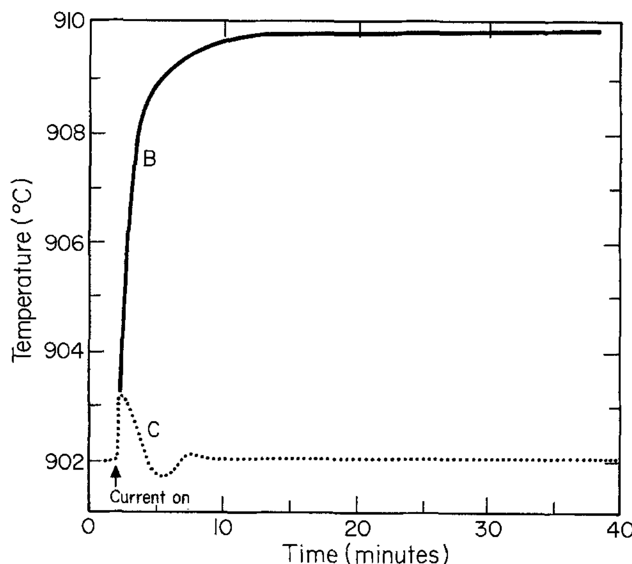

Fig. 3. Thermal equilibration after applying current. Curves B and C were obtained with the controlled thermocouple in positions B and C, respectively from Fig. 1.

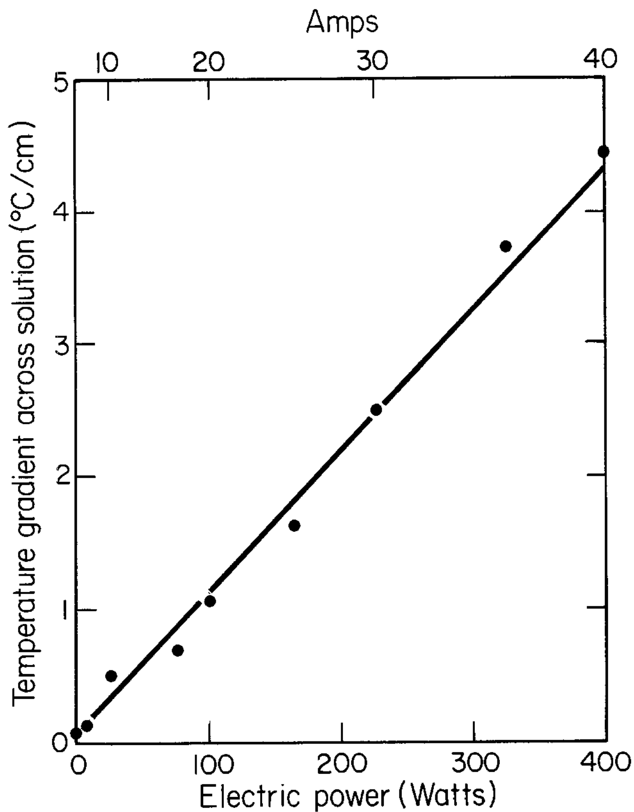

Fig. 4. Temperature gradient across the solution vs. electric power at 902°C.

case no substrate dissolution took place and electroepitaxy was carried out without applying a.c. prior to d.c.

The above results can account for the discrepancy in electroepitaxy findings reported in the literature: one group (8) found extensive backmelting of the substrate upon passage of current and could obtain growth only when a.c. was applied prior to d.c.; a second group (2) experienced no difficulties in carrying out electroepitaxy and found it unnecessary to introduce a.c. In the light of the present results, differences in the effect of joule heating on the thermal configuration of the growth cell resulting from differences in experimental arrangement are the apparent cause of this discrepancy.

Minimization of temperature gradients due to joule heating.—In order to decrease joule heating the cross section of the stainless steel rods was increased by a factor of ten (from 0.1 to 1 cm^2). In addition, the contact area between the rods and the graphite was increased by welding a 2 cm^2 stainless plate at the end of the rods. These modifications decreased the resistance of the system from 0.19-0.25Ω down to 0.05-0.08Ω. In turn, the horizontal temperature gradient across the solution was reduced from 1.4° to 0.4°C/cm for a current flow of 20A at 902°C.

In order to decrease further the horizontal temperature gradient across the solution, the following procedure was employed. Prior to growth the graphite segments were positioned in the furnace so that the horizontal temperature gradient in the solution was of the same magnitude but of opposite sign to the horizontal temperature gradient change caused by the joule heating. Thus, during current flow, the resulting horizontal gradient in the solution was minimized. The smallest gradient achieved across the solution was 0.05°C/cm for a solution temperature of about 900°C, a current flow of 25A, and a total system resistance of 0.05Ω. In most experiments at this temperature and for the same current flow the horizontal gradient ranged from 0.1 to 0.15°C/cm (resistance range 0.05-0.08Ω) as shown in Fig. 5.

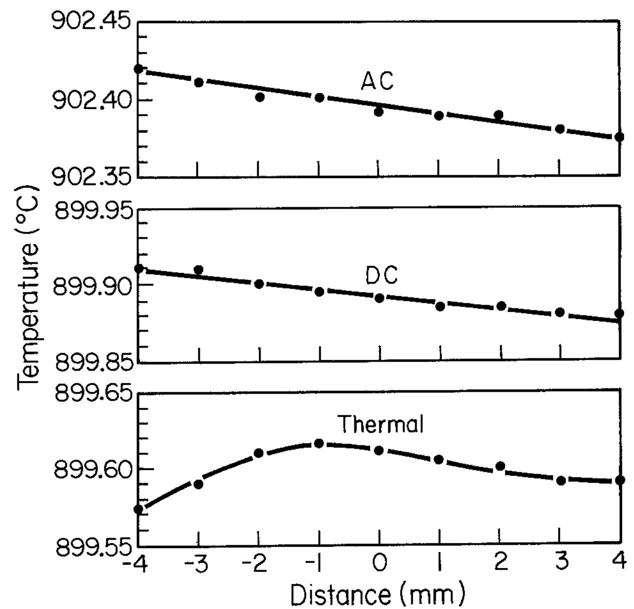

Fig. 5. Horizontal temperature gradient in the solution while passing 25A a.c. (upper curve), 25A d.c. (middle curve), and no current (lower curve). Data obtained with Cr-doped 1 mm thick substrate.

It has been reported (12) that Peltier cooling can lead to horizontal temperature gradient changes (over and above those introduced by joule heating). No such effects were found in the present study. Thus, it is seen in Fig. 5 that passing 25A a.c. (no Peltier cooling) instead of d.c. under identical experimental conditions the horizontal temperature gradient in the solution remains the same, although with d.c., the average temperature decreased about 2.5°C due to Peltier cooling.

Layer thickness uniformity.—The uniformity of the layer thickness was studied in conjunction with various growth conditions such as current density, extent of joule heating, solution height, and the nature of the electric contact to the substrate. Two types of thickness fluctuations were observed: random fluctuations associated with nonuniform current flow through the substrate and systematic fluctuations associated with temperature gradients or convective flow in the solution.

Random thickness fluctuations.—Random fluctuations of the layer thickness associated with nonuniform current density were found to originate in nonuniform electric contacts to the substrate and in variations of the substrate thickness.

Thus, Fig. 6a depicts an epilayer grown in 1 hr under a current density of 5 A/cm^2 at 850°C (substrate thickness 400 μm, n-type 10^{18} $carriers/cm^3$). On some areas of the substrate (identified by numbers) essentially no growth took place. These areas correspond to areas of poor electric contact to the substrate, where gallium did not wet the substrate. They are identified by numbers in Fig. 6b, corresponding to the numbers on the epilayer of Fig. 6a.

Fluctuations in substrate thickness were also found to originate in nonuniform dissolution depth of the substrate by the gallium layer used for electric contact. These variations in the substrate thickness led to variations in the resistance across the substrate and thus in fluctuations in layer thickness. They were particularly pronounced in thin substrates (of the order of 300 μm) where dissolution by gallium represented a significant part of their thickness, since a minimum thickness of about 150 μm of a gallium layer was found to be necessary for a satisfactory spread of gallium over the substrate surface.

Nonuniformities in the ohmic contacts were eliminated by placing the layer of Ga on the substrate (~150 μm), then a Ta foil (~50 μm thick), and then a second thin layer of Ga which served as the contact

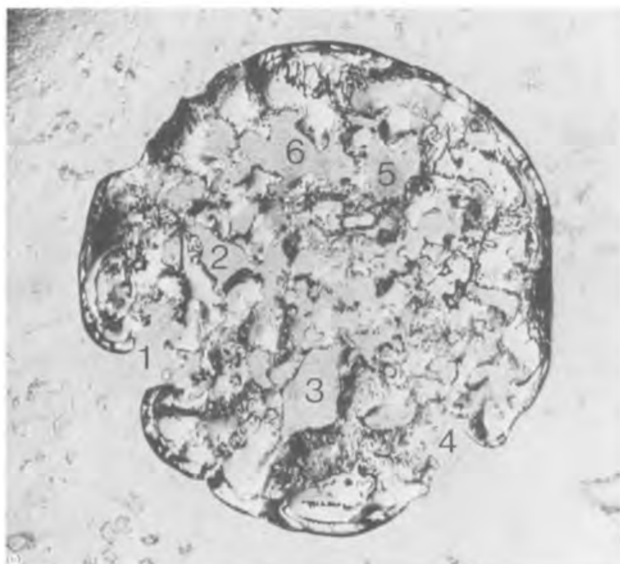

Fig. 6. Defects in the epilayer caused by a defective electric contact. The numbers indicate the defects (a) in the epilayers; and (b) in the corresponding defects in the electric contact.

between the Ga foil and the graphite pedestal (Fig. 1) (2). This assembly was heated at 940°C for 1½ hr prior to the growth experiment. At this temperature Ga is quite soluble in Ta so that the extent of the dissolution of the substrate by the Ga layer is significantly decreased and the electric contacts become very uniform as indicated by the elimination of the random fluctuations of the epilayer thickness. Thus, the role of the Ta foil is to decrease the effective thickness of the gallium layer involved in establishing the electric contact with the substrate.

Systematic thickness variations. Large horizontal temperature gradients in solution.—Epitaxial layers were grown from solutions with a horizontal thermal gradient of 2.5°C/cm at 900°C and a current flow of 30A (resistance of the system 0.25Ω). The substrate was n-type (2×10^{17} carriers/cm^3), its thickness was 450 μm, and its area 1.2 cm^2. Three solution heights were used—0.3, 0.6, and 1.2 cm. The results are shown in Fig. 7.

It should be first pointed out that the increased thickness near the edge of the epilayers is due to the fact that the diameter of the pedestal is larger than the diameter of the solution well, which leads to an increased current density near the wall of the well. When the diameter of the pedestal is smaller than the diameter of the solution well, the thickness of the layers near their periphery is decreased (see below) due to decreased current density. In the subsequent discussion of thickness variations, the thickness near the edges will not be taken into consideration.

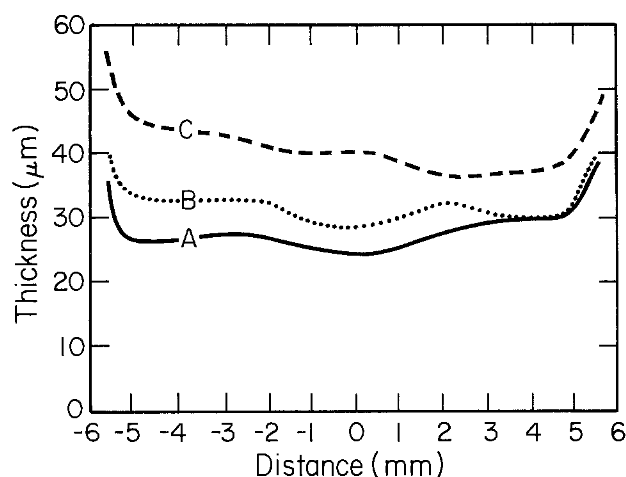

Fig. 7. Thickness profiles after 10 min of growth in the presence of a large horizontal temperature gradient (2.5°C/cm) at 900°C with a current of 30A; solution height: curve A, 0.3 cm; B, 0.6 cm; C, 1.2 cm.

A comparison of the layer thickness after 10 min of growth shows that when the solution height increases from 0.3 to 0.6 cm, the growth rate increases by 15%; when the height increases from 0.6 to 1.2 cm the growth rate increases by 35%. This increase in growth rate with increasing solution height indicates increased transport of As to the growth interface which is attributed to increased convective flow (12).

If the As transport to the interface is controlled by convective flow, the thickness profiles B and C in Fig. 7 must reflect the pattern of the convective flow (14). The thickness variations in case A of Fig. 7 are not controlled by convective flow, as is discussed below.

It is of interest to consider the magnitude of the Grashof number, Gr, (a criterion of convective flow) for the above solution

$$\mathrm{Gr} = \frac{\alpha g}{\nu^2} \Delta T h^4 / w \qquad [1]$$

where α is the coefficient of thermal expansion (10^{-4}) (15); ν is the kinematic viscosity (10^{-3} cm^2/sec) (15); g is the gravitational constant (10^3 cm/sec^2); ΔT is the horizontal temperature difference across the solution (~2.5°C), h is the solution height, and w is the width of the cell (1.2 cm). Thus, for h = 1.2, 0.6, and 0.3, Gr is approximately 2×10^5, 5×10^4, and 2×10^3, respectively. In solutions with a Grashof number of this magnitude and a Prandtl number ($\mu c_p/\kappa$, where κ is the thermal conductivity, μ is the absolute viscosity, and c_p is the specific heat) of about 10^{-2}, which is typical for metallic solutions (16), significant convective flow should be present. Thus, for Gr of the order of 10^4 the flow velocity should be about 10^{-2} cm/sec (16).

It is of interest to point out that the growth rate and the thickness profile of the layers grown from solutions with a height of 0.3 cm (Gr $\simeq 2 \times 10^3$) is the same as that of layers grown from solutions with the same height under the same current density but with a ΔT across the solution an order of magnitude less (Gr $\approx 10^2$) than that in the above experiment. As is seen below, the layers grown under very small horizontal thermal gradients exhibit no thickness variations attributable to convective flow. Thus, in the case A of Fig. 7 (Gr $\approx 2 \times 10^3$) convective flow (expected to be about 10^{-3} cm/sec) (16) does not seem to cause variations in the layer thickness.

On the basis of the experimental values and the above approximate calculations it appears that the growth process in the present case is not affected by convective flow until Gr exceeds a value of the order of 10^4. It is not understood at this time why such a

relatively high value of Gr is necessary before significantly convective flow is present in the solution to affect the growth process. It is possible that a stabilizing solute (As) boundary layer is present. However, no quantitative data are available at this time to determine the thickness of such a stabilizing solute layer.

Systematic thickness variations. Very small horizontal temperature gradients in solution.—Very small horizontal thermal gradients in the solution were obtained by the procedure described above whereby the position of the growth cell in the furnace was so chosen as to compensate the gradients that joule heating would introduce. Employing this procedure, layers 0.5 cm^2 were grown at 900°C on semi-isolating Cr-doped substrates 350-450 μm thick from solutions varying in height from 0.5 to 1.2 cm under current densities of 5, 25, 50, and 60 A/cm^2. The horizontal gradients ranged from 0.05°C/cm for a current density of 5 A/cm^2 to 0.15°C/cm for current density of 60 A/cm^2 (the temperature was higher at the side of the current carrying rods).

The results are shown in Fig. 8 and 9 for a solution height of 0.7 cm. Excluding the thickness near the edges, for reasons pointed out above, it is seen (Fig. 8) that for a current density of 5 A/cm^2 there is a decrease in thickness from right to left. As the current density increases (Fig. 8) the thickness becomes fairly uniform. This fact and the fact that the growth rates were found to be independent of the solution height indicate that no convective flow was present affecting the growth process.

The decrease in thickness from right to left in Fig. 8 is believed to be associated with the systematic small

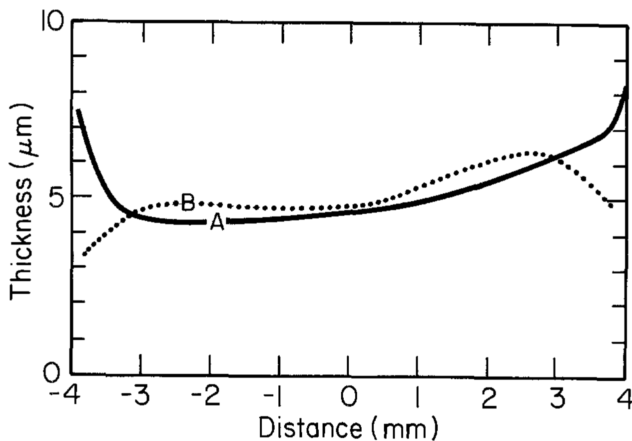

Fig. 8. Thickness profiles after 10 min of growth at 900°C with a current density of 5 A/cm^2 in the presence of a very small temperature gradient. Curves A and B were obtained with graphite pedestals of different diameters (see text).

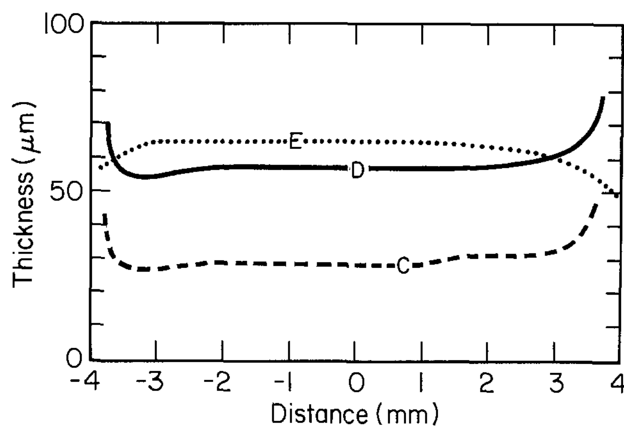

Fig. 9. Thickness profiles after 10 min of growth at 900°C in the presence of a very small temperature gradient: current density; curve C, 25 A/cm^2; D, 50 A/cm^2; E, 60 A/cm^2.

variation of the current density across the growth interface due to the geometry of the system. Since both current-carrying rods are located on one side of the growth cell, it is expected that the resistance to current flow will be smallest, the current density will be largest, and thus the thickness of the layer will be largest on that side of the cell.

At increased current densities (Fig. 9) apparently the effect of the current density gradient (an increase in growth rate from right to left) is essentially compensated by the effect of the 0.15°C/cm horizontal thermal gradient (an increase of the growth rate from left to right); another compensating factor is perhaps diffusion of As from areas of higher current density [higher As concentration due to electromigration (4)] to areas of lower current density (lower As concentration).

Summary

Although electroepitaxy has been used for several years for the successful growth of III-V compound layers and devices, the role of various experimental parameters on the characteristics of the layers has not as yet been extensively studied. The present work is concerned with parameters affecting the thickness uniformity of the layers.

Two types of epilayer thickness variations were observed: random fluctuations and systematic variations. The random fluctuations were found to be associated with nonuniform current density at the growth interface, resulting from random defects in the electric contact to the substrate. Random fluctuations were also found to result from fluctuations in the resistance across the substrate, which in turn were caused by fluctuations in the depth of substrate dissolution by the Ga contact layer. For relatively thin substrates the dissolution depth represented a significant fraction of their thickness since a relatively thick layer of Ga (~150 μm) is necessary for a satisfactory spread. These fluctuations were eliminated by placing a tantalum foil in contact with the gallium layer. This foil dissolves part of the gallium when the assembly is heated to establish electric contact. Thus, the Ta foil essentially decreases the effective thickness of the gallium layer and thus the extent of dissolution of the substrate by the gallium.

In the presence of convection in the solution the thickness profile of the layers was found to reflect the convective flow pattern in the solution. The primary cause of convection was identified with the horizontal temperature gradients resulting from joule heating which was found to be more pronounced at the contacts of the current carrying rods and the graphite segments. Convective flow affecting the growth was observed for Grashof numbers greater than about 10^4. Convective interference was eliminated by minimizing the temperature gradient across the solution through reduction of the system's resistance and by positioning the solution well in the furnace so that the horizontal gradient in the solution prior to current flow was of the same magnitude but opposite sign to that induced by joule heating. The thickness profiles of the layers grown without convective interference were found to reflect the gradient of the current density across the growth interface associated with the geometry of the growth system and a very small horizontal temperature gradient due to joule heating. These two effects compensated each other at high current densities, and thus epilayers with the most uniform thickness were obtained at current densities of 50-60 A/cm^2.

Although random thickness fluctuations and convective interference were minimized or essentially eliminated, work for achieving epilayers with perfectly uniform thickness continues.

Silicon Oxidation Studies: The Oxidation of Heavily B- and P-Doped Single Crystal Silicon

E. A. Irene* and D. W. Dong*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The present oxidation study covers the 780°-1150°C temperature range using 0.001 Ω-cm Si which is heavily B- and P-doped Si ($6\text{-}8 \times 10^{19}$ cm^{-3}) in dry O_2 (<1 ppm H_2O). Emphasis is on the lower temperatures thereby extending the scope of already published studies. For 0.001 Ω-cm Si at temperatures greater than 1000°C, the over-all oxidation rates were found to conform to the order

B doped > P doped > STD

(where STD is 2 Ω-cm B-doped Si), which is in agreement with published results for the higher temperatures. However, for the lower oxidation temperatures of the present study (≤1000°C), the order for the over-all oxidation rates was found to be

P doped > B doped ≥ STD

The oxidation data was taken using an automated ellipsometer *in situ* and was analyzed using a linear-parabolic oxidation model. The resulting linear rate constants could be correlated with well-known B depletion and P accumulation effects near the Si-SiO_2 interface while a consideration of the structural roles of B and P in the SiO_2 network was necessary to explain the parabolic rate constants. Phase separation of B_2O_3 occurred in the SiO_2 grown on B-doped Si and Si precipitation was observed in all the oxides grown at 1150°C but neither of these phenomena are believed to affect the oxidation kinetics. The extended temperature range showed non-Arrhenius behavior which could explain the divergent activation energies reported from published studies.

An understanding of the oxidation kinetics for single crystal silicon which has been heavily doped (~10^{20} cm^{-3}) with donor or acceptor impurities is important in the practice of planar technology. Previous studies on this topic (1-5) have shown that a redistribution of the electrically active impurities (As, B, P, etc.) occurs during the thermal oxidation of Si. Specifically, it was discovered (3, 4) that during oxidation the acceptor impurities studied (Al, B, Ga, and In) depleted near the Si surface while the donor impurities studied (As, P, Sb) piled up at the Si surface. The extent to which the redistribution occurs depends on the oxidation temperature and ambient 3-5). At lower temperatures and in an H_2O-containing oxidation ambient, B depletes more and P accumulates more. In order to understand these observations several factors are important. First, the relative solubilities of the impurity in Si and SiO_2 are important with donor impurities usually being relatively more soluble in Si (3). Second, the diffusivity of the impurity in SiO_2 is important with B having a slightly larger value than P at lower temperatures (6) but in an H_2O-containing ambient the diffusivity of B in SiO_2 increases several orders of magnitude.

By utilizing the linear-parabolic model for Si oxidation (7) in conjunction with the published redistribution effects and the fact that the Si dopants increase the oxidation rate when they affect it at all (5), the kinetics of the oxidation of heavily B- and P-doped Si can be qualitatively predicted. In the

linear-parabolic model, the linear rate constant, k_L, is correlated with the reaction between the Si surface and oxidant, while the parabolic rate constant, k_P, is related to the diffusion of oxidant through the SiO_2 film. Then, it is predicted that at lower oxidation temperatures (<1000°C) where P accumulates and B depletes maximally, an accumulation of P at the Si surface will increase k_L maximally and the depletion of B from the surface should yield a minimal effect on k_L. At higher temperatures, where the B depletion is less, the effect on oxidation of a heavily B-doped Si surface on k_L should be observed. In order to predict changes in k_P values, the structural implications of B and P on the SiO_2 network must be assessed (8, 9). The role of P in SiO_2 is to substitute for Si in the network. The P in SiO_2 is tetrahedrally surrounded by O atoms similarly to Si in Si-O_4 tetrahedra, except that in the P-O_4 tetrahedra one of the O atoms is doubly bonded to P which precludes that O atom from bridging to an adjacent tetrahedron. A loosening of the SiO_2 network results. The net effect of this loosening on oxidation kinetics would be to increase k_P and it would be more pronounced at lower experimental temperatures where other network loosening mechanisms are minimized (such as thermal expansion and thermal vibration). The substitution of B in the SiO_2 network is difficult in low alkali SiO_2. This is due to the fact that B preferentially forms a three coordinate planar trigonal arrangement of O atoms which is structurally incompatible with the Si-O_4 tetrahedra. Consequently, a study aimed at defining the subliquidus miscibility gap in the SiO_2-B_2O_3 system (10) has shown that phase separation extends to the Si phase boundary with an upper consolute temperature of ~520°C. However, the effect of phase separation on the oxidation kinetics would be minimal because the amount of B_2O_3 phase is less than 1 mole percent (m/o) and the separation would not occur above 600°C, *i.e.*, during oxidation. An alternate mechanism has been proposed (11) in which a large number of oxygen vacancies are created when B cations enter the SiO_2 network. These defects occur as BO_3 is oxidized to BO_4 and are most likely to occur at higher temperatures where thermal vibrations create the greatest number of broken bonds. Therefore, the effect of B should be to increase k_P predominantly at high temperatures.

In order to test these predictions of the effect of B and P on k_L and k_P values, the oxidation data already published (5) needs to be extended to cover a broader temperature range, in particular lower temperatures. Also, the data need to be generated in a well-defined ambient and analyzed according to the linear-parabolic model. For these purposes an automated ellipsometer which can observe oxidation *in situ* (12, 13) was used to obtain oxidation data in pure dry O_2 (<1 ppm H_2O) (13, 14) over the temperature range 780°-1040°C and with point by point measurements up to 1150°C. The resulting data were analyzed for k_L and k_P values using a previously developed iterative least squares technique (13). Transmission electron microscopy (TEM) was used to survey whether any obvious morphological changes could explain the kinetic results.

Experimental Procedures

Wafer preparation.—The B-, P-, and As-doped Si slices were commercially acquired 3.2 cm diam, 0.025 cm thick, <100> oriented chem-mechanically polished Si slices. They were purchased as having a nominal bulk resistivity of 0.0008-0.0012 Ω-cm. Measurements at our laboratory yielded average values of 0.0016 Ω-cm for B-doped, 0.0009 for P-doped, and 0.0022 for As-doped material, all values within ±5% across the wafers. These resistivity values correspond to concentrations of about 6×10^{19} cm^{-3} for B-doped and 8×10^{19} cm^{-3} for P-doped material.

Prior to oxidation the wafers were thoroughly cleaned by a previously detailed procedure (14). For transmission electron microscopy observations, 3 × 3 mm chips of Si with the SiO_2 film on one side were prepared by a previously outlined procedure (15).

Gas purity.—The moisture content of O_2 and its effect on Si oxidation kinetics has been the subject of several previous studies at our laboratory (13, 14, 16). The gaseous O_2 used for the present study is from boil-off of liquid oxygen and has been purified by a previously published procedure (14) which removes hydrocarbons and thereby reduces the H_2O content to less than 1 ppm as measured at the oxidation tube exit under oxidation conditions.

Ellipsometry.—The automated ellipsometer which can measure oxide thickness while oxidation is occurring, *in situ*, has been described previously (12). The procedures for the use of the automated ellipsometer, temperature calibration, and optical constants used for ellipsometry calculations have also been previously published (12, 13). The analyses of thickness (d) and time (t) data have been done by a linear least squares technique (13). Preliminary ellipsometry measurements made on oxide grown on heavily B- and P-doped Si have shown that the doping does not alter the optical constants or procedures used for the ellipsometry performed on undoped silicon.

Results and Discussion

Over-all oxidation rates.—From the thickness-time oxidation data presented in Fig. 1a-f, several observations can be made. First, when B and P affect the oxidation rate, both dopants enhance the rate as previously reported [see for example Ref. (5)]. At the higher experimental temperatures (1040° and 1150°C) and for thicker films the heavily B-doped Si exhibits a higher over-all rate than P-doped and lightly doped Si, again in nominal agreement with a previous study (5). However, at lower oxidation temperatures, the heavily P-doped Si exhibits the highest over-all rate and the heavily B-doped Si has about the same rate as lightly doped material. Although, this is not in agreement with published results (5), our results are more extensive at the lower temperatures and the trends in our data are predictable based on published depletion and accumulation effects (3-5) as presented below. The crossover in the oxidation rates between the heavily P- and B-doped Si occurs for the 1040°C oxidation at about 2000Å. Finally, one experiment using heavily As-doped Si displayed the same oxidation behavior as for heavily P-doped Si but with a slightly lower over-all oxidation rate. In order to gain further insight into the "crossover" behavior between P and B as a function of temperature the linear, k_L and parabolic, k_P rate constants need to be considered.

Rate constants.—The k_L and k_P values are shown in Table I. The errors associated with the 780°-1040°C data are less than 10% and are primarily due to the approximate nature of the linear-parabolic model (13). For the 1150°C data the errors are estimated to be larger but less than 20%, and the increase is due to larger curve fitting errors with the fewer available data points. In accordance with the predictions made earlier which are directly deduced from previous impurity redistribution studies (3-5), the k_L values for B at the lower oxidation temperatures do not show any enhancement effect due to B, since B is expected to deplete maximally at these temperatures; P shows an enhancement effect on k_L at all temperatures due to the accumulation effect. Also as predicted, at the highest temperatures of the present study (1150°) where the B-depletion effect is minimum, the k_L is considerably higher than for P. The fact that the over-all rate for heavily P-doped Si is greater than B for the thinner films even at 1040°C is clearly seen as a k_L effect. For thinner films k_L is dominant and k_L for heavily P-doped Si is greater than k_L for heavily B-doped Si up to 1040°C.

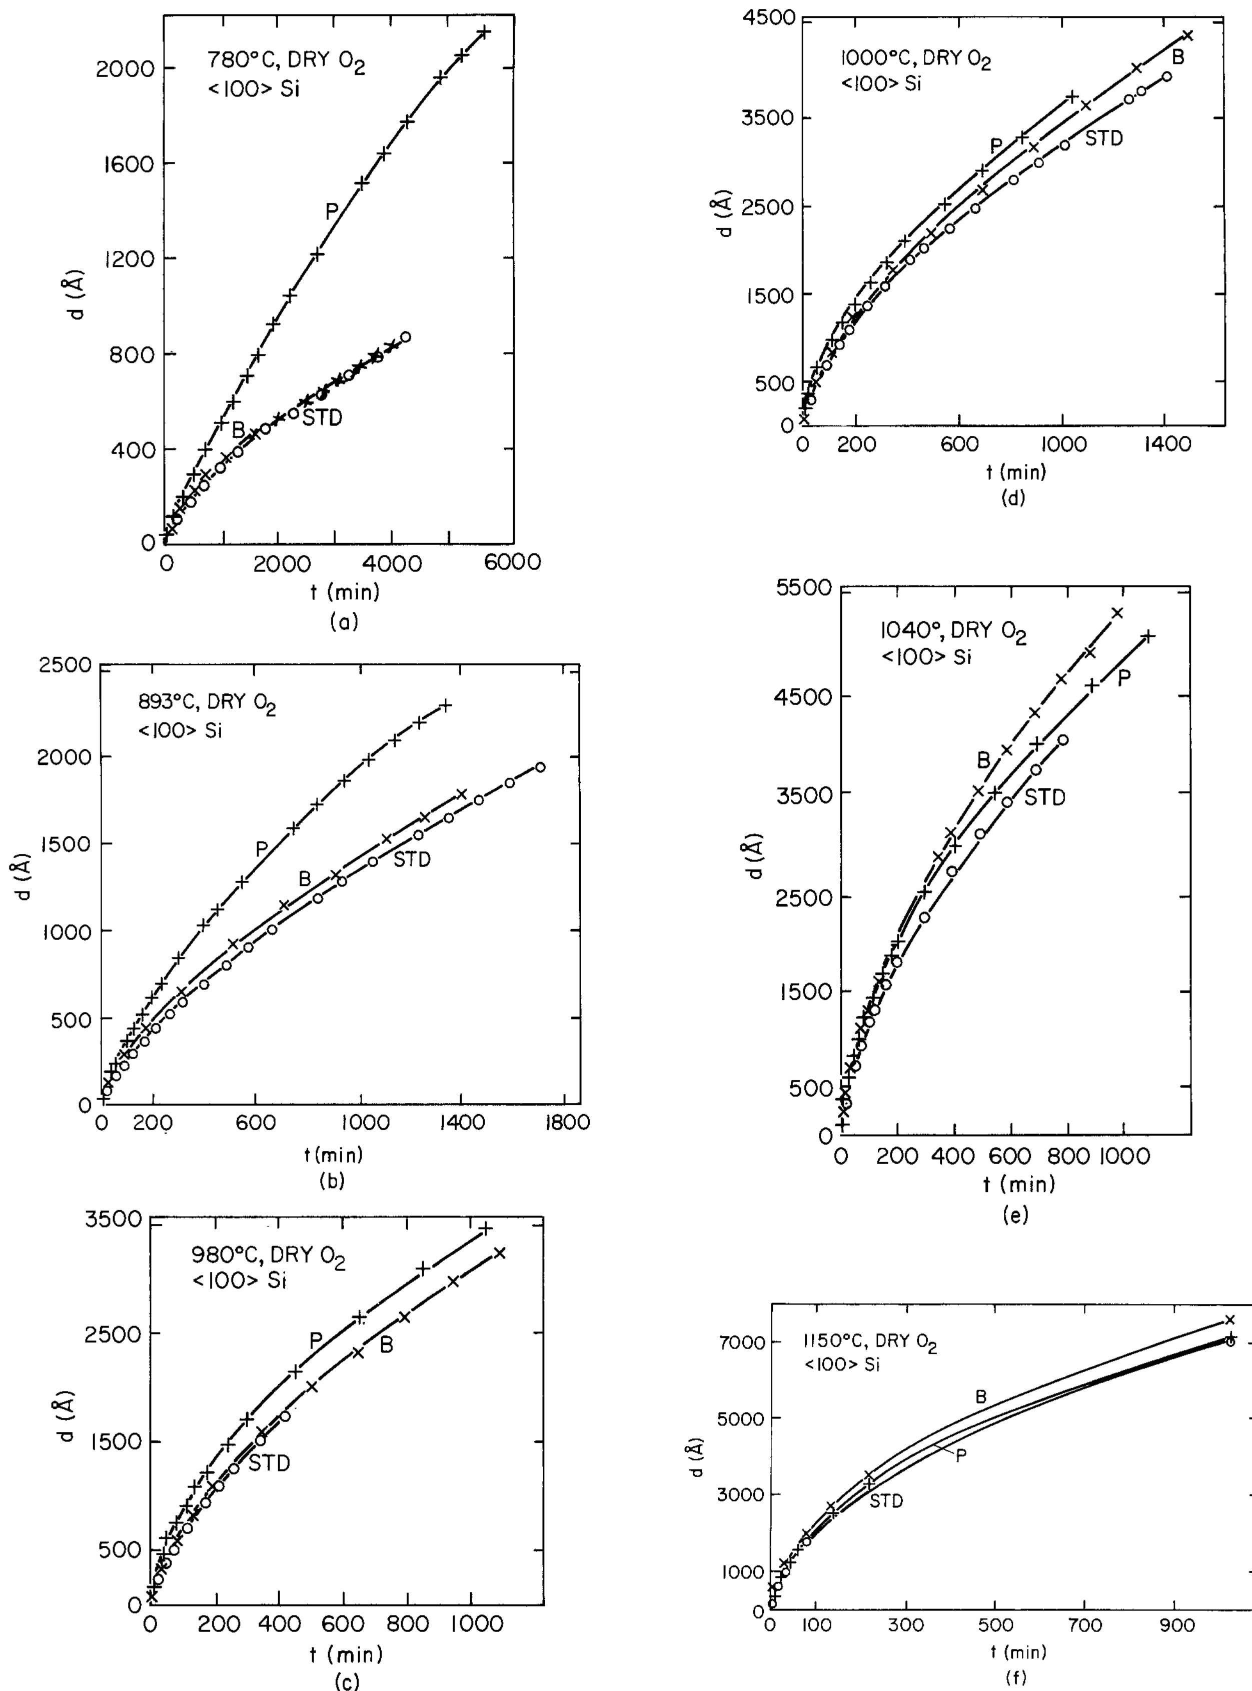

Fig. 1. Plots of SiO_2 film thickness, *d* (Å), *vs.* oxidation time, *t* (min), for heavily B (X), and P (+) doped Si against lightly doped Si (O) showing every fifth data point at (a) 780°C, (b) 893°C; (c) 980°C; (d) 1000°C; (e) 1040°C; and (f) 1150°C, all the data are shown.

Therefore, the crossover which occurs for larger thicknesses at 1040°C must be a k_P effect. The observation that both heavy B and P doping of Si causes an increase in k_L may be related to the fact that these impurities cause a substantial increase in the total (neutral plus ionized) vacancy concentration in Si (17). An enhanced vacancy concentration at the Si surface increases the number of Si atoms exposed to oxidant (by forming ledges, steps, etc.) thereby enhancing the amount of reaction at the surface.

The k_P for heavily P-doped Si is clearly greater than the standard at the lower temperatures as predicted. The network loosening attributable to P is lost at high temperatures where thermal vibrations

* The maximum spread in k_L and k_P values is less than ± 10%.
** The errors in d_o values are estimated to be ± 50A for STD values and ± 100A for B and P data. The 1150°C data has a larger error of about ± 150A due to having only 10 data points per curve.
† 200A represents the maximum value considering a large scatter.

and expansion dominate. However, even larger amounts of P in SiO_2 than in the present study should extend the enhanced k_P to higher temperatures.

In addition to the enhanced k_L for heavily B-doped Si at high temperatures due to less B depletion, the k_P for B is also enhanced. This latter effect is consistent with Kang's arguments (11) which are predicated on defect equilibria being shifted toward larger defect concentrations at higher temperatures. The B effect on k_P requires many network bonds to be broken as $B\text{-}O_3$ changes coordination to become $B\text{-}O_4$. This can most easily occur at higher temperatures where the network vibrations are largest and simultaneously during interstitial diffusion of oxidant where there exist large forces exerted on the network. The net effect of B on k_P is a large enhancement at temperatures above 1000°C and hence gives rise to the crossover between P and B.

It is also interesting to note the variation of d_o values with temperature. As defined in the present study, d_o represents the upper thickness limit of the initial oxidation regime which does not conform to linear parabolic kinetics (7, 13, 14). The values of d_o are found using the iterative linear least squares analysis previously described (13). From Table I it is seen that d_o values for all the samples increase with temperature in the low temperature regime as previously reported for lightly doped material (13) but at higher temperatures the d_o values decrease. The smaller values of d_o mean that the oxidation data conform to linear-parabolic kinetics earlier during oxidation. The observation that d_o values go through a maximum near 1000°C suggests a change in oxidation mechanism near this temperature. The values of d_o near 200Å for higher temperature oxidation data agrees with a previous study (7).

Activation energies.—With k_L and k_P values over an extended temperature range, further insight into the oxidation mechanism may be obtained by interpreting the activation energies calculated according to an Arrhenius equation of the form

$$k = k_o e^{-Ea/RT}$$

Figure 2 shows that neither the linear nor parabolic rate constants obey the above Arrhenius equation. This probably means that both k_L and k_P represent a composite rate constant rather than a kinetically simple step. Therefore, a straightforward interpretation of the E_a values is not possible.

The curvature of the Arrhenius plots suggests that the discrepancies which exist between previous studies (7, 13) may be due to the different temperature ranges used. To clarify this situation, E_a values were calculated by least squares analysis of four k_L and k_P values at the lower temperatures (780°, 893°, 980°, and 1000°C) and separately using four k_L and k_P values at the highest four temperatures (980°, 1000°, 1040°, and 1150°C). These E_a values as well as the literature values are compared in Table II. Since one study considered mainly higher temperature data (7) and the other lower temperature data (13), the discrepancy

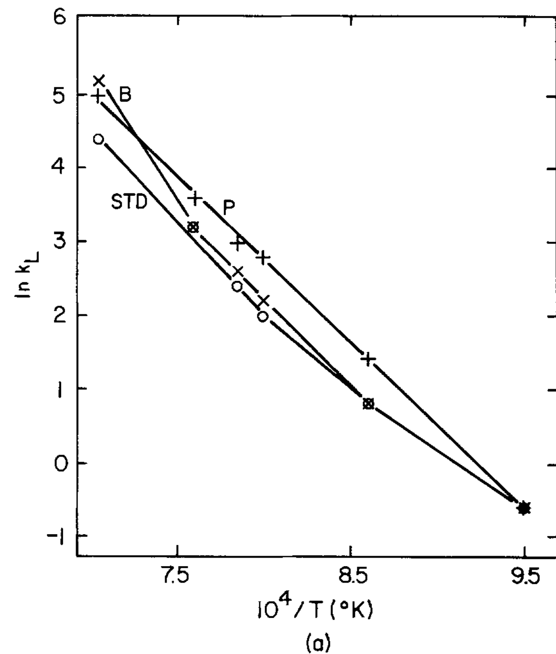

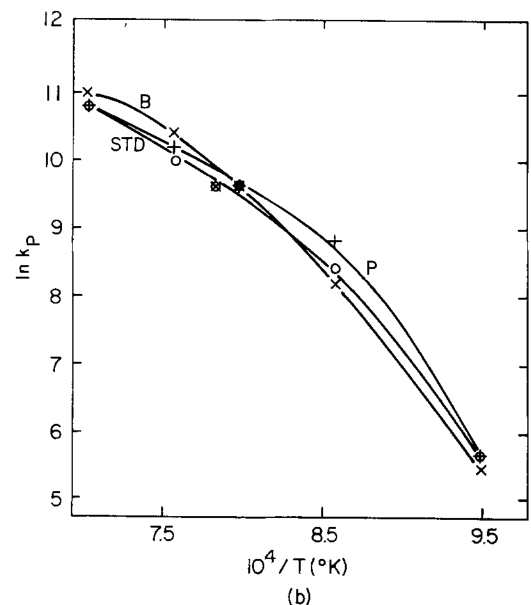

Fig. 2. Arrhenius plots of (a) ln k_L vs $1/T$ and (b) ln k_P vs. $1/T$ for the data from Table I.

is clearly due to the non-Arrhenius behavior. Even though one study (7) used <111> Si while the other used <100> Si, it was previously shown (14) that there is less than ±0.2 eV difference between E_a values for <111> and <100> Si orientations in the same temperature interval.

Transmission electron microscopy (TEM).—Samples of SiO_2 grown on heavily P- and B- doped Si as well as lightly doped Si at 780° and 1150°C were compared by TEM. The TEM investigation was directed at finding microstructure (such as voids or channels) which could account for the differences in diffusion behavior. However, except for two observations relating to the appearances of microphases and described below, there were no differences in the different films resolvable in the present TEM study. As to be discussed, the microphase phenomena cannot explain the kinetic results. Therefore, based on this negative TEM result, it is concluded that the diffusion enhancement caused by P in SiO_2 at lower temperatures and B in SiO_2 at higher temperatures is due to the creation of smaller defects (<20Å) than resolvable in the present study by TEM and probably involves network defects as hypothesized by Kang (11).

As shown in Fig. 3, certain areas of the SiO_2 films grown on heavily B-doped Si at 1150°C and to a lesser extent on 780°C grown SiO_2 displayed an amorphous microphase. Since B_2O_3 is expected to phase separate due to structural incompatibilities (8-10), we believe that the microphase is amorphous B_2O_3. As estimated from the micrographs the B_2O_3 phase comprises about 0.5% by volume of the film. However, since the regions of SiO_2 film which displayed phase separation were widely separated, a more realistic estimate would be about 0.05%. If all the B were incorporated in the SiO_2, about 0.3% B_2O_3 would be expected. Considering the large errors in estimating the volumes from micrographs and the possibility of loss of B during oxidation, the agreement is reasonable. Because phase separation in the amorphous B_2O_3-SiO_2 system occurs on cooling from the oxidation temperature to about 520°C (the upper consolute temperature), there should be no effect on the oxidation kinetics.

In addition to the B_2O_3 microphase in B-containing SiO_2 samples, Si islands were observed in all the SiO_2 films grown at 1150°C, and an example is shown in Fig. 4. The distribution is sparse as most areas observed has no Si islands. Selected area diffraction and dark field techniques positively identified the islands as crystalline Si (Fig. 4). Only rarely was the same structure seen for films grown at lower temperatures. The fact that this microstructure occurs predominantly at the high temperatures suggests that a disproportionation reaction with chemical transport is taking place. A reaction such as

$$Si(s) + SiO_2(s) = 2SiO(g)$$

goes further to the right at higher temperatures near the Si-SiO_2 interface The gaseous SiO produced diffuses away from the interface into the SiO_2 film and equilibrates producing Si(s) and SiO_2(s). At the high temperatures a larger amount of SiO(g) is produced, and the Si which comes from SiO has enough mobility to form islands. Thermochemical calculations have shown that at 1150°C the partial pressure of SiO(g) is about 10^{-3} atm. That pressure of SiO(g) would provide a pressure of Si(g) of more than 10^{-6} atm at 1150°C. At 1150°C the saturation pressure for Si is about 2×10^{-5} atm. Therefore considering a nonideal system the conditions for the production of free Si in SiO_2 can occur. However, since this effect was seen for the standard, as well as for B- and P-doped SiO_2 films

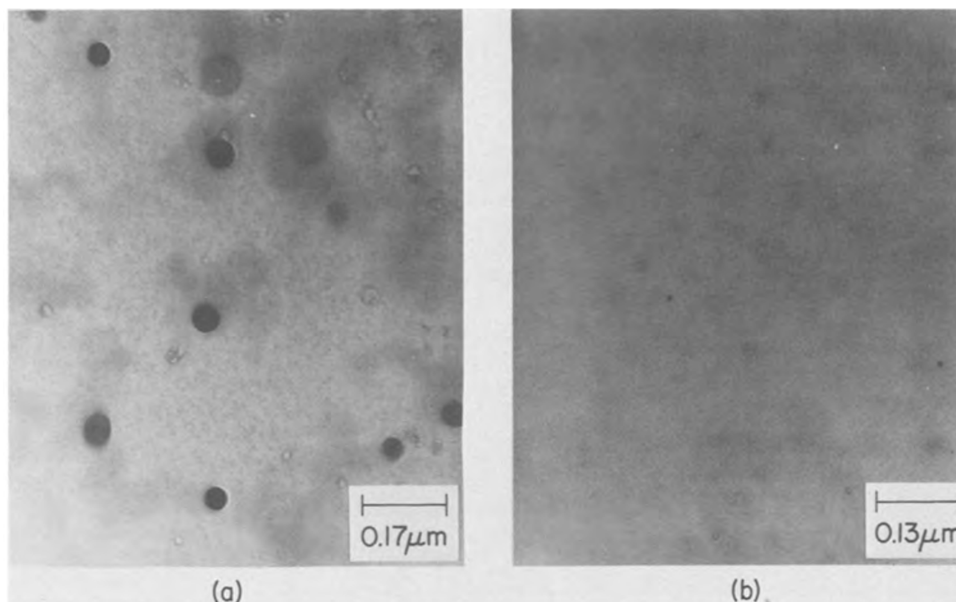

Fig. 3. TEM micrographs showing B_2O_3 phase separation at (a) 1150°C and (b) 780°C in SiO_2 films grown on heavily B-doped Si.

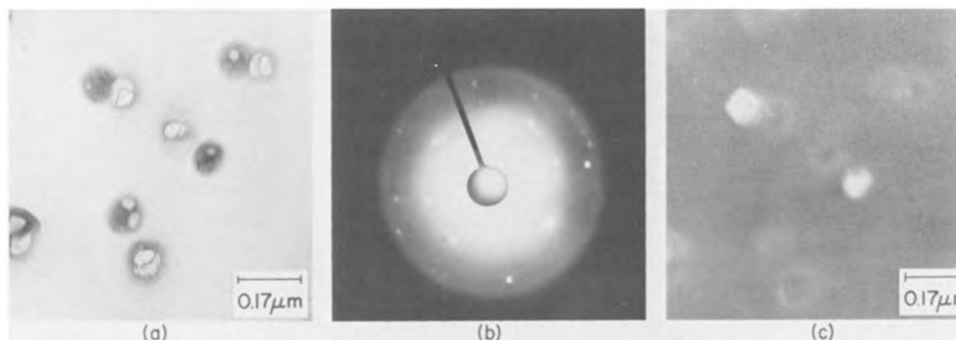

Fig. 4. TEM micrographs showing typical Si island formation in SiO_2 films grown at 1150°C on lightly doped Si (a) bright field, (b) selected area diffraction, (c) dark field.

at 1150°C, no impurity driven effect on oxidation is attributed to the Si precipitation.

Since this study deals with the oxidation of heavily B- and P-doped Si, the B_2O_3 phase separation effect and the Si precipitation effect will be discussed at greater depth in a future publication.

Conclusions

From an extension of the oxidation data for heavily B- and P-doped Si to lower temperatures and an analysis of the data in terms of the linear-parabolic model several conclusions are made:

1. P primarily increases the over-all oxidation rate at lower temperatures while B is more effective at the higher oxidation temperatures.
2. The accumulation of P and depletion of B at the Si surface explain the variation of k_L values with temperature.
3. The enhancement effect of P on k_P is due to a loosening of the SiO_2 network. When P substitutes for Si in Si-O_4 tetrahedra, fewer bridging oxygens are provided. The net loosening effect is most pronounced at lower temperatures where other network loosening factors are smaller.
4. The enhancement of k_P due to B is due to the creation of defects when B-O_3 is oxidized to B-O_4. This mechanism is favored at higher temperatures where bonds are more likely to be broken.
5. TEM supports the atomistic arguments to explain the k_P results, since no morphological differences were found in the various oxides which could be correlated with an enhanced diffusion of oxidant.
6. Over the extended temperature range of the present study, the Arrhenius relationship is not obeyed. Hence there is no straightforward interpretation of E_a values. However, divergent results from two previous studies (7, 13) are explained based on the Arrhenius plots.

High Oxygen Czochralski Silicon Crystal Growth Relationship to Epitaxial Stacking Faults

L. E. Katz* and D. W. Hill

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

With larger diameter Czochralski-grown silicon crystals an increase in the oxygen content is observed. Oxygen in excess of the solubility limit will precipitate resulting in bulk crystal defects which can modify gettering of impurities known to degrade electrical characteristics. In this study we have investigated crystal growth parameters and related them to the properties of the crystal. Wafers were processed from crystals grown under various conditions. Defect formation was evaluated as a function of processing and related to the crystal properties. By growing 2 in. diam crystals at high seed rotation rates so as to maximize the oxygen content, we were able to suppress saucer etch pit formation and epitaxial stacking fault formation. The high oxygen content crystals behaved in the same manner as 3 in. diam crystals with respect to defect formation.

With the general introduction of larger diameter (3 in. or greater) Czochralski grown silicon crystals the oxygen content becomes of increasing concern due to the greater incorporation into the crystal during crystal growth and subsequent modification of defect formation during processing. Recently, correlations between process-induced defects and the interstitial oxygen content of the wafers being processed have been made (1-3). Defects studied have typically been saucer or shallow etch pits, oxidation-induced stacking faults, bulk stacking faults, epitaxial stacking faults, and precipitates.

* Electrochemical Society Active Member.

Key words: crystal growth, epitaxial stacking faults, oxygen in silicon, silicon defects.

The interstitial oxygen content can be controlled simply by selecting those crystals or wafers with the lowest oxygen content, by heat-treatment of the wafers to lower the interstitial oxygen content near the wafer surface (4), or by crystal growth modification.

Conceptually, oxygen in silicon can be both beneficial and harmful. Oxygen in excess of the solubility limit can precipitate with the subsequent formation of bulk stacking faults bounded by partial dislocations. Such defects, if penetrating the active device area, may prove harmful to junction characteristics. On the other hand, proper control over the positioning of the oxygen-induced defects can be potentially beneficial since they can act as gettering sites. Ideally, one might prefer to have the surface and perhaps the first 20-30 μm in depth void of bulk oxygen defects, while confining the bulk oxygen defects to the central portion (in depth) of the wafer. This can be controlled by proper processing (4).

It has been found that epitaxial stacking faults sometimes formed during standard buried collector integrated circuit fabrication (3). The nucleation sites for the stacking fault formation were suppressed in the regions which received an Sb buried collector diffusion. If the diffusion was carried out from an ion implanted source, subsequent formation of the epitaxial stacking faults was also suppressed in the non-Sb diffused regions. This was attributed to implant damage lateral gettering (3). A study of the epi stacking fault nucleation and growth mechanism (5) for similar standard buried collector transistor processing as discussed above indicates the nucleation process to be complicated and involving precipitates, dislocation, and voids as well as Ni and/or Cu contamination. The purpose of the work described in this paper was to: (*i*) investigate crystal growth parameters and relate these to the various characteristics of the crystal (interface shape, radial resistivity variation, and carbon and oxygen content using ASTM procedure F-121); (*ii*) process wafers from the various crystals through buried collector and epitaxial deposition and evaluate defect formation following each high temperature operation; and (*iii*) correlate the defect formation with the crystal properties.

Experimental

Dislocation-free silicon single crystals doped to $10^{15}/cm^3$ range and of (111) orientation were grown from 5.5 kg melts. Typically, the seed and the crucible containing the molten silicon are counter rotated. The crystal growth variables studied here were seed and crucible rotation rates which were varied from 5 to 40 rpm (seed) and 2 to 20 rpm (crucible). Following crystal growth, a section ~25 cm long from the seed end of each crystal was heat-treated to annihilate the donors formed during crystal growth. The remainder of each crystal was intentionally not heat-treated for comparative purposes. Following centerless grinding, slicing, and polishing, wafers were processed through epitaxial deposition. An outline of the processing sequence is presented in Table I. Two lots of 100 wafers each were processed. Each lot contained random wafers from the first section (seed end) of each crystal. The first section consisted of two parts, A and B, where A was subjected to the oxygen stabilization heat-treatment and B was not. Wafers from each of the sections were removed for analysis following each high temperature operation.

Table II. Rotation rates and carbon and oxygen content of seed and rear end of crystal

RPM		Oxygen (PPMA)		Carbon (PPMA)	
Seed	Cruc	Seed	Rear	Seed	Rear
40	20	58	37	0.37	1.35
40	10	45	28	0.37	1.10
40	2	52	33	N.D.	1.03
20	20	51	33	0.36	2.00
20	10	33	28	1.11	2.95
20	2	41	26	0.57	2.42
10	5	35	26	1.11	3.21
5	2	34	27	0.57	2.02

The crystals were evaluated with respect to (*i*) carbon and oxygen content using infrared techniques (6),[2] (*ii*) solid-liquid interface shape using chemical etching (8), (*iii*) radial and longitudinal resistivity uniformity using the spreading resistance technique, and (*iv*) defect formation and distribution using the Secco etch (9) for wafers processed up to epi and interference contrast microscopy for the epi wafers.

Experimental Results and Discussion

Crystal properties.—Carbon and oxygen content.— Table II shows the seed and crucible rotation rates as well as carbon and oxygen content at the seed and rear end of the heat-treated section of the crystal. The rear in this case represents a distance approximately 25 cm from the seed end representing ~1/3 of the solidified portion of the crystal. An oxygen stabilization heat-treatment was carried out prior to infrared analysis. This treatment did not appreciably change the measured oxygen content. Carbon detection limits are ~0.35 ppm with the technique used, whereas all oxygen levels reported are well above detection limits. It is apparent that the oxygen concentrations are highest at the seed end of each section. The high seed rotation rate increases the oxygen content and the carbon behaves in an inverse manner to oxygen. Oxygen profiles were also taken across wafers from the various crystals. Results are similar to those presented by Rozgonyi *et al.* (3) and show that the peripheral regions of a wafer have lower oxygen content than the center.

The equilibrium segregation coefficient of oxygen in silicon is ~1 (10, 11) while that of carbon in silicon is ~0.07 (12). It is expected that vigorous crystal rotation may result in a departure from equilibrium. Kaiser and Breslin (11) have determined that the oxygen content of liquid silicon at its melting point is proportional to the bare silicon surface. Carruthers *et al.* (4) have shown that macro and microsegregation are dominated by thermal convection flows in the melt. In Czochralski growth, forced convection as accomplished by crystal rotation is used to modify the effects of thermal convection. Those authors (13) have discussed theoretically the effect of the thermal convection flows on segregation behavior. Hrostowski and Kaiser (14) have shown that crystals produced without rotation contain less oxygen than those which are rotated. This is presumably due to the stirring action of the rotating crystal supplying melt with high oxygen concentration to the growing interface (10). Their (14) observations are in line with the experimental observations presented here.

Interface shape.—Etching (8) of longitudinal sections taken from the seed end of the crystal after heat-treatment revealed there was little effect of seed or crucible rotation rate (over the range investigated) on the solid-liquid interface shape which was concave toward the melt. No faceting was observed. Interface shape is important since it is one factor related to the radial solute distribution, *i.e.*, radial resistivity uniformity. The lack of an interface facet is generally necessary in achieving good radial resistivity uniformity.

[2] For a more complete discussion see, Ref. (7).

Resistivity uniformity.—Radial resistivity traces using the spreading resistance technique were taken across the entire 2 in. diam. of heat-treated (oxygen stabilized) sections from each crystal. Readings were taken every 250 μm across the wafer. Results showed no clear cut trend. Flatter resistivity traces seemed to be associated with the 20 and 40 seed rpm. Absolute values in terms of concentration correlated with the bulk doping level.

In addition, longitudinal spreading resistance traces were taken at 5 μm intervals on sections cut parallel to the growth axis. Typically, a distance ~0.7 mm was scanned. Generally, the resistance profiles were flat to within a few percent.

Processing results.—Wafers from each crystal were processed through buried collector and epi. Figure 1 after initial oxidation and Secco etching (3) shows the various macroscopic etching patterns observed on wafers from three crystals. These are typical of the etching patterns observed for all oxidized wafers examined. The photographs were taken in dark field, hence regions which show up as light on the photograph appear as cloudy to the naked eye. These regions will be referred to as cloudy etched regions. Regions which are dark in the photograph are clear to the naked eye and will be referred to as clear etched regions. We define three types of etching patterns shown in Fig. 1 as: Type 1, uniform etch pattern, cloudy to the naked eye across the entire wafer; type 2, radial etch pattern, clear and cloudy etch regions; type 3, edge etch pattern, clear over most of the wafer and cloudy at the edge. The vast majority of wafers grown at 40 seed rpm exhibited type 3 behavior shown in Fig. 3. In most cases such wafers were clear across the entire wafer. Pattern type 1 and 2 were observed on wafers taken from crystals grown with a seed rotation rate of 20 rpm and below with type 1 being more prevalent at the lower seed rotation rate. There was no correlation with crucible rotation rate. It will later be shown that the clear etched regions do not result in epitaxial stacking faults whereas the cloudy regions do. In addition, wafers which were not subjected to the buried collector processing did not result in epitaxial stacking fault formation.

Figure 2 shows higher magnification photographs of the clear and cloudy Secco etch regions for type 2 wafer from Fig. 1. The cloudy region, Fig. 2a, shows a high density of "saucer pits" (~10^7/cm^2) along with

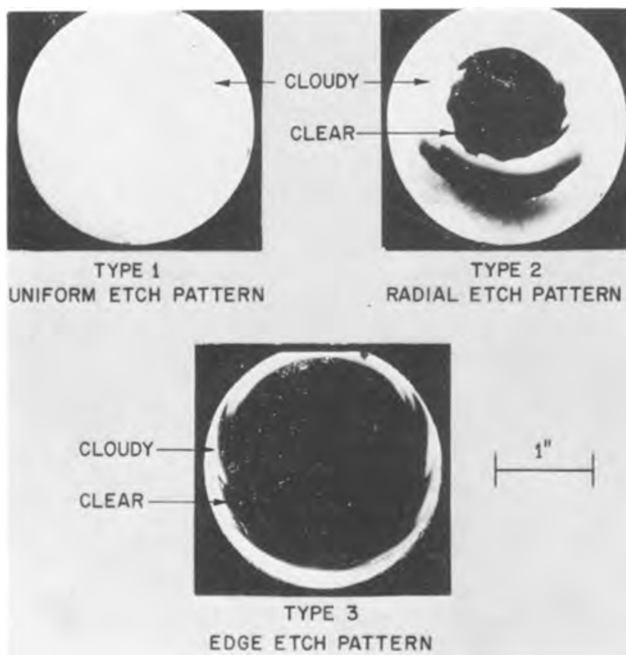

Fig. 1. Secco etched wafers after initial oxidation

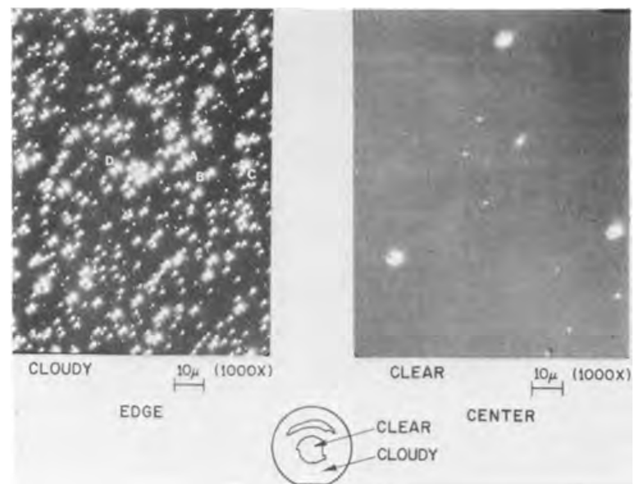

Fig. 2. Secco etched wafer after initial oxidation, clear and cloudy regions (a, left; b, right).

a lower density of oxidation-induced stacking faults (labeled A, B, C, and D). The saucer pits are generally not observed in the clear etch regions, but stacking faults at a nonuniform density ~10^2-10^3/cm^2 are often seen (Fig. 2b). The defects which we labeled A, B, C, and D in Fig. 2a have been identified by transmission electron microscopy as stacking faults (15). Type 1 and 3 wafers also showed similar etching and defect behavior as shown in Fig. 2a for cloudy regions and Fig. 2b for clear regions.

In order to determine whether the stacking faults were present in depth, 0.002 in. of material was removed by Syton polishing from a type 3 wafer. Results after etching, showed that stacking faults were still present in the clear etch regions. This demonstrates that bulk stacking faults were present in these wafers. Regions which etched cloudy still showed a high density of small saucer pits along with an occasional bulk stacking fault. Examination in cross section of cleaved wafers confirmed these observations.

The same gross etch pattern observed after initial oxidation (Fig. 1) followed through the buried layer processing with each high temperature operation. Thus wafers showing type 3 behavior after initial oxidation showed type 3 behavior after predeposition and drive-in. Similar wafers showing type 1 and 2 characteristics followed through the processing sequence showing the same behavior. As we show later, those areas etching "cloudy" on any type wafer resulted in epi stacking faults in the nondiffused regions. Those areas etching "clear" showed no epi stacking faults.

Secco etch results after predeposition are shown in cloudy and clear area, both diffused and nondiffused in Fig. 3 for type 2 and type 3 wafers. A similar study following drive-in is shown in Fig. 4. As is evident a high density of saucer pits is observed in cloudy etch regions, but a much lower density or complete absence is observed in clear etch regions.

Figure 5 shows the appearance of diffused and nondiffused regions, in unetched samples, following epitaxial deposition. Those defects in the photos which are V-shaped or triangular in appearance are epitaxial stacking faults. The photograph on the left was obtained from a type 1 sample whereas the one on the right was obtained from a clear region in a type 3 sample. Examination of over 100 wafers led to the firm conclusion that regions which exhibit cloudy etch behavior, as evidenced by a high density of saucer pits, will result in the formation of stacking faults in nondiffused regions during epitaxial deposition. In addition, regions which exhibit clear etch behavior do not reveal epitaxial stacking faults. In this particular study no deleterious effects were observed as a result of the high oxygen content.

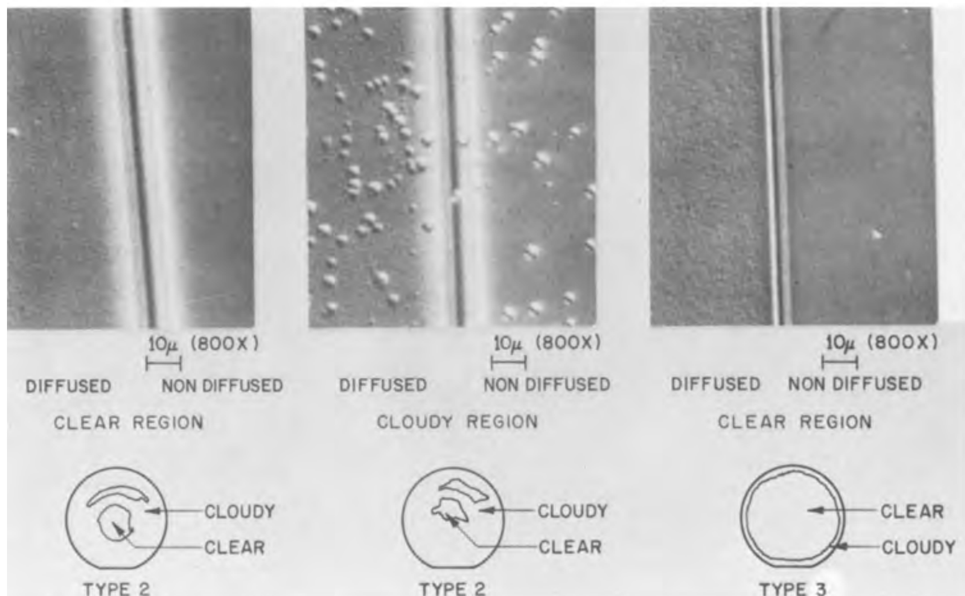

Fig. 4. Secco etched wafer after Sb drive-in.

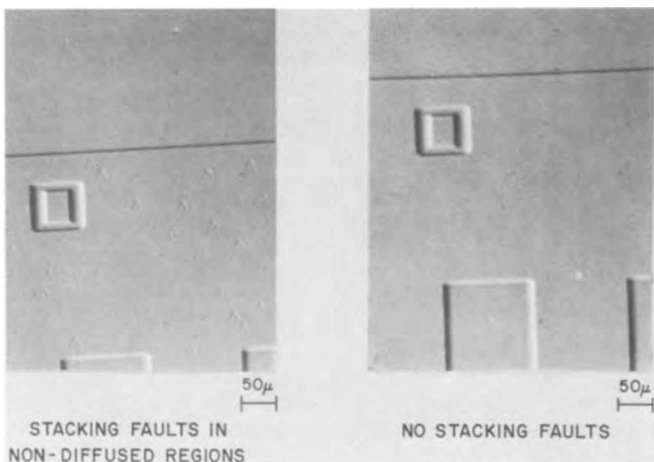

Fig. 5. Post epitaxial surfaces, (a, left) shows stacking faults in the nondiffused regions and (b, right) shows no stacking faults.

Correlation of defect formation with crystal characteristics.—Upon examination of wafers following epitaxial deposition, five categories of epitaxial stacking fault severity were chosen; they are (*i*) none, (*ii*) stacking faults at edge, (*iii*) radial distribution (from

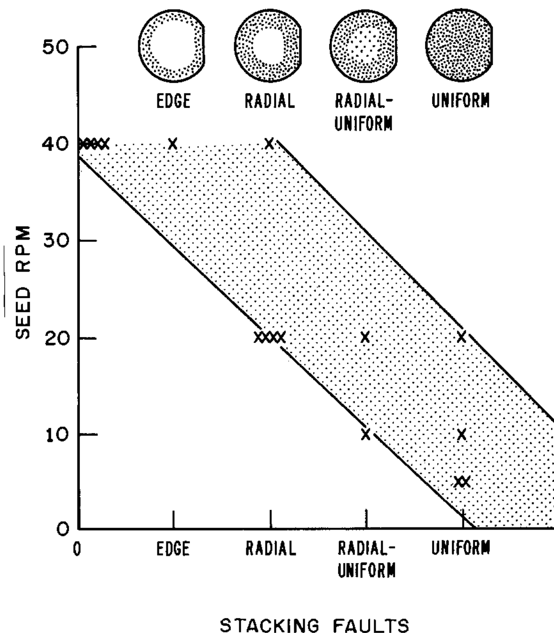

Fig. 6. Degrees of stacking fault formation as related to seed rotation rate.

edge part way toward center), (*iv*) radial to uniform distribution, and (*v*) uniform distribution. After all wafers were examined, the effect of crucible rpm on stacking fault formation was studied and no correlation was obtained. However, a similar study of seed rpm *vs.* stacking faults, Fig. 6, showed that high seed rpm, *i.e.*, 40 rpm, practically eliminated the epitaxial stacking fault problem; thirty-one out of thirty-six wafers from six different ingots showed no epi stacking faults at all. All wafers obtained from crystals grown at 20, 10, and 5 rpm showed stacking faults; sixty-four out of sixty-four wafers examined showed epi stacking faults. No difference was observed between heat-treated and nonheat-treated ingots for both high rpm and low rpm with respect to epi stacking fault formation. Presumably the initial oxidation equalizes the "heat-treated" and "nonheat-treated" wafers with respect to oxygen precipitation.

The radial oxygen profiles from our wafers and also those of others (3, 4) show that a correlation exists between radial stacking fault density and radial oxygen profile; namely, that the edge regions have lower oxygen levels than the central regions. In crystals grown at low turn rates, 20 rpm and lower, the epi stacking faults are observed most predominantly at the edge where the oxygen is lowest. Once the oxygen level becomes higher, even at the edge such as in the 40 rpm crystals, a drastic reduction in stacking fault level is observed. It thus appears that a strong correlation exists between (low) oxygen and stacking fault formation. This does not preclude a similar correlation with (high) carbon.

Since the epi stacking faults generally were not present in the 3 in. diam crystals where the oxygen content is typically near 40 ppm, it appears this value of the oxygen content is approximately the threshold above which the saucer pit formation is suppressed, presumably due to a gettering action by oxygen-induced defects. Thus by changing the crystal growth parameters we were capable of growing 2 in. diam crystals which exhibited properties of normal 3 in. diam crystals.

In analyzing the defect mechanisms involved, we must first consider those defects appearing at the initial oxidation. In lower oxygen content regions a high density of saucer pits was observed ($\sim 10^7/cm^2$) along with a much lower density of stacking faults. In high oxygen regions the predominant defect was the stacking fault which appeared in low density. Based on evidence obtained when 0.002 in. of silicon was removed after oxidation (which indicated the primary defect as stacking faults in high oxygen regions and saucer pits in low oxygen regions), it must be concluded that at least some of the stacking faults observed prior to the 0.002 in. removal are bulk stacking faults. These bulk stackings are presumably nucleated by the bulk oxygen precipitation in high oxygen regions. In addition, the high oxygen concentration presumably acts to suppress the saucer pit formation to a large enough degree that on further processing they do not form. The high oxygen content is just as effective in preventing subsequent epi stacking faults as implant buried layer gettering; however, the mechanisms are different. With implanted buried layers the gettering of the nondiffused regions takes place laterally whereas the oxygen gettering takes place immediately on the initial oxidation and appears to be a bulk effect.

A calculation of approximate defect densities of some of the defects observed shows:

surface stacking faults—low O_2 area $\sim 10^5$-$10^6/cm^2$
surface stacking faults—high O_2 area $\sim 10^2$-$10^3/cm^2$
saucer pits—low O_2 area $\sim 10^7/cm^2$
epitaxial stacking faults—low O_2 area $\sim 10^4/cm^2$.

A separate transmission electron microscope study has been carried out to determine the nucleating defects for the epitaxial stacking fault (5). This study showed that the stacking fault nucleation correlated well with the presence of defect centers resulting from metallic contamination of the epi-substrate interface.

Conclusions

We have shown here that altering crystal growth parameters can produce crystals which have significantly different defect properties. Increasing the oxygen content of 2 in. diam wafers suppresses epitaxial stacking fault formation in nonburied layer regions, thus making the 2 in. crystals behave similarly to 3 in. crystals. The high oxygen concentration prevents the formation of epi stacking fault nuclei.

As we emphasized earlier, high oxygen content wafers can result in the formation of process-induced defects. Bulk oxygen defects, properly positioned, can provide a beneficial gettering effect. Hence when using high oxygen content silicon an understanding and control over the distribution of oxygen in depth is important. Additionally, control must be exercised as to whether the oxygen is present in interstitial form or in a precipitated form.

Output Stability of n-CdSe/Na_2S-S-NaOH/C Solar Cells

A. Heller,* G. P. Schwartz, R. G. Vadimsky, S. Menezes, and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

When operated at the current densities in excess of 10 mA/cm^2 that are typical of efficient solar-irradiated photovoltaic cells, n-CdSe/1M Na_2S-1M S-1M NaOH/C semiconductor-liquid junction cells deteriorate with time. In CdSe electrodes that have lost activity, formation of a CdS-enriched film has been detected by means of Auger spectroscopy and electron beam-induced luminescence. Such a layer is a barrier to the flow of holes to the surface. The rate of deterioration increases with light flux, usually decreases with stirring, and depends on the crystal face exposed to the solution. Addition of small amounts of elemental selenium to the solution substantially improves the stability by preventing excessive sulfide enrichment of the surface. For example, with 0.5M Se added, the output of $\langle 11\bar{2}0 \rangle$ face electrodes run at 35 mA/cm^2 is essentially unchanged beyond 2×10^4 C/cm^2 charge passage.

Although numerous photoelectrochemical (1) and photochemical (2) systems have been cited as potentially useful solar to electrical power converters, none, to the authors' knowledge, has as yet simultaneously achieved high efficiency, low cost, and long-term output stability. Recently we have addressed some of these issues (3-10) and have shown that 7-9% solar to electrical conversion efficiency can be achieved with single crystal-based cells (3-6), that semiconducting photoelectrodes can be formed by the relatively economic means of metal anodization (7) or of hot pressing and annealing a powdered semiconductor (8), that cells with polycrystalline photoelectrodes reach 70% of the efficiency of cells with single crystals (8), and that a stable power output can be maintained in a semiconductor liquid junction solar cell by controlled, very slow etching of the surface of a photoelectrode (5). We noted, however, that in some of the more interesting cells, including the n-CdSe/Na_2S-S-NaOH/C cell for which we have examined single crystal, pressure-sintered polycrystalline, and anodically formed CdSe films, the power output deteriorates during operation (5). While confirming practically no weight change (9-11) in the photoelectrode upon prolonged use, we noted very substantial, and occasionally very rapid, drop in the power output of the cell at solar irradiance levels.[1] The constancy of weight is only poorly predictive of the stability of an electrode. While the photoelectrode may not dissolve, a film which blocks the flow of holes to the liquid junction may form, causing both current and voltage losses.

In this paper we examine how the output current of the n-CdSe/Na_2S-S-NaOH/C cell is affected by the interposition of a blocking film and the conditions under which this results. We find that a slight modification in the composition of the aqueous solution diminishes the tendency to form an inhibiting film and stabilizes the power output of the cells.

Experimental

The materials, solutions, light sources, electrochemical cells, and instrumentation were similar to those described earlier (4-8). Both single crystal (4) and polycrystalline, hot-pressed (8) CdSe electrodes were used. Their surface treatment was carried out in four steps prior to each run. First, the electrodes were etched for 30 sec in 4:1 HCl:HNO_3 (stored in a glass-stoppered bottle to reduce escape of vapors), then rinsed in distilled water. Next they were immersed 30 sec in a 10% aqueous KCN solution to dissolve any selenium that may be present following oxidation by the aqua regia. The electrode is then rinsed again in distilled water and used. This sequence of treatments to which we now add the KCN step provides a more reproducible electrode with a more consistent open-circuit voltage and better short-circuit current than those we previously observed.

We find that impurities introduced by storage of "analytical grade" $Na_2S \cdot 9H_2O$ crystals in dark glass bottles accelerate the deterioration of the CdSe photoanodes. Therefore, the crystals were purified until the results obtained were identical to those with Na_2S solutions prepared by bubbling H_2S into an aqueous NaOH solution. Also, the solutions were best formulated from the components directly in the electrochemical cells under a positive nitrogen pressure. Prolonged exposure to air induces earlier deterioration and stability runs were maintained under nitrogen.

Runs to measure the effect of stirring were accomplished with magnetic bars; in these cases the electrodes were stationary. The trends in such data were verified by separate experiments with CdSe rotating-disk electrodes (8), although only curves with magnetically stirred or quiet solutions are cited here.

In extended runs the cells were operated with 1Ω precision resistor loads between photoanode and carbon cathode to approximate short circuit, and the voltage (0-10 mV) across the resistor was monitored.

The CdSe surfaces were prepared for the Auger/e-beam luminescence experiments as follows: the photoanode control specimens were etched as earlier described, then immersed in a 0.5M Na_2S solution and rinsed with deionized water. The photoanodes which saw Na_2S-S-NaOH solutions were rinsed with 0.5M Na_2S and deionized water. The equipment used for the Auger spectroscopy and for the luminescence experiments consisted of a PHI ESCA/Auger spectrometer (Model 548). The 376 eV Cd, 153 eV S, and 1315 eV Se Auger peaks were monitored.

Results

Figure 1 shows the dependence of the short-circuit current density on the charge per unit area passed through two stationary photoelectrodes of different crystal faces when individually operated in unstirred 1M Na_2S-1M S-1M NaOH solution with a one ohm load to a carbon cathode. That the drop in current density is due entirely to the photoelectrode, and not to the solution or to the counterelectrode, was shown by the fact that mild etching of the semiconductor at any time restores the cell output to its initial value. As seen in Fig. 1, the relative rate of loss in current density for either crystal face depends on the initial current density and thus the light flux. The stability is expressed in coulombs/cm^2 rather than time. This

[1] G. Hodes, J. Manassen, and D. Cahen have indicated that electrode to be long lived at lower output levels (efficiencies). We are concerned with maintaining the initial higher values of which we have determined this system to be capable.

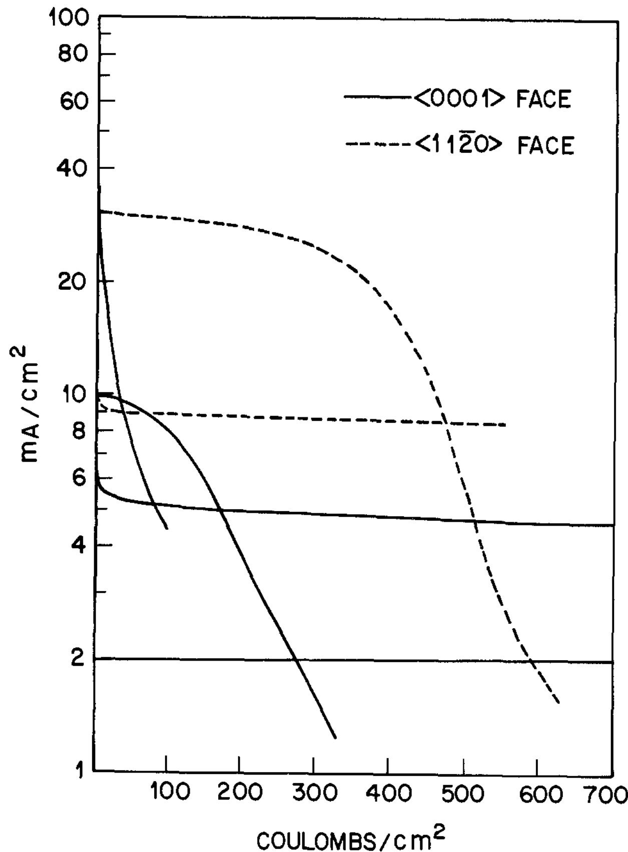

Fig. 1. Dependence of the short-circuit current stability of two n-CdSe photoanodes in a 1M Na_2S-1M S-1M NaOH solution on the initial current density (light flux). Solid lines are for <0001> face electrodes; dashed for <11$\bar{2}$0>. The solutions are not stirred.

allows us to compare electrode stability for different light fluxes along an axis expressing charge capacity, which is the significant factor for an energy source. For the <0001> face electrodes, light fluxes producing >10 mA/cm^2 evince nearly total deterioration in less than 400 C/cm^2. At lower fluxes stability is better maintained, and at 2 mA/cm^2 no deterioration is observed up to 700 C/cm^2. The behavior of the <11$\bar{2}$0> face is similar except that higher currents are tolerated. The curves for either face cross over, showing that initial operation at higher current densities results in lower activity after the passage of a sufficient charge in spite of the higher light flux. The <0001> and <000$\bar{1}$> planes consist of either Cd or Se atoms, the ions of opposite charge lying slightly below the plane. The <11$\bar{2}$0> plane contains an equal number of Cd and Se atoms.

Figure 2 shows the effect of stirring on the stability of the short-circuit current density of a freshly etched photoanode. The results shown are for the <0001> face, which deteriorates more rapidly (see above). Improved stability upon stirring is observed throughout the range of current densities studied (to 45 mA/cm^2) and is most pronounced for rapidly deteriorating electrodes. The long-term drop of the output cannot be simply ascribed to depletion at the electrode surface of electroactive species (which may be in sluggish equilibrium) since recovery of a previously unstirred cell with a deteriorated electrode cannot be achieved by stirring.

Figure 3 shows the effect on stability of the addition of elemental selenium to the 1M Na_2S-1M S-1M NaOH solution. Small concentrations of selenium dramatically improve the constancy of the short-circuit current density, even at a light flux sufficient to generate over 40 mA/cm^2. At 0.05M Se concentrations (not shown) there is virtually no change from the initial 35 mA/cm^2 short-circuit current density of a

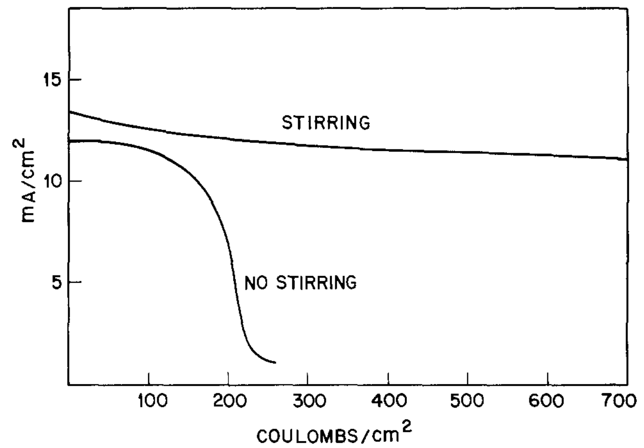

Fig. 2. Dependence of the short-circuit current stability on an n-CdSe <0001> face photoanode in a 1M Na_2S-1M S-1M NaOH solution on stirring.

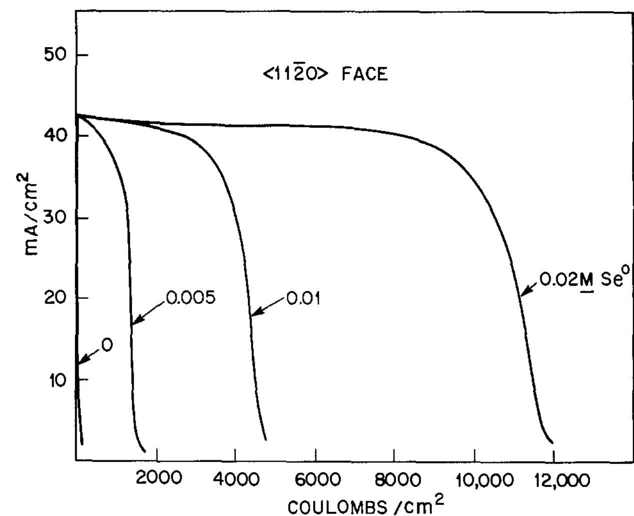

Fig. 3. Effect of Se addition on the short-circuit current output stability of an n-CdSe <11$\bar{2}$0> face photoanode in a 1M Na_2S-1M S-1M NaOH solution.

stationary, unstirred <11$\bar{2}$0> photoanode run to 20,000 C/cm^2.

Auger analysis of the near surface region was performed on freshly etched and deteriorated photoanodes. The near surface depth from which 95% of the Auger intensity emanates is given by 3λ cos 42.3°, where λ is the mean free path for an electron and the cosine term accounts for the collection geometry of our cylindrical mirror analyzer. Published values (12) for the dependence of λ on the electron's kinetic energy allow us to estimate detection depths ranging from roughly 11Å for sulfur LVV (153 eV) to 40Å for selenium LMM (1315 eV) transitions.

Deteriorated photoanodes evidenced an appreciable sulfur intensity (typically S(153 eV)/Cd(376 eV) ≈ 1.5) even after repeated rinsing to remove the physically adsorbed electrolyte. None of the surfaces was ion sputtered prior to measurement, and total contaminant levels due to carbon, oxygen, and Na_2S (detected by Na) varied from practically zero to an estimated 40% of the surface composition on various electrodes. The conversion of contaminant intensities into an atomic percentage of the detected volume is quite approximate because of errors in sensitivity factors and the assumption of a homogeneous distribution of elements in the surface.

However, the measurements systematically revealed a reduction in the Se/Cd intensity ratio on deteriorated electrode surfaces. The starting etched surface (Se × 10)/Cd ratio was 0.85, which is close to that of

samples of pure CdSe powder (0.83 ± 0.06). The corresponding ratios for samples run at light intensities which produced current densities of 2.5 and 20 mA/cm² were 0.61 and 0.34, respectively. This reduction in the observed Se/Cd ratio cannot be explained by a deposited sulfur or contaminant overlayer because the energy dependence of the inelastic mean-free path for electrons scales roughly as $\sqrt{E}$ (for $E \gtrsim 50$ eV) (12). Any such blocking layer would thus attenuate the low kinetic energy Cd intensity (376 eV) relatively more than the Se signal (1315 eV), thus increasing the Se/Cd ratio in contrast to what was observed.

During the Auger measurements, electron beam-stimulated luminescence in the red was observed. Of the many products whose existence was probable on the surface (CdSe, $CdS_{1-x}Se_x$, CdS, CdO, $Cd(OH)_2$, Na_2S, free S), CdS and $CdS_{1-x}Se_x$ (with $x << 1$) are unique in luminescing in the red. This luminescence was observed on samples simply immersed in the 1M Na_2S-1M S-1M NaOH solution, indicative of a CdSe → CdS replacement reaction even without passage of current. Qualitative visual observation of the luminescence intensity indicated a distinct increase in brightness on deteriorated electrode surfaces. Thus, both electron beam-stimulated luminescence and Auger studies are consistent with extensive surface substitution of CdS for CdSe in deteriorated electrodes.

The observation of luminescence on freshly etched, working electrodes which were immersed in sulfide-polysulfide solutions indicates that some replacement of the CdSe by CdS can be tolerated. Following passage of 1000 C/cm², the thickness of the zone in which CdS is detected is about 50-80Å, as estimated from the signal attenuation of the Se intensity and an electron inelastic mean free path of 15-25Å at 1315 eV.

Surfaces of electrodes run in 1M Na_2S-1M S-1M NaOH solutions containing 0.075M Se (in which they are stable) maintain their selenium surface content. Thus, while passage of 1000 C/cm² at a light flux producing an initial current density of 20 mA/cm² reduces the Auger Se/Cd peak intensity ratio by a factor of 2 on a <11$\bar{2}$0> face, there is no change in the same ratio when the solution contains 0.075M Se. Furthermore, the (Se × 10)/Cd peak intensity ratio drops from 0.83 to ~0.34 when 150 C/cm² are passed in the 1M Na_2S-1M S-1M NaOH at 20 mA/cm² through a polycrystalline photoanode, which deteriorates in that period. At low current densities (2.5 mA/cm²) at which the polycrystalline electrode remains active, the (Se × 10)/Cd ratio is 0.61 following the passage of the same charge.

Figure 4 compares the transmittance of the 1M-Na_2S-1M S-1M NaOH and the 1M Na_2S-1M S-1M-NaOH-0.075 Se solutions. Figure 5 compares the efficiencies (current-voltage curves) of two cells, one with a 1M-Na_2S-1M S-1M NaOH solution, and another with the same solution to which 0.075M Se has been added. As expected from Fig. 4, addition of Se decreases the short-circuit current. This >12% loss is, however, partly compensated for by an increase in the fill factor (from 0.50 to 0.55) and in the open-circuit voltage (from 0.755 to 0.765V). The net result is that 97% of the original solar to electrical conversion efficiency of 7.1% for the crystal used is retained in the solution of sharply improved output stability.

Exposure of the sulfur-sulfide solution to air during (or before) CdSe cell operation causes premature failure of the semiconductor electrode. Etching of the surface restores activity for only a very brief time (a few coulombs/cm²) in such an air exposed solution after initial failure. Although quantitative measurements of oxidative conversion of the solutions were not made, little or no visible bleaching of color could be detected after air exposures sufficient to make the cells deteriorate rapidly; these effects cannot be repressed by selenium additions and air access must be rigorously excluded.

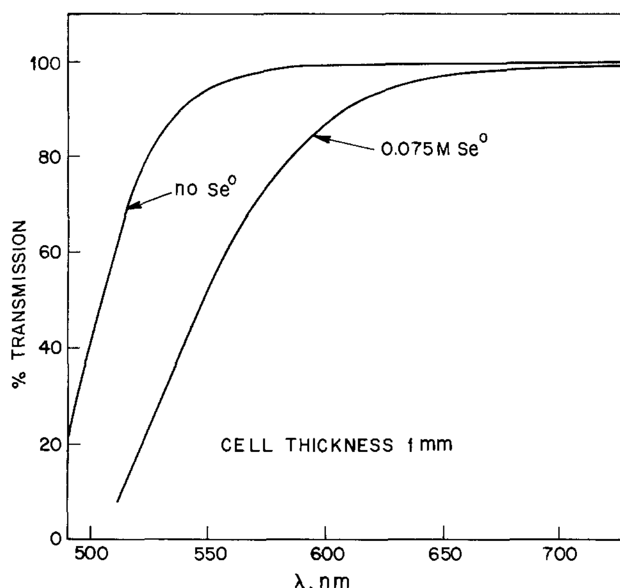

Fig. 4. Comparison of the transmittances of 1M Na_2S-1M S-1M NaOH and 1M Na_2S-1M S-1M NaOH-0.075M Se° solutions. The sample thickness is 1 mm.

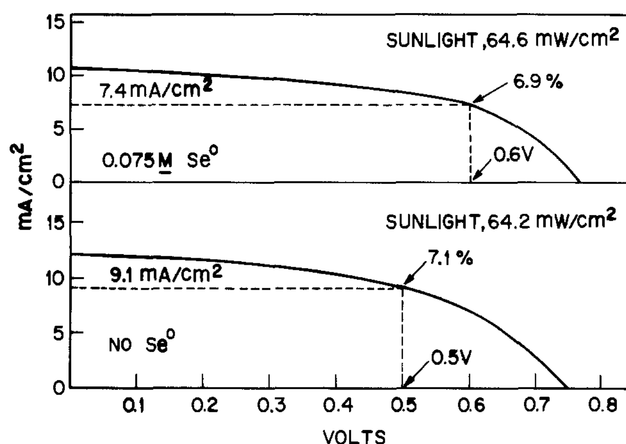

Fig. 5. Current-voltage curves under nearly identical solar irradiance for the same n-CdSe crystal run in 1M Na_2S-1M S°-1M NaOH with and without 0.075M Se present. Without Se(bottom): insolation 64.2 mM/cm²; open-circuit voltage 0.755; short-circuit current 12.1 mA/cm². With 0.075M Se (top): insolation 64.6 mW/cm²; open-circuit voltage 0.765; short-circuit current 10.6 mA/cm. Maximum efficiency parameters are indicated.

Polycrystalline hot-pressed CdSe photoanodes (8) deteriorate less rapidly than electrodes made with single crystal electrodes with <0001> faces exposed to the solution, but more rapidly than electrodes with exposed <11$\bar{2}$0> faces. Improvements upon addition of Se to the solutions parallel those described for <11$\bar{2}$0> electrodes, both for polycrystalline and <0001> photoanodes.

Discussion

Surface processes at CdSe in sulfide-polysulfide solution depend on the equilibria and kinetics of exchange processes typified by

$$CdSe(s) + S^{=} \rightarrow CdS(s) + Se^{=} \quad [1]$$

These will be modified by reactions

$$X^{=} + X_n \leftrightarrows X_{n+1}^{=} \quad [2]$$

for both sulfur and selenium and the existence of mixed complexes such as $S_pSe_q^{=}$, as well as incorporation of OH^-. Literature tabulations of the free energy of formation for CdS (13-15) and CdSe (16-19) show variations in excess of 5 kcal/mole. If we adopt the

NBS thermochemical compilation value of ΔG°_{298}(CdS) (15) = −37.4 kcal/mole and use the average of Ref. (16-19) for ΔG°_{298}(CdSe) = −24 kcal/mole, then the reaction

$$CdSe(s) + S(s) \rightarrow CdS(s) + Se(s) \quad [3]$$

is favored by ~13 kcal/mole. However, from standard electrode potentials of chalcogen/chalcogenide couples (−0.92V, Se and −0.50V, S) (20), the reaction

$$Se + S^{=} = Se^{=} + S \quad [4]$$

is thermodynamically unfavorable by 19 kcal/mole. Addition of Eq. [3] and [4] would imply that Eq. [1] is unfavorable by roughly 6 kcal/mole. Other sources however quote −0.78V for the Se/$Se^{=}$ couple (21), which reduces the instability of Eq. [4] by 6.5 kcal/mole. Our own potential measurements in fact are close to this more positive value. In view of the uncertainties in the tabulated free energies for reactions [3] and [4] and our omission of equilibria implied by Eq. [2], one cannot make a compelling argument concerning the relative thermodynamic stability of either bulk CdS or CdSe under the conditions of these experiments.

However, our Auger/luminescence observations indicate that exposure of an area of CdSe crystals to a volume of pure (*i.e.*, selenium-free) polysulfide will cause some exchange at the surface (with $Se^{=}$ either transported to the bulk or oxidized to the elemental state) until an over-all equilibrium is reached. A molecular layer contributes approximately 10^{-9} moles/cm^2 and therefore to a 10 cm^3 volume 10^{-7} molar concentration of the dissolved species. From the standard potential difference driving reaction (4) the concentration of $Se^{=}$ in the presence of excess polysulfide must be small if the total selenium content results from the CdSe crystal and any impurity content of the polysulfide solution. Auger spectroscopy data here and electron microprobe and x-ray diffraction results by Manassen *et al.* (11) point to sulfur and CdS on the surface when CdSe is removed from sulfide solutions. That the sulfur represents more than absorbed or occluded material and is actually bound as CdS is substantiated here by the red luminescence seen when the previously immersed n-CdSe specimen is stimulated by electron bombardment. The luminescence of freshly etched n-CdSe is practically undetected by the human eye which is insensitive at the 1.7 eV bandgap energy corresponding to 720 nm. The presence of 2.4 eV bandgap CdS shifts the emission into the visible.

The sulfur-containing layer resulting solely from immersion of n-CdSe in sulfide-polysulfide solution is very thin. In these thin films, electrons may tunnel from the solution to the semiconductor to enable photoanodic oxidation of electrolyte ions. However, development of thick layers of $CdSe_{1-x}S_x$, as measured by Auger spectroscopy, is associated with a blockage of current flow through the photoanode of the cell.

Two possible reasons for this blocking action are the following. First, and most important, a heavily doped large bandgap n-type semiconductor on a similar semiconductor of smaller bandgap blocks the passage of holes to the surface. From the electron affinities of CdS and CdSe, it is known (22) that the conduction band of CdS is closer to the vacuum level by about 0.2 eV. Under short-circuit conditions, the Fermi levels of the four phases are equal relative to vacuum, as shown in Fig. 6. At the interface of CdS and CdSe band bending of about 0.2 eV may exist, depending on the relative doping level. (We ignore the band bending due to the solution interface since the depletion layer is much thicker than the scale of this figure.) The major consequence of the presence of a CdS layer will, however, be the barrier-to-hole transfer between the valence bands (and ultimately to the solution interface) which amounts to

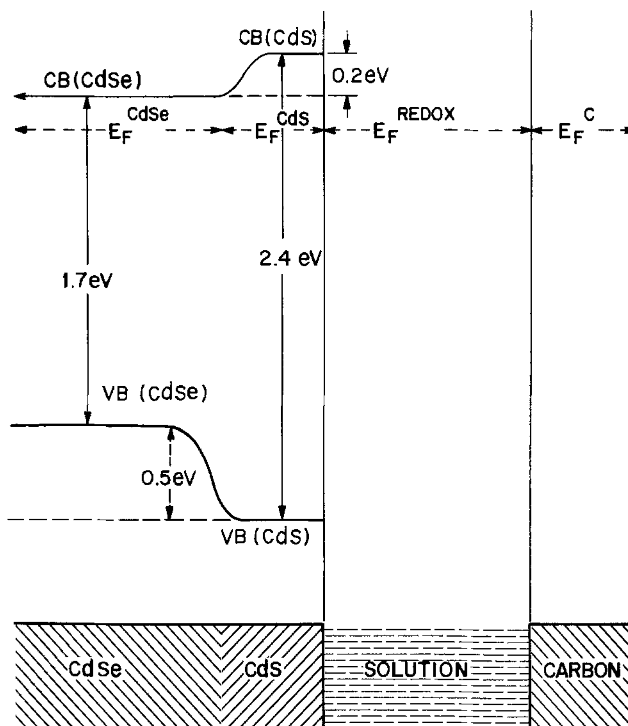

Fig. 6. Schematic diagram showing a barrier for hole transport from an n-CdSe photoanode to a redox couple solution by an n-CdS surface layer under short-circuit conditions. To keep the diagram simple, the band bending in the depletion region is not shown.

0.7-0.2 eV. This barrier is progressively lowered as x decreases in the series of compounds $CdSe_{1-x}S_x$, accounting for our observation that the current is not blocked unless x is high. Liquid junction cells with $CdSe_{1-x}S_x$ photoanodes were recently studied by Noufi, Kohl, and Bard (23).

A second reason for current blockage is lattice mismatch. If a layer of CdS is deposited on CdSe there is an abrupt shrinkage in the interatomic distance. The resulting stresses are known to be relieved by the formation of nonstoichiometric compounds in which the element forming stronger bonds with itself (*i.e.*, is more metallic) dominates. In the case of cadmium sulfide, the interface is likely to be Cd rich. Such a layer would introduce a discontinuity and block the flow of holes to the liquid interface even if the bandgaps of CdS and CdSe were equal. Furthermore, even in the absence of this interface the defects at the interface may be traps and thus sites for carrier recombination.

Passage of current appears to promote the exchange of ions that results in a current reducing film (Fig. 1). At low levels of illumination (cell current density ≤ 2 mA/cm^2) no decline in current is observed, but at levels normal to solar illumination (≥10 mA/cm^2 cell output) blocking layers are eventually formed. An explanation may lie in the possibility that at sufficiently high light intensities the concentration of the kinetically most active electron donor-hole acceptor species at the electrode surface may become depleted due to slow equilibria in spite of a relatively small reduction of the total $S^{=}$ containing species concentration in these molar solutions. The rates of reactions like Eq. [2] may become limiting. Photocorrosion may then become competitive and be followed by reprecipitation of the more prevalent chalcogenide

$$S_n^{2-} + CdSe + 2H^+ \rightarrow Cd^{2+} + S_nSe^{2-} \quad [5]$$

$$Cd^{2+} + 2S_n^{2-} \rightarrow CdS + S_{2n-1}^{2-} \quad [6]$$

Such depletion at high current density may also account for the fact that stirring or rotation of elec-

trodes decelerates the degradation process (Fig. 2 and 3). Finally, however, this sort of inhibition produces a less active surface for which stirring no longer improves the current.

Our model for current blockage predicts that maintenance of an adequate amount of selenium in the surface film should reduce or eliminate the photoanode deterioration problem; it is also obvious from thermodynamic arguments that the film will become richer in Se as the concentration of the element in the solution increases. These conclusions are supported by the plots in Fig. 3 in which the deterioration at 0-0.02M Se° concentrations in a 1M Na_2S-1M NaOH solution is shown. Cell life increases dramatically with the Se concentration. Our data indicates that with 0.05-0.075M Se added, runs at solar irradiance levels ought to have a stable output well beyond our 2×10^4 C/cm^2 cutoff.

As seen in transmittance data of Fig. 4 and in the 12% drop of short-circuit current in Fig. 5, some quantum efficiency loss results upon addition of 0.075M Se. However, this is practically compensated by a slightly higher open-circuit voltage and a significantly better fill factor in the presence of selenium. Possible sources of these positive features of the Se stabilized solution are a higher open-circuit voltage caused by a negative shift of the flatband potential, faster rates for the electrochemical oxidation, and reduction of losses due to hole transfer across the sulfide containing barrier, the latter two leading to fill-factor improvement.

In summary, we show in this paper that (*i*) absence of weight loss is not adequately predictive of stability of photoelectrodes; (*ii*) the deterioration of n-CdSe in sulfide-polysulfide solutions derives from a CdS-rich film which blocks the flow of current; (*iii*) if the CdS film contains an adequate amount of CdSe the flow of current is not blocked; and (*iv*) an adequate amount of CdSe in the film that is formed can be assured by adding a small amount of elemental selenium to the sulfide-polysulfide solution.

Growth Kinetics and Catalytic Effects in the Vapor Phase Epitaxy of Gallium Nitride

S. S. Liu*,[1] and D. A. Stevenson**

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

The kinetics of the heteroepitaxial film growth of GaN on sapphire by chemical vapor deposition was investigated under a variety of experimental conditions. The growth rate was observed to be linear with time for all conditions studied and was found to be significantly influenced by the following factors: composition of the reactants in the vapor, temperature in the reaction zone, substrate orientation, and dopant concentration. The Gibbs free energy change for the main deposition reaction was evaluated as a function of temperature and reactant composition using available thermochemical data and compared with the observed deposition rate. An apparent discrepancy between predicted and observed deposition rate was attributed to local differences in NH_3 composition due to decomposition and/or to the uncertainty in available thermochemical data. Significant observations are reported concerning the decomposition kinetics of NH_3 in different growth ambients.

Gallium nitride (GaN), a III-V compound semiconductor, has a direct bandgap of 3.4 eV at room temperature (1, 2) and crystallizes in the wurtzite structure. Nominally pure GaN is invariably an n-type conductor with the carrier concentration in the 10^{18}-10^{19} cm^{-3} range and resistivity in the 10^{-2}-10^{-3} Ω-cm range (3-7), the donors presumably being native defects such as nitrogen vacancies (3, 5, 8, 9) or gallium interstitials. Attempts to change the carrier type by p-type doping have been unsuccessful, presumably due to self-compensation; however, addition of group II elements such as Mg (3) and Zn produce insulating material (10-12). The large direct bandgap has prompted interest in this material for optoelectronic devices and recently GaN metal-insulator-semiconductor (MIS) light emitting diodes have been reported that emit violet (13), blue (10), green (11), and yellow (12) light. In addition, the piezoelectric properties and high acoustic velocities in this material make it attractive for acoustic devices (14). A major problem encountered in these device applications has been the quality of the material, particularly the reproducibility in the synthesis of material suitable for devices. The preparation of this material is an intriguing and challenging problem.

Gallium nitride is chemically inert but thermally unstable; GaN decomposes into the component elements prior to melting (15-18) (the normal decomposition temperature is ~800°C) and the high temperature and pressure for the coexistence of solid and liquid [estimated to be 2000°C and 10^5 atm (19)] make melt growth unfeasible. All practical methods for the synthesis of GaN utilize an active source of nitrogen, such as ammonia, NH_3. The most promising growth technique for device material has been the heteroepitaxial chemical vapor deposition utilizing NH_3, a vapor source of Ga (usually GaCl), and a sapphire substrate. A significant feature of this process is the use of NH_3 as an active nitrogen source under conditions where NH_3 is thermodynamically unstable. Thus, factors influencing the kinetics of NH_3 decomposition are highly relevant to this deposition process.

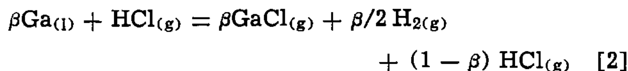
The present work was undertaken to interrelate the growth conditions, the growth kinetics, and the film characteristics for the heteroepitaxial deposition of GaN films. We present the following relevant observations and analyses: a development of the thermodynamics for the deposition reaction, measurements of the catalytic decomposition of NH_3 in typical growth environments, and measurements of growth kinetics under a variety of experimental conditions. These experimental observations are discussed in terms of the optimum conditions for GaN film growth for device applications.

Gallium nitride growth apparatus.—A previous study (20) has established the main GaN deposition reaction to be

$$GaCl_{(g)} + NH_{3(g)} = GaN_{(s)} + H_{2(g)} + HCl_{(g)} \quad [1]$$

for the conditions used in the present investigation. The growth apparatus is a conventional hot wall open flow reactor and is diagrammed schematically in Fig. 1. The essential zones of the reactor are a source zone where $GaCl_{(g)}$ is generated by passing HCl over Ga, a mixing zone where $GaCl_{(g)}$ is mixed with $NH_{3(g)}$, and the deposition zone where the reaction mixture produces a deposit of GaN on the substrate as well as on the reactor walls. A sidearm, containing a crucible filled with Mg, is used to introduce Mg vapor into the mixing zone for the purpose of Mg doping. The temperature of the Mg source and the carrier gas flow rate determine the relative amount of Mg introduced. A stopcock and forechamber accommodate the introduction and withdrawal of the substrate without cooling the system to room temperature, thus facilitating several successive runs with a minimum of interruption. Palladium-diffused hydrogen was the carrier gas for all components. Thermocouples were used to monitor the temperature of the Mg source crucible and the substrate. Sapphire substrates of either basal plane orientation (0001) or R-plane orientation $(1\bar{1}02)$ were used. Further details of the process, such as specific temperatures and flow rates, are given in the discussion below and in a previous publication (13).

Basic reaction.—There are four reactions of central interest for the GaN deposition, two concerning the supply of reactants to the reaction chamber and two concerned, respectively, with the formation and depletion of GaN. The Ga source reaction is its conversion to GaCl by the reaction



$$\beta Ga_{(l)} + HCl_{(g)} = \beta GaCl_{(g)} + \beta/2\, H_{2(g)} + (1-\beta)\, HCl_{(g)} \quad [2]$$

where β is the conversion efficiency. At the temperature in question, the equilibrium conversion efficiency is essentially unity; however, the extent of attainment of equilibrium depends on several factors, principally the residence time of the $HCl_{(g)}$ over the liquid Ga source, the Ga surface area, and the nature of the stir-

Fig. 1. Schematic diagram of the open-flow vapor growth system for preparing GaN

ring of the gaseous environment in the source zone. The other reaction that concerns the source of reactants is the decomposition of $NH_{3(g)}$

$$NH_{3(g)} = (1-\alpha)NH_{3(g)} + \alpha/2\ N_{2(g)} + \frac{3\alpha}{2} H_{2(g)} \quad [3]$$

where α is the degree of dissociation and is influenced principally by the temperature, partial pressure of $NH_{3(g)}$, the residence time of NH_3 in the reaction zone, and the catalytic nature of the environment in the reaction zone. The main formation reaction of GaN was given in Eq. [1]. As was already mentioned, GaN is unstable at elevated temperatures and tends to decompose into the elements

$$GaN_{(s)} = Ga_{(l)} + \frac{1}{2} N_{2(g)} \quad [4]$$

It is informative to compare the standard Gibbs free energy changes for the last three reactions, as given in Fig. 2. It is obvious from this figure that the decomposition of NH_3 and GaN is overwhelmingly favored in the temperature regime of interest (growth temperatures *ca.* 1200°-1400°K). The fact that epitaxial growth actually occurs at these temperatures is a consequence of the sluggishness of the NH_3 decomposition. It is appropriate to consider the influence of the extent of ammonia decomposition, α, and the conversion efficiency to GaCl, β, on the driving force for the deposition reaction by applying the reaction isotherm to Eq. [1]

$$\Delta G = \Delta G^\circ + RT \ln(a_{GaN}a_{HCl}a_{H_2})/(a_{GaCl}a_{NH_3}) \quad [5]$$

where a's are the activities of the different species denoted by the subscripts and ΔG and ΔG° are the change in Gibbs free energy and the standard Gibbs free energy, respectively.

Assuming that the gaseous species are ideal and GaN is a pure phase, then

$$a_{GaN} = 1,\quad a_{HCl} = (1-\beta)p_{HCl},\quad a_{GaCl} = \beta p_{HCl},$$
$$a_{H_2} = p_{H_2} + \beta/2\ p_{HCl} + 3\alpha/2\ p_{NH_3},\quad a_{NH_3} = (1-\alpha)p_{NH_3}$$

The flow rate of HCl is much smaller than that of NH_3 or H_2, or

$$p_{HCl} << p_{NH_3}\ p_{H_2}$$

and the total pressure is 1 atm, thus

$$p_{H_2} = 1 - p_{NH_3}$$

and we may write

$$\Delta G = \Delta G^\circ + RT\{\ln(1-\beta/\beta) + \ln[1 + (3\alpha/2 - 1)p_{NH_3}]/(1-\alpha)p_{NH_3}\} \quad [6]$$

Here

$$\Delta G^\circ = (\Delta G^\circ_{GaN} + \Delta G^\circ_{HCl} + \Delta G^\circ_{H_2}) - (\Delta G^\circ_{GaCl} + \Delta G^\circ_{NH_3})$$

and ΔG°'s are the standard Gibbs free energy of formation for each species in question. Literature values for ΔG° as a function of T (in °K) are

$$\Delta G^\circ_{GaN} = 1.34 \times 10^{-2} T^2 - 15.27T + 1.48 \ (15)$$
$$\Delta G^\circ_{GaCl} = 2.14 \times T \ln T - 29.42T - 1.68 \times 10^4 \ (21)$$
$$\Delta G^\circ_{HCl} = 1.41 \times T \ln T - 12.71T - 2.08 \times 10^4 \ (21)$$

with $\Delta G^\circ_{H_2} = 0$ and $\Delta G^\circ_{NH_3}$ taulated in the JANAF table (22).

ΔG° and ΔG can therefore be plotted as a function of T with different values of α and β, as shown in Fig. 3 and 4. As can be seen in these figures, ΔG° and all ΔG's go through a maximum as temperature changes. The peak shifts toward the lower temperature side with decreased value as either α increases or β decreases. This indicates the existence of an optimum temperature as far as the local thermodynamic affinity is concerned. The broken lines in the figures indicate the temperature regime commonly used for growth.

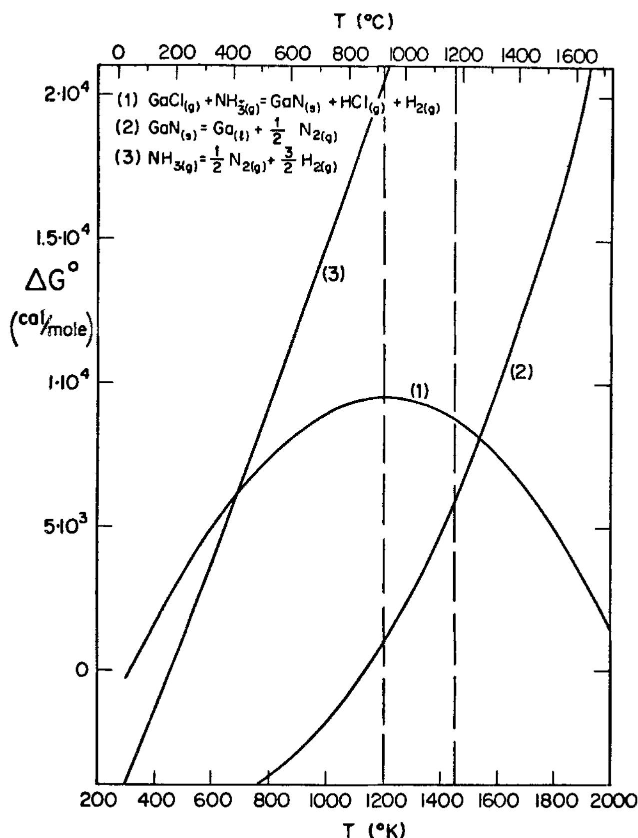

Fig. 2. Plot of ΔG° *vs.* *t* for three possible reactions in the deposition zone.

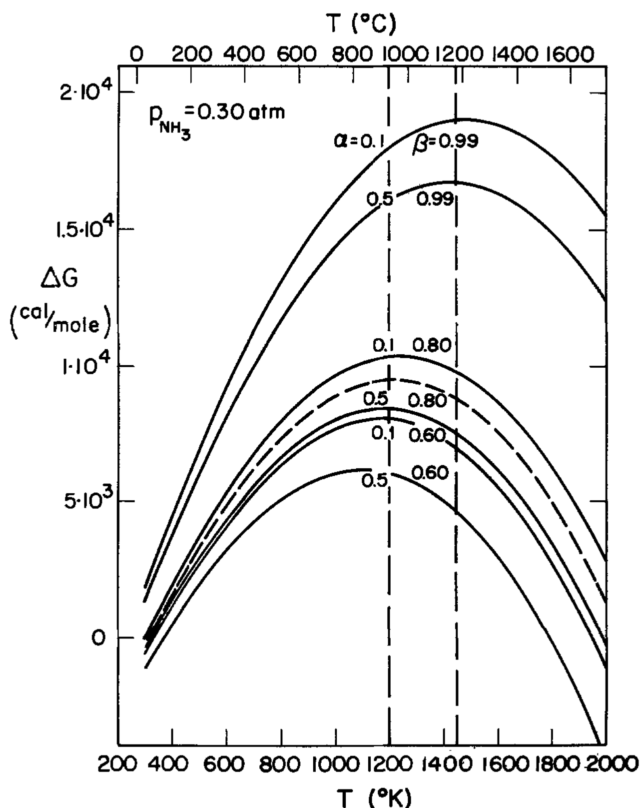

Fig. 3. Plot of ΔG *vs.* *T* for $p_{NH_3} = 0.30$ atm

It should be noted that the affinity in question is the initial affinity and as the reaction proceeds the concentration of HCl increases and causes the affinity to decrease in accord with Eq. [5].

Experimental

It is obvious from the foregoing discussion that the concentrations of $GaCl_{(g)}$ and $NH_{3(g)}$ are key factors

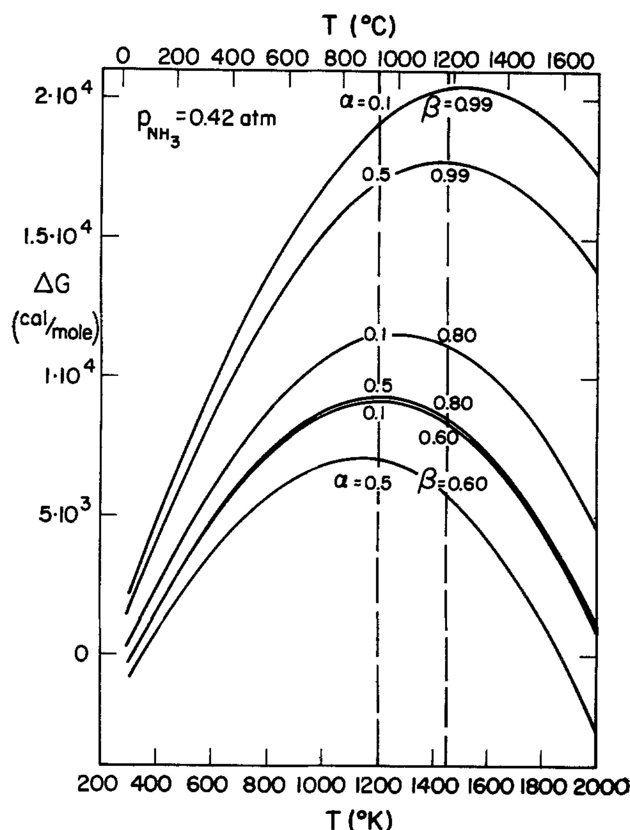

Fig. 4. Plot of ΔG *vs.* *T* for $p_{NH_3} = 0.42$ atm

in determining the basic thermodynamic driving force for the deposition reaction. Hence, factors affecting their concentration will certainly influence the nature of the GaN deposit. In this section we describe the techniques that were employed to study the conversion efficiency of $Ga_{(l)}$ to $GaCl_{(g)}$ and the parameters involved in the decomposition of NH_3. In addition, we describe techniques that were used to measure the growth rate of the deposits under a variety of experimental conditions.

Determination of the Ga-GaCl conversion and the extent of NH_3 *decomposition.*—Both the Ga-GaCl conversion and the extent of NH_3 decomposition were accomplished by a straightforward acid-base titration technique. For all determinations, the actual growth system was used (Fig. 1) with the addition of a manometer connected to the sidearm to monitor the pressure of the system and the addition of a series of three traps at the outlet to trap the effluent gases for analysis. The three traps were used to ensure that there was complete trapping of the gas in question. The conditions of temperature, gas composition, and gas flow rates spanned the range of interest for the actual epitaxial growth procedure. In the case of the Ga-GaCl conversion, a mixture of HCl and H_2 gases was flowed over the Ga boat in the source zone and the unreacted HCl collected in a series of three aqueous traps. The total HCl collected was determined by titration with a standard 0.1*N* NaOH solution. The actual HCl flow rates were checked by running the experiment without the presence of Ga, thus, no conversion of the HCl. A cross check on the Ga-GaCl conversion was obtained by measurement of the weight loss of the Ga boat in the source zone. In the case of the NH_3 decomposition study, the approach was similar except that in this case a NH_3-H_2 gas mixture, after passing through the furnace, was passed through a series of traps containing HCl; the first trap contained a standardized 5*N* HCl and the second and third 1*N* HCl. The respective flow rates of NH_3 and H_2 were 1060 and 1440 ml/min and the back pressure caused by the traps was approximately 0.8 psi, a pressure well below the level corre-

sponding to any significant leak rate. The amount of NH_3 trapped was determined by titration of the remaining HCl in all three traps using a standard 1*N* NaOH solution. In these experiments, an appreciable amount of time was allowed for the system to reach a steady state before sampling of the effluent was begun. The NaOH and the HCl solutions were standardized using potassium biphthalate weighed on a Mettler microbalance. The indicators used in the standardization and the HCl titration were o-cresolphthalein and methyl red, respectively. Similar to the HCl case, the actual flow of NH_3 was checked by flowing the gases through a cold furnace under conditions such that no decomposition would occur.

Growth rate determination.—The growth of GaN was determined by weighing the sapphire substrate on a Mettler microbalance prior to and subsequent to the GaN deposition for a given time of deposition with specified deposition conditions. The growth rate, expressed in terms of micrometers per minute was obtained by converting the weight gain to thickness. The latter assumption was justified as reasonable by observations of the deposit using both optical and scanning electron microscopy. The growth rate was also determined by direct thickness measurements by fracturing the sample and viewing the layer in cross section with a vernier lens, using optical microscopy.

Experimental Results

Conversion efficiency of HCl to GaCl (β) and the extent of decomposition of NH_3 (α).—The quantities β and α are essential for the prediction of the affinity of the main deposition reaction and were determined for a variety of experimental conditions in the range of interest for actual deposition systems. Figure 5 shows the results of the determination of the HCl conversion efficiency as a function of the HCl flow rate at a temperature of 950°C. As expected, the conversion efficiency decreases as the flow rate increases, presumably due to a decreased residence time. For the highest flow rate studied, the conversion efficiency was ~97% as compared with ~99% for the slowest flow rate (which was ~1/10 of the maximum). Thus, for all the conditions used in the present study, the conversion may be regarded as complete.

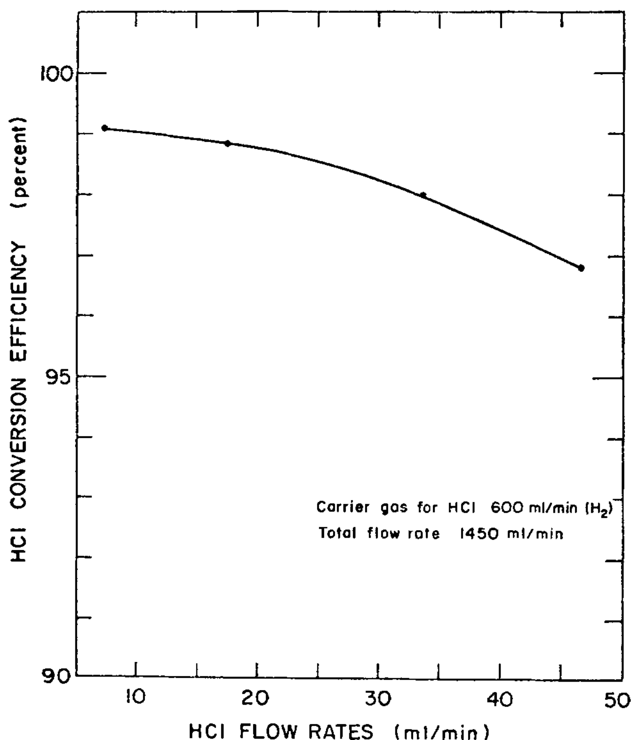

Fig. 5. Plot of the HCl conversion efficiency vs. HCl flow rates for a temperature of 950°C.

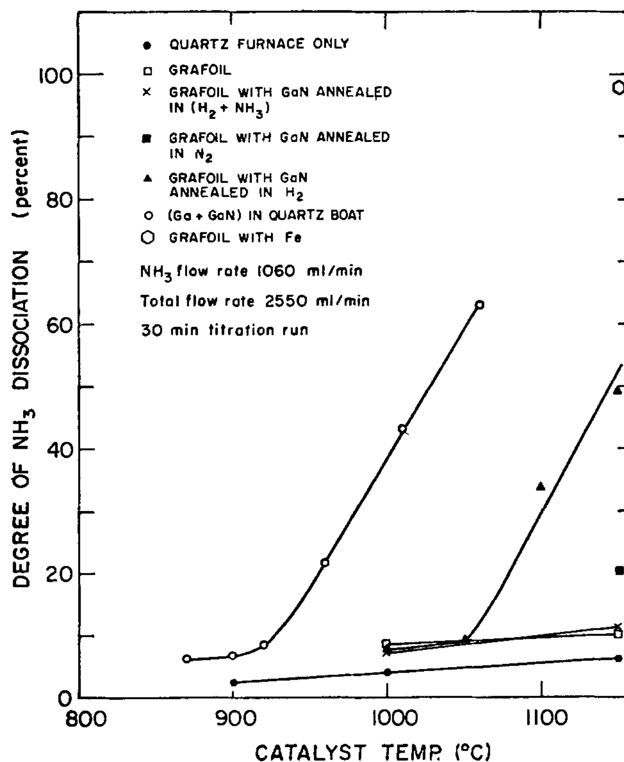

Fig. 6. Plot of the degree of NH_3 decomposition vs. the temperature of different catalytic environments prepared in the growth furnace.

The degree of NH_3 dissociation was determined as a function of temperature for several different environments and the results are summarized in Fig. 6. As shown by this figure, if the NH_3 contacts only pure quartz tubes (vitrified or devitrified) or a new graphite liner (Grafoil) the degree of dissociation is linear with temperature and ranges between 2 and 5 and 10%, respectively, for the temperature interval of 900°-1150°C. If, however, GaN is predeposited on the Grafoil liner, the thermal history of the liner becomes important. When the predeposited GaN was annealed in an ambient of NH_3 sufficient to prevent decomposition of GaN, the extent of decomposition was the same as for the pure graphite environment. When GaN is annealed in pure N_2 or pure H_2 prior to exposure to NH_3, a significant enhancement in α occurs at elevated temperatures, with an apparent threshold temperature of ~1050°C for the H_2 annealing case. To ascertain the reason for the enhanced catalytic effect and the significance of an apparent threshold temperature, the surfaces of GaN were examined by scanning electron microscopy (SEM) after appropriate anneals and the results are shown in Fig. 7. After annealing in a pure H_2 ambient at 1000°C for 1 hr, the appearance of Ga droplets due to the decomposition is easily detected. Subsequent annealing in a NH_3-containing ambient results in a uniform texture if annealing is carried out at a temperature below the threshold temperature, presumably due to the reformation of GaN from the Ga droplets. By contrast the droplets will persist if the annealing with NH_3 is performed above the threshold temperature. The supposition of the presence of Ga in the SEM micrographs was confirmed using x-ray diffraction. Since GaN itself was shown to have little influence on the decomposition of NH_3, there are two possible reasons for the anomalous enhancement in the catalytic decomposition of NH_3 caused by the partial decomposition of GaN: the presence of pure liquid Ga, or the coexistence of Ga-GaN.

To determine the role of liquid Ga, a sample of pure Ga was placed in a boat located at the NH_3 inlet. There was no significant influence on the NH_3 decomposition for temperatures below 1000°C and a thin coat

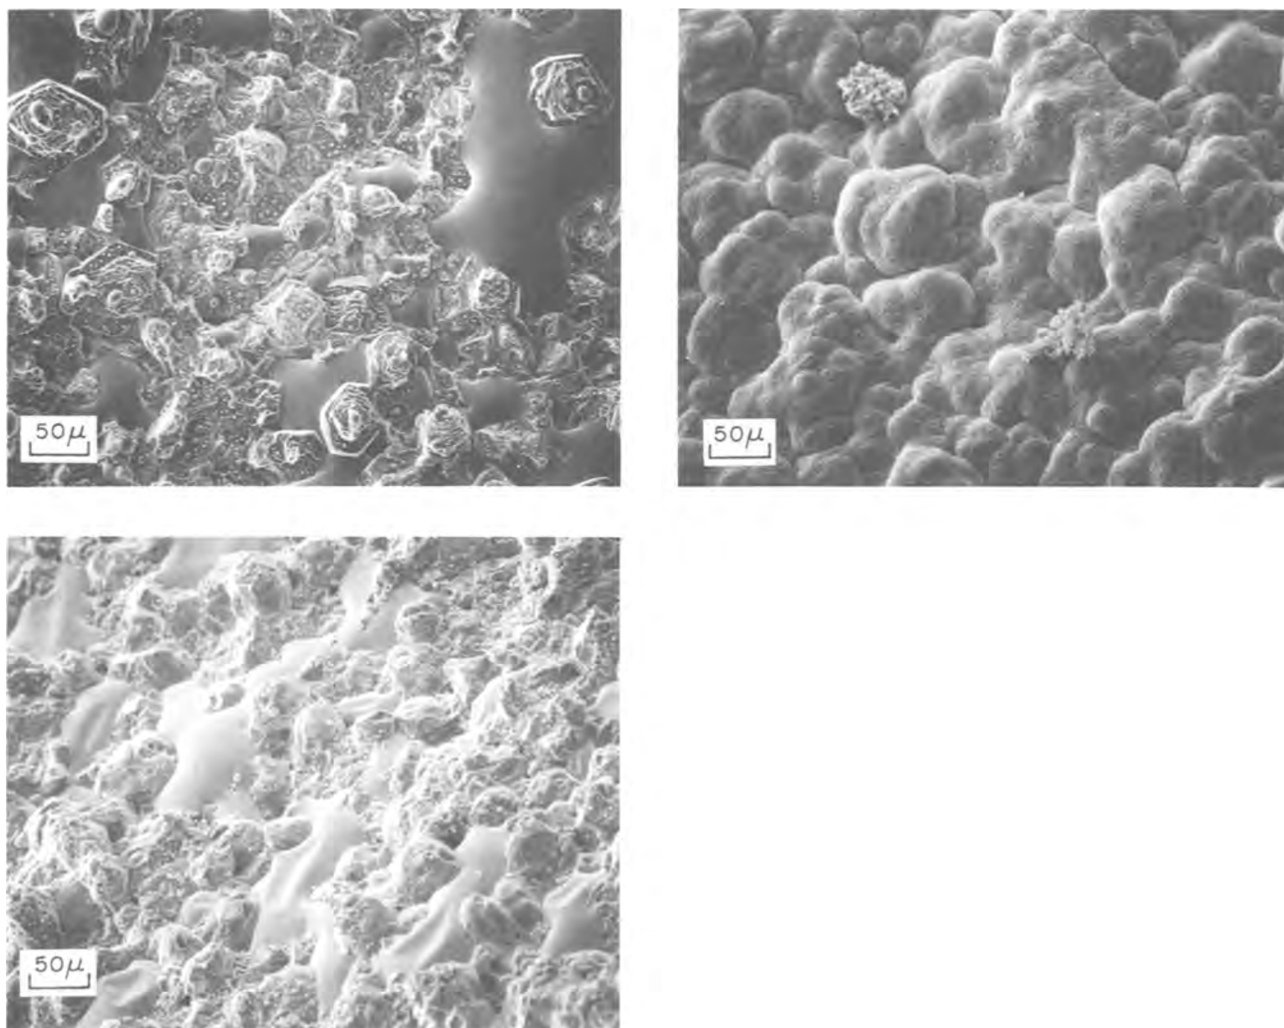

Fig. 7. Secondary emission micrographs of GaN-predeposited Grafoil liner: (a, left) after annealing in H_2-only ambient for 1 hr at about 1000°C after passing NH_3 through the liner shown in (a) for 30 min; (b, right) at temperatures below the "threshold" point; and (c, bottom) at temperatures above the "threshold" point.

of GaN formed on the Ga. Above 1025°C, however, a dramatic change occurred; significantly more NH_3 was decomposed and the Ga reacted to form a large amount of dark gray spongy material which filled the tube but did not block the gas flow. Between 1000° and 1025°C, a golden spongy material was generally formed with no enhancement in the extent of NH_3 decomposition. The fact that pure Ga reacts with NH_3 at all temperatures investigated implies that it does not decompose NH_3 rapidly, otherwise NH_3 would not be available for the formation of GaN.

The material obtained above 1025°C was analyzed by x-ray diffraction and by chemical analysis. It was found to be a conglomerate containing about 60% Ga and 40% GaN in polycrystalline form. The SEM micrographs of this material, Fig. 8, demonstrated the general porosity of the materials (Fig. 8a) which was the result of the formation of numerous fine dendritic crystallites (Fig. 8b). The Ga in the conglomerate was removed with aqua regia exposing micrometer-sized GaN dendrites (Fig. 8c). The catalytic nature of this conglomerate material was investigated by placing a sample near the NH_3 inlet and performing the titration analysis as previously described. The results, shown in Fig. 6, show a similar behavior to the hydrogen-annealed GaN material except that the "threshold" temperature is lower. This confirms that the coexistence of Ga and GaN has a significant catalytic effect for the decomposition of NH_3. The lower threshold temperature for the conglomerate material is presumably the result of more total surface area.

For comparison purposes, the catalytic activity of a well-known catalyst for NH_3 decomposition was evaluated in our system. The catalyst was fine Fe particles obtained by decomposition of $FeCl_3$ on Grafoil in a hydrogen ambient and caused virtually complete decomposition of the NH_3 at 1150°C, as seen from Fig. 6, and it is known that this catalyst is of comparable effectiveness at lower temperatures as well. It must be emphasized that the GaN-Ga conglomerate would not be an effective commercial catalyst for ammonia synthesis; however, its catalytic effect would certainly influence the chemical vapor deposition of GaN.

Growth rate studies.—The growth rate of heteroepitaxial GaN depends on the following parameters: the growth temperature, the flow rate of reactants, substrate orientation, growth environment, and Mg-doping.

To study the influence of these growth variables, different temperature profiles, providing growth temperatures within the range of interest as indicated in Fig. 2-4, were investigated and two representative profiles selected for more extensive examination. The results are summarized in Fig. 9 and 10 for average temperatures of 1050° and 950°C, respectively. The modest increase in the furnace temperature during actual growth (the dashed curve) as compared to the profile when only H_2 carrier gas is passed through the furnace (the solid curve) is attributed to the exothermic nature of the reaction. Since it was established that the growth rate is linear, for given growth conditions (Fig. 11), the growth rate for each individual condition may

Fig. 8. Secondary emission micrographs of Ga-GaN mixture: (a, left) at 50×; (b, right) at 2500×; and (c, bottom) at 2500×, after removing Ga.

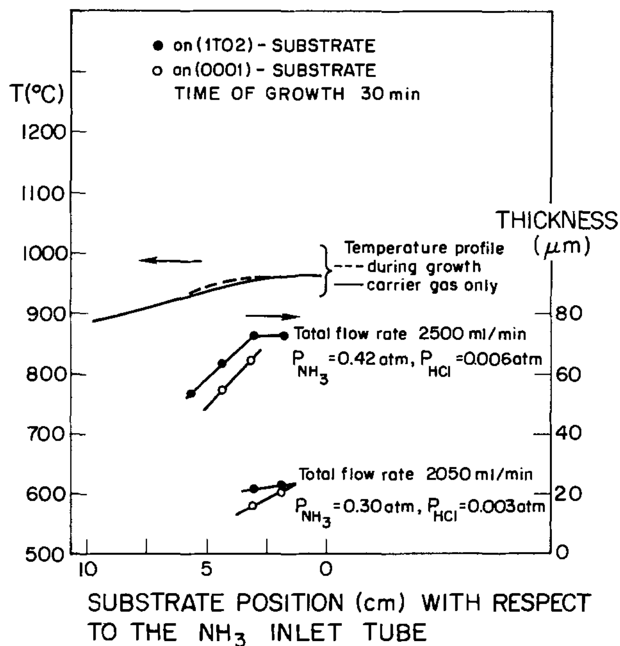

Fig. 10. Plot of growth temperature (<1000°C) and undoped GaN layer thickness *vs.* substrate position.

be obtained from the layer thickness after 30 min of growth. Several important trends that are apparent from these graphs may be summarized as follows:

(*i*) *Growth temperature.*—Comparison of identical substrate positions for the high and low temperature cases established that the growth rate decreases with

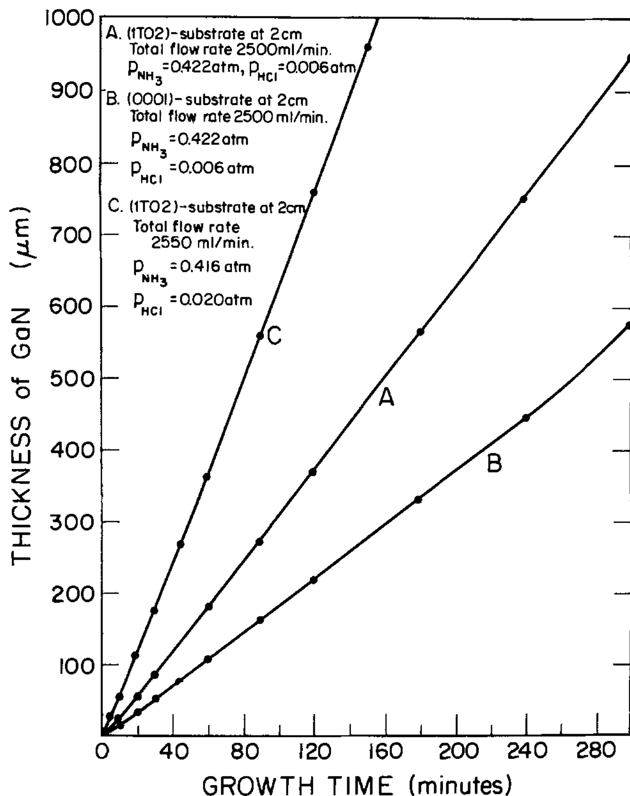

Fig. 11. Plot of undoped GaN layer thickness vs. growth time

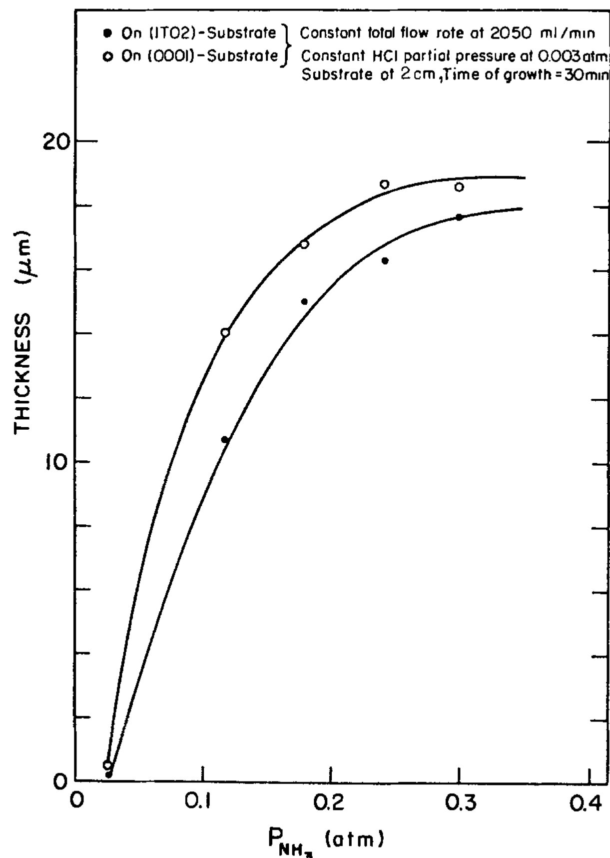

Fig. 12. Plot of undoped GaN layer thickness vs. p_{NH_3} for constant p_{GaCl}.

increasing temperature within the temperature regime of interest for both R-plane and basal-plane substrates. The temperature gradient at a specific growth site is generally not a major factor unless it is extremely shallow or steep. For shallow gradients, the heat of reaction is not conducted away as rapidly and the temperature increases as growth proceeds with a consequent influence on the growth rate and the surface morphology. For steep gradients, there is evidence of a homogeneous reaction in the gas stream prior to the heterogeneous reaction at the substrate.

(*ii*) *Flow rate*.—The influence of gas flow rate concerns the total flow rate, the carrier gas flow rate, and the flow rates of the reactant gases (HCl and NH_3). The influence of changing the individual reactant gas flow rates was most extensively studied. The results for two sets of NH_3 and HCl flow rates, with the hydrogen carrier gas flow rate kept constant, are shown in Fig. 9 and 10, and the influence of varying individual reactant gas flow rate is described in Fig. 11 and 12. It is evident that the growth rate increases with increasing flow rates of the reactant gases if either one or both rates are increased.

(*iii*) *Substrate position*.—As shown in Fig. 9 and 10, the growth rate decreases as the substrate position is moved downstream from the NH_3 inlet, presumably due to the depletion of the reactant species caused by deposition on the Grafoil liner prior to encountering the substrate.

(*iv*) *Substrate orientation*.—The growth rate on the (1$\bar{1}$02) or R-plane orientation was observed to be greater than that on the (0001) or basal-plane orientation for all the conditions investigated in this study, as shown in Fig. 9-12.

(*v*) *Growth environment*.—The enhanced NH_3 decomposition caused by the coexistence of Ga-GaN, as described in the previous section, has a direct influence on the growth rate at temperatures where part of the system is above the threshold temperature of ~1000°C for enhanced ammonia decomposition (cf. Fig. 6). Thus, for the higher temperature series, described in Fig. 9, there is a significant decrease in the growth rate if the growth environment includes Ga-GaN coexistence, as the result of the annealing of pregrown GaN in a H_2 ambient. For the low temperature series, however, where there is no part of the system above the threshold temperature (Fig. 10), there is no difference observed for two different growth environments.

(*vi*) *Mg-doping*.—A previous study (1) had shown that the rate of GaN deposition was lower during Mg doping than during growth prior to the doping. This implied that either Mg doping retarded the growth rate or the growth rate was not linear with time (*i.e.*, the growth rate was smaller at later times when Mg doping was occurring). The present study has established that the growth rate of the undoped layer is linear with time, thus Mg doping must decrease the growth rate. This decrease was established experimentally, with the results shown in Fig. 13. As can be seen from this graph, there is a substantial decrease in growth rate for either substrate orientation as the partial pressure of the Mg (as controlled by the temperature of the Mg reservoir) is increased in the growth system.

Discussion

Catalytic effect.—It has been established in this study that the growth environment can significantly influence the extent of NH_3 decomposition; limited decomposition occurs in quartz and graphite environments (up to ~10%) whereas more extensive decomposition occurs (up to ~60%) above a threshold temperature of 950°-1050°C if Ga and GaN coexist. It is appropriate to compare these results with previous investigations and to speculate on the causes and implications of this behavior. Other workers (20, 23) have reported that graphite and devitrified quartz exhibit catalytic effects for NH_3 decomposition in various vapor growth systems. As established in the present study, however, their influence is relatively modest compared to the Ga-GaN mixture. Recently, Raman spectroscopy has been applied to profile the NH_3 composition in the vicinity of a graphite susceptor in a CVD system and

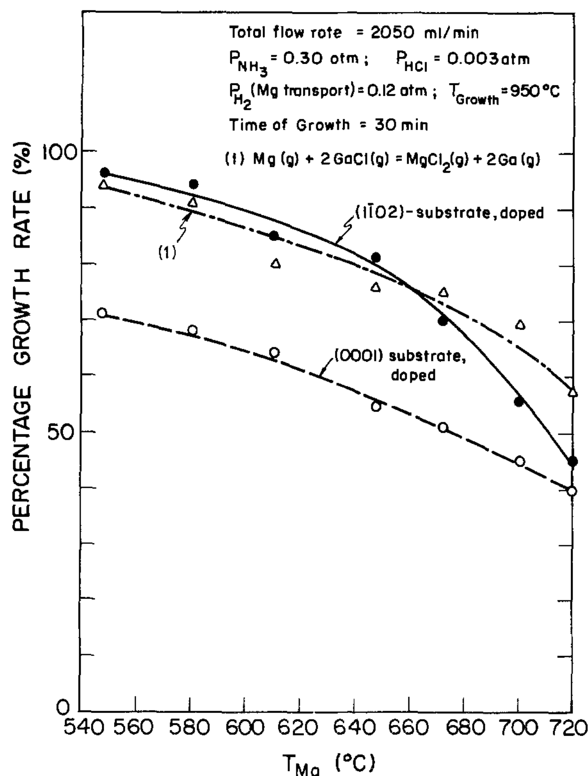

Fig. 13. Plot of percentage growth rate (with respect to the undoped) for doped GaN layer vs. Mg source temperature.

the catalytic effect of graphite confirmed (24). (This latter work, which measures the NH_3 concentrations at individual points, should be contrasted to the integral effects obtained in the previous studies and in the present work.) Our results of the modest catalytic effect of quartz and graphite for the decomposition of NH_3 are thus in agreement with the present literature.

Our significant finding, however, concerns the more pronounced enhancement of NH_3 decomposition with the coexistence of Ga-GaN above a threshold temperature. The need for the coexistence of both Ga and GaN clearly implies a critical interaction between the two components. This is analogous to the interaction between metal and support in the case of supported-metal catalysts (25, 26) except that there is no clear definition of which component plays the role of support in the present case. Two types of interaction might be possible: either a "bifunctional" catalyst (27) in which one reaction occurs on one component to yield an intermediate product which further reacts on the other component, with neither one capable of producing the enhanced effect alone, or a modification of the chemical properties of one of the components at the interface (28). For the latter case, the enhancement might be caused by a modification of one or more of the following at the interface: the electronegativity of the metal, the surface composition, and the surface structure. There is no clear evidence to allow an evaluation of the relative merits of possible mechanisms and detailed account of catalytic mechanisms is beyond the scope of this study.

The implications of these results are obvious. Since several runs are made in succession in the same reaction zone in a typical growth system, the treatment of this zone between runs will clearly influence the basic driving force for the deposition reaction, particularly in the early stages of the deposition. Furthermore, the early stage of the deposition is critical since the initial nucleation will have a pronounced influence on the deposition in general. It was found that the morphology of the GaN is changed if GaN is grown in the presence of coexisting Ga-GaN as would be expected from the decrease in the affinity for the reaction that results from the NH_3 decomposition. Another example is the procedure established to improve the microstructure for GaN light emitting diodes by use of higher affinities at the early stage of growth. This was achieved by the use of Ar gas instead of H_2 gas as a carrier gas (29). Furthermore, if nitrogen vacancies are the dominant donors in GaN that are responsible for the large intrinsic electron concentration, their concentration would be expected to vary with a change in the chemical potential of nitrogen which is clearly a function of the NH_3/H_2 ratio. Obviously, in cases where one wishes to maximize the affinity of a reaction involving nitrogen as a reactant, one should avoid conditions conducive to the decomposition of NH_3. The general concept of catalytic potency of the reactor environment will certainly be important for other CVD processes, such as the synthesis of GaAs and GaP, especially when NH_3 is used as a dopant.

Growth kinetics.—The experimental observations concerning the growth rate of GaN heteroepitaxial layers can be summarized as follows: (*i*) the growth rate is constant with respect to time; (*ii*) the growth rate decreases with increasing temperature within the temperature range of 850°-1150°C; (*iii*) the growth rate increases with increased flow rate of NH_3 and/or HCl, and generally saturates; (*iv*) the growth rate is a function of the substrate position in the gas stream, it decreases as the substrate position is moved further downstream; (*v*) the growth rate depends on the catalytic nature of the growth environment and decreases under conditions of greater NH_3 decomposition; (*vi*) the growth rate is significantly more rapid on R-plane substrates as compared to basal-plane substrates; (*vii*) the concurrent incorporation of Mg in the deposit, produced by the presence of Mg vapor in the growth zone, decreases the growth rate substantially.

The temperature dependence of the growth rate is an apparent contradiction to predictions based on thermodynamics, as illustrated in Fig. 3 and 4. Since, in the majority of the growth runs studied, the extent of NH_3 decomposition in the bulk stream was less than 10%, one would predict an increase in the equilibrium extent of reaction with increasing temperature in the temperature range studied. One would also expect the relative attainment of equilibrium to increase with increasing temperature since the detailed kinetic processes involved should be enhanced with increasing temperature. This apparent contradiction may be the result of a combination of two or more factors: inaccurate literature values for the thermodynamic data and the discrepancy between the bulk extent of decomposition of NH_3 and the local extent of decomposition in the vicinity of the reaction interface. The weakest factor in the development of the thermodynamics of the deposition reaction is the standard Gibbs free energy of formation for GaN (15). These values were estimated since direct measurements of the standard enthalpy of formation, entropies, and heat capacities are not available at present. Thus, a discrepancy in the values that would displace the maximum in the curves in Fig. 3 and 4 downward by ~250°K is not an unreasonable expectation. Furthermore, it must be noted that the extent of decomposition of NH_3 that was experimentally determined in the present study was an integrated effect. It is possible and indeed probable, based on the recent work of Sedgwick (24), that the local extent of decomposition would shift the maxima in these curves to lower temperatures. It is obvious that in nonuniform reacting systems, such as CVD reactors, an *in situ* analysis technique for composition and temperature, with fine space resolution, is necessary to rigorously establish the thermodynamics near an interface.

The relative importance of two rate-limiting mechanisms in the epitaxial growth, mass transfer and surface reaction, cannot be clearly established for the present CVD system, but there is some evidence that it is a mixed controlled case. While there is a definite dependence of growth rate on the substrate and crys-

tal orientation (item *vi*), an observation commonly used to imply the existence of a surface reaction-controlled process, there is a dependence on the rate of supply of the reactants (items *iii* through *v*), commonly associated with mass transfer control mechanism. It is certainly clear that the reaction is not surface catalyzed since the deposition is not restricted to a definite surface and nucleation is easily accomplished. (These two conclusions are based on the fact that the deposition of GaN is not surface sensitive; for conditions used in typical growths, polycrystalline GaN can be deposited on practically any surface in the growth chamber, such as the fine textured Grafoil liner and fused quartz substrate holder.) It appears that there may be a homogeneous reaction producing a precursor for the GaN deposit. Indeed, in the presence of steep temperature gradients, noncoalescent randomly oriented GaN clusters appear on single crystal sapphire substrates and, for extreme conditions, ultrafine powders (~100Å) of GaN are formed (30).

The pronounced decrease in the growth rate caused by Mg doping, as illustrated in Fig. 13, might arise for two reasons: the displacement reaction between Mg and GaCl to produce a less reactive source of Ga, and the poisoning of the growth surface by the adsorption of Mg or MgCl. The Gibbs free energy of formation of GaCl is about −35 kcal/mole at the growth temperature (21), whereas it is −110 kcal/mole for $MgCl_2$ (22). Thus the displacement reaction

$$Mg(G) + 2GaCl(G) = MgCl_2(G) + 2Ga(G)$$

should be complete in the vapor, if kinetic factors are favorable. From the geometrical configuration of the growth reactor (Fig. 1) the reaction will take place between the sidearm entrance and the NH_3 inlet tube; thus, GaCl will be depleted before mixing with NH_3. Since in the growth of insulating layers, it is necessary to have a partial pressure of Mg that is 10-20% of the value for the partial pressure of GaCl in order to fully compensate the native donors in GaN, the depletion of the GaCl concentration due to this reaction can be significant.

One may calculate the decrease in the growth rate due to the addition of Mg, making the assumption that the above reaction goes to completion and that the reduced Ga does not react to form GaN. Comparison of such calculations with observations for the R-plane substrates (Fig. 13) shows good agreement at lower Mg concentrations, whereas the actual growth rate is depressed even further at Mg concentrations corresponding to full electrical compensation. This implies a surface poisoning effect at these higher concentrations, in addition to the depletion effect. It is also noticed in this regime of Mg concentration that there is a change in the surface morphology (31), as might be expected for a surface poisoning effect. The proposed surface poisoning effect correlates to a detrimental change in the substrate surface. This change may be caused either by a high Mg concentration in the lattice inducing a change in the GaN layer surface morphology or the presence of adsorbed Mg species on the growth surface. For growth on the basal plane, a pronounced effect was observed even at low Mg source temperatures, which is consistent with our observation that surface morphologies are altered with low Mg concentration for the basal-plane substrate (31).

Summary

The nature of the growth ambient in the chemical vapor deposition of GaN was found to influence the extent of NH_3 decomposition. Pure quartz, graphite, and GaN surfaces had a minor influence on the decomposition (up to a maximum of ~10%) whereas the coexistence of Ga and GaN caused extensive decomposition (up to ~60%) for the temperature range of 950°-1050°C. The catalytic effect of the growth environment is thus a significant variable when NH_3 is used as a reactant or dopant in chemical vapor deposition processes.

Several significant trends in the growth rate of GaN are reported for typical growth conditions: (*i*) The growth rate is linear with time. (*ii*) The growth rate decreases with increasing temperature, in the range 850°-1150°C. (*iii*) The growth rate increases with increasing reactant composition. (*iv*) The growth rate decreases as the substrate is located further downstream. (*v*) The growth rate decreases when the growth environment favors the catalytic decomposition of NH_3. (*vi*) The growth rate is more rapid on R-plane sapphire substrates than on basal plane sapphire substrates. (*vii*) The growth rate decreases substantially when Mg is concurrently incorporated in the deposit.

An apparent discrepancy between the temperature dependence of the growth rate and the Gibbs free energy is noted and it is postulated that the discrepancy arises from local variations in NH_3 concentration caused by decomposition and/or by incorrect thermodynamic data for the reactant species.

ABSTRACT

An efficient implementation of multilayer potential analysis for spreading resistance measurements is described. A precalculated partial integral technique reduces computation time by a factor of 20 with no significant loss of accuracy. Spreading resistance measurements on beveled samples are compared to spreading resistance and four-point probe measurements on anodically sectioned samples and to Schottky C-V measurements. The results demonstrate the accuracy, versatility, and limitations of the technique.

Spreading resistance measurements on beveled samples allow convenient, high resolution determination of arbitrary impurity profiles in semiconductor devices (1, 2). Mechanical manipulation of the probes, probe tip design, bias conditions, and sample preparation have been optimized so that repeatable contacts can be achieved over a wide range of resistivities (1). Calibration curves can be generated from measurements on homogeneous samples to account for nonideal contact phenomena such as piezoresistive effects, contact potentials, and noncircular contact area, so that the resistivity of a homogeneous sample can be inferred directly from the spreading resistance measurement. However, for nonuniformly doped semiconductors the resistivity profile distorts the potential distribution beneath the probes resulting in a spreading resistance measurement which depends on the resistivities throughout the structure. A relationship between surface resistivity and measured spreading resistance which incorporates the effect of the nonuniform profile must be utilized to derive an impurity profile from the measured data.

Several methods have been developed for calculating spreading resistance "correction factors" on nonuniform samples. The simplest approach utilizes a two-layer model in which a single homogeneous layer of finite thickness is separated from a semi-infinite substrate by a perfectly insulating or perfectly conducting boundary. Analytical expressions for the correction factor can be derived for this idealized geometry by solving for the potential distribution with the method of images (3, 4). This approach is attractive for concentration profiles which change a negligible amount in a distance comparable to the contact radius, approximately 3 μm. However, a more sophisticated model is essential for the accurate analysis of measurements on the shallow diffusions, implantations, and epitaxial layers characteristic of modern integrated circuit technology.

Recent correction factor schemes have utilized a multilayer model in which the continuous concentration profile is approximated by a staircase function, Fig. 1. Each layer is assumed to have uniform concentration and finite thickness, equal to the distance between measurement points. If a p-n junction exists within one probe radius of the surface then a differential spreading resistance technique, analgous to four-point probe incremental sheet resistance, can be applied (5, 6). The resulting correction factors are explicit functions of the profile slope and are fairly accurate for shallow structures. A second approach solves for the potential distribution in the multilayer structure by the image method (7). Calculation of the correction factors requires a summation over the infinite series of image charges generated by each probe. The accuracy and range of applicability of this technique have yet to be established.

Of all the correction factor algorithms multilayer analysis (8-11) most nearly reflects the true physical nature of spreading resistance measurements on nonuniformly doped samples. It is basically a technique for solving Laplace's equation for the idealized multilayer geometry of Fig. 2. The semiconductor is assumed to be planar and of infinite extent in the Z and r directions. The sample is divided into layers of homogeneous resistivity and finite thickness Δh where Δh usually corresponds to the distance between measurement points. The probes are separated by a distance D and are assumed to make ideal contacts with the semiconductor surface, *i.e.*, the contact area is flat and circular of radius a, and all barrier potential and piezoresistive effects are neglected. These effects are often incorporated into the correction factor calculation empirically through a calibration curve (1, 2). With these assumptions Laplace's equation can be solved for the potential distribution in each of the layers. The expression for the correction factor, CF is derived directly from the surface potential V_1

$$CF = \frac{4}{\pi} \int_0^\infty \{1 + 2\theta\} \left\{ \frac{J_1(\lambda a)}{\lambda a} - \frac{J_0(\lambda D)}{2} \right\} \frac{\sin \lambda a}{\lambda} d\lambda$$

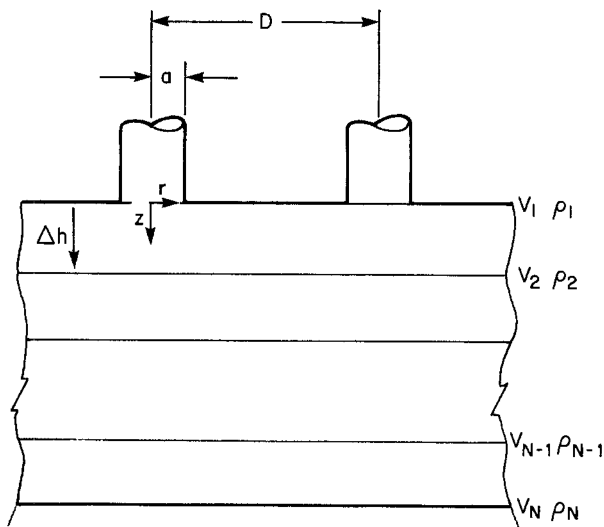

Fig. 2. Idealized multilayer geometry. *D* is the distance between the probes, *a* is the contact radius, Δh is the layer thickness, V_i are the potentials at each interface, and ρ_i are the resistivities of each layer.

The zero and first-order Bessel functions, J_0 and J_1, are characteristic of solutions to Laplace's equation for problems with cylindrical symmetry. The integration factor, θ, is derived from the boundary conditions of current and voltage continuity at each interface and is therefore dependent on all the resistivities ρ_1 through ρ_N as well as the layer thickness and the integration variable, λ. The infinite integral is required to satisfy the boundary conditions at each interface and the surface.

Multilayer potential analysis is generally applicable to any type of resistivity profile and its accuracy for measurement in beveled samples is limited mainly by the assumptions of planar geometry and charge neutrality. General application of this method has been inhibited by the complexity of the calculations. Originally, over 10,000 integrand evaluations were required to insure convergence of the integral resulting in excessive computation time and limiting the usefulness of this approach. Several authors simplified the computations by limiting or partitioning the number of layers (11-14). Others simplified the calculation of θ (which originally required the solution of a $2N$ by $2N$ matrix) first by power law interpolation (11, 14) and later by the derivation of exact recurrence formulas (15, 16). Recently an integration scheme has been devised which significantly reduces the number of integrand evaluations (17). The foregoing methods increase the efficiency of multilayer analysis but still include the time-consuming evaluation of the infinite integral. The following section describes an approach which removes the resistivity dependence from the integrand so that the integrals can be precalculated and stored. This particular implementation, called precalculated partial integrals, reduces the computation time by a factor of 20 as compared to an implementation including the recurrence formula calculation of θ.

Spreading resistance measurements on beveled samples are compared to spreading resistance and four-point probe measurements on anodically sectioned samples and Schottky *C-V* measurements. The results indicate several limitations inherent in the application of multilayer potential analysis to spreading resistance measurements on beveled samples.

Precalculated partial integrals.—The integration factor, θ, is a well-behaved function of λ and can be readily approximated by interpolation. θ is evaluated exactly at several judiciously chosen values of λ (the λ_i's in the following discussion) while in the intervals between λ_i's θ is approximated by the interpolation function. Figure 3 shows the exact evaluations of $1 + 2\theta$ (open circles) and a cubic natural spline interpolation (solid line) for 2 and 33 layers. For these examples, the interpolation error does not exceed 1% and is less than the error resulting from power law interpolation. For the cubic spline approximation, a distinct cubic polynomial is determined in each interval with the first and second derivatives constrained to be continuous at the boundaries. The expression for the integration factor becomes

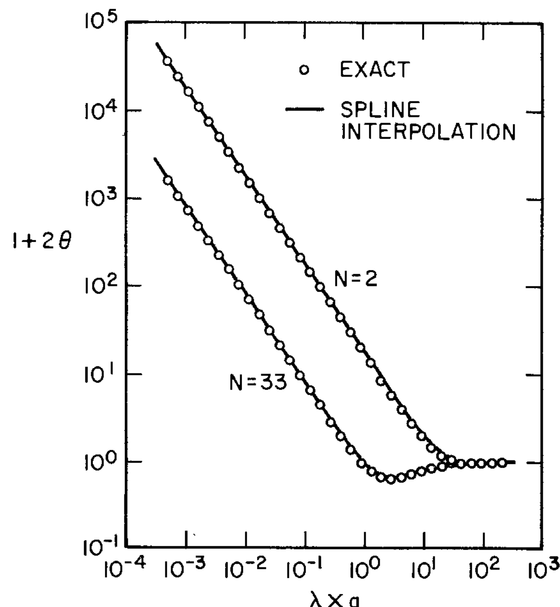

Fig. 3. Spline interpolation of the integration factor, $1 + 2\theta$, for 2 and 33 layers. λ is the integration variable and *a* is the contact radius.

$$1 + 2\theta(\lambda) = A_i\lambda^3 + B_i\lambda^2 + C_i\lambda + [1 + 2\theta(\lambda_i)]$$

for $\lambda_i \leq \lambda < \lambda_{i+1}$. A_i, B_i, and C_i are the cubic polynomial coefficients and are constant over the intervals between λ_i and λ_{i+1}.

The spline approximation for $(1 + 2\theta)$ can be substituted into the expression for the correction factor and the integral can be divided into partial integrals with limits of integration corresponding to the interpolation interval boundaries. The resulting expression is

$$CF = \frac{4}{\pi}\sum_{i=1}^{m-1}\left\{ A_i\int_{\lambda_i}^{\lambda_{i+1}} \lambda^3 f(\lambda)d\lambda + B_i\int_{\lambda_i}^{\lambda_{i+1}} \lambda^2 f(\lambda)d\lambda + C_i\int_{\lambda_i}^{\lambda_{i+1}} \lambda f(\lambda)d\lambda + D_i\int_{\lambda_i}^{\lambda_{i+1}} f(\lambda)d\lambda \right\}$$

where

$$f(\lambda) = \left\{ \frac{J_1(\lambda a)}{\lambda a} - \frac{J_0(\lambda D)}{2} \right\} \frac{\sin(\lambda a)}{\lambda}$$

$$\lambda_1 = 0$$

and λ_m, the upper integration limit, is chosen to insure convergence of the integrals. The spline coefficients are constant over the interpolation intervals and can be removed from the integration. The resulting integrands are independent of resistivity and layer thickness and can therefore be precalculated and stored for any given contact radius and probe separation.

The method of precalculated partial integrals significantly reduces computation time without compromising the inherent accuracy of multilayer potential analysis. Figure 4 shows the uncorrected and corrected profiles for an epi-buried layer structure. A full multilayer implementation including the recurrence formula

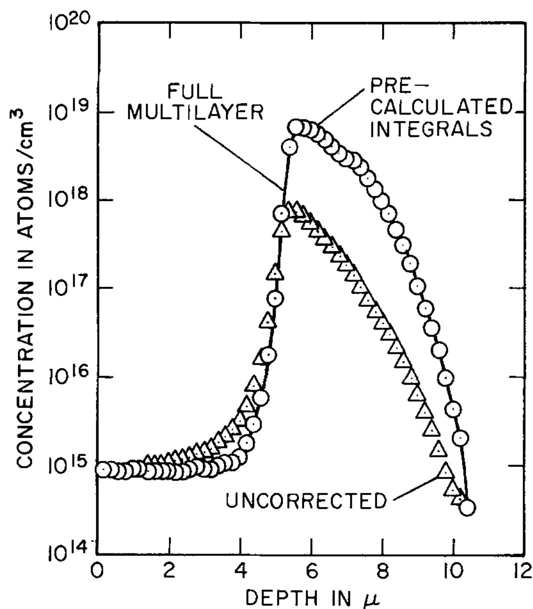

Fig. 4. Comparison of full multilayer and precalculated partial integral analysis of an epi-buried layer structure, including the corrected and uncorrected impurity profiles (a), and tabulated execution times and maximum percent deviation, (b).

	Execution time (min	Max. deviation of impurity concentration (%)	Limiting computation step per iteration
Full multilayer	50	0.1	10,000 integrand evaluations
Precalculated partial integrals	2.5	0.1	Calculation of 280 spline coefficients

calculation of θ required over 50 min on an HP 2100 minicomputer with a memory cycle time of 1 μsec. In comparison, use of precalculated partial integrals reduced the execution time by a factor of 20 to less than 2.5 min while introducing a maximum deviation in concentration of only 0.1%.

The error introduced by spline interpolation of $1 + 2\theta$ is apparently negligible. However, the approximations inherent in multilayer potential analysis can be a source of inaccuracy in isolated portions of certain types of impurity profiles. The comparative results of the next section demonstrate some of these limitations as well as the general utility of the multilayer method.

Comparative Results

To verify the accuracy of multilayer potential analysis on beveled samples, several impurity profiles have been measured by alternative methods including four-point probe incremental sheet resistance, two-point probe incremental spreading resistance, and Schottky C-V.

For the incremental sheet resistance method material is removed in 500Å layers by anodic sectioning. Successive sheet resistance measurements are made with a four-point probe and the resistivity is calculated from the standard incremental conductance model (18).

Incremental spreading resistance also utilizes anodic sectioning to remove material. However, in this case, measurements are made with a two-point spreading resistance probe and the data are analyzed with multilayer potential theory. The incremental spreading resistance technique offers an excellent test of multilayer theory, since the planar geometry and absence of junction space charge regions in the anodically sectioned samples are consistent with the assumptions of the multilayer model

The alternative measurement techniques are compared to the standard two-point probe spreading resistance on beveled surfaces, corrected by multilayer analysis. The beveled samples were polished with water soluble abrasives (Metadi, Quso, or Syton) on Plexiglas in an SSM LP Machine.[2] Angles on the order of 16′ to 1° were measured with the small angle measurement technique (SAM) (19) or multibeam interferometry. The spreading resistance measurements were made with a commercially available automatic probe, the ASR 100.[2]

The first example is a fairly deep phosphorus emitter diffusion into a 4 Ω-cm p-type substrate. Figure 5 compares the concentration profiles measured by incremental spreading resistance and incremental sheet resistance. Agreement in profile shape and absolute concentration values is excellent. Figure 6 compares incremental spreading resistance on an anodically sectioned surface to spreading resistance on a beveled surface. Agreement is good throughout most of the diffusion, including junction depths and peak concentrations as well as in the familiar dip due to concentration-dependent diffusivity. However, significant

Table I. Calculated and measured sheet resistance for 2 μm phosphorus diffusion

Calculated from	Sheet resistance (Ω/□)
Beveled spreading resistance	7.5
Incremental spreading resistance	6.3
Incremental sheet resistance	6.5
Measured by four-point probe	6.3 ± 5%

discrepancy exists at the surface where the concentration on the beveled sample falls below the concentration on the anodically sectioned sample. This effect, which has been observed by others (11), is in some way caused by the bevel geometry and is consistently present as is shown in the following examples. Probable causes of the surface anomaly are discussed in a later section.

As an additional verification of the measurement accuracy sheet resistance values were calculated by integrating the corrected conductivity profiles and compared to the sheet resistance measured by a four-point probe, Table I. The calculated values for both the incremental spreading resistance and incremental sheet resistance profiles are in excellent agreement with the measurement The slightly higher value for beveled spreading resistance is a result of the decreased surface concentrations.

The second sample is a three layered structure which forms the source, channel, and drift regions in VMOS and DMOS transistors (20). The channel region is formed by boron implantation into an n^- substrate while the source region is diffused from an arsenic-doped oxide. Incremental spreading resistance is compared to incremental sheet resistance in Fig. 7 and beveled spreading resistance in Fig. 8. Agreement between the two incremental profiles is excellent throughout the n^+ source, but both demonstrate a considerably higher surface concentration than the beveled spreading resistance. In the channel region beveled spreading resistance falls below incremental spreading resistance near the source junction but follows it closely throughout the rest of the p diffusion. The discrepancy near the junction may be caused by the presence of the space charge region in the beveled sample. Since all the n-type material has been removed by anodic sectioning there is no space charge region extending into the channel for the incremental case.

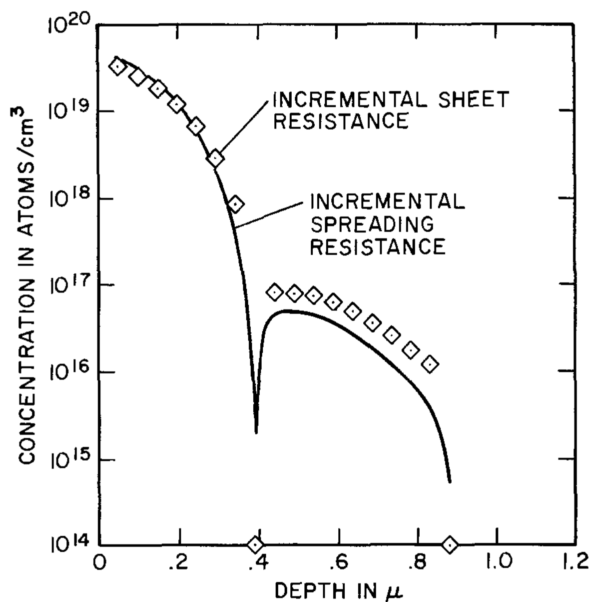

Fig. 7. Incremental spreading resistance (—), and incremental sheet resistance (◇) for the source-channel region of a DMOS/VMOS transistor.

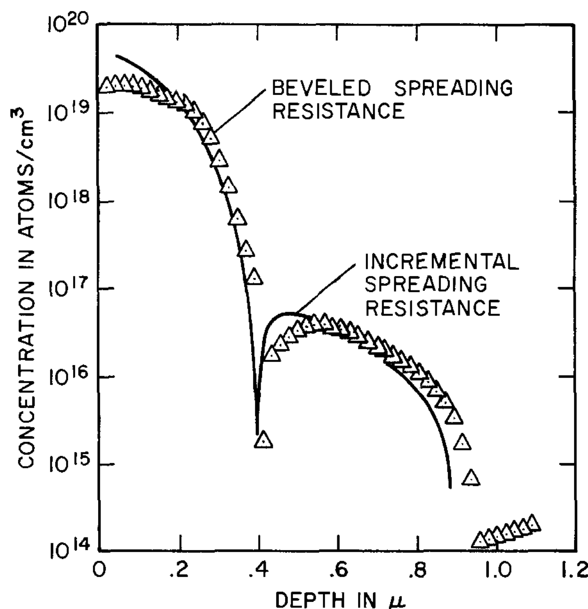

Fig. 8. Incremental spreading resistance (—), and beveled spreading resistance (△) for the DMOS/VMOS process.

The channel concentrations from incremental sheet resistance are approximately 30% higher than the values derived from the two spreading resistance methods. To further evaluate these results calculated sheet resistance is compared to measured values in Table II, where channel resistance is measured on a pinched base resistor. Incremental spreading resistance agrees best with the measured values, both in the source and channel regions, while beveled spreading resistance is high in both regions due to the low concentration at the surface and at the source junction. The high concentrations of the incremental sheet resistance profile result in a calculated channel sheet resistance which is about 30% lower than the measured. The discrepancy may be attributed to the inaccuracy of the four-point probe measurement for narrow, lightly doped layers with sheet resistance on the order of 10 kΩ/□. Table III compares the calculated (from beveled spreading resistance) and measured sheet resistance values for several channel implants and drive-in schedules. The difference never exceeds 15% for channel lengths between 0.5 and 2.0 μm.

The third example is a high frequency bipolar transistor with a diffused phosphorus emitter and a boron base resulting in an emitter junction depth and base

width of approximately 0.4 μm. The comparisons in Fig. 9 and 10 demonstrate the same regions of discrepancy and correspondence observed in the previous example. Comparisons of the calculated and measured sheet resistance values, Table IV, again verify the excellent accuracy of multilayer potential theory applied to anodically sectioned structures and demonstrate the limitations of the measurement on beveled samples

The over-all repeatability of the spreading resistance method on beveled samples is demonstrated in

Table IV. Measured and calculated sheet resistance for the bipolar transistor

Calculated from	Sheet resistance (Ω/□) Emitter	Base
Beveled spreading resistance	38.3	6.9×10^3
Incremental spreading resistance	17.2	4.5×10^3
Incremental sheet resistance	—	4.7×10^3
Measured	16.1 ± 5%	

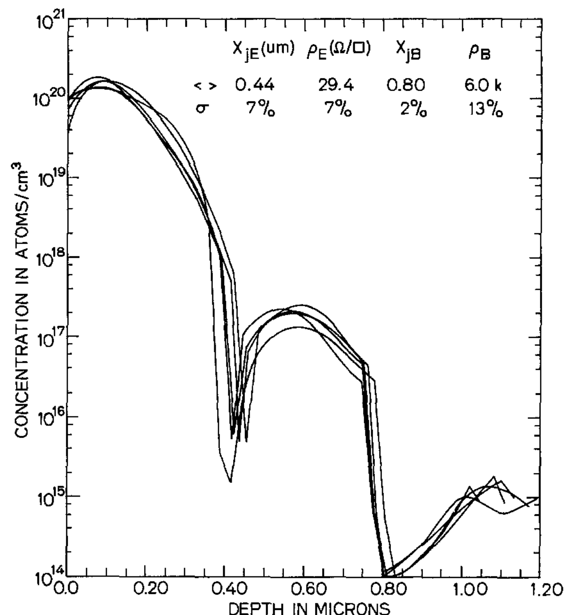

Fig. 11. Comparison of beveled spreading resistance measurements on samples taken from the same bipolar wafer. The tabulated results are the average (< >), and standard deviation in percent of the average (σ), for the emitter (X_{jE}) and base (X_{jB}) junction depths and the calculated sheet resistances in the emitter (ρ_E), and in the base (ρ_B).

Fig. 11. For this experiment a single high frequency bipolar wafer was chosen, from which one sample per week was scribed, beveled, measured, and analyzed. As can be seen from the tabulated statistics repeatability in junction depths and calculated sheet resistances is very good. As can be expected the regions demonstrating the least repeatability are at the surface and in the base near the emitter junction.

The final example, Fig. 12, compares Schottky C-V and beveled spreading resistance measurements for a shallow n^- epitaxial layer on an n^+ buried layer. The two step epitaxial layer process was designed to minimize autodoping. The resulting dip in concentration at the epi-buried layer interface is detected by both profiling techniques. This structure demonstrates the over-all range and versatility of the spreading resistance method which is capable of measuring the epitaxial layer, and the buried layer while the C-V technique is limited by breakdown to the lightly doped epitaxial layer.

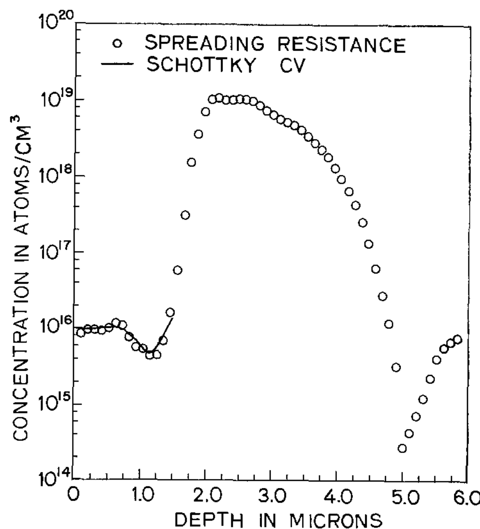

Fig. 12. Beveled spreading resistance (○), and Schottky C-V (—) for an epi-buried layer profile.

Discussion

The preceding comparative measurements demonstrate the utility and accuracy of the spreading resistance technique in combination with multilayer potential analysis. The comparisons of incremental spreading resistance with incremental and total sheet resistance measurements suggest that the multilayer model accurately (to within 10%) describes spreading resistance measurements on idealized planar structures with junction depths on the order of 0.5 μm and larger. However, measurements on beveled samples indicate that the bevel geometry introduces second-order effects which result in significant underestimation of diffused profiles near the Si-SiO_2 interface and in the vicinity of junctions. Several probable causes for these discrepancies are discussed.

The multilayer model assumes a semi-infinite planar geometry so that cylindrical symmetry can be invoked in the solution to Laplace's equation. The bevel geometry only approximates this situation in the limit of small bevel angles. The two dimensional asymmetry in a beveled structure will distort field and potential distributions as insulating interfaces are approached. This phenomenon can be expected to effect the results similarly at material interfaces such as Si-SiO_2 and Si-air and metallugical junctions. In both cases the sampling volume of the measurement is diminished due to the presence of an insulating boundary resulting in higher values of measured resistance and lower corrected concentrations. While exact analysis of the edge effect would require three-dimensional solutions, two-dimensional analysis of limiting cases in conjunction with empirical corrections may prove useful.

In practice the bevel geometry is never ideal in the sense that two flat planes intersect at an obtuse angle. Instead the beveled surface tends to curve or round, especially at the Si-SiO_2 interface. Figure 13 shows surface profiilometer plots for two beveled samples, one prepared with mechanical diamond polish, Metadi, in an aqueous medium and the other with the chem-mechanical, silica polish, Syton. Rounding extends several micrometers into the beveled surface for both samples and is more pronounced in the case of the chem-mechanical polish. The relatively high viscosity of the Syton mixture may be responsible for the excessive rounding. The analysis procedure assumes a fixed vertical distance between each measurement point, which is derived from a bevel angle measurement and the horizontal stepping distance. For the curved bevel surface actual vertical spacing will increase with increasing depth. In general, the bevel angle measurement will be an average over the surface so that the distance between points will tend to be overestimated near the bevel edge and corrected concentrations will be diminished. Possible solutions to this particular problem include optimization of the beveling process to minimize rounding and quantitative measurement of the bevel contour.

As previously mentioned, the presence of space charge in beveled samples may be responsible for the discrepancy on the lightly doped side of p-n junctions. Multilayer potential analysis, which is a solution to Laplace's equation, inherently neglects the effects of space charge. Since spreading resistance is an electrical measurement, only mobile carriers can be detected resulting in an underestimation of impurity concentrations in space charge regions.

An additional source of inaccuracy arises for measurements of p-type profiles due to the nonideal nature of the calibration. Figure 14 is a typical p-type calibration for samples polished in Metadi. The curve is generated by measuring spreading resistance on a number of uniformly doped samples of varying resistivities. The effective contact radius is derived from a power law fit to the measured data so that $Rm = C\rho^m$ and $a = 1/(2C)$. An exponent of 1.0 would imply a constant contact radius as is assumed in the multilayer model. For n-type calibrations m is consistently on the order of 0.95 while for p-type it decreases to 0.85. The deviation from unity results in underestimation of p-type concentrations greater than 10^{18} cm^{-3}. The degree of nonlinearity in the calibration curve is highly dependent on sample preparation and is consistently higher for mechanical polishes such as Metadi in comparison to chem-mechanical abrasives, including Syton and Quso (2). The trends indicate that the effects of nonideal contact phenomena, such as barrier potentials, and piezoresistance, increase with increasing surface damage. The nonlinearity in the calibration curve can be compensated by including an empirical barrier resistance into the correction algorithm (2, 6).

Finally, finite probe penetration and surface extent will ultimately limit the achievable vertical resolution. For this work probe loading was a nominal 20g resulting in a contact radius of about 3.0 μm. Considerable error can be expected from profile smearing at this load for junction depths less than 0.2-0.3 μm. Lighter loads on the order of 6g reduce the contact radius to less than a micrometer significantly increasing potential resolution.

Conclusion

The spreading resistance technique is a potentially powerful tool for measuring arbitrary impurity profiles in semiconductors. An accurate data analysis scheme is essential for the determination of shallow profiles. Of the methods currently available, multilayer potential analysis is most consistent with the physical nature of the measurements An implementation of multilayer analysis has been presented which reduces computation time by a factor of 20 with no significant loss of accuracy. Comparative results demonstrated the excellent accuracy of the model for junction depths of 0.5 μm and larger as well as limitations for the application of the method to beveled structures. Proposals for future development include theoretical investigation of three dimensional bevel edge effects, quantitative measurement of the bevel contour, analysis of space charge effects, and physical investigation of the metal probe-semiconductor contact and its effect on calibration measurements.

Abnormal Undercutting in Etched Cr/Au Films

ABSTRACT

The etching of gold films deposited on chromium adhesion layers in iodine solution creates cavities at the base of the films. These cavities or abnormal undercutting are revealed and studied by means of the scanning electron microscope. The abnormal undercutting causes the lifting of gold in the etching of high resolution patterns. The alkali cyanide etching solution creates normal undercutting and its use is recommended. It is suggested that the abnormal undercutting results from the formation of an electrochemical cell in the final stage of the etching process when the chromium layer and the gold layer are simultaneously exposed to the electrolyte. The partial oxidation reaction of gold dissolution at the gold surface is balanced by triiodide reduction at the chromium surface as well as at the gold surface. The electrochemical cell formation accelerates the etching of gold near the chromium-gold boundary and causes the formation of cavities. The mechanisms for the normal and abnormal undercutting processes are discussed.

One of the most commonly used metal systems in solid-state technology is Cr-Au layers. This combination is often used for microstrip MIC's for multilayer thin film MIC's as well as for hybrid circuitry in general (1). Cr-Au is also often used as metallization for interconnections and bonding pads in semiconductors other than Si (2).

Because of its great technological importance and the common trouble of gold lifting in the etching of high resolution patterns, the study of the undercutting of etched gold lines was undertaken. The etchants which were employed are the commonly recommended, commercially available etchants, *i.e.*, the iodine etch and the alkali cyanide solutions.[1]

It was found that while the alkali cyanide solution created normal undercutting, the iodine etch caused an abnormal undercut. At high magnification the optical microscope revealed what appeared to be a small degree of undercut—seemingly very favorable for fine lines. However, the scanning electron microscope (SEM) showed that narrow but deep penetrating cavities were formed at the base of the etched lines.

The damaging nature of the phenomenon manifests itself in the lifting of the gold where fine lines in patterns of high resolution are etched. The gold is lifted mainly during the second stage of the etching process. The chromium etching solution penetrates through the cavities and etches away the entire chromium adhesion layer from underneath the gold.

In this paper the undesired phenomena of cavities under etched gold are studied by means of the SEM. A mechanism for the abnormal undercut of gold films on chromium with the iodine etch is proposed. In the discussion the various etching processes of gold are theoretically evaluated.

Experimental

Pattern etching.—Gold was etched with the iodine etch in the presence of conventional positive photoresists and with alkali cyanide solutions containing peroxide in the presence of conventional negative photoresists. Negative photoresists were employed because of the high *p*H of the solution. Iodine etch is made from 400g KI, 100g I_2, and 400 ml of water. Alkali cyanide powder with the proper amount of peroxide is available commercially. Chromium was etched with either concentrated HCl and hydrazine or with an alkaline ferricyanide etch (3). For both layers the etching is selective.

Substrates.—The layers used for the etching experiments were from varied origin: Sputtered or evaporated Cr/Au films with a chromium layer of 500-1000Å and a gold layer about 0.5 μm thick and commercially Cr-Au-coated substrates with an additional electroplated gold layer of several microns. The layers were deposited on glass, sapphire, and alumina. While the texture of the films was dependent on the nature of the substrate, the observed phenomena were general and independent of the substrate or the photoresist. Normal or abnormal undercut developed only as a direct result of the specific etching solution which was used.

Results and Discussion

Figure 1 shows the profile and surface of 6 μm thick gold film etched at room temperature with iodine solution. The cavity which is formed at the base of the gold line is clearly seen. Figure 2 shows a schematic diagram of the film cross section showing the deep cavities which are referred to as abnormal undercutting.

In order to measure quantitatively the depth of the cavity in relation to the film thickness and time of exposure to the etching solution, the etched films were overexposed to the chromium etching solution. The lines lifted, were turned over, and photographed again.

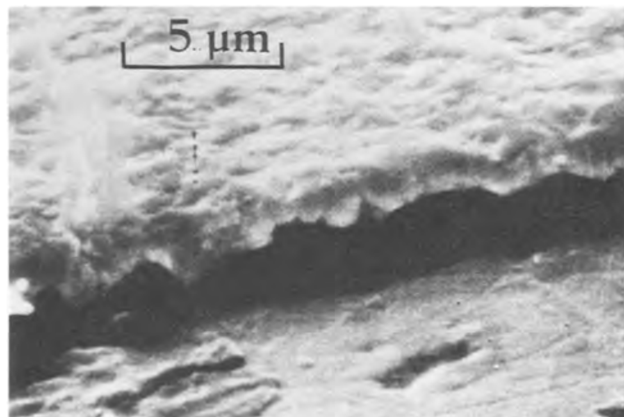

Fig. 1. SEM micrograph of a gold line edge etched with iodine solution. A deep cavity is seen underneath.

Key words: films, circuits, corrosion, etching.

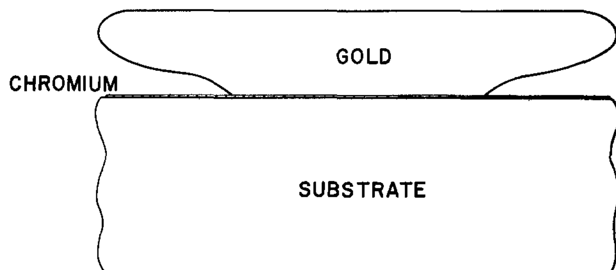

Fig. 2. A schematic cross section showing the abnormal undercutting of a Cr/Au line etched with iodine solution.

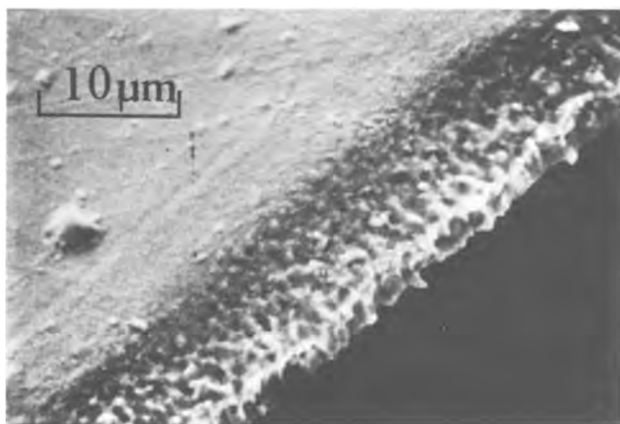

Fig. 3. SEM micrograph of the base of the gold line etched with iodine solution.

Figure 3 is a top view of the base of the etched line. Another technique which was employed was to evaporate Cr/Au films on glass substrate and then measure the degree of abnormal undercut through the backside of the transparent substrate using an optical microscope. The cavities extended quite often 10 μm underneath the gold film.

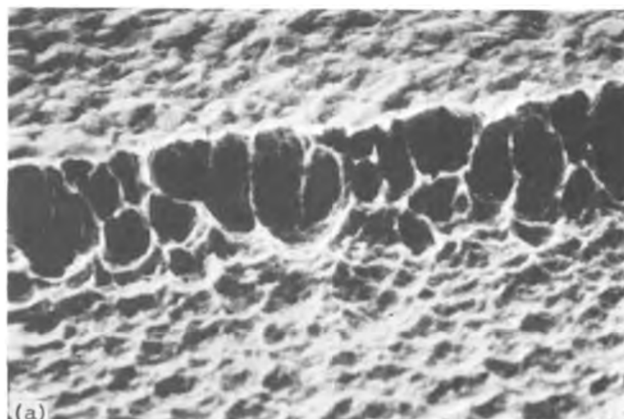
Finally, Fig. 4 shows the successive stages of the etching process of a 6 μm thick gold film. Figure 4 was obtained by interruption of the etching at different stages of the process, removal of the photoresist, and recording the result by the SEM. Figure 4a shows the morphology of the gold edge when the etchant has not yet reached the chromium. No cavities are observed at this stage. Figure 4b shows the edge shortly after the etchant reached the chromium interface. The chromium is first seen at the gold edge but some holes can be seen elsewhere in the film. Subsequently more holes appear in the field and a cavity develops around each hole and the film edge. When the entire gold is finally etched away, a deep cavity remains under the gold edge (Fig. 4c).

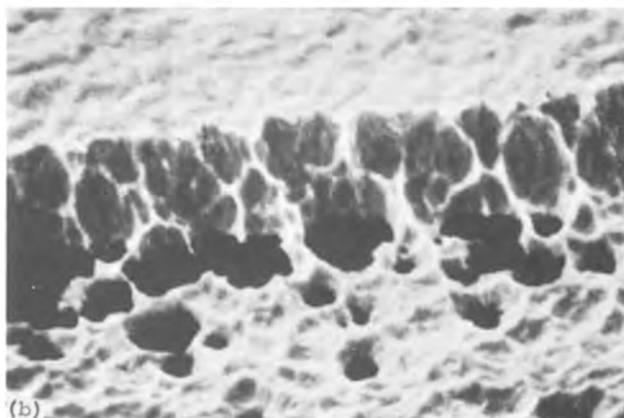
Figure 5 shows the profile and surface of gold film etched with the alkali cyanide solution. It clearly indicates the proper way of etching fine-lines of gold. The etching process is referred to as normal undercutting because of the uniform slope at the film edge devoid of any reentrant slopes or cavities.

The rate of the etching process in the iodine solution was then compared with that of a pure gold surface and a couple of gold with chromium. The exposed area of the latter was about ten times larger than that of gold. The etching rate increased from 30 to 200 nm/sec by the couple, the gold being the anode. In the actual etching process (see Fig. 4) the etch rate of gold at the final stage is increased significantly since the area of the chromium surface which is exposed to the etching solution rapidly increases (8).

The actual behavior of the couple Cr/Au during etching in the iodine solution indicates that the gold acts as the anode in respect to the exposed chromium. The potential of the chromium surface which was measured against the gold surface at open circuit was found to be approximately 3 mV. The relatively active potential of the gold could possibly be the result of formation of a complex, iodoaurate (AuI_2^-) as the anodic product. The chromium is expected to be passivated at the prevailing mixed potential when both are in contact and exposed simultaneously to the solution. The galvanic cell created between the gold and the exposed chromium thus enhances gold etching near the junction and causes the observed undercut if free gold dissolution is assumed in the electrolyte.

The open-circuit conditions leading to the observed polarity between chromium and gold is schematically illustrated in Fig. 6.





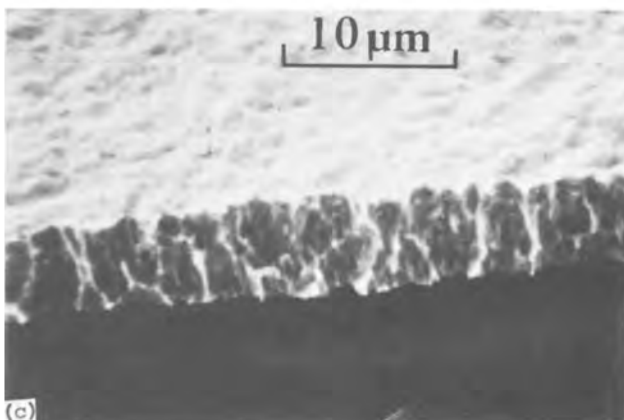


Fig. 4. The development of holes and cavities during successive stages of the etching process with iodine solution: (a) Film edge just before reaching the Cr interface; (b) holes form at the film edge and in the field; (c) after completion a deep cavity formed under the gold edge.

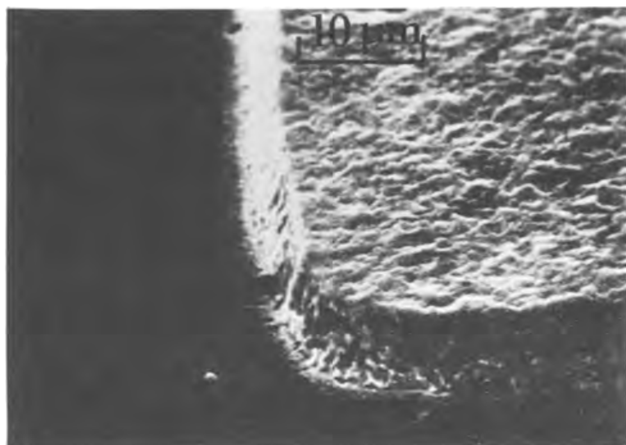

Fig. 5. SEM micrograph of gold film etched with alkali cyanide solution showing normal undercutting.

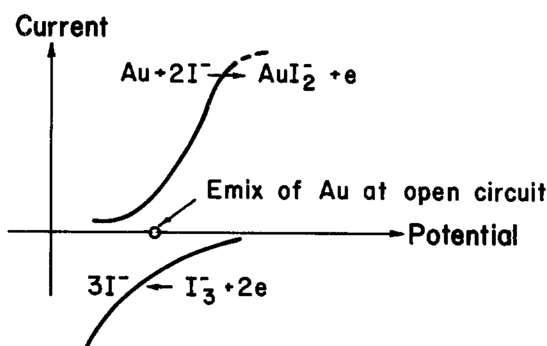

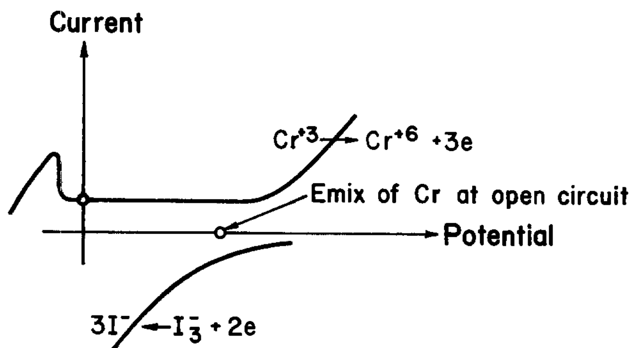

Fig. 6. Schematic diagram of the current-voltage curves for etching of gold and the passivation of chromium in iodine solution.

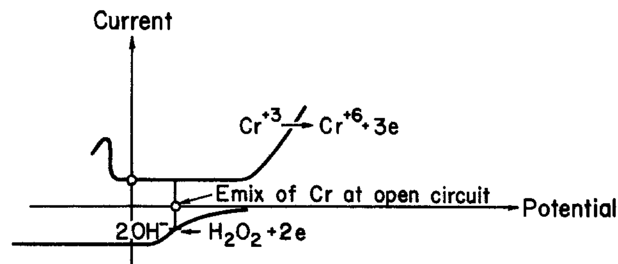
In the cyanide solution, where no undercutting took place, the gold was nevertheless still found to be at a more negative potential than the chromium. The potential of a chromium surface against a gold surface at open circuit in the alkali cyanide solution was found to be +250 mV. The active potential of gold is due to the formation of stable complexes. The cathodic depolarizer is hydrogen peroxide. Under such conditions the exposed chromium is again expected to be passivated (7). The complete selectivity in the etching of gold which was observed would indicate passivity for the chromium layer. The fact that no enhancement of dissolution occurred in this case at the gold adjacent to the chromium layer in spite of the galvanic cell created between them should indicate limiting-current conditions at the gold surface. The current in this case is con-



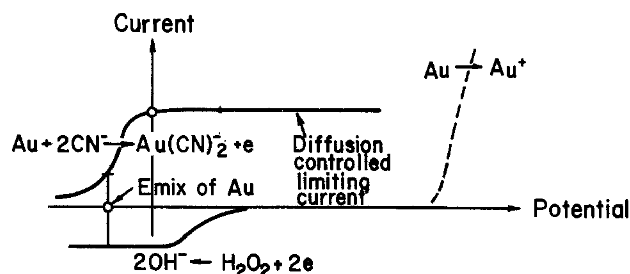


Fig. 7. Schematic diagram of the current-voltage curves for the etching of gold in the alkali cyanide solution.

trolled by the diffusion of the cyanide ions. The open-circuit situation is schematically illustrated in Fig. 7.

Summary

It has been shown that the iodine etchant for gold films which are deposited on chromium adhesion layers forms cavities at the base of the films. This abnormal undercutting causes the lifting of gold in the etching of high resolution patterns.

It is believed that the cavities are created at the final stage of the etching process when the chromium and gold layers are simultaneously exposed to the electrolyte. The gold acts as the anode and the chromium becomes the cathode. The electrochemical cell formation accelerates the etching of gold near the chromium-gold boundary and causes the formation of cavities.

In the alkali cyanide etchant abnormal undercutting is avoided due to the limiting diffusion of the cyanide ions. The use of alkali cyanide solution is therefore recommended for the etching of fine lines.

Manuscript submitted Sept. 23, 1977; revised manuscript received Feb. 15, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Perturbation of Parabolic Kinetics Resulting from the Accumulation of Stress in Protective Oxide Layers

H. E. Evans, D. J. Norfolk, and T. Swan

Berkeley Nuclear Laboratories, Central Electricity Generating Board, Berkeley, Gloucestershire, England

ABSTRACT

A frequent observation in metal oxidation is the development of subparabolic kinetics, variously described as cubic or quartic. Although a number of detailed mechanisms have been proposed to account for this effect, none seem generally applicable. This paper presents a model of the oxidation process which is divorced from such restrictions. It is argued that deviations from parabolic behavior occur as a result of the concurrent development of stresses within the oxide. It is shown that the presence of stress fields can influence significantly the rate of transport of vacancy defects within the oxide such that tensile stresses produce positive deviations and compressive stresses, negative deviations from parabolic behavior. The model is applied in detail to Zircaloy-2 oxidation at 773°K. It is predicted that the kinetics should be insensitve to the oxygen potential of the environment and this has been confirmed by previous experimental work. In addition, the absolute value of the oxidation rate is closely predicted using measured values of diffusion coefficients and the observed gradual departure from parabolic kinetics with increasing oxide thickness is accounted for.

Simple models for the protective oxidation of metals based on reaction control by the diffusion of species across the oxide layer predict parabolic kinetics, *viz*

$$\xi = k_p t^{1/2} \quad [1]$$

where ξ is the oxide thickness, t is elapsed time, and k_p is the parabolic rate constant. However, there are many instances where reaction rates decline more rapidly than parabolic kinetics predict, *e.g.*, on zirconium (1), Zircaloy-2 (1), nickel (2-4), titanium (5), tantalum (5), and copper (5). No entirely satisfactory explanation has been given of this behavior. Thus, both Mott (6) and Anderson (7) have argued that the existence of space-charge effects within the oxide could produce such a departure from parabolic kinetics but this is likely to be important only for thin films. Irving (8) using Whipple's analysis (9) for diffusion in a polycrystalline aggregate attempted to demonstrate that cubic-type kinetics could occur if the dominant diffusion paths were grain boundaries, but Gibbs (10) has emphasized the shortcomings of this approach. There is good evidence, however, that mass transport in growing oxides can occur predominantly along short-circuit paths [*e.g.*, (11, 12)] and any variation with time in the density of such paths will lead to departures from parabolic kinetics.

On this basis a number of authors (13-16, 18) have developed a "decay" hypothesis which accounts for subparabolic kinetics by a decrease in the density of paths. More explicitly, observations of a tendency for increased oxide grain size with increasing oxide thickness (15-17) combined with the assumption that grain boundaries are the only important short-circuit routes can account for cubic (18) or even quartic (19) oxidation kinetics. This view gives rise to two reservations. The first is the assumption that grain boundaries are the only significant short-circuit paths, whereas calculation (14) and observation (15, 16) show that both dislocations and subboundaries are also important. The second reservation is that the evidence for an increasing oxide grain size is based on comparatively few observations for Zircaloy (17, 18), where data for only one pretransition film were presented. An additional difficulty with these measurements is that the scatter in grain size in any one transverse section was very large and resulted in considerable overlap of size ranges from one part of the film to another. Bearing in mind that observations of subparabolic kinetics are a frequent occurrence [for a summary of data on Zircaloy see Ref. (19)] the purpose of this paper is to present an alternative theory which does not require a systematic variation of structure with extent of oxidation. It is still recognized that short-circuit diffusion can occur, but the over-all density of such paths (*e.g.*, dislocations, subboundaries, and grain boundaries) is taken as constant.

An additional factor in the reported examples of nonparabolic behavior seems to be the development of compressive stress within the oxide. Thus, Pawel and Campbell (20) attribute at least part of their observed curvatures in specimens of tantalum and niobium to stresses within the oxide film; Tylecote and Appleby (21) consider that low temperature oxides grown on copper contain stresses which Borie *et al.* (22) attribute to epitaxy; Engell and Wever (23) have suggested the presence of strong compressive stresses in films of NiO and FeO; Roy and Burgess (24) have measured average stress levels of 1.7×10^9 nm^{-2} in films grown on Zircaloy-2 in oxygen and 1.1×10^9 nm^{-2} in films grown on zirconium. Accepting that the defects which control oxidation are in equilibrium at the oxide/metal and oxide/environment interfaces, the presence of stress may influence defect migration in two ways. The first arises because oxidation generally causes changes in solid volume at one or both of the interfaces. In the presence of stress such volume changes involve mechanical work and so displace the equilibrium positions of the interfacial reactions. Defect concentrations at either interface consequently vary with stress. This aspect is considered in this paper for the example of vacancy defects. The second arises because the volume occupied by a defect is different from that of a normal lattice site. The presence of a stress gradient within the oxide therefore imposes a bias on the random migration of defects. This is considered in the present work when the general transport equation is solved for particular distributions of stress. A comparison of the theory is then made with experimental data on Zircaloy-2 since reasonable measurements of stress exist for this material.

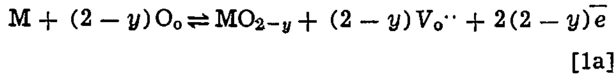
Because of this, the theory is developed for a metal M forming a stable dioxide MO_2 which grows by the formation of oxide at the oxide/metal interface. The volume increase so produced results in the accumulation of compressive stresses within the oxide. The

Key words: metal, oxidation, oxide layer stress.

oxide ions are transported to this interface by a vacancy-exchange mechanism. It is assumed that departures from stoichiometry are accommodated by single vacancies and that space-charge effects are negligible. It should be pointed out that the choice of this specific example does not detract from the generality of the concepts used. A further purpose of this paper is to make a numerical evaluation of the effect for this particular case.

Influence of Stress on Vacancy Equilibria

At the oxide/metal interface diffusing oxide ions are incorporated into the metal lattice to form a substoichiometric oxide, MO_{2-y}, and an anion vacancy within the original oxide layer. This is illustrated in Fig. 1. The over-all reaction may be written



$$M + (2-y)O_o \rightleftharpoons MO_{2-y} + (2-y)V_o^{\cdot\cdot} + 2(2-y)\bar{e} \quad [1a]$$

For convenience, this reaction can be split into two parts, the first describing the formation of gaseous oxygen by dissociation of the oxide, *i.e.*

$$O_o \rightleftharpoons V_o^{\cdot\cdot} + 2\bar{e} + \tfrac{1}{2}O_2 \quad [1b]$$

and the second, describing the oxidation of the metal by oxygen

$$M + \tfrac{1}{2}(2-y)O_2 \rightleftharpoons MO_{2-y} \quad [1c]$$

Here O_o is a lattice oxygen ion, $V_o^{\cdot\cdot}$ is a doubly charged anion vacancy, $\bar{e}$ is an electron, and O_2 is a molecule of oxygen in the gaseous phase.

At the oxide/atmosphere interface, vacancies react with oxygen and are replaced by oxide ions; this is the reverse of reaction [1b]. This model assumes that the vacancy concentration at oxide interfaces is dictated by the local oxidation potential and that the concentration arising from extrinsic factors (*e.g.*, impurities) is negligible.

Since the rate of oxidation is limited by vacancy diffusion through the oxide, the chemical reactions in which vacancies are formed are in equilibrium at both the inner and outer interfaces. The respective volume changes for the reactions [1b] and [1c] are

$$\Delta\Omega_B = (\Omega_{O_o} - \Omega_{V_o^{\cdot\cdot}}) \quad \text{and} \quad \Delta\Omega_A = (\Omega_{MO_{2-y}} - \Omega_M)$$

where Ω_M is the volume of a metal atom; $\Omega_{MO_{2-y}}$ the volume of the oxide per metal atom; Ω_{O_o} the volume of an anion in the oxide and $\Omega_{V_o^{\cdot\cdot}}$ the volume of a doubly charged anion vacancy. The over-all volume change $\Delta\Omega$ is then

$$\Delta\Omega = \Delta\Omega_A - (2-y)\Omega\Delta_B$$

When $\Delta\Omega$ is positive (volume increase) the oxide experiences a compressive stress of hydrostatic component $(-\sigma)$ and further oxide growth has to do work against this stress.

Under these conditions the chemical potentials of the various constituents are

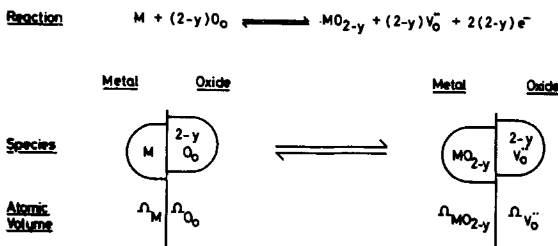


Fig. 1. Model of the oxidation process at the metal/oxide interface.

$$\mu_{O_o} = \mu^\circ_{O_o} + kT \ln \frac{[O_o]}{[O_o]^\circ} - \sigma\Omega_{O_o} \quad [2a]$$

$$\mu_{V_o^{\cdot\cdot}} = \mu^\circ_{V_o^{\cdot\cdot}} + kT \ln \frac{[V_o^{\cdot\cdot}]}{[V_o^{\cdot\cdot}]^\circ} - \sigma\Omega_{V_o^{\cdot\cdot}} \quad [2b]$$

$$\mu_e = \mu^\circ_e + kT \ln \frac{[m]}{[m]^\circ} \quad [2c]$$

$$\mu_{O_2} = \mu^\circ_{O_2} + kT \ln \frac{p}{p^\circ} \quad [2d]$$

where the subscripts are self-explanatory and the superscript "o" represents a standard state which is stress free and contains concentrations of oxide ions, vacancies, and electrons in equilibrium with an oxygen pressure p°. These concentrations are related by the equations

$$[O_o] + [V_o^{\cdot\cdot}] = N$$

where N is the number of lattice sites, and

$$[m] = 2[V_o^{\cdot\cdot}]$$

where $[m]$ is the concentration of electrons. It should be noted that σ in Eq. 2 is negative if compressive. Expression [2b] is obtained by envisaging the vacancy as being created by removal of an interior ion to a surface step, thereby increasing the total number of lattice sites by 1.

Applying the equilibrium condition that $\Sigma\, \mu_i dn_i = 0$ to Eq. [2] and noting that $[m]/[m]^\circ = [V_o^{\cdot\cdot}]/[V_o^{\cdot\cdot}]^\circ$ and that, for realistic stoichiometries, $[O_o]/[O_o]^\circ \approx 1$ it can be shown that the equilibrium vacancy concentration is given by

$$[V_o^{\cdot\cdot}] = K[V_o^{\cdot\cdot}]^\circ (p/p^\circ)^{-1/6} \exp \frac{-\sigma\Delta\Omega_B}{3kT} \quad [3]$$

where $K = \exp(-\, \Sigma\, \mu^\circ_i dn_i/3kT)$ and p is the local value of the oxygen pressure. Since the standard state is also at equilibrium, $K = 1$.

In particular, at the oxide/metal interface the oxygen partial pressure is set by the dissociation pressure of the oxide via the equilibrium of reaction [1c]. If σ_I is the value of σ at the interface, the chemical potentials of the constituents of reaction [1c] become

$$\mu_{MO_{2-y}} = \mu^\circ_{MO_{2-y}} - \sigma_I\Omega_{MO_{2-y}} \quad [4a]$$

$$\mu_M = \mu^\circ_M - \sigma_I\Omega_M \quad [4b]$$

$$\mu_{O_2} = \mu^\circ_{O_2} + kT \ln p/p^\circ \quad [4c]$$

Here again σ_I is negative if compressive and the μ°'s refer to stress-free, standard states. Applying the equilibrium condition $\Sigma\, \mu_i dn_i = 0$ to Eq. [4] it can be shown, after some algebra, that the oxygen partial pressure, p_σ, in the presence of a stress is related to the stress-free value, $p_{diss.}$, by

$$p_\sigma = p_{diss.} \exp\left[-\frac{\sigma_I\Delta\Omega_A}{kT}\left(\frac{2}{2-y}\right)\right] \quad [5]$$

At the oxide/environment interface, the stresses in the oxide will have a negligible effect on the oxygen partial pressure. The latter will be the equilibrium value set by the environment and is designated p_s.

The Transport Equation

General solution.—The driving force for anion vacancy diffusion is the negative gradient of the difference $(\mu_{V_o^{\cdot\cdot}} - \mu_{O_o})$. The flux of vacancies, j_v, is obtained from the Nernst-Einstein equation

$$j_v = -\frac{D_v[V_o^{\cdot\cdot}]}{kT} \frac{\partial}{\partial x} (\mu_{V_o^{\cdot\cdot}} - \mu_{O_o}) \quad [6]$$

where x is the distance coordinate originating at the oxide/environment interface. D_v is an effective vacancy-diffusion coefficient which allows for short-

circuiting paths, and the ensuing treatment assumes that lateral diffusion at the oxide/metal interface is so rapid that the oxide continues to grow uniformly. The preceding derivations of chemical potentials will still apply to diffusion along such paths provided that the process is one of vacancy/atom exchange. This is considered a reasonable assumption.

Substitution of the general Eq. [2a] and [2b] in Eq. [6] then gives

$$j_V = -\frac{D_V[V_o^{\cdot\cdot}]}{kT}\frac{\partial}{\partial x}\left\{\mu^{\circ\prime} + \sigma\Delta\Omega_B + kT\ln\frac{[V_o^{\cdot\cdot}]}{[V_o^{\cdot\cdot}]^\circ}\right\} \quad [7]$$

where $\mu^{\circ\prime} = \mu^\circ{}_{V_o^{\cdot\cdot}} - \mu^\circ{}_{O_o}$, $\Delta\Omega_B = \Omega_{O_o} - \Omega_{V_o^{\cdot\cdot}}$ and for realistic stoichiometries $[O_o]/[O_o]^\circ \approx 1$. In order to preserve the convention of expressing vacancy concentrations in terms of oxygen partial pressure, Eq. [3] can be substituted in the form

$$\frac{[V_o^{\cdot\cdot}]}{[V_o^{\cdot\cdot}]^\circ} = \left(\frac{p}{p^\circ}\right)^{-1/6}\exp\left(-\frac{\sigma\Delta\Omega_B}{3kT}\right) \quad [8]$$

Insertion of this into Eq. [7] and differentiating gives the transport equation

$$j_V = -D_V\frac{[V_o^{\cdot\cdot}]}{kT}\left(\frac{p}{p^\circ}\right)^{-1/6}\exp\left(\frac{-\sigma\Delta\Omega_B}{3kT}\right)\left(\frac{2}{3}\Delta\Omega_B\frac{\partial\sigma}{\partial x} - \frac{kT}{6}\frac{\partial\ln p}{\partial x}\right) \quad [9]$$

This equation describes the vacancy flux in terms of both a stress gradient and a concentration gradient, but these cannot be easily separated because the concentration gradient is also a function of stress. If we now define a new variable

$$P^* = [V_o^{\cdot\cdot}]^\circ\left(\frac{p}{p^\circ}\right)^{-1/6}\exp\left(\frac{2\sigma\Delta\Omega_B}{3kT}\right) \quad [10]$$

then

$$\frac{\partial P^*}{\partial x} = \exp\left(\frac{2\sigma\Delta\Omega_B}{3kT}\right)\left(\frac{p}{p^\circ}\right)^{-1/6}\frac{[V_o^{\cdot\cdot}]^\circ}{kT}\left(\frac{2\Delta\Omega_B}{3}\frac{\partial\sigma}{\partial x} - \frac{kT}{6}\frac{\partial\ln p}{\partial x}\right) \quad [11]$$

Substituting Eq. [9] in [11] gives

$$\frac{\partial P^*}{\partial x} = -\frac{j_V}{D_V}\exp\left(\frac{\sigma\Delta\Omega_B}{kT}\right) \quad [12]$$

This can be integrated noting that, as pseudosteady-state conditions are assumed, j_V is constant with x for any given oxide thickness ξ. Thus

$$j_V = \frac{-D_V(P^*_I - P^*_s)}{\int_0^\xi \exp\left(\frac{\sigma\Delta\Omega_B}{kT}\right)dx} \quad [13]$$

where P^*_I is the value of P^* at the inner oxide interface, $x = \xi$, and P^*_s is the corresponding value at the surface $x = 0$. To obtain explicit expressions for the oxidation rate, it is necessary to know the variation of σ with x and examples are considered below. In the limiting case of uniform or zero stress throughout the oxide Eq. [13] reverts to parabolic form.

Specific solutions.—Stress concentrated at the inner (oxide/metal) interface, (Case I).—Measurements of stress distribution through an oxide layer are particularly difficult to make. Roy and Burgess (24) have attempted to do so with both zirconium and Zircaloy-2 by determining the change in average stress on solution of part of the oxide during annealing. The technique is crude, but the results indicate that approximately 70% of the stress may be associated with the 10% of the oxide thickness adjacent to the metal. The data are not sufficiently extensive to allow the fitting of a meaningful distribution function, but do show that a model of the oxide in which the stress is considered zero everywhere except at the oxide/metal interface, may not be unreasonable. This is shown diagramatically in Fig. (2a). Under these circumstances, the denominator of Eq. [13] reduces to ξ and the equation becomes

$$j_V = -\frac{D_V}{\xi}(P^*_I - P^*_s) \quad [14]$$

where, from Eq. [5] and [10]

$$\left[\begin{aligned} P^*_I &= [V_o^{\cdot\cdot}]\frac{P_{diss}}{p^\circ}^{-1/6}\exp -\frac{\sigma_I\Delta\Omega_B}{3kT}\exp\frac{\sigma_I}{kT}\left\{\left(\frac{\Delta\Omega_A}{3(2-y)} + \Delta\Omega_B\right)\right\} \\ \text{and}\quad P^*_s &= [V_o^{\cdot\cdot}]^\circ\frac{p_s}{p^\circ}^{-1/6}\end{aligned}\right] \quad [15]$$

where p_s is the oxygen partial pressure at the surface of the oxide.

The flux of oxygen ions arriving per unit area of metal surface is then the negative of Eq. [14] so that, as the volume of oxide produced per ion is $\approx (\Omega_{MO_{2-y}}/2)$, the oxide growth rate is

$$(d\xi/dt) = \frac{D_V\Omega}{2\xi}(P^*_I - P^*_s) \quad [16]$$

where the symbol $\Omega_{MO_{2-y}}$ has been abbreviated to Ω.

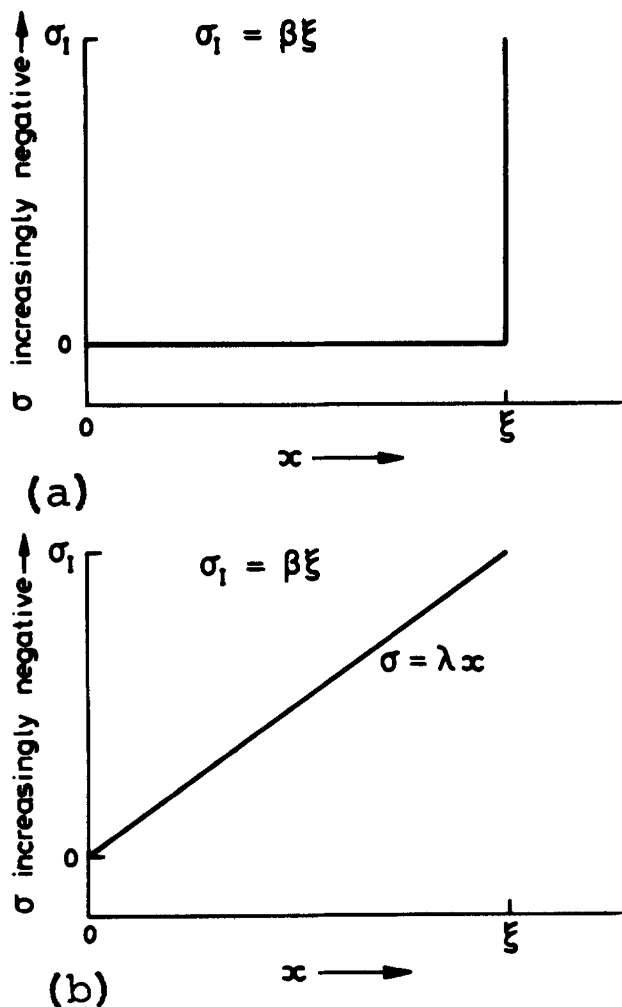

Fig. 2. Assumed stress distribution in oxide layers. (a) Stress concentrated at inner interface; (b) linear stress gradient with zero stress at oxide/environment interface.

Noting, in addition, that Roy and Burgess (24) find an approximately linear relationship between oxide thickness and stress, *i.e.*, in the context of this approximation

$$\sigma_I = \beta\xi \qquad [17]$$

where β is an empirical constant, the oxidation rate can be obtained finally as

$$\left(\frac{d\xi}{dt}\right) = \frac{D_V\Omega[V_o^{\cdot\cdot}]^o}{2\xi(p^o)^{-1/6}} \left\{ p_{\text{diss.}}^{-1/6} \exp\left(-\frac{\sigma_I \Delta\Omega_B}{3kT}\right) \exp\left\{\frac{\beta\xi}{kT}\left[\frac{\Delta\Omega_A}{3(2-y)} + \Delta\Omega_B\right]\right\} - p_s^{-1/6} \right\} \qquad [18]$$

It is clear that with compressive stresses at the oxide/metal interface, (*i.e.*, β is negative) the oxidation rate decreases below parabolic with time. Parabolic kinetics pertain in a stress-free oxide ($\beta = 0$) and with tensile stresses present the rate will be higher than parabolic.

A linear compressive stress gradient, (Case II).—Calculations [*e.g.*; (25)] of the stress distribution within anion deficient oxides inevitably predict a linear gradient. The compressive stress at the inner interface decreases in value through the oxide and acquires tensile values at the outer surface depending on the stress borne by the metal substrate. Simply for comparative purposes with the result of the preceding section, the outer surface stress is again taken as zero and the stress σ_I is assumed to obey Eq. [17] (with β negative). The stress distribution within the oxide is then

$$\sigma = \frac{\sigma_I x}{\xi} = \lambda x \qquad [19]$$

and this is shown diagramatically in Fig. (2b). The denominator of Eq. [13] is now

$$\int_0^\xi \exp\left(\frac{\lambda x \Delta\Omega_B}{kT}\right) dx = \frac{kT}{\lambda\Delta\Omega_B}\left\{\exp\left[\frac{\lambda\xi\Delta\Omega_B}{kT}\right] - 1\right\} \qquad [20]$$

Since the values of P^*_I and P^*_s are the same in both Case I and Case II, the ratio of the rates for the two cases is

$$R = \frac{\text{Case II}}{\text{Case I}} = \frac{\xi}{\dfrac{kT}{\lambda\Delta\Omega_B}\left\{\exp\left[\dfrac{\lambda\xi\Delta\Omega_B}{kT}\right] - 1\right\}} \qquad [21]$$

i.e.

$$R = \frac{A}{(\exp A) - 1}, \quad \text{where } A = \frac{\sigma_I \Delta\Omega_B}{kT} \qquad [22]$$

It follows from Eq. [18] and [22] that the oxidation rate for the linear-compressive-stress case is

$$\left(\frac{d\xi}{dt}\right) = \frac{\dfrac{D_V\Omega[V_o^{\cdot\cdot}]\lambda\Delta\Omega_B}{2kT(p^o)^{-1/6}}\left\{p_{\text{diss.}}^{-1/6}\exp\left(-\dfrac{\sigma_I\Delta\Omega_B}{3kT}\right)\exp\left\{\dfrac{\beta\xi}{kT}\left[\dfrac{\Delta\Omega_A}{3(2-y)} + \Delta\Omega_B\right]\right\} - p_s^{-1/6}\right\}}{\exp\left[\dfrac{\lambda\xi\Delta\,\Omega_B}{k\,T}\right] - 1} \qquad [23]$$

The ratio, R, of rates (expression [22]) is plotted as a function of A in Fig. 3 for σ_I compressive. Clearly, the two solutions predict rates which are negligibly different, say $\leq 20\%$ in ratio, for $-A \leq 0.38$, the rate in Case II being the larger. The error, however, becomes increasingly large with higher values of σ_I and the ratio is ~ 2 at $-A = 1.6$.

An interesting feature in both cases (Eq. [18] and [23] is that the predicted oxidation rate will become zero when the (compressive) interfacial stress, $(-\sigma_I)$ is

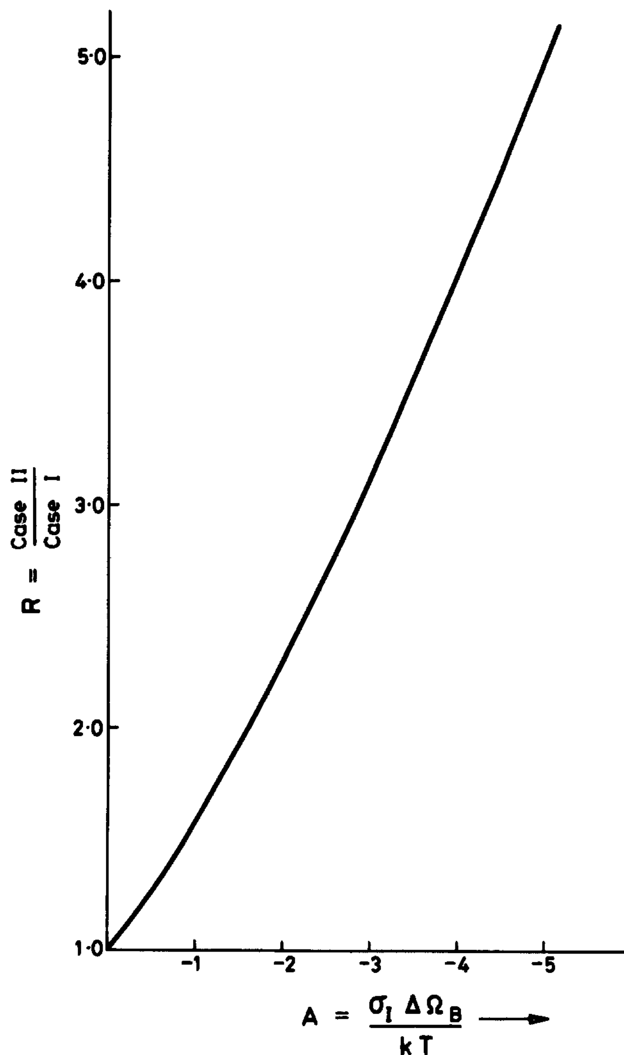

Fig. 3. Ratio of rates for Case II and Case I, vs. A

$$(-\sigma_I) = -\frac{kT\ln\left(\dfrac{p_s}{p_{\text{diss.}}}\right)^{-1/6}}{\left[\dfrac{\Delta\Omega_A}{3(2-y)} + \dfrac{2\Delta\Omega_B}{3}\right]} \qquad [24]$$

Application to Zircaloy-2

There must be some uncertainty over the correct value of $\Delta\Omega_B = (\Omega_{O_o} - \Omega_{V_o^{\cdot\cdot}})$, but if the vacancy volume is taken, reasonably, as 0.7 of that of the ion, $\Delta\Omega_B$ becomes 0.3×10^{-29} m^3. Using Roy and Burgess' (24) measurements, the maximum value of $(-\sigma_I)$ obtainable at 773°K (at least) is $\simeq 1.7 \times 10^9$ nm^{-2}, so that the maximum value of A at this temperature is ~ 0.45. Reference to Fig. 3 shows that the ratio of oxidation rates for the two stress distributions previously discussed is ~ 1.25 for this particular value. Since this error exists only during the late stages of protective oxidation, it seems adequate to use the simplified stress distribution of Case I.

Taking a typical value of $\Delta G°$ for the oxidation reaction of 950 kJ mole O_2^{-1} (26) gives $p_{\text{diss.}}^{-1/6} = 2 \times 10^{10}b^{-1/6}$. It is clear that the first pressure term in the main bracket of Eq. [18] is dominant and the

second may therefore be neglected for all likely values of p_s. It follows that the inhibition condition of Eq. [24] is unlikely to apply to Zircaloy oxidation and the oxidation rate will be essentially independent of the oxidation potential of the environment. The latter is in fact found experimentally (cf. the data sources shown in Fig. 5). In addition, the large values of $p_{diss.}^{-1/6}$ will dominate any extrinsic effects due to trace impurities and permits application of the present analysis to Zircaloy oxidation.

The expression for the oxidation rate now becomes

$$\left(\frac{d\xi}{dt}\right) = \frac{D_v\Omega[V_o^{\cdot\cdot}]^\circ}{2\xi}\left(\frac{p_{diss.}}{p_o}\right)^{-1/6} \exp\left(-\frac{\sigma_I\Delta\Omega_B}{3kT}\right)\exp\left(\xi\Delta\Omega_\sigma\right) \quad [25]$$

where

$$\Delta\Omega_\sigma = \frac{\beta}{kT}\left(\frac{\Delta\Omega_A}{3(2-y)} + \Delta\Omega_B\right)$$

The term $(D_v\Omega/2)\ [V_o^{\cdot\cdot}]^\circ (p_{diss.}/p_o)^{-1/6} \exp(-\sigma_I\Delta\Omega_B/3kT)$ may be rewritten using Eq. [8] when it becomes $(D_v\Omega/2)\ [V_o^{\cdot\cdot}]^{diss.}$ where $[V_o^{\cdot\cdot}]^{diss.}$ is the vacancy concentration in equilibrium with the oxygen potential at the oxide metal interface. The quantity $(\Omega/2)\ [V_o^{\cdot\cdot}]^{diss.}$ is the fractional vacancy concentration N_v so that the product D_vN_v is equivalent to the diffusion coefficient for anions, $D_o^{diss.}$, at the inner interface. The rate expression thus becomes

$$\frac{d\xi}{dt} = \frac{D_o^{diss.}}{\xi}\exp\left(\xi\Delta\Omega_\sigma\right) \quad [26]$$

This can be integrated using the initial condition that $\xi = 0$ when $t = 0$ to give

$$(1 + \xi\Delta\Omega_\sigma)\exp(-\xi\Delta\Omega_\sigma) = 1 - D_o^{diss.}(\Delta\Omega_\sigma)^2 t \quad [27]$$

This relationship between oxide growth and time can be evaluated if $D_o^{diss.}$ is known. Because of the low values of $p_{diss.}$ there are no direct measurements on bulk specimens, but an adequate compromise would be to obtain values from oxide films. This has the advantage that since $D_o^{diss.}$ has a large contribution from short-circuit paths (11) the value obtained from films will reflect accurately the oxide structure existing during the oxidation process. Cox and Pemsler (11) present a number of measurements of D_o, but of these the one obtained by Cox and Roy (27) is deemed to be the most reliable since it was obtained by a method which measured the transport of oxygen directly. At 773°K the value is 1.0×10^{-16} m² sec⁻¹.

Comparison with experimental reaction rates.—A direct check of the present theory may be made only at 773°K since it is only for this temperature that β may be established from the data of Roy and Burgess. The dependence of oxide stress on thickness is very variable but three cases are presented in Fig. 4 for different values of β and compared with the simple parabolic case where $\beta = 0$. The β values of -6.5×10^{14} and -2.5×10^{14} nm^{-3} present the extremes of the data presented by Roy and Burgess (24). The intermediate value of -3.4×10^{14} nm^{-3} represents a subjective average value of β for specimens of a thickness similar to fuel tube material. As expected, the departure from parabolic kinetics increases with increasing compressive stress (*i.e.*, increasing $-\beta$). The value of β applicable to pretransition behavior may be derived if it is assumed that the oxide fractures at the kinetic transition at $\simeq$ 34 g·dm^{-2} (2.3 μm).[1] If Young's modulus (E) for ZrO_2 is taken as 2.1×10^{11} nm^{-2} (28) and the fracture ductility ϵ_f as ~0.01 (25) then the uniaxial rupture stress is $\sigma_F = E\epsilon_f = 2.1 \times 10^9$ nm^{-2}. For a 2.3 μm oxide thickness this gives $\beta_{max} = 6.1 \times 10^{14}$ nm^{-3} if a biaxial stress state is assumed. This value is in good agreement with the upper value deduced from the data of Roy and Burgess (24) for relatively thin oxides, and is used in the comparison below. Other numerical data used in these calculations are $\Delta\Omega_A = (\Omega_{ZrO_{2-y}} - \Omega_{Zr}) = 1.0 \times 10^{-29}$ m³ and $y = 0.04$ giving a stoichiometry of $ZrO_{1.96}$ at the inner interface.

[1] To convert $X\mu$m to W mg · dm^{-2} the formula 0.0675W = X has been used.

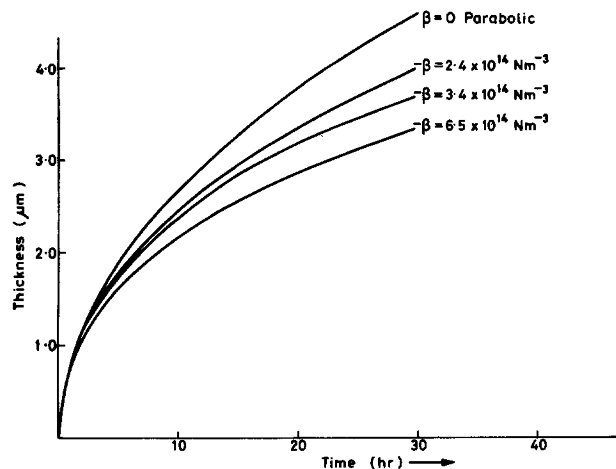

Fig. 4. Theoretical plots of thickness against time from Eq. [28]

Figure 5 shows 500°C (773°K) experimental data for oxide thickness plotted against time determined by a number of different authors for Zircaloy-2. The solid line on this graph is a plot of Eq. [27] with $\beta = -6.5 \times 10^{14}$ nm^{-3}. Clearly, the theory is capable of predicting not only the absolute rate, but also the gradual deviation from parabolic behavior with increasing oxide thickness up to the point of the kinetic transition at 34 mg·dm^{-2}.

Conclusions

A model has been developed which describes the effect of a stress field within the oxide film on the rate of vacancy transport.

The oxidation kinetics for oxides which accumulate compressive stress during growth are predicted to be slower than parabolic; those for oxides which accumulate tensile stress will be faster than parabolic.

When applied to Zircaloy-2 corrosion at 773°K, the model yields kinetics in good agreement with experimental data predicting both the absolute rate and the increasing deviation from parabolic kinetics with oxide thickness. Comparison of theory with experiment at other temperatures is not possible due to lack of data.

The model predicts that Zircaloy-2 corrosion rates should be independent of the oxidation potential of the environment while the rate-controlling step remains anion diffusion within the oxide. This is in agreement with experiment.

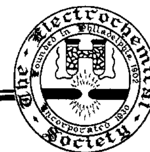
Technical Notes



Localized Avalanche Breakdown on GaAs Electrodes in Aqueous Electrolytes

J. C. Tranchart, L. Hollan, and R. Memming[1]

Laboratoires d'Electronique et de Physique Appliquée, 94450 Limeil-Brévannes, France

GaAs electrodes have been the subject of various electrochemical studies (1-4). It has been shown that the basic anodic process in aqueous electrolytes is the anodic dissolution of the GaAs electrode (2) whereas the cathodic process is mainly due to hydrogen evolution (2, 4). The first process occurs via the valence band, *i.e.*, holes are consumed. Using n-type electrodes in the dark, the corresponding anodic current is limited to a very low value since only few holes are available. In the case of hydrogen evolution, a process involving electrons from the conduction band, a corresponding limiting cathodic current is expected for p-type electrodes.

These effects, typical for semiconductor electrodes, have been found with many other materials. It is interesting to note, however, that in all cases reported in the literature, the limiting currents at GaAs electrodes controlled by the diffusion of minority carriers toward the surface, remain at low levels only for small electrode potentials (< 1-2V). At higher potentials a steep current rise has always been observed. In the present paper the mechanism of this current rise is studied in more detail.

Experimental

The samples used in this study are grown in our laboratory by vapor phase epitaxy on (100) n^+ substrates (5). The layers are sulfur doped in the range of 10^{15}-10^{18} cm^{-3} and their thicknesses are chosen greater than 10 μm in order to avoid any substrate or interface effects. These layers show a much lower density of defects than the more often studied bulk material and, also, lower carrier concentration layers are available. Tin ohmic contacts are soldered by short annealing (< 1 min) in pure H_2 atmosphere at 400°C. The samples are etched in a H_2SO_4, H_2O_2, H_2O (5:1:1) solution just before mounting in a classical electrochemical cell where the sample area is limited and defined by an O-ring. The commonly used electrolyte is a 1*N* NaOH solution.

Results and Discussion

Typical current potential curves, as obtained with epitaxial layers of n-GaAs, are shown in Fig. 1. The

Key words: defects, doping, semiconductor.

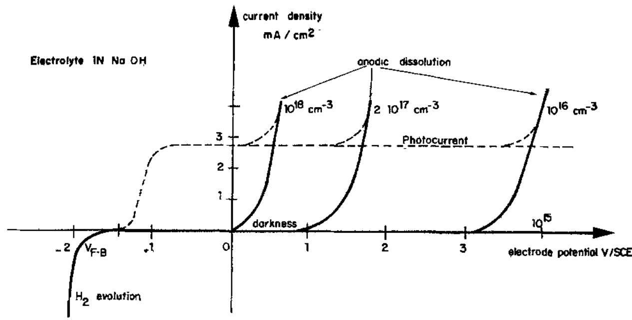

Fig. 1. Current-potential curves for n GaAs (epitaxial layers on GaAs substrates in 1N NaOH).

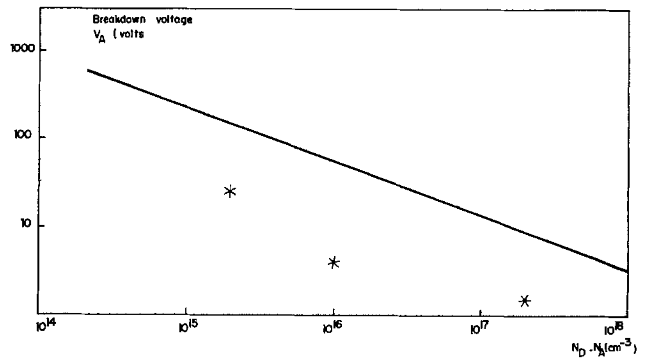

Fig. 2. Breakdown voltage vs. concentration of GaAs. Continuous line, calculated values; *, experimental values from anodic polarization.

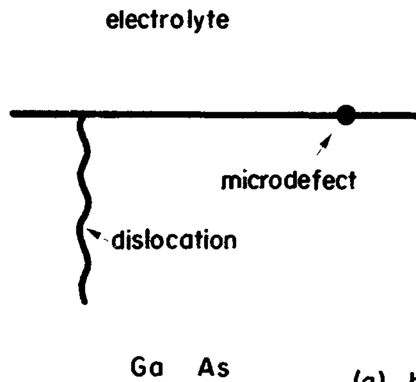
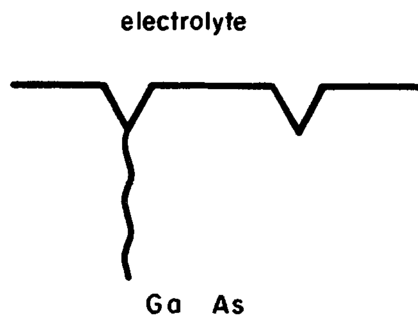
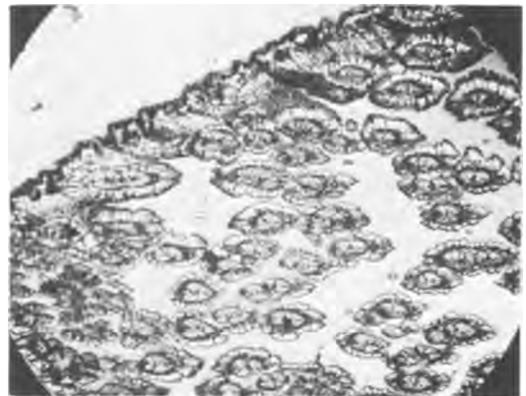
limiting anodic current could be kept at a very low level for layers of a rather small carrier density. In the case of a doping level of 10^{15} cm^{-3}, an extremely low anodic current has been observed up to about 20-30V. The breakdown occurs at lower potentials for electrodes of higher carrier densities (Fig. 1).

The question arises whether the increase of the anodic current at n-type is due to a tunneling of electrons through the space-charge layer or to an ava-

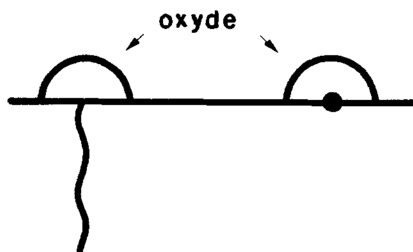


(a) before avalanche (x 90)





(b) after avalanche



(c) anodic oxydation

Fig. 3. Schematic presentation of defects in n GaAs electrodes during anodic dissolution and anodic oxidation.

lanche breakdown. Both mechanisms can occur if the band bending is larger than the bandgap of 1.4 eV. This condition is fulfilled for $V > 0$ since the flatband potential occurs at -1.4 V/SCE, as determined from capacity measurements. The thickness of the space-charge layer, however, is of the order of several hundred angstroms for $N_D = 10^{18}$ cm^{-3} (6, 7) so that any tunneling process has to be ruled out at doping levels $N_D \leq 10^{18}$ cm^{-3}.

The avalanche process was investigated in more detail. In Fig. 2 the potentials at which breakdown occurs *vs.* the carrier density are represented. These values are lower than the calculated bulk avalanche values represented by the continuous line (8). These calculated values have been confirmed experimentally by several authors using solid-state diodes (9) and in our laboratory using Schottky diodes and epitaxial material (10) Furthermore, the values obtained by anodic oxidation are the same (11, 12). We assume, therefore, a localized avalanche mechanism starting at surface defects, dislocations, or dopant variation, as schematically shown in Fig. 3a and 3b. According to this model, a microbreakdown occurs which induces a short etching around the defect (Fig. 3b). The latter process is confirmed by the occurrence of etch pits after the avalanche breakdown as shown on the microscopic pictures in Fig. 3b and also observed by others (13). A further support for this mechanism is given by the current-potential curve itself. For example, an n-type GaAs electrode of $N_D = 10^{15}$ cm^{-3} can be initially polarized up to 25V before avalanche breakdown occurs (Fig. 4). As the potential is then decreased, the current remains at a higher level. A low current is only obtained again below about 2V. As the potential is increased again, the current rises at about 2V (see curve 3 in Fig. 4). Thus, as soon as some defects have been developed avalanche breakdown occurs at much lower potentials. Accordingly, the presence of defects determines the avalanche breakdown, their density, and the limiting anodic current at n-GaAs electrodes. Since the quality of the material plays such a dominant role, small currents up to very large potentials can only be observed by using epitaxial layers in which the density of defects could be kept at a sufficiently low level.

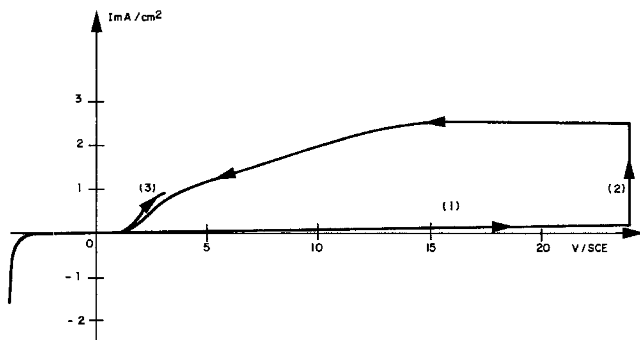


Fig. 4. Current potential curve for n GaAs ($N_D = 2 \cdot 10^{15}$ cm^{-3}) in 1*N* NaOH. (1) First anodic potential scan; (2) breakdown; (3) second scan.

It should be emphasized that the situation is quite different for electrolytes of neutral *p*H values. In this case, anodic oxidation occurs which is an autolimiting process: any initial avalanche, localized on a defect, leads immediately to an oxide formation, as shown schematically in Fig. 3c. The local resistance is strongly increased and etching at the defect is stopped. So, in this case the avalanche is not controlled any more by the defects but only by the bulk properties, as has been observed by Colquhoune and Hartnagel (11) and by ourselves (12). As mentioned above, in these conditions the experimental values fit well with the theoretical curve calculated for a bulk avalanche process (Fig. 2).

Stabilized Fused-Quartz Tubes with Reduced Sodium Diffusion for Semiconductor Device Technology

K. M. Eisele

Institut für Angewandte Festkörperphysik der Fraunhofer Gesellschaft, Eckerstrasse 4, D-7800 Freiburg, Germany

and R. Ruthardt

Heraeus Quarzschmelze GmbH, Postfach 463, D-6450 Hanau, Germany

Fused quartz can be produced with a sodium content below 1 ppm. But for high temperature applications it is not only the amount of sodium in a material that matters but also the velocity with which it diffuses through the tube walls. The importance of the diffusion coefficient becomes evident when considering that the hot ceramics of a furnace present a nearly inexhaustible source of sodium. The diffusion coefficient of sodium in fused quartz depends very much on the type of fused quartz and can vary three orders of magnitude (1-3). In addition, due to its specific structure, fused quartz offers the advantage of permitting modification by replacing some of the four positively charged silicon atoms by atoms with lower positive charge which can equally well be incorporated into the spatial network of the silicon dioxide. These defect points with a deficit of positive charge then serve as a kind of trap for the diffusing sodium.

As the latest stage in fused-quartz diffusion tube development stabilized fused-quartz diffusion tubes (CFQ_{st}) obtain a high temperature stability from a layer of crystobalit on their outside. The patent literature (4, 5) points out that in these materials the diffusion of impurities is reduced. The results of investigations of this phenomenon are the subject of this paper. A more detailed report will be given elsewhere. Principally we have chosen a mass spectroscopic method to compare the sodium diffusion through stabilized fused-quartz CFQ_{st} with other vitreous silica materials for which the diffusion coefficients are already known.

Experimental

A test tube, 25 mm diam, was closed at one end and fused to a metal flange at the open end. It was connected to a vacuum chamber with a quadrupole mass spectrometer and an ionization pressure gauge (Fig. 1). The tube to be tested was surrounded by a larger tube made of regular CFQ-type fused quartz. Within it sodium vapor was guided along the surface of the test tube by a nitrogen gas stream. All parts could be degassed by heating to 120°C. In a well-degassed state the pressure in the system was $1 \cdot 10^{-8}$ Torr. The concentric glass tubes were positioned in a furnace whose temperature profile was determined for a nominal temperature of 1000°C. To immerse the test tube in sodium vapor during the diffusion experiment a molybdenum boat filled with metallic sodium was deposited at an exactly known temperature zone of the outer fused-quartz tube. By this means sodium will appear at the ionizer of the mass spectrometer if its vapor pressure at a given temperature is higher than the partial pressure of sodium in the vacuum system, provided it is not held by any mechanism to the surface at which it appears by the diffusion process or by condensation. To confirm that the prerequisites of the experiment are given, the following test was performed: A few pieces of a sodium containing silicate glass were placed in a fused quartz tube identical to the actual test tubes. Then the silicate glass was slowly heated and the sodium arriving at the mass spectrometer observed. When the temperature was raised, a spontaneous increase in the amount of sodium was observed which dropped again after passing through a maximum (Fig. 2). This drop can be explained by the process first being governed by a desorption process of the sodium at the surfaces of the soft glass and afterwards by the outdiffusion of sodium from the bulk. A better picture was obtained when the sample cooled off whereby the sodium level decreased corresponding to the lowering temperature (Fig. 3). This result proved that the sodium already leaves the surface at moderately high temperatures, a necessary condition for the feasibility of the actual experiment.

For a quantitative comparison of all contributions to the total pressure it is required that in the mass range of interest the sensitivity of the spectrometer remains the same. The mass spectrometer employed permitted adjustment of the sensitivity by applying a bias to opposite poles of the mass filter. Furthermore it is important for the comparison of the spectra that during the experiments all parameters that do not linearly affect the signal amplitude must be kept constant. This refers to resolution, pole bias, ΔM, SEM voltage, ionization- and extraction-voltages.

Key words: semiconductors, fused-quartz, sodium diffusion.

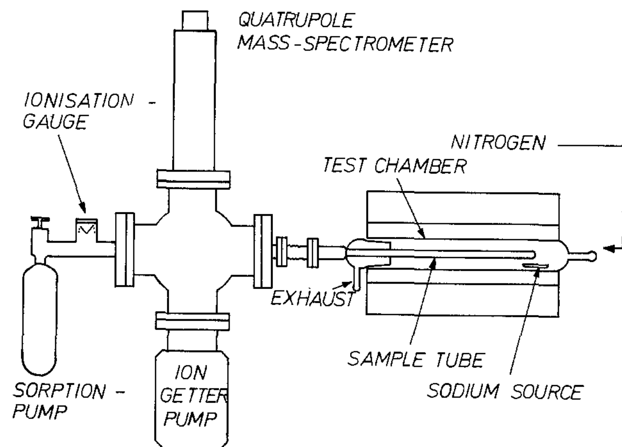

Fig. 1. Schematic of the apparatus used for the measurements

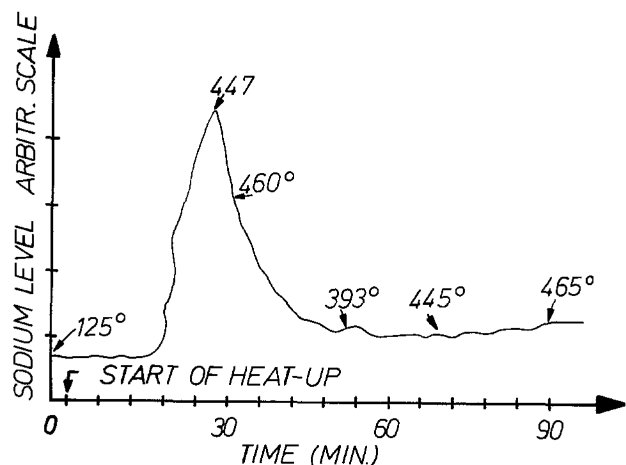

Fig. 2. Emanation of sodium from moderately heated soft glass

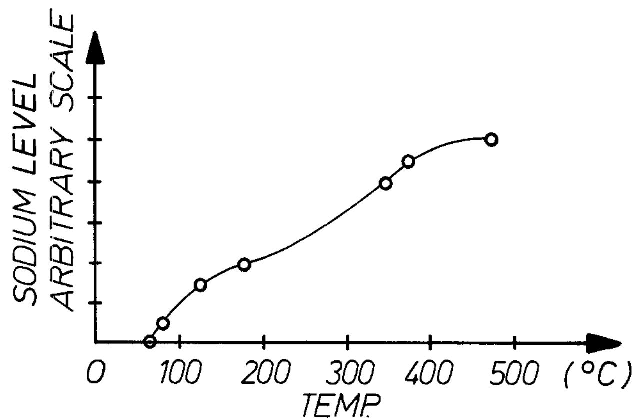

Fig. 3. Decrease of sodium level with decreasing temperature of the soft glass.

A mass spectrum was taken before exposing the test tube to sodium, and then the sodium level was monitored continuously during the exposure until a second total spectrum was recorded for the purpose of calibration. The amplitudes of all the lines in the spectra were measured in millimeters from the recorded graphs, divided by the ionization cross section to determine the partial pressure of sodium from the total pressure readings.

Kinetic gas theory yields the molecular velocity

$$V = \sqrt{\frac{3\,kT}{m}}$$

where k is Boltzmann's constant, T absolute temperature, m molecular mass of Na. The gas density of each component present is

$$\rho = \frac{3p}{V^2} = \frac{pm}{kT}$$

where p is its partial pressure. Then the number of particles causing this partial pressure is

$$n = \frac{\rho}{m} = \frac{p}{kT}$$

We can therefore plot the number of sodium atoms in the vacuum chamber during the time sodium vapor is surrounding the sample tube. It is necessary to point out that the temperature to be used in this equation is room temperature, and not the temperature of the fused-quartz tube, because only a relatively small surface of the total system is at a higher temperature than 30°C.

For a quantitative evaluation of the mass spectra not only equal sensitivity for all masses is required, but also the ionization probability of the various molecules or atoms has to be considered. For some atoms, especially the noble gases, ionization probabilities have been measured (6), but for our range of interest such measurements are not available. Therefore we used the calculated theoretical values for ionization cross sections of Mann (7) to correct the amplitudes of the measured spectral lines.

Results

The number of sodium atoms per cubic centimeter in the vacuum chamber is plotted in Fig. 4 against the time beginning with zero at the moment the molybdenum boat filled with sodium is moved into the zone where the furnace is between 500° and 600°C. The three types of fused quartz tubes tested were of the type CFQ, made of natural quartz crystal, of Suprasil, made from synthetic vitreous silica, and finally of CFQ_{st}, made from natural quartz and stabilized as mentioned before.

For the CFQ-tube the increase of the sodium partial pressure is most pronounced. It begins at 1208 cm^{-3}, reaches a maximum of 2243 cm^{-3}, and at the end

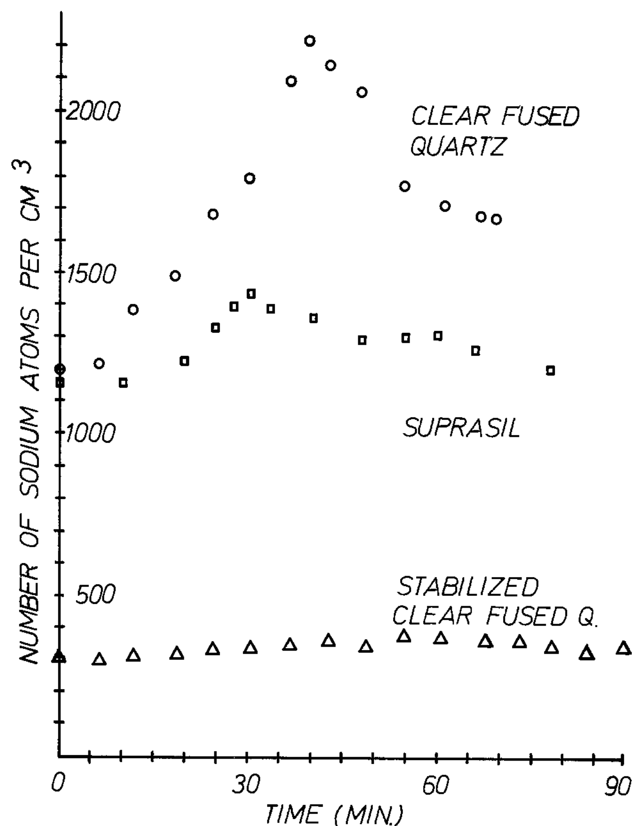

Fig. 4. Increase in time of the sodium level in the vacuum chamber after the sodium source has been placed at a predetermined temperature zone of the furnace.

stands at 1680 cm^{-3}. The Suprasil tube started with 1150 cm^{-3} sodium atoms. After exposure to the sodium vapor the level increased to 1442 cm^{-3} and dropped then to 1225 cm^{-3}. The material CFQ_{st} clearly withstood the sodium diffusion best. The sodium level only increased from 295 to 377 cm^{-3}.

The behavior with time was similar with all tubes. Generally 30-35 min after exposure to sodium the level reached a maximum. For demonstrative purposes we made the simplifying assumption that the level rises linearly and calculated the increase of sodium atoms per minute. This showed even more clearly the advantage of the CFQ_{st} tube. The rate of increase with Suprasil was less than half found with CFQ material, and CFQ_{st} was another factor 1/7 lower than Suprasil. Altogether stabilization brought a reduction by a factor of 1/15. After 30-35 min the sodium supply had evaporated and the sodium level decreased again to settle slightly higher than it was prior to the experiment.

Conclusion

The results obtained for CFQ and Suprasil are as expected from their different diffusion coefficients.

Stabilized clear fused-quartz CFQ_{st} exhibits even lower permeability for sodium than Suprasil. This is to be expected because the stabilization is achieved by infusing a metal oxide into the quartz which according to a hypothesis of Ligenza (8) forms a sodium-metal complex which diffuses as an entity. If, for example, a sodium-aluminum-oxide complex has the diffusion coefficient of aluminum, the diffusion coefficient of which has been measured by Frischat (9) to be $1.3 \cdot 10^{-13}$ cm^2/sec at 998°C, then a sodium atom attached to aluminum affords a time longer by a factor of 30,000 to diffuse through a given fused-quartz thickness than a sodium attached to silicon and oxygen only. This fact gives CFQ_{st}-type diffusion tubes especially favorable properties for application in semiconductor device manufacture. This becomes distinctly clear when comparing the diffusion coefficient of sodium at 1000°C

through CFQ $9 \cdot 10^{-6}$ cm²/sec (2), through silicon $4.45 \cdot 10^{-7}$ cm²/sec (10), and through Suprasil $9 \cdot 10^{-9}$ cm²/sec (3). Because the measurements presented in this paper show the superiority of CFQ_{st} over Suprasil one must conclude that as far as diffusion of sodium is concerned diffusion tubes made of fused-quartz type CFQ_{st} are presently singularly preferable for the manufacture of integrated circuits.

Acknowledgments

A Device of Electrostatic Lens for Electron Microscopy

S. Yamaguchi*

National Institute for Researches in Inorganic Materials, Sakura-mura Niihari-gun Ibaraki-ken, 300-31, Japan

One can charge up a dielectric substance with electrons in vacuum. Strength of the electrostatic field produced at the surface of this dielectric is very high, to wit, about 10000 kV/cm in the case of dielectric ruby (1). It was attempted here to turn this field to account for microscopy.

Construction of an electrostatic lens for microscopy is illustrated in Fig.1. This lens is a small brass cylinder (outside and inside diameters: 3 and 2 mm, height: 2 mm) which is filled with dielectric substance. There are disposed here the two electrodes of aluminum sheets with mirror surfaces. There are pinholes along the central axis of the lens. The electrostatic field realized in this lens remained stationary, insofar as stationary monochromatic electron beam was running along the central axis of the lens. The focal length of the lens could be changed by controlling the current density and the accelerating voltage of the electron beam applied. Amorphous glass, paraffin or polyethylene served as the dielectric for the lens illustrated in Fig.1. A brass wire gauze with standard mesh size has been employed as an object for testing electron optical ability of the device concerned.

The electron micrograph observed from the object with a single lens

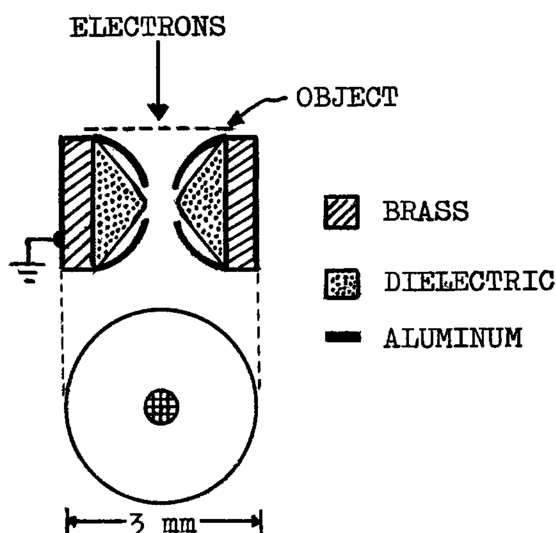

Fig. 1 Electrostatic lens which works only when an electron beam is running along its central axis.

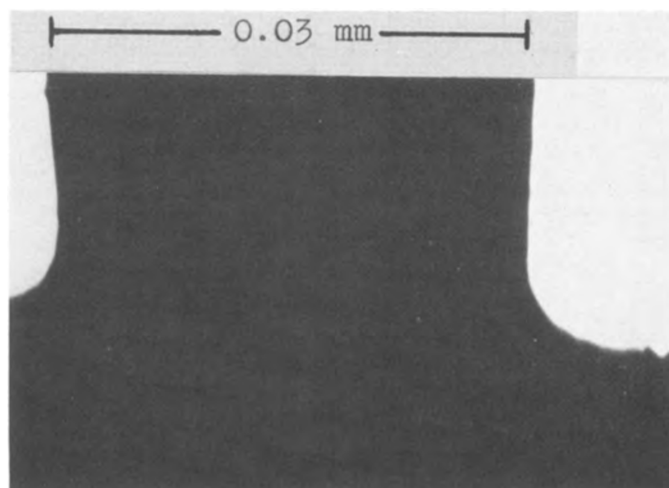

Fig. 2 Electron micrograph of a wire gauze.

*Electrochemical Society Active Member. Key words: electrostatic lens, dielectrics, electron diffraction.

is reproduced in Fig.2. This figure is referred to the photomicrograph of the same object that is seen in Fig.3. Fig.2 demonstrates that the electrostatic lens here devised performed well for microscopy. Here the beam current, the potential difference for accelerating the electrons and the diameter of the electron flux were 0.05 mA, 75 kV and 0.1 mm.

It was possible to observe diffraction pattern from an object placed on the gauze support. Only the lens was removed out of the electron path in the microscope by a mechanical means, and so the object alone remained in situ. This was easy to do, since the lens of interest was small and light enough to be moved. The diffraction pattern observed from a thin foil of gold that was placed on the support is shown in Fig.4. This figure was precisely analysed, because the distance between the object and the photographic emulsion was fixed to be 50 cm. It is impossible, on the other hand, for the conventional magnetic lens microscope to carry out this diffraction procedure.

In the present study, a simple way for observing electron microscopic and diffraction figures was devised, in which solid state properties of dielectrics were utilized in order to give rise to a strong electrostatic field for microscopy.

Steady-State Composition Profiles in Mixed Molten Salt Electrochemical Devices

I. Lithium/Sulfur Battery Analogs

C. E. Vallet and J. Braunstein*

Oak Ridge National Laboratory, Chemistry Division, Oak Ridge, Tennessee 37830

ABSTRACT

During charge or discharge of batteries with a binary molten salt mixture as the electrolyte, composition gradients are produced by the electrode reactions and the differences in mobilities of the electroactive and nonelectroactive ions. The effects of current density, electrode separation, and initial composition of the electrolyte are predicted by an analytical solution of the flux equations derived with transport properties similar to those of LiCl-KCl mixtures. Numerical solution of the flux equations predicts the composition profiles in lithium sulfur battery analogs with LiCl-KCl mixtures of differing compositions. Either complete depletion of the electroactive constituent at one electrode, or precipitation of a solid phase at the electrodes, could result from the predicted composition gradients. Changes in electrolyte composition at the electrodes may also affect J-phase formation at the sulfur electrode during discharge.

Electrochemical devices employing mixed electrolytes and operated at high current densities, such as molten salt batteries and fuel cells (1, 2), are subject to composition gradients resulting from the faradaic and migrational processes occurring at the electrodes, a phenomenon we have referred to as migrational polarization. Since such composition gradients can have significant effects on the performance of molten salt batteries and fuel cells, an understanding of the phenomenon and its characterization is important to design and modeling studies (3).

In a previous paper (2), the time evolution of composition at the electrodes and simulated composition profiles were computed by finite difference solution of the nonlinear partial differential equation of transport (3) for a molten salt battery analog and for a molten salt fuel cell analog. For both cases considered a limiting steady-state composition gradient was indicated. In this paper we present an analytical solution of the flux equations for the steady-state composition gradient in binary molten salt mixtures analogous to molten salt battery electrolytes (LiCl-KCl). Porosity of electrodes and of the electrolyte support must have important effects and will be treated in subsequent work, as will coupling of the mass flows to thermal energy flows. Here we concentrate on the effects of current density, initial electrolyte composition, electrode separation, and ion mobilities on steady-state migrational polarization and on possible phase separation in mixed electrolytes at high current density.

Flux Equations and Boundary Conditions

The electrochemical flux equations for a binary electrolyte designated LC-KC have been derived previously (2) for the cases where: (*i*) one of the two like-charged ions is produced at one electrode and consumed at the other [Ref. (2), Equation 3]; and (*ii*) the common ion is produced at one electrode and consumed at the other [Ref. (2), Equation 14]. The general one dimensional flux expressions may be written

$$-J_L^* = D\frac{\partial C_L}{\partial \xi} - M_L^*\, I/\mathbf{F} \qquad [1]$$

$$-J_K^* = D\frac{\partial C_K}{\partial \xi} - M_K^*\, I/\mathbf{F} \qquad [2]$$

where the J_i^*'s are the flows of ions i (in equivalents) relative to the reference frame*. D is interdiffusion coefficient of L and K, the C_i's are the equivalent concentrations, the M_i^*'s are migrational terms related to the transference numbers in the appropriate reference frame, and flows, concentrations, and migrational terms also satisfy the relations

$$I/\mathbf{F} = J_L^* + J_K^* - J_C^*; \quad C_L + C_K = C_C; \quad M_L^* + M_K^* = 1 + M_C^* \qquad [3]$$

where I is the current density. ξ is a distance variable, which in a pseudoconstant volume system is the distance from an electrode. For systems of variable volume, ξ can be defined such that equal distance increments contain equal numbers of the common ion, in order to compensate for the volume change of the electrolyte with composition change (3). In a system with fixed electrodes, this volume change may introduce an additional flow term or stress term which will be dealt with in subsequent work, although the general features of the shapes of the composition profiles will remain.

For the case where the electrode reactions consume and produce one of the two like-charged ions (rather than the common ion C), as for an Li electrode in an LiCl-KCl melt, the common ion C is conveniently

* Electrochemical Society Active Member.

Key words: LiCl, KCl, battery, diffusion, migration.

taken as the reference frame. The migrational terms in this case become simply the Hittorf transference numbers, *i.e.*, the transference numbers of ions L and K relative to the common ion C

$$M_L{}^C = t_L{}^C; \quad M_K{}^C = t_K{}^C; \quad M_C{}^C = 0 \qquad [4]$$

For the case where the common ion, C, of the mixture reacts at electrodes, as for a chlorine electrode in an LiCl-KCl melt or a CO_2-O_2 electrode in a carbonate melt, the fluxes are more conveniently taken relative to the electrode surface (2), which in a constant volume system is simply related to the common ion reference frame. In this case, $J_C{}^V = -I/\mathbf{F}$ and the migrational terms are

$$M_L{}^V = t_L{}^C - X_L; \quad M_K{}^V = t_K{}^C - X_K \quad \text{and} \quad M_C{}^V = -1 \qquad [5]$$

The boundary conditions at the two electrodes separated by a distance Ξ, are, when the cation L reacts at electrodes

$$J_L{}^C = I/\mathbf{F} \text{ at } \xi = 0 \text{ and } \xi = \Xi$$

$$J_K{}^C = 0 \text{ at } \xi = 0 \text{ and } \xi = \Xi \qquad [6]$$

When the common anion C reacts at electrodes the boundary conditions are

$$J_L{}^V = J_K{}^V = 0 \text{ at } \xi = 0 \text{ and } \xi = \Xi \qquad [7]$$

In a constant volume system, $X_L = VC_L$, where V is the equivalent volume. Here V will represent the mean partial equivalent volume of L and K. The use of equivalents rather than moles in Eq. [1] makes the equation general for charge symmetric or charge unsymmetric mixtures (4).

The Steady State

The concentration changes with time are given by

$$\frac{\partial C_K}{\partial t} = -\frac{\partial J_K{}^*}{\partial \xi} \qquad [8]$$

Equation [6], written with the fluxes from Eq. [1] and [4], is a nonlinear partial differential equation whose solutions we have computed by finite difference methods (3). Stationary composition profiles with respect to time were found (2) numerically in some cases, and an analytical solution for the steady state is possible. In the steady state the concentrations remain unchanged at all points between the electrodes, and Eq. [8] becomes

$$\frac{\partial C_K}{\partial t} = 0 = -\frac{\partial J_K{}^*}{\partial \xi} \qquad [9]$$

Since the flux of K vanishes (Eq. [6] and [7]) at the electrode surfaces for the cases where either L or C reacts at electrodes, Eq. [9] requires that it vanish at all points between the electrodes

$$J_K{}^* = 0; \quad 0 \leq \xi \leq \Xi \qquad [10]$$

The differential equation of the steady-state composition profile becomes, by Eq. [2]

$$\frac{\partial C_K}{\partial \xi} = \frac{M_K{}^* I}{\mathbf{F} D} \qquad [11]$$

Since $M_K{}^*$, D, and C_K are functions of composition only, Eq. [11] is an ordinary differential equation which can always be integrated if the functions $M_K{}^*$ and D are known. However, some simple but plausible forms of composition dependence of M_K and D lead to especially simple analytical solutions which provide insight into the effects of various parameters on the composition gradients between the electrodes.

Lithium/Sulfur Battery Analog

In a lithium/sulfur battery with an LiCl-KCl mixture as the electrolyte, lithium cations are produced at one electrode and are consumed at the other electrode. Consequently, the migrational term in Eq. [2] is the transference number of potassium relative to chloride ions. During charge the sulfur electrode is the positive anode, at which the lithium cations enter the electrolyte; lithium cations leave the electrolyte at the negative lithium alloy cathode. During discharge, the negative lithium alloy electrode becomes the anode at which lithium cations are produced in the electrolyte; lithium ions leave the electrolyte at the positive sulfur cathode. Thus, during either charge or discharge, the flows of ions are in the same direction relative to anode or cathode rather than relative to the positive or negative electrode. Calculated composition gradients from anode to cathode, therefore, refer to gradients from the negative (Li) electrode to the positive (S) electrode on discharge and in the reverse direction on charge.

Steady-state composition profiles.—Analytical solution.—A very simple case to treat, which is a not unreasonable approximation of the LiCl-KCl system, is that of a constant volume system with a constant interdiffusion coefficient and with a transference number of potassium equal to the mole fraction X_K. Equation [11] becomes

$$\frac{d \ln C_K}{d\xi} = \frac{d \ln X_K}{d\xi} = \frac{VI}{\mathbf{F}D} = q \qquad [12]$$

which is readily integrated to give

$$C_K = C_K' e^{q\xi} \qquad [13]$$

where C_K' is the concentration of K at the anode ($\xi = 0$). It is thus seen that the predicted composition gradient with this model is not linear but exponential (although not far from linear in appearance for small electrode separations).

The value of the steady-state concentration at the anode, C_K', can be obtained from the conservation condition, since the number of equivalents (N_K) of K between the electrodes remains constant

$$N_K = \int_0^{\Xi} C_K d\xi = \overline{C}\Xi \qquad [14]$$

where $\overline{C}$ is the initial uniform melt composition. The steady-state composition profile (Eq. [13]) may thus be written in terms of the initial ($\overline{X}$, $\overline{C}$) and steady-state ($X(\xi)$, $C(\xi)$) values of the equivalent fraction or volume concentration of K

$$\frac{C(\xi)}{\overline{C}} = \frac{X(\xi)}{\overline{X}} = \frac{q\Xi}{e^{q\Xi} - 1} e^{q\xi} \qquad [15a]$$

Numerical solution.—A more exact description of transport in LiCl-KCl can be provided by using the partial equivalent volumes $\overline{V}_L = 28.4$ cm³ and $\overline{V}_K = 49$ cm³ obtained from density measurements (5) and the Hittorf measurements (6) of the transference number of potassium relative to chloride, which can be represented over the entire composition range by

$$t_K{}^C = X_K + (X_K - 0.2)\, X_K - 0.8\, X_K{}^3 \quad 0 \leq X_K \leq 1 \qquad [16]$$

The transference number is equal, within 10%, to the mole fraction X_K. The interdiffusion coefficient of the melt probably varies little with composition, as in similar melts (7). We assumed in our calculations the value of 1×10^{-5} cm² sec⁻¹ for the interdiffusion coefficient of lithium and potassium. Although the steady-state differential equation (Eq. [11]) and the conservation condition (Eq. [14]) can also be readily integrated, they result in a pair of transcendental equations whose solution requires numerical methods. In such cases it is more reasonable to solve the partial differential equation (Eq. [8]) numerically since this solution can provide the composition profiles at any time rather than at steady state only.

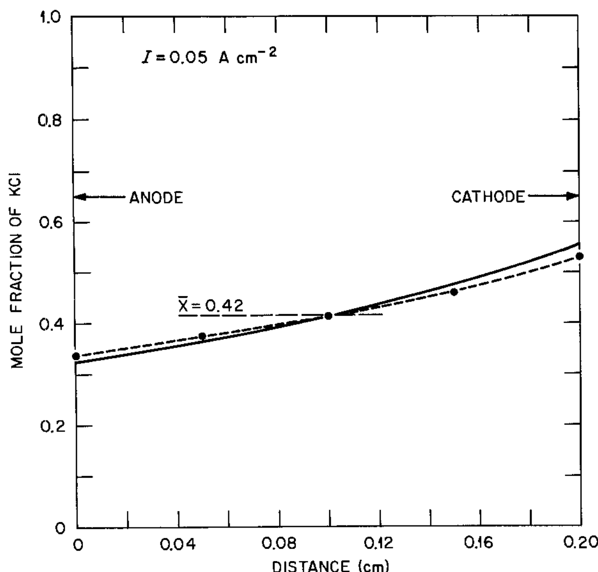

Fig. 1. Steady-state composition profile numerically calculated ——— with differing partial molar volumes and experimental (6) transference number of LiCl-KCl, - - - - with constant equivalent molar volume $V = 37$ cm³ equiv.⁻¹ and $t_K^C = X_K$, ● analytical solution with $V = 37$ cm³ equiv.⁻¹ and $t_K^C = X_K$.

Figure 1 shows steady-state composition profiles calculated for a 0.42 KCl-0.58 LiCl mixture with constant current density of 50 mA cm^{-2} and electrode separation of 0.2 cm. The profile calculated analytically by Eq. [15a] with a constant volume (37 cm^3 $equiv.^{-1}$) and transference number equal to the mole fraction coincides with the numerically calculated profile for the same volume and transference number. Even the profile calculated numerically with unequal equivalent volumes, and with the transference number given by Eq. [16], differs by less than 5% from the analytical solution for equal equivalent volumes. The simple analytical solution (Eq. [15a]) thus provides a very useful approximation to the steady-state composition profile for evaluation of the effects of current density, electrode separation, and initial composition on concentration gradients.

Effect of current density and electrode separation on concentration gradients.—Equation [15a] may be rewritten in terms of a dimensionless parameter, $Q = VI\Xi/\mathbf{F}D$, and a fractional distance between the electrodes $0 \leq \theta = \xi/\Xi \leq 1$

$$X(\theta) = X'e^{Q\theta} \quad [17a]$$

with the compositions at electrodes

$$\text{(anode)} \quad \xi = 0; \quad X' = \frac{\overline{X}Q}{e^Q - 1} \quad [17b]$$

$$\text{(cathode)} \quad \xi = \Xi; \quad X'' = \frac{\overline{X}Q}{e^Q - 1} e^Q \quad [17c]$$

The effects of current density and electrode separation thus appear through the value of their product in the parameter Q. For a fixed current density, the slope of the steady-state profile remains nearly unchanged as the distance between the electrodes is changed, but the difference of concentration between the two electrodes will decrease with decreasing electrode separation. This can be seen readily from a linear approximation of Eq. [15a]. For very low current densities and very small electrode separations, Eq. [15a] can be approximated by expansion of the exponential, as

$$X(\xi) \rightarrow X(0)\,[1 + q\xi]$$

or

$$X(\xi) \xrightarrow[(q \to 0)]{} \overline{X}\left[1 + q\left(\xi - \frac{\Xi}{2}\right)\right] \quad [15b]$$

Even for values of $q\Xi$, for which the truncated expansion is not strictly valid, the profiles in many cases do not, in fact, differ greatly from linearity, as seen in profiles A and B in Fig. 3, for which $q\Xi \simeq 1$. Increasing current at fixed electrode separation leads to increased slope and increased composition differences between the electrodes.

Effect of initial composition; chronopotentiometric transition.—An example of the magnitude of the composition gradient is given in the following calculation. Since in LiCl-KCl melts the diffusion coefficient is probably of the order of 10^{-5}, the quantity $\mathbf{F}D$ is approximately one, hence $Q \approx VI\Xi$. A mean value of the equivalent volume is about 35 cm^3 $equiv.^{-1}$, so that a plausible approximation to the steady-state concentration profile for the free electrolyte case, neglecting convection, would be

$$\frac{X(\theta)}{\overline{X}} = \frac{35I\Xi}{e^{35I\Xi} - 1} e^{35I\Xi\theta}$$

For Ξ of the order of 0.2 cm and for a current density of 200 mA cm^{-2}, the compositions along the steady-state profile fall within the range

$$0.46\overline{X} < X(\theta) < 1.86\overline{X} \quad [18]$$

In a real system X cannot exceed unity. Equation [18] indicates that before attainment of a steady state, the composition $X = 1$ would be attained at the cathode ($\theta = 1$) at this current density and electrode separation and for initial equivalent fractions $\overline{X}_K > 0.538$; *i.e.*, the vicinity of the cathode would be completely depleted of the electroactive constituent L, and maintenance of constant current would require the potential to be increased to where another electrode process would take place. This is the analog of a chronopotentiometric transition (4, 8). At low temperatures, however, precipitation of the constituent being enriched (K) might occur before the chronopotentiometric transition could be reached. The increase in X_K (and corresponding decrease in X_L) occurs always at the cathode, where Li^+ is being consumed from the electrolyte, *i.e.*, at the sulfur (positive) electrode in the Li/S battery on discharge and at the lithium (negative) electrode on charge.

Conditions for attainment of steady state.—Attainment of the steady state rather than a chronopotentiometric transition requires that X'', as calculated in Eq. [17c], be less than unity, which leads to

$$\overline{X} < \frac{e^Q - 1}{Qe^Q} \quad [19]$$

For a given value of the parameter Q (or of the product $I\Xi$), the calculation indicates a decreasing steady-state composition difference between the electrodes with decreasing initial concentration of the nonelectroactive component. Since the initial rate of change of composition is proportional to the current, while the steady-state composition is determined by the parameter Q (or product $I\Xi$), high current favors a rapid approach to the steady state (or transition). At a given initial composition, furthermore, low current densities and small electrode separations (*i.e.*, low values of Q) favor the steady state rather than transition. When inequality [19] is not satisfied (*i.e.*, for higher initial composition or for higher values of Q), the composition at the cathode ($\xi - \Xi$) becomes pure nonelectroactive constituent before the steady state can be reached, and this complete depletion of the electroactive constituent from the cathode region is the analog of a chronopotentiometric transition. Figure 2 is the plot of the right-hand side of inequality [19] *vs.* the values of the parameter Q calculated with a partial equivalent volume of 35 cm^3 $equiv.^{-1}$. The plot distinguishes the values of Q and of the initial composi-

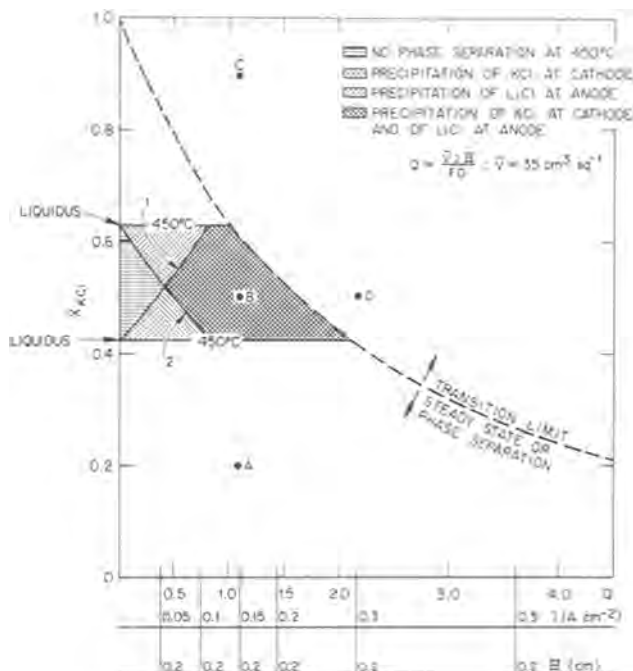

Fig. 2. Conditions for phase separation, transition, or steady state in analog of Li/LiCl-KCl/S battery. A, $X_{KCl} = 0.2$; $I = 0.15$ A cm^{-2}; $\Xi = 0.2$ cm. tion leading to the establishment of a steady-state composition gradient from those leading to a chronopotentiometric transition by complete depletion of LiCl at the cathode. A and B represent conditions for which a steady state is predicted, while C and D are cases of transition. Composition profiles in these four cases are shown in Fig. 3. The two numerically obtained steady-state profiles A and B are identical to the corresponding analytical profiles. The profiles C and D show

the chronopotentiometric transitions predicted in Fig. 2.

Conditions for avoidance of phase separation.—In experimental devices, precipitation of a solid phase at one electrode could limit the current density and other performance characteristics. In molten salt batteries, the initial compositions are often eutectics [or other mixtures chosen to optimize melting temperatures, conductance, and other physical and chemical properties (9, 10)]. The composition gradient between the two electrodes must be kept in a range where the mixture is liquid in order to avoid the precipitation of a solid phase. Thus the compositions at the two electrodes, X' and X'' in Eq. [17b] and [17c], must fall within the range of the liquidus compositions, designated X_I and X_{II}, respectively, at the temperature in question. The initial composition must therefore satisfy the inequalities

$$X_I \frac{e^Q - 1}{Q} \leq \overline{X} \leq X_{II} \frac{e^Q - 1}{Qe^Q} \qquad [20]$$

Comparison of the third term in Eq. [20] with the right-hand side of Eq. [19] shows, since $X_{II} < 1$, that phase separation may prevent attainment of the steady state even though the conditions for avoidance of a transition are satisfied. Precipitation of the component being enriched at the anode is predicted if the left-hand side of the inequality Eq. [20], plotted in curve 1 in Fig. 2, is violated, *i.e.*, for points below curve 1; and precipitation of the other component is predicted at the cathode if the right-hand side, plotted in curve 2, is violated, *i.e.*, for points above curve 2. Only in the region between these two curves and the ordinate would the steady state be predicted rather than transition or phase separation. In the LiCl-KCl eutectic composition at 450°C, phase separation would occur (11) for $Q \geq 0.22$, *e.g.*, with electrode separation of 0.15 cm, phase separation is expected at current densities greater than 40 mA cm^{-2}. At temperatures above the melting point of KCl, with the same electrode separation, a steady state would be predicted at currents below 240 mA cm^{-2}, and a higher current would result in transition. Thus the blocking of the approach to the steady state might result at either electrode depending on the conditions of current density, electrode separation, initial composition, and operating temperature. At a temperature of 400°-430°C, with LiCl-KCl eutectic, Askew and Holland (12) reported that the lithium electrode was markedly polarized at current densities exceeding 500 mA cm^{-2}. They conjectured that this polarization was caused by precipitation of solid LiCl at the anode. Our calculations suggest that under the conditions of the experiment both LiCl precipitation at the anode and KCl precipitation at the cathode might be expected, but KCl precipitation at the cathode would probably occur first as the current density is increased.

Example of development of steady state, transition, or phase separation.—Figure 4 shows composition profiles numerically calculated for LiCl-KCl melts of the same compositions as in Fig. 3 but with the transference number given by Eq. [16] and the different equivalent volumes of LiCl and KCl. A′ and B′ are composition profiles for initial compositions of 0.2 and 0.5 mole fraction KCl, respectively, at a current density of 0.15 A cm^{-2}. For both cases, A′ and B′, the simple analytical expression (Fig. 2) is consistent with a steady state. The calculation with variable volume and mobilities shows the expected steady state for case A′ but a chronopotentiometric transition for B′ occurring after about 6 min in a situation where the values of Q and $\overline{X}$ are close to the condition for attainment of steady state. The numerically calculated profile B′ exhibits only upward curvature, similar to the shape of the numerical steady-state profile A′. E′ is a steady-state profile calculated for $\overline{X} = 0.5$ and a lower cur-

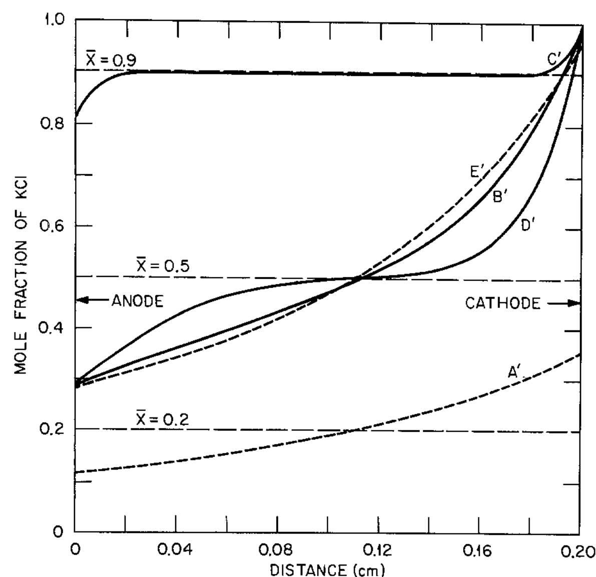

Fig. 4. Steady-state profiles (----) and profiles at transition (—+—) numerically calculated with differing partial equivalent volumes and transference number from Ref. (6). A′, $\overline{X}_{KCl}$ = 0.2; I = 0.15 A cm^{-2}. B′, $\overline{X}_{KCl}$ = 0.5; I = 0.15 A cm^{-2}. C′, $\overline{X}_{KCl}$ = 0.9; I = 0.15 A cm^{-2}. D′, $\overline{X}_{KCl}$ = 0.5; I = 0.3 A cm^{-2}. E′, $\overline{X}_{KCl}$ = 0.5; I = 0.1 A cm^{-2}.

rent density of 0.1 A cm^{-2}. As shown in curve B of Fig. 3, the calculation for the initial composition and current density of curve B′, but with the mean equivalent volume and transference number $t_K^c = X_K$, leads to prediction of a steady state, but one close to transition. Thus the effect of disparity of $\overline{V}$ values is small and appears only near the border between transition and steady-state.

The profile C′ in Fig. 4 corresponds to the composition 0.1LiCl-0.9KCl at a current density of 0.15 A cm^{-2}. It is calculated at the transition time, which is a little more than 4 sec. The simple analytical expression (Fig. 2) also predicts transition at this composition and current density. The transition shown in D′, corresponding to $\overline{X}$ = 0.5 and I = 0.3 A cm^{-2}, is attained after 85 sec, the profile showing downward curvature near the anode and upward curvature near the cathode. A transition also is predicted from the value of the parameter Q with the mean equivalent volume of 37 cm^3 $equiv.^{-1}$. The simple calculation in terms of the parameter Q, a mean equivalent volume and a transference number equal to the mole fraction is thus useful and reliable for predicting conditions for steady state or transition. Only small differences from the numerical solution appear, and these only near the border between transition and steady state.

Relaxation of composition gradients and chemical effects.—Composition gradients in operating cells have received little attention. Postoperative examinations, conducted after a slow cooling of the cell, may show little composition change. In Fig. 5, our calculation simulates the relaxation of compositions at anode and cathode after cessation of current flow following establishment of a steady-state composition profile. The initial composition is 0.5KCl-0.5LiCl, the current density for establishing the gradient is 100 mA cm^{-2}, and the electrode separation is 0.2 cm. The electrolyte composition between the electrodes extends from 0.28 to 0.96 mole fraction of KCl on cessation of current flow. The gradient relaxes after 2.5 min to a composition range 0.36-0.69; after 10 min the range is 0.45-0.56. Since cooling and disassembly of cells may take even longer, these gradients may be difficult to detect by chemical analysis. A relaxation in agreement with that predicted has been observed (13) by means of potential changes

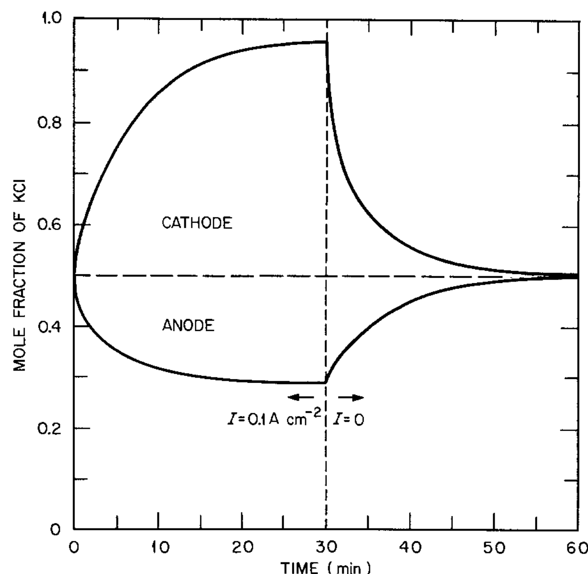

Fig. 5. Composition changes with time at the cathode and at the anode (during charge or discharge) followed by relaxation on open circuit.

of both electrodes in an analogous system, $Ag/AgNO_3$-KNO_3/Ag.

The composition profiles we predict by considering diffusion and migration in the electrolyte are consistent with observations made on the formation of J-phase (possibly $LiK_6Fe_{24}S_{26}Cl$) at the cathode of Li/S cells on discharge (10). A recent report (14) on the effects of electrolyte composition on the formation of J-phase during the discharge of FeS electrodes shows that increasing the LiCl concentration from 58 to 70 mole percent (m/o) eliminated the J-phase. Figure 6 shows predicted steady-state composition profiles in the mixtures 0.58LiCl-0.42KCl and 0.7LiCl-0.3KCl with electrode separation of 0.2 cm and current density of 0.05 and 0.1 A cm^{-2}. In the first mixture, where J-phase has been reported (14), the steady-state composition of the melt near the cathode is calculated to be about 0.5LiCl at 0.05 A cm^{-2}; in the other mixture, where no J-phase is reported, the calculated composition at the cathode is 0.64 mole fraction LiCl at the same current density. This is consistent with recent thermodynamic calculations (15) indicating that J-phase formation could be prevented by increasing the ratio of the activities of LiCl to KCl in the electrolyte. Choice of initial compo-

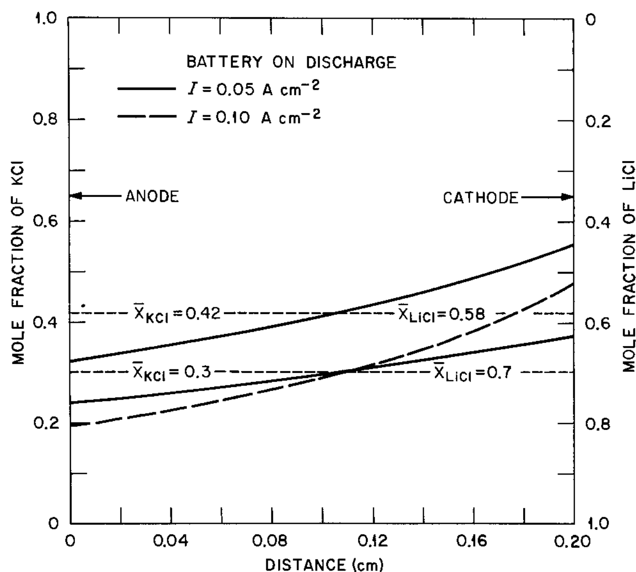

Fig. 6. Steady-state composition profiles: dependence on initial composition and on current density.

sition alone, however, independent of current density and electrode separation, may be insufficient to eliminate J-phase formation. An increase of the current density or of the electrode separation may lead to compositions at the cathode in the range favoring J-phase formations even for melts with the higher lithium chloride content. For example, in Fig. 6 the dashed curve is the steady-state composition profile calculated for the melt with the higher LiCl content but at 0.1 A cm^{-2}. The composition of about 58 m/o LiCl predicted at the cathode is close to the value predicted at the lower current in the melt of lower LiCl content. Doubling the electrode separation, instead of the current density, would lead to a similar composition at the cathode.

Conclusions

Composition gradients in analogs of Li/S batteries (with LiCl-KCl as the electrolyte) are predicted to result from the faradaic, migrational, and diffusive processes. A simple, useful analytical expression has been derived for steady-state composition profiles in terms of a single parameter, Q, incorporating the current density, the mean equivalent volume, the electrode separation, and the interdiffusion coefficient. A steady-state composition gradient, a chronopotentiometric transition, or phase separation are predictable from the value of Q, together with the initial composition and the phase diagram of the system. Numerical solution of the diffusion-migration equation has been used to calculate profiles at the transition time, at other times prior to reaching the steady state, or for unequal equivalent volumes of the mixture components and unequal mobilities of the two like-charged ions. However, comparison of computed steady-state profiles shows little difference between results from the simple analytical expression and from the numerical solution with equivalent volumes and mobilities corresponding to LiCl-KCl.

Composition gradients have been recognized in aqueous fuel cells (16, 17) and electrolyzers (18-20), but have received little prior attention in connection with molten salt batteries. Since they may result in the depletion of the electroactive constituent at one electrode, or in phase separation, they must be taken into account in the chemistry and phase equilibria of the electrolytes. Further refinements in the predictions will require attention to convection and to the porosity of the electrolyte matrix.

ABSTRACT

The anodic and cathodic polarization behavior of titanium and four commercial alloys (Ti-5Al-2.5Sn; Ti-6Al-4V; Ti-8Al-1Mo-1V; Ti-13V-11Cr-3Al) has been investigated in boiling acidic chloride solutions (0.1M HCl; 0.1M HCl + 0.5M NaCl; 0.1M HCl + 5M NaCl) and in 0.1M H_2SO_4 solution as a function of tensile stress (equal to $0.9\sigma_y$). All materials exhibit an active to passive transition. Pitting corrosion was observed at very noble potentials for the Ti-5Al-2.5Sn; Ti-6Al-4V, and Ti-8Al-1Mo-1V alloys, and a transpassive behavior was observed for the Ti-13V-11Cr-3Al alloy. The kinetics of the hydrogen evolution reaction (HER) is substantially facilitated by increasing the chloride concentration and by going from the most dilute chloride solutions to dilute sulfuric acid solutions. The tensile stress does not modify in our experimental conditions (of aggressive medium, temperature, surface state, and stress type and level, etc.) the electrochemical behavior of all materials examined.

Titanium and its alloys have found, despite their high cost, fairly extensive application in the naval, aeronautic, and chemical industries thanks to their high strength/weight ratio and to their good resistance to general and localized corrosion in various environments. Titanium and its alloys are characterized by the tendency to be easily passivated, by stable passivity over a wide range of potential and temperature, and by insensitivity to the detrimental effect of aerated or other oxygen-containing chloride solutions.

However, it is well known that these materials are susceptible to pitting and crevice corrosion (1-5) in the hot concentrated solutions employed in desalination plants and to stress corrosion cracking (6-9). In particular, stress corrosion cracking is promoted by crevices, as Brown and collaborators have clearly demonstrated (9).

Many authors have studied the corrosion behavior of titanium and its alloys in sulfuric acid (11-17), in acidic sulfate solutions (18), in hydrochloric acid (10, 19), and in halide solutions of various pH (20-24), mostly at ambient temperature. Most studies concern the anodic dissolution mechanism in the active and passive range, the active-passive transition *vs.* temperature, acidity, and aggressive anions of the solution, and also the effect of alloy composition and microstructures. The corrosion and primary passivation potentials, the critical and passivation current density, and the critical pitting potential values have been reported in these papers.

Other studies (17, 23) have examined the cathodic hydrogen evolution process on these materials with the determination of the rate-controlling step and of parameters such as the exchange current density, the transfer coefficient, the reaction order, and the Tafel slope.

With reference to what has been reported above it appears that the tensile stress effect on the electrochemical behavior of titanium and its alloys in boiling acidic chloride solutions has not been systematically examined apart from some results of Wijman in 10% H_2SO_4 + 8% HCl at room temperature (25) and from the paper of Levy (5) which is, however, restricted to the 0.17M sodium chloride solution (approximate NaCl concentration in blood, plasma, and lymph) and to Hank's physiological solution (a fairly close imitation, from the chemical viewpoint, of the fluid in muscle and bone) at a temperature of 37°C.

The present investigation was undertaken to obtain a more complete understanding of the role of the tensile stress on the anodic dissolution process (in the active condition), on the formation and stability of the passivating films, hence on localized corrosion, *i.e.*, on pitting, crevice, and stress corrosion cracking, and on the cathodic hydrogen evolution process. For this reason, the electrochemical behavior of titanium and four commercial alloys (Ti-5Al-2.5Sn; Ti-6Al-4V; Ti-8Al-1Mo-1V; Ti-13V-11Cr-3Al) was investigated in boiling acidic chloride solutions with stressed specimens to 90% yield strength and unstressed tensile specimens as electrodes, and was extended to boiling 0.1M HCl and 0.1M H_2SO_4 solutions for comparison.

Experimental

Materials.—Chemical composition, factory heat-treatment, microstructures, and yield strength of the titanium Contimet 35 and of the alloys used in this work are given in Table I. The conventional test specimens were cut from 1.0 mm thick sheet, degreased for 15 min in 90% ethanol (reagent grade chemical), washed in boiling distilled water, and then dried with pure ethanol. The specimen surface area, equal to nearly 9 cm^2, was accurately outlined with two silicon rubber gaskets (see details in Fig. 1) and was measured after every experiment.

Solutions.—The following solutions were used at their boiling temperature (100°-105°C): 0.1M HCl (I); 0.1M HCl + 0.5M NaCl (II); 0.1M HCl + 5.0M NaCl (III); 0.1M H_2SO_4 (IV). Reagent grade chemicals and bidistilled water (3 μS specific conductivity) were

Key words: hydrogen evolution reaction, localized corrosion, passivity, tensile stress, titanium and titanium alloys, transpassivity.

employed. Molar concentrations are referred to 25°C without taking in to account variation in density with temperature. The solution volume, referred to 1 cm² of the electrode surface area, was equal to approximately 50 ml.

Cell and electrode arrangements.—The stressed specimen polarization cell is a Pyrex glass standard cell (26). It consists of two compartments joined by a bridge containing a fritted glass disk. The first compartment is a 0.5 liter spherical flask with five necks to introduce the working electrode, the gas inlet and outlet tubes, the thermometer, the condenser, and the Haber-Luggin probe; the second compartment is a cylindrical flask containing the platinum auxiliary electrode. It was necessary to design the special electrode arrangement shown in Fig. 1, which is able to apply an uniaxial tensile stress on the plate working electrode and to minimize or avoid the crevice effect.

Teflon, Vyton, and silicon rubber were the insulating materials selected because of their chemical inertness in hot acidic solutions. The cell and all the Teflon parts in contact with the solutions were washed in hot chromic solution, rinsed several times in distilled water, and dipped in the test solution with the Vyton and silicon rubber parts.

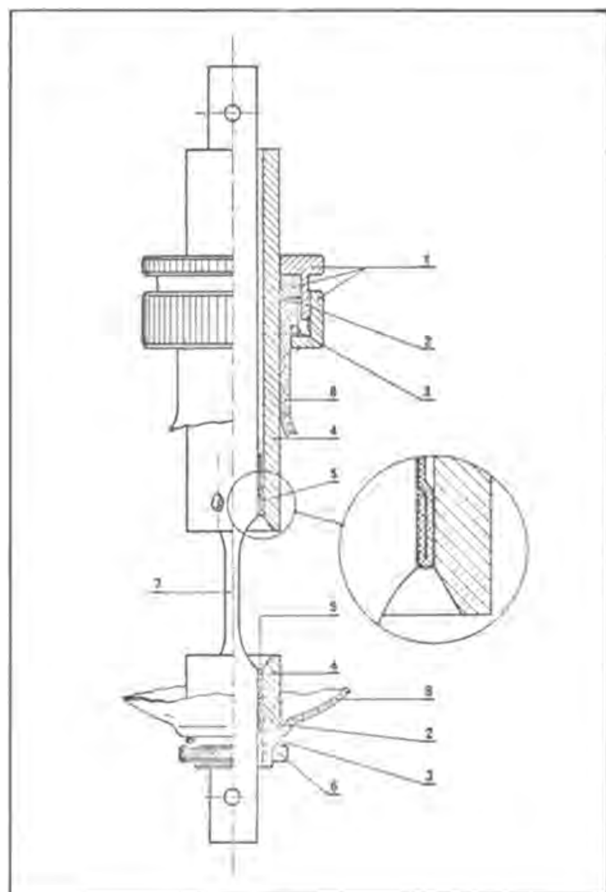

Fig. 1. Electrode assembly used for electrochemical measurements: 1, upper polypropylene seal; 2, Vyton O-ring; 3, neoprene O-ring; 4, Teflon seal; 5, silicon rubber gasket; 6, AISI 304 hold-down nut; 7, specimen; 8, Pyrex glass cell.

Electrochemical procedure.—The electrochemical cell and the electrode assembly were mounted in the tensile machine (Model Unisteel with arm 1:30 length ratio) keeping the specimen unstressed. The solution was poured into the cell at room temperature and then high purity nitrogen was bubbled through the solution at a rate of 10 liters/hr for 24 hr to ensure a very low oxygen concentration in the solution. During this time the specimen was in the passive state.

The solution cell was then heated with a glass wool mantel and the electrode potential recorded. The potential of the unstressed specimen at first decreases slowly and then falls quickly in the active direction. The specimen in the active state was then stressed at a tensile stress level equal to 90% of yield strength and after 5 min (carefully controlled) was polarized. The applied stress virtually does not change the specimen potential.

For anodic polarization, the potentiodynamic method was used at a sweep rate of 20 mV/min up to 2V *vs.* SCE; for cathodic polarization, the potentiostatic method was used (steps of 20 mV for 30 sec). At each step the polarization was interrupted for 5 sec. All polarizations were performed in triplicate. The electronic device (*i.e.*, potentiostat, electrometer, recorder, and so on), have previously been described (27). All potentials are referred to the saturated calomel electrode (SCE), which was kept at room temperature and joined with a potassium chloride agar-agar salt bridge to a Luggin probe positioned 1-2 mm from the specimen surface. The potential values were not corrected for the small ohmic drop and for Sorel thermal potential errors.

Results and Discussion

The anodic polarization curves of the unstressed and stressed titanium and Ti-8Al-1Mo-1V alloy are given in Fig. 2 and 3 as examples of the behavior of the

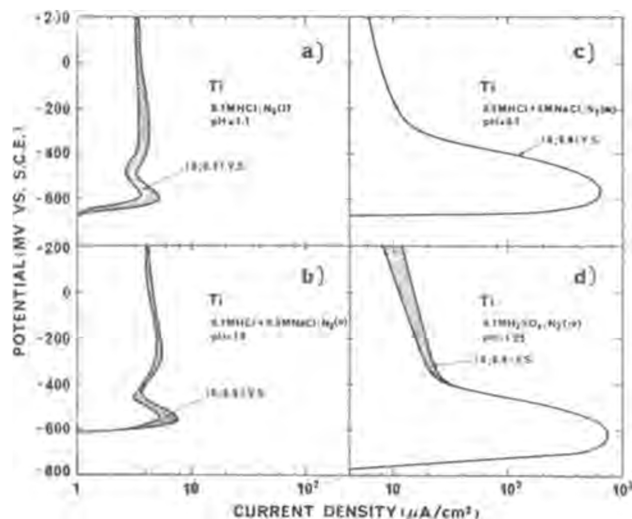

Fig. 2. Anodic polarization curves of unstressed and stressed titanium in various deaerated solutions at boiling point (Y.S. = yield strength).

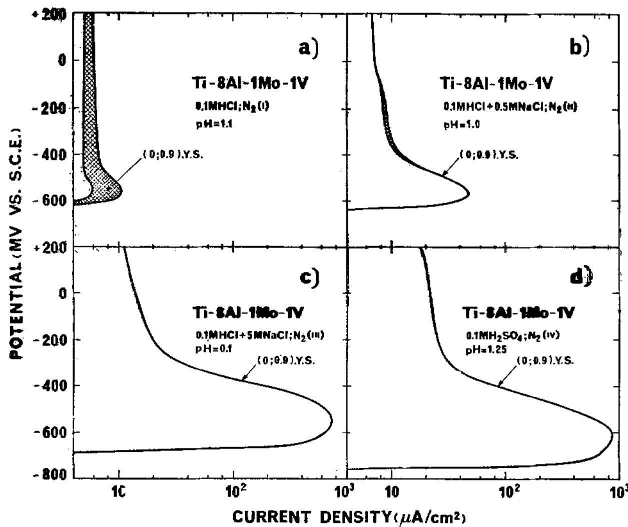

Fig. 3. Anodic polarization curves of unstressed and stressed Ti-8Al-1Mo-1V alloy in various deaerated solutions at boiling point (Y.S. = yield strength).

tested materials. The most important parameters for a quantitative classification of the corrosion behavior of active-passive metallic materials are summarized in Table II.

The anodic curves were plotted up to + 200 mV *vs.* SCE since the current density was practically constant and less than 10 $\mu A/cm^2$ at more noble potentials, *e.g.*, up to 2000 mV *vs.* SCE for titanium and up to the potential values, summarized in Table III, for the titanium alloys. The potential above which the titanium alloys' anodic current density markedly increased is reported in Table III; this potential indicates the breakdown of passivity, that is, the onset of pitting in the case of Ti-5Al-2.5Sn, Ti-6Al-4V, and Ti-8Al-1Mo-1V alloys, and for the onset of the transpassive corrosion in the case of the Ti-13V-11Cr-3Al alloy. The pitting occurs generally on the edges, *i.e.*, on the transversal cut surfaces and never beneath the silicon rubber gasket. The data are in good agreement with the values reported by Griess (1) and Levy and Sklover (10) for the same titanium alloys.

From the examination of all the anodic polarization data, we can formulate the following remarks.

Titanium.—In solutions I and II, titanium exhibits only a slight active-passive transition (Fig. 2a and b)

Table III. Breakdown potential (mV *vs.* SCE) of unstressed and stressed specimens

Solution		Alloy: Ti-5Al-2.5Sn (α)	Ti-6Al-4V ($\alpha + \beta$)	Ti-8Al-1Mo-1V ($\alpha + \beta$)	Ti-13V-11Cr-3Al* (β)
0.1M HCl	US**	1650	1625	1580	N.D.
	S	1800	1570	1430	N.D.
0.1M HCl + 0.5M NaCl	US	1540	1570	1360	725

	S	1140	1470	1020	825

* For this alloy the values reported refer to the initiation of transpassive behavior.
** US = unstressed specimen; S = stressed specimen.

but a more pronounced one is observed in solutions III and IV (Fig. 2c and d). In solutions I and II, there was an initial transient drop in corrosion potential followed by an increase as the passive film was reformed (see Fig. 4). A similar activation and repassivation phenomenon was observed by the authors in 0.1M H_2SO_4 at 40°C (28).

From the Fig. 2 it is also noted that the active anodic loop spreads out when the chloride anion concentration increases. This effect is more evident when solution II is compared with solution III. In 0.1M H_2SO_4 (solution IV) the anodic loop is practically equal to that of the most concentrated chloride solution (III), but shifted in the less noble direction.

Therefore, it is important to point out that according to Griess (1) the chloride anion catalytic effect on the titanium active-passive transition is not only direct [*i.e.*, by increasing the water-complex reactivity through the substitution of coordination water with the anion or by means of anion preferential adsorption on the metallic surface, the anion functioning as a "bridge" between the metallic phase and the solution (29)], but above all indirect by increasing the activity or reactivity of the other ions in the solution which are operating in the heterogeneous charge transfer reaction, *i.e.*, in this particular case, H^+ ions. In fact comparing solution II with solution III, the chloride anion concentration is increased by nearly 10 times and the *p*H value is decreased from 1.0 to 0.1 [and so the H^+ activity is increased by nearly 8 times (1)]. On comparing Fig. 2a with d (the solutions have the same *p*H), it is evident that the SO_4^{2-} anion has a stronger acceleration action on the titanium active dissolution than the Cl^- anion.

* Passivity current density (at 0 mV *vs.* SCE) $\leqq$ 10 $\mu A/cm^2$. US = unstressed specimen; S = stressed specimen.

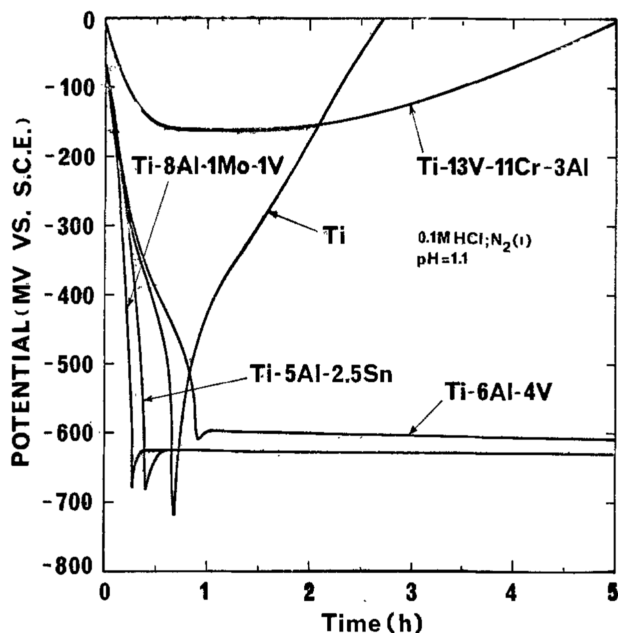

Fig. 4. Potential-time curves of unstressed titanium and unstressed Ti-5Al-2.5Sn, Ti-6Al-4V, Ti-8Al-1Mo-1V, and Ti-13V-11Cr-3Al alloys in deaerated 0.1M HCl at boiling point.

The effect of the applied tensile stress on the titanium anodic behavior is practically negligible, the difference observed being due to scatter in the experimental data. In any case, the titanium remains passive up to a potential of 2V *vs.* SCE in the acidic chloride solutions tested.

Ti-5Al-2.5Sn.—This alloy has an evident active-passive transition behavior in all solutions tested. The chloride and sulfate anions and the applied tensile stress effects are similar to those observed and discussed for titanium. Unlike titanium, the Ti-5Al-2.5Sn alloy is susceptible to pitting corrosion in all the acidic chloride solutions tested. An important point is the lack of tensile stress effect on the pitting resistance evaluated as breakdown potential (see Table III).

Ti-6Al-4V and Ti-8Al-1Mo-1V.—These alloys have, as shown in Fig. 3 for the Ti-8Al-1Mo-1V alloy, the same anodic behavior as the Ti-5Al-2.5Sn discussed above (see also Tables II and III).

Ti-13V-11Cr-3Al.—This alloy has the same anodic primary loop as the alloys discussed above. In particular this alloy is not susceptible to pitting corrosion in all the acidic chloride solutions tested, according to Levy and Sklover (10), but it is susceptible to transpassive dissolution, as shown in Fig. 5 and reported in Table III.[1] This alloy does not spontaneously shift to the active state in 0.1M HCl (Fig. 4).

Figures 6 and 7 show, for example, the cathodic polarization curves of the Ti-6Al-4V and Ti-5Al-2.5Sn alloys *vs.* the chloride or sulfate concentration and the applied tensile stress. A comparison of the curves allows the following remarks to be made concerning the cathodic hydrogen process.

(*i*) The titanium and Ti-6Al-4V alloy (Fig. 6) have substantially the same kinetics of the hydrogen evolution reaction (HER), *i.e.*, characterized for equal polarization by the same cathodic current density values and by the presence of a linear Tafel region with slope of 200 mV/decade in boiling chloride solutions (I, II, and III) and of 400 mV/decade in boiling 0.1M H_2SO_4 (IV). These high values of the Tafel slopes suggest the presence of a mixed oxide film of TiO_2 and Ti_2O_3, as shown by Tomashov *et al.* (30), on the titanium and on the Ti-6Al-4V alloy surface.

The cathodic polarization, measured as $\Delta E = E(i_{cat.}) - E_{corr.}$ at $i_{cat.} = 10^3$ $\mu A/cm^2$, decreases with increasing chloride concentration (I: $\Delta E = 250$ mV; II: $\Delta E = 180$ mV; III: $\Delta E = 75$ mV) and going from the most dilute solutions (I and II) to 0.1M H_2SO_4 solution (IV: $\Delta E = 50$ mV). It has been observed in the cathodic polarization of titanium in 0.1M HCl + 0.5M NaCl solution that, at approximately − 1.1V *vs.* SCE, deviations from linear Tafel behavior commenced with an anomalous increase in the cathodic current density. In agreement with the interpretation reported by Thomas and Nobe (17) a possible explanation of this phenomenon is the complete reduction of the oxide film or the possible hydride formation from the oxides at this potential and the subsequent hydrogen ion discharge on oxide-free titanium.

(*ii*) The Ti-5Al-2.5Sn (Fig. 7), Ti-8Al-1Mo-1V, and Ti-13V-11Cr-3Al have the same kinetics of hydrogen evolution reaction (HER), *i.e.*, characterized for equal polarization by the same cathodic current density values and by the absence of a linear Tafel region. The

[1] The complex formed by the hexavalent chromium ion and diphenylcarbazide was spectrophotometrically detected at the end of each anodic polarization. The presence of this complex was particularly evident in 0.1M H_2SO_4 solution.

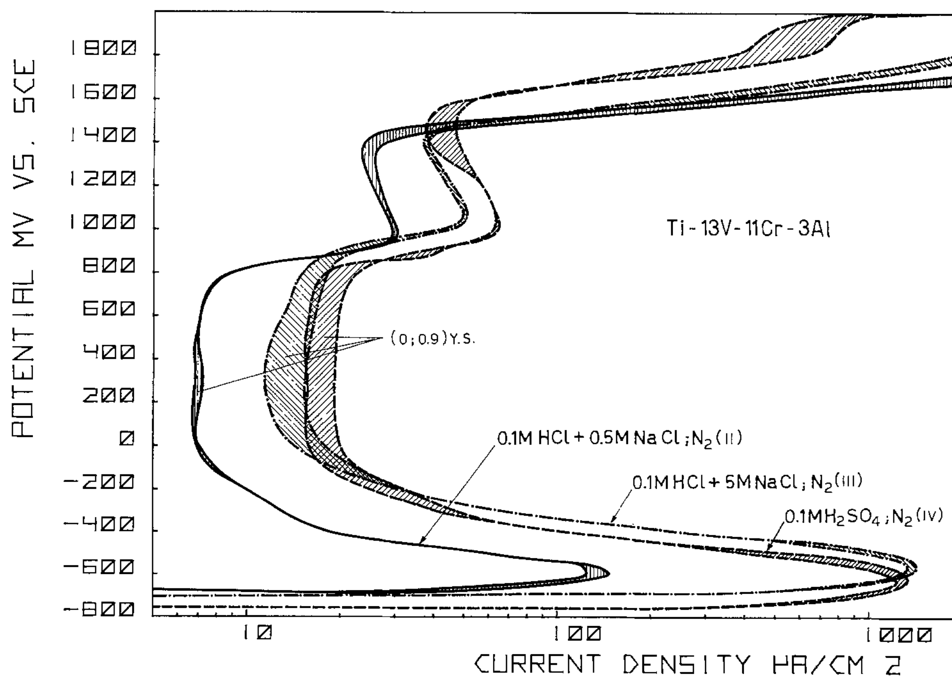

Fig. 5. Anodic polarization curves of unstressed and stressed Ti-13V-11Cr-3Al alloy in various deaerated solutions at boiling point. (Y.S. = yield strength).

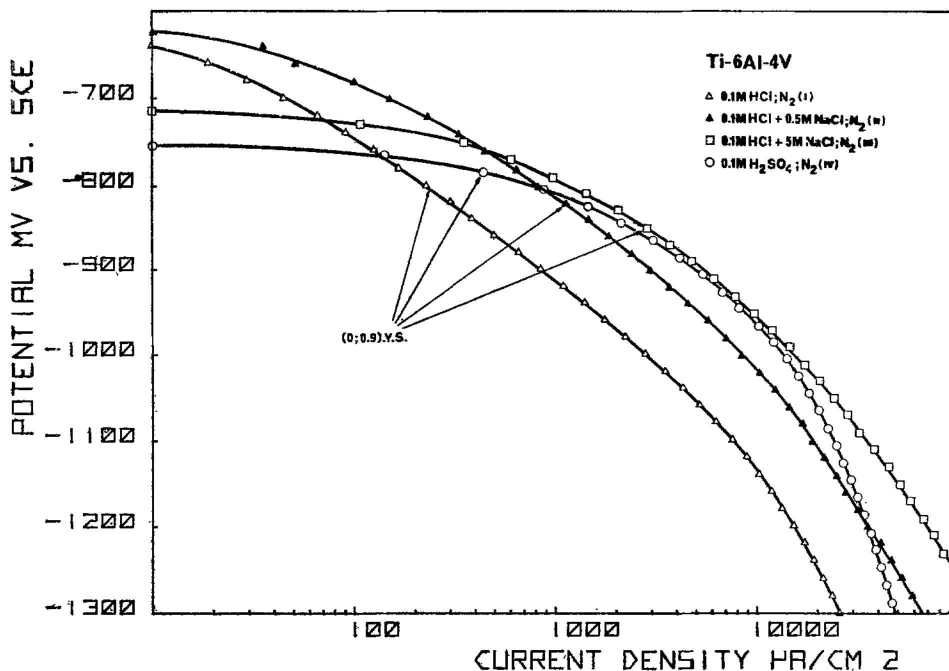

Fig. 6. Cathodic polarization curves of unstressed and stressed Ti-6Al-4V alloy in various deaerated solutions at boiling point (Y.S. = yield strength).

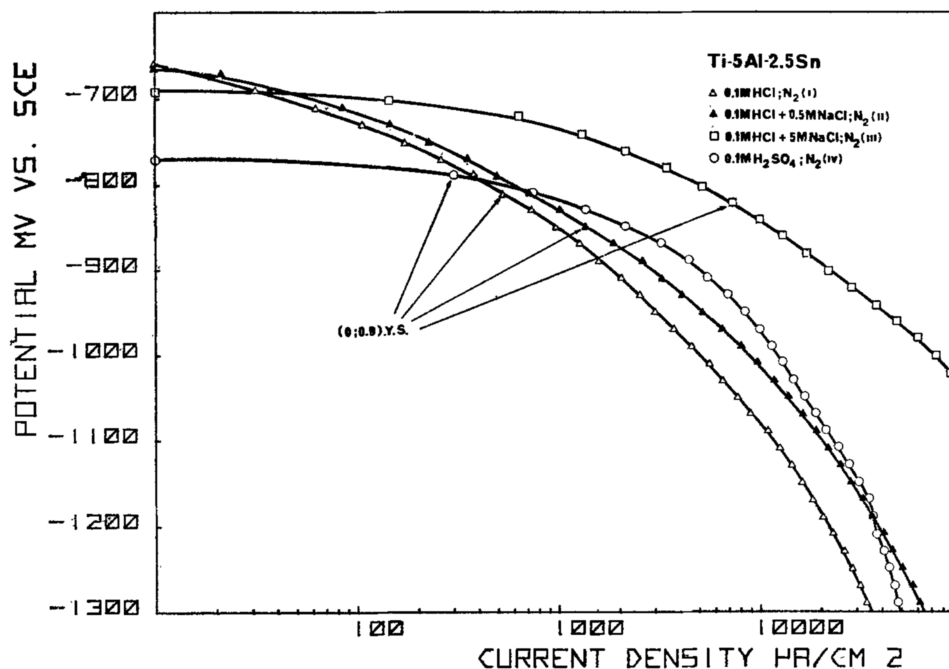

Fig. 7. Cathodic polarization curves of unstressed and stressed Ti-5Al-2.5Sn alloy in various deaerated solutions at boiling point (Y.S. = yield strength).

cathodic polarization, measured in (*i*), decreases with increasing chloride concentration and going from the most dilute chloride solutions (I and II) to 0.1M H_2SO_4 solution (IV). Moreover the HER of these alloys tends to take place more easily.

(*iii*) The cathodic behavior of titanium and the alloys studied is independent of the tensile stress applied in all the solutions.

Conclusions

The study of the electrochemical and corrosion behavior of titanium and the alloys (Ti-5Al-2.5Sn, Ti-6Al-4V, Ti-8Al-1Mo-1V, and Ti-13V-11Cr-3Al) under tensile stress in boiling sulfuric acid and acidic chloride solutions indicated that:

1. All the materials exhibit an active anodic loop (except the Ti-13V-11Cr-3Al in 0.1M HCl) with an active-passive transition characterized by the same primary passivation potential values. The critical current densities increase in the order: Ti <Ti-8Al-1Mo-1V <Ti-5Al-2.5Sn <Ti-6Al-4V <Ti-13V-11Cr-3Al. Passivity characterized by a low current density value ($\simeq$ 10 $\mu A/cm^2$) indicates the formation of a very protective film.

(*ii*) Unlike titanium, the alloys Ti-5Al-2.5Sn, Ti-6Al-4V, and Ti-8Al-1Mo-1V are susceptible to pitting corrosion (generally on the sample edges) and the alloy Ti-13V-11Cr-3Al to transpassive anodic dissolution. Since the pitting phenomena, in absence of crevices, appear at very high potentials ($\simeq$ 1000 mV *vs. SCE*), that is, an aggressive environment with a very high oxidizing power is required, the alloys have the same resistance to pitting corrosion as titanium but better mechanical properties.

(*iii*) The kinetics of cathodic hydrogen evolution is substantially facilitated by increasing chloride concentration. Therefore, it is possible to conclude that the active corrosion rate of titanium and the alloys examined increases with the chloride anion content in acidic solutions.

(*iv*) Tensile stress has no appreciable effect on anodic and cathodic behavior in the experimental conditions

tested (*i.e.*, of aggressive medium, temperature, surface state, and stress type and level).

Effect of Molybdenum on the Pitting Potential of High Purity 18% Cr Ferritic Stainless Steels

J. R. Galvele,*[1] J. B. Lumsden,[2] and R. W. Staehle*

The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The anodic behavior of high purity 18% Cr ferritic stainless steels, with a content from 0 to 5% molybdenum, was studied in 1*N* NaCl and in 1*N* HCl solutions. The studies were complemented by Auger electron spectroscopy analysis of the films in HCl solutions. It was found that the effect of molybdenum on the pitting potential of these alloys in NaCl solutions could be rationalized assuming that pit initiation is related to localized acidification at the metal-solution interface. The Auger analysis showed a high concentration of chloride ions in the films formed in HCl solutions. No molybdenum enrichment was found in the films. The anodic behavior of these alloys in HCl solutions was related to the formation of a slowly dissolving salt layer of $CrCl_3$ on the alloy surface. The results suggest that molybdenum exerts its influence by reducing the dissolution rate of the salt layer.

It is well documented in the literature (1-4) that molybdenum has a beneficial effect on the resistance of stainless steels to pitting in NaCl solutions. It was first assumed (5, 6) that molybdenum was enriched in the surface film, increasing its chemical resistance. Nevertheless, recent Auger electron spectroscopy (AES) analysis (7, 8) has shown that no molybdenum was enriched in the oxide film of molybdenum containing stainless steels.

Recent work on the pitting of metals (9) has indicated that many of the variables that affect the pitting potential can be related to localized acidification. According to this mechanism the alloying elements exert their effects by changing the anodic behavior in the acid solutions which exist inside pits. Then, the effect of molybdenum should not be found in enrichment in the oxide film, but rather in changing the anodic kinetics of the alloys in the pit-like solutions.

* Electrochemical Society Active Member.
[1] Present address: Comision Nacional Energia Atomics, Buenos Aires, Argentina.
[2] Present address: North American Rockwell, Science Center, Thousand Oaks, California 91360.

In the work reported herein, it was attempted to verify such a mechanism. Pitting potential measurements obtained by techniques such as scratching the metal surface (10) give the potential at which pits start from very small dimensions and grow to visible sizes. In the initial steps of pit growth no substantial changes of the electrolyte concentration should be found (9, 11); it was concluded that the chloride concentration inside the pits at the initial stage, for surfaces exposed to a 1*N* NaCl solution, should also be 1*N*. The pH inside pits has been measured for large pits only (12, 13) and values between 0 and 1 have been reported. No measurements have been reported for the initial stages of pit growth. Thus a 1*N* HCl solution was chosen in the present work to represent the pit-like solution.

Very good correlation was found between the values of pitting potential predicted by the acidification mechanism and those reported by Lizlovs and Bond (3) for the same alloys in a 1*N* NaCl solution.

Materials

The materials employed were high purity ferritic stainless steels having 18% Cr and containing 0-4.75% Mo. All the steels were annealed at temperatures which avoid the formation of chi and sigma phases. The alloys containing 0, 1, and 2% Mo were heat-treated for 1 hr at 815°C and then water quenched. The alloy containing 4.75% Mo was heat-treated for 1 hr at 980°C, followed by water quenching. Metallographic examination did not show the presence of intermetallic phases in any of the materials. The chemical composition of the alloys is given in Table I.

Experimental

The samples for the electrochemical measurements were mounted in bakelite metallographic mounting and mechanically polished; the final polish was alumina No. 3. An epoxy was used to mask the borders of the samples leaving exposed an area of approximately 1 cm^2. Electrical contact was made by drilling a hole through the mounting. The solutions were prepared with analytical-grade reagents and double distilled water and were deaerated with high purity argon. All the measurements were made at room temperature (24°C). Potentials were measured with respect to the saturated calomel electrode.

The polarization curves were determined in steps of 50 mV with the potential held constant for 10 min before the current was recorded. General dissolution occurred at potentials below −0.200V SCE. Above this potential pits were found on the surface.

Pitting-potential values were measured by the scratch technique described by Pessal and Liu (10). While the samples were kept at constant potential, the surface of the metal was scratched with an SiC point mounted on the Luggin capillary. The change of current with time was recorded to determine the repassivation time. After repassivation the potential was charged 25 mV and the surface was again scratched. This procedure was repeated until a potential was reached at which repassivation no longer occurred, *i.e.*, the pitting potential.

Pits were allowed to grow at constant potential and the mean current density inside the pits was calculated. All the pits observed were hemispherical; most of them were covered by a thin oxide film. This film was removed by light mechanical polishing. Measurements of the diameter of the pits were made under a microscope at 100 times. Assuming that the pit grew at a constant rate, the current density inside the pits was calculated

$$\text{Current density (A/cm}^2) = \frac{rd\mathbf{F}}{tE} \quad [1]$$

where r is the pit radius (in cm), d is the alloy density (in g/cm^3), **F** is the Faraday constant, t is the exposure time (in seconds), and E is the equivalent weight of the alloy. Assuming that iron dissolves as Fe^{2+} and chromium as Cr^{3+}, the mean equivalent weight is $E = 25$ g-equiv.

Table I. Chemical composition of the ferritic stainless steels

Stainless steel type	Element, w/o			
	Cr	Mo	C	N
18Cr-0 Mo	17.35	<0.01	0.002	0.003
18Cr-1Mo	17.53	1.14	0.003	0.004
18Cr-2Mo	17.61	2.02	0.004	0.004
18Ca-4.75Mo	17.38	4.75	0.004	0.004

Results

The pitting potential of these alloys in 1*N* NaCl solution has been reported previously by Lizlovs and Bond (3, 4). However, some of the measurements were repeated in the present work. Figure 1 shows a typical example of the results. This figure gives the current-time response of the 18Cr-1Mo alloy. The alloy was exposed at constant potential to a 1*N* NaCl solution. Up to +0.175V SCE, a current transient was observed after scratching the surface which returned to the initial value after 10-15 sec. Although the potential was kept constant for another 5-10 min, no further changes in the current were observed. This behavior was independent of the number of times the surface was scratched. At +0.200V SCE and after scratching, the current density was followed by a current increase, which after 1 min was 6×10^{-5}A, after 5 min reached 1.5×10^{-4}A, and was still increasing after 30 min. Microscopic observation of the samples showed that pits were nucleated along the scratch line.

The pitting potential values found in these experiments were in accordance with those reported by Lizlovs and Bond. After the current started to increase, samples were kept at constant potential for approximately 20-30 min to allow the pits to grow. Then they were removed from the cell and the mean radius of the pits was measured under the microscope. The current density inside the pits was calculated with Eq. [1], and the values found are given in Table II. The value obtained at the pitting potential was approximately 5×10^{-1} A/cm² for all the alloys tested.

Another important observation from these experiments is that in the range of 25 mV a transition from

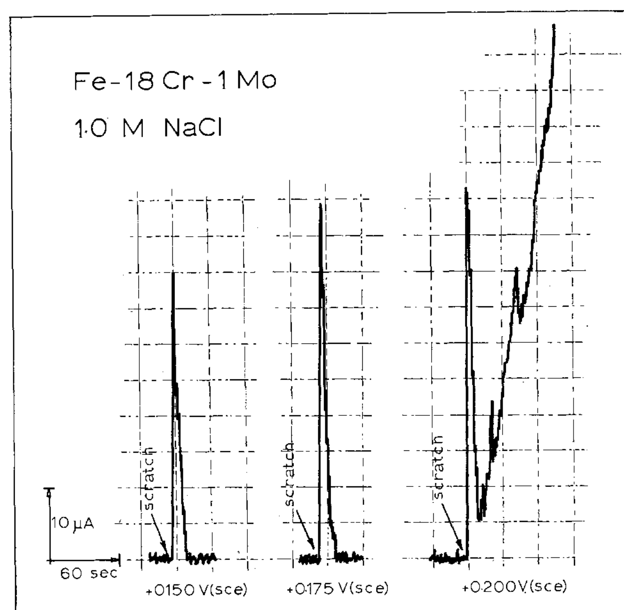

Fig. 1. Typical current-time curves recorded after scratching the metal surface with an SiC point, at constant potential. Type 18 Cr-1Mo ferritic stainless steel in deaerated 1*N* NaCl solution at 24°C.

Table II. Calculated current density inside the pits, at constant potential, deaerated 1*N* NaCl solution at 24°C

Stainless steel type	Potential V (SCE)	Current density (A/cm^2)
18Cr-0 Mo	+0.200	7.43×10^{-1}
18Cr-1Mo	+0.200	3.55×10^{-1}
18Cr-2Mo	+0.300	5.11×10^{-1}
18Cr-4.75Mo	+0.525	4.37×10^{-1}

repassivation after scratching to pitting after scratching takes place. It is concluded that no pits are nucleated, for example in Fig. 1, after scratching +0.175V SCE. Otherwise, even if the current density inside the pits was one order of magnitude lower than at +0.200V SCE, current changes should have been observed after a 5-10 min exposure at constant potential.

Anodic Behavior in 1*N* HCl Solution

Anodic polarization curves were measured for all the alloys in deaerated 1*N* HCl solution at 24°C (Fig. 2). The corrosion potential was found to increase with the molybdenum content, as shown in Fig. 3. The alloy with 4.75% Mo had a corrosion potential approximately 100 mV higher than that of the 18Cr-0 Mo alloy.

As the potential was increased above the corrosion potential, the current density also increased and the surface of the samples showed generalized etching. The current density continued to increase with potential up to approximately −0.300V, above which it began to decrease. At −0.200V the current density reached a minimum value, increasing again at higher potentials. Current densities which did not vary with time were found between the corrosion potential and −0.200V. For higher potentials the current density increased with time. All the samples exposed at potentials higher than −0.200V pitted.

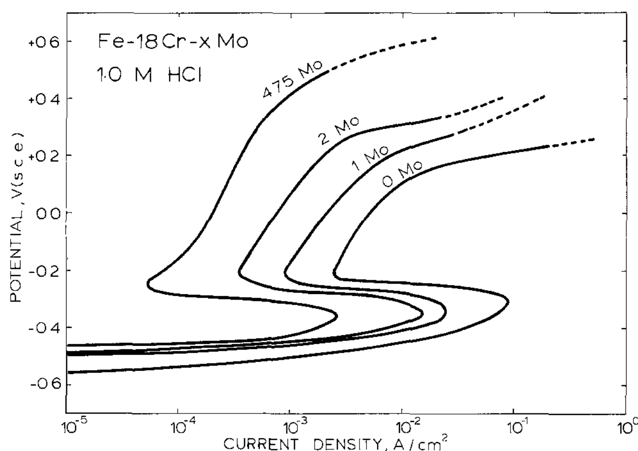

Fig. 2. Anodic polarization curves for Type 18Cr-X Mo ferritic stainless steels in deaerated 1*N* HCl solution at 24°C.

This time-dependent behavior at high potential was confirmed with the scratch technique. An 18Cr-1Mo alloy was exposed to the 1*N* HCl solution at constant potential. It was observed that at −0.400 and −0.300V the stationary current density was not affected by scratching the metal surface. The current density was also stable at −0.200V. After scratching the surface at this potential, the current increased but returned almost immediately to the initial value. At −0.100V, on the other hand, the current increased after scratching, and continued to increase with time. Pits were observed along the scratch.

These results show that curves like those in Fig. 2 are real polarization curves with true current densities only between the corrosion potential and −0.200V. For higher potentials the true polarization curve is not given by Fig. 2. To overcome this difficulty, constant potential experiments were performed with all the alloys at potentials higher than −0.200V. After exposure the pits were measured with a microscope, and the current density inside the pits was calculated using Eq. [1]. Figure 4 shows the composite polarization curves obtained by direct measurement below −0.200V, plus calculated current density values for higher potentials.

Figure 4 shows that the 18Cr-X Mo alloys underwent active dissolution between the corrosion potential and −0.200V. The current density in this zone, as reported by Lizlovs and Bond (3), was strongly affected by the molybdenum content of the alloy; the dissolution rate for the 18Cr-4.75Mo alloy was approximately two orders of magnitude lower than that for the 18Cr-0 Mo alloy. The active dissolution zone was followed by a reduction in the current density which could not be taken as a true passivation because of the high current densities involved. Above −0.200V (SCE) a process of localized corrosion entered into competition with the pseudopassivity. This transition took place at the same potential for all the alloys tested; thus it was not affected by the molybdenum content of the alloy. The current densities calculated, on the other hand, were strongly affected by the molybdenum content being almost two orders of magnitude lower for the 18Cr-4.75Mo alloy than for the 18 Cr-0 Mo alloy. The current density in this region followed a logarithmic law, with a slope ranging from 150 to 200 mV.

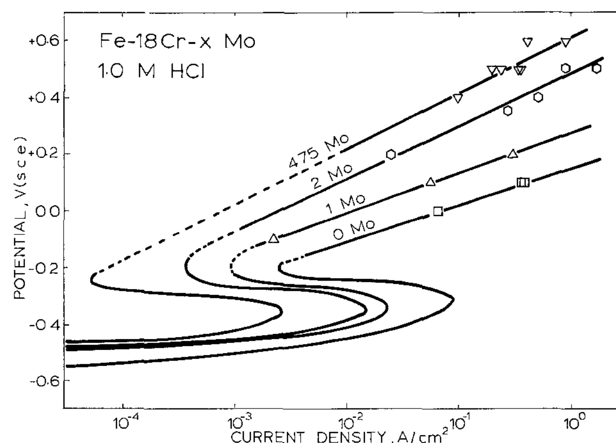

Fig. 4. Composite anodic polarization curves for Type 18Cr-X Mo ferritic stainless steels in deaerated 1*N* HCl solution at 24°C. Below −0.2V SCE direct current density measurements; above −0.2V SCE current density calculated with Eq. [1].

AES Analysis of Films Formed in HCl Solutions

AES analysis was used to identify the products responsible for the pseudo-passivity found in the anodic polarization curves. The samples were polarized in the active zone to dissolve any air-formed film, and then the potential was switched to −0.200V. Two different techniques were used to remove the samples from the cell. In one the potentiostat was switched off and the sample was removed, and washed with distilled water. It was then dried with hot air. In the second procedure, the technique used by Vetter and Strehblow (14) was applied. In this technique a layer of benzene is poured over the electrolyte in the cell. The sample is slowly removed from the electrolyte into the benzene layer without switching off the potentiostat. They were then washed with acetone and dried. The AES results were the same for both procedures.

Figures 5 and 6 show typical examples of the results found with AES analysis. The results are given as in previous publications (7, 15). It is assumed that the normalized peak heights are approximately proportional to the elemental concentration. Figure 5 gives the Auger analysis of the 18Cr-4.75Mo alloy which was polarized for 90 min at −0.400V. Figure 6 shows the Auger results for the same alloy which was polarized for 90 min at −0.400V, followed by 10 min at −0.200V.

The sputtering technique used removed about 3Å/min. No enrichment in molybdenum was found in the films on any of the alloys tested. There was a slight depletion of iron in the film plus a small enrichment in chromium. The oxygen content decreased uniformly from a high value in the near-surface layers until the metal-oxide interface was reached. One important feature found in this analysis was the high content in chloride in films formed at −0.200V and above. This is different from that which was reported for these alloys in NaCl solutions (8). The amount of chloride in the film increased with potential for potentials higher than −0.200V. There was also a tendency for alloys with higher Mo contents to have larger amounts of chloride in the film. However, the latter conclusion must still be taken as tentative. A few examples were found in which there was no change in the chloride content with Mo concentration in the alloy.

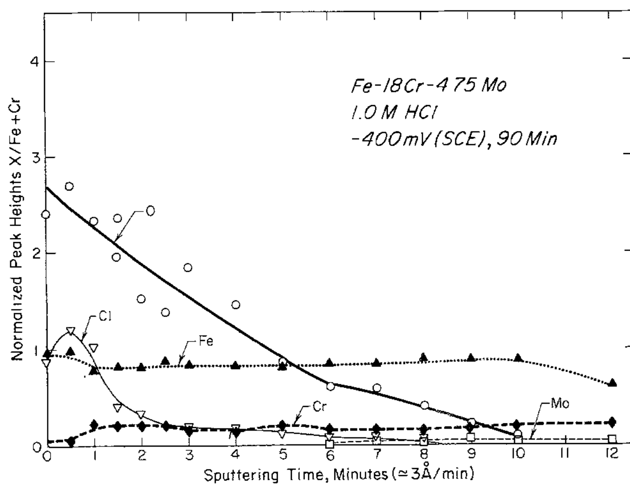

Fig. 5. Auger normalized peak heights vs. sputtering time for Type 18Cr-4.75Mo stainless steel polarized for 90 min at −0.400V SCE.

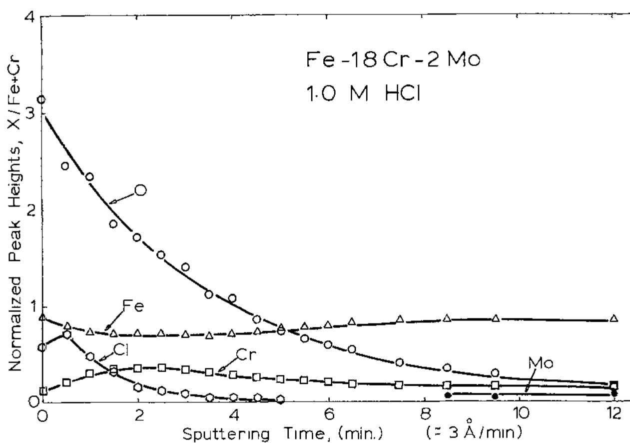

Fig. 6. Auger normalized peak heights vs. sputtering time for Type 18Cr-4.75Mo ferritic stainless steel polarized for 90 min at −0.400V SCE plus 10 min at −0.200V SCE in deaerated 1*N* HCl solution at 24°C.

Theoretical Pitting-Potential Calculation

According to the mechanism of localized acidification (9), the pitting potential of a metal or alloy in a neutral solution can be evaluated from the anodic behavior of the same metal or alloy in a low pH solution. The pitting potential in the neutral solution is given by

$$E_p = E_c{}^* + \eta + \phi + E_{inh} \qquad [2]$$

where E_p is the pitting potential, $E_c{}^*$ is the corrosion potential in the acidified solution, η is the polarization necessary to obtain a current density high enough to maintain acidity inside the pit, ϕ is the potential drop inside the pit, and E_{inh} is the contribution to the pitting potential due to inhibitors in the media.

$E_c{}^*$ was taken from Fig. 3, and η was taken from Fig. 4, assuming that the current density inside the pits at the pitting potential was 0.5 A/cm^2 (Table II). The values from Fig. 4 include the potential drop inside the pit; a high ϕ arises because of the technique used to evaluate the current density values. E_{inh} is ignored since no inhibitors were used in the measurement of the pitting potential in NaCl solutions.

Table III shows the calculated pitting potential values, as given by Eq. [2], compared with the experimental values reported by Lizlovs and Bond (3, 4). A very good correlation was found between the calculated pitting potential values and the experimental ones.

Discussion and Conclusions

Very good agreement was found between the pitting potential values predicted by Eq. [2] and those found experimentally. It is interesting to note that the pseudopassivity found in the polarization curves of the stainless steels in HCl solutions results in a high contribution of η to the pitting potential. In some systems, like high purity iron (16), high purity zinc (17), high purity cadmium (18), Al-Cu alloys (19), and Al-Zn alloys (11) in NaCl solutions, high current densities are obtained in acid solutions with small polarizations. In these cases the contribution of η to the pitting potential was small, and the pitting potential was found to be close to the corrosion potential inside the pit, $E_c{}^*$. In other systems, for example pure nickel (20), pure aluminum (19), Al-Mg (19), and 18 Cr-X Mo alloys in NaCl solutions, sizable polarizations had to be applied to obtain the necessary current density.

In the system studied in the present work, η is an important component of the pitting potential. The ex-

Table III. Pitting-potential values for 18Cr-X Mo alloys in 1*N* NaCl solution, calculated with Eq. [2], and compared with the experimental values reported by Lizlovs and Bond (4)

Stainless steel type	$E_c{}^*$	+	η	=	E_p	Experimental pitting potential V (SCE)
18Cr-0 Mo	−0.55	+	0.67	=	0.12	0.10-0.14
18Cr-1Mo	−0.49	+	0.74	=	0.25	0.16-0.22
18Cr-2Mo	−0.48	+	0.88	=	0.40	0.22-0.34
18Cr-4.75Mo	−0.45	+	1.00	=	0.55	0.52-0.56

perimental results described above could be used to attempt an explanation for this behavior. Lizlovs and Bond (3) reported that molybdenum had a big effect on the pitting potential of the ferritic stainless steels, and that the higher the chromium content of the alloys the more pronounced the effect of molybdenum. From the AES analysis it was found that there was a high chloride content in the film formed in the pseudopassive region in HCl solutions. The pseudopassivity could be due to the accumulation of a salt film of chromic chloride on the alloy surface. It is known that the dissolution rate of $CrCl_3$ is very slow (21, 22). The molybdenum could act by reducing this rate still further. The detailed mechanism by which this process occurs is not yet clear, but it is known that the presence of certain metal ions can change the dissolution rate of $CrCl_3$. For example, it was reported that in the presence of either Cr^{2+} or $SnCl_2$, the dissolution rate of $CrCl_3$ is significantly accelerated (21, 22). It is possible that molybdenum retards the dissolution rate of $CrCl_3$. According to Hedinfor *et al.* (21) the presence of oxidizing agents reduces the dissolution rate of $CrCl_3$. This agrees with recent publications (23) where it was reported that pitting corrosion of stainless steels was inhibited by the presence of MoO_4^{2-} ions in the solution.

From the above results it can be concluded that there are two ways by which the resistance of an alloy to pitting can be improved. One is by increasing E_c^*, *e.g.*, by accelerating the cathodic reaction inside the pit, and the other one is by increasing the value of η, *i.e.*, by reducing the dissolution rate of the metal in the acid solution.

Two processes of pitting were described in the present work. One was found in neutral NaCl solutions. There pitting started as the result of localized acidification, and Eq. [2] accounted for the effect of molybdenum on the pitting potential of the alloy. The other one was observed in HCl solutions. The pitting initiation potential was not affected here by the molybdenum content of the alloy. Molydenum changed the rate of pit propagation. The potential of pit initiation for 18Cr-X Mo alloys in HCl solutions could be related to either the potential of formation of $CrCl_3$ or to a potential-dependent dissolution rate of $CrCl_3$.

The Calcium Anode in Molten Nitrate Electrolytes

M. H. Miles,* D. A. Fine, and A. N. Fletcher*

Naval Weapons Center, Chemistry Division, Research Department, China Lake, California 93555

ABSTRACT

The electrochemical behavior of the calcium anode in molten nitrates was determined using constant current methods. Investigations were made in both $LiNO_3$ and KNO_3 at 350°C and in KNO_3-$LiNO_3$ (60-40 mole percent) over a temperature range of 250°-400°C. Differential scanning calorimetry studies were also made on calcium in many nitrate mixtures. No exothermic reactions were detected for calcium in any pure alkali metal nitrate melt; however, chemical reactions were apparent for many calcium-molten nitrate systems which contained added halide salts. The rate of the calcium electrode reaction is determined largely by the passivating oxide film formed on calcium in molten nitrates. The addition of halides that promote breaks in the film can greatly improve both the electrode kinetics and the open-circuit potential. With sufficient breakdown of the passivating layer, high current densities can be obtained for the calcium anode with very little polarization. The effectiveness of the added halides in reducing polarization generally decreased in the order $I^- > Br^- > Cl^- > F^-$. The experimental results can be explained by a passivating layer model involving specific adsorption of anions at the CaO/solution interface.

Molten nitrates are attractive for possible use in thermal batteries due to their favorable physical properties which include low melting points and high electrical conductivities. In addition, alkali metal nitrate melts are stable over a reasonable temperature range, have low volatility, and have a viscosity and surface tension similar to aqueous solutions (1, 2). Thermal batteries fulfill unique military applications which require rapid activation and high discharge rates for short time periods (3). Generally, thermal batteries operate at temperatures between 500° and 600°C using the LiCl-KCl [59-41 mole percent (m/o)] eutectic which melts at 352°C. Much lower melting points are possible with nitrate electrolytes; for example, KNO_3-$LiNO_3$ (57-43 m/o) melts at 132°C and KNO_3-$LiNO_3$-$NaNO_3$ (53-30-17 m/o) melts at 120°C (1, 2). Furthermore, problems associated with formation of a calcium-lithium alloy, $CaLi_2$, at the calcium anode in LiCl-KCl melts (3, 4) could be eliminated or perhaps controlled with the use of molten nitrates.

Since molten nitrates are strong oxidizing agents (5), a passivating film on the calcium surface is required to restrict the corrosive reaction of the molten nitrate with the calcium anode. This protective layer must also permit the passage of calcium ions into the solution during battery operation. Ideally, this film would act as a solid electrolyte interphase between the metal and solution and would be a good electronic insulator (6, 7). The formation of such passivating layers has been reported for the magnesium electrode in thionyl chloride solutions (6) as well as for the lithium anode in aqueous electrolyte (8, 9).

Alhough calcium anodes are often used in thermal batteries, there is very little literature data on the dissolution process for calcium in molten salts or in any other type of solution (10-14). The electrochemical behavior of calcium metal is reported in this paper, and experimental conditions are defined which yield promising results for the use of this anode in molten nitrates. The addition of certain salts is required to attack the passivating film sufficiently to permit high current densities with very little polarization.

Experimental

The electrochemical cell and electrodes are shown in Fig. 1. The calcium electrode was cut from sheet (ROC/RIC), 99%, 0.5 mm thick and generally had a geometrical area close to 1 cm². The major impurity in the metal is magnesium. The calcium sample was cleaned by treatment with dilute nitric acid in dimethyl formamide (DMF) until a bright, metallic surface was obtained and then rinsed in DMF. Connection to the working electrode was made by spot-welding the calcium metal to the aluminum lead wire. The back side and edges of the calcium electrode and the portion of the aluminum wire exposed to the solution were masked off by using a thin layer of Sauereisen cement (No. 1) which was quickly dried with use of a heat gun. The calcium surface was then recleaned with the nitric acid in DMF just prior to use. When the calcium electrode is placed in molten nitrates, a dark oxide forms on the electrode surface. By use of the external nickel lead wire, the calcium electrode was positioned within 1-2 mm of the tip of the Luggin capillary. A magnesium electrode cut from sheet (ROC/RIC), 99.8%, was prepared in a similar manner and used in several experiments.

All potentials were measured against a $Ag/AgNO_3$ (0.1m) reference electrode in KNO_3-$NaNO_3$ (50-50 m/o). A Tesla coil spark was used to form a minute hole through the glass tip of the reference electrode. This hole provided contact while allowing only minimal electrolyte leakage. The electrolytic resistance through this opening was generally greater than 10,000Ω. Small asbestos fibers sealed in glass were also used with good results when the fibers were kept small to minimize electrolyte leakage. The Ni/Ag junction of the reference electrode and the Ni/Al junction of the working electrode were positioned at about the same level in the cell to cancel thermocouple effects due to temperature gradients. A series of reference electrodes was kept for internal checks which generally gave potential readings within 10 mV. A platinum wire coil sealed to the cell wall served as the counterelectrode.

Temperature control was maintained by placing the electrochemical cell in a fluidized sand bath (Tecam) and measuring the temperature of the bath adjacent to the cell with both a digital thermocouple thermometer and a dial thermometer. The temperature readings generally agreed within 5°C. The electrochemical measurements were made using a Beckman Electroscan 30 instrument.

Molten salt solutions were prepared from reagent grade chemicals which were dried overnight in a vacuum oven at 150°C. Exactly 28g of nitrate salt were used in each experiment. When not in use, these salts

were stored in a desiccator containing anhydrous calcium sulfate (indicating Drierite).

The chemical reactivity of calcium with the various molten salt mixtures was determined using a differential scanning calorimeter (Perkin-Elmer DSC-1b). A temperature scan rate of 10°C/min was selected, and the resulting endotherms and exotherms were recorded using a strip chart recorder (Honeywell Electronik 194). For safety reasons, small samples were tested by this method before studies on larger samples in electrochemical cells were made. However, violent reactions of calcium with pure alkali metal nitrates were never observed, in contradiction to results reported by Brough and Kerridge (15).

Results

The electrochemical behavior of the calcium anode in molten nitrates was determined galvanostatically. Potential measurements were recorded at current settings of 100, 30, 10, 3, 1, and 0.3 mA/cm². Open-circuit potentials were also determined. The potential was generally recorded over a time period of 30-100 sec and was usually quite steady; however, the variation

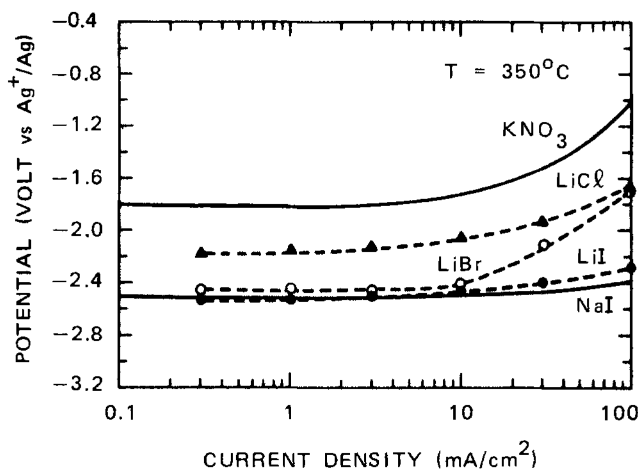

Fig. 2. Current density-potential measurements for the calcium anode in molten KNO_3 at 350°C. Effects of addition of 5 m/o LiCl, LiBr, LiI, or NaI to molten KNO_3.

was often greater at the higher current densities. Results for the calcium anode in molten KNO_3 at 350°C are shown in Fig. 2. The potential-current density line for calcium dissolution in pure KNO_3 represents the average results of nine different experiments. The standard deviation for the measured potentials ranged from ±0.14V at 100 mA/cm² to ±0.040V at 1 mA/cm². The other potential-current density lines in Fig. 2 show how additions of 5 m/o LiCl, LiBr, LiI, or NaI to the molten KNO_3 improve the performance of the calcium anode. For example, the addition of 5 m/o NaI changes the potential at 100 mA/cm² by more than 1.3V. The results shown for the addition of NaI represent the average of four different experiments. The good reproducibility of these experiments is reflected by the small standard deviations of ±0.022V at 100 mA/cm² and ±0.025V at 1 mA/cm². The results shown in Fig. 2 for solutions containing 5 m/o LiCl, LiBr, or LiI were obtained from single experiments which were repeated at least once to check for reproducibility. Table I summarizes the effect of other added salts on the calcium anode.

Constant current investigations of the calcium anode in molten $LiNO_3$ systems at 350°C are shown in Fig. 3. The addition of either LiCl or LiBr reduces the polarization. The amount of added salt also has a marked effect; *i.e.*, 10 m/o LiCl is much more effective in reducing polarization than the 5 m/o LiCl. In $LiNO_3$ containing 10 m/o LiCl, the open-circuit potential for the calcium anode was −2.83V at 350°C, and the polarization was small at the lower current densities. The current-potential line for calcium in pure $LiNO_3$ represents the average of four different experiments with standard deviations of ±0.056V at 100 mA/cm² and ±0.017V at 1 mA/cm², while the results for solutions containing 10 m/o LiCl represent the average of five experiments in which the standard deviation was ±0.155V at 100 mA/cm² and ±0.044V at 1 mA/cm².

Figure 4 shows the temperature effect on the potential-current density measurements for the calcium anode in KNO_3-$LiNO_3$ (60-40 m/o) containing 10 m/o LiCl. At the higher current densities, the polarization

is greatly reduced as the temperature is increased from 250° to 400°C. The temperature effect is small at low current densities except for a notable improvement in the performance of the calcium electrode between 350° and 400°C.

Constant current experiments at 100 mA/cm² were used to determine the long-term behavior of the calcium anode as well as the current efficiency for the dissolution process. Potential *vs.* time plots are shown in Fig. 5 for the calcium anode in molten KNO_3 containing 5 m/o of various salts. Results in pure KNO_3 are also included for comparison. When dissolution of the calcium anode is complete, a sudden shift in the potential to large, positive values is observed. The most electronegative potentials are obtained when 5 m/o of NaI or KI is added; however, the short dissolution time periods indicate extensive reaction of calcium with the electrolyte when iodides are present. Since the calcium electrode weight was in the neighborhood of 70 mg/cm², the electrochemical dissolution of the electrode at 100 mA/cm² would require about 3400 sec if two electrons per calcium atom were obtained. The actual electron yields per calcium atom in various experiments are presented in Table II. Both the type of added salt and the experimental temperature affect the number of electrons obtainable per calcium atom. It is interesting to note that calcium in KNO_3 + 5 m/o KCl gave exactly one electron per calcium atom while smaller yields were obtained in all other experiments. In an experiment using a magnesium electrode in molten KNO_3 at 350°C, however, anodic dissolution at 100 mA/cm² gave a yield of 1.8 electrons per magnesium atom. The experimental potentials obtained using magnesium were generally about 0.8V less negative than those obtained with calcium.

Figure 6 shows differential scanning calorimetry (DSC) results for calcium in KNO_3 systems when a temperature scan rate of 10°/min is used. The actual baseline has been adjusted in this figure to make it horizontal. For calcium in pure KNO_3 (solid line), a lattice transition occurs at 120°C (129°C, lit.), and the KNO_3 melts at about 338°C (334°C, lit.). No exothermic reaction of calcium with molten KNO_3 is observed. In the presence of 5 m/o NaI (dashed line) or 5 m/o LiCl (dotted line), exothermic reactions are easily detected beginning at about 350°C.

Table III presents a partial summary of many other DSC studies of calcium in molten nitrate systems. No

Table II. Electron yield per calcium atom in molten nitrate systems

Electrolyte*	Temperature (°C)	e^-/Ca atom
$LiNO_3$ + 10 m/o LiCl	350	0.15
KNO_3 + 5 m/o NaI	350	0.22
KNO_3 + 5 m/o KI	350	0.22

* Highest temperature is that of the melting endotherm; others are lattice transitions.

† The temperature given is that of the highest peak of the exotherm. Most exotherms were broad and many had several peaks. s = strong, m = moderate, and w = weak.

exothermic reactions were observed for calcium in any pure alkali metal nitrate melt. Exothermic reactions, however, were apparent for many calcium-nitrate systems which contained halide salts. Generally, with halide present but calcium absent, no exothermic reactions were detected in the molten nitrates; therefore the reactions involve the calcium metal. The magnitude of the exotherm usually increased with increasing concentration of the halide salt. In fact, at salt concentrations much above 10 m/o LiCl in $LiNO_3$, explosive reactions with calcium were observed near 400°C. Calcium with silver nitrate gave a violent reaction with a flash of light as soon as the silver nitrate melted. Evidence for metallic silver shows that this was simply the reaction of calcium metal with silver ions; $Ca + 2Ag^+ \rightarrow Ca^{++} + 2Ag$. This reaction becomes slower and controllable in KNO_3-$AgNO_3$ mixtures containing lower concentrations of silver ions.

Discussion

Examination of Fig. 2 and 3 and Table I suggests that both kinetic and thermodynamic properties are influenced by the passivating film on the calcium electrode. For example, Fig. 2 shows that the overvoltage at high current densities is greatly reduced when NaI or LiI is added to molten KNO_3 and a more negative open-circuit potential (OCP) is also established. In the absence of resistive films, most metal-metal ion electrode reactions in molten salts show high exchange current densities and very little true polarization (10).

The experiments show somewhat erratic trends on addition of halide salts to the molten nitrates. Judging from the potentials measured at 100 mA/cm² (Fig. 5 and Table I), the effectiveness of the added salt decreases in the order KI > KCl ~ KBr > KF while the current efficiencies (Table II) decrease in the order of KCl > KBr > KF > KI. The DSC studies (Table III) indicate that the ability of the halide salt to promote exothermic reactions with calcium decreases in the order KF ~ KI >> KBr ~ KCl in molten KNO_3 while the order is KI ~ KBr >> KCl ~ KF in molten $LiNO_3$. Figure 2 shows that the effectiveness of lithium salts added to molten KNO_3 decreases in the order LiI > LiBr > LiCl.

The experimental results for the calcium anode in molten nitrates can be interpreted in terms of the passivating layer model proposed in Fig. 7. A similar model has been used by Peled and Straze (6) to explain the behavior of the magnesium electrode in thionyl chloride solutions. Two interfaces are present in this model; the calcium/passivating layer interface involving the formation of calcium ions and the passivating layer/solution interface involving the passage of calcium ions into the solution. For calcium in molten nitrates, the passivating layer likely consists of CaO since electrodes which had become completely passivated in molten nitrates yielded the characteristic precipitate of $Ca(OH)_2$ when placed in water. Studies of the reaction of calcium in the $LiNO_3$-KNO_3 eutectic indicate that the net reaction is

$$14Ca + 6NO_3^- \rightarrow 14CaO\downarrow + 2N_2\uparrow + N_2O\uparrow + 3\,O^= \quad [1]$$

according to analyses of the precipitate and gaseous products (15). In many experiments in this study, the slow evolution of colorless gas could be detected at the calcium electrode. This reaction also accounts for the relatively large exotherms shown in Fig. 6 since about 2900 cal are evolved per gram of calcium reacted compared with only 28 cal per gram for the heat of fusion of KNO_3.

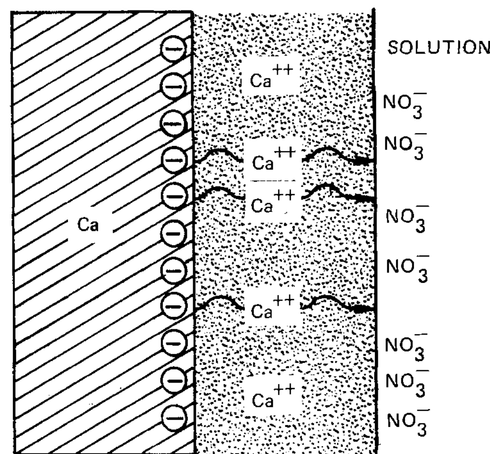

Fig. 7. Passivating layer model for the calcium anode in pure molten nitrates. The passivating layer is positively charged due to the excess concentration of calcium ions within the film. An excess of anions are electrostatically attracted to the passivating layer/electrolyte interface. Only anions at the interface are shown. A nonuniform distribution of anions is expected due to the preferential transfer of calcium ions through cracks or other imperfections in the passivating layer.

Corrosion of a metal requires both an anodic area where metal ions are transferred and a cathodic area where the surplus electrons can be transferred (16, 17). In battery systems, the corrosion rate of active metal anodes depends on the solubility of the protective film and on the transference number of the film for electrons (7). The slow corrosion rate for calcium in pure molten nitrates indicates a small transference number for electrons in the passivating layer as would be expected for an ionic compound such as calcium oxide. Assuming molten nitrates form ideal solutions (18), an unusually low solubility of 0.04 m/o is calculated for CaO at 350°C. The low solubility observed in molten nitrates for the CaO formed on the electrode surface indicates approximate agreement with this calculated value.

Oxidizing agents such as nitrates can act as anodic corrosion inhibitors by repairing faults in protective oxide films (16). As sketched in Fig. 7, the negative nitrate ions would normally be favorably positioned adjacent to the positively charged film. The adsorption of anions on electrodes, however, decreases in the order $I^- > Br^- > Cl^- \sim NO_3^- > F^-$ (19-21). The added I^- would displace NO_3^- from the electrode surface, thereby preventing the repairing of the film when

a break occurs. Pitting corrosion, which was usually observed with the effective salts, is believed to be caused by the inability of anodic inhibitors to rectify every fault in the protective oxide film (16). Other studies on active metals have also shown that halides have a tendency to promote pitting (22).

The effectiveness of iodide ions in reducing the polarization of the calcium anode may also be enhanced by their tendency to become oxidized in molten nitrates (1)

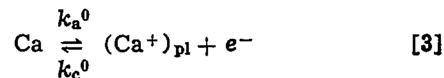
$$2I^- + NO_3^- \rightarrow NO_2^- + O^= + I_2 \qquad [2]$$

In fact, iodide salts could not be used in molten $LiNO_3$ at 350°C due to the rapid production of violet iodine fumes. In molten KNO_3, however, the reaction was much slower. Some yellow coloration developed at 350°C as the iodide salt dissolved to give regions of high local concentrations of iodide ions, but this gradually dissipated. Specific adsorption of iodide ions at the electrode surface giving high local concentrations could lead to reaction with nitrate ions to form I_2 or I_3^-. Faults developing in the passivating film enabling the iodine to react directly with calcium metal could account for the low current efficiencies (0.22 e^-/Ca atom) obtained in the presence of NaI and KI.

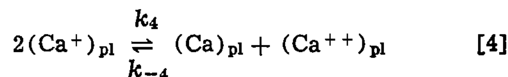
Since fluoride ions have a smaller tendency for anion adsorption than nitrate ions, their addition to the molten nitrate would have little effect on the passivating layer/solution interface. Breaks in the oxide film would be readily repaired by the chemical reaction of calcium with adsorbed nitrate ions leading to high overvoltages. In Fig. 5 the anodic dissolution of calcium in KNO_3 + 5 m/o KF is similar to that obtained in pure KNO_3. Both experiments gave large polarizations and low current efficiencies of 0.52 e^-/Ca atom (Table II). No pitting of the electrode surface took place in either experiment and a thick, brittle film gradually formed which had a final weight greater than the initial weight of the calcium. The increase in both the film thickness and the anodic polarization with the discharge time suggests that anions are injected into the passivating layer during discharge (7). In the presence of other salts such as KI or KCl, the calcium electrode was completely consumed so that only the Sauereisen backing remained. Experiments using KNO_3 + 5 m/o KF gave the electronegative open-circuit potentials expected for calcium, but these were unstable and unusually large polarizations occurred on drawing anodic currents. This may result from the penetration of the small fluoride ions into the film lattice and precipitation of CaF_2 clogging the pores of the film during anodic dissolution of the calcium.

The addition of chloride and bromide ions to molten nitrates generally gave results intermediate to those found for iodide and fluoride ions. Both apparently displace adsorbed nitrate ions sufficiently to permit breaks to exist in the passivating film. It is interesting to note that infrared studies in molten KNO_3-$Ca(NO_3)_2$ mixtures show that Cl^- ions can also displace NO_3^- ions from the $Ca^{2+}\cdot\cdot ONO_2^-$ complexes (23). The highest current efficiency observed (1.0 e^-/Ca atom) involved the use of 5 m/o KCl in KNO_3. A possible explanation is that chloride ions displace nitrate ions at the surface of the calcium oxide film which prevents the chemical reaction of calcium metal with nitrate ions when breaks in the film occur. Furthermore, the chloride ions are not oxidized by nitrate ions, hence, unlike iodide ions, they do not contribute to any other chemical reaction of calcium. In $LiNO_3$-KNO_3 melts, it is reported that iodide was oxidized by nitrate ions at 147°C, bromide ions reacted at 300°C, while chloride ions did not react until 470°C (1). The reactivity of the halides would be even less in pure KNO_3 since the lithium ion is a stronger Lux-Flood acid than the larger potassium ion (1, 24). The low current efficiency found for $LiNO_3$ + 10 m/o LiCl (0.15 e^-/Ca atom) may reflect the possible formation of the liquid $CaLi_2$ alloy (mp = 230°C) where breaks in the passivating film occur causing rapid corrosion.

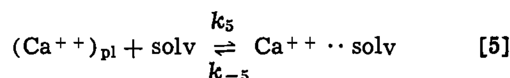
The fact that exactly 1.0 e^-/Ca atom was obtained for the calcium anode in KNO_3 + 5 m/o KCl suggests that Ca^+ may be involved in the electrode reaction. Other experimenters have also proposed this possibility (12, 13, 25). The calcium electrode reaction in molten nitrates may then involve the steps



$$Ca \underset{k_c^0}{\overset{k_a^0}{\rightleftharpoons}} (Ca^+)_{pl} + e^- \qquad [3]$$



$$2(Ca^+)_{pl} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} (Ca)_{pl} + (Ca^{++})_{pl} \qquad [4]$$



$$(Ca^{++})_{pl} + \text{solv} \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} Ca^{++}\cdot\cdot\text{solv} \qquad [5]$$

where the parentheses denote a substance within the passivating layer. If the calcium atoms produced by the disproportionation reaction become isolated from the electrode and react with the solvent or solute, then the maximum current efficiency expected would be 1.0 e^-/Ca atom.

According to the above reaction mechanism, the current density would be given by

$$i = \mathbf{F}\cdot k_a^0 \cdot \exp\left(\frac{\alpha \mathbf{F} E}{RT}\right) - \mathbf{F}\cdot k_c^0 \cdot (a_{Ca^+})_{pl} \cdot \exp\left[\frac{-(1-\alpha)\mathbf{F}E}{RT}\right] \qquad [6]$$

where k_a^0 and k_c^0 are the formal anodic and cathodic rate constants at zero potential (26). The open-circuit potential (OCP) where $i = 0$ would then be

$$E_{OCP} = \frac{RT}{\mathbf{F}}\ln\frac{k_c^0}{k_a^0} + \frac{RT}{\mathbf{F}}\ln (a_{Ca^+})_{pl} \qquad [7]$$

When reaction [5] reaches equilibrium, then

$$(a_{Ca^+})_{pl} = \left(\frac{a_{Ca^{++}..solv}}{K_4K_5}\right)^{1/2} \qquad [8]$$

hence the equilibrium potential is

$$E_{eq} = \frac{RT}{\mathbf{F}}\ln\frac{k_c^0}{k_a^0} - \frac{RT}{2\mathbf{F}}\ln K_4K_5 + \frac{RT}{2\mathbf{F}}\ln a_{Ca^{++}..solv} \qquad [9]$$

where K_4 and K_5 are the equilibrium constants of the corresponding reactions. Equation [9] is simply the Nernst equation for the calcium electrode reaction with the first two terms representing the standard potential. The difference between the open-circuit potential and the true equilibrium potential is given by

$$\Delta E = E_{OCP} - E_{eq} = \frac{RT}{\mathbf{F}}\ln (a_{Ca^+})_{pl} + \frac{RT}{2\mathbf{F}}\ln K_4K_5 - \frac{RT}{2\mathbf{F}}\ln a_{Ca^{++}..solv} \qquad [10]$$

Although the passivating film does not affect the equilibrium potential, it can make the kinetics of reaction [5] so slow that true equilibrium cannot be readily attained during open-circuit potential measurements. The activities of Ca^+ and Ca^{++} in the passivating layer, therefore, build up to unusually high levels producing a positive shift in the open-circuit potential. Judging from the large shifts observed (Fig. 2 and 3), the activity of Ca^+ in the passivating layer may become 5-8 orders of magnitude larger than its equilibrium value. Addition of halides which produce breaks in the passivating film allows the excess calcium ions

to pass into the solution, thereby restoring the true equilibrium potential.

Chronopotentiometric studies of the lithium anode in aqueous electrolytes indicate that a concentration gradient of Li^+ ions exists across the oxide layer even at open circuit (9). Investigations of the calcium electrode in aqueous electrolytes show that the addition of chloride ions affects both the passivation and the observed open-circuit potential (14). The kinetic study of the magnesium electrode in thionyl chloride solutions shows that the migration of Mg^{++} through a passivating layer is the rate-determining step (6).

Conclusions

The protective oxide film formed by calcium in molten nitrates greatly influences the kinetics of the anodic reaction. The slow step appears to be the migration of calcium ions across the passivating film and into the solution. The addition of I^- and other halides capable of displacing NO_3^- ions from the passivating layer/solution interface promotes breaks in the film to give faster kinetics and more electronegative open-circuit potentials. High current densities can then be obtained with very little polarization. Therefore, the calcium anode in molten nitrates looks promising for applications in high discharge rate thermal batteries operating at temperatures between 300° and 400°C. A maximum current efficiency of 1.0 e^-/Ca atom observed experimentally suggests the involvement of monovalent Ca^+ in the electrode reaction. Results in molten $LiNO_3$ were often quite different from those in KNO_3 due to the stronger oxidizing power of the $LiNO_3$, and also, perhaps, to the formation of the liquid $CaLi_2$ alloy in molten $LiNO_3$.

Analysis of SnNi Electroplate by Secondary Ion Mass Spectrometry, Ion Scattering Spectrometry, and Rutherford Backscattering

Rudolf Schubert

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

Two batches of SnNi electroplate, expected to be composed of equal atomic amounts of Sn and Ni, have been examined by secondary ion mass spectrometry, ion scattering spectrometry, and Rutherford backscattering. Tin oxides and hydroxides were found in the surface region, which is Sn-rich; no Ni oxides or hydroxides were seen. The Sn/Ni ratio for the two batches was 45/55 and 52/48 a/o. After Ar^+-sputter cleaning, films of the type which occur during and immediately after electroplating could not be reproduced in 10^{-6} Torr O_2. The regenerated films contained substantial amounts of nickel oxides and hydroxides.

Electroplated metastable SnNi is of technological interest for a broad range of metallic coating applications. It is suitable as a decorative coating and as a protective corrosion barrier (1). Usage as one of the electroplated components of electrical components has also been proposed (2). Its main attractive feature is that surface films on electroplated SnNi form rapidly in air or most aqueous solutions and exhibit a high degree of passivity to further corrosion (3-5). In order to understand the nature of these films, a detailed analysis is important.

With reasonable care during electroplating, the deposit is expected to have equiatomic composition (3), although a broad range of compositions can be plated (6). Current knowledge of the surface film composition has been obtained through Auger electron spectroscopy (AES), electron spectroscopy for chemical analysis (ESCA), and passivation potential curves. AES studies show the surface to be a tin-rich oxide (7) or a nickel polystannate (8). These two results are not in conflict since AES does not detect hydrogen nor chemical bonding in general. The ESCA study has reached a similar conclusion (9). Passivation-potential techniques indicate that the surface is nickel stannate (3, 4), however, with films that are only tens of angstroms thick (7, 9), electrochemical techniques are not sufficient to give an unambiguous analysis.

This paper describes the surface analysis of SnNi electroplate by three techniques; Rutherford backscattering (RBS), ion-scattering spectrometry (ISS), and secondary ion mass spectrometry (SIMS).

Experimental

The SIMS experiments were carried out in a stainless steel ion pumped UHV system. These included molecular composition depth profiles and film regeneration with O_2 exposure. A 2 keV focused Ar^+ ion source with variable current density has been described previously (10). Detection of secondary ions is made through an energy filter and quadrupole mass spectrometer equipped with an electron multiplier; this has also been previously described (11).

Ion-scattering spectroscopy experiments were done on a commercially available 3M ISS machine. 2 keV $^4He^+$ ions were used as the primary beam with the scattered ions being detected at 138° to the incident ions. Rutherford backscattering with 2 MeV $^4He^+$ ions was also carried out on the same samples used for the ISS measurements. Both of the techniques complement the SIMS measurements. RBS yields quantitative (12) elemental data (± 5% of component values) from a depth of approximately 1000Å, thus providing a quantitative bulk analysis to check the steady-state ISS values after sputtering through the surface film. One can now use these bulk values to find quantitative elemental data with depth profiling as the low energy ions sputter into the sample.

Electroplated SnNi samples were prepared at two separate times. Both sets of samples were plated in a conventional fluoride bath (13) with the current density (20 mA/cm^2), bath temperature (75°C), time and bath pH monitored and controlled. One set of samples was plated on stainless steel strips (SnNi/SS) which yielded chips (~15 mm^2) of SnNi when a bending (14) stress was applied to the plated stainless steel. All measurements were made on the surface opposite that in contact with the stainless steel. The second set of samples was barrel plated on Cu coupons (SnNi/Cu). Plating thickness was several microns. In addition, pure Ni and pure Sn samples were used to calibrate the spectrometers for relative sensitivity and oxidation studies.

Results

Typical relative intensities of the positive and negative Ni and positive Sn containing secondary ions from natural air-formed surface oxide films are listed in Table I for pure material. Also listed are the relative

Key words: corrosion, surface films, depth profies, oxidation.

Table I. Relative* intensities of Ni- and Sn-containing secondary ions from pure Ni and Sn

	$^{58}Ni^+$	$^{58}Ni_2^+$	$^{58}NiOH^+$	$^{58}NiO^-$	$^{58}NiO_2^-$	$^{120}Sn^+$	$^{120}SnH^+$	$^{120}SnO^+$	$^{120}SnOH^+$

intensities of positive ions formed after the surfaces were sputtered clean. For sputter-cleaned data, the precision of the data is ± 50%. Exposure for up to 3.3 × 10^{-3} Torr sec of O_2 in the vacuum system was made. The SIMS ion beam was on during the O_2 exposure, however, its effect is negligible since the arrival rate of O_2 to Ar ions is ~10^3. During oxygen exposure, H_2O and H_2 were less than 1% of the total pressure of 2 × 10^{-6} Torr. Similar results are presented for SnNi/SS electroplate in Table II.

Depth profiles of both batches of SnNi electroplate were made with positive ion-detection SIMS. Six segments of the mass range from 1 to 140 were scanned repeatedly using a 6 amu width. These segments were at amu's 1-7, 12-18, 57-63, 73-79, 118-124, and 134-140. By scanning segments of the mass range one could check for the proper isotopic abundance and chemical combinations with hydrogen. Segment scanning also allows one to skip the mass ranges where there are no masses of interest. Depth profiles of H, CH, Ni, Sn, ^{120}SnH, $^{119}SnOH$ and ^{120}SnO, and $^{120}SnOH$ are shown for SnNi/SS and SnNi/Cu in Fig. 1 and 2, respectively. NiH^+, NiO^+, or $NiOH^+$ were not seen in positive SIMS in the samples with naturally formed films, nor was NiO^- or NiO_2^- seen by using negative SIMS. The above data are typical of three samples from each electroplating batch.

Impurity differences between the two electroplated sample batches exist. SnNi/Cu samples had approximately 10 times more Ca and CaOH present than the SnNi/SS. The total Ca impurity was still only a fraction of a percent. Higher Ca concentrations are attributed to a leak between the electrodeposition bath and the cooling system bath.

Two samples of each batch were also analyzed by RBS using 2 MeV $^4He^+$. Results showed different amounts of Sn and Ni in the two batches. The SnNi/Cu had a Sn/Ni = 45/55 atomic percent (a/o) and the SnNi/SS had a Sn/Ni = 52/48 a/o. This is a greater difference than the ±2% precision of the samples analyzed and the accepted component accuracy of ±5% for the RBS technique (12).

The same two samples were then sputter profiled by ISS with a sputtering rate of ~0.5 Å/min. As expected, only Sn and Ni peaks were distinctly seen. A typical profile (±2% precision) from each electroplate

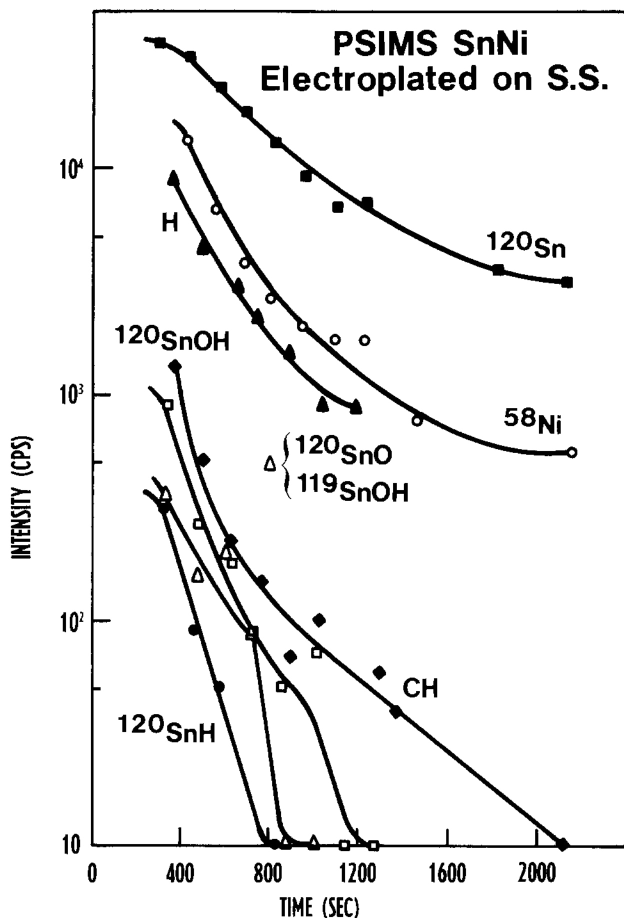

Fig. 1. Positive SIMS depth profile of electroplated SnNi on stainless steel. No NiH^+ or $NiOH^+$ were seen in the positive spectrum, nor were NiO^- or NiO_2^- seen in the negative spectrum. Primary 2 keV Ar^+ beam density was 0.065 μA/cm² which equals 4 × 10^{12} Ar^+/sec-cm². The surface monolayer of material was lost during sample alignment and beam stabilization. Data has been adjusted for isotopic abundances.

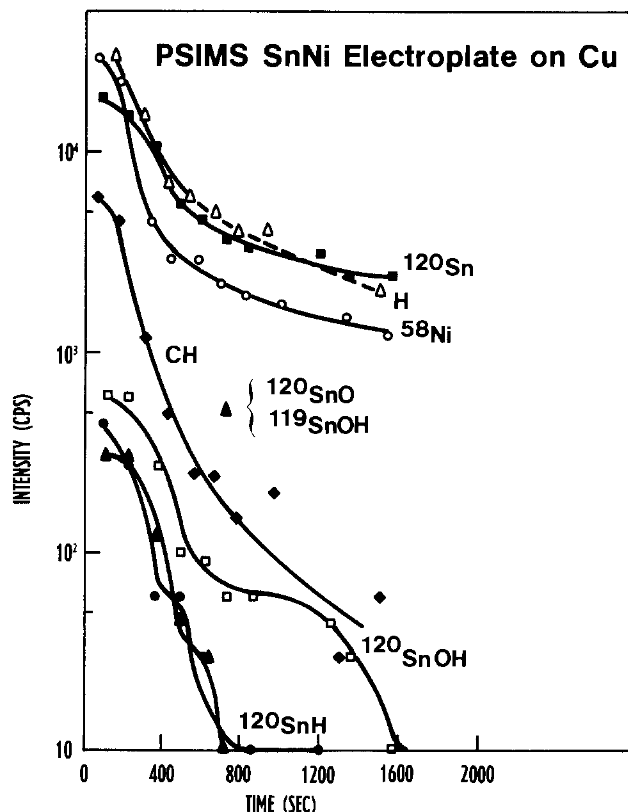

Fig. 2. Positive SIMS depth profile of electroplated SnNi on OFHC Cu coupons. Comments of Fig. 1 are applicable here also.

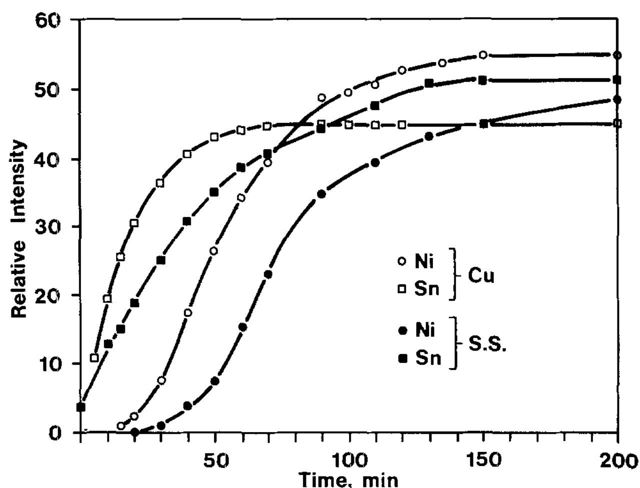

Fig. 3. Depth profiles determined by ISS on electroplated SnNi. Signals were normalized from RBS data on Cu-backed samples such that the total signal was 100%. Assuming a sputtering rate of unity, the sputtering rate is calculated as ~0.5 Å/min.

batch is shown in Fig. 3. The data were normalized such that the Sn/Ni ratio of the samples on Cu at steady state was the same as for RBS and the total was 100%. The same normalization factor was then applied to the SnNi/SS sample and the Sn/Ni ratio was found to be 52/48 after steady state was achieved, indicating consistency between ISS and RBS techniques.

The lack of ISS signal for the initial times in Fig. 3 is very normal for air-exposed samples which have not been cleaned in UHV. ISS ($^4He^+$) does not detect H at all. The sensitivity to C is also extremely poor. In general, hydrocarbons and other air contaminants neutralize the reflected beam and shadow the underlying metal atom (15).

Discussion

Pure Sn and Ni.—All the data in Tables I and II are normalized to a $^{120}Sn^+$ signal of 1000 for a natural air-formed film. The effects of oxygen on the ion yields of pure Ni samples are in agreement with other work (16), but no data could be found for Sn. It is important to note the different surface chemistry occurring in samples that have been sputter cleaned and then exposed to O_2 as compared to air-formed films. In Table I one sees that the $^{58}Ni^+$ signal from an air-formed film on Ni is approximately 16 times lower than the signal from an O_2 exposure after sputter cleaning. It is well known that oxygen strongly enhances the secondary ion yields of most elements (17). This is an electronic surface structure or chemical-bonding effect due to the interaction with the electronegative oxygen. Table I also shows that the $^{120}Sn^+$ signal behaves substantially different than the Ni. The Sn^+ yield is greatest after a natural air film has formed. Obviously the interaction of the other gases contained in air also plays a role in the film formation since the SIMS signals are so different between air and oxygen formed films. Although the exposure is much smaller in this experiment as compared to the air exposure of the native film, it is not probable that the oxides formed would decrease with longer exposures and reach the low Ni^+ yield of air-formed films. The data in no way suggest that there is more or less metal present at the surface, but rather that the surface matrix is a different chemical entity for the two formation conditions.

SnNi electroplate.—This matrix effect is also very evident in the SnNi electroplate. In the initial film the Ni SIMS signal was higher than the signal from the pure Ni, whereas by ISS, as discussed below, and Auger (7, 14) the Ni concentration was actually less than 50% in the near surface region. Conversely, substantially greater O_2 exposures are needed to enhance the Ni^+ signal from the electroplate as compared to the pure material when normalized to the 120 Sn signal. The Sn^+ is also less enhanced by O_2 exposure when it is in the SnNi matrix. However, the Ni and Sn hydroxide signals were much larger in the regenerated film than in the initial film, even though less than 1% of the gas was H_2O and H_2. As expected, Table I and II do not have a one-to-one correspondence, but the trends of both Sn and Ni are similar with regards to ion yields even though their matrixes are substantially different.

From the above discussion it is evident that caution must be used when interpreting results of cleaned surfaces as compared to electroplated and air-formed surfaces, as has been reported by others (18).

Sharma and Thomas (18) have reported that sputtering of the surface and later exposure to air and O_2 does not reproduce the native surface films. Recently, Antler (19) has reported that partial etching in a HCl bath *vs.* complete etching appears to have different regrowth kinetics of films as determined by contact-resistance measurements. This paper shows that Ni compounds form much more readily on the sputter-cleaned surface than on the native electroplate.

Typical SIMS depth profiles shown in Fig. 1 and 2 from the two batches of electroplated material indicate that the batches are not the same. Looking at the figures one sees that the bulk ratios of Sn to Ni are different. However, the ratio differences are much greater than the precision of ±2% per component from RBS, ISS, and AES measurements (7,8,14). (Sn/Ni)Cu is 2/1 and (Sn/Ni)SS is ~6/1. Since SIMS data derived from an Ar^+ beam are not quantitative with present theories (20-22), the SIMS depth profiles indicate only relative depth, chemical compounds, and approximate concentrations.

Figures 1 and 2 also show a hydrocarbon signal. Only mass 13 is plotted, although many others are present. They appear to be surface contaminants as is found on all samples which have been in room air. The H^+ signal is much higher at deeper levels from the surface in the Cu-backed film as is the $SnOH^+$ signal. It cannot be said what percentages of the H^+ signal were due to free hydrogen in the film, decomposition of hydrocarbons, or to decomposition of tin hydroxide. At no time could NiO^+ or $NiOH^+$ ions nor any negative Ni oxide ions be detected in the native film. It is calculated from Table I, Row I [also Ref. (15)] that the routine lower detection limit of nickel oxides with SIMS is of the order of 0.5% of the surface concentration of Ni. This work is in agreement with ESCA results (9) which required signal time averaging of $>6.5 \times 10^4$ sec to indicate nickel hydroxides.

The conclusion drawn from the above discussion is that the two batches of electroplate have different compositions and surface films after electroplating.

It is very questionable if the differences are attributable to the two different substrate materials (Cu and stainless steel), since in both batches the electroplate is several microns thick. Similarly, length of time in the laboratory environment should not be a factor since the SnNi/SS film has less oxide but is 12 months older. Atomic surface composition and possibly surface chemical structure (*i.e.*, the different Sn/Ni ratios reported above), appear to play a major role.

Conclusions

Two batches of electroplated SnNi were carefully plated under controlled conditions and expected to have equal atomic percentages of Sn and Ni. They have subsequently been examined by SIMS, RBS, and ISS. RBS has shown the Sn/Ni ratio to vary from 45/55 to 52/48 a/o. In both cases the surface regions were Sn rich as found by ISS. Natural surface films were shown to be primarily Sn oxides and hydroxides;

no Ni oxides or hydroxides were found. Surface films formed in 10^{-6} Torr of O_2 after removal of native films by Ar^+ sputter cleaning were not the same as the original films since they contain substantial amounts of nickel oxides and hydroxides.

Acknowledgments

The author thanks G. V. McIlhargie for supplying the samples. RBS and ISS measurements were made by J. C. Nelson of Sandia Laboratories.

Manuscript submitted Oct. 14, 1977; revised manuscript received March 20, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by Bell Laboratories.

On the Functioning and Malfunctioning of Dimercaptothiadiazoles as Leveling Agents in Circuit Board Plating from Copper Pyrophosphate Baths

Dennis Tench* and Cameron Ogden*

Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

Foldback of copper electrodeposits to form lines of demarcation and voids in circuit board through-holes plated from pyrophosphate baths containing dimercaptothiadiazole brightening additives has been studied on rotating planar electrodes prepared from cross sections of actual multilayer circuit boards. The macro surface roughness of deposits was used as a quantitative measure of foldback to show that this problem results from a deficiency of the brightener at the electrode surface. Cyclic voltammetric data for a rotating Pt-disk electrode are presented which show that higher concentrations of the brightener inhibit or decelerate the copper deposition rate, whereas lower concentrations exert an accelerating effect. A mechanism is proposed to explain how acceleration of deposition occurs and how the brightener functions to induce leveling or malfunctions to produce foldback. Scanning-electron micrographs revealing deposit morphology are presented in support of this mechanism.

A key process in the manufacture of multilayer circuit boards is the plating of through-hole interconnections, which involves both electroless and electrodeposition methods. When high reliability is required, as in military and space applications, through-holes are frequently electroplated from copper pyrophosphate baths (1). An organic leveling additive widely used is proprietary brightener PY61-H (2, 3), whose active ingredient is a dimercaptothiadiazole. To our knowledge, the mechanism by which this additive functions to produce leveling has not previously been reported.

An important problem in through-hole plating from pyrophosphate baths is foldback of copper electrodeposits to form lines of demarcation and voids, as illustrated by the cross section in Fig. 1. In addition to being cosmetically undesirable, folded-back deposits may fail on thermal cycling or be too thin to meet specifications. This problem occurs predominantly at the insulator-conductor boundaries, especially after positive etch-back. The latter procedure recesses the insulating layers relative to the conducting sheets, forming ring-shaped pockets where conventional solution agitation is expected to be less effective in maintaining adequate concentrations of solution species. This suggests that mass transport in the electrolyte is an important factor in the foldback problem. Irregular deposition of copper can result from Cu^{++} depletion within substrate recesses, and this effect has recently been treated

* Electrochemical Society Active Member.

Key words: electroplating, copper pyrophosphate, dimercaptothiadiazoles, leveling mechanism, foldback.

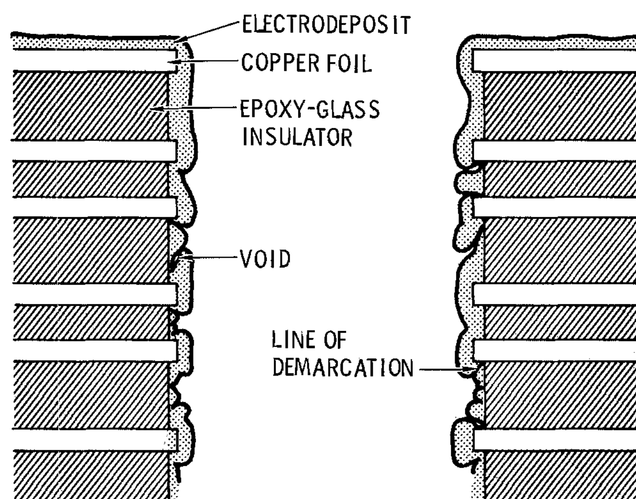

Fig. 1. Representation of foldback of the copper electrodeposit in a circuit board plated through-hole.

quantitatively for the acid copper sulfate system in the literature (4, 5). However, our results show that foldback is a special case involving brightener depletion, with Cu^{++} ion transport playing only a secondary role.

Experimental Details

Rotating circuit board electrodes.—Electrodes were prepared for foldback studies by mounting 3 mm^2 circuit board cross sections (having 12 copper layers) flush with the ends of 12 mm diam Teflon right cylinders which could be rotated for accurate mass transport control in the solution. This type of electrode is illustrated schematically in Fig. 2, where parallel lines on the circuit board material represent alternate copper layers of ~0.05 mm thickness separated by 0.1-0.3 mm of epoxy-fiberglass insulator. The mounting material (Hysol epoxy R9-2039/H9-3469) used to seal the circuit board cross sections in the 7 mm diam holes in the Teflon cylinders was chosen because of its similarity to the G-10 epoxy (Mica Corporation) used in circuit board construction. Electrical contact was made to a rotating shaft through the threaded brass connector, which was bonded to the circuit board electrode by low temperature soldering.

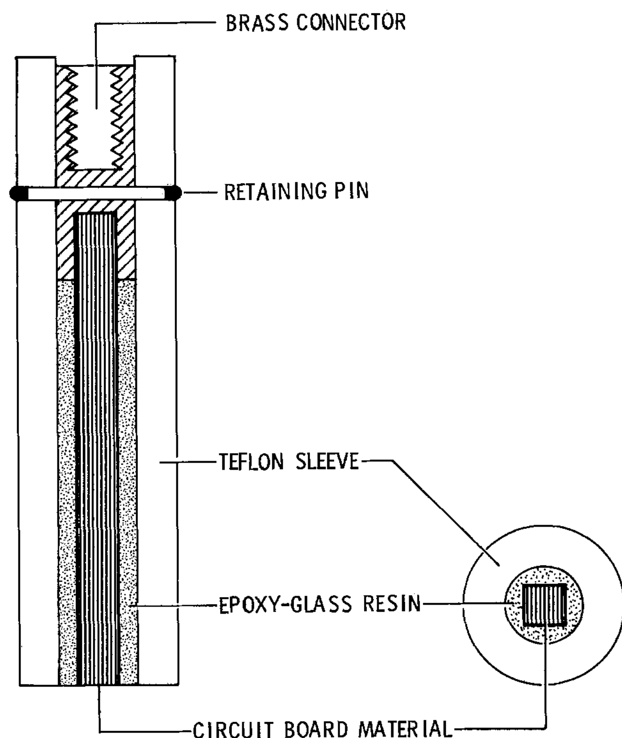

Fig. 2. Representation of a planar rotating circuit board electrode

Circuit board electrode pretreatment.—After fabrication, electrodes were polished on 600 grit SiC paper before undergoing etch-back, conditioning, and activation treatments identical to those generally used to process actual circuit boards. All baths used for these treatments were proprietary formulations of Enthone, Incorporated, except the deionized water rinses, copper pyrophosphate plating baths (M&T Chemicals, Incorporated), and H_2SO_4 and HF solutions. All baths operated at room temperature, except Enplate 453 and copper pyrophosphate, which were maintained at 55°C. During the pretreatment procedure, the electrode was always rotated at ~200 rpm. Details of this procedure follow.

The etch-back procedure removes epoxy-fiberglass insulator material smeared onto the copper layers by polishing (drilling in the case of through-holes), and recesses the insulating layers relative to the conducting sheets. The etch-back sequence is 60 sec in >94% H_2SO_4, rinse; 30 sec in >42% HF, rinse; and 5 sec in >94% H_2SO_4, which is followed by a rinse. Positive etch-back is accomplished by repeating the normal etch-back sequence. The former procedure further recesses the epoxy-fiberglass, resulting in an interlocking structure within the plated through-holes. Unless otherwise indicated, only the normal etch-back procedure was used in the studies described here. This leaves the surface reasonably flat, so that the electrode more closely approximates a rotating disk as described by Levich (6).

The conditioning procedure used after etchback is 150 sec in the Enplate 453, 60 sec rinse, and 60 sec in AD 481, which is followed by a 60 sec rinse. Enplate 453 is a strongly alkaline solution which conditions and cleans the through-holes and outsides of the circuit board. Enthone AD 481 is an ammonium persulfate solution that reduces and etches the copper layers, leaving clean active surfaces.

The insulating surfaces are prepared for electroplating by electroless copper deposition. This involves a cleaning and conditioning sequence of 180 sec in Enplate 453, rinse, 180 sec in Enplate 50104 (concentrated HCl solution), rinse, 60 sec in AD 481, rinse, 60 sec in Enplate 11105 (HCl-chloride solution) and 60 sec in another Enplate 11105, followed by activation. The latter involves adsorption of reduced Pd on the epoxy-fiberglass and copper surfaces from a mixed Pd-Sn chloride solution (180 sec in Activator 443), followed by a rinse, removal of excess metal chlorides in Accelerator 09043 (180 sec), and then another rinse. The adsorbed Pd catalyzes the electroless reduction of Cu^{+2} by formaldehyde in the electroless copper bath Cu 404 (360 sec), producing a thin layer of Cu over the surface (~1.5 μm thick). In the laboratory studies, any electroless Cu deposited on the Teflon mounting material was removed by scraping.

Circuit board plating conditions.—Copper electrodeposition on the rotating electrodes was performed from air-saturated copper pyrophosphate solutions prepared from plating bath concentrates C10XB, C11XB, and PY61-H obtained from M&T Chemicals, Incorporated. Baths typically had a pH of 8.3 and contained 22.5 g/liter Cu^{++}, 173 g/liter $(P_2O_7)^{-4}$, and 2.25 g/liter NH_3. Before use, baths were conditioned for 16 hr at 50°C and the temperature was maintained at 55° ± 1°C during electrodeposition by water circulated around the 150 ml jacketed glass cell from a Haake FT circulator-controller. The OFHC copper coil anode was dipped directly into the bath. Electrical contact to the cathode was made via silver-graphite brushes and the electrode rotation was controlled by a Motomatic E-550M controller and d.c. motor. Cell current was maintained at 38 mA/cm^2 (35 ASF) by a

Keithley Model 227 constant current source. Plating time was 60 min so that the average deposit thickness was 0.05 mm.

Cross section preparation.—After electroplating, a 1-2 mm slice was removed from the plated end of the cylindrical electrode using a low speed diamond saw. The disk obtained was mounted in Buehler Epoxide resin (20-8130) to protect the electroplate. A section of the disk was then cut perpendicular to both the plated surface and the parallel laminated copper sheets. This procedure exposed a cross section of the electroplate across alternating copper and epoxy-fiberglass circuit board layers. The surface of the cross section was then polished on successively finer aqueous alumina powder slurries to a 1 μm particle size to facilitate examination of the macro features of the deposit and substrate. For microstructure examination, samples were then etched for 2-3 sec in a mixture of concentrated acids (65% acetic, 34% nitric, and 1% hydrochloric).

Rotating Pt disk electrode studies.—The effect of brightener concentration on the rate of copper electrodeposition was investigated by voltammetrically cycling a rotating (2500 rpm) Pt disk electrode at 50 mV/sec from -0.700 to $+1.000$V *vs.* SCE (saturated calomel electrode) in air-saturated copper pyrophosphate baths at 55°C. Typical voltammetry curves are shown in Fig. 3 for baths containing 0.0 and 1.8 ml/liter PY61-H. Deposition of copper occurs between -0.3 and -0.7V for both sweep directions and the copper deposit is removed from the inert electrode by oxidation, *i.e.*, stripped, on the anodic sweep between -0.3 and -0.05V *vs.* SCE. The area under the stripping peak corresponds to the charge required to oxidize the copper deposit and is proportional to the average deposition rate for that cycle (7). At a concentration of 1.8 ml/liter, it is evident from Fig. 3 that the brightener decelerates Cu deposition.

The test electrode was a 99.95% Pt disk of 0.13 cm^2, which was mounted concentric and flush with the end of a 12 mm diam Kel-F cylinder by compression molding at elevated temperature. After mounting, the electrode was polished on successively finer aqueous alumina powder slurries to 1 μm particle size and then potential cycled to steady state in a bath containing no PY61-H. Both the Pt-40% Rh counterelectrode and commercial SCE were dipped directly in the cell. The indicator electrode potential was controlled relative to the SCE reference with a PAR Model 173 Potentiostat/Galvanostat in conjunction with a PAR Model 175 Universal Programmer. Steady-state voltammograms were generally obtained after 3-5 cycles. Anodic current peaks were integrated electronically to -0.05V *vs.* SCE using a PAR Model 179 Digital Coulometer.

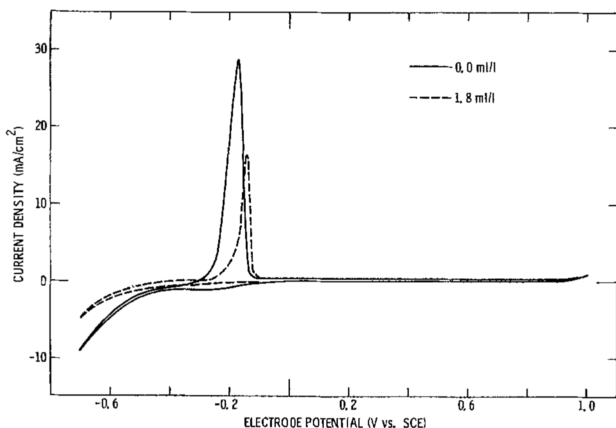

Fig. 3. Steady-state linear sweep cyclic voltammograms at 50 mV/sec for a Pt disk electrode rotating at 2500 rpm in copper pyrophosphate plating baths at 55°C containing 0.0 and 1.8 ml/liter of PY61-H.

Results and Discussion

The cause of foldback.—Cross sections of electrodeposits obtained on rotating circuit board electrodes at low (45 rpm) and moderate (95 rpm) rotation rates in baths containing 2.0 ml/liter of PY61-H are shown in Fig. 4 and 5, respectively. It is evident from these figures that foldback can be studied on rotating planar electrodes and that increased mass transport (faster electrode rotation) mitigates the problem. Similar experiments with positively etched-back electrodes show an increased incidence of foldback at the insulator-conductor boundaries, in agreement with studies of actual circuit board through-holes.

Since the activity of the brightener increases with bath heating time and varies by as much as 60% for different PY61-H batches (7), only the relative concentrations are really significant. To minimize errors caused by variations in brightener activity, baths were always prepared fresh using the same PY61-H batch and were heat-treated at 50°C for a specific amount of time (16 hr) before use. Time at operating temperature may be necessary to promote formation of a copper complex or polymerization of the brightener to an active form.

To facilitate data handling and display, a quantitative measure of foldback is desirable. To generate such numbers, advantage can be taken of the disrup-

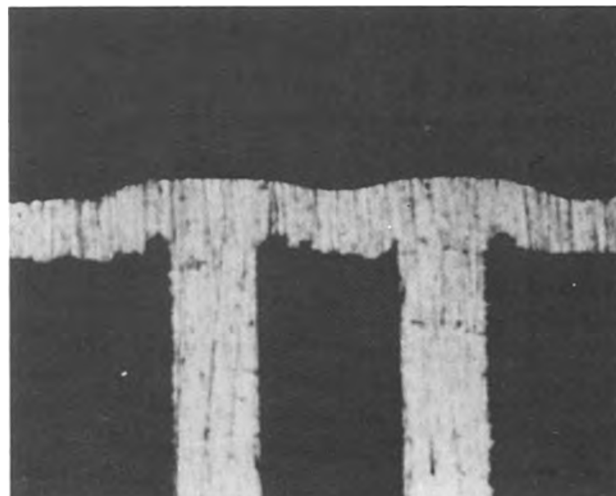

Fig. 5. Same as Fig. 4 except at 95 rpm

tions in the electrodeposit contour which result from foldback. Referring to Fig. 6, we define the foldback ratio (R_{FB}) as the length (L) along the contour of the electrodeposit surface divided by the corresponding distance (D) along the substrate. Thus, R_{FB} is larger as foldback becomes more severe and approaches unity as the problem disappears. Foldback ratios were measured from 330 times enlargements of electrodeposit cross sections.

Values of R_{FB} are plotted in Fig. 7 as a function of electrode rotation rate (ω) for various concentrations of PY61-H. It is evident from these curves that foldback is caused by insufficient brightener at the electrode surface. At the highest bulk brightener concentration (3.0 ml/liter), foldback is appreciable only at the lower rotation rates (<40 rpm) for which mass transport is slow, resulting in brightener depletion at the surface. For the lowest bulk brightener level (0.5 ml/liter), foldback is appreciable even at the highest rotation rate. This interpretation is based on the assumption that brightener is consumed at the electrode by inclusion in the deposit, which was shown to be the case by XPS analysis of deposits obtained on a Cu disk electrode rotating at 2500 rpm in baths at 55°C

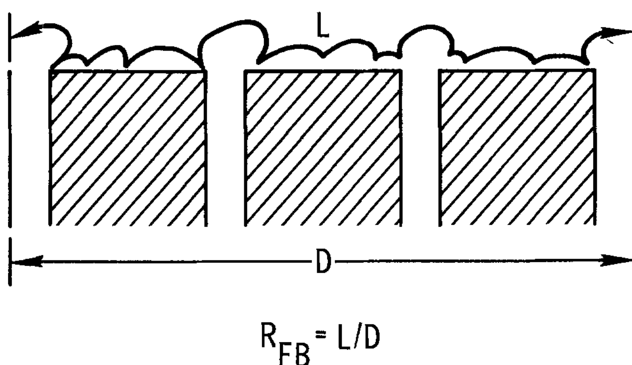

Fig. 6. Representation of a rotating circuit board electrode cross section illustrating the foldback ratio (R_{FB}).

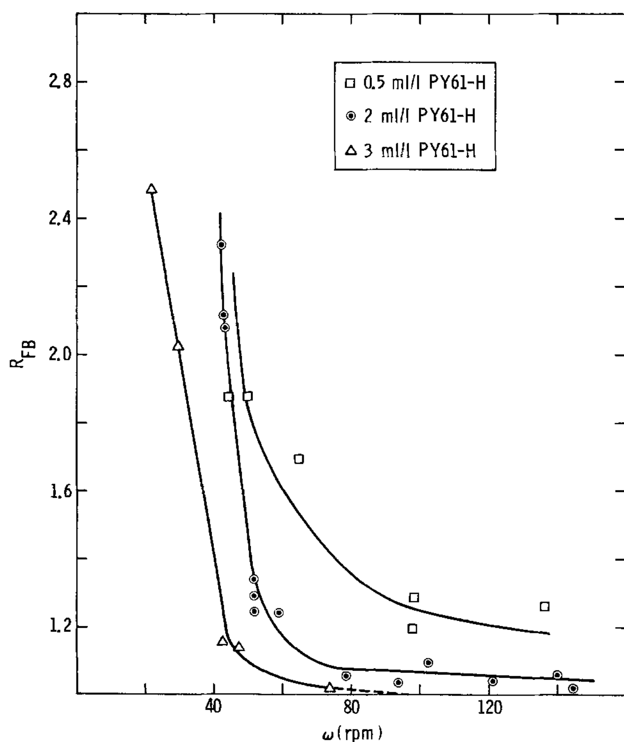

Fig. 7. Plots of foldback ratio (R_{FB}) vs. rotation rate (ω) of planar circuit board electrodes plated at 55°C from copper pyrophosphate baths containing various concentrations of PY61-H.

containing 2.0 ml/liter of PY61-H. An appreciable concentration of sulfur (0.3-0.6 atom percent) was detected.

The relationship between foldback and brightener concentration is more clearly illustrated by the topograph of foldback ratio *vs.* brightener level and current density shown in Fig. 8 for an electrode rotation of 100 rpm. This topograph is based on about 75 data points. Since brightener is consumed more rapidly at higher deposition rates, R_{FB} increases sharply with current density for the lower bulk brightener levels. Above 2 ml/liter, however, brightener depletion is less severe and foldback is suppressed even at the higher current densities. The increase in R_{FB} with increasing current density and decreasing PY61-H concentration is much more pronounced for similar plots at lower rotation rates. Dashed lines are used at the lower PY61-H concentrations since the data scatter is considerable in this region. Also, as the brightener concentration approaches zero, irregularities in the deposit contour result more from the absence of leveling than from the effects of insufficient brightener which are discussed below. This change of mechanism also accounts for the apparent decrease in R_{FB} at lower brightener concentrations.

Because of decreased mass transport of brightener to recessed areas of the electrode, foldback is generally more pronounced for positively etched-back surfaces and less evident for unetched samples, as shown in Fig. 9. Thus, at a given bulk brightener concentration, more vigorous agitation is required to prevent foldback when positive etch-back is used.

A mechanism proposed.—The mechanism by which the PY61-H brightener functions to induce uniform deposition of copper (leveling) and malfunctions to produce foldback can be understood from the voltammetric results for a rotating Pt disk electrode summarized in Fig. 10. As explained above, the copper stripping peak area (A_r) is a measure of the rate of copper electrodeposition. Since the absolute magnitude of A_r depends somewhat on the electrode pretreatment, only the relative values are significant. It is evident that the brightener accelerates the rate of electrodeposition at lower concentrations, but exerts a decelerating effect at higher levels. In actual circuit board plating, freshly prepared baths generally contain 2.0 ml/liter of PY61-H, so that the brightener presumably induces deceleration when functioning properly.

The results above are consistent with the view that the effectiveness of the brightener in producing leveling results from its ability to either decelerate or accelerate deposition of copper. Thus, as brightener is depleted at the electrode by inclusion in the deposit,

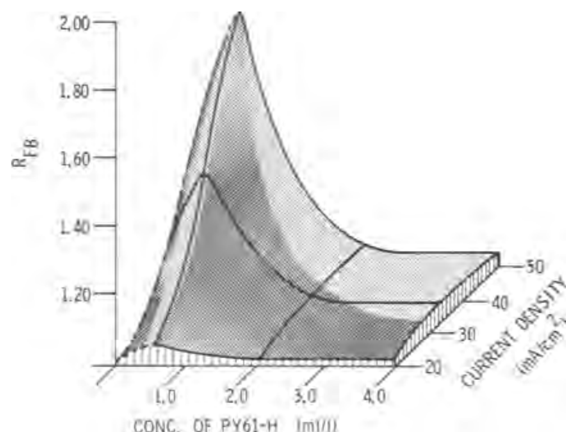

Fig. 8. Topographical plot of foldback ratio (R_{FB}) vs. current density and PY61-H concentration for planar circuit board electrodes rotated at 100 rpm during plating at 55°C from copper pyrophosphate baths.

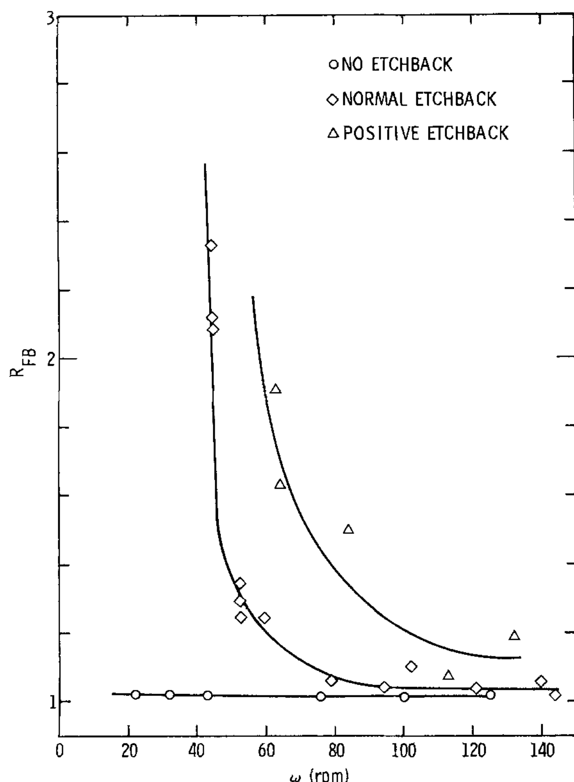

Fig. 9. Plots of foldback ratio (R_{FB}) vs. rotation rate (ω) of planar circuit board electrodes receiving various pretreatments before plating at 55°C from copper pyrophosphate baths containing 2.0 ml/liter of PY61-H.

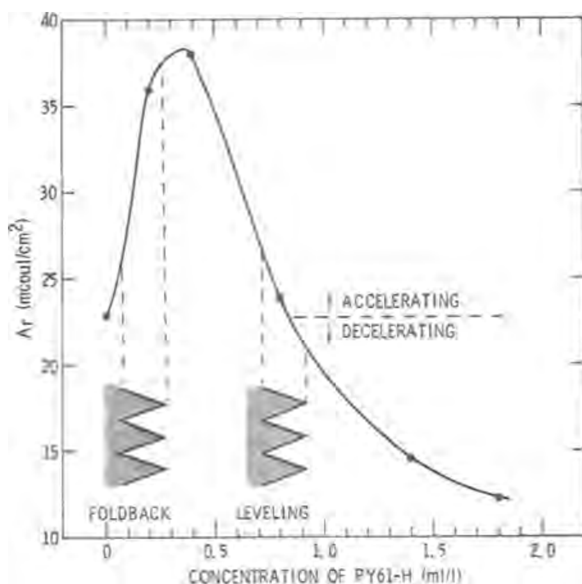

Fig. 10. Brightener concentration dependence of the steady-state Cu stripping peak area (A_r) for a rotating (2500 rpm) Pt disk electrode cycled at 50 mV/sec between −0.700 and 1.000V vs. SCE in copper pyrophosphate baths at 55°C. Inserts represent micro or macro surface roughness of substrates during plating.

its concentration at micro and macro peaks remains sufficient to inhibit deposition, as long as solution agitation and bulk brightener level are adequate. At the same time, because of reduced solution agitation in recesses, the brightener concentration becomes sufficiently depleted that acceleration of deposition occurs. Referring to Fig. 10, the brightener concentration at substrate peaks remains in the "decelerating" range, while that at recesses moves to the "accelerating" region. Hence, peaks are plated more slowly than without brightener and recesses are plated more rapidly, so that very efficient leveling results. Of course, either acceleration or deceleration alone would also level the deposit by the generally accepted mchanism (8), but the two operating together should be most effective.

Foldback, then, occurs when solution agitation or the PY61-H level becomes inadequate, resulting in sufficient depletion of brightener concentration at the electrode to produce acceleration of deposition at peaks in the substrate. At the same time, enhancement of deposition in recesses is reduced because of even more severe brightener depletion. In this case, the brightener concentration is always in the "accelerating" range, but at surface protrusions it is nearer to the maximum acceleration in Fig. 10. Thus, substrate peaks grow more rapidly than recesses, folding back over the latter. As foldback proceeds, the problem is compounded by increasingly restricted fluid flow to the recesses, perhaps resulting in severe depletion of copper pyrophosphate ions. Depletion of the latter species may also play some role in the early stages of foldback.

Additional insight is provided by comparison of electron micrographs taken along folded-back deposits with those obtained on flat copper disk electrodes rotating at 2500 rpm in baths containing known concentrations of brightener. Our data of the latter type show that deposits are: coarse-grained when the brightener concentration at the electrode surface is too small to appreciably affect the electrodeposition rate; composed of fine nodules less than 1 μm in diameter when the brightener exerts an accelerating effect; and extremely fine-grained when the effect is decelerating. In Fig. 11 and 12, typical electron micrographs are shown, respectively, for the bottom of a crevice and the top of a peak on the same folded-back deposit plated with electrode rotation of 45 rpm from a bath containing 2.0 ml/liter of PY61-H. Although the bulk additive concentration falls in the decelerating

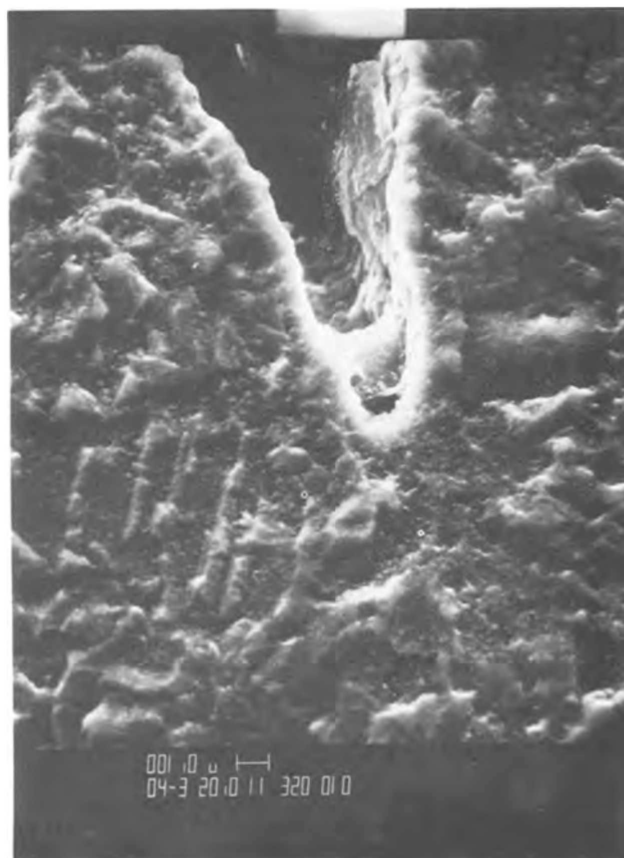

Fig. 11. Cross-sectional scanning electron micrograph at 4000 times of the bottom of a crevice on a folded-back deposit plated on a circuit board electrode rotating at 45 rpm in a copper pyrophosphate bath at 55°C containing 2.0 ml/liter of PY61-H.

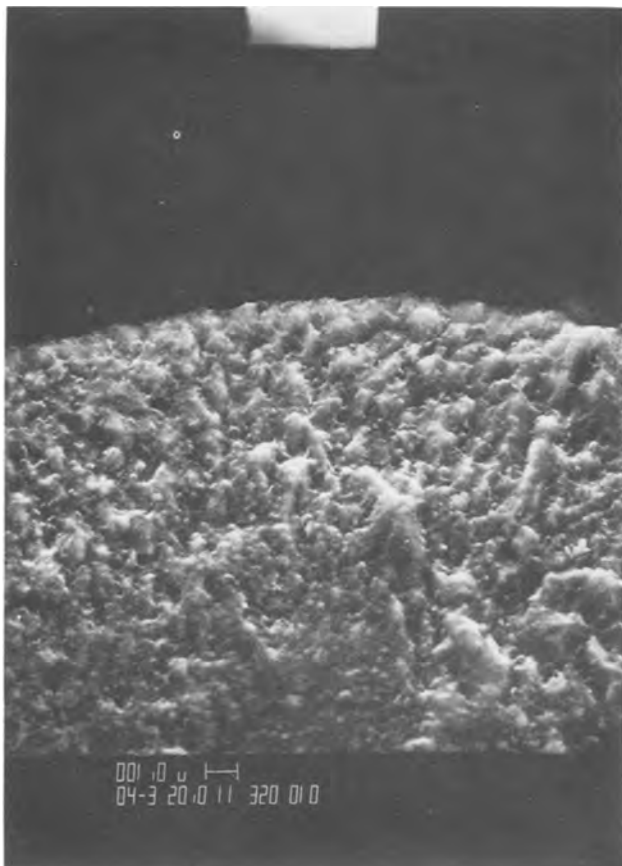

Fig. 12. Cross-sectional scanning electron micrograph at 4000 times of a peak on a folded-back deposit plated under the same conditions as for Fig. 11.

range, it is evident from the coarse-grained structure in Fig. 11 that the brightener is severely depleted within substrate recesses and has little effect on the electrodeposition rate. On the other hand, the fine nodular structure in Fig. 12 indicates that the folded-back peaks result from locally accelerated electrodeposition caused by less severe brightener depletion at the surface protrusions. This provides additional support for the mechanism proposed to explain foldback.

A possible mechanism by which the brightener can accelerate copper deposition at one concentration while inhibiting it at another can also be inferred from the deposit morphology observed under various plating conditions. In the absence of organic addition agents, which would interrupt grain growth, large-grained deposits (see Fig. 11) are typically obtained from copper pyrophosphate baths (9). Likewise, baths containing organic additives have generally been found to produce extremely fine-grained deposits (3), presumably because the organics adsorb at normal growth sites (kinks and steps) and force renucleation (10). It is proposed here that acceleration of electrodeposition occurs when the coverage of growth sites by brightener molecules is in the intermediate range, resulting in a large number of isolated growth centers. In this case, individual grains resemble dendrites or nodules growing out into the solution. The rate of electrodeposition is enhanced by the concomitant increase in the actual surface area of the electrode and because solution mass transport is increased by spherical diffusion to the tips of the protrusions (11). The resulting fine nodular deposit structure is evident in Fig. 12. At higher brightener concentrations, nodules do not form since most growth sites are blocked by adsorption of brightener molecules soon after nucleation. In this case, renucleation must occur much more often, so that fine-grained deposits are obtained and the deposition rate is decreased at a given electrode potential.

Nodules formed at high rotation rates (~2500 rpm) when the bulk brightener concentration is in the accelerating range are always an order of magnitude smaller than those obtained by lowering the electrode rotation rate at constant bulk brightener level to achieve the same concentration of brightener at the electrode surface. This result indicates that the depletion of Cu^{++} ions also contributes significantly to the growth of nodules when the solution mass transport rate is low.

It is interesting to note that, although leveling is induced only at brightener concentrations greater than that producing maximum acceleration of deposition, some brightening is produced over the entire concentration range. The latter occurs because specular reflection is increased by grain refinement, which is observed even for the lower brightener concentrations that produce fine nodular deposits. For leveling, however, the deposition rate within surface recesses must be faster than at surface protrusions where the brightener concentration is generally higher.

Although foldback has been shown to result from a deficiency of brightener at the electrode surface, other factors may also contribute indirectly to the problem. For example, the quality of the electroless deposit may be important since flaws in the conductive layer could act as centers for the initiation of foldback. The quality of the electroless deposit may in turn depend on the nature and pretreatment of the laminate used.

Conclusions

In through-hole plating from copper pyrophosphate baths, foldback of the electrodeposit to form lines of demarcation and voids has been shown to result from a deficiency of brightener at the electrode surface. Foldback can be understood from the voltammetric results which show that higher concentrations of brightener decelerate the deposition rate, whereas lower concentrations exert an accelerating effect. It is proposed that accelerated deposition results from nodular growth of centers isolated by partial coverage of growth sites by brightener molecules. When functioning properly, the brightener induces leveling by inhibiting deposition at peaks where its concentration remains high, and enhancing deposition in recesses where its concentration becomes depleted as it is included in the deposit. Foldback occurs when insufficient electrolyte agitation or additive level results in a low brightener concentration at the electrode surface, producing acceleration of deposition at the peaks. Thus, the problem can be controlled by maintaining an adequate brightener level and efficient solution agitation.

Acknowledgments

The authors are indebted to Dr. Alan Harker for performing the XPS analysis, Mr. John White for performing some of the experiments, and Mr. Joe Nagy of Enthone, Incorporated, for providing the plating bath concentrates.

Surface Properties of Nickel after Each Step of the Activation Process for Nickel Plating

Tennyson Smith and G. Lindberg

Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

The surface properties of nickel, after each step of the activation process for nickel plating, have been measured with ellipsometry, surface potential difference (SPD), photoelectron emission (PEE), water contact angle (ϕH_2O), and Auger electron spectroscopy (AES). The unique properties of properly activated nickel are compared with those for improperly prepared nickel and reveal the requirements for proper activation.

Properly activated nickel (anodic etch in H_3PO_4, rinse, cathodic activation in H_2SO_4, rinse) yields strong adhesion of the electrodeposited nickel to the substrate. A properly activated surface allows a uniform layer of nickel plate with a strong bond, whereas on an improperly activated surface, nickel is deposited in patches in the early stages of nucleation. The detailed description of the physical and chemical properties of the metal surface after each step of the activation process and the relationship of surface properties to successful plating has not been known.

Linford *et al.* (1) have prepared a literature review of the effects of contamination films (organic and inorganic, *e.g.*, oxides) in electroplating. They concluded that due to the active nature of metals that have been cleaned of all contamination, it is virtually impossible to place an absolute clean surface in the electroplating bath. There will always be a thin layer of oxide or oxide and other contaminants. Although the presence of oxide films is generally considered to be detrimental to plating, Linford *et al.* (1) indicate the presence of an oxide film may either prevent or promote adhesion depending on the circumstances. Almost all of the conclusions concerning the presence or absence of oxide between the substrate and the plate are based on indirect rather than direct observations.

Proposed mechanisms for plating at the interface include reduction of the oxide in the plating bath followed by plating on bare metal, plating on top of or in the pores of the oxide or lack of plating, depending on the conductivity of the oxide. Linford *et al.* state "there is no direct evidence to substantiate any of these mechanisms" (1). There is also little conclusive evidence as to whether very thin films are reduced by cathodic reduction in electrolysis or plating baths. They conclude that the structure of electrodeposits is controlled by the relative rates of crystal nucleation and growth and that the early stage of nucleation is dramatically affected by substrate topography and electric fields associated with sharp points, ledges, and ridges (*i.e.*, roughness on an atomic scale).

A more recent investigation (2) reveals that contamination from exposure to air causes isolated 3-D nuclei to form as well as larger blocklike growths, in contrast to smooth monolayer-type growths for uncontaminated surfaces. No effort was made to discover the nature of the contamination.

The lack of information available from the literature concerning detailed analysis of the state of metal surfaces prior to plating is due to the difficulty in the past of analyzing the region of interest, *i.e.*, the first few atom layers on the surface. Recent advances with respect to surface analysis make it possible to make such a study. The surface tools that have been used in this investigation are: light scattering, ellipsometry, surface potential difference (SPD), photoelectron emission (PEE), water contact angle (ϕH_2O), and Auger electron spectroscopy (AES). In addition, a technique has been developed for simultaneous ellipsometry and Auger spectroscopy during removal of films (EARF) by heating samples in ultra-high vacuum to evaporate the films, layer by layer, from the outer surface. The properties that are probed by these tools are listed in Table I. Interpretations of the experimental parameters revealed by these tools are given in Ref. (3).

The physical and chemical state of the nickel surface after each step of the proper activation process for plating nickel on nickel have been evaluated with these surface physics tools. Investigations were also made during and after steps that are not used in the proper treatment, but may be involved by inadvertent errors in the activation process.

Prior to the activation process, the electrodeposited nickel (EDNi) samples were wet-polished with silicon

Table I. Surface tools and the physical properties they probe

Tool	Properties
Profilometer	Roughness, topography
Light scattering	Roughness
Ellipsometry	Film thickness, film refractive index

(ϕH_2O) water contact angle	Surface energy (outer atom layer)
(PEE) photoelectron emission	Film electron emission and attenuation properties
(AES) Auger electron spectroscopy	Elemental composition in outer 20A
(EARF) ellipsometry and Auger spectroscopy during removal of films	Depth profile of film thickness, optical properties and chemical composition

Key words: ellipsometry, Auger spectroscopy, surface potential difference, photoelectron emission.

carbide and cleaned in a mild alkaline cleaner (21g Vitro Klene[1] in 400 ml water, referred to as VK) at 80°C for 10 min. The first activation step is anodic etch (AE) in 81.5% by volume H_3PO_4, for 90 sec at 100 mA/cm^2 and room temperature, followed by a rinse in deionized water. The second activation step is cathodic activation (CA) in 25% by volume H_2SO_4, for 90 sec at 100 mA/cm^2 and room temperature, followed by a rinse in deionized water. VK alone or one of the activation steps by itself yield poor nickel adhesion (4).

Experimental Results

Film properties after each step.—Table II gives reproducible values (within ~ 10%) of equivalent film thickness (from ellipsometry), SPD, PEE, ϕH_2O, and Auger peak-to-peak heights (APPH) for carbon, phosphorus, sulfur, and silicon, relative to the APPH for the 850 eV peak of nickel. The term "equivalent film thickness" refers to an equivalent nickel oxide film of refractive index 2.6 and absorption index of zero. The nickel samples were rinsed and dried in flowing nitrogen after each step to prepare them for analysis with the surface tools.

No activation, VK only.—All samples were cleaned in Vitro Klene. "No activation" indicates the samples were polished but not activated. According to Table II the VK samples have an oxide film which is about 22Å thick. Removal of this oxide is indicated by the drift of the triangles in Fig. 1, up and to the left.[2]

The lowest value of Δ for the triangles corresponds to about 20Å of oxide. The highest value of Δ corresponds to a porous film of pure metal. For the porous film of pure metal, the ellipsometer cannot distinguish between a 20Å layer with about 50% porosity and a layer of about 300Å with about 5% porosity.

After VK, Table II reveals SPD to be approximately zero; this is because the reference electrode is also a nickel foil with natural oxide. That is, the work function of the sample and reference are about the same. The absolute value of SPD is difficult to interpret but the change from one treatment to another can be interpreted in terms of the changes in the outer dipole layer (3). The photoelectron emission has previously (3) been shown to come from the nickel oxide rather than the underlying metal. The attenuation index for nickel oxide (3) is ~ 71Å. The nickel oxide thickness calculated from the emission current proves to be approximately that from ellipsometry, 22Å. The low contact angle for water on VK nickel indicates that the surface is clean of low energy contamination.

One must not interpret the magnitude of the APPH ratio in Table II as relative surface concentration of one element with respect to another. The magnitude is strongly dependent on the position of the peak in the spectrogram. However, there is direct relative relation between the magnitude of the APPH ratio, for a given element, from one surface treatment to another, and the surface concentration of that particular element. For example, the fact that APPH(X)/APPH(Ni) is 15 for X = Si and 3.5 for X = C does not mean that

[1] TURCO Products, Wilmington, California.

[2] It should be noted in comparing Δ, ψ values in EARF with those not in EARF, that the angle of incidence is 79.2° in EARF as compared to 70° for other experiments. Δ is the phase shift and ψ is the arctan of the amplitude ratio, respectively, of the orthogonal components of reflected polarized light from ellipsometry.

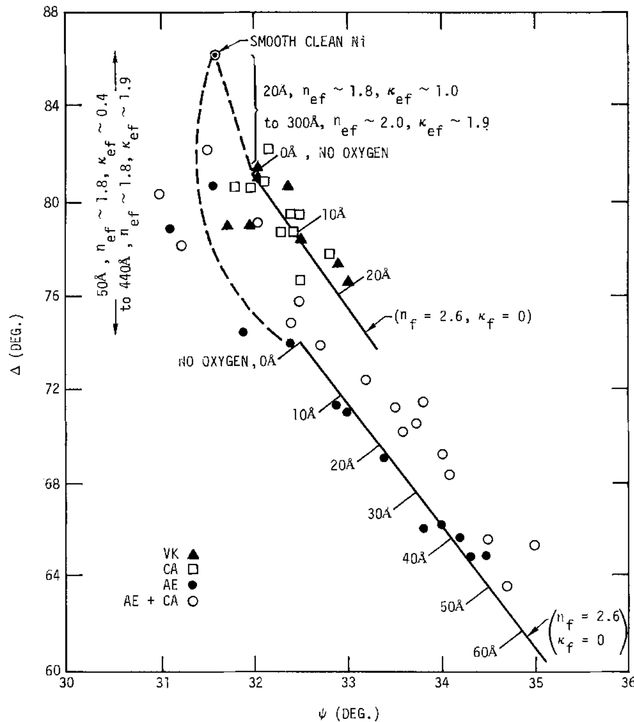

Fig. 1. Δ vs. ψ plots for the removal of films in EARF

there is about four times as much Si as C. However, the ratio of 15 for Si in the VK treatment and 4 in the CA treatment indicates that there is about four times as much Si on the surface after the VK treatment as after the CA treatment. The large silicon and carbon APPH ratios may be due to SiC particles from the mechanical polishing. As noted in Table II the AE treatment seems to remove these particles (APPH Si = 0).

The results for surface topography, from profilometry and light scattering measurements, are not reported in Table II, but indicate that compared to smooth polished nickel, the Vitro Klened samples which had been polished with 600 SiC paper are very rough (rms roughness ~ 0.25 μm for VK *vs.* 0.0005 μm for smooth nickel).

Cathodic activation only.—If a Vitro Klened sample is subjected to cathodic activation without prior anodic etch, the equivalent oxide film thickness and optical properties have not been changed (see Table II and open squares, Fig. 1) but the nature of the film has. The outer dipole layer has changed to increase SPD to 0.46V (due to a dipole layer with positive end pointing away from the surface), the emission yield has doubled, and the contact angle cannot be reduced below 20°. Most of the silicon (but not all) has been removed and sulfur has been increased. The ratios of the sulfur, carbon, and chlorine peaks in the CA film to that for a proper treatment (AE + CA) are plotted as a function of depth into the oxide film in Fig. 2. For CA only, oxygen and chlorine are in the outer atomic layer, whereas sulfur and carbon are found throughout the 20-30Å film. It is concluded that the sulfuric acid cathodic activation of a Vitro Klened sample has

Table II. Surface properties of films on nickel after each activation step

Surface treatment	Surface properties							
	Film thickness (Å)	SPD (V)	PEE (A × 10^{11})	ϕH_2O (deg)	APPH/APPH(Ni)			
					C	P	S	Si

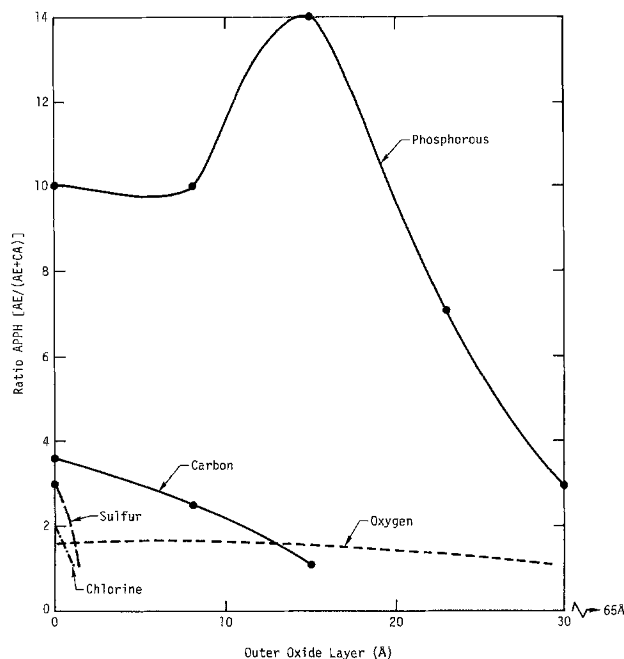

Fig. 3. APPH profile for elements in the outer atomic layers of the film formed during anodic etch of nickel.

changed the air-formed oxide film to a sulfide-carbide film, with resultant changes in SPD, PEE, and ϕH_2O, but essentially no change in thickness or optical properties.

The surface roughness, as measured by profilometry and light scattering, is essentially unchanged by CA, which has to be expected since no metal removal should occur during application of a cathodic current.

Anodic etch only.—If a Vitro Klened sample is subjected to anodic etch but not cathodically activated, a new equivalent film (~ 65Å) is observed after the AE step. Note that this 65Å film is measured *in situ* in the phosphoric acid but remains unchanged if the sample is removed, rinsed, and dried. It is only slightly changed (remove 3 or 4Å) by exposure to vacuum. Figure 1 (solid circles) shows the Δ *vs.* ψ results obtained by EARF for another AE sample. The lowest value of Δ and the largest value of ψ correspond to about 50Å of oxide on or within a porous layer of pure nickel. Heating to about 500°C in the UHV system drives off the oxide, following the theoretical curve for 50-0Å, at which point almost no oxygen is observed by AES. Further heating drives Δ and ψ toward the value for smooth clean nickel due to some sintering. The ellipsometer indicates that the porous nickel film remaining after heating has a thickness between 50Å with about 75% porosity and 440Å with just a few percent porosity. In contrast continued heating after removal of oxide from VK or VK + CA treated samples does not drive Δ, ψ toward the smooth-clean values, indicating that these surfaces are rough but not porous.

The SPD for the AE sample (see Table II) is only increased half as much as for CA, but the PEE is doubled due to the increased oxide thickness. Although the surface is very wettable (ϕH_2O ~ 3°), the carbon and phosphorus peaks are large. There is no sulfur or silicon at the outer surface of the oxide.

Figure 3 shows a profile after anodic etch alone, which is similar to Fig. 2. Relative to the proper treatment (AE + CA), sulfur and chlorine are only in the outer atomic layer, phosphorus and carbon are predominant in the outer 20-30Å whereas oxygen remains fairly uniform throughout the 60-80Å films. It is concluded that AE leaves an oxide that is primarily nickel phosphate in the outer part of the film.

The anodic etch has little effect on the rms surface roughness, but does increase the autocorrelation length (roughness wavelength) and thus smooths the surface with respect to VK only.

Proper treatment (AE + CA).—If a Vitro Klened sample is subjected to proper treatment, *i.e.*, anodic etch followed by cathodic activation, the anodic film is either changed in physical and electrical character but not removed or, if it is removed, another film of about the same average thickness but different properties replaces it. The film formed by AE + CA is observed *in situ* in the activation solutions and is only slightly changed upon rinsing and drying and under vacuum. The EARF results are seen in Fig. 1 (open circles).

The CA treatment following AE produces an outer dipole layer similar to that for CA after VK in the absence of AE. The change in dielectric properties is noted by the change of SPD from 0.2V (AE) to that of a CA-type outer surface (0.46V). The lack of change of PEE due to CA after AE is further confirmation of a film of thickness similar to that existing after AE. However, CA has reduced the carbon and phosphorus levels, and there is very little sulfur in the film after AE and AE + CA (see Table II). The low contact angle indicates a low level of nonpolar organic contamination. The most significant effect of the CA treatment after AE is to remove phosphorus which had been deposited in the AE step and to substantially decrease the carbon content in the outer layers.

Surface roughness, as measured by profilometry and light scattering, is unchanged by the CA treatment after AE. This is to be expected, since although the film chemistry was changed to CA, the film thickness was not, and even if it had been removed, 60-80Å removal would have little effect on topography.

Surface contamination from process solutions.—It had been noted that reproducible water contact angles were obtained on Vitro Klened samples (ϕH_2O ~ 3°, always wettable), whereas irreproducible contact angles were obtained for AE, CA, or AE + CA. Table III shows the effect of transfer of organic contamination from the surface of process solutions to the nickel sample upon removal of the sample. A series of experiments was performed in which the organic sur-

face contamination from the surface of the activation solution was removed by suction prior to sample entrance and exit. It is seen in Table III that except for CA alone, a dramatic decrease in ϕH_2O resulted (samples 2, 3, 13, and 14). Exposure of the samples to laboratory air for 5 hr caused an increase of about 10° in ϕH_2O in each case, indicating slow contamination. The contact angle for CA only is invariably 20° regardless of cleaning procedures. Either the sulfide film has a lower surface energy or this film attracts contamination much faster and more strongly than the others.

Table IV gives results for a Ni sample that had been processed through AE + CA but was highly contaminated. The unusually high contamination resulted from the VK step, as evidenced by the large contact angle ($\phi H_2O = 26°$), and after the AE + CA step ($\phi H_2O = 46°$). The Auger carbon peak was so large that other elements could not be observed and therefore the actual peak-to-peak heights are reported rather than the ratio with respect to the Ni 850 eV peak. After 30 min of Ar^+ sputtering, the carbon peak was 60. The sample was moved during the next Auger sweep, which increased the carbon peak observed on the new area to 180. Exposure to the electron beam rapidly decreased the carbon peak. This indicates that the gross organic contamination is easily removed by the electron beam. A means for detecting the type of carbon on the surface has therefore been discovered because the rate of decrease of the carbon peak is directly related to the heat of adsorption of the contamination. Figure 4 is a plot of Δ *vs.* ψ for the contaminated sample. The data fall along the theoretical curve between zero and 60Å of nickel oxide on or within a nickel film, but then follow the theoretical curve for an organic film of about 50Å on top of the oxide.

For some samples, the regrowth of oxide after cleaning by EARF was monitored by ellipsometry during exposure of the clean metal to air. Figure 4 shows that just prior to AE + CA (after VK) the oxide film was about 14Å and after exposure to air about 10Å. All such measurements reveal that exposure of clean

nickel to air produces a film of oxide about 10Å thick within seconds, after which very little further film growth occurs in many hours. This result is consistent with reported (5) oxidation of clean nickel and confirms the interpretation of the ellipsometric results.

In situ ellipsometry during activation.—Ellipsometric measurements were performed *in situ* as the activation steps were made in the acid solutions. Figure 5 is a Δ-ψ plot tracking a nickel surface from VK into H_3PO_4 followed by CA, AE, and CA again (with and without stirring).[3] The drastic variations in ψ during these steps led us to make a careful study of the interpretation of ellipsometry during polarization. The results of this study are given in Ref. (6). The significant conclusion is that changes in Δ reflect changes in film thickness, whereas changes in ψ reflect changes in thickness and surface roughness, but predominantly in surface roughness. Values of ψ move to the left of the dashed curve for oxide on a smooth nickel surface (labeled S in Fig. 5) with increased roughness.

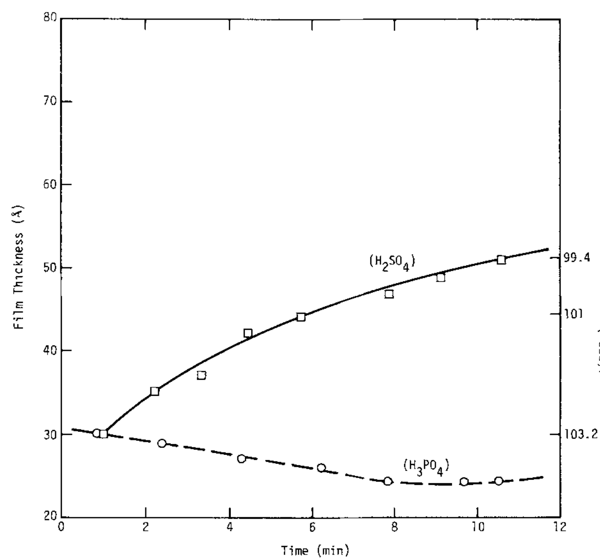
After VK, the sample had a film about 40Å thick. The coordinates of such a film in H_3PO_4 ambient are identified as the open crosses along curve S in Fig. 5. Figure 6 tracks the estimated film thickness that corresponds to Fig. 5. The first measurement in solution corresponds to point 1 at 1 min (Fig. 5). On the basis of the study in Ref. (6), exposure of the 40Å film to H_3PO_4 for 2.5 min (Fig. 5) has greatly roughened the surface, *i.e.*, the surface is dissolving. Cathodic treatment in H_3PO_4 between 2.5 and 5.7 min (point 2) produces no decrease in film thickness, only continued roughening. Anodic etch between 5.7 and 7.5 min moved the Δ-ψ coordinates to point 3. The shift of ψ to higher values indicates smoothing of the surface at the submicroscopic level and the decrease in Δ indicates formation of a film during or immediately following AE. It should be noted that measurement of Δ and ψ cannot be performed during AE or CA due to the copious gas bubble evolution. It is emphasized that after AE, the surface is still quite rough, otherwise point 3 would have moved to the dashed curve for film growth on a smooth substrate (curve S). These results are consistent with the analysis of Fig. 1 after AE. The formation of a rough surface (from recrystallization of dissolved nickel by cathodic reduction of dissolved nickel), as indicated by the large decrease in ψ to point 4 in Fig. 6, is evidence of a similar condition, but to a lesser extent, at point 3 after AE.

Removing the nickel from the H_3PO_4, rinsing, and placing in H_2SO_4 moves the Δ-ψ coordinates to point 5 (Fig. 5), which is only slightly changed from position 3 in the H_3PO_4. Exposure to H_2SO_4 moves Δ-ψ along the dashed line to position 6. This corresponds to the formation of a porous film somewhat similar to that observed after CA in unstirred H_3PO_4 (point 4),

[3] The experiments described in this section do not correspond to the correct activation procedure but were considered to evaluate the reaction occurring during the individual steps of the process.

i.e., H_2SO_4 is dissolving and reprecipitating a corrosion product film. The cathodic activation treatment between points 6 and 7 has little effect on the Δ-ψ coordinates, but has changed the film from a growth mode to a dissolution mode, as indicated by movement to position 8. Anodic etch moves Δ-ψ to 9, which corresponds to a thin but very rough film. Exposure to H_2SO_4 after AE drives Δ-ψ to a higher value (point 10, a smoother surface) but an additional CA step roughens it to point 11. Subsequent exposure to H_2SO_4 tends to smooth the surface again, moving Δ-ψ to position 12. At this point the experiment was terminated.

Effect of acid exposure.—Since exposure to acids in the absence of applied currents after the activation treatment may be detrimental to the plating process, nickel samples were Vitro Klened, treated with AE, CA, or AE + CA, and then exposed to H_2SO_4 or H_3PO_4 to establish the effect of exposure to acid on the surface activity. Figures 7, 8, 9 show Δ, ψ, and estimated film thickness changes as a function of time in these acids after each treatment. After VK the 30Å air-formed oxide layer dissolves in H_3PO_4 but a porous nickel film of corrosion products deposits in H_2SO_4 as noted by the decrease in Δ and ψ. The behavior in



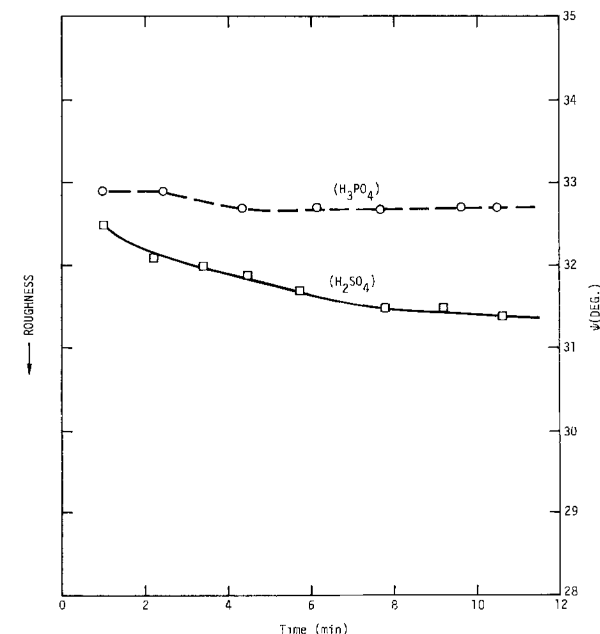


Fig. 7. Δ and ψ plot for EDNi in H_2SO_4 and H_3PO_4 after VK, showing estimated change in film thickness and roughness.

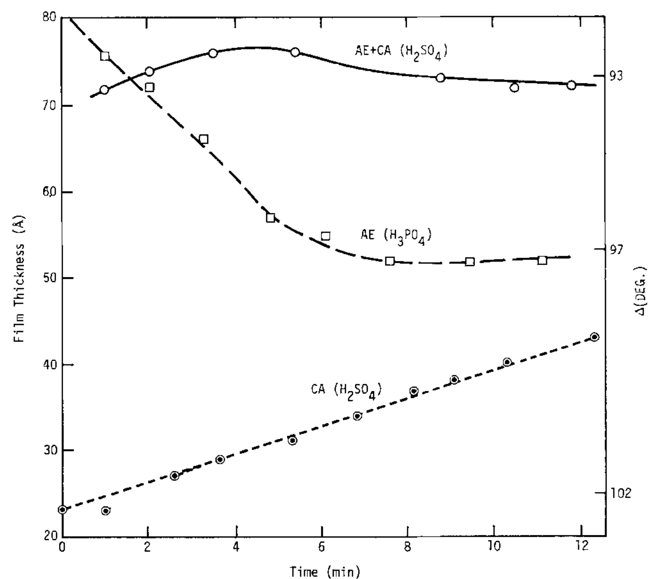

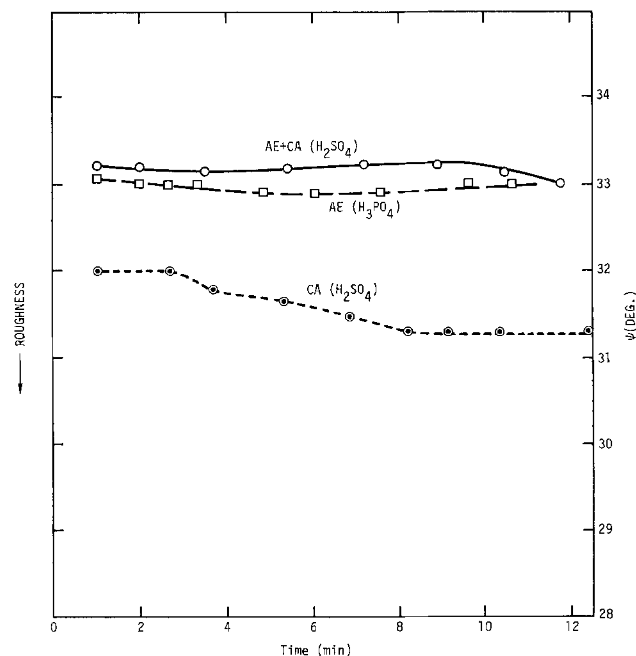

Fig. 8. Δ and ψ plot for nickel in H_2SO_4 and H_3PO_4 after AE, CA, and AE + CA, showing estimated changes in film thickness and roughness.

H_2SO_4 is about the same after CA (Fig. 8) as after VK only (Fig. 7). After AE, exposure to H_3PO_4 dissolves about 30Å of the 80Å film, *i.e.*, the outer layer of nickel phosphate may be removed. Figure 9 tracks Δ, ψ, film thickness, and corrosion potential (corrected) in H_2SO_4 after various treatments. About 30Å of the 80Å formed in AE dissolves in H_2SO_4 as it did in H_3PO_4, *i.e.*, the H_2SO_4 may also remove the phosphate layer and then allows the continued formation of oxide or corrosion product layers. If cathodic activation is performed after AE, the phosphate layer is replaced by an oxide which does not dissolve in H_2SO_4. This film continues to grow in H_2SO_4 as it did after AE (but after dissolution of the phosphate layer). This interpretation is in need of verification by surface analysis by EARF after exposure to these acids. If this interpretation is correct, the large decrease in corrosion potential in the first 2 min (after AE, Fig. 9), which from an electrochemical standpoint results from breakdown of a passive film, corresponds to dissolution of the outer phosphate layer. The trend of film growth in H_2SO_4 is the same as for the sample in Fig. 8, but somewhat

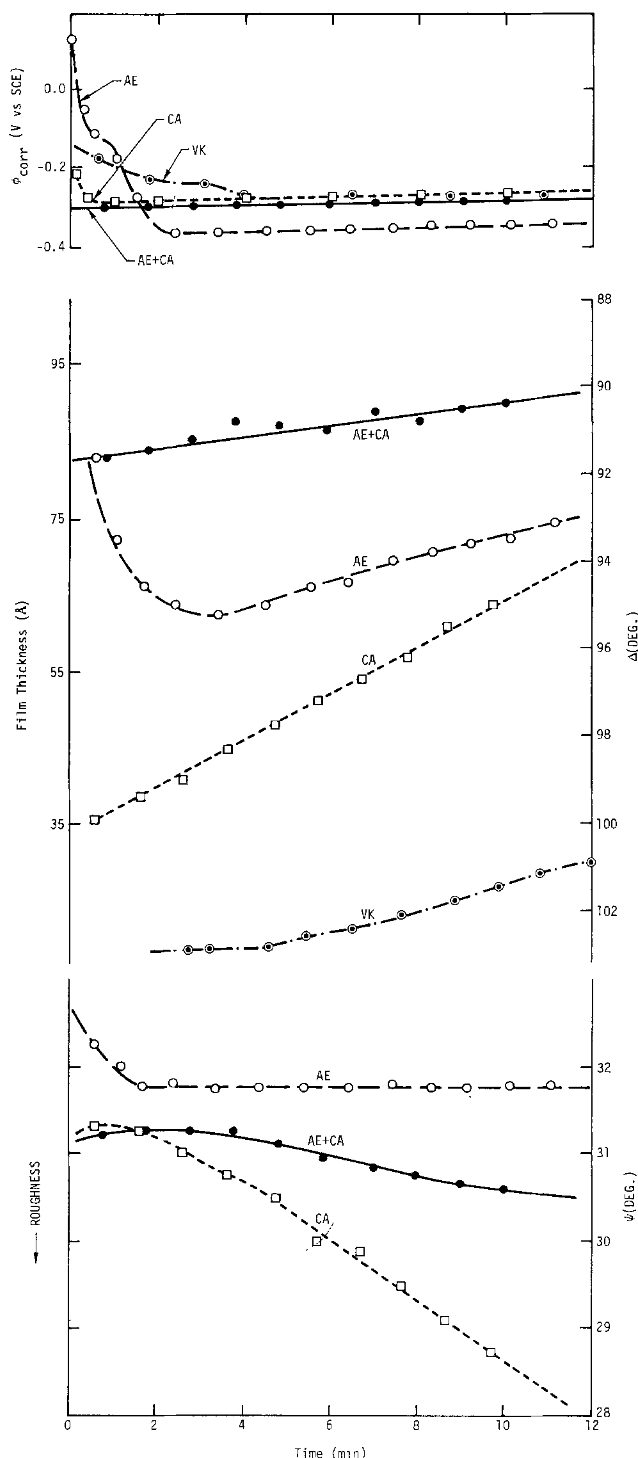

Fig. 9. EDNi in H_2SO_4 after AE, CA, and AE + CA

faster. The film on a VK sample is initially thinner than for the other treatments and slowly grows in H_2SO_4.

Exposure to acids always increases SPD and ϕH_2O. It may increase or decrease the film thickness and corresponding PEE's depending on the activation treatment, as seen above. Light scattering reveals little change in surface roughness due to acid exposure, whereas changes in ψ indicate roughening on a submicroscopic scale (porous film deposition) by exposure to H_2SO_4.

Solubility in nickel sulfamate.—It has been shown in the preceding that each step of the activation process produces a film with unique surface properties. It is supposed that the unique properties of the correct treatment (AE + CA) are responsible for its unique nickel plating success, but the reason is still obscure. One hypothesis, proposed in the literature (1), is that proper plating occurs only if the plating bath and plating current first remove any films so that nickel is plated on clean, bare nickel. Another hypothesis (1) is that nickel can plate on oxide films if they have certain properties. We have attempted to determine if the film formed on properly treated (AE + CA) nickel is removed in the plating bath, whereas the film formed on improperly prepared nickel (AE only) is not.

This is a very difficult problem to resolve with ellipsometry, because the nickel sulfamate bath is opaque to the red laser light, making *in situ* measurements impossible. To avoid these problems, nickel treated with AE only was placed in nickel sulfamate plating bath for various lengths of time without current flow, removed, rinsed, dried, and examined with ellipsometry to see if the film had dissolved. The same experiment was conducted with a properly treated (AE + CA) nickel sample. Figure 10 indicates that there is no dramatic difference between the change in film thickness for exposure to the Ni sulfamate bath after AE only and AE + CA. The slight tendency for the properly treated surface to exhibit slow dissolution of the film as compared to the tendency to increase the film thickness for the improperly treated surface may be greatly accentuated by applying the plating current. Unfortunately, ellipsometry cannot distinguish between reduction of oxide film on nickel and growth of a nickel deposit on the oxide. The resolution of this problem must await careful experiments to monitor the presence or absence of oxide between the plate and substrate by sputtering through the plate and monitoring with AES or ESCA.

Summary and Conclusions

Each step of the preparation of nickel for electroplating involves complex physical and chemical changes that we have attempted to elucidate with various sophisticated surface tools. Based on all results the schematic representation of the condition of the surface after each step of the activation process is given in Fig. 11.

Mechanical polish and VK of the samples leave them with about 20Å of oxide, some embedded silicon carbide polish particles, but little organic contamination. If the VK sample is treated with CA in H_2SO_4, the film is replaced by nickel sulfide of about the same thickness. However, if the sample is treated with AE after VK, the oxide is dissolved. Rapid dissolution of nickel (~5 μm/hr) (4) leaves particles of nickel and a saturated solution of nickel ions near the nickel surface. Turning off the anodic current, or removing

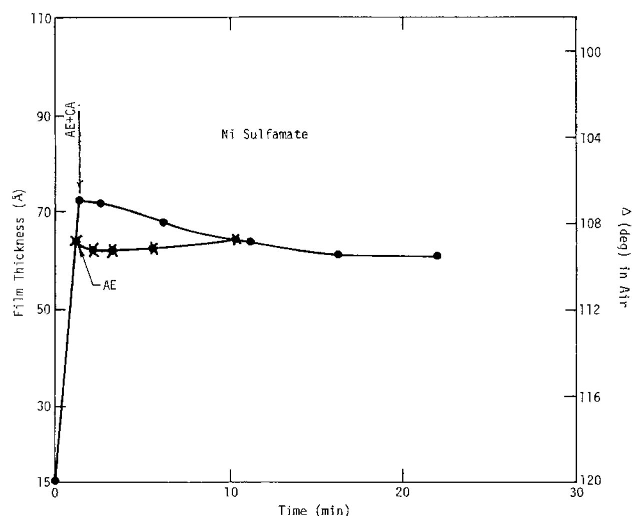

Fig. 10. Plot of Δ and corresponding film thickness on nickel after AE only and after AE + CA, as a function of exposure time.

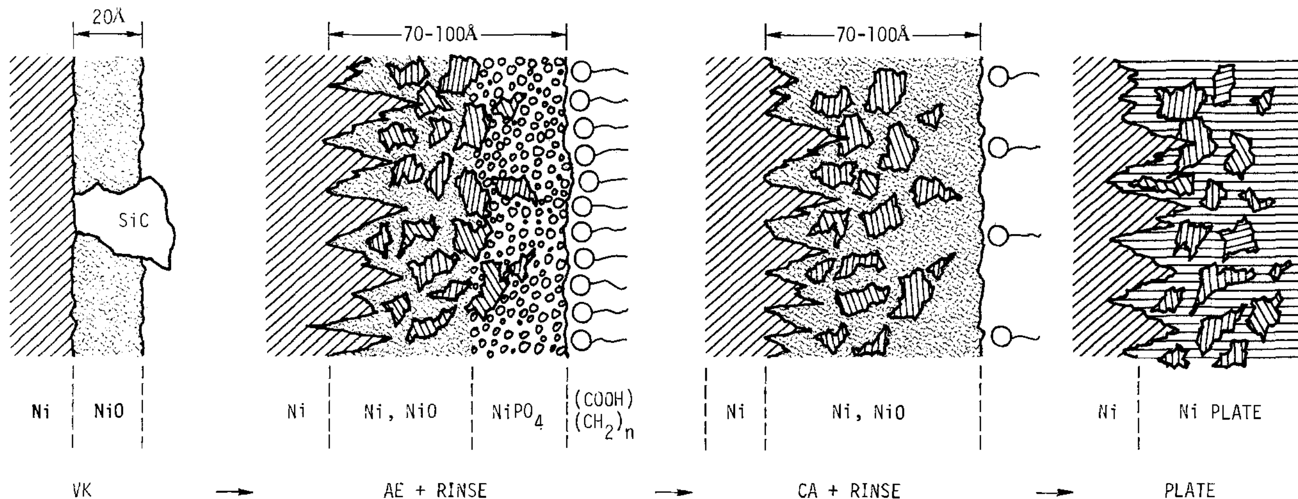

Fig. 11. Schematic representation of surface after each step

the sample from the solution, causes precipitation of small particles of nickel and precipitation of a porous layer of nickel phosphate, particularly at the outer surface. Rinsing removes phosphoric acid from the porous layer and oxidizes the porous nickel, particularly within the layer.

If the sample with AE treatment only is placed in the sulfamate plating bath, the phosphate layer cannot be reduced and plating occurs only at a few active points where reduction can occur. Nonuniform nucleation and growth of the deposit yield a weak interface and poor bonding. However, if the CA is carried out after AE, the phosphate film is reduced and perhaps the oxide film is also reduced, but upon stopping the current and rinsing of the sample, the porous nickel surface is reoxidized. The reoxidized nickel surface can, however, be reduced in the plating bath and plating occurs within and on the porous nickel. The result is a uniform plate with strong, tough bonding.

There appear to be three requirements for achieving a satisfactory deposit with a strong bond to the substrate: (*i*) a large concentration of nucleation sites, provided by the roughening and precipitation of nickel nuclei during and following AE (revealed by ellipsometry), (*ii*) reduction of the phosphate layer and reformation of an oxide that can be reduced in the plating bath (revealed by AES), and (*iii*) organic contamination must be reduced below some critical level.

If this mechanism is valid, other experiments could reveal possible alternative activation procedures that may be simpler and therefore less expensive and perhaps more reliable.

Catalysis of the Electroreduction of Allyl Chloride by Cobalt 2,2′-Bipyridine Complexes

Shlomo Margel and Fred C. Anson*

Arthur Amos Noyes Laboratory, California Institute of Technology, Pasadena, California 91125

ABSTRACT

The electrochemical reduction of allyl chloride is strongly catalyzed in the presence of cobalt complexes of 2,2′-bipyridine. A prominent reaction product of the catalyzed reduction is 1,5-hexadiene. Voltammetry, coulometry, and gas chromatographic data are presented and analyzed and a mechanistic scheme proposed to account for the catalytic action of the cobalt-2,2′-bipyridine complexes.

Recently we reported studies (1) which examined a previous claim (2) that the electroreduction of acrylonitrile in acetonitrile was catalyzed by a complex of cobalt with 2,2′-bipyridine. These studies demonstrated the absence of such catalysis for acrylonitrile and a number of other vinyl monomers but one substrate, allyl chloride, did exhibit a very large enhancement in its reduction rate in the presence of cobalt 2,2′-bipyridine complexes. This report summarizes our experimental observations with this system and presents a possible reaction scheme to account for the observed catalysis.

Experimental

Reagents.—The solvent was prepared from spectroscopic grade acetonitrile which was stirred over CaH_2 for 24 hr, distilled near room temperature under reduced pressure, and stored under argon. Polarographic grade tetraethylammonium perchlorate (TEAP) (Southwestern Analytical Company) was vacuum dried and used as the supporting electrolyte without additional purification.

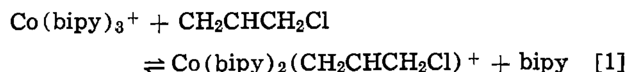
$Co(bipy)_3(ClO_4)_3$, $Co(bipy)_3(ClO_4)_2$ (bipy ≡ 2,2′-bipyridine), and $Co(phen)_3(ClO_4)_2$ (phen ≡ 1,10-phenanthroline) were prepared as previously described (1). Solutions of $Co(bipy)_2(ClO_4)_2$ were prepared by mixing $Co(ClO_4)_2$ and 2,2′-bipyridine in a molar ratio of 1:2 in acetonitrile. Allyl chloride (Eastman) and allyl alcohol (Aldrich) were distilled just prior to their use.

Apparatus.—Cyclic voltammograms were obtained with a Princeton Applied Research (PAR) Model 173 potentiostat driven by a PAR Model 175 programmer. Current-voltage curves were recorded with a Tektronix Model 564 storage oscilloscope and photographed with a Tetronix Model C-12 camera. Controlled potential coulometry was conducted with the same potentiostat equipped with a Model 179 digital coulometer. A three-compartment electrochemical cell was employed with double isolation of the Ag/0.1M Ag^+ reference electrode against which all potentials are quoted. Solutions were deoxygenated with prepurified argon which was passed successively through aqueous chromous chloride solution, a calcium chloride drying tower, and purified acetonitrile before entering the test solution. Concentrations of allyl chloride and 1,5-hexadiene were monitored gas chromatographically with a Hewlett-Packard Model 5830 chromatograph using a 12 ft column packed with Carbowax 20M on Chromosorb W.

Results

Of the three characteristic voltammetric waves exhibited by $Co(bipy)_3^{3+}$ in acetonitrile (1, 2) the second is the first to be affected by the presence of allyl chloride. In addition, as was true for acrylonitrile (1), a new wave appears between the original second and third waves. These features are shown in Fig. 1. The peak current of the new wave with a peak potential near −1500 mV increases at the expense of the third wave ($E_p = -1950$ mV) as the concentration of added allyl chloride is increased (Fig. 1). At a fixed concentration of allyl chloride the ratio of peak current to square root of scan rate for the new wave at first increases as the scan rate decreases (Fig. 2) but eventually decreases again at very low scan rates. The magnitude of the wave is also suppressed by the presence of excess 2,2′-bipyridine (Fig. 2).

The behavior is rather similar to that obtained with acrylonitrile and is consistent with an analogous interpretation of the origin of the new wave (1): It corresponds to the reduction of a mixed allyl chloride, 2,2′-bipyridine complex of cobalt(I) that is the product of reaction [1]



$$Co(bipy)_3^+ + CH_2CHCH_2Cl \rightleftharpoons Co(bipy)_2(CH_2CHCH_2Cl)^+ + bipy \quad [1]$$

However, in contrast with the cobalt(I) acrylonitrile system, the mixed complex with allyl chloride is unstable with respect to intramolecular reduction of the coordinated allyl chloride by the cobalt(I). This reaction, which results in the regeneration of cobalt(II) at the electrode surface, is the reason that the addition of allyl chloride causes the peak current of the wave corresponding to the reduction of cobalt(II) to cobalt(I) to exceed its value in the absence of allyl chloride (Fig. 2) except at scan rates high enough to prevent reaction [1] (and the subsequent intramolec-

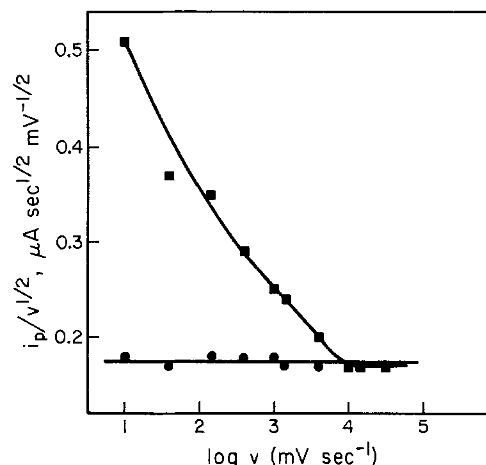

Fig. 4. Scan rate dependence of the ratio of voltammetric peak current, i_p, to square-root of scan rate for reduction of $Co(bipy)_3^{2+}$ to $Co(bipy)_3^{+}$. ●, 0.5 mM $Co(bipy)_3^{2+}$; ■, 0.5 mM $Co(bipy)_3^{2+}$ + 10 mM allyl chloride. Other conditions as in Fig. 2.

ular reduction reaction) from proceeding significantly from left to right.

The instability of the mixed cobalt(I)-allyl chloride complex made it impossible to evaluate the equilibrium constant for reaction [1] from cyclic voltammetric data as was done for the acrylonitrile complex. However, from the qualitative observation that larger concentrations of allyl chloride than of acrylonitrile are required to cause the formation of the new wave, it seems likely that the equilibrium constant is smaller for the allyl chloride complex.

The voltammograms in Fig. 3 show that substitution of $Co(bipy)_2^{+}$ for $Co(bipy)_3^{+}$ significantly increases the rate at which reaction [1] proceeds from left to right (the same is true for the analogous reaction involving acrylonitrile). In the case of $Co(bipy)_3^{+}$ the slow step is apparently the loss of one of the coordinated 2,2'-bipyridine ligands.

No evidence of the formation of a mixed complex was obtained when $Co(bipy)_3^{+}$ was exposed to allyl alcohol or when $Co(phen)_3^{+}$ was exposed to even large excesses of allyl chloride.

Note that the rate of the reduction of the coordinated allyl chloride is apparently slower than the rate at which it coordinates to $Co(bipy)_3^{+}$ or $Co(bipy)_2^{+}$. Otherwise, the new wave in Fig. 2 and 3 arising from the reduction of the mixed complex would not appear. Instead, the wave corresponding to the reduction of cobalt(II) to cobalt(I) would merely increase in magnitude as all of the allyl chloride was reduced.

The ratio of peak current to square root of scan rate for the reduction of $Co(bipy)_3^{2+}$ to $Co(bipy)_3^{+}$ becomes strongly dependent on scan rate in the presence of allyl chloride as shown in Fig. 4. Only at scan rates high enough to prevent reaction [1] from proceeding does the ratio of i_p to $v^{1/2}$ decrease to its value in the absence of allyl chloride.

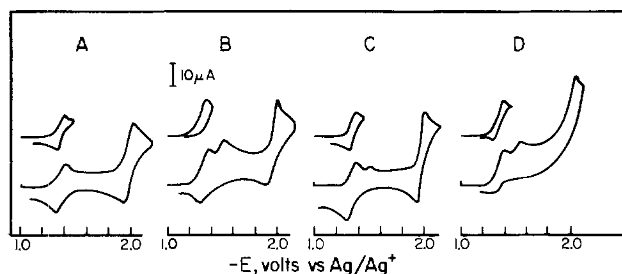

Fig. 3. Comparison of cyclic voltammograms for $Co(bipy)_3^{2+}$ and $Co(bipy)_2^{2+}$ in the presence of allyl chloride. Concentrations of cobalt complex: 1.0 mM; A, $Co(bipy)_2^{2+}$; B, $Co(bipy)_2^{2+}$ + 1 mM allyl chloride; C, $Co(bipy)_3^{2+}$ + 1 mM allyl chloride; D, $Co(bipy)_3^{2+}$ + 11 mM allyl chloride. The small upper voltammograms in each case show the response obtained if the potential scan is reversed just after the first (Co(II) → Co(I)) peak. Scan rate: 0.5 V sec^{-1}. Other conditions as in Fig. 2.

The behavior of the anodic half of the cyclic voltammograms in Fig. 2 and 3 is also understandable on this basis: Little or no wave is observed for the oxidation of $Co(bipy)_3^{+}$ and $Co(bipy)_2^{+}$ under conditions where the mixed complex is formed because the product of its further reduction is apparently not oxidizable. The anodic wave for Co(I) → Co(II) appears only under conditions where most of any allyl chloride present has been consumed so that $Co(bipy)_3^{+}$ or $Co(bipy)_2^{+}$ can persist at the electrode surface and be reoxidized.

By using a mercury electrode it proved possible to use the anodic depolarization of mercury at +400 mV to monitor the concentration of chloride ion released as the allyl chloride was reduced. There was a good correlation between the magnitude of the anodic wave due to chloride and the increase in the peak current of the wave for the reduction of cobalt(II) to cobalt(I).

Controlled Potential Coulometry

Electrolysis of solutions of $Co(bipy)_3^{2+}$ in acetonitrile at −1400 mV results in the quantitative formation of the intensely blue $Co(bipy)_3^{+}$ ion (1). If allyl chloride is present during such an electrolysis, the deep blue color does not develop during the initial stages of the electrolysis. Gas chromatographic analysis of the solution shows that the allyl chloride is consumed and 1,5-hexadiene is produced as the electrolysis proceeds (Fig. 5). The blue color of the $Co(bipy)_3^{+}$ ion persists in the solution only after all of the allyl chloride has been removed. The yield of 1,5-hexadiene and the quantity of charge required to reduce the allyl chloride are functions of the relative amounts of allyl chloride and cobalt complex present. Table I summarizes the coulometric data. When the ratio of allyl chloride to $Co(bipy)_3^{+}$ is small, *e.g.*, experiments 1 and 2 in Table I, the reduction consumes precisely one electron per molecule of allyl chloride and a prominent reaction product is 1,5-hexadiene (the other reaction products were not determined). As this ratio increases allyl chloride disappears from the solution before one electron per molecule is consumed (experiments 3 to 7, Table I), the more so the higher the concentration of allyl chloride. Gas chromatograms of the solutions resulting from such electrolyses (Fig. 6) contain a series of ill-defined peaks corresponding to components with high retention times as would be expected for oligomers of allyl chloride.

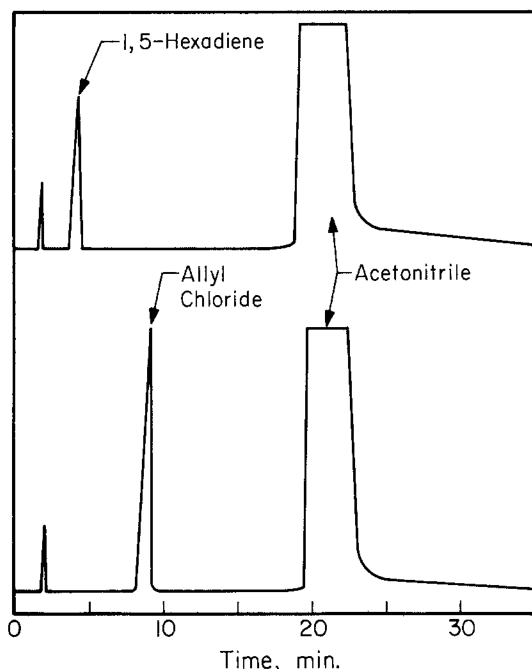

Fig. 5. Gas chromatograms of electrolysis solution before (lower chromatogram) and after (upper chromatogram) exhaustive electrolysis at −1.4V *vs.* Ag/0.1M Ag^+ at a platinum gauze electrode. Initial solution composition: 10 mM $Co(bipy)_3^{2+}$, 10 mM allyl chloride, 0.2M TEAP. The small peak with a retention time near 3 min was obtained in all chromatograms and may be an impurity in the solvent.

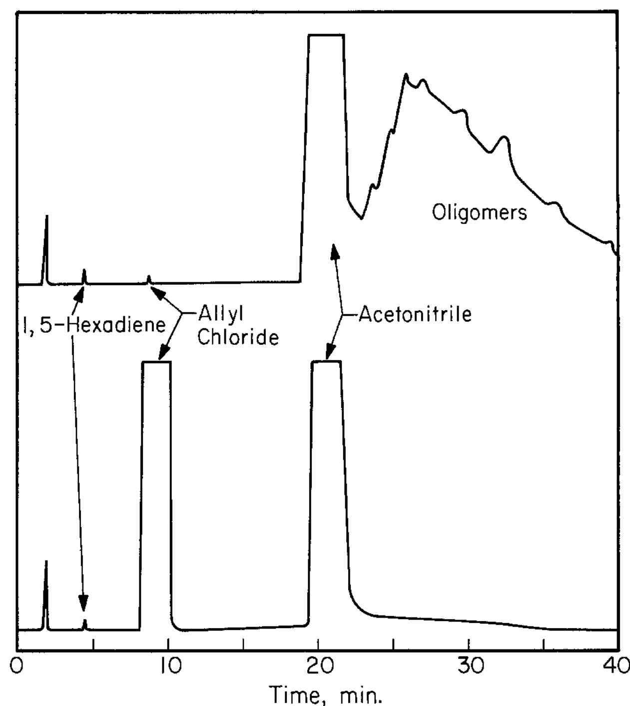

Fig. 6. Gas chromatograms of electrolysis solutions before (lower chromatogram) and after (upper chromatogram) exhaustive electrolysis at −1.4V *vs.* Ag/0.1M Ag^+. Initial solution composition: 4 mM $Co(bipy)_3^{2+}$, 5.7M allyl chloride, 0.2M TEAP. Other conditions as in Fig. 5.

During the electrolysis for experiment 7 in Table I a small amount of a white, pastelike solid precipitated from the solution. The solid was collected, washed with water, and vacuum dried at room temperature. Elemental analyses of the solid showed: (percentages) C, 47.5; H, 6.3; Cl, 44. Calculated for $(CH_2CHCH_2Cl)_n$: C, 47.1; H, 6.5; Cl, 46.4. Thus, at high ratios of allyl chloride to cobalt(I) polymerization of the allyl chloride ensues and is the major pathway by which it is removed from electrolysis solutions.

It is not necessary for the allyl chloride to be present during the electrolytic reduction of $Co(bipy)_3^{2+}$ to $Co(bipy)_3^+$ in order to achieve the reduction of allyl chloride. For example, the addition, under argon, of 0.1 mM of allyl chloride to 10 ml of a 10 mM solution of $Co(bipy)_3^+$ prepared by the electrolytic reduction of $Co(bipy)_3^{2+}$ resulted in the rapid fading of the intense blue color of the solution. Gas chromatographic analysis showed that all of the allyl chloride had been consumed and about 50% had been converted to a 1,5-hexadiene. Cyclic voltammograms of the resulting solution were indistinguishable from those obtained with a fresh solution of $Co(bipy)_3^{2+}$.

The cobalt catalyzed reduction of allyl chloride may also be carried out chemically using borohydride as the reductant since sodium borohydride rapidly reduces $Co(bipy)_{3\text{ or }2}^{2+}$ to $Co(bipy)_{3\text{ or }2}^{+}$.

Table I. Coulometric data for the catalyzed reduction of allyl chloride in the presence of $Co(bipy)_3^+$*

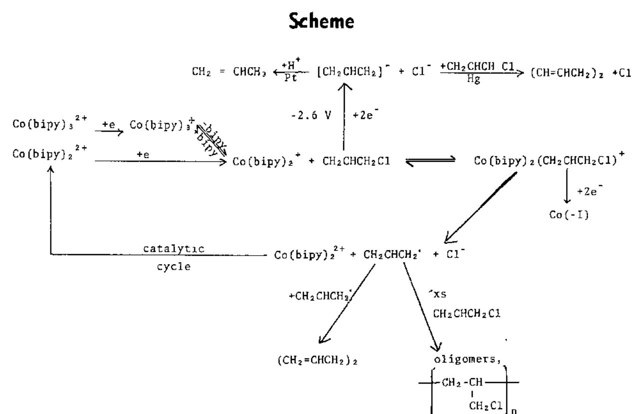
* Reduction at a platinum gauze electrode maintained at −1400 mV *vs.* Ag/0.1M Ag^+ in acetonitrile. Supporting electrolyte: 0.1M tetraethylammonium perchlorate; solution volume: 10 ml.
** n_{app} is the ratio of the charge consumed up to the point at which the blue color of $Co(bipy)_3^+$ first appeared to the calculated charge for the one-electron reduction of the allyl chloride present.
† The fate of the reduced allyl chloride which did not appear as 1,5-hexadiene was not determined.
‡ Electrode potential was −2600 mV.
§ Products were not monitored. Allyl chloride is reported to be reduced to a mixture of 1,5-hexadiene and 1-propene under these conditions (3, 4).

Discussion

The reduction of allyl chloride in the absence of cobalt complexes at mercury electrodes occurs near −2.6V (*vs.* Ag/0.1M Ag^+) in nonaqueous solvents and the polarographic limiting current corresponds to two electrons per molecule of allyl chloride (3). Nevertheless, the primary reduction product of nonexhaustive electrolysis in which the concentration of allyl chloride is maintained relatively high is 1,5-hexadiene (4) which requires only one electron per allyl chloride molecule (1-propene is also formed). These results have been rationalized (4) in terms of a chemical reaction between allyl chloride and allyl carbanion, the primary, two-electron reduction product.

In exhaustive, controlled potential electrolysis of 10 mM solutions of allyl chloride with platinum electrodes we obtained rapid, clean, two-electron reduction at −2.6V in acetonitrile which we presume leads to the quantitative formation of 1-propene (no 1,5-hexadiene was detected by gas chromatography). The essential difference produced by the addition of cobalt-2,2′-bipyridine complexes to the electrolysis solution is the conversion from the two-electron reduction which yields allyl carbanion to a one-electron reduction yielding the allyl radical. The Scheme summarizes the proposed course of the reduction of allyl chloride both in the presence and in the absence of cobalt-2,2′-bipyridine complexes.

Scheme



In the absence of cobalt a very negative electrode potential (−2.6V) is required for the reduction of allyl chloride but quantitative reduction can be achieved at −1.4V in the presence of $Co(bipy)_3^{2+}$ (or $Co(bipy)_2^{2+}$). In the catalytic cycle which leads to the reduction, $Co(bipy)_3^{2+}$ is regenerated and this accounts for the enhancement of the reduction wave for this complex in the presence of allyl chloride (Fig. 1-3).

The proposition that the catalytic reduction involves an intermediate in which the allyl chloride is bonded to a complex of cobalt(I) and 2,2′-bipyridine is supported by several pieces of evidence: (*i*) Addition of 2,2′-bipyridine inhibits and eventually eliminates the catalytic reduction of allyl chloride (Fig. 2) even though the production of $Co(bipy)_3^+$ is not impeded; (*ii*) the rate of the catalyzed reduction (as measured by the extent of the enhancement of the cobalt(II) reduction wave in cyclic voltammograms) is much higher when $Co(bipy)_2^+$ is used as catalyst (Fig. 3); (*iii*) the new voltammetric wave at −1500 mV produced by the addition of allyl chloride to solutions of $Co(bipy)_3^{2+}$ resembles in all regards the similar wave produced by acrylonitrile which is believed (1) to correspond to a stable, π-bonded, mixed complex in which the cobalt(I) is reduced to cobalt(−I). With acrylonitrile, the mixed complex is stable toward an intramolecular oxidation-reduction reaction, but with the more readily reducible allyl chloride the mixed complex decomposes as depicted in the Scheme.

The release of chloride anion in the decomposition of the mixed complex was confirmed by the appearance of an anodic wave at +400 mV when a mercury electrode was used to record cyclic voltammograms. That the other initial decomposition product is allyl radical is supported by the coulometric data (Table I). One electron per allyl chloride molecule is consumed in controlled potential electrolyses at ratios of allyl chloride to cobalt near unity. In addition, the appearance of oligomers of allyl chloride at higher ratios (Table I) is a strong indication that allyl radicals are present since the polymerization of allyl chloride requires radical (or cationic) initiation (5).

A rival mechanism for the decomposition of the mixed complex might involve the formation of a π-allyl anion complex of Co(III) similar to a species prepared by Bercaw *et al.* (6) from reaction of allyl alcohol with a mixed cyano and phosphine complex of cobalt(I). Such a reaction sequence seems less attractive for the cobalt 2,2′-bipyridine complexes because $Co(bipy)_2^{3+}$ is a rather strong oxidant ($E_f \sim -70$ mV *vs.* Ag/0.1M Ag^+) and allyl anion is so powerful a reductant ($E_{1/2} \sim -2.0$V *vs.* Ag/0.1M Ag^+) (3) that rapid decomposition of such a complex to $Co(bipy)_2^{2+}$ and allyl radical would be favored unless extraordinary stability were attributed to the bond between cobalt(III) and the π-allyl anion.

Conclusions

The primary purpose of this communication was to point out the remarkable effectiveness of cobalt-2,2′-bipyridine complexes as catalysts in the electroreduction of allyl chloride. The potential where the reduction commences becomes *ca.* 1.2V less negative in the presence of the catalyst. The mechanism proposed for the catalysis includes the initial formation of a π-complex between allyl chloride and $Co(bipy)_2^+$ which parallels the recently described coordination chemistry of $Co(bipy)_2^+$ and acrylonitrile (1). In the latter case, the lower reactivity of acrylonitrile terminates the reaction sequence with the coordination but with allyl chloride an intramolecular oxidation-reduction reaction ensues. Allyl bromide is itself reduced at potentials only slightly more negative than that at which $Co(bipy)_3^{2+}$ is reduced but addition of the latter does result in the catalyzed reduction of allyl bromide.

The ability of a number of activated olefins to form π-bonds with low valent cobalt-2,2′-bipyridine complexes (1) suggests that these complexes may serve a general role as catalytic agents for the reduction of sufficiently activated (*e.g.*, allyl chloride but not allyl alcohol or acrylonitrile) coordinated molecules.

Interfacial Behavior of *D*-Ribose, 2′-Deoxy-*D*-Ribose, and *D*-Ribose 5′-Phosphate

Viktor Brabec, Sherril D. Christian, and Glenn Dryhurst

Department of Chemistry, University of Oklahoma, Norman, Oklahoma 73019

ABSTRACT

The adsorption of *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate at the mercury electrode-electrolyte solution interface at *p*H 8.0 (0.5*M* NaF plus 0.01*M* Na_2HPO_4) has been studied by electrocapillary measurements. Each of these compounds is only weakly adsorbed with the free sugars being adsorbed at potentials close to the potential of zero charge (electrocapillary maximum potential). *D*-ribose 5′-phosphate, being extensively ionized at *p*H 8.0, is adsorbed mainly at a positively charged electrode. The areas occupied by these molecules at monolayer surface saturation suggest that they are all adsorbed with the average plane of atoms of the 5-membered sugar ring parallel to the electrode surface, *i.e.*, in a flat surface orientation. Information about the interfacial behavior of these sugars and sugar phosphate has been used to interpret in more detail the interfacial conformation of purine and pyrimidine nucleosides and nucleotides adsorbed at an electrode surface. It appears that pyrimidine nucleosides and nucleotides, such as uridine and uridine 5′-monophosphate, are adsorbed with the planar pyrimidine base adsorbed in a flat orientation on the electrode. The sugar residues must be adsorbed perpendicular to the electrode surface. Since pyrimidine nucleosides and nucleotides preferentially adopt an *anti* conformation, these molecules occupy significantly more surface area than the base. On the other hand, purine nucleosides and nucleotides, such as those of adenine, adopt a *syn* conformation in the adsorbed state at monolayer surface saturation. Again the purine base is adsorbed in a flat orientation on the electrode. This results in the sugar or sugar phosphate residues being largely rotated out of the plane of the electrode surface so that the adenine moieties can pack closely together. It is for this reason that the areas occupied by adenine, deoxyadenosine, and deoxyadenosine 5′-monophosphate are close to those observed for the free purine base.

Recent reports from this laboratory have described the interfacial behavior of adenine (1), thymine (2), and uracil (3) and their nucleosides and nucleotides at the mercury-aqueous solution interface at *p*H 8-9. These purines and pyrimidines are found naturally in all living organisms, particularly as components of nucleic acids. We are attempting to interpret the interfacial behavior of the purine and pyrimidine constituents of nucleic acids with a view to ultimately understanding the interfacial behavior of the complex nucleic acids themselves. There is considerable literature evidence that the nucleic acids are extensively associated with charged biological surfaces, such as the surfaces of mammalian cells and other biological membranes (4-7). There are indications that interactions of nucleic acids with biological interfaces (adsorption and subsequent conformational changes) are a prerequisite for the manifestation of the biological effects of these polynucleotides in mammalian systems *in vivo* and *in vitro* (8-10). It has also been known for some time that electric fields having magnitudes equivalent to those existing within the inner double layer at a charged cell surface-biological fluid interface affect the conformation of various polynucleotides in solution (11-13).

Recent work by Brabec and Palecek (14) strongly suggests that various double-stranded polynucleotides unfold at certain potentials at a mercury electrode.

We are employing a mercury electrode-electrolyte solution interface as a model of a biological surface-biological fluid interface to study the interfacial behavior of the constituents of nucleic acids and, ultimately, of natural and biosynthetic polynucleotides.

All of the compounds that we have studied exhibit an initial adsorption region where they are adsorbed with the virtually planar purine or pyrimidine residue in a flat orientation on the electrode surface. This region has been referred to as the dilute adsorption region (1-3, 15). In the case of thymine and uracil a surface reorientation process occurs at critical concentrations and potentials such that the molecules adopt a perpendicular stance on the electrode (3, 16). We suspect that a similar reorientation occurs with the adenine derivatives although this is currently being investigated.

In order to facilitate further discussion some results relevant to this paper for adenine and uracil and their nucleosides and nucleotides in the dilute adsorption region are presented in Table I. It will be noted that in the adenine series the areas occupied by adenine and its nucleosides and nucleotides are very similar. This has been interpreted (1) as indicating that primarily the adenine residue is adsorbed to the electrode

§ From work in progress in this laboratory.

surface with substituent ribose, deoxyribose, ribosephosphate, or deoxyribosephosphate groups being largely tilted away from the electrode surface at surface saturation, *i.e.*, as $\theta \to 1$. However, in the case of the uracil series, the areas occupied by the nucleoside and nucleotide are significantly larger than for the free base. This has been interpreted (3, 16) as indicating that substituent sugar or sugar-phosphate groups remain in the vicinity of the electrode surface at surface saturation.

The standard free energy of adsorption of these various purine and pyrimidine derivatives reveal that the nucleosides and nucleotides have significantly larger negative ΔG° values than the free bases (Table I). The ΔG° values reported in Table I are those at the ECM potential for the supporting electrolyte. The same general trend is also noticed at the potentials of maximum adsorption of each species, which are normally within *ca.* 50 mV of the ECM potential for pure supporting electrolyte solution. These observations imply that the sugar and sugar phosphate residues enhance the adsorption of these compounds at potentials in the region of maximum adsorption.

This investigation was initiated, therefore, to elucidate the interfacial behavior of *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate at the mercury-solution interface. The very high cost of 2′-deoxy-*D*-ribose 5′-phosphate precluded an investigation of this material, although we expect it to parallel *D*-ribose 5′-phosphate.

Experimental

Chemicals.—*D*-Ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate were obtained from Calbiochem and were used without further purification. All measurements were performed in 0.5*M* sodium fluoride with 0.01*M* Na_2HPO_4, *p*H 8.0. Samples were weighed directly into this supporting electrolyte solution and, after dissolution, deaerated with water-saturated nitrogen before study.

Differential capacitance measurements.—Differential capacitance measurements were obtained by the phase-selective a-c polarographic method outlined in previous reports (1, 2). Differential capacitance *vs.* potential (*C vs. E*) curves for *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate were not coincident with the *C vs. E* curve of pure background electrolyte solution at very negative potentials. It was not possible, therefore, to use the double back-integration method of Grahame *et al.* (17) to calculate interfacial tension values.

Direct interfacial tension measurements.—An apparatus for interfacial tension measurements, similar to that used by Hansen *et al.* (18) and described in detail elsewhere (16), was utilized. A J-shaped Pyrex capillary was employed; this capillary was siliconized. With this capillary, the pressure at a particular applied potential necessary to cause mercury drops to form at the capillary tip was measured with a Mensor Corporation Quartz Manometer pressure gauge. This method is, of course, a maximum bubble pressure experiment. The internal radius, *r*, of the J-shaped capillary at its tip was 0.004105 cm; hence, the total measured pressure, Δp, is directly proportional to the interfacial tension, γ, by the relationship

$$\gamma = \frac{\Delta p}{2r} \quad [1]$$

The value of *r* was determined with 0.10*N* $HClO_4$ where the interfacial tension at −0.500V at 25°C is 425.56 dyne cm^{-1} (18). All potentials are referred to the saturated calomel electrode at 25°C.

Measurements of interfacial tension were normally taken at 50 mV intervals between −0.2 and −1.8V.

In order to obtain charge values from interfacial tension measurements, the electrocapillary data were first fitted to a sixth-order polynomial of the type $\gamma = A_1(E - E_{ECM})^2 + A_2(E - E_{ECM})^3 + \ldots A_5(E - E_{ECM})^6$, where E_{ECM} is the potential of the electrocapillary maximum. A nonlinear least squares procedure was employed to obtain optimum values of all parameters. The root mean square (rms) deviation observed over all concentrations for each adsorbate never exceeded 0.1 dyne cm^{-1}. The use of polynomials of higher degrees did not improve the γ *vs. E* fit. Charge, *q*, *vs.* potential, *E*, curves were then obtained by analytical differentiation of the fitted electrocapillary curves with respect to potential.

Results and Discussion

Because it was necessary to employ quite high concentrations of the sugars studied in order to obtain significant changes in interfacial tension, the activities of each compound were measured over the entire concentration range of interest in fluoride buffer *p*H 8.0. Solute activities were inferred from surface spreading pressure-surface charge data by methods which have been outlined elsewhere (19). In the case of *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate there was no evidence for activity being different from concentration even at the highest bulk-solution concentrations used (*vide infra*).

Typical electrocapillary curves (γ *vs. E*) for *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate are shown in Fig. 1. These curves indicate that all three compounds are adsorbed, *i.e.*, decrease interfacial tension compared to pure supporting electrolyte solution. *D*-ribose 5′-phosphate is adsorbed extensively only at potentials more positive than about −0.6V.

From γ *vs. E* data of the type presented in Fig. 1 the surface spreading pressure, π, as a function of electrode potential, *E*, and solute activity, *a*, was calculated from Eq. [2]

$$\pi = \gamma_w(E) - \gamma(E) \quad [2]$$

where γ_w is the value of the interfacial tension for the pure background electrolyte solution at $a = 0$.

For each compound studied, plots of π *vs.* the logarithm of the solute activity had the same geometrical shape at different potentials and, hence, were superimposable by abscissa translation (Fig. 2). The calculated curve in Fig. 2 represents the least squares fit of π, *a*, and *E* data to the empirical equation

$$\pi = A\{\ln[1 + Ba]\}\left[1 + \frac{\alpha a}{(1 + Ba)^2} + \frac{\beta_a{}^2}{(1 + Ba)^3} + \cdots\right] \quad [3]$$

In this equation *A* is equal to $\Gamma_m RT$, where Γ_m is the surface excess of the solute at $\theta = 1$. The detailed method of applying this equation has been outlined in previous reports (2, 3, 16).

Once a composite fit was obtained for data at several potentials, the same functional form was used to fit data at fixed potentials. In performing these fits it was assumed that the value of $\Gamma_m RT$ (or *A* in Eq. [3]) was constant, which is quite reasonable considering the excellent composite π *vs.* ln *a* fits. Analytical differentiation of the π *vs.* ln *a* fits obtained at fixed potentials gives, according to the Gibbs equation (Eq. [4])

$$\Gamma = \frac{1}{RT} \cdot \frac{d\pi}{d \ln a} \quad [4]$$

the value of ΓRT corresponding to each activity at each electrode potential.

The congruence of adsorption isotherms with respect to both potential and charge was tested for in the following fashion (2, 3, 16). In order to test for congruence with respect to potential plots of charge, *q vs.* ΓRT were prepared at fixed potentials. Throughout ranges of potential where *q vs.* ΓRT plots are linear the

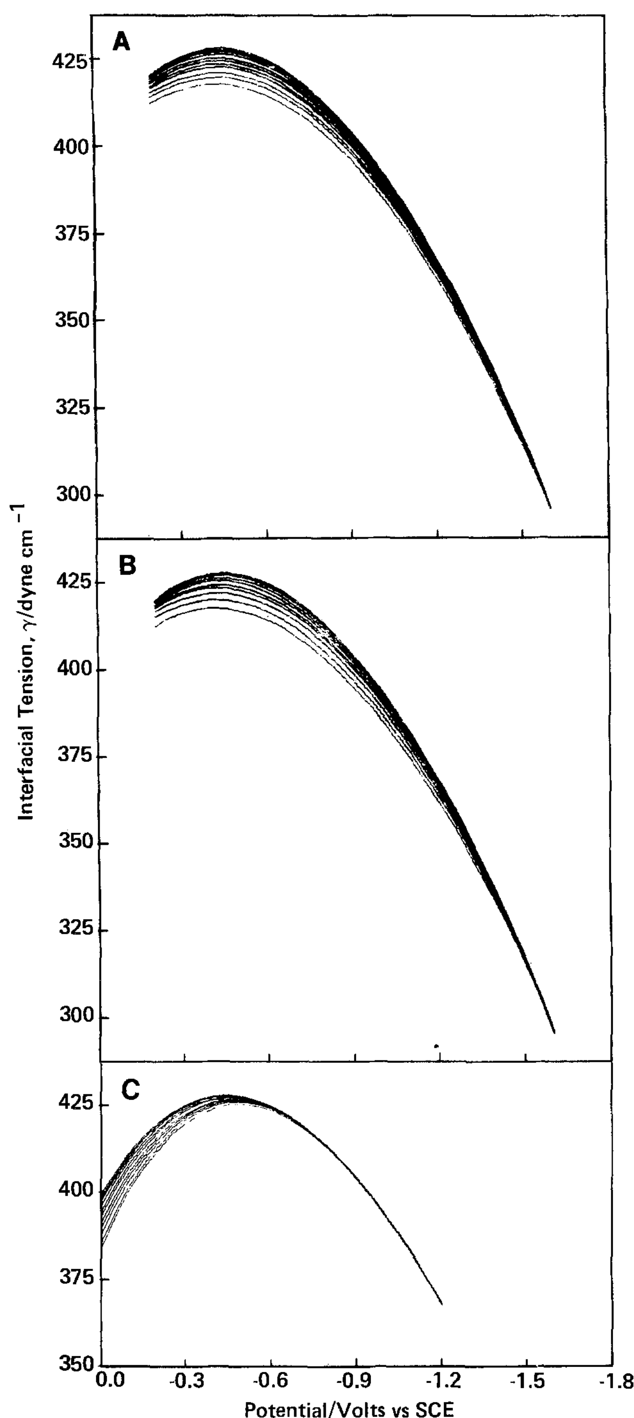

Fig. 1. Electrocapillary curves for (A) *D*-ribose (0-300 mM), (B) 2′-deoxy-*D*-ribose (0-100 mM), and (C) *D*-ribose 5′phosphate (0-200 mM) in 0.5*M* NaF with 0.01*M* Na_2HPO_4 buffer *p*H 8.0. Interfacial tension, γ, was measured by the maximum bubble pressure method.

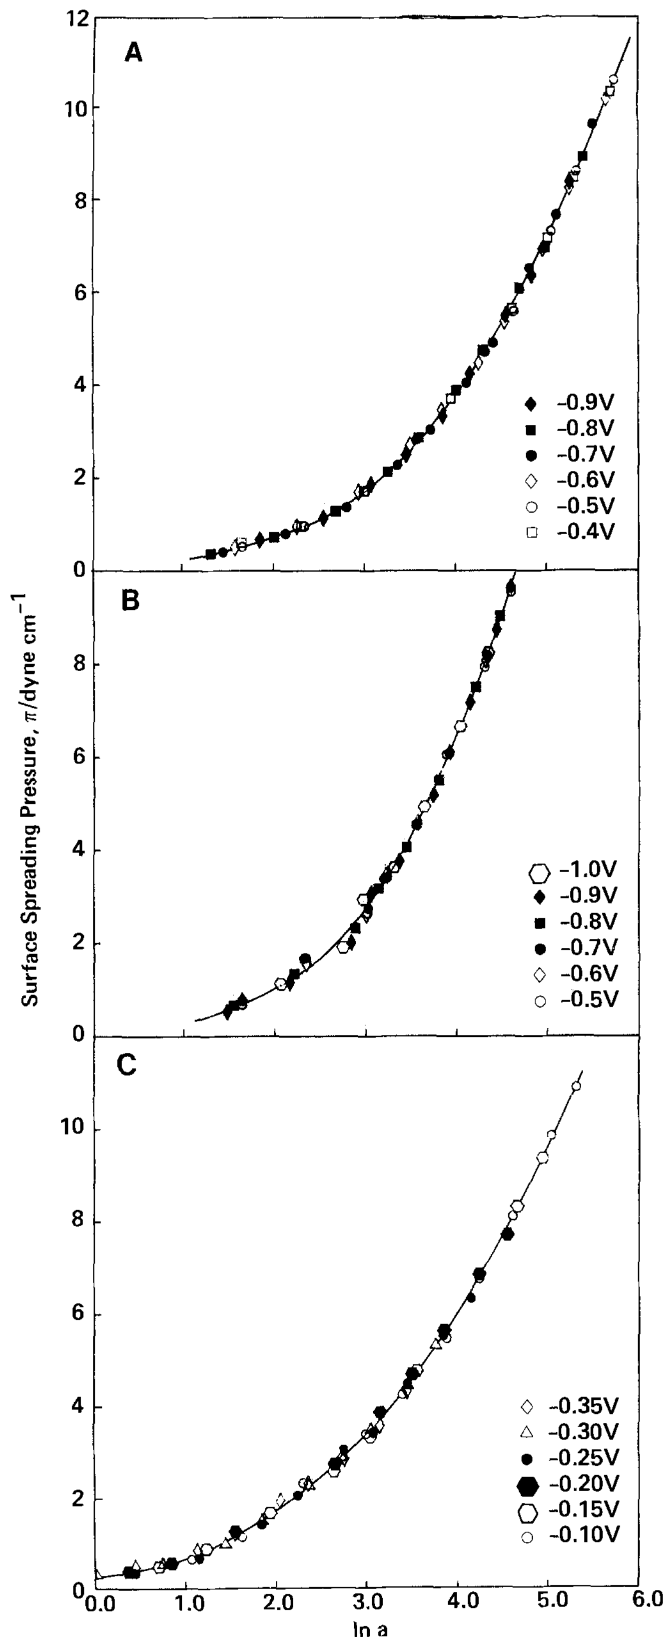

Fig. 2. Composite π *vs.* ln *a* plots for (A) *D*-ribose, (B) 2′deoxy-*D*-ribose, and (C) *D*-ribose-5′-phosphate in 0.5*M* NaF with 0.01*M* Na_2HPO_4 *p*H 8.0. Potentials for each point are indicated in the figure. Data were obtained from maximum bubble pressure experiments. The solid line is the best least squares fit of all π, *a*, *E* data. The rms deviation in π from the calculated curve for (A) is 0.094 dyne cm^{-1}, (B) 0.133 dyne cm^{-1}, and for (C) 0.096 dyne cm^{-1}.

isotherms must be congruent with respect to potential. Charge values at each potential and solute activity were obtained by analytical differentiation of electrocapillary curves (see Experimental). The values of ΓRT at the same potential and solute activity were obtained by analytical differentiation of individual π *vs.* ln *a* curves and hence are independent of any adsorption model. Typical *q* *vs.* ΓRT data for *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate are shown in Fig. 3. It is clear that for *D*-ribose and 2′-deoxy-*D*-ribose (Fig. 3A and B) the isotherms are congruent with respect to potential between at least -0.2 and -1.1V. In the case of *D*-ribose 5′-phosphate (Fig. 3C), however, the congruence conditions prevail between -0.1 and *ca.* -0.4V. At potentials more negative than -0.4V ΓRT values become extremely small. It is possible that the reason for the apparent noncongruence

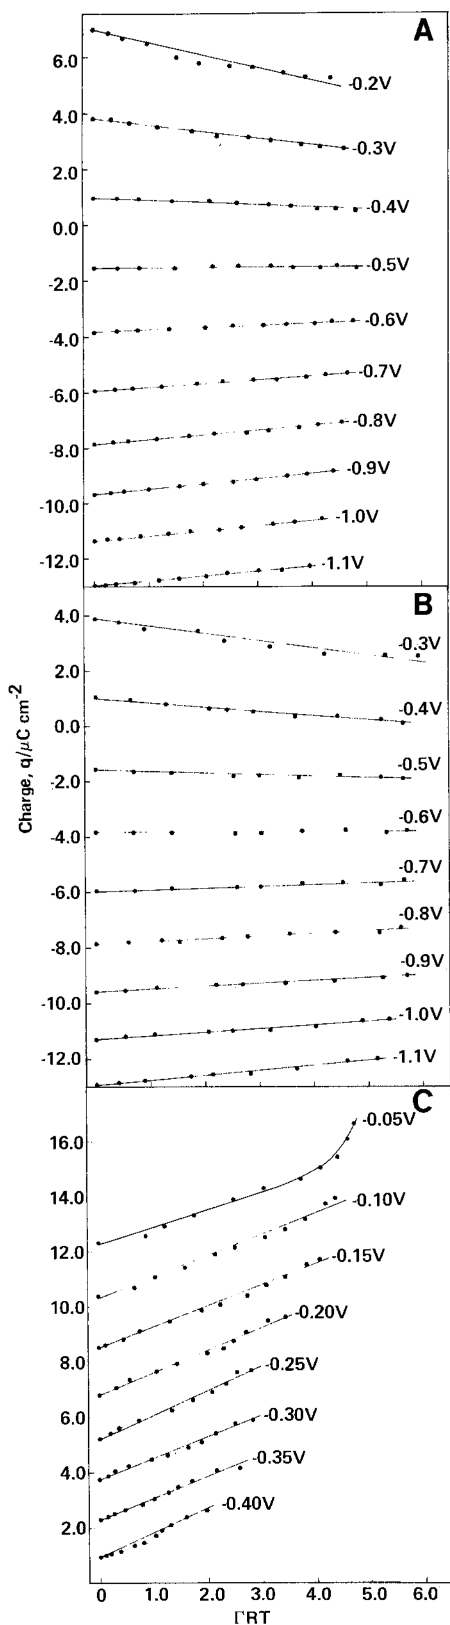

Fig. 3. Test of congruence of electrosorption isotherms with respect to potential in 0.5M NaF with 0.01M Na_2HPO_4 pH 8.0 for (A) D-ribose, (B) 2′-deoxy-D-ribose, and (C) D-ribose 5′-phosphate. Potential values are shown in the figure. Data obtained from maximum bubble pressure results.

of the isotherms of D-ribose 5′-phosphate at −0.05V (Fig. 3C) is that at this positive potential significant oxidation of the mercury electrode begins to take place.

Nevertheless, the plots shown in Fig. 3 indicate that, over the range of accessible potentials were the compounds adsorb to an appreciable extent, the adsorption isotherms are congruent with respect to potential.

Plots of potential, E *vs.* ΓRT at fixed charge values were prepared to decide whether the electrosorption isotherms were congruent with respect to charge (2, 3, 16). Excellent linear relationships between E and ΓRT were noted over a relatively large range of charge values (Fig. 4) which implies that the electrosorption

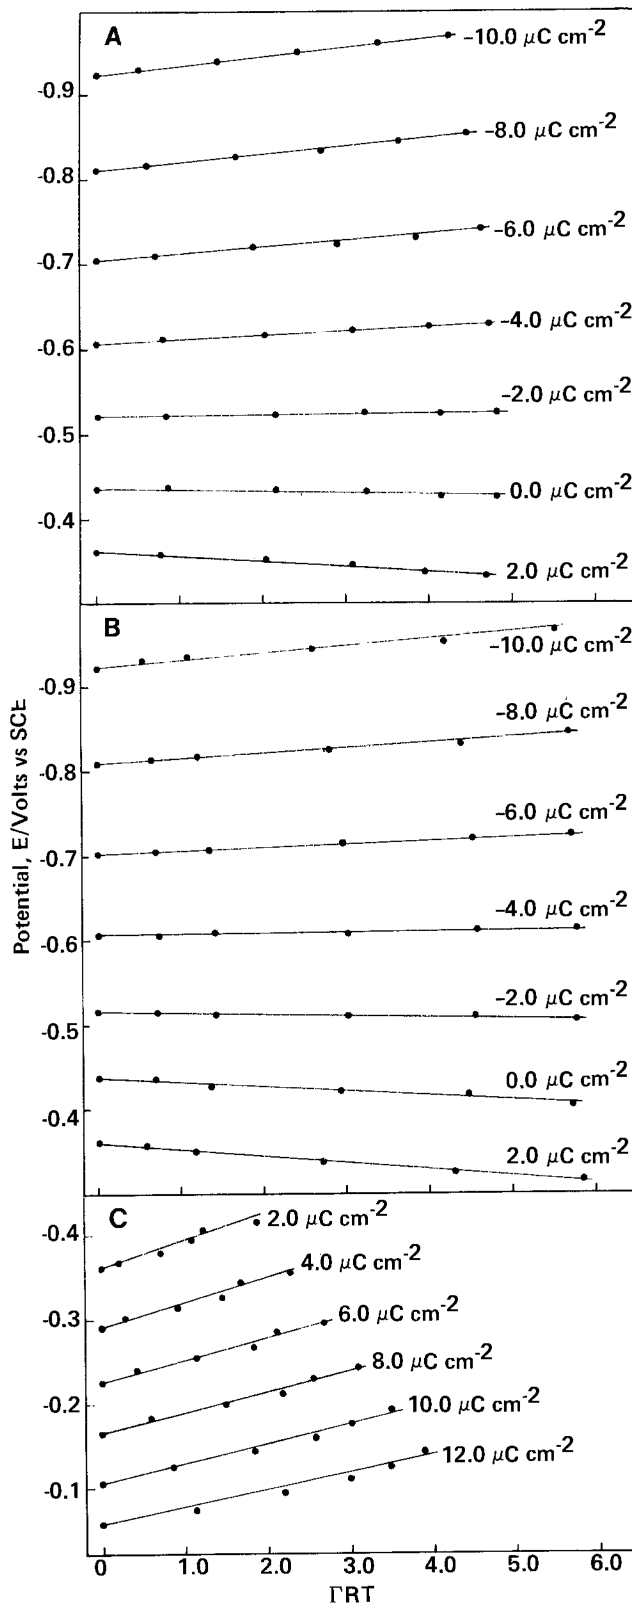

Fig. 4. Test of congruence of electrosorption isotherms with respect to charge in 0.5M NaF with 0.01M Na_2HPO_4 pH 8.0 for (A) D-ribose, (B) 2′-deoxy-D-ribose, and (C) D-ribose 5′-phosphate. Charge values are shown in the figure. Data obtained from maximum bubble pressure results.

of the sugars and sugar phosphate is apparently congruent with respect to charge.

The observation that the adsorption isotherms of these compounds are congruent with respect to both potential and charge has been noted for other compounds (16). Such behavior is expected for organic solutes having relatively large C' values [where C' is the capacitance at complete monolayer saturation and which is assumed to be constant and independent of potential (20)], at relatively low surface activity (21).

Since the electrosorption isotherms of *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate are all congruent with respect to potential, π, E, and a data were fitted to the Frumkin isotherm model. The fixed potential form of the Frumkin equation is shown below (Eq. [5])

$$\frac{\theta}{1-\theta} = Ba \exp 2\alpha\theta \qquad [5]$$

where θ is the fractional surface coverage, and B and α are constants depending on interactions between the adsorbed molecules and the electrode surface and on lateral intermolecular interactions between the adsorbed organic molecules, respectively. The constant B is dependent on potential according to Eq. [6] (22)

$$B = B_0 \exp -[\phi/\Gamma_m RT] \qquad [6]$$

where the function ϕ is defined in Eq. [7]

$$\phi = [\gamma_w(O) - \gamma_w(E)] + C'EE_N - \frac{C'E^2}{2} \qquad [7]$$

In this expression E is the potential relative to the ECM potential for the pure supporting electrolyte solution, E_N is the ECM potential for $\theta = 1$, and γ_w is the interfacial tension for the pure electrolyte solution. The term B_0 in Eq. [6] is the value of the constant B at the ECM potential for pure electrolyte solution. Combination of Eq. [5] and [6] gives the generalized form of the Frumkin equation (Eq. [8])

$$\frac{\theta}{1-\theta} = B_0 a \exp (2\alpha\theta) \cdot \exp -[\phi/\Gamma_m RT] \qquad [8]$$

The parameters C', E_N, α, B_0, and Γ_m are evaluated from Eq. [7] and [8] by a nonlinear least squares method described extensively elsewhere (1, 2, 16).

Some reduced isotherms for all three solutes studied are shown in Fig. 5. Experimental ΓRT values were obtained by differentiation of π *vs.* ln a plots at individual potentials. The solid curve is the best fit of all π, E, and a data to the Frumkin model. The individual experimental points, which were obtained without assuming an adsorption model, were in excellent agreement with the calculated Frumkin isotherm. The superimposability of the isotherms at various potentials shown in Fig. 5 may also be regarded as a test of congruence of the electrosorption isotherms as a function of potential (23).

Detailed results of analysis of π, E, and a data for *D*-ribose, 2′-deoxy-*D*-ribose, and *D*-ribose 5′-phosphate are presented in Table II. A number of conclusions may be drawn from these results and those presented elsewhere in this report. First, the free energy of adsorption, $\Delta G°$, at the ECM potential indicates that in the potential regions where adenine, uracil, and their derivatives are most strongly adsorbed (*ca.* −0.4 to −0.6V) the sugar and sugar phosphate groups are significantly less strongly adsorbed than the molecules which contain a purine or pyrimidine base residue. The sugar and sugar phosphate groups are not appreciably adsorbed at very negative potentials.

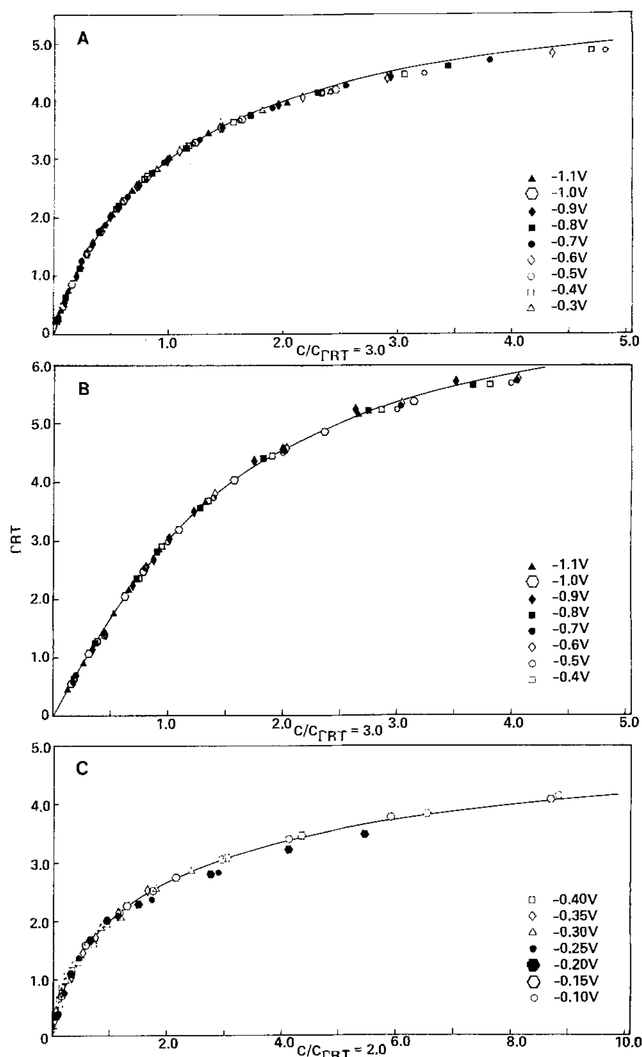

Fig. 5. Reduced adsorption isotherms in 0.5*M* NaF with 0.01*M* Na_2HPO_4 *pH* 8.0 for (A) *D*-ribose, (B) 2′-deoxy-*D*-ribose, and (C) *D*-ribose 5′-phosphate. The solid line is the best fit of all π, E, and a data to the generalized Frumkin equation with (A) $\alpha = 0.28$, $B_0 = 16.45 \times 10^3$, $\Gamma_m RT = 6.76$, $C' = 17.42$ μF cm^{-2}, $E_N = -0.414$V; (B) $\alpha = 0.41$, $B_0 = 20.83 \times 10^3$, $\Gamma_m RT = 7.47$, $C' = 17.86$ μF cm^{-2}, $E_N = -0.395$V; and (C) $\alpha = -0.91$, $B_0 = 3.83 \times 10^3$, $\Gamma_m RT = 5.86$, $C' = 33.68$ μF cm^{-2}, $E_N = -0.539$V. Potentials are shown in the figure.

† Standard free energy of adsorption at the ECM potential for pure background electrolyte solution based on infinite dilution standard states for the adsorbate both in solution (at unit molarity) and on the surface (at unit value of $\theta/1-\theta$). $\Delta G° = -RT \ln B_0$.
‡ ECM potential when $\theta = 1$.

The area occupied by D-ribose is 61Å^2, by 2'-deoxy-D-ribose 55Å^2, while that occupied by D-ribose 5'-phosphate is 70Å^2 (Table II).

In order to decide from the latter values the probable surface orientation of each of the molecules, projected areas were calculated based on their crystal structures (24). These areas were calculated for each molecule in two orientations. The first was the area that the molecule would be expected to occupy when the approximately planar sugar ring system is in a flat orientation on the electrode surface [specifically, with the plane formed by the C'(1), O'(1), and C'(4) atoms parallel to the electrode surface]. The second was the area the molecule should occupy when the approximately planar sugar ring is perpendicular to the electrode surface [*i.e.*, the plane formed by C'(1), O'(1), and C'(4) atoms]. These areas were calculated using the ORTEP programs of Johnson (25). Some typical projected areas for D-ribose, 2'-deoxy-D-ribose, and D-ribose 5'-phosphate with the sugar ring in a flat surface orientation are shown in Fig. 6. Projected areas for the same molecules with the sugar ring in a perpendicular surface orientation are presented in Fig. 7. It should be noted that the areas shown in Fig. 6 and 7 are based on the C'(3)-*endo* conformation of D-ribose and the C'(2)-*endo* conformation of 2'-deoxy-D-ribose. These conformations were used because in RNA D-ribose is in the C'(3)-*endo* form while in the common form of DNA (B-DNA) the 2'-deoxy-D-ribose occurs in the C'(3)-*endo* conformation. An excellent review of the conformation of purine and pyrimidine bases, nucleosides, and nucleotides has been prepared by Ts'o (26).

The projected areas occupied by D-ribose, 2'-deoxy-D-ribose, and D-ribose 5'-phosphate in the flat surface orientation are 52, 39, and 59Å^2, respectively (Fig. 6). When in a perpendicular surface orientation the projected areas occupied by D-ribose and 2'-deoxy-D-ribose are 43 and 45Å^2, respectively, while for D-ribose 5'-phosphate the area with the perpendicular orientation of the sugar, 61Å^2, is essentially identical to that observed for the flat orientation of the sugar, 59Å^2 (Fig. 7).

Comparison of the projected areas shown in Fig. 6 and 7 with the measured areas at the electrode surface at surface saturation (Table II) clearly supports the view that in the case of D-ribose the molecule is probably adsorbed at the electrode surface in a flat orientation.

Since the projected area of 2'-deoxy-D-ribose in the flat and perpendicular orientations (39 and 45Å^2, respectively) are so similar it is difficult to be certain of the real surface orientation. However, by analogy with D-ribose it seems reasonable to assume that the flat orientation is more likely. The projected area of D-ribose 5'-phosphate is also virtually the same when the sugar residue is flat or perpendicular to the electrode and both areas are close to that observed from experimental measurements. However, in view of the flat surface orientation of the free sugars, it is probable that the sugar phosphate is also adsorbed with the sugar in a flat orientation.

Interfacial behavior of nucleosides and nucleotides.—The results presented in this report indicate that D-ribose, 2'-deoxy-D-ribose, and D-ribose 5'-phosphate are relatively weakly adsorbed (Table II) and only at potentials close to the ECM potential for pure supporting electrolyte solution. The electrode areas occupied by these molecules at surface saturation have been measured experimentally and indicate that they are probably adsorbed with the sugar ring in a flat surface orientation.

These results may be used to better understand the surface conformation of purine and pyrimidine nucleosides and nucleotides at the electrode/solution interface. Typical adsorption parameters for adenine and uracil and their nucleosides and nucleotides are presented in Table I.

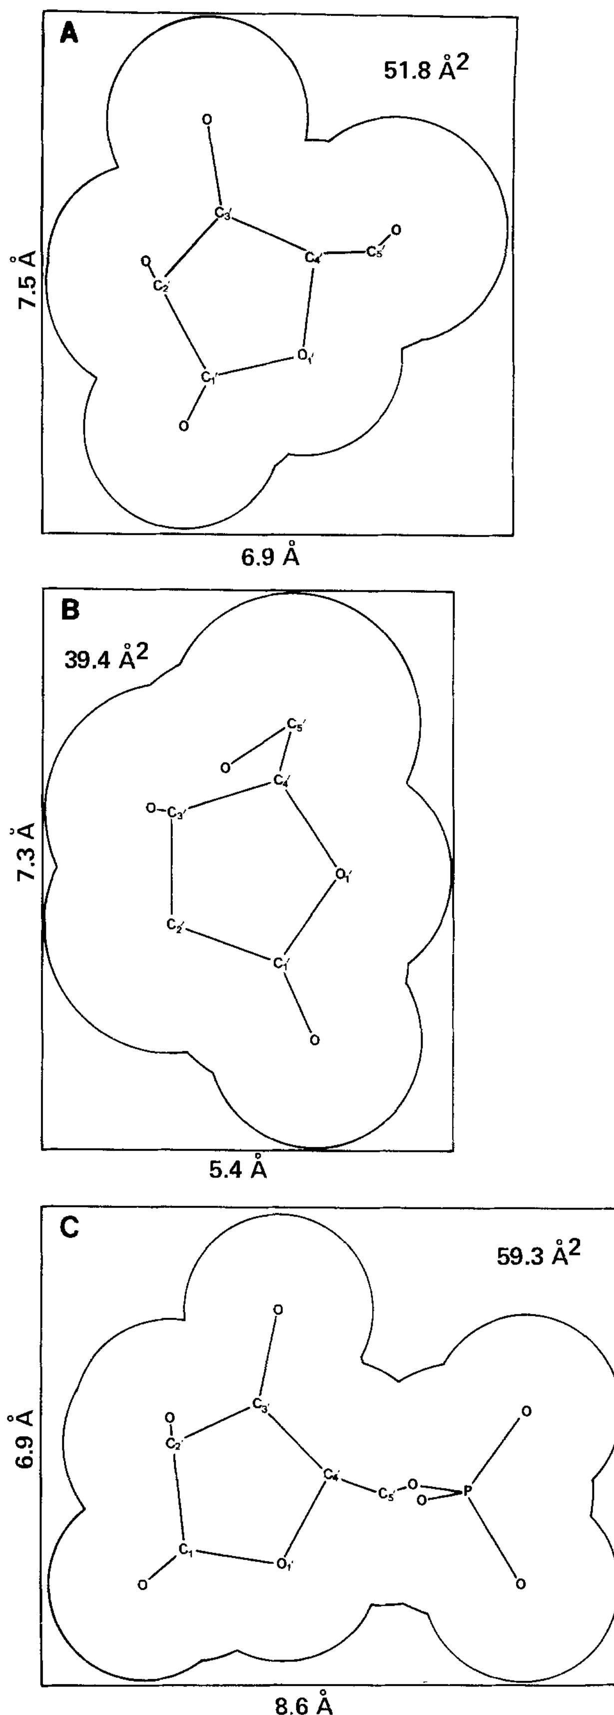

Fig. 6. Projected areas occupied by (A) D-ribose, (B) 2'-deoxy-D-ribose, and (C) D-ribose 5'-phosphate when the sugar ring is in a flat surface orientation. The projections refer to the C(3) *endo* conformation of the ribose residue and C'(2) *endo* conformation of deoxyribose.

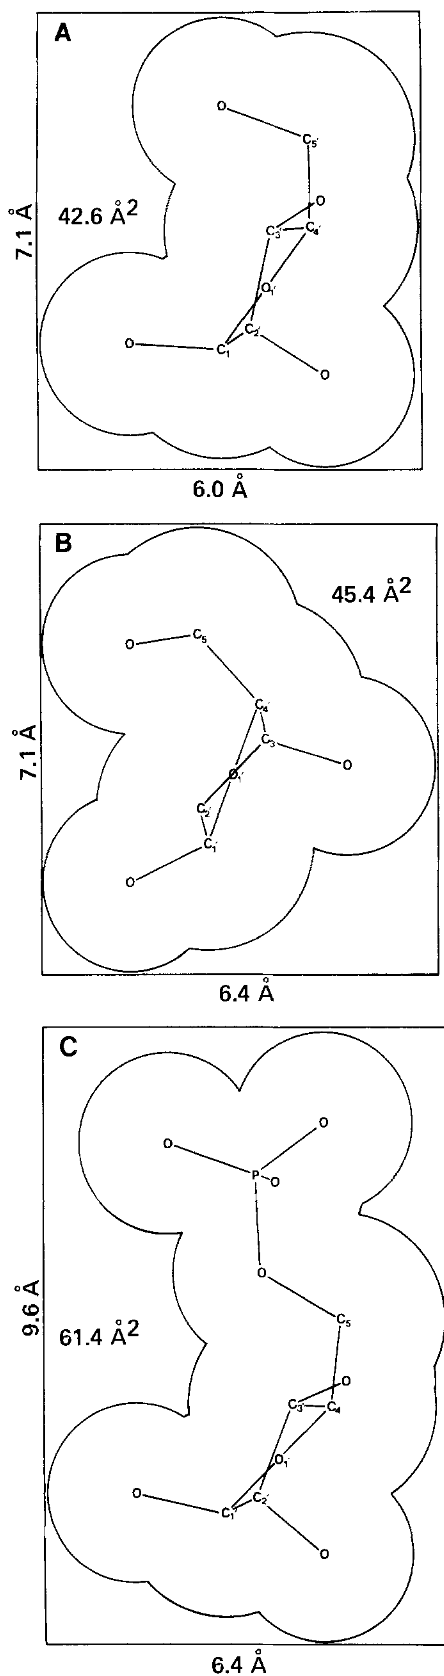

Fig. 7. Projected areas occupied by (A) *D*-ribose, (B) 2'-deoxy-*D*-ribose, and (C) *D*-ribose 5'-phosphate when the sugar ring is in a perpendicular surface orientation. The projections refer to the C'(3) *endo* conformation of the ribose residue and C'(2) *endo* conformation of the deoxyribose residue.

In considering the adsorption of such purine and pyrimidine nucleosides and nucleotides it seems reasonable to conclude that the base residue will preferentially adsorb with the planes of the rings parallel to the surface. This is so because the base is always more strongly adsorbed than the sugar or sugar phosphate residue (compare $\Delta G°$ values in Tables I and II). If the purine or pyrimidine base residue is adsorbed with plane of the ring parallel to the electrode surface, then it is clearly impossible for the sugar residue to adopt a similar surface orientation because the average plane of atoms in the sugar ring is approximately perpendicular to the base ring system (26).

The conformations of purine and pyrimidine nucleosides and nucleotides can be better understood by consideration of the sugar-base torsion angle, ϕ_{CN}, and the related *syn* and *anti* conformations which are defined in Fig. 8.

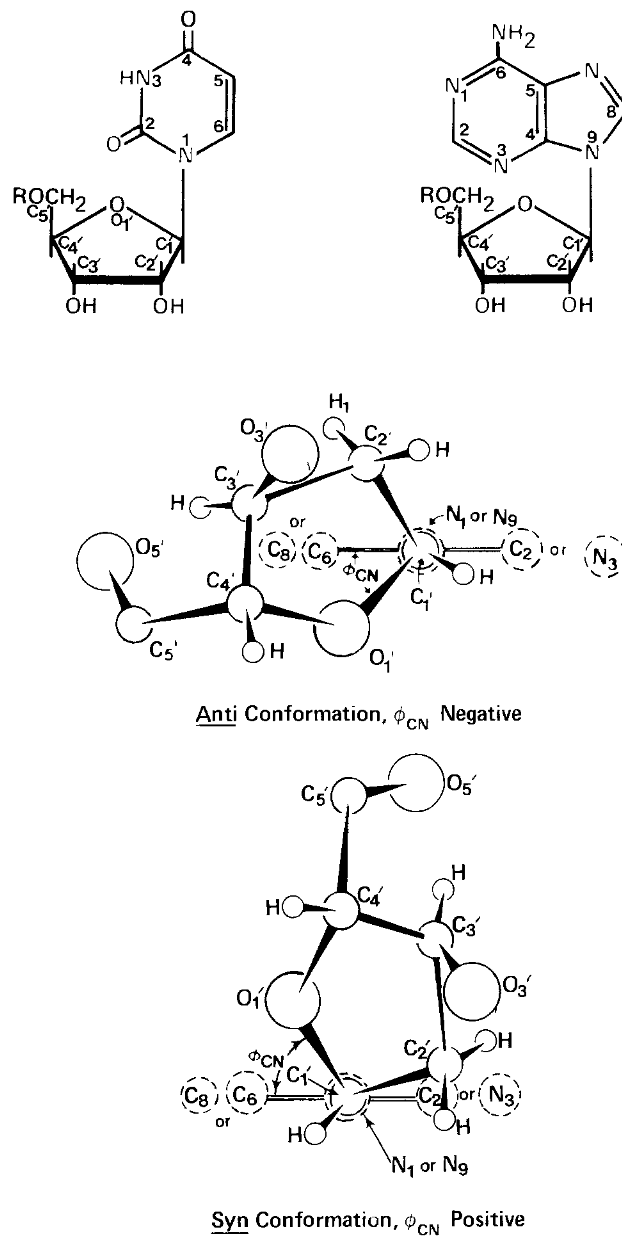

Fig. 8. Schematic illustration of the torsion angle in a pyrimidine or purine nucleoside [after Ts'o (26) and Hashemeyer and Rich (27)]. The plane of the base is viewed end-on with the glycosyl bond between C'(1) and *N*(1) (for a pyrimidine) or *N*(9) (for a purine) of the base perpendicular to the page. The torsion angle, ϕ_{CN}, is the dihedral angle between the plane of the base and the plane formed by the C'(1) to *N*(1) bond. The torsion angle is zero when *O*'(1) lies directly in front of C(6) [or C(8) for a purine] and positive angles are measured when C'(1) to *O*'(1) is rotated in a clockwise direction when viewing from C'(1) to *N*. When ϕ_{CN} is negative (*ca.* $-30°$) the system is in an *anti* conformation. When ϕ_{CN} is positive (*ca.* $+150°$) the system is in a *syn* conformation (28).

Extensive x-ray diffraction studies have revealed that pyrimidine nucleosides and nucleotides, including those of uracil, have negative values of ϕ_{CN} and exist in the *anti* conformation (26). In the case of thymidine ϕ_{CN} is $-39°$ (29) while for uridine the value is probably similar (26). In the case of deoxyadenosine [$\phi_{CN} = -3°$ (30)] the *anti* conformation is also adopted. However, the extensive studies of Haschemeyer and Rich (27) and others (31, 32) indicate that for the pyrimidine nucleosides and nucleotides the barriers between the *syn* and *anti* conformations are large. On the other hand, the steric barrier to the interconversion between *syn* and *anti* conformations in purine nucleosides and nucleotides is very low. The difference in energy between the *syn* and *anti* forms in the purine systems is probably quite small, although somewhat larger energy differences may exist for the pyrimidine systems.

In the *anti* conformation with a value of ϕ_{CN} of about $-30°$ and the base plane parallel to the electrode surface molecular models reveal that the surface area occupied by uridine should be equal to the projected area of the base [53Å^2 (3)] plus the projected area of the *D*-ribose moiety in a perpendicular orientation [43Å^2 (Fig. 7)] for a total area of 97Å^2. This is very close to the area occupied by uridine measured by capacitance and maximum bubble pressure techniques [104Å^2, Table I (2)]. Similarly, the area occupied by uridine 5′-monophosphate should, on the basis of the above conformation, be the area of base [53Å^2 (3)] plus that of the perpendicular sugar with attached phosphate [61Å^2, Fig. 7] or 114Å^2, which again compares very well with the experimentally determined surface occupied of 120Å^2 (Table I).

Thus, these results seem to support the general conclusion that the nucleosides and nucleotides of uracil adopt the expected *anti* conformation on the electrode surface. It should also be stressed that in the latter conformation the almost perpendicular sugar residue and the phosphate residue are in close vicinity to the electrode surface and occupy projected areas very similar to that shown in Fig. 7C. Although we have not presented the data in this report, the interfacial behavior of thymine, thymidine, and thymidine 5′-monophosphate may be rationalized by the same arguments presented for the uridine systems.

In the case of adenine and its nucleosides and nucleotides, experimental measurements (Table I) reveal that the nucleotide occupies only about 20% more surface than the nucleoside which in turn occupies an area very similar to the parent base. This behavior can be rationalized by the fact that little energy is required to cause rotation about the $N(9)$- $C'(1)$ glycosyl linkage; *i.e.*, adenosine or adenosine 5′-monophosphate can readily adopt either the *syn* or *anti* conformations. In the *syn* conformation (*i.e.*, positive values of ϕ_{CN}) molecular models reveal that the sugar ring oxygen (O′(1)) and the $C'(5)H_2OH$ or $C'(5)$-H_2OPO_3 groups can be moved completely out of the plane of the surface. The net result is that in the closely packed monolayer (at $\theta \rightarrow 1$), the adsorbed nucleoside or nucleotide molecules attach with $C'(1)$ and $C'(2)$ in close proximity to the plane of the surface and with $C'(3)$, $C'(4)$, and $C'(5)$ and the ring oxygen elevated above the plane of the electrode. This arrangement permits the adenine moiety to have maximum contact with the mercury and to adsorb in a two-dimensional array with relatively little increase in the area over that of the purine itself.

Some additional comments may be made relative to the values of $\Delta G°$ for the sugars, sugar phosphates, nucleosides, and nucleotides. As has been noted above, it seems unlikely on structural grounds that both the purine or pyrimidine ring and the average plane of the sugar ring will simultaenously lie in the plane of the surface. Therefore, it is somewhat surprising that the sum of $\Delta G°$ values for the sugar (or sugar phosphate) and the free bases nearly equals $\Delta G°$ for the nucleosides (or nucleotides). Thus, the increase in $-\Delta G°$ (from base to nucleoside) is on average about 1290 cal/mole for the three systems, compared to $-\Delta G° =$ 1700 cal/mole for *D*-ribose and 1800 cal/mole for 2′-deoxy-*D*-ribose, and the increase in $-\Delta G°$ from base to nucleotide averages 620 cal, compared to $-\Delta G° = 800$ cal for *D*-ribose 5′-phosphate. It may be that the free energy of adsorption for ribose and ribose phosphate is not very different if these molecules adsorb in the plane of the Hg or nearly perpendicular to it, with the ring oxygen and 5′ polar groups close to the surface.

The fact that the nucleosides and nucleotides of adenine have values of $\Delta G°$ significantly more negative than adenine, but nearly the same molecular areas as adenine, requires further explanation. Note that $\Delta G°$ refers to the standard free energy of adsorption at low degrees of coverage, in the region where the adenine moiety of the nucleoside or nucleotide will not be able to displace sugar and sugar-phosphate groups from the surface. We propose, therefore, that at small values of θ the nucleosides and nucleotides of adenine adsorb similarly to uridine and uridine 5′-monophosphate, with the sugar oxygen and the $C'(5)CH_2OH$ or phosphate ester groups near the surface. At large values of θ, rotation about the $N(9)$-$C'(1)$ bond occurs to permit as large a fraction of the surface as possible to be covered with the purine rings. Thus, values of Γ_{max} and area per molecule (which reflect the dependence of π on ln activity in the limit as $\theta \rightarrow 1$) do not vary greatly in the series base-nucleoside-nucleotide for adenine even though the sugar and sugar phosphate groups contribute to the adsorption free energy at low values of θ. The reorientation which supposedly occurs as θ increases does not lead to sizable deviations from the Frumkin equation; this relation applies wth a single set of B_o, α, and Γ_{max} values throughout a wide range of potentials and surface concentrations.

Measurement of Electrochemical Reactions at the Anodized Tantalum Electrode

R. B. Diegle* and C. R. Hassler

Battelle, Columbus Laboratories, Columbus, Ohio 43201

ABSTRACT

Electrochemical activity occurring at anodized tantalum and platinum electrodes was evaluated *in vitro* during pulsed d-c stimulation. The pH of physiological saline was used as an indicator of electrochemical charge transfer at the electrodes, pH change being proportional to the amount of reaction products created by electrochemical processes. The pH changes produced by platinum were large and predictable by electrochemical theory, whereas no detectable changes occurred at either tantalum anode or cathode. It has thus been demonstrated that anodized tantalum can be used as a nearly ideal capacitor electrode, and therefore it is suitable for stimulating tissue *in vivo* in the absence of undesirable faradaic reactions.

Healing of bone in laboratory animals and in humans has been shown to be accelerated if the fracture site is subjected to electrical stimulation by means of implanted electrodes (1-6). Investigators have also demonstrated that rapid healing can occur if the fractured region is merely exposed to an electromagnetic field from a coil placed near the fracture but external to the body (7-9). Results from the former group of experiments suggest that the cause of accelerated healing may be related to either (*i*) the presence of an electric field within the tissue; or (*ii*) altered body fluid chemistry near the electrodes. Concerning item (*ii*), faradaic electrode reactions occur which may include oxygen reduction and hydrogen ion reduction leading to a pH increase at the cathode, and acidification at the anode due to oxidation of water. (The extent of such changes on local chemistry and the resultant effects on bone growth presently are not well characterized, but such changes conceivably could be important.) Because invasive electrodes are not used in the technique employing electromagnetic fields, results from this technique suggest that healing can be produced solely by the presence of an electromagnetic field, and in the absence of changes in body fluid chemistry produced by electrochemical charge transfer in the classical sense.

This present work complements earlier research which sought in part to determine whether accelerated healing results from an electric field or an altered body fluid chemistry (6). The earlier program used both platinum electrodes, which permitted faradaic reactions and hence changes in electrolyte chemistry, and also anodized tantalum. Anodized tantalum was used as a capacitor electrode to prevent electrochemical reactions by insuring charge transfer in a capacitive mode only. That is, a capacitor electrode causes ionic current flow in the body fluids due to the electric field present, but it prevents classical electrochemical reactions from occurring at the anode and cathode and attendant large changes in chemistry of the fluids.

Attempts have been made previously in recent years to pass current in a capacitive rather than faradaic mode. The underlying principle is that electrical charge transfer across the metal-electrolyte interface is suppressed because current is passed by transient charging and discharging of the double layer across a dielectric. The first reported example of an insulated, or capacitor-type, electrode was by Mauro in 1960 (10); his electrode consisted of Teflon[R]-coated wire coiled within a plastic chamber, which was filled with Ringer's solution and had a small opening at the stimulation site to concentrate the ionic current. An improved capacitor electrode was devised by Schaldach (11) for cardiac pacemakers. It consisted of an insulated metallic tip on the end of a transvenous catheter; the tip was covered with a thin layer of tantalum pentoxide, Ta_2O_5, which is a good dielectric material, possessing extremely high electrical resistance and a large dielectric constant. Guyton and Hambrecht (12) improved the charge-storage capacity of the tantalum electrode still further by using a porous sintered electrode, which increased the total surface area by a factor of nearly 90 over the projected area. These porous electrodes were used for surface stimulation of the human visual cortex. Other investigators

* Electrochemical Society Active Member.

Key words: healing, bone, electric field, dielectric.

have used capacitor electrodes to electrically augment the healing of bone (6, 13, 14). In two studies (6, 14), anodized tantalum electrodes were implanted within osteotomies to effect accelerated healing in the absence of detrimental faradaic reactions which can destroy bone, especially near the anode.

Relatively few investigators have undertaken to characterize *in vitro* the performance of the anodized tantalum electrode, specifically, its effectiveness in accomplishing the desired objectives of suppressing electrochemical reactions. Pilla (15) performed an *in vitro* comparative evaluation of tantalum, titanium, stainless steel, and platinum by using a potential sweep method to determine overvoltages for faradaic activity. He demonstrated that tantalum and titanium, unlike stainless steel and platinum, exhibit little faradaic current over a nearly 2V potential range in Ringer's and McCoy's tissue culture media. He concluded that these metals, therefore, would be better suited for pulsed current stimulation and minimization of tissue damage. Guyton and Hambrecht (12) used pH paper to show that the level of electrochemical activity at porous anodized tantalum anodes was significantly reduced relative to that occurring at platinum. Again, no quantitative comparison was made, and an indifferent metal electrode was used as cathode.

In the earlier study (6) it was demonstrated that healing of rabbit calvaria can be accelerated by using anodized tantalum as well as platinum for electrodes. It was therefore initially concluded that the electric field alone is responsible for healing. However, during these *in vivo* experiments, anodized tantalum had been used not only as the anode but also as the cathode. It has been demonstrated (16, 17) that tantalum pentoxide is an extremely leaky dielectric under forward (metal negative) bias, and the question arose as to whether the desired objective of preventing electrochemical reactions had been achieved. Therefore, the *in vitro* research reported herein was performed to determine the degree to which tantalum electrodes actually suppress electrochemical activity under experimental conditions simulating those used in the previous *in vivo* studies.

Experimental

Material and preparation.—Tantalum for the earlier *in vivo* research and for this study was obtained from Materials Research Corporation as 0.25 mm diam wire of 99.996+% purity. High purity material was used to minimize flaws in the Ta_2O_5 dielectric and therefore to maximize its electrical resistivity. Before anodization the wire was coiled in the form of a helix of 1 cm^2 surface area and etched for 10 sec in a chemical polishing solution consisting of a 5:2:2 (volume) mixture of commercial strength analytical reagent grade H_2SO_4, HNO_3, and HF (18). This etch was followed by a 10 sec immersion in 48% HF to remove the chemical polishing residue, a quick water rinse, and anodization in 0.2*N* H_2SO_4. Anodization was performed at a constant current density of 1 mA/cm^2 until a total cell voltage of 20V was reached, at which time the current was allowed to decay at constant applied voltage to $2 \cdot 10^{-5}$ A/cm^2. The electrode was removed without mechanical contact with the anodized region and inserted into a glass electrode holder for mounting in the cell.

Capacitance of the anodized electrodes was measured at a frequency of 60 Hz with a General Radio Model 1650-B impedance bridge and General Radio Model 1310-A external oscillator. Measurements were made in 0.9% NaCl solution (physiological saline) by using a platinum counterelectrode of many square centimeters area, to minimize its series capacitance contribution.

Electrolytes were prepared with analytical reagent-grade chemicals and distilled water. Ringer's solution was a commercial preparation.

Electrochemical cell.—Change of pH as function of charge passed was used to measure the degree to which tantalum prevented electrochemical charge transfer during current flow. For this purpose an electrochemical cell was constructed from Teflon[R] as shown in Fig. 1. The separate anode and cathode compartments, which were connected by a string bridge saturated with electrolyte, permitted measurement of pH of anolyte and catholyte in the absence of diffusional mixing. Figure 1(b) shows the placement of the helical wire and pH electrodes (Corning semi-micro combination electrode) within one of the chambers. In practice, the string bridge was thoroughly rinsed to remove electrolyte from the previous experiment, and the cell was filled with 0.75 ml electrolyte in the chamber in which pH was to be measured and 1 ml in the other chamber. If an anodized tantalum electrode was used, it had been reanodized after insertion into the cell to heal any damaged areas to the dielectric created during mounting in the glass capillary and positioning within the cell. The pH electrode was carefully inserted into one chamber and the pH reading was allowed to stabilize. Pulsating direct current was next applied and the pH was continuously recorded on a strip chart recorder connected to the proportional output of the meter.

Electrical circuitry.—The circuitry used to deliver the current consisted of a pulse generator/constant current generator combination adjusted to give square wave d-c pulses. When tantalum electrodes were used, a reed relay microswitch was placed in the circuit to short the electrodes between pulses and thereby discharge them from the previous pulse. The waveform used throughout most of this work consisted of a square wave with an amplitude of 1 mA, duration of 5 msec, and repetition rate of 60 Hz. The waveform was adjusted and monitored by means of an oscilloscope connected to the electrochemical cell prior to and during each experiment. This waveform, therefore, provided a current density of 1.0 mA/cm^2 with a duty cycle of 30%; *i.e.*, the current was applied for 30% of the duration of each experiment.

Dielectric resistance.—Electrical resistance of the Ta_2O_5 dielectric layer was measured under forward

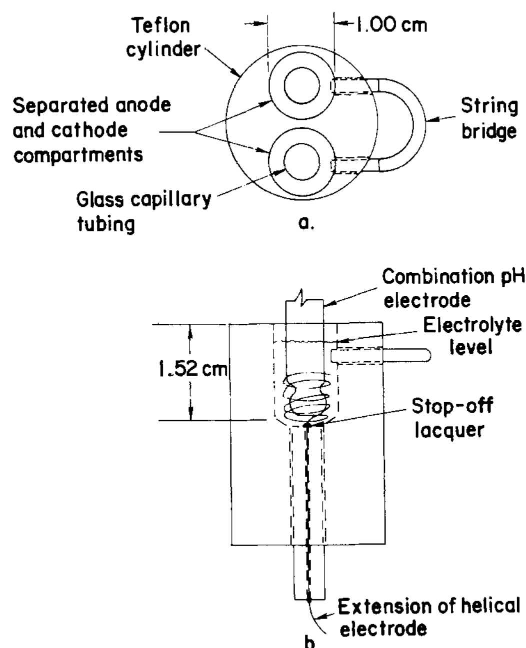

Fig. 1. Schematic diagram of the electrochemical cell used for electrode evaluation. (a) Top view, illustrating separated anode and cathode compartments and string bridge; (b) side view illustrating placement of spiral electrode and combination *pH* electrode.

bias by potentiostatically polarizing an anodized tantalum electrode in a stepwise manner to ever-increasing cathodic potentials and recording the steady-state or near-steady-state current flow through a microammeter. Potentials were measured relative to a saturated calomel electrode (SCE) with a high impedance Keithley electrometer.

Miscellaneous measurements.—Additional experiments included measuring the impedance of the string bridge, developing an equivalent circuit model of the electrochemical cell, and measuring *in situ* electrode potentials during direct current pulsing. Electrode potentials were measured between the anode or cathode and an SCE immersed directly in the anolyte or catholyte. The leads were connected directly to an oscilloscope differential amplifier to prevent distortion by interface circuitry, such as an electrometer.

Results

pH measurements.—Results of pH measurements made on platinum and anodized tantalum in physiological saline are shown in Fig. 2.

The curves designated "theoretical" were calculated on the basis that all charge produces electrochemical reactions at the anode and cathode. It was assumed that the only possible reactions in catholyte and anolyte were

$$H_2O + e = \tfrac{1}{2} H_2 + OH^-, \text{ cathode} \quad [1]$$

$$\tfrac{1}{4} O_2 + \tfrac{1}{2} H_2O + e = OH^-, \text{ cathode} \quad [2]$$

$$\tfrac{1}{2} H_2O = \tfrac{1}{4} O_2 + H^+ + e, \text{ anode} \quad [3]$$

The possibility of another anodic reaction

$$Cl^- = \tfrac{1}{2} Cl_2 + e, \text{ anode} \quad [4]$$

was considered, but experimental results indicated that it did not participate to a detectable degree in the reaction scheme, presumably because it occurs at a potential well anodic to that required for reaction [3]. Inspection of Eq. [1]-[3] shows that the passage of current produces, in physiological saline, only reactions which directly change the pH (see "Discussion" for further treatment). In addition, an equivalent pH change is produced in the catholyte regardless of how the charge is apportioned between reactions [1] and [2]. Therefore, electrochemical charge transfer in physiological saline produces changes in an easily monitored and well-understood quantity, namely, pH.

To calculate the expected pH change if all of the charge enters into the electrochemical reactions shown above, we proceed as follows. The charge Q passed in any time interval is

$$Q = It\alpha \quad [5]$$

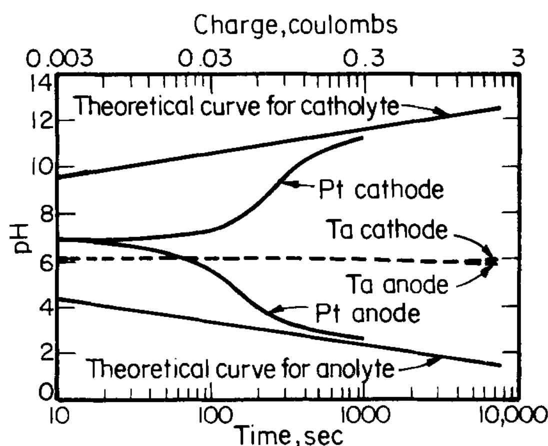

Fig. 2. pH vs. time (or charge) for platinum and anodized tantalum electrodes in physiological saline. Waveform: square d.c.; amplitude 1 mA; duration 5 msec; repetition rate 60 Hz. Theoretical curves were calculated for reactions [1]-[3], see text.

in which I is the current and α is the duty cycle of the wave form, *i.e.*, the fraction of time during which the pulse is applied. The moles reacted, M, is

$$M = \frac{Q}{n\mathbf{F}} = \frac{It\alpha}{n\mathbf{F}} \quad [6]$$

in which n is the number of equivalents per mole and $\mathbf{F}$ is the Faraday, 96,500C per equivalent. The resulting concentration, m, of reaction product is

$$m = \frac{M^o + M}{V} = \sim \frac{M}{V} \quad [7]$$

in which M^o is the initial amount of product at time $t = 0$, M is the amount produced by current flow, Eq. [6], and V is the electrolyte volume. For the conditions used in this study, M (the amount of H^+ or OH^-) greatly exceeded M^o within a few seconds after application of current, so that the approximation in Eq. [7] is justified.

For the anolyte m gives the concentration of H^+, such that

$$pH = -\log a_{H^+} \cong -\log m \cong -\log \frac{It\alpha}{Vn\mathbf{F}} \quad [8]$$

(It was found that for the concentration of electrolyte used, a good approximation of pH was obtained by substituting the molar concentrations of H^+ and OH^- for the activities, a_{H^+} and a_{OH^-}). For the catholyte the expression for pH is

$$pH = -\log \frac{K_w}{(OH^-)} \cong 14 - \log \frac{Vn\mathbf{F}}{It\alpha} \quad [9]$$

K_w is the ionization constant of water, which at 22°C is $1.0 \cdot 10^{-14}$.

As evident in Fig. 2, agreement between the theoretical, or calculated, pH curves and those produced with platinum electrodes is very good for times exceeding about 1000 sec. Poor agreement at shorter times is due simply to the delay in diffusive mixing of reaction products formed at the platinum-electrolyte interface with the bulk of the electrolyte. This delay in mixing was demonstrated by shutting the current off at shorter time intervals and monitoring pH: it continued to drift until it approached the theoretical value. Likewise, reapplication of the current was followed by a slight delay in pH change while the reaction products were migrating toward the pH electrode.

The curves obtained with anodized tantalum indicate that no pH change, outside of experimental drift, occurred at times exceeding 7000 sec.

Results of similar experiments conducted in lactated Ringer's and Dulbecco's tissue culture media are shown in Fig. 3. The change in pH produced by platinum in these culture media at a particular time was less than that in physiological saline because not only were the former electrolytes strongly buffered, but electrochemical reactions were possible other than those which directly affect pH. Examples include oxidation and reduction of carbonate, bicarbonate, phosphate, and sulfate ions, and in addition, organic species in Dulbecco's. There was again no evidence of pH change produced by anodized tantalum.

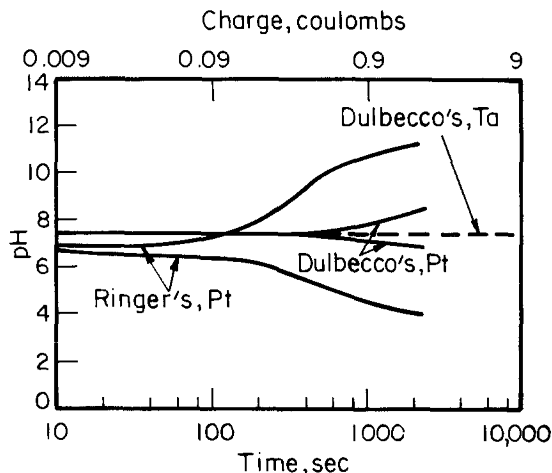

Fig. 3. pH *vs.* time (or charge) for platinum and anodized tantalum electrodes in lactated Ringer's and Dulbecco's tissue culture media. Waveform: square d.c.; amplitude 1 mA; durotion 5 msec; repetition rate 60 Hz.

The effect with tantalum electrodes of increasing the duration of the current pulse from 5 to 15 msec is shown in Fig. 4. It is evident that some pH change occurred at times exceeding 400 sec, although the rate of change is still considerably less than that for platinum, Fig. 2.

Electrode potential measurements.—Electrode potential-time traces of tantalum anode and cathode are shown in Fig. 5 together with the square-wave current pulse used to produce them. The anode reached a potential of 7V (SCE) by the end of the pulse, and it was not completely discharged between pulses. [The potential of discharged tantalum in physiological saline was about 0 ± 0.2V (SCE)]. The cathode reached −2.6V (SCE) during pulse application and was completely discharged between pulses.

Dielectric resistance.—Anodic potentiostatic polarization of anodized tantalum in physiological saline to potentials exceeding 10V (SCE) did not produce detectable current flow (>10^{-7} A/cm^2). Therefore the direct current leakage resistance of the Ta_2O_5 under reverse bias exceeded $10^8\Omega$, which is in agreement with previously published values (17).

Results of cathodic polarization are illustrated in Fig. 6 for two electrolytes. Physiological saline was used because it was the working electrolyte throughout most of this study. In addition, a 0.1M $Ce(SO_4)_2$/1M H_2SO_4 solution was used to eliminate polarization

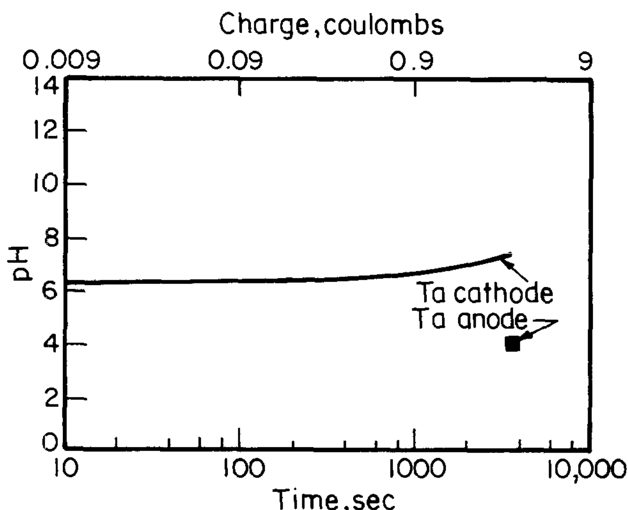

Fig. 4. pH *vs.* time (or charge) for anodized tantalum cathode in physiological saline. Waveform: square d.c.; amplitude 1 mA; duration 15 msec; repetition rate 60 Hz.

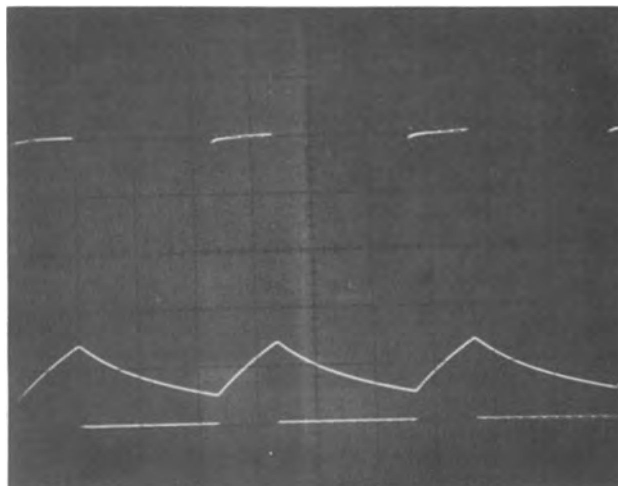

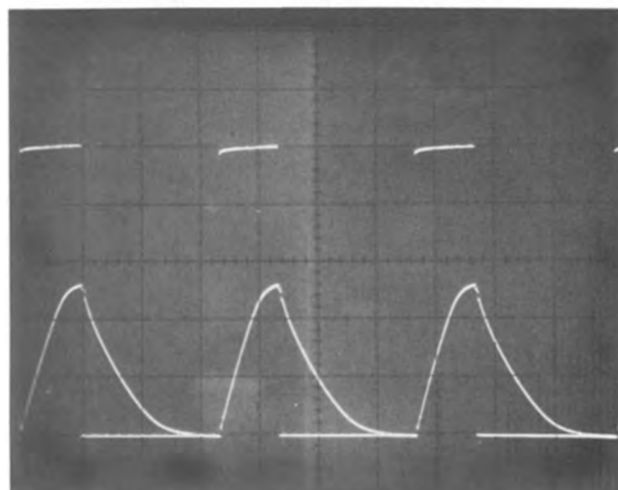

Fig. 5. Current-time and potential-time behavior of anodized tantalum electrodes in physiological saline. Potentials measured relative to the saturated calomel electrode. (a) Tantalum anode: Current, 200 μA/vertical division; potential, 5V (SCE)/vertical division; time, 5 msec/horizontal division; (b) tantalum cathode: As in (a), except 1V (SCE)/vertical division.

due to charge transfer involved in reactions 1-3 (17); such polarization is minimal for reactions involving the change of valence of a metallic ion, *e.g.*, ceric to cerous ion. The 0.6V cathodic shift of the curve for physiological saline was presumably caused by the overvoltage required to drive reactions [1] and [2].

Discussion

It should be emphasized at this point that physiological saline was chosen as the working electrolyte, rather than a more complex tissue culture medium, because it permitted quantification of leakage current through the Ta_2O_5 dielectric film. That is, any current which passed through the dielectric produced electrochemical changes which of necessity changed the pH. Therefore, simply monitoring pH enabled quantification of this leakage current. It is not implied that pH is all-important in producing accelerated bone growth, nor that electrochemical reactions occurring *in vivo* would not include oxidation and reduction of species other than those shown in reactions [1]-[4]. Physiological saline was used merely to enable convenient detection of electronic charge transfer *in vitro*; because such charge transfer does not occur *in vitro* for anodized tantalum, it can be stated with considerable confidence that it also does not occur *in vivo*, and thus neither do the many electrochemical reactions which otherwise would be possible.

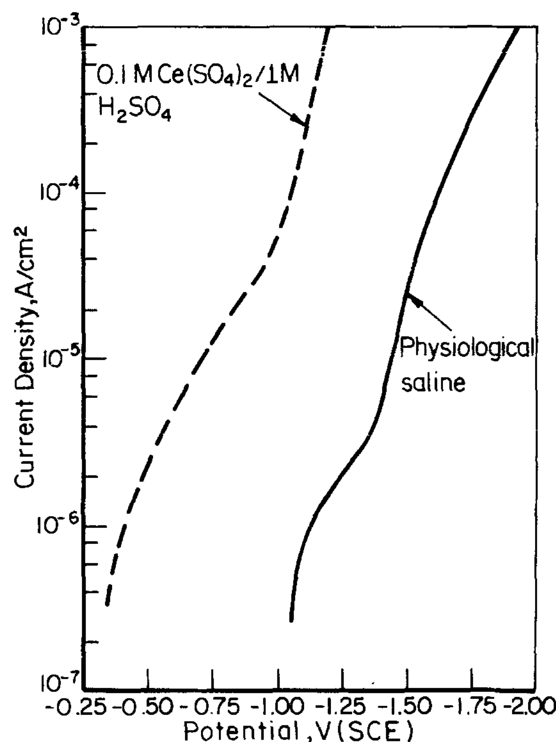

Fig. 6. Pseudosteady state current density vs. electrode potential of tantalum anodized to 20V, then polarized in ceric sulfate solution and physiological saline.

The major observation from this research is that anodized tantalum, used both as anode and cathode in pulsed d-c circuitry, functions as a nearly perfect capacitor electrode. This fact is evident from the lack of significant pH change created by tantalum electrodes, Fig. 2. Leakage through the dielectric of even 1% of the total charge passed in 7000 sec would have produced a pH change of over 3 units. The excellent capacitor behavior of anodized tantalum is reinforced by the results obtained in Ringer's and Dulbecco's tissue culture media, Fig. 3.

The absence of electrochemical activity at the tantalum anode was expected, in light of the excellent dielectric properties of Ta_2O_5 under reverse bias and the results of previous research. Indeed, Guyton and Hambrecht (12) demonstrated semiquantitatively that anodized tantalum behaves well as a capacitor anode; but they used an indifferent platinum electrode as cathode in their work on the presumption that anodized tantalum does not function well as a cathode. However, this present research has demonstrated that anodized tantalum can also function effectively as a capacitor when used as a cathode.

It is not clear why there was no net charge transfer through the cathode dielectric. Figure 5 indicates that the electrode attained a potential of -2.6V (SCE) at the completion of the 5 msec current pulse. Reference to Fig. 6 shows that, at near-steady state, a current density in physiological saline of 1 mA/cm^2 was attained at -1.93V (SCE). It is apparent that current-potential dependence between the transient (pulse) and steady-state measurements do not agree. This differing behavior was presumably not due to unusual properties of the particular Ta_2O_5 films grown in this study, because the film conductivity as measured in ceric sulfate electrolyte was quite similar to that determined in previous work (19). It is concluded that the conductivity of the Ta_2O_5 may be time dependent under forward bias such that insignificant current passed within 5 msec, or perhaps a symmetric oxidation-reduction reaction occurred at the cathodic electrode-electrolyte interface. Such a reaction would involve oxidation, during electrode shorting, of chemical species produced by reduction reactions occurring during application of the current pulse, such that no net change occurred in catholyte chemistry.

The reason for the slight pH shift illustrated in Fig. 4 is that the charge-storage capacity of the electrodes was exceeded by the 5 msec pulse. That is, the maximum amount of charge, Q_m, which can be stored in an anodized metal electrode is

$$Q_m = V_a \cdot C \qquad [10]$$

in which V_a is the voltage to which the film was grown (the anodization voltage) and C is the capacitance. Anodization of the tanatalum wire to 20V produced a total capacitance for 1 cm^2 electrode area of 0.6-0.8 μF, in good agreement with published values (20). Therefore, taking C as 0.7 μF

$$Q_m = 20\text{V} \cdot 7 \cdot 10^{-7}\text{F}$$
$$= 14 \cdot 10^{-6}\text{C}$$
$$= 14\,\mu\text{C}$$

In practice, an anodized electrode is usually operated at no more than about 80% of V_a to prevent additional film growth and to minimize electronic leakage current. Thus, a more conservative value for Q_m is about 11 μF. The charge contained in each 15 msec pulse was 15 μC, which exceeded Q_m by 34%. The pH shift in Fig. 4 was therefore caused by electrochemical reaction produced by a small rate of anodization in the anolyte and electronic leakage in the catholyte. The preceding analysis indicates one of the basic limitations of the capacitor electrode, namely, that the quantity of charge which can be passed per pulse is limited by the electrode capacitance. The total capacitance of an electrode of given outside dimensions can be greatly increased by using a porous structure (12).

The equivalent model circuit of the electrochemical cell is shown in Fig. 7. The anode capacitance, C_a, is 0.7 μF, and the string bridge resistance, R_b, is 20,000Ω. The diode in parallel with C_c simulates the low electronic resistance of Ta_2O_5 under forward bias. No resistance was required in parallel with C_a due to the extremely low leakage under reverse bias. Use of the preceding values, which were determined from measurements of the individual components of the actual electrochemical cell, resulted in excellent simulation of the waveforms shown in Fig. 5 and of the waveform across the entire cell (not shown).

The behavior of anodized tantalum was measured at only one frequency, namely, 60 Hz. This is because the primary objective of this research was to simulate *in vitro* the behavior of tantalum in the previous *in vivo* study, for which the frequency of stimulation was predominantly 60 Hz. A more complete indication of the behavior of anodized tantalum as a capacitor electrode can be acquired by using a range of frequencies, and this is recommended for future research involving tantalum.

Conclusions

It has been quantitatively demonstrated that anodized tantalum behaves as a nearly ideal capacitor when used within its charge storage capability in a pulsed-current circuit. This supports the premise of earlier *in vivo* research (6) and suggests that healing is the result of an applied electric field, not of changes in local electrolyte chemistry. Significantly, anodized tantalum can be used as a cathode as well as an anode, thereby eliminating the need for an indifferent metal electrode or the use of a continuous positive bias voltage on the cathode. (It is emphasized that this latter conclusion has been demonstrated only for the specific circuit and frequency used in this research.) Absence of pH change at the cathode may be due either to significant capacitive behavior of the tantalum cathode for short times upon cathodic polarization, or to symmetric

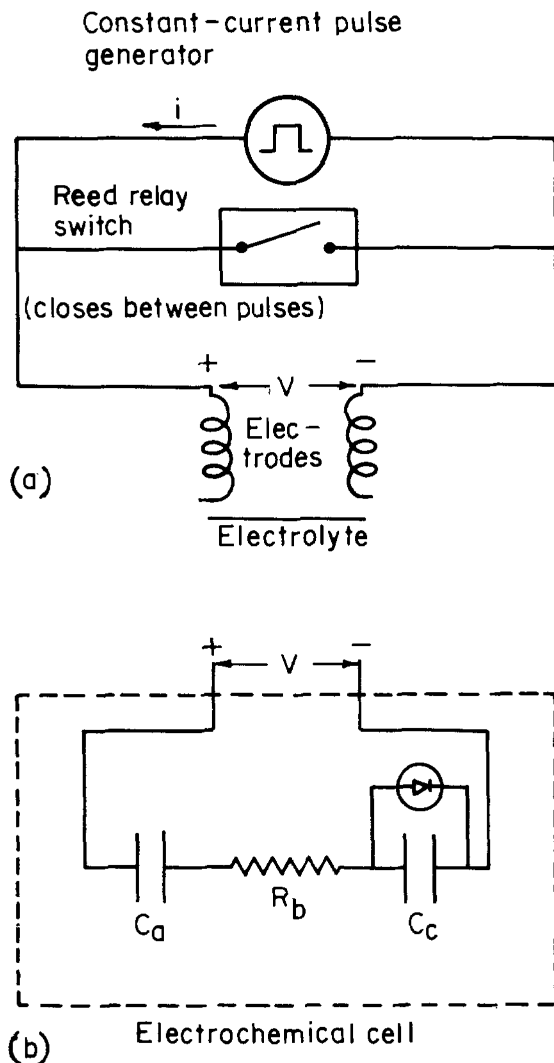

Fig. 7. (a) Stimulating circuit used in this research; (b) equivalent model of electrochemical cell, including tantalum anode (C_a), tantalum cathode (C_c), and string bridge (R_b).

oxidation-reduction reactions resulting in no net change in catholyte chemistry.

Electrode Kinetics of Heme and Electron-Transfer Mechanisms of Heme and Hemoproteins

Karl M. Kadish*,[1] and Joseph Jordan

Department of Chemistry, Pennsylvania State University, University Park, Pennsylvania 16802

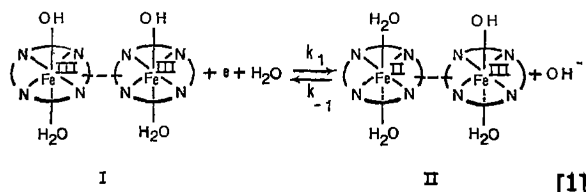
ABSTRACT

The electroreduction of ferriheme was investigated by controlled potential coulometry, polarography, and cyclic voltammetry in solvent systems ranging from pure water to ethanol water mixtures containing as much as 75% ethanol. In pure water, ferriheme was dimerized and was reduced by a one electron transfer to a mixed ferric-ferrous intermediate whose disproportionation yielded a dimeric ferroheme product. Redox reactivities of hemoproteins and relevant electrochemical kinetics are intercompared critically with the aid of R. A. Marcus' unified theory of electron transfer.

Electron-transfer reactivities of hemoglobin, myoglobin, and cytochrome c are of evident interest in the context of their biological relevance. The first two function *in vivo* as oxygen transport (or storage) moieties, while cytochrome c is outstandingly efficient as an "electron transferor" (1,2). The very fact that oxymyoglobin and oxyhemoglobin are capable of existence for appreciable time periods is due to sluggish redox kinetics; the heme iron in oxyhemoglobin remains divalent even though thermodynamics (*i.e.*, differences in the standard potentials of the redox couples hemoglobin/methemoglobin and myoglobin/methmyoglobin on the one hand and water/oxygen on the other hand) require virtually complete conversion to the ferric state (3).

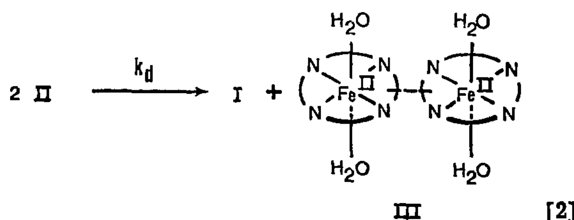
The electroreduction of ferriheme has been studied extensively in aqueous and nonaqueous media (4-9). Tailor-made synthetic "model oligohemochromes" (2-3 heme units linked by poly-4 vinylimidazole or poly-L-histidine chains) exhibit ferrous-ferric electron transfer reactivities decreased (9) by a factor of 10^{18}-10^{28}. On the other hand, electroreduction of ferriheme itself is diffusion controlled at the dropping mercury electrode in aqueous solution and involves dimeric or monomeric species depending on pH (8).

In a preliminary communcation (10) we have reported the formation of the transient ferrous-ferric hybrid II, *viz.*

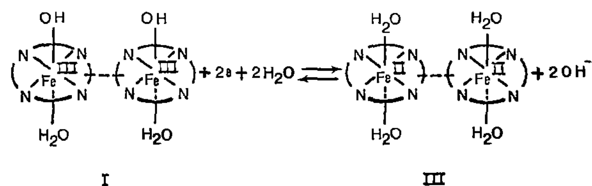


where the tetrapyrrole ring denotes protoporphyrin IX with its normal side chains.

Results are presented and discussed in this paper substantiating that the disproportionation reaction



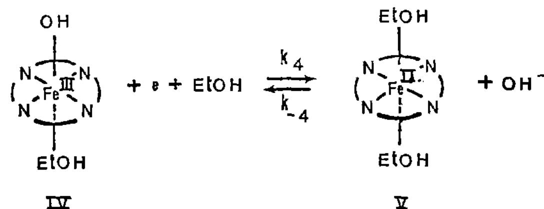
was the rate-determining step in the over-all process



occurring in aqueous solutions of pH 9.5-12.5.

The formulation of the several species in pure water solvent in Eq. [1]-[3] was predicated by assignments of the two axial ligands which have been substantiated conclusively in previous relevant work (8), *viz.*, in the case of Fe(III), OH^- coordinated at one Z position and H_2O at the other; in the case of Fe(II), water coordinated at both Z positions. The nature of the dimer bond in the compounds I, II, and III is not known in aqueous solution. Oxo-bridging (4a) is inconsistent with the established axial ligand assignments. Apparently, two discrete types of dimers may prevail, depending on *pH* (8). However, the question of the dimerization bond is only of periferal interest in the context of the present paper.

In this work we report an estimate of the electrochemical standard (formal) rate constant of reaction [1] which prevailed at the appropriate standard (formal) potential $E°$ where $k_{+1} = k_{-1} = k_1°$. Likewise, we have measured the rate of the reaction



and found that the specific rate constants $k_1°$ and $k_4°$ were of the same order of magnitude as the specific rate constant $k_5°$ of the dicyanohemochrome couple

Key words: ferriheme, disproportionation, cyclic voltammetry, Marcus theory.

which has been previously determined in another laboratory (7).

We have calculated rationally comparable hypothetical rate assignments (*vide infra*) for hemoglobin, myoglobin, and cytochrome c based on the unified electron transfer theory, developed by Marcus (11). A critical assessment of these data (presented later on in this writeup) revealed remarkable features of internal consistency. This led us to postulate that in compounds I-VII, as well as in myoglobin and hemoglobin, electron transfer occurred through similar "hindered paths" via the porphyrin plane.

Experimental Methodology

Apparatus and procedure.—All measurements were made with a three-electrode system using a controlled potential polarograph, assembled from operational amplifiers (Heath Company, Benton Harbor, Michigan). A hanging mercury drop electrode, HMDE, of Kemula's design (Model E-410, Metrohm Limited, Herisau, Switzerland) served as the indicator electrode. The capillary was Kemula's Model EA-842, having a 12 cm length and drop diameter to 0.83 mm. The reference electrode was a commercial saturated calomel half-cell, and platinum served as counterelectrode. The voltage waveform was generated with the aid of a variable frequency function generator (Wavetek, San Diego, California), which could be dialed directly and measured to an accuracy of 0.5%. The waveform from the signal generator consisted of the first arm of a triangular wave for linear sweep and both arms for cyclic sweep; linearity of the potential scan was verified by substitution of a standard resistor for the cell.

One of two detectors was used as a readout device depending on the sweep rate employed. For voltage scans less than 150 mV/sec, voltammograms were recorded with a Model 7000A X-Y recorder (Hewlett Packard, Pasadena, California), while for sweeps greater than 120 mV/sec, the detector was a Model 503 oscilloscope (Tektronix, Beverton, Oregon), which was equipped with a camera for recording the trace.

For peak polarography (linear sweep and cyclic voltammetry) a 100 ml jacketed reaction flask served as the electrolysis cell into which the three electrodes were placed. A tube was inserted into the cell for bubbling nitrogen through the solution, thus facilitating the removal of dissolved oxygen. After deaeration, the bubbler was raised above the solution and a nitrogen atmosphere maintained in the supernate during electrochemical experiments. Nitrogen was prepurified by passing it through two vanadous scrub solutions, a basic wash solution, and finally through a portion of the test solution before entering the cell. The last bubbling step prevented the cell from losing or gaining volatile components during deaeration. The lid of the cell was made of Teflon and machined to fit the cell. Holes were drilled in the lid to allow insertion of the three electrodes along with the nitrogen inlet tube. The lid was further equipped with an orifice for the insertion of a dropping mercury electrode so that conventional steady-state d-c polarograms could be run on the same test solution. The electrolysis cell was maintained at 25.00° $\pm$ 0.05°C by circulation of water through the cell jacket from a constant temperature bath controlled by a thermistor thermoregulator. In order to eliminate uncompensated IR losses resulting from the resistance of the HMDE capillary, a "positive feedback" circuit was used in which part of the current output was returned to the potential input (12). If IR drop was not compensated for, a distortion or shift in the position and height of the peak would occur at high scan rates (13). Since mechanistic sequences of electrode reactions were diagnosed in this study with the aid of the shifts of peak potential with scan, it was essential that no IR drop remain uncorrected.

The over-all number of electrons (faradays per mole of electroreduced ferriheme) transferred in reactions [3] and [4] was determined by controlled potential coulometry. A modified Wenking Model 61-TR potentiostat (supplied by Brinkmann, Westbury, New York) was used to control the potential at which experiments were run. Electronic integration of the current-time curve was achieved by means of an operational amplifier difference integrator (14) yielding a voltage output that was recorded on a strip chart recorder (supplied by Varian Associates, Palo Alto, California). The coulometric cell was similar to that used for peak polarography and described in the preceding paragraph. A large coiled platinum wire served as the anode and was separated from the catholyte compartment by means of a fritted disk which fitted into the center of the cell. A stirred mercury pool, area 7 cm^2, served at the cathode and a saturated calomel electrode was the reference electrode. Stirring of the solution was achieved by means of a magnetic stirring bar positioned atop the mercury pool and actuated by a motor beneath the cell. Deaeration of both the anodic and cathodic chambers was rigorously controlled before beginning the experiment, and nitrogen was passed over the solution in both compartments during the experiment with the aid of a Y tube connector.

Chemicals.—Several buffer solutions (15) were employed in the pH range 9.5-12.5, *viz.*, in the systems potassium bicarbonate-carbonate, potassium biphosphate-phosphate, and potassium hydroxide, the pH ranges were 9.5-11, 10.9-12, and 12-12.5, respectively. pH was monitored with the aid of a Model 801 digital pH meter (supplied by Orion Research, Cambridge, Massachusetts) using a Beckman glass electrode and a fiber-type saturated calomel reference half-cell. Reagent grade chemicals and triply distilled water were used throughout this investigation. Hemin chloride (FW 651.59, Nutritional Biochemical Corporation, Cleveland, Ohio) served as the source material for preparing ferriheme solutions in the range of concentrations between 5×10^{-4} and 10^{-3}F. Experiments were advisedly restricted to this narrow concentration range in order to minimize interfering complications due to adsorption at the electrode interface (8). The ionic strength was maintained in a range between 0.1-0.2 by adding potassium chloride when necessary.

Units, sign conventions, etc.—Potentials reported in this paper are referred to the normal hydrogen electrode (NHE) in accordance with the 1972 Manual of Physico Chemical Nomenclature of the International Union of Pure and Applied Chemistry (IUPAC) (16). The relevant sign convention is the reverse of the one used in Latimer (17), *i.e.*, a more positive potential is more anodic (oxidizing) and a more negative potential more cathodic (reducing).

Electric double layer and specific adsorption effects.—Specific adsorption effects were negligible under the experimental conditions due to the prevailing high ionic strength. Results reported in this paper have been advisedly restricted to those ranges where specific adsorption could be ascertained to cause no appreciable distortions of the current-voltage curves. At high scan rates ($v > 1$ V/sec in ethanol-water mixtures and, $v > 12$ V/sec in pure water) adsorption effects were evident and could be identified by the variation of peak currents as a function of scan rate (linear dependence on sweep rate, etc.). Since it is known that adsorption distorts current voltage curves, these high scans were not employed in the measurement of electrochemical rate constants (and were indeed not needed in the determination of the mechanism described in this paper). Thus, higher values of Nicholson's (18) dimensionless parameter ψ (Eq. [7] below) were not used where interpretations would be open to question due to the presence of adsorption.

Table I. Controlled potential coulometry of $6.00 \times 10^{-4}M$ ferriheme[a] in various ethanol-water mixtures containing 0.1M KOH

Ethanol present (percent by volume)	Faradays found ($\times 10^{6}$)	Faradays per mole of Fe(III) converted to Fe(II)[b]
0.0	5.9 ± 0.2	0.98 ± 0.03
25.0	5.9 ± 0.1	0.98 ± 0.02
75.0	5.8 ± 0.2	0.97 ± 0.03

[a] 100 ml samples of $6.0 \times 10^{-4}F$ ferriheme were electrolyzed at potentials corresponding to 99.9% conversion of Fe(III) to Fe(II).
[b] Corrected for background (residual current) effects; precision expressed as standard deviation of the mean of three replicates.

Results

Coulometric verification of "over-all" electrode process.—It has previously been substantiated (6, 8) that ferriheme yielded diffusion-controlled steady-state polarograms at the DME, both in pure water and in ethanol-water mixtures containing 25-30% EtOH. The relevant current-voltage curves had the sigmoid shape of classical polarographic waves whose mathematical analysis invariably suggested the transfer of 1 faraday per gram atom of iron. This correspondence has previously been verified in our laboratories by controlled potential coulometry in aqueous solutions over a range of pH 8-13. In the present investigation this relationship was reinvestigated and again verified over the broader domain of solvent compositions ranging from pure water to 25% water-75% ethanol. The relevant current time integrals are listed in Table I.

Cyclic voltammetry in ethanol-water mixtures.—Cyclic voltammograms of ferriheme were obtained at Kemula's HMDE in the presence of 25-75% ethanol, at potential sweep rates in the range between 0.01-1.0V/sec. A typical cyclic voltammogram of ferriheme is illustrated in Fig. 1. The analytic geometry of the relevant curves was invariant up to scan rates of $v = 0.1$V/sec. The corresponding peak currents were a linear function of $v^{1/2}$ and the anodic and cathodic peaks were separated by 0.057V (2.2 RT/nF, where $n = 1$). However, at higher scan rates the separation between the anodic and cathodic peak potentials ($E_{p,a}$; $E_{p,c}$) appeared to increase slightly, *viz.*, to the 0.061-0.062V range. At any given scan rate peak potentials varied as a function of pH in accordance with Eq. [6]

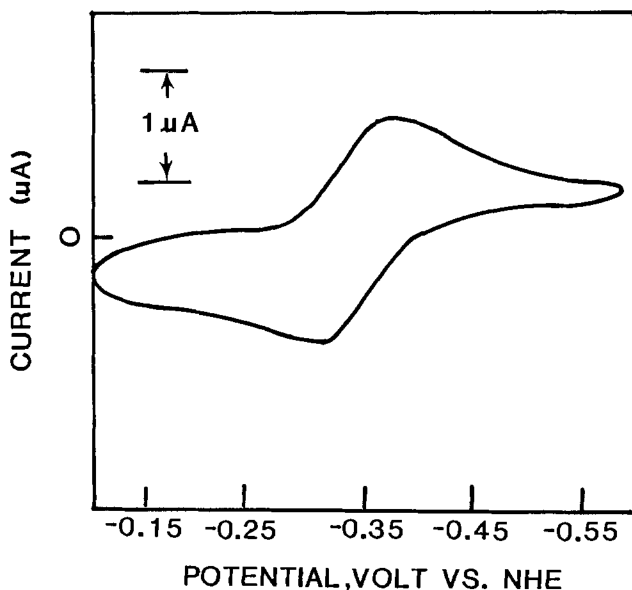

Fig. 1. Cyclic voltammogram of $5 \times 10^{-4}F$ ferriheme in 50% ethanol-water mixture: $pH = 9.96$ (carbonate-bicarbonate buffer); ionic strength = 0.14; scan rate = 0.21 V/sec.

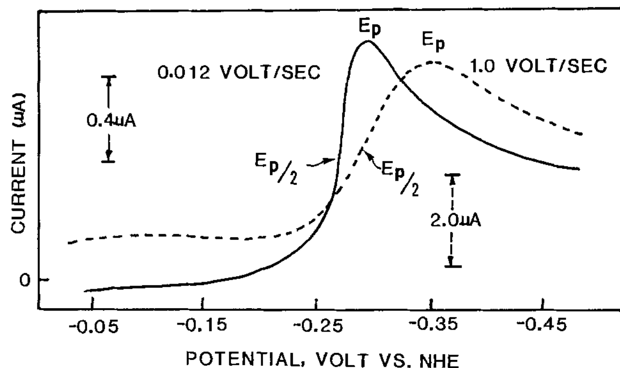

Fig. 2. Cathodic peak voltammogram of $9.1 \times 10^{-4}F$ ferriheme in aqueous carbonate-bicarbonate buffer of pH 9.96, ionic strength = 0.14.

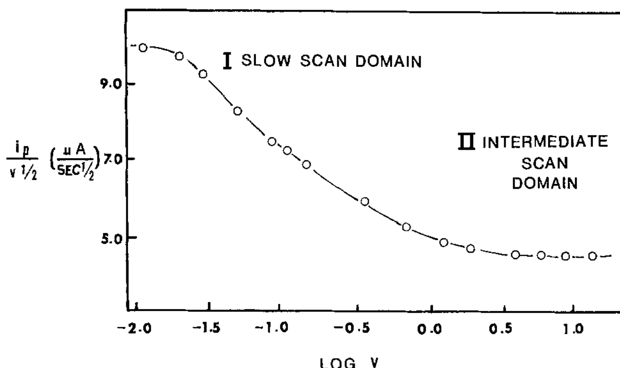

Fig. 3. "Diagnostic plots" of $i_p/v^{1/2}$ vs. scan rate. The value of $i_p/v^{1/2}$ is proportional to the current function maximum χ_P.

$$\frac{\Delta E_{p,c}}{\Delta pH} = \frac{\Delta E_{p,a}}{\Delta pH} = \frac{-2.3RT}{F} = -0.059\text{V at } 25°\text{C} \quad [6]$$

Peak polarography in aqueous solutions at pH 9.5-12.5.—Cathodic linear sweep voltammograms of ferriheme varied between two extreme analytic geometries depending on potential scan rates. Representative current voltage curves are shown in Fig. 2 [similar results obtained under somewhat different experimental conditions have been reported in Ref. (12)]. Plots of variation of the quantity, $i_p/v^{1/2}$, as a function of v (in a given solution of ferriheme) yielded interesting sigmoid curves are illustrated in Fig. 3. The quantity $i_p/v^{1/2}$ is an experimentally accessible proportional measure of the well-known "peak current function" which was used in this investigation as an important diagnostic criterion for identifying reaction mechanisms (see Discussion Section).

The difference between the peak potential (E_p) and the half-peak potential ($E_{p/2}$) is a convenient parameter for characterizing relevant analytic geometries. Observed $E_{p/2}$-E_p assignments are listed as a function of scan in Table II. Peak potentials were essentially invariant at potential scan rates in a range between 3

Table II. Variation of $E_p - E_{p/2}$ with potential scan rate[a,b]

Potential scan rate (V/sec)	$E_p - E_{p/2}$ (V)	$\frac{2.2\,RT}{F(E_p - E_{p/2})} = n$
0.02	0.028	2.00
0.09	0.034	1.65
0.15	0.040	1.40
0.50	0.047	1.19
6.00	0.058	0.97

[a] From cathodic peak polarograms exemplified in Fig. 2.
[b] The dimensionless quantity listed in the last column is equal to the "average number of electrons" transferred per molecule of the electroreducible species (see Discussion).

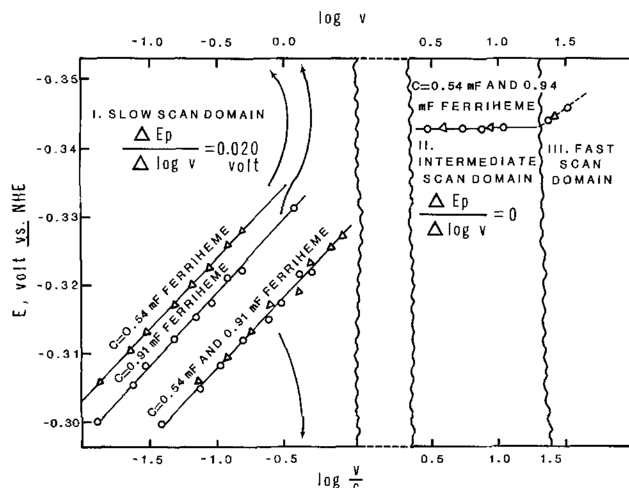

Fig. 4. Experimental cathodic peak potentials for the reduction of ferriheme plotted vs. log v and log v/C. Different curves are obtained for each concentration in domain I while in domain II and III all concentrations yield the same curve.

and 12 V/sec (Fig. 4). However, E_p became gradually more positive as scan rates decreased in the range between 1.0 and 0.01 V/sec and shifted to progressively more negative values when scan rates were increased beyond 12 V/sec. Thus a plot of E_p *vs.* log v had three discrete domains, as is apparent in Fig. 4 and outlined below.

In the "slow scan domain" reported qualitatively in Ref. (12) the plot of E_p *vs.* log v (see upper abscissa scale) yielded a family of parallel lines of slope 0.020V ($2.3\ RT/3\mathbf{F}$), each corresponding to a specified concentration of ferriheme. Two of these ($C = 0.54$ m**F** and 0.91 m**F** ferriheme) are shown in the figure. Using as abscissa log v/c (lower scale) in lieu of log v, caused these discrete lines to coalesce into a single line of the same slope.

In the "intermediate scan domain" the peak potential was independent of the concentration of ferriheme, as well as of scan rate. Cyclic voltammograms recorded in the "intermediate scan domain" yielded normal diffusion-controlled anodic and cathodic peaks separated by 0.057V. In this range the pH dependence of the current voltage curve was the same as described by Eq. [6].

In the "fast scan domain," peak potentials were independent of ferriheme concentration (but varied slightly with scan rate).

Discussion

Kinetics and mechanisms of electroreduction of ferriheme to ferroheme.—Our experimental findings are accounted for by the following interpretation. Considering solely initial (stable) reactants and ultimate products (*i.e.*, disregarding transient intermediates), one faraday of electricity was transferred per mole of iron under all experimental conditions prevailing in this investigation.

The main contribution of the experiments described in this paper was to unravel mechanisms and estimate rate constants of electron-transfer and coupled chemical reactions. Our interpretive rationale relied on the fact that an electrode reaction involved invariably at least two types of competing rate processes, *viz.*, diffusion to and from the electrode surface on the one hand and electron transfer on the other hand. Under the experimental conditions, diffusion rates were inversely proportional to the thickness of the concentration polarization layer $\delta = (\pi Dt)^{1/2}$. In classical polarography at the dropping mercury electrode ($3 < t < 6$ sec) diffusion was the rate-controlling "slow step" yielding "Nernst reversible" current-voltage curves whose shapes were determined solely by the initial reactants and final products. Consequently, our previously reported steady-state polarograms of hemin (8) were not illuminating with respect to electrooxidation-reduction kinetics and mechanisms. In the present investigation we made judicious use of rapid potential scan rates at a HMDE to minimize t, thus providing "time windows" sufficiently small to permit measurements prior to increase of δ to levels where diffusion takes over as the slow rate-determining step.

Rate constants of electron transfer effective at the formal potential were evaluated from the expression (18)

$$\psi = \left(\frac{D_{III}{}^{\alpha}}{D_{II}}\right)\frac{k^o}{\left(\pi D_{III}\frac{n\mathbf{F}v}{RT}\right)^{1/2}} \approx \frac{k^o}{\left(\pi D\frac{n\mathbf{F}v}{RT}\right)^{1/2}} \quad [7]$$

In Eq. [7], k^o is the standard (formal) rate constant expressed in centimeters per second and is correlated as follows with the actual electrooxidation and electroreduction rate constants effective at any potential E

$$k_{red} = k^o \exp\left(\frac{-\alpha n\mathbf{F}}{RT}[E - E^o]\right) \quad [8]$$

$$k_{ox} = k^o \exp\left([1-\alpha]\frac{n\mathbf{F}}{RT}[E - E^o]\right) \quad [9]$$

where $0 < \alpha < 1$ is the transfer coefficient and E^o denotes the formal potential (18). In accordance with the concepts of the Marcus theory (11) we have elected to use k^o for intercomparing rates of different electrode reactions. The other symbols in Eq. [7] have the following connotation: D, diffusion coefficient (cm^2/sec) of the relevant ferri- and ferroheme species (identified by the subscripts III and II, respectively); v, the potential scan rate expressed in V/sec; ψ, Nicholson's dimensionless parameter (*vide infra*), which was accessible from anodic and cathodic peak-potential separations and recorded as a function of the scan rate, v. The latter was manipulated as an experimental variable.

The approximation $D_{III} = D_{II} = D$, incorporated in Eq. [7] was warranted by the similarity in molecular size between ferroheme and ferriheme. The rate-determining step of the electroreduction of ferriheme in the presence of ethanol was found to be indistinguishable from the over-all reaction [4]. The latter has been unambiguously substantiated in previously published work (7, 9) and was verified in this paper.

Application of Eq. [7] yielded the estimate $k_4{}^o \geqq 0.2$ cm/sec. This assignment holds for the entire range of solvent composition investigated, *i.e.*, between 25% ethanol-75% water to 75% ethanol-25% water. From Eq. [6] it appears that hydroxyl-ethanol ligand exchange occurred concomitantly with the electron transfer and was kinetically inseparable (*i.e.*, the ligand exchange per se was fast, compared to electron transfer).

It was previously shown (8) that both ferriheme and ferroheme were dimerized in the aqueous solutions used in the present investigation and that the over-all reaction 3 was diffusion controlled at the DME. This was confirmed in the "limiting case" when slow scan rates (0.01 V/sec) at the HMDE were used (Fig. 2, solid curve), yielding a separation between half-peak ($E_{p/2}$) and peak potential (E_p) which corresponded indeed to a Nernst-reversible two-electron transfer: the quantity

$$n = \frac{2.2RT}{\mathbf{F}(E_{p/2} - E_p)} \quad [10]$$

listed in the last column of Table II represents a measure of the number of faradays per mole involved in a diffusion-controlled reaction of the type: Ox + $ne \rightleftharpoons$ Red.

As can be seen in Table II the apparent value of n decreased gradually with increased potential scan rates. At a scan rate of 0.02 V/sec, Eq. [10] yielded $n = 2.00$ while at scan rate of 6 V/sec, Eq. [10] yielded $n = 0.97$, corresponding to a diffusion-controlled one-electron transfer. This is remarkable behavior, accounted for as follows: Within the 'time window" of slow potential scans, reaction [3] was completed *in toto*, the rate-determining step being the diffusion of the ferriheme dimer I from the bulk of the solution to the HMDE surface. Diffusion of that species remained the rate-determining process at fast scan rates as well. However, when $v = 6$ V/sec the small "time window" effectively isolated reaction [1] and excluded from "peak polarographic visibility" a slower follow-up process necessary to complete the two-electron reduction. Evidence for the follow-up reaction and a conclusive clue as to its nature transpires from Fig. 3 and 4. Peak potentials plotted in Fig. 4 were invariant in domain II where $n = 1$. In contradistinction, E_p shifted anodically with decreasing scan rates in domain I. Such behavior is known to be a diagnostic criterion for the occurrence of a chemical reaction following charge transfer (19). Such sequences include an electrochemical reaction followed by a rate-determining chemical reaction (EC); and an ECE (electrochemical-chemical-electrochemical reaction sequence) or ED (electrochemical reaction followed by a rate-determining disproportionation step). Figure 3 is based on a special analog of the Randles-Sevcik Eq. (20), *viz.*

$$i_p = (n_i\mathbf{F}A)(\pi D n_i \mathbf{F}/RT)^{1/2} v^{1/2} C \chi_P \qquad [11]$$

where n_i denotes the number of electrons involved in the initial electrochemical reaction; A and C denote the area of the electrode and the bulk concentration of the electroactive species, respectively. χ_P is a dimensionless "current function maximum" which is accessible on the basis of theoretical calculations. In a given solution at a given electrode area, A and C are constant and therefore

$$i_p/v^{1/2} \text{ is proportional to } \chi_P \qquad [12]$$

Equation [12] is the rationale for the choice of ordinates in Fig. 3. In the intermediate scan domain, substitution of $n_i = 1$ (based on the experimental n, Table II, Column 3) into Eq. [11] yielded $\chi_P = 0.45$ which is in excellent agreement for a diffusion-controlled process (20-21) and thus eminently compatible with Eq. [1]. A drastic increase in $i_p/v^{1/2}$ with the decreasing scan rates is strikingly apparent in Fig. 3. At slow scans a limit corresponding to $\chi_P \approx 1.0$ was attained. This assignment of χ_P is compatible only with the sequences ECE and ED (22, 23), eliminating all other alternatives (19, 24-28). Of these, ECE can be counted out on the basis of the experimental finding that in scan domain I of Fig. 4

$$\frac{\Delta E_p}{\Delta \log v} = -\frac{2.3RT}{3\mathbf{F}} = -0.020\text{V at } 25°\text{C} \qquad [13]$$

This finding is compatible with the following theoretical relationships appropriate for an ED sequence (22, 23) *viz.*

$$n_i(E_p - E°) = \frac{RT}{3\mathbf{F}}(\ln \rho_2 - \text{const.}) \qquad [14]$$

$$\rho_2 = \frac{RT}{n\mathbf{F}}\frac{k_2 C}{v} \qquad [15]$$

where k_2 is the appropriate second-order disproportionation rate constant and n_i denotes the number of electrons involved in the electrochemical step which precedes the disproportionation. In contradistinction, for an ECE mechanism where the "interposed chemical reaction" has first-order kinetics, theory predicts (22)

$$\frac{\Delta E_p}{\Delta \log v} = -\frac{2.3RT}{2\mathbf{F}} = -0.030\text{V at } 25°\text{C} \qquad [16]$$

because

$$n_i(E_p - E°) = \frac{RT}{2\mathbf{F}}(\ln \rho_1 - \text{const.}) \qquad [17]$$

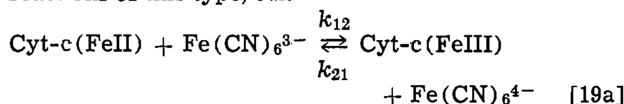
$$\rho_1 = \frac{RT}{n\mathbf{F}}\frac{k_1}{v} \qquad [18]$$

where k_1 is the first-order rate constant of the interposed chemical reaction. The ρ's in Eq. [15] and [18] are dimensionless parameters which differ by the factor C (concentration, which appears in Eq. [15], but is conspicuous by its absence in Eq. [18]). The reason for the difference between ρ_1 and ρ_2 is inherent in the second-order kinetics of the disproportionation process. A consequence of Eq. [15] and [18] was that plots of E_p *vs.* log v for two different ferriheme concentrations were parallel and separated by an intercept of 2.3 $RT/3\mathbf{F}$ log C. The two lines merged when E_p was plotted *vs.* log v/C in lieu of log v (Fig. 4, lower curve). The internal consistency of these findings established unambiguously the sequence of reactions [1] and [2] as the mechanism of the over-all reaction [3]. It should be noted that the rate-determining step was the disproportionation process 2 ($k_2 = 6 \times 10^5$ M^{-1} sec^{-1}).[2] Nevertheless, we succeeded in estimating the standard rate constant for the faster reaction [1]. This was accomplished with the aid of Eq. [7] yielding a $k_1° \geqq 0.8$ cm/sec.

Comparison of electron transfer reactivities of simple heme moieties and of hemoproteins.—Data presented in this paper have enriched somewhat the information available on the electrode kinetics in aqueous media (including ethanol-water mixtures up to 75% ethanol) of the process Fe(III) + $e \rightleftarrows$ Fe(II) occurring in low molecular weight (MW < 1500) heme entities. Combined with earlier experimental findings reported in the literature, we now have estimates of relevant electrochemical rate constants for systems ranging in complexity from the simplest monomers with symmetrically coordinated axial (Z) ligands (*e.g.*, the dicyanohemi(o)chromes, VI and VII, through monomeric hemes with asymmetric Z ligands (*e.g.*, the hydroxy ethanolato ferriheme, IV) to the dimeric ferri- and ferroheme moieties I, II, and III.

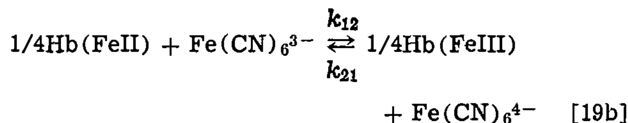
It is of evident interest to correlate these electrochemical rates with the kinetics of the ferrous-ferric redox processes as it occurs in macromolecular hemoproteins (10^4 < MW < 10^5). However, no direct comparison of electrode kinetics is currently feasible. The reason for this is inherent in the fact that any electrode reaction involves as a competing-rate process the transport of the electroreactive (electrooxidizable or electroreducible) species from the bulk of the electrolyte to the electrode interface. The rate of the transport process depends on the diffusion coefficient of the electroreactive species, which is necessarily small for macromolecules. Consequently, any currents resulting from the electrooxidation-reduction of iron in hemoproteins are bound to be diffusion controlled, and thus, nonilluminating as far as electron transfer kinetics are concerned [diffusion-controlled polarograms of cytochrome c have indeed been recently described (29)].

On the other hand, rates of oxidation by ferricyanide of divalent iron in hemoglobin, myoglobin, and cytochrome c have been measured (30, 31). Rates of cross-reactions of this type, *viz.*

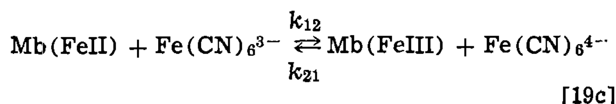


$$\text{Cyt-c(FeII)} + \text{Fe(CN)}_6^{3-} \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} \text{Cyt-c(FeIII)} + \text{Fe(CN)}_6^{4-} \qquad [19a]$$

[2] The value of this rate constant is not of central interest in the context of the principal emphasis of the present paper. Its determination depended on Eq. [14]-[15], using assignments tabulated by Nicholson (23) and Saveant and co-workers (22) as a function of χ_P whose experimental values as a function of v were taken from Fig. 3 and similar experimental data.

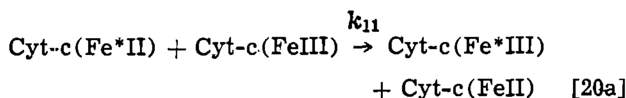


$$1/4\text{Hb(FeII)} + \text{Fe(CN)}_6^{3-} \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} 1/4\text{Hb(FeIII)} + \text{Fe(CN)}_6^{4-} \quad [19b]$$

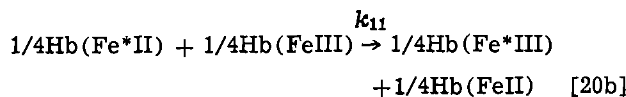


$$\text{Mb(FeII)} + \text{Fe(CN)}_6^{3-} \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} \text{Mb(FeIII)} + \text{Fe(CN)}_6^{4-} \quad [19c]$$

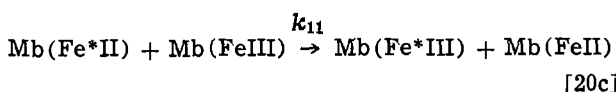
can be correlated via the Marcus theory (11) with the kinetics of the isotopic electron self-exchange of the two redox couples involved, *viz.*



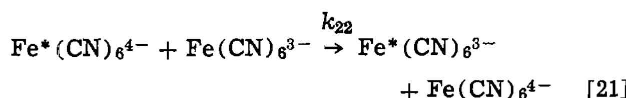
$$\text{Cyt-c(Fe*II)} + \text{Cyt-c(FeIII)} \xrightarrow{k_{11}} \text{Cyt-c(Fe*III)} + \text{Cyt-c(FeII)} \quad [20a]$$



$$1/4\text{Hb(Fe*II)} + 1/4\text{Hb(FeIII)} \xrightarrow{k_{11}} 1/4\text{Hb(Fe*III)} + 1/4\text{Hb(FeII)} \quad [20b]$$



$$\text{Mb(Fe*II)} + \text{Mb(FeIII)} \xrightarrow{k_{11}} \text{Mb(Fe*III)} + \text{Mb(FeII)} \quad [20c]$$



$$\text{Fe*(CN)}_6^{4-} + \text{Fe(CN)}_6^{3-} \xrightarrow{k_{22}} \text{Fe*(CN)}_6^{3-} + \text{Fe(CN)}_6^{4-} \quad [21]$$

Recently, the Marcus theory has been successful in correlating the rate constants for reaction of ferri- and ferrocytochrome c with several oxidants and reductants (32-35), including $Ru(NH_3)_6^{2+}$, $Co(phen)_3^{3+}$, $Fe(CN)_6^{3-}$, $Fe(EDTA)^{2-}$ as well as the peroxide complex of cytochrome c peroxidase.

The relationship between cross reactions as given in Eq. [19a]-[19c] and the self-exchange reaction rate constants given in Eq. [20a]-[20c] and Eq. [21] can be formulated as follows

$$k_{11} = \frac{k_{12}^2}{K_{12}k_{22}} \quad [22]$$

where K_{12} is the equilibrium constant for the cross reactions given in Eq. [19] and k_{11} is the homogeneous isotopic electron exchange reaction rate constant. When the work terms are negligible, k_{11} can be related to the standard electrochemical rate constant k^o by the following equation (11)

$$\left(\frac{k_{11}}{Z_{\text{hom}}}\right)^{1/2} = \frac{k^o}{Z_{\text{het}}} \quad [23]$$

where Z_{hom} and Z_{het} are the collision frequencies of the chemical and electrochemical reactions, respectively, (10^{11} 1 mole^{-1} sec^{-1} and 10^4 cm sec^{-1}).

Assuming, as a *pro tempore* working hypothesis, that the Marcus correlations hold for Reactions [19]-[21], Eq. [22] and [23] can be combined and rearranged to explicit k^o

$$k^o = \frac{k_{12}}{(K_{12}k_{22}10^3)^{1/2}} \quad [24]$$

If one assumes that the Marcus theory holds for a comparison between the cross reaction [19a]-[19c] on the one hand and the isotopic exchange processes [20a]-[20c] on the other hand, electron-transfer rate constants can be calculated from Eq. [24] for the hypothetical electrode reactions [25a]-[25c]

$$\text{Cyt-c(FeIII)} + e^- \overset{k^o}{\rightleftarrows} \text{Cyt-c(FeII)} \quad [25a]$$

$$1/4\text{Hb(FeIII)} + e^- \overset{k^o}{\rightleftarrows} 1/4\text{Hb(FeII)} \quad [25b]$$

$$\text{Mb(FeIII)} + e^- \overset{k^o}{\rightleftarrows} \text{Mb(FeII)} \quad [25c]$$

An illuminating comparison of these hypothetical rate parameters of hemoproteins *vs.* their analogs determined experimentally in simpler less molecular weight heme couples is presented in Table III. Presentation of the rates in terms of k^o is equivalent to expressing the same information in terms of k_{11} (*i.e.*, via a hypothetical self-exchange rate). In a recent authoritative review aimed at inorganic chemists Wherland and Gray (35b) have indeed elected to use that alternative form of presentation. We have advisedly chosen to use the electrochemical k^o instead because it is more appropriate for an electrochemical audience. Naturally, the two types of presentation are readily interchangeable.

Equilibrium parameters K_{12} for reactions [19a]-[19c] were evaluated from relevant redox potentials available in the literature (30, 36) with the aid of the equation

$$\Delta G^o = -n\mathbf{F}\Delta E^o = RT \ln K_{12} \quad [26]$$

where ΔE^o denotes the difference in formal potentials between the couples involved in reactions [19a]-[19c].

For comparison we have also calculated the hypothetical rate constant for reaction [25a] utilizing Eq. [23] directly and the experimental self-exchange rate of horse heart cytochrome c (10^3-10^5 M^{-1} sec^{-1}) obtained by Gupta (37) using NMR techniques. Experimental self-exchange rates are not available for hemoglobin or myoglobin.

Table III reveals a surprising similarity between the ferrous-ferric electron-transfer rate parameters of simple heme compounds on the one hand, and hemoglobin and myoglobin on the other hand. This invariance is particularly impressive because the upper limit of the calculated comparable rate constants for cytochrome c is three orders of magnitude faster, *i.e.*, $k^o \simeq 1.4 \times 10^2$ cm/sec.

The rate constant assignments for Eq. [25a]-[25c] are admittedly based on a comparison of experimental measurements with values calculated from the Marcus theory which implies that all the relevant (actual and/or hypothetical) electron transfer processes (reactions [25a]-[25c]), isotopic exchange reactions (Eq. [20a]-[20c], and cross-redox reactions (Eq. [19a]-[19c]) proceeded via similar transition states. We postulate, accordingly, that all the one-electron transfer processes which are schematized in Fig. 5 proceeded through similar mechanisms regardless of whether the electron was transferred at an electrode interface, by isotopic self-exchange, or in a chemical cross reaction

Table III. Comparison of theoretical and experimental formal rate constants, k°, for the electrooxidation reduction of various heme moieties[a]

Electrode reaction	Hypothetical k^o (cm sec^{-1})	Experimental k^o (cm sec^{-1})
Cyt-cFe(III) $\overset{e}{\rightleftarrows}$ Cyt-cFe(II)	0.1-1.4 × 10^2 [b] (1-10) [c]	—
¼HbFe(III) $\overset{e}{\rightleftarrows}$ ¼HbFe(II)	0.05-0.2 [d]	—
MbFe(III) $\overset{e}{\rightleftarrows}$ MbFe(II)	0.2-0.5 [d]	—
PFe(III)-Fe(III)P $\overset{e}{\rightleftarrows}$ P-Fe(II)-Fe(III)P (aqueous, pH 10)	—	≧0.8
PFe(III) $\overset{e}{\rightleftarrows}$ PFe(II) (50% EtOH)	—	≧0.2
PFe(III)CN $\overset{e}{\rightleftarrows}$ PFe(II)CN	—	4.0 [e]

[a] The symbol P denotes the protoporphyrin IX equatorial ligand of heme.
[b] Calculated from Eq. [24] using the cytochrome c exchange rates calculated in Ref. (35) from cross reactions with $Co(phen)_3^{3+}$, $Fe(CN)_6^{3-}$ and $Fe(EDTA)^{2-}$.
[c] Calculated from Eq. [23] using the experimental self-exchange rates in Ref. (37).
[d] Calculated from Eq. [24] using k_{11} = 5-50 × 10^3 for cytochrome c (43).
[e] Ref. (7).

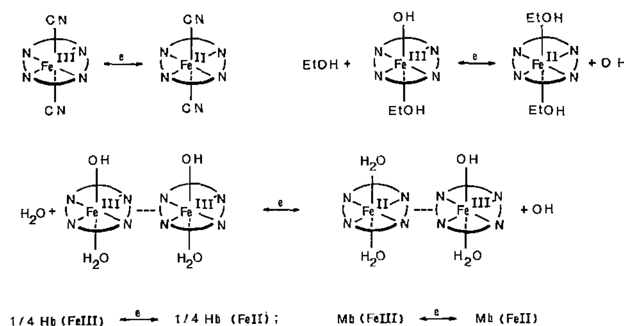


Fig. 5. Moieties exhibiting kinetically comparable electron-transfer behavior.

with another redox couple. Furthermore, the invariance of the rates in all these instances (in contradistinction to cytochrome c, *vide infra*) suggests a common "reaction path" via the porphyrin plane (which was identical in all moieties of Fig. 5) rather than through the Z orbitals which had widely different ligand coordination (cyanide, water, ethanol, hydroxyl, imidazole nitrogen). Indeed, electron transfer paths via the π bonded tetrapyrrole porphyrin plane have been suggested (32, 33, 35, 38-40). The over-all conclusion which emerges from the experimental evidence *in toto* is that (within a first approximation) the electron donor-acceptor reactivity of heme iron was the same (at least for the first electron transfer step) in all the compounds and reactions shown in Fig. 5. In other words, the behavior of heme iron was essentially invariant, irrespective as to whether the heme was monomeric (as in the presence of ethanol) or dimeric (as in aqueous solution) or imbedded in the proteinic matrices of hemoglobin or myoglobin.

On the other hand, our estimate of the electron-transfer reactivity of the heme iron in cytochrome c was 1-3 orders of magnitude faster and corresponded to an upper k^o assignment which approximated the limiting rate of 10^4 cm/sec within two orders of magnitude (41). This is in complete agreement with related conclusions (on the efficiency of cytochrome c as an electron transporter) by Urry and Eyring (42). The prosthetic group of cytochrome c differs by two cysteine linkages between the equatorial porphyrin ligand and the polypeptide chain of the protein moiety. One is tempted to speculate that involvement of sulfur atoms may provide electron-transfer paths of greatly enhanced reactivity which account for the fundamental difference between cytochrome c and the heme compounds in Fig. 5.

ABSTRACT

The mechanism of formation and the changes of different deposits obtained on a Pt cathode in THF-$LiClO_4$ medium are studied by means of polaromicrotribometry (PMT). Their chemical nature is determined by infrared and x-ray induced photoelectron spectroscopy (XPS). For a polarization between −1.6 and −2.5V, a thin porous homogeneous film of lithium hydroxide occurs, which is characterized by a low friction coefficient $f = 0.7\ f_0$, where f_0 is the value in the absence of polarization. Small amounts of carbon dioxide in solution react on lithium hydroxide and convert it into lithium carbonate. This chemical change provokes a strong increase in the friction coefficient (f rises from 0.7 to 2 f_0) and is marked by the appearance of a very regular stick-slip phenomenon. Under galvanostatic control and at a weak electrolysis current, the formation of lithium hydroxide and then lithium metal is successively observed. The friction curves clearly show that Li^+ ions migrate through the porous lithium hydroxide layer and are reduced on the metal surface. When electrolysis is continued over a longer period of time the lithium hydroxide layer is coated with lithium metal. At a higher current density and at a lower water concentration, a layer of metallic lithium can be obtained in the electrode surface without the prior formation of lithium hydroxide.

The use of organic solvents and metallic electrodes in electrochemistry generally leads to a demetallization of the electrode surface, produced by the formation of organic or mineral layers (1). Such phenomena have recently been observed in hexamethylphosphoramide (HMPA) (2, 3) and their effects on electrochemical catalysis have been determined especially in the case of the reduction of quaternary ammonium salts (3). The obtention of homogeneous organic or inorganic films by an electrochemical method presents a practical value in the area of material protection and microelectronics, and knowledge of these phenomena is very important in the elucidation of organic electrochemical reactions.

In the case of an electrolytic medium composed of an organic solvent and an alkaline salt we show that some electrode reactions which can lead to irreversible changes in the surface occur in the medium. Such observations have been noted in reduction and in the case of dimethylsulfoxide (DMSO), acetonitrile, propylene carbonate, or tetrahydrofurane (THF), when a salt such as $LiClO_4$ is added to the solvent.

* Electrochemical Society Active Member.

The THF-$LiClO_4$ electrolytic medium is very often used in organic electrochemistry, and several studies have already been devoted to the reduction of Li^+ ions on a platinum electrode in this solvent (4-7). Thus, Burrows and Kirkland (4) and Dey (5) have described the behavior of Li^+ ions in the presence of water and have indicated the formation of a lithium hydroxide layer. As far as we know, however, the chemical nature of these layers has not been proved. We thus propose to study the structural modifications of the metal-solution interface in an attempt to elucidate the chemical nature and formation mechanism of the different layers.

Aside from infrared and XPS spectroscopies, we have developed a new means of analyzing the metal-solution interface, called polaromicrotribometry or PMT (8, 9). This technique, based on the measurement and recording of a friction coefficient between the electrode surface and a microslider, has proved to be particularly well adapted to the study of the formation of oxide layers (10), organic films (11, 12) and, more recently, to adsorbed layers (13, 14). This system enables one to follow *in situ* the formation and behavior

of films as a function of time, and electrical and physicochemical parameters.

Experimental

Reagents and solvents.—The THF solvent (Baker) was purified according to the following process: (*i*) The peroxides were destroyed by reaction of potassium hydroxide on the solvent over several weeks. The solvent was then distilled under atmospheric pressure. (*ii*) The distilled solvent was dried over naphthalene-sodium for 8-10 days and then redistilled as previously. (*iii*) A final distillation of the THF was carried out in the presence of $LiAlH_4$ and the middle fraction of the distilled solvent was kept under inert atmosphere.

Lithium perchlorate (Fluka grade) was dried at 100°C under vacuum for several days before being used.

All the experiments were carried out in a glove box with a strictly controlled argon atmosphere. All oxygen, carbon dioxide, and water traces were removed by trapping all these impurities with suitable filters. All the THF-$LiClO_4$ $3 \cdot 10^{-1}$M solutions were degassed for 10 min in an argon stream. The water content of the solution was around 120 ppm.

Electrodes.—Depending on the surface analysis technique, different electrode models were used.

PMT.—The PMT cell is composed of a previously described three-electrode assembly (8). The working electrode was a PTFE embedded platinum pellet (Pt Lyon-Allemand pure grade). The active surface of the electrode was a 0.6 cm² disk, polished with a 1μ diamond paste (Struers); it was rinsed by ultrasonic agitation in acetone (RP grade) and dried under nitrogen before each experiment. The reference electrode was an Ag-Ag^+ 10^{-2}M system in THF-$LiClO_4$ (7). A sintered glass tube provided electrolyte contact between the working and reference electrodes. All the potentials were measured with respect to this reference. The counterelectrode was a large surface cylindrical platinum grid centered on the working electrode.

Infrared absorption, x-ray photoelectron spectroscopy (XPS).—The working electrode used to obtain infrared and XPS spectra was composed of a rectangular glass plate on which a layer of platinum with a thickness of about 5000Å was obtained by sputtering (Balzers Model Sputron II) according to a previously described process (15).

Analysis techniques and layer characterization.—*PMT.*—The apparatus used in this work had the same characteristics as the one previously described (8, 9); the applied load on the microslider was 10g.

Multiple reflection infrared absorption spectroscopy.—We used a Perkin Elmer 225 spectrophotometer fitted with a Wilks device (Wilks Scientific Corporation, Model 49). The spectra were recorded after the infrared beam had been reflected several times between two parallel flat metallic mirrors facing each other which have been coated with the film.

Electron spectroscopy (XPS).—Spectra were recorded on an AEI ES 200 spectrometer with FRR adaptation using a Mg anticathode.

Results

PMT curves under potentiodynamic control (rate polarization 1 V/min).—Current-potential and friction-potential curves between 0 and − 1.6V show no appreciable changes. The current is negligible and the friction coefficient remains constant and has the same f_o value as in the absence of polarization (Fig. 1) (f_o = 0.17). However, between − 1.6 and − 3.5V, several electrode reactions are observed. A first current peak, whose maximum is located at − 2.3V, appears. The corresponding integrated electricity value is an increasing function of the water concentration (8000 μC/cm² for (H_2O) = $8 \cdot 10^{-3}$M). This electrode reaction is accompanied by major variations in f which rises to 1.8 f_o and then decreases and becomes constant at a value less than f_o (f = 0.7 f_o).

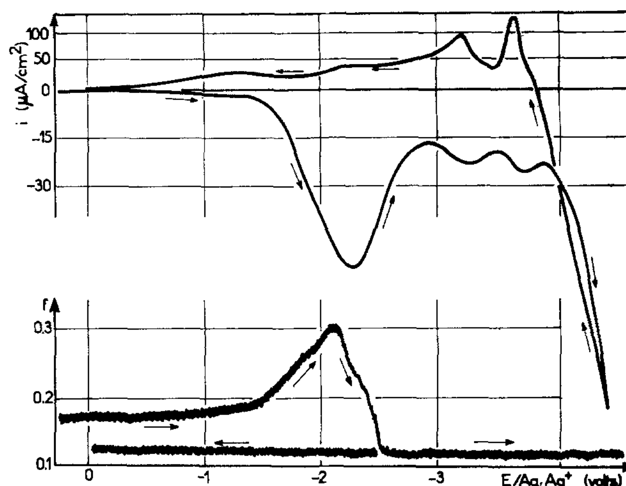

Fig. 1. Potentiodynamic and PMT curves obtained on a platinum electrode in THF-$LiClO_4$ 0.3M medium (water content, $8 \cdot 10^{-3}$M; sweep rate, 1 V/min).

Between − 3 and − 4V, the friction coefficient has the constant value 0.7 f_o, although two small current peaks are observed at − 3.25 and − 3.5V. At potentials below − 3.7V, the reduction potential of Li^+ ions is reached; the current intensity increases very rapidly, but f remains constant at 0.7 f_o. This constant value of f = 0.7 f_o is also observed in the back sweep, although several oxidation peaks appear. The height of one of them, located at − 3.6V, increases as the current intensity for the reduction of Li^+ ions increases.

PMT curves under galvanostatic control.—For anhydrous solutions (water content less than $5 \cdot 10^{-3}$M) with an applied constant current between 120 and 1500 μA/cm², the polarization of the cathode occurs at − 3.7V. The friction coefficient increases considerably and is characterized by a great irregularity whose mean value is nearly 2.5 f_o (Fig. 2). However, for hydrated solutions (H_2O = $8 \cdot 10^{-2}$M) with the same current density values as above, the potential-time curves are very different and are characterized by a first reduction wave at − 2V, followed by a second one at − 3.7V (Fig. 3).

In contrast, the friction curves are quite similar to those obtained during polarization sweeps; there is a fast increase in the friction coefficient to f = 1.3 f_o

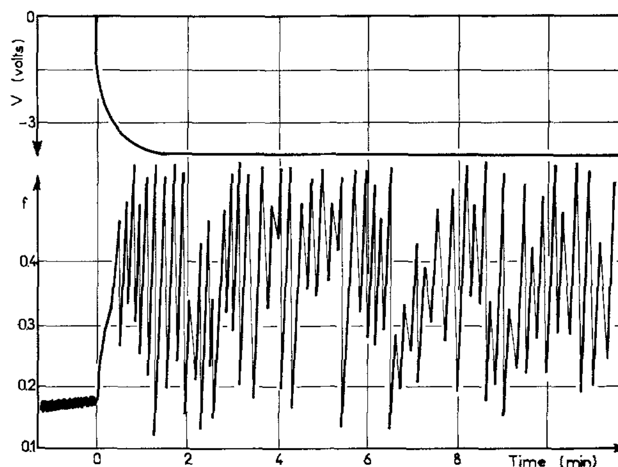

Fig. 2. Galvanostatic and PMT curves obtained on a platinum electrode in THF-$LiClO_4$ 0.3M medium (water content, less than $5 \cdot 10^{-3}$M; i = 1500 μA/cm²).

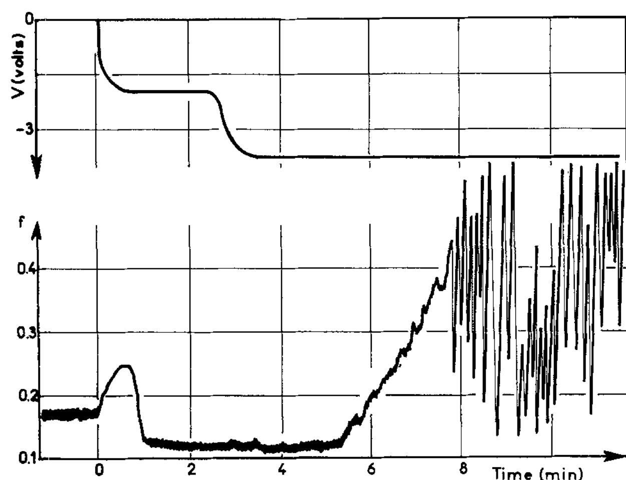

Fig. 3. Galvanostatic and PMT curves obtained on a platinum electrode in THF-$LiClO_4$ 0.3M medium (water content, $8 \cdot 10^{-2}$M; $i = 1500\ \mu A/cm^2$).

when the electrode is polarized, followed by a decrease to 0.7 f_0. This value of f remains constant for several minutes (2-3 min) and rises again to a mean value of 2.5 f_0, with very irregular variations of f. It should be noted that this new increase in the friction coefficient appears well after the electrode potential has reached −3.7V (Fig. 3).

PMT curves under potentiostatic control.—As with the potentiodynamic curves, a very fast passivating effect is observed under potentiostatic control when the platinum electrode is polarized at − 2.5V (for a water concentration of $5 \cdot 10^{-3}$M, the current density decreases from 1500 to 200 $\mu A/cm^2$ after a 3 min electrolysis) (Fig. 4). The friction curves have the same characteristics as previously: an increase in the friction coefficient of f_0 to 1.7 f_0, then a decrease to the constant value of 0.7 f_0 which, moreover, remains constant when the circuit is opened after a 10 min polarization. It is noteworthy that the decrease from 1.7 to 0.7 f_0 in the friction coefficient is also independent of the applied potential. If the polarization is interrupted when the friction has attained its maximum value (f = 1.7 f_0), it then decreases to f = 0.7 f_0 as previously observed. This transition of the friction coefficient is highly dependent on the water concentration (Fig. 5). For a water concentration of 10^{-3}M the maximum value f_M of the friction coefficient is 2 f_0; it is only 1.3 f_0 for a water content of $8 \cdot 10^{-2}$M.

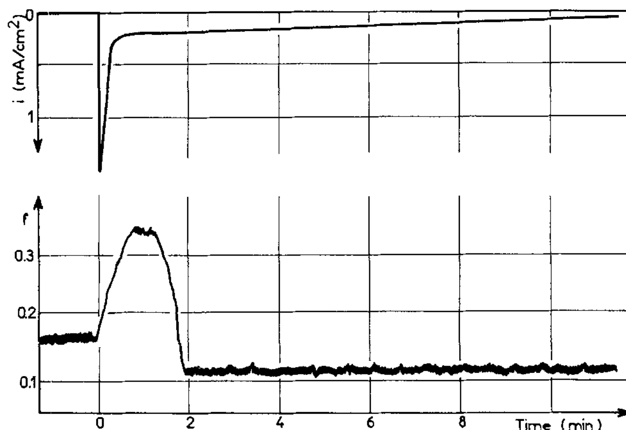

Fig. 4. Potentiostatic and PMT curves obtained on a platinum electrode in THF-$LiClO_4$ 0.3M medium (water concentration, $5 \cdot 10^{-3}$M; applied potential, −2.5V).

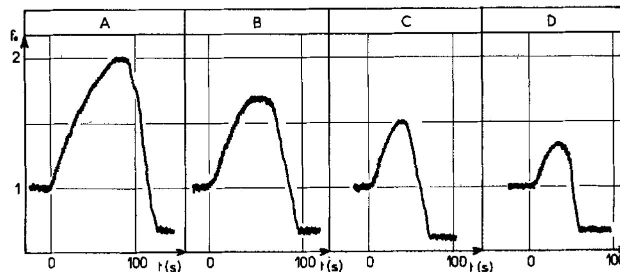

Fig. 5. Variation of the PMT curves maximum vs. the water concentration of the THF-$LiClO_4$ 0.3M medium in the case of a platinum electrode polarized at −2.5V. Water concentration: A, 10^{-3}M; B, $5 \cdot 10^{-3}$M; C, 10^{-2}M; D, $8 \cdot 10^{-2}$M.

Friction changes observed with a THF-$LiClO_4$ solution containing CO_2 traces.—Other very different friction variations are observed if the potentiostatic experiments are conducted in air or in presence of CO_2. We just showed that, when the platinum electrode is polarized at − 2.5V in a water concentration of $5 \cdot 10^{-3}$M, the friction coefficient rises to 1.7 f_0, then decreases and stays constant at 0.7 f_0. If the same experiment is operated in air, the friction coefficient remains constant for only a few minutes. There is a new increase in f whose mean value is about 2 f_0 and which is accompanied by a stick-slip phenomenon (9).

Another experiment performed with the same highly degassed solution, from which oxygen and CO_2 have been totally removed, also gives the constant friction coefficient of 0.7 f_0. If CO_2 is reintroduced into the solution by bubbling, the increase in the friction coefficient from 0.7 f_0 to a mean value of 2 f_0 is very fast (less than 30 sec) and is again accompanied by a very regular stick-slip phenomenon (Fig. 6).

Identification of layers by multiple reflection infrared spectroscopy and electron spectroscopy (XPS).—*Analysis of the layer whose friction coefficient is f = 0.7 f_0.*—A large surface thin layer platinum electrode was polarized at − 2.6V for 10 min in a THF-$LiClO_4$ solution in a very pure N_2 atmosphere. This led to the formation of a film whose friction coefficient was also 0.7 f_0.

The infrared absorption spectrum of this film is composed of several peaks located at 3580, 1580, 1000, 850, 630, 680 cm^{-1}, and of a wide one centered at 2900 cm^{-1} (Fig. 7a). This spectrum is identical to the one obtained for a layer of chemically prepared hydrated lithium hydroxide (16, 18).

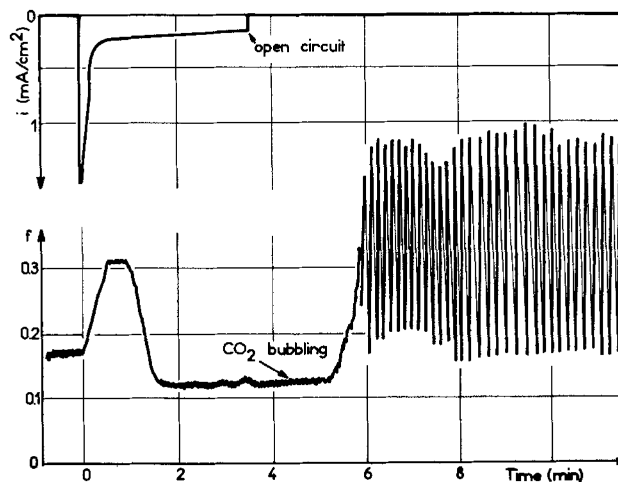

Fig. 6. PMT curves obtained on a platinum electrode after bubbling of CO_2 in THF-$LiClO_4$ 0.3M medium (the electrode is polarized at −2.5V for 3.5 min, then placed in open circuit before CO_2 bubbling; the water concentration is around $5 \cdot 10^{-3}$M).

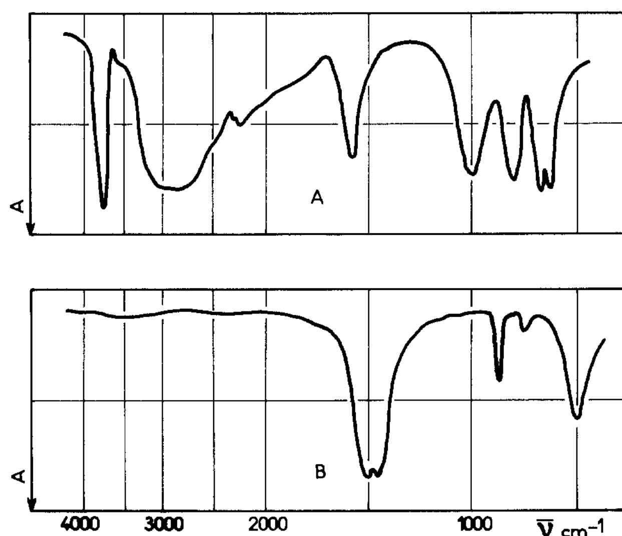

Fig. 7. Multiple reflection infrared absorption spectra obtained from thin platinum layers polarized at − 2.5V for 10 min. A. In THF-$LiClO_4$ 0.3M $H_2O \sim 5 \cdot 10^{-2}$M medium; lithium hydroxide film. B. In THF-$LiClO_4$ 0.3M saturated with CO_2, $H_2O \sim 5 \cdot 10^{-2}$M; lithium carbonate film.

The XPS spectrum composed of peaks at 285, 531.9, 74, 55.3, and 70.8 eV (Fig. 8a) confirms the hypothesis of a lithium hydroxide layer. The peak at 531.9 eV is related to O 1_S, the peaks at 74 and 70.8 eV to platinum 4 f doublet, the one at 55.3 eV to Li 1_S, and the peak at 285 eV to C 1_S, resulting from natural contamination of the samples.

Identification of the layer obtained in presence of CO_2.—The salient features of these layers are a regular stick-slip phenomenon with a dynamic friction coefficient whose mean value is $f = 2\ f_o$.

The infrared spectrum was obtained with electrode surfaces treated in the same conditions as previously except for bubbling of CO_2 in the THF-$LiClO_4$ solution. The peaks at 1510, 1450, 870, and 730 cm^{-1} (Fig. 7b) are characteristic of a lithium carbonate layer (16, 17).

The XPS spectrum is composed of the same signals as previously: 285, 531.9, 55.3, 74, and 70.8 eV with, however, a new peak at 289.8 eV corresponding to carbon 1_S of lithium carbonate (Fig. 8b). The shift in energy observed for this new peak is in total agreement with the results obtained by Siegbahn *et al.* (19) in the case of sodium carbonate.

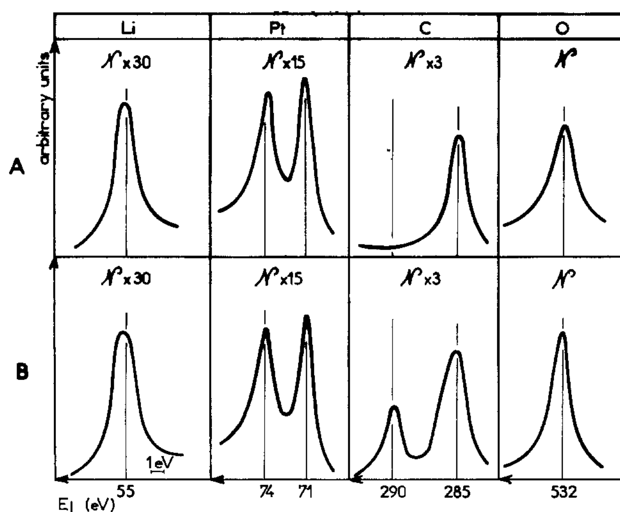

Fig. 8. XPS spectra obtained from thin platinum layers polarized at −2.5V for 10 min. A. In THF-$LiClO_4$ 0.3M, $H_2O \sim 5 \cdot 10^{-2}$M medium; lithium hydroxide film. B. In THF-$LiClO_4$ 0.3M saturated with CO_2, $H_2O \sim 5 \cdot 10^{-2}$M; lithium carbonate film.

Discussion

The results obtained by PMT and by infrared and XPS spectroscopies clearly show the formation of different layers on the platinum electrode surface. Thus, a first current peak centered at −2.3V whose intensity increases with the water concentration is observed. As proposed by Burrows and Kirkland (4), this reaction is due to water reduction and is followed by the formation of lithium hydroxide according to the diagram

$$H_2O + e \rightarrow OH^- + \frac{1}{2} H_2$$

$$OH^- + Li^+ \rightarrow LiOH$$

The lithium hydroxide is adsorbed on the platinum surface, and the infrared and XPS spectroscopy results confirm that it is indeed a lithium hydroxide film, characterized by a low friction coefficient ($f = 0.7\ f_o$). However, it must be noticed that the friction curve obtained under potentiostatic control is composed of two distinct zones. In the first one the friction coefficient goes through a maximum value, $f_M > f_o$, whose amplitude decreases as the water concentration increases, and in the second one, f has the steady value of 0.7 f_o which is independent of the applied potential.

The first part of the friction curve cannot be attributed to adsorption of generated electrode species. With a carefully degassed solution the only generated chemical species are OH^- and H_2. Hydrogen adsorption must be set aside because we have seen that on platinum it entails a decrease in friction (10); the presence of OH^- ions in THF also has no effect on the friction coefficient, as was verified in the case of basic solutions.

It thus seems likely that this rise in the friction coefficient is related to the friction of silica on bare platinum. This result is in agreement with the fact that friction on a perfectly clean metallic surface generally entails high friction coefficients (20).

This phenomenon is very pronounced in the case of an anhydrous medium. If the water concentration is about $5 \cdot 10^{-3}$M, the friction coefficient rises from f_o to 2 f_o and remains constant for 30 to 45 sec before falling to 0.7 f_o 120 sec later. With a higher water concentration ($H_2O \simeq 10^{-2}$M) the maximum value f_M is only 1.5 f_o and the time necessary to attain the 0.7 f_o value is shorter (75 sec).

These friction variations are schematically shown in Fig. 9a. It can be supposed that at −2.5V the platinum surface is completely free of any adsorbed species; this provokes a fast rise of f along CD from f_o to f_1, where f_1 is supposed to correspond to the theoretical value of friction on bare Pt. Afterward, the OH^- ions combine with Li^+ ions to give lithium hydroxide which is adsorbed onto the Pt surface. This new deposited layer provokes a decrease in the friction coefficient from f_1 to 0.7 f_o along AB, and this latter variation is independent of the polarization.

For a very high water content, the concentration of lithium hydroxide in the neighborhood of the surface is also higher and, therefore, the film formation occurs more quickly. The decrease in friction will be quicker along A'B' parallel to AB and the maximum value f_M will be much smaller than f_1. Indeed, this is what we have qualitatively observed (Fig. 9b). Thus, the polarization applied at −2.5V temporarily cleans the surface electrode and involves an increase in the friction coefficient, followed by lithium hydroxide adsorption which causes the decrease in the friction coefficient from f_M to 0.7 f_o.

When this lithium hydroxide layer is observed with an optical microscope it appears to be porous and with a poor homogeneity. For small water concentrations, this layer is very thin and its thickness is less than 100Å. This observation is confirmed by XPS analysis

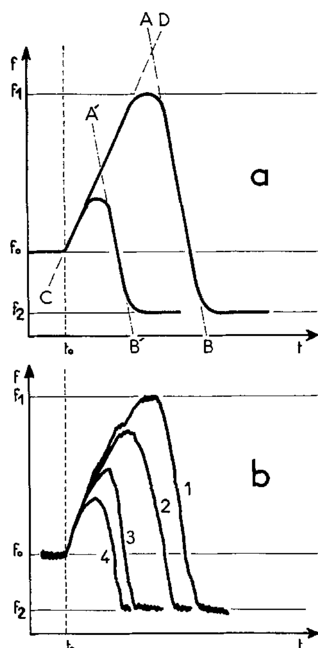

Fig. 9. Water concentration effect on the variation of the friction maximum observed after polarization at −2.5V of a platinum electrode in THF-$LiClO_4$ 0.3M medium. A. Theoretical variation. B. Experimental variation.

which shows the 70.8 and 74 eV peaks characteristic of the platinum 4f doublet.

This porosity and lack of homogeneity in the LiOH layer, which nevertheless has some passivating properties, explain the fact that for a second cathodic sweep there is again a reduction current peak which is less high than for the first sweep, but whose friction characteristics remain unchanged. They further account for the fact that all the MIM sandwich devices realized with these lithium hydroxide films are short-circuited.

This lithium hydroxide layer does not prevent the reduction of the Li^+ ions from occurring. The PMT results obtained under galvanostatic control prove that the discharge occurs through the pores of the film. Burrows and Kirkland (4) have advanced similar ideas in their study of a polarized platinum cathode in THF or propylene carbonate medium.

In the case of a very anhydrous medium (H_2O = $5 \cdot 10^{-3}$M), the application at the cathode of a constant current ($120 < i < 1500$ μA/cm^2) provokes the instantaneous formation of a metallic Li layer, which entails a high and irregular friction coefficient and the polarization of the electrode at −3.7V corresponding to the Li/Li^+ equilibrium potential (6, 7) (Fig. 2). Identical results (friction and potential) are obtained with massive Li.

However, the same experiment in a hydrated medium gives quite different results. A first potential plateau observed at −2.3V corresponds to the water reduction. As previously, the friction coefficient increases to the f_M value and then decreases to 0.7 f_o, the characteristic friction of the lithium hydroxide film. If the polarization of the cathode is continued, a second plateau appears at −3.7V, characteristic of the Li/Li^+ redox system, although the friction coefficient remains at 0.7 f_o. It is only 2 min after the potential has reached −3.7V that the friction rapidly increases again, to attain the same value as in the previous experiment (mean f value = 2 f_o).

The nonsimultaneity of the friction and the potential rises cannot be attributed to the response time of the apparatus, because it is about 1 sec (9). It seems more likely that Li^+ ions are diffusing through the lithium hydroxide layer and are reduced on the metal surface.

The hypothesis of the formation of a Li deposit on the lithium hydroxide layer must be ruled out, because in this case a rapid increase of the friction coefficient would occur. These results are quite similar to the ones we have observed in the case of a platinum electrode coated by a polymeric film which is permeable to Li^+ ions (12).

Thus it appears that the strong increase in the friction coefficient must be attributed to a Li coating of the lithium hydroxide layer, after it has been saturated by Li. Furthermore, if the electrolysis is carried out under ambient atmosphere or in the presence of CO_2 traces, the lithium hydroxide is rapidly transformed into lithium carbonate which provokes a strong increase in the friction coefficient (mean f value = 2 f_o) and a stick-slip phenomenon. These results are also confirmed by infrared and XPS analysis. Successive etchings of the layer surface by means of an Ar^+ ion beam show, moreover, that the lithium hydroxide was completely changed into lithium carbonate as is expressed by the simultaneous disappearance of XPS energy peaks for C_{1S} (carbonate) and Li 1_S.

Polaromicrotribometric (PMT) and Spectroscopic (Infrared-XPS) Study of the Formation and Modifications of Films Formed on a Polarized Platinum Electrode in THF-LiClO$_4$ Medium

II. Anodic Polarization

ABSTRACT

The surface changes occurring when a platinum electrode is anodically polarized in THF-LiClO$_4$ or in THF-LiClO$_4$-9,10 diphenylanthracene (DPA) are detected and investigated by means of polaromicrotribometry (PMT). The formation of a homogeneous film on the metal surface is associated with a very small value of the friction coefficient. The thickness of this film, designated by the general symbol Pt|THF, LiClO$_4$, Ox|, may be adjusted from 100 to 5000Å. It appears as a very pure variety of polyTHF, uncontaminated by the electrolyte. Multiple-reflection infrared spectroscopy and x-ray photoelectron spectroscopy (XPS) are used to determine its structure. Its formation results from the polymerization of THF via an ionic mechanism initiated by $ClO_4{\cdot}$ or $DPA^{\cdot +}$ radicals. It only occurs if the water content is less than 250 ppm. This film has well-defined physical properties: a marked hydrophobicity, very strong adherence on the platinum surface, and great homogeneity; although it is a nonconductor out of the solution, its porous structure makes it a conductor in electrolyte solution.

The development of the technology in the area in microelectronics and, more recently, in that of integrated optics is more and more dependent on different methods of elaborating organic or mineral films (1). In the case of organic films, numerous techniques for deposition on metallic surfaces have been described. The most common methods are based on vapor deposition or sublimation (1), adsorption (2) or polymerization of an organic vapor subjected to electronic bombardment (3) or to an electric discharge (4). Electrochemical techniques can also be used for the elaboration of mineral or organic films, applicable to the previous areas. The film quality (purity, adherence, and homogeneity) depends on the chemical system chosen, on the polarization conditions, and also on the choice of the chemical medium in which the electrode reaction is occurring.

Generally speaking, it is possible to obtain an organic polymer film adsorbed on a metallic surface by oxidizing or reducing a compound which produces polymerizable radical or ionic species. The chosen reagent may either be a monomer dissolved in a solvent, or the solvent itself. The THF example belongs to this latter case, and in a previous work (5) we show that several mineral films are formed on the electrode under cathodic polarization.

The polymerization of THF by chemical (6) or electrochemical (7-10) means has already been described in the literature, but it is only related to the formation of the dissolved polymer in solution. As far as we know, no study has been devoted to the phenomena which occur on the electrode surface for an anodic polarization.

By using the PMT technique (11, 12), we have been able to show important modifications of the platinum surface in the anodic zone. These are related to the appearance of a deposit which could not be detected by analysis of the *i-E* curves alone. This first observation is confirmed by means of other analytical techniques such as multiple-reflection infrared absorption and x-ray photoelectron (XPS) spectroscopy. We have studied the mechanism by which this deposit is formed, its chemical structure, and its physical properties.

Experimental

Reagents and solvents.—THF (Baker pure grade) and the lithium perchlorate (Fluka) were purified as previously described (5). All experiments were performed in THF-LiClO$_4$ 0.3M solutions or in THF-LiClO$_4$ 0.3M diphenylanthracene (DPA) 0.03M solutions which were degassed by bubbling argon through them for 15 min. Before measurements, the water content of these solutions was about 120 ppm.

Film detection and analysis techniques.—Polaromicrotribometry (PMT).—As previously outlined for the cathodic THF study, the film formation was followed *in situ* by means of PMT. The electrolysis cell, the electrodes, and the apparatus used for friction measurements were the same as those described in the preceding work (5). The Pt working electrode was always polished with diamond paste before each experiment and rinsed in acetone.

Spectroscopic measurements.—Chemical identification of the electrode films was obtained as previously by means of x-ray photoelectron spectroscopy (XPS) and by multiple-reflection infrared spectroscopy. The same apparatuses were used under the same conditions as described in the preceding work (5).

Physical characteristics of the film.—Wettability.—The hydrophobic properties of the surface were characterized by measuring the contact angle between water and the film surface (13) from the projected image of a water drop resting on the film.

* Electrochemical Society Active Member.

Thickness.—The thickness was measured by an optical method with a Tolansky interferential device mounted on a Leitz metalloplan microscope or by the capacity of a sandwich (Pt|film|metal) device.

Capacity and conductivity.—A (Pt|film|gold) device was realized by evaporating a thin gold counterelectrode (1000Å) on the film under a vacuum of 10^{-6} Torr. Its conductivity under a-c polarization and its capacity were measured with a Wayne Kerr impedance bridge (Model B 641) at a residual pressure of 10^{-5} Torr and at constant temperature (25°C). The d-c conductivity was measured by application of Ohm's law, $V = Ri$, where V is the applied potential between the two electrodes and i is the current intensity.

Results and Discussion

PMT curves under potentiodynamic control (polarization rate 1 V/min).—In the case of a THF-$LiClO_4$ 0.3M solution, the current-potential curves obtained between 0 and +4V show two distinct zones: the first is located between 0 and +0.7V where the current intensity is small, and the second beyond +0.7V where it increases rapidly (Fig. 1). In contrast, f keeps a steady value, f_0, from 0 to +3 or +3.5V which is the value of f on the platinum electrode surface before polarization. Beyond 3 or 3.5V, f increases slightly and reaches 1.25 f_0. On the back sweep, no hysteresis is observed on the current-potential curve, but f remains constant at 1.25 f_0 from +4 to 0V.

With successive potential sweeps between 0 and +4V, the current-potential curves remain the same as with the first sweep. However, after three cyclic potential sweeps, the friction-potential curve is seriously modified: after f has increased toward 1.25 f_0, it slowly decreases to 0.2 f_0 and then remains constant, even if the electrode is in open circuit.

In the case of THF-$LiClO_4$ 0.3M solution with diphenylanthracene (DPA) 0.03M, the current-potential curves obtained between 0 and +2.5V have the same features as in the previous case. However, the appearance of a blue color near the surface is observed when the polarization reaches +1.8V. The friction coefficient stays at the constant value f_0, and it is only after three cyclic potential sweeps that f increases to 1.25 f_0 which is reached at the same time as the blue color near the electrode surface disappears. If the potential sweeps are pursued (around 10), f decreases and reaches the same constant value as that observed in THF-$LiClO_4$ ($f = 0.2 f_0$). This proves that the layer which has formed in the presence of DPA is the same as the latter one, but was obtained for smaller potentials.

PMT curves under potentiostatic control.—When the platinum electrode is polarized at +3.5V in THF-$LiClO_4$ medium, the current intensity is instantaneously 1.8 mA/cm^{-2} and remains steady at this value as long as the electrolysis continues (Fig. 2). The friction coefficient remains constant for 1 or 2 min and then increases to 1.25 f_0. After a 3 min electrolysis, it decreases slowly and stabilizes at the low value of 0.2 f_0. This value remains constant when the electrode is placed in open circuit. If the electrode is disconnected after 3 min of polarization at +3.5V where f is at a maximum, a slow decrease of f toward 0.2 f_0 is observed as in the latter case (Fig. 3).

In the case of a THF-$LiClO_4$ medium with DPA, an applied potential of 1.8V at the platinum electrode entails a current density of 1.2 mA/cm^2 and the appearance of a blue color. In contrast to the previous case, the current intensity decreases slightly and stays at 0.5 mA/cm^2 after 30 min. The time-friction curve in this case is identical to the one observed in THF-$LiClO_4$, *i.e.*, f increases to 1.25 f_0 and then decreases and stabilizes at 0.2 f_0. The initial increase of f is also accompanied by the disappearance of the blue color near the electrode surface.

Film identification and formation mechanism.—Spectroscopic analysis.—The deposit characterized by the small value of the friction coefficient ($f = 0.2 f_0$) is analyzed by multiple-reflection infrared absorption and XPS spectroscopy.

The infrared spectra of the film obtained in the THF-$LiClO_4$ and THF-$LiClO_4$-DPA media are identical and correspond to the poly-THF spectra obtained in solution chemically (14). They are characterized by several absorption peaks centered at 2940, 2860, 1460, 1360, and 1110 cm^{-1}, and by a peak at 1720 cm^{-1} which is not observed in the bulk polymer spectrum (Fig. 4). The peaks located at 2940 and 2860 cm^{-1}

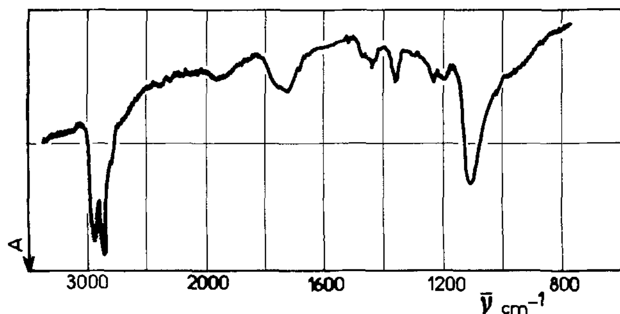

Fig. 4. Multiple-reflection infrared absorption spectrum obtained from a thin platinum layer polarized at +3.5V for 50 min in THF-LiClO$_4$ 0.3M.

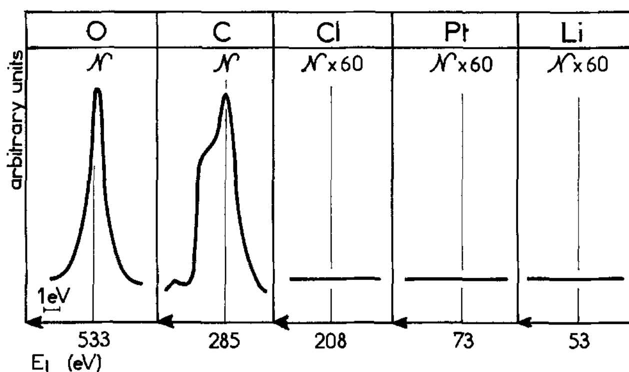

Fig. 5. XPS spectrum obtained from a thin platinum layer polarized at +3.5V for 50 min in THF-LiClO$_4$ 0.3M.

are due to stretching CH vibrations; those which are centered at 1460 and 1360 cm^{-1} are CH bending vibrations, and the one at 1110 cm^{-1} corresponds to the C—O vibration of an aliphatic ether. The peak at 1720 cm^{-1} is due to the carbonyl C=O stretching vibration.

In the case of XPS, the spectrum is composed only of peaks at 532.8, 289, 286.2, and 285 eV (Fig. 5). If we suppose that the film is made of poly-THF, two different carbons can be distinguished in the polymer formula $[O-(CH_2)_4-]_n$: one of them is bound to two neighbor carbons, the other to a carbon atom and an oxygen. Therefore, two peaks will be observed in the photoelectron energy spectrum, which are indeed the two peaks at 286.2 and 285 eV. The first one corresponds to the carbon in the α position with respect to the oxygen atom, the second one to the C—C bond. However, it should be noted that these two carbon peaks do not have the same intensity, but are in the proportion 1:1.2. The 1.2 eV energy difference between these two carbons, which was also observed by other workers (15), can be calculated by considering the electronegativity of each element.[1] The peaks located at 532.8 and 289 eV are respectively due to O_{1S} and C_{1S} of the carbonyl group.

The film appears to be very pure and uncontaminated by electrolyte elements; the analysis results are similar to those obtained in the case of bulk poly-THF.

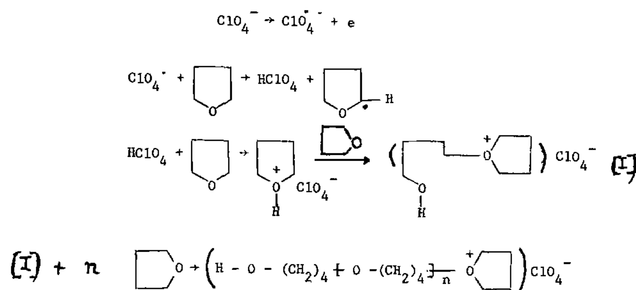
Formation mechanism.—The results obtained by XPS, infrared, and PMT confirm the deposition on the electrode surface of a very adherent poly-THF film characterized by a very small friction coefficient. The appearance of this deposit depends on the applied potential and on the composition of the electrolytic medium.

In THF-LiClO$_4$, it is necessary to polarize the electrode at very positive potentials (+3.5V) in order to observe the film formation. In contrast, by addition of DPA to the latter solution, the same result is obtained by applying only a polarization of +1.8V.

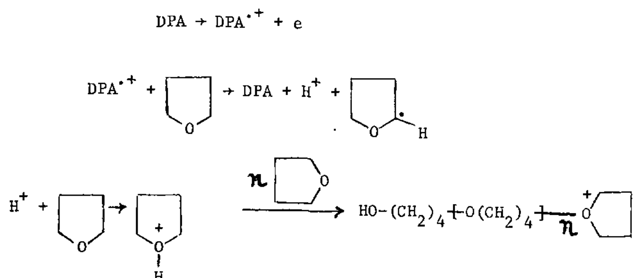
When the polymerization is started, it can continue if the polarization is suppressed. This result clearly appears on the friction-time curves obtained in open circuit after a polarization has been applied for a short time (Fig. 3). These observations tend to prove that polymerization is initiated via electrochemical species and then proceeds via a chemical chain process which no longer depends on the electrogenerated precursors.

The film formation clearly appears to be due to the presence of radicals at the electrode level. The very positive potential of +3.5V likely involves the oxidation of perchlorate anion into $ClO_4\cdot$ radical, and that of +1.8V the oxidation of DPA to $DPA^{\cdot+}$. In this latter case, the oxidation of DPA is confirmed by the appearance of a blue color in the electrode vicinity which may be attributed to the presence of the $DPA^{\cdot+}$ radical cation. Thus it may be considered that $ClO_4\cdot$ and $DPA^{\cdot+}$ radicals initiate the THF polymerization, a very likely hypothesis as we know that DPA is very often used for cationic polymerization (18). This hypothesis is also confirmed by the work of Nakahama *et al.* (8) but is in opposition to the mechanism proposed by Dey *et al.* (10), who assume that the polymerization is initiated by the THF electrooxidation.

Nakahama *et al.* have proposed a reaction path in which $ClO_4\cdot$ radical reacts on a THF molecule and gives $HClO_4$, which in turn induces the polymerization according to the diagram



A similar mechanism may be considered in the case of THF-LiClO$_4$ with DPA. The anodic polarization produces $DPA^{\cdot+}$ radical cation which reacts on THF and gives H^+ which, as previously, initiates the polymerization. As added proof, it must be noted that in each case, after the electrode was anodically polarized, we observed a reduction peak at −0.5V, characteristic of H^+ ions. In this last case we propose the following reaction diagram



The polymerization process can fail in the presence of nucleophilic species such as water (6). Indeed, this has been observed when the water content of the solution was above 250 ppm. It is possible that water destroys the radicals which initiate the polymerization

[1] It is possible in XPS to correlate the peak energy values of an element with the partial electric charge located on this element. This partial charge, q, is calculated in the electrostatic theory by the relationship $q = Q + \Sigma I$, where Q is the charge of the element, and ΣI the added ionic partial character of the bonds attached at the element (16). According to the Pauling theory (16), for the C/O linkage. $I = 1 - e^{-0.25 (\chi_C - \chi_O)^{1/2}}$, where χ_C and χ_O are respectively the C and O electronegativities. By setting χ_C equal to 2.5 and χ_O to 3, we compute, in the case of poly-THF, a partial ionic character of 0.22 for the C—O bond and therefore a partial charge of 0.22 for the carbon which entails an energy shift between 1 and 2 eV (17).

or reacts on the cationic adduct and stops the chain propagation.

It must also be noticed that the infrared and XPS spectra reveal some aldehydic bonds which may be attributed to the polymer peroxidation by air. Such reactions have been observed with the bulk polymer in contact with air (19). These are oxidation reactions which entail a fragmentation of the chain and the formation of aldehyde fragments (19). These aldehydic groups may also originate from a secondary polymerization process between the  cation and the THF molecules (20, 21).

Finally, it should also be noticed that the PMT curves show two different friction coefficient values; the one observed at the beginning of the polarization is high ($f = 1.25\ f_0$), the other one is weak and independent of the potential. Up to now this observation has not been clearly explained. We think it is probably only due to a difference of friction between the first growing polymer layers and those corresponding to the thick deposit.

Physicochemical and electrical properties of Pt|THF, $LiClO_4$, Ox| films.—Physicochemical properties.—The film analysis by means of XPS shows that the film is very pure and does not contain impurities such as lithium, chlorine, and perchlorate. Moreover, it is very homogeneous, a feature not found with other electrochemically formed polymers, which are very often unhomogeneous [surface formed of small spheres (22)] or contaminated by the support electrolyte (23). An optical microscopic view of the surface at 1300 magnification does not show any defects (Fig. 6).

This film homogeneity is also revealed by the steady value of the friction coefficient at 0.2 f_0 without any irregular fluctuation. Moreover, this value is the same when the measurement is operated in the solution or outside after the film has been rinsed with acetone and dried in a stream of nitrogen.

This homogeneity is only observed with a film thickness less than 2000Å. With very thick films (1 or 2μ) obtained for a lengthy polarization (more than 120 min), the top layers are less adherent and they rearrange when the film is rinsed to give an unhomogeneous surface aspect. The film thickness is generally independent of the nature of the electrolyte but is very sensitive to small variations in water content.

These films have marked hydrophobic properties: The contact angle between the surface and a drop of water increases from 8° to 70° from bare to film-coated platinum. When heated in air between 100° and 120°C, the films are destroyed; this result must be related to the melting point of bulk poly-THF which has a similar value (19).

Fig. 6. Optical microscope view of a poly-THF film obtained after polarization of a platinum surface at +3.7V for 40 min. $THF\text{-}LiClO_4$ 0.3M, $H_2O \sim 10^{-3}$M. Magnification 1300×.

Electrical characteristics.—They are measured from (Pt|film|gold) sandwich devices. For a film thickness of 1200Å obtained after electrolysis of Pt at +3.5V in $THF\text{-}LiClO_4$ for 20 min, the device capacity is 25 **nF** · cm^{-2}, the loss ($tg\delta$) is $8 \cdot 10^{-3}$, the breakdown field is $2.5 \cdot 10^6\ V \cdot cm^{-1}$; the dielectric constant measured at 10 mV a-c with polarization at a frequency of 10^4 rad · sec^{-1} is 3. The film conductivity is very weak: under a-c polarization, $\sigma_{1000Hz}^{25°C} = 2 \cdot 10^{-9}\ \Omega \cdot cm^{-1}$; under d-c polarization, $\sigma^{25°C} = 10^{-14}\ \Omega \cdot cm^{-1}$. These latter results show that the film conductivity in solution is not electronic but is due to ion diffusion through the polymer matrix. We have indeed checked that the presence of the film on the electrode surface does not disturb the discharge of alkaline cations such as Li^+, Na^+, which migrate through the film before being reduced at the film-metal interface (24).

This film permeability to ions is probably due to the fact that the polymer chains are parallel and regularly spaced, thus having a partially crystalline character, as has been shown in the case of bulk poly-THF (25, 26). Experiments on this point are currently under way.

Conclusion

The results obtained by spectroscopic analysis and by PMT confirm the possibility of depositing an organic film in $THF\text{-}LiClO_4$ or $THF\text{-}LiClO_4$-DPA medium. This film obtained on a platinum electrode is thin, homogeneous, free of impurities, and very adherent to the surface. It has been shown with the help of PMT and electrochemical techniques that its formation is slow, initiated by radicals $ClO_4\cdot$ or $DPA^{\cdot +}$, and needs an anhydrous medium. This film is a nonconductor, but its permeability to ions makes it a conductor in solution. This latter possibility eventually could be used for doping and for making organic semiconductor films.

The Activation and Deactivation of Iridium Electrodes in Acid Electrolytes

J. O. Zerbino, N. R. de Tacconi, and A. J. Arvía*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, Sucursal 4, 1900 La Plata, Argentina

ABSTRACT

The electrochemical behavior of the Ir/1*M* H_2SO_4, Ir/96% H_2SO_4, and Ir/$KHSO_4$(melt) interfaces at different temperatures was investigated using potentiodynamic techiques, covering the potential range between the H_2-evolution reaction and the O_2-evolution reaction. Electrodes with different degrees of activation were employed. The surface electrooxidation is explained by a sequence of reactions involving oxo-hydroxo species and IrO_2 electroformation. The activation effect, particularly noticed with 1*M* H_2SO_4 at 25°C, is assigned to an accumulation of oxo-hydroxo species on the electrode and the occurrence of proton transfer reactions. The activation effect is practically absent in the $KHSO_4$ melt, but instead, it exhibits an aging of the electroformed oxygen-containing species, which under a complete coverage probably entails an IrO_2 monolayer. Results with 96% H_2SO_4 correspond to an intermediate situation between 1*M* H_2SO_4 and molten $KHSO_4$, depending on the temperature.

The potentiodynamic polarization of Ir electrodes in acid electrolytes using symmetric triangular potential perturbation from 0.4 to 1.4V and vice versa, reveals the electroformation and electroreduction of oxygen-containing layers (1-8). These processes apparently behave in a manner considerably different from most of the other metals of the Pt group. Under certain experimental conditions the amount of charge that the Ir surface can store in the oxide region increases during cycling. The electrode activation depends on the limits of the potential excursion, on the rate of the potential perturbation, and on the electrolyte composition (8-23).

The anodic and cathodic potentiodynamic current/potential (*I/E*) profiles of Ir either in acid aqueous electrolyte at room temperature or in molten potassium bisulfate electrolyte show very little hysteresis. Nevertheless, the oxide charge capacity increase observed in the aqueous electrolyte at room temperature is drastically reduced in the molten electrolyte (24, 25). Then, the Ir/$KHSO_4$ (melt) interface behaves more like other Pt/acid solution interfaces. This means that both the composition and the temperature should be included in the number of variables playing a part either in the activation or deactivation of the Ir electrode.

Various explanations have been advanced for the electrochemical behavior of Ir in aqueous solutions such as an expanded lattice theory for oxide growth on noble metals (5), an irreversible oxide formation with subsequent stoichiometry changes (16), oxide-filled pitting formation, and formation of a polymeric layer of oxygen-bridged hydrated oxy-hydroxo species (18, 19). These attempts, however, are only qualitative and restricted to a relatively limited range of experimental conditions. They are unable to explain that the electrode activation observed in the potential region of the oxygen-containing electrosorbed species is absent in the potential region of the hydrogen electrode reactions. The results reported so far therefore indicate the complexity of the electrochemical processes at the Ir/acid electrolyte interface and suggest the importance of attempting further research of this system under a wider range of experimental conditions with the aim of attaining a more extended mechanistic interpretation of these processes.

Experimental

The electrolysis cell system was the same one previously described (26). The working electrode consisted of an Ir wire (spectroscopically pure, Johnson, Matthey and Company) of 1.5 cm^2 apparent area. A Pt counterelectrode and a Pt/H_2 (1 atm)/electrolyte reference electrode completed the electrolysis cell arrangement. The following electrolytes were used: 1*M* H_2SO_4 (at 25°C); 96% H_2SO_4 (at 25° and 90°C); and $KHSO_4$ (melt) (at 230°C). Analytical grade reagent chemicals and triple distilled water were employed. Experiments were made under continued N_2-saturation. Two basic experimental techniques were used, namely, the triangular potential sweep (TPS) technique, either single (STPS) or repetitive (RTPS), also employing other potential/time perturbation functions, and the triangular modulated linear potential sweep technique (TMLPS), either single sweep (TMLPS) or triangular sweep (TMTPS).

The corresponding circuitry was essentially the same as in previous publications (27, 28), including a fast rise time potentiostat (Tacussel Type PIT 20-2 X, rise

time 0.2 μsec) and an ohmic drop compensator (Tacussel Type CDCO).

Results

Types of Ir electrodes.—The electrochemical response of the Ir electrode is strongly dependent on the history of the electrode. The types of electrodes are characterized as: (*i*) clean wire electrodes "as received" previously treated with HNO_3-H_2SO_4 mixture (type I); (*ii*) electrodes potentiodynamically activated by cycling the potential between 0.0 and 1.6V (type II); (*iii*) electrodes of type II anodically deactivated at $E = 1.6V$ in 1*M* H_2SO_4 at 25°C (type III); (*iv*) electrodes of type II deactivated by heating *in vacuo* at 300°C for 2 hr (type IV); and (*v*) electrodes of type II mechanically deactivated by rubbing its surface with a filter paper or more effectively with very fine Al_2O_3 powder (type V). Activated surface electrodes (activated electrodes) mean electrodes with a high charge capacity in the potential region where the oxygen-containing species are electroformed and electroreduced. The reverse corresponds to the so-called deactivated electrode.

The rest potential of the Ir/1M H_2SO_4 interface.—The rest potential, E_r, of type I electrodes immersed in 1*M* H_2SO_4 at 25°C is *ca.* 0.85V. The E_r value is attained spontaneously both from the anodic potential side and from the cathodic potential side. They require 17 min to reach E_r from 1.3V and only 90 sec from 0.03V. Type II electrodes require about twice that time to attain E_r starting from 1.3V.

The E/I voltammograms obtained with symmetric triangular potential scans.—Electrodes of type III in 1*M* H_2SO_4 at 25°C exhibit repetitive voltammetric *E/I* displays in which the amount of charge, particularly that involved in the processes occurring in the 0.4-1.50V potential range (Fig. 1), depends on the perturbation conditions. The current peaks located in the 0-0.4V range mainly pertain to the hydrogen electrode reaction (peaks Ia, IIa, IIIa, IIc, and IIIc) while those found in the 0.4-1.6V range correspond to the electroformation and electrodesorption of oxygen-containing species on Ir (peaks IVa, Va, VIa, VIIa, VIIIa, IVc, VIc, VIIc, and VIIIc). The anodic current beyond 1.6V principally corresponds to the oxygen evolution on the oxidized surface (22, 29-31). The first TPS swept from −0.07 to 1.62V at $V = 0.15$ V/sec (Fig. 1a) involves a total apparent anodic charge density, Q_a, equal to 0.95 mC/cm² which increases to 2.7 mC/cm² beyond the 100th cycle, the Q_a/Q_c ratio remaining always very close to one. The charges required both in the hydrogen region and in the region of formation of oxygen-containing species are in agreement with previous results (22, 29).

During the RTPS an increase of the total charge in the 0.8-1.6V range is observed, but the charge change in the hydrogen electrode reaction region is relatively small. The time, *t*, required to obtain a fixed charge increase is, in principle, proportional to *V*. The number and location of the current peaks are strongly dependent on the degree of activation of the electrode surface as well as on $E_{\lambda a}$ and $E_{\lambda c}$, the anodic and cathodic potential limits (switching potentials), respectively.

Dependence of the electrode activation and deactivation on $E_{\lambda a}$ and $E_{\lambda c}$.—Type II electrodes show a relatively high degree of activation when dipped into a 1*M* H_2SO_4 solution at 25°C (Fig. 2). Under a RTPS covering the 0.060-1.4V potential range at 0.3 V/sec they exhibit a further and continued increase of activation even after a RTPS lasting 10 min (Fig. 2a). But if $E_{\lambda a}$ is decreased down to 1.25V (Fig. 2b), a net decrease of the over-all charge is observed. The deactivation process operates even after a RTPS of 90 min. In both cases no appreciable change is observed in the hydrogen electrode potential range.

A change of $E_{\lambda a}$ during the RTPS ($E_{\lambda c} = 0V$) from 1.35-0.62V and the RTPS continued for 10 min (Fig. 3a) produces a decrease of the cathodic profile and an increase of the hydrogen adatoms electrooxidation current. But the following potential excursion run again between 0.0 and 1.35V involves a charge equal to that observed during the initial sweep. A continuing RTPS during another 10 min between the latter potential limits exhibits a partial inhibition for the hydrogen adatoms electrooxidation together with an increasing electrode activation.

Electrodes of type IV previously perturbed for 60 min by RTPS in the 0.60-1.45V range show a very slow increase of the electrode activation (Fig. 3b), but when $E_{\lambda c}$ is changed to 0.18V and the RTPS continued between the new switching potentials, the first RTPS presents a small current contribution of current peaks IVa and IVc which increases during the following RTPS simultaneously with the electrode activation. The anodic charge, under the present circumstances, attains a limiting value beyond the 100th cycle. These effects are again observed as $E_{\lambda c}$ is fixed at more cathodic potentials. The characteristics of Fig. 3a and 3b are independent of the type of electrode. There are just slight modifications in the electrode activity within the corresponding range of potentials either with small

variations in the switching potentials or with the time spent during cycling.

The current peak IVa is clearly observed with an intermediate degree of the electrode activation but it is practically unnoticed with highly activated electrodes. The contribution of the anodic current VIa during the first RTPS is quite large after the previous cathodization at 0.03V for 25 min, but no increase of the activation degree is noticed.

Type I electrodes under RTPS, with $E_{\lambda a}$ stepwise either decreasing or increasing, show that in the former case there is a net decrease of the cathodic current peaks IIc and IIIc. The reverse is noticed for current peak IIa. Nevertheless, when $E_{\lambda a}$ becomes larger than 1.1V the cathodic profiles between 0 and 0.45V change appreciably. Furthermore, because there is a clear potential difference between the anodic and cathodic current peaks of the hydrogen electrode reaction at 0.150 V/sec, the latter exhibits an appreciable degree of irreversibility. On the other hand, the jump of the current at the switching potential seems to indicate that the processes related to the electroformation and electroreduction of the oxygen-containing species are quite reversible under the perturbation conditions already mentioned. When the TPS is initiated from 0.43V upward no appreciable change of charge is found either as $E_{\lambda a}$ increases stepwise from 0.53 to 1.33V or as it decreases from 1.3V downward. When the Ir electrode is under a RTPS in the 0-0.35V range at 0.150 V/sec no charge increase is observed when $E_{\lambda a}$ is afterward extended up to 1.35V.

Electrode capacitance.—The apparent electrode capacitance at 25°C obtained for type I electrodes in 1*M* H_2SO_4 is 0.39 mF/cm² at 0.350V, in good agreement with previously reported results (22, 23). This value, however, largely exceeds that of the same electrodes in the $KHSO_4$ melt which is equal to 0.09 mF/cm² at 230°C (24).

Triangular potential runs with changing $E_{\lambda a}$ using a highly activated electrode.—The runs in 1*M* H_2SO_4 at 25°C with type II electrodes of different degrees of activation depend on *V* as has been well established (22, 23). Q_a and Q_c involve two contributions, namely, that of the reactions related to the oxygen-containing species (Q_O) and that corresponding to the hydrogen adatoms (Q_H), so that $Q_a = Q_{Oa} + Q_{Ha}$ and $Q_c = Q_{Oc} + Q_{Hc}$. The *E/I* records show that for a particular *V*, $Q_a = Q_c$ (at $V = 0.3$ V/sec, $Q_a = Q_c = 11.3$ mC/cm² and at $V = 3.0$ V/sec, $Q_a = Q_c = 7.0$ mC/cm²) but $Q_{Oa} > Q_{Oc}$ while $Q_{Hc} > Q_{Ha}$. Furthermore, the *E/I* characteristics at 0.3 V/sec are more reversible in spite of more accumulation of charge than those recorded at 3.0 V/sec. Any possible distortion of the *E/I* profiles by an ohmic polarization contribution have been eliminated. Anyway, the initial slope of the cathodic scans which increases when $E_{\lambda a}$ increases, indicates that at 3 V/sec the electrochemical process exhibits some degree of irreversibility.

Electrochemical deactivation: Activation of thermally deactivated electrodes.—The E/I profiles run with type III electrodes in the 0.30-1.40V potential range at 0.150 V/sec are very similar to those recorded with type I electrodes. The two anodic current peaks at *ca.* 0.9 and 1.3V and the two cathodic ones reproduce very well after a RTPS of 10 min. When $E_{\lambda c}$ reaches 0.11V and after another RTPS of 10 min in that range of potentials the anodic current scarcely increases and finally, when $E_{\lambda c}$ is 0.010V, there is a net increase of the charge involved in the potential region exceeding 0.4V with a simultaneous definition of the current peaks related to the redox system at *ca.* 0.5V.

An electrochemical deactivation of a type II electrode is achieved after a prolonged anodic polarization. The *E/I* display obtained between 0.65 and 1.30V after polarizing at 1.625V during 10 min (i = 95 mA) involves $Q_a = Q_c = 2.2$ mC/cm², but a second anodization at the same potential for another 10 min (i =

115 mA) yields a smaller E/I display and lower charges, namely, 1.48 mC/cm^2. The second display also shows an anodic shift of both current peaks.

The potential cycling of type IV electrodes between 0.65 and 1.25V involve initial Q_a and Q_c values of the order of 0.250 mC/cm^2 with no appreciable change of the profile during 10 min but can be slowly activated by RTPS between 0.65 and 1.46V at 0.3 V/sec. After 20 min Q_a becomes 0.865 mC/cm^2 and Q_c, 0.685 mC/cm^2. The increase of Q_a is due to an accumulation of an anodic product which is only partially electroreduced during cycling within the 0.65 and 1.46V range. Then, the area remains always small but the shape of the E/I contour changes slightly. The cathodic current at $E_{\lambda c}$ decreases during cycling while the reverse occurs with the cathodic current at $E_{\lambda a}$.

A type IV electrode can be rapidly activated by running RTPS from 0.85V toward cathodic potentials down to 0.03V, then continuing upward to 1.47V, and finally following the potential cycling between the latter potential limits. If the E/I display is arbitrarily divided in two regions at 0.4V and the area between 0.4 and 1.3V is assigned to a reaction involving the oxygen-surface species, then $Q_{Oa} > Q_{Oc}$ while $Q_{Ha} < Q_{Hc}$. The charge involved in the anodic scan is, however, equal to that involved in the cathodic scan. This clearly reveals that a fraction of the oxygen-containing species anodically formed is most likely electroreduced in the hydrogen electrode reaction region since any contribution of molecular oxygen or molecular hydrogen is discarded.

Triangularly modulated linear potential scans.—Under the TMTPS perturbation conditions of Fig. 4 in 1*M* H_2SO_4 both the anodic and the cathodic excursions are quite symmetric with respect to the potential (time) axis. The E/I display within the 0-0.4V potential range contains the current peaks related to hydrogen adatoms, together with the hydrogen ion discharge current and the anodic current associated with hydrogen diffusion-controlled electrooxidation. Within the 0.4-1.4V potential range there are three anodic and three cathodic current peaks clearly distinguished which apparently pertain to three redox systems. Their kinetic behavior appears to be rather irreversible under the prevailing perturbation conditions. Another point worth noting is that during the anodic excursion (Fig. 4a), Q_a is larger than Q_c, while the reverse occurs during the cathodic excursion (Fig. 4b).

The Ir/96% H_2SO_4 interface.—RTPS runs with type I electrodes at 0.3 V/sec in the -0.34 to $+1.50$V range at 25°C exhibit poorly defined anodic and cathodic current peaks (Fig. 5), but when $E_{\lambda a}$ extends stepwise to $+1.55$V, overlapping the potential of the net evolution of oxygen, a further RTPS produces a net increase of the charge involved and a clearer definition of the anodic and cathodic current peaks related to the oxygen-containing species at *ca.* 0.6V. Simultaneously, the baseline within the -0.34 to $+0.4$V range changes downward due to the electrochemical reduction of molecular oxygen. Those current peaks are associated with a reversible over-all reaction. The increase of the current peaks at *ca.* 0.6V shows more clearly the anodic and the cathodic current contributions in the 0.8-1.4V range until the E/I profile finally comprises at least three redox couples in good agreement with the TMTPS described later. Dissolved oxygen has no appreciable influence in the potential range involving the formation of oxygen-containing species. The degree of surface activation is, however, in principle, unchanged when the electrode is potentiostated at cathodic potentials such as at -0.35V for about 1 hr. To achieve a net activation of the electrode surface the potential cycling requires, therefore, an anodic potential limit larger than 1.5V at 25°C. On the other hand, if $E_{\lambda a}$ is fixed at 1.5V and $E_{\lambda c}$ is larger than 0.15V, the RTPS produces practically no change in the voltammogram. But if $E_{\lambda a} < 1.5$V and $E_{\lambda c}$ is kept at -0.35V (Fig. 5c) a slight but steady deactivation of the electrode is noticed.

The effect of increasing $E_{\lambda a}$ during successive STPS with type II electrodes (Fig. 5b) is practically the same either for $E_{\lambda a}$ increasing or $E_{\lambda a}$ decreasing. The charge involved between 0.5 and 0.6V is related to the pseudofaradaic processes occurring in the 0.4-0.8V range. The anodic and cathodic peaks located therein correspond apparently to a single redox couple (Fig. 5c). The increase of the cathodic current between 0.8 and 1.2V when $E_{\lambda a}$ increases is related to the appearance of two anodic current peaks at 1.10 and 1.35V and two cathodic current peaks at 0.95 and 1.20V, approximately.

Finally, once the display shown in Fig. 5b is attained the following RTPS between -0.35 and $+1.37$V (Fig. 5c) exhibits a decrease of Q_a and Q_c, a large decrease of the current peak heights located at *ca.* 0.6V, and a slight decrease of those located at higher potentials. The contribution of the redox couple located at *ca.* 0.95V is also enhanced. The electrode surface becomes first increasingly active with respect to the oxygen evolution reaction but finally it turns in the reverse way. This change is also clearly reflected in the potential range where the oxygen electroreduction takes place. An over-all deactivation effect is observed. The shape of the final E/I display shown in Fig. 5c coincides with the first E/I profile depicted in Fig. 5a for a practically deactivated electrode.

The STPS E/I profiles run at 25°C, from $E_{\lambda c}$ = 0.35V to a stepwise changing $E_{\lambda a}$ (0.1V $\leq E_{\lambda a} \leq$ 1.38V), at 0.3 V/sec (Fig. 6), exhibit practically no anodic cur-

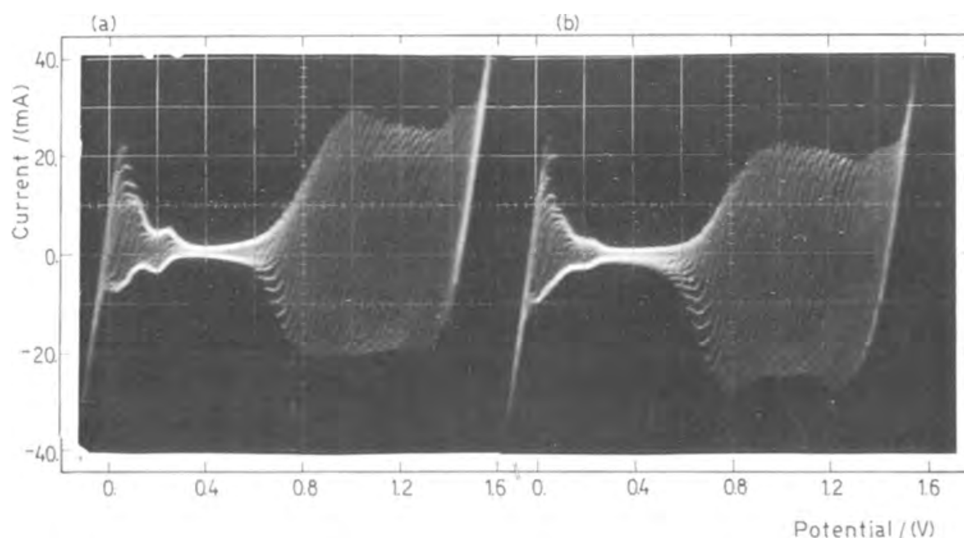

Fig. 4. TMLPS E/I displays. 1M H_2SO_4, 25°C, type I electrode (1.0 cm^2). V(guide) = 0.15 V/sec; V(modulation) = 2 V/sec; amplitude of the modulating signal = 0.18V. (a) Anodic scan. (b) Cathodic scan.

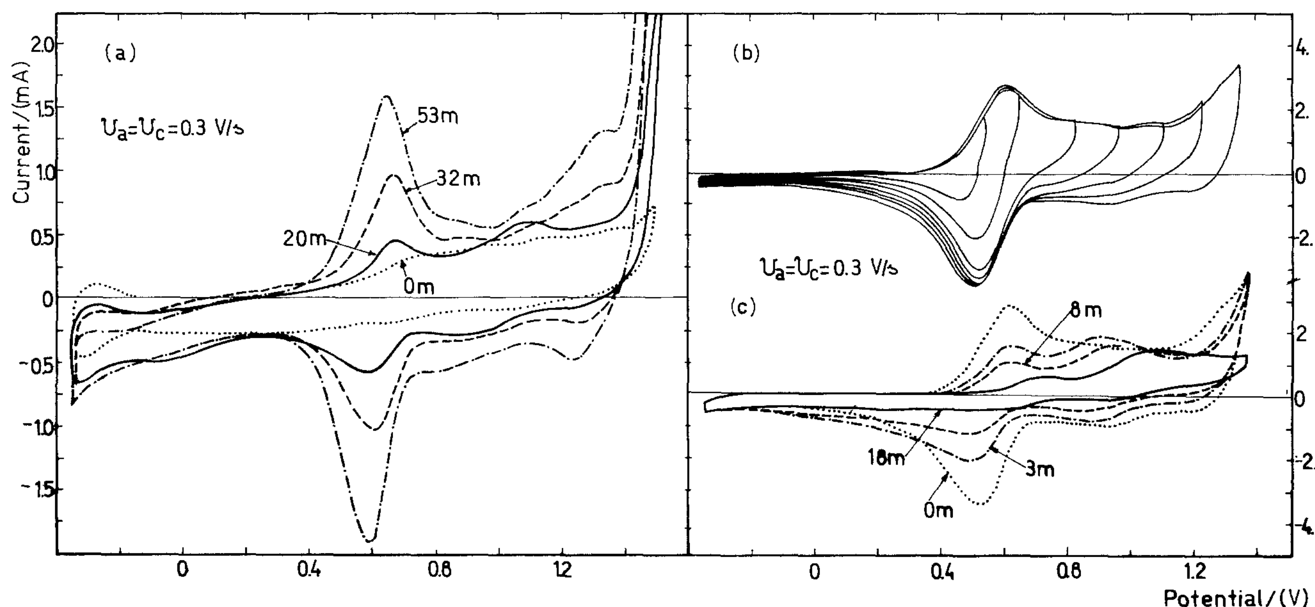

Fig. 5. *E/I* profiles (TPS). 96% H_2SO_4, 25°C, type I electrodes (1.0 cm²). (a) RTPS at 0.3 V/sec. First cycle (dotted trace). Other traces are recorded after RTPS during 20, 32, and 52 min. (b) STPS at 0.3 V/sec. $E_{\lambda a}$ stepwise changing during each cycle from 0.75-1.55V. (c) RTPS at 0.3 V/sec. Electrochemical deactivation. First cycle (dotted trace). The following profiles are recorded after RTPS during 3, 8, and 18 min.

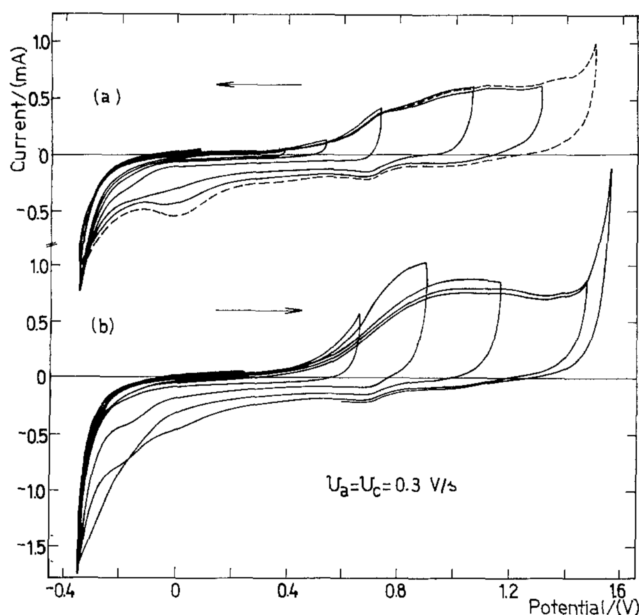

Fig. 6. *E/I* displays at 0.3 V/sec. 96% H_2SO_4, 25°C, type I electrode (1.0 cm²). (a) STPS $E_{\lambda a}$ decreasing from 1.5 to 1.0V. The dotted trace corresponds to RTPS between −0.35 and 1.5V. (b) RTPS with $E_{\lambda a}$ stepwise increasing.

rent in the −0.35 to 0.4V range but instead four humps at *ca.* 0.75, 1.0, 1.15, and 1.35V. The anodic current during the anodic scan increases when $E_{\lambda a}$ increases; the effect, however, is less obvious when $E_{\lambda a}$ moves in the decreasing direction. The cathodic potential excursion shows a cathodic limiting current at *ca.* 0.85V and two cathodic current peaks at 0.7 and 0V, the latter only being distinguished when $E_{\lambda a} > 0.9$V. This suggests that some species electroformed at high anodic potentials are electroreduced at the cathodic potential extreme. At −0.35V a net hydrogen evolution takes place. In either circumstance no hydrogen adatoms are clearly depicted in the *E/I* records, except the small couple at −0.3V (Fig. 5a). Q_a, which is of the order of 2.0 mC/cm², is always larger than Q_c. After an RTPS of 15 min the over-all charge increases slightly and simultaneously the definition of both the anodic and cathodic current peaks are appreciably improved. Most of the features just described are also observed during the TPS perturbation of the Ir/$KHSO_4$ (melt) interface as described later.

STPS *E/I* records between −0.120V and $E_{\lambda a}$, where the latter is either increased or decreased stepwise from 0.08 to 1.0V at 0.05 V/sec and 25°C (Fig. 7a and 7b), show the following features: When $E_{\lambda a} > 0.55$V, two anodic current peaks at *ca.* 0.3V and *ca.* 0.5V are recorded during the anodic potential excursion together with a hump at *ca.* 0.8V and during the cathodic scan a cathodic current peak is also observed at *ca.* 0.25V together with a hump at *ca.* 0.45V. When $0.3\text{V} \leq E_{\lambda a} \leq 0.55$V only the anodic current peak at 0.3V is seen. Finally, no current peaks are distinguished for lower $E_{\lambda a}$ values. These responses suggest that the cathodic current peak at *ca.* 0.30V comes from a product formed during the anodic potential excursion at

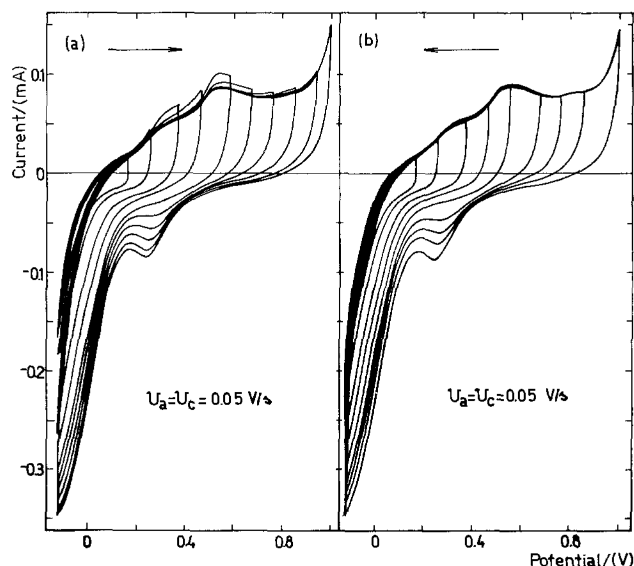

Fig. 7. *E/I* displays (STPS) at 0.05 V/sec. 96% H_2SO_4, 25°C, type I electrodes (1.0 cm²). (a) $E_{\lambda a}$ stepwise increasing. (b) $E_{\lambda a}$ stepwise decreasing.

high potentials. From the kinetic standpoint the over-all process becomes slightly more irreversible the larger the $E_{\lambda a}$ values are. Furthermore the Q_a and Q_c values confirm that some product anodically formed is electroreduced, at least in part, in the hydrogen evolution region. The resulting metal surface remains covered by some oxide species since no hydrogen adatom electrooxidation is observed.

The E/I profiles run at 90°C between −0.58 and 1.2V depend also very markedly on V (3 V/sec $\leq V \leq$ 10 V/sec) and on the charge playing a part at the cathodic potential extreme. Nevertheless the situation becomes somewhat involved as the electroreduction of the oxygen-containing species occurs at more cathodic potentials as V increases. Then, the shape of the E/I profile approaches that of a type I electrode in 96% H_2SO_4 at 25°C.

The E/I profile run between 0.09 and 1.0V involves Q_a = 0.55 mC/cm² and Q_c = 0.41 mC/cm² (Fig. 8a). When $E_{\lambda a}$ decreases the current peaks disappear and at the cathodic potential side there is a partial but systematic electroreduction of the surface species yielded by the anodic process.

The same profiles recorded after keeping a RTPS between fixed limits during 10 min (Fig. 8b) with $E_{\lambda a}$ decreasing stepwise, exhibit approximately the same features described for Fig. 8a, but there is no coincidence among the E/I lines in the potential region of the anodic current peak.

An electrode, which has attained a Q_a/Q_c ratio equal to one through RTPS between 0.09 and 1.0V, is then successively perturbed with RTPS between 0.09 and 0.2V during 5 min and is finally perturbed with three TPS between 0.09 and 1.0V (Fig. 8c), presents the following characteristics. The first of the three scans involves $Q_a > Q_c$, but the second and the third scans repeat the E/I profile as already known. The most abrupt current decrease occurs in the 0.4-0.8V potential range. This effect becomes more evident at the highest temperature and increases in going from 1M H_2SO_4 to the $KHSO_4$ melt.

Triangularly modulated triangular potential sweeps with the Ir/96% H_2SO_4.—The TMTPS at 95°C changes quite markedly with the cathodic potential limit of the base signal (Fig. 9a-b). The current peaks existing within the 0-1.2V range for the anodic excursion differ from those recorded during the cathodic excursion (Fig. 9b). Thus, the anodic excursion exhibits an anodic peak at 0.5V and two small humps at 0.8 and 1.0V with the corresponding complementary cathodic current contributions. The over-all anodic profile is somewhat symmetric with respect to the potential axis. The cathodic excursion presents an anodic envelope which is very similar to that already described for the anodic excursion but the cathodic envelope presents, in addition, a net current peak at 0.2V. The display is much more complex when it initiates from −0.4V. Then, the anodic envelope during the anodic excursion comprises a small limiting current at *ca.* −0.3V, a first hump at 0V, a second hump at 0.3V, a net current peak at 0.5V, a small one at 0.75V, another

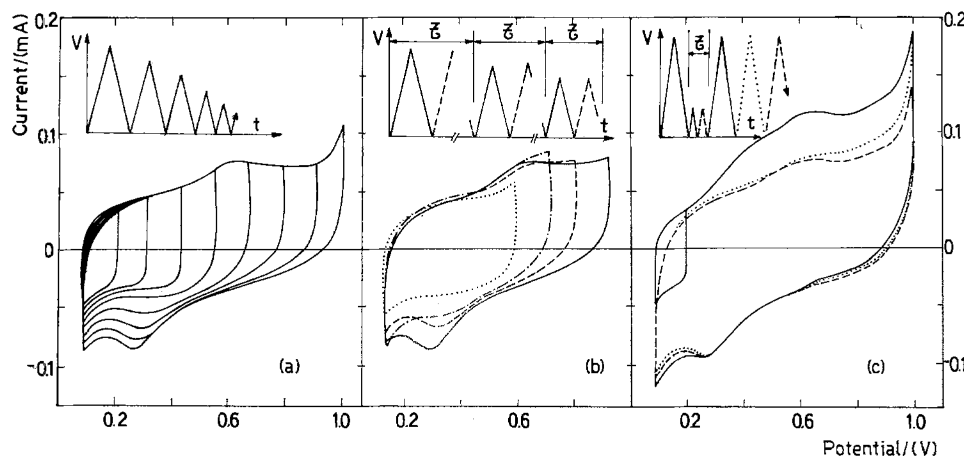

Fig. 8. E/I profiles. 96% H_2SO_4, 90°C, type I electrodes at 0.1 V/sec (1.0 cm²). (a) STPS, $E_{\lambda a}$ successively decreased from 1.0 to 0.2V. (b) RTPS. The E/I records correspond to the first TPS at the preset $E_{\lambda a}$ value but the interface is previously perturbed by a RTPS during 10 min at the preceding (higher) $E_{\lambda a}$. (c) RTPS between 0.09 and 0.2V followed by three RTPS between 0.09 and 1.0V. The full trace corresponds to the first scan, the dotted trace belongs to the second scan, and the dashed trace is the third scan.

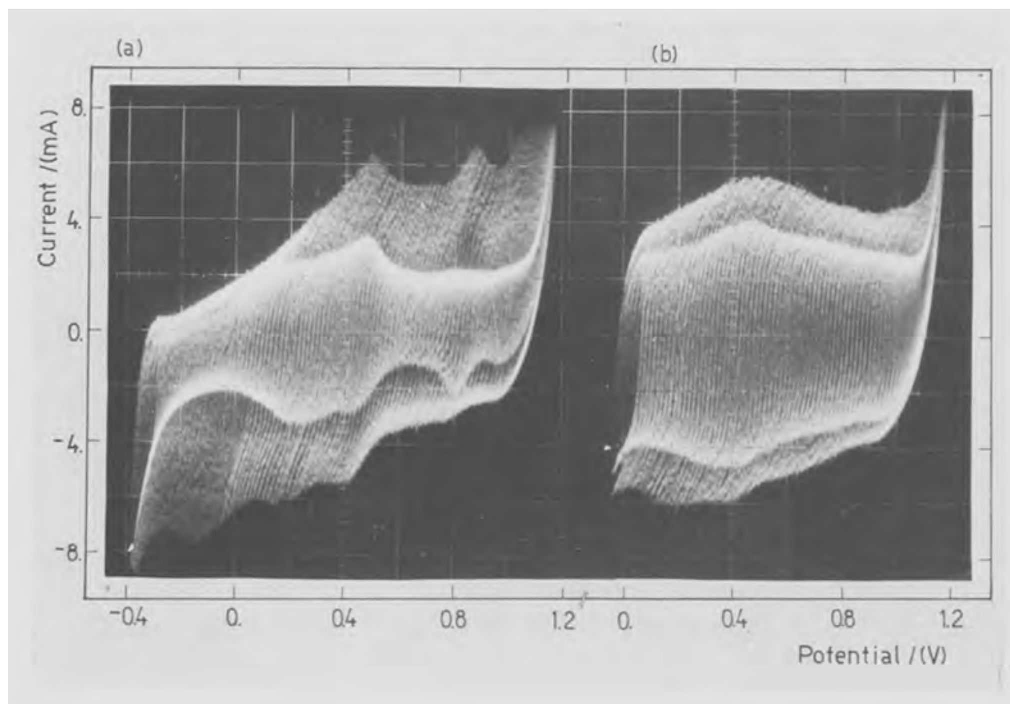

Fig. 9. TMTPS displays. 96% H_2SO_4, 95°C, type I electrode (1.0 cm²). V(guide) = 1.5 V/sec; V(modulation) = 20 V/sec; amplitude of the modulating signal = 0.12V. (a) $E_{\lambda c}$ = −0.4V and $E_{\lambda a}$ = 1.2V. (b) $E_{\lambda c}$ = −0.04V and $E_{\lambda a}$ = 1.2V.

net current peak at 0.9V, and a hump at 1.1V. The cathodic envelope contains a current peak at 0.95V, a well-defined peak at 0.8V, and two current peaks at 0.4 and 0.25V, respectively.

Now, the anodic envelope of the cathodic excursion exhibits small humps at 1.0 and 0.8V, and a current peak at *ca.* 0.5V, and the rest of details already referred to for the anodic potential excursion. The cathodic envelope contains practically the same characteristics as before although the peaks are appreciably reduced and a new wide cathodic current peak appears at −0.15V thereabouts. The current peaks at 0.3, 0.75, and 0.9V are intimately related to the high initial cathodic potential. The same occurs with current peaks at 0.8V. The current peak at −0.15V is directly produced by the high anodic potential limit reached. The anodic current involved during the cathodic excursion is largely magnified in the 0V potential region. Probably these current peaks are related to surface products yielded by the electrolyte electrooxidation at high anodic potentials.

Characteristics of activated electrodes.—An electrode that has been activated by RTPS in 1*M* H_2SO_4 and kept in the solution maintains its activation state after the circuit is open for a certain time, as confirmed by the reproducible *E/I* profile observed afterward. The same occurs if the electrode is removed from the solution and placed back into the cell. Furthermore, no deactivation occurs even after keeping the electrode for various days at open circuit. The degree of activation of the Ir electrode maintained in solution for 5 days at open circuit in a N_2 atmosphere remains practically unaltered. The activation state persists longer in 1*M* H_2SO_4 than in the concentrated acid.

The RTPS *E/I* profiles at 25° involving an $E_{\lambda a} <$ 1.24V in 1*M* H_2SO_4 and $E_{\lambda a} <$ 1.38V in concentrated H_2SO_4 produce the deactivation of an activated electrode. The deactivation is definitely more marked for the concentrated acid and under these circumstances it is even faster than that occurring under open circuit. In 1*M* H_2SO_4 the activation disappears when the electrode is placed in contact with 96% H_2SO_4. The degree of deactivation reached depends on the time elapsed in the concentrated electrolyte. But an electrode previously activated in 1*M* H_2SO_4 placed in contact for 5 min with any of several solutions (1:1 HCl; 1*M* NaOH; 65% HNO_3; 85% H_3PO_4; absolute ethyl alcohol; distilled water) remains unaltered. If an electrode is activated in concentrated H_2SO_4, it behaves as a deactivated one after potential cycling in 1*M* H_2SO_4. The reverse is also true. An electrode activated in 96% H_2SO_4, after a rinse in distilled water, behaves as a deactivated electrode when it is dipped again in the same electrolyte. The activation is newly gained by RTPS. The same electrode dipped for 5 min in one of the following media: 85% H_3PO_4; 65% HNO_3, or absolute ethyl alcohol, presents only a small deactivation.

The Ir/KHSO$_4$ (melt) interface.—The *E/I* displays obtained with STPS with decreasing $E_{\lambda a}$ (Fig. 10a) at 6 V/sec show during the anodic excursion the anodic current peak at *ca.* 0.4V while during the cathodic excursion the current peaks are seen in the 0-0.2V potential range. For $E_{\lambda a}$ of 0.3V, although a low surface coverage degree is attained, the amount of surface species anodically formed is enough to inhibit the electroformation of either hydrogen atoms or molecules. The *E/I* curves run with RTPS between −0.2 and +0.30V are appreciably distorted. They exhibit a steady decrease of the cathodic current associated with the electroreduction of the oxygen-containing surface species and an enhancement of both the cathodic and anodic current associated with the hydrogen electrode reactions. Undoubtedly, the complete electroreduction of the oxygen-containing surface species takes place at the cathodic potentials where the hydrogen electrode reactions should proceed.

The first TPS always involves a Q_a that is almost twice Q_c (Fig. 10b). After a few TPS, Q_a approaches $Q_a/Q_c = 1$ ($Q_a = Q_c = 0.4$ mC/cm^2). This suggests that for the present system there is also a partial reduction of the anodic product at the cathodic potential reached. When the interface is perturbed first with RTPS between −0.075 and +0.16V during 5 min and then with four successive RTPS up to $E_{\lambda a} = 0.52$V, the changes of the *E/I* profile at the cathodic potential extreme are less pronounced at 0.05 V/sec than at 6 V/sec. For the latter the potential range of the electroreduction of the oxygen-containing species overlaps largely the hydrogen ion discharge potential region. However, the effect at 6 V/sec (Fig. 10a) can be equally reproduced at 0.05 V/sec by maintaining the RTPS for a longer time.

Although the first TPS always involves $Q_a > Q_c$, the $Q_a = Q_c$ conditions can, however, be achieved during the second RTPS for $E_{\lambda a} > 0.550$V. Otherwise, if the runs are made by changing $E_{\lambda a}$ stepwise from

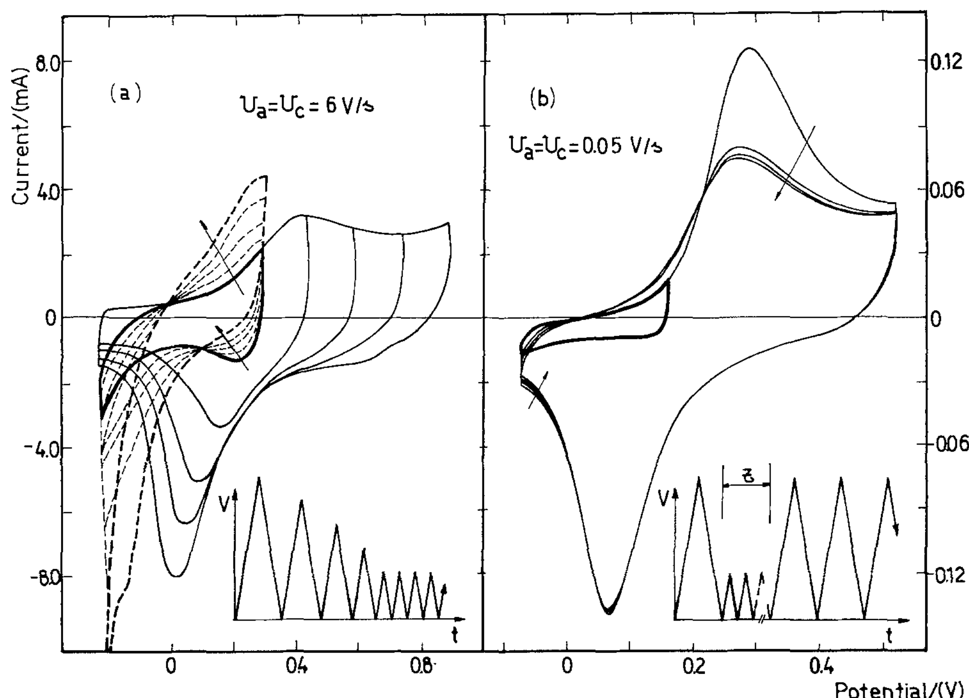

Fig. 10. *E/I* profiles. Molten $KHSO_4$, 230°C, type I electrodes (1.0 cm^2). (a) STPS at 6 V/sec, $E_{\lambda a}$ stepwise decreasing from 0.9 to 0.3V. The dashed trace corresponds to RTPS in the −0.2 to 0.3V range. (b) RTPS during 5 min in the −0.075 to 0.16V range followed by four RTPS in the −0.075 to 0.52V range.

0.16V upward, the successive scans involve anodic currents increasingly exceeding those reached for a stabilized E/I profile only until $E_{\lambda a}$ becomes equal to the anodic current peak potential. Further increases of $E_{\lambda a}$ tend to decrease gradually this effect, which finally disappears when $E_{\lambda a} > 0.55V$. The sum of the excesses of Q_a corresponding to the anodic excursion with increasing $E_{\lambda a}$ are practically equal to the Q_a change obtained between the first and the second anodic scans run between E_i and $E_{\lambda a} > 0.55V$. This feature of the Ir/$KHSO_4$ interface resembles that already described for the Ir/H_2SO_4 96% at 25° and 90°C and to a lesser extent for the Ir/1M H_2SO_4 at 25°C. The latter, however, implied the activation of the electrode.

Consider the E/I profiles in the case of an electrode which has previously attained a stable E/I profile and is perturbed with RTPS by a stepwise decreasing of $E_{\lambda a}$ (Fig. 11a). As $E_{\lambda a}$ decreases, it is quite clear that $Q_a < Q_c$ and the location of the cathodic current peak is more anodic until finally disappearing when $E_{\lambda a} \leqq$ 0.1V. However, if the E/I profiles are recorded after 5 min RTPS at each preset $E_{\lambda a}$ value (Fig. 11b), one also observes a net decrease of the anodic E/I contour. The reverse situation is seen when $E_{\lambda a}$ increases (Fig. 11c). The E/I records in this case are obtained successively after an initial RTPS from −0.075 to 0.52V followed by another 5 min of RTPS from −0.075 to 0.16V. Afterward each successive E/I record involves a stepwise increase in $E_{\lambda a}$. Now as $E_{\lambda a}$ increases there is a steady slight decrease of the anodic charge in the 0-0.2V range and a major current increase at the anodic current peak. The rate of increase of the latter diminishes for the following potential sweeps involving $E_{\lambda a}$ values larger than 0.36V. The described effect is enhanced if the RTPS at $E_{\lambda a} = +0.150V$ is prolonged for 40 min (Fig. 11d). The broadening of the anodic current peak as $E_{\lambda a}$ increases might be due to an increasing interaction. If it were due to hydrogen atom accumulation one would expect the effect to be independent of the direction of changing $E_{\lambda a}$.

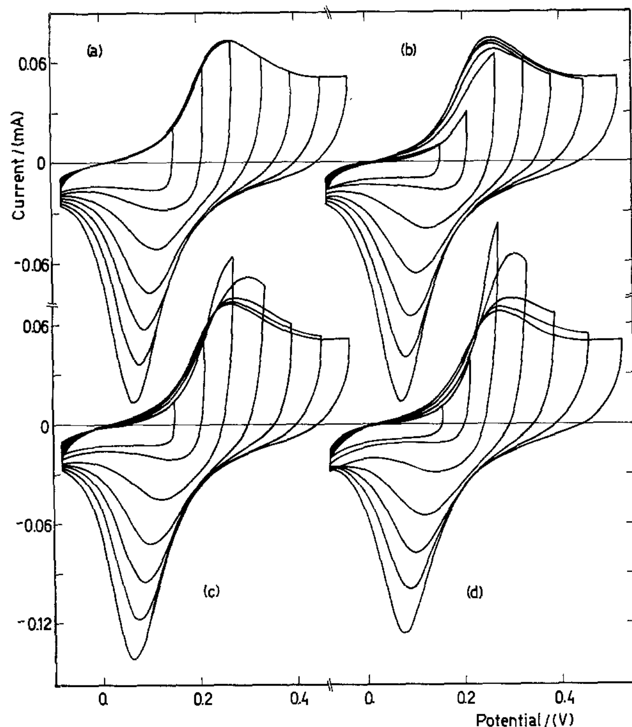

Fig. 11. *E/I* displays at 0.05 V/sec. Molten $KHSO_4$, 230°C, type I electrode (1 cm^2). (a) STPS, $E_{\lambda a}$ stepwise decreasing as in Fig. 10a. (b) The system is initially cycled (RTPS) in the −0.075 to 0.52V range to attain a Q_a/Q_c ratio equal to one. Then the amplitude is stepwise decreased but the *E/I* profile is only recorded after 5 min RTPS at each $E_{\lambda a}$. (c) The same as (b) but the amplitude is directly decreased to $E_{\lambda a} = 0.16V$ and the RTPS continued during 45 min before the following record involving the higher $E_{\lambda a}$ value. (d) The same as (c) but the RTPS lasts for 40 min.

Discussion

Preliminary considerations.—The results are strongly dependent both on the electrolyte composition and temperature. Thus, under constant perturbation conditions the activation of Ir electrodes, as measured from the increase of Q_a and Q_c during the RTPS, is more manifested in 1M H_2SO_4 acid at room temperature than either in the concentrated acid or in the $KHSO_4$ melt at higher temperatures. In the former solution the two potential limits for the activation, one located in the hydrogen adatom electrosorption region (cathodic activation limit) and the other in the region preceding the oxygen evolution (anodic activation limit), coincide with those reported earlier by other authors (22, 23). The strong dependence of the potentiodynamic E/I profiles run under RTPS on V is at the same time confirmed (9, 22, 23). Besides, two electrochemical deactivation potential limits are observed which correspond, respectively, to the potentials of the net hydrogen and oxygen evolution reactions. Nevertheless, neither the electrode activation nor its deactivation are sensitive to the hydrogen gas saturating the electrolyte. The accumulation of charge in the potential range preceding the oxygen evolution during the RTPS is apparently bound to an increase of irreversibility of the various processes either anodic or cathodic, as noticed through the shifts of the corresponding current peak potentials with cycling at constant V. Furthermore, the location of the various current peak potentials depends on V. Thus, the potential of current peak V_a, which emerges when the potential excursion extends into the hydrogen ion discharge region, becomes more positive when V increases. This same shift is noticed for the potentials of the anodic current peaks located at higher potentials. The reverse influence is found for the complementary cathodic current peaks. The anodic current peaks, however, move more rapidly with V than the cathodic ones. There is also a net shift of the anodic current peaks toward more anodic potentials as n, the number of potential cycles, increases. This is independent of $E_{\lambda c}$ and entails an apparent increasing irreversibility of the over-all anodic processes as n increases. Both $E_{\lambda c}$ and $E_{\lambda a}$ are very important in defining the changes of the E/I contour recorded under RTPS. Thus, when $E_{\lambda c}$ lies within the potential range of the hydrogen adatom it has influence on the anodic process occurring at higher potentials. On the other hand, when $E_{\lambda a}$ is about 1.4V there is an accumulation of anodic reaction products which are not readily electroreduced during the cathodic scan, not even when the hydrogen ion discharge takes place, and consequently this certainly restrains the sites for hydrogen adatoms. No clear aging effect of the anodic film is noticed for the activated electrode.

The other extreme situation is found in the case of the Ir/$KHSO_4$ (melt) interface which shows practically no activation effect, but it does exhibit a net aging of the electroformed film (24). The results corresponding to the 96% H_2SO_4 electrolyte are intermediate between those of the 1M H_2SO_4 and the $KHSO_4$ melt, depending on the temperature.

On the basis of these results the following discussion deals first with the probable reactions involved in the range of the monolayer formation and afterward the buildup of the thicker layer related to the electrode activation from the monolayer film either complete or incomplete. For the latter the amount of charge is within the order of an oxygen-monolayer thickness, the stoichiometry of the stable oxidized surface probably corresponding to an Ir/O ratio equal to 0.5 (24, 25).

The probable surface species anodically formed in the monolayer thickness film.—The following equilibria

and the corresponding standard potential ($E°$) of Ir metal/Ir oxide systems are reported (7, 22, 32)

$$Ir + H_2O = IrO + 2H^+ + 2e, \quad E°/V = 0.870 \quad [1]$$

$$Ir + 2H_2O = IrO_2 + 4H^+ + 4e, \quad E°/V = 0.926 \quad [2]$$

$$Ir_2O_3 + H_2O = 2IrO_2 + 2H^+ + 2e, \quad E°/V = 0.926 \quad [3]$$

Therefore, stoichiometries such as IrO and IrO_2 are, in principle, thermodynamically possible. However, taking into account that the electrochemical reaction in 1*M* H_2SO_4 and 96% H_2SO_4 at room temperature involves at least three anodic and three complementary cathodic current peaks within the potential range of the activation process, various different surface species must exist. These redox systems are clearly detected through the TMTPS experiments. Various successive processes are quite reasonably already starting from a pure Ir surface dipped into the pure acid solutions. In this case the structure of the metal/solution interface may be relatively complicated since adsorption of water, the eventual formation of hydrogen adatom and OH-species, and, to a less extent, anion adsorption are possible. During the initial anodic STPS from the hydrogen electrode potential upward, the hydrogen adatoms, if present, are first electrodesorbed. Then, on the same surface the OH-species are electrosorbed. The very initial steps can be idealized as follows

$$n\,[Ir] + H_2O \rightleftharpoons [Ir]_n(OH) + H^+ + e \quad [1a]$$

followed by

$$[Ir]_n(OH) + H_2O \rightleftharpoons [Ir]_n(OH)_2 + H^+ + e \quad [1b]$$

$$[Ir]_n(OH)_{n-1} + H_2O \rightleftharpoons [Ir]_n(OH)_n + H^+ + e \quad [1z]$$

where n is the number of surface sites available on the metal. Steps [1a] to [1z] involve the electrosorption of water on a surface increasingly covered by the OH-species. Step [1z] implies the ideal situation of the metal surface covered by a monolayer of electrosorbed OH-species. Following the reaction sequence, the latter undergoes a further oxidation at higher potentials which can be generalized as

$$[Ir]_n(OH)_y \rightleftharpoons [Ir]_n(O)(OH)_{y-1} + H^+ + e \quad [2a]$$

$$[Ir]_n(O)_{y-1}(OH) = [Ir]_n(O)_y + H^+ + e \quad [2z]$$

where $0 \leq y \leq n$ and again $y = n$ when the degree of surface coverage expressed in terms of the IrO stoichiometry is one. In this case the overall reaction agrees with reaction [1].

A further oxidation must be associated with a higher oxidation state of Ir which can be achieved according to

$$[Ir]_n(O)_n + H_2O = [Ir]_n(O)_{n+1} + 2H^+ + 2e \quad [3a]$$

$$[Ir]_n(O)_{(2n-1)} + H_2O = [Ir]_n(O)_{2n} + 2H^+ + 2e \quad [3z]$$

Eventually, the $(n + 1)/n$ ratio would approach 3/2 when a monolayer of Ir_2O_3 is formed. The reaction pathway [1a] to [3z] implies, in principle, that various OH- and O-containing species are possible on the Ir surface in the absence of any activation. The presence of nonstoichiometric oxides (hydrated oxides) in the anodic film has already been considered as probable (22, 23). Formally, the proposed reaction pathway resembles those earlier postulated for Pt and Au in aqueous acid solutions (33, 34) and quite reasonably can be extended to the Ir/$KHSO_4$ (melt) interface. But it fails to explain the charge increase related to the Ir activation process. It should be remarked that the advance of the process from step [1a] to step [3z] implies the oxidation of Ir and the concomitant decrease of the binding energy of the Ir atom to the bulk metal, so that when the Ir atom is completely saturated either with OH-species or O-atoms it becomes detached from the lattice, the metal undergoing electrodissolution. As a matter of fact, the anodic dissolution rate of Ir on potential cycling in 1*M* H_2SO_4 is claimed to be *ca.* 8-9 times that found for Pt under the comparable experimental conditions (20). The metal corrosion, therefore, should be considered as the initial stage yielding the formation of a multilayer anodic film, which is responsible for the electrode activation.

The charge increase at the Ir/H_2SO_4 (aq) interface.—Various interpretations have been advanced to explain this effect: (*i*) The accumulation of an oxide species, probably IrO_2, that is irreversibly electroreduced at potentials overlapping those of the hydrogen ion discharge (16). An IrO_2 covered metal surface can probably still adsorb an appreciable amount of water. (*ii*) Oxygen absorption through the surface oxide film (5). Comparing radius of Ir and oxygen-species, it is difficult to see, as already pointed out (22), how oxygen could be adsorbed or desorbed through an oxide film of *ca.* 100 atoms thickness rapidly enough to give a reversible response in the case of an activated Ir electrode. (*iii*) A possible, although unlikely, occurrence of a roughness factor that manifests preferentially in the region of the electroformation and electroreduction of the oxygen-containing species. (*iv*) Migration of hydrogen ion into the oxide layer with further electrochemical reaction in the bulk of the solid phase. In terms of hydrogen ion migration the effect should become more unnoticed when the electrode potential is positive with respect to the potential of zero charge of the metal and it becomes enhanced in the reversed situation (32). The formation of either an IrO and an IrO_2 surface or an IrO multilayer results. This explanation, in principle disregarded, seems to be more likely for the oxygen layers formed on Pt at high anodic potentials (9, 15). (*vi*) A possible dissolution of hydrogen atoms into the bulk of the metal which may react electrochemically. This is unlikely as a major contribution since the experimental data (35) which sustains the idea of Ir dissolving an appreciable amount of hydrogen is questionable because most of them were obtained with powdered metal (36). (*vii*) Finally, pitting corrosion is assumed to be a major contribution in the anodic charge increase during the RTPS (18, 19).

The various explanations briefly summarized only deal with partial aspects of the electrochemical process. Thus, the existence of potential limits for the so-called "activation state" of Ir, the influence of acid concentration and temperature, and the apparent discrepancy in charge accumulation in the hydrogen electrode reaction region in contrast with the potential region of the oxo- and hydroxo-species formation are not clearly explained.

The line of thought to develop a model for explaining the electrochemical behavior of the Ir/H_2SO_4 (aq) interface is based on the following evidence: (*i*) In H_2SO_4 (aq) the potential region of Ir activation involves at least three clear anodic current contributions, which are complemented by the corresponding cathodic currents. The pertaining redox couples exhibits a very reversible behavior which is particularly obvious in the TMTPS experiments. (*ii*) X-ray analysis of the surface products formed during the electrooxidation of Ir in 0.1*N* H_2SO_4 solutions reveals IrO_2 as the only surface compound in the 0.5-2.2V potential range (37). This compound in aqueous solutions exists as $Ir(OH)_4$, that is, $IrO_2 \cdot 2H_2O$ in agreement with the x-ray diffractometry. Compounds of this type involving polymeric films of hydrated-oxy-hydroxide species are often postulated during electrodissolution and passivation of some metals in aqueous electrolytes (38) and the electrical conduction operates through a proton transfer mechanism (39-41). On the other hand, the formation of a compound such as $Ir(OH)_4$ means that the binding forces left on Ir in relation to the metal lattice have been practically canceled out and, instead, the metal atom becomes part of a complex IrOH lattice on the surface of the metal. (*iii*) The activation effect

decreases as the dehydrating power of the electrolyte increases, the latter being related either to the acid concentration increase or to the temperature increase. Certainly the largest dehydrating effect is expected in the $KHSO_4$ (melt). (*iv*) The activation effect occurs in different acid electrolytes independently of the presence of SO_4^{-2} ions (42).

Therefore, the charge increase of the Ir/H_2SO_4 (aq) interface during the RTPS comes out from a simultaneous occurrence of steps [1a] to [3z] and proton transfer reactions related to the $Ir(OH)_4$-type species yielded by the metal electrodissolution. Hence, as steps [1a] to [1z] occur statistically, the saturation condition corresponding to the stable $Ir(OH)_4$ structural configuration should be attained in some places before achieving a full coverage of the surface by the OH-species. Therefore

$$[Ir]_n(OH)_m \rightleftharpoons [Ir]_{n-1}(OH)_{m-4} + Ir(OH)_4 \quad [4]$$

where $n \geqq m$. Reaction [4] yields simultaneously a surface species and free metal sites. When the amount of $Ir(OH)_4$ exceeds that of a monolayer, the electrochemical interface formerly defined in terms of the metal/solution plane (π_1), embraces now another plane (π_2) corresponding to the $Ir(OH)_4$/solution interface. Both planes π_1 and π_2 are, in principle, charge transfer planes, either for electron transfer or for ion transfer, and the region between them corresponds to the hydrated-oxy-hydroxide phase where the following are feasible processes

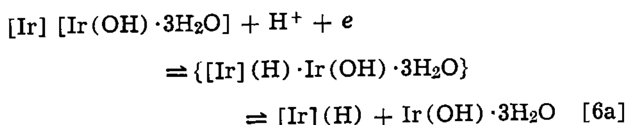
$$Ir(OH)_4 + H^+ + e \rightleftharpoons Ir(OH)_3 \cdot H_2O \quad [5a]$$

$$Ir(OH)_3 \cdot H_2O + H^+ + e \rightleftharpoons Ir(OH)_2 \cdot 2H_2O \quad [5b]$$

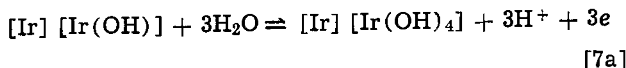
$$Ir(OH)_2 \cdot 2H_2O + H^+ + e \rightleftharpoons Ir(OH) \cdot 3H_2O \quad [5c]$$

Reactions [5a] to [5c] are deprotonation processes which take place both at π_1 and in the region between π_1 and π_2. These reactions explain the three relatively reversible redox couples appearing at the activation potential range. They occur at potentials lower than the thermodynamic threshold to form IrO_2 according to reaction [2] and involve a proton transfer process between π_1 and π_2. The possibility of a proton transfer mechanism in the film formed on Ir in aqueous H_2SO_4 has recently been proposed (22). Such a mechanism has also been considered by other authors for other metals/film systems in aqueous solutions (38-43).

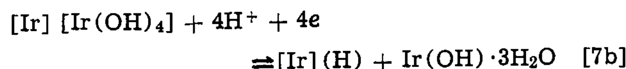
The hydrogen atom electrosorption and electrodesorption must occur principally on the π_1 plane. It can be represented as three limiting possibilities



$$[Ir]\,[Ir(OH) \cdot 3H_2O] + H^+ + e \rightleftharpoons \{[Ir](H) \cdot Ir(OH) \cdot 3H_2O\} \rightleftharpoons [Ir](H) + Ir(OH) \cdot 3H_2O \quad [6a]$$



$$[Ir]\,[Ir(OH)] + 3H_2O \rightleftharpoons [Ir]\,[Ir(OH)_4] + 3H^+ + 3e \quad [7a]$$



$$[Ir]\,[Ir(OH)_4] + 4H^+ + 4e \rightleftharpoons [Ir](H) + Ir(OH) \cdot 3H_2O \quad [7b]$$

and

$$[Ir]\,[Ir(OH) \cdot 3H_2O] + H^+ + e \rightleftharpoons [Ir]\,Ir + 4H_2O \quad [8a]$$

$$[Ir]\,Ir + H^+ + e \rightleftharpoons [Ir]\,Ir(H) \quad [8b]$$

Reaction [6a] implies that the reaction product of step [4], although it mainly contributes to the film, still leaves the possibility that a new metal plane becomes covered by hydrogen adatoms. Reactions [7a] and [7b] promote a thickening of the hydrated-oxy-hydroxo layer and reactions [8a] and [8b] involve a complete electroreduction of the surface without layer thickening. The energetics of these processes are probably slightly different so that the extent of the contribution of each possibility depends on the electrode potential. Reaction [7b] explains the cathodic potential limit for the electrode activation. Moreover, the amount of charge playing part in the hydrogen adatom region when no IrO_2 has been formed is confined to the adsorption capacity at the π_1 plane and it is certainly independent of the amount of hydroxo compound lying between planes π_1 and π_2. Hence, the electrode roughness factor should be actually related to the π_1 plane. The formation of either $Ir(OH)_4$ or some equivalent hydrated-oxy-hydroxo species produces the enlargement of the metal-metal bond through the introduction of a new coordinated oxygen atom. But the reduced species $Ir(OH) \cdot 3H_2O$ produced from $Ir(OH)_4$ will not begin to form the film until the potential makes possible a reaction such as [6a]. When the latter takes place it is possible the $Ir(OH) \cdot 3H_2O$ reduction and also the adsorption of a hydrogen atom interacting with an Ir atom of the second layer and the concomitant displacement of the $Ir(OH) \cdot 3H_2O$ species form the film.

On the other side when the anodic potential just exceeds that of reaction [2], the IrO_2 formation begins to take place at the π_1 plane and this process again should enhance the increase of charge. As a matter of fact the thermodynamic potential for such reaction comes close to the anodic potential limit required for activating the electrode. The complete electroreduction of the IrO_2 surface species should only be achieved at cathodic potentials of net hydrogen evolution, probably through a series of reactions such as [7b] to [8b].

On the basis of the proposed model any process which either produces a net corrosion of the metal as IrO_2 or leaves a new reduced metal surface contributes to the $Ir(OH)_4$ formation within the π_1 and π_2 planes. Therefore, the two potential limits to achieve the increasing electrode activation are related to the processes just described. Under these circumstances, the potential change of the activated electrode kept within those limits is predominantly bound to reactions [4] to [5c]. The change of the electrode activity will depend on the rate of shifts of the π_1 and π_2 planes caused by the various possible steps already discussed.

Furthermore, one reasonably admits that at the plane π_2 either a dissolution of the hydroxo species or a dehydration or both simultaneously take place. The latter is probably favored by the dehydrating power of the electrolyte.

The proposed explanation involves the net metal electrodissolution after a continuous RTPS and the formation of a relatively loosely attached layer between the π_1 and π_2 planes. This renders possible either a partial or total mechanical detachment of the layer, thus accounting for either the anodic or cathodic electrode deactivation limits. Otherwise, at high anodic potentials a change to a valence state +6 and a breaking of the film structure may occur but this is far from proved.

The activation process in concentrated H_2SO_4 exhibits a major contribution of the first redox couple to the detriment of the others. Then, the film composition may approach a predominant $Ir(OH)_2$ stoichiometry due to a competence between the film formation and the dehydration of the hydroxo-containing species by the concentrated acid. Finally, no hydrated species can exist in the molten $KHSO_4$ so that no charge increase is observed.

The reaction model also explains that a direct oxidation of the surface to IrO_2 entails the formation of a difficulty reducible surface species since the hydrogen adatom current peaks practically disappear. As earlier presumed, this indicates that a complete surface reduction can only be achieved after a drastic electroreduction at cathodic potentials exceeding by far that of the hydrogen electrode potential. This is perhaps more clearly observed in the case of the $Ir/KHSO_4$ (melt)

interface where no hydrogen adatom contributions are seen for an electrode attaining a stable E/I profile and where the potential excursions are limited to the monolayer oxygen electrosorption region. Only after a drastic electroreduction the current peaks related to the hydrogen adatoms are then recorded. The complete surface reduction would imply the electroreduction of Ir-O-Ir species or related ones which have already been assumed by other authors (23).

Finally, aging effects such as those described for monolayers of oxygen-containing species in other noble metal/acid electrolyte interfaces (26, 34) become clearly evident when there is no electrode activation interference and the charge involved in the process is of the order of one monolayer, as recently reported for the Ir/$KHSO_4$ (melt) interface (24).

The Theoretical Energy Conversion Efficiency of a High Temperature Fuel Cell Based on a Mixed Conductor

D. S. Tannhauser

Department of Physics, Technion—Israel Institute of Technology, Haifa, Israel

ABSTRACT

We have calculated the voltage *vs.* current characteristic and the energy conversion efficiency of a fuel cell based on a mixed ionic-electronic conductor. The transport equations for the electrolyte are solved exactly and the material parameters which determine the shape of the characteristic are determined. The equations are then applied to the special case of doped ceria, which becomes a mixed conductor only at low oxygen pressures. We then show that for the purpose of efficiency calculations, the finite but small ratio of ionic to electronic mobility valid for ceria can be safely taken as zero, and we compare the resulting simple equations with the equivalent circuit approach to a fuel cell. The characteristic is found to be curved instead of being a straight line and for typical operating conditions the best energy conversion efficiency is, for the transport theory approach, 50% higher than for the equivalent circuit one. We conclude from the calculated new values of conversion efficiency that the equivalent circuit underestimates the conversion efficiency of a mixed conductor seriously and that doped ceria as a solid electrolyte is a more serious contender to doped zirconia than believed up to now.

A very important factor in judging the economic performance of a fuel cell is its energy conversion efficiency, η, defined as (power delivered to the load)/(rate of conversion of chemical energy). A fuel cell based on a purely ionic conductor and operating under a very light load can have an efficiency close to 100%. This, however, is not an economical way of using the fuel cell because it implies a very small current density. For a fuel cell based on a mixed ionic-electronic conductor, η will never be 100% because of the internal short by the electronic current. However the efficiency of a purely ionic conductor under actual working conditions will also be much less than 100%, and we need, therefore, a detailed analysis to judge the relative suitability of a given purely ionic conductor *vs.* a given mixed conductor. It may well happen that in spite of a slightly smaller η the mixed conductor will be more suitable because its internal resistance is smaller or because it has less electrode problems.

The calculation should start from the experimentally determined material properties of the mixed conductor and result in the maximum obtainable energy conversion efficiency under given external conditions. Takahashi (1) has done such a calculation but his analysis is based on averaged material properties which lead to a simple equivalent circuit and to a linear current-voltage characteristic of the fuel cell. A more reliable calculation of the efficiency should start from the transport relations for ions and electrons in the material, this has never been done. A similar physical problem is that of migration of ions and electrons during oxidation of a metal under the influence of an electric field, an approximate solution is given by Kroeger (2). The approximations used by Kroeger, when applied to a fuel cell material, lead to a linear dependence of current on voltage, *i.e.*, to the equivalent circuit used by Takahashi.

The purpose of this paper is to present a detailed calculation of the maximum theoretical energy conversion efficiency for a fuel cell based on a mixed conductor and working under given external conditions. The result of this calculation, which starts from the transport equations, is of interest because it defines an upper limit which can be reached, given the right technology. It serves a similar purpose as the theoretical energy conversion efficiency of a silicon solar cell, in both cases the reason why the theoretical limit is not easily reached is connected with the electrodes which collect the current.

We shall not do the calculation in the most general form but shall base our terminology and the application of our results on the properties of doped CeO_2 (3). This material is a competitor to doped ZrO_2, the material on which most of the development of high temperature fuel cells has been concentrated. Doped zirconia is a purely ionic conductor at any oxygen pressure of interest in fuel cells, but because of its relatively low conductivity it has to be used near 1000°C to get a reasonable current density. Doped ceria has a somewhat higher conductivity and can therefore be used near 800°C, it also seems to have less aging and polarization problems than doped zirconia. Its one disadvantage is that it becomes a mixed ionic-electronic conductor at the low oxygen pressures which prevail on the fuel side of a fuel cell.

After defining the system mathematically we first solve the set of transport equations. Among our assumptions is that of electrical neutrality, but we arrive at a solution with a small space charge. We show in Appendix A that for the material properties of doped ceria the space charge is so small that the approximation of neutrality is justified. We then apply the general solution to doped ceria, where the electronic conductivity at the cathode can be neglected, and calculate for this material the characteristic and maximum efficiency. In the last section we compare the calculated efficiency with that obtained from the equivalent circuit solution, and find that η for the transport model is considerably larger. We conclude that the equivalent circuit does not represent the system very well and specifically that doped ceria should be considerably more suitable as a fuel cell material than believed up to now.

In our analysis we assume that the power delivered by the fuel cell is limited by bulk properties and not by electrode or surface reactions.

The results of this paper can be applied, with slight modifications, to fuel cells based on mixed conductors other than doped ceria.

Description and Defining Equations of the System

In this and the next section we calculate the relationship between the load current, j_L, the electronic loss current, j_e, and the load voltage, E_L, of a fuel

Key words: fuel cell, transport theory, energy conversion, cerium dioxide.

cell made of a solid electrolyte which becomes a mixed ionic-electronic conductor at low oxygen pressure. From the $j_L(E_L)$ and $j_e(E_L)$ curves we then find the energy conversion efficiency. We base our terminology on doped CeO_2, the calculation however is quite general.

The electrolyte, a membrane of doped CeO_2, is typically at 800°C and extends from $x = 0$ to $x = l$ (see Fig. 1a). The oxygen partial pressure is $p_{O_2}{}^{I}$ (normally about 10^{-20} atm as in $H_2/H_2O = 10/1$) at $x = 0$ and $p_{O_2}{}^{II}$ (normally 0.21 atm) at $x = l$. The electrolyte is doped substitutionally with a lower valent metal ion, which we take for definiteness to be Ca^{2+}, in the range $[Ca_{Ce}''] = 10\%$ molar concentration. This doping creates oxygen vacancies, $V_O^{\cdot\cdot}$, with an effective double positive charge, in addition to those which already exist in the undoped material. These charged vacancies conduct the ionic current. At $x = 0$ and at $x = l$ there are electrodes and we assume that the electrode-electrolyte interface presents a negligible resistance to the transfer of electrons or ions, *i.e.*, that the reaction

$$2e + V_O^{\cdot\cdot} + \tfrac{1}{2}\, O_2(\text{gas}) \leftrightarrow \text{zero} \qquad [1]$$

is in equilibrium near each of the electrodes. Therefore, even when current flows, the concentration of electrons, n, and of vacancies, $[V_O^{\cdot\cdot}]$, obeys near $x = 0$ the equation

$$(n^I)^2[V_O^{\cdot\cdot}]^I(p_{O_2}{}^I)^{1/2} = K_O(T) \qquad [2]$$

while near $x = l$

$$(n^{II})^2[V_O^{\cdot\cdot}]^{II}(p_{O_2}{}^{II})^{1/2} = K_O(T) \qquad [2a]$$

$K_O(T)$ is the equilibrium constant of reaction [1] at temperature T. Equations [2] and [2a], together with the condition of local neutrality

$$2[V_O^{\cdot\cdot}] = 2[Ca_{Ce}''] + n \qquad [3]$$

determine n and $[V_O^{\cdot\cdot}]$ near each of the electrodes, these concentrations will subsequently serve as boundary conditions. In doped ceria the value of n^I is such that the electronic conductivity at $x = 0$ competes with the ionic conductivity. The validity of the neutrality condition [3] will be discussed in Appendix A.

An expression for the load voltage may now be derived. For convenience we use the formalism of electrochemical potentials, for the electrons these are $(\tilde{\mu}_e{}^I)$ and $\tilde{\mu}_e{}^{II}$ in the two electrodes. The load voltage is given by

$$-qE_L = \tilde{\mu}_e{}^I - \tilde{\mu}_e{}^{II} \qquad [4]$$

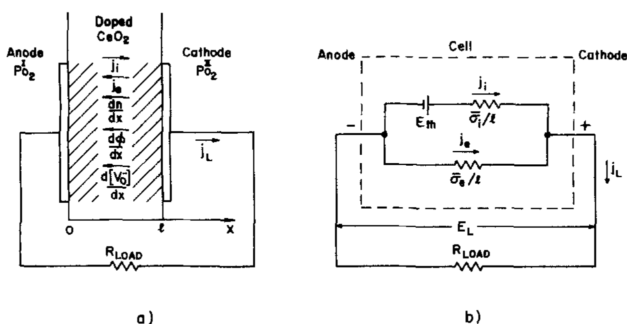

Fig. 1. (a) Schematic cross section of a fuel cell based on doped ceria. The directions of the electric currents and of the gradients correspond to normal operation of the cell. The thickness l is typically 1 mm. The electronic current is seen to be negative. The ratio $p_{O_2}{}^{II}/p_{O_2}{}^{I}$ is typically 10^{20}. (b) Equivalent circuit of a fuel cell with mixed conductivity. E_{th} is the theoretical open-circuit voltage of the ideal fuel cell. $\bar{\sigma}_i$ and $\bar{\sigma}_e$ are specific ionic and electronic conductivities. The current directions are drawn for all currents positive, as defined after Eq. [10].

The electrochemical potential $\tilde{\mu}_e$ is the same in the electrode and in the outer layer of electrolyte next to it, since we assumed nonblocking electrodes. For electrons $\tilde{\mu}_e = \mu_e - q\phi$, Eq. [4] is therefore equivalent to

$$-qE_L = (\mu_e{}^{II} - \mu_e{}^{I}) - q(\phi^{II} - \phi^{I}) \qquad [5]$$

Here μ_e is the chemical potential and ϕ the electrical potential in the electrolyte, and q is the elementary charge, defined positive.

We can calculate $\Delta\mu_e$ for the electrolyte from $\mu_e = kT \ln n + \text{const.}$ which gives

$$\mu_e{}^{II} - \mu_e{}^{I} = kT \ln \frac{n^{II}}{n^{I}} \qquad [6]$$

The ratio n^{II}/n^{I} is determined by Eq. [2] and [3] and, in order to calculate $E_L(j_L)$, we are left with the problem of expressing $(\phi^{II} - \phi^{I})$ in terms of the load current j_L.

To do this we have to solve the set of coupled transport equations for the ionic current density j_i and for the electronic current density j_e. These are

$$j_i = -2qD_i \frac{d[V_O^{\cdot\cdot}]}{dx} - 2qv_i[V_O^{\cdot\cdot}] \frac{d\phi}{dx} \qquad [7]$$

and

$$j_e = qD_e \frac{dn}{dx} - qv_e n \frac{d\phi}{dx} \qquad [8]$$

Here D_i is the diffusion coefficient of vacancies and v_i their mobility; D_e is the diffusion coefficient of electrons and v_e their mobility. The mobilities and diffusion constants are connected through the Einstein relations

$$D_i = \frac{kT}{2q} v_i \qquad [9]$$

$$D_e = \frac{kT}{q} v_e \qquad [9a]$$

and we assume that the mobilities do not depend on the defect concentrations. The currents in Eq. [7] and [8] are electric, not particle, currents. As usual the field currents flow in the direction of decreasing ϕ while the diffusion currents flow toward low concentrations for the positive vacancies and toward high concentrations for electrons. Particle conservation demands that both j_e and j_i are independent of x. The current per unit area delivered by the fuel cell to the load is given by

$$j_L = j_i + j_e \qquad [10]$$

We define the direction from the anode to the cathode as positive and shall see later that j_e is negative under normal operating conditions, and therefore, $j_L < j_i$. In Fig. 1a we show the directions under normal operating conditions of the various currents and gradients introduced above.

Calculation of Cell Characteristic and Efficiency

We first derive a differential equation for the dependence of n on x. Substitution of [9] and [10] into [7] gives

$$j_L = j_e - kTv_i \frac{d[V_O^{\cdot\cdot}]}{dx} - 2qv_i[V_O^{\cdot\cdot}] \frac{d\phi}{dx} \qquad [11]$$

Equation [3] leads to $2d[V_O^{\cdot\cdot}]/dx = dn/dx$, and Eq. [8] together with [9a] to

$$q \frac{d\phi}{dx} = -\frac{j_e}{v_e n} + \frac{kT}{n} \frac{dn}{dx} \qquad [12]$$

Substitution into Eq. [11] gives

$$j_L = j_e - \frac{kTv_i}{2}\frac{dn}{dx} - 2kTv_i\frac{[V_O^{\cdot\cdot}]}{n}\frac{dn}{dx} + 2\frac{[V_O^{\cdot\cdot}]}{n}\frac{v_i}{v_e}j_e \quad [13]$$

We substitute now Eq. [3] and get the following differential equation

$$\left(A + \frac{3}{4}Cn\right)\frac{dn}{dx} - (1+D)n - B = 0 \quad [14]$$

where we have defined

$$C \equiv \frac{2kTv_i}{j_e - j_L}, \quad A \equiv [Ca_{Ce}'']C,$$

$$D \equiv \frac{v_i}{v_e}\frac{j_e}{j_e - j_L}, \quad B \equiv 2[Ca_{Ce}'']D$$

To calculate $(\phi^{II} - \phi^{I})$ we start from Eq. [12], which can be written

$$\left[q\frac{d\phi}{dn} - \frac{kT}{n}\right]\frac{dn}{dx} = -\frac{j_e}{v_e n} \quad [15]$$

We substitute dn/dx from Eq. [14] and get after some algebra

$$q\frac{d\phi}{dx} = kT\frac{1 - \frac{1}{2}D}{B + (1+D)n} \quad [16]$$

Integration gives

$$q(\phi^{II} - \phi^{I}) = kT\frac{1 - \frac{1}{2}D}{1+D}\ln\frac{B + (1+D)n^{II}}{B + (1+D)n^{I}} \quad [17]$$

and we write this in terms of the material properties in the form

$$\Delta\phi = \frac{kT}{q}\frac{\frac{v_i}{2v_e} - y}{\frac{v_i}{v_e} + y}\ln\frac{1 + \left(\frac{v_i}{v_e} + y\right)\frac{\sigma_e^{I}}{\sigma_i^{\circ}}}{1 + \left(\frac{v_i}{v_e} + y\right)\frac{\sigma_e^{II}}{\sigma_i^{\circ}}} \quad [18]$$

Here we have defined

$$\Delta\phi \equiv \phi^{II} - \phi^{I}, \quad y \equiv \frac{j_e - j_L}{j_e}, \quad \sigma_e \equiv qv_e n,$$

$$\sigma_i^{\circ} \equiv 2qv_i[Ca_{Ce}'']$$

From Eq. [5], [6], and [18] we can now calculate $E_L(y)$

$$E_L(y) = \frac{kT}{q}\ln\frac{n^{I}}{n^{II}} + \Delta\phi(y) \quad [19]$$

The characteristic of the fuel cell, $E_L(j_L)$, will subsequently be described parametrically by $E_L(y)$ and $j_L(y)$.

For later use in this paper we note that Eq. [19] can be written

$$E_L = E_{th} + \frac{kT}{2q}\ln\frac{1 + (\sigma_e^{II}v_i/\sigma_i^{\circ}v_e)}{1 + (\sigma_e^{I}v_i/\sigma_i^{\circ}v_e)} + \Delta\phi \quad [20]$$

Here E_{th} is the theoretical open-circuit voltage of the ideal fuel cell, which is in our case

$$E_{th} = \frac{kT}{4q}\ln\frac{p_{O_2}^{II}}{p_{O_2}^{I}} \quad [21]$$

To derive Eq. [20] we add and subtract E_{th} to Eq. [19] and use the relation

$$n^2 p_{O_2}^{1/2} = \frac{K_O}{[Ca_{Ce}''] + \frac{n}{2}} \quad [22]$$

which is derived from Eq. [2] and [3]. This gives

$$E_L = E_{th} + \frac{kT}{2q}\ln\frac{2[Ca_{Ce}''] + n^{II}}{2[Ca_{Ce}''] + n^{I}} + \Delta\phi \quad [23]$$

which is easily converted to [20].

In order to calculate $E_L(j_L)$ we still need an expression for $j_L(y)$. Integration of Eq. [14] and use of the boundary values for n leads to

$$l = \frac{3}{4}\frac{C}{1+D}(n^{II} - n^{I}) + A\frac{1 - \frac{1}{2}D}{(1+D)^2}\ln\frac{B + (1+D)n^{II}}{B + (1+D)n^{I}} \quad [24]$$

or

$$l = \frac{1}{1+D}\left\{\frac{3}{4}C(n^{II} - n^{I}) + Aq\frac{(\phi^{II} - \phi^{I})}{kT}\right\} \quad [25]$$

This converts easily to

$$j_e = \frac{\sigma_i^{\circ}\Delta\phi}{l\left(\frac{v_i}{v_e} + y\right)}\left\{1 + \frac{3}{2}\frac{\sigma_e^{II} - \sigma_e^{I}}{\sigma_i^{\circ}}\frac{v_i}{v_e}\frac{kT}{q\Delta\phi}\right\} \quad [26]$$

Equations [18] and [26] permit calculation of $\Delta\phi$, and j_e as a function of the parameters σ_i°/l, v_i/v_e, $\sigma_e^{II}/\sigma_i^{\circ}$, $\sigma_e^{I}/\sigma_i^{\circ}$, T, and the dummy variable y. Note that $j_e \leq 0$. The numerical relation $j_L(y)$ is now described by Eq. [26] and $j_L = (1 - y)j_e$.

We would like to show now that the shape of the characteristic $E_L(j_L)$ is determined only by four parameters. We normalize the load voltage E_L by division by E_{th} and get from Eq. [18] and [20]

$$\frac{E_L}{E_{th}} = \frac{f\left(\frac{v_i}{v_e}, \frac{\sigma_e^{II}}{\sigma_i^{\circ}}, \frac{\sigma_e^{I}}{\sigma_i^{\circ}}, y\right)}{\ln(p_{O_2}^{II}/p_{O_2}^{I})} \quad [27]$$

For given values of the three material parameters and $p_{O_2}^{II}/p_{O_2}^{I}$, E_L equals zero at a certain y_o; this y_o determines the short-circuit current, $j_{s.c.}$. It follows then from Eq. [18], [26], and the relation $j_L = (1 - y)j_e$ that

$$\frac{j_L}{j_{s.c.}} = \frac{g\left(\frac{v_i}{v_e}, \frac{\sigma_e^{II}}{\sigma_i^{\circ}}, \frac{\sigma_e^{I}}{\sigma_i^{\circ}}, y\right)}{g\left(\frac{v_i}{v_e}, \frac{\sigma_e^{II}}{\sigma_i^{\circ}}, \frac{\sigma_e^{I}}{\sigma_i^{\circ}}, y_o\right)} \quad [28]$$

The relation between the normalized values E_L/E_{th} and $j_L/j_{s.c.}$ depends, therefore, only on the three material parameters and on $p_{O_2}^{II}/p_{O_2}^{I}$ but not explicitly on the temperature. The same is true for the relation between E_L/E_{th} and $j_e/j_{s.c.}$.

With these relations we are ready now to calculate the energy conversion efficiency η, which is of central interest in this work. The value of η, which is defined as (power delivered to the load)/(rate of conversion of chemical energy) is given by

$$\eta = \frac{E_L j_L}{E_{th} j_i} = \frac{E_L j_L}{E_{th}(j_L - j_e)} = \frac{y-1}{y}\frac{E_L}{E_{th}} \quad [29]$$

Equation [29] implies that η_{max}, the maximum fuel conversion efficiency for a given material, also depends only on the three material parameters and on the ratio $p_{O_2}^{II}/p_{O_2}^{I}$.

Up to this point the calculation is exact, except for the use of the neutrality condition which is discussed in Appendix A.

The open-circuit voltage calculated from Eq. [18] and [19] with $y = 1$ agrees with that calculated by Wagner (4) from more general thermodynamic considerations. This is shown in Appendix B.

Application to Doped Ceria

We now calculate the characteristic and efficiency for doped ceria used under the conditions described earlier. We note that for this system the ratio $\sigma_e^{II}/\sigma_i^\circ$ is about 10^{-4} and $\sigma_e^I/\sigma_i^\circ$ is of order 1. The ionic conductivity of $(CeO_2)_{0.90}(La_2O_3)_{0.10}$ at 800°C is $\sigma_i = 10^{-1}\ \Omega^{-1}\ cm^{-1}$ (1, 5), which corresponds to $v_i = 1.2 \times 10^{-4}$ cm²/V-sec, and v_e at 800°C is reported to be about 3×10^{-3} cm²/V-sec (6). For doped ceria the mobility ratio is therefore about 0.04.

We can neglect therefore all the terms containing σ_e^{II} in Eq. [18], [20], and [26] and get with the help of the relation $j_L = (1 - y)j_e$

$$\Delta\phi = \frac{kT}{q}\,\frac{\dfrac{v_i}{2v_e} - y}{\dfrac{v_i}{v_e} + y}\ln\left[1 + \left(\frac{v_i}{v_e} + y\right)\frac{\sigma_e^I}{\sigma_i^\circ}\right] \quad [30]$$

$$E_L = E_{th} - \frac{kT}{2q}\ln\left(1 + \frac{\sigma_e^I v_i}{\sigma_i^\circ v_e}\right) + \Delta\phi \quad [31]$$

and

$$j_L = \frac{\sigma_i^\circ\Delta\phi(1-y)}{l\left(\dfrac{v_i}{v_e} + y\right)}\left(1 - \frac{3}{2}\frac{\sigma_e^I}{\sigma_i^\circ}\frac{v_i}{v_e}\frac{kT}{q\Delta\phi}\right) \quad [32]$$

The shape of the characteristic $E_L(j_L)$ is now determined by the two material parameters v_i/v_e and $\sigma_e^I/\sigma_i^\circ$ and by the ratio $p_{O_2}^{II}/p_{O_2}^I$ and is expressed by the above equations in terms of the parameter y. The conversion efficiency η is calculated from Eq. [29] and is maximized by varying y.

In Fig. 2 we have plotted the characteristics for various mobility ratios and in Fig. 3 the maximum conversion efficiency η_{max} *vs.* $\sigma_e^I/\sigma_i^\circ$, again for various mobility ratios. We see from Fig. 2 that at $\sigma_e^I/\sigma_i^\circ = 5$ the characteristic calculated for $v_i/v_e << 1$ describes the behavior of doped ceria still quite well. Figure 3 shows that even at $\sigma_e^I/\sigma_i^\circ = 15$, corresponding to $\eta_{max} = 0.5$, the characteristic for $v_i/v_e << 1$ can be safely used to calculate η_{max}. This value of η_{max} is about the limit where the fuel cell stops being of interest. We shall therefore base the continuation of our discussion and the comparison with the equivalent circuit on $v_i/v_e << 1$, this simplifies the equations considerably.

Comparison with Equivalent Circuit

In this section we compare the characteristic calculated with $v_i/v_e << 1$ with that calculated by Takahashi (1), who used an equivalent circuit to describe the fuel cell. The use of such a circuit actually goes back to Jost, see, for instance, Kroeger (2). To make the comparison meaningful we assume that we have measured σ_i° by measuring the conductivity of the material in air, and we have also measured the total conductivity at $p_{O_2}^I$. We calculate the characteristic and η_{max} by both methods.

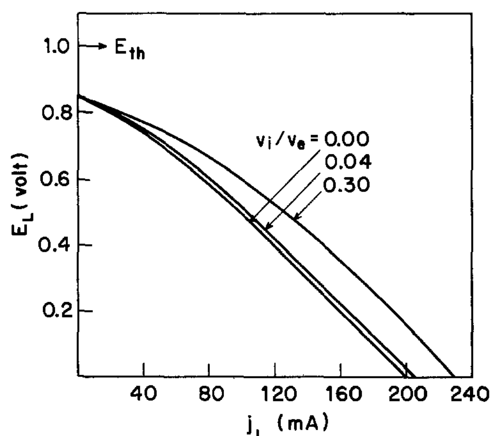

Fig. 2. Transport theory characteristic of a fuel cell made of doped ceria for various ratios of ionic to electronic mobility. The calculation is based on the following parameters: $T = 735$°C, $p_{O_2}^{II}/p_{O_2}^I = 10^{20}$, $\sigma_i^\circ/l = 0.2\ \Omega^{-1}\ cm^{-2}$, and $\sigma_e^I/\sigma_i^\circ = 5$. $E_{th} = 1$V under these conditions.

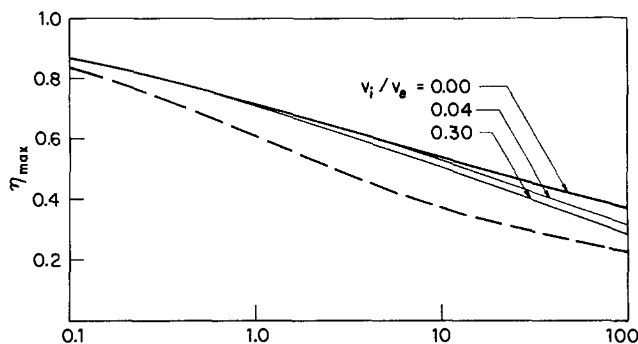

Fig. 3. Maximum fuel conversion efficiency vs. $\sigma_e^I/\sigma_i^\circ$ for a fuel cell based on doped ceria. The thick full line is calculated from transport theory with $v_i << v_e$, the two thin lines correspond to two finite values of v_i/v_e. The dashed line follows from the equivalent circuit approach. $p_{O_2}^{II}/p_{O_2}^I$ is taken as 10^{20}.

In order to facilitate the comparison, we now assume that $v_i\sigma_e^I/v_e\sigma_i^\circ = n^I/[Ca_{Ce}''] << 1$. This permits us immediately to neglect the second term in Eq. [31]. We have seen in Fig. 3 that the practical limit of use of fuel cells made from doped ceria is $\sigma_e^I/\sigma_i^\circ \cong 10$ so that even with $v_i/v_e = 0.04$ this assumption is almost always very good. It implies, together with Eq. [6] and the fact that $n(x) < n^I$, that $[V_O^{\cdot\cdot}] \simeq [Ca_{Ce}'']$ throughout the electrolyte, and therefore that $\sigma_i(x) = \sigma_i^\circ$. From the total conductivity at the anode we can then calculate the ratio $\sigma_e^I/\sigma_i^\circ$, which we need in Eq. [30] to [32].

The open-circuit voltage expected from the fuel cell may now be calculated under the simplifying conditions assumed above. This then is used to set up the equivalent circuit.

Under normal operating conditions $y \geq 1$ and we can, therefore, neglect the term v_i/v_e in Eq. [30] and [32]. Furthermore, it is easy to show that the second term in the parenthesis of Eq. [32] is of order v_i/v_e and can, therefore, also be neglected. Equations [30] to [32] now simplify further to

$$\Delta\phi = -\frac{kT}{q}\ln\left[1 + y\frac{\sigma_e^I}{\sigma_i^\circ}\right] \quad [33]$$

$$E_L = E_{th} + \Delta\phi \quad [34]$$

$$j_L = \frac{\sigma_i^\circ\Delta\phi(1-y)}{ly} \quad [35]$$

and the open-circuit voltage is

$$E_{o.c.} = E_{th} - \frac{kT}{q}\ln\left[1 + \frac{\sigma_e^I}{\sigma_i^\circ}\right] \quad [36]$$

We introduce now the transport fraction defined by $t_i \equiv \sigma_i/(\sigma_i + \sigma_e)$ and get

$$E_{o.c.} = \frac{kT}{4q}\left(\ln\frac{p_{O_2}^{II}}{p_{O_2}^I} + 4\ln t_i^I\right) \quad [37]$$

With the further definition $\overline{t_i} \equiv E_{o.c.}/E_{th}$ this leads to the following relation between the average transport fraction $\overline{t_i}$ and the transport fraction at the anode, t_i^I

$$\overline{t_i} = 1 + \frac{4\ln t_i^I}{\ln(p_{O_2}^{II}/p_{O_2}^I)} \quad [38]$$

The equivalent circuit used by Takahashi (1) is of the form shown in Fig. 1b. In Takahashi's notation E_{th} is, as before, the open-circuit voltage of the ideal fuel cell, $\overline{\sigma_i}/l$ is the ionic conductance per unit area of the electrolyte, and $\overline{\sigma_e}/l$ is the electronic one.

The characteristic of this circuit is

$$j_L = \frac{\overline{\sigma_i}}{l}(E_{th} - E_L) - \frac{\overline{\sigma_e}}{l}E_L \quad [39]$$

and its open-circuit voltage is, therefore, $E_{o.c.} = E_{th}\overline{\sigma_i}/(\overline{\sigma_i} + \overline{\sigma_e})$. Since the equivalent circuit should give the same $E_{o.c.}$ as the exact theory we have to take

$$\frac{\overline{\sigma_i}}{\overline{\sigma_i} + \overline{\sigma_e}} = \overline{t_i} \quad [40]$$

where $\overline{t_i}$ is given by Eq. [38].

The characteristic $j_L(E_L)$ (Eq. [39]) is evidently a straight line, and so is the relation $j_e(E_L)$

$$j_e = -\frac{\overline{\sigma_e}}{l}E_L \quad [41]$$

In Fig. 4 we plot these lines and compare them with the corresponding lines for the transport model calculated with the same values of open-circuit voltage $E_{o.c.}$ and short-circuit current $j_{s.c.}$. Since the calculations of η which follow rely only on the ratio j_L/j_e it is not really essential to choose the same $j_{s.c.}$ for both models, but it facilitates the graphical comparison.

We see from Fig. 4 that at any particular value of E_L, j_L comes out slightly larger in the transport model, and that j_e, which determines the internal loss current of the fuel cell, is considerably smaller. Since the fuel conversion efficiency is determined by the ratio j_L/j_e (see Eq. [29]), the transport model predicts a larger value for this efficiency than the equivalent circuit model. The values of η_{max} are 0.59 and 0.44 for the parameters of Fig. 4.

To make the comparison quantitative we use in the case of the equivalent circuit an equation for η_{max} derived by Takahashi (1)

$$\eta_{max} = \frac{1 - (1 - \overline{t_i})^{1/2}}{1 + (1 - \overline{t_i})^{1/2}} \quad [42]$$

The dashed line in Fig. 3 describes this equation, $\overline{t_i}$ is connected with the abscissa scale, $\sigma_e^I/\sigma_i^\circ$, through Eq. [39] and the relation $t_i^I = \sigma_i^\circ/(\sigma_i^\circ + \sigma_e^I)$.

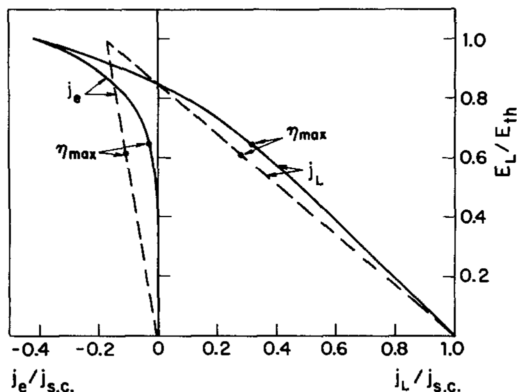

Fig. 4. Load current j_L and electronic loss current j_e against output voltage E_L of a fuel cell made of doped ceria. The scales are normalized by division with $j_{s.c.}$ and with E_{th}, respectively. The full lines are calculated from transport theory with $v_i << v_e$; the dashed lines follow from an equivalent circuit approach. The current values at η_{max} are shown for both models. η_{max} is 0.59 for the transport model vs. 0.44 for the equivalent circuit. The conductivity ratio at the anode is taken as $\sigma_e^I/\sigma_i^\circ = 5$ ($t_i^I = 0.166$) and the ratio $p_{O_2}^{II}/p_{O_2}^I$ is 10^{20}. Negative values of j_L imply an outside current source.

It is seen from Fig. 3 and 4 that the equivalent circuit is not a good approximation to the fuel cell under load. The maximum efficiency predicted by the transport calculation is, for typical operating conditions of a ceria fuel cell, about 50% higher than that predicted by the equivalent circuit. The main reason for the difference is that in the transport model the electronic current decreases very much faster with decreasing E_L than predicted by the equivalent circuit.

Since for doped ceria used at 800°C in H_2O/H_2 = 10/1, $\sigma_e^I/\sigma_i^\circ$ is approximately 9, and Fig. 3 gives then η_{max} = 55%, we expect that this material will now be considered more seriously than before as an electrolyte in fuel cells.

Thanks are due to N. Klein and I. Riess for their helpful remarks concerning this paper. This work was supported by a grant from the National Council of Research and Development, Israel, and the KFA, Jülich, Germany.

Manuscript submitted Dec. 7, 1977; revised manuscript received March 17, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

APPENDIX A

In the process of solution of our equations we assumed the validity of the local neutrality Eq. [3] throughout the electrolyte. This assumption is not quite exact, since the solution which it generates implies a small space charge. We really should have used Poisson's equation in the form

$$2[V_O^{\cdot\cdot}] - 2[Ca_{Ce}''] - n = \delta(x) = -\frac{\epsilon_0}{q}\frac{d^2\phi}{dx^2} \quad [A\text{-}1]$$

this however leads to the extremely complicated differential equations.

We now show that the approximation of local neutrality is justified, *i.e.*, that the space charge δ is negligible.

In Eq. [11] we substituted $2d[V_O^{\cdot\cdot}]/dx = dn/dx$, *i.e.*, we assumed that $d\delta/dx << dn/dx$. In Eq. [13] we substituted $2[V_O^{\cdot\cdot}] = 2[Ca_{Ce}''] + n$, this is justified if $\delta << n$. δ is given by $\delta = -(\epsilon_0/q)d^2\phi/dx^2$ and we calculate an upper limit for δ as follows

$$\frac{d\phi}{dx} = \frac{d\phi}{dn}\frac{dn}{dx} = \frac{kT}{q}\frac{1 - \frac{1}{2}D}{A + \frac{3}{4}Cn} \quad [A\text{-}2]$$

(see Eq. [15] + [17])

$$\frac{d^2\phi}{dx^2} = \left(\frac{d}{dn}\frac{d\phi}{dx}\right)\frac{dn}{dx}$$

$$= -\frac{3}{4}\frac{kT(1 - \frac{1}{2}D)}{q(A + \frac{3}{4}Cn)^2}\frac{[B + (1 + D)n]}{(A + \frac{3}{4}Cn)} \quad [A\text{-}3]$$

We use $D << 1$ and get

$$\frac{d^2\phi}{dx^2} = \frac{3}{16}\frac{j_i^2}{qkTv_i^2}\frac{\left(2\frac{v_i}{v_e}\frac{1}{y}[Ca_{Ce}''] + n\right)}{([Ca_{Ce}''] + \frac{3}{4}n)^3} \quad [A\text{-}4]$$

We use now $n << [Ca_{Ce}'']$ in the denominator and substitute $[Ca_{Ce}'']$ for the parenthesis in the nominator, which is a very rough upper limit. This gives

$$\frac{d^2\phi}{dx^2} < \frac{3}{16}\frac{j_i^2}{qkTv_i^2[Ca_{Ce}'']} \quad [A\text{-}5]$$

Substitution of the following values typical for CeO_2 under normal operating conditions

$j_i = 0.2\ A/cm^2$, $v_i = 10^{-4}\ cm^2/V\text{-sec}$,

$kT = 0.1$ eV, $[Ca_{Ce}''] = 2 \times 10^{21}\ cm^{-3}$

gives

$\delta < 10^8$ (charge carriers)/cm^3

Since n varies from $\sim 10^{21}$ at the anode to 10^{16} at the cathode, we get $\delta < 10^{-8}n$.

A similar calculation gives $d\delta/dx < 10^{-12}\, dn/dx$. Our assumptions are, therefore, justified by the solution.

APPENDIX B

We now show that the open-circuit voltage $E_{o.c.}$ calculated from Eq. [19] with $y = 1$ agrees with $E_{o.c.}$ calculated from the general equation derived by Wagner (4) without the use of the neutrality condition

$$E_{o.c.} = \frac{kT}{4q} \int_{p_{O_2}{}^{I}}^{p_{O_2}{}^{II}} t_i(p_{O_2})\, d \ln p_{O_2} \quad \text{[B-1]}$$

We substitute in Eq. [B-1]

$$t_i \equiv \frac{\sigma_i}{\sigma_i + \sigma_e} = \frac{(2[\text{Ca}_{\text{Ce}}''] + n)v_i}{(2[\text{Ca}_{\text{Ce}}''] + n)v_i + nv_e} \quad \text{[B-2]}$$

and

$$\ln p_{O_2} = \ln K_o - 4 \ln n - 2 \ln \left([\text{Ca}_{\text{Ce}}''] + \frac{n}{2} \right) \quad \text{[B-3]}$$

(see Eq. [22]). The result of the integration is

$$E_{o.c.} = \frac{kT}{q} \ln \frac{n^{I}}{n^{II}} + \frac{kT}{q} \frac{\dfrac{v_i}{2v_e} - 1}{\dfrac{v_i}{2v_e} + 1} \ln \frac{\sigma_i{}^{I} + \sigma_e{}^{I}}{\sigma_i{}^{II} + \sigma_e{}^{II}} \quad \text{[B-4]}$$

This agrees with Eq. [19], since $\sigma_i = \sigma_i{}^{o} + \sigma_e(v_i/v_e)$. In Eq. [B-2] and [B-3] we have used the neutrality condition $2[V_O{}^{\cdot\cdot}] = 2[\text{Ca}_{\text{Ce}}''] + n$, so the agreement is perhaps not surprising.

APPENDIX C

We collect here some additional mathematical relations which illustrate the main text.

(*i*) In the case of the section on Comparison with Equivalent Circuit we get from Eq. [34] and [35] the following rather intuitive expression for E_L

$$E_L = E_{th} - j_i \frac{l}{\sigma_i{}^{o}} \quad \text{[C-1]}$$

which agrees with the equivalent circuit model if we set $\sigma_i{}^{o} = \overline{\sigma_i}$.

(*ii*) From Eq. [33] to [35] one can derive an explicit expression for j_L (E_L)

$$j_L = \frac{\sigma_i{}^{o}}{l}(E_{th} - E_L) - \frac{\sigma_e{}^{I}(E_{th} - E_L)}{l\left[\exp \dfrac{q(E_{th} - E_L)}{kT} - 1\right]} \quad \text{[C-2]}$$

This should be compared with Eq. [39] for the equivalent circuit. For $\sigma_e = 0$ both models give, of course, the same straight line.

(*iii*) For the equivalent circuit we get from Eq. [39] $j_{s.c.} = E_{th}\overline{\sigma_i}/l$. For the transport model we have to a very good approximation $j_{s.c.} = E_{th}\sigma_i{}^{o}/l$ (see Eq. [C-2]. In order to get for both models not only the same $E_{o.c.}$ but also the same $j_{s.c.}$, we set $\overline{\sigma_i}$ equal to $\sigma_i{}^{o}$. It is easy to show that once we have done this both approaches give for $j_L = 0$ $j_e = (\overline{t_i} - 1)E_{th}\overline{\sigma_i}/l$. This intersection point of the two models can be seen in Fig. 4. Furthermore, both models give $j_e = j_L$ when $E_L = E_{th}$. This last condition happens, of course, only when a negative load current is impressed on the cell from an outside current source.

(*iv*) A useful way to illustrate the calculation is to plot η_{max} for the two models *vs.* $p_{O_2}{}^{I}$, the oxygen pressure at the anode. As material parameter we take here $p_{O_2}{}^{*}$, the oxygen pressure where $\sigma_e/\sigma_i = 1$. This oxygen pressure is often called the limit of the ionic domain.

In Fig. 5 we have plotted η_{max} for representative values of $p_{O_2}{}^{*}$ and compared again with the equivalent circuit calculation, where $\overline{t_i}$ was calculated from the following equation, first derived by Schmalzried (7)

$$\overline{t_i} = \frac{\ln[(p_{O_2}{}^{*})^{1/4} + (p_{O_2}{}^{II})^{1/4}] - \ln[(p_{O_2}{}^{*})^{1/4} + (p_{O_2}{}^{I})^{1/4}]}{1/4[\ln p_{O_2}{}^{II} - \ln p_{O_2}{}^{I}]} \quad \text{[C-3]}$$

We see from the figure that the oxygen pressure at

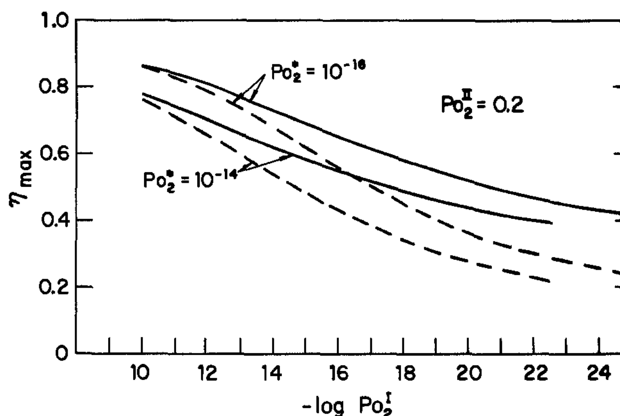

Fig. 5. Maximum fuel conversion efficiency vs. oxygen pressure at the anode for a fuel cell based on doped ceria. The oxygen pressure at the cathode is taken as 0.2 atm and $p_{O_2}{}^{*}$ is the oxygen pressure at which the ionic transport number, t_i, equals 0.5. The full lines are calculated from transport theory with $v_i << v_e$, the dashed lines are calculated from an equivalent circuit approach.

which $\eta_{max} = 0.5$ is for the transport model four orders of magnitude lower than for the equivalent circuit.

LIST OF SYMBOLS

A, B, C, D	constants defined after Eq. [14]
$[\text{Ca}_{\text{Ce}}'']$	concentration of Ca^{2+} ions on Ce^{4+} sites
D_e	diffusion coefficient of electrons
D_i	diffusion coefficient of ions
E_L	voltage of fuel cell under load
$E_{o.c.}$	open-circuit voltage of fuel cell
E_{th}	theoretical open-circuit voltage of fuel cell
j_e	electronic current density
j_i	ionic current density
j_L	load current per unit area of fuel cell
$j_{s.c.}$	short-circuit current per unit area of fuel cell
l	thickness of electrolyte
$K_o(T)$	equilibrium constant in Eq. [2]
n	concentration of electrons
p_{O_2}	partial pressure of oxygen
$p_{O_2}{}^{*}$	oxygen pressure at which $t_i = 0.5$
q	absolute value of electronic charge
T	temperature
t_i	transport fraction of ions
$\overline{t_i}$	average of t_i, defined after Eq. [37]
$[V_O{}^{\cdot\cdot}]$	concentration of vacancies on oxygen sites
v_e	mobility of electrons
v_i	mobility of vacancies
x	dimension through electrolyte
y	ratio $(j_e - j_L)/j_e$
σ_e	electronic conductivity
σ_i	ionic conductivity
$\sigma_i{}^{o}$	ionic conductivity for zero electron concentration
$\overline{\sigma_i}$	average ionic conductivity in the equivalent circuit model
$\overline{\sigma_e}$	average electronic conductivity in the equivalent circuit model
η	energy conversion efficiency
$\tilde{\mu}_e$	electrochemical potential for electrons
μ_e	chemical potential for electrons
ϕ	electrical potential
I, II	(superscripts) refer to the immediate neighborhood of anode and cathode, respectively

The Effect of NaCl(g) on the Oxidation of NiAl

J. G. Smeggil* and N. S. Bornstein

United Technologies Research Center, East Hartford, Connecticut 06108

ABSTRACT

NaCl is ingested into operating gas turbines. The effect of this salt on the high temperature surface stability properties of turbine hardware is not well understood. The involvement of NaCl(g)[1] in the high temperature oxidation of NiAl, a principal component in many high temperature environmental coatings, is herein examined. The results of this work indicate that NaCl(g) present in an oxidizing atmosphere affects the formation of Al_2O_3 whiskers on a dense Al_2O_3 layer. Such whisker growth, attributed to vapor transport processes through an otherwise dense Al_2O_3 scale. increases the aluminum depletion of the NiAl substrate.

Materials for hot-section gas turbine applications must be strong enough to physically support the mechanical loads impressed upon them without failing, and they must also exhibit sufficient surface stability to the hot combustion gases. In current high temperature superalloys, it is frequently difficult to simultaneously obtain sufficient strength and surface stability characteristics. The present solution to this problem, therefore, involves the use of high strength materials which are subsequently coated to impart sufficient high temperature oxidation and corrosion resistance.

Currently used coatings involve either the simple aluminides or one of the many MCrAl(Y) chemistries or a combination of the two. A critical component in these coatings is the cubic β-NiAl or -CoAl formed in the nickel- or cobalt-based systems, respectively (1).

The presence of the β phase in such coating compositions is principally responsible for the formation of an adherent Al_2O_3 scale, thus accounting for the ability of such coatings to afford suitable surface protection (1).

In service, these aluminide coatings are believed to degrade by the depletion of aluminum from the coating layer as a result of both high temperature exposure and thermal cycling (1-3). This effect is manifested in two ways. Initially, aluminum in the coating forms a protective alumina scale, however, the spallation of this film on thermal cycling and its replenishment eventually depletes the coating composition of aluminum at the gas-oxide interface. In the second place, aluminum diffuses from the coating into the substrate. Therefore the coating loses protective efficiency from both gas-coating and substrate-coating interactions.

Both the air and fuel which enter the gas turbine can contain minute quantities of impurities such as sea salt. Sodium chloride is the principal constituent of sea salt crystals which can be carried far inland by prevailing winds. Depending on wind conditions, the concentration of sea salt in the air can vary from less than one tenth to more than 5 ppm (4, 5).

Bessen and Fryxell have shown that the compressors of gas turbine engines are effective physical separators of the chloride and sulfate components of sea salt (6). They reported constant levels of Na_2SO_4, ~0.1 mg/cm², present on all stages of the compressors of an LM-2500 engine which had been operated for over 7000 hr. NaCl, on the other hand, was found to vary from 0.1 mg/cm² at the first stage of compressor to ~0.02 mg/cm² at the seventh stage. After this stage and through the sixteenth stage, no meaningful chloride levels were detected, *i.e.*, < 0.01 mg/cm². Furthermore, their surveys of the high pressure turbine components from several engines failed to reveal the presence of any condensed chlorides.

The deposited salts present on the compressor components can periodically shed. The composition of the salt entering the burner will be dependent upon the compressor location from which it was shed. The condensed salt particles shed from compressor sections in passing through the burner can (*i*) react within the burner; (*ii*) vaporize; or (*iii*) impact the turbine components as particulate matter. The high vapor pressure of NaCl, *e.g.*, 0.35 Torr at 800°C, would be expected to lead to its rapid removal (7). This would account for the virtual absence of chlorides in deposits found on turbine surfaces (6).

Although some NaCl ingested into the turbine burner section may be converted to Na_2SO_4, equilibrium thermodynamic calculations indicate that for gas turbines operating under conditions favoring Na_2SO_4-induced hot corrosion attack, the engine hot section environment is relatively rich in the contaminant gases NaCl, HCl, and NaOH (8).

Intensive work by many investigators has shown that condensed NaCl or NaCl-Na_2SO_4 mixtures can be very corrosive (9-25). Additionally, several investigations have shown that gaseous NaCl is not innocuous. Hancock, using a vibrational technique, has reported that NaCl(g) adversely affects isothermal oxide scale adherence with respect to elements, simple alloys, and superalloys (9, 10, 11b). Stearns *et al.* (26) and Fryburg *et al.* (27) have reported enhanced rates of chromium transport loss for certain materials oxidized in an atmosphere containing NaCl(g), however, none of the studies involving gaseous NaCl report how the observed results manifest themselves microstructurally.

The work reported here is primarily a microstructural study of the effects of NaCl vapor on the oxidation behavior of NiAl, an alumina former. The levels of NaCl vapor examined range from 100 to less than 1 ppm. The latter level approximates the concentration of NaCl vapor anticipated to be found in the combustor and high pressure turbine sections of marinized or industrial gas turbines.

Key words: alloys, coatings, whiskers, corrosion.

[1] In this report the bracketed c implies the phase is present in the condensed state, solid, or liquid. The bracketed g similarly refers to the gaseous state.

Experimental Procedures

The NiAl alloy was prepared by rf melting the desired nominal composition in an argon atmosphere and pouring the melt into an alumina mold. The ingot was then heat-treated in a hydrogen atmosphere at 1350°C for two days. Subsequent chemical analysis of a section of the ingot was found to contain 31.06 ± 0.09 weight percent Al. The annealed ingot was found to be single phase by metallographic examination.

Sample specimens cut from the ingot measured approximately 2.5 × 1.0 × 2.0 cm. These samples were then ground to 600 grit SiC. A platinum wire was welded on one end for sample support. The samples, prior to insertion into the experimental apparatus, were washed and degreased; the final rinse was given with absolute ethanol. The air used in these experiments was taken from the laboratory service strip. The water content of this air was brought to a constant level by passage over anhydrous calcium sulfate (Drierite). The air flow rate for all the experiments was 300 sccm as determined from a calibrated flow meter, and the flow velocity was 0.18 cm/sec.

All oxidation experiments were conducted using an Ainsworth Type RV-AU-1 balance which is readable to 0.01 mg and reproducible to ±0.03 mg. The specimens were introduced into a quartz tube (2.5 in. OD) which was within a heated furnace. The temperature inside the three-zone Marshall furnace was maintained to within ± 5°C by a Leeds and Northrup proportional controller series 60.

The NaCl vapors were generated from condensed NaCl in a platinum crucible fixtured to a movable pedestal in the oxidation tube. The temperature of the crucible was measured by a thermocouple fixtured into a quartz tube and lying immediately adjacent to the NaCl-containing platinum crucible. The NaCl used here was an ultrapure grade obtained from Alfa-Ventron. The data of Ewing and Stern (7) were used to calculate NaCl vapor pressures and gas-phase compositions. Thus the temperatures of the NaCl-containing Pt crucible and the "anticipated" nominal gas phase compositions used here were 802°C, 1000 ppm; 710°C, 100 ppm; 630°C, 10 ppm; and 566°C, 1 ppm. However, recognizing that equilibrium may not have been established between NaCl in the condensed and vapor states, the actual NaCl partial pressure was determined from the difference in weights of platinum crucible before and after each experiment. From these calculations, it was found that the empirical vapor pressures were lower than those expected by a factor of about 10 at the three higher temperatures used here, *i.e.*, 802°, 630°, and 710°C. However, good agreement was observed at the lowest temperature, 566°C. Accordingly, the empirical (as opposed to theoretical) gas-phase compositions for atmospheres involving NaCl vapor are herein cited. The weight change data for samples exposed to NaCl vapors at concentrations above 10 ppm were corrected for condensation of NaCl onto the Pt suspension wire. No correction was made for samples oxidized in atmospheres with NaCl vapors at concentrations of less than 10 ppm.

Subsequent to oxidation, selected samples were examined by optical metallography, scanning electron microscopy (SEM), and transmission electron microscopy techniques. Examination of the oxidized coupons by x-ray diffraction techniques indicated only the presence of the β-NiAl structure because the Al_2O_3 scale was so thin.

Experimental Results

Oxidation (NaCl-free air).—Thermogravimetric studies.—NiAl is a classical alumina former, and the rate of weight gain for NiAl oxidized in pure air at 900° and 1050°C is shown in Fig. 1 and 2, respectively. These data are in agreement with data reported by Pettit (28).

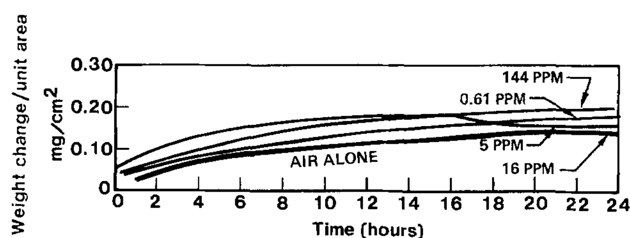

Fig. 1. Thermogravimetric data for NiAl oxidized in air with and without NaCl vapors present at 900°C.

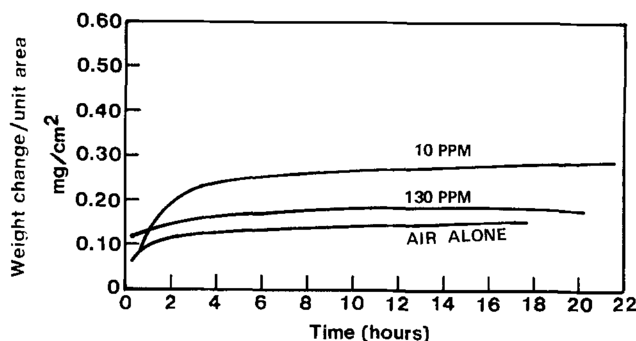

Fig. 2. Thermogravimetric data for NiAl oxidized in air with and without NaCl vapors present at 1050°C.

SEM studies.—During 1050°C oxidation, an adherent dense Al_2O_3 layer is formed, Fig. 3. Occasionally an area of the NiAl substrate can be seen where the Al_2O_3 oxide layer locally spalled on cooling to room temperature, Fig. 4. Such rupturing did not occur isothermally since the substrate would have attempted to reform a protective oxide scale and no indication of any such healing oxide scale was observed. The undulations of the NiAl substrate seen where the scale has locally spalled derive from the final polish (600 grit SiC) used to prepare the specimens. The sample oxidized in air at 900°C also formed a dense Al_2O_3 layer similar to that exhibited by the sample oxidized at 1050°C.

Oxidation (NaCl-containing air).—Thermogravimetric studies.—The thermogravimetric data for samples oxidized at 900° and 1050°C in atmospheres containing approximately 1-140 ppm NaCl is also shown in Fig. 1 and 2, respectively. On the basis of the experi-

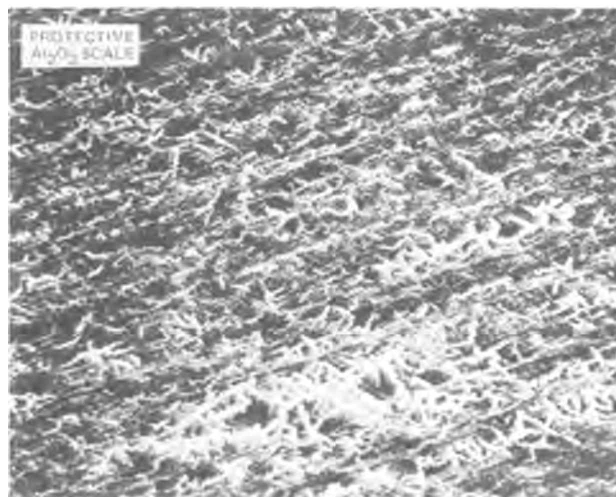

Fig. 3. NiAl oxidized in air at 1050°C for 24 hr

mental techniques used here, no significance is attached to the differences in the thermogravimetric data between samples exposed to pure air and those exposed to NaCl-containing air atmospheres. However, this does not indicate that NaCl vapors are innocuous. The effect of NaCl vapor on the weight gain data is further discussed in the following section.

SEM studies.—In the presence of NaCl vapors, marked differences are seen in the morphologies of the Al_2O_3 oxide scales formed on NiAl. At 1050°C whiskers were formed on the surface of samples of NiAl exposed to 10 and 130 ppm NaCl, Fig. 5. Subsequently these whiskers were shown by transmission electron microscopy techniques to be α-Al_2O_3. No dramatic differences are seen in the whiskers grown with two different NaCl vapor concentrations (10 and 130 ppm) except that the higher NaCl level produces whiskers which are more blade-like while the lower level results in more needle-like Al_2O_3 crystals. EDAX techniques indicated only the presence of alumina in these fibers. Even though they were extensively sought for, neither sodium nor chlorine (above background levels) were detected either in the whiskers growing on the surface, in the NiAl substrate, or at the gas-oxide interface of the dense Al_2O_3 layer. The Al_2O_3 whiskers grew from the dense Al_2O_3 layer which, in turn, formed on the NiAl substrate, Fig. 6.

The surface of the sample oxidized for 24 hr at 900°C in the presence of 16 ppm NaCl is shown in Fig. 7. The dense oxide layer has extensively spalled upon cooling. The spallation did not occur at temperatures during oxidation because there is no evidence of oxide reformation in any of the spalled areas. Furthermore, this type of spallation was not observed in the samples oxidized in air alone at 900°C.

In an attempt to determine if very low levels of NaCl had a similar effect on the oxidizing substrate, an NiAl sample was oxidized at 900°C in an atmosphere containing 0.61 ppm NaCl. The general surface of the oxidized sample, Fig. 8, appears as if at temperature the oxide scale were in the continual process of locally forming, breaking, and then reforming. In some areas of the surface, Al_2O_3 whiskers, as seen earlier, *cf*. Fig. 5, abound. In other areas, the compact Al_2O_3 oxide scale has spalled and was in various stages of reforming and healing when the experiment was terminated, Fig. 9-11.

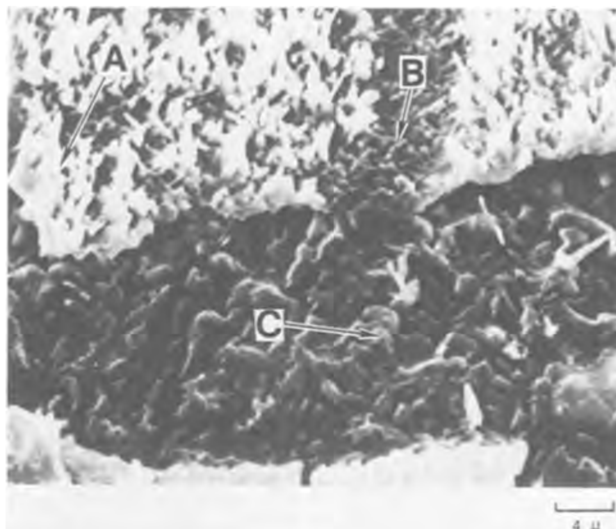

Fig. 6. α-Al_2O_3 fibers growing from dense Al_2O_3 found on NiAl oxidized at 1050°C for 24 hr. A, Al_2O_3 whiskers; B, protective Al_2O_3 scale; C, NiAl.

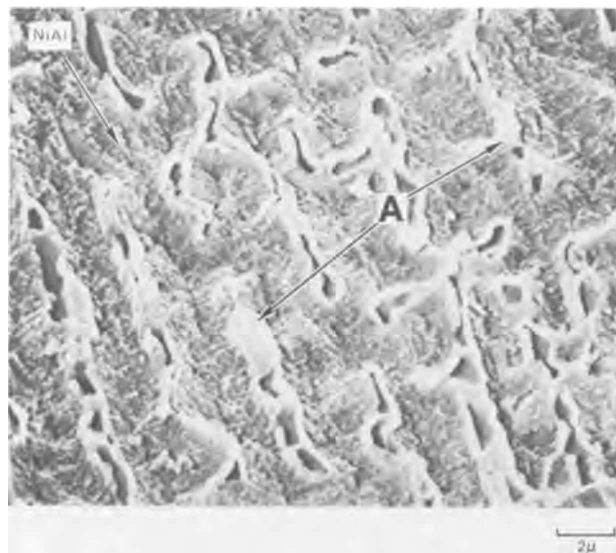

Fig. 9. NiAl oxidized at 900°C for 24 hr in air with 0.61 ppm NaCl vapor showing a region where the compact Al_2O_3 oxide spalled. A, remains of spalled dense Al_2O_3 layer.

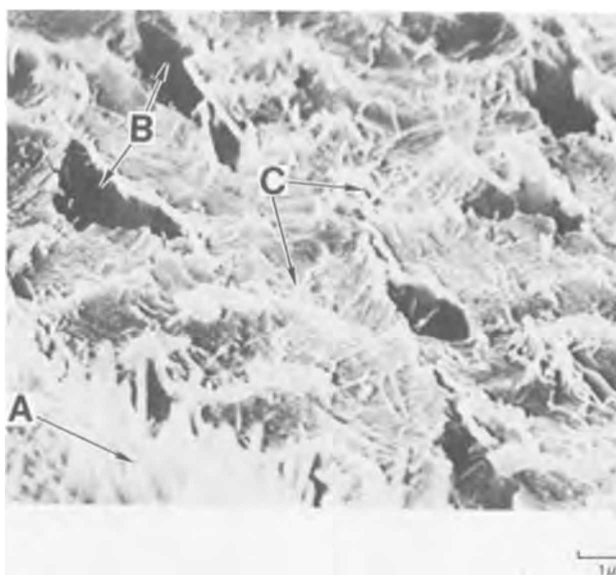

Fig. 11. NiAl oxidized at 900°C for 24 hr in air with 0.61 ppm NaCl showing Al_2O_3 reforming over spalled oxide region. A, original Al_2O_3 scale; B, pegs from spalled oxide; C, protective Al_2O_3 scale reformed over spalled oxide region.

The black appearing regions in Fig. 12, *cf.* Fig. 8, represent areas where the oxide scale has broken and fallen back to the compact oxide surface showing the side of the oxide scale which was initially attached to the substrate metal, Fig. 13. By comparison, Fig. 13 shows that Al_2O_3 whiskers are growing from the inverted base (or original surface) of a similar spalled Al_2O_3 oxide layer. The sample shown in Fig. 13, however, had been oxidized at 1050°C in air containing 128 ppm HCl, not NaCl (29). The EDAX technique applied to the sample oxidized in an HCl-air atmosphere indicated no chloride in the fibrous Al_2O_3 growths either on the original surface or on the upturned sections. Furthermore, no chloride was detected at the surface of the exposed substrate.

Additionally fine Al_2O_3 fibers have formed on the blackened surface, Fig. 14. This result suggests that the compact oxide spalled at temperature and that spallation occurred long enough before the experiment was terminated to allow for the Al_2O_3 fibrous growth to occur.

Furthermore, examination of the base of the overturned oxide in regions where Al_2O_3 growths were not present indicated the presence of both Na and Cl, Fig. 15. Regions of the overturned dense oxide surfaces examined by EDAX techniques where Al_2O_3 whiskers are not present are the only areas where Na and/or Cl have been detected in samples oxidized in NaCl-bearing atmospheres. The detection of Na and Cl on such overturned surfaces was not limited to the particular area of the spalled surface shown here. Such an analysis was typical of numerous separate overturned oxide surfaces. However this appearance of Na and Cl only on this kind of surface is difficult to understand. Questions arise such as: Why it was observed there and not on the original surface of the oxidizing sample; and How it could have survived any period of time at that site without vaporizing since at 900°C the partial pressure of NaCl is approximately 2.5 mm (7)? Thus it seems that the Na and Cl found here may be incorporated at reduced activities (but not necessarily as NaCl) into the dense Al_2O_3 layer itself. Similar effects involving isothermal dense alumina scale spal-

lation have been observed by SEM techniques for other NiAl samples oxidized at 900°C in atmospheres containing < 1 ppm NaCl(g).

Experiments were conducted to determine if the alumina in the Al_2O_3 whiskers in the work reported herein derived from a rearrangement of the surface Al_2O_3 at the gas-oxide surface or from aluminum at the metal-oxide interface. Both impure (a Coor's alumina crucible of ordinary commercial quality) and high purity dense (99.5% from Western Gold and Platinum Company) alumina were exposed to both pure air and to air containing NaCl vapors. The concentrations of NaCl examined were in the range of 100-200 ppm, at a temperature of 1050°C for 24 hr. Subsequently both samples were examined by SEM techniques. In all cases whiskers were not observed. Thus, the aluminum source for the Al_2O_3 whiskers does not lie at the surface of the oxidizing NiAl coupons. The Al_2O_3 whiskers are not forming simply in response to a drive to lower the free energy of the surface Al_2O_3 layer. The inability to grow Al_2O_3

whiskers on Al_2O_3 substrates under the "mild" experimental conditions used here is in full agreement with literature reports describing the preparation of such whiskers where substantially higher temperatures (~1300°C) and more vigorous atmospheres are required (30, 31).

Occasionally a citation is observed in the literature briefly mentioning observing a few Al_2O_3 whiskers which formed on oxide scales in the course of an oxidation study, *e.g.*, Kuenzly and Douglass (32). Because such whisker growth is not concomitantly associated with a large difference in the thermogravimetric weight change data, their presence is largely ignored. Sodium chloride is anticipated to be a ubiquitous contaminant at low levels unless precautions are taken to exclude it from the experimental environment. The fact that such whiskers have not been observed more frequently likely results from two factors. In the first place, equipment used for oxidation experiments is frequently kept very clean. This itself would tend to minimize the concentration of NaCl which would cause such effects. In the second place, oxidation studies generally emphasize optical metallography as a tool to examine oxide-substrate interfaces. Although metallographic techniques can be used to see whiskers under favorable circumstances, it is really not the optimum instrument for examining features such as the Al_2O_3 blades discussed here.

Discussion

The results of these experiments show that gaseous products interact with oxidizing NiAl. A product of this interaction is Al_2O_3 whiskers which form on the dense Al_2O_3 scale. These whiskers are not observed unless the environment contains gaseous NaCl.

A number of mechanisms involving the Al_2O_3 fiber growth effects observed here can be speculated on. Potential growth mechanisms can involve compact oxide growth stresses or chemical transport processes. Chemical vapor transport processes might result from reactions involving either Al_2O_3(c) alone or Al_2O_3(c) with the gas-phase corrodent, NaCl(g). In turn, NaCl(g) could react with Al_2O_3 either directly as NaCl or indirectly as its hydrolysis products, NaOH and HCl. These possibilities are discussed further.

Kuenzly and Douglass (32) have suggested that Al_2O_3 whiskers, observed in oxidation experiments involving Ni_3Al specimens, grew by a cation-diffusion mechanism resulting from growth stresses in the compact oxide scale. If this is the case in the work discussed here, then it might be expected that if oxide scale growth stresses and cation, *i.e.*, Al^{+3}, diffusion through Al_2O_3 were the dominant factors in Al_2O_3 whisker growth, Al_2O_3 whisker growth should have occurred independently of the presence or in the absence of NaCl(g) in the oxidizing atmosphere. Furthermore, differences in NaCl(g) concentrations should have no effect on whisker morphology. However, differences, though subtle, in Al_2O_3 whisker morphology are seen for samples oxidized at the same temperature and with different levels of NaCl(g) in the oxidizing atmosphere. Thus, this mechanism does not explain the effects reported here.

With respect to the possible chemical vapor transport processes, a conceptual reaction for the Al_2O_3 fiber growth might involve the disproportionation-vaporization of Al_2O_3(c)

$$Al_2O_3(c) = AlO(g) + AlO_2(g) \quad [1]$$

However, the blank experiments involving dense Al_2O_3 failed to show any whisker growth. This result is readily anticipated since at 1300°C the calculated K_p for the above reaction is approximately 10^{-43} (33). Therefore, a disproportionation-vaporization mechanism is again not applicable.

Another chemical-transport process could involve the reaction of HCl(g) with Al_2O_3. The HCl vapors for such reactions could be intentionally present in the oxidizing atmosphere or derive from the hydrolysis of NaCl, *i.e.*,

$$NaCl(g) + H_2O(g) = NaOH(g) + HCl(g) \quad [2]$$

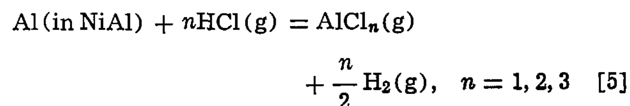
The HCl(g) present would then diffuse through the dense Al_2O_3 scale formed on the oxidizing NiAl sample. At the metal-oxide layer interface, the HCl could react either with the Al_2O_3 scale itself or with the aluminum in the substrate. Examples of the former equilibria are

$$Al_2O_3(c) + 2HCl(g) = 2AlOCl(g) + H_2O(g) \quad [3]$$

and

$$Al_2O_3(c) + 6HCl(g) = 2AlCl_3(g) + 3H_2O(g) \quad [4]$$

The free energy values for these reactions at 1300°K are positive and quite large, *i.e.*, 142 and 77 kcal for reaction [3] and [4], respectively (33). Similarly, the reaction involving the substrate can be represented by



$$Al(\text{in NiAl}) + nHCl(g) = AlCl_n(g) + \frac{n}{2}H_2(g), \quad n = 1, 2, 3 \quad [5]$$

The free energies for these reactions at 1300°K are −13, −27, and −50 kcal for the formation of the monochloride, dichloride, and trichloride, respectively, (33).

Thus, if the dense Al_2O_3 oxide layer can keep the oxygen potential sufficiently low at the metal-oxide interface and if the HCl and aluminum halides and oxyhalides can diffuse through the dense Al_2O_3 scale, then Al_2O_3 whiskers could form from the appropriate disproportionation reactions. Such a mechanism would not allow for easy "short circuit" diffusion of aluminum halide gaseous species through cracks in the protective Al_2O_3 scale, because if HCl and the appropriate aluminum vapor species can diffuse through such cracks, so could oxygen. Such oxygen would then interact with the transporting aluminum vapor species forming Al_2O_3 which would be expected to plug up such easy diffusion paths. Grain boundary diffusion would not be precluded by such a model as long as the diffusivity of the oxygen was much less than that for the responsible halogen and aluminum-halogen vapor species.

A mechanism such as this would suggest extensive and virtually continuous dense oxide scale rupture, spallation, and reformation at constant temperature. As more and more material was removed from the scale-metal interface, the oxide scale would become locally nonadherent. Cracks then would locally develop in the scale because of heterogeneous dense scale growth kinetics. Gross oxidation of the substrate immediately below the locally spalled area would then proceed rapidly as a protective scale tried to reform. This type of behavior was seen here for NiAl oxidized at 900°C in an atmosphere containing 0.61 ppm NaCl(g).

The transport of aluminum to form Al_2O_3 blades has been described in terms of a cycle involving aluminum chloride or aluminum-oxychloride vapor species derived from HCl vapors. Stearns *et al.* (26) and Fryburg *et al.* (27) have observed the gaseous species $(NaCl)_{1,2,3}$ CrO_3, $(NaOH)_{1,2}$ CrO_3, $(NaCl)_{1,2}$ $(MoO_3)_3$, and (NaOH) MoO_3. These vapor species may be viewed as volatile complexes of NaCl (or its hydrolysis product NaOH) and a metal oxide. If similar but as yet unidentified species exist in case of alumina, the over-all interpretation of the transport effect suggested above in the case of HCl remains the same while the specifics, *e.g.*, the vapor species responsible for transport, will obviously differ. Alternatively, it might be speculated that only the chloride component of the NaCl species diffuses through the dense alumina scale

to form volatile aluminum chloride species at the substrate-protective scale interface. However such an explanation alone would not account for the sodium found at the base of the dense alumina scale, *cf.* Fig. 15.

On the basis of the surface structures seen for NiAl samples exposed to slowly moving oxidizing atmospheres containing NaCl vapors, the thermogravimetric data for such samples should not yield net weight losses. The aluminum removed from the alloy by such vapor processes is partially redeposited on the outer surface of the oxide layer. However, in a rapidly moving gas stream, the fine Al_2O_3 whiskers would not be expected to form on the substrate surface. Rather the chemical species responsible for their growth would be swept down the turbulent gas stream. Accordingly, examination of turbine hardware would only fortuitously be expected to show the presence of such Al_2O_3 fibers.

Furthermore, from empirical observations of the factors leading to Al_2O_3 whisker formation, the higher the temperature the more effective will be the diffusivity of pertinent vapor species through the dense Al_2O_3 oxide layer and so aluminum will be increasingly more rapidly removed from below the dense Al_2O_3 scale. Again, NaCl for such processes need not be reformed in the chemical cycle. In the 1 ppm NaCl-air composition range, the NaCl(g) should be lost to and gained from the atmosphere of a marine or industrial gas turbine, in the absence of an unidentified chloride sink, at approximately equal rates (4). Although these experiments dealt strictly with NiAl, similar NaCl(g) effects are expected with other coating and alloy compositions which are also Al_2O_3 formers.

The description here of aluminum transport effects has been admittedly both speculative and qualitative because of our present lack of knowledge of specific factors controlling this effect. The precise nature (composition and properties) of the pertinent chemical species and the diffusion mechanism(s) responsible for transport through an otherwise dense alumina scale are unknown.

Summary and Conclusions

NaCl has been known to be an effective corrodent in the liquid phase with and without condensed Na_2SO_4 (9-25). However, the work presented herein has shown NaCl vapor present at low concentrations substantially modifies the high temperature oxidation behavior of the alumina former NiAl. The role of NaCl vapor in the oxidation of NiAl is two-fold. In the first place aluminum is removed from a dense protective Al_2O_3 scale and redeposited on the surface of the scale as Al_2O_3 whiskers. Secondly, the NaCl vapor effects isothermal protective Al_2O_3 scale spallation. Such effects are contrary to those reported for Na_2SO_4 which, to be an effective corrodent, must be present in the condensed phase (34).

The interaction of NaCl(g) with NiAl is not expected to be unique and likely occurs with other alumina-forming coating and substrate compositions.

Thermodynamic and kinetic treatments of oxidation phenomena in actual turbine atmospheres should, in order to be accurate, take NaCl(g) effects into account. The presence of NaCl(g) in the tenths of a ppm range in turbine atmospheres is anticipated to be virtually ubiquitous resulting from either fuel or atmosphere contamination. The effects of NaCl(g) in the absence of condensed Na_2SO_4 will contribute to the high temperature degradation of alumina-forming protective coatings used in gas turbines.

Chromate Passivation Protection of Zn- and Al-Zn-Coated Steel Sheet Against Wet-Storage Stain

H. E. Townsend and J. C. Zoccola

Bethlehem Steel Corporation, Homer Research Laboratories, Bethlehem, Pennsylvania 18016

ABSTRACT

The results of laboratory wet-pack tests show that chromate-passivation treatments provide temporary protection for both Zn- and Al-Zn-coated steel sheet against wet-storage staining. Compared with Zn coatings, the Al-Zn coating requires about half as much chromium deposited on the surface to achieve a given level of protection. Also, chromate passivation of the Al-Zn coating is consistently more effective and less sensitive to application conditions than chromate passivation of zinc coatings. Unlike the dark-colored aluminum-rich corrosion products (mostly aluminum hydroxide) that form on unpassivated Al-Zn-coated sheet, the corrosion products that eventually form at long exposure times on passivated Al-Zn-coated sheets are richer in zinc and lighter in color.

Zinc coatings are widely used to protect steel from atmospheric corrosion (1). The protective qualities of the zinc coatings on galvanized steel result from the formation of a protective layer of insoluble basic zinc carbonate that forms on the surface of the zinc coating during bold exposure (2). However, in the absence of air and in the presence of moisture, zinc coatings corrode with the formation of a relatively nonprotective zinc hydroxide, often called "white rust" (1, 3). These conditions can occur during shipment or storage of galvanized steel if water is allowed to enter the capillary channels that form when sheets are coiled or stacked. The resulting phenomenon, referred to as "wet storage staining," usually produces only superficial attack of the coating and thus is objectionable only in terms of esthetics. In extreme cases, however, significant amounts of coating may be consumed, thus reducing the longevity of the product upon subsequent exposure to the atmosphere (4).

Passivation of Zn-coated steel in chromate solutions provides temporary protection against wet-storage staining. Many types of chromate passivation treatment have been described (1, 5, 6). Chromate passivation produces a thin film on the surface of the sheet that contains hexavalent and trivalent chromium compounds. Most investigators believe that the trivalent chromium present as chromium hydroxide or zinc chromate acts as a protective barrier, whereas the soluble hexavalent portion of the film serves to repair the barrier at areas of localized breakdown.

An Al-Zn-alloy [weight percent (w/o) 55 Al-43.4 Zn and 1.6 Si] coating that is at least 2-4 times more resistant to atmospheric corrosion than zinc coatings of equivalent thickness has been developed for steel sheet by Bethlehem Steel Corporation (7). The coated product is currently being marketed in the U.S. under the name Galvalume sheet steel. Like Zn, the Al-Zn-alloy coating is subject to wet-storage staining, but the corrosion product on unpassivated sheet is characteristically black. The experimental program described in this paper demonstrated that chromate passivation is effective in preventing corrosion, *i.e.*, "black staining," on the Al-Zn-coated sheet during shipment and storage.

Key words: coatings, corrosion, inhibitors, products, testing.

Experimental

Zn- and Al-Zn-alloy-coated steel sheets produced without chromate passivation on a continuous hot-dip production facility were chromate-treated in the laboratory after solvent-vapor degreasing. Chromate-treatment consisted of preheating the coated sheet in air to the temperature of the chromate bath, immersion in the chromate solution for times that were varied in the range 1-5 sec, removal of excess solution by passing the treated sheet through rubber squeegee rolls, and drying in air at 165°F. Temperatures of the chromate bath were varied in the range 120°-180°F. Chromate baths were prepared from a proprietary mixture available as Iridite 9L6.[1] This mixture is described by its supplier as a fluoboric acid-activated chromate passivation treatment comprised of approximately 10% hexavalent chromium, 8% fluoride compounds, and 1.6% boron compounds. For our experiments, the mixture was diluted with distilled water to produce solutions with hexavalent chromium concentrations which were varied in the range 1.3-7.7 g/liter and with pH 2-3.

The amounts of chromium deposited on the passivated sheet were determined by stripping the film and analyzing the stripping solution by use of either colorimetry or atomic absorption. Water-soluble chromium was determined by partially stripping the film in boil-

[1] Trademark of the Richardson Company, Des Plaines, Illinois.

ing distilled water. Total chromium was determined by stripping the entire film in a dilute solution of phosphoric and sulfuric acid.

Total chromium deposited on the strip was found to increase systematically with increasing solution concentration, solution temperature, or immersion time. Thus it was possible to control the amount of chromium deposited in several ways through selection of different combinations of these parameters.

Resistance to wet-storage staining was determined in laboratory pack tests conducted as follows. The surfaces of 8 × 10 × 0.02 in. sheets were wetted with distilled water and the sheets were placed in stacks to simulate severely corrosive (complete wetness) storage conditions. Each stack comprised 50 sheets and had a 25 lb weight placed on top to assure uniformity of spacing between sheets from top to bottom. Once each week, the stacks were opened for visual evaluation of degree of stain, then wetted and stacked again. Visual ratings are based on a scale of 0-10, where 0 corresponds to 100% of the surface area stained and 10 to no staining. The nonlinear scale (Table I) is defined in order to emphasize differences when only small amounts of staining have occurred. We consider a ranking of 6 or more to represent acceptable performance in the wet-pack test.

Corrosion products formed on Al-Zn-coated sheet were analyzed by several techniques, including x-ray diffraction (XRD), secondary ion mass spectrometry (SIMS), and energy-dispersive x-ray fluorescence (EDXRF).

Results and Discussion

Wet-pack test results.—The results of wet-pack tests on the Zn-coated sheets after 4 weeks exposure, Fig. 1, show that the level of protection increases rapidly with increasing amounts of chromium applied up to about 8 $\mu g/in.^2$. With further increases in chromium above 8 $\mu g/in.^2$, the degree of protection does not increase as quickly and there is considerable variability in the results. We observed that for a given amount of chromium above 8 $\mu g/in.^2$ satisfactory results (*i.e.*, a rating of 6 or more) were obtained only when the sheets were treated in hotter ($T \geq 150°F$) and more concentrated (hexavalent chromium ≥ 4.1 g/liter) solutions. Longer contact times to produce equivalent chromium levels in cooler, less concentrated solutions did not provide satisfactory passivation. Thus above 8 $\mu g/in.^2$ the protection is dependent more on application conditions than on chromium level for galvanized sheet.

Four-week wet-pack test results for Al-Zn-coated sheet, Fig. 2, show increasing protection with increasing chromium until complete protection is achieved at about 4 $\mu g/in.^2$, a value roughly half that required to reach satisfactory behavior for the Zn-coated sheet. Above the 4 $\mu g/in.^2$ level, complete protection against wet-storage stain was achieved by chromate passivation of the Al-Zn-coated sheet, regardless of application conditions such as solution temperature and concentration. Thus, chromate passivation of Al-Zn coatings is consistently more effective and less sensitive to application conditions than chromate passivation of zinc coatings.

Typical time dependence for wet-pack corrosion of chromate-treated sheets, Fig. 3, shows that the protec-

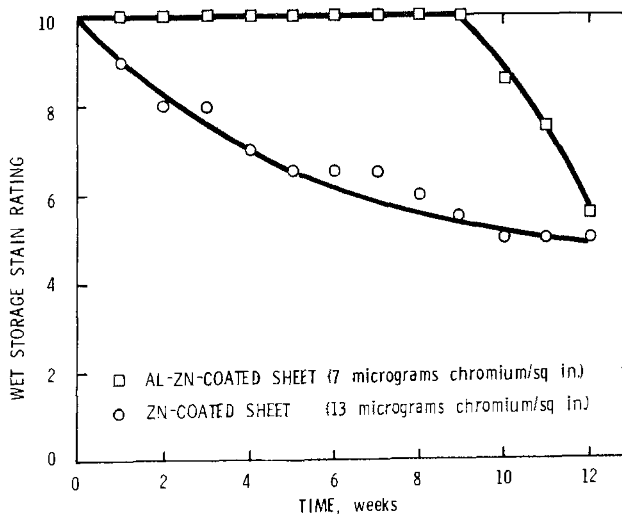

Fig. 3. Typical time dependence of storage staining for a chromate-treated steel sheet.

tion afforded by chromate passivation diminishes with longer exposure time. Compared to unpassivated sheet, which within a few days in the wet-pack test exhibits

severe storage stain ratings (of 3 or less), the protection imparted by chromate (ratings of 6 or more) lasts for several weeks.

Soluble chromium content of passivation films.—The film that forms on a chromate-passivated sheet contains varying amounts of water-soluble and water-insoluble chromium compounds. We observed that the water-soluble fraction decreases slowly with time as the film ages. The relative amounts of water-soluble and total (water-soluble plus water-insoluble) present in the film two weeks after application are shown in Fig. 4. We note that soluble chromium is not observed in the passivation film until the total chromium exceeds 4 and 8 $\mu g/in.^2$ for Zn- and Al-Zn-coated sheet, respectively. Above these levels, the amounts of water-soluble chromium increase with increasing total chromium. The coincidence of these values with those required for attainment of satisfactory behavior in the wet-pack tests suggests that availability of water-soluble chromium for film repair is needed to achieve the higher levels of protection.

Analysis of corrosion products on Al-Zn-coated sheet.—Corrosion products formed on the surface of an unpassivated Al-Zn-coated sheet in the wet-pack test are generally black in color. Another study previously reported that the dark corrosion product is comprised of beta-$Al(OH)_3$ (bayerite) (8). Our XRD analysis of the dark corrosion product found evidence of beta-$Al(OH)_3$ and also trace amounts of alpha-$Al(OH)_3$ (gibbsite). Although gibbsite is the most commonly occurring mineral form of $Al(OH)_3$, its presence in corrosion products is regarded as unusual (9). By use of SIMS and EDXRF, we also found the presence of small amounts of zinc in the black corrosion product.

Analyses of the light-colored corrosion products that eventually form on the passivated Al-Zn-coated sheet at long exposure times indicates a much higher content of zinc. In view of the fact that the Al-Zn coating is a two-phase structure comprised of about 80 volume percent aluminum-rich cored dendrites with zinc-rich alloy occupying the interdendritic regions (7), this result suggests that chromate passivation is more effective on the aluminum-rich portion of the coating. Thus, the zinc-containing portions of the passivated sheet are the first to be attacked at longer exposure times and light-colored zinc corrosion products are formed. Conversely, the dark color associated with aluminum corrosion products that form on unpassivated sheet is avoided.

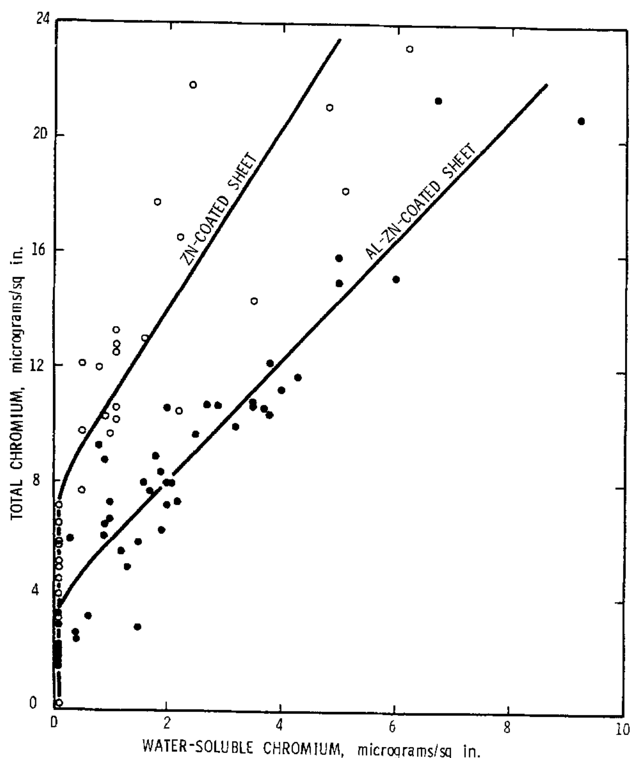

Fig. 4. Relationship of water-soluble chromium to total chromium on Zn and Al-Zn-coated steel sheet (film aged for 2 weeks prior to analysis).

Summary

1. For both the Zn- and Al-Zn-coated sheet steel, chromate passivation provides several weeks protection against wet storage staining.

2. Compared with Zn coatings, Al-Zn coatings require about half as much chromium to achieve this level of protection.

3. Chromate passivation of Al-Zn coatings is consistently more effective and less sensitive to application conditions than chromate passivation of zinc coatings.

4. Corrosion products formed on the Al-Zn-coated sheet under wet-pack conditions are black and aluminum-rich on unpassivated sheet but are light-colored and zinc-rich on passivated sheet.

High Dose Ion Implantation into Photoresist

Y. Okuyama, T. Hashimoto, and T. Koguchi

Nippon Electric Company, Limited, IC Division, Kawasaki, Japan

ABSTRACT

The characteristics of heavily ion-implanted photoresist films were studied in relation to types of photoresist, ion species, accelerating energies, and dose levels. By high energy, high dose ion implantation it was observed that the optical transmission of the resist film was exceedingly decreased and the resist becomes more mechanically, thermally, and chemically resistant. Several experimental data indicated that these results are due to the change of photoresist to disordered graphite. As an application of this ion-implanted resist, a new photomask fabrication process is developed.

Photoresist films are commonly used as a mask against ion implantation in MOS integrated circuits production. For practical applications at present, the implantation dose ranges from 10^{11} to 10^{14} ions/cm^2 (1, 2). In this dose level, the photoresist films are easily removed after ion implantation. As the dose level increases, however, they cannot be stripped off completely by chemical strippers, hot nitric acids, or hot sulfuric acids; the chemical durability and hardness of the resist films are increased. The scratch resistance and thermal durability are also increased and the optical transmission is decreased. This paper describes (*i*) the characteristics of high energy and high dose ion-implanted resist films; (*ii*) the reason for such a drastic change in the characteristics by heavy ion implantation; and (*iii*) the application of these characteristics to a new photomask fabrication method (3).

Experiments and Results

Photoresist films (Shipley's AZ-1350, Tokyo Oka Kogyo's OMR-83 or OSR) with thickness of 0.2 ~ 1 μm were spin coated on silicon wafers or on glass substrates. The name and structure of the base polymers and sensitizers of these photoresists are shown in Table I. The photoresist was then patterned through the steps of prebaking, exposure, development, and postbaking. An argon ($^{40}Ar^+$), phosphorus ($^{31}P^+$), or boron ($^{11}B^+$) ion beam with an energy of 20 ~ 180 keV and a current density of 0.16 ~ 1.25 μA/cm^2 was implanted into the resist film at the dose level of 10^{14} ~ 10^{16} ions/cm^2. Estimated ion ranges in the unreacted resists are shown in Table II (4-6). The original characteristics of the photoresist film changed drastically by this treatment (7),

Figure 1 shows the infrared light absorption peak of the negative photoresist layer (OMR-83, 8000Å), which was $^{11}B^+$ ion implanted to a dose level of 3×10^{14} ions/cm^2 at various accelerating energies. There is an absorption peak at a wave number of 2800 cm^{-1} which corresponds to the C-H bonds in the resist. The peak decreases as an accelerating energy increases. But, it is clear from Fig. 1 that ion beam density has no effect on the destruction of the C-H bonds.

Figure 2 shows the optical transmission variation of the positive photoresist layer (AZ-1350, 4300Å), which was $^{31}P^+$ ion implanted at 120 keV with a dose level of 10^{15} ~ 10^{16} ions/cm^2. The optical transmission in an ultraviolet ray and in visible light zones was decreased greatly with increasing dose level. Corresponding to the increase of dose level, the color of the resist layer changed from brown to black. The tendency of these two results shown in Fig. 1 and 2 was observed with any types of photoresist, positive or negative, and with any ion species, *e.g.*, $^{31}P^+$, $^{40}Ar^+$, $^{11}B^+$, or $^{49}BF_2^+$. The efficiency in changing the characteristics of photoresist film was found to depend on the ion species; it was ranked in the order of $^{40}Ar^+ > {}^{31}P^+ > {}^{11}B^+$ in our experiments. On this basis, the following experiments were conducted, using AZ-1350 as the positive photoresist, OSR as the negative photoresist, and $^{40}Ar^+$ as the ion species. Figure 3 shows the chemical

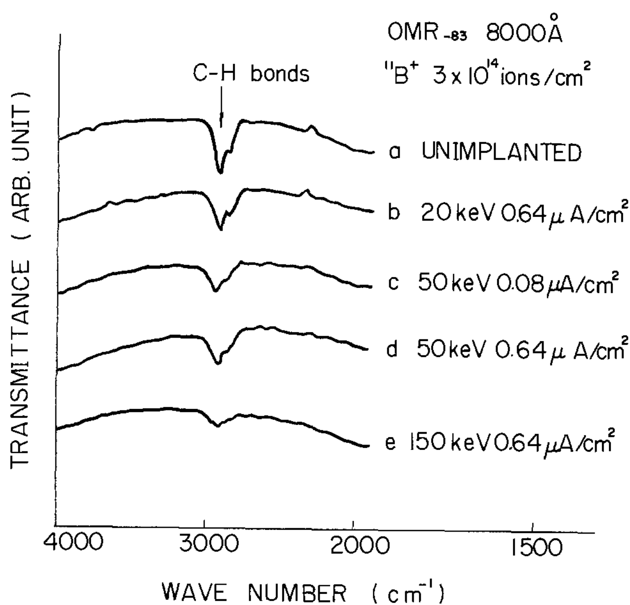

Fig. 1. The variation of infrared light absorption peak of negative photoresist by ion implantation.

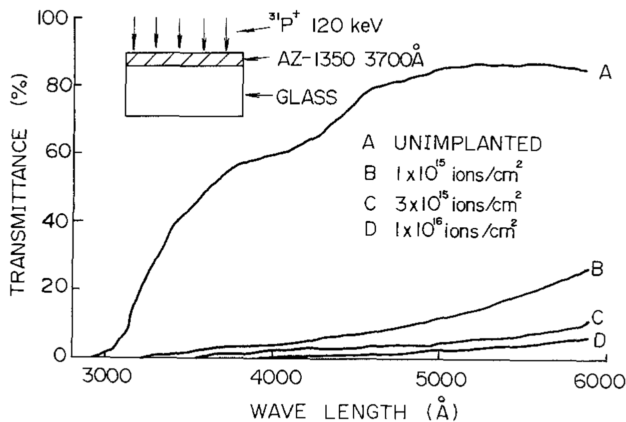

Fig. 2. Optical transmission variation of the negative photoresist layer with $^{31}P^+$ ion implanted at 120 keV. The photoresist becomes opaque to ultraviolet and visible light by the ion implantation.

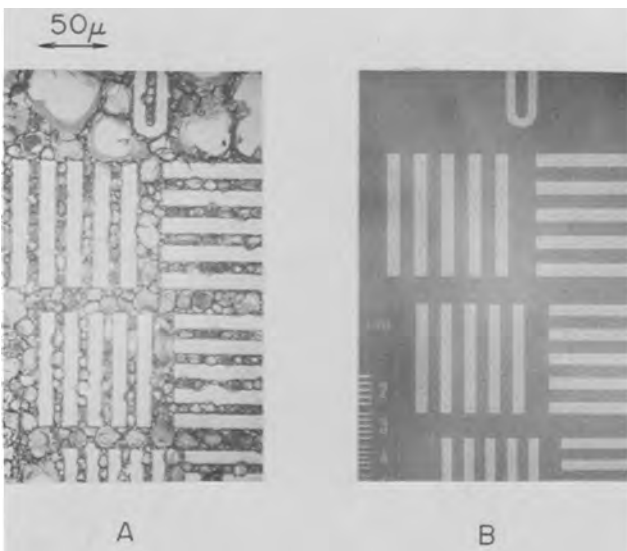

Fig. 3. The chemical durability of negative photoresist (OSR) against 49% hydrofluoric acid. (A) Unimplanted, dipped for 5 min in HF; (B) implanted ($^{40}Ar^+$, 170 keV, 1 × 10^{16} ions/cm^2), dipped for 1 hr in HF.

durability against 49% (hydrofluoric acid). The negative photoresist layer (OSR of 4000Å initial thickness) could not endure for less than a few minutes in the solution, while the $^{40}Ar^+$ ion-implanted resist with a dose of 10^{16} ions/cm^2 at 170 keV endured for more than 1 hr in the same solution.

Figure 4 also shows the chemical durability against hot nitric acid and hot sulfuric acid. The manufacturing conditions of the sample for this test were the same as shown in Fig. 3, except that a transparent glass was used as a substrate. At first the initial transmission was measured to be 0.5% at a wavelength of 405 nm. Then the sample was subjected to a series of HNO_3-H_2SO_4 cleaning; in which the following cycle was repeated: (*i*) dipping the sample in 75% HNO_3 at 90°C for 2 min; (*ii*) dipping the sample in 85% H_2SO_4 at 120°C for 2 min; (*iii*) dipping the sample in 75% HNO_3 at 90°C for 2 min. After five cycles of this chemical treatment, no variation was observed in the transmission at 405 nm wavelength.

Figure 5 shows the optical density variation (at a wavelength of 405 nm) of the photoresist layers on a transparent glass substrate at increasing doses and at constant accelerating energy. The initial photoresist thickness for this evaluation was 4300 and 3000Å for AZ-1350 and OSR, respectively. The optical density increases in proportion to the logarithm of the dose level.

Figure 6 shows the optical density variation (at a wavelength of 405 nm) of photoresist layers, having the same initial thickness as the preceding evaluation in Fig. 5 with a constant dose and with increasing accelerating energies. Figure 6 shows that optical density increases linearly with increasing accelerating energies. From the two experiments shown in Fig. 5 and 6 it may be concluded that the optical density increases as a function of the total energy which is effectively conveyed to the photoresist layer from the implanted ions.

Figure 7 shows the variation of the photoresist thickness before and after ion implantation (150 keV, 10^{16} ions/cm^2). It is evident from Fig. 7 that the initial photoresist thicknesses are decreased by about half as a result of the ion implantation. Figure 8 shows the etching rate of the photoresist film by O_2 gas plasma. The etching rate of unimplanted photoresist was about 1500 Å/min, and it decreased as dose level increased; about 300 Å/min at a dose level of 10^{15} ions/cm^2 and about 200 Å/min at 10^{16} ions/cm^2.

Figure 9 shows the variation of pattern width by ion implantation to the positive photoresist (AZ-1350,

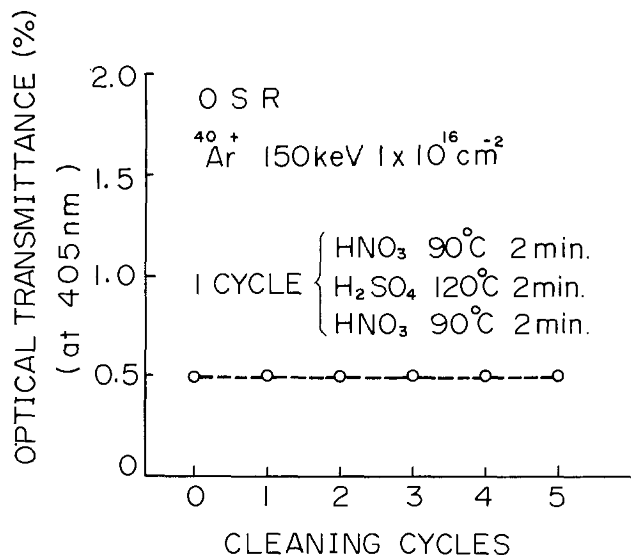

Fig. 4. Chemical durability against hot HNO_3-H_2SO_4. The resist on a transparent glass substrate was ion implanted and its optical transmission was measured after each cleaning cycle.

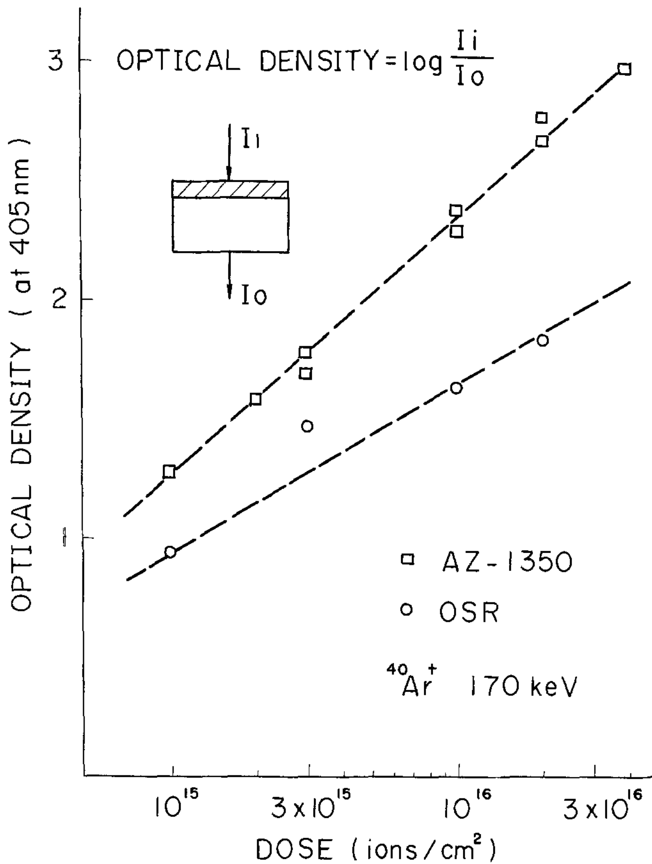

Fig. 5. Optical density variation as a function of dose. The initial photoresist thickness was 4300 and 3000Å for AZ-1350 and OSR, respectively.

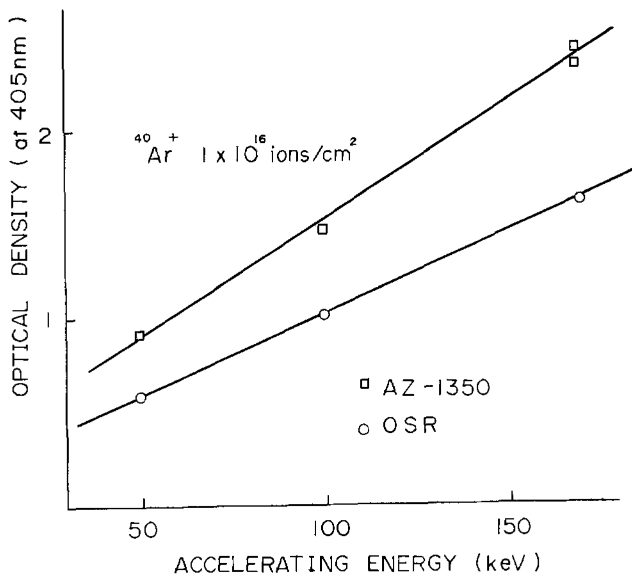

Fig. 6. Optical density variation as a function of accelerating energy.

4300Å as initial thickness). The variation of the pattern width before and after ion implantation (170 keV 10^{16} ions/cm^2) is within ± 0.2 μm, which is within permissible measuremental error. Therefore it may possibly be concluded that no measurable variation occurred in the pattern width of photoresist by the ion implantation.

Figure 10 shows the scratch-resistance variation of the photoresist layers by ion implantation at a constant accelerating energy and at increasing dose levels. The initial photoresist thickness of AZ-1350 and OSR was 4300 and 3000Å, respectively. The scratch resistance was expressed by the weight at which a sapphire needle could scratch the sample surface. A sapphire needle of 0.6 mm diam was positioned straight above the sample surface and then lowered downward with a weight. For comparison, the scratch resistance of chromium-oxide (Cr_xO_y) by the same measurement method was also shown in this chart. The figure shows that the scratch resistance for AZ-1350 and OSR increases to the level of chromium oxide as the dose level is increased. However in case the initial thickness is thick enough, *i.e.*, more than 1 μm, the scratch resistance stays very weak even after the ion implantation of the same conditions as mentioned above. This is a result of the insufficient ion range and the ion implantation did not harden the bottom of the resist.

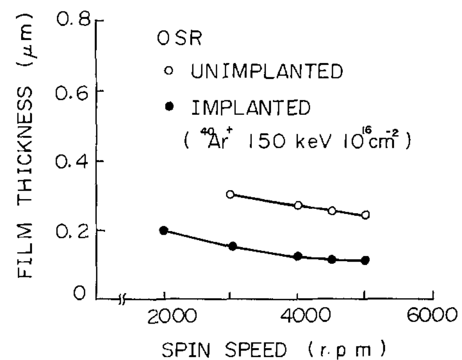

Fig. 7. Variation of the film thickness before and after ion implantation.

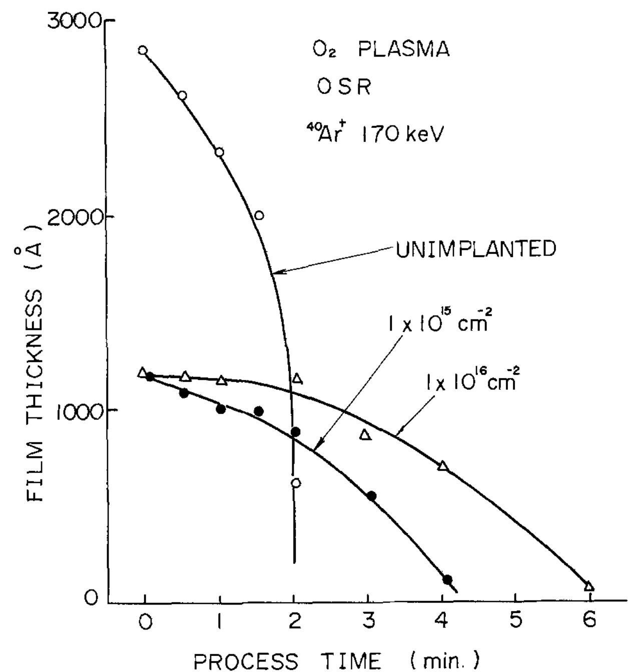

Fig. 8. Film thickness as a function of time in oxygen gas plasma

Figure 11 shows the thermal durability of the photoresist layer in dry O_2 atmosphere. The photoresist (OSR, 2600Å as initial thickness) was patterned on a silicon substrate in this case. Argon ions were implanted into the sample at 170 keV to a dose level of $10^{15} \sim 10^{16}$ ions/cm^2. The photoresist film thickness was decreased to 1200Å by this implantation. Then the sample was exposed to dry O_2 atmosphere in a variable temperature furnace for 15 min. After each heat-treatment the film thickness was measured by a Talystep. Figure 11 shows that the thermal durability of the resist films gradually increases with increasing dose levels.

Figure 12 shows the same evaluation as in Fig. 11 in dry N_2 atmosphere. The thermal durability of unim-

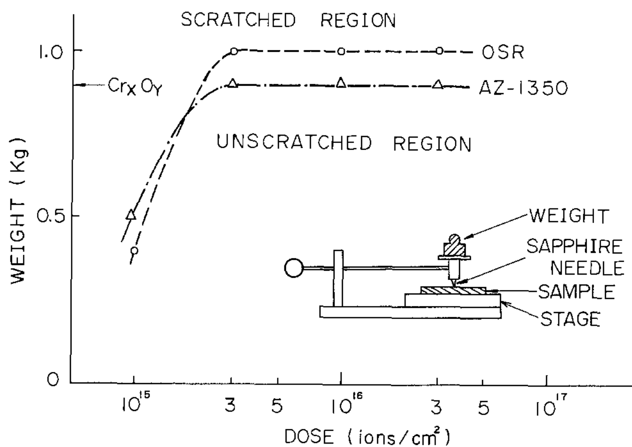

Fig. 10. The scratch resistance variation as a function of dose. The thickness of unimplanted photoresist was 4300Å (AZ-1350) and 3000Å (OSR), and $^{40}Ar^+$ was implanted at 170 keV.

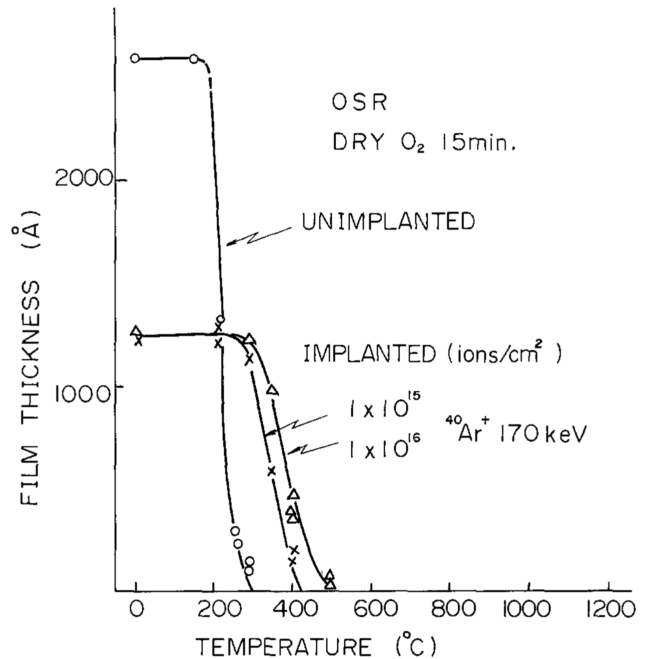

Fig. 11. Thermal durability of the photoresist film in dry O_2 atmosphere.

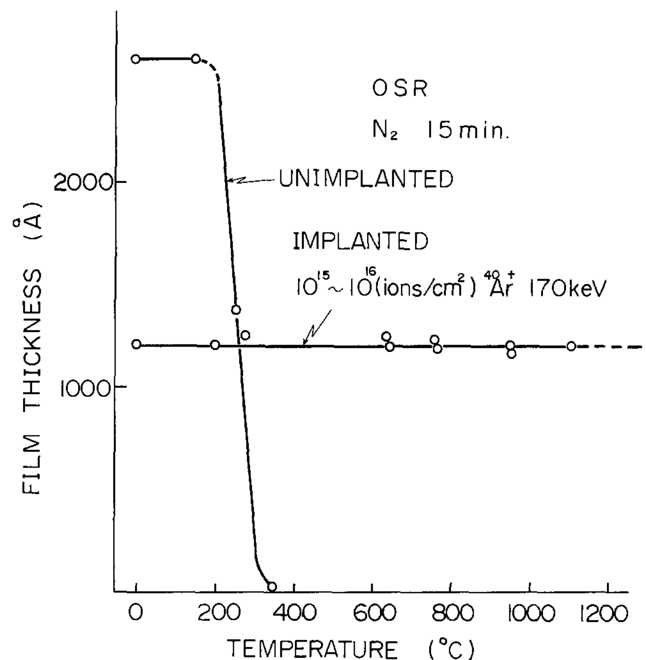

Fig. 12. Thermal durability of the photoresist film in N_2 atmosphere.

planted photoresist layer was very weak and the film thickness was decreased exceedingly at a certain temperature between 250° and 350°C. In contrast, the film thicknesses of ion-implanted photoresist did not decrease even at 1100°C, but after heat-treatment of more than 600°C, it was observed that the film became fragile and was easily scratched by a pincette. This result indicates that some change in quality occurred during the heat-treatment.

Graphitization by Ion Implantation

In our experimental activity, we noticed three phenomena which characterized high dose ion-implanted photoresist layers; (*i*) the color changed to brown or black according to the dose level; (*ii*) the thermal, physical, and chemical resistances were greatly improved; and (*iii*) the only way to strip the film off from the substrate was to combine it with oxygen. As these characteristics resemble those of graphite (disordered), we deduced that these phenomena by ion implantation were a result of graphitization.

In order to confirm this assumption, the ion-implanted photoresist was subjected to infrared absorption spectrum analysis and gas chromatographic analysis. Figure 13 shows the infrared light absorption spectrum of the photoresist layer before and after ion implantation. The ion-implanted photoresist was scraped off from the surface of silicon wafers using a diamond point and then it was collected for evaluation. The major absorption peaks of the unimplanted photoresist correspond to certain organic radicals, *e.g.*, $-CH_3$, $-C_6H_3$, and $-C{=}O$, which characterize the base polymer of the photoresist. They decreased by the ion implantation and finally they disappeared completely as shown in the figure at a dose level of 10^{16} ions/cm². This phenomenon suggests that the photoresist layer was converted from organic to inorganic material by the ion implantation and that the reaction

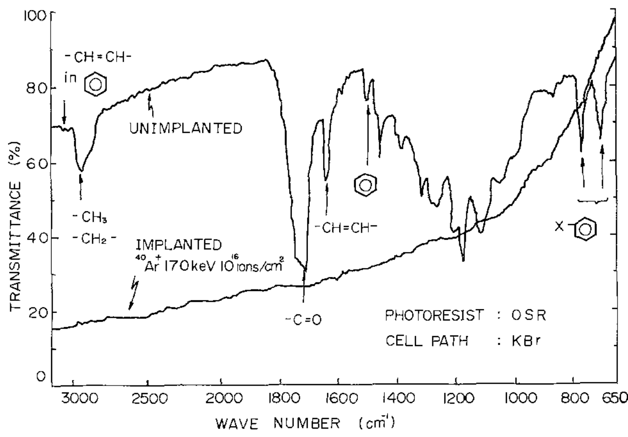

Fig. 13. Infrared light absorption spectrum of the photoresist layer before and after ion implantation.

had more to do with the base polymer than with the photoactive sensitizers.

Figure 14 shows the result of gas-chromatographic analyses for the resist layer before and after ion implantation. The sample preparation was the same as in the case of Fig. 13. The analyses were performed under the following conditions: thermal decomposition temperature, 720°C; column, molecular sieve, 50°C; carrier gas, He 0.8 kg/cm^2; detector, FID. The large peak for the unimplanted resist is due to poly (-vinyloxyethylcinnamate) (the composition of OSR). This peak became negligibly small by the ion implantation. For comparison, pure graphite (disorder) was subjected to the same analysis described above. A small peak appeared after the same retention time as in the case of OSR. Because of this resemblance of the peaks, we concluded that the ion-implanted resist was changed to nearly the same material as disordered graphite. This chemical change of photoresist, *i.e.*, graphitization, was supposed to be caused either by thermal or by mechanical effect of the ion implantation. The former possibility, however, was excluded because of the following two reasons: (*i*) Ion beam density (heat-generation rate) has no effect on the change of photoresist layer (Fig. 1); (*ii*) Unimplanted resist evaporates even in an inactive gas atmosphere at a certain temperature between 250° and 350°C (Fig. 12). Therefore we attributed the graphitization of photoresist to the mechanical bombardment effect by ions. According to this model, incident ions break the chemical bonds within photoresist, and successively scatter hydrogen and oxygen atoms away from the major radicals of the resist. As a result, the resist becomes relatively richer in carbon.

Application to a New Photomask

As one of the most profitable applications of ion-implanted resist, a new photomask manufacturing process is explained in detail.

In Fig. 15(A) a conventional process for making a photomask is described. A film of metal or metal oxide, *e.g.*, chromium oxide, is evaporated to a thickness of 1000-5000Å on the surface of a transparent glass substrate. Photoresist is patterned by using a conventional photolithographic technique. Then the film of metal or metal oxide is etched selectively using photoresist as a protective mask against an etching solution. Finally, the photoresist is removed and a conventional hard-type photomask is obtained.

Figure 15(B) shows a new photomask manufacturing process. At first, photoresist is patterned on a transparent glass substrate by using a conventional photolithographic technique. Then the entire top surface of the glass substrate is implanted with some suitable ions, such as $^{31}P^+$, $^{40}Ar^+$, etc. By this treatment ion-implanted photoresist becomes opaque to ultraviolet light. On the other hand, the glass substrate remains transparent to ultraviolet and to visible light. As a result, a high quality photomask can be readily obtained. In order to obtain a hard-type photomask by this method, it is necessary that the initial thickness of photoresist be less than 4000Å, accelerating energy be more than 120 keV, and the dose level be more than 3×10^{15} ions/cm^2. A requirement of increased optical density is easily achieved by thickening the photoresist and increasing the accelerating energy.

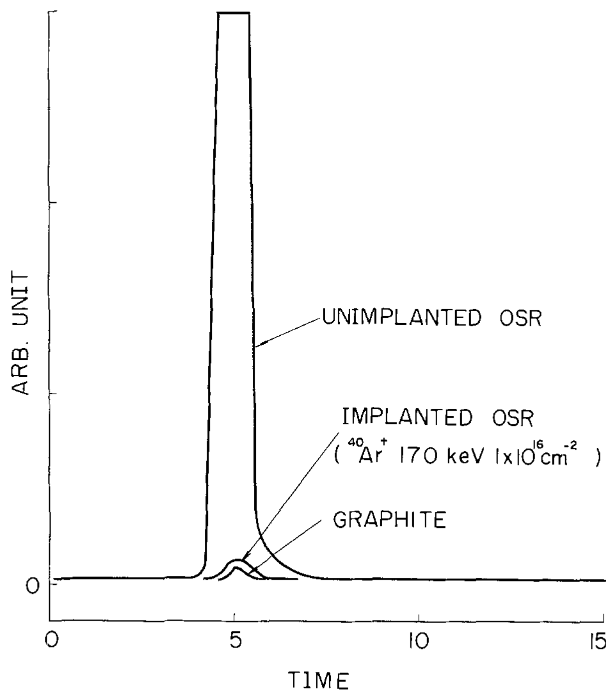

Fig. 14. Gas-chromatographic analysis of the photoresist layer before and after ion implantation.

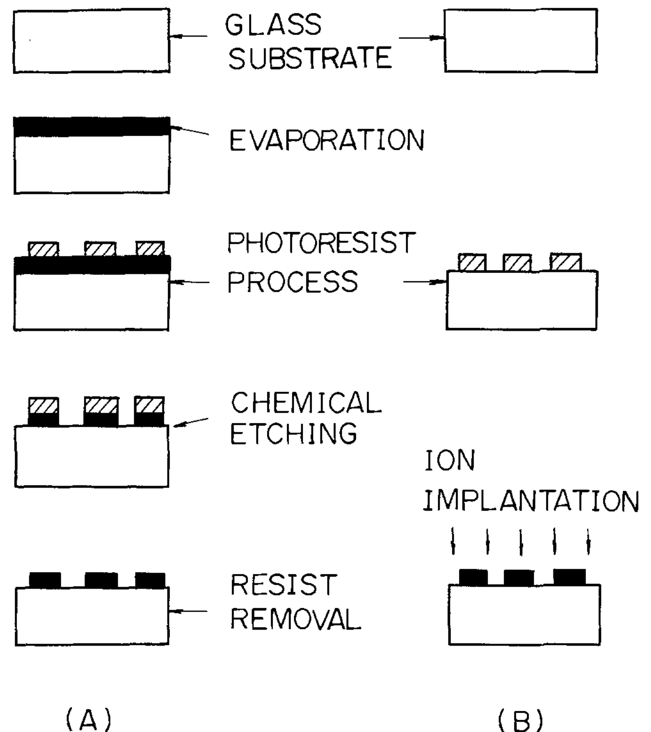

Fig. 15. Comparison of (A) conventional and (B) new process for photomask production.

This new process has completely eliminated the etching process. Accordingly, so-called "over-etching" will not appear at all. Therefore, the dimensional accuracy of photomask patterns is much improved. In addition, the production cost of photomask can be decreased due to the process simplicity.

Summary

The characteristics of heavily ion-implanted photoresist films are studied. Optical density increases in proportion to accelerating energy and to the logarithm of dose level. Other properties such as chemical durability, thermal resistance, scratch resistance, and adherence to a substrate are also improved greatly. No conventional stripping method can effectively remove the resist from the substrate except a forced recombination of the resist with oxygen. Moreover, no variation of the resist pattern is caused by ion implantation. Visible and ultraviolet light spectrometric and gas chromatographic experiments indicate that these characteristics are due to the change of photoresist to disordered graphite. By using ion-implanted resist as the dark portion of a photomask, economical yet excellent photomasks are successfully obtained.

Acknowledgments

The authors wish to thank Messrs. H. Tajima, H. Okabayashi, K. Uda, T. Igarashi, and T. Tashiro for preparing samples and for their assistance in ion implantation, and also Mr. H. Tsunemitsu for useful discussions and the reviewing of this paper. The authors also would like to thank Dr. M. Kamoshida, Messrs. K. Shimakura, K. Takahata, and K. Yamamoto, Drs. T. Yanagawa, Y. Miura, and T. Okada, and Mr. K. Sato for their encouragement.

Deposition of Fluorine-Doped Silica Layers from a $SiCl_4/SiF_4/O_2$ Gas Mixture by the Plasma-CVD Method

D. Küppers, J. Koenings, and H. Wilson

Philips GmbH Forschungslaboratorium Aachen, 5100 Aachen, Germany

ABSTRACT

Silica layers doped with fluorine have been deposited inside a quartz glass tube from a $SiCl_4/SiF_4/O_2$ gas mixture. The oxidation reaction was initiated by a nonisothermal microwave plasma maintained at pressures of about 10 Torr and wall temperatures in the region of 1000°-1100°C. From the experiments it was found that fluorine was incorporated in the silica deposit, producing layers with a lower refractive index than that of pure silica. Although the reaction to form SiO_2 from a SiF_4/O_2 gas mixture is different from that with $SiCl_4/O_2$, the efficiency of the deposition reaction with $SiCl_4/SiF_4/O_2$ is comparable to that with $SiCl_4/O_2$.

Various techniques for the fabrication of low loss optical fibers have been described (1-3). To date, one of the most promising procedures utilizes a local reaction zone to deposit glassy layers of varying refractive indexes on the inner surface of a silica tube. To yield homogeneous deposition over a considerable length, the reaction zone must be moved to and fro. In a subsequent step the tube is collapsed to a rod called the preform, and a fiber is drawn (Fig. 1).

In order to guide light, the fiber core must have a refractive index slightly higher than that of the pure silica and, therefore, the deposit has to be doped. Hitherto the dopants most used have been GeO_2, P_2O_5, and B_2O_3, because they introduce negligible absorption losses in the wavelength region of interest, *viz.*, 0.8-1.3 μm. While nearly all dopants increase the refractive index of silica, the addition of B_2O_3 decreases it.

Commonly used dopants have been found to give rise to some unfavorable properties, such as: (*i*) the small change in refractive index on increasing the dopant concentration (B_2O_3); (*ii*) the quenching dependent nature of the change in the refractive index of silica on doping (B_2O_3); (*iii*) the formation of large stresses on doping (GeO_2); (*iv*) the depletion of the dopants from surface adjacent layers on collapsing of the tube to a rod (P_2O_5, GeO_2); and (*v*) the large decrease of the softening point of the glass when doped with the oxide (B_2O_3, P_2O_5).

Key words: doping, glass, plasma chemistry.

Recently it has been pointed out that doping with fluorine might be very attractive (4) since all these disadvantages are avoided. However, the application of the so-called modified chemical vapor deposition (MCVD) to fluorine containing gases gave rise to serious problems. Here, thermal reactions in the gas phase led to soot particles which fused into a compact layer at about 1400°-1600°C. It was found that the total deposition rate of fluorine-doped silica decreased remarkably, the more silicon tetrafluoride present in the gas phase (5). Further it would be desirable to incorporate more fluorine into the deposit in order to obtain a greater variation of the refractive index. The

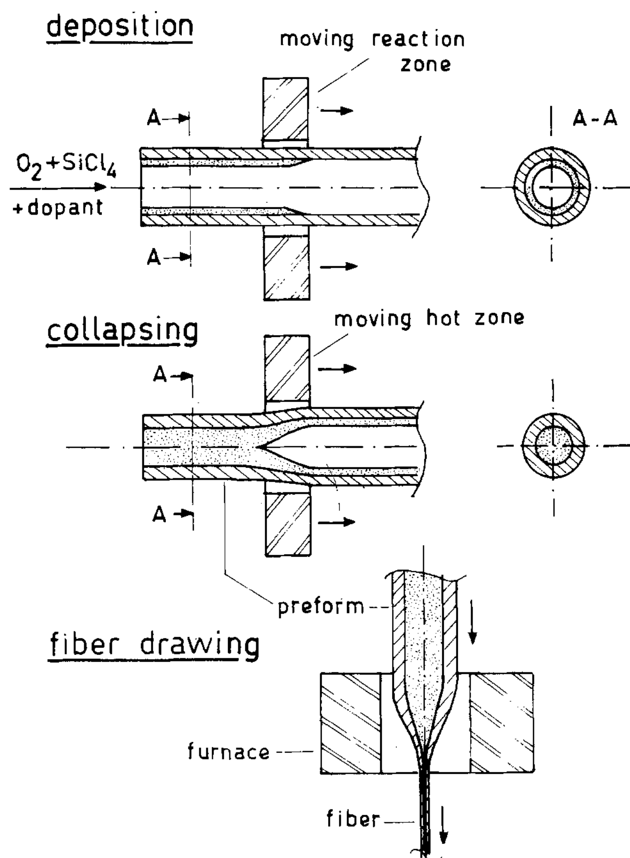

Fig. 1. Preparation steps in the optical fiber production route

core region of an optical fiber usually has a refractive index about 1% higher than the cladding glass. This implies that a fluorine content of at least 3 atomic percent (a/o) should be present (5, 6).

The plasma-activated CVD process (PCVD) had previously been applied successfully to the deposition of pure silica from a gas phase of composition $SiCl_4/O_2$ (7) and for deposition of doped silica from $SiCl_4/GeCl_4/O_2$ (3) for the preparation of optical fibers (8). The question arose whether it is also capable of fabricating fluorine-doped fibers.

From earlier work (9) it was known that oxyfluorides were formed by a SiF_4/O_2 nonisothermal plasma at temperatures of about 100°C and at pressures of about 0.8 Torr. Polymers were obtained of the approximate composition $(SiO_{1.5}F)_n$. The refractive index of the polymers was found to be less than 1.4, considerably lower than that of pure silica. In our plasma experiments the conditions normally differ from those mentioned above in that the total pressure is in the 1-30 Torr region and that the substrate temperature is typically 1000°-1200°C.

Experimental

The experimental setup consisted of a gas-supply system, a reactor, and a pumping system. The gas-supply system was made of stainless steel tubing and connectors. Mass flow controllers for $SiCl_4$, SiF_4, and O_2 allowed gas flow measuring and control. Prior to the measurements the gas supply system was checked for leakage, which was found to be less than 10^{-9} Torr · liter/sec. The $SiCl_4$ of electronic grade was obtained from Wacker Chemie. Oxygen of 99.998% purity (H_2O < 2 ppm) was used. The SiF_4 was obtained from Matheson and had the impurity specification of 0.3% air and 0.04% sulfur dioxide.

The reactor is shown schematically in Fig. 2. It consists of a silica tube with inner and outer diameters of $\phi_{id} = 8$ mm and $\phi_{od} = 10$ mm, respectively, a furnace

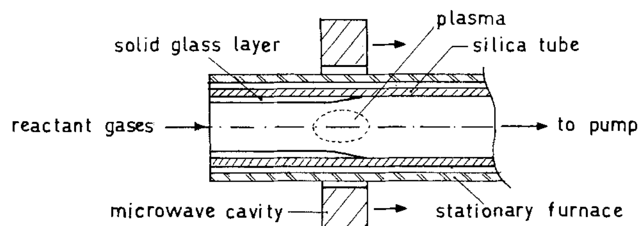

Fig. 2. Microwave reactor set up for the inside coating of a quartz tube.

and a microwave cavity. The furnace heats the tube to a temperature T_f of about 1100°C. The microwave plasma is maintained with the aid of a microwave cavity which is connected to a power supply capable of delivering $E_m = 200$ W at 2.45 GHz. The water-cooled cavity together with the furnace is mounted on a slide and can be moved rapidly to and fro. For mechanical reasons the maximum speed in our experiments was 17 cm/sec and the deposition length was 30 cm.

A sorption pump filled with a synthetic zeolite and cooled by liquid nitrogen was used to maintain an oil- and water-free atmosphere. Typical gas flows during the experiments were $Q_{O_2} = 100$ sccm, $Q_{SiCl_4} = 9\text{-}25$ sccm, and $Q_{SiF_4} = 0\text{-}5$ sccm, while the pressure in the reaction zone was normally between 10 and 20 Torr, as indicated by a capacitance manometer.

Results and Discussion

Microwave reactor stationary.—In the first experiments the reactor was held stationary and constant gas mixtures were supplied for a certain period of time. The results are discussed by means of Fig. 3. The upper photograph shows the results of an experiment in which oxygen together with silicon tetrachloride enters the tube from the left. The detailed experimental data are given in the legend to the figures. The result has been discussed earlier in detail (7). Silica is deposited in a small zone about 10 mm long, shifted in the direction of the incoming gas flow and 45 mm from the middle of the resonator cavity, which is indicated by a mark. The deposit is transparent and free from cracks.

The photograph in the middle is from an experiment in which silicon tetrachloride was replaced by silicon tetrafluoride at a lower flow rate. The other experi-

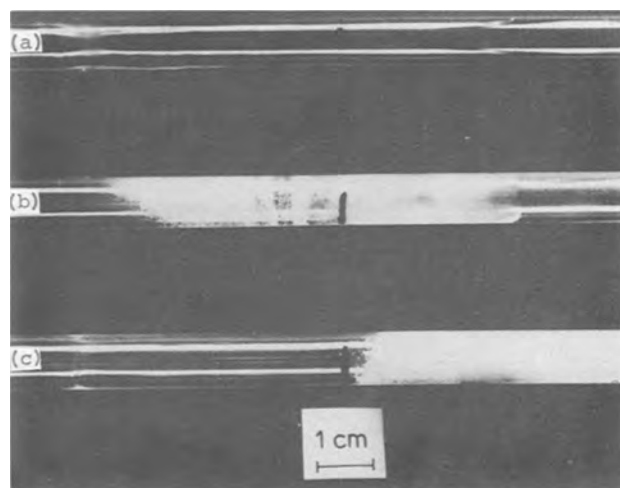

Fig. 3. Stationary deposition experiments, with the experimental conditions: $\phi_{od} = 10$ mm, $\phi_{id} = 8$ mm; $T_f = 1100$°C, $p = 8$ Torr, $E_m = 170$W. (a) $Q_{SiCl_4} = 9$ sccm, $Q_{O_2} = 110$ sccm; (b) $Q_{SiF_4} = 4$ sccm, $Q_{O_2} = 110$ sccm; (c) $Q_{SiCl_4} = 9$ sccm, $Q_{SiF_4} = 4$ sccm, $Q_{O_2} = 110$ sccm.

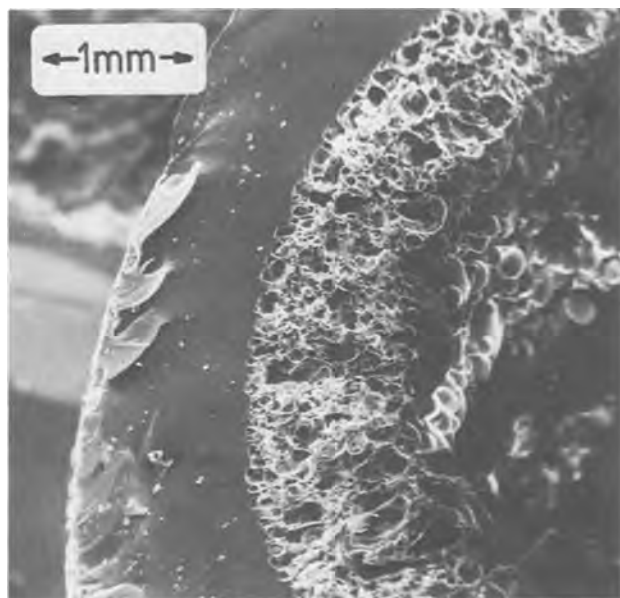

Fig. 4. SEM photograph of the opaque part of the deposit

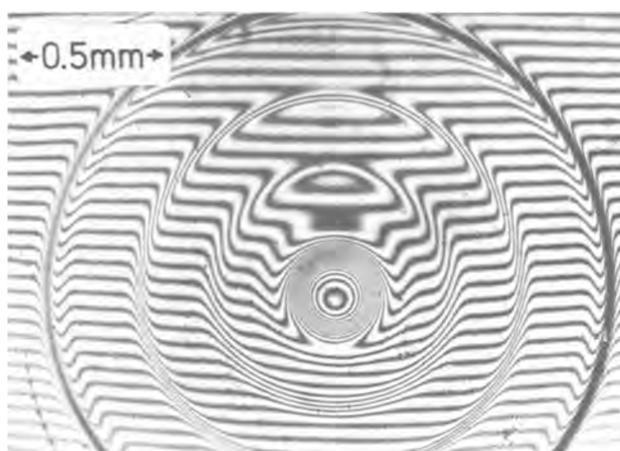

Fig. 5. Michelson interference micrograph of a preform core showing the decrease of refractive index with increasing fluorine content in the gas phase. (Wavelength, 550 nm; sample thickness, 200 μm).

mental conditions remained unchanged. Now the deposit was milky and opaque, it extended over a length of about ten times the inner diameter of the tube and it was approximately symmetrical about the middle of the resonator cavity.

The result of the third experiment, which is a combination of the former two, is given in the lower photograph. It is not a simple superposition of the two preceding photographs. The local deposit of silica appears at the same position as in the first experiment followed by a region which is transparent to the middle of the resonator. Thereafter the deposit is opaque again and even more extended than the deposit from SiF_4 alone. Figure 4 shows the consistency of the deposit in the opaque areas. It has a granular appearance and looks as though it was sintered from small spherical particles.

From these experiments it is clear that the deposition reaction from SiF_4/O_2 and $SiF_4/SiCl_4/O_2$ gas mixtures differs from that occurring with $SiCl_4/O_2$. No measurements characterizing the plasma itself have been carried out and therefore no detailed description of the processes occurring in the gas phase can be given. One may speculate, however, that the different gas-phase compositions lead to different species in the plasmas and also to different deposition kinetics.

Microwave reactor moving.—The experiment in which the deposition was studied from a mixture of $SiCl_4$ and SiF_4 was repeated with the reaction zone moving to and fro along the tube. About 1000 layers were deposited over a length of 30 cm. During the deposition the flow ratio of $SiF_4/SiCl_4$ was maintained at four increasing levels. The resulting deposit looked uniform and transparent apart from an opaque layer downstream from the main layer. This result is not to be expected from considerations of the static experiments. It is reminiscent of the case of a $SiCl_4/GeCl_4/O_2$ gas-phase composition (3) where it was found that the deposition profiles of SiO_2 and GeO_2 did not coincide in the static experiments. Instead they led to a partial separation of both oxides. When a multilayer structure was formed by moving the reactor rapidly to and fro to make the individual layers less than 1 μm thick, the separation was no longer detectable either in the collapsing behavior or in the optical properties of the preform. By analogy it is assumed that in the case of fluorine doping the multilayer structure also leads to a seemingly homogeneous layer when the individual layers are thin enough.

After deposition of the fluorine-containing layers, the tube was collapsed to a rod, with the core consisting of the deposited material. Slices were cut from the rod and viewed by Michelson interference microscopy. Figure 5 shows the resulting interference pattern. It is obvious that fluorine has been incorporated during deposition, leading to a remarkable decrease in refractive index. The influence of the flow ratio changes can be seen very clearly. Each of the steps consists of some hundreds of layers corresponding to the number of passes of the reaction zone. The increase in the refractive index at the center, as indicated by the concentric rings, reflects the fact that fluorine evaporates from the layers near the surface during collapsing. This is very similar to what happens with GeO_2 as the dopant. In practice, this effect is not of importance for the fabrication of optical fibers, since, in contrast to most other dopant materials, fluorine-rich layers must first be deposited, followed by layers containing less fluorine. This is a direct consequence of the fact that the refractive index of silica is lowered when fluorine is used as the dopant material.

Figures 6 and 7 give the results of two experimental runs, (x) and (·),[1] where the $SiF_4/SiCl_4$ ratio was changed, although the volumetric flow $Q_{SiX_4} = Q_{SiCl_4} + Q_{SiF_4}$ remained constant. In Fig. 6 the decrease in the refractive index is plotted *vs.* the ratio $q = Q_{SiF_4}/Q_{SiX_4}$. The greatest change in refractive index obtained under these experimental conditions is $\Delta n_{max} = -2.1 \times 10^{-2}$, corresponding to a change of 1.5% relative to pure silica. A first attempt with 50 mole percent (m/o) SiF_4 in the gas phase to get even greater changes in refractive index failed. Although the layer was of good appearance after deposition, bubbles developed on collapsing of the tube into a rod. It is thought that this is due to fluorine being released in the deposit at high temperatures. Analogously to the case of chlorine doping (4), we found that the curve is sensitive to changes in the deposition temperature.

The two experiments were made with two different microwave cavities. The cavity which gave the curve indicated by crosses ($\times$) had an inner length of 30 mm with a hole in the side walls of 30 mm diam which was off the cavity axis. The other cavity, with data designated by dots (·), had an inner length of 10 mm with a hole of 15 mm diam on the axis of the cavity.

The efficiency of the deposition process with $SiCl_4$ partially substituted by SiF_4 has been studied. The total volume of silica deposited per unit time dV_{SiO_2}/dt is given by

[1] With different microwave cavities as described later.

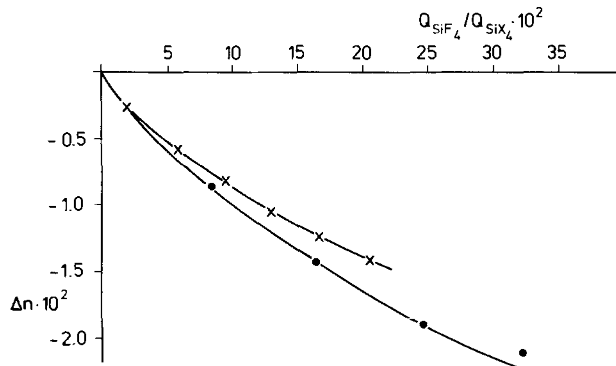

Fig. 6. Change of refractive index with increasing silicon tetrafluoride content in the gas phase for two separate runs, $Q_{SiX_4} = 10$ sccm.

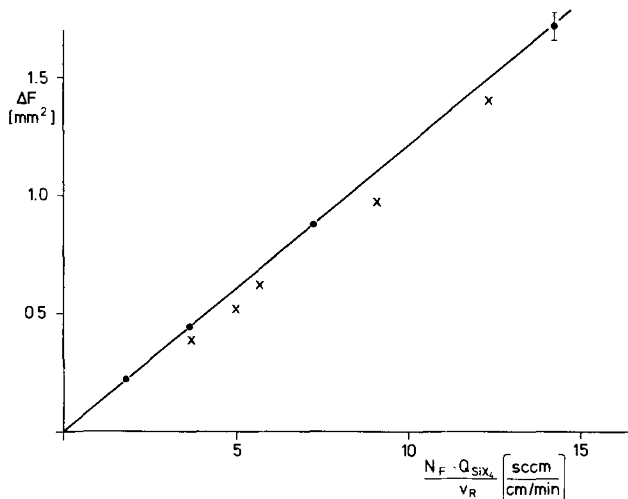

Fig. 7. Cross section of the rings as obtained for an increasing number of individual layers: $Q_{SiX_4} = 10$ sccm, $v_R = 2$ m/min (x), and $V_R = 3.5$ m/min (·).

$$dV_{SiO_2}/dt = \frac{f \cdot L}{t} = \Delta F/N_F \times v_R \quad [1]$$

where L is length of the deposition zone, f is cross-section area of one layer, t is time for one pass, v_R is the reaction zone velocity, N_F is the number of layers, and ΔF is the cross-section area of N_F successive layers, $\Delta F = N_F \times f$.

The maximum volume of SiO_2 that can be deposited if all SiF_4 and $SiCl_4$ is converted into SiO_2 is given by the formula

$$dV_{SiO_2}/dt = (Q_{SiX_4} \times M_{SiO_2})/(R \times T \times \rho_{SiO_2}) \quad [2]$$

where M_{SiO_2} = molecular weight of silica, R = gas constant per mole, $T = 273°K$, and $\rho_{SiO_2} = 2.201$ g/cm^3, the mass density of silica.

In Eq. [2] the influence of the incorporation of fluorine on the density of the deposit has been neglected. From Eq. [1] and [2] we get

$$\Delta F = M_{SiO_2}/(R \times T \times \rho_{SiO_2}) \times (N_F \times Q_{SiX_4})/v_R \quad [3]$$

From photographs similar to that of Fig. 5 ΔF can be obtained by measuring the radius of each ring. The number of layers N_F in each area is known from the experiments. Thus the theoretical curve of Eq. [3] for complete reaction can be calculated and is given in Fig. 7 as the full curve together with the measured values of two experimental runs.

There is no drastic decrease in the efficiency of the over-all reaction when SiF_4 is added to the gas flow, in contrast to the results of the MCVD process (6). In Fig. 7 it can be seen that the cavity with the greater field strength (·) gives complete reaction within experimental error. The other cavity (×) reflects a slightly lower yield.

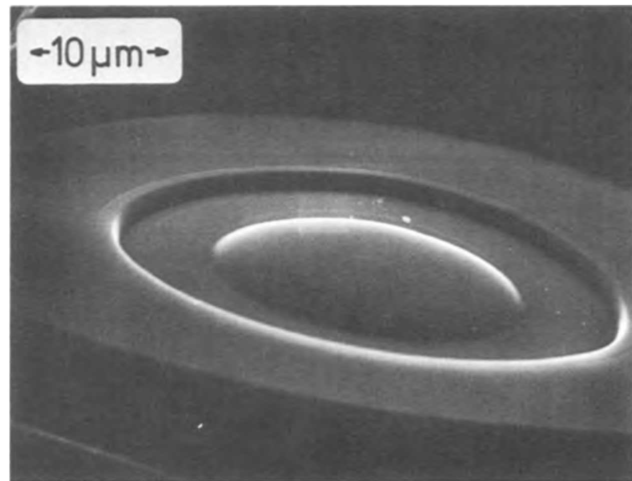

Fig. 8. Etch relief of a fluorine-doped graded index fiber

A graded index preform was prepared by coating the inner surface of a quartz tube with 400 layers of pure silica, followed by 1070 silica layers with constant fluorine concentration, and finally by 820 layers with decreasing fluorine content. The total flow of silica halides was up to 30 sccm in these experiments. After the collapsing of the tube into a rod, a fiber was drawn. Figure 8 shows a cross section of the fiber etched in HF solution. The fluorine-doped areas of the fiber are clearly visible due to the greater etch rate.

First fibers drawn from preforms prepared by the method described above show a minimum total loss of about 5 dB/km at 1050 nm wavelength. This indicates that the fluorine-doped layers are of good optical quality.

Summary

Highly transparent, thick glass layers doped with fluorine have been obtained by means of the plasma-activated CVD method. Although the stationary experiments gave nonuniform layers, good results were obtained when the reaction zone was moved repeatedly over some length of the substrate tube.

The over-all efficiency of the deposition process is not greatly influenced when silicon tetrafluoride is added to silicon tetrachloride. Under the experimental conditions applied, the greatest change in refractive index is found to be $\Delta n = -0.021$ with respect to pure silica.

Room Temperature Instabilities of p-Channel Silicon Gate MOS Transistors

Haruo Nakayama, Yoshihiro Osada, and Masahiro Shindo

Mitsubishi Electric Corporation, Kita-Itami Works, 4-1 Mizuhara, Itami, Hyogo, Japan

ABSTRACT

New unusual phenomena such as a rapid negative shift of a threshold voltage due to positive bias treatment, a time-dependent increase of a junction leakage current, and a fast recovery of a breakdown voltage after walk-out are observed on specially processed p-channel silicon gate MOS transistors. Furthermore the charge decay in specially processed FAMOS devices is found to be very fast compared with that in correctly processed devices. Process conditions inducing the instability are investigated and it is found out that 400°-500°C heat-treatment with a trace of ethyl alcohol or acetone after metallization induces the instability if a gate oxide contains a large quantity of boron. The activation energy of the mobile species which cause the threshold voltage shift is found to be 0.54 eV. A new model to explain these phenomena is proposed.

A room temperature instability of p-channel silicon gate MOS devices has been reported by Faggin *et al.* (1) and by Shimakura *et al.* (2). This instability appears as a rapid negative shift of a threshold voltage when positive bias is applied on a gate electrode even at room temperature. A breakdown voltage degradation (1) and an increased junction leakage current (2) have also been reported. The instability is observed only on silicon gate devices the gate oxide of which contains a large quantity of boron diffused from a boron-doped polysilicon electrode. Therefore, the existence of boron in the gate oxide must be an important factor of the instability. This alone, however, does not induce the instability, as is seen from the fact that correctly processed p-channel silicon gate devices are stable. Therefore, there must be other factors. Faggin *et al.* have reported that the instability occurs when devices are "prealloyed," that is, annealed at 500°C before metal mask so that aluminum covers the entire device. Shimakura *et al.*, on the contrary, observed the instability on the devices which were not "prealloyed." According to Shimakura *et al.*, the other factor of the instability is boron drive-in ambients.

In our work, process conditions inducing the instability are investigated and it is found out that a 400°-500°C heat-treatment after definition of aluminum, with a trace of ethyl alcohol or acetone attached to the wafers, induces the instability. Neither "prealloy" nor boron drive-in ambients are the major factor of the instability. Furthermore, various electrical characteristics of unstable devices are investigated in detail. And besides the threshold voltage shift, new unusual phenomena are observed on unstable devices: a time-dependent increase of a junction leakage current, a fast recovery of a breakdown voltage after walk-out, and a fast charge decay in FAMOS devices. Finally a new model to explain the instability is proposed.

Process Conditions Inducing the Instability

N-type (111) silicon wafers of 4-6 Ωcm resistivity were used. A 1200Å gate oxide was grown in a dry O_2 ambient at 1100°C. A 4000Å polysilicon film was deposited and defined by photolithographic technique. Boron predeposition was carried out for 20 min with B_2H_6 as a source gas, temperature being changed over a range from 950° to 1030°C. Subsequent boron drive-in was carried out in dry N_2 at 1100°C, in dry O_2 at 1100°C, or in H_2O at 950°C. As a result of boron-diffusion processes, source regions and drain regions were formed and gate electrodes were heavily doped with boron. The parameters of boron diffusion processes were decided in order to get a wide range of the boron concentration in the gate oxide. A 8000Å oxide was deposited and contact holes were defined. An aluminum film was evaporated, defined, and then alloyed in dry N_2 at 500°C. Finally, the wafers were subjected to 400°C heat-treatment in H_2 to reduce surface-state densities. Some wafers were dipped in ethyl alcohol prior to metallization. Some wafers were "prealloyed" for 10 min at 500°C in dry N_2 immediately after aluminum evaporation, that is, before definition of aluminum. The flow of sample preparation is illustrated in Fig. 1.

Table I summarizes the experimental parameters and threshold voltage shifts, ΔV_{th}, which were measured after 1 min BT treatment of $V_g = +20V$ at room temperature. Threshold voltage shifts were not uniform within a wafer, therefore the averages of 10 transistors are shown in Table I. It can be seen that ethyl alcohol attached to the wafer prior to metallization plays an important role. Negative shifts of threshold voltages were observed on all the samples treated with ethyl alcohol (Flows A and B), while the samples not treated with ethyl alcohol (Flows C and D) were all stable. Boron diffusion parameters were not the major factor of the instability. "Prealloy" did not induce the instability either.

In the second experiment, all the samples were fabricated without ethyl alcohol dip (Flow D), and therefore no threshold voltage shift was observed at the final stage of the usual wafer process. After the ΔV_{th} measurement, the samples were dipped in ethyl alcohol, acetone, toluene, trichloroethylene, freon, or deionized water, and baked for 30 min at temperatures

Key words: threshold voltage shift, junction leakage, walk-out, alumina silica catalyst.

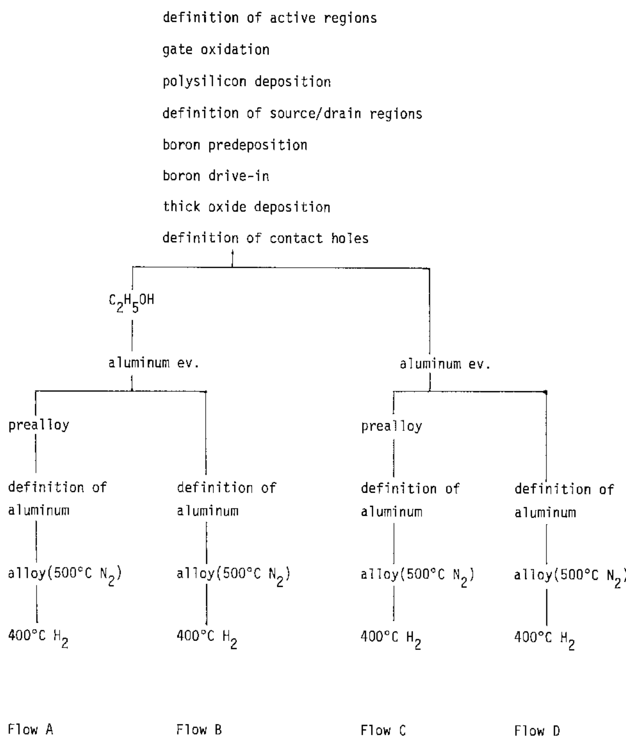

Fig. 1. Flow of sample preparation

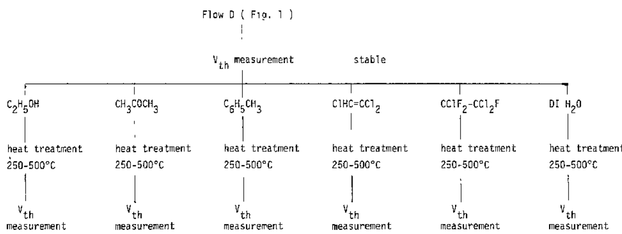

Fig. 2. Flow of sample preparation after usual wafer process

of 250°-500°C, and ΔV_{th} were measured again (Fig. 2). The experimental results are shown in Fig. 3, in which ΔV_{th} after 1 min BT treatment ($V_g = +20V$, room temperature) are plotted against the baking temperature. It can be seen that ethyl alcohol and acetone induce the instability at temperatures above 400°C. It is deduced, therefore, that in the case of the first experiment shown in Fig. 4 the instability was induced during the 500°C alloying step. Toluene, trichloroethylene, freon, and deionized water did not induce the instability over the experimented temperature range.

Alkali ion contaminations in ethyl alcohol or in acetone may be suspected to induce the instability, but this is not the case; ethyl alcohol dip performed prior to important processes such as gate oxidation, boron predeposition, and boron drive-in did not induce the instability.

In short, 400°-500°C heat-treatment after metallization induces the instability if the gate oxide contains a large quantity of boron and if ethyl alcohol or acetone is attached to the wafer. The mechanism is discussed later.

* Each $\overline{\Delta V_{th}}$ is the average ΔV_{th} of 10 transistors in a wafer (Three wafers for each process conditions).

Electrical Characteristics

Some interesting characteristics were observed on "unstable" MOS devices. The sample preparation conditions were as follows; boron predeposition at 1030°C for 20 min, boron drive-in at 1100°C in dry N_2 for 30 min, and ethyl alcohol dip prior to metallization (Flow B).

Threshold voltage shift.—The dependence of a threshold voltage shift, ΔV_{th}, on a biasing time and a temperature is shown in Fig. 4 for an applied gate bias of +20V. A large negative shift of a threshold voltage is observed. This shift is attributed to the change in the positive charge distribution in a gate oxide; positive charges move to the SiO_2/Si interface during positive bias treatment. The activation energy for the diffusion coefficient of the positive charge is calculated to be 0.54 eV.

Threshold voltage shifts were not uniform even within a wafer. An example is shown in Fig. 5, in which a large variation of ΔV_{th} is seen and contour lines can be drawn. This large variation of ΔV_{th} cannot be attributed to the variation of the boron concentration in a gate oxide, for the boron concentration was rather uniform within a wafer. The distribution of ΔV_{th} seems to be related to evaporation of liquid, probably ethyl alcohol.

Time-dependent increase of a junction-leakage current.—A drain-junction leakage current was measured with a gate electrode grounded. Figure 6 shows the experimental results. A reverse bias of −15V was applied to a drain and the leakage current was observed to increase rapidly. The rate of the increase depends on temperature. In the case of a measurement at 100°C, the leakage current after 10 min became two orders as much as the initial value. Then suddenly, the drain bias, V_d, was changed to −1V, and the leakage current was observed to decay to its saturation value for V_d = −1V.

The mechanism of this increase of a junction leakage current is considered to be as follows. Since the gate electrode is grounded and a negative bias is applied to the drain, the electric field in the gate oxide moves the positive charges to the vicinity of the drain. These positive charges in the vicinity of the drain enhance the electric field across the junction and increase the leakage current. The junction leakage current I_R is given by

$$I_R = MI_{Ro}$$

where M is a multiplication factor (3)

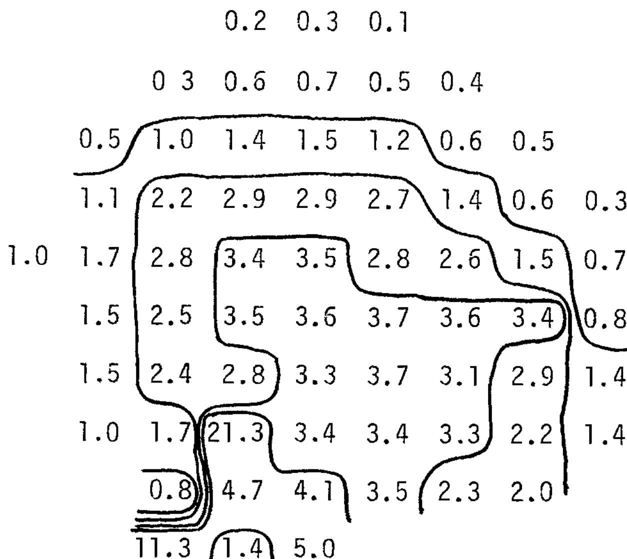

Fig. 5. Distribution of V_{th} shifts within a wafer due to 1 min bias treatment of +20V at room temperature.

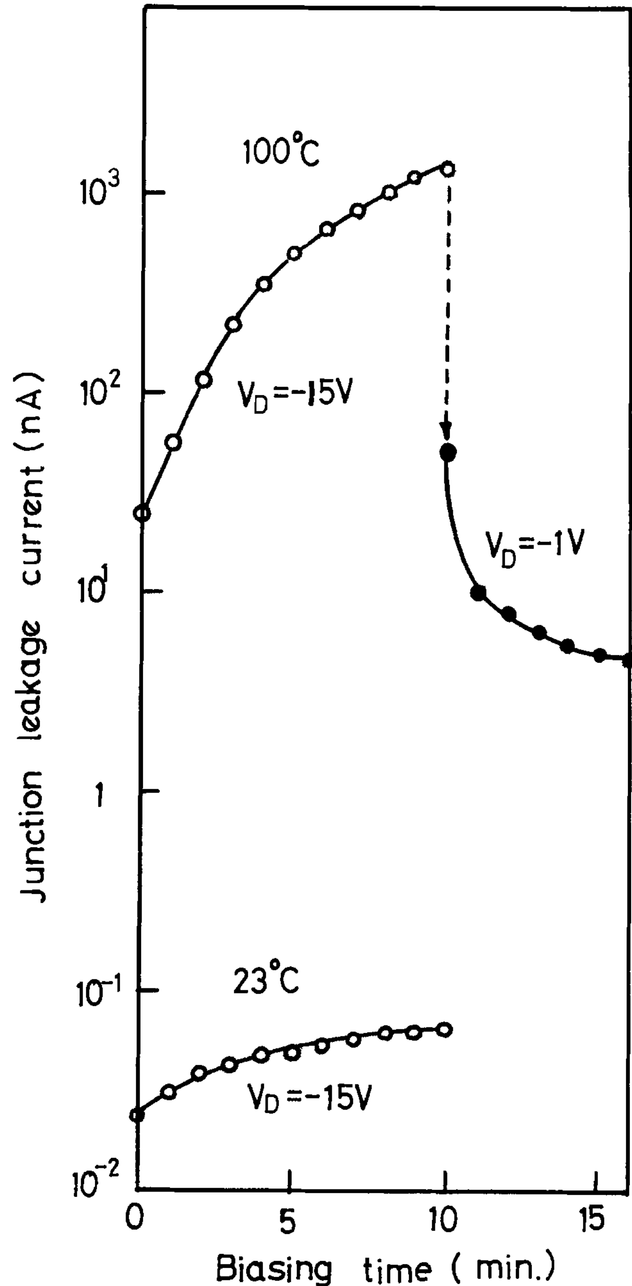

Fig. 6. Increase and decay of a junction leakage current observed on an "unstable" device.

$$M = \frac{1}{1 - (E/E_B)^n}$$

where E is the electric field across the junction; E_B is the electric field across the junction which induces an avalanche breakdown; and n is 3 ~ 6. If E is not negligible compared to E_B, as is the case of the experiment shown in Fig. 6, a small increase of E causes a large increase of a leakage current.

The mechanism proposed above was verified experimentally as is shown in Fig. 7. A reverse bias of −15V was applied to a drain of a "stable" MOS device and the dependence of the leakage current on a gate bias was investigated. A strong dependence can be seen for positive gate biases; the leakage current with a gate bias of +20V is two orders as much as that with the gate grounded. This positive gate bias simulates the effect of the positive charges near the drain of "unstable" gate-grounded devices because both enhance the electric field across the drain junction. This phenomenon is considered to correspond to a junction breakdown voltage degradation reported by Faggin *et al.* (1).

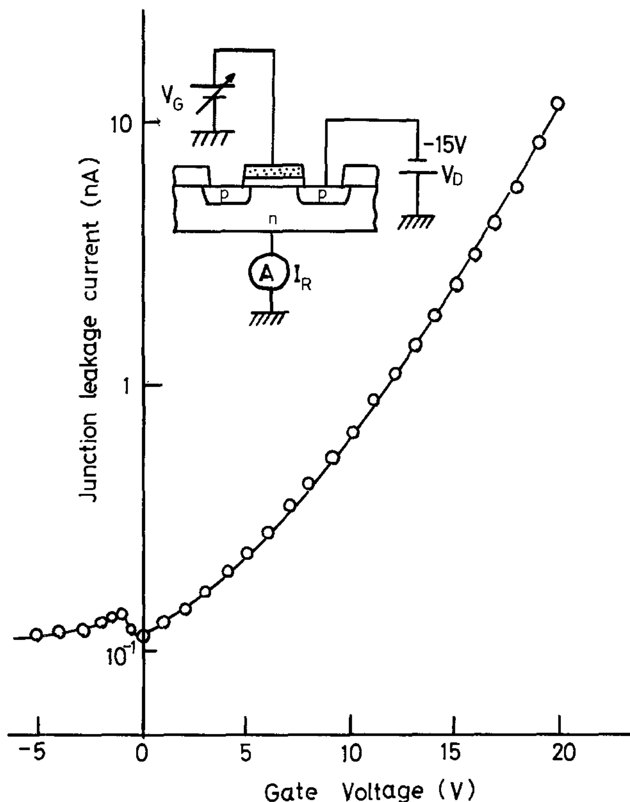

Fig. 7. Effect of a gate bias on a junction leakage current of a "stable" device.

Fast recovery of a breakdown voltage after walk-out.—It is well known that a junction breakdown voltage, V_B, shifts to a higher value when a high voltage enough for an avalanche breakdown is applied to a drain. This phenomenon is called walk-out. In the case of a p-channel MOS transistor, walk-out is considered to be caused by an injection of hot electrons, which are generated during avalanche, into the gate oxide near the drain (4). After avalanche has ceased, V_B will remain at its high value initially but after a long period of time it will recover to its initial value, V_{Bo}. This recovery is considered as a consequence of the escape of the trapped electrons. This recovery characteristic was studied for "unstable" MOS transistors as well as "stable" devices.

Breakdown voltages were measured with the gate electrodes grounded. Initial breakdown voltages, V_{Bo}, were -30V for all samples. Then walk-out was carried out with the gates grounded, a reverse bias of -50V being applied to the drain electrodes for 1 min. As a consequence of walk-out, breakdown voltages became -50V. In other words, the breakdown voltage shifts immediately after walk-out, $\Delta V_B(0)$, were 20V. In the next step, the samples were stored at temperatures of 100°-200°C for time t. Then breakdown voltages were measured again. In Fig. 8 $\Delta V_B(t)/\Delta V_B(0)$ are plotted against storage time t for various temperatures. Here $\Delta V_B(t)$ are the differences between the initial V_{Bo} and V_B after high temperature storage. The recovery of walk-out is described by

$$\Delta V_B(t)/\Delta V_B(0) \propto t^{-\lambda}$$

where λ is a function of temperature and varies for different devices (5). From Fig. 8 it is found that the recovery is extremely fast for "unstable" devices. This means that trapped electrons escape much faster in "unstable" devices than in "stable" devices.

Charge decay in p-channel FAMOS devices.—In a p-channel FAMOS device, the electrons transported from substrate across a gate oxide by an avalanche injection are stored in a floating polysilicon gate and induce a channel between a source and a drain. The storage of electrons in the floating gate needs no power supply, therefore a FAMOS device is a kind of a nonvolatile memory.

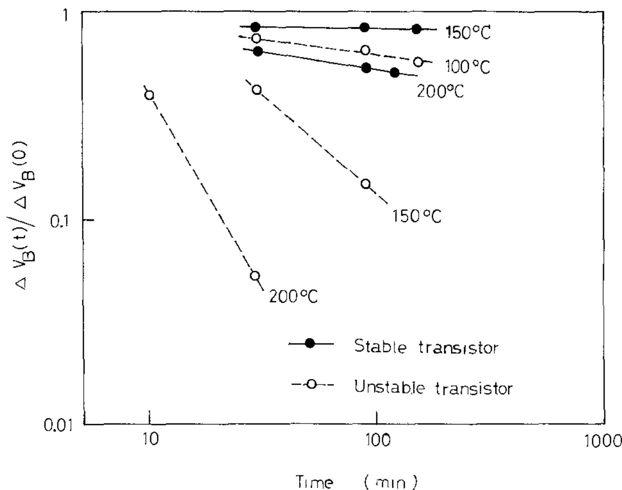

Fig. 8. Recovery of a junction breakdown voltage after walk-out

The retention characteristics were studied for correctly processed FAMOS devices and for FAMOS devices treated with ethyl alcohol (6). The memory retention time τ_{ret} depends on temperature exponentially

$$\tau_{ret} \propto \exp(\Delta E/kT)$$

In the case of correctly processed FAMOS devices, $\tau_{ret}(250°C)$ is an order of 10^6 sec and ΔE is 2.8 ~ 3.2 eV, therefore, the electrons will be stored for more than 10 years at a temperature lower than 150°C. On the other hand, the retention capability of FAMOS devices treated with ethyl alcohol was found to be very poor; $\tau_{ret}(250°C)$ is 10^3 ~ 10^5 sec and ΔE is 0.8-2.2 eV.

Mechanism of the Instability

This instability is considered to be due to positive charges which move fast in a gate oxide. In Faggin's model, H^+ ions are generated during prealloy and these H^+ ions are the moving species. One of the reasons is the agreement of the diffusion constants as shown in Fig. 9, which is cited from Fig. 11 of the Ref.

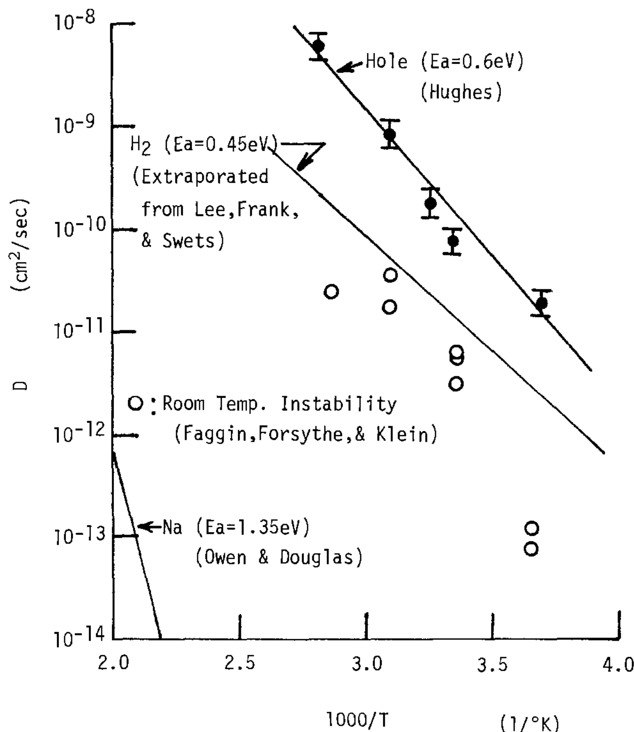

Fig. 9. Temperature dependence of diffusion constants

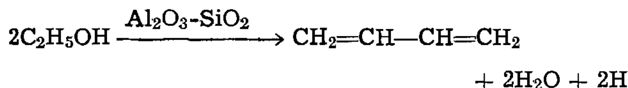
(1). But this model cannot explain the reason the instability appears only on p-channel silicon gate MOS devices. An explanation proposed by Shimakura *et al.* is based on an assumption that H^+ ions move much faster in a boron-doped oxide than in a nondoped oxide. According to their model, the amount of a threshold voltage shift depends on the thickness of a boron-doped oxide layer which is formed in the upper region of a gate oxide during the boron drive-in process. But our experimental results showed no dependency on the boron diffusion conditions, which must be related to the thickness of the boron-doped oxide layer, as shown in Table I.

An alternative model, which is based on our experimental results, is as follows. H^+ ions or H atoms are generated from ethyl alcohol at temperatures of 400°-500°C.



$$2C_2H_5OH \xrightarrow{Al_2O_3\text{-}SiO_2} CH_2{=}CH{-}CH{=}CH_2 + 2H_2O + 2H$$

Al_2O_3-SiO_2 is known to be an effective catalyst of the chemical reaction and considered to exist at the Al/SiO_2 interface (Fig. 10). The hydrogen generated must be in a reactive form to induce the instability, because our experiment showed that heat-treatment at 400°C in an H_2 ambient does not induce the instability if the sample is processed correctly (Flows C and D of Fig. 1). The reactive hydrogen diffuses to a gate oxide which contains a large quantity of boron. Boron is a kind of network former, and a rearrangement of the SiO_2 network may take place with the aid of reactive hydrogens, and hole traps may be generated as illustrated in Fig. 10. Holes which are initially located near the poly-Si/SiO_2 interface drift to the SiO_2/Si interface by positive bias and induce the instability. The amount of a threshold voltage shift depends on the number of hole traps in the gate oxide, which in turn depends on the amount of hydrogen generated from ethyl alcohol or acetone.

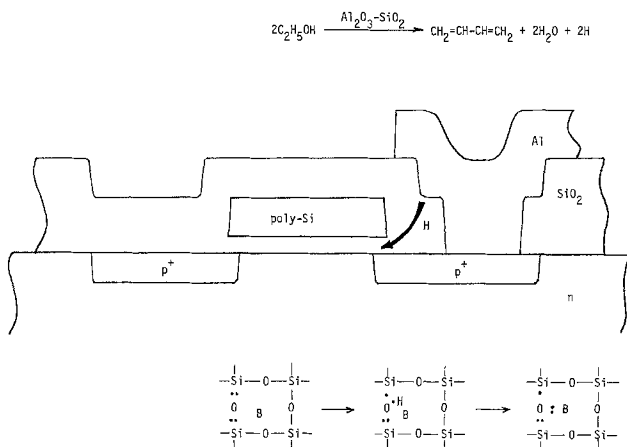


Fig. 10. Proposed model for the generation of hole traps

The mobility of hole in an oxide film has been measured by R. C. Hughes and found to follow $\mu = 20 \exp(-0.6 \text{ eV}/kT)$ cm/Vsec. The diffusion constant D can be calculated from μ using Einstein's relation

$$D = kT\mu/q$$

and it is plotted in Fig. 9. Fairly good agreement is recognized.

Summary

A room temperature instability has been found to occur if the following conditions are satisfied: (*i*) a large quantity of boron is contained in the gate oxide; (*ii*) a trace of ethyl alcohol or acetone is attached to the wafer; and (*iii*) heat-treatment of 400°-500°C. The latter two suggest the chemical reaction that hydrogen is generated from ethyl alcohol or acetone with Al_2O_3-SiO_2 catalyst. To explain why the first condition is necessary, a new model has been proposed; that is, hole traps are generated in a boron-containing gate oxide with the aid of hydrogen and holes are the moving species of the instability.

New unusual phenomena are observed on the unstable devices besides the already reported V_{th} drift. A junction leakage current increases with time. A junction breakdown voltage after walk-out recovers to its initial value much faster than stable devices. The charge decay of p-channel FAMOS devices is very fast. All these phenomena are related to charge transport in a gate oxide.

Concentration Dependence of a Diffusion Coefficient at Phosphorus Diffusion in Germanium

Satoru Matsumoto and Tatsuya Niimi

Department of Electrical Engineering, Keio University, Hiyoshi, Yokohama 223, Japan

ABSTRACT

Phosphorus diffusion into germanium is carried out at 600°-750°C by using red phosphorus powder as a diffusion source. Source temperatures are maintained at 240° and 430°C, corresponding to low and high surface concentrations, respectively. At low surface concentration, C_s 3-7 $\times$ 10^{18} cm^{-3} ($C_s \sim n_i$, n_i; intrinsic carrier concentration at the diffusion temperature), concentration profiles agree well with the erfc curves, showing the behavior of Fick's law. While at high surface concentration, C_s 5-8 $\times$ 10^{19} cm^{-3} ($C_s > n_i$), profiles deviate from the erfc curves. Diffusion coefficients depend both on the local and surface concentrations, representing the same result as that of phosphorus diffusion into silicon.

There is little information regarding diffusions of group III and V elements into germanium. As for phosphorus diffusion into germanium, three researches by Dunlap (1), Meer *et al.* (2), and Lehovec *et al.* (3) have been reported. It is not clear in these experiments, however, except in those by Lehovec *et al.* whether diffusions were carried out under low surface concentration or under high surface concentration. The precise concentration profiles of phosphorus were not given in those reports. Moreover, the concentration dependence of the diffusion coefficient of phosphorus in germanium has not been reported yet.

In this article, in order to investigate the concentration dependence of the diffusion coefficient of phosphorus in germanium, diffusions are carried out both at low and high surface concentrations and the diffusion coefficients of phosphorus are determined for the respective cases. Furthermore, the mechanism of the phosphorus diffusion in germanium is discussed by comparison with the phosphorus diffusion in silicon.

Experimental procedure.—Substrates used were (111) oriented p-type germanium single crystals of resistivity 1.9-2.7 $\Omega \cdot cm$ and of thickness 200 μm. They were chemically polished by etching with CP-4A solution. Phosphorus diffusions into germanium were carried out from the vapor phase with red phosphorus powders as a diffusion source. Red phosphorus powders were placed at one end of a vacuum-sealed quartz tube and a germanium substrate on the other end. The range of the diffusion temperature was from 600° to 750°C. In order to carry out phosphorus diffusions under conditions of low and high surface concentrations, the source temperatures of red phosphorus were held at 240° and 430°C, respectively. The technique with the anodic oxidation and sheet resistivity measurement was used to determine the concentration of phosphorus in germanium. The anodic oxidation was done in the solution of *N*-methylacetamide ($CH_3CONHCH_3$) and 0.04*N* potassium nitrate (KNO_3). The thickness of germanium dioxide (GeO_2) formed by the anodic oxidation was controlled by the oxidizing time. GeO_2 on the substrate was washed by deionized water and sheet resistivity was measured by the four-point probe method at each step. The thickness of the removed thin layer by one step was previously determined by the repetition of the anodic oxidation of a dummy sample. Phosphorus concentrations at various depths from the surface were determined by using the relation between resistivity and impurity concentration (4).

Results and Discussion

Figure 1 shows a typical concentration profile of phosphorus, which was obtained at a source temperature of 240°C and a diffusion temperature of 700°C. In the diffusion temperature range of the present work, 600°-750°C, the values of the surface concentration of phosphorus obtained at the source temperature of 240°C are 3-7 $\times$ 10^{18} cm^{-3}. The values of the intrinsic carrier concentration n_i corresponding to this diffusion temperature range are 3-7 $\times$ 10^{18} cm^{-3} (5). Therefore, at the source temperature of 240°C, diffusions are carried out under condition of low surface concentration. A full line in Fig. 1 is a theoretical curve (erfc), showing a good agreement with the measured points. From this result, Fick's law is obeyed under condition of low surface concentration. At low surface concentration, concentration profiles obtained at other diffusion temperatures also agree well with the erfc curves.

Figure 2 shows typical concentration profiles of phosphorus which were obtained at a source temperature of 430°C and a diffusion temperature of 700°C for 2 and 10 hr. In the case of a source temperature

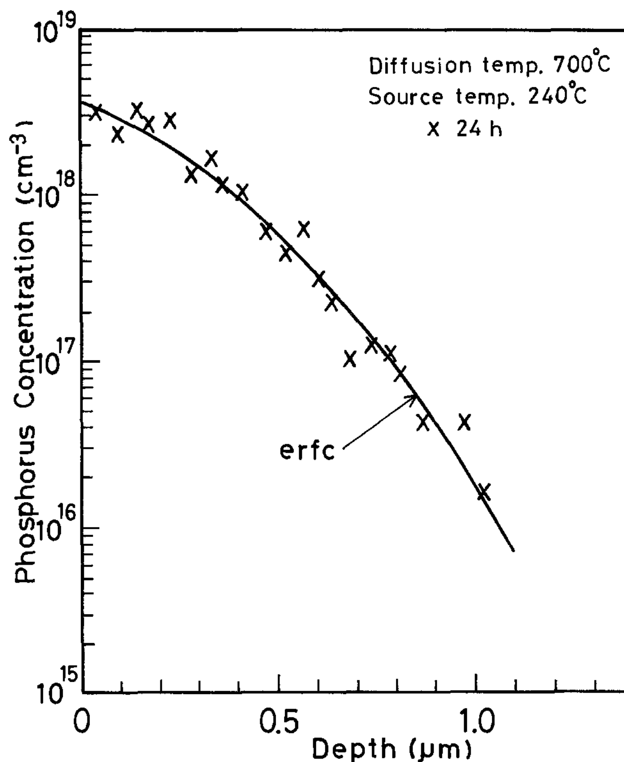

Fig. 1. Concentration profile of phosphorus in germanium. A full line is a theoretical curve (erfc).

Key words: vapor phase phosphorus diffusion, germanium, concentration-dependent diffusion coefficient.

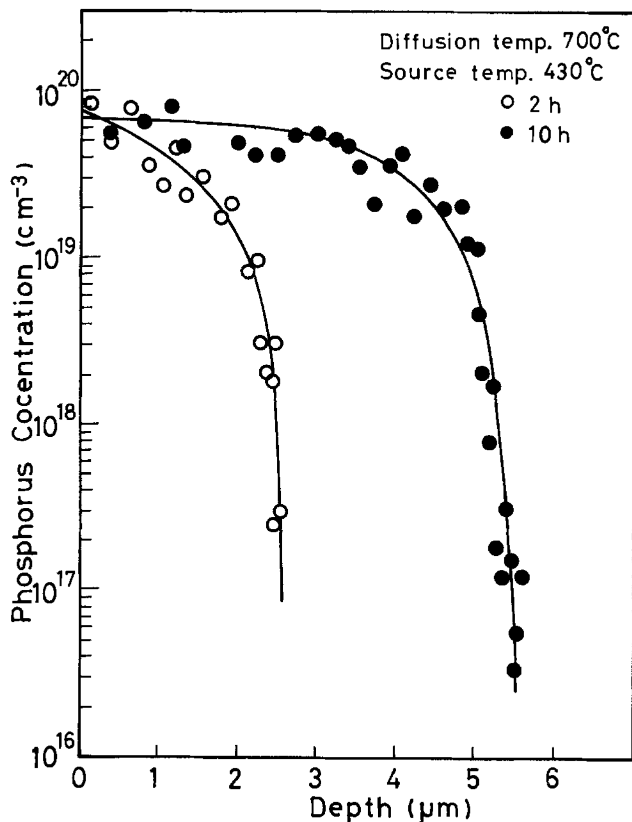

Fig. 2. Concentration profiles of phosphorus in germanium

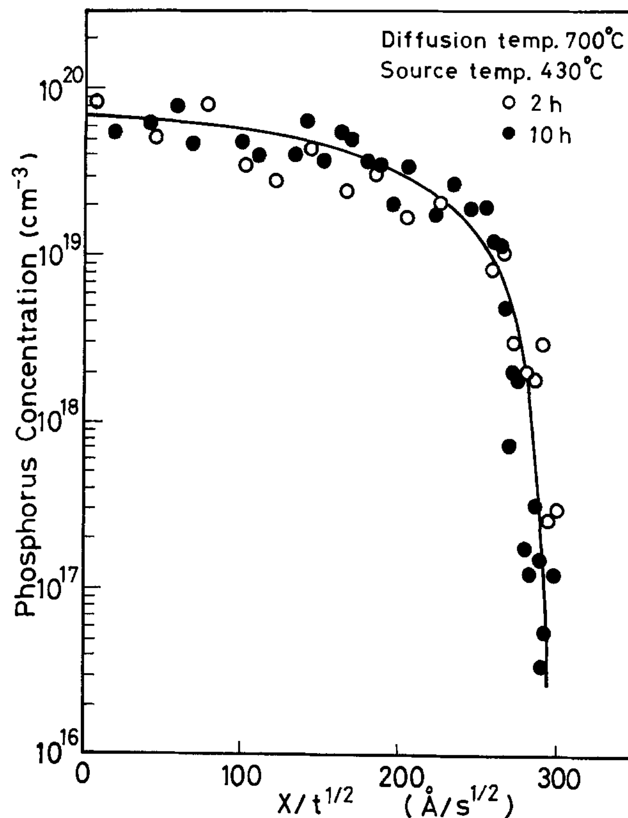

Fig. 3. Concentration profile of phosphorus as a function of $x/t^{1/2}$, which is obtained from Fig. 2.

such as this, the values of the surface concentration are 5-8 $\times$ 10^{19} cm^{-3} at the diffusion temperature range of the present work. The surface concentrations are much larger than n_i's at the diffusion temperatures. Therefore, in the case of 430°C, diffusions are carried out under condition of high surface concentration. Unlike the profile at low surface concentration, the concentration profiles in Fig. 2 do not agree with the erfc curves. For the diffusions at high surface concentration, the concentration profiles at other diffusion temperatures also do not agree with the erfc curves. Since the diffusion coefficients cannot be determined with ease in such case, Boltzmann-Matano analysis (6) can be used to determine them. In Fig. 3, phosphorus concentrations in Fig. 2 are plotted as a function of $x/t^{1/2}$, where x is the depth and t is the diffusion time. As shown in Fig. 3, phosphorus concentrations are a function of $x/t^{1/2}$ only, and then the applying condition of the analysis is satisfied. For the other diffusion temperatures in addition to 700°C, this applying condition is also satisfied.

The diffusion coefficients calculated by Boltzmann-Matano analysis are shown in Fig. 4 as a function of the local phosphorus concentration for respective diffusion temperatures. Diffusion coefficients are nearly constant at lower phosphorus concentration but increase rapidly with the phosphorus concentration for every diffusion temperature. Diffusion coefficients at the concentration of 1 $\times$ 10^{17} cm^{-3} where no local concentration dependence of the diffusion coefficient is seen in Fig. 4, D_h's are tentatively chosen. D_h's are plotted in Fig. 5 as a function of the reciprocal of absolute diffusion temperatures. Diffusion coefficients, D_l, which are obtained under conditions of low surface concentration, are also shown in Fig. 5. D_l and D_h are expressed by the following equations

$$D_l = 3.3 \times 10^2 \exp(-3.1\ \mathrm{eV}/kT)\ \mathrm{cm^2/sec} \quad [1]$$

$$D_h = 1.0 \times 10^{-2} \exp(-2.1\ \mathrm{eV}/kT)\ \mathrm{cm^2/sec} \quad [2]$$

Equation [1] is determined by the present results, including the data by Lehovec *et al.* (3). It should be noted that the diffusion coefficients in Fig. 4 are larger

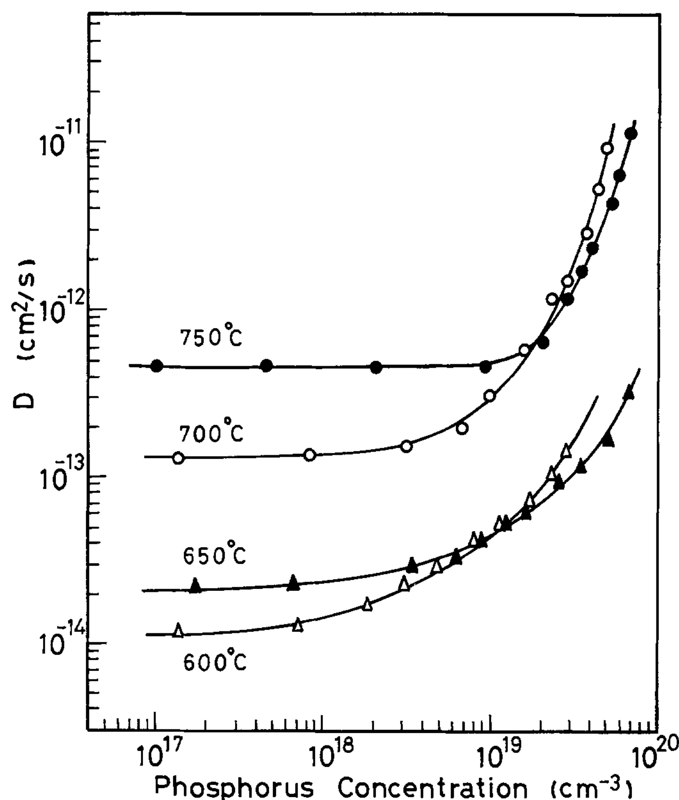

Fig. 4. Diffusion coefficient *vs.* phosphorus concentration for diffusions at source temperature 430°C, with diffusion temperature as a parameter.

than D_l not only at higher phosphorus concentration but also at lower ones. Results by Dunlap (1) and Meer *et al.* (2) are also shown in the figure, though their experimental conditions were not clear.

After diffusion, the layer with a thickness of 20-30μm was lapped from the surface to investigate the influence of the thermal treatment of the sample. The change in conductivity type was not seen through the diffusion. Little change was observed in resistivity through the diffusion with the high surface concentration, though a little change was observed at the low surface concentration. Therefore, the influence of the thermal treatment of the sample was negligibly small.

The theoretical curve in Fig. 1 is based on a constant surface concentration throughout the diffusion. It is well known that the surface barrier is present at the surface of germanium for impurity diffusion from the vapor phase (7) though. It is, however, confirmed that the diffusion times used in the present work are long enough to establish the state of equilibrium at the surface. It is shown in Fig. 2 that the surface concentration does not change with the diffusion times.

From the results of Fig. 4 and 5, it is found that the diffusion coefficients in germanium depend not only on the local concentration but also on the surface concentration. This is the same result as that of phosphorus diffusion into silicon. The present result seems to indicate that the diffusion mechanism of phosphorus in germanium is the same as that of phosphorus in silicon. Recently, a model on the basis of E center (phosphorus-vacancy pair) diffusion has been proposed to explain the dependence of the diffusion coefficient of phosphorus in silicon on the local and the surface concentrations (8). Although the presence of E centers is not identified in germanium, it is inferred that E centers may control the phosphorus diffusion in germanium. Furthermore, it has been made clear that the local concentration dependence of the diffusion coefficient of phosphorus in silicon is attributed to the diffusion-induced strain (9). The remarkable increase of the diffusion coefficient at the higher concentration in Fig. 4 is also considered to be due to the strain effect by the difference of the covalent radii of germanium and phosphorus.

It is well known that at phosphorus diffusion in silicon with high surface concentration, a kink is found in the concentration profile at relatively low diffusion temperatures (below approximately 1000°C) (8). The kink is, however, not found in the concentration profile in the present work. On the other hand, a diffusion "tail" was reported by Lehovec *et al.* (3). It is, however, considered that this tail has no relation with the mechanism of the kink formation in silicon because it was observed at very low concentration region and at low surface concentration unlike the case in silicon. Further investigation must be required to decide whether the kink formation is peculiar to phosphorus diffusion into silicon.

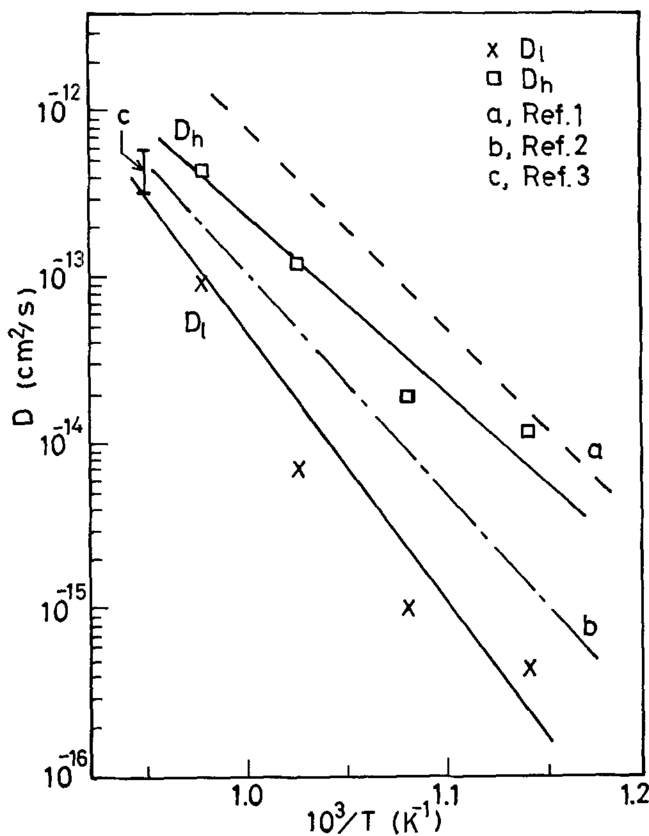

Fig. 5. Diffusion coefficient vs. reciprocal absolute temperature. D_l (×) are obtained at source temperature 240°C and D_h (□) at 430°C.

Summary

Phosphorus diffusion into germanium is performed under conditions of low and high surface concentrations. At low surface concentration Fick's law is obeyed, while at high surface concentration, concentration profiles deviate from the erfc curves. Diffusion coefficients in this case depend both on the local and on the surface concentrations. This result is the same one as that of phosphorus diffusion into silicon, indicating that phosphorus in germanium diffuses via the diffusion of E centers.

Growth of $Ga_yIn_{1-y}As/InP$ Heterostructures by Molecular Beam Epitaxy

B. I. Miller* and J. H. McFee*

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

Lattice-matched layers of $Ga_yIn_{1-y}As$ ($y = 0.47$) have been grown at 510°C on (100) InP substrates by molecular beam epitaxy. Epitaxial layers of highly uniform composition were achieved by mixing Ga and In together in a single source, Reproducible flux control was achieved by careful use of a quadrupole mass analyzer. In addition, the morphology, reflection electron diffraction, and electrical properties of $Ga_yIn_{1-y}As$ epitaxial layers were studied as function of y. When $y \simeq 0.47$ the epitaxial layers exhibit mirror-smooth, featureless morphology devoid of misfit dislocation-induced crosshatching. Such crosshatching becomes prominent when $y = 0.41$ and $y = 0.50$. Further, those epitaxial layers which are under tensile stress ($y > 0.47$) tend to exhibit cracking when thermally cycled. The best unintentionally doped epitaxial layers had $N_d - N_a \simeq 2 \times 10^{17}$ cm^{-3} and $\mu_{77} = 6500$ cm^2/Vsec. $InP/Ga_{0.47}In_{0.53}As/InP$ double heterostructures have also been fabricated and made to lase at 77°K under optical excitation conditions. These lasers have a threshold of 6.2 kW/cm^2 and an output wavelength of about 1.425 μm.

Recently there has been a great deal of interest in sources and detectors in the 1.5-1.0 μm range for possible application to optical fiber communications. In this wavelength range the optical fibers exhibit less loss (1, 2) and zero dispersion (3). LED's and lasers have been made covering this wavelength range using the double heterostructure (DH) GaInAs/InP (4, 5) GaInAs/GaInP (6), GaInPAs/InP (7-9), and AlGaAsSb/GaSb (10, 11) systems. All these double heterostructure devices were grown either by liquid-phase epitaxy (LPE) or vapor-phase epitaxy (VPE). To our knowledge no such DH devices in this range have been fabricated by molecular beam epitaxy (MBE). The unique capabilities of MBE, such as allowing abrupt atomically smooth interfaces and the ability to use masks, make it attractive as a method of growth for these systems. A further advantage of MBE is the ability to grow lattice-matched heterostructure alloy systems which are difficult or impossible to grow by LPE or VPE. An example of such a system is $(Al_xGa_{1-x})_{0.47}In_{0.53}As/InP$ where an exact lattice match is possible over a wavelength range from 1.44 to 0.85 μm at 300°K.[1] The first step in growing epitaxial layers in this attractive alloy system by MBE is to successfully grow the lattice matched ternary system $Ga_{0.47}In_{0.53}As/InP$. The growth of lattice-matched $Ga_{0.47}In_{0.53}As$ onto InP requires that the flux ratio of Ga/In be precisely controlled, whereas in the case of binary or even AlGaAs compounds this problem does not exist. We have developed a technique for precise flux control which allows us to grow such lattice-matched layers reproducibly. Also, by evaporating Ga and In from a single source, $Ga_yIn_{1-y}As$ epitaxial layers of highly uniform composition have been grown. These advances have permitted a systematic study of the morphology and electrical properties of $Ga_yIn_{1-y}As$ grown on InP as a function of the degree of lattice mismatch. Finally, $InP/Ga_{0.47}In_{0.53}As/InP$ lattice-matched double heterostructures have been grown which exhibit lasing under optical pumping at 77°K.

Experimental

The MBE system and its use in growing homoepitaxial layers of InP has been described previously (14). In the present work, GaInAs layers were grown epitaxially on (100) and $(\bar{1}\bar{1}\bar{1})$ InP substrates which were cut from single-crystal boules grown by Buehler using the liquid-encapsulated Czochralski (LEC) method described by Bachmann *et al.* (15, 16). In most growth runs Sn-doped ($n \sim 10^{18}$ cm^{-3} and also Fe-doped semi-insulating substrates were mounted side by side on the sample block. The semi-insulating substrates were included so that the electrical properties of the epitaxial layers could be measured. A typical substrate size is 1 cm^2.

The substrates were indium-soldered to a molybdenum sample block and chemically polished to a mirror finish on a dextilose paper lap saturated with weak bromine-methanol solution. The sample block is then promptly loaded into the MBE system which is pumped and mildly baked (150°C) overnight to a typical base pressure of 1×10^{-9} Torr or less. In the morning the sample block (which had remained at ambient overnight) is heated to 365°C and the substrates are sputter etched for about 5 min in 5×10^{-5} Torr of argon at 3 kV and about 5 μA/cm^2 current density. Following this sputter cleaning the samples are annealed at 365°C for at least 1 hr behind a shutter which shields the substrates from the direct source fluxes. During the annealing period the Ga, In, and As [2] source ovens are brought to operating temperature and fluxes adjusted to the desired values. The source fluxes are monitored by a UTI Model 100C quadrupole mass analyzer which is situated so that it has direct line of sight to the source ovens at all times. A chopper wheel is placed between the source ovens and mass-analyzer ionizer cage and synchronous detection is used to enhance the signal-to-noise ratio of the mass analyzer. Epitaxial layer growth is initiated by raising the sample temperature to 510°C (typical for GaInAs) and then opening the sample shutter.

Initially we attempted to grow $Ga_yIn_{1-y}As$ of lattice-matched composition ($y \simeq 0.47$) by using separate Ga and In sources. This method gave erratic results which we believe were due to spatial nonuniformity in the composition of the epitaxial layers. For example, the GaInAs layers exhibited significant variations in photoluminescent efficiency and line shape over the surface of the layers. Also, the surfaces were not smooth but rather had complicated morphologies not typical of good epitaxy. Compositional analysis of

[1] This wavelength range was determined by using the bandgaps corresponding to the end points of $Ga_{0.47}In_{0.53}As$ and $Al_{0.47}In_{0.53}As$, which lattice-match InP. For $Ga_{0.47}In_{0.53}As$ we used the results of Baliga *et al.* (12), and for $Al_{0.47}In_{0.53}As$ we used the results of Lorenz and Onton (13).

[2] The Ga used was 99.9999% pure and obtained from Alusuisse, Fort Lee, New Jersey. The In and As were 99.9999% pure and supplied by Kawecki Berylco, Incorporated.

these $Ga_yIn_{1-y}As$ layers using a scanning electron microscope (SEM) equipped to perform energy dispersive x-ray spectroscopy (EDS) disclosed variations in y as large as 10% between positions separated by only 5 mm. The sources in this case were open cylindrical crucibles situated 6.5 cm distant from the substrates. Actual investigation of the angular distribution of flux by evaporating Ga and In onto glass slides mounted on the sample block confirmed that the observed nonuniformities in the GaInAs layers could easily be explained in terms of the angular distribution of flux from the two separate sources. The situation can be improved by moving the two sources closer together and/or by increasing the source-to-substrate distance, but either of these options can be pursued to only a limited extent. Moreover, there is another serious disadvantage in the case of separate Ga and In sources: A small change in the melt configuration or temperature of one source oven during a growth run can change the Ga/In flux ratio significantly and cause a compositional gradient in the direction of film thickness. Both of the foregoing disadvantages are virtually eliminated by use of a common source containing a homogenous Ga-In mixture. The Ga/In flux ratio will then be exactly the same in all directions and will be independent of the melt configuration. Also, a change in the single source oven temperature will cause only a second-order change in the Ga/In flux ratio.

For all of the foregoing reasons we found it advantageous to change over to a single source crucible in which Ga and In are premixed in proper proportion to achieve the desired film composition. Through use of this technique, and by careful use of the mass analyzer to monitor the Ga/In flux ratio, we have been able to grow GaInAs layers of precisely controlled and highly uniform composition. For a typical source temperature near 800°C (corresponding to a growth rate $\simeq 1$ μm/hr) the evaporation rate of In is more than an order of magnitude greater than that of Ga. A calculation based on tabulated evaporation rates shows, and experiment verifies, that a mass ratio $M_{Ga}/M_{In} \simeq 10$ in the crucible yields the approximately equal Ga and In fluxes required for a lattice matched composition in the growing layer. The vapor pressure of Ga varies slightly more rapidly with temperature than does the vapor pressure of In. Thus, raising the temperature of the single source will increase the Ga/In flux ratio, and vice versa. Changing the source temperature is a convenient way to make fine adjustments in the GaInAs film composition to achieve precise lattice match. The range of adjustment is eventually limited by the much larger changes produced in the growth rate. For example, at a source temperature of 800°C the Ga/In flux ratio increases by ~0.5%/°C while the individual Ga and In fluxes increase at a rate of ~3%/°C.

The required 10:1 M_{Ga}/M_{In} mixture means that only a relatively small amount of In will be present in the single source. Thus, if the source volume is small, In depletion in the source during film growth will lead to a nonuniformity in the film composition. Our standard oven crucibles hold about 1.5 cm^3 of charge. In this case, for a growth rate of 0.8 μm/hr the Ga/In flux ratio is observed to increase 2.5%/hr due to In depletion. For an initially lattice-matched $Ga_yIn_{1-y}As$ film this increase means that y would vary from 0.470 to 0.476 from bottom to top of a 2 μm thick film. However, even this small amount of change in the Ga/In ratio can be compensated by reducing the source temperature gradually, as explained above. Also, of course, the effects of In depletion could be made negligible by substantially increasing the source volume.

In order to grow ternary layers of precise composition, a reliable means of measuring the Ga/In flux ratio before and during growth is almost a necessity. The UTI mass analyzer can serve this purpose provided it is properly used. During growth of a GaInAs layer a background pressure of order 10^{-6} Torr of As is present in our MBE system. The presence of this much As has several effects on the performance of the mass analyzer when used in the Faraday Cup mode without the electron multiplier. Firstly, the basic sensitivity of the analyzer for any given mass number is increased, but the magnitude of the increase is a function of mass number. Thus if the Ga ($M = 69$) and In ($M = 115$) fluxes are measured with the analyzer, the current ratio i_{69}/i_{115} obtained will be a function of the As background pressure. Secondly, we have observed occasional abrupt changes in the basic sensitivity of the analyzer which take place without apparent cause. Fortunately, these abrupt sensitivity changes appear to be independent of mass number and do not alter the current ratio i_{69}/i_{115}. Finally, we find that setting the mass analyzer to read the As (M = 150 or M = 75) flux will cause the basic sensitivity to change drastically. Following a reading of the As flux the basic sensitivity gradually relaxes toward its original value over a period of about 1 hr. Thus, when precise Ga/In flux measurements are desired, As flux readings must be avoided.

In order to demonstrate that the mass analyzer can be reliably calibrated in terms of the Ga/In ratio in the epitaxial layer, a series of five $Ga_yIn_{1-y}As$ epitaxial layers were grown on InP substraes as listed in Table I. Each layer was grown on a separate day's run. The $Ga_yIn_{1-y}As$ layer composition was changed from decidedly In rich in the first run (071877), through approximately lattice-matched composition (072577), to decidedly Ga rich in the final growth run (072977). In all of these runs the Ga and In were mixed together in a single source and the y values given in Table I for each grown layer were measured with the SEM equipped to do compositional analysis via EDS. Each y value is the average of repeated readings made at two different points (separated by ~1 cm) on each sample. These average values typically agree to within 1%, which demonstrates the improved spatial uniformity of the GaInAs layers grown from a common Ga-In source. Indeed, the spatial uniformity of composition may be better than these figures indicate because the relative error in the EDS measurements is estimated to be 1%. The i_{69}/i_{115} values in Table I represent an average of many readings taken with the mass analyzer during the growth of each GaInAs layer. In all growth runs listed in Table I the As background pressure was maintained at or near 6.0×10^{-7} Torr to eliminate the effect of a changing As background on the measured current ratio. The accuracy of the current ratios given is estimated to be about 2%.

It is most revealing to plot $y/1-y$ for the five runs listed in Table I *vs.* the corresponding i_{69}/i_{115} ratio as measured by the mass analyzer. This is done in Fig. 1. If the mass analyzer is linearly indicating the Ga/In flux ratio, one would expect a simple linear relationship between $y/1-y$ and i_{69}/i_{115}. From Fig. 1 it appears that $y/1-y$ is, within experimental error, a linear function of i_{69}/i_{115}. The straight line drawn in Fig. 1 is the best least squares linear approximation to the data, and has slope = 2.0. The vertical error bars correspond to the 1% uncertainty in the y values as measured with the SEM. If it is assumed that the mass analyzer behaves linearly, a "theoretical" value for the constant relating $y/1-y$ and the i_{69}/i_{115} current

Table I. Summary of mass analyzer and SEM data on $Ga_yIn_{1-y}As$ growth runs

071877	0.30	0.39	0.64
072777	0.36	0.414	0.706
072577	0.41	0.46	0.85
072177	0.50	0.50	1.0
072977	0.75	0.59	1.44

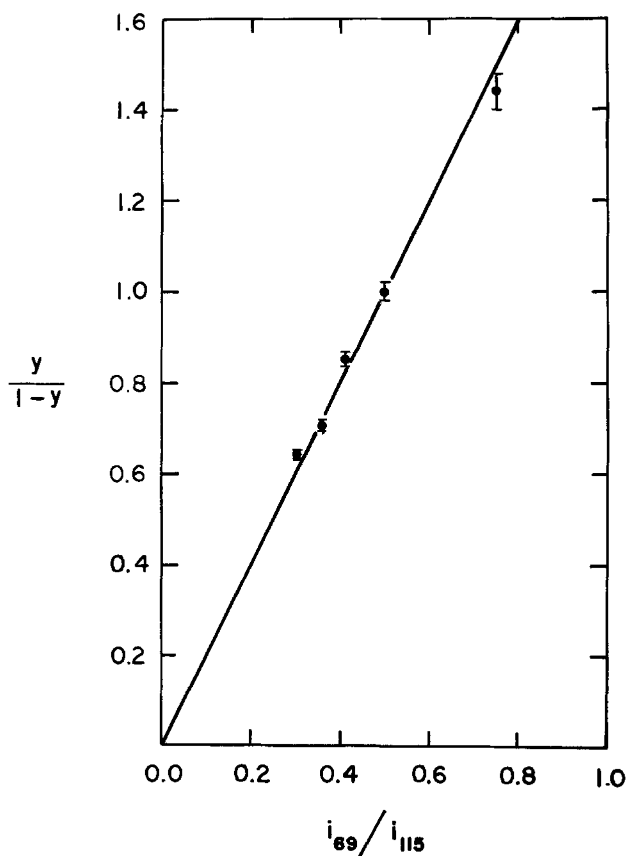

Fig. 1. Ga/In ratio, $y/1 - y$ in $Ga_yIn_{1-y}As$ epitaxial layers (as measured by SEM) *vs.* mass analyzer current ratio, i_{69}/i_{115}, recorded during layer growth.

ratio can be calculated from the ionization efficiency (I) and quadrupole transmission (T) data given for $M = 69$ and $M = 115$ in the UTI 100C instruction manual. The relative masses and isotopic abundances of $M = 69$ and $M = 115$ also come into this calculation. We further assume unity sticking coefficients for Ga and In, and get the result $y/1 - y = 1.5 \times i_{69}/i_{115}$. This calculated slope of 1.5 is surprisingly close to the experimental slope of 2.0 (Fig. 1) when one considers the substantial uncertainties in the I and T data and, particularly, when one recalls that the mass analyzer operates in an ambient of 6×10^{-7} Torr of As which, as we have noted, significantly alters its basic sensitivity.

In summary, then, Fig. 1 gives a calibration of our mass analyzer. If we are careful to reproduce the conditions under which the data of Fig. 1 were obtained, namely the same As ambient and a single source for Ga + In, we can use Fig. 1 to determine the mass analyzer current ratio which corresponds to any desired value of y. When this i_{69}/i_{115} ratio is maintained throughout the growth period, the composition of the resulting $Ga_yIn_{1-y}As$ layer will be within about 1% of the desired value. In this way lattice-matched GaInAs can be grown reproducibly.

Results

$Ga_yIn_{1-y}As$ grown on InP.—In order to demonstrate how the degree of lattice mismatch affects the various epitaxial film parameters such as morphology, surface structure (as revealed by reflection electron diffraction), carrier concentration, etc., the series of five epitaxial layers listed in Table I was investigated in some detail.

Morphology.—The resulting morphology is shown in Fig. 2. The polished substrate is also shown for reference. When $y = 0.39$ and $y = 0.41$ there appears a strong crosshatching, stronger for the larger lattice mismatch. This type of crosshatching has been observed in other lattice-mismatched epitaxial systems (17) and is believed to be associated with arrays of misfit dislocations. In Fig. 2, where $y = 0.46$, there is essentially a lattice match ($y = 0.468$ according to Vegard's law) and the morphology of the grown layer is nearly indistinguishable from the substrate. There

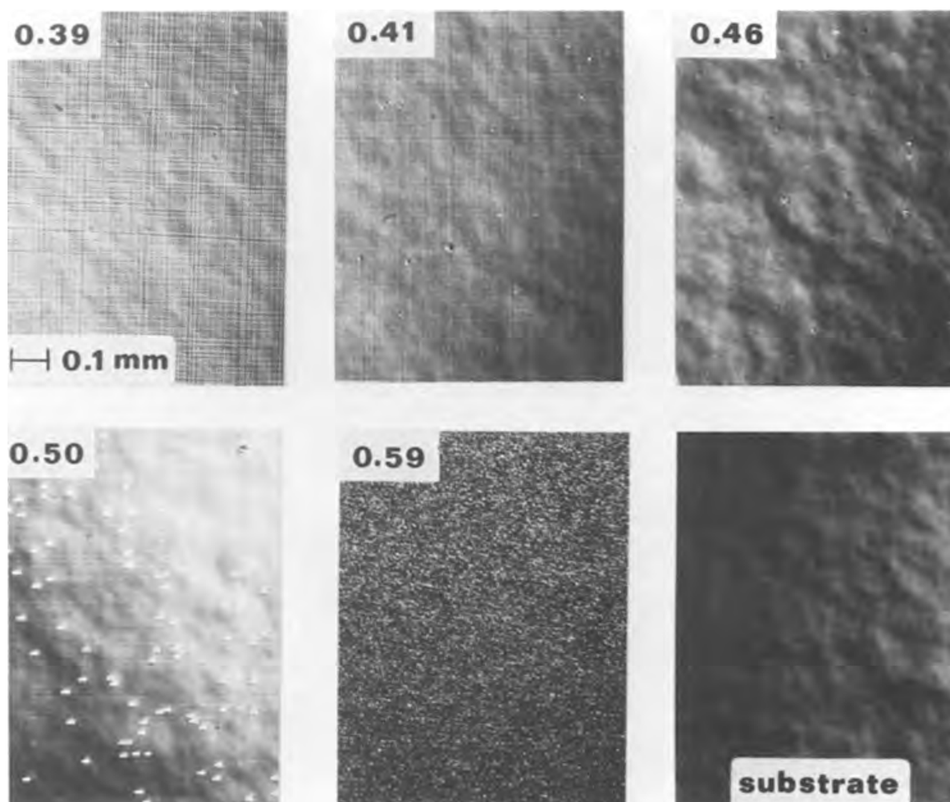

Fig. 2. Nomarski interference-contrast photographs of (100) $Ga_yIn_{1-y}As$ epitaxial layer surfaces, showing effect of lattice mismatch on surface morphology. Measured composition, y, given at upper left of each photograph. The Nomarski photograph of a polished InP substrate also shown for reference.

appear to be a few defects scattered about whose density is roughly $\sim 10^4/cm^{-2}$. This suggests that these defects may be related to or generated by dislocations, since the dislocation count in the LEC-grown InP crystals used for substrates is typically $\sim 10^4$ (15).

When $y = 0.50$, the crosshatching appears as before. It is interesting to note here that when $y = 0.39$ and $y = 0.41$ the GaInAs layer is under compression since its lattice constant is larger than the InP substrate. When $y = 0.50$ and $y = 0.59$, however, the epitaxial layer is under tension and, in fact, when $y = 0.59$ the layer has so much tension that it becomes very rough and fragmented. Examination of this latter surface with an SEM shows a grain size $\sim$ 1-2 μm, rather than a continuum as for the other surfaces.

Reflection electron diffraction (RED).—Figure 3 shows the RED patterns taken from these five surfaces. In Fig. 3 the RED pattern from the polished InP substrate is shown for reference. In this case the electron beam is along the $(\bar{1}\bar{1}0)$ azimuth and a typical C(2 $\times$ 8) pattern (18) is seen. The arrows point to the streaks corresponding to the bulk lattice spacing, and the one-half order lines corresponding to the surface reconstruction can also be distinctly observed. When there is a lattice match ($y = 0.46$), a similar pattern can be seen, with the major streak spacing corresponding to the bulk lattice spacing of $Ga_{0.46}In_{0.54}As$. However, in this case we notice that the one-half order lines are not quite as distinct as in the case of the InP substrate, but are somewhat fuzzy and broadened. This may reflect the lack of order in our crystal, as this is a mixed III-V alloy system. Locally there is a large degree of disorder in the crystal due to the difference in lattice constants between InAs (19) and GaAs (20). When this same $Ga_{0.46}In_{0.54}As$ layer is subsequently covered by a top layer of InP, the RED pattern recovers and often becomes sharper than the pattern from the substrate. For InP, of course, there is no disorder. It is interesting to note that in the AlGaAs system this degree of disorder does not occur since AlAs and GaAs have very nearly the same lattice constant.

The RED patterns coming from the lattice mismatched samples show the lack of lattice perfection in their spotty, less streaked character, and also the almost complete lack of the one-half order lines. The $y = 0.59$ layer shows almost no RED pattern at all indicating the granular nature of this film.

Cross sections.—The cleaved cross section of the five samples of Table I are shown in Fig. 4 in the same sequence as before. The cleaved cross section of the lattice-matched epitaxial layer ($y = 0.46$) appears to be as strain-free and smooth as a homoepitaxial layer. The epitaxial layers shown for $y = 0.39$ and $y = 0.41$, although lattice mismatched and under compression, also show little evidence of lattice strain. For the slight mismatch where $y = 0.41$ the cross section is as smooth as when $y = 0.46$, while for the greater mismatch ($y = 0.39$) the slight roughness is an indication of some lattice strain. When $y = 0.50$ the epitaxial layer is under tension, the cleaved cross section is considerably rougher, and the epitaxial surface itself is also rough. Yet the magnitude of the lattice mismatch is less than when $y = 0.41$ where the cleave is featureless. When $y = 0.59$ the epitaxial layer is under

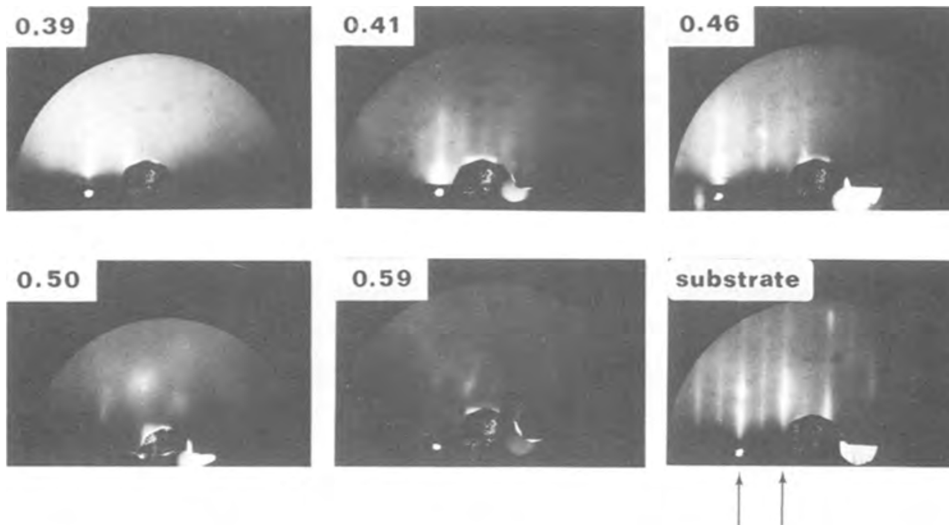

Fig. 3. Reflection electron diffraction (RED) patterns (3 keV) obtained from the $Ga_yIn_{1-y}As$ epitaxial layers of Fig. 2. Primary beam direction is along $(\bar{1}\bar{1}0)$ azimuth. The corresponding RED pattern obtained from a polished (100) InP substrate is shown for reference.

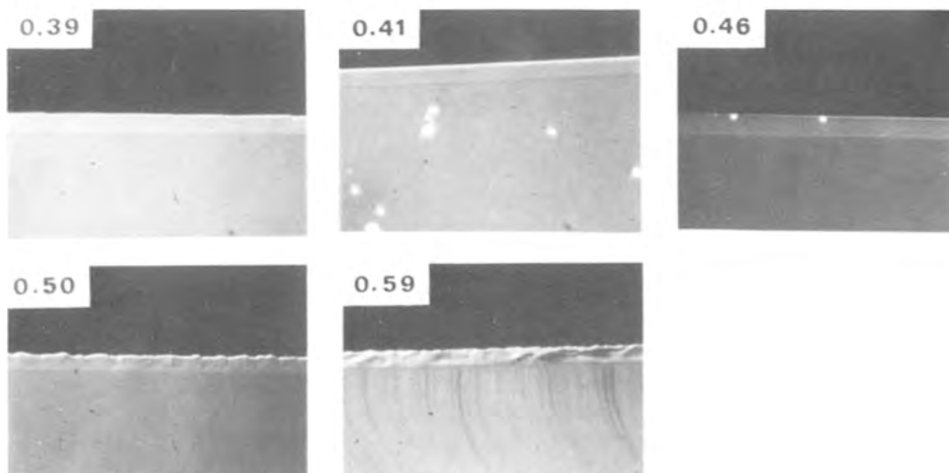

Fig. 4. Cleaved cross section of $Ga_yIn_{1-y}As$ epitaxial layers of Fig. 2. The layers, approximately 2 μm thick, are grown on (100) InP substrates.

much greater tension than when $y = 0.50$. This is reflected in the great roughness of the cleave and epitaxial surface. In general, it appears that the epitaxial layer will tolerate a lattice mismatch in the direction of compression ($y < 0.47$) much more readily than tension ($y > 0.47$). These findings have also been observed by others (17, 4).

It should be noted that those epitaxial layers which are under tension tend to crack and peel upon temperature cycling from 300° to 77°K and back, while those under compression do not.

Scattered light.—The film smoothness during growth is monitored by observing the nonspecular scattered light coming from the epitaxial surface which is illuminated by a He-Ne laser beam. In Fig. 5 the nonspecular scattered laser light output is plotted *vs.* growth time for some of the samples shown in Fig. 2 to 4. At time $t = 0$ min, just before initiating epitaxial growth, the scattered light comes from the uncoated substrate. All three curves are plotted unnormalized and thus at $t = 0$ the scattered light is a measure of the reproducibility of the substrate smoothness from run to run. Curve 3 corresponds to the lattice-matched epitaxial layer ($y = 0.46$) and remains relatively unchanged during the growth period. The $y = 0.41$ epitaxial layer, the layer under slight compression, has a curve (not shown) similar to 3. Curve 2 corresponds to the $y = 0.39$ epitaxial layer and increases by almost two orders of magnitude during the growth and curve 1 corresponding to the $y = 0.59$ epitaxial layer increases by over three orders of magnitude. The scattered light curve from the $y = 0.50$ epitaxial layer (not shown) lies somewhere between curves 1 and 2, having their same general shape.

The most noteworthy feature of these curves besides their sensitivity to lattice match is the initial dip in the scattered light at the onset of growth. This dip in light output lasts for approximately 5-15 min. Assuming an average growth rate of 0.75 μ/hr, the dip corresponds to a 600-1900Å thick layer or 120-360 monolayers. It appears that the dip is caused by the accommodation to the substrate of the epitaxial layer, which is under strain but smoother than the substrate. After a certain thickness the epitaxial layer can no longer accommodate itself to the substrate, and the strain is relieved by dislocations which cause the crosshatching and surface roughness seen in Fig. 2. Even the "lattice-matched" layer $y = 0.46$ (curve 3) shows a slight increase of scattered light after the initial dip, however, the final scattered light intensity is about the same as that coming initially from the substrate. The slight drop in the scattered light output in curves 1 or 2 during the latter part of the run may be due to a specular component of the scattering coming from the crosshatching and from surface faceting. As the run progresses these surface features may change with time and cause more or less specular scattering. In many instances the scattered light does not change at all during the latter half of the run.

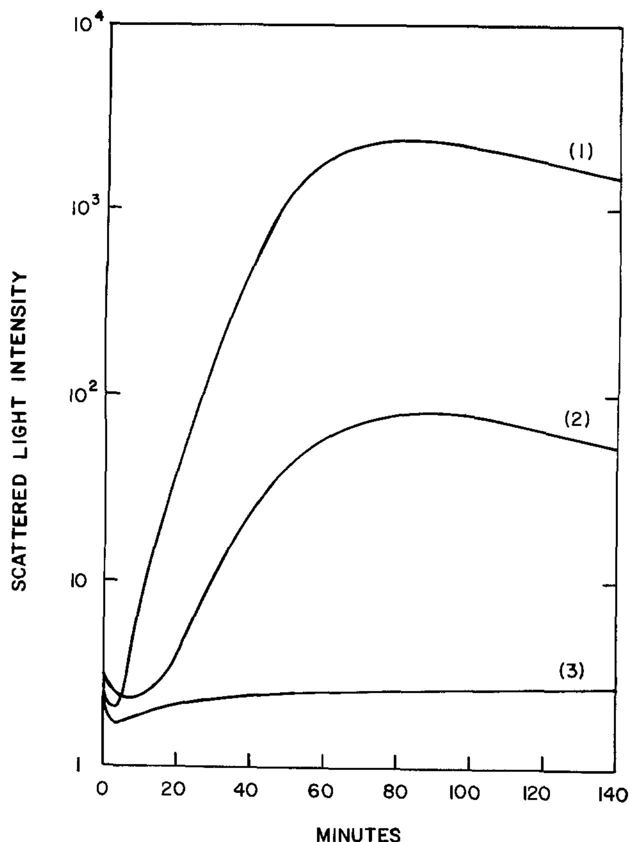

Fig. 5. Time evolution of nonspecular scattered laser light from surface of the growing epitaxial layer for some of the samples shown in Fig. 2-4. Growth starts at 0 min. Curve 1, $Ga_{0.59}In_{0.41}As$ on InP; Curve 2, $Ga_{0.39}In_{0.61}As$ on InP; curve 3, $Ga_{0.46}In_{0.54}As$ on InP.

Electrical properties.—Table II is a summary of the electrical properties of the various $Ga_yIn_{1-y}As$ layers grown on InP. The first five samples correspond to the same growth runs referred to in Fig. 1-5. All these layers were grown unintentionally doped. The purest material grown to date is n-type with $n = 2 \times 10^{17}$, $\mu = 5300$ at 300°K, and $n = 1.8 \times 10^{17}$, $\mu = 6500$ at 77°K. The mobility of $Ga_{0.75}In_{0.25}As$ grown by vapor phase epitaxy on GaAs has been reported by Glicksman *et al.* (21) to be 5950 at 300°K and 17,700 at 77°K, for $n = 10^{15}$. At the impurity levels reported in Table II one would expect the mobility to be dominated by impurity scattering as the following considerations show. Glicksman *et al.* (21) write the mobility of $Ga_yIn_{1-y}As$ as

$$1/\mu = 1/\mu_{ph} + 1/\mu_d + 1/\mu_I \quad [1]$$

where μ_{ph} is the phonon contribution to mobility, μ_d the disorder contribution arising from the alloy composition y, and μ_I the impurity contribution coming from both ionized donors and acceptors and the number of free electrons. Both μ_I and μ_{ph} are implicitly dependent only upon the alloy composition y, through the effective mass (m^*) variation with y. In addition to its implicit dependence on m^*, μm_d varies as $[y(1-y)]^{-1}$. For $y = 0.47$ we find, using formulas given in Ref. (21), that at room temperature $\mu_{ph} =$ 13,200 and $\mu_d =$ 41,000. For our best sample (041377, see Table II) $\mu = 5300$ so that from Eq. [1], $\mu_I =$ 11,300. Similarly at 77°K, $\mu_{ph} =$ 310,000 and $\mu_d =$ 80,000; thus using the 77°K mobility of $\mu = 6500$, we get $\mu_I = 7700$ for this sample.

From these considerations it is obvious that in the samples listed in Table II the major contribution to the mobility comes from impurity scattering. Any variation of mobility with alloy composition would not be expected to play a significant role at these impurity levels. In fact, this is borne out by comparing the mo-

* Sample cracked after immersion in liquid nitrogen.

bilities in Table II for the first five samples, which have similar carrier concentrations, where y ranges from 0.39 to 0.59. The mobilities are essentially the same except for those samples under tension ($y > 0.47$) where cracking had occurred while undergoing a 77°K temperature cycle prior to the Hall test. The carrier concentrations even for the purest samples is rather high, $\geq 2 \times 10^{17}$. The fact that there is virtually no carrier freezeout from 300° to 77°K implies that the impurities are coming from shallow donors and we estimate that any deep impurities are contributing $\sim 10^{16}$ donors or less. It is interesting to note that on $(\overline{111})$ oriented samples grown simultaneously along with the (100) samples shown in Table II, n is generally 2-5 times greater. At present, we have made no systematic effort to reduce the carrier concentration.

Double heterostructure.—In order to test the optical quality and potential application for LED's and heterostructure lasers, a lattice-matched $InP/Ga_yIn_{1-y}As/InP$ double heterostructure was grown for optical pumping purposes. It is common practice to grow a buffer layer between the substrate and the active layer. In this case the buffer layer would be InP grown on the InP substrate followed by the $Ga_yIn_{1-y}As$ active layer. We have grown such buffer layers but have found that prior to changeover from InP to GaInAs growth, the small background pressure ($\lesssim 10^{-7}$ Torr) coming from the shuttered As source was sufficient to cause InAsP growth because of the much greater sticking coefficient of As compared to P. In order to avoid this, the InP growth must be terminated prior to the heating of the As source. This requires that the freshly grown InP surface be exposed to the ambient background behind the sample shutter for ~15 min while the As oven is heated and stabilized. For this reason some of the advantages of growing a buffer layer are negated.[3] In the present case, in order to minimize complications in growing, the buffer layer was omitted and the substrate served as one of the cladding layers. Only the $Ga_yIn_{1-y}As$ layer and top InP layer were grown by MBE. The resulting morphology was mirror smooth as seen in Fig. 6. The cross section of the double heterostructure is shown in Fig. 7. The active layer thickness of 1 μm was chosen as a compromise between the maximum optical absorption of the Nd:YAG (1.06 μm) pump and the optimum carrier confinement. The wafer of Fig. 6 was cleaved into bars of various cross sections, typically 400-800 μm spacing between Fabry-Perot faces. A Nd:YAG laser (either cm or Q-switched) was focused normal to the surface of the cleaved bar. The pump light was able to penetrate the InP ($\lambda^{gap} = 9000$Å) cladding layer and optically excite the $Ga_{0.47}In_{0.53}As$ layer. The beam was focused through cylindrical optics and had a cross section of 3 × 0.3 mm. The pumping configuration was such that the 3 mm dimension of the beam lay perpendicular to the Fabry-Perot faces. In this way the beam can be centered on the bar with very uniform excitation along the direction of lasing. At low excitation the pump was operated cw, but at the higher power necessary for lasing, the pump was Q-switched, putting out 0.25 μsec wide pulses at a repetition rate of ~500 Hz. The resulting signal was passed through a ½ m Jarrall-Ash spectrometer, detected with a Ge detector (cooled for cw measurements) and amplified and integrated by a boxcar integrator.

[3] Possibly a better isolated As source, where the background As pressure is $<10^{-8}$ Torr when shuttered, would allow a more rapid changeover (<1 min).

Fig. 6. Lattice-matched, MBE-grown $InP/Ga_{0.47}In_{0.53}As/InP$ double heterostructure. Mirror-smooth InP cladding layer is shown.

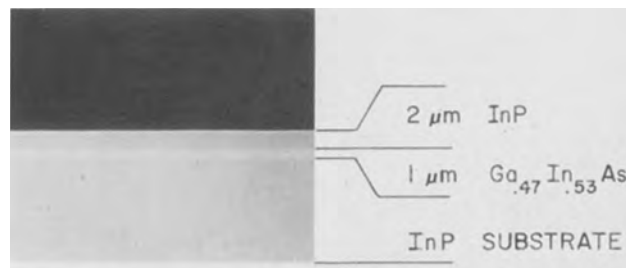

Fig. 7. Cleaved cross section of the lattice-matched $InP/Ga_{0.47}In_{0.53}As/InP$ double heterostructure shown in Fig. 6.

At low cw excitation the resulting photoluminescence of the $Ga_{0.47}In_{0.53}As$ layer at 77°K is as shown in Fig. 8. The peak is at 1.368 μm (0.907 eV) and a

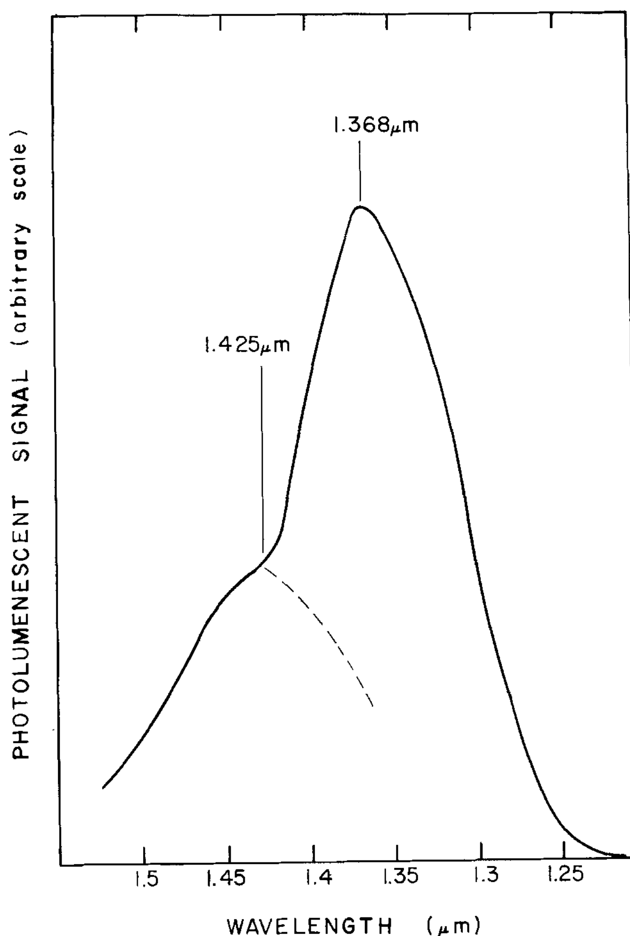

Fig. 8. Photoluminescent spectrum of $Ga_{0.47}In_{0.53}As$ layer of the double heterostructure shown in Fig. 6 and 7. The GaInAs layer was excited through the InP cladding layer by means of a Nd:YAG (1.06 μm wavelength) laser.

shoulder appears at 1.425 μm (0.870 eV). The half-width is rather broad, $\Delta E/E \simeq 0.084$, typical of most of these GaInAs layers. The half-width varies from $\Delta E/E = 0.047$ to $\Delta E/E = 0.15$ and roughly correlates with the carrier concentration of the ternary layer. All samples grown from the single Ga-In source show little spatial variation of the photoluminescence over the epitaxial surface ~1 cm². For comparison, in bulk GaSb ($p \sim 10^{17}$-10^{18}) at 77°K the photoluminescent peak occurs at 1.57 μm and $\Delta E/E = 0.030$. Also the photoluminescent peak height for the $y = 0.46$ epitaxial layer is about the same as for the bulk GaSb. If one assumes a linear relation for E_g *vs.* y in the $Ga_yIn_{1-y}As$ (22) system and takes the bandgaps of GaAs (23) and InAs (24) at 77°K for end points, one gets the relation between alloy composition and badgap that

$$E_g = 0.410 + 1.094y \qquad [2]$$

Assuming the 1.368 μm photoluminescent peak is coming from a band-to-band transition, then from Eq. [2] we derive $y = 0.455$ in agreement with the SEM microprobe which gives $y = 0.45$ for this sample. This fairly close lattice match is also confirmed by the smoothness of the cleaved cross section (Fig. 7) and smooth surface morphology (Fig 6).

A shoulder appears at 1.425 μm in the photoluminescence spectrum of Fig. 8. This represents a level ~40 mV deep. This kind of level is quite common in GaAs at 30 mV (25) and in InP at 40 mV (26), and is usually associated with an acceptor such as Zn.

Under high power pulse conditions at 77°K the double heterostructure bar lases with the spectrum shown in Fig. 9. Three peaks appear at 1.420, 1.428, and at 1.437 μm approximately 85Å apart. It is interesting to note that the lasing peaks coincide with the broad shoulder at 1.425 μm in Fig. 8, corresponding to the 40 meV acceptor level. The widths of the peaks are limited by the resolution of the spectrometer, which in this case is 16Å. The peaks are not exactly evenly spaced nor are they quite symmetrical; the reason for this, we believe, is that the lasing is very unstable due to the inherent instability of the Q-switched Nd:YAG laser and also because of vibrations which displace the beam along the bar causing different areas of the bar to lase in a random fashion. By sitting on the 1.428 μm line we were able to plot the laser power out *vs.* pump power (Fig. 10). Above 6 kW/cm² lasing occurs and the power output rises rapidly. By extrapolating the power output to zero power (dotted line in Fig. 10) we can get a measure of the threshold which in this case is ~6.2 kW/cm². Although it is difficult to compare this threshold directly to a GaAs/AlGaAs DH laser, a typical optically pumped threshold reported in the literature (27) for this system is ~10^4 W/cm² at 300°K. It appears then that this material may hold some promise for LED's and lasers.

Discussion

We have shown that it is possible to grow lattice-matched ternary layers of GaInAs on InP substrates by MBE at substrate temperatures of 510°C. Layers having a high degree of spatial uniformity of composition result from premixing the Ga and In in a single source. The mass analyzer has been successfully used to accurately monitor the Ga/In flux ratio and thereby achieve the desired lattice-matched composition reproducibly. Typically, we are able to grow a

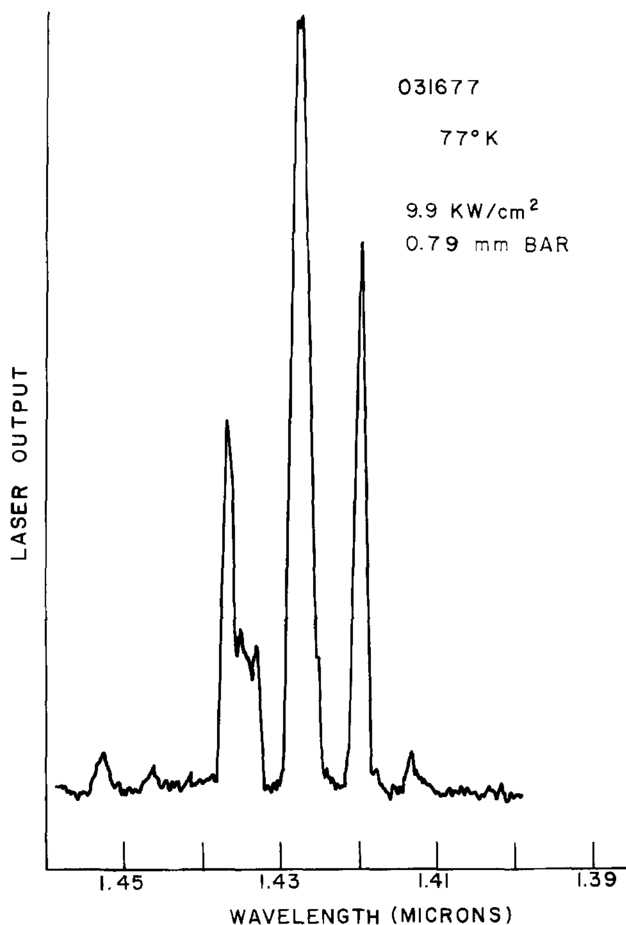

Fig. 9. Lasing spectrum at 77°K of a bar (0.79 mm between cleaved Fabry-Perot faces) cut from the $InP/Ga_{0.47}In_{0.53}As/InP$ double heterostructure of Fig. 6. The high intensity (9.9 kW/cm²) pump power at 1.06 μm was provided by a Q-switched Nd:YAG laser.

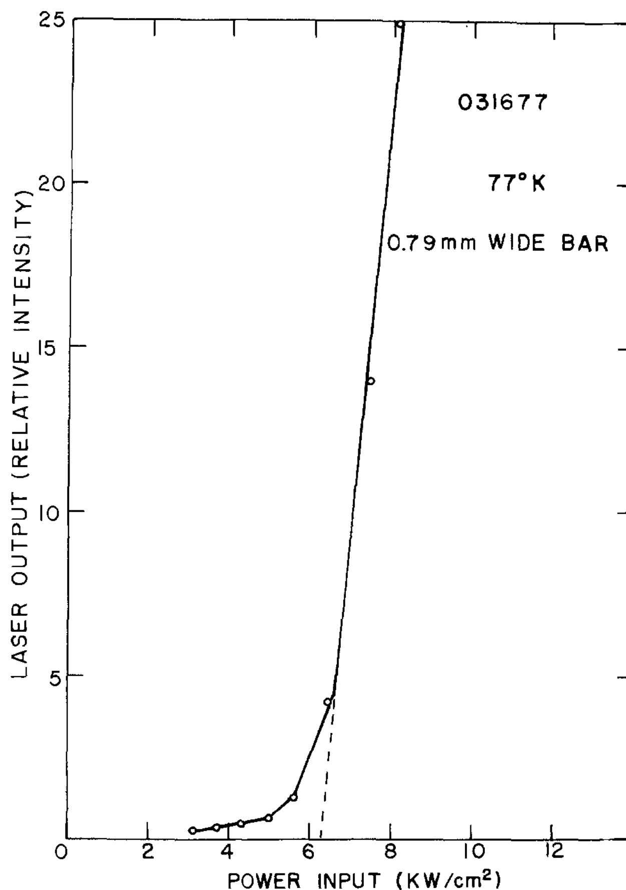

Fig. 10. Laser output power at 1.482 μm wavelength vs. pump power for laser bar of Fig. 9. Extrapolation (dotted line) yields a threshold pump power of 6.2 kW/cm.

$Ga_yIn_{1-y}As$ layer where $y = 0.47 \pm 0.005$. For comparison, the lattice mismatch between $Al_{0.3}Ga_{0.7}As$ and GaAs, the composition most commonly used for laser and LED's, is about 0.04%. Since the lattice constants of GaAs and InAs differ by 7%, a 0.04% mismatch in the $Ga_yIn_{1-y}As/InP$ system implies that $y = 0.47 \pm 0.006$. Thus we are able to obtain the same degree of lattice-match as is commonly achieved in the AlGaAs/GaAs system.

We have also demonstrated the dependence of the morphology of the $Ga_yIn_{1-y}As$ epitaxial layers on deviations from the lattice-matched composition. For example (100) layers for which $y = 0.41$ and $y = 0.50$ are covered with the crosshatching known to be associated with arrays of misfit dislocations. Furthermore, those layers having $y > 0.47$ are under tensile stress because their lattice constants are smaller than that of the InP substrate, and these layers tend to be discontinuous or develop cracks. When $y < 0.47$, the epitaxial layers are under compression and do not exhibit these deleterious effects. For these reasons it is desirable to aim for the In-rich side of the lattice-matched composition, *i.e.*, $y = 0.46$-0.47.

Except for those layers which exhibited cracking or discontinuous morphology, the electrical properties (carrier concentration and mobility) showed little correlation with composition y. The high carrier concentration ($n > 10^{17}$ cm^{-3}) found in our unintentionally doped GaInAs layers is due to the presence of shallow donors which probably come from contaminants in the Ga-In source. Prolonged degassing of this source might be beneficial in this respect; a prolonged bake-out of the In source oven in the case of MBE-grown InP resulted in decreasing the carrier concentration of the unintentionally doped layer from $n \sim 3 \times 10^{16}$ cm^{-3} to $n \sim 5 \times 10^{15}$ cm^{-3}, and increasing the mobility from $\mu_{77} \sim 8000$ to $\mu_{77} \sim 20,000$ cm^2/Vsec.

Double heterostructures were made by growing a cladding layer of InP on top of the lattice-matched GaInAs epitaxial layer. Such a structure was optically pumped and found to lase at a pump level of 6.2 kW/cm^2. This threshold pump power is comparable to that reported for AlGaAs/GaAs DH lasers. Thus our InP/GaInAs/InP double heterostructure appears to be a promising candidate for long-wavelength LED's or injection lasers. Work toward this goal is in progress.

Acknowledgments

We gratefully acknowledge the encouragement and support of P. K. Tien. We wish to thank R. J. Martin for fabrication of the DH lasers and for expert technical assistance, Steven Forman for analysis of the photoluminescence data and for Hall and resistivity measurements on the epitaxial layers, and E. Buehler for providing the InP substrate material used in this work.

Note added in proof.—We now know that our photoluminescent spectra were significantly shifted toward shorter wavelengths by band filling (Burstein Shift). This effect is enhanced in GaInAs, as compared to GaAs, because of a smaller electron-effective mass. Thus our carrier concentration, $n \sim 10^{18}$ cm^{-3}, gives considerable band filling. As a result, our attempts to relate the peak position of the GaInAs photoluminescent spectra to film composition are not valid.

Evaluation of S- and Se-Implanted GaAs by Contactless Mobility Measurement

B. Molnar* and T. A. Kennedy

Naval Research Laboratory, Washington, D.C. 20375

ABSTRACT

Implantation of S and Se into GaAs has been studied with a novel contactless mobility measurement. The method, in which the mobility is obtained from a microwave measurement of the conducting layer's magnetoconductivity, is described in detail. Comparisons with Hall mobility are provided. Evaluation of different GaAs substrate material is described. A wide range of implantation and annealing conditions for S and Se in GaAs have been explored. S implantation of $5 \times 10^{12}/cm^2$ with a 850°C, 20 min anneal is found to produce FET quality layers.

As ion-implanted GaAs FET's (1-3) approach the quality of those made by epitaxial growth, ion implantation is being used more to produce semiconductor devices. The implantation-processing steps must be optimized and tightly controlled in order to produce uniform, high quality layers. In order to assure the quality of particular processing steps, layer characterization must be carried out. In the present work, a new characterization technique (4, 5) has been used to study the implantation of S and Se into GaAs.

Since carrier mobility directly affects FET transconductance and high frequency cutoff, a mobility measurement provides a relevant characterization. The traditional resistivity and Hall method provides two parameters, the sheet resistivity and the Hall mobility, but the measurement requires alloyed contacts. Problems associated with contacts have led to investigation of various noncontacting (6-8) methods. In the present work, the implanted layer mobility is obtained from a microwave measurement of the magnetoconductivity. Since contacts are not necessary, the method is rapid and nondestructive.

Employing the mobility characterization, a variety of GaAs implantation parameters have been evaluated. Choice of qualified substrates and Se implantation have been examined. A full study of dose and annealing for S implantation has been carried out and recommendations are provided for optimization of the parameters.

Experimental

Mobility determination.—The microwave mobility measurement was made in an 11 GHz reflection microwave spectrometer employing an IMPATT diode source (see Fig. 1). The samples were placed a quarter wavelength from the short. The microwave power reflected from the shorted waveguide section is monitored and recorded on the y axis of an X-Y recorder. The d-c magnetic field was provided by the NRL 14 Tesla Bitter solenoids with the x axis derived from the magnetic field. The orientations of the magnetic field and the microwave E field with respect to the sample are shown in the insert in Fig. 1.

The results of the microwave measurement, the reflected microwave power as a function of magnetic field B for thin n-type layers on semi-insulating GaAs, are shown in Fig. 2. The change in detected power for each sample relative to the empty waveguide was small. When the sample produces only a small perturbation on the fields in the waveguide, the detector output is linearly proportional to the free-carrier power absorption. The free-carrier power absorption is directly proportional to σV, where σ is the semiconductor conductivity and V is the volume. In two-layer structures the conductivities add linearly. However, in the semi-insulating substrate, the conductivity is negligible. Therefore, the measurement represents only the contribution of the conductive n-type layers. One condition, however, must be satisfied. The skin depth at the operating frequency has to be large compared to

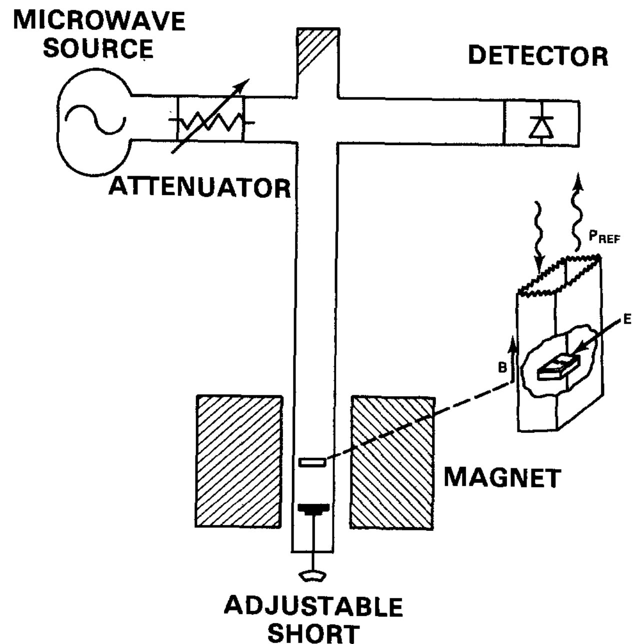

Fig. 1. Diagram of the microwave mobility-measurement apparatus

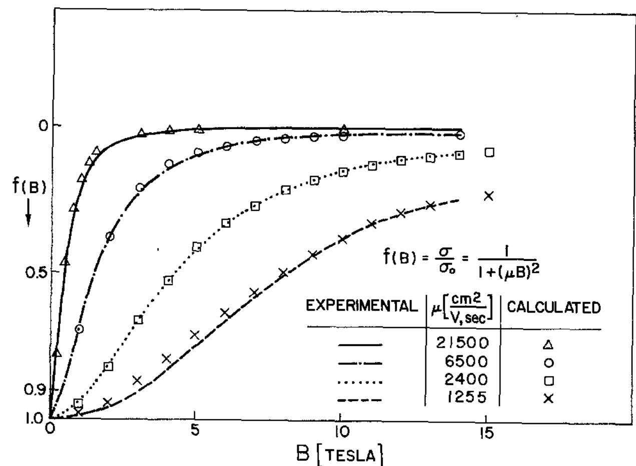

Fig. 2. The magnetic field-dependent part of the reflected power for four thin n-type layers on semi-insulating GaAs. The curves are normalized for comparison to the theoretical expression $f(B) = 1/[1 + (\mu B)^2]$.

Key words: semiconductor, microwave, GaAs substrate.

the thickness of the layers. This condition is always satisfied in implanted layers for FET's.

The mobility of the free electrons is determined from the magnetic field B dependence of the conductivity σ. Since the frequency-scattering time product, $\omega\tau$, is much less than one at 11 GHz, the simple Drude theory conductivity in a magnetic field B can be approximated by the expression

$$\sigma(B) = \frac{\sigma(0)}{1 + \Omega^2\tau^2} \qquad \Omega = \frac{eB}{m^*}$$

where $\sigma(0)$ is the zero magnetic field conductivity, m^* is the effective mass, e is the magnitude of the electronic charge, and Ω is the Larmor frequency. Note that (in MKS units) $\Omega\tau = \mu B$ where μ is the electron mobility. The Drude theory describes the change of conductivity with $\sigma(B)/\sigma(0)$ equal to 1/2 when the mobility times magnetic field B is equal to 1. The inverse of B at the half-power point, therefore, gives the mobility of the free carriers. The microwave mobility values in Fig. 2 have been determined in the way described above. The experimental curves are well described by the simple $1/[1 + (\mu B)^2]$ formula. Some deviation, however, is present for the low mobility case. At low mobilities, the asymptotic value determination, and therefore, the half-power point determination, is hindered by the available magnetic field. The 14 Tesla magnet limits this technique to mobilities greater than 1000 cm^2/Vsec.

While it is not necessary to know the exact relationship between the microwave mobility and the Hall mobility in order to use the microwave measurements for studying processing parameters, the relationship must be known in order to compare our results with the Hall mobilities reported by other workers. Therefore, experimental comparisons of the microwave and the Hall mobilities on two sets of samples have been made. For one set, the GaAs samples were subjected to identical implantation and annealing treatments. The Hall mobility and the microwave mobility were measured for each sample. The reproducibility on a single sample of either mobility measurement is about 2.5%. The average microwave mobility is 20% smaller than the average Hall mobility with standard deviations for each around 13%.

A comparison between the Hall mobility and the microwave mobility on some thin epitaxially grown layers with a wide range of doping levels is shown in Fig. 3. The doping concentration of the n-type layers varied between $1 \times 10^{14}/cm^3$ and $1 \times 10^{17}/cm^3$ and the thickness varied between 0.2 and 10.0 μm. For convenient reference, the Hall mobility as a function of impurity concentration in n-type GaAs from Sze and Irvin (9) is also shown. The microwave mobility follows the same type of concentration dependence as the

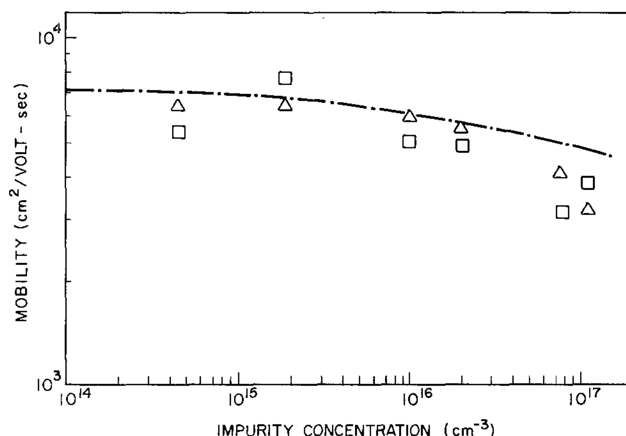

Fig. 3. The mobilities of a set of epitaxial layers on GaAs as measured by microwave (△) and Hall (□) measurement at 300°K *vs.* impurity concentration. The curve is the bulk mobility *vs.* concentration for GaAs (9).

Hall mobility. However, differences of up to 20% are found. Differences between the two mobilities arise from differences in the effect of low and high magnetic fields on the important electronic scattering processes, effects of sample geometry, and effects of sample inhomogeneities, such as doping gradients. Thus, relating the microwave mobility to the Hall mobility by a simply proportionality factor is only possible under tightly controlled conditions. In most cases, the mobilities measured by the two methods are fairly close.

Implantation procedure.—GaAs slices with (100) surfaces were cut from different, often Cr-doped, semi-insulating ingots. The wafers were chemical-mechanically polished. Each wafer was cleaved into several 5×5 mm^2 samples, which were etched in 5 H_2SO_4:1 H_2O_2:1 H_2O solution. Immediately after etching the samples were implanted with S^+ or Se^+ ions. The implanted samples were then coated with approximately 1500Å of Si_3N_4 using either plasma or reactive-sputtering deposition and annealed between 600° and 900°C in forming gas. The implantation process produced a submicron thick n-type layer on a 0.3-0.5 mm semi-insulating GaAs substrate. After annealing the microwave mobilities were determined either with or without the Si_3N_4 encapsulating layers.

Results

The microwave mobility has been used as a control parameter for the evaluation of the influence of substrate, implantation, and annealing conditions on GaAs FET-type n-channel layers.

The influence of the semi-insulating substrate on the implanted layer mobilities is shown in Table 1. Three different Cr-doped semi-insulating ingots were tested. The wafers were implanted at room temperature with $1 \times 10^{13}/cm^2$ 120 keV S^+ ions, and were annealed at 900°C for 60 min with a Si_3N_4 cap. Since all conditions except the starting wafers were identical, the large difference in the microwave mobilities originates from the different semi-insulating substrates.

A complete understanding of the influence of the starting semi-insulating GaAs substrate on the sulfur implantation has not yet been achieved. Eisen (10) observed little variation in the carrier concentration and mobility when he used different semi-insulating GaAs substrates. On the other hand, Stolte (11) did find significant substrate dependence. Kellner (3) has shown that the electrical activation of sulfur depends critically on the substrate material. Lower mobility may indicate an excessive carrier concentration which might come from the pile-up of the implanted sulfur at the surface during annealing (12). When processing is identical, the critical factor controlling the sulfur redistribution should be related to the presence of residual impurities in the GaAs substrates. Stolte (11) correlated the excess carriers with the amount of Cr and Si found in the substrates. The result of a high resolution chemical spectroscopy on our starting material is also shown in Table I. As in the case of Stolte, the decreased mobilities correlate with increased concentrations of Si and Cr.

The microwave mobility has been used for examination of the influence of other implantation-processing steps, such as the dose level, ion type, annealing time, and annealing temperature. As an example of these experiments, the influence of the annealing tempera-

Table I. Mobilities of S-implanted layers on different semi-insulating GaAs substrates

Mg	0.008	0.014	0.04
Cu	0.004	0.02	0.03

Table II. The influence of annealing temperature on the mobility of sulfur-implanted layers

Annealing temperature (°C)	620	700	800	900
Microwave mobility (cm^2/Vsec)	3100	3400	3800	4000

ture on S-implanted layers is shown in Table II. Mobilities less than those shown in Table II were found when samples were annealed at less than 600°C. The mobility increases with temperature up to 900°C.

These observed microwave mobilities represent good values for implants in Cr doped semi-insulating substrates. Such substrate material contains up to $5 \times 10^{15}/cm^3$ Cr atoms as well as around $10^{16}/cm^3$ oxygen and carbon atoms (13). Therefore, it is not surprising that the mobilities are not greater than 4000 cm^2/Vsec. The mobility *vs.* annealing temperature on sulfur-implanted MESFET structures has previously been examined (3) by van der Pauw measurements. The present findings are in agreement with their results. For short anneals, one expects the mobility to increase with annealing temperature, indicating that the damage is being removed. Such behavior has been observed by Sanbury (14), who examined the isochronal annealing behavior of n-type dopant of GaAs. He found that the 600°C anneal greatly increased both the mobility and the carrier concentration and that both increase slowly above 600°C.

The diffusion which occurs during the high temperature anneal must also be considered. Thus, the influence of the annealing time was studied. At 800°C, by increasing the annealing time from 20 to 120 min, the mobility increased from 3800 to 4200 cm^2/Vsec. The diffusion of sulfur leads to a decreased carrier concentration level which could account for the increased mobility found at longer anneal time. Such diffusion of the implanted sulfur has contributed to the high mobilities on sulfur-implanted Gunn devices (15). However, as far as FET devices are concerned, the doping level and the layer thickness cannot be allowed to change by diffusion.

The microwave mobility *vs.* Se concentration is illustrated in Fig. 4. Double implantation has been used in order to achieve a flat selenium concentration. The implantations were carried out at 260°C with 480 and 160 keV Se^+ ions with fluences necessary to achieve the indicated concentrations. The samples were capped

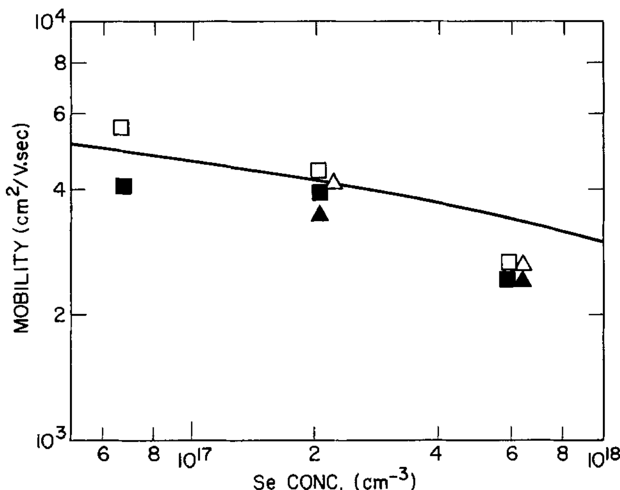

Fig. 4. The microwave mobilities for different concentrations on implanted Se. The triangle and square signs indicate two starting materials. The solid points were obtained at 300°K, while the unfilled points were measured at 77°K. The curve is the bulk mobility (9).

with Si_3N_4 and were annealed at 800°C for 30 min. The two different semi-insulating substrates introduced only slight differences. We see that the implanted samples' microwave mobilities compare favorably with Sze-Irvin (9) Hall mobilities except at higher carrier concentrations. But such an effect is in line with the increased compensation from radiation damage, which should be present at increased doses. Note also that the presence of compensation is more pronounced at 77°K where the impurity scattering is dominant.

Conclusions

We have shown that the microwave mobility is a valuable parameter for rapid, contactless evaluation and control of many implantation processing steps. Evaluation of starting wafers has been described. Optimization of the processing parameters for sulfur-implanted layers for FET's structures leads to the conclusion that at around $5 \times 10^{12}/cm^2$ dose level an anneal at 850°C for about 20 min is optimal. Different encapsulation procedures, which are observed to affect the mobility, are now under investigation using the contactless mobility technique.

ABSTRACT

Arrays of nozzles of uniform size ($\simeq 25 \times 25\ \mu m^2$) and spacing ($\simeq$0.3 mm) suitable for high quality and high speed ink-jet printing have been fabricated by the anisotropic etching of holes through (100) Si wafers using conventional Si-processing techniques. The etchant used is a mixture of pyrocatechol, ethylene diamine, and water. The nozzles are well-defined truncated, square pyramidal cavities bounded by 4 convergent {111} planes. The square orifice, side W_O, is given by $W_O = W_B - \sqrt{2}\, t_{Si}$, where W_B is the side of the square base and t_{Si} the wafer thickness. Successful fabrication of these silicon microstructures requires the application of well-controlled patterning and etching processes and the selection of a uniform, defect-free, accurately oriented single crystal substrate.

Arrays of nozzles of uniform size and spacing are required to generate drops of ink with uniform characteristics for high speed and high resolution ink-jet printing using binary, deflected, electrostatically charged ink jets (1-5). In ink-jet printing, fine jets of conductive ink are formed by forcing the pressurized ink through an array of nozzles; the jets break up into uniform streams of droplets by vibrating the nozzle array at a fixed frequency by means of a piezoelectric transducer. In one method of printing, unwanted drops are selectively charged and deflected electrostatically from the main streams, and the uncharged drops are allowed to strike the paper to form the required characters (1, 6).

Arrays of nozzles with square orifices of potential usefulness in ink-jet printing have been fabricated by etching holes through single crystal silicon wafers of (100) orientation (4-5, 7) using an anisotropic (crystallographically preferential) etching solution containing pyrocatechol, ethylene diamine, and water

(8-12). Each nozzle in the array is a truncated square pyramidal cavity bounded by 4 convergent {111} planes and 2 {100} surface planes as shown in Fig. 1. The high degree of symmetry exhibited by these three-dimensional microstructures results from the crystallographic perfection of the starting wafer and the well-controlled, high etch rate of the {100} planes relative to the {111} planes.

The size and shape of the holes etched in single crystal Si depend on the geometry and orientation of the openings in the surface masking film, *e.g.*, SiO_2, the duration of etching, and the wafer thickness. As shown in Fig. 1, a small opening forms a cavity with a rectangular base hole on the Si surface which encloses the original opening in the SiO_2 film. The sides of the rectangle represent the intersections of the {111} planes with the (100) surface plane and are parallel to the <110> direction. Because the etch rate of {111} planes is very low, cavities and nozzles bounded only by exposed {111} planes are self-limiting and thus do not change significantly in size or shape even after prolonged etching.

In a perfect crystal the angle between the {111} planes and the (100) surface is 54.74° (Fig. 1). Assuming no misorientation of the Si wafer, the side dimen-

Fig. 3. SEM photomicrograph of an 8 nozzle array etched in silicon. The array is 0.25 cm long, the base hole 290 × 290 μm^2, the orifice 28 × 28 μm^2, wafer thickness 185 μm, and the center-to-center spacing is 305 μm.

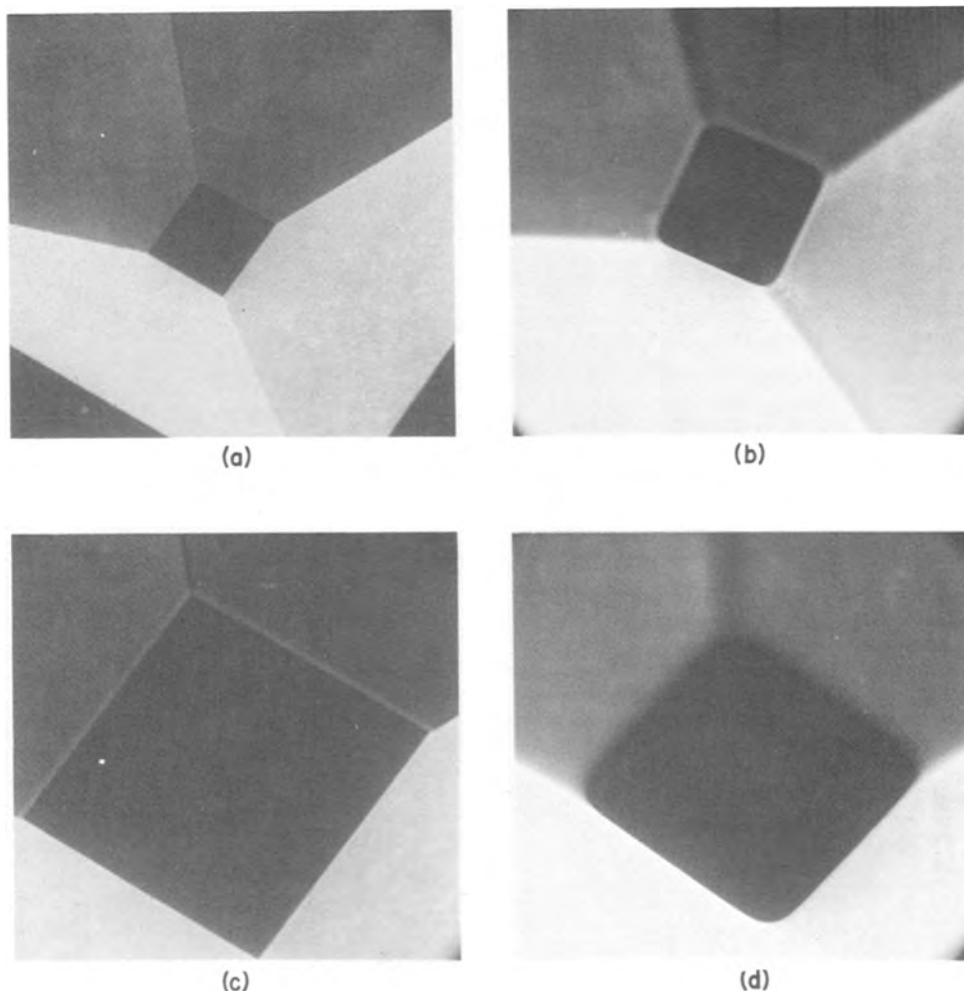

Fig. 4. SEM photomicrographs of uncoated Si nozzle orifices 30 × 30 μm^2. The knife edge corners of the orifice in (a) and (c) can be rounded by successive thermal oxidation and stripping. Rounding shown in (b) and (d) is obtained after growing 5 μm SiO_2.

sion W_O of the square orifice which results after etching through a wafer of thickness t_{Si} is given by the expression $W_O = W_B - \sqrt{2}\, t_{Si}$, where W_B is the side of the square-base hole etched in the Si surface. The processing conditions and the results obtained in fabricating uniform nozzle arrays in (100) Si are described below.

Experimental

The fabrication of Si nozzle arrays is carried out using conventional Si-processing techniques. The sequence of steps in the process are shown in Fig. 2. Czochralski-grown, p- or n-type Si wafers 32 mm diam, 200 μm thick, (100) orientation, chem-mechanically polished on both sides are cleaned in ammonia peroxide and acid peroxide solutions, then thermally oxidized in steam to form an SiO_2 film 0.5 μm thick. Photoresist is applied to both surfaces of the wafers and using standard photolithographic methods, arrays of square openings are defined and etched in the SiO_2 film on one side of the wafers. The wafers are then etched in an aqueous solution containing 4 mole percent (m/o) pyrocatechol $C_6H_4(OH)_2$, (P), 46.4 m/o ethylene diamine $NH_2(CH_2)_2NH_2$ (ED), and 49.6 m/o water. The P-ED solution is used at its boiling point 118° ± 1°C in a quartz flask fitted with a condenser to maintain the composition constant and N_2 gas is bubbled through the solution to prevent it from oxidation. The total etching time required is 3-4 hr based on an average etching rate of ~50 μm/hr on the (100) plane. Etching is stopped when orifices appear on the opposite side of the wafers. After cleaning, the oxide is etched off, and the wafers are oxidized in steam to form a uniform coating of thermal SiO_2 on the nozzle surfaces.

Results and Discussion

Arrays of silicon nozzles possessing uniform physical characteristics suitable for ink-jet printing were fabricated reproducibly by the above procedure. An array of 8 identical nozzles with square orifices ~ 25 × 25 μm^2 on 0.3 mm centers and with smooth well-defined defect-free surfaces is shown in Fig. 3. Structural symmetry and uniformity as well as the absence of visible defects in the nozzles are necessary requirements for high quality printing at high speed. Surface irregularities or contaminants and variations in orifice dimensions alter the flow characteristics of the streams of droplets generated across an array, resulting in a degradation of printing performance (4). The tapered geometry of each nozzle is a useful feature which permits by means of a simple microscopic examination to determine the suitability of an array of nozzles for printing purposes. Due to the brittle properties of single crystal silicon and the small size of the orifices, the nozzles are subject to chipping and clogging if they are poorly handled. By treating these structures in the same way as microelectronic devices they can be processed and tested with relative ease. Ink-jet printing experiments are performed by mounting an array of nozzles on a printhead, forcing ink under pressure (~2 atm) through each nozzle, and simultaneously vibrating the printhead at high frequency (~100 kHz) by means of a piezoelectric crystal. To protect the silicon from attack by the corrosive inks a layer of SiO_2 ~1 μm thick is thermally grown on the nozzles. The square orifice has sharp knife-edge corners and edges which are susceptible to structural damage from stress concentrations resulting from the induced oscillations and the pressurized ink in the printhead. To overcome this potential problem, rounding of the orifice corners and edges was attempted by a technique which uses repeated thermal oxidation and oxide-stripping cycles. In each cycle a thickness of silicon is removed equivalent to ~44% of the thermally grown SiO_2 thickness. Since thermal oxidation is a surface diffusion process, rounding of corners and edges occurs symmetrically and uniformly in each nozzle across an array. Figure 4 shows the rounding obtained after growing a

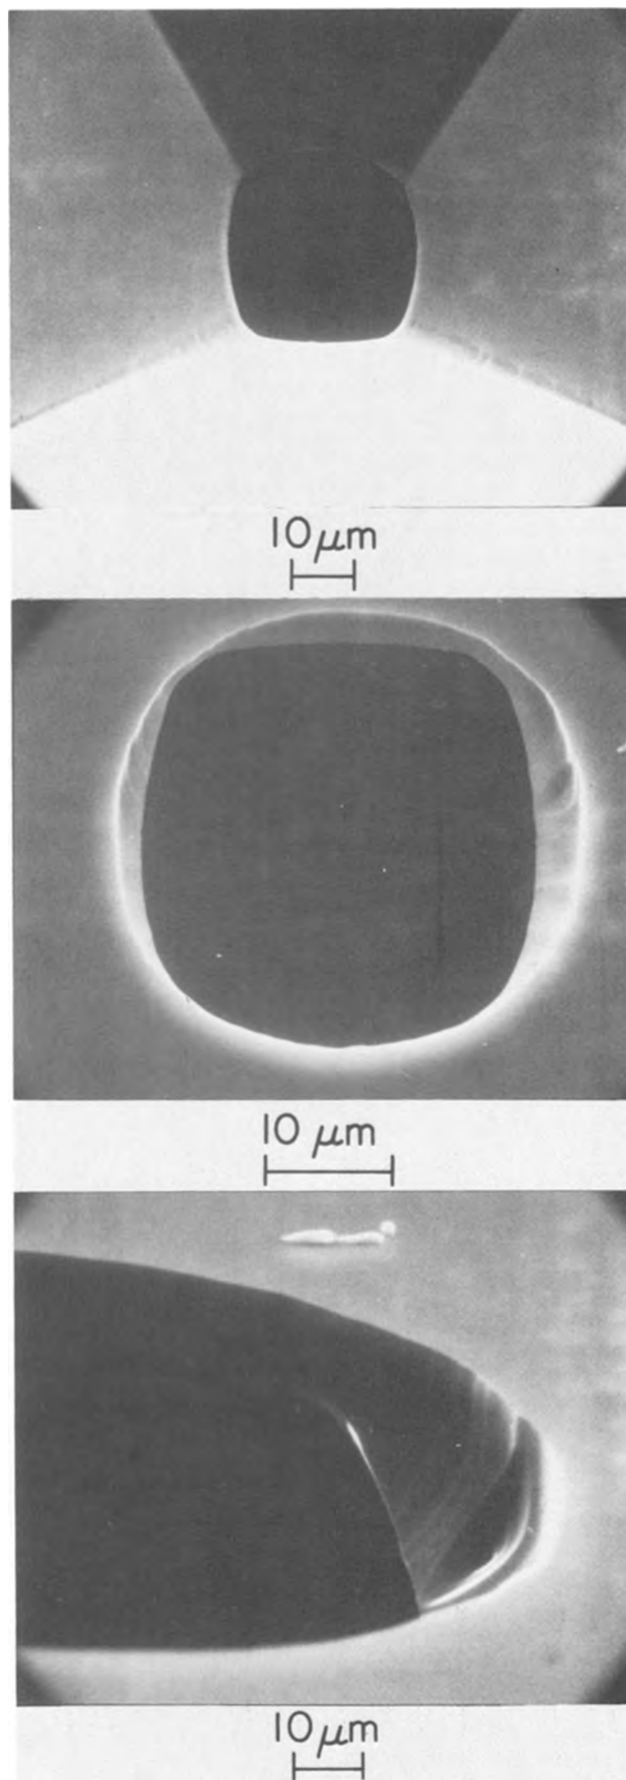

Fig. 5. SEM photomicrographs of an uncoated Si nozzle which was rounded by etching ~ 5 μm Si in a mixture of HF, HNO_3, and HAc. (Upper) nozzle viewed from the base hole side: (middle) nozzle viewed from the orifice side; (lower) edge of orifice showing nonsymmetrical etching.

total of 5 μm thermal SiO_2 in steam at 1000°C in 5 successive oxidation and stripping cycles. This technique causes orifice dimensions to increase incrementally with each cycle and therefore allows orifice area to be controlled with a high degree of precision. An etching method for rounding nozzles using a mixture of HF, HNO_3 and acetic acid was also attempted. This method yielded a geometry which was not as symmetrical and uniform as the oxidation and stripping technique. Figure 5 shows SEM photomicrographs of a nozzle which was rounded by etching ~5 μm of Si from the (100) Si surface. The lack of symmetry is mostly due to the differential etch rate of the various Si planes exposed to the etchant and to the nonuniform flow of etchant through the nozzles during the etching process. Under similar operating conditions, the performance of square and rounded nozzles is identical provided the orifice areas are equal (4).

The successful fabrication of arrays of nozzles with predictable dimensions is accomplished by selecting an appropriate substrate, defining and aligning the array pattern accurately on the wafer surface, and controlling the anisotropic etching conditions. Orifice dimensions are determined by the size of the base hole W_B and wafer thickness only. In practice, the required base hole for a wafer of a given thickness is obtained by controlling the underetching U of the cavity formed in the Si surface (Fig. 6). This is a critical factor in the fabrication of microstructures which require prolonged etching in anisotropic etchants. The underetching shown in Fig. 6, given by $U = R_{(111)}t/\sin\theta$ where $R_{(111)}$ is the etch rate of the {111} planes and t the etching time, is the minimum which can be achieved under ideal processing conditions. Factors which contribute to variations in underetching and hence to variations in orifice dimensions are discussed below.

Substrate.—The orientation of the {100} surface planes and the <110> flat are critical and should be accurate within ± 1° in order to control the symmetry, size, and relative alignment of the arrays of nozzles. Wafer orientation, though critical, is seldom a problem in practice because a precision $\leq \pm 1°$ is routinely obtained in commercially available wafers. The variation in wafer thickness (t_{Si}) affects orifice size uniformity for the same base hole dimensions. A change Δt_{Si} across an array results in $\sqrt{2}\,\Delta t_{Si}$ variation in the orifice side dimension W_O (Fig. 1). Defects originating at the Si surfaces, due, for example, to poor polishing or cleaning, induce pinholes in the surface masking film (SiO_2) which result in characteristic square etch pits in the Si surface. These defects are distinguishable from process-induced defects in the SiO_2 by the formation of both square and rectangular etch pits in the Si surface as shown in Fig. 7. Any small defect at the Si-SiO_2 interface located on the perimeter of the etched-base hole causes enlargement or merging of adjacent holes (Fig. 7).

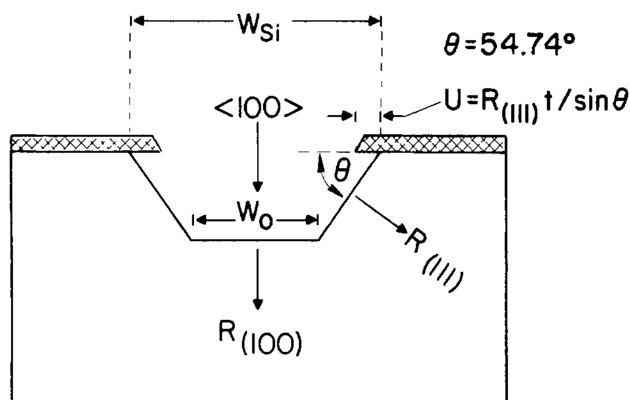

Fig. 6. Nozzle dimensions are critically dependent on control of the underetching U below the edge of the surface etch mask. Under ideal conditions $U = R_{(111)}\ t/\sin\theta$, where $R_{(111)}$ is the etch rate of the {111} planes, and t the etching time.

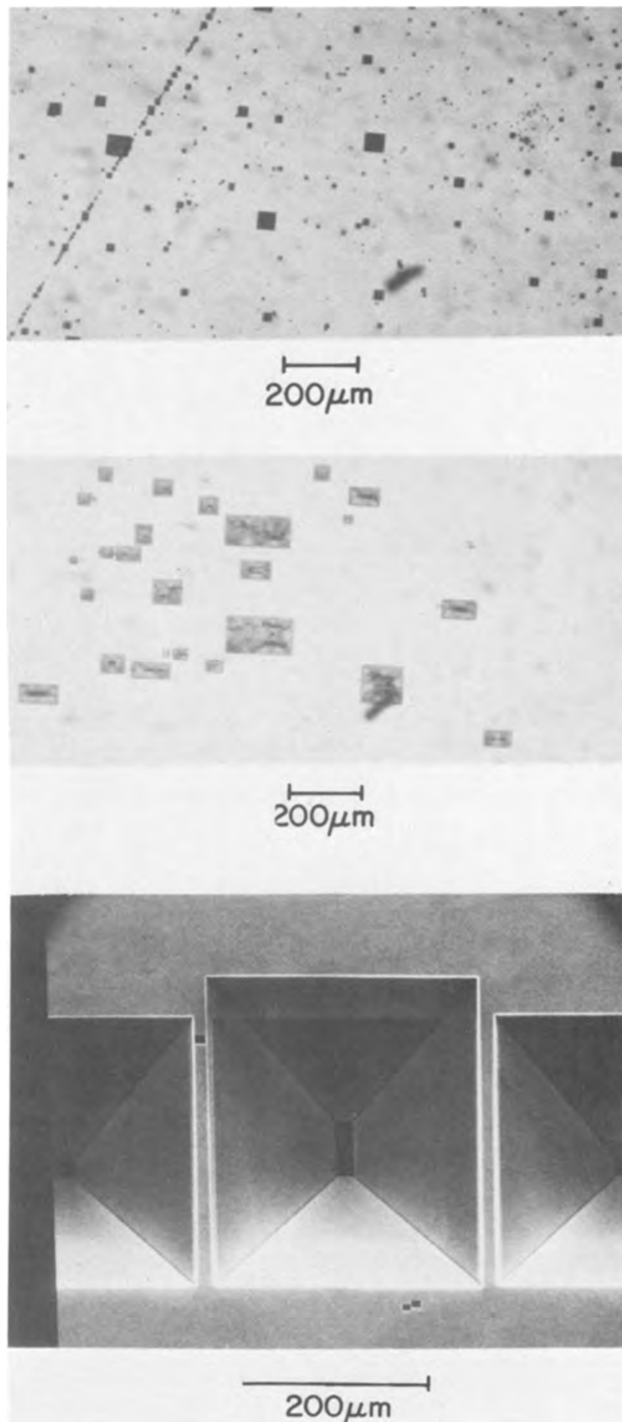

Fig. 7. Characteristic square and rectangular etch pits on Si surfaces after anisotropic etching in pyrocatechol-ethylene diamine-water mixture using thermal SiO_2 as the surface etch mask. Upper photomicrograph: square etch pits result from pinholes in the SiO_2 induced by defects in the Si surface. Middle photomicrograph: rectangular etch pits result from process-induced defects in the SiO_2. Lower SEM photomicrograph: defect on the perimeter of the base hole leads to an enlargement of the nozzle.

Pattern definition.—A square opening, side W, in the surface masking film produces minimum underetching if it is precisely aligned parallel to the <110> direction (Fig. 1). A misalignment $\theta°$ results in an increase to $W' = W(\sin\theta + \cos\theta)$ which reaches a maximum at $\theta = 45°$ as shown in Fig. 8.

Small circular openings in the SiO_2 surface film form octagonal base holes which eventually became a square pyramidal cavities after prolonged anisotropic etching of the substrate. A circular opening and an ac-

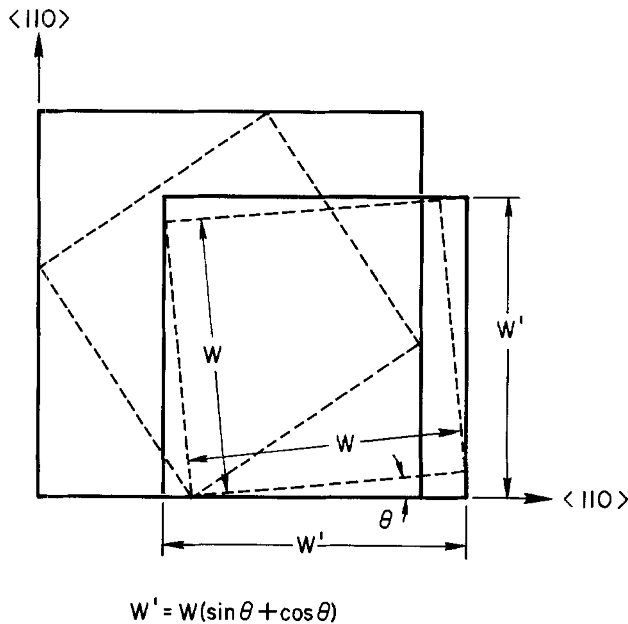

Fig. 8. The size of an etched hole (solid lines) increases in proportion to the misalignment of the original square opening (dashed lines) in the surface-masking film and reaches a maximum at $\theta = 45°$.

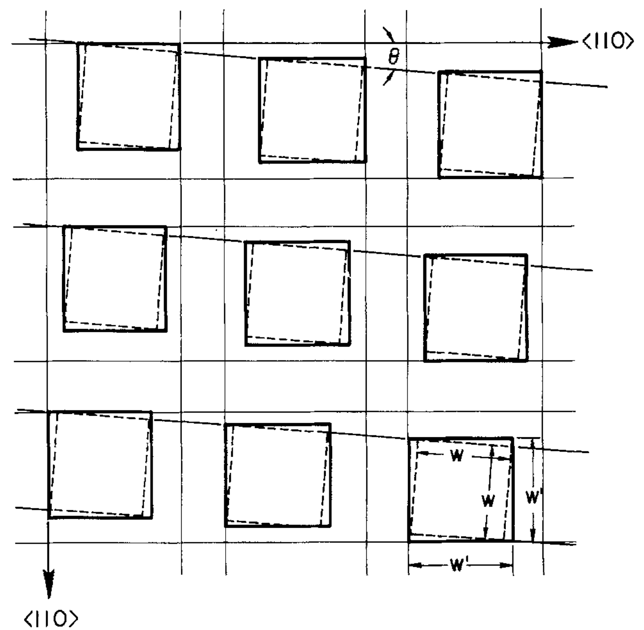

Fig. 10. Staggered square-etched holes (solid lines) resulting from a misalignment of an array of square openings (dashed lines) along the vertical and horizontal [110] directions.

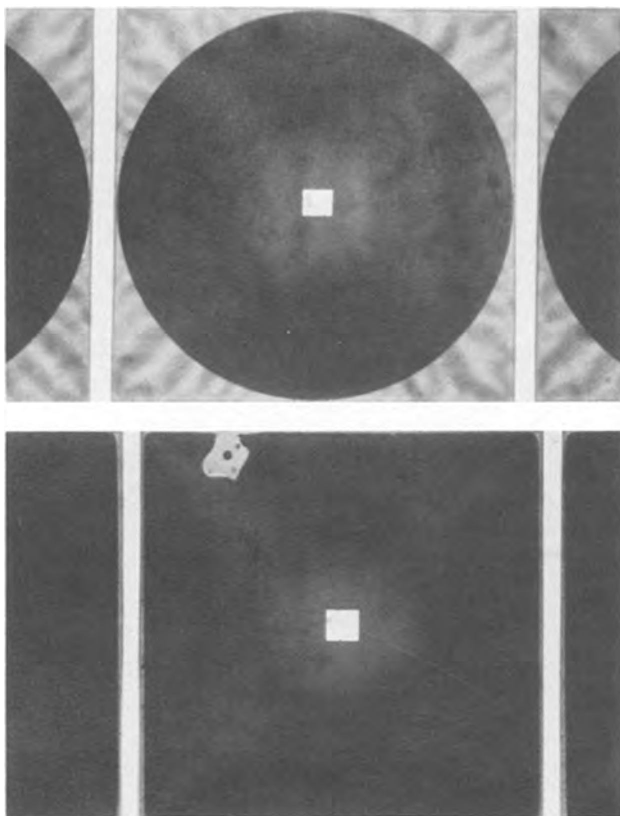

Fig. 9. Photomicrographs of nozzles formed in (100) Si by etching through circular and square openings in the surface-masking film (SiO_2). The nozzles are identical if the side of the square is accurately aligned ond equal to the diameter of the circular opening.

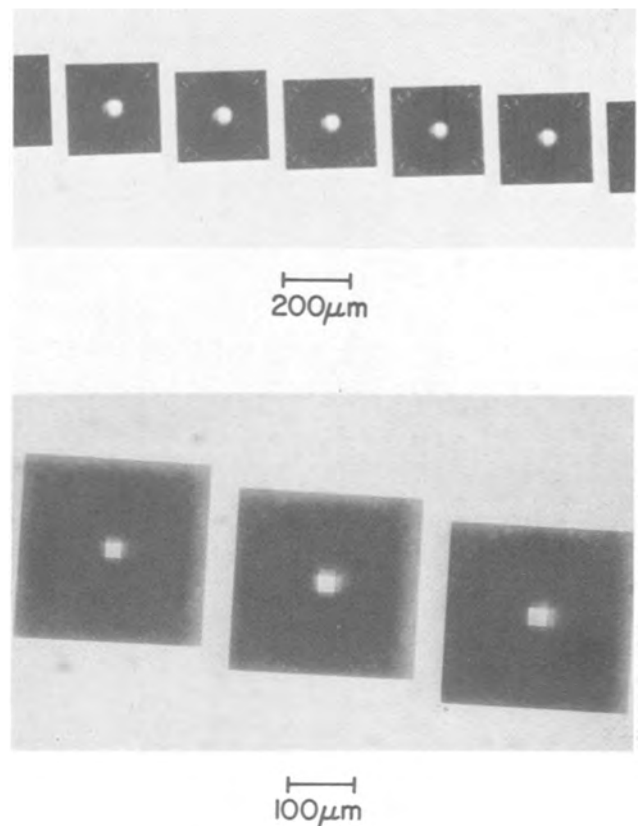

Fig. 11. Photomicrographs of a single array of nozzles etched through an Si wafer showing the staggered orifices resulting from misalignment of the array relative to the <110> direction.

curately aligned square opening form identical nozzles when the side of the square and the diameter of the circle are equal (Fig. 9). Small openings of any geometry form nozzles which are staggered in the vertical and horizontal directions if the arrays are not accurately aligned parallel to the <110> direction (Fig. 10 and 11).

Anisotropic etching.—Solutions of KOH (13-17), P-ED (8-12), and hydrazine N_2H_4 (18-20) are commonly used anisotropic etchants for single crystal silicon. Of the 3 etchants, KOH is the most stable and the most convenient to use; however, it attacks SiO_2 at a rapid rate especially at defect sites, and thus SiO_2 films cannot be used as etch masks in the fabrication of Si

devices which require prolonged etching in KOH. Despite the fact that other masking films could be used with KOH, *e.g.*, Au, they are not as practical as thermally grown SiO_2 films for the fabrication of precision nozzles. P-ED and N_2H_4 solutions attack SiO_2 at a very low and comparable etch rate, but N_2H_4 tends to etch (100) Si nonuniformly by forming pyramidal-shaped crystalline hillocks (13-15) on {100} surfaces in deeply etched cavities. Hillock formation also occurs with the P-ED etch composition used by Finne and Klein (8), particularly at temperatures below 110°C. In a solution containing 4 m/o (P), 46.4 m/o (ED), and 49.6 m/o water, used at its boiling point 118° ± 1°C, hillock formation is inhibited and (100) Si is etched at a high, uniform, and reproducible etch rate

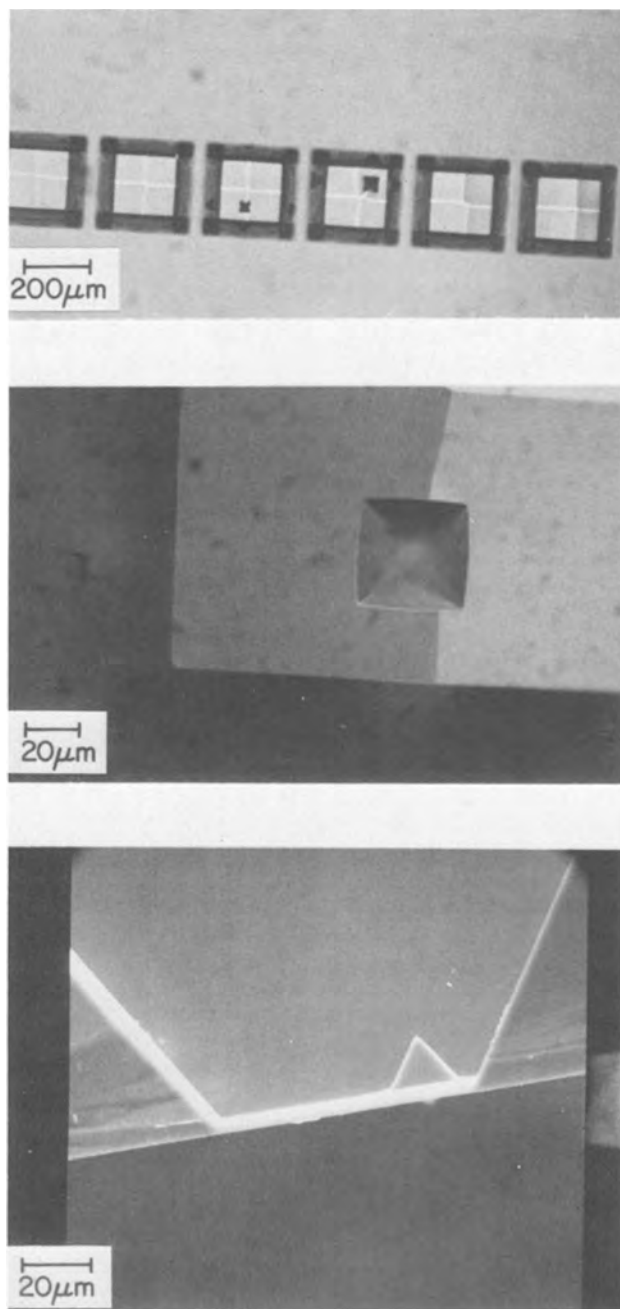

Fig. 12. Pyramidal-shaped crystalline hillocks formed on anisotropically etched {100} surfaces. Upper, array etched 30 μm deep, showing single hillocks in 2 holes; middle, magnified image of a single hillock; lower, SEM photomicrograph of a cross section through a partially etched nozzle with a hillock on the (100) plane. The hillock is a mesa with side walls parallel to the convergent {111} crystal planes of the nozzle.

with an anisotropic etch rate ratio $R_{(100)}/R_{(111)} = 50/1$. Solutions containing higher concentrations of (ED) at 110°-118°C are equally effective in preventing hillocks on {100} surfaces. Hillocks are structures bounded by 4 {111} planes (Fig. 12) which etch very slowly in P-ED and often cause a partial or total blockage of nozzles during the fabrication process (Fig. 13). The hillocks tend to form readily on poorly cleaned surfaces and in etchants containing excessive amounts of dissolved silicon; thus it is likely that they result from local masking by contaminants or from reaction products of the etching process (8). Although P-ED solutions etch (100) Si uniformly, chem-mechanically polished surfaces tend to develop a fine wavy texture which becomes coarser as etching progresses (Fig. 14). As the surfaces remain clean and specular throughout the etching reaction their topography does not affect the nozzle fabrication process. A similar etching behavior has been observed with KOH (13, 16) and N_2H_4 (19).

The average etch rate of the (100) plane in the P-ED etchant of the given composition at 118° ± 1°C is ≃ 50 μm/hr based on measurements of the total etching time required to etch nozzles through 200 μm thick wafers. The etch rate of the {111} plane is ≃ 1 μm/hr determined from measurements of the oxide overhang or "underetching" of the base hole in the Si surface.

For consistently good etching results the Si surface should be highly polished and free from contaminants such as photoresist and oxide residues. Prior to anisotropic etching, the substrates are etched in buffered HF to ensure complete removal of the native oxide on the Si surface. Similarly, wafers are etched in buffered HF after removal from P-ED solution to dissolve the deposit which forms on etched surfaces. P-ED solutions are stable in the absence of oxygen and oxidizing agents and can be used over periods of 2-3 weeks provided the amount of dissolved silicon is small. A solution containing a large concentration of silicon forms a heavy white precipitate of a pyrocatechol-silicon complex (8) when it is cooled to room temperature. Such solutions are generally not suitable for making precision structures which require etching of deep cavities.

Conclusions

Silicon nozzle arrays with uniform orifice dimensions suitable for ink-jet printing applications have been fabricated reproducibly by the anisotropic etching of

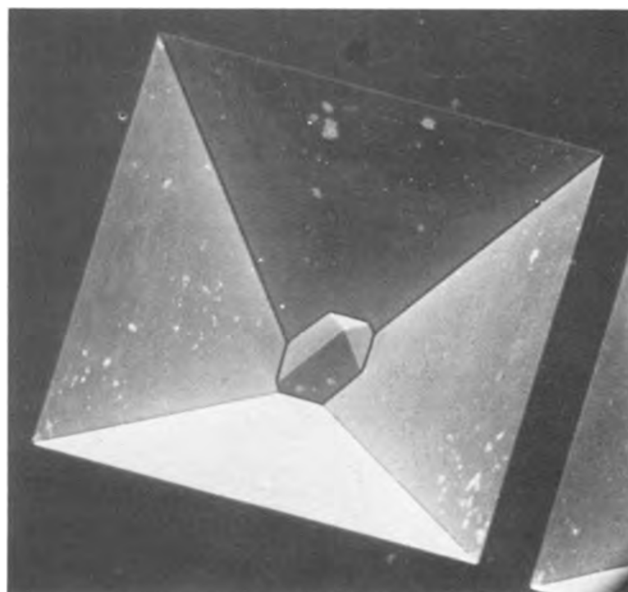

Fig. 13. SEM photomicrograph of a nozzle with the orifice totally blocked as a result of poor etching conditions. Base hole is 300 × 300 μm^2.

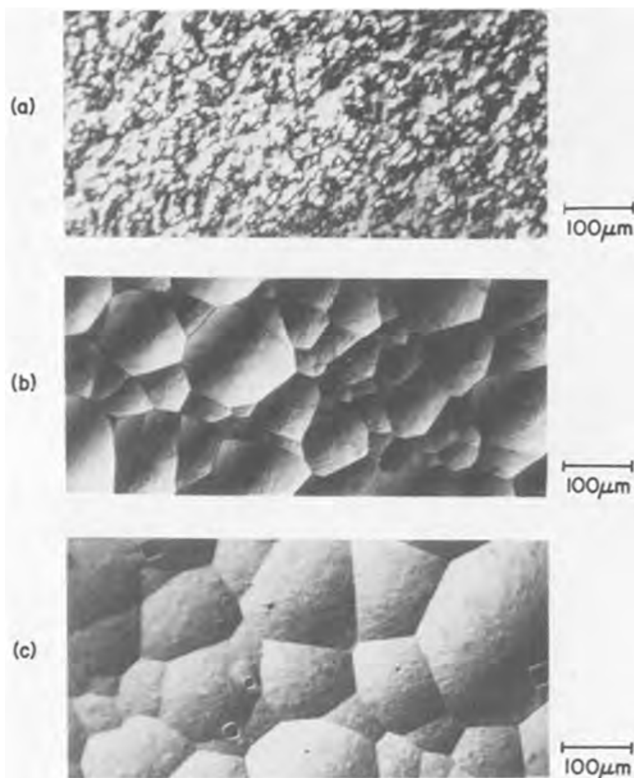

Fig. 14. Photomicrographs using phase-contrast illumination (Nomarski) of {100} Si surfaces before and after anisotropic etching. Chem-mechanically polished wafers also yield wavy textured surfaces after anisotropic etching.

holes through Si wafers of (100) orientation using standard Si-processing methods. The successful fabrication of these novel three-dimensional microstructures which require unusually long etching times is strongly dependent on the crystallographic perfection and the physical uniformity of the silicon wafer and on the control exercised in the patterning and etching processes. A key factor in the fabrication process is the use of an anisotropic etching solution containing pyrocatechol 4 m/o ethylene diamine 46.4 m/o, and water 49.6 m/o, at its boiling point 118° ± 1°C.

Determination of Electron Affinity of In_2O_3 from Its Heterojunction Photovoltaic Properties

Edward Y. Wang and Lan Hsu

Department of Electrical and Computer Engineering, Wayne State University, Detroit, Michigan 48202

ABSTRACT

In_2O_3-Si, In_2O_3-Ge, In_2O_3-GaAs, and In_2O_3-InP heterojunction solar cells have been fabricated and their photovoltaic properties have been investigated. All devices show rectifying and photovoltaic effects. The experimental results can be explained by a simple heterojunction energy band diagram. In order to match the experimentally observed polarities of the open-circuit voltage and short-circuit current of these heterojunction solar cells, the electron affinity of In_2O_3 materials is determined to be 4.45 eV. The substrate-resistivity dependence of open-circuit voltage is consistent with the energy band diagram using the electron affinity value of 4.45 eV for In_2O_3.

The formation of heterojunctions between conducting glasses, silicon (1-3), and other materials (4) has previously been reported. The current-transport mechanism of In_2O_3-Si heterojunction solar cells has generally been explained by a simple heterojunction model or by a metal insulator-semiconductor model. In both models, the value of the electron affinity of the oxide semiconductor is one of the most important factors in determining the photovoltaic properties. Very few studies, however, have been reported (5-7) on the properties of In_2O_3: its electron affinity was uncertain and its estimated value was about 4.31 eV, 0.3 eV greater than that of Si (1).

In this paper, we report the first successful formation of In_2O_3-Ge, In_2O_3-GaAs, and In_2O_3-InP heterojunctions through the chemical vapor deposition method. These heterojunction cells show the photovoltaic effects. Based on the simple heterojunction energy band diagram, an electron affinity of 4.45 eV was obtained for In_2O_3 in order to match the experimentally observed polarities of the open-circuit voltage and the short-circuit current of these heterojunction solar cells. Built-in potential values from constructed heterojunction energy band diagrams agree with experimental V_b values from capacitance and current-voltage measurements. Results on photovoltaic cells using various substrate resistivities of Si and Ge materials are also consistent with the energy band diagram using electron affinity value of 4.45 eV for In_2O_3.

Experimental

Cell fabrication.—Mechanically polished semiconductor wafers, p- and n-type Si, Ge, GaAs, and n-type InP, were used in this experiment. Wafers were cleaned with diluted HF, acetone, and methanol solutions. The deposition of thin film In_2O_3 was carried out by hydrolysis of $InCl_3$. $InCl_3$ powder was formed by boiling indium wire (99.999%) in concentrated HCl solution. The reaction took place upstream from a boat, containing a melted $InCl_3$ powder source placed in the zone close to the inlet. The semiconductor substrate was placed on a holder in the center zone of the furnaces (about 500°-550°C) with helium or oxygen bubbled through deionized water as the carrier gas to form the In_2O_3/semiconductor heterojunction cells. In the indium-oxygen system, In_2O_3 is the only stable crystalline-oxide phase (8). The temperature of the optimum heterojunction formation was different for various substrate materials. It was 500°C for Si and Ge; 450°C for GaAs and InP. The front contact to the In_2O_3 layer was made with aluminum evaporated through a finger mask. For back contacts, In-Ag was applied for p-GaAs, n-GaAs, and p-Ge; Sn-Ag for n-InP and n-Ge. For better ohmic contacts, cells were sintered at 500°C for 8 min.

Results.—Photovoltaic properties.—Figure 1 shows the current-voltage characteristics on a linear scale both in the dark and under illumination for the (n-p) In_2O_3-Si heterojunction solar cell. Under air mass zero (AM0) illumination, a short-circuit current (J_{sc}) of 22 mA/cm², open-circuit voltage (V_{oc}) of 0.34V and fill factor (FF) of 45% are obtained. Its simple heterojunction energy band is also shown in Fig. 1. Under illumination, the polarities of V_{oc} and I_{sc} (negative for the In_2O_3 side and positive for the Si side) are in accordance with the direction of the energy-band bending. Obviously, the construction of a heterojunction energy band diagram depends on the Fermi level E_F. We take the Fermi level of In_2O_3 in equilibrium to be 0.05 eV below its conduction band. This is supposed by the experimental evidence of ohmic-tunneling behavior for In_2O_3 depositing on 0.0003 Ω-cm p-type germanium substrate and rectify-

ing behavior for 0.004 p-type silicon substrate. Also, conductivity measurements on In_2O_3 thin film deposited on glass slides indicates that the In_2O_3 film is a heavily doped, near degenerate, n-type semiconductor.

The spectral response of a typical (n-p) In_2O_3-Si heterojunction solar cell under AM0 condition is shown in Fig. 2. The maximum sensitivity occurs near a wavelength of 0.9 μm. The spectral response of the bare 3 Ω-cm silicon homojunction cell fabricated in the normal diffusion process is superimposed on the same plot for comparison. There is a clear increase of the spectral response in the short wavelength region for heterojunction solar cells. The junction depth of the homojunction is about 0.2 μm for silicon homojunction cell. For a heterojunction, the In_2O_3 is transparent and junction begins at the interface of the In_2O_3 and the semiconductor. The decrease of spectral response in the long wavelength region is probably due to the difference of the minority carrier lifetime in the base material. Results on other heterojunction solar cells including both (n-p) and (n-n) In_2O_3-semiconductor heterojunction devices are summarized in Table I.

Capacitance measurements.—Figure 3 shows the capacitance results for some of the typical (n-p)In_2O_3-Si and In_2O_3-GaAs solar cells. The capacitance results seem to fit the straight lines of the C^{-2} *vs.* V plot. Built-in potential V_b is 0.4V for an (n-p)In_2O_3-Si heterojunction (1.4 × 10^{15} cm^{-3} Si substrate) and 0.86V for an (n-p)In_2O_3-GaAs heterojunction (5 × 10^{17} cm^{-3} GaAs substrate). It was difficult to apply the capacitance measurement technique to the capacitance of the In_2O_3-Ge heterojunction solar cell because of its high junction leakage current. Values of built-in potential deduced from the heterojunction energy band diagram listed in Table I are also in good agreement with the values through the linear extrapolation of the *I-V* characteristics at high forward current and capacitance measurements.

Resistivity dependence of V_{oc}.—The bending direction of heterojunction energy band is dependent on the electron affinity of semiconductors and the Fermi level (E_f) in the base materials. For example, as the E_f-E_v increase, we expect a change of polarity for V_{oc} and I_{sc} in the p-type substrate. Therefore, 10, 3, 1, and 0.004 Ω-cm p-type silicon were used to fabricate the (n-p)In_2O_3-Si heterojunction solar cells. Their open-circuit voltages (V_{oc}) increase in accordance with the decrease of resistivity value. Tables II and III show the results for (n-p) and

Table I. Summary of results for In_2O_3/semiconductor heterojunction solar cells

Heterojunction	Substrate impurity concentration (cm^{-3})	Polarity of V_{co}, I_{sc} w.r.t. substrate	Experimental J_{sc}, V_{oc}, obtained (~ AM0 condition) J_{sc} (mA/cm^2)	V_{oc} (mV)	Built-in voltage from heterojunction energy band diagram, V_b (mV)	Built-in voltage from *I-V* characteristics, V_b (mV)
(n-p)In_2O_3/GaAs	5 × 10^{17}	−	6.17	84	850	500*
(n-n)In_2O_3/GaAs	8.7 × 10^{14}	+	1.2	82	320	280
(n-p)In_2O_3/Ge	1 × 10^{15}	−	3.0	5.5	80	75
(n-n)In_2O_3/Ge	1.5 × 10^{15}	+	3.6	5.7	120	120
(n-n)In_2O_3/InP	3 × 10^{16}	+	0.6	18	60	80
(n-p)In_2O_3/Si	7 × 10^{15}	−	22.0	340	430	430
(n-n)In_2O_3/Si	2.1 × 10^{15}	+	1.5	100	220	210

Operating temperature = 300°K.
The In_2O_3 film was formed by the CVD method and all devices had good rectifying characteristics.
Electron affinity values are 4.01 eV for Si; 4.13 eV for Ge; 4.07 for GaAs; and 4.38 eV for InP (9).
* The energy band diagram indicates that an inversion layer might exist at the interface as the device behaves like a homojunction. However, direct comparison may not be valid.

(n-n)In_2O_3-Ge heterojunction solar cells with substrates of various resistivities. There is a clear polarity change of V_{oc} and I_{sc} between 37 Ω-cm and 20 Ω-cm p-type Ge substrates. The heterojunction energy band diagram, which was constructed by using the In_2O_3 electron affinity value of 4.45 eV, fits this result reasonably well.

Discussion and Conclusion

According to the (n-p) heterojunction energy band diagram in Fig. 4, under the illumination conditions, the electron-hole pairs created by the photons will be separated by the built-in electric field. A negative voltage with respect to the semiconductor substrate will exist at the (n-p) heterojunction barrier. Either electrons from the semiconductor side will flow downhill to the conduction band of In_2O_3, or there will be thermionic emission of holes from the valence band of the semiconductor substrate into the interface state where they recombine with the electrons from the conduction band of In_2O_3 to give the observed short-circuit current. Those interface states exist uniformly between the interface of In_2O_3 and the semiconductor substrate. The electrons at the interface states are supplied by the nearby conduction band of In_2O_3 because of their proximity to the interface states. There is very little band bending on the In_2O_3 side because of the high electron concentration in In_2O_3. The experimental observations in this paper also confirm this finding. For (n-n) heterojunction devices (Fig. 5), the dark current is mainly due to the majority carriers; however, the main factor leading to the short-circuit current has to be the recombination of electrons from the conduction band of In_2O_3, with holes from the semiconductor substrate at the interface states. If the holes at the interface states recombine with the electrons in semiconductor side, it will be a loss mechanism and contributes no short-circuit current. The other loss mechanism is probably due to the recombination process in the depletion region.

All In_2O_3-semiconductor heterojunction solar cells show photovoltaic effects and rectifying characteristics except the 0.0003 Ω-cm germanium substrate material. The results of V_{oc} and I_{sc} are inferior to those of homojunction devices. The limiting factors

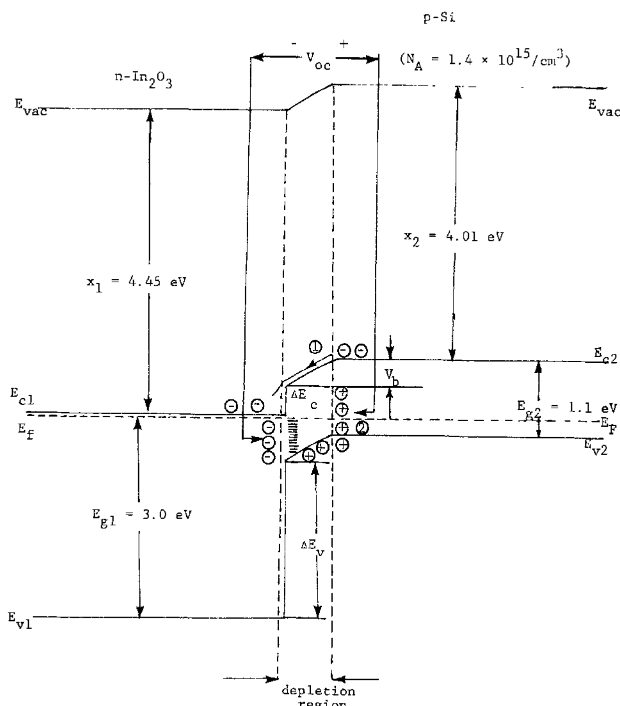

Fig. 4. Energy band diagram of an n-p heterojunction showing possible processes contributing to the generation of photocurrent.

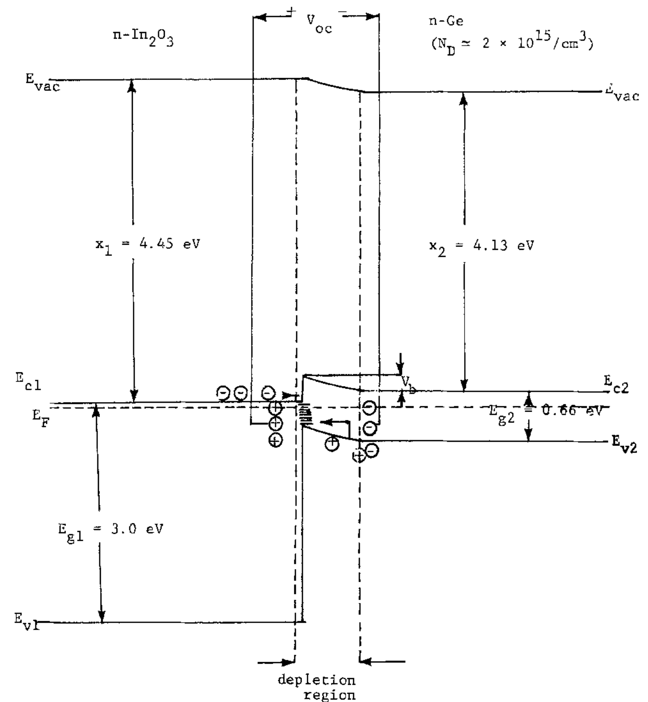

Fig. 5. Energy band diagram of an n-n heterojunction with possible processes contributing to the generation of photocurrent.

are high series resistance (R_s) and junction leakage current. In this work, no attempt is made to optimize the energy conversion efficiency of solar cell. The main objective is to determine the electron affinity of In_2O_3 based on the polarities of V_{oc} and I_{sc} from the In_2O_3-semiconductor heterojunction energy band diagrams.

In conclusion, we have successfully determined the electron affinity value of In_2O_3 from its photovoltaic properties. In addition, we believe that we have reported for the first time the success of In_2O_3-Ge, In_2O_3-GaAs, and In_2O_3-InP heterojunction formation by the chemical vapor deposition method. Based on the determined electron affinity value of In_2O_3, we can construct the heterojunction energy band at equilibrium. From this, we have successfully explained: (*i*) that the observed polarities of V_{oc} and I_{sc} of the heterojunction devices are consistent with the band bending in the energy band diagram; (*ii*) that the built-in potentials are in good agreement with those deduced from the capacitance-voltage and the current-voltage results; and (*iii*) that the semiconductor substrate resistivity dependence of the V_{oc} results is consistent with heterojunction energy band diagram.

Color-Band Generation during the High Dose Ion Implantation of Silicon Wafers

Chemistry Division, AERE Harwell, England

ABSTRACT

Color-bands may be observed on silicon wafers following high dose ion implantation. The implantation conditions which give rise to color band generation are described. The temperature variations occurring across the wafer during implantation are shown to be of primary importance in generating color bands. The colors observed result from interference effects when light is reflected from subsurface interfaces of amorphous and crystalline silicon; the surface layer may be amorphous or crystalline silicon. The depth and nature of the surface layer determines the color observed. The depth-color relationship for these layers is discussed together with the variation of color-bands with implantation conditions. Experimental results show that the color-bands are evidence of damage nonuniformity across the wafer. This damage nonuniformity may also be evident after high temperature annealing.

Color-bands on ion-implanted silicon wafers were first reported by Freeman *et al.* (1) who used high beam currents while studying sheet resistance uniformity for high dose implantations. They also showed that the colored regions were associated with crystalline surface layers and the effect was due to variations in temperature across the wafer during high current implantations. Csepregi *et al.* (2) qualitatively associated the thickness of the surface crystalline layers with visual color changes. Seidel *et al.* (3) quantitatively correlated thickness measurements of the surface crystalline layer with "optical-thicknesses" derived from peaks in the visible optical reflectance spectrum. They also correlated thicknesses of thicker (mostly buried) amorphous layers with peaks in the near infrared reflectance spectrum. Their interpretation is based primarily on the fact that amorphous and crystalline silicon have different indexes of refraction and absorption.

In the present work it is pointed out that visible interference colors may also be generated when the amorphous layer is continuous to the surface. A more general model has been developed to explain this (4). The color-bands are only evident on implanted specimens when the conditions during implantation are not identical at all points on the specimen. Electrostatically scanned wafers experience the same thermal conditions at all points during implantation and consequently will not exhibit color-bands unless a thermal gradient is established by nonuniform cooling (3) or as a result of nonuniform doping. Similarly, color-bands are not produced on wafers bonded to a constant temperature heat-sink.

To enable high dose implants to be completed within a reasonable time, high beam currents are commonly utilized, but the beam heating then becomes significant (5). The temperature rise of the wafer can be reduced by increasing the scan area if a mechanical scanning technique is employed. This approach has an associated advantage of improved dose uniformity. However, the resulting temperature changes cause sections of the wafers to be implanted at different temperatures with a consequent damage nonuniformity across the wafer.

The color-bands of a typical wafer are shown schematically in Fig. 1; however, many variants on this form are possible, as is explained later. In most cases a sharply defined color-band is evident (region 2, Fig. 1). It is obviously a region of the wafer in which the conditions for amorphous zone generation are par-

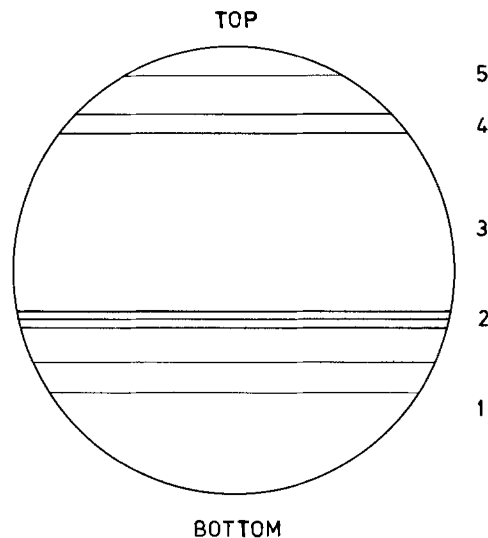

Fig. 1. Schematic diagram of color-bands formed on a silicon wafer implanted to high dose with mechanical scanning.

ticularly sensitive to temperature changes for the implantation parameters employed.

The damage created by implantation into silicon and described by the color-bands is the result of the disordering processes caused by the deposition of the energy of the incident ions and the dynamic annealing which occurs during the implantation process. The annealing is strongly dependent on the implantation temperature (6). This effect can be considered as a shift of the amorphous threshold as a function of implantation temperature. Nelson and Mazey (7) demonstrated for 60 keV Ne^+ implants that the amorphous threshold, as determined by the "milkiness" criterion, rose from approximately 1×10^{14} cm^{-2} at 20°C to approximately 4×10^{15} at 200°C. Morehead and Crowder (8) showed a similar variation for the amorphous thresholds of B^+, P^+, and Sb^+ implants, as determined by EPR data. They also proposed a model for this behavior.

Experimental Conditions

The silicon wafers were 5 cm diam and of <111> orientation. All were implanted in the Mk IV Harwell-Lintott isotope separator (9) which uses double-axis mechanical scanning (10) to scan the wafers through the stationary 3 cm high line focus ion beam. The wafers move with a horizontal stroke of 17 cm and then drop a small distance, as determined for the beam current and the total dose required, before again sweeping through the beam.

A number of analysis techniques were used to analyze the color-bands formed during high dose implantation. The conditions used are presented with the results in the following section. The details of the implantation conditions for the various wafers discussed in this paper are presented in Table I, together with the maximum temperature calculated to have been reached by the wafer during implantation. It should be noted that the examples discussed throughout this paper are related to the particular scanning system employed. The data and discussion can be applied to other scanning systems only if the relevant implantation conditions are carefully noted.

Results and Discussion

Temperature variation during implantation.—The ion-beam power density, which determines the temperature rise of the wafer, has been defined as the irradiance (1)

$$\text{Irradiance} = \frac{I \cdot E}{A}$$

where I is the beam current, E is the energy of the incident ions, and A is area scanned by the beam.

Freeman *et al.* (1) measured the temperature rise of silicon targets implanted at various irradiances and showed that the wafer has an effective average emissivity, ϵ, of approximately 0.45. The relationship they obtained between temperature rise and irradiance is shown in Fig. 2. It assumes that the entire target area is being scanned. The heat loss from the silicon is almost entirely by radiation. Parry (11) has shown the back surface to be a less efficient radiator than the front surface but has obtained a similar average emissivity for a silicon wafer mounted on a plate by a clamping mechanism without the use of a thermal bonding agent. The equilibrium temperature rise of the wafer thus varies as the fourth root of the irradiance

$$T_w - T_a = \left(\frac{\text{Irradiance}}{2\epsilon\sigma}\right)^{1/4}$$

where T_w is the wafer temperature, T_a is the ambient temperature, σ is the Stephan-Boltzmann constant, and 2ϵ is the effective total emissivity, assuming heat conduction from the wafer to the holder to be negligible (11).

The equilibrium temperature rise-irradiance relationship of Fig. 2 assumes that the ion beam is scanning the entire area of the target specimen. In the Mk IV Harwell-Lintott separator, a 3 cm high beam is used to progressively scan across a 5 cm diam silicon wafer. The percentage area of the target being scanned by the ion beam is thus a function of the relative location of the ion beam centerline and the wafer. It increases to a maximum when the ion beam is scanning the center of the wafer; the relationship is shown in Fig. 3. The beam power transmitted to the wafer is proportional to the area of the wafer being scanned. The heat deposited into the wafer is conducted through it with a time constant of approximately 20 sec (11). Heat dissipation only occurs by radiation from the entire surface area, since conduction to the mounting plate is negligible. If it is assumed that the lateral conduction time constant is negligible compared to the total time taken by the implantation cycle, the "equilibrium" temperature rise as a function of the ion beam centerline position can be calculated as a percentage of the temperature predicted in Fig. 2 when complete scanning of the wafer occurs. The result is shown in Fig. 4. Each horizontal strip on the wafer has a unique temperature-time profile as the scan proceeds across it. Strips at the bottom are initially at a low temperature with an increasing temperature during implantation, strips at the center have high and relatively consistent temperatures during implantation, while strips at the top of the wafer have an initially high temperature which decreases as the implantation cycle is concluded. This temperature variation during implantation is shown in Fig. 5 for some points on the wafer. These results, however, assume that implantation has proceeded sufficiently slowly for lateral heat conduction to maintain a uniform temperature across the wafer and that the wafer has negligible thermal capacity, so that cooling is equally efficient. It is known that wafer cooling has an appreciable time constant and this effect has been estimated to determine the more realistic temperature variation curves of Fig. 6.

Table I. Implantation conditions

Ion species	Ion energy (keV)	Dose (cm^{-2})	Beam current (μA)	Irradiance (W/m^2)	Maximum temperature during implantation (°C)
P	40	2×10^{16}	500	3900	220
P	60	1×10^{16}	660	7800	290
P	80	1×10^{16}	500	7800	290
P	118	1×10^{16}	340	7800	290
P	154	1×10^{16}	260	7800	290
Ne	80	1×10^{16}	500	7800	290
P	80	2×10^{15}	500	7800	<290

The thermal conditions of a wafer scanned by such a mechanical scanning system are thus seen to vary in a complex manner during implantation when beam heating is significant. Each horizontal strip of the wafer has a unique thermal behavior during implantation. The temperatures attained, in addition to being determined by the ion beam irradiance, are also modified by the efficiency of the thermal contact with the mounting, the duration of the implantation cycle, and the efficiency of radiation to the surroundings.

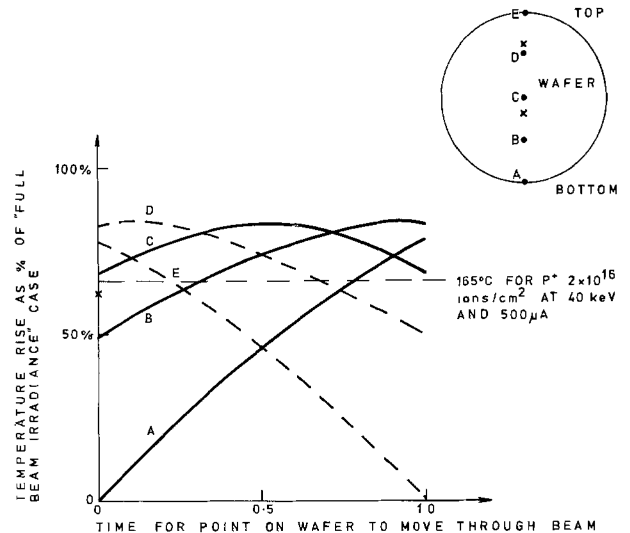

Fig. 5. Temperature variation of horizontal strips across the wafer during implantation with no thermal capacitance.

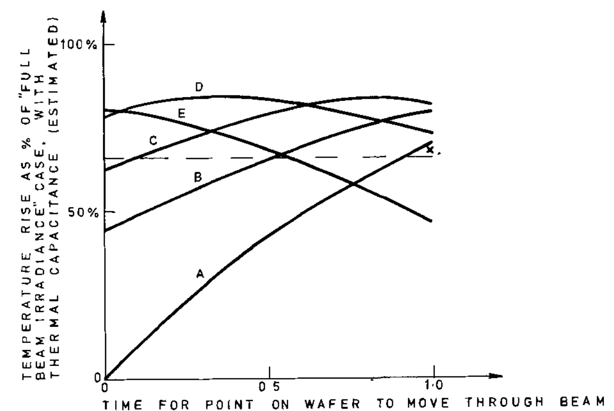

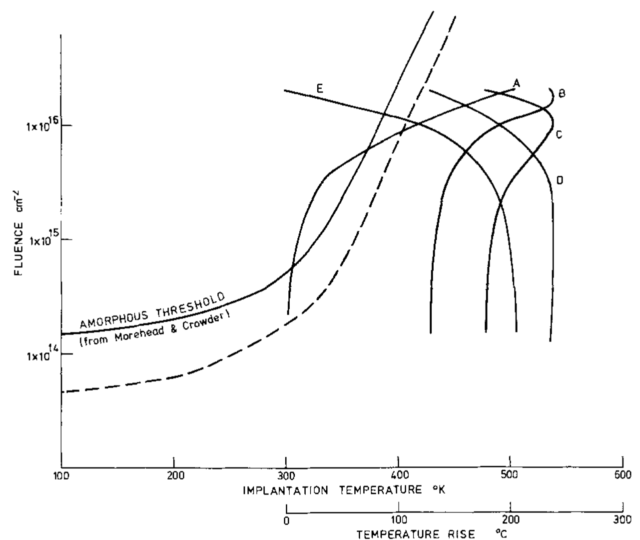

Fig. 6 (top). Temperature variation of horizontal strips across the wafer during implantation with estimated thermal capacitance.

Fig. 7 (bottom). Fluence variation as a function of implantation temperature (with no thermal capacitance).

Generation of amorphous regions during varying temperature implantation.—As was noted earlier, the amorphous threshold increases with implantation temperature because the dynamic annealing process becomes more efficient. The amorphous threshold is not, however, a concept which is readily applicable to implantation at varying temperatures. A more general concept of an amorphizing fluence, ϕ_{am}, is required to

account for the varying temperatures during the implantation cycle.

The effective amorphizing fluence, which is a function of the implantation temperature-time cycle, is less than the actual fluence because of the temperature-time dependent dynamic annealing

$$\phi_{am}(\theta, t) = \int_0^\phi \{1 - k(\phi, \theta, t)\}\, d\phi$$

where ϕ = fluence, t = time, and θ = temperature.

In addition, the amorphous threshold should be related to a volumetric disorder density rather than a surface fluence. Since, at the present time. inadequate data exists to enable a more adequate consideration to be made, a simplified discussion based on amorphous threshold variation is presented. It must, however, be noted that it only represents an approximation to the more complex actual situation.

In the Mk IV Harwell-Lintott separator the beam current density is approximately constant along the height of the line focus beam. Therefore, as the sweep proceeds the fluence, ϕ, increases αt. Since the θ-t relationship has already been established (see Fig. 5) the θ-ϕ relationship can be readily derived for the various horizontal strips of the wafer. These are plotted for points A-E in Fig. 7 using a logarithmic scale for the fluence. The numerical scale is for a 2×10^{16} cm^{-2}, 40 keV P^+ implant at 500 μA. Also plotted in Fig. 7 is the variation of amorphous threshold with implantation temperature for 280 keV P^+ implants using the EPR data of Morehead and Crowder (8), who predicted that for temperatures above 430°K the P^+ implants will not be amorphous at any dose. Even though this data cannot be expected to predict the "milkiness" threshold accurately, it exhibits the expected relationship with temperature.

Although the approach of Fig. 7 is approximate, some interesting trends are indicated. For implants which commence at low temperatures, *i.e.*, point A at the bottom of the wafer, it is relatively easy to generate an amorphous layer. (An amorphous layer is certainly generated when a ϕ-t cycle crosses the amorphous threshold curve from a lower temperature. An amorphous layer will be generated at a dose lower than that predicted by the amorphous threshold curve because of the integrated effect of the damage as the implantation proceeds.) For a point such as B an amorphous layer may be established if the integrated damage, as the temperature increases, is sufficiently high. The damage occurring before the temperature increases significantly is the determining factor. For point C on the wafer the temperature is too high, when it is implanted, for an amorphous layer to be created. Amorphousness could be created at D, but it is unlikely as it approaches the amorphous threshold curve with much less damage than a constant temperature implant, since the majority of the damage has been generated at high temperature. It is, however, likely that amorphousness is created at point E as the wafer cools.

The steepness of the amorphous threshold variation with temperature can be seen to be of fundamental importance in determining the generation of amorphous regions of varying thickness across a wafer implanted with the conditions just considered. The amorphous layer generation is primarily determined by the behavior of the wafer during its lowest temperature phases of the implantation process.

Typical color-bands.—The color-bands observed on the silicon wafers after implantation have infinite variations because the depth of the amorphous-crystalline silicon interface which determines the color (see section on Interference colors) and the position of the bands is also effected by all the implantation parameters (see section on Variation of color-bands). They do, however, exhibit a general form, as shown in Fig. 1, which is now explained.

The bottom of the wafer, being implanted first at a low, but rising, temperature, is likely to generate a deep amorphous layer extending to the surface. The depth of the amorphous layer is reduced in the successive horizontal strips of the wafer which are implanted at progressively higher temperatures. This corresponds to region 1 in Fig. 1. The colors are relatively diffuse and change to indicate layers of reducing depth.

This is usually followed by a narrow brightly colored band (region 2). For low voltage implants this corresponds to a region of rapid reduction of amorphous layer thickness. In this case, region 3 may either have a thin amorphous layer or be heavily damaged but crystalline silicon, depending on the implant conditions. In this region, the implant temperature is high but relatively constant and relatively uniform colors are likely when a thin amorphous layer results.

For high voltage implants, which have a peak energy deposition density some distance below the surface, region 2 is a narrow, more brightly colored band in which the order of colors is reversed. It is the region in which the amorphous layer is buried below a layer of crystalline silicon. The colors are brighter because of the greater optical transparency of crystalline silicon. The color order is reversed because the depth at which the colors are generated now increases as the implantation temperature is increased. For such implants region 3 is then crystalline silicon.

Regions 4 and 5 may not be evident if insufficient cooling of the wafer occurs. When they are evident, region 4 is a bright band; it is less distinct than region 2 because it has been formed on cooling and the amorphous-silicon interface is apparently less abrupt. Region 5 is similar to region 1, exhibiting diffuse colors arising from deep amorphous layers continuous to the surface.

Experimental evaluation of "color-band" wafers.—In this section, experiments conducted on the wafers to determine the properties of the color-band regions of the wafers are discussed. The discussion has been mainly restricted to experiments relating to the 40 keV P^+ implant to 2×10^{16} cm^{-2} at 500 μA, although observations have been made on wafers implanted under many different conditions.

Sheet resistance.—The sheet resistance (R_s) variation across the diameter of the P^+ implanted wafer, in a direction normal to the color-bands, was measured using the four-point probe technique following 30 min isochronal anneals at temperatures to 1100°C. The results are shown in Fig. 8, together with the color-bands on the "as implanted" wafer. A large sheet resistance variation exists across the wafer after implantation, due to the amorphous layers being of greater depth in the high R_s regions at the top and bottom of the wafer. This variation is maintained throughout the annealing cycle, but is reduced to a maximum variation of 14% after annealing to 1100°C. The central section of the wafer, which was implanted at approximately 200°C, exhibits the lowest sheet resistance after each annealing cycle.

It should also be noted that the sheet resistance annealing characteristics vary dramatically at different parts of the wafer. The annealing characteristics for points A, B, and C (as denoted in Fig. 8), are shown in Fig. 9. Curve D was obtained on a wafer implanted with the same implantation parameters, but with the temperature increasing from room temperature to 220°C during implantation. Also included in Fig. 9. is the result of Shannon *et al.* (12) obtained following room temperature implantation. It will be seen that the room temperature implant anneals more efficiently during the epitaxial regrowth phase at approximately 600°C, but that the implant at approximately 200°C is much more efficient than the implants which are undertaken over a range of temperatures from room temperature to 200°C. It is considered that under

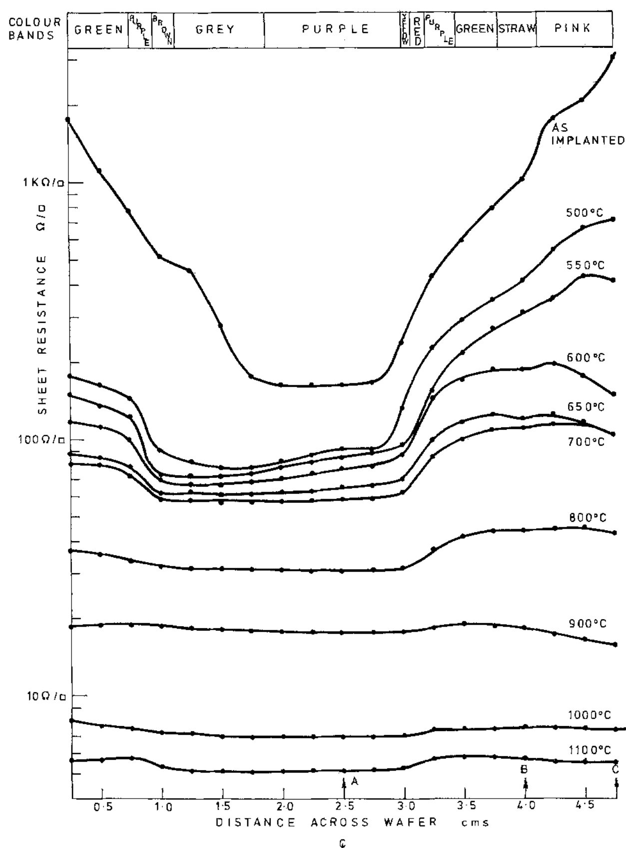

Fig. 8. Sheet resistance profiles across wafer implanted with 2 × 10^{16} cm^{-2} P^+ at 40 keV, 500 μA and isochronally annealed. Bottom of wafer at the right.

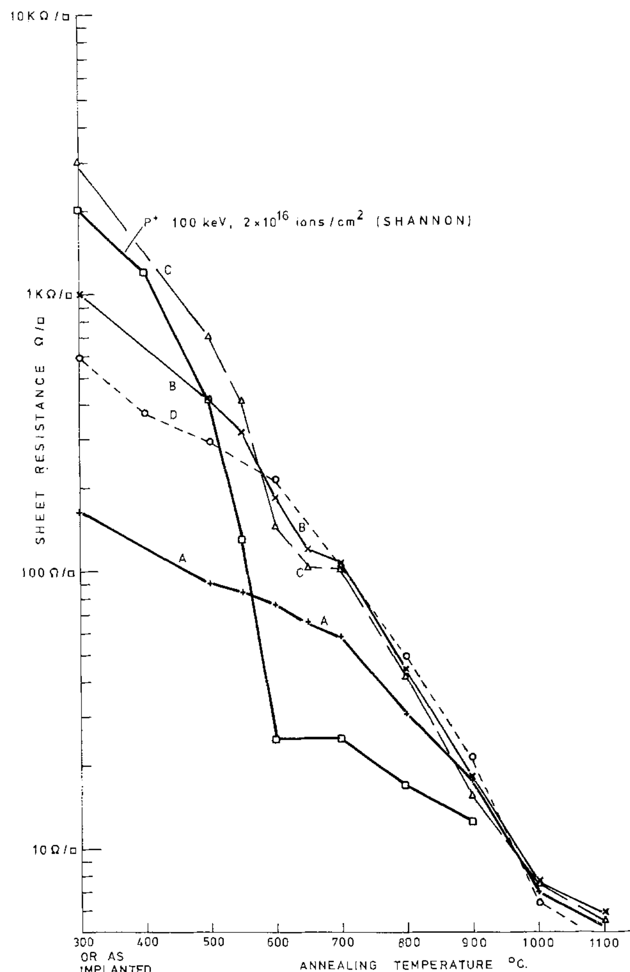

Fig. 9. Isochronal anneal characteristics of sheet resistance for 40 keV P^+ implant to 2 × 10^{16} cm^{-2} at 500 μA with varying implant temperature conditions.

such conditions (curves B, C, and D) the dynamic annealing, which reduces the depth of the amorphous layer, permits disorder, generated during the low temperature phase of the implantation process to remain in the deep subamorphous layers.

Anodization and stripping.—Areas of the color-banded P^+ wafer were oxidized using a calibrated anodization facility. The oxide was removed with a buffered HF solution and the depth of silicon removed confirmed by optical interferometry. In the stripped region the color-bands moved since they then were generated by a thinner surface layer. By this method the colors generated by thinner surface regions were confirmed and for particular differences in depth the color changes were observed (refer to section on Interference colors).

Scanning electron microscopy.—The electron channeling patterns (ECP's) (13) generated by the surface layers of the color-banded specimens were observed in the SEM after implantation. The clarity of the channeling patterns gives a qualitative indication of the crystal quality in the 500Å surface layer.

In Fig. 10 the ECP's from various positions on a color-banded wafer implanted with 1 × 10^{16} cm^{-2}, 80 keV Ne^+ at 500 μA are shown. The section of the wafer implanted first is at the top. It will be seen that the crystal quality of the surface layers changes abruptly within a distance of 0.5 cm across the wafer. At position 1, the amorphousness extends to the surface. At position 2, there is a thin surface crystalline region above a buried amorphous layer. This is also true at position 3, but the surface crystalline layer is thicker. The ECP obtained from position 4 is of much better quality. In this region there is no surface coloration and no buried amorphous layer. Since the wafer was not annealed the ECP quality from the crystalline silicon is limited by the disorder generated in the implanted layer.

Transmission electron microscopy.—Specimens from different regions of the 2 × 10^{16} cm^{-2} 40 keV P^+ at 500 μA implanted wafers were examined by TEM. The specimens were ultrasonically cut from implanted wafers, annealed at 800°C for 30 min in a vacuum, and then jet thinned (14) from the back. The defect structure resulting in different regions of the color-banded wafers showed considerable variation. The micrographs of Fig. 11 enable a comparison of the damage in specimens near the bottom and the center of the wafer. The specimen from a "pink" region near the bottom of the wafer had been implanted with increasing temperature and a thick amorphous layer continuous to the surface formed. The micrograph showed a dense dislocation network with extensive twinning. The specimen from the "purple" central region had been implanted at a relatively uniform and high temperature and a very thin amorphous layer formed. The resulting dislocation structure is much less dense with less twinning. This is consistent with the sheet resistance observations reported in section on Sheet resistance which showed this latter region to have a much lower sheet resistance after annealing at 800°C.

Rutherford backscattering analysis.—The Rutherford backscattering (RBS) channeling technique was applied to various points on the 2 × 10^{16} cm^{-2} 40 keV P^+ at 500 μA implanted wafer. During analysis a 2.9 MeV He^+ beam was used in a <111> direction. The thickness of the damaged layer on the surface of the Si was examined at various points on the wafer. In each case the damage depth observed was approximately 2000Å. It is evident that the damage below the amorphous layer was too large to permit the amorphous layer thickness to be measured with this

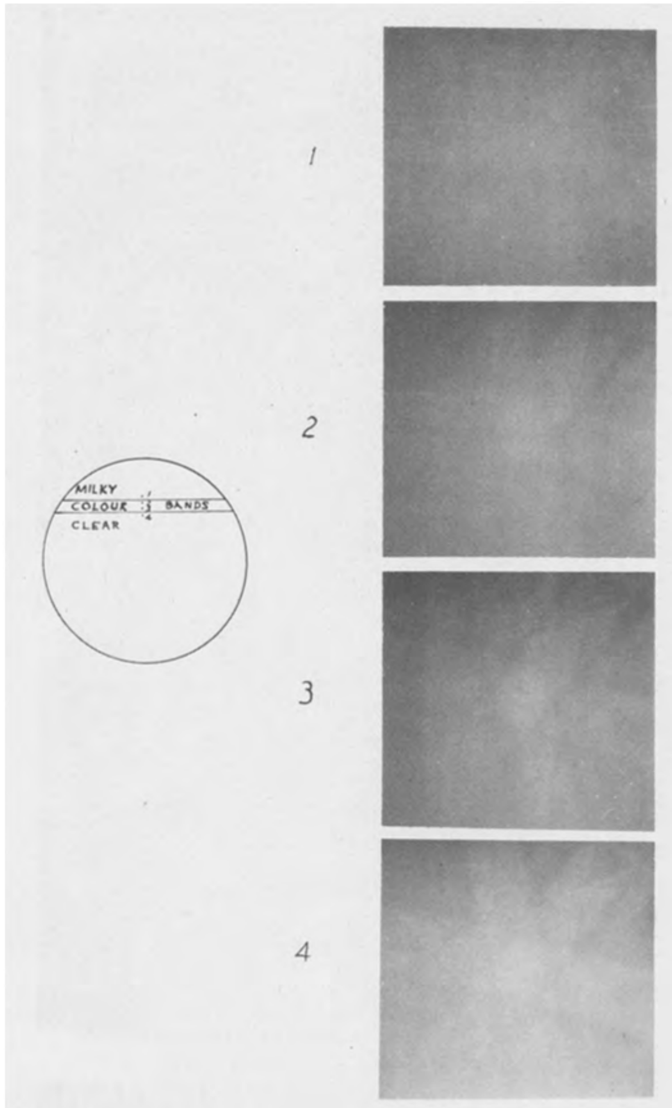

Fig. 10. Electron channeling patterns from various regions of a color-banded wafer implanted with 1 $\times$ 10^{16} cm^{-2} 80 keV, Ne^+ at 500 μA. Section of wafer implanted first is at the top.

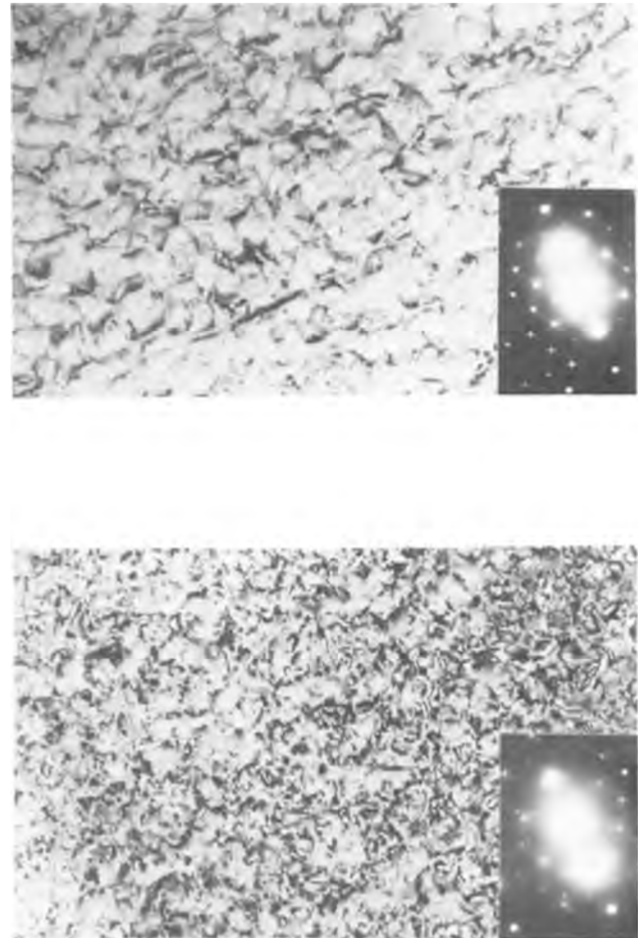

Fig. 11. Transmission electron micrographs of 2 $\times$ 10^{16} cm^{-2}, 40 keV P^+ at 500 μA implanted into Si and annealed for 30 min at 800°C. Upper specimen was from the bottom of wafer and lower specimen was from the center.

technique at this dose of P^+ ions since RBS cannot distinguish between amorphous and heavily damaged regions (15). (An identical region with 300Å removed by anodic stripping indicated a depth of approximately 1700Å.)

RBS measurements were also undertaken on a wafer with less damage. The disorder produced at various points on a color-banded wafer implanted to 2 $\times$ 10^{15} cm^{-2} with 80 keV P^+ at 500 μA was measured. A 2.0 MeV He^+ beam was directed in the <111> direction to four points each spaced at a distance of 1 mm from the previous point, as shown in Fig. 12. The RBS spectra are also given in Fig. 12. The "clear" region can be seen to have very little disorder. The "blue" and "purple" bands are confirmed to have buried amorphous layers beneath a surface crystalline region, while the "green" region has a deep amorphous layer which is continuous to the surface. The RBS measurements of the crystalline layer depth are 500 and 375Å for the "blue" and "purple" regions. These thicknesses can be compared to the approximate depth predicted on the basis of interference colors (section on Interference colors), of 410 and 340Å, respectively. The depth of the amorphous layer in the "green" region is 1375Å by RBS as compared to 1200Å by interference color prediction. The agreement is quite reasonable, in each case, considering the approximations involved.

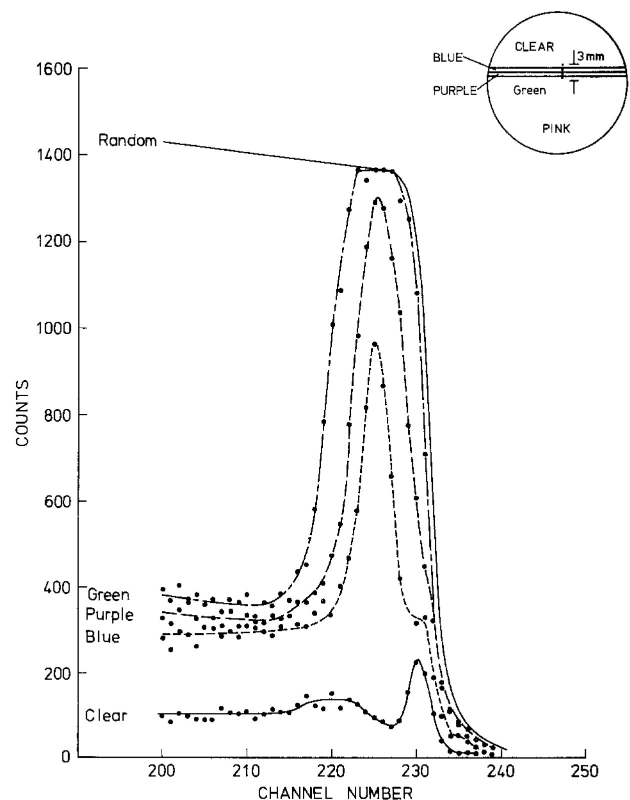

Fig. 12. Rutherford backscattering data for areas of color-banded wafer implanted with 2 $\times$ 10^{15} cm^{-2}, 80 keV P^+ at 500 μA.

Ellipsometry.—The method of ellipsometry (16) was used to study the properties of the various regions of the color-banded wafers. Ellipsometry can be used to measure the refractive index and thickness of uniform absorbing layers on a substrate of known optical constants. Unfortunately, implanted layers do not have uniform optical properties and the substrate properties are also modified by the implantation process. In addition, a thin oxide layer is formed on the surface of the wafer. Complete analysis of the layers is possible if the multiple-angle-of-incidence method of Adams and Bashara (17) is used.

Single angle measurements only were taken and, although accurate depth determinations cannot be made for the reasons stated above, it is possible to identify, because of the entirely different results, when the amorphous layer is buried and when it is continuous to the surface. Also the results obtained for regions of various colors are consistent with large changes of thickness occurring in the surface layer.

Surface height measurements.—The change of surface height of the silicon wafer in the region of various color-bands was measured using a surface profilometer on a masked 2 × 10^{16} cm^{-2}, 40 keV P^+ at 500 μA implant. The increase in surface height was of the order of 25Å and no significant changes, correlated with the color-bands, were observed.

Color changes during annealing.—The color-bands disappear after annealing to 650°C. At this temperature the epitaxial recrystallization of the amorphous region is known to be complete (7). The color-bands are observed to move as the amorphous layer anneals in the temperature range 400°-650°C. The color movement is consistent with the epitaxial regrowth, of amorphous layers continuous to the surface, occurring from the crystalline substrate. The annealing of the buried amorphous layer shows a color shift in the direction of increasing surface layer depth, *i.e.*, the crystalline surface layer grows into the amorphous layer. The colors may also brighten considerably during annealing.

Interference colors as a function of depth.—The observed colors result from the interference of light reflected from the surface with that reflected from the subsurface interface at which the refractive index change occurs. The particular wavelength attenuated, λ, is dependent on the depth of the surface layer, *d*, and is given by (18)

$$\lambda = \frac{4 - n}{2k - 1} d$$

where $k = 0, 1, 2, 3, \ldots$, and n = refractive index of surface layer.

Since the interference is subtractive, the color observed is the complement of the wavelength attenuated. Using $n = 3.865 - j\ 0.14$ for crystalline silicon and $n = 4.25 - j\ 0.45$ for amorphous silicon, which are consistent with experimental results which have been reported by other workers (17, 19, 20), the colors likely to be observed have been calculated for both amorphous and crystalline silicon surface layers of various depths; they are given in Fig. 13. These depths must be considered approximate because the damage variation throughout the surface layers can cause the optical constants of the layers to be nonuniform and phase shifts (3) can result in an error of approximately 25% for the first-order colored layers.

Color assessment is also somewhat subjective and depends on the light source. It is also affected by the absorption of the surface layer, particularly for amorphous surface layers. The colors associated with surface crystalline layers are usually brighter and more distinct. It is difficult to assess the order of the interference color; colors up to fourth order have been observed. However, if an approximate damage profile is known, the depth of the damage peak is a convenient reference point for wafers which show color-bands in addition to having a "clear" crystalline region on the wafer. The color at the interface between the color-band and the "clear" silicon represents the depth of the damage peak. Also the region at the bottom of the wafer, which is implanted cold, can be used as a reference point by utilizing the theoretical damage profile in conjunction with room temperature data of the amorphous threshold.

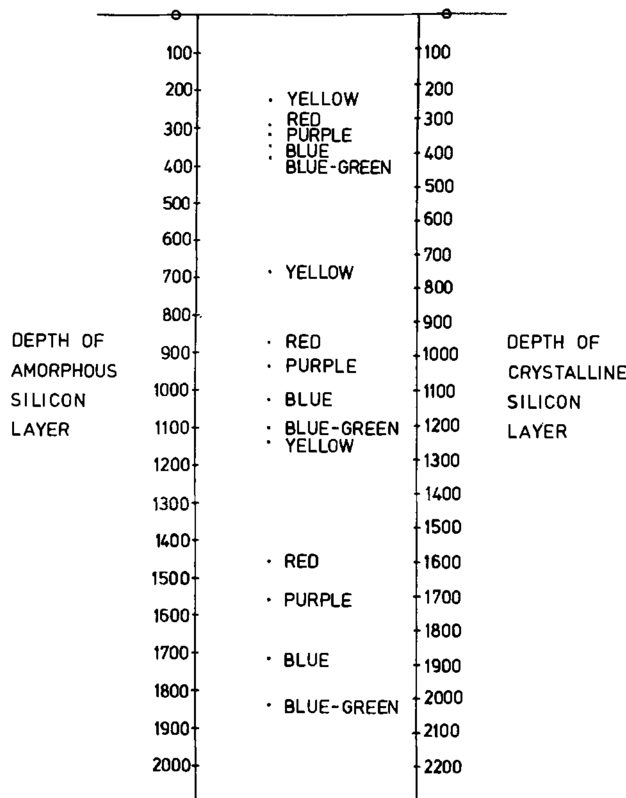

Fig. 13. Interference colors as a function of depth for amorphous and crystalline silicon surface layers (1st and 2nd and 3rd order).

For P^+ implants at various voltages the depth of the peak of the damage profile can be determined from the color-band table (Fig. 13) and compared to the calculated damage profile peak (21). The results are compared in Table II. The agreement is very good considering the limitations discussed above.

Variation of color-bands with implant conditions.—The color-bands observed on silicon wafers are a function of the implantation temperature and the total energy deposition function. The implantation temperature is a function of the ion energy, the ion beam current, the scan cycle used in the implantation process, and the radiative and conductive cooling of the wafer. The total energy deposition function is dependent on the ion energy, the ion dose, and the ion species. With so many variables there are obviously many possible variations of color-bands. Some brief general comments are now given to describe the variations which have been observed over a wide range of conditions.

The range of colors observed on a particular wafer is determined primarily by the depth scale of the damage profile, *i.e.*, by the ion species and its energy. The posi-

Table II. Comparison of damage peak depths determined by color-bands, with calculated values

Ion energy (keV)	Color at damage peak	Approx. depth of damage peak from color-band (Å)	Calculated depth of damage peak (Å)
40	(Peak not observed)	—	220
60	Yellow	240	280
80	Blue	390	440
118	Red	950	800
154	Light blue	1150	1140

tion of the color-bands is determined primarily by the temperature rise of the wafer. The implantation temperature is more critical than the peak damage density, as can be seen from Fig. 7. The temperature rise at the beginning of the implantation process is particularly important for high dose implants, as is the final temperature at the end of the implantation cycle. Wafers with the same maximum temperature, but a different rate of rise of temperature will consequently produce different color-bands.

The variation of the amorphous threshold as a function of temperature is an important parameter which relates to the color-band position for different ion species. For a species such as B^+, which will not produce amorphous silicon if the implantation temperature rises more than approximately 20°C, color-bands will only arise when the temperature rise during implantation is very small. For many species a maximum temperature rise of approximately 200°-250°C will generate bright color-bands as this temperature will produce crystalline silicon irrespective of dose. Color-bands are only generated when the thermal behavior varies across the wafer during the implantation cycle.

Conclusions

The observation of the color-bands formed during the implantation of silicon wafers to high doses, with conditions which result in significant temperature rises, can quickly provide useful information about amorphous layer formation. It is possible to tell whether the amorphous layer is continuous to the surface or buried and to obtain an approximate estimate of the depth of the surface layer which will be amorphous or crystalline silicon, respectively. A knowledge of the temperature variations undertaken by each section of the wafer during implantation, for the particular scanning system employed, is advantageous in assisting such interpretation.

Temperature rises during implantation of 200°C or more from room temperature will generate color-bands on high dose implants of medium mass ions if the thermal behavior varies across the wafer. Mechanical scanning systems, which are often used for high dose implants because they reduce the temperature rise of wafers implanted with high beam currents, are likely to generate color-bands. The color-bands indicate a damage nonuniformity across the wafer, and, even after annealing to high temperatures, an electrical activity nonuniformity may result. For applications where a high degree of implant uniformity is required across the wafer, care should be taken to avoid implant conditions which generate color-banded wafers. If R_s measurements are made on such a wafer, or TEM specimens examined, the experimental results can vary considerably depending on the area of the wafer examined.

Baker and Ogden (22) discussed such a case where nonuniformity of crystal imperfections was observed in the epitaxial layers grown on a substrate implanted with 150 keV As^+ to 1×10^{16} cm^{-2} at 1 mA and annealed at 1200°C for 2 hr. The implanted wafers exhibited color-bands and the density of defects observed was greater in the implanted regions which produced the thicker amorphous layers.

Consideration should be given to the development of ion implantation scanning systems which are suitable for high dose, high dose rate implants and result in uniformly low disorder.

Although the generation of color-bands can be adequately explained, the prediction of their location on a wafer is difficult without much better information on the generation of amorphous regions in silicon under conditions of varying temperatures. It is, however, much easier to predict the implant conditions which will result in their generation.

Structure of Porous Silicon Layer and Heat-Treatment Effect

Takashi Unagami and Masahiro Seki

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo, 180, Japan

ABSTRACT

The structure of an as-grown and heat-treated porous silicon layer (PSL) and silicon epitaxial growth on PSL are investigated. Many micropores are formed inside of PSL and zig-zag in the thickness direction. The crystalline structure of PSL is single crystal, but there is a polycrystal silicon on the surface and lattice strain exists. The structure of PSL is changed by high temperature heat-treatment. At 1000°C, PSL is a mosaic crystal. Above 1070°C, PSL is a single crystal. After heat-treatment, PSL remains porous and both the pore distribution and the pore size are changed. The surface roughness and the pore size become large with rising heat-treatment temperature. From the experimental results of silicon epitaxial growth on PSL it is found that good epitaxial layers grow on PSL.

The anodic reaction of silicon in hydrofluoric acid solution was investigated by Uhlir (1) and Turner (2). They found that a porous silicon layer (PSL) is formed by anodization below the critical current density. PSL is very chemically reactive and consists of silicon with a small amount of fluorine, hydrogen, and oxygen (3, 4). Recently Watanabe *et al.* noticed that PSL can be oxidized much more easily than silicon single crystal and suggested the application of oxidized PSL to dielectric isolation in integrated circuits (5).

The authors carried out silicon epitaxial growth on PSL and found that epitaxial layers of good quality grow on PSL. The quality of the epitaxial growth layer strongly depends on the surface morphology and the crystalline structure of the substrate. In order to investigate the epitaxial growth on PSL, the structure of PSL used as a substrate of epitaxial growth needs to be known. In this paper, the dependence of the structures of as-grown and heat-treated PSL on both the heat-treatment condition and the PSL formation condition and the result of silicon epitaxial growth on PSL are described.

Experimental

Formation of PSL.—Silicon wafers were anodized in 50% hydrofluoric acid solution with the equipment shown in Fig. 1. Silicon wafers were cut from (111) oriented p-type single crystal grown by the Czochralski method (boron doped). The wafer surfaces were metallographically polished, cleaned, and etched. Etch pit density of each wafer was less than 500/cm^2. Before anodization, aluminum alloy layers were formed on the back of silicon wafers as the low resistivity contact layer in order to make the anodic current distribution uniform. The wafer was coated with acid-proof wax to prevent current flow from the aluminum alloy layer to hydrofluoric acid solution and to perform anodic reaction selectively on the wafer's surface. Bubbles are produced on the surface of PSL, so an ultrasonic oscillator source was used to prevent the sticking of bubbles at the PSL surface.

Observation of PSL structure.—The surface morphology of as-grown and heat-treated PSL was observed by the scanning electron microscope (SEM). The inner structure of PSL was investigated by the observation of thin PSL with the transmission electron microscope (TEM) and the observation of the cleaved thin film of PSL was made using SEM. The crystalline structure of PSL was examined by reflection electron diffraction (ed) and x-ray diffraction.

Preparation of the PSL thin film for TEM and SEM observation.—Thin films of PSL were formed in order to investigate the inside structure of PSL, in particular, the distribution of pores in PSL. A fabrication process is shown in Fig. 2. The p$^-$ type layer in (a)

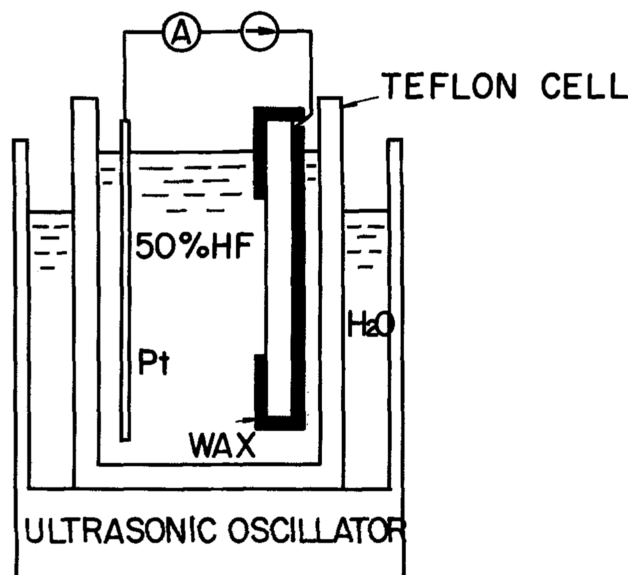

Fig. 1. The equipment for anodization in hydrofluoric acid solution.

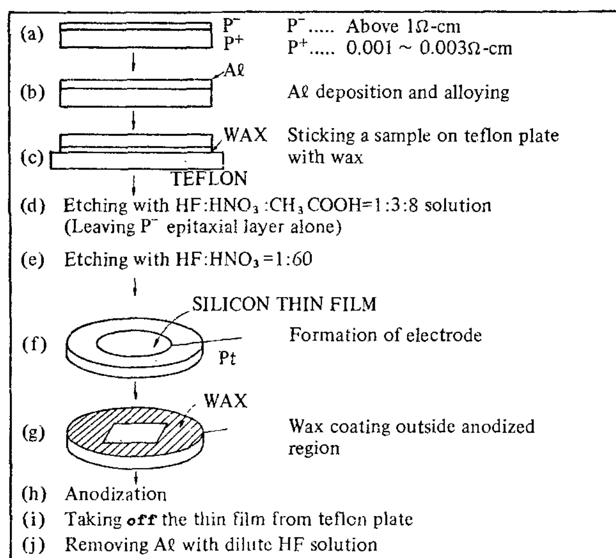

Fig. 2. Fabrication process for the thin film of PSL

Key words: porous silicon, film structure, heat-treatment.

is an epitaxial layer whose thickness is 0.6 μm. In (b), 300Å aluminum is deposited and then alloyed. ~100Å aluminum alloy layer is formed on the p^- type epitaxial layer. After that, thick aluminum is additionally evaporated in vacuum. The $HF:HNO_3:CH_3COOH = 1:3:8$ solution in (e) is the solution which has selectivity of etching rate against impurity concentration in silicon crystal (6). Thereby this solution can leave the p^- layer alone. p^- layer is etched further in $HF:HNO_3 = 1:60$ solution in order to be about 0.4 μm in thickness. In final process, this thin p^- layer is anodized in hydrofluoric acid solution. In the case of forming the thin film of PSL to observe the cleaved cross section, p type substrate was used instead of p^- on p^+ wafer, and the etching processing (d) was omitted.

Results and Discussion

PSL region.—A cross-sectional view of PSL is shown in Fig. 3. The sample was angle lapped with a plane inclined from the surface and slightly etched in an etchant ($HF:HNO_3 = 1:60$ solution). The region of PSL is observed to be black and the boundary of PSL and the silicon substrate region is clearly revealed. The PSL thickness is determined by this angle-lapping method. The surface step between the surface of PSL and that of the unreacted region is shown in Fig. 4. An interference microscope was used to observe it. The surface step does not appear; that is, PSL keeps the original surface contour.

Structure of PSL.—Some investigations about the structure of PSL have been reported (5, 7-9). However, those observations were not directed toward investigation of the detailed structure of PSL. In this section, the results of the detailed structure of PSL observed by TEM and SEM as well as the crystalline structure of PSL are reported. Figure 5 shows ED

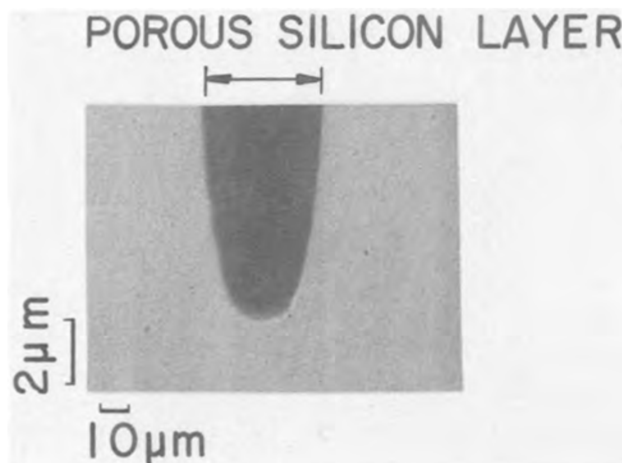

Fig. 3. Cross-sectional view of PSL observed by angle lapping

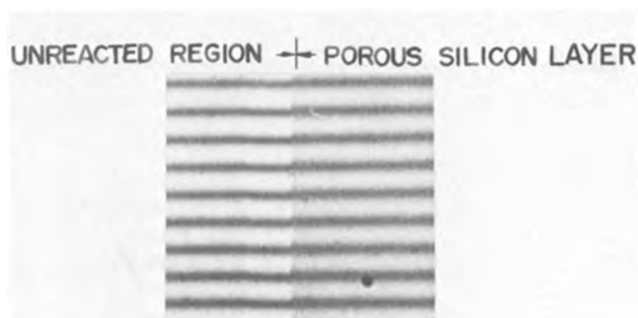

Fig. 4. Interference micrograph of the surface after anodization

and x-ray diffraction patterns of PSL. Figure 5(a) is the ED pattern of the PSL surface immediately after anodization. PSL was 15 μm in thickness and formed at 100 mA/cm² in anodic current density. Figure 5(b) is the x-ray diffraction pattern of PSL which is about 60 μm in thickness. Both Kikuchi's line and ring pattern are observed in ED pattern. However in the x-ray diffraction pattern, only the peak of the (111) plane is observed. The breadth of the x-ray diffraction line becomes broad in comparison with bulk single silicon. In the case of PSL in another orientation of single silicon crystal, the x-ray diffraction pattern shows only the peak of its orientation and the breadth of line also becomes broad. X-ray line broadening seems to be caused by the strain in PSL from the following three results: (*i*) The existence of the strain in PSL is confirmed by x-ray topograph observation (Lang method) (10); (*ii*) The transmission ED of PSL thin film does not show the pattern of mosaic structure but shows the pattern of single crystal structure; (*iii*) No grains which have the size (about 0.13 μm) equivalent to the broadening of the half-peak breadth of x-ray line can be observed in a transmission electron micrograph of PSL thin film given in the following paragraph. Consequently, PSL is thought to be a single crystal from the results of x-ray diffraction, but polycrystal silicon is observed only on the surface of PSL by ED.

Figure 6 shows the surface feature of PSL observed by SEM. Figure 6(a) indicates the surface immediately after anodization, and Fig. 6(b) indicates the surface which was etched in $HF:HNO_3 = 1:300$ solution for 4 sec. The surface immediately after anodization, as shown in Fig. 6(a), has microunevenness, but pores cannot be observed. In the case of Fig. 6(b), many pores of some 10-300Å appear below the surface. These pores are disorderly located and have various shapes. The inside structure of PSL was examined by TEM observation of PSL thin film which was prepared by the method shown in Fig. 2. The anodic current density and the reaction time were 30 mA/cm² and 10 sec, respectively. The results of observing an ~0.4 μm thick PSL film in the bright

field image by TEM is shown in Fig. 7. Figure 7(a) indicates transmission image of PSL observed vertically. Figure 7(b) is the transmission image of PSL observed with tilted illumination at 40°. The bright and dark-striped image is observed, but the image does not have the regular pattern. The contrast of brightness and darkness in Fig. 7(b) is more intense than that in Fig. 7(a). The irregularity of the pattern becomes increased with increasing the tilt angle of observation. As shown in Fig. 6(b), there are many pores in PSL. However, definite image corresponding to these pores is not observed in transmission micrograph. As a result, it can be said that the pores distribute at random in PSL and the pores are not formed straight, that is, the pores are formed zig-zag in the thickness direction of PSL. This result is quite different from that of aluminum anodic oxide film. In the case of aluminum anodic oxide film, a definite (bright and dark) image corresponding to straight pores formed by anodization was observed (11).

To prevent the structure of PSL from changing by chemical and mechanical treatment, the samples were prepared by cleavage of PSL thin films. PSL was roughly cleaved when silicon substrate under PSL was thicker than PSL. PSL has the same crystalline structure as silicon substrate (see Fig. 5), but the cleavage direction of PSL becomes different from that of silicon substrate. PSL is cleaved toward the thickness direction, that is, the cleavage plane of PSL is perpendicular to the surface. In order to prevent PSL from being cleaved roughly, the sample, in which the unreacted region of silicon substrate was sufficiently thinner than PSL, was prepared by the method shown in Fig. 2. PSL was about 17 μm thick and the unreacted region under PSL was about 3 μm thick. The cleaved cross section of PSL observed by SEM is shown in Fig. 8. As shown in Fig. 8(a), the cross section of PSL is uniform from the surface to the boundary between PSL and the silicon substrate. It means that the anodization is achieved uniformly toward the thickness direction. In Fig. 8(b) the vertical striations corresponding to the straight pores, which are perpendicular to the silicon substrate, can be observed near the boundary between PSL and the silicon substrate. But no straight striations continuing from the surface of PSL to the boundary can be observed by the enlarged cross section of PSL as shown in Fig. 8(c).

From the investigation of structures of PSL, the obtained results are following. PSL is formed uniformly in the thickness direction, so it can be said that silicon is dissolved uniformly by anodization toward the thickness direction. PSL is a single crystal and is cleaved perpendicularly, and it seems that silicon is dissolved locally and vertically in PSL for

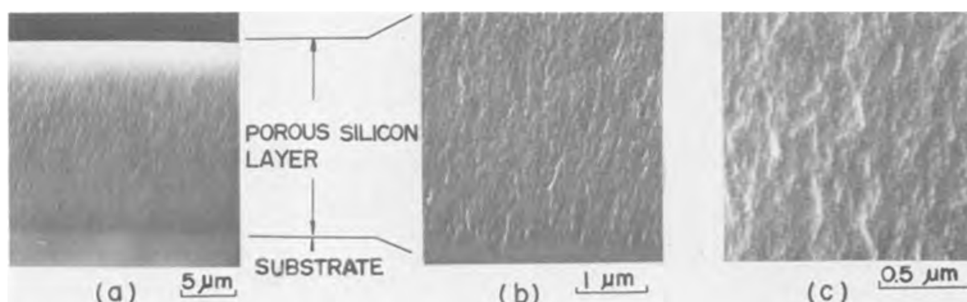

Fig. 8. Scanning electron micrograph of cleaved cross section of PSL. (a) Total view; (b) view at the boundary between PSL and the silicon substrate; (c) enlarged cross-sectional view of PSL.

the most part. Pores are not formed straight, that is, they are formed zig-zag and the pore distribution is irregular.

Changes of PSL by heat-treatment.—In the case of epitaxial growth, PSL is heated at high temperature. It is therefore important to investigate the changes of the distribution of pores and crystalline structure of PSL. These changes were observed by SEM and ED. Heat-treatment was performed in a hydrogen atmosphere. Hydrogen gas was purified by passing through a paladium filter because PSL is very susceptible to oxidation. Figure 9 shows the heat-treatment conditions, scanning electromicrographs, and ED patterns of heat-treated PSL. The silicon substrates were 0.2-0.4 Ω-cm in resistivity. PSL was 4 μm in thickness. The anodic current density and the reaction time were 30 mA/cm^2 and 140 sec, respectively. On the surface of PSL heat-treated at 1000°C little pits and cracks are observed. The crystalline structure is a mosaic pattern. By the heat-treatment above 1070°C, the crystalline structure of PSL is changed to a single crystal. But on the surface of PSL, large pits begin to appear. As shown in Fig. 9, the surface roughness becomes violent with the rise in heat-treatment temperature. Figure 10 shows the cross section of heat-treated PSL which was prepared by cleavage of PSL heat-treated at 1070°C. It can be seen that there are pores inside corresponding to pits observed on the surface.

The migration of silicon in PSL occurs by high temperature heat-treatment, so the crystalline structure becomes a single crystal and the distribution of pores is changed. Heat-treated PSL has larger pores than as-grown PSL. Heat-treated PSL has the third dimensional mesh structure which consists of single crystal grains associated with neighbors.

In order to investigate the dependence of pore distribution of heat-treated PSL on both the anodic current density and the substrate resistivity, the surface of heat-treated PSL was observed by SEM (Fig. 11). The temperature of heat-treatment was 1070°C and PSL was 4 μm in thickness. The surface roughness becomes larger both at high resistivity region and at high anodic current density. This tendency seems to depend on the change of the silicon density in PSL (9).

Silicon epitaxial growth of PSL (12).—From the results mentioned above, for the purpose of epitaxial growth of good quality on PSL, PSL needs to be recrystallized by the heat-treatment above 1070°C and it is profitable to use a low resistivity silicon substrate. Therefore, a p-type (111) single silicon wafer, which was 0.004-0.15 Ω-cm in resistivity, was used as a silicon substrate for anodization. The anodic current density and the anodic reaction time were 50 mA/cm^2 and 60 sec, respectively. Epitaxial silicon was grown at 1170°C by the commonly used thermal decomposition of $SiCl_4$ with hydrogen. The growth rate of epitaxial silicon was 0.4 μm/min and the nondoped epitaxial layer was grown to be about 5 μm in thickness. Figure 12 shows the surface morphology and the crystalline structure of silicon epitaxial layer grown on PSL. The surface morphology was obtained from observation of shadowed carbon replicas by TEM. It is clear that the surface is flat and the crystalline structure observed by ED is single crystal. Figure 13 shows the cross section of this sample. The cross section was obtained by angle lapping and etched for several seconds in HF:HNO_3 = 1:60 solution. Three layers can be observed, these being an epitaxial layer, PSL, and silicon substrate. Observation of etch pits by Sirtl etching makes it clear that stacking faults are very few. From these results, it is revealed that silicon epitaxial layer of good quality can be grown on PSL.

Conclusions

The structures of PSL formed by anodization and the change by high temperature heat-treatment were investigated by SEM, TEM, ED, and x-ray diffraction. PSL is formed uniformly in the thickness direction. Pores cannot be observed on the surface by SEM, but many pores are observed inside. These pores are formed zig-zag in the thickness direction. The cleavage plane of PSL is perpendicular to the surface, so silicon dissolution by anodization seems to be performed vertically in the silicon substrate. The crystalline structure of PSL is a single crystal, but there is a polycrystal silicon on the surface and the strain exists in PSL.

High temperature heat-treatment modifies the microstructure of PSL. Silicon migrates during the heat-treatment, changing the pore size and distribution of the pores. After heat-treatment at a temperature greater than 1070°C, PSL is single crystalline and porous. The surface roughness and pore size increase with heat-treatment temperature.

For the purpose of growing single crystalline silicon on PSL, PSL needs to be a single crystal. In the method of epitaxial growth, which includes heat-treatment above 1070°C, PSL is recrystallized to be a single crystal when silicon epitaxial growth is performed. So single crystalline silicon can be grown on PSL. But in spite of the rough surface of heat-treated PSL, the surface of the epitaxial layer is flat as shown in Fig. 12. This is a very interesting phenomenon, but the reason is not clear now. So it is expected that the reason becomes clear in the future by the investigation of silicon epitaxial growth mechanism.

Electrochromism in Anodically Formed Tungsten Oxide Films

A. Di Paola, F. Di Quarto, and C. Sunseri
Istituto di Ingegneria Chimica, University of Palermo, Italy

ABSTRACT

By anodization of tungsten in acid solutions, oxide films were obtained whose composition depended on the working temperature. In particular, the composition of the films was WO_3 at 25° and 50°C, but $WO_3 \cdot H_2O$ at 70°C. Studies of electrochromism in these films seem to show that the electrocoloration occurs with different mechanisms according to the oxide chemical composition. For WO_3 films the coloration is due to a simultaneous injection of electrons and H^+ ions with formation of hydrogen tungsten bronzes H_xWO_3. For $W_3 \cdot H_2O$ films the coloration could occur as a result of the injection of electrons and oxygen ion vacancies with formation of blue oxide hydrate $WO_{3-x} \cdot H_2O$.

The phenomenon of electrochromism in WO_3 films is under active investigation because of its potential use for passive alphanumeric displays.

Electrochromism in WO_3 films was first reported by Deb (1). A reversible blue coloration was generated at the cathodic area on applying a d-c electric field across an evaporated WO_3 film. Deb has proposed (2) that the coloration occurred as a result of the formation of F or F^+ color centers in oxygen ion vacancies. Chang *et al.* (3) have attributed the blue color to the formation of reduced oxides of general formula WO_{3-x} according to the electrochemical reaction

$$mWO_3 + 2nH^+ + 2ne^- \rightarrow W_mO_{3m-n} + nH_2O \quad \text{(blue)} \qquad [1]$$

Other authors (4-8) have suggested the formation of hydrogen tungsten bronzes by double injection of protons and electrons

$$WO_3 + nH^+ + xe^- \rightarrow H_xWO_3 \quad (O \leq x \leq 0.6) \quad \text{(blue)} \qquad [2]$$

In this hypothesis the phenomenon of coloration was explained by Faughnan *et al.* (8) as an intervalence transfer absorption

$$W^{5+}(A) + W^{6+}(B) + h\nu \rightarrow W^{6+}(A) + W^{5+}(B) \qquad [3]$$

Recent studies (9-11) have confirmed the model proposed by Faughnan and co-workers.

In almost all previous investigations, the WO_3 films were prepared by evaporation of WO_3 onto transparent substrates (generally quartz or glass). The films were amorphous and with an unknown water content.

Although all the authors have recognized the importance of the water presence, only Hurditch (12) has studied the dependence of the coloration phenomenon on the water content of the films. For the case of hydrated oxides represented as $WO_3 \cdot aq$, Hurditch has proposed the formation of blue hydrogen tungsten bronzes of general formula $WO_{3-m}(OH)_m \cdot aq$. The H_2O molecules provide H^+ ions which are reduced at the cathode giving rise to active hydrogen atoms, which form a reduced tungsten blue phase

$$WO_3 \cdot aq + mH \rightarrow WO_{3-m}(OH)_m \cdot aq \qquad [4]$$

This tungsten blue phase does not correspond to any of the phases studied by Glemser *et al.* (13, 14), who have obtained blue tungsten compounds by reduction of WO_3, $WO_3 \cdot H_2O$, and $WO_3 \cdot 2H_2O$ by means of nascent hydrogen.

Key words: tungsten oxide films, electrochromism, hydrogen tungsten bronzes, blue tungsten oxide hydrates.

In this paper we report some results on the electrochromism of anodically formed tungsten oxide films. The experimental results indicate that different coloration mechanisms can occur, depending on the oxide chemical composition.

Experimental

The electrodes were obtained from spectrographically pure tungsten sheets 0.1 mm thick. They were electropolished in 15% NaOH at room temperature, rinsed with distilled water, and dried in a nitrogen stream. The anodization was performed at three different temperatures (25°, 50°, 70°C) but always at the same constant current density of 8 mA cm^{-2}. The current was supplied by a Keithley Model 227 constant current generator.

After the oxidation the electrodes were either submitted to x-ray analysis or inserted into an electrochemical cell containing H_2SO_4 1*N* at room temperature to investigate the coloration process. Nitrogen was bubbled through the solution before and during the experiments. The auxiliary electrode was Pt. The electrode potential was measured with respect to a Hg/Hg_2SO_4 (1*N* H_2SO_4) reference electrode with a Keithley Model 610 C electrometer. Cyclic voltammetry measurements were carried out with a Amel Model 557 potentiostat and a Systron-Donner Model 410 function generator. All potentials reported are referred to the standard hydrogen electrode at 25°C.

Direct x-ray diffraction patterns of the films on the tungsten sample were obtained using a Philips Model PW 1130 generator and PW Model 1050 goniometer. Copper $K\alpha$ radiation was used and the scanning rate of 2θ 1°/min. Measured d spacings were compared with the ASTM index values. The data reported by Glemser *et al.* (13, 14) were used mainly for the identification of the hydrated oxides.

Results and Discussion

Oxide film formation.—In previous works (15, 16) it has been shown that the temperature and the electrolyte composition strongly influence the anodic behavior of tungsten in acid solutions.

1*N* H_2SO_4 solutions were used for the anodization at 50° and 70°C. 1*N* HNO_3 solutions were preferred at 25°C, since a poor mechanical stability of the layers was observed in H_2SO_4 solutions at high potentials (15).

Figure 1 shows the influence of temperature on the anodic charging curves at constant C.D. During the first instants of anodization, the shape of the curves is the same for every temperature investigated. With the increase of time all curves reach a maximum.

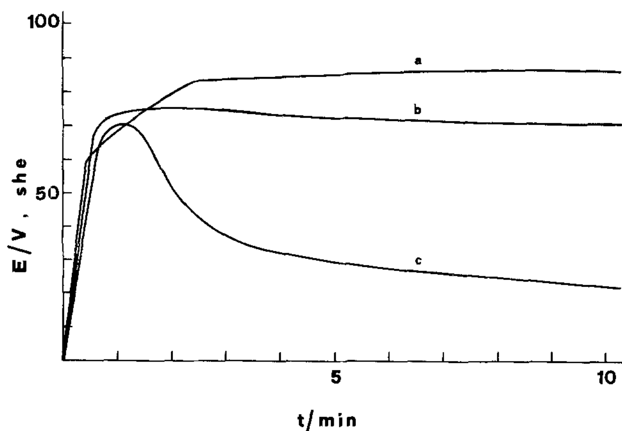

Fig. 1. Effect of temperature on anodic-charging curves at 8 mA cm^{-2} (pen recorded): (a) 1N HNO_3 at 25°C; (b) 1N H_2SO_4 at 50°C; (c) 1N H_2SO_4 at 70°C.

However, while at 25° and 50°C the electrode potential remains practically constant thereafter, at 70°C it decreases until a quasisteady-state value is obtained. This last value is about 50V smaller than the maximum. In any case by increasing the anodization time the oxide films thicken. This oxide growth indicates that a corrosion process is operating with formation of a thicker porous layer outside a barrier layer. This process depends on the temperature and the electrolyte composition (17). The times of anodization were selected so as to produce comparable thickness and weight of the films.

At the end of the experiments, at 25° and 50°C, the electrodes were normally covered by a whitish-gray oxide film, while a yellow-green film was obtained at 70°C. All the oxide layer have shown a good adherence to the metallic substrate.

X-ray analysis of the oxidation products.—Recent investigations (17) have shown that the temperature plays a fundamental role in determining the chemical composition and the morphology of the oxide layers.

Figures 2a, 3a, and 4a, show the x-ray diffraction patterns of the films obtained at different temperatures. The experimental data were compared with the ASTM and Glemser *et al.* (14) d spacings, which are reported in the Tables I and II.

Both at 25° and 50°C the composition of the anodic films is mainly WO_3. At 25°C the diffraction pattern shows two peaks for 2θ values near 13° and 27° which could be attributed to the simultaneous presence of $WO_3 \cdot 2H_2O$.

The whitish-gray color of the electrodes does not seem due to the presence of white $WO_3 \cdot 2H_2O$ (18) but to the morphology of the layers. In fact whitish films often do not show peaks characteristic of $WO_3 \cdot 2H_2O$.

At 70°C the diffraction data have shown that the composition of the films is $WO_3 \cdot H_2O$. Also at this temperature there are sometimes very weak reflections of the dihydrate phase.

In conclusion, by means of the x-ray analysis the following aspects can be emphasized: (*i*) in every electrolyte solution and for working temperatures up to 50°C the oxide film is mostly composed of WO_3[1]; (*ii*) the increase of temperature above 50°C causes the formation of $WO_3 \cdot H_2O$. This compound is practically the only phase present above 70°C and for 1N H_2SO_4 solutions. $WO_3 \cdot 2H_2O$ can be found in the films, especially in those formed at 25°C.

Coloration of the films.—The coloration process of the anodic oxide films was studied by cathodic polarization of the specimens at different current densities. The shape of the potential/time curves was similar for any chemical composition of the starting films.

[1] On the basis of the available data one cannot definitely exclude the presence of H_2O, though at very low levels, in these films.

Also the final value of the potential was practically equal for all electrodes at the same C.D. In any case the final process was hydrogen evolution as evidenced by gas bubble generation at the electrode.

During the cathodic reduction the electrode surface became more and more blue with the increase of the injected charge. Colored electrodes exposed to air showed a different rate of bleaching depending on their chemical composition. Generally, reduced hydrated oxides bleached faster.

In Fig. 5 and 6 the cyclic voltammetry measurements of WO_3 and $WO_3 \cdot H_2O$ are reported. The voltammograms show significant differences both in the anodic and cathodic portions. In the cathodic curve two peaks were observed. For WO_3 electrodes, the former (more anodic) can be attributed to the formation of hydrogen tungsten bronzes (7); the latter is obviously due to the hydrogen evolution process.

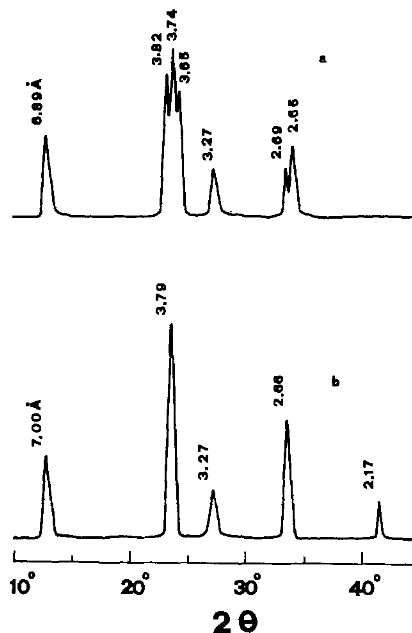

Fig. 2. X-ray diffraction patterns: (a) film obtained by oxidation in 1N HNO_3 at 25°C for 10 min; (b) the same film after reduction in 1N H_2SO_4 at 25°C.

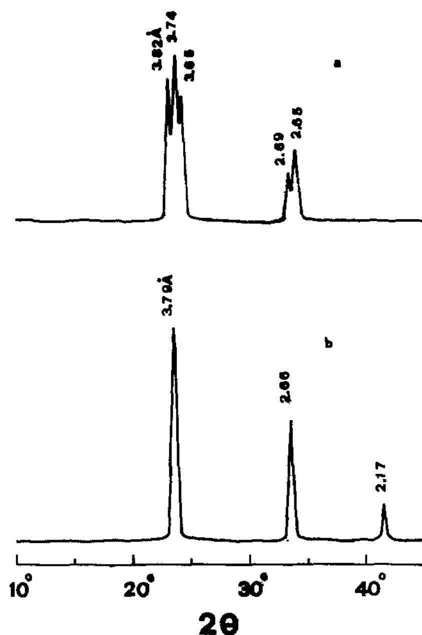

Fig. 3. X-ray diffraction patterns: (a) film obtained by oxidation in 1N H_2SO_4 at 50°C for 15 min; (b) the same film after reduction in 1N H_2SO_4 at 25°C.

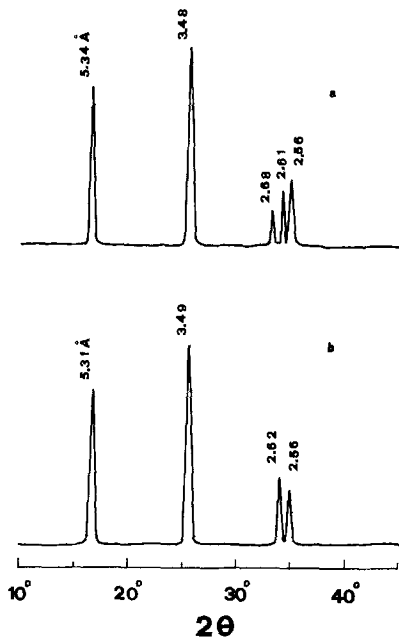

Fig. 4. X-ray diffraction patterns: (a) film obtained by oxidation in 1N H_2SO_4 at 70°C for 60 min; (b) the same film after reduction in 1N H_2SO_4 at 25°C.

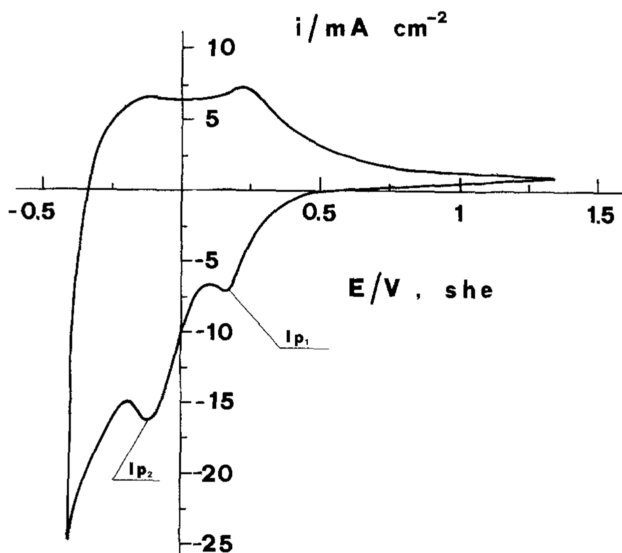

Fig. 5. Cyclic voltammetry measurement of a WO_3 film in 1N H_2SO_4 at 25°C, sweep rate 210 mV min^{-1}.

For $WO_3 \cdot H_2O$ electrodes both peaks were found at more anodic potential values. In this case, the former could be attributed to the formation of a reduced hydrate tungsten oxide (see below).

The voltammograms were not significantly modified by repetitive cycling. The different bleaching rate of the electrodes was evident also during the cyclic voltammetry measurements. Electrodes obtained by reducing WO_3 were pale blue even at the end of the anodic sweep when the electrode potential

2.31	40	2.27	10	2.27	10	2.29	20

value was about 1.4V. This color was maintained even though an anodic potential of 5V was applied for a few seconds. Instead, electrodes obtained by reducing $WO_3 \cdot H_2O$ were completely bleached already about 1V.

The relative heights of the two peaks of cathodic current show further differences. In fact for WO_3 electrodes the ratio $I_{p2} - I_{p1}/I_{p1}$ is about 1.25, while for $WO_3 \cdot H_2O$ this ratio is one.

X-ray analysis of the reduction products.—After the coloration process the electrodes were rinsed with distilled water, dried rapidly in a nitrogen stream, and immediately submitted to x-ray analysis.

Figures 2b, 3b, and 4b show the x-ray diffraction patterns of the electrodes after cathodic reduction. When the composition of the formed film was WO_3, the reduction products were hydrogen tungsten bronzes, whose hydrogen content changed with change of the charge injected during the cathodic polarization. For bronzes with a high hydrogen content ($x > 0.1$), the diffraction patterns proved difficult to index (see Table I) as already reported by Chevrier *et al.* (7).

Instead, sharp peaks attributable to $H_{0.1}WO_3$ were exhibited by the patterns of the same electrodes analyzed after waiting a time sufficient for a partial reoxidation to air (see Table III). $H_{0.1}WO_3$ was also the composition of the films at the end of the anodic sweep in the cyclic voltammetry measurements of WO_3 electrodes.

For cathodic reduction of $WO_3 \cdot H_2O$ films, a "tungsten-blue" phase was obtained whose diffraction pattern could be interpreted in terms of the reduced oxide hydrate $WO_{2.88} \cdot H_2O$. It was the only phase found also after a prolonged cathodic polarization at constant C.D. The attribution was made by comparison of the d spacings with the index values (see Table II) reported by Glemser *et al.* (14). This conclusion was supported by the diffraction patterns of the electrodes reoxidized to air. In fact these last d spacings matched those obtained by Glemser (14) for reoxidized $WO_3 \cdot H_2O$.

Reduced dihydrate oxides were obtained for cathodic reduction of $WO_3 \cdot 2H_2O$ in those specimens where this species was present. Mention should be made that the same reduction products were obtained by reducing the films with indium in 20% H_2SO_4 solution (19).

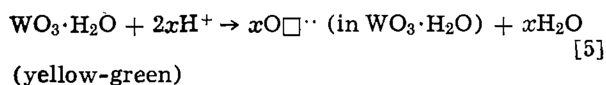
Conclusions

By anodization of tungsten at various temperatures, different oxide films are obtained which exhibit the electrochromism effect as WO_3 evaporated films. The coloration occurs whatever is the composition of the starting oxide, but the bleaching seems reversible only for the hydrate oxides.

Two different mechanisms can be suggested for the coloration process of tungsten oxide films according to their chemical composition. The most direct evidence is given by the x-ray analysis and the cyclic voltammetry measurements. In fact, different reduction products and different cathodic processes are obtained depending on the starting oxide film. For WO_3 anodic films the coloration can be attributed to the formation of blue hydrogen tungsten bronzes of formula H_xWO_3, as a result of a diffusion of H^+ ions from the electrolyte into the WO_3 lattice and a simultaneous injection of electrons from the oxide-metal interface (8-11).

Otherwise, for anodic-hydrated oxide films of formula $WO_3 \cdot H_2O$ or $WO_3 \cdot 2H_2O$, the coloration could occur as a result of the injection and trapping of electrons in oxygen ion vacancies $O\square^{\cdot\cdot}$ (where the square indicates a vacancy and the dots the number of positive charges).

These vacancies are likely originated by the reaction of H^+ ions in the electrolyte with the oxide surface

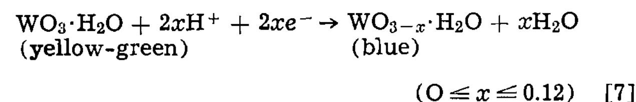


$$WO_3 \cdot H_2O + 2xH^+ \rightarrow xO\square^{\cdot\cdot} \text{ (in } WO_3 \cdot H_2O) + xH_2O \quad [5]$$
(yellow-green)

Then the vacancies $O\square^{\cdot\cdot}$ diffuse in the bulk of the oxide layer and capture the electrons injected from the oxide-metal interface according to the reaction

$$xO\square^{\cdot\cdot} \text{ (in } WO_3 \cdot H_2O) + 2xe^- \rightarrow \underset{\text{(blue)}}{WO_{3-x} \cdot H_2O} \quad [6]$$

The over-all reaction is



$$\underset{\text{(yellow-green)}}{WO_3 \cdot H_2O + 2xH^+ + 2xe^-} \rightarrow \underset{\text{(blue)}}{WO_{3-x} \cdot H_2O} + xH_2O$$
$$(0 \leq x \leq 0.12) \quad [7]$$

In conclusion, two different mechanisms of coloration seem possible in tungsten oxide films depending on their starting composition.

For anhydrous oxides of formula WO_3 the appearance of color centers is due to the formation of the H_xWO_3 phase (with $x \leq 0.6$), while for hydrate oxides of formula $WO_3 \cdot H_2O$, F or F^+ centers in oxygen ion vacancies are involved. In $WO_3 \cdot H_2O$ oxides the presence of H_2O in the WO_3 matrix likely hinders the diffusion of H^+ ions into the otherwise "open" crystal structure of WO_3, and therefore the coloration takes place with formation of blue $WO_{3-x} \cdot H_2O$.

This interpretation is in agreement with the hypothesis reported by Witzke (10), who found that already blue WO_{3-y} films, which therefore contain large densities of oxygen vacancies, may be colored to a deeper blue according to the reaction

$$\underset{\text{(clear)}}{WO_{3-y}} + xH^+ + xe^- \rightarrow \underset{\text{(blue)}}{H_xWO_{3-y}} \quad [8]$$

A diffusion of the H^+ ions from the electrolyte with formation of hydrogen tungsten bronzes of formula H_xWO_{3-y} seems so possible also for anhydrous oxides substoichiometric but not for hydrated oxides. The experimental evidence is consistent with this interpretation, but further work seems necessary to verify the validity of this model. In view of technological applications, the anodic $WO_3 \cdot H_2O$ films could be a new interesting material for display devices.

The Defect Structure of Pure and Doped ZnSe

A. K. Ray*,[1] and F. A. Kröger*

Department of Materials Science, University of Southern California, Los Angeles, California 90007

ABSTRACT

Measurements of Hall effect and Zn self-diffusion on single crsytals of ZnSe doped with various amounts of Al or As were performed at 800°, 900°, and 1000°C when the crystals were in equilibrium with atmospheres of well-defined zinc pressures; Hall effect measurements were also performed on crystals cooled after high temperature equilibration. Analysis of the results leads to the conclusion that Schottky disorder is the main type of atomic disorder. Values of the parameters for various equilibrium constants are determined.

ZnSe has potential as a material for electroluminescent diodes and windows for high power infrared lasers. Knowledge of the high temperature defect structure is important for predicting the properties of materials made under different preparative conditions. A considerable amount of work has been devoted to the determination of the position of energy levels of various defects in the forbidden gap. Some levels are unambiguously assigned to certain foreign defects, while others are attributed to native defects, the exact nature of which (vacancies or interstitials, state of ionization) is not known. So far efforts to reach an understanding of the defect structure of ZnSe have been limited. High temperature Hall effect and conductivity measurements (1, 2) and self-diffusion measurements (3) were interpreted differently and no single model has emerged on the basis of which all the observations on ZnSe can be explained. In this investigation we attempt to determine the defect structure of ZnSe by high temperature measurements of the Hall effect and zinc tracer self-diffusion for Al- and As-doped ZnSe crystals. Measurements of the electron concentration at room temperature on ZnSe crystals quenched from high temperature after equilibration with atmospheres with well-defined zinc pressures provide information on the processes taking place during cooling.

Al substituting for Zn acts as a single donor with a level close to the conduction band. Solubilities of 2×10^{19} cm^{-3} (4) and 1.5×10^{20} cm^{-3} (5), reached by in-diffusion, have been reported. In the latter case the samples are degenerate. Implantation also gives rise to large Al concentrations (6). Often the electron concentration is a small fraction (10%) of the Al concentration as a result of self-compensation with formation of $(Al_{Zn}V_{Zn})'$ (4, 7). The largest electron concentrations are found after annealing in zinc vapor (8, 9). As substituting for Se acts as a single acceptor (10, 11) with an As_{Se}' acceptor level at $E_v + 0.5$ eV (12). Another level caused by As is found at $E_v + 0.22$ eV; the nature of the center responsible for this level is not known (12). As_{Se}' is believed to be involved in luminescence at 1.67 eV (11) and 2.328 eV (12). Whereas the latter fits the level at $E_v + 0.5$ eV, the former does not.

Samples and Experimental Procedures

Crystal boules of ZnSe grown from melts containing 3, 10, 30, or 300 ppm Al or 50 ppm As were obtained from the Eagle Picher Company. Plates of $10 \times 10 \times 1$ mm were cut from the boules for the electrical measurements and blocks of $10 \times 8 \times 1.5$ mm for the diffusion experiments. The samples are referred to as sample No. 1, 2, 3, 4 in sequence of Al content; ZnSe:As is sample No. 5. After cutting, the samples were etched for 5 min in a boiling aqueous solution of NaOH and were then rinsed with deionized water. Measurements of Hall effect and resistivity were performed at temperatures from 800° to 1000°C in an apparauts as described by Hershman and Kröger (13) which allowed establishment of well-defined zinc pressures. The van der Pauw method (14) was used with a magnetic field of 0.35 Weber/m² (= 3.5 kilogauss) and d-c currents ranging from 0.5 to 50 mA depending on the resistivity of the sample. Ohmic contacts were "written" on the etched crystal surface with the aid of an indium wire dipped in a (In, Hg) alloy; the crystals were then heated for 2-3 min to 300°C in a hydrogen atmosphere and then cooled to room temperature (15). Electron concentrations were calculated from $[e'] = (Rq)^{-1}$, R being the Hall constant and q the electronic charge.

For zinc tracer diffusion measurements, Zn^{65}, γ, 1.12 MeV tracer was obtained from the New England Nuclear Corporation in the form of $ZnCl_2$ in 0.5*N* HCl. The tracer was dissolved in normal zinc by the procedure described for Cd by Kumar and Kröger (16). After diffusion anneal, tracer penetration profiles were determined by the procedure reported by Kumar and Kröger (16).

Experimental Results

High temperature Hall measurements.—Figures 1, 2, 3, and 4 show the variation with p_{Zn} of high temperature resistivity and electron concentration of samples 1, 2, 3, and 4, respectively. For samples 1, 2, and 3, containing the lowest amounts of Al, the electron concentration and resistivity were independent of p_{Zn} at high zinc pressures. Under these conditions the electron concentration was also independent of temperature. Electron concentration was proportional to $p_{Zn}^{1/2}$ and resistivity to $p_{Zn}^{-1/2}$ at low zinc pressures. For

Key words: ZnSe:Al, ZnSe:As, Hall effect, self-diffusion.

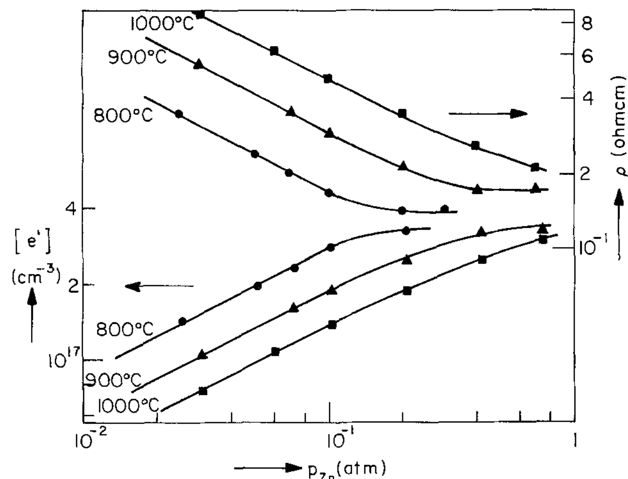

Fig. 2. Resistivity (ρ) and electron concentration of sample 2 as a function of p_{Zn} at 800°, 900°, and 1000°C.

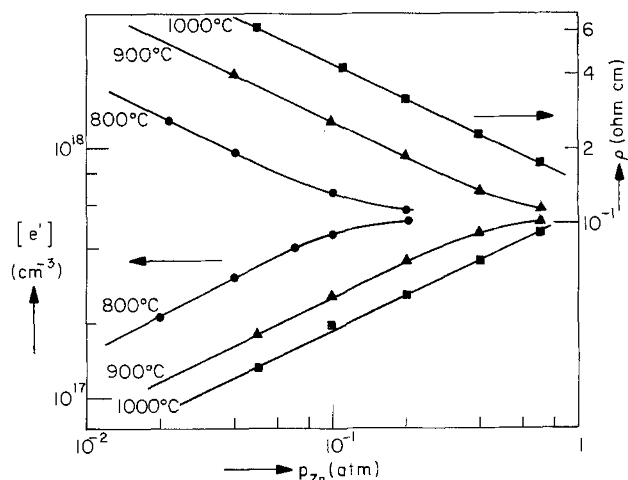

Fig. 3. Resistivity (ρ) and electron concentration of sample 3 as a function of p_{Zn} at 800°, 900°, and 1000°C.

sample 4, containing a large concentration of Al, electron concentration varied as $p_{Zn}^{1/2}$ and resistivity as $p_{Zn}^{-1/2}$ over the entire zinc pressure range investigated. In all ZnSe:Al samples electron concentration decreased and resistivity increased with increase in temperature. Electron concentration in the low p_{Zn} region was found to be proportional to the square root of Al added in the melts from which crystals were grown. The activation energy of electron concentration in this region was −0.5 eV.

Figure 5 shows the variation of high temperature resistivity and electron concentration of ZnSe:As (sample 5) as a function of p_{Zn}. At all temperatures the electron concentration is proportional to $p_{Zn}^{1/2}$ and resistivity to $p_{Zn}^{-1/2}$ in the zinc pressure range investigated. Different from what was found for ZnSe:Al, the electron concentration increased and resistivity decreased with increase in temperature. The activation energy of electron concentration was 0.9 eV. At a given temperature and p_{Zn} the electron concentration of the ZnSe:As sample was less than that of the ZnSe:Al samples. For all samples, the accuracy of the p_{Zn} exponents is ± 0.03.

Room temperature Hall measurements.—Figures 6 and 7 show room temperature electron concentrations of ZnSe:Al samples when quenched from 800° and 900°C, respectively. At high p_{Zn}, room temperature electron concentrations are the same as those at high temperature. At medium p_{Zn}, the electron concentration follows a $p_{Zn}^{1/2}$ law over a fairly wide zinc pressure range. For each sample there is a critical p_{Zn} at which there is a sharp cutoff of the electron concentration. Crystals quenched after equilibration at p_{Zn} lower than $p_{Zn,\,cutoff}$ have a high resistivity at room temperature.

ZnSe:As crystals always have a high resistivity at room temperature, independent of p_{Zn} and temperature at which they have been equilibrated.

Diffusion experiments.—Zinc tracer diffusion coefficients measured in ZnSe:Al crystals at 900°C and $p_{Zn} = 10^{-2}$ atm are shown in Fig. 8. D_{Zn}^* is seen to be proportional to [Al] for medium and high Al concentrations. Figure 9 shows D_{Zn}^* of samples 4 and 5 as a function of temperature at $p_{Zn} = 10^{-2}$ atm. The diffusion coefficients of Zn are represented by

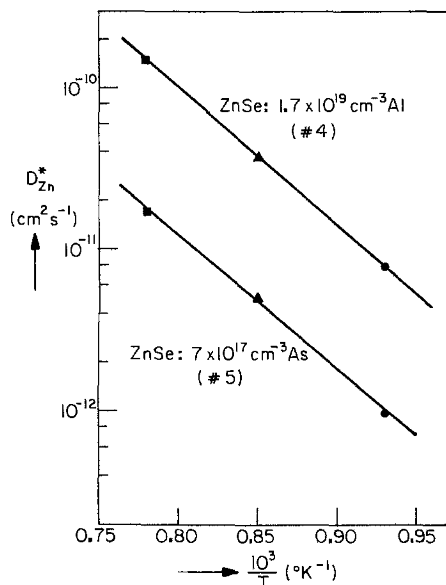

Fig. 9. Temperature dependence of zinc tracer diffusion coefficients for ZnS: 1.7 × 10^{19} cm^{-3} Al and ZnSe: 7 × 10^{17} cm^{-3} As.

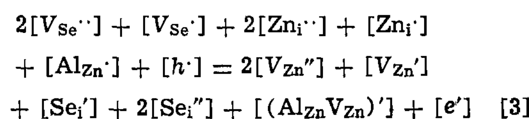
$$(D_{Zn}^*)_{Al} = 8.4 \times 10^{-4} \exp - (1.70 \pm 0.05\ eV/kT)\ cm^2\ sec^{-1} \quad [1]$$

$$(D_{Zn}^*)_{As} = 5.0 \times 10^{-5} \exp - (1.65 \pm 0.05\ eV/kT)\ cm^2\ sec^{-1} \quad [2]$$

Discussion

High temperature Hall effect measurements.—ZnSe: Al.—All our observations on ZnSe:Al can be explained with the aid of defect chemistry, which consists of ionization and incorporation reactions and the corresponding mass action relations combined with the neutrality relation



$$2[V_{Se}^{\cdot\cdot}] + [V_{Se}^{\cdot}] + 2[Zn_i^{\cdot\cdot}] + [Zn_i^{\cdot}] + [Al_{Zn}^{\cdot}] + [h^{\cdot}] = 2[V_{Zn}''] + [V_{Zn}'] + [Se_i'] + 2[Se_i''] + [(Al_{Zn}V_{Zn})'] + [e'] \quad [3]$$

and the aluminum balance relation

$$[Al]_{total} = [Al_{Zn}^{\times}] + [Al_{Zn}^{\cdot}] + [(Al_{Zn}V_{Zn})'] + [(Al_{Zn}V_{Zn})^{\times}] \quad [4]$$

The symbols used here follow the convention proposed by Kröger and Vink, on-line symbols indicating species (atoms or vacancies, V), subscripts indicating the site occupied by the species (an interstitial site being indicated by i), while superscripts dot (·), dash ('), and multiplication sign (×) indicate positive, negative, or zero effective charges with the electronic charge $|q|$ as the unit. Square brackets indicate concentrations in numbers per cubic centimeter.

When the neutrality and mass balance relations are approximated by their dominant members (17) the concentrations of all species can be expressed as $[Al]^m p_{Zn}^n$ where m and n can be integers or simple fractions. In principle 36 neutrality approximations can be made from Eq. [3]. Only 11 of those need to be considered as a possibility for ZnSe doped with Al. Schottky disorder will be assumed to be the dominant disorder process in ZnSe. The justification of this assumption is given later. Defect concentrations for various neutrality and Al balance approximations are shown in Table I. By comparing experimental results with the expressions in Table I, it is found that at low zinc pressures all Al-doped ZnSe crystals are in range 8 whereas at high zinc pressures samples 1, 2, and 3 are in range 10 but sample 4 is still in range 8. The

neutrality conditions 1, 2, and 9 which would also give $[e'] \propto p_{Zn}^{1/2}$ are rejected because for them the electron concentrations are independent of Al concentration. Electron concentration at any p_{Zn} can be determined by considering the incorporation reaction

$$V_{Zn}'' + Zn(g) \rightleftarrows Zn_{Zn}^{\times} + 2e'; \; K_{ZnV} \quad [5]$$

$$[e'] = K_{ZnV}^{1/2} \, [V_{Zn}'']^{1/2} \, p_{Zn}^{1/2} \quad [6]$$

In range 8, the neutrality condition is

$$[Al_{Zn}^{\cdot}] = 2[V_{Zn}''] \quad \text{and} \quad [Al_{Zn}^{\cdot}] = [Al]_{total}$$

therefore

$$[e']_{Al,8} = 2^{-1/2} \, K_{ZnV}^{1/2} \, [Al]^{1/2} \, p_{Zn}^{1/2} \quad [7]$$

In range 10, the electron concentration is given by

$$[e'] = [Al]_{total} \quad [8]$$

The zinc pressure at which transfer from range 8 to range 10 takes place is found by equating the expressions for $[e']$ in the two regions

$$p_{Zn(8,10)} = \frac{2[Al]}{K_{ZnV}} \quad [9]$$

Therefore at a given temperature, transfer from range 8 to range 10 takes place at a value of p_{Zn} that is the higher, the higher the Al concentration. This explains why sample 4 was never in range 10. The Al concentration in ZnSe can be found from the electron concentration if the sample is in the range where $[Al_{Zn}^{\cdot}] = [e']$. In this manner sample 1 was found to contain 1.6×10^{17} Al cm^{-3}. Aluminum concentrations of samples 2, 3, and 4 were computed from the electron concentration in range 8 using [7] and were found to be 5.2×10^{17}, 1.5×10^{18}, and 1.7×10^{19} cm^{-3} Al, respectively. Comparison with the corresponding Al contents of the melt shows that the distribution constant $k_{Al} = [Al]_{ZnSe}/[Al]_l = 0.44 \pm 0.03$. Spectrographic analysis of sample 4 gave an Al concentration of 1.44×10^{19} cm^{-3} close to the value mentioned above, thus supporting the assumptions underlying the estimate. The Al concentrations of other samples were below the detection limit of the spectrographical analysis. The constant K_{ZnV} in [7] as $f(T)$ was determined from the temperature dependence of the electron concentration of a ZnSe:Al sample at a particular p_{Zn}. It can be represented by

$$K_{ZnV} = 4.65 \times 10^{13} \exp{(1.0 \text{ eV}/kT)} \text{ atm}^{-1} \text{ cm}^{-3} \quad [10]$$

ZnSe:As.—Sample 5 showed $[e'] \propto p_{Zn}^{1/2}$ in the entire zinc pressure range investigated. It is *a priori* uncertain whether this sample is acceptor dominated or shows intrinsic behavior because of compensation Let us first consider the last possibility. In this case the defect structure of the sample in the zinc pressure range investigated would correspond to range 1 or 2 of Table I. If the sample would be in range 1, then $[e']$ is given by

$$[e'] = K_{ZnV}^{1/2} \, K_S''^{1/4} \, p_{Zn}^{1/2} \quad [11]$$

Here K_S'' is the equilibrium constant of Schottky disorder

$$O \rightleftarrows V_{Zn}'' + V_S''; \quad K_S'' = [V_{Zn}''][V_S^{\cdot\cdot}] \quad [12]$$

The measured activation energy for the electron concentration in sample 5 was 0.9 eV. With $K_{ZnV} = K_{ZnV^{\circ}} \exp{(-H_{ZnV}/kT)}$ and $K_S'' = K_S^{\circ} \exp{(-H_S''/kT)}$ then according to Eq. [11], $\frac{1}{2} H_{ZnV} + \frac{1}{4} H_S'' = 0.9$ eV. Or, with $H_{ZnV} = -1.0$ eV, $H_S'' = 5.6$ eV. As we shall see, such a high value of H_S'' is unacceptable.

If the defect structure of sample 5 would correspond to range 2, then the room temperature electron concentration of crystals quenched to room temperature after annealing at high temperature with different p_{Zn} should be almost equal to that at high temperature because the $V_{Se}^{\times}$ level is only 0.008-0.02 eV below the conduction band (18-20). This was not observed for sample 5: It had almost no free carriers after cooling. Therefore, it must be concluded that the sample is acceptor dominated, As being the acceptor.

Our experimental results indicate that As is not incorporated according to $[As_{Se}'] = [V_{Se}^{\cdot}]$, because in that case $[e']$ would be proportional to p_{Zn}. On the other hand, incorporation of As as $[As]_{total} = [As_{Se}'] = 2[V_{Se}^{\cdot\cdot}]$ leads to the observed dependence $[e'] \propto p_{Zn}^{1/2}$. Substituting $[V_{Zn}'']$ in Eq. [6] by $[V_{Zn}''] = K_S''/[V_{Se}^{\cdot\cdot}] = 2K_S''/[As_{Se}']$, we get

$$[e']_{As} = 2^{1/2} \, K_{ZnV}^{1/2} \, K_S''^{1/2} \, [As_{Se}']^{-1/2} \, p_{Zn}^{1/2} \quad [13]$$

Hence $\frac{1}{2} H_{ZnV} + \frac{1}{2} H_S'' = 0.9$ eV, the observed activation energy. We found earlier $H_{ZnV} = -1.0$ eV; therefore, $H_S'' = 2.8$ eV, an acceptable value.

If $[As_{Se}']$ would be known, it would also be possible to determine $K_S^{\circ\prime\prime}$. Unfortunately the As content of the sample was below the detection limit by spectro-

graphic analysis. It is possible, however, to estimate the As concentration indirectly by comparing our results with those obtained by Smith (1). This author measured the high temperature electron concentration in ZnSe crystals containing 10^{17} to 3×10^{18} cm^{-3} electrically active impurities and found an activation energy of 0.8 ± 0.1 eV, almost the same as that found by us for sample 5. He also found that crystals quenched after a high temperature anneal had a high resistivity, again similar to what we found for sample 5. This suggests that Smith's sample was not undoped (as believed by him) but acceptor dominated with an acceptor concentration $\approx 10^{18}$ cm^{-3}. The electron concentrations found by us were two times larger than those of Smith's sample, indicating a four times smaller acceptor concentration in our sample. We shall assume sample 5 to contain 7×10^{17} cm^{-3} As. Since the melt from which the crystal was grown contained 50 ppm or 2.2×10^{18} cm^{-3} As, this corresponds to $k_{As} = [As]/[As]_l = 0.32$. We can now compute $K_S''^{\circ}$. Rather than do this using Eq. [13] which tends to add the errors in $[e']$ and K_{ZnV}, we calculate K_S'' from

$$K_S'' = \frac{[Al_{Zn}^{\cdot}]\,[As_{Se}']}{4[e']_{Al}^2/[e']_{As}^2} \qquad [14]$$

an expression obtained by combining [7] and [13]. Here $[e']_{Al}$ and $[e']_{As}$ are values of the electron concentration in Al- and As-doped samples at the same temperature and zinc pressure. $[e']_{Al}/[e']_{As}$ values for each ZnSe:Al crystal at one temperature were computed at different zinc pressures. The average value was used in the calculation of K_S''. Each ZnSe:Al sample yields values of K_S'' at various temperatures. In Fig. 10 values of $K_S''^{1/2}$ obtained in this manner are plotted against $1/T$. K_S'' is found to obey the relation

$$K_S'' = 4.84 \times 10^{44} \exp\{-(2.9 \pm 0.1)\ \text{eV}/kT\}\ \text{cm}^{-6}$$

$$= 1 \times \exp\{-(2.9 \pm 0.1)\ \text{eV}/kT\}\ \text{site}\ fr^2 \qquad [15]$$

Electron concentrations at room temperature.—ZnSe:Al.—At high temperatures electrons are minority species compared to atomic defects. It will be assumed that during cooling from the annealing temperature to room temperature, atomic defects are frozen in, but that electron and hole equilibria are maintained, excess of electrons over holes remaining free or changing the charge of atomic defects. At high p_{Zn}, room temperature electron concentrations are the same

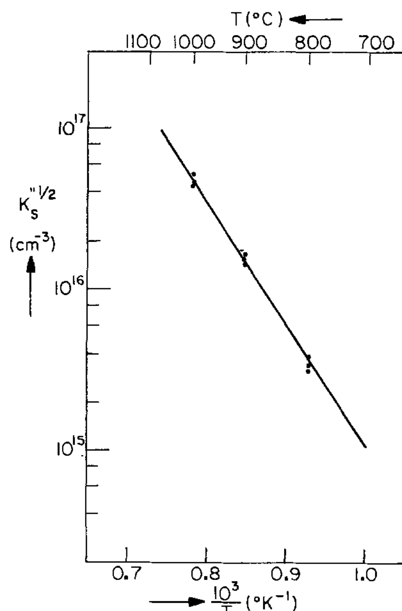

Fig. 10. Temperature dependence of $K_S''^{1/2}$

as those at high temperatures. This indicates that $Al_{Zn}^{\times}$ is a shallow donor, consistent with the observation of Aven and Segall (19) who found $E_d \approx 0$. It also shows that precipitation of donors does not occur. The cutoff in electron concentration at low p_{Zn} can be due to recombination with holes or to trapping of electrons at V_{Zn}' or some transition metal impurity which gives rise to a deep acceptor level inside the bandgap.

If the cutoff in electron concentration is caused by recombination with holes, the p_{Zn} at which this takes place is given by the condition $[e'] = [h^{\cdot}] = K_i^{1/2}$ at high temperature, K_i being the equilibrium constant of intrinsic electronic disorder. Using Eq. [7] this zinc pressure is given by

$$p_{Zn([e']=[h^{\cdot}])} = 2K_i/(K_{ZnV}[Al]) \qquad [16]$$

Thus the zinc pressure at which the cutoff in electron concentration takes place should vary inversely with [Al]. If at high temperature $[V_{Zn}'] > [e']$, electrons would be trapped by V_{Zn}' centers at room temperature, transforming these centers to V_{Zn}'' centers. The zinc pressure at which the cutoff in electron concentration takes place is given by the condition $[V_{Zn}'] = [e']$ at high temperature. Using

$$V_{Zn}'' \rightleftarrows V_{Zn}' + e'; \quad \frac{[V_{Zn}']\,[e']}{[V_{Zn}'']} = K_{a2}' \qquad [17]$$

we find

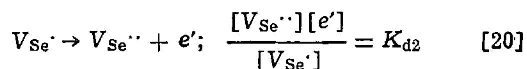
$$p_{Zn,\text{cutoff}} = K_{a2}'/K_{ZnV} \qquad [18]$$

i.e., the cutoff should be a material constant, independent of [Al]. As seen in Fig. 6 and 7, $p_{Zn,\text{cutoff}}$ follows neither relation [16] nor [18]. Apparently the third possibility, trapping at transition metal impurities has to be invoked. In samples with small Al concentration, $[V_{Zn}']$ may be lower than the transition metal impurity concentration and the cutoff in electron concentration takes place by trapping of electrons at the impurities. Only in the sample with the highest Al concentration the cutoff may be caused by trapping of electrons at V_{Zn}'. Since K_{ZnV} is known, the temperature dependence of $p_{Zn,\text{cutoff}}$ for this sample gives us K_{a2}' as $f(T)$. Interpreting the results in terms of

$$K_{a2}' = 4(2\pi m_e^* kT/h^2)^{3/2} \exp(-E_{a2}'\ \text{eV}/kT)\ \text{cm}^{-3} \qquad [19]$$

with $m_e^* = 0.1m$ (21) gives $E_{a2}' = 1.1$ eV, *i.e.*, the V_{Zn}'' level is 1.1 eV below the conduction band. Calculation of the ratio $[V_{Zn}']/[e']$ at $p_{Zn,\text{cutoff}}$ for sample 4 from $[V_{Zn}']/[e'] = K_{a2}'/(K_{ZnV}\,p_{Zn})$ gives values in the range 0.63-0.66 (*i.e.*, close to 1), thus indicating the validity of our model. In this sample 4, the cutoff in electron concentration does not take place due to recombination with holes because the calculated electron concentration for sample 4 at 900°C and $p_{Zn,\text{cutoff}}$ is 7.8×10^{16} cm^{-3}. Equating this with $K_i^{1/2}$ would make $K_i^{1/2}$ greater than $K_S''^{1/2}$ which is inconsistent with the experimental results.

ZnSe:As.—Arsenic-doped ZnSe crystals, when quenched from high temperature, had a high resistivity at room temperature which was independent of p_{Zn} and the equilibration temperature from which the crystals were quenched. Smith (1) also found that the electron concentration dropped from 10^{16} cm^{-3} at 1000°C to 10^{10} cm^{-3} or less at room temperature. This is due to the fact that at high temperature $[e'] \ll [V_{Se}^{\cdot\cdot}]$: During quenching electrons are trapped at some $V_{Se}^{\cdot\cdot}$ centers. If the $V_{Se}^{\cdot}$ level is fairly deep the electron concentration at room temperature would be very low. We can estimate the $V_{Se}^{\cdot}$ level position from Smith's results. Let us assume the acceptor concentration of Smith's sample was 3×10^{18} cm^{-3}, *i.e.*, $[V_{Se}^{\cdot\cdot}] = 1.5 \times 10^{18}$ cm^{-3}



$$V_{Se}^{\cdot} \rightarrow V_{Se}^{\cdot\cdot} + e'; \quad \frac{[V_{Se}^{\cdot\cdot}][e']}{[V_{Se}^{\cdot}]} = K_{d2} \qquad [20]$$

$$[V_{Se}^{\cdot}]_{1000^\circ C} = \frac{[V_{Se}^{\cdot\cdot}]_{1000^\circ C}[e']_{1000^\circ C}}{(K_{d2})_{1000^\circ C}} = \frac{1.5 \times 10^{18} \times 10^{16}}{(K_{d2})_{1000^\circ C}} \quad [21]$$

$$[V_{Se}^{\cdot}]_{27^\circ C} = \frac{[V_{Se}^{\cdot\cdot}]_{27^\circ C}[e']_{27^\circ C}}{(K_{d2})_{27^\circ C}}$$

With

$$[V_{Se}^{\cdot\cdot}]_{27^\circ C} = [V_{Se}^{\cdot\cdot}]_{1000^\circ C} - [e']_{1000^\circ C} = 1.5 \times 10^{18}\ \text{cm}^{-3}$$

and

$$[e']_{27^\circ C} = 10^{10}\ \text{cm}^{-3}$$

$$[V_{Se}^{\cdot}]_{27^\circ C} = \frac{1.5 \times 10^{28}}{(K_{d2})_{27^\circ C}} \quad [22]$$

But also

$$[V_{Se}^{\cdot}]_{27^\circ C} = [V_{Se}^{\cdot}]_{1000^\circ C} + [e']_{1000^\circ C} = [V_{Se}^{\cdot}]_{1000^\circ C} + 10^{16} \ldots \quad [23]$$

Combining Eq. [21]-[23] we get

$$\frac{1.5 \times 10^{28}}{(K_{d2})_{27^\circ C}} = \frac{1.5 \times 10^{34}}{(K_{d2})_{1000^\circ C}} + 10^{16} \quad [24]$$

Analytical solution of [24] with $K_{d2} = (2\pi m_e^* kT/h^2)^{3/2} \exp(-E_{d2}/kT)$ and $m_e^* = 0.1m$ (21) gives $E_{d2} = 0.4$ eV.

The major type of atomic disorder.—At this point it is necessary to justify the arbitrary choice of Schottky over Frenkel disorder as the main disorder mechanism.

H_S'', the enthalpy of Schottky disorder with formation of doubly charged defects, is related to the corresponding enthalpy for formation of neutral defects, $H_S^{\times}$, through (22)

$$H_S^{\times} = H_S'' + 2E_i - E_d - E_{d2} - E_a - E_{a2} \quad [25]$$

E_i being the width of the bandgap, E_d and E_{d2} the first and second ionization energy of $V_{Se}^{\times}$, and E_a and E_{a2} the first and second ionization energy of $V_{Zn}^{\times}$. E_d is of the order of 0.01 eV (18-20). Values reported for E_{d2} vary widely (23, 24); we shall use $E_{d2} = 0.4$ eV as found in the previous section. Values reported for E_a vary from 0.5 to 0.75 eV (18, 24). We shall use $E_a = 0.65$ eV and for E_{a2} we shall take $E_{a2} = E_i - E_{a2}' = 2.7$ (25) $- 1.1 = 1.6$ eV (with E_{a2}' as determined in the previous section. Then $H_S^{\times} = 2.9 + 2 \times 2.7 - 2.66 \approx 5.6$ eV. Van Vechten (26) calculated $H_S^{\times} = 6.18$ eV. According to this author his values are $\approx 12\%$ too high, giving 5.4 eV as the corrected value. A second estimate for $H_S^{\times}$ is obtained from $H_S^{\times} \leqq H_{atom}$, H_{atom} being the enthalpy of atomization of ZnSe (27). Combining H_{ZnSe}, the heat of sublimation of ZnSe with formation of Zn(g) and Se_2(g) (28), with H_D, the heat of dissociation of Se_2(g) (29) we find

$$H_{atom} = H_{ZnSe} + \tfrac{1}{2} H_D = 3.75 + 1.71 = 5.46\ \text{eV}$$

Thus the observed $H_S^{\times}$ is larger than, but close to, both estimates of H_{atom}. If Frenkel disorder would be the dominant type of atomic disorder, with $H_F'' < H_S''$, our results, interpreted on the basis of this disorder, would give $H_F^{\times} = 5.6$ eV with $H_S^{\times} > 5.6$ eV, making the discrepancy with the estimated $H_S^{\times}$ even larger. Therefore, it may be concluded that Schottky disorder is the major type of atomic disorder, the small discrepancy between $H_S^{\times}$ and H_{atom} probably being caused by errors in the energy level positions used in Eq. [25].

Diffusion.—In general, tracer diffusion of zinc is the sum of contributions by the zinc defects V_{Zn} and Zn_i in various states of ionization. Under the conditions of our experiments, *i.e.*, $p_{Zn} = 10^{-2}$ atm, our electrical measurements show that $[V_{Zn}''] >> [V_{Zn}']$ and $[V_{Zn}^{\times}]$ in ZnSe:Al and $[Zn_i^{\cdot\cdot}] >> [Zn_i^{\cdot}]$ and $[Zn_i^{\times}]$ in ZnSe:As. On the other hand, the linear relation between D_{Zn}^* as f[Al] shown in Fig. 8 indicates that only one species is involved: $[V_{Zn}''] >> [Zn_i^{\cdot\cdot}]$ and

$$(D_{Zn}^*)_{Al} = f_V D_V [V_{Zn}''] = f_V D_V [Al_{Zn}^{\cdot}]/2 \quad [26]$$

f_V being the correlation constant and D_V the diffusion constant of V_{Zn}''. For ZnSe:As where $[As_{Se}'] \approx 2[V_{Se}^{\cdot\cdot}]$

$$(D_{Zn}^*)_{As} = f_i D_i [Zn_i^{\cdot\cdot}] + f_V D_V [V_{Zn}''] \quad [27]$$

f_i being the correlation constant and D_i the diffusion constant of $Zn_i^{\cdot\cdot}$. But $[V_{Zn}'']_{As} = r[V_{Zn}'']_{Al}$ with $r = 4K_S''/[Al_{Zn}^{\cdot}]\ [As_{Se}']$ and thus

$$(D_{Zn}^*)_{As} = f_i D_i [Zn_i^{\cdot\cdot}] + r(D_{Zn}^*)_{Al} \quad [28]$$

As seen from [14], $r = ([e'']_{As}/[e']_{Al})^2$; its value was determined earlier. With this value and the value of $(D_{Zn}^*)_{Al}$ we find that the second term in [28] is equal to 1.5×10^{-15} cm^2 sec^{-1} $<< (D_{Zn}^*)_{As} = 5 \times 10^{-12}$ cm^2 sec^{-1}. Thus

$$(D_{Zn}^*)_{As} \approx f_i D_i [Zn_i^{\cdot\cdot}] = f_i D_i (K_F''/K_S'')[As_{Se}']/2 \quad [29]$$

Since both $[Al_{Zn}^{\cdot}] \approx [Al]_{total}$ and $[As_{Se}'] \approx [As]_{total}$ are known, Eq. [26] and [29] combined with [1] and [2] give

$$f_V D_V = 2.17 \exp - \{1.70 \pm 0.05\}\ \text{eV}/kT\ \text{cm}^2\ \text{sec}^{-1} \quad [30]$$

$$f_i D_i K_F''/K_S'' = 3.14 \exp\{-1.65 \pm 0.05)\}\ \text{eV}/kT\ \text{cm}^2\ \text{sec}^{-1} \quad [31]$$

Since the two enthalpies are approximately equal

$$H_V = H_i + H_F'' - H_S'' = 1.65\ \text{eV} \quad [32]$$

where H_V and H_i are the enthalpy of migration of V_{Zn}'' and $Zn_i^{\cdot\cdot}$. Since $H_F'' > H_S''$ (required to make Frenkel disorder less important than Schottky disorder) $H_V > H_i$. D_{Zn}^* of undoped ZnSe measured at a p_{Zn} such that $[V_{Zn}''] = [V_{Se}^{\cdot\cdot}] = K_S''^{1/2}$ is given by

$$D_{Zn}^* = f_V D_V [V_{Zn}''] + f_i D_i [Zn_i^{\cdot\cdot}] = \left(f_V D_V + \frac{f_i D_i K_F''}{K_S''}\right) K_S''^{1/2} \quad [33]$$

Taking the activation energies for D_V and $D_i K_F''/K_S''$ to be equal at 1.65 ± 0.05 eV, leaving preexponentials unchanged

$$D_{Zn}^* = 5.3 \exp\{-(3.1 \pm 0.1\ \text{eV}/kT\}\ \text{cm}^2\ \text{sec}^{-1} \quad [34]$$

This is almost exactly the expression

$$D_{Zn}^* = 9.8 \exp\{-3.0\ \text{eV}/kT\}\ \text{cm}^2\ \text{sec}^{-1} \quad [35]$$

found by Henneberg and Stevenson (3) for crystals containing 2.9-10 $\times 10^{16}$ cm^{-3} Al and 1-25 $\times 10^{16}$ cm^{-3} Cu. Apparently these crystals were exactly compensated.

Defect isotherms for ZnSe, ZnSe:Al, and ZnSe:As.—Expressions for the various equilibrium constants are summarized in Table II. Values calculated at 800°, 900°, and 1000°C are given in Table III. Approximate defect

Table II. Expressions for various defect constants

Table III. Values of various constants at 800°, 900°, and 1000°C

Temp (°C)	K_{ZnV} (atm^{-1} cm^{-3})	K_{d2} (cm^{-3})	K_{a2}' (cm^{-3})	$K_S''^{1/2}$ (cm^{-3})	$K_i^{1/2}$ (cm^{-3})
800	2.3×10^{18}	3.65×10^{16}	7.3×10^{13}	3.3×10^{15}	3.6×10^{14}
900	9.2×10^{17}	5.97×10^{16}	2.3×10^{14}	1.3×10^{16}	1.5×10^{15}
1000	4.25×10^{17}	9.0×10^{16}	6.1×10^{14}	4.0×10^{16}	5.0×10^{15}

isotherms for ZnSe, ZnSe: 1.6×10^{17} cm^{-3} Al and ZnSe: 7×10^{17} cm^{-3} As at 800°C are shown in Fig. 11, 12, and 13. The fact that both the electrical measurements and the diffusion measurements do not indicate the presence of pairs $(Al_{Zn}V_{Zn})'$ at $[Al] = 1.7 \times 10^{19}$ cm^{-3} at 800°C indicates that $[(Al_{Zn}V_{Zn})'] = K_P[Al_{Zn}^{\cdot}]$ $[V_{Zn}''] < 10^{19}$ cm^{-3} or the pairing constant $K_P < 6.92 \times 10^{-20}$ cm^3. If H_P is the enthalpy of pairing, $K_P = K_P^{\circ} \exp(H_P/kT)$ with $K_P^{\circ} = Z/N = 12/2.2 \times 10^{22}$ $cm^{-3} = 5.45 \times 10^{-22}$ cm^3. Here Z is the number of nearest neighbor metal sites and N is the number of molecules ZnSe per cubic centimeter. Then $-H_P \leq 0.45$ eV. With the relative dielectric constant $\epsilon_r = 8.1$ (21) and $r_{Al\text{-}V} = r_{Zn\text{-}Zn} = 8.01$Å, $(H_P)_{coulomb} = -2q^2/4\pi\epsilon_r r_{Al\text{-}V} = -0.44$ eV. Thus practically no pairs will be formed at high temperature; pairs at room temperature must have largely been formed during cooling (4, 7). On the basis of Fig. 11, the expected room temperature electron concentration for undoped ZnSe equilibrated at 800°C with molten zinc is $\approx 10^{16}$ cm^{-3}. Values reported for undoped ZnSe after the so-called zinc extraction process (to remove impurities such as copper) are indeed in the range $0.6\text{-}2 \times 10^{16}$ cm^{-3} (19, 21).

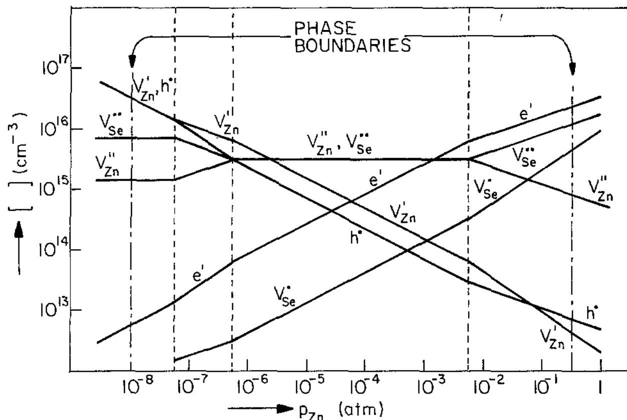

Fig. 11. Defect isotherms for undoped ZnSe at 800°C

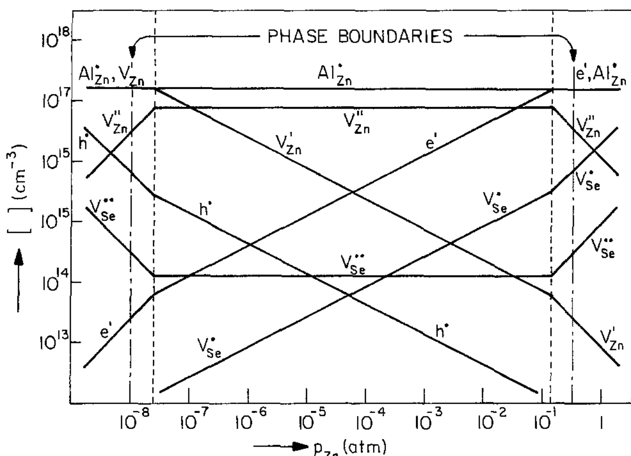

Fig. 12. Defect isotherms for ZnSe: 1.6×10^{17} cm^{-3} Al at 800°C

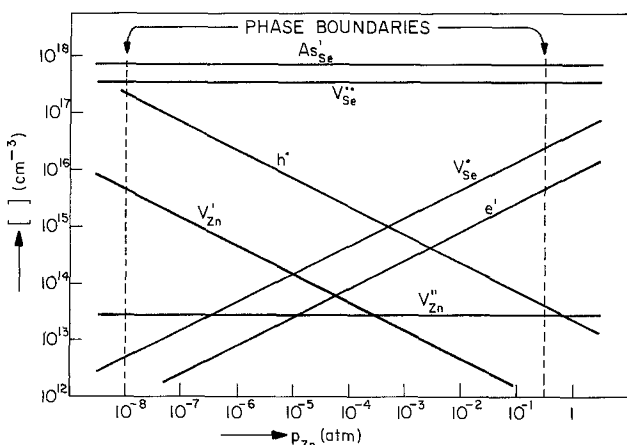

Fig. 13. Defect isotherms for ZnSe: 7×10^{17} cm^{-3} As at 800°C

Figure 11 also indicates that it should be possible to make undoped ZnSe p-type by annealing in a Se_2 atmosphere. It would, however, be a poor hole conductor, the V_{Zn}' level being far from the valence band. Similarly with the help of Fig. 12 we can explain that at high p_{Zn} the room temperature electron concentration must be the same as that at high temperature, but at p_{Zn} below $p_{Zn,cutoff}$ (*i.e.*, where $[V_{Zn}'] = [e']$ at high temperature) ZnSe:Al will have a high resistivity at room temperature. ZnSe:As will have a high resistivity at room temperature at all p_{Zn} because $V_{Se}^{\cdot}$, $As_{Se}^{\times}$, and V_{Zn}' levels are all deep, even though there is a transition from n to p type at the relatively large p_{Zn} where $[e'] = [h^{\cdot}]$ at high temperature.

Summary

Measurements of the Hall effect, resistivity, and zinc self-diffusion of crystals of ZnSe doped with Al or As at high temperatures, where the crystals are in equilibrium with zinc vapor, and of the Hall effect of crystals cooled after equilibration are used to determine the defect structure of pure and doped ZnSe. Schottky disorder with doubly charged defects dominates the defect structure of undoped ZnSe at medium zinc pressures. Table II gives parameters of various equilibrium constants determined in the analyses, with the aid of which properties of crystals equilibrated under various conditions can be predicted.

ABSTRACT

Hall effect and resistivity measurements on single crystal samples of ZnSe doped with various amounts of gallium were performed both at high temperature while the crystals were in equilibrium with atmospheres of known zinc pressures and after cooling to room temperature. At high temperatures, gallium present at a low concentration behaves as aluminum and acts as a single donor. At high concentrations and high zinc pressures, the donor efficiency is strongly reduced. This reduction is attributed to the precipitation of a fraction of the gallium as GaSe. Cooled crystals with low Ga concentrations show a similar behavior, the only difference being a sharp reduction in electron concentration at low p_{Zn} when $[V_{Zn}'] \gtrsim [e']$. At high Ga concentrations and high zinc pressures, black precipitates are formed near the surface during cooling. In addition, changes take place in the ZnSe phase which strongly reduce the electron concentration. These changes are believed to consist of the transfer of Ga from Zn to Se sites with formation of centers acting as multiple acceptors and electron traps.

Trivalent metal atoms substituting for zinc in ZnSe are expected to act as donors. Such a behavior was actually found for Al: at high zinc pressures free electrons are formed with $[e'] \approx [Al_{Zn}^{\cdot}]$, at low zinc pressures self-compensation occurs, with $2[V_{Zn}''] \approx [Al_{Zn}^{\cdot}]$ (1-4). A different behavior was reported for Ga, In, and Tl: Samples doped with Ga were found to contain fewer free electrons than undoped samples prepared under the same conditions (5). Ga_{Zn}, In_{Zn}, and Tl_{Zn} are believed to be deep donors as opposed to Al_{Zn} which is a shallow donor (6). ZnSe: 5×10^{19} Ga/cm^3 grown from (Ga(l) had $\rho = 250 \pm 50$ Ω cm and was thus heavily compensated (7). With increasing concentration of Ga or In, electronic conductivity decreases and the Fermi level drops to $E_c - 0.2$ eV (8). Heating of Ga-doped crystals in zinc vapor leads to the formation of black precipitates (8). N-type conductivity with 2×10^{16} to 5×10^{17} electrons/cm^3 was found for ZnSe equilibrated with dilute (Zn, Ga) alloys (9). P-type conductivity was found in the surface of an iodine donor-doped crystal after in-diffusion of Ga or In from a molten (Ga, Zn) or (In, Zn) alloy at 560°C followed by a 30 min anneal of crystal plus alloy in a closed capsule at 950°C (10, 11). The p-type behavior was attributed to the tendency of Ga, In, and Tl to form monovalent positive ions which were believed to be the acceptors, divalent ions being donors (and trivalent ions ionized donors) (10). This explanation can, however, not be correct. Since Ga_{Zn}' contains one electron more than $Ga_{Zn}^{\times}$, the energy level of Ga_{Zn}' must be above the level of $Ga_{Zn}^{\times}$. Since the latter is a donor level close to the conduction band at $E_c - 0.028$ eV (12), the Ga_{Zn}' level must be even higher and thus cannot give rise to appreciable hole conduction.

In the present paper we report on an investigation of the semiconductor properties of ZnSe: Ga, both at high temperatures where the crystals are in equilibrium with atmospheres of well-defined zinc pressure and at low temperatures after high temperature equilibration.

Experimental

Single crystals of ZnSe grown from melts containing, respectively, 1.6×10^{18}, 4.8×10^{18}, 1.6×10^{20}, and 1.6×10^{21} Ga cm^{-3} were obtained from the Eagle Picher Company. Electrical analysis of the first two crystals assuming Ga to be a single donor gives for the Ga content of these crystals 5×10^{17} and 2.0×10^{18} Ga cm^{-3}. Spectrographic analysis of the last two, using the other ones as a standard, yielded values of 5.2×10^{19} and 6×10^{20} Ga cm^{-3} indicating a distribution coefficient $k = c_s/c_l = 0.3 \pm 0.05$. Samples of $10 \times 10 \times 1$ mm were cut from the crystals for measurement of Hall effect and resistivity by the van der Pauw technique (13). High temperature measurements with the crystals in equilibrium with atmospheres of known zinc

Key words: Hall effect, resistivity, precipitates.

pressures were performed in an apparatus described earlier (14). Room temperature measurements on crystals cooled after equilibration with a known p_{Zn} at temperatures from 800°-1000°C were performed in air. Electron concentrations were calculated from the Hall constant R by the formula $c_e = (Rq)^{-1}$, q being the electronic charge.

Experimental Results

Figure 1 shows values of $[e']$ and ρ for ZnSe: 5×10^{17} Ga cm^{-3} as a function of p_{Zn} at 800°, 900°, and 1000°C. Similar results were obtained for ZnSe: 2×10^{18} Ga cm^{-3}. Figures 2, 3, and 4 show the p_{Zn} dependence of samples with different amounts of gallium at 800°, 900°, and 1000°C, respectively. Figure 5 shows $[e']$ as a function of gallium concentration for samples annealed under $p_{Zn} = 2 \times 10^{-2}$ atm at 900° and 1000°C. Figure 6 shows the corresponding behavior of $[e']$ for $p_{Zn} = 0.7$ atm. Both figures show for comparison data for ZnSe: Al. Crystals quenched after annealing at high temperatures at low zinc pressures were orange to red in color, the density of the coloration increasing with [Ga]. Samples with $[Ga] \geq 2 \times 10^{18}$ cm^{-3} quenched after annealing at high p_{Zn} were

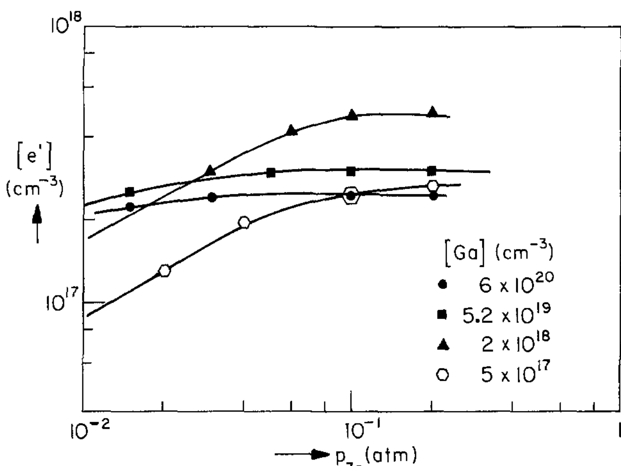

Fig. 2. Electron concentrations in different ZnSe:Ga crystals as a function of p_{Zn} at 800°C.

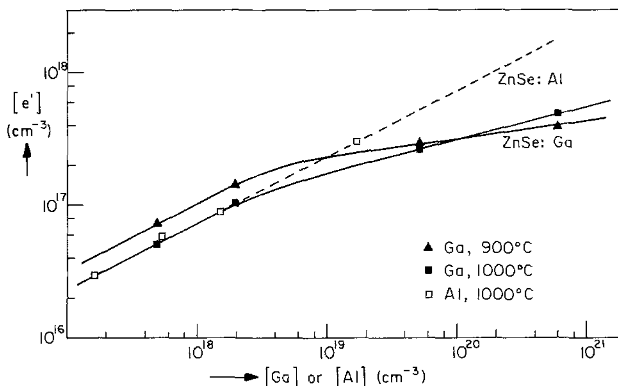

Fig. 5. Electron concentrations as a function of dopant concentration in ZnSe:Ga at 900° and 1000°C (solid lines) and in ZnSe:Al at 1000°C (dashed line); all at $p_{Zn} = 2 \times 10^{-2}$ atm.

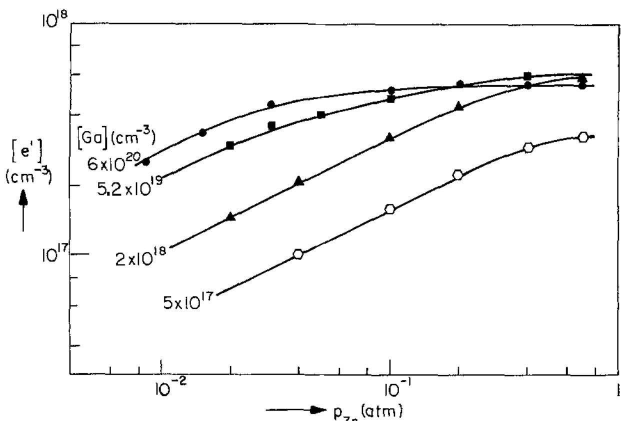

Fig. 3. Electron concentrations in different ZnSe:Ga crystals as a function of p_{Zn} at 900°C.

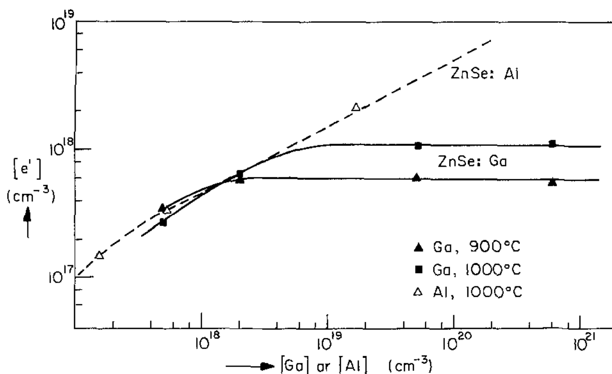

Fig. 6. Electron concentration as a function of dopant in ZnSe:Ga at 900° and 1000°C (solid lines) and in ZnS:Al at 1000°C (dashed line); all at $p_{Zn} = 0.7$ atm.

black; only the sample with 5×10^7 Ga cm^{-3} remained yellow. Inspection of the samples showed the black coloration to be limited to a surface layer that is the thicker the higher $p_{Zn_{anneal}}$, [Ga], and T_{anneal}.

The two most strongly doped samples quenched after annealing at 1000°C, $p_{Zn} = 2.25$ atm were black throughout. For a particular T_{anneal}, the lowest p_{Zn} at which blackening occurs decreases with increasing [Ga]. Observation under an optical microscope in transmission of a black sample, thinned by jet polishing with 40 HCl-10 H_2O_2-1H_2O showed the presence of black star-shaped precipitates, 5-8 μm in size (Fig. 7); similar precipitates were reported in Ref. (8). The precipitates were not visible in reflection. Attempts to determine the nature of the precipitates by electron microscopy failed, probably because the etchant used to thin the samples etched away the precipitates. Whereas it is clear that the blackening is due to the presence of dark precipitates, the facts that the precipitates are generally restricted to surface layers and are only formed after annealing at high p_{Zn} suggest that the precipitates are not present during the high temperature anneal, but are formed during cooling. Since the degree of blackening depends on [Ga], the precipitates almost certainly contain gallium. Their probable nature is discussed later.

Electron concentrations in crystals quenched after annealing at various temperatures and p_{Zn} are shown in Fig. 8-10 (as a function of p_{Zn}) and Fig. 11 (as a function of [Ga]). For samples that were blackened after quenching, the electron concentration determined from the Hall effect measured at room temperature was a function of the thickness of the sample and depended on whether the black surface layer was or was not removed. In Fig. 8-10, points of such samples measured without removal of the black surface layer are connected by dashed lines. Points given in Fig. 11 are the results of measurements after removal of the black surface layer (if any).

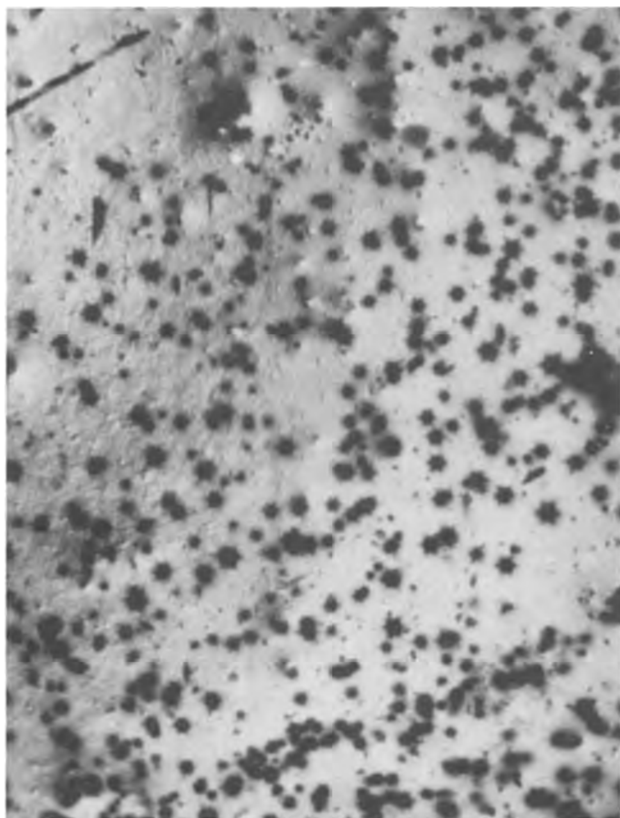

Fig. 7. Optical micrograph in transmission (magnification 200×) of ZnSe: 5.2 × 10^{19} Ga cm^{-3} cooled after an anneal at 1000°C, $p_{Zn} = 2$ atm.

Discussion

High temperature results.—Inspection of Fig. 1 and 2 shows that at low p_{Zn} and small [Ga], $[e'] \propto p_{Zn}^{1/2}$; [e'] approaches a constant level that is almost equal to [Ga] at high p_{Zn}. Note the negative temperature dependence of [e'] at low p_{Zn}. The behavior is similar to that observed for ZnSe:Al (1). Interpretation of the results at low p_{Zn} on this basis, assuming Ga_{Zn} to be a single donor with

$$[Ga]_{total} = [Ga_{Zn}^{\cdot}] = 2[V_{Zn}''] \quad [1]$$

leads to

$$[e'] = 2^{-1/2} K_{ZnV}^{1/2} [Ga_{Zn}^{\cdot}]^{1/2} p_{Zn}^{1/2} \quad [2]$$

Here K_{ZnV} is the equilibrium constant of the reaction

$$V_{Zn}'' + Zn(g) \rightleftarrows Zn_{Zn}^{\times} + 2e' \quad [3]$$

$$K_{ZnV} = [e']^2/[V_{Zn}''] p_{Zn} \quad [4]$$

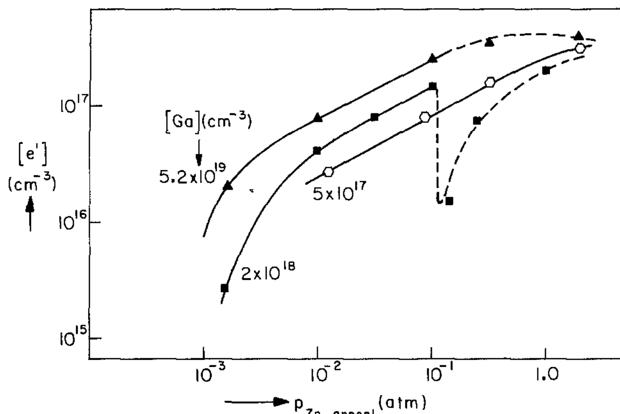

Fig. 10. Electron concentrations at room temperatures in ZnSe:Ga crystals cooled after annealing under different p_{Zn} at 1000°C. Solid lines, homogeneous crystals; dashed lines, partly blackened crystals.

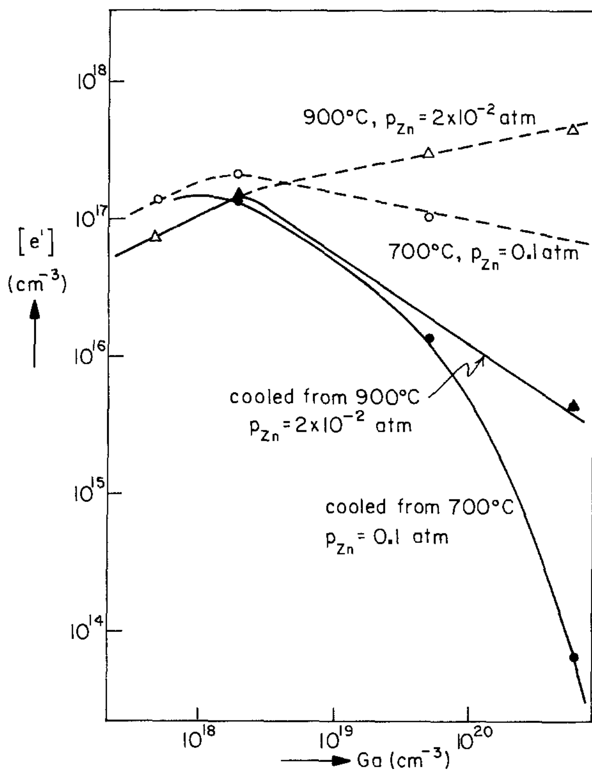

Fig. 11. Electron concentrations in ZnSe:Ga crystals annealed at $p_{Zn} = 2 \times 10^{-2}$ atm, 900°C or $p_{Zn} = 10^{-1}$ atm, 700°C at temperature (dashed lines) and after cooling (solid lines).

Use of the value of K_{ZnV} as determined in Ref. (1) in Eq. [2] leads to Ga contents of the weakly doped samples of 5×10^{17} and 2×10^{18} Ga cm^{-3} as mentioned earlier.

At higher gallium concentrations at $T_{anneal} = 800°C$, [e'] is almost independent of [Ga] and p_{Zn} (Fig. 2). At higher T_{anneal} the p_{Zn} dependence is restored (Fig. 3 and 4), but a decreased dependence of [e'] on [Ga] at high [Ga] still pertains for $T_{anneal} = 900°C$ (Fig. 3).

Similarity in behavior of Ga and Al at low [Ga] and low p_{Zn} is also seen in Fig. 5, Eq. [2] being satisfied. At high p_{Zn}, $[e'] \approx [Ga]$ at small [Ga], but $[e'] < [Ga]$ at large [Ga] (Fig. 6). At low p_{Zn} and $[Ga] \geqq 10^{19}$ cm^{-3}, $[e'] \propto [Ga]^m$ with $m = 0.15$ to 0.22 (Fig. 5). At large p_{Zn}, [e'] is independent of [Ga], but dependent on temperature (Fig. 6).

These facts strongly suggest that part of the Ga precipitates at a relatively low annealing temperature (800°C), less at medium annealing temperature (900°C), and less again at the highest annealing temperature (1000°C); precipitation, if occurring, occurs above a certain critical value of p_{Zn} which decreases with increasing [Ga]. As we shall see, the observations can, in fact, be explained on this basis if Ga_{Zn} is assumed to be a single donor, the precipitated phase being GaSe. Figure 12 shows a schematic isothermal phase diagram in which it is assumed that of the compounds of the Ga-Se system, GaSe (red) and Ga_2Se (black) can coexist with ZnSe; in addition ZnSe can coexist with $ZnGa_2Se_4$ and with alloys (Ga, Zn) which are molten at the temperatures of our experiments. Coexistence with Ga_2Se is questionable for two reasons: Although the existence of this compound was reported by Klemm and von Vogel (15) and Rustamov *et al.* (16), a different compound (Ga_3Se_2) was found by Terhell and Lieth (17) while Susuki and Mori (18) found no compound at all between GaSe and Ga. The second reason is that, even if Ga_2Se exists, coexistence with ZnSe may not be possible. In this case the tie lines between Ga_2Se and ZnSe have to be replaced by tie lines GaSe(Ga,Zn), *i.e.*, from GaSe to point a in Fig. 12. Various three-phase regions (triangles in Fig. 12), valid for the tie lines as drawn, are marked with the type of coexisting condensed phases. With modified tie lines the two upper three-phase regions change to ZnSe + GaSe + $(Ga\text{-}Zn)_{1,a}$ and GaSe + Ga_2Se + $(Ga\text{-}Zn)_{1,a'}$.

The activities of Zn and Se in ZnSe are variable because of ZnSe(s) → Zn(g) + ½ Se_2(g), giving

$$p_{Zn}p_{Se_2}^{1/2} = K_{ZnSe} \quad [5]$$

When another condensed phase is present, a similar relation exists for the components of that phase; *e.g.*, for GaSe

$$GaSe(s) \rightarrow Ga(l) + \tfrac{1}{2}Se_2(g)$$

or

$$a_{Ga}p_{Se_2}^{1/2} = K_{GaSe} \quad [6]$$

If ZnSe and GaSe coexist, both [5] and [6] have to be satisfied and thus

$$a_{Ga} = K_{GaSe}K_{ZnSe}^{-1}p_{Zn} \quad [7]$$

i.e., there is a relation between a_{Ga} and p_{Zn}. Similarly, for coexistence of ZnSe with $ZnGa_2Se_4$ or Ga_2Se

$$a_{Ga}^2 = K_{ZnGa_2Se_4}K_{ZnSe}^{-4}p_{Zn}^3 \quad [8]$$

$$a_{Ga}^2 = K_{Ga_2Se}K_{ZnSe}^{-1}p_{Zn} \quad [9]$$

A relation similar to [8] would be obtained if Ga_2Se_3 rather than $ZnGa_2Se_4$ would occur as the phase coexisting with ZnSe.

If the constants K_{ZnSe}, $K_{Ga_2Se_3}$, $K_{ZnGa_2Se_4}$, K_{GaSe}, and K_{Ga_2Se} were known, it would be possible to construct a diagram with log a_{Ga} and log p_{Zn} as ordinates consisting of single-phase regions and regions of coexistence of two and three condensed phases. In the absence of such detailed knowledge it is only possible to draw a schematical figure. Figure 13 shows such a figure. In this figure single phase regions are areas:

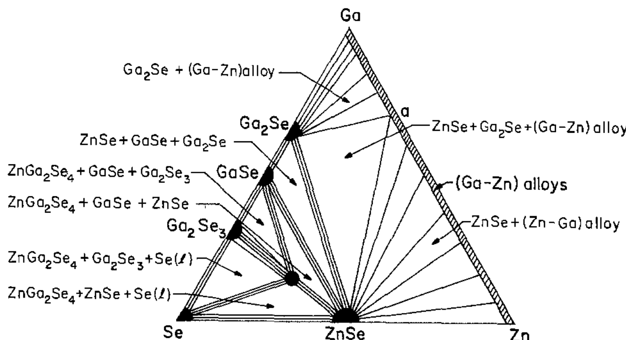

Fig. 12. Schematic isotherm of the Ga-Zn-Se system

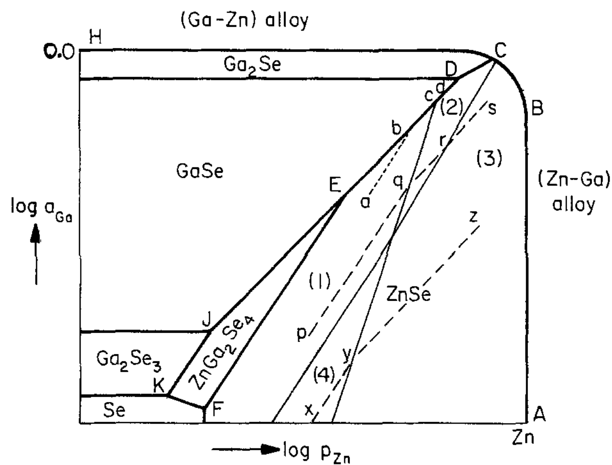

Fig. 13. a_{Ga} vs. p_{Zn} isothermal phase diagram of the system Ga-Zn-Se showing phase boundaries (heavy solid lines), range boundaries (thin solid lines), and lines of constant [Ga] (dashed lines). At the top $a_{Ga} = 1$, $\log a_{Ga} = 0$.

A B C D E F is the ZnSe area; areas to the left of CD, DE, EF, and FSe are, respectively, the areas of Ga_2Se, GaSe, $ZnGa_2Se_4$, and Se. Owing to the low solubility of Se in $(Ga, Zn)_l$, the liquid alloy phase is represented by a line A B C H. Lines separating neighboring areas represent coexistence of two condensed phases. Meeting points of phase boundaries represent coexistence of three condensed phases (corresponding to the triangles of Fig. 12). Thus, point E represents coexistence of ZnSe, $ZnGa_2Se_4$, and GaSe. If the defect structure consists of various ranges dominated by different approximations to the neutrality condition and/or mass balance, range boundaries are represented by straight lines inside the single phase areas; 1, 2, 3, and 4 indicate such ranges for ZnSe; for the characterization of these ranges see Table I. Isotherms for constant gallium concentration are represented by straight, dashed lines inside the single-phase fields. The lines change slope when a range boundary or a phase boundary is reached, *i.e.*, when a second phase is formed. The former give a gradual, the latter a sharp change of slope. The lines xyz, pqr, and abc correspond to increasing gallium concentrations. As is shown below, abc corresponds to the experimental specimens.

As shown earlier, at low gallium concentrations and low p_{Zn}, the behavior is described by Eq. [1] and [2]; this corresponds to region 4 in Fig. 13. At higher p_{Zn} the neutrality and Ga balance change to $[Ga]_{total} \approx [Ga_{Zn}^{\cdot}] \approx [e']$ (region 3 in Fig. 13). The concentration of $Ga_{Zn}^{\cdot}$ in ZnSe is related to the activity of gallium as measured in an outer phase by

$$Ga_{outside} + Zn_{Zn}^{\times} \rightleftarrows Ga_{Zn}^{\cdot} + e' + Zn(g) \quad [10]$$

or

$$[Ga_{Zn}^{\cdot}][e'] \propto a_{Ga} p_{Zn}^{-1} \quad [11]$$

Thus in region 3

$$[Ga_{Zn}^{\cdot}] = [e'] \propto a_{Ga}^{1/2} p_{Zn}^{-1/2} \quad [12]$$

Elimination of $[e']$ from [11] and [4] gives

$$[Ga_{Zn}^{\cdot}]^2 [V_{Zn}''] \propto a_{Ga}^2 p_{Zn}^{-3} \quad [13]$$

Thus in region 4

$$[Ga_{Zn}^{\cdot}] = 2[V_{Zn}''] \propto a_{Ga}^{2/3} p_{Zn}^{-1} \quad [14]$$

Table I. Characterization of the defect structures in the various ZnSe regions of Fig. 13

Region	Neutrality condition	$[Ga]_{total}$
1	$[Ga_{Zn}^{\cdot}] = 2[V_{Zn}'']$	$1/2[(2Ga_{Zn}V_{Zn})^{\times}]$
2	$[Ga_{Zn}^{\cdot}] = [e']$	$1/2[(2Ga_{Zn}V_{Zn})^{\times}]$
3	$[Ga_{Zn}^{\cdot}] = [e']$	$[Ga_{Zn}^{\cdot}]$
4	$[Ga_{Zn}^{\cdot}] = 2[V_{Zn}'']$	$[Ga_{Zn}^{\cdot}]$

At the boundary between regions 3 and 4 both [12] and [14] hold, *i.e.*

$$(a_{Ga})_{3,4} \propto p_{Zn}^3 \quad [15]$$

Isotherms for $[Ga_{Zn}^{\cdot}] = [Ga]_{total}$ = constant follow the path xyz in Fig. 13 as defined by [14] and [12]; point y shifts to higher p_{Zn} for higher gallium concentrations.

In region 4 associates $(Ga_{Zn}V_{Zn})'$ and $(2Ga_{Zn}V_{Zn})^{\times}$ increase their concentrations with increasing gallium concentration. The properties of ZnSe:Ga at high gallium concentration can be explained if the triplet becomes the dominant Ga species before the pair (the pair gives a dependence on p_{Zn} that is not in agreement with experiment). This leads to a new region 1 dominated by

$$[Ga]_{total} = \tfrac{1}{2}[(2Ga_{Zn}V_{Zn})^{\times}] \quad [16]$$

and

$$[Ga_{Zn}^{\cdot}] = 2[V_{Zn}''] \quad [17]$$

It is easily shown that both the boundary 1, 4, and the isotherm path ab inside region 1 satisfy $a_{Ga} \propto p_{Zn}^{3/2}$, *i.e.*, both are parallel to xy, FE, and JK. This means that it is impossible to move from 4 into 1 or from 1 into the $ZnGa_2Se_4$ region by increasing p_{Zn}; it can only be done by increasing $[Ga]_{total}$. On the other hand ab intersects the phase boundary ZnSe-GaSe with increasing p_{Zn} at point b; beyond b the phase boundary bcd is followed. For intermediate Ga concentrations (path pq in region 1) a change in the neutrality condition to [12] occurs before the phase boundary is reached. A new region 2 governed by Eq. [16] and [12] is reached in which $a_{Ga} \propto p_{Zn}$. With increasing p_{Zn} the system follows the path pqrs (a transition from 2 to 3 occurring at point r. Defect isotherms along path abcd are shown in Fig. 14. Three ranges occur: I ≡ ab, II ≡ bc, and III ≡ cd. Since $2Ga_{Zn}^{\cdot} + V_{Zn}'' \rightarrow (2Ga_{Zn}V_{Zn})^{\times}$ with

$$\frac{[(2Ga_{Zn}V_{Zn})^{\times}]}{[Ga_{Zn}^{\cdot}]^2 [V_{Zn}'']} = K_T \quad [18]$$

in range I (as in the whole of region 1)

$$[Ga_{Zn}^{\cdot}] = 2[V_{Zn}''] = [Ga]_{total}^{1/3} K_T^{-1/3}$$

and

$$[e'] \propto [V_{Zn}'']^{1/2}/[V_{Zn}^{\times}]^{1/2} \propto [Ga]_{total}^{1/6} p_{Zn}^{1/2} \quad [19]$$

In range II, where GaSe is present as a second phase

$$Zn_{Zn}^{\times} + 2GaSe(s) \rightleftarrows (2Ga_{Zn}V_{Zn})^{\times} + Zn(g) + 2Se_{Se}^{\times} \quad [20]$$

and thus

$$[2(Ga_{Zn}V_{Zn})^{\times}] \propto a_{GaSe}^2 p_{Zn}^{-1} \quad [21]$$

which for $a_{GaSe} = 1$ is independent of $[Ga]_{total}$

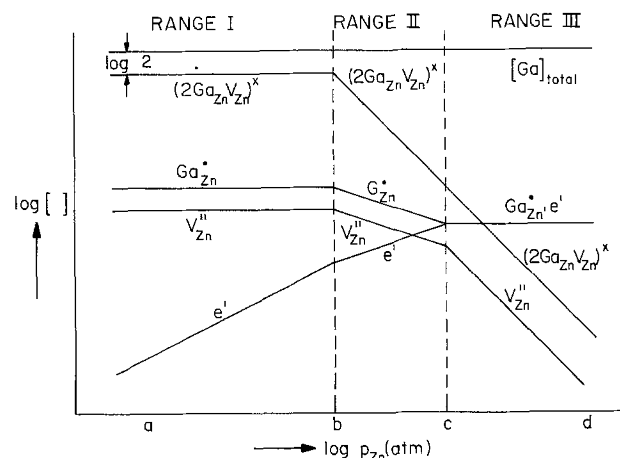

Fig. 14. Defect isotherms corresponding to the path abcd in Fig. 13 (schematical) of ZnSe:Ga with large [Ga] at 900°C.

$$[Ga_{Zn}^{\cdot}] = 2[V_{Zn}''] = 2^{1/3}K_T^{-1/3}p_{Zn}^{-1/3}$$

and

$$[e'] \propto p_{Zn}^{1/3} \quad [22]$$

independent of $[Ga]_{total}$. In range III [21] still holds. From [18] and [21], $[Ga_{Zn}^{\cdot}]^2[V_{Zn}''] \propto p_{Zn}^{-1}$. With $[e']^2 \propto [V_{Zn}'']/[V_{Zn}^{\times}]$ and $[V_{Zn}^{\times}] \propto p_{Zn}^{-1}$, $[Ga_{Zn}^{\cdot}] \approx [e']$ = constant, independent of both $[Ga]_{total}$ and p_{Zn}.

Ranges I, II, and III show the behavior observed in Fig. 2-6 for ZnSe with higher Ga contents and, therefore, may be accepted as the defect model for such crystals. As can easily be verified, the region boundary 1, 2 has the same slope as the boundary 3, 4, while the boundary 2, 3 has $(a_{Ga})_{2,3} \propto p_{Zn}^{5/3}$. Table I summarizes the characterizations of regions 1 to 4 in Fig. 13. It is conceivable that with increasing [Ga], the pair $(Ga_{Zn}V_{Zn})'$ becomes dominant before the triplet $(2Ga_{Zn}\ V_{Zn})^{\times}$. In that case a region 5 dominated by $[(Ga_{Zn}V_{Zn})'] \approx [Ga_{Zn}^{\cdot}]$ will occur between regions 1 and 4 with boundaries 1, 5 and 4, 5 parallel to the present boundary 1, 4. Since no experimental evidence for such a region was obtained, it was not introduced.

Interpretation of low temperature results.—Precipitate formation.—Formation of black precipitates at high [Ga] and high p_{Zn} during cooling can be explained on the basis of a phase diagram such as Fig. 13, but drawn for the lower temperature at which precipitation occurs. Figure 13 was drawn with the assumption that coexistence of ZnSe and Ga_2Se is possible. If this is indeed the case, the precipitates can be either Ga_2Se (which is black) (15) or (Ga, Zn) alloy. If coexistence with Ga_2Se is not possible the boundary CD in Fig. 13 would be missing, and the only possible black second phase would be (Ga, Zn) alloy. Both phase boundaries DC and CBA have the property that they can be crossed with increasing p_{Zn} (or with increase of Zn incorporation during cooling) as required for the formation of precipitates. GaSe is not considered as a possible black precipitate because of its red color. Although the color might possibly darken with deviation from stoichiometry, the model fitting the electrical properties discussed earlier requires formation of almost invisible precipitates at zinc pressures that are lower than those required for blackening to occur. These precipitates are believed to be GaSe, the black precipitates being Ga_2Se or a (Ga,Zn) alloy. Precipitation of an alloy (In, Cd) was previously proposed for CdTe:In (19).

Electrical properties.—Comparison of the electron concentrations in cooled crystals with those in the same samples at high temperatures (*e.g.*, Fig. 8 and 2, Fig. 9 and 3, Fig. 10 and 4) shows that in the two samples with the lowest Ga content the electron concentrations are approximately the same as long as $p_{Zn\ anneal} > p_{Zn,\ cutoff}$ (10^{-3} atm in Fig. 10). Such a cutoff occurs in all donor doped II-VI compounds and is well understood. It is due to trapping of electrons at the empty V_{Zn}'' level and occurs when $[e'] \leq [V_{Zn}']$. In the samples with the largest Ga content there is a marked reduction in the electron concentration on cooling, the concentrations in the cooled crystals being even smaller than those in the samples with less gallium. This is also evident from Fig. 11. Since the points of Fig. 11 were measured after removal of the black surface layer, the reduction in electron concentration of the samples with large gallium concentrations cannot be due to formation of the black precipitates. Although formation of less conspicuous red (15, 20, 21) precipitates of GaSe is possible and is even likely, since such precipitates were already assumed to be formed at high temperatures, reduction of the electron concentration in this manner can be ruled out by the fact that the largest concentration reduction (to $\simeq 10^{14}\ e'\ cm^{-3}$) was found for the crystal with the largest gallium concentration after an anneal at high p_{Zn} at the lowest temperature of anneal, 700°C. Once precipitation occurs there should no longer be a dependence on gallium concentration. Evidently processes other than participation must occur in the crystals during cooling. The decrease of $[e']$ with increasing [Ga] observed at 700°C at $p_{Zn} = 0.1$ atm (Fig. 11) indicates that these processes occur to a certain extent even at the annealing temperature.

One possibility is the transfer of Ga from zinc sites where it is a donor to selenium sites where it is a multiple acceptor

$$Ga_{Zn}^{\cdot} + 4e' + 2Zn(g) \rightleftarrows Ga_{Se}''' + 2Zn_{Zn}^{\times} \quad [23]$$

The high charge of Ga_{Se}''' makes pairing with Ga_{Zn} likely

$$Ga_{Zn}^{\cdot} + Ga_{Se}''' \rightleftarrows (Ga_{Zn}Ga_{Se})'' \quad [24]$$

or, combining [23] and [24]

$$2Ga_{Zn}^{\cdot} + 4e' + 2Zn(g) \rightleftarrows (Ga_{Zn}Ga_{Se})'' + 2Zn_{Zn}^{\times} \quad [25]$$

$$[(Ga_{Zn}Ga_{Se})''] = K_{Ga}''[Ga_{Zn}^{\cdot}]^2[e']^4 p_{Zn}^2 \quad [26]$$

For a neutrality condition $2[(Ga_{Zn}Ga_{Se})''] \approx [Ga_{Zn}^{\cdot}]$ and a Ga balance $[Ga]_{total} = [Ga_{Zn}^{\cdot}] + 2[(Ga_{Zn}Ga_{Se})''] = 2[Ga_{Zn}^{\cdot}]$, the equilibrium electron concentration is given by

$$[e'] = K_{Ga}''^{-1/4}[Ga]_{total}^{-1/4}p_{Zn}^{-1/2} \quad [27]$$

showing that the electron concentration decreases with increasing gallium concentration and zinc pressure. Since Zn(g) is involved, this process involves interaction between crystal and atmosphere and depends on diffusion of Zn from the crystal surface to the interior (or of Se in the opposite direction). Nevertheless, the process may occur at $T < T_{anneal}$. Similar reactions and mass action relations can be formulated for Ga_{Se}'' and $(Ga_{Zn}G_{Se})'$, with 3 rather than 4 electrons as in Eq. [23] and [25]. This leads to

$$[(Ga_{Zn}Ga_{Se})'] = K_{Ga}'[Ga_{Zn}^{\cdot}][e']^3 p_{Zn}^2 \quad [28]$$

which combined with [27] and the Ga balance gives

$$[(Ga_{Zn}Ga_{Se})'] = \tfrac{1}{2}K_{Ga}'K_{Ga}''^{-3/4}[Ga]_{total}^{1/4}p_{Zn}^{1/2} \quad [29]$$

$(Ga_{Zn}Ga_{Se})'$ must be expected to be a deep electron trap and may be responsible for the loss of electrons beyond that corresponding to [27]. Such trapping is indicated by the observation of a large activation energy of conduction in the samples with a low electron concentration (8).

Summary

Measurements of Hall effect and resistivity were performed for ZnSe crystals doped with various amounts of gallium, both at high temperature when the crystals were in equilibrium with zinc vapors of known pressures and on crystals cooled after the high temperature equilibration. Crystals with low Ga concentrations behave as ZnSe:Al, $Ga_{Zn}^{\times}$ acting as a single donor. Strongly doped crystals annealed at high zinc pressures show a different behavior. At high temperatures this is explained by formation of GaSe precipitates. At low temperatures both the formation of black precipitates of Ga_2Se or (Ga, Zn) alloy and processes inside the ZnSe phase are involved. Transfer of Ga from Zn to Se sites with formation of multiple acceptors Ga_{Se}''' and clusters $(Ga_{Zn}Ga_{Se})''$ and $(Ga_{Zn}Ga_{Zn})'$ acting as electron traps is proposed as a possible mechanism.

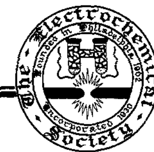
Technical Note



The Possibility of Black Zinc Oxide as Spectrally Selective Coating for Low Temperature Solar Collectors

M. van der Leij

Department of Applied Physics, Delft University of Technology, Delft, The Netherlands

The utilization of solar energy for space heating requires, especially at higher latitudes where a sea climate dominates, solar collectors with high efficiency. That means that for a flat absorber plate in the first instance the total solar absorptivity (α) should be near one and secondly the infrared total emissivity (ϵ) should be near zero. Such a surface is called spectrally selective. A more detailed description about this can be found in the paper of Mattox and Sowell (1). The solar spectrum concerned at higher latitudes is mostly confined in the wavelength region 0.3-2.4 μm, while the thermal radiation spectrum has its maximum intensity at about 9 μm for a black body at 60°C and extends from about 2 μm to infinity. The smallest overlap of these two spectra is at about 2.2 μm, this is also called the cutoff wavelength. It is often convenient, in researching spectrally selective surfaces, to work with spectral reflectivities instead of spectral absorptivities. The relation between the directional spectral absorptivity or emissivity and the directional hemispherical spectral reflectivity (ρ) at temperature T is, following Kirchhoff's law (2), briefly given by

$$\alpha(\lambda, T) = \epsilon(\lambda, T) = 1 - \rho(\lambda, T)$$

in which λ is the wavelength in μm.

The ideal spectrally selective reflectivity curve is shown in Fig. 1. A simple spectrally selective absorber consists of a metal substrate covered with a thin semiconductor film. This semiconductor must then have a high absorptivity for wavelengths shorter than 2.2 μm and a high transmissivity for wavelengths longer than 2.2 μm. The mechanism concerned was earlier described by Christie (3). An example of such a semiconductor is metal oxide, but only certain types of metal oxides will have suitable spectrally selective properties. The chemical compound and, therefore, the optical and electrical properties are strongly determined by the way these oxides are produced. In other words, the process parameters and the working circumstances are of great importance. In this paper the effect of different process parameters as well as the effect of aging tests on the solar absorptivity and the thermal emissivity are discussed.

Key words: solar, absorptivity, emissivity, durability, anodic.

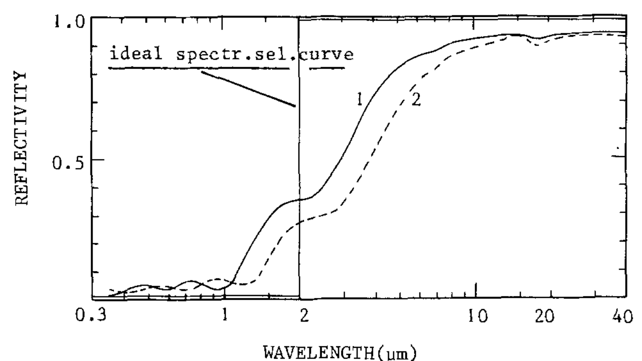


Fig. 1. Near-normal hemispherical spectral reflectivity of zinc oxide on leaf-zinc prepared by anodic treatment of the substrate in a solution containing 30 g/l NaOH and 20 g/l $NaNO_3$ at 40°C bath temperature, with current density of 20 (a.c.) A/dm^2 during 1 min (curve 1) and 3 min (curve 2).

Table I. Effect of different process parameters on the normal total solar absorptivity α_n and the normal total thermal emissivity ϵ_n for 60°C

Sample number	NaOH (g/l)	$NaNO_3$ (g/l)	$NaClO_2$ (g/l)	Bath temp. (°C)	Current density (A/dm^2)	Voltage (V)	Process time (min)	α_n	ϵ_n (60°C)

Experimental Techniques

Optical measurements.—In the solar spectrum (here from 0.35 to 2.5 μm) an integrating sphere according to Saftwat's design (4) attached to a spectrophotometer has been used to measure the near-normal hemispherical spectral reflectivity in steps of 0.05 or 0.1 μm, depending whether the intensity of the solar energy is high or low. The coating of the inner wall of the sphere consists of $BaSO_4$. The reliability and reproducibility were first checked with some reference standard samples as Minnesota 101-C10-3M Nextel velvet black coat paint, vacuum-evaporated gold film, diffuse white standard ceramic material No. 22614 from Zeiss, and a pressed-pure $BaSO_4$ powder. In the thermal radiation spectrum (from 2.5 to 40 μm) a Beckman Acculab VI infrared spectrophotometer has been available to measure the near-normal specular spectral reflectivity. A vacuum-evaporated gold film has always been used as a reference.

The connection between the two reflectivity curves at 2.5 μm was rather close because our surfaces always have mirrorlike appearance in the visible region so that the near-normal specular reflectivity can be considered as near-normal hemispherical reflectivity. The normal total solar absorptivity, α_n, was calculated by numerical integration of the normal spectral absorptivity multiplied by the normalized spectral distribution of solar energy. Here a standard direct spectral solar energy distribution of Moon (5) for air mass 2 (in accordance with a zenith angle of 60°) was taken as a weight factor. The integration boundaries are 0.3 and 2.2 μm. The same procedure was carried out on calculation of the normal total emissivity ϵ_n, only here the black body radiation function at temperature of 60°C was taken as a weight factor. The total experimental and numerical relative error of α_n was less than 2%; that of ϵ_n was about 10%.

Preparation techniques.—The basic materials for the anodic treatments are commercial leaf-zinc (1.5% Pb + Si) and plate steel 37 (0.12%C). All the samples have a diameter of 28 mm and a thickness of 2 mm. These samples were initially ground with grit 400 and 600, then polished with 3 μm diamond paste, and finally polished after with 1 μm diamond paste until a mirrorlike surface appeared. The root mean square roughness measured was less than 0.5 μm. The chemical and electrochemical treatments of the samples were done by the Dutch Organization of Applied Scientific Research (T.N.O.) at Apeldoorn, The Netherlands.

After polishing, the steel samples received a 2 min hot anodic and a cold cathodic pretreatment (TNO recipes). In between they were rinsed in cold tap water and dipped in 50% hydrochloric acid solution. The final pretreatment consisted of rinsing the steel samples in cold tap water and dipping them in a 10% sulfuric acid solution. The clean steel samples now were electroplated with bright zinc for about ½ hr in an electrolyte containing: 75 g/l zinc cyanide, 125 g/l sodium cyanide, 85 g/l sodium hydroxide, 2 g/l TNO organic brightener, at pH > 13, temperature of 25°C, and with a current density of 4 A/dm^2. A zinc anode was used. There was no stirring in the bath. The zinc thickness is approximately 20 μm. The pretreatment of the leaf-zinc samples consisted only of degreasing with calcium hydroxide, dipping in 1% sulfuric acid solution and, rinsing in cold tap water. All the zinc substrates received an a-c (50 Hz) anodic treatment in solutions with NaOH and $NaOH_3$ as used by Encheva (6). The concentration of the bath components, the bath temperature, and the current density were chosen such as to obtain the best corrosion resistance as reported extensively by Encheva (6), namely: 20-30 g/l NaOH, 15-20 g/l $NaNO_3$, 25°-40°C bath temperature, 10-140 A/dm^2, treatment time of 8-15 min, and coating thickness of 4-6 μm. As far as the last two requirements are concerned, they are hard to fulfill because thick coatings usually have high emissivities, which are not suitable as spectrally selective coatings. Our process times are mostly near 1 min.

In Table I all the different process parameters used are summarized. In this table the zinc oxide coatings on bright zinc-electroplated steel are not included. It concerns samples prepared on the same way as No. 5 and 8. It was not our intention in the first instance to optimize zinc oxide coatings by varying all the parameters involved, but we are interested in the effect of some process parameters on the spectral selectivity, taking into account the corrosion resistance recommendations as reported by Encheva (6). In a few cases these recommendations were not wholly followed, see No. 3, 5, 6, and 8 in Table I. The purpose of these deviations was to examine the effect of gas evolution, higher a-c voltage, and the use of d-c voltage, respectively, on the radiation properties α_n and ϵ_n. In one case (No. 7 in Table I) 5 g/l $NaClO_2$ were added. This was done because, following Pushpavanam's (7) suggestion, the coating would have a deep black color and would have high corrosion and abrasion resistance. After the anodizing process all the samples were washed in a stream of cold tap water and then rinsed after in hot deionized water.

Temperature and ultraviolet aging.—Some of the samples (see Table II) were exposed to air heating at 80°C for two weeks and at 180°C for one week at a stretch. 80°C was chosen because these surfaces are supposed to work beneath this temperature, while 180°C is the maximum temperature of a stagnating flat plate collector which must be avoided anyhow.

The same samples were also exposed to a u.v. radiation test of 120 W/m^2 for about 72 hr. The aim of these tests was to get a rough idea about the

stability of the radiation properties α_n and ϵ_n for the short term.

Results and Discussion

The normal hemispherical spectral reflectivity curves of zinc oxide on leaf-zinc samples of number 1-8 are presented in Fig. 1-4. In Table I the process parameters are given with the normal total solar absorptivity α_n and normal total thermal emissivity ϵ_n values concerned. Zinc oxide coatings on zinc-plated steel produced in the same way as No. 5 and 8 are not included in the figures as well as in Table I, because the optical properties are not different from No. 5 and 8, respectively. In Table II the effect of short-term heating and u.v. tests on α_n and ϵ_n of some surfaces is shown including those (No. 5a and 8a) with a zinc-electroplated substrate.

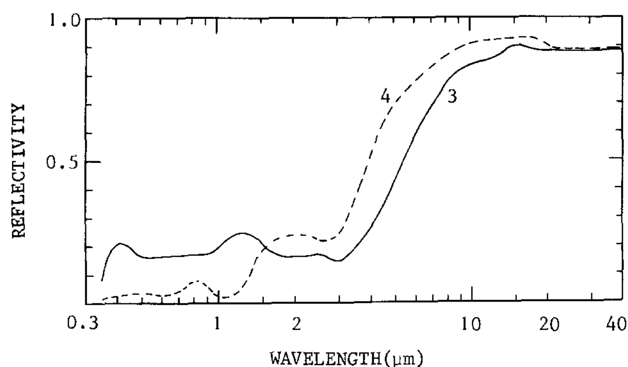

Fig. 2. Near normal hemispherical spectral reflectivity of zinc oxide on leaf-zinc prepared by anodic treatment of the substrate in a bath with 30 g/l NaOH and 20 g/l $NaNO_3$ for 1 min with 20 (a.c.) A/dm^2 at 60°C (curve 3) and with 40 (a.c.) A/dm^2 at 40°C (curve 4).

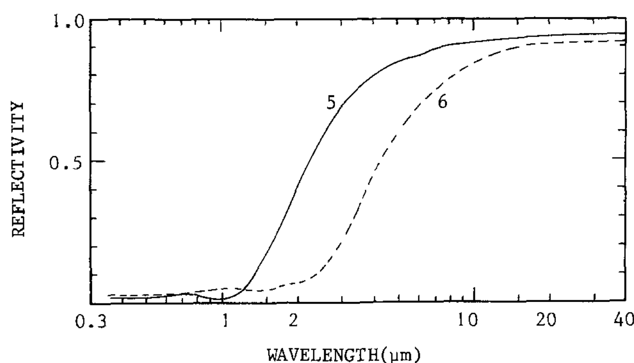

Fig. 3. Near normal hemispherical spectral reflectivity of zinc oxide on leaf-zinc produced by treating the substrate anodically in an electrolyte with 10 g/l NaOH and 20 g/l $NaNO_3$ at 40°C with 20 (a.c.) A/dm^2 and for a process time of 1 min (curve 5) and 1.5 min (curve 6).

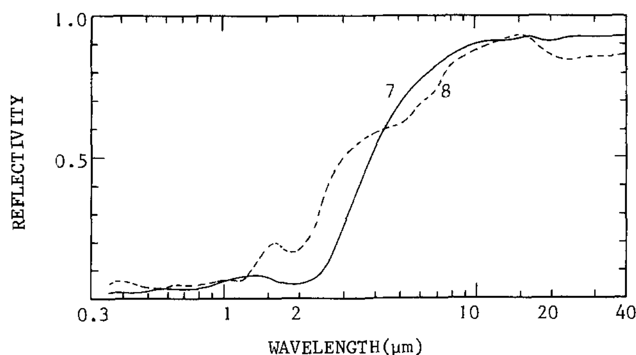

Fig. 4. Near normal hemispherical spectral reflectivity of zinc oxide on leaf-zinc produced by anodic treatment of the substrate in a solution with 30 g/l and 20 g/l $NaNO_3$ at 40°C with 20 (d.c.) A/dm^2 for 1 min (curve 8); for curve 7, 5 g/l $NaClO_2$ was added and an a-c current density of 20 A/dm^2 was used.

In general most of the zinc oxide coatings investigated here have a black color and mirrorlike appearance. Unfortunately the blackness is not uniform; some of the surfaces show tiny white dots sparsely spread, perhaps white zinc oxide or zinc which was not affected by the anodic treatment.

The black color is, according to the literature (7, 8), due to nonstoichiometric effects. Usually an excess of zinc has been found (7-9), but here we have found in our zinc oxide coatings a deficit of zinc. (Analysis was carried out with a MeV-Van de Graaff-accelerator.) Sample No. 5 reveals an atomic ratio of zinc/oxygen of 0.86 and sample No. 8 a ratio of 0.95.

Each sample or set of samples will be discussed successively from the standpoint of spectral selectivity and corrosion resistance (6, 7).

Sample No. 1 and 2, Table I, Fig. 1.—The spectrally selective property is not bad in the first instance. Because of corrosion resistance longer treatment times are desirable, but this was not possible due to adhesion problems.

Sample No. 3, Table I, Fig. 2.—It has been found that a higher bath temperature seems to damage the surface too much, resulting in a poor spectral selectivity.

Sample No. 4, Table I, Fig. 2.—This surface has nearly the same optical properties as surface No. 2, as can be expected. In practice, however, high current densities are usually not attractive.

Sample No. 5, Table I, Fig. 3.—Reflectivity curve No. 5 approaches the ideal spectral selective curve (Fig. 1) best. The coating thickness is 0.38 μm. A thicker coating was obtained by a little longer treatment time (No. 6), but then the normal total emissivity raised very strongly. Besides this, following Encheva's corrosion test results, the concentration of NaOH is rather low and therefore high corrosion resistance can not be assured.

Sample No. 7, Table I, Fig. 4.—The addition of 5 g/l $NaClO_2$ to the electrolyte, as suggested by Pushpavanam (7), resulted as expected in a deep black coating with good spectrally selective properties. A treatment time of 40 sec yielded a normal total emissivity of 0.10. The expectation is that a treatment time of 1.5 min will give an ϵ_n of 0.15. This value is still acceptable for low temperature solar collectors. For corrosion resistance it is better to have the thickest coating as possible.

Sample No. 8, Table I, Fig. 4.—In Fig. 4 we see that a d-c current reveals a capricious form of the spectral reflectivity curve with poor α_n and ϵ_n values. The thickness of this coating is 0.46 μm.

If we consider the short term heating and u.v. test results, we may say in general that the low temperature aging as well as the u.v. aging have not changed the radiation quantities α_n and ϵ_n very much. This is in contrast with the 180°C test, after which different results have been obtained: the anodized zinc-plated steel sample of No. 5a shows the largest change in α_n and ϵ_n, while the corresponding sample No. 5 with leaf-zinc as a substrate and also sample No. 7 show the smallest change. The cause of these different results has not yet been understood.

Conclusion

The best spectrally selective surface, taking into account corrosion resistance considerations and thermal and u.v. stability, seems to be zinc oxide on polished leaf-zinc prepared by anodic treatment of the substrates in a solution containing 30 g/l NaOH, 20 g/l $NaNO_3$, and 5 g/l $NaClO_2$ at 40°C bath temperature with 20 (a.c.) A/dm^2 for 1 min or slightly longer treatment time. Before applying this oxide even in

low temperature collectors, long-term durability tests should be carried out first.

Acknowledgment

The author wishes to thank Ir. C. A. Boose of Apeldoorn T.N.O. for the preparation of the samples and Dr. L. W. Wiqqers of F.O.M. Institute in Amsterdam for the chemical analyses of some of the surfaces with a MeV-Van de Graaff-accelerator.

Manuscript submitted May 6, 1977; revised manuscript received March 21, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by the Delft University of Technology.

Heinz Gerischer—Palladium Medalist

Charles W. Tobias[1]

The Palladium Medal of the Society, established in 1951, is given for distinguished contributions to the field of electrochemical science and corrosion. What this award is designed to recognize was clearly demonstrated already in 1951 by the selection of Carl Wagner as the first medalist. The 13th recipient of this award, Professor Heinz Gerischer, follows a list of eminent scientists: Wagner, Furman, Evans, Bonhoeffer, Frumkin, Uhlig, Hackerman, Delahaye, Hoar, Brewer, Levich, and Pourbaix. A commendable lack of chauvinism has been evident in the selection of the medalists: eight of the 13 recipients were foreign nationals.

Heinz Gerischer's career started out under what one could call less than auspicious circumstances. A series of nearly miraculous turn of events are responsible for his having been admitted at all, in 1938, to any university in Germany. No sooner did he complete his first year as a student in chemistry in Leipzig, then in 1939 he had to join the German army, only to be ejected as a half-aryan in 1941. Allowed to return to continue his studies in Leipzig, obviously a serious mistake on the part of Nazi authorities, he obtained his chemistry diploma in 1943. Then, with another forced interruption during war time in "Arbeitsdienst," he stayed on as a researcher in Karl-Friedrich Bonhoeffer's laboratory.

In 1946, after obtaining his doctorate, he followed Bonhoeffer to the University of Berlin. According to Gerischer, Bonhoeffer, a great scientist and an exceptional human being, was perhaps the greatest single influence in his life. At a time when all intellectual and human values crumbled Bonhoeffer saved not only human lives, he was among the few who succeeded in maintaining a thin thread of continuity in the great tradition of science in Germany.

In 1949, during the blockade of Berlin, Gerischer again followed his mentor, this time to Gottingen, where Bonhoeffer was named the director of the newly created Max Planck Institute für Physikalische Chemie.

During the five years Gerischer spent in Gottingen he developed a definite interest in an academic career. As a consequence of the somewhat rigid structure of the German academic scene, he had to move on to work toward his habilitation to achieve the status of a dozent. In 1954 he joined the Max Planck Institute für Metallforschung in Stuttgart, heading a small department of corrosion science. In Stuttgart Gerischer enjoyed a considerable degree of freedom in the selection of research topics and in accepting students working on their doctoral dissertations. In 1955 he became a dozent at the University of Stuttgart and began to lecture there, and in 1960 he was advanced to full membership of the Max Planck Gesellschaft. Soon thereafter, in 1962, he accepted an invitation to the Technische Hochschule in Munich as a Professor Extraordinarius.

Seven years later, in 1969, after he had advanced in academic rank, and following service in various important academic administrative positions, he accepted an invitation to become the director of the Fritz Haber Institute of the Max Planck Gesellschaft in Berlin. Since 1970 he resides in the director's villa on Faradayweg and heads an institution of great renown, one that was directed earlier by Fritz Haber, under whose guidance Bonhoeffer obtained his doctorate. The series of events that led to Gerischer's directorship of this famed institution involved many improbable turns, many near miracles. It is indeed fortunate for Germany and for science that today a man of Gerischer's intellectual caliber and integrity occupies this very influential post.

Gerischer's early work addressed various problems in the area of kinetics and mechanisms of electrode processes. Numerous papers originating from the 1950's and early 1960's concern the elucidation of mechanisms of anodic and cathodic reactions involving simple and complex ions, others pertain to corrosion and electrocatalysis. His papers on electrode reactions of complex ions and on electrocrystallization processes are examples of the best work published on these subjects in the fifties and sixties.

Gerischer made important contributions to the development of new experimental techniques for the investigation of fast electrode reactions. Among these the potential-step and current-step methods, and the invention of the double-pulse method deserves particular mention. He designed and employed a special flow cell for the study of fast homogeneous reactions and also developed a temperature step method for similar purposes.

These earlier investigations were based on classical concepts, macroscopic treatments of electrode phenomena, in which Gerischer's contributions were particularly significant through the introduction of new experimental techniques, resulting in important improvements in the accuracy with which kinetic parameters could be obtained.

Already during his student days in Leipzig, Gerischer, after reading Gurney's book, "Ions in Solutions," thought of the desirability of employing electronic energy levels to the description of electrode reactions. However it was only in the mid-fifties, after he came across Brattain and Garrett's work involving the first electrochemical experiments with germanium, that he realized the opportunity offered by semiconductors for the application of electronic states in the interpretation of electrode reactions. His first paper on the anodic dissolution of n- and p-type germanium, coauthored with his student Fritz Beck, was published in 1957, and some 70 papers concerning semiconductor electrodes have followed since. When Gerischer moved to Munich, his nascent interest in photoelectrochemistry received a strong boost by the long tradition in spectroscopy and photochemistry in the institute he joined. Here he

[1] Introductory remarks by C. W. Tobias, Department of Chemical Engineering, University of California, Berkeley, on the occasion of the presentation of the Palladium Medal Award to Heinz Gerischer on October 11, 1977, at the Atlanta Meeting of the Society.

began to use semiconductor and insulator electrodes to study the reactions of excited molecules, especially of dyes. Finally, in Berlin he extended his work to include photoreactions at metal electrodes, specifically photoelectron emission into electrolytes and photooxidation of electrolyte components.

Thus, Gerischer is realizing the dream he had as a student in Leipzig; the analysis of electrode reaction mechanisms from an atomistic point of view, using atomic and electronic energy schemes. Many of you already know that his work established the foundations on which some of the present, very exciting developments in the area of photogalvanic cells are based.

It is evident that the recipient of the Palladium Medal of 1977 has covered in his research activities a large part of electrochemical science, and that he has made significant contributions to a number of disciplines represented in the various Divisions of this Society. To the surprise of no one his nomination to the Palladium award was cosponsored by an unprecedented large number of Divisions of the Society.

In concluding my introduction of the Palladium Medalist I only want to add a brief personal note. I studied Professor Gerischer's papers far before I met him in the early sixties. In subsequent years I have seen him on many occasions, and had the opportunity for close interaction with him during his stay as a visiting scientist in the Lawrence Radiation Laboratory in 1967-1968. This personal knowledge of the man allows me to say that Professor Gerischer's great talent and fine contributions to science are matched by his qualities as a human being.

For this reason it is with the greatest of pleasure that I present to you Professor Heinz Gerischer, the Palladium Medalist of 1977.

Electrochemistry of the Excited Electronic State

Heinz Gerischer[2]

Since the Palladium Medal of The Electrochemical Society is one of the greatest honors an electrochemist can be awarded with, I feel very pleased and honored to be the thirteenth recipient of this medal. I want to express my sincere thanks to you, Mr. President, as the representative of the society and particularly to you, Charles, for your so very kind and friendly introduction. You have mentioned therein how decisive my personal contact with K. F. Bonhoeffer was for my life, scientifically and otherwise. It was 20 years ago that this medal was awarded to him, but he tragically passed away before he received the message. Now, I am standing here in his succession being strongly reminded of his unforgettable personality. This is a very personal reason for me to acknowledge this medal particularly highly and to be so especially touched at this occasion.

I would not be standing in this place if I should not have found, over the years, the cooperation of a number of highly talented co-workers. Most of my contributions to various fields of electrochemistry have been made possible by their enthusiasm and their devotion to research. Without mentioning individual names, I wish to express my gratitude to all of them for their personal contributions.

The subject of my lecture has little to do with the problems which I have studied 10-20 years ago. Although it was apparently my contributions to these areas—according to the published appreciation—which should be acknowledged by this award, I have deliberately chosen a different subject for my presentation. This not only corresponds to my more recent interests, it also demonstrates that electrochemistry is still widening its objectives and far from being exhausted although it has a very long history.

Most of the electrochemistry work is still done in the dark and the electrochemists hope to enlighten themselves to understand the complicated systems with which they have to deal. However, more than a century ago, Becquerel had already illuminated the electrodes of Galvanic cells and detected photovoltaic effects (1). This created great excitement among the then very small and exclusive scientific community, but it certainly did not promote the understanding of electrochemistry. On the contrary, the speculations about such photoelectrochemical phenomena contributed to the fact that some parts of electrochemistry, especially the nonthermodynamic ones, appeared to the scientists of neighboring fields for a long period of time as quite obscure.

This situation has changed since the time when electrochemists could profit from the development of solid-state physics and photochemistry and have learned to combine these experiences with their classical electrochemical knowledge. This has demonstrated once more that electrochemistry is an interdisciplinary science and that a competent electrochemist must be alert to developments in various fields. We know today that all these photoelectrochemical effects are caused by the generation of excited electronic states, and my intention is to explain in this lecture the basic phenomena which are due to the presence of excited electronic states. I am especially pleased that I can address this lecture to a society which has combined in its development so closely the interests of electrochemists and solid-state physicists. The topic I will discuss today demonstrates forcibly how necessary it is to connect these two fields.

Reactivity in the Excited State

Electron transfer between a donor and an acceptor is one of the most common of electrochemical reactions. In Galvanic cells the donor or the acceptor is the electrode. It is obvious that this type of electrochemical reaction must be affected by electronic excitation. Figure 1 shows in a very simple picture how electronic excitation influences electron transfer processes.

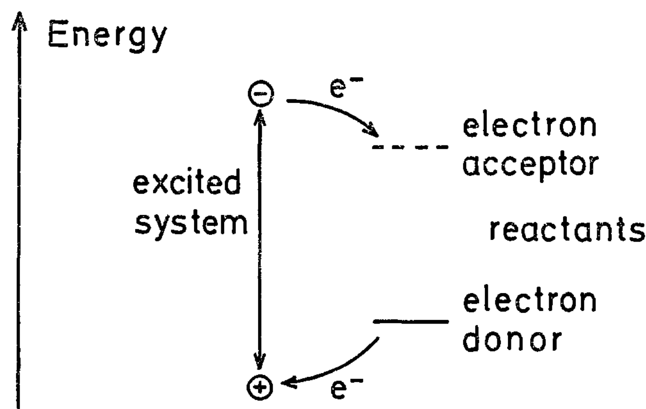

Fig. 1. Energy scheme for electron transfer between excited system and electron donor or acceptor.

[2] Palladium Medal Address delivered October 11, 1977, at the Atlanta, Georgia, Meeting of The Electrochemical Society. The medal was struck from palladium supplied by the International Nickel Company, 67 Wall Street, New York, New York 10005.

Electron transfer occurs between an occupied and a vacant electronic quantum state. Light absorption changes the distribution of electrons over the available electronic energy levels. As a consequence, electrons at higher energy levels are created simultaneously with vacant electronic states at low energies. The electrons of the high energy levels can be transferred to electron acceptors in this energy range. The vacant electronic states at low energy levels can be filled by electron donors with electronic energies in this region as is indicated in Fig. 1. We see immediately that, in electrochemical language, cathodic redox processes will be accelerated by light absorption and also anodic redox reactions will be enhanced. If the excitation energy is large enough, redox processes will become possible which cannot occur in the dark.

There are other possibilities of generating excited electronic states, for example, the application of very high electric fields to solids. We shall, however, limit our discussion with one exception to the generation of excited states by light absorption only.

What happens in an electrochemical system after light absorption depends both on the light absorber, which can be the electrode or one component of a redox couple, and on the reaction partner, which can be a redox couple or an electrode. In Fig. 2 three typical cases are shown which we shall later discuss in more detail. The excited molecule corresponds to the excitation of a redox system, and a possible consequence is, as we see, electron transfer in two opposite directions in contact with an electrode. In case of an electronic excitation in the electrode we shall distinguish between a metal and a semiconductor electrode. At both types of electrodes, cathodic and anodic electron-transfer processes can be induced by light absorption as is indicated in this figure. We shall discuss this in more detail later.

The other type of electrochemical reaction which occurs at interfaces is ion transfer. How electronic excitation affects an ion transfer process is much less obvious than for electron transfer. One can, however, expect that ion-transfer reactions also can be accelerated by electronic excitation. The reasons are given in Fig. 3. Ion transfer at the interface between an electrode and electrolyte must involve an energy barrier. If the initial state of this process is electronically excited, the energy of this state will be increased. How much depends on the localization of the excitation energy. The influence on the transition state will be much smaller, and there is no influence on the final state. Figure 3 shows schematically that the activation energy for the ion-transfer process will be reduced by electronic excitation, and in some cases, as we shall later discuss, this effect even controls the possibility of ion transfer.

We will make a brief estimation of how large these effects might be. It must be taken into consideration that excited electronic states have a limited lifetime.

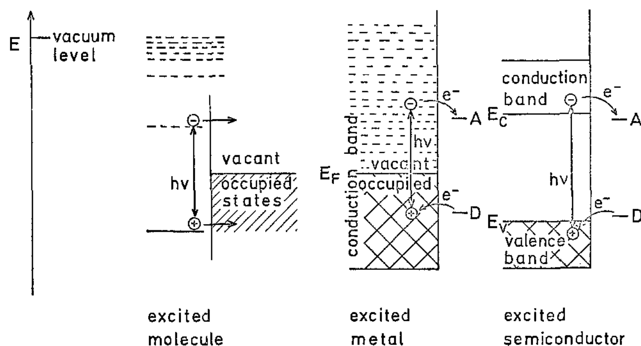

Fig. 2. Energy scheme for electron transfer between excited molecule and metal, excited metal, or excited semiconductor and redox couples.

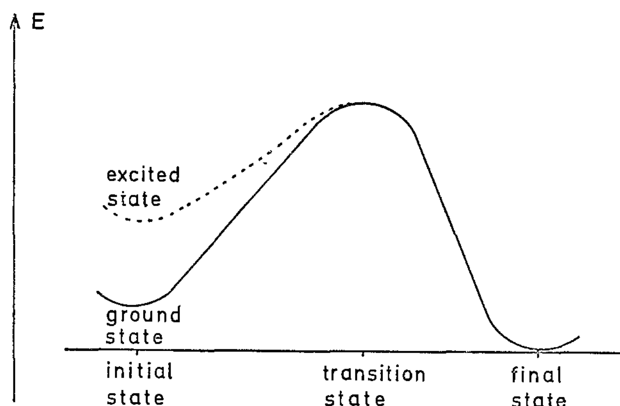

Fig. 3. Influence of electronic excitation on ion transfer reaction

The efficiency will therefore depend on the relation between the lifetime of the excited state and the time needed for completing the electrochemical reaction. Table I gives some characteristic time constants for electron transfer, ion transfer, and the lifetimes of excited states.

It is obvious that the chance to see the effect of electronic excitation is much larger for an electron-transfer process than for ion transfer, because electron transfer is so much faster. On the other hand, the efficiency of electronic excitation in metal electrodes will be very low because of the extremely short lifetime of excited states in metals. This is quite different for semiconductors and insulators where we therefore can expect to find very pronounced effects. In the following we shall discuss a typical case for every kind of excitation.

Excited Molecules as Redox Reactants

To understand the action of an excited molecule as an electron donor or electron acceptor we must get some idea of the redox potential of an excited redox system (2). This depends clearly on whether the reduced or the oxidized component of the redox system is excited. For this discussion we shall use the so-called absolute scale of redox potentials which is closely related to the electronic energy level system of solid-state physics (3, 4). The relation between the electrochemical redox scale and this absolute scale is given in the definitions and the energy scheme shown in Fig. 4. A comparison of the two scales is shown in Fig. 5.[3]

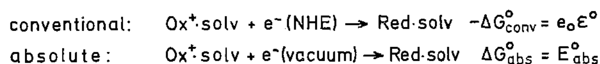
What happens with the redox potentials of a molecule in the excited state is shown in the following two figures. Figure 6 describes this in a very simplified molecular orbital picture. We consider a molecule in its singlet state and assume that the lowest vacant molecular orbital is the acceptor orbital for the reduction of this molecule while the highest occupied orbital is the donor orbital. By electronic excitation to the lowest excited singlet state an electron will be promoted from the donor orbital to the acceptor orbital. We see that the situation is just inverted now. The previous donor orbital becomes an acceptor orbital while the previous acceptor orbital has become the donor orbital. This means that the redox potential

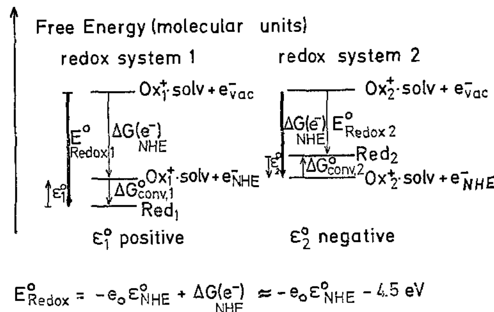
[3] It should be mentioned that the position of the NHE, located in this picture at E_{NHE} = −4.5 eV, is still open to discussion (31, 32).

Table I. Comparison between reaction time and lifetime

Electron transfer		10^{-12}-10^{-14} sec
Ion transfer		10^{-10}-10^{-12} sec
Molecules	Excited singlets	10^{-8} 10^{-12} sec
	Excited triplets	10^{-3}-10^{-10} sec
Metals	Excited electrons	10^{-14}-10^{-15} sec
Semiconductors and insulators	Excited electrons or holes	10^{2}-10^{-13} sec

Conventional and Absolute Scale of Redox Potentials





$$E^{o}_{Redox} = -e_o \varepsilon^{o}_{NHE} + \Delta G(e^-)_{NHE} \approx -e_o \varepsilon^{o}_{NHE} - 4.5 \text{ eV}$$

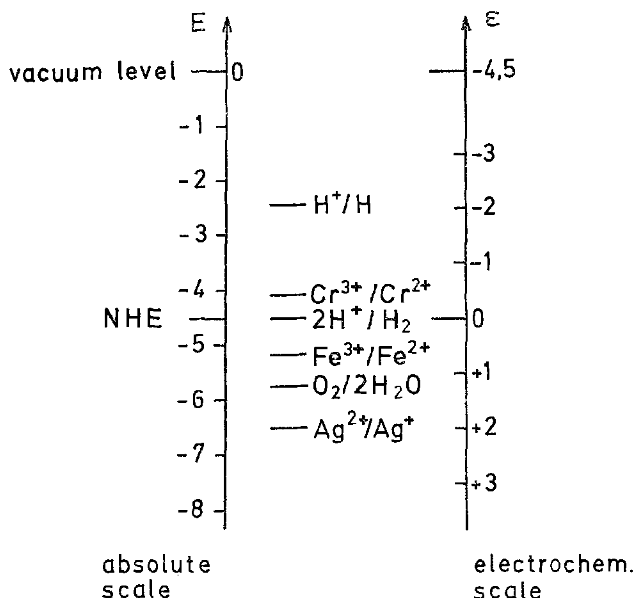

Fig. 5. Comparison of conventional and absolute scale of redox potentials.

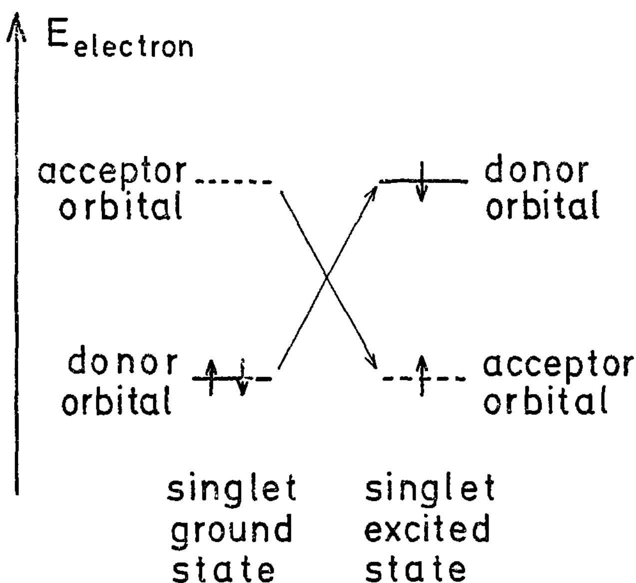

Fig. 6. Energy position of redox orbitals of a molecule in the ground state and the excited state according to simplest M O-picture.

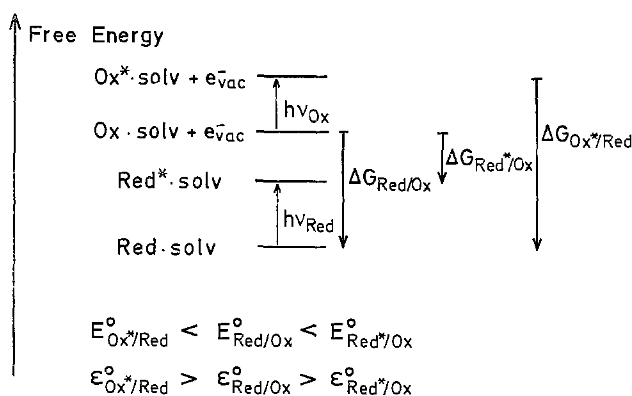

$$E^{o}_{Ox^*/Red} < E^{o}_{Red/Ox} < E^{o}_{Red^*/Ox}$$

$$\varepsilon^{o}_{Ox^*/Red} > \varepsilon^{o}_{Red/Ox} > \varepsilon^{o}_{Red^*/Ox}$$

Fig. 7. Shift of redox potentials by electronic excitation of the reduced or the oxidized species of a redox couple derived from the free-energy changes.

of an excited molecule is shifted in two directions. Its reductive power has been increased simultaneously with its oxidative power. Figure 7 shows this more concretely in a free energy scale for a redox system with two components where either the reduced species is excited or the oxidized species. This picture demonstrates that the shift of the redox potential between the reaction in the ground state and in the excited state is just given by the stored excitation energy in the molecule. If the reduced component is excited, the free energy for electron abstraction is reduced by this amount and the redox potential is shifted in the negative direction in the conventional electrochemical scale while excitation of the oxidized component increases the energy gained by electron addition, this meaning that the redox potential of the system is shifted in the positive direction of the conventional electrochemical scale.

What happens when such an electronic excitation occurs exactly at the interface between the electrolyte and an electrode? The various possibilities are shown in Fig. 8 where metals, semiconductors, or insulators are assumed as the electrode material (5, 6). The positions of the electronic energy levels in the excited molecule are represented again in the simplified molecular orbital picture. The figure shows that in contact with a metal in a situation where no dark reaction is possible, electron transfer in both directions will be opened after excitation of the molecule. This means that no external current can be observed in such cases since both processes will compensate each other. This is a mechanism of energy quenching by mutual electron exchange. Even if one of these processes should be faster than the other, the reverse process will occur in the dark as a consecutive reaction. The chance that such photocurrents can be found at metal electrodes is, therefore, very dim. Only in cases where a very fast chemical reaction follows one of the electron-transfer steps which prevents the reverse process can photocurrents be observed in such systems. If photoeffects are found, they are usually caused either by the existence of nonmetallic surface layers on the electrode or by photochemical reactions in the electrolyte which generate species with a different redox potential which can either be oxidized or reduced at the electrode during their lifetime.

The attractive cases involve contact between an excited molecule and a semiconductor as shown in (b) and (c) of Fig. 8. What happens in such a case depends on the relative position between the energy bands and the redox orbitals of the excited molecules. In case (b) electron injection into the conduction band is possible and can be observed as an anodic photocurrent. In case (c) electron extraction from the valence band equivalent to hole injection will occur, and a cathodic photocurrent is found. Case (d) shows a system

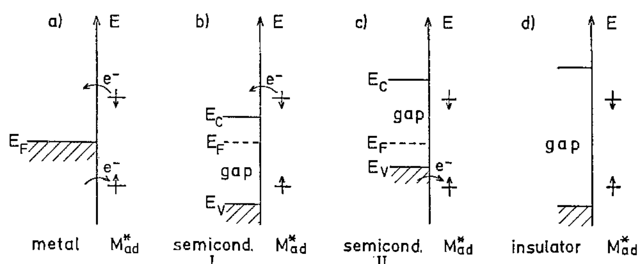

Fig. 8. Typical situations for electron transfer between an excited molecule and various solids.

where the bandgap is too wide to permit any kind of electron transfer.

In this picture we have not yet discussed another possibility of energy quenching which is very efficient at a contact with metals, that is, energy transfer. This is found whenever the absorption spectrum of the electrode overlaps the fluorescence spectrum of the excited molecule (7, 8). To avoid this, the bandgap of the semiconductor must exceed the energy stored in the molecule after excitation. This is another reason why photocurrents at metal electrodes are usually not caused by direct electron transfer in the excited state.

Figures 9 and 10 give examples of cases (b) and (c) of Fig. 8. Figure 9 shows a comparison between the absorption spectrum of a dye molecule in solution and the action spectrum of the photocurrents if this dye is brought into contact with a ZnO electrode which is suitably polarized to collect all injected charge carriers (9). This requires an anodic bias in case of electron injection, as found at the ZnO electrode. Figure 10 shows hole injection by the same excited dye molecule at a p-type GaP-electrode (10) where we have the situation of Fig. 9(c). Since the bandgap

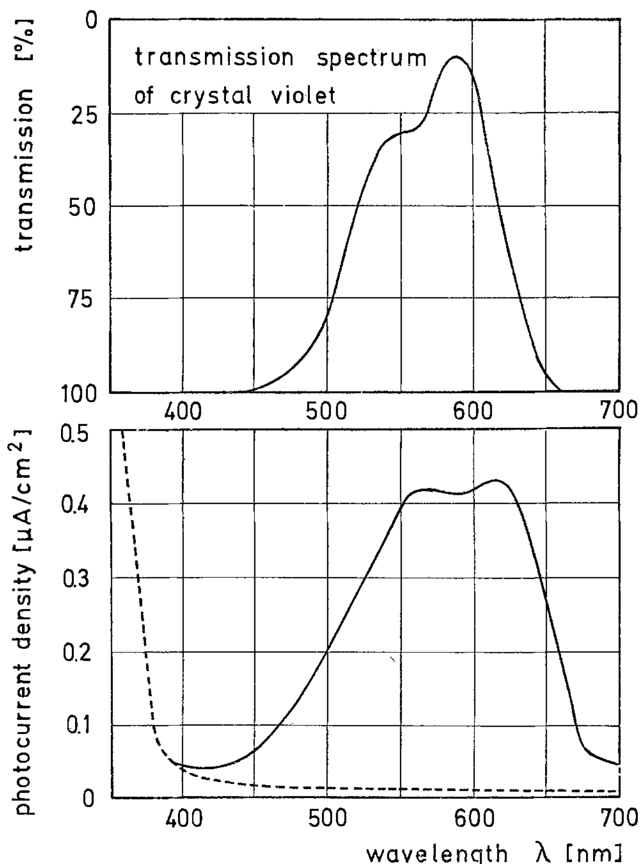

Fig. 9. Photocurrent spectrum for electron injection from crystal-violet into a ZnO electrode in comparison with absorption spectrum of the dye in solution.

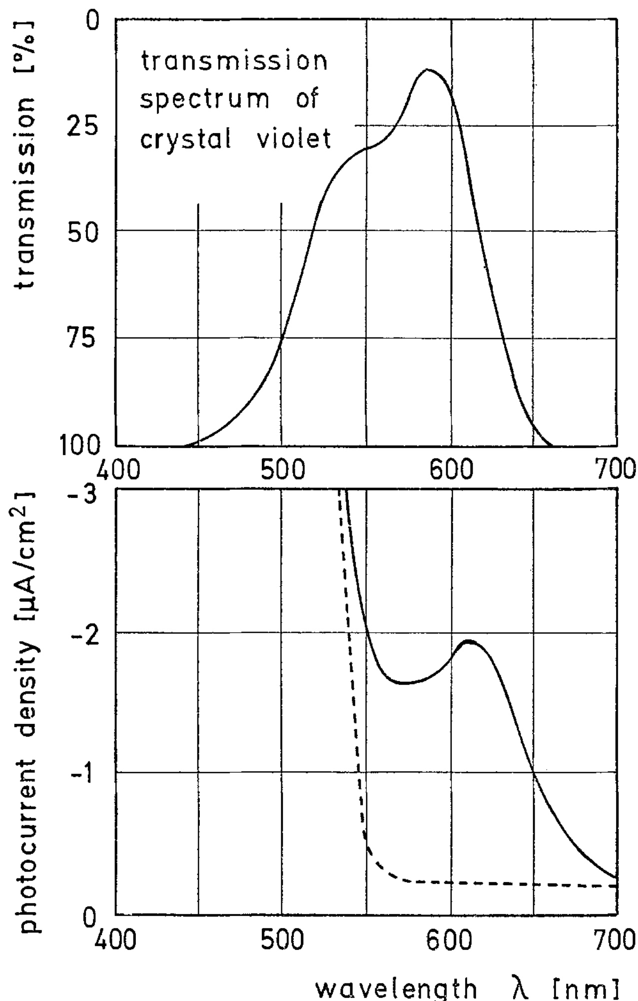

Fig. 10. Photocurrent spectrum for hole injection from crystal-violet into a GaP electrode in comparison with absorption spectrum of the dye in solution.

of GaP is not wide enough, only the long range part of the dye absorption spectrum can be used for this kind of sensitization.

Such experiments provide sensitive tests of models for the spectral sensitization of solid materials (11), which has long found wide technical application in photography. This demonstrates again the close relationship of electrochemistry and solid-state physics.

Electronically Excited Metals

Now we consider electronic excitation in metals. Although we have stated earlier in the paper that we should not expect large effects due to the short lifetime of excited states in a metal, we are all aware that photoemission from metals into vacuum is a process well known for a long time. The reason that there is any chance to observe an effect of electronic excitation despite the short lifetime is the fact that electrons have an enormous velocity and therefore a chance to reach the surface in a very short time after excitation. Photoemission from a solid into vacuum is limited by the height of the energy barrier for leaving the solid material. For a metal in contact with the electrolyte the situation is not different. Only the shape of the energy barrier and its height are modified. In case of an aqueous electrolyte there is some interaction between the free electrons and the solvent which reduces the energy barrier. In addition to this, the electric potential drop in the electrical double layer at the interface influences the barrier height drastically and gives the means to alter it systematically.

Photoelectron emission into electrolytes has been studied in recent years quite intensively by the Russian School (12, 13), centered in the Institute of the Academy of Sciences which was headed by the late Professor Frumkin, after it had been started by the pioneering work of Barker (14). Some recent investigations in our institute, mainly done by J. K. Sass, have demonstrated that this technique is especially useful for studying the excitation and emission mechanism of electrons from solids in energy ranges which are not accessible to experiments *in vacuo* (15, 16).

Figure 11 shows the modification of the threshold for photoelectron emission by the presence of a condensed medium like an aqueous solution. The magnitude of the photocurrent depends on the quantum energy of the light, on the electrode material, and on the electrode potential. Two typical results are shown in Fig. 12 for a gold electrode. One sees, however, that not only cathodic photocurrents can be observed but also anodic ones (17). It can be concluded that the anodic photocurrents mean the oxidation of water by vacant electronic states at deep energy levels. These are excited holes in the metal.

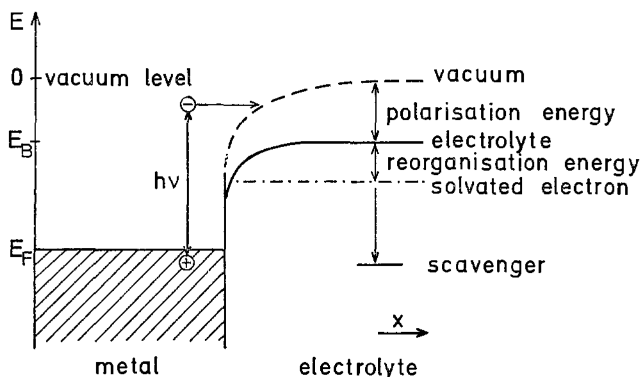

Fig. 11. Energy barrier for photoelectron emission from a metal into an electrolyte in comparison to the barrier against vacuum.

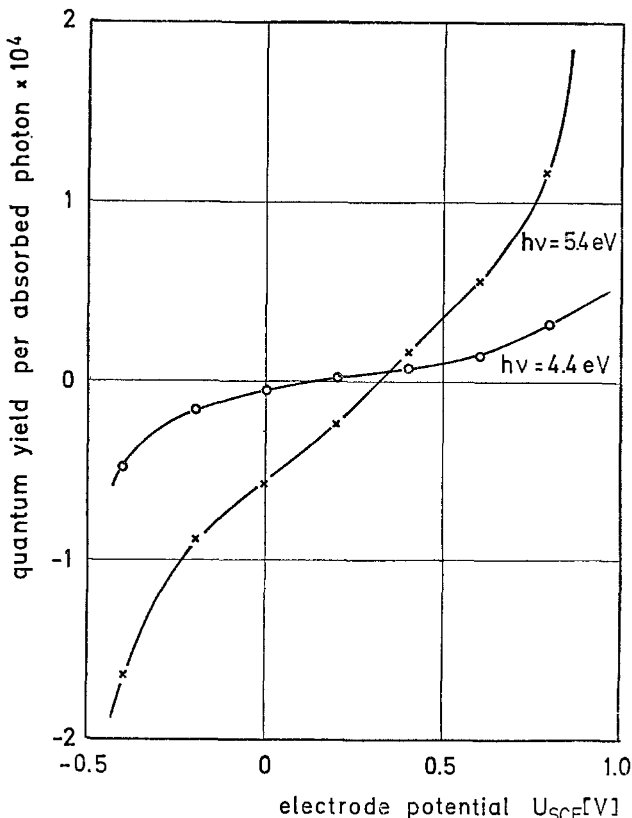

Fig. 12. Photocurrent-potential curves for a gold electrode in 1M H_2SO_4 for two different light energies.

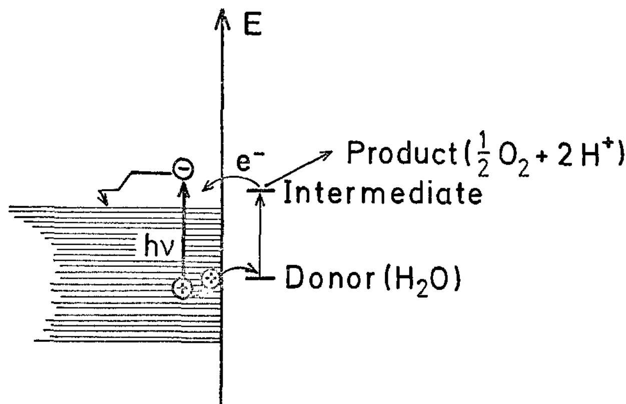

Fig. 13. Water oxidation by excited holes at the metal-electrolyte contact in terms of energy levels.

Figure 13 shows the mechanism of this reaction which ends in molecular oxygen. The potential dependence of the cathodic and anodic photocurrents clearly indicates that there is an energy threshold for both processes, photoelectron emission and water oxidation, which varies with the applied potential. If we assume that the potential drop between the electrode and the electrolyte is located exclusively in the Helmholtz double layer, a variation of the electrode potential means that the Fermi level, relative to the energy levels in solution, is shifted up or down by the applied voltage, and both thresholds are shifted in parallel, but in opposite direction. This is shown in Fig. 14.

Photoelectron emission studies at single crystal faces demonstrate that the crystal orientation plays an important role for the quantum yield. One knows from thermodynamics that the energy threshold between the bulk of a metal and the electrolyte is the same for any face at a given electrode potential. Nevertheless, photoemission quantum yield varies drastically with orientation as shown in Fig. 15 (18). This effect is most pronounced if polarized light is used (19). One

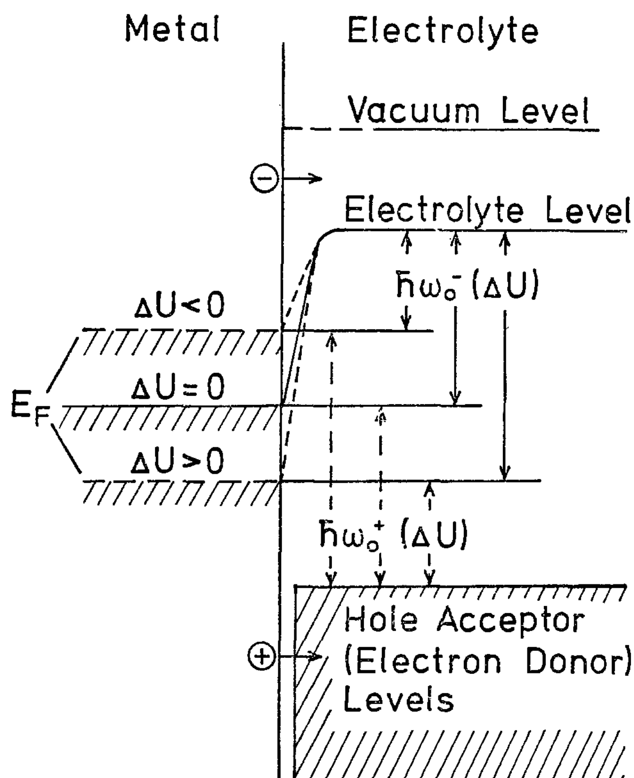

Fig. 14. Variation of the energy thresholds for photoelectron emission and photohole oxidation by the electrode potential.

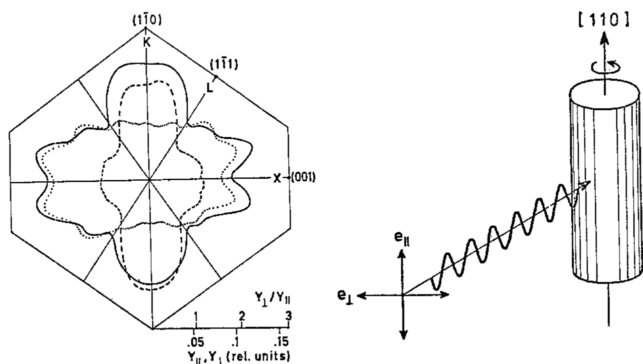

Fig. 15. Variation of the photoemission yields ($Y_{\perp}$ (———), $Y_{\parallel}$ (· · ·), and the ratio $Y_{\perp}/Y_{\parallel}$ (– – –) with crystallographic orientation on the single crystal cylinder surface for $h\nu = 3.45$ eV. A schematic illustration of the experimental geometry is shown on the right-hand side of the figure.

sees in Fig. 15 considerable differences in the efficiency for the two modes of polarization. This can be understood by correlating the different excitation conditions with the band structure of a metal. The momenta of the excited electrons and the chance to pass the barrier depend on crystalline direction.

As mentioned at the beginning of the paper, one should expect also that ion transfer should be accelerated by electronic excitation. There is, however, to my knowledge only one case where this effect has been observed at a metal electrode in the absence of a surface coverage with an oxide layer or other surface compound (20). This case is shown in Fig. 16. The gold electrode tends to dissolve in the presence of halide ions in a narrow range of electrode potentials just before an oxide layer is formed on the surface. The figure shows that in this range the dissolution rate is somewhat enhanced by illumination. The mechanism of this phenomenon, however, is still somewhat obscure and needs further studies.

Electronic Excitation in Semiconductors

As we expect from our estimation earlier in the paper, semiconductors show much more pronounced photoeffects than metals if light is absorbed beneath the surface. Quantum yields close to 1 can be obtained if the light is absorbed exclusively in a space-charge layer underneath the surface where a high enough electric field provides full separation of the electron hole pairs generated by light absorption. Such a situation can be reached at n- or p-type semiconductors by applying a suitable voltage which creates a depletion layer of large enough depth (21, 22), as is shown in Fig. 17. If electron donors or acceptors are present, the minority carriers reaching the surface will undergo redox reactions with these components of a redox couple. This will create a photovoltage of opposite sign to the initially present voltage across the space charge layer as is indicated in Fig. 17. Such photovoltages are the driving force for any kind of photoelectrolysis as in photoelectrochemical solar cells based on light absorption in semiconductors.

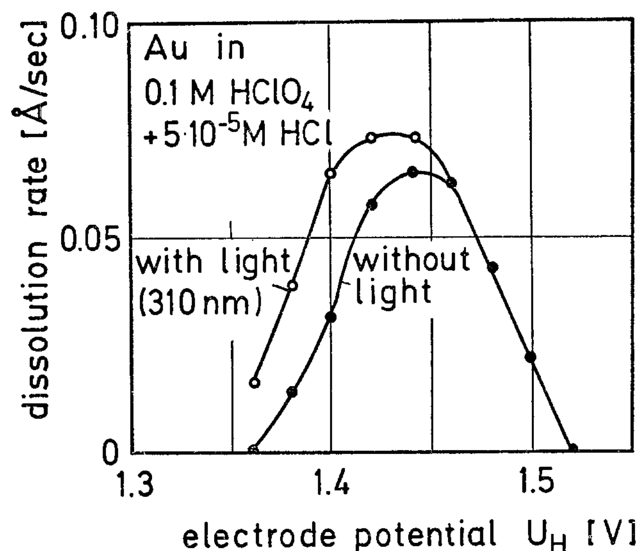

Fig. 16. Influence of illumination on the dissolution rate of gold in chloride-containing electrolyte.

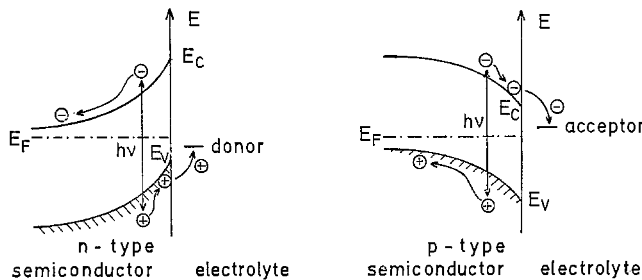

Fig. 17. Electron hole pair separation in illuminated depletion layer of a semiconductor.

If no suitable components of a redox couple are present the minority carriers will accumulate in the surface and the chance for ion-transfer reactions is enhanced (23). In most semiconductors the accumulation of holes means the weakening of bonding states and the preformation of a cationic state in the surface (24). Such cationic states react easily with nucleophilic reagents from the electrolyte and form reaction products which can be soluble in the form of ions or may be deposited as another compound on the surface.

The accumulation of electrons in the surface also usually results in the weakening of the surface bonds by the occupation of antibonding or nonbonding states. The consequence is a preformation of an anionic state in the surrace which easily can react with electrophilic components of the electrolyte. Decomposition of the semiconductor is the result. Table II summarizes a number of such reactions.

The quantum yield of all these photoreactions by excitation of the semiconductor depends on the penetration depth of the light and the extension of the space charge layer. The penetration depth of the light decreases drastically as the photon energy approaches the bandgap energy. The extension of the space-charge layer increases with applied voltage. These two effects are clearly shown in Fig. 18 for an n-type ZnO-electrode, where the photocurrents are compared at equal light intensities for different wave lengths and at different voltages. If one measures the photocurrent at a given voltage, the action spectrum of the semiconductor is revealed in the photocurrents. Some examples are given in Fig. 19 for two n-type and one p-type material.

These large effects of photoexcitation in semiconductors have in recent years found great interest for the purpose of solar light to energy conversion (25-27). In such systems the sensitivity of semiconductors to decomposition reactions in contact with electro-

lytes is the largest obstacle (28) Many research groups are working hard to overcome these difficulties and to develop devices by which either hydrogen or electric power can be generated in a photoelectrochemical cell.

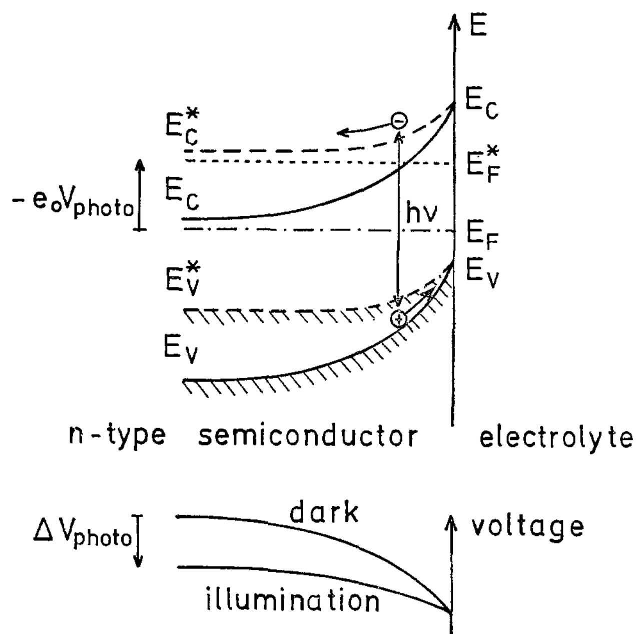

Fig. 20. Generation of a photovoltage in illuminated Schottky barrier.

The common bases of all these devices is the fact that semiconductor/electrolyte contacts form a Schottky barrier if the electrolyte contains a suitable redox system. Illumination of this Schottky barrier generates a photovoltage which acts as the driving force for electrolysis. As shown in Fig. 20, the source of the power and the mechanism of light to electrical energy conversion is the same as in photovoltaic solid-state devices. Therefore, semiconductor/electrolyte systems are subject to the same limitations in energy conversion efficiency as are the usual solid-state devices. The advantage of the electrochemical systems is the fact that this type of Schottky barrier can be formed very easily and without any problems with regard to the epitaxial conditions to avoid lattice misfit at the contact between two solids. The price one pays, however, is a susceptibility of the material to decomposition. The future will show whether technically reliable and efficient devices can be built on this principle.

Generation of Excited States by Electrolysis

Finally, we discuss somewhat the inverse of the processes discussed earlier, *i.e.*, the electrolytic generation of excited states. I shall not include the generation of excited states in homogeneous electrolytes which leads to luminescence and where the reaction partner can be generated by electrolysis. The discussion shall be restricted to the direct generation of excited states by electrode reactions.

Again, this can only be observed at semiconductors since the signal which indicates the generation of an excited electron state is light emission. How this is accomplished at the semiconductor electrode is shown in Fig. 21. If conditions can be found where the redox system injects minority carriers into the surface, they will recombine with the majority carriers. This is often a radiative process. Figure 21 shows this schematically for electron injection into a p-type semiconductor and hole injection into an n-type. In Fig. 22 are given the spectra of the emitted light from various electrodes where the conditions of Fig. 21 were met (29). These spectra for various n-type semiconductors show that the emitted light not only stems from band-to-band recombination, but sometimes contains light with smaller energy. It can be assumed that this light comes from recombination via surface states according to a mechanism which is shown in Fig. 23. Similar results have been obtained by electron injection into

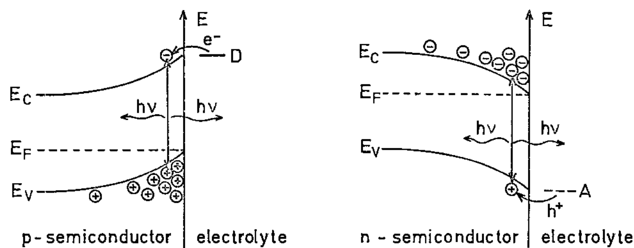

Fig. 21. Generation of luminescence by injection of minority carriers from redox systems into accumulation layer at the semiconductor/electrolyte contact.

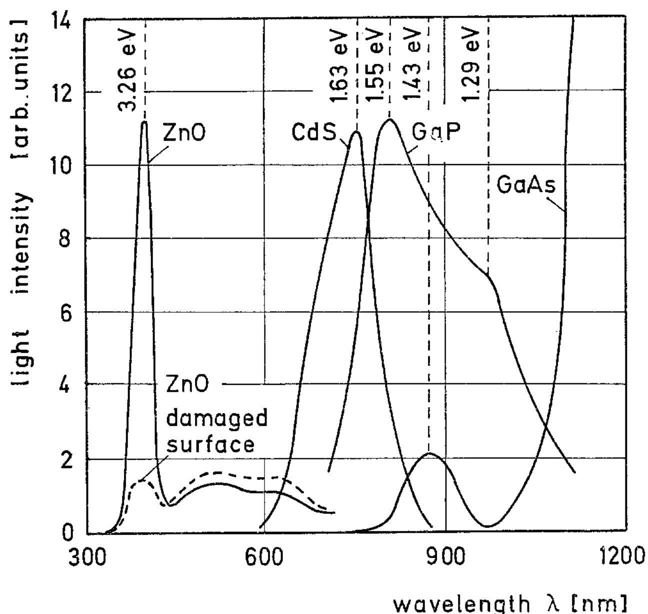

Fig. 22. Luminescence spectra of n-type semiconductors with hole injection by the radical SO_4^- with high oxidation potential.

p-type GaP (30). Such experiments can be very useful for elucidating the mechanism of electrochemical reactions at semiconductors and also for characterizing the electronic situation at a semiconductor electrolyte contact.

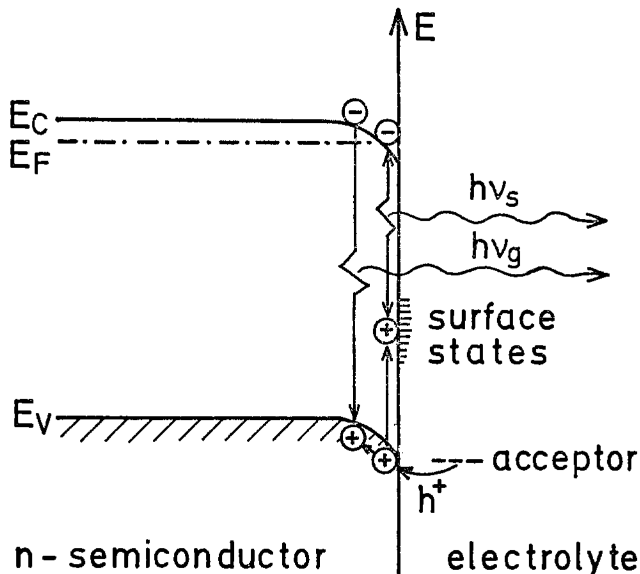

Fig. 23. Energy terms for luminescence by recombination from band-to-band or via surface states.

Summary

I have treated in my brief review only the simplest cases. As usual, the problems are in reality much more complicated and many questions are still open to discussion. There are many more applications of electronic excitation as a sensitive tool for studying the mechanism of electrode reactions or the properties of surface layers formed in an electrochemical process. I hope that the few examples given have demonstrated that the study of excited electronic states in electrochemistry is an exciting subject and I am convinced that many more electrochemists will be fascinated by this field in years to come. I am sure that this subject will contribute further to improving the understanding between electrochemists and solid-state physicists.

Acknowledgments

Those of my former and present co-workers who have made possible the contributions from my laboratory to the field which I have discussed in this lecture are portrayed in my last picture. I wish to express my appreciation.

Process and Equipment Developments in Electrothermics and Metallurgy over the Last Twenty-Five Years

R. Bakish*

Bakish Materials Corporation, Englewood, New Jersey 02631
and Fairleigh Dickinson University, Teaneck, New Jersey 07666

The Electrothermics and Metallurgy Division of The Electrochemical Society has a relatively broad mission in the subject matter which it considers as its province, and in the past 25 years much has transpired here. Reference is made to the period 1952-1977, the first year of which coincides with this writer's graduation as a metallurgist from Columbia University. Progress in these areas has had a major influence in much that is related to materials and materials processing today.

Let us begin by examining the scope of interests of the Division by considering the definition of the scope of its mission. By definition metallurgy is the science and art of extracting metals from their ores, refining them, and preparing them for use, while electrothermics in its broadest connotation is the use of electrical energy for heat generation and the application of this heat to a wide range of metal and nonmetal processing operations.

A thorough examination and review of all developments which took place in the last 25 years and which have had impact upon our Division will exceed the scope of this article. The writer instead will concentrate on the more important events of the period which affected materials processing technology of interest to our Division. He will also make passing reference to evolutionary changes in this technology and to areas which, though in most general terms fall within the definition of our Division's mission, have never been made part of its activities.

Perhaps the single most important development affecting activities of our Division in the period is the fact that vacuum and vacuum processes have become virtually an inseparable component in the preparation of an important number of materials today. To quote Winkler (1) of Balzers: "Almost all metals in the periodic table nowadays belong to the vacuum metals and are thus produced by vacuum methods, or to those that undergo vacuum processes at some stage in their manufacture."

Today by a wide variety of pumping schemes we can readily produce vacuums from 10 to 10^{-10} Torr. Much of the tremendous growth and advances of vacuum technology are both a product and fallout of effort to meet the needs of both the nuclear energy and aerospace fields, the latter triggered by that eventful October 4, 1957, when the Russian Sputnik appeared in the sky. Requirements of these two important domains of national scientific and engineering thrusts made possible the development of capabilities for the generation of vacuum on an industrial scale unheard of in the past. By virtue of this tremendous growth in scope and scale, costs have come to levels deemed well acceptable to the economics of the prevailing industrial climate, and as a consequence vacuum has made tremendous inroads in all kinds of industrial operations and is an integral part of the materials processing and industrial scene.

* Electrochemical Society Active Member.

Extractive Metallurgy, Materials Purification, and Crystal Growth

The advances in vacuum technology have played an important role and influenced the field of extractive metallurgy in this period. They made it possible to effect major, though really only evolutionary, advances (2) in the carbothermic and metallothermic reduction processes for V, Nb, Ta, Cr, Mo, W, Mg, Ti, Sm, Eu, La, Ce, and Ca. Not only metal production has benefited here, benefits were also derived in the production of a variety of carbides of these metals.

Advances of vacuum technology have played an equally important role in the area of metals refining as manifested in a number of ways. There was major growth in distillation techniques for metal purification on metals produced in large tonnage. For example in the case of lead almost the total world production (3) is subjected to the so-called vacuum dezincing process. An intermediate product in the refining of lead bullion, the so-called reichshaum (silver crust), is also processed by distillation (4) to separate such noble metals as Ag and Au which lead readily collects. Distillation processes for production of commercial purity indium and cadmium as well as the rare earth, alkali, and alkaline earth metals have equally benefited from the advances of vacuum technology.

The beginning of the 25 year period being considered here saw also the first paper (5) on the subject of zone melting, a technique which revolutionized the concept of realistic material purity attainable by those working in or with materials. I am now talking of production on much smaller scale than materials just mentioned. Perhaps the most significant initial application of Pfann's discovery was its application to the refining of germanium (6), the first important solid-state device material. This led to explosive adoption of the technique, where today its application is first and foremost for purification of silicon, and then for other materials for solid-state devices. Subsequent to this we saw its application for the purification of many metals. Work for purification of ionic compounds with activities directed to the alkali halides followed, though this work was by no means limited to these compounds.

In 1957, through utilization of electron beams by Calverley and his associates (7), the zone-melting technique was also adopted for the refining of the refractory metals and for single crystal growing. This was of considerable importance because of the role these metals were to play in the aerospace industry and in the conquest of space. While it will be discussed later, one should mention here that electron beams, through evaporative purification in cold-mold drip-melting techniques, also made important advances in the purification of refractory metals on a large industrial scale. Another matter to be discussed briefly later is the problem of vacuum and related processes for the purification and refining of steels for the pur-

pose of property beneficiation. It should also be stated that in the mid-1960's organic compounds joined the list of materials available in ultrapure condition, as a result of purification by zone-refining techniques.

In addition to making solid-state devices possible, this new generation of materials obtained through application of the new refining technique, *i.e.*, zone refining, has helped improve our understanding of materials on one hand and also established new uses for some of these materials. Ultrapure materials have shown properties differing from those of the very same materials of lesser purity. In metals, for example, plastic deformation studies revealed as expected much lower values for critical resolved shear stresses. In some organics (8) odors believed to be typical of certain compounds were established to be actually due to the presence of trace impurities within the compounds. In other cases of organic compounds, some believed to be by their nature self-oxidizing in air actually were stable after zone refining. Many other such examples (9) showing major changes in the properties of zone refined materials could be referred to.

Zone-melting techniques have actually had broader applications than simply for the purification of material. This technique has also been adopted to the so-called zone-leveling process, a method that makes it possible for us to distribute uniformly throughout the volume any trace impurities left.

Of much importance to the semiconductor industry were also the ideas of Dash (10-12) which led to the growth of essentially dislocation-free crystals. These ideas have been widely adapted to industrial crystal growing techniques and by integrated circuit materials manufacturers. By virtue of the considerable competitive importance of growing dislocation-free crystals to those in device manufacture, not all facts here have reached the literature. While single crystal growing techniques proceeded by many years the period which we are looking at, one must state that the most important advances with far-reaching commercial implications were made in this period.

When in 1955 the Bell System licensed electronic companies to manufacture the most elementary of the solid-state devices, the point contact transistor, the licensing agreement brought blueprints and instructions for a germanium single crystal growing installation. I became familiar with the Sprague system built under this license in 1955 and 1956. This company was growing 2-2.5 cm diam crystals using induction heating for the melting of the germanium in a carbon vessel. Both the growing crystal and the melt were contained under inert atmosphere. We were aware of dislocations and were suspicious that they could lead to problems in the simple devices which Sprague, like most other companies in the field, manufactured at that time. Yet in 1956 and 1957 we were a long way from a thorough understanding of the role of imperfections in electronic devices. Today silicon rather than germanium dominates the semiconductor industry and the bulk of commercial or captive silicon crystal growers produce 7.5 cm diam silicon crystals. Some can grow up to 10 cm and for that matter larger diameter crystals, but with the larger diameters a host of problems are encountered including those brought by the economics of this time. The crystals produced often reached 10 kg in weight and up to 1m in length; not only can we grow crystals of such size, but as indicated we can grow crystals with controlled dislocation distributions, grow these crystals virtually dislocation-free, and grow them with almost no impurities. The highest documented purity ever reached in any material (2×10^{10} defects/cm^3) was reported in 1974 by Hall of GE for germanium (13). We not only grow elemental single crystals from the melt today, but also crystals of compounds of elements with important divergence in their vapor pressures, and of controlled stoichiometry, problems also resolved in this period. Today we have readily available commercial crystal growers capable of growing crystals from notably low pressure ambients up to inert atmosphere environments with pressures reaching 150 atm (see Fig. 1 and 2). Units of this type, of units powered by diverse heat sources, produce single crystals of virtually any elemental or compound material and at almost any purity level.

We should add that these 25 years also saw the development of a single crystal growing industry, an industry producing a tremendous variety of materials in single crystal form. Crystals are made for: solid-state devices including IC's, transducers, fundamental studies of any type, and optical elements with properties tailored for a wide diversity of applications. We also produce organic crystals with large interatomic spacings for focusing and deflection of x-rays and, last but not least, crystals for decorative and jewelry uses. All these crystals are not grown from the melt, though the largest part probably are. The single crystal industry of the 1970's utilizes diverse techniques which, among others, grow crystals from the melt by vapor condensation (expitaxial layers), in the solid state, by the hydrothermic, and by the Verneuil processes. Because of its diversity and nonrelated final application of its products, it is difficult to place a dollar value on the total product of this industry, but it is quite considerable.

New Heat Sources and New Processes

Another major development which has had profound effect upon materials-processing technology has been the discovery and perfection of new heat sources to be used either in conjunction with the now more readily available vacuum environment or without it. These heat sources have led to the development of numerous new processes and these in turn have become an integral part of our industrial scene.

In the pages to follow I would like to look at two of these heat sources and the innovative processes and systems which they brought into our technology. I will illustrate my discussion with an occasional example of

Fig. 1. Single crystal silicon growing furnace, 75 mm diam capacity. Courtesy: Ham Company.

Fig. 2. "Melbourne" gallium phosphide single crystal growing system capable of maximum working pressure of 150 atm. Courtesy: Dr. J. Barret, Cambridge-Iman Company.

systems which embody these processes coming out of the manufacturers' lines today.

The electron beam, which is a collimated beam of highly accelerated electrons, has unusual characteristics which have made it a powerful tool for a diverse range of applications. These beams, which in principle had been proposed for some of these applications long before the period which we are considering, are best suited to vacuum operations. The now readily available vacuum made possible the development of a whole new technology, "The Electron Beam Technology." This is a technology with far-reaching consequences which encompasses a broad spectrum of applications. Our Division has closely monitored progress here since 1964 (14), and will again be taking pulse of the situation in May 1978 in Seattle. I would like to refer to the more important achievements in the areas where electron beams have made major contributions and give some reasons for the level of developments here.

Though in principle the first application of electron beams for metal melting and purification was proposed in 1907 (15), electron beams did not really begin to make a real contribution here until 1957 when their successful application to metal purification was realized by the then newly established Temescal Metallurgical Corporation. This was a company devoted to exploitation of electron beams as heat sources for metal processing. Shortly after this modest beginning the writer had a 2 cm Ta ingot processed by an early Temescal electron beam furnace in 1958 for subsequent rolling to capacitor foil. Electron beams in melting, refining, and welding have since moved far (16-19). Their success in the first two fields is a consequence of their ability to efficiently melt any metal including tungsten without contamination in a cold-walled ingot mold which permits evaporative removal of virtually all impurities as already mentioned. Electron beams today are responsible for most of the tonnage of reactive and refractory metals and alloys reaching the field. Typical analyses from various sources for several electron beam processed materials are given in Table I (20-24). This today is a mature process which truly developed in the period in review, but a process which, by virtue of costs and other competitive processes, has not made inroads in the processing of ferrous metals which still remains the largest tonnage in the metallurgical field. Nevertheless, it has captured virtually all the reactive and refractory metal and alloy-processing business, as well as a very small tonnage fraction in the production of specialty steels for corrosion resistance, tool, die, and bearing applications. Some of the steel work has been carried out in hybrid vacuum induction/electron beam installations.

A diversity of gun types and configurations exist, and installations which initially were capable of only melting a few pounds have developed into systems capable of melting ingots of several tons. Specifically for a long time the simple Temescal-developed transverse guns competed with the von Ardenne-developed, LEW-built, axially deflected, differentially pumped, sophisticated electron optical system. The relatively inexpensive Temescal type guns made important contributions to the state of the art because of their cost-effective performance at low power levels. To this writer it appears that they also had restraining effects on the over-all U.S. industrial development at the upper power levels because of inherent instability of systems based on these guns at high power levels. For reliable and stable performance at the high ambient pressures typical of electron beam melting installations the differentially pumped guns certainly have excelled in the past and continue to do so. In fact they have displaced the unsophisticated electron guns from melting installations where such conditions prevail. I believe that the hybrid 6 MW Airco/Temescal steel-refining installation for production of E-Brite stainless steel in Berkeley, which is now out of commission, could probably have continued to produce today. It would have produced in a much more trouble-free fashion and more efficiently had its multitude (over 20) of transverse electron guns which powered its cold-wall refining trough, been powered by programmed, axial deflection, differentially pumped guns. To appreciate what has happened here one need only look at a 1200 kW installation available as a standard product today, see Fig. 3.

With the energy pinch and the EPA's continued tightening of environmental standards, the writer sees a new potential for the highly efficient and extremely clean electron beam melting and refining installations. As a matter of fact, plans for electron beam furnaces capable of producing 30 and 150 ton ingots are in the making (25).

Electron beams were responsible indirectly for a major advance in our understanding of refractory metals by making it possible to grow refractory metal single crystals as already mentioned. While used on a routine basis today virtually without notice, these systems and the work done with them were in the headlines of many a meeting where metallurgists and solid-state physicists gathered in the mid-sixties.

The evaporation area is another area where electron beams played and continue to play a most important role. Today their applications span the gamut from thin film components and related production activities through major installations for coating for corrosion protection; from items as down to earth as aluminum-coated steel strip used in the manufacture of sardine cans (see Fig. 4) to as sophisticated an application as coated components for gas turbines and jet engines. A number of installations using electron beam evaporation for R-C circuit manufacture have been produced. These systems actually utilize electron beams both for

evaporation of the resistance film and thermal machining, an alternate electron beam application, for trimming of these circuits.

Thermal electron beam machining then is another area where electron beams have made major contributions. It has, however, had a relatively slow growth. Since its original entry in 1959 as a commercial electron beam machine, these have been used for drilling of jeweled bearings, drilling of breathable jet engine blades, for drilling of plastics, and even for cutting of green ceramics. The electron beam thermal machining system of today is a major piece of capital equipment with costs approaching $300,000 and we can perhaps count a world population of only 20 units, if indeed that many. An example of such a machine produced by Steigerwald Strahltechnik can be seen in Fig. 5.

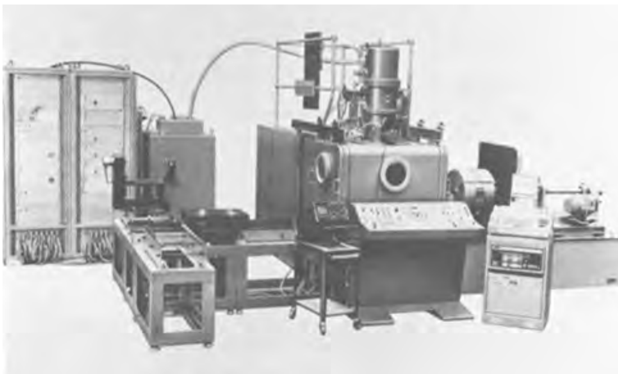

Fig. 5. Micro machining installation. Courtesy: Mr. Jack Drew, Steigerwald Strahltechnic-Farrel Corporation.

Perhaps the most consequential contribution of thermal electron beams to today's technology and affecting the widest possible number of people has been their application in welding. The electron beam (EB) welding process was invented independently in 1957 and almost simultaneously by Stohr (26) at the Saclay laboratories of the French Atomic Energy Commission, and by France and Wayman (27) at the General Electric Company, Hanford, Washington. Both inventions arose from efforts fostered by the needs of the atomic power field in the mid-fifties. The ensuing years have seen tremendous growth in acceptance of EB welding, substantial broadening of its capabilities, and the development of most sophisticated systems. Today the simple work-accelerated electron beam welders of Stohr and Wayman's time have been replaced by work-accelerated welding systems which operate, depending on the ultimate application, in three ranges of pressure, *i.e.*, 1 atm., 10^{-2} and 10^{-4} Torr, and below. These are the so called IAEBW, the commercial or soft-vacuum process and the hard-vacuum process. The simple manual control systems of yesterday have been replaced by sophisticated NC, fully programable installations capable of high production rates and outstanding quality of welding operations. The early producers and sucessors of the important pioneering entries in electron beam equipment are very much still part of the manufacturing scene today. Sciaky, Leybold-Heraeus (as successor of Zeiss) and Hamilton Standard and Steigerwald Strahltechnik very much dominate the scene with large welding systems, while the Torvac-EBTEC alliance has taken the lead in the small systems field. Despite the high initial capital cost of electron beam welding equipment, there is no segment of the metal processing industries where the process has not made major inroads by virtue of its performance capability, speed of welding, and cost effectiveness—this despite the high initial capital investment. Examples illustrating the status today are seen in Fig. 6, 7, and 8.

Perhaps the most exciting and sophisticated electron beam application which emerged in the period is that which uses the electron beam as an ionizing radiation source rather than as a heat source. Reference is made to the technique called electron beam lithography, which has all but revolutionized production of IC's. The "crown jewels" of this revolution are systems of the type developed by IBM (28), Bell Laboratories (29), and the commercial version of the EBES produced by its two licensees, Extrion and ETEC, to name a few (see Fig. 9, 10, and 11). These systems are capable either of manufacturing masks for IC production, or of actually producing individual IC's on silicon chips. The integrated circuit which has changed the face of the free world's electronic industry continues to shrink in size, improve in reliability and decrease in cost. The electron beam systems referred to above have made readily possible the generation of 1-2 μm device structural details. I believe that machines with the

capability to produce 0.1 μm details are not really that far in the future and are certainly present in research hardware at hand in the laboratories of the leaders of

Fig. 9. Vector scan—electron beam lithography system. Courtesy: Dr. P. Chang, IBM Corporation, Yorktown Heights.

the industry. When one talks of an electron beam microfabrication system, a 2 million dollar price tag is well in the range of reality. In closing my discussion on electron beam technology I wish to remind readers of the continued publication of our Society's proceedings (14) in this field and those of conferences jointly sponsored by the American Vacuum Society and the IEEE (30).

Perhaps one of the most exciting inventions to be made in the last 25 years is that of the laser. It was actually independently proposed by a number of investigators (31-37). Last October (1977) the U.S. Patent and Trademark Office, however, granted a patent to R. Gordon Gould dealing with the fundamental technology of lasers. This patent is being issued 18 years after Gould's invention. If it survives in a likely court challenge, it will confirm Gould as one of the laser's primary inventors—a distinction long denied to him by the fame of others. Today the developments emanating from laser work have had far-reaching repercussions in the world of science and technology. The laser by now is a firmly established measuring tool, and it has contributed much to spectroscopy as it has to holography. Strides with the laser in the communications field have been made but their full potential in this field has yet to be developed.

The laser is also an important heat source with distinctive characteristics, and it is its application as a materials processing tool that is of particular interest to us. The finely collimated laser beam is capable of producing effects similar to those of the electron gun even though by a much different mechanism. The greatest plus of the laser in comparison to the electron beam is the fact that it does not need vacuum for its operation. Thus, despite the fact that the laser is at best only about 10% efficient when contrasted with the better than 95% conversion efficiency of the electron beam, it does offer unique capabilities, and it is a most powerful material-processing tool. The primary applications here have been in welding, machining, and, more recently, heat-treating. Let us look at welding first because we have had the largest growth here. From initial work with pulsed ruby and neodymium glass lasers with output of 100-200W, we have moved today to the readily available multikilowatt lasers with the upper power limit of commercially available lasers for welding being 25 kW. Virtually all of these high power lasers in welding are operating in the continuous duty mode, and in most cases they are CO_2 lasers (38). From simple manually controlled lasers, we have gone to NC installations for reliably high rate part processing. This growth of power capability has seen the relatively limited upper thickness capability of 0.005-0.010 in. bypassed with today's lasers welding materials exceeding 1.00 in. in thickness. Many of the laser welding installations of today use inert gas assist for joining of some materials. The laser in a welding system is but the power source and much effort has been invested in the system design and system control to develop the capabilities of the systems which we have on the market today (see Fig. 12). Often welding system designers acquire the laser from a laser man-

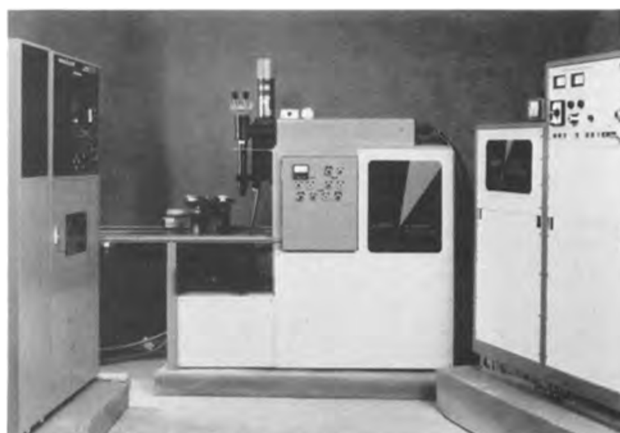

Fig. 12. NC-controlled laser welding system. Courtesy: Mr. L. Derose, EBTEC Corporation.

ufacturer, but they are the sellers of the integrated system. The acceptance of the laser as a welding tool also has led to expanded use in many industries including aerospace, electronics, and automotive.

The capability of the laser to ablate materials has led to its adoption as a machining tool. Today we have extensive laser machining applications including: extensive thin film applications in resistor trimming, jewel-bearing drilling, cutting of quartz tubing, cutting of metallic materials including titanium and super-alloys (these are often performed with an oxygen assist), cutting of materials for the packaging and the garment industries, and many more.

A third quite interesting and recently developed materials-processing application for lasers has been the area of heat-treating of materials, specifically highly localized heat-treating. It takes advantage of phase-transformation responsiveness of some alloys to the rapid heat cycles which lasers can produce. Essentially we are talking of the performance of a task equivalent to the case-hardening produced by more conventional approaches. In this case the laser technique permits local or selected-area heat-treating. One can also carry out surface alloying by depositing materials on the surface of parts to be alloyed and then performing laser-assisted local-diffusion treatments.

The laser as a heat source has also made important inroads in surgery and specially opthalmic surgery and of course the laser is intimately tied to fusion research and will most likely trigger most, if not all, fusion reactions of the future. Last but not least, the laser has tremendous potential for destruction, these applications of course being in the province of the military. There has been a virtual torrent of publications in the laser field and numerous references on all possible aspects of lasers can be found. A few of general utility are suggested here (39-41).

Our Division has usually stayed away from covering steel-processing activities of any sort, but as these are related to much already referenced in the paper, a brief reference to this area of materials processing is made here. Production difficulties with the manufacture of large forgings in the mid-fifties and the realization that high gas content was one of the main causes for these problems acted as catalysts for much of the developments that affected specialty steel processing. The introduction of the now more readily obtainable vacuum for the processing of these steels was one of the first developments which led to a variety of processes. Many of them have been well publicized while specific details of others have remained in the realm of "company confidential." While new installations based on these developments have been built in the U.S., it is believed that much larger investments in this area have been made by overseas manufacturers including those in Japan, France, and Germany. The Electrochemical Society's interest in this area is evidenced by the 1975 symposium (42) on metal-slag-gas reactions.

In addition to various degassing schemes for the specialty steels, the vacuum-arc process and the vacuum-induction process which combine both the melting and degassing operation have made important strides. Today installations exceeding 100 tons capacity have become available as standard industrial products. Another high quality steel-processing technique, the so-called electroslag remelting, became so identified in the mid-fifties by the Soviets (43). While the writer has not investigated the origins of the process, there is considerable evidence that processes of refining steel under a slag blanket with an electric arc as the power source were practiced in the U.S. under different names since the forties, this of course being the essence of the electroslag processing as defined today. It is quite conclusively demonstrated, however, that with the introduction of the term "electroslag melting" by the Soviets in the mid-fifties, a new phase in the development of this steel-refining process was initiated.

In 1963 the writer visited the Paton Institute for Electrowelding in Kiev and inspected what was considered one of the early electroslag remelting installations in the Soviet Union. Today we have reached and exceeded 100 tons size capacity electroslag (ESR) installations. These are presently manufactured by a number of companies both in the U.S. and abroad. A 165 ton furnace produced by Leybold-Heraeus is illustrated in Fig. 13. Electroslag remelting has seen an acceptance and steady growth by virtue of its ability to produce a high quality, cost-effective product with competitive properties meeting a diversity of ultimate applications. The electroslag process appears to have surpassed the growth rates of vacuum arc and vacuum induction for the specialty steel processing in the Soviet Union and has also achieved major industrial significance in the U.S. where two comprehensive reviews of the process have just appeared in print (44, 44a).

In 1960, among other activities, the writer became involved in what at the time was referred to as vapor phase metallurgy, the technique of producing metallic materials through the decomposition of inorganic or organometallic compounds. This technique was used then as now either to prepare very pure metals, metal coatings, or diverse free-standing metal shapes (45-48). The subject, which has since been renamed chemical vapor deposition or CVD, has been another important area of activities of the Electrothermics and Metallurgy Division with a number of meetings held under its auspices since 1955 (49-54). Its application to the electronics field was reviewed in some detail a few years ago by Tietjen (55).

Although the electric arc has been used industrially since the turn of the century, and for welding since about the time of World War I, only in the 1960's was this energy source used extensively for deposition of metallic and refractory compound coatings. In the plasma-arc spray process, powdered material is fed, together with a gas, through an electric arc where it is heated sufficiently to cause melting and then to be deposited on a cool substrate. Electrons from the arc cause substantial ionization of the gas atoms, and the resultant state is referred to as a plasma, although 100% ionization does not occur. Such plasma-arc sprayed coatings have been applied as thermal barriers, solid lubricants, corrosion- or abrasion-resistant surfaces, ablative layers, or for spray forming; but few of these are yet important commercially. Plasma spraying competes with both oxygas flame spraying and detona-

Fig. 13. 165 ton electro slag remelting installation. Courtesy: Dr. W. Dietrich, Leybold-Heraeus, and Stahlwerke, Rochling Burbach, GmbH.

tion coating, not usually on an economic basis but wherever the quality of the deposit, the diverse range of materials that can be sprayed, the feasibility of large scale application, and the suitability of plasma arc spraying to both metallic and nonmetallic substrates give it unique advantage over the other processes. Fisher (56) has provided a recent review.

The combination of vacuum and heat sources has led to the development of another important area of concern to our Division which can be referred to as thin film technology. This technology plays a key role in diverse segments of industry today, but has developed to its greatest level of sophistication in the electronics industry. In the last 25 years and most importantly in the last 15 years, we have seen this industry adopt evaporation approaches for material deposition in large scale manufacturing operations, and of recent date diverse sputtering approaches are gaining ground here relative to the former type. Table II (57) shows a comparison between electron beam evaporation and high rate sputtering (15 kW sources) for thin film deposition. Table III (57) shows the types of variation that are encountered in these processes and the reasons for those variations. Thornton (58) discusses the application of the sputtering process to thick film growth.

When small amounts of material are to be evaporated one can either use direct wire evaporation or foil evaporant containers. Special ceramics or ceramic-coated vessels become containers as the scale of applications grows. Of greatest importance for assuring deposit purity and prevention of contamination of the melt is the nature of the liquid metal container. Depending on the material to be evaporated and final use of the film, we can find as the container: refractory metals, oxides, boron, nitrides, and carbon. These are selected in order to assure no or minimum reaction of the evaporant with the container. The container can be either water cooled or heated, the latter used when higher rates are needed. Resistance heating and electron beams of diverse configuration have become the backbone of evaporation processes with each specific material and ultimate application determining the selection of the heat source.

Perhaps one of the earliest large scale commercial evaporative applications was the metallization of paper with zinc, and then mylar with aluminum for the manufacture of film capacitors. In the electronics industry the next thrust was brought about by requirements in manufacture of passive microcomponents, specifically resistors and capacitors. A steady growth in the application of thin films in the areas of active components has occurred in the last five years with both magnetic and semiconductor devices participating. The electronics applications are but one of the areas within what is referred to as thin film technology (59). We must also mention here the widest variety of thin films for the coating of optical lenses for diverse applications and including all types of optical filters. From here we can go to thin films in glass panels in simple or thermopane configuration for both decorative and functional uses. Last but not least, we come upon thin films for corrosion protection in specialized situations. When corrosion and oxidation resistance are the main reason for application of these coatings, much thicker coatings are often used (micrometers rather than angstoms).

Table II. Comparison of parameters for electron beam evaporation and high rate sputtering

Parameters	Electron beam evaporation	High rate sputtering
Deposition materials	Very restricted	Somewhat restricted
Condensation rate	Equal magnitude	
Evaporation rate/ sputter rate	$a_v = 1$ $a_v{}^* = 5\text{-}10a_v$	$a_s = 0.2\text{-}0.5a_v$
Particle source characteristic	Small area source	Large area linear source
Energy utilization	Less favorable with hr-sputtering	
Material utilization	Equal magnitude	
Uninterrupted operating time	Comparable in case of eb-evaporator with feed and hr-sputtering source	
Mean particle energy on substrate	0.1-0.2 eV	0.2-10 eV
Thermal load on substrate	0.1 Wcm^{-2}	0.2-1 Wcm^{-2}
Irradiation of substrate by	X-rays, (electrons)	Photons, low energy electrons, ions (low)
Residual gas effects	Higher in case of sputtering	
Impurity sources	Crucible reactions*	Sputtering of source components
Adaptability to substrate fixture	Favorable with hr-sputtering	
Extending feasibilities of basic processes	Generally by additional equipment	Generally by parameter selection
Instrumental expenditure source and power supply process control extended process variants	Referred to equal power: low in case of hr-sputtering	

* Hot crucible evaporation.

Table III. (57) Process variations of evaporating and sputtering techniques

Processing variants	Goal	Basic process: Evaporation	Basic process: Sputtering
High vacuum deposition	Avoidance of residual gas interactions	Internal HV or UHV evaporation	With ring-gap sources mean-free path $>h$ (the distance between source and substrate) working pressure $p = 5 \times 10^{-2}$ Pa or 1×10^{-4} Torr
Gas-scattering deposition	Particle scattering step coverage	Pressure plating (PP) (inert gas inlet)	Internal sputtering in inert gas
Reactive decomposition		Reactive evaporation (RE) (reactive gas inlet)	Internal
Electron-activated or plasma-activated reactive deposition	Chemical reaction	Activated reactive evaporation (ARE) (reactive gas inlet and electron or plasma generation)	Reactive sputtering in reactive gas
Ion-aided deposition, intermediate	Activated condensation	Ion plating (IP) (gas inlet and ion generation)	Internal bias sputtering
		Plasma plating Plasma pretreatment and EB-evaporation	

I wish to close my discussion on sources and processes by referring briefly to ion implantation. For a long time high temperature diffusion treatments were the only means available to the manufacturers for composition modification of semiconductor materials in device production. These diffusion treatments which by their very nature necessitate high temperature led to substantial control difficulties, high costs, and often low yields. This was a situation ripe for a take-over by a superior technique. But not only were the difficulties of the existing techniques favorable to the advent of a new technique, the requirements evolving from the very direction of development of solid-state devices and integrated circuitry, *i.e.*, much tighter specifications, higher frequencies, and in general ever increasing demands from this circuitry could be better served with the new technique of ion implantation.

Ion implantation then had a ready stage for its development and growth. Yet initial costs and limits on early implantation equipment capabilities (in particular the slow rates of material processing) led to slower than expected progress in adopting this technique. Nevertheless ion implantation is here to stay and is slowly but irreversibly replacing the gaseous diffusion process as a manufacturing tool for both individual and integrated solid-state devices.

I believe that ion implantation will eventually lead to complete displacement of gaseous diffusion for a number of reasons. If we consider composition uniformity we are capable of reducing variation from $\pm$ 15% to better than $\pm$ 1%. Ion implantation permits a much better lateral spread for most practical purposes and there is virtually no contamination from it. We have by far superior delineation techniques and, of course as we already mentioned, it is a clean vacuum operation against an operation in an alien high temperature environment. We can also implant a considerable variety of impurities with relative ease. Today cost of an ion implantation system depending on type is up to 2-3 times higher than a comparable diffusion system. While this cost differential is still important today, its importance will decrease in the future as the requirements of IC's and devices become such that diffusion techniques would no longer be capable of meeting them. A commercial ion implantation system, vintage 1977, is seen in Fig. 14. Progress in ion implantation has been recorded in both monographs (60-62), conference proceedings (63-66), and review articles (67).

Summary

The writer has attempted to convey an impression of what has happened in the last 25 years in the areas delineated within the mission of the Electrothermics and Metallurgy Division of the Society. He also brought into the discussion items related to these, even though they have not been considered in the customary proceedings of the Division. It was felt that bringing these into the discussion will help round up the impression of the happenings here. Under no circumstances should this be considered as a thorough reveiw of the subject. The author also wishes to express sincere thanks to the companies which provided the illustrations.

Progress in Electroanalytical Chemistry 1952-1977

H. A. Laitinen*

Department of Chemistry, University of Florida, Gainesville, Florida 32611

Even though electroanalytical chemistry was not covered in the series of technical reviews published in 1952, the present article will cover events only during the past 25 years. The early history was covered in 1971 by Kolthoff (1). The subject has gradually broadened from analytical measurements and titrations based upon electrode potential, conductance, and coulombic charge to include a diversity of measurements based upon interaction between charge transfer, mass transport, and heterogeneous and homogeneous chemical processes preceding or following charge transfer. A classification and systematic nomenclature of electroanalytical methods was suggested by Delahay, Laitinen, and Charlot (2). Three main categories are recognized: those for which electrode reactions, if any, need not be considered; methods involving only double layer phenomena at zero faradaic current; and methods involving faradaic electrode reactions. These three categories will be considered in turn.

Methods for Which Electrode Reactions, If Any, Need Not Be Considered

Conductance measurements and conductometric titrations have seen relatively few analytical applications during the past 25 years. Early in this period, there was a flurry of activity in the area of high frequency titrimetry, in which a combination of dielectric constant changes and conductance changes gives rise to changes in electrical characteristics of a high frequency oscillator. These methods have not found wide application, evidently because simpler alternative methods are usually available. Direct monitoring of dielectric constant changes to detect traces of polar materials in nonpolar solvents does find occasional application.

Methods Involving Double Layer Phenomena at Zero Faradaic Current

Under carefully controlled conditions, the differential capacity of the double layer can be related to surface excess. Limited examples of analytical application to adsorption, especially at mercury electrodes, are available. Similarly, interfacial tension, a closely related quantity, can in principle be used for analysis, although only in limited cases because of the lack of specificity.

The term "tensammetry" was introduced by Breyer and Hacobian to the measurements of pseudocapacitance corresponding to the adsorption and desorption of organic substances at a dropping mercury electrode without the passage of faradaic current. Such measurements are often useful as a diagnostic test in the study of electrode processes but have found limited use in analysis.

* Electrochemical Society Active Member.

Methods Involving Faradaic Electrode Reactions

Potentiometry at zero current.—By the beginning of our review period, 1952, classical potentiometry had long since reached a state of maturity. The glass electrode had largely replaced other *p*H electrodes, and had been widely used in nonaqueous as well as aqueous solutions for acid-base titrations.

The most important advances during the past 25 years have been in the area of ion-selective electrodes, which have been reviewed by Buck (3). These fall into several classes (4).

Glass electrodes.—They have been developed with varying degrees of selectivity for various univalent cations: H^+, Na^+, K^+, NH_4^+. In particular, glasses responding to Na^+ in preference to K^+, and to a lesser degree, the reverse, are available (5).

Solid-state electrodes.—Although the principles of using silver halide membranes for halide ion activity measurements had been demonstrated as early as 1937 (6), the modern era was stimulated by the work of Pungor and associates in the 1960's (7). Their electrodes consisted of particles of an insoluble solid imbedded in an inert matrix such as silicone rubber. More recent versions have emphasized silver sulfide without a binder as an ionically conductive membrane responsive to silver ion and sulfide ion. Composite membranes incorporating other heavy metal sulfides (*e.g.*, CdS, PbS, CuS) into a silver sulfide membrane have been found responsive to the corresponding heavy metal ions. Other composite structures involve silver halides with silver sulfide and selenite. Still another form that has seen limited application consists of an insoluble film directly on a metal surface.

The outstandingly successful solid-state electrode is the doped LaF_3 single crystal fluoride ion electrode described by Frant and Ross (8). This electrode responds specifically to fluoride ion activity over a wide range, and has found many thermodynamic as well as analytical applications.

Liquid membrane electrodes.—A family of electrodes consisting of a liquid organic membrane has emerged in several forms. The liquid itself may be selective to a given species of cation or anion through reaction and extraction, or it may serve as a solvent for a selective reagent. The liquid may be contained in a suitable structure to contact two solutions, or it may be placed in direct contact with an electronic conductor such as a metal or graphite. A commercial form uses graphite impregnated with polytetrafluoroethylene.

By selecting appropriate combinations of selective reagent and solvent, a large variety of membranes responsive to cations, anions, and neutral species is possible. Electrodes of this type are actively being studied, and new varieties continue to be reported.

Gas-sensing electrodes.—Glass electrodes have long been used as indirect sensors of CO_2 and NH_3 through their *p*H-dependent equilibria in water. More recently, such electrodes have been rendered truly responsive to gas tension through the interposition of hydrophobic membranes permeable to the gas. In addition, this arrangement permits measurements in complex systems such as biological fluids by preventing access of macromolecular and colloidal species to the surface. An important gas-sensing electrode operating on an entirely different principle (amperometric) is discussed below.

Enzyme electrodes.—Incorporation of an enzyme onto a membrane coupled with a suitable ion-selective or gas-sensing membrane permits the monitoring of a substrate through its generation or consumption of a detectable species such as H^+, CO_2, or NH_3. Conversely, enzyme concentrations in solution can be monitored by using a fixed concentration of substrate. An extension of the use of specific biochemical interactions is represented by the use of a silver sulfide sensor for sensing proteins, and indirectly for monitoring antibody-antigen reactions (9).

Methods based on transitory electrode phenomena.—*Polarography.*—By 1952, the beginning of our review period, classical polarography was well established as an analytical method for many inorganic, organic, and biochemical species. Several current-limiting processes were recognized (diffusion, migration, convection, charge transfer, reaction kinetics, adsorption) at the dropping mercury electrode, and some, such as diffusion or purely kinetically limited currents, could be treated in an adequate way theoretically. It remained for Koutecky (10) to derive the mathematical solution of the interaction between diffusion and reaction kinetics for the case of the dropping mercury electrode. This treatment permitted a quantitative interpretation of irreversible polarographic waves, in which charge-transfer rate controls the current at the foot of the wave and diffusion at the plateau. It also permitted a calculation of rate constants of homogeneous reactions coupled with charge transfer reactions under partial diffusion control. The 1954 book by Delahay (11) was a milestone in acquainting electroanalytical chemists generally with this treatment as well as several other techniques to be discussed below.

During the 1950's, the instrumentation group at Oak Ridge National Laboratory, headed by D. J. Fisher and M. T. Kelley, made several refinements in polarographic instrumentation. These included a precision drop timer, a three-electrode measurement system, a means of measuring instantaneous currents, and circuits for registering first and second derivatives of current-voltage curves as a function of potential (12).

Various modifications of classical polarography have appeared over the years. In "Tast" polarography, the instantaneous current is measured relatively late in drop life to minimize the nonfaradaic charging current, which decreases during drop growth, and to maximize diffusion or kinetic-controlled currents, which increase during drop life.

Superimposing periodic potential changes on a gradually increasing applied potential leads to several types of modified polarography. The simplest form, in which a small sinusoidal voltage signal is applied and the rectified a-c component is recorded, has been exploited especially by Breyer and his co-workers (13). Later modifications include the measurement of current at second and higher harmonics of the applied frequency to minimize charging currents, and the use of phase-sensitive amplifiers for the same purpose. A typical modern minicomputer controlled circuit has been described by Glover and Smith (14). The square wave polarograph of Barker (15) has largely been supplanted by the pulse polarograph (16) in which a single voltage pulse is applied at some instant in drop life, and the current measurement is made relatively late during the pulse to allow charging current transients to decay. The original Barker circuit (16) was greatly simplified by Parry and Osteryoung (17). A commercial instrument introduced by Princeton Applied Research Corporation, operating both in the direct and derivative modes, has done much to popularize the applications of pulse polarography. An automated version operated by means of a microprocessor is also available.

Little analytical application has been made of several types of polarographic methods involving a-c techniques, such as faradaic rectification (low and high levels, depending upon the magnitude of the a-c signal), radio-frequency polarography, intermodulation polarography, and polarography with complex plane analysis of cell impedances. These techniques have primarily found use in the study of electrode reaction mechanisms. A summary is available in several reviews (18-20).

Chronopotentiometry.—The concept of transition time, marking the instant of attaining zero surface concentration under diffusion-controlled constant current electrolysis, dates back to Sand in 1901. Some

mechanistic studies had been made with the technique in the 1930's and 1940's. However, the modern era dates back only to 1953, when Gierst and Juliard (21) applied the technique to a dropping mercury electrode under conditions such that the current pulse was applied relatively late in drop life, and of sufficient magnitude to yield transition times of 1-100 msec. In that same year, Berzins and Delahay (22) presented the theory of the method as applied to several types of electrode processes. The present name was suggested by Delahay and Mamantov (23) and in an adjoining paper Reilley and co-workers (24) described several experimental studies. The method received a flurry of attention during the late 1950's and early 1960's. Reinmuth (25) listed criteria for various kinetic schemes, based upon measurement of potential-time transients and transition times. The popularity of the method, both for theoretical and practical studies, has waned more recently because of some inherent problems. Of these, two merit special mention. First, there is the problem of adequate correction for charging current, which limits the accuracy of transition time measurements. Second, the influence of adsorbed reactants, which becomes relatively more important at short transition times, is dependent upon the sequence of events, *i.e.*, whether the adsorbed reactant is reduced first, last, or continuously during the electrolysis. For certain applications, *e.g.*, the estimation of diffusion coefficients in molten salts, and the use of current reversal technique to distinguish between soluble or insoluble reaction products, chronopotentiometry still merits consideration because of its inherent simplicity.

Linear sweep voltammetry (single scan and cyclic).—The technique of applying a single linear voltage sweep to a dropping mercury electrode relatively late in the formation period of the drop and observing the current-time trace with a cathode ray tube was introduced in 1947 by Randles (26). A related technique, consisting of a triangular voltage-time signal applied continuously during the formation of mercury drops, was independently introduced by Sevcik (27). Both authors gave theoretical interpretations of the current-time relationship for reversible processes. The book of Delahay (11), describing both reversible and totally irreversible processes, greatly stimulated research into this technique. One of the earlier applications to trace analysis was the technique of anodic stripping using a stationary hanging mercury drop for the deposition of one or more metals at a constant cathodic potential, followed by a linear scan anodic stripping cycle. In recent years this technique has been applied in the form of thin-film mercury coatings, usually on graphite, with a greatly increased sensitivity due to the use of electrodes of larger area (30). By using exceedingly thin films, the diffusion rate of amalgamated metals can be increased to the point that quantitative anodic dissolution occurs, and the method can also be applied in a coulometric mode by measuring peak area rather than height. Commercial apparatus permitting anodic stripping to be operated in the derivative as well as direct mode has stimulated applications of the technique to trace analysis.

A landmark paper was that of Nicholson and Shain (31), who presented a comprehensive theory of linear scan voltammetry, both single scan and cyclic, as applied to reversible and irreversible charge transfer, including those coupled with preceding or following chemical reactions. This paper greatly stimulated applications of the technique, which has become accepted by organic and physical chemists as a diagnostic tool, as well as an analytical method.

Christie and Osteryoung (32) presented a theory of staircase voltammetry to replace linear sweep voltammetry for stripping analysis using the thin film mercury electrode. They concluded that the decrease in faradaic sensitivity is more than compensated by the decrease in charging current. The theoretical expectation was verified by Osteryoung and co-workers (33), who concluded that the method is similar in sensitivity to that of differential pulse stripping, but is much faster. Both techniques were applied to trace metal determinations in the 0.1-10 μg/l concentration range.

Thin-layer electrochemistry.—Anson (34), in studying the chronopotentiometry of iron (III) at platinum electrodes, found that the redox behavior persisted even after electrodes that had been soaked in acidic iron (III) solutions were rinsed and immersed in acid solutions containing no iron (III). He at first believed he was observing the behavior of adsorbed iron (III), but later concluded that the redox behavior was due to a thin film of solution trapped in a faulty seal of the platinum into glass.

Later work by Christensen and Anson (35) using uniform thin films of solution established the technique as a form of constant current coulometry on a time scale of the order of a few seconds. Hubbard and Anson (36) devised improved electrodes and Reilley and co-workers (37) carried out electrochemical studies using controlled potential as well as controlled current. By measuring transition times at sufficiently high current densities, diffusion coefficients can be estimated without a knowledge of the solution concentration or electrode area if the thickness of the solution layer is first evaluated. The status of this subject was reviewed by Hubbard (38) in 1973. A more recent development is the optically transparent thin-layer cell of Heineman and co-workers (39) which was used to measure formal potentials of enzyme systems by controlling the ratio of oxidized to reduced forms by applying a potential and monitoring the corresponding concentration ratio optically.

Chronocoulometry.—The technique of chronocoulometry involves the determination of coulombic charge, Q, as a function of time under specified conditions of potential change. The first version as described by Osteryoung, Lauer, and Anson (40) involved application of a linear voltage scan. Because the shape of the current time transient depends upon charge transfer rate except for reversible systems under pure diffusion control, the applicability of this method proved to be quite limited. By using a potential step of relatively large magnitude, Christie *et al.* (41) showed that even for irreversible systems the intercept of a plot of Q *vs.* $t^{1/2}$ (which is linear for diffusion-controlled processes) allowed the detection of surface films or adsorbed layers. Still another refinement by Anson (42) was the introduction of a double potential step method, in which the potential was returned to its initial state after a definite time τ. In this way, any effect of double layer charging could be eliminated because the initial and final states of the double layer should be the same. The method permits an evaluation of adsorbed reactant by extrapolation to eliminate the diffusion controlled reduction and reoxidation of reactant. It is, however, limited to reversible charge-transfer processes.

Semiintegral and semidifferential electroanalysis.—In 1972, Oldham (43) introduced a technique called semiintegral electroanalysis which has the property of being independent of the form of the applied voltage-time signal, provided that the electrode, during an excursion of potential in a time interval τ, proceeds from a condition of no reaction to a condition of complete concentration polarization, under semiinfinite diffusion control. Thus, the method in principle is insensitive to imperfections in the shape of the applied signal, as, for example, a finite rise time in a potential-step method. The method involves a mathematical device called the semiintegral of the current-time function, intermediate between the current itself and its time integral, the coulombic charge. A plot of the semiintegral, M, *vs.* E is termed a neopolarogram. Shapes of neopolarograms have been theoretically and experimentally examined for reversible and irreversible processes by Goto and Oldham (44).

A related technique, semidifferential electroanalysis, generated by semidifferentiation of the current, produces a quantity *e* which is the time derivative of M. The plot of *e vs.* potential has the same relationship to a neopolarogram as a derivative polarogram has to a classical polarogram, and is therefore called a derivative neopolarogram (45). The characteristics of this technique in qualitative and quantitative analysis, using a stationary hanging drop electrode and a ramped voltage-time signal, have been described (45).

Steady-State Processes

Voltammetry and amperometric titrations.—Earlier versions of voltammetry with stationary electrodes in unstirred solutions have largely fallen into disuse because of the slowness with which steady-state mass transport is attained, and because of the sensitivity of the steady-state condition to disturbances such as vibration. Nevertheless, Blaedel and Jenkins (46) noted that with glassy carbon electrodes steady-state voltammetry has the distinct advantage of smaller residual currents as compared with scanning voltammetry because of the slow adjustment of surface states to changes of potential. Blaedel and Iverson (47) have recently studied steady-state voltammetry using tubular electrodes. By using pulsed flow at constant potential, the response time was shortened considerably and sensitivity in the micromolar concentration range was achieved.

Steady-state voltammetry with rotated wire microelectrodes were at first interpreted in terms of a simple Nernst diffusion layer model. Later work showed that, owing to complications such as turbulent flow, such electrodes are not favorable for mechanistic studies. Nevertheless, many analytical applications, especially amperometric titrations, continue to be made (48), because of the inherent simplicity and sensitivity of the method. All classes of reactions, *i.e.*, acid-base, precipitation, complexation, and redox, operated in the classical volumetric mode as well as by coulometric generation of reagents are represented in titrations involving single indicator electrodes as well as in biamperometric titrations (49). The latter is the ultimate in simplicity, because only a pair of polarized electrodes, without a salt bridge or reference electrode, needs to be used.

By attaching a membrane to the electrode surface, the disturbing effects of convection can be eliminated, but the nature of the diffusion process is altered (50). A fundamentally different membrane system is the lyophobic gas-diffusion membrane, introduced in 1956 by Clark (51) for sensing oxygen amperometrically. Because oxygen diffuses across the membrane in the gas phase, its diffusion rate is not affected by the viscosity of the solution, and the response is truly an oxygen tension independent of salt effects upon solubility. A great many applications are being made, for example, in clinical chemistry and oceanography.

The rotating-disk electrode, described theoretically by Levich in 1942, was experimentally studied by several investigators, especially in the U.S.S.R., in the 1940's. The book of Delahay (11) stimulated applications to analytical chemistry. Among the earlier publications in the analytical literature are papers by Adams and co-workers (52) and by Azim and Riddiford (53) in 1962. The rotating ring-disk electrode, introduced by the Frumkin school in the U.S.S.R., has been studied extensively by Bruckenstein and co-workers. Albery and Bruckenstein (54) refined the calculation of the collection efficiency at the ring for soluble species generated at the disk. The rotating-disk electrode is of analytical importance because the limiting current can be accurately related to hydrodynamic quantities (55). The effective diffusion layer thickness has a known relationship to rotation speed, so calibration need not be done on a purely empirical basis.

Hydrodynamic modulation of rotating-disk electrodes as a means of avoiding interfering currents that are mass transport-independent was suggested by Miller and Bruckenstein (56). The ring-disk electrode is primarily useful in mechanistic studies and is not discussed further.

Hydrodynamic techniques have proven to be useful in monitoring effluents from chromatographic columns. Johnson and Larochelle (57) have reviewed past designs of flow-through cells, operating both in the amperometric and coulometric modes. Blaedel, Olson, and Sharma (58) confirmed the theoretical Levich equation for convective-diffusional mass transport under conditions of negligible consumption of electroactive species, and Blaedel and Boyer (59) applied a tubular platinum electrode at concentrations down to $10^{-8}M$.

Coulometry.—Steady-state coulometry, both in the controlled-potential and controlled-current modes, was well established as an electroanalytical method by 1952, the beginning of the present survey. Many applications continue to be reported (60), generally as adaptations of well-established principles to new situations. Monitoring of chromatographic column effluents by coulometric determination using flow-through cells is an active field of application. An example is the packed tubular platinum electrode which was shown to operate at 100% electrolytic efficiency for copper(II) and iron(III) in microgram quantities (57). Thin-layer electrochemistry has already been mentioned above as a form of coulometry on a short-time scale.

Another modern form of coulometry is represented by the measurement of peak areas rather than peak heights in anodic (or cathodic) stripping voltammetry. This version of stripping analysis has already been mentioned above in connection with thin mercury film electrodes operated under slow scan rate so that quantitative electrolysis can occur. The method is so sensitive for solid deposits that fractional monolayers can readily be detected. In fact, Andrews and Johnson (61) reported quantitative results for stripping selenium from a rotating gold-disk electrode only when less than a monolayer equivalent layer had been deposited. Laitinen and Watkins (62) were clearly able to distinguish fractional monolayers of PbO_2 on a substrate of conductive SnO_2 and to determine the total PbO_2 by cathodic stripping coulometry.

Spectroelectrochemistry

Many spectroscopic techniques have been applied to the examination of electrode surfaces. Strictly speaking, these are not electroanalytical techniques and therefore will not be covered in this review, but mention may be made of ellipsometry, infrared absorption, x-ray photoelectron spectroscopy (XPS or ESCA), ultraviolet photoelectron spectroscopy (UPS), Auger electron spectroscopy (AES), low energy electron diffraction (LEED), and scanning electron microscopy (SEM), which are primarily aimed at the study of electrode surfaces and thin films on them. Similarly, electrochemiluminescence has received considerable attention from electroanalytical chemists, but the technique is rarely, if ever, used for analytical purposes as such, and is not discussed further.

The use of spectrophotometric techniques to study species generated at the electrode or products of their reaction in solution represents analysis at least in an enlarged if not in the traditional sense. The use of optically transparent electrodes coupled with u.v.-visible spectrophotometry has been an established technique since 1964 (63). The subject has been more recently reviewed by Kuwana and Winograd (64). By using rapid scanning spectrophotometry, it is possible to follow the kinetics of homogeneous reactions following the charge-transfer step. The use of thin-layer optically transparent electrodes has already been mentioned (39).

An elegant application of laser-Raman spectroscopy was described by Van Duyne and co-workers (65). Taking advantage of the resonance Raman effect, they

were able to procure vibrational information about species generated electrochemically during a short voltage pulse. Using double laser beams, the technique has recntly been extended to include electronically excited states.

Electron spin resonance has become well established as a technique to determine radicals generated at electrodes. A review by Kastening (66) in 1974 summarized experimental techniques and results. Kinetic experiments using ESR coupled with constant current pulses have been described by Goldberg and Bard (67). A new coaxial cavity ESR cell using a helical gold-wire working electrode surrounding an auxiliary electrode and Luggin capillary reference electrode probe has been described (68) as being especially advantageous for solutions of high resistivity using potential sweep and pulse experiments.

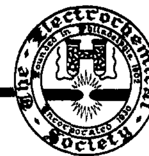
REVIEWS AND NEWS



JULY 1978

75th Anniversary Review Series
Primary Batteries 1951-1976

R. J. Brodd,* A. Kozawa,* and K. V. Kordesch*
Union Carbide Corporation, Battery Products Division, Parma, Ohio 44130

The past twenty-five years have seen many changes in primary batteries. Although the Leclanché cell celebrated its 100th Anniversary in 1966, it is still the main commercial primary cell. Table I shows the growth of dry batteries over the past 25 years. The growth rate is 8-12% per year, depending on the year and country (U.S.A., Japan, and Western Europe). Total dry cell production in Japan is roughly 1/3 the total production of that in the U.S.A., and the total production in Western Europe (West Germany, France, Great Britain, Switzerland, etc.) is roughly the same as that in the U.S.A. Dry cell consumption is about 8-15 cells per person annually in the U.S.A., Japan, and Western Europe in recent years. The steady growth of the dry cell industry is mainly due to the increase of electronic or electrical devices using dry cells.

The key to this growth has been the advent of low cost consumer devices such as watches, transistor radios, tape recorders, and calculators which require small portable power sources. Table II shows production figures of several devices using primary cells in Japan from 1956-1976. This figure is a good indicator of the worldwide trend regarding devices using primary cells.

Growth has been due in part to new systems which have increased ability to store and deliver energy. New battery systems which have been established commercially are: (*i*) zinc chloride, (*ii*) alkaline MnO_2-Zn (high-rate), and (*iii*) silver-zinc (miniature).

Many other systems have been developed, but they have reached only limited commercial production. Some of the more publicized systems in this group include: (*i*) lithium-iodine (charge-transfer complex), (*ii*) lithium-sulfur dioxide, (*iii*) lithium-CF_x, (*iv*) lithium-MnO_2, (*v*) Ca-$CaCrO_4$ thermal battery, (*vi*) magnesium-MnO_2, (*vii*) divalent silver-zinc, (*viii*) lithium-oxyhalide ($SOCl_2$ and SO_2Cl_2), and (*ix*) lithium-Ag_2CrO_4.

While growth has emphasized smaller size and higher energy density, two large-size systems, the Zn-CuO and Zn-air box cells, have decreased or almost disappeared from the commercial market.

In addition to the systems listed above, many new anode and cathode combinations and battery-related fundamental discoveries have been reported in the literature. At the risk of omitting an important future system, only those systems for which significant published information exists are discussed below. Several excellent books and symposium volumes which review the status of primary batteries have been published recently (1-5). The reader is referred to these references for more detailed discussions of specific battery systems.

Zinc-MnO_2 Batteries

From 1920 to 1950, flashlights using C and D size cells were the major devices using dry cells. Today, many other devices such as tape recorders, hand-held calculators, electric clocks, and radios are being used.

* Electrochemical Society Active Member.

Table I. Growth* of dry battery industry
(Unit: million dollars) Reference (6-8)

	1950	1960	1970	1977
U.S.A.	95	153	400 (e)	600 (e)
Japan	—	43	105	200 (e)

* Approximate value of dry batteries shipped from manufacturers.
(e): estimated values.

Table II. Production of devices using dry cells in Japan
(Unit: million units) Reference (8)

	1956	1966	1976
1. Battery operated toys	20	20	45
2. Hand held calculators	—	—	40
3. Tape recorders	1	6	27
4. Dry cell operated clocks	0.3	1.6	18
5. Flashlights	10	21	13
6. Transistor radios	2	25	9

Because of this, many new smaller cells (the AA, AAA, and N sizes) are becoming popular.

Table III summarizes Zn-MnO_2 cells on the market today. The Leclanché (or type I) in Table III is the traditional regular cell which was introduced in the late 1860's. It is still the least expensive of the battery systems. The heavy-duty Leclanché, zinc chloride, and alkaline cells (types II, III, and IV) are the cells which were developed after 1950 in Japan and are now being produced in large quantities. Type II cells were produced earlier in the United States. The major changes in the cell's design are shown in Fig. 1. In 1977, about 70% of the total cell production in Japan was of types II, III, and IV. In the United States, about 50% of cell production was made up of new types of cells; percentage-wise, more alkaline cells are used in the U.S. than in Japan. One important raw material which is common in the three new cells is EMD (electrolytic manganese dioxide). EMD is made by electrolysis of $MnSO_4$ in a near-boiling solution.

Table III. Four types of MnO_2-Zn cells on the market today
(See the performance shown in Fig. 1, 2, and 3)

Type I:	A natural MnO_2 ore* cell using a starch paste separator, NH_4Cl electrolyte and zinc can. (Production started in late 1800's.) Example: Eveready 950, Ray-O-Vac *1D*.
Type II:	An EMD** cell using a starch paste separator, NH_4Cl electrolyte containing some $ZnCl_2$, and a zinc can. (A large production started in Japan around 1960-1963.) Example: Hi-Top in Japan.
Type III:	An EMD** cell using a coated paper separator liner in a zinc can, and $ZnCl_2$ electrolyte usually containing some NH_4Cl. (A large scale production started around 1970.) Example: Eveready 1250, Ray-O-Vac 6D.
Type IV:	Alkaline MnO_2-Zn cell using KOH electrolyte and a gelled zinc powder as anode and a mixture of graphite and EMD as a cathode molded in a steel can. Examples: Eveready E95, Ray-O-Vac 813, Mallory Duracell.

* Cells I, II, and III use a mixture of acetylene black and MnO_2 powder as the cathode.
** EMD = Electrolytic manganese dioxide made by electrolysis of $MnSO_4$ solution.

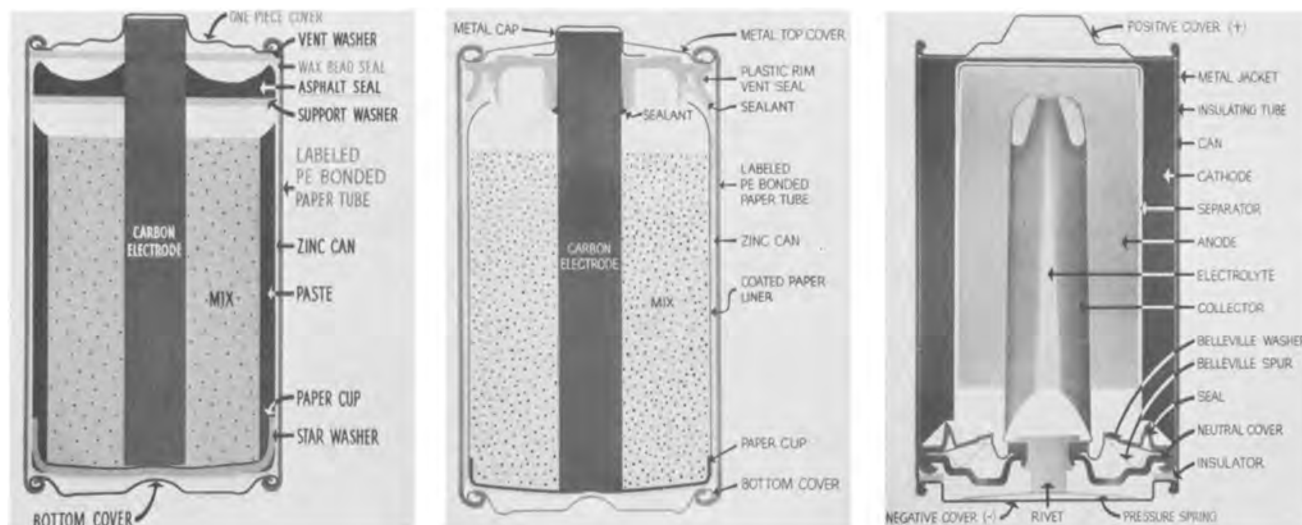


Fig. 1a. Schematic presentation of the progress in cell design, type I and II since late 1800. (A bobbin cathode cell using asphalt seal, paste separator and natural MnO_2 ore.); b. Type III since around 1970. (A paper lined $ZnCl_2$ electrolyte cell using plastic seal and EMD.); c. Type IV since around 1960. (An alkaline KOH electrolyte cell using plastic seal and EMD).

In the traditional Leclanché cells, natural MnO_2 ore (MnO_2 content: 70-75%) is used in the bobbin cathode. In the new cells mostly EMD (MnO_2 content: 91-93%) is used in the cathode. A large-scale EMD production started around 1960 in Japan (in two plants having a capacity of 500 tons/month). Because of the use of EMD, the new cells (types II, III, and IV in Table III) have a discharge capacity of two to five times greater than that of the regular cell (type I in Table III), as noted in Fig. 2-4. Details of the new cells have been described elsewhere (9-12). Therefore, only the main technical features of each type are pointed out here.

The heavy-duty Leclanché (or type II cell) has the same cell structure as the regular (type I) cell but uses EMD in the cathode rather than natural MnO_2 ore as well as a more oxidation-resistant chemically treated starch (10). The chemically treated starch withstands the low pH concentrated zinc solution. In

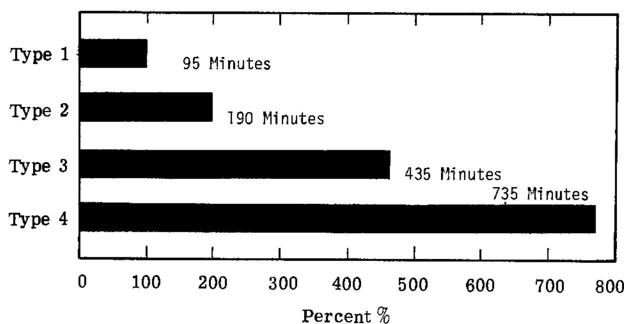

Fig. 2. Discharge capacity of D-size cells at 2.25Ω continuous discharge to 0.9V.

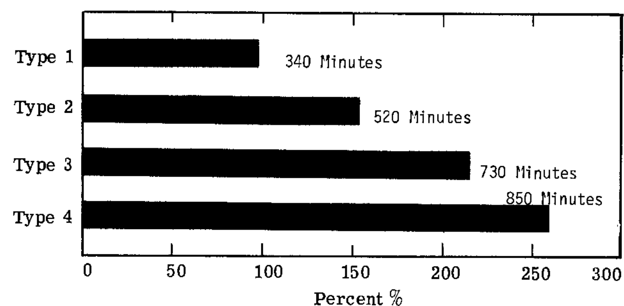

Fig. 3. Discharge capacity of D-size cells at 2.25Ω LIF test to 0.9V. (LIF test: 5 min discharge every hour for 8 hr period per day.)

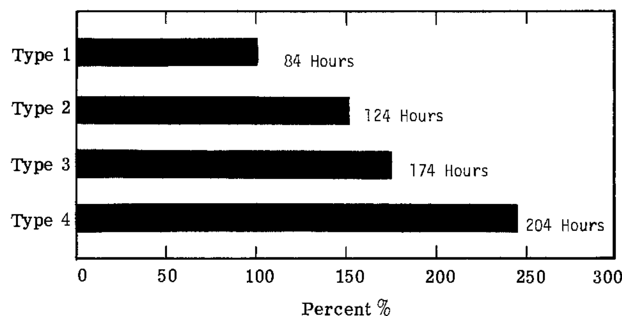

Fig. 4. Discharge capacity of D-size cells at 25Ω test (4 hr per day to 0.90V.)

this cell, the solution produced on discharge near the zinc anode has a very low pH of 0-1, and the starch-gel layer hydrolyzes and becomes liquid. This combination enhances the tendency to leak through the perforation of the zinc can.

The zinc chloride (type III) cell uses, in place of the starch gel layer, a paper separator which is coated either with a cross-linked starch (10-14) mixed with a binder (15) such as polyvinyl alcohol, hydroxyethyl cellulose, vinyl acetate, etc., or with a cross-linked polymer such as polyacrylamide (16). Since the paper is much thinner than the starch layer, the cell contains about 10% more capacity than the type II cell. Another significant difference is the use of $ZnCl_2$ solution (about 28-30%) as the electrolyte. In NH_4Cl electrolyte cells, when the cell is discharged, particularly at a continuous high rate, an electrolyte solution called "spew" is pushed into the upper space of the cell. By using $ZnCl_2$ electrolyte, the cell leakage is considerably reduced because the solution produced on discharge is absorbed in the cathode and does not enter the top space of the cell (15).

The alkaline (or type IV) cell is the so-called alkaline manganese cell. Union Carbide introduced this in 1959, and its construction differs considerably from the "Crown" cell described by Herbert (17, 18). The cell uses concentrated KOH electrolyte and, with about 10.4 A-hr of EMD (for a D cell) based on the one-electron reaction, $MnO_2 + H_2O + e \rightarrow MnOOH + OH$. This type of cell is excellent for high rate discharge applications. Also, the reliability is greater and leakage is far less than for the other cells.

It is most convenient to compare the cell performance of the various cells in the D size (R20 cell in IEC designation). Since the cells are used in various ways (low rate, high rate intermittent, and high rate continuous), three types of discharge tests (2.25Ω continu-

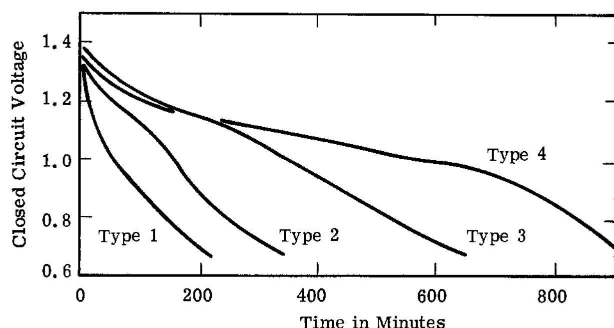

Fig. 5. Discharge curves of D-size cells on 2.25Ω continuous test at 21°C.

ous, 2.25Ω intermittent, and 25Ω) to a cutoff voltage of 0.90V are presented in Fig. 2-4, and the relative value (%) was calculated based on the discharge capacity of type I cells (100%). Figure 5 shows typical discharge curves for the four cell types on a continuous discharge test. It can be seen from the data in the above figures that really significant progress has occurred in the past 25 years. Since the size and shape of dry cells have remained the same since the late 1800's (for example, a D size cell is 3.5 cm in diam and 5.8 cm in height), such great technical progress has not been recognized by the general public. Major recent progress in dry cells in Japan has been summarized by Watanabe (13).

As mentioned earlier, the material responsible for the remarkable improvements of the cell capacity is EMD. Its production process and properties have been described in detail (11). It is, however, worth mentioning a few key properties. Today's EMD is very pure (most of the metallic impurities are of the order of less than a few ppm) and the average particle size is 10-15 μm and the net MnO_2 is 91-93% (7-9% being water). The particles have numerous micropores of diameter 40-50Å and the BET surface area is 40-60 m^2/g depending on the preparation conditions. Electrochemical polarization of EMD is much less than that of natural MnO_2 ore as shown in Fig. 6. CMD is a MnO_2 produced by a chemical process for dry cell use. CMD is equivalent or superior to EMD in certain types of cells. The total MnO_2 used for dry cells in the world is about 350,000 tons per year (1976). Of this amount about 60,000 tons are EMD and about 20,000 tons are CMD. The increase in the EMD production for Japan is shown in Fig. 7.

Significant progress in understanding the reduction processes of MnO_2 has been made. Kozawa *et al.* (19-21) have shown that the electron-proton mechanism is the major discharge reaction particularly in KOH electrolyte. The results show that γ-MnO_2 (EMD) which is most important for dry cells is a homogeneous phase solid redox system as Brenet (22) and Vosburg (23) proposed in the 1950's. The theory and the experimental results on the discharge mechanism of MnO_2 were summarized recently by Kozawa (11, 24). Miyaski (25) and Leger and Brodd (26) have reported heterolyte formation relating to the crystal structure of the MnO_2. The discharge process beyond MnOOH (Mn^{+3}) in KOH electrolyte is not well established and it was restudied by McBreen (27, 28).

Despite the numerous previous studies of MnO_2, many unsolved problems on MnO_2 remain, particularly concerning the intrinsic activity and the surface and the pore structure. The Battery Division and the Cleveland Section of the Electrochemical Society established the I.C. Sample Office in 1971 in order to promote the study of the characteristics of MnO_2. Currently 12 different MnO_2 samples are kept and distributed upon request. It is extremely difficult to reproduce exactly the same MnO_2 material even when the conditions described in the literature are followed closely. Therefore, the use of common samples for studies is not only

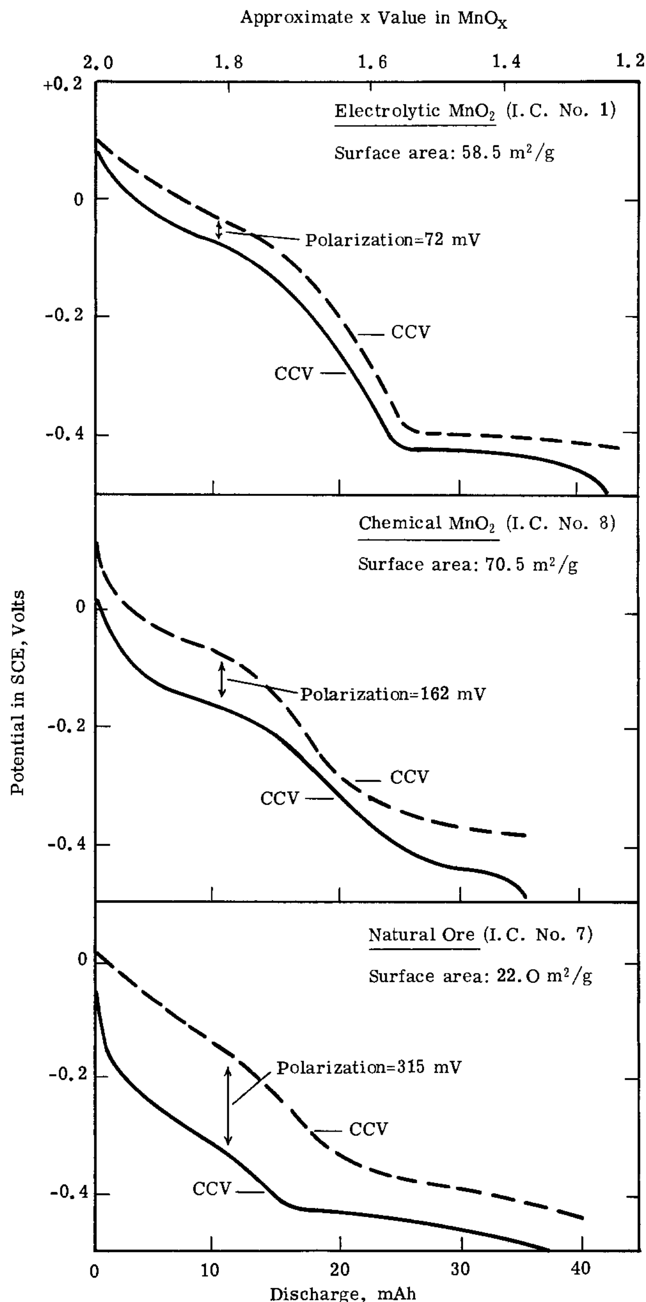

Fig. 6. Open-circuit voltage (OCV) and closed-circuit voltage (CCV) of three types of MnO_2 in 9M KOH.

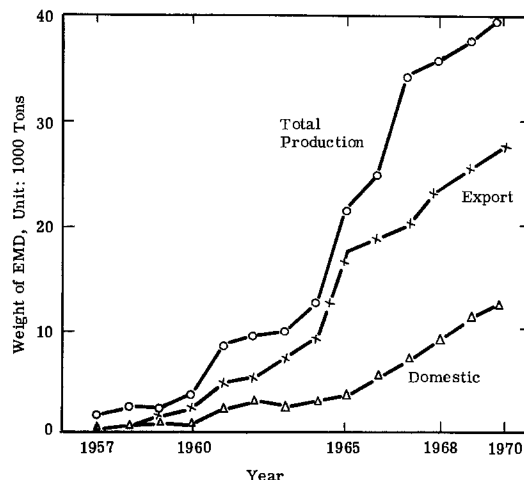

Fig. 7. Production and export and domestic consumption of electrolytic manganese dioxide (EMD) in Japan.

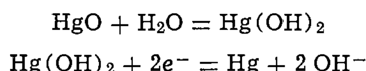
convenient but almost essential in order to compare results from one laboratory to those of another. The proceedings of a symposium on MnO_2 held in Cleveland in 1975 was printed (5).

Mercury and Silver Miniature Cells

The mercury cell is essentially unchanged in construction concept since its introduction in the 1940's. Of course, many new sizes have since been introduced. Ruetschi (29) reported that the reaction proceeds through a soluble intermediate



$$HgO + H_2O = Hg(OH)_2$$

$$Hg(OH)_2 + 2e^- = Hg + 2\ OH^-$$

The species $Hg(OH)_2$ rather than $HHgO_2^-$ is postulated because of an apparent lack of dependence of HgO solubility on the OH^- concentration.

The mercury cell discharges at a constant voltage of 1.35V (1.4-1.35, if MnO_2 is added to the cathode). For many applications, a higher voltage discharge is desirable. To satisfy this need, the $Zn/KOH/Ag_2O$ cell system was developed and introduced by Union Carbide in 1961. The cell has a similar design to that of the present mercury cell, except that Ag_2O is used instead of HgO in the cathode. Figure 8 shows a typical construction. The silver cell discharges at a constant 1.65-1.5V, depending on current drain. It can handle pulses upward to 50 mA/cm^2. The coulombic capacity is about 10% lower than the equivalent size mercury cell.

Divalent silver oxide (AgO) has higher energy density and essentially twice the coulombic capacity/gram of Ag_2O. AgO is metastable and should, thermodynamically, spontaneously decompose with oxygen evolution. As a result, it has not been suitable for use in sealed cells because

$$2AgO \rightarrow Ag_2O + \tfrac{1}{2}\ O_2$$

Considerable effort has been expended to render AgO stable for use in sealed miniature cells. This effort consummated in 1976 when ESB introduced the divalent silver cell. Cells being marketed contain both Ag_2O and AgO and provide about a 20% increase in capacity over monovalent Ag-Zn cells.

The rate of AgO decomposition can be reduced by the presence (and adsorption) of small amounts of impurities or additives. Cahan (30) showed that PbO additions reduced significantly the decomposition rate. Amlie and Ruetschi (31) found Cd and Zn additions decreased the decomposition rate. Tvarusko (32) reported that Ni and Co additives increase the rate of decomposition while Cd, Zn, Al, and Pb decrease the rate of decomposition. He also found that stability depended on the mode of preparation of AgO. Davis (33) has reported the beneficial effect of gold additives. A common thread underlying these studies is the thought that stability results from a protective coating of Ag_2O on the surface of the AgO particle.

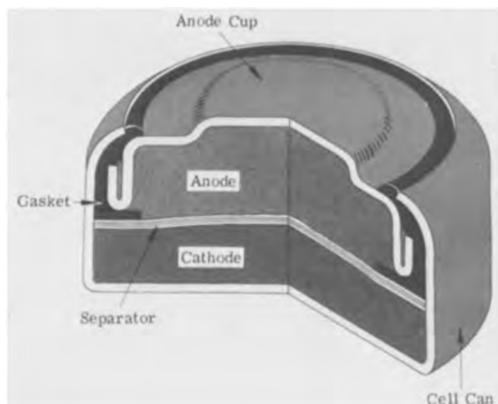


Fig. 8. Schematic of HgO-Zn and Ag_2O-Zn miniature cells

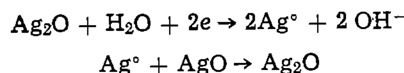
AgO has a monoclinic crystal habit with four AgO in the unit cell (34). There are two nonequivalent silver sites which are postulated to be Ag^+ and Ag^{+3}. The dual valency accounts for the observed diamagnetism and unusually high conductivity. The so-called divalent silver oxide is really a combination of Ag^+ and Ag^{+3} although the formula is still written AgO.

AgO normally discharges with a two-step discharge. Certain applications require substantially constant voltage discharge. Krebs (35) has reported a technique for stabilization of AgO which results in discharge at the constant Ag_2O voltage (monovalent voltage) but with the coulombic capacity essentially that of AgO. Dawson (36) disclosed a construction in which the monovalent oxide provides the contact to the current collector and isolates the AgO from the collector and the electrolyte. During discharge an exchange takes place to regenerate the monovalent material



$$Ag_2O + H_2O + 2e \rightarrow 2Ag^\circ + 2\ OH^-$$

$$Ag^\circ + AgO \rightarrow Ag_2O$$

Thus the cell discharges at the monovalent voltage but the exchange permits utilization of coulombic capacity of AgO. The isolation of AgO can be obtained by reducing the surface of the AgO particles chemically or electrochemically.

Organic Depolarizers

Organic cathode materials or depolarizers have been studied for possible replacement of MnO_2 in primary batteries. Because of their low operating potential, magnesium anodes have been used to give an acceptable unit cell voltage. Of all the depolarizers metadinitrobenzene (MDB) has been the most extensively studied (37, 38). Figure 9 shows a comparison of the performance of MDB with MnO_2. The results are typical of most organic depolarizers. To high voltage cutoff (1.1V) the performance is poor but to the lower cutoff (0.65V) the organic depolarizers give excellent service compared to MnO_2. Best performance has been obtained with high surface area carbons and $MgClO_4$ electrolyte (39, 40). Andre and Reilly (41) reported that catalysts influenced the reaction path and efficiency in practical cells with acetylene black conductor. With V_2O_5 and Fe_2O_3 catalyst, the principal products are *m*-nitroaniline and *m*-nitrophenylhydroxylamine, respectively. Other products form depending on the current drain, pH, etc.

Workers at American Cyanamid (41-43) identified several high voltage organic depolarizers based on benzofuroxan oxide and azodicarbonamides which do not require the use of a magnesium anode to obtain

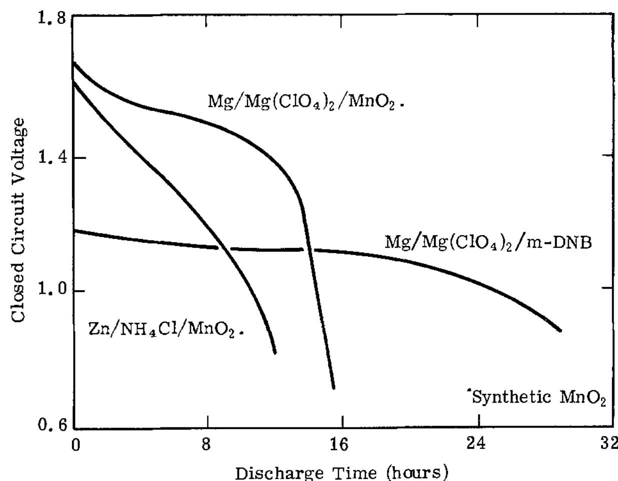


Fig. 9. Discharge curves of magnesium and zinc A-size cells on 16-2/3Ω test. Discharge curves for dry cells tested at 70°F (A cells), 16-2/3Ω drain. m-DNB represents *meta*-dinitrobenzene. Reference (40), with permission from PSC Publication Committee.

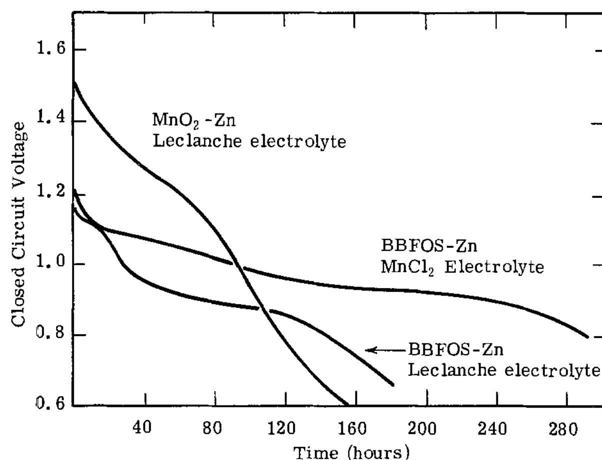

Fig. 10. Discharge curves through 150Ω of AA size cells comparing standard MnO_2 cathods cells with BBFOS organic depolarizer in two electrolytes. Reference (42).

a satisfactory cell emf. A comparison of the performance is shown in Fig. 10 for similar cell constructions with zinc anodes. Longer service to low cutoff voltages was obtained when the electrolyte contained $MnCl_2$ (42). Because benzofuroxans have limited solubility, modification of the structure such as BBFOS (5, 5′ sulfonyl bisbenzofurazan 3, 3′ dioxide) is preferred for its low solubility. Unlike MDB, catalysts have no effect on the performance of BBFOS.

Another series of compounds azobisdicarbonamides, also have as good activity as cathodes. Substitution improves their chemical and thermal stability as well as lowers the solubility. The compound 1,1′azobis(N-n-butyl formamide) gave the best performance (43). This compound also exhibits rechargeability. Cells made with the reduced product, biurea, have excellent stability and can be stored for prolonged periods, then charged for use (44).

Magnesium and Aluminum

Magnesium batteries $Mg/MgClO_4/MnO_2$ (40, 45, 46) have been produced for the military since 1971. The use of perchlorate electrolyte reduces the delay over the older $MgBr_2$ electrolyte. $BaCrO_4$ inhibitor is usually added to reduce wasteful corrosion. Figure 11 shows typical construction. Once put into service, the batteries must be used to exhaustion. This controlled application circumvents the difficulties of commercial application, *e.g.*, voltage delay (less than 1 sec), excess H_2 evolution on discharge, and very poor intermittent service. Magnesium anodes have also found considerable application in seawater batteries with $CuCl_2$ or AgCl cathodes (47).

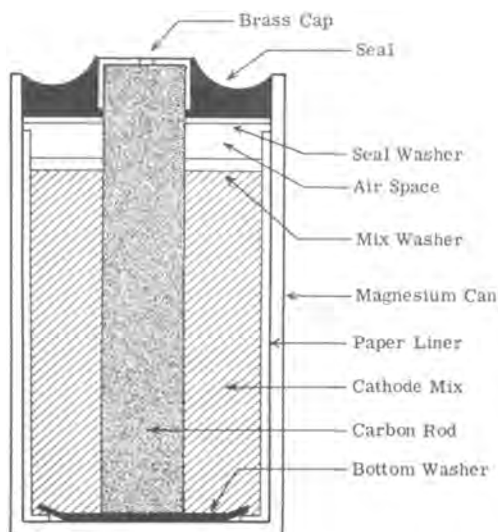

Fig. 11. Cross-section view, $Mg/Mg(ClO_4)_2/MnO_2$ dry cell. With permission from PSC Publication Committee.

Aluminum has not proved to be a satisfactory anode for aqueous electrolyte batteries (48). Aluminum can compete with Zn and Mg only on continuous discharge. The protective film which stabilizes aluminum in the environment contributes to its failure as a battery material. The anode shows delay characteristics. The activation of the cell destroys the passive film and leads to poor intermittent service, excessive H_2 evolution, and rapid perforation on discharge (49). Alcoa has developed a two-layer zinc alloy anode which minimizes but does not solve the problems (50). Other alloys, electrolytes, and inhibitors have been reported, but none fully solve the aluminum anode problem areas.

Reserve Batteries

Thermal batteries are reserve batteries which are activated by heating from a pyrotechnic device. On reaching the melting point of the electrolyte (usually KCl-LiCl eutectic, mp 352°C), the cell is ready to deliver current. The activation time is 0.5 sec or less. Thermal batteries find application mainly in military ordnance devices. Goodrich and Evans (51) reviewed the early work up to 1952. Other reviews have also appeared (52-54). The first thermal batteries of Ca-WO_3 were produced about 1948. The early cells were of the "cup" or closed-cell design in which the cathode faces both sides of the anode and the entire cell is enclosed into a can construction.

McKee (55) described the Ca-$CaCrO_4$ system which gave better high rate performance than the Ca-WO_3 battery. However, the self-discharge reaction of the $CaCrO_4$ cathode accelerates with temperature and, above 600°C, can lead to thermal runaway conditions. This is thought to be due to the increased solubility of the salt with increased temperature. Other thermal batteries of the cup type included Ca-K_2CrO_4 and Ca-V_2O_5 in which the V_2O_5 and boric acid formed a glaze coating on the cathode (56). Heat pads of Zr-$BaCrO_4$ were used in the cup batteries. The problems of the cup or closed-cell construction include short activated stand (5 min or less), and intricate battery design (intercell connections, etc.). Also, the heat pad can induce thermal shocks which damage battery operation.

Workers in the United States and England developed a bipolar construction shown in Fig. 12 which has been used in subsequent thermal battery designs (57-59). The cells are constructed with three layers or pellets: a heat pellet, a combination depolarizer-electrolyte-binder (DEB) pellet, and a calcium anode on an ion collector.

A kaolin or powdered silica binder holds the electrolyte in place to reduce shorting and to permit operation in high spin applications (60). The KCl-LiCl eutectic is the electrolyte for most cells, although LiBi-KBr has been used in some instances. The heat pellet of powdered iron and potassium perchlorate has excess iron to serve as the intercell connector after performing its heating function. The pellets are stacked one on top of each other, heat pad, anode, DEB tablet, heat pad, etc, to give the bipolar construction which

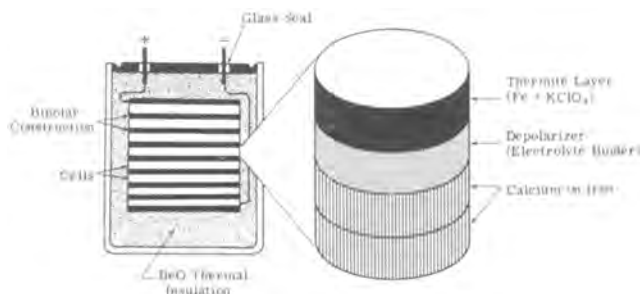

Fig. 12. Cross-section of typical thermal battery. Reference (58)

is efficient and simple to construct. A BeO sleeve or container is used as an electrical insulator, but it has good thermal conductivity to maintain heat balance. The heat pad is usually activated with an electrical match. Typical construction is shown in Fig. 12. The original pellet or open-cell construction was applied to the Mg-V_2O_5 system, but the Ca-$CaCrO_4$ system gives better performance. Goldman and Smith (61) demonstrated that the pellet construction gave superior performance to that of the cup construction for the same chemical combination. They also reported that the depolarizer with best performance was $CaCrO_4$. Thow (59) showed that the open-cell construction gave faster activation.

The chemistry of calcium has several features which can lead to poor cell performance. The calcium anode reacts with the lithium electrolyte to form the alloy, $CaLi_2$. The alloy tends to collect at the edges of the anode and leads to intermittent shorts and electrical noise, especially in spin applications. It is thought that the formation of the alloy may contribute to good anode performance. It is reported that acetic acid treatment reduced alloy formation (62). Chromate in the electrolyte can also form a protective anode film. Calcium chloride formed by anode reaction forms an insoluble double salt $CaCl_2 \cdot KCl$, mp 575°C. This compound can precipitate and prematurely passivate the calcium anode. In spite of these problems the calcium anode is preferred because of its high electrode potential, excellent energy density, and high discharge rate capability.

Longer lived thermal batteries have been reported (63) as has the use of other cathode reactants, *e.g.*, Fe_2O_3, CuO (64, 65). Ammonia and SO_2 reserve batteries have also been developed for use in military ordnance devices (54). Other systems with good storage and activated life include Cd/HgO (66-68) and solid electrolyte cells discussed below.

Solid Electrolyte

The interest in solid electrolytes with high conductivity was stimulated by the discovery of the super ionic conductor silver rubidium iodide by Bradley and Green (69) and Owens and Argue (70). Solid electrolyte cells offer the advantages of low shelf discharge rates and thus long shelf life, wide temperature range of operation, absence of leakage, and ease of miniaturization. Table IV lists several properties of solid electrolyte systems which have been developed. The silver-based electrolytes have the disadvantage of low energy density and low voltage but can have good high rate performance. The lithium iodide and β-Al_2O_3 cell systems based on lithium or sodium conduction, respectively, have high unit cell voltages and high energy density but are relatively poor conductors at room temperature. They perform satisfactorily where low currents and long life are required, such as in heart pacers. The incorporation of Al_2O_3 in the Li-PbI_2PbS cell is an example of the improvement of the conductivity by inclusion of an inert material to enhance surface conductivity (76). Several of the iodine cathode systems use a charge-transfer complex to enhance cathode activity (73, 77). The LiI cells have the disadvantage of increased internal resistance as the discharge progresses. The lithium iodide forms at the interface between lithium and the iodine cathode. Thus the contact develops a thin layer of LiI electrolyte which also serves as the separator. It is sufficiently thin so that the poor LiI conductivity does not contribute significant voltage loss at the current drains of normal operation (*e.g.*, 10-100 μA).

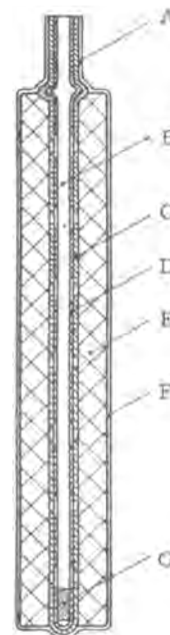

Fig. 13. Cross-section of the air electrode designed by Siller (Pertrix, 1961), Reference (85). A, electrode seal; B, air-access space; C, conductive foil with holes; D, aluminum foil; E, carbon plates; F, cellulose acetate film; G, paper spacer.

When low steady drains over extremely long periods, *e.g.*, 10 years, are required, atomic batteries greatly exceed the capabilities of chemical systems. Atomic batteries convert the heat from radioactive decay, *e.g.*, Pu^{238}, Po^{210}, etc., by use of thermoelectric converters. The cells are very rugged and can withstand incineration at about 1300°C for 2 hr or direct impact from a 0.44 magnum pistol without rupture. Systems have been developed for long lived pacemaker applications and for power in remote areas (81, 82).

Zinc-Air Cells

A strong effort was made at the Pertrix, A.G. (now Varta Batterie, A. G.) to improve the neutral electrolyte cells by substituting manganese chloride and magnesium chloride for the usual ammonium and zinc chloride electrolytes (83). Siller attempted to adapt the vapor pressure of the solution to the relative humidity ranges of the ambient. Siller also used thin carbon plates for large cells to improve the current output. Figure 13 shows the air electrode as manufactured in 1961 (84, 85).

The alkaline cells with thin-walled, molded-type air cathodes shown in Fig. 14 and 15 were manufactured

in the early 1950's (86-88) as hearing aid cells. These cells reached energy densities of 200 W-hr/kg, which was more than any primary cell of previous aqueous types. Like the neutral electrolyte cells in Europe which had far lower current densities, they became obsolete when the current demanded by radios and other portable electronic devices rapidly dropped into the low milliampere range with the advent of the transistor.

The designs shown in all three air cell figures have one common feature: the use of thin plates with improved oxygen-transport capabilities. The high ampere-hour capacities were achieved because most of the remaining cell volume was occupied by the anode and the electrolyte. The neutral salt electrolyte cells manufactured by Pertrix, A.G. used solid zinc anodes, while the alkaline cells made by Union Carbide Corporation used large surface powder zinc anodes and wire coils along with gelled sodium hydroxide. Earlier, large box air cells using liquid NaOH were improved by the addition of calcium hydroxide (89) which reduced the electrolyte requirement from 9 to 4 ml/A-hr. The small hearing aid cells described in Fig. 14 and 15 reduced this value to less than 1 ml/A-hr. Both cells were sealed in plastic which was opened before use.

Figure 16 shows a D-size cell which was manufactured in 1951 by the Austrian firm W. I. F. (88) and was based on utilization of the spinel-catalyzed carbon electrodes invented a few years earlier by Marko and Kordesch (90). This cell could deliver 200 mA continuously for 75 hr and more than equaled the output

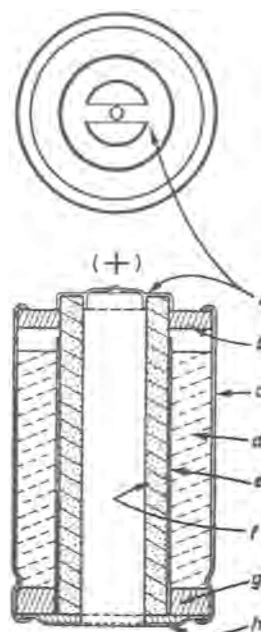

Fig. 16. The D-size zinc-air cell of W. I. F. (1951). a, Metal cap; b, spacer; c, steel can; d, electrolyte paste with zinc particles; e, separator; f, carbon tube; g, spacer; h, bottom contact.

of a (R-20) mercuric oxide cell. The electrolyte used was potassium hydroxide gelled with sodium carboxymethylcellulose, and zinc was distributed in the form of very small leaflets (less than 0.05 mm thick) which were produced by breaking up amalgamated zinc foil. A reserve cell of this type but with the carbon tube as the outside shell gave 500 mA current and had a capacity of 18 A-hr. However, this cell suffered from carbon dioxide pickup as well as drying out or wetting up after the seal was broken. The cell was soon abandoned. Even so, the design of the modern alkaline MnO_2-zinc cell with its outside cathodic sleeve is strongly related to the above-mentioned outside carbon-air cell.

Even though no commercial interest developed for the small zinc-air cells for use in portable devices, the unexcelled capacity of these cells was attractive for military applications and several versions (mostly reserve-type) of thin plate cells were produced using air electrodes from fuel cell technology (91, 92). A mechanically rechargeable zinc-air battery was developed by Leesona-Moos Laboratories for the U.S. Army Electronics Command (93). This "bicell" construction, shown in Fig. 17, was capable of delivering up to 160 W-hr/kg. For "recharging," the zinc plates were renewed, and one set of cathodes permitted up to 50 refillings. An air-blower was incorporated to sustain high rates and to provide air cooling. The anode packages, which were activated with water, contained powder zinc and dry KOH. A similar battery was developed by Energy Conversion, Limited, in England.

Several large air cells have been constructed. General Motors built an experimental vehicle in 1969 which included a 20 kW mechanically rechargeable zinc-air battery (94). The sodium-amalgam/(carbon) oxygen cell gained recognition as a high power, high voltage system, and considerable effort went into its technical realization by the M. W. Kellogg Company (95) in the mid-1950's.

Realizing that aluminum-air is a galvanic element with theoretically 7900 W-hr/kg metal consumed, many attempts were made to reduce such a system to practice. Zaromb Research Corporation (96) reported in 1967 that a 2 kW system with provisions for the exchange of the spent alkaline electrolyte was feasible.

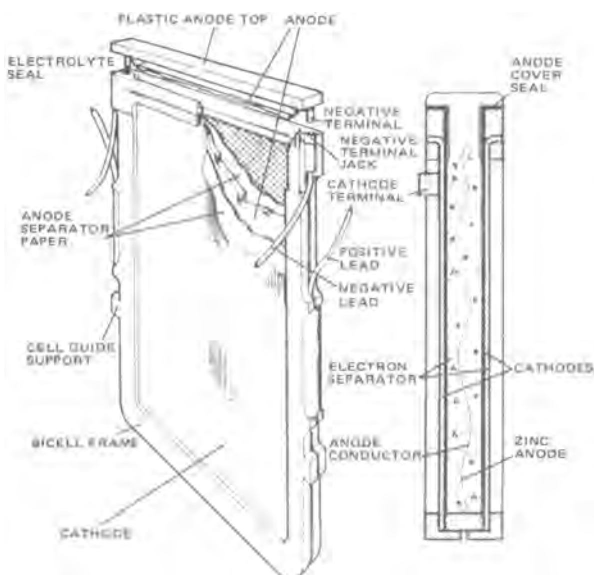

Fig. 17. Zinc-air bicell construction (Leesona Moos, 1968)

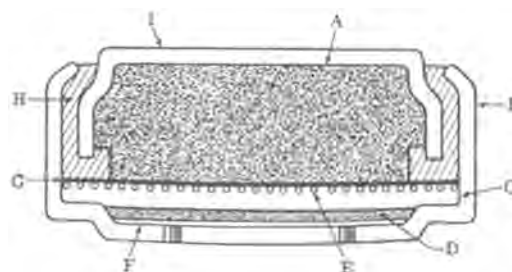

Fig. 18. Schematic of zinc-air miniature cell. Courtesy of Gould, Incorporated. A, Zinc powder; B, cathode casing; C, cathode; D, porous Teflon; E, current collector; F, absorbent material; G, separator; H, gasket.

Magnesium-air systems operate with neutral electrolytes. However, the achieved current densities are low (97). An air-sodium amalgam cell combined with a molten salt-liquid sodium "supply" half-cell to operate at temperatures above 100°C was proposed by Atomics International (98).

In recent years, there have been attempts to revive small size air-zinc primary cells. An experimental high capacity zinc-air D-size cell produced by Energy Conversion Limited, England, is pictured in a 1972 air cell review by Gregory (99). The capacity was claimed to be 22 A-hr. The air cathode is on the outside (Teflon-coated and screen protected), and the powder zinc anode is in the center of the cell. In all likelihood, the "old problems" encountered with alkaline cells once again manifest themselves. A powerful air cell needs the thin electrode with good diffusion properties, but if this is achieved then the cell suffers from exposure to air. For this reason, it is understandable why another recent attempt to build a nonreserve-type high power alkaline zinc-air cell (100) achieved no real breakthrough in technology despite excellent packaging prior to self storage.

The Russian Krona cell version of small alkaline zinc-air cells constitutes a compromise. The carbon electrode is kept rather thick (2-3 mm) and serves as a barrier to protect the zinc from air access. In addition, MnO_2 is added to the carbon to provide peak power capabilities for a short period, while the recharging action of the air electrode is utilized to regenerate the MnO_2.

Recently, miniature cell applications for hearing aids were found for the hybrid zinc-air MnO_2 (alkaline) primary system. The approach at Gould (101) is to restrict air access to the minimum needed to provide the average current (in the order of mA and μA) and thereby minimize the exchange of CO_2 and water vapor. These cells are claimed to have about twice the ampere-hour capacity of corresponding mercuric oxide-zinc cells. A cross section of a Gould No. 675 cell is shown in Fig. 18. Air access is limited through the use of very small holes. Activated (open) shelf life is quoted to be satisfactory in the hearing aid as well as for calculator and watch applications.

Lithium Batteries

Nonaqueous cell systems have received increasing attention during the past 25 years, starting with the use of liquid ammonia for reserve cells (54). Since lithium has the highest potential on the emf scale, it is one of the highest available energy anode systems. Its low equivalent weight makes lithium batteries very lightweight and enhances their aerospace and military applications. The lightness of weight, together with good low temperature operation, was responsible for much of the early interest. For most earth-based applications, the volume energy density is more important. In this case, the low density of lithium detracts from the energy density of lithium battery systems. Of the lithium battery systems listed in Table V, only the lithium-$SOCl_2$ system has clearly superior volume energy density over those of the commercial silver and mercury aqueous systems shown in Table VI. The real advantages for lithium batteries are in their excellent storage life, their ability to operate over a wide temperature range, and, in some cases, in their high unit cell voltage. Eichinger and Basenhard (102, 103) have surveyed the large literature of lithium battery reactions. The better-known systems are discussed below.

The early SO_2 batteries were developed as reserve batteries for the military, in which the SO_2 served only as the ionizing solvent base for the electrolyte (54). In the early 1960's, a group at American Cyanamid observed an emf generated by SO_2 in an electrolysis cell. This discovery led directly to the development of lithium-SO_2 cells where the SO_2 served a dual purpose: as the ionizing solvent for the electrolyte and as the cathode reactant (104-106). This new concept of a liquid cathode cell led to higher energy density through greater efficiency of utilization of the cathode material. A solvent, *e.g.*, acetonitrile, propylene carbonate, is sometimes added to lower the vapor pressure of SO_2 to help control the lithium-passivation problem, and to provide a conductive solution for greater SO_2 efficiency. The preferred solute is LiBr.

One would expect lithium and SO_2 to react spontaneously in the cell. The formation of a thin protective film of SO_2 reduction product (LiS_2O_4?) on the sur-

Table V. Primary cell systems (nonaqueous base)

	Nominal voltage	Nominal W-hr/in.³	Comments
Li-SO_2	2.9	8.0	Military, safety
Li-CuO	1.6	10.0	C-Zn replacement
Li-CF_x	2.8	10.0	High unit cell voltage
Li-CuS	2.0	8.0	Low rate
Li-Ag_2CrO_4	3.3	10.0	Pacemakers
Li-I_2	2.8	4.1	Pacemakers
Li-$SOCl_2$	3.5	15.0	Safety, high rate
Li-V_2O_5	3.4	11.0	Electronic
Li-MoO_3	2.9	10.0	Electronic

Table VI. Primary cell systems (aqueous base)

	Nominal voltage	Nominal W-hr/in.³	Comments
Leclanché	1.5	2.5	Low cost
Zinc chloride	1.5	2.6	Medium cost, higher rate
Alkaline	1.5	2.7	High rate, low leakage
Magnesium	1.7	4.1	High rate continuous
Mercury	1.35	9.5	High energy density
Silver	1.6	8.8	High energy density
Divalent silver	1.6	10.0	Leakage, stability
Zinc-Air	1.4	12.0	Shelf problems

face of the lithium electrode inhibits the internal self-discharge. This film is responsible for the observed voltage delay during cell discharge, but it also provides the protection for good shelf life of the cell.

Power Conversion, Incorporated first marketed the Li-SO_2 cells in 1972. Typical discharge characteristics and cell construction are shown in Fig. 19 and 20. Lithium passivation effects are noted during the initial portions of the discharge. The cells exhibit good performance, especially at low temperatures. This is due to the good transport properties of the SO_2 electrolyte and the extended surface area electrode construction. Figure 21 shows the performance of Li-SO_2 compared with present commercial and military batteries as a function of temperature. The good performance at low temperature is especially attractive for military applications. Safety is still an unresolved problem area (110).

The discovery of oxyhalides, thionyl chloride, and sulfuryl chloride as liquid cathodes represents another recent advance in battery technology (111-113). The lithium cells with oxyhalide cathode reactant have been reported to deliver 18 W-hr/in.^{3}; this is significantly better that any other lithium battery. As with the Li-SO_2 cell, the soluble cathode construction results in increased efficiency in cell performance.

The oxyhalide cell construction for high rate cells is very similar to that of the Li/SO_2 in Fig. 19. Typical cell performance of the high energy construction is shown in Fig. 22. Film formation in lithium, mainly

LiCl, during open-circuit stand results in a severe voltage delay in some cases (116, 117). The film from self-discharge reaction effectively blocks the surfaces. Various techniques have been reported to eliminate this problem, including purification of the electrolyte and protective plastic film on the lithium (118-120). The ionizing solute is $LiAlCl_4$. A wide spectrum has been reported of cell sizes which range from 40 mA-hr button cells to several thousand ampere-hour high current power supplies. Larger cells have some unresolved safety problems, and Mallory has reported on thermal runaway conditions (121-122).

Two types of lithium anode-nonaqueous cells, Li-CF_x (123, 124, 126) and Li-MnO_2 (125), were developed in Japan and were introduced commercially in 1973 and 1976, respectively. Polycarbonmonofluoride (or CF_x), having an x value close to 1.0, is usually used. The advantage of using CF_x is that the material does not dissolve in the organic electrolyte and also produces carbon (a conductive material) upon discharge: $CF_x + xe^- \rightarrow C + xF^-$.

Six types of Li-CF_x cells are being offered, with capabilities ranging from 500 to 5000 mA-hr. A small cylindrical cell (BR-435 cell, shown in Fig. 23), 4 mm diam $\times$ 30 mm long, is the most popular, and about 4 million such cells were produced in 1977. The BR-435 cell is being used mostly to power a light-emitting diode to illuminate fishing floats in Japan. Figure 24 shows a comparison of the discharge capacity of C-size cells against regular MnO_2-Zn type cells. The Li-CF_x cell has a closed-circuit voltage of 2.8V, and its energy density is 4 to 5 times greater than that of the Leclanché cells. Figure 25 shows that the cell voltage during the discharge depends on the temperature.

Li-MnO_2 cells are being offered in sizes from 30 to 5000 mA-hr capacity (125). Among these cells, a thin (2.8 mm thick) coin-type cell is in limited commercial production, mainly for hand-held calculators. The typical discharge curves of the thin coin-type cell (LF-½W) are shown in Fig. 26. Manganese dioxide used for Li-MnO_2 cells is electrolytic MnO_2 which is properly heat-treated in order to remove the water and to modify the crystal structure. Figure 27 shows the effect of heat-treatment on the MnO_2 reactant. It was confirmed by x-ray study (128) that the MnO_2 lattice expands when it is discharged. This is believed to be due to Li^+ ion penetration into the MnO_2 lattice, similar to the proton penetration (20) in the case of discharge of γ-MnO_2 in aqueous solution. This was supported from the cell voltage by the shape of the

discharge curve. The cell voltage is calculated based on the following reaction: $2Li + 2MnO_2 = Mn_2O_2 + Li_2O$; the expected voltage is only 2.69 ($= E°$). Actual cell voltage is 3.0-3.4V. To explain this, Ikeda *et al.* (127) assumed that Li^+ ion incorporation into the MnO_2 lattice is similar to the familiar manganite and hetaerolyte reactions in aqueous media.

A low drain Li/Ag_2CrO_4 cell system has been developed by SAFT (129). Cell construction is very similar to that of the miniature silver-zinc in Fig. 8. They report excellent stability with the organic $LiClO_4$ electrolyte. The cells deliver their initial fresh capacity after 4-years' storage at 45°C. The cells are suitable for electronic applications requiring low steady currents, and at pacemaker drains the cells deliver current at a steady 3.0V for 6-8 years.

Lehmann *et al.* (130) have reported a low cost Li/CuO cylindrical cell of nonspiral construction. Figure 28 depicts typical cell performance with a comparison

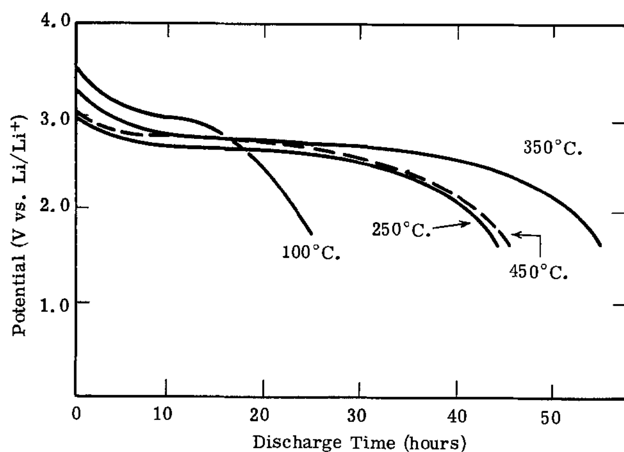

Fig. 27. Discharge characteristics of MnO_2 heat-treated at various temperatures. The current density was 1.2 mA/cm^2. Reference (127).

to Leclanché and alkaline cell systems. Although the cell has a thermodynamic voltage of 2.4V, it discharges at 1.4-1.0V depending on current drain. The system has good storage properties and delivers 95-100% of its original capacity after six months and has no measurable loss after 3 weeks at 70°C.

Other lithium cell systems in advanced states of development include Li/CuS, Li/MoO_3, and Li/V_2O_5 (131-133).

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1977 the following graduate students received $1000 each, representing the three Summer Fellowship Awards of The Electrochemical Society.

Mr. Paul A. Kohl, University of Texas, Austin, Texas, was awarded the Edward Weston Fellowship.

Mr. Paul D. Tyma, Michigan State University, was designated as the recipient of the Colin Garfield Fink Fellowship.

Mr. Harold C. Faulkner III, University of California, Riverside, California, received the Joseph W. Richards Fellowship.

The Summer Fellowshp Awards are made "without regard to sex, citizenship, race, or financial need, to a fellow or teaching assistant pursuing work between the degrees of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." They are intended to cover a period during which the recipient has no financial support for the continuance of his or her work.

The Edward Weston Summer Fellowship Report

Mr. Kohl's report is given below.

The Photoelectrochemical Behavior of Semiconducting n- and p-GaAs and InP Electrodes in Acetonitrile Solutions

Semiconductor electrodes have recently shown promise as a means of electrochemically converting light energy into chemical and/or electrical energy. Since the photoassisted oxidation of water into hydrogen and oxygen on n-TiO_2 was suggested (1), an increasing amount of research has been aimed at utilizing smaller bandgap semiconductors which absorb a greater fraction of the solar spectrum than TiO_2 and extend the concepts of electron transfer in semiconductors to new systems such as different solvents, photocatalysis, and solution kinetics.

The semiconductor-solution interface (2) is analogous to a semiconductor-metal junction where light of energy greater than the bandgap (E_g) can promote electrons from the valence band (VB) to the conduction band (CB) as shown in Fig. 1. Photogenerated minority carriers (electrons in p-type semiconductor or holes in n-type semiconductor) can be forced to the solution interface and be consumed by electroactive species in solution with the gross work available given by $|E_{fermi} - E_{redox}|$. However, key factors in the utilization of semiconductor electrodes in electrochemical cells are knowledge of the relative location of the energy levels in the semiconductor and solution and an understanding of the role surface states or intermediate levels within the bandgap play in charge-transfer processes.

In this work, the electrochemical behavior of the small bandgap semiconductors n- and p-GaAs (E_g = 1.35 eV) and InP (E_g = 1.27 eV) was investigated in acetonitrile (ACN) solutions which contained various one-electron Nernstian redox couples. The use of ACN not only allows the use of a larger working potential range (5V) than water (1.23V) and a greater number of reversible redox couples, but also the rate of dissolution of the semiconductor (Eq. [1], [2]), which readily occurs in aqueous solutions at potentials where holes are forced to the interface, is decreased because of the poor solvation of the products of dissolution

$$GaAs + h^+ - Ga^{+3} + As\ (III) \quad [1]$$

$$InP + h^+ - In^{+3} + P\ (III) \quad [2]$$

where h^+ represents a hole in the VB of the semiconductor

The cyclic voltammetric current-voltage curves (3) suggest three main conclusions in this work. The first is that the dissolution of the semiconductors (Eq. [1], [2]) is decreased and does not occur until the electrode potential is more positive than observed in aqueous solutions. This enables electroactive solution species to compete more favorably with dissolution for photogenerated holes in the n-type semiconductors over a wider potential range.

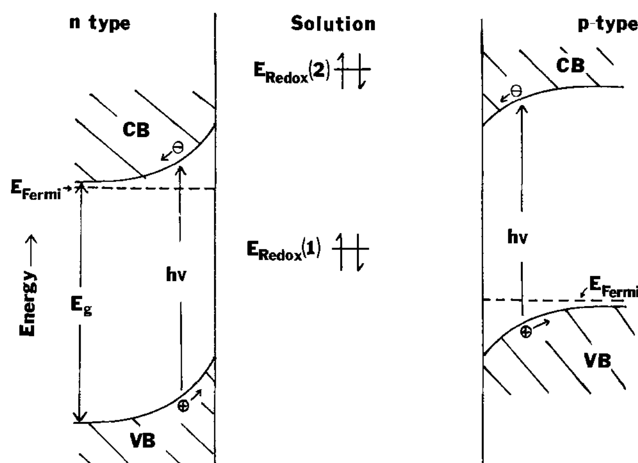

Fig. 1. Energy level representation of an n-type and p-type semiconductor in contact with a solution containing a redox couple located within the bandgap [E_{redox} (1)], and negative of the CB edge [E_{redox} (2)]. CB and VB are the conduction and valence bands, respectively, E_{fermi} is the Fermi level, and E_g is the bandgap.

Secondly, redox couples lying within the bandgap region (Fig. 1) seem to follow previously proposed models for electron transfer via intermediate levels within the bandgap region (4, 5). Reduction of solution species lying below the midgap region occurred at potentials near the middle of the gap through the intermediate level. Photoassisted reductions (on p-type material) and oxidations (on the n-type materials) were observed with underpotentials (negative overpotentials due to the utilization of light energy) up to 700 mV. The magnitude of the underpotential appeared to be limited by the position of the intermediate level, $|E_{\text{flatband}} - E_{\text{intermediate band}}|$. That is, the underpotential observed upon photooxidation was limited by the potential of the reduction of oxidized species (or back reaction).

The third and most unique result was the photoassisted electron transfer observed with redox couples located negative of the CB edge. Ideally, degeneracy and metal-like behavior is observed as seen with n-ZnO, n-CdS (4), and n-TiO_2 (5). Photooxidations (within-GaAs) are observed at potentials more negative than observed with a Pt disk electrode, and photoreductions are observed (on p-GaAs and InP) at potential more positive than Pt similar to that observed with redox couples located within E_g. Reasonable evidence for the formation of surface layers which produce a photovoltage when illuminated analogous to a semiconductor-metal junction exists. Thus, the potential range of photoassisted electron transfer is at least twice the size of the bandgap while a 1.35 eV or larger photon can be used.

The simplest illustration of photoassisted electron transfer and its possible uses is in regenerative photoelectrochemical cells such as

n-GaAs |0.01*M* BQ, 0.01*M* $BQ^{\bar{\cdot}}$, 0.1*M* TBAP (ACN) | Pt

where BQ is p-benzoquinone and TBAP is the supporting electrolyte tetra-n-butylammonium perchlorate. Upon irradiation of the n-GaAs, the radical anion is oxidized to BQ and BQ is reduced to $BQ^{\bar{\cdot}}$ at the Pt electrode. The driving force and current in the external circuit are produced by light of energy greater than the bandgap. An open-circuit photovoltage of 700 mV was measured and when the GaAs was irradiated with 96 $\mu W/cm^2$ of 600 nm light, the maximum power was produced at 28 $\mu A/cm^2$ and 0.4V, yielding a 12% conversion of light to electricity. While the intensity was corrected for solution absorption, no attempts were made to optimize the cell concentrations or intensities to the maximum power.

The electrochemical behavior was also found to be very dependent on the condition and pretreatment of the semiconductor surfaces. The density and position of the intermediate levels within the bandgap which can provide a mechanism for the back reaction and thus a recombination or quenching of photogenerated minority carriers in the semiconductor can be changed by chemical pretreatments.

In general, nonaqueous investigations of the mechanism of electron transfer at the semiconductor surface can be used as a basis to predict the behavior of other photoassisted reactions for possible photocatalytic synthetic work, photoelectrochemical cells, upconversion of light (6), or behavior in other solvents.

Mr. Tyma's report is given below.

Determination of Kinetic Parameters from Polarographic Data Obtained at Short-Sampling Times

An over-all objective of our research efforts is to correlate electrochemical reactivities with the structure of both the reactants and the interphasial region. Studying rate responses to systematic changes in solution composition can lead, for example, to determining whether the activated state prior to electron transfer leaves the inner coordination sphere of the reactant unchanged (outer-sphere mechanism) or whether the reaction proceeds *via* an intermediate which involves specific interactions between reactant ligands and the electrode surface (inner-sphere mechanism) (1). Such experiments can also provide information concerning the position of the reaction site for electron transfer (2). In the case of a liquid metal electrode, one can characterize the interphasial structure; therefore, rate responses to changes in the structure of the interface brought about by variations in solution composition can be monitored. This process can then be turned around so that these "kinetic probes" yield information about interphasial structure from rate data for solid electrodes for which the former is not readily accessible.

The simplest method of polarographic data analysis to extract the electrochemical rate constants as a function of overpotential is to record the ratio of the current measured at a time *t* following drop birth to the current measured at time *t* when the reaction is completely diffusion-controlled and to use the Koutecky treatment of irreversible polarographic waves (3). There are, however, two types of systems for which this approach will not succeed. Because it is necessary to correct voltammetric data of limited precision for diffusion polarization at potentials beyond the foot of the wave, a natural limit of about 10^{-2} cm/sec is imposed upon rate constants determined in this manner *via* conventional polarography; polarograms of faster systems appear reversible. Furthermore, systems which give maxima are not amenable to this technique. The theory of Koutecky predicts that the upper limit to rate constants ascertained by the polarographic method should increase an order of magnitude for each hundredfold decrease in the time at which the currents are measured (3). Moreover, it may be possible to outrun maxima if the phenomena leading to their occurrence develop in the later stages of drop-life. Cover and Connery have shown (4) that maxima can be reduced or eliminated from polarographic concentration determinations by measuring the current at the end of the life of a drop which is forcibly dislodged from the capillary at frequencies as high as 210 Hz. For natural drop-times down to 1.25 sec and forced drop-times as low as 160 msec it has been demonstrated that the Ilkovic equation is applicable (5). The purpose of the present study is to develop instrumentation suitable for determining under what conditions the Koutecky theory can be applied to the polarographic data obtained at times shortly after the birth of the drop.

Two general approaches to this technique have evolved. The first, and by far the more common, is to

Mr. Tyma's report is given below.

Determination of Kinetic Parameters from Polarographic Data Obtained at Short-Sampling Times

An over-all objective of our research efforts is to correlate electrochemical reactivities with the structure of both the reactants and the interphasial region. Studying rate responses to systematic changes in solution composition can lead, for example, to determining whether the activated state prior to electron transfer leaves the inner coordination sphere of the reactant unchanged (outer-sphere mechanism) or whether the reaction proceeds *via* an intermediate which involves specific interactions between reactant ligands and the electrode surface (inner-sphere mechanism) (1). Such experiments can also provide information concerning the position of the reaction site for electron transfer (2). In the case of a liquid metal electrode, one can characterize the interphasial structure; therefore, rate responses to changes in the structure of the interface brought about by variations in solution composition can be monitored. This process can then be turned around so that these "kinetic probes" yield information about interphasial structure from rate data for solid electrodes for which the former is not readily accessible.

The simplest method of polarographic data analysis to extract the electrochemical rate constants as a function of overpotential is to record the ratio of the current measured at a time *t* following drop birth to the current measured at time *t* when the reaction is completely diffusion-controlled and to use the Koutecky treatment of irreversible polarographic waves (3). There are, however, two types of systems for which this approach will not succeed. Because it is necessary to correct voltammetric data of limited precision for diffusion polarization at potentials beyond the foot of the wave, a natural limit of about 10^{-2} cm/sec is imposed upon rate constants determined in this manner *via* conventional polarography; polarograms of faster systems appear reversible. Furthermore, systems which give maxima are not amenable to this technique. The theory of Koutecky predicts that the upper limit to rate constants ascertained by the polarographic method should increase an order of magnitude for each hundredfold decrease in the time at which the currents are measured (3). Moreover, it may be possible to outrun maxima if the phenomena leading to their occurrence develop in the later stages of drop-life. Cover and Connery have shown (4) that maxima can be reduced or eliminated from polarographic concentration determinations by measuring the current at the end of the life of a drop which is forcibly dislodged from the capillary at frequencies as high as 210 Hz. For natural drop-times down to 1.25 sec and forced drop-times as low as 160 msec it has been demonstrated that the Ilkovic equation is applicable (5). The purpose of the present study is to develop instrumentation suitable for determining under what conditions the Koutecky theory can be applied to the polarographic data obtained at times shortly after the birth of the drop.

Two general approaches to this technique have evolved. The first, and by far the more common, is to

record the current throughout the entire drop and to obtain the value at a desired time by knocking off the drop at that time through suitable mechanical means. Since the maximum current for each drop occurs prior to the forced drop-fall, the envelope of the polarogram constitutes the current-voltage curve at the specified time. However, since the capillary is in motion just after the drop is knocked off, convection in the vicinity of the electrode is enhanced and the current increased early in the drop-life. This enhancement becomes relatively larger as the forced drop-time is decreased, and the frequency-response requirements of the recording system correspondingly become more stringent. What remains to be determined is whether there is a significant difference between kinetic parameters measured by that approach and those obtained by the second method, which is to use currents sampled at short times following the natural birth of the drop.

Since the accoutrements for the former technique are familiar and readily assembled, attention was focused on the development of the latter. A programmable sample-and-hold system was constructed for use with a Princeton Applied Research (PAR) Model 174 Polarographic Analyzer and a Hewlett-Packard Model 7045 XY Recorder; a schematic representation is shown in Fig. 1 and 2. Rather than being used to drive the Y axis of the recorder directly, the output of the potentiostat's current-to-voltage converter is applied to the analog input of the sample-and-hold amplifier (Fig. 2) whose output, which normally tracks its input, is connected to the recorder. At the appropriate time following the birth of the drop, an $\overline{\text{ENABLE}}$ negative-going logic pulse triggers two monostables with periods of 100 and 600 msec. The latter causes the sample-and-hold amplifier to hold its current value and activates the Y axis servo, which is normally disengaged to minimize unnecessary pen travel. After the delay provided by the former, a third monostable is triggered, momentarily dropping the pen to plot the measurement and resetting the delay logic. At the heart of the timing circuitry (Fig. 1) is a Mostek MK5009 time-base chip which divides a 1 MHz master oscillator frequency by the number of decades selected by a binary-coded decimal (BCD) thumbwheel switch or remote frequency-selection lines which may be driven by a computer interface. At the beginning of each measurement cycle, a two-digit BCD counter is loaded from switches or remote lines with the number of scaled oscillator pulses necessary to achieve the desired time delay between the detection of drop-fall and the sampling of the cell current. Once a detector pulse is received, the counters count down to zero and an $\overline{\text{ENABLE}}$ pulse is generated.

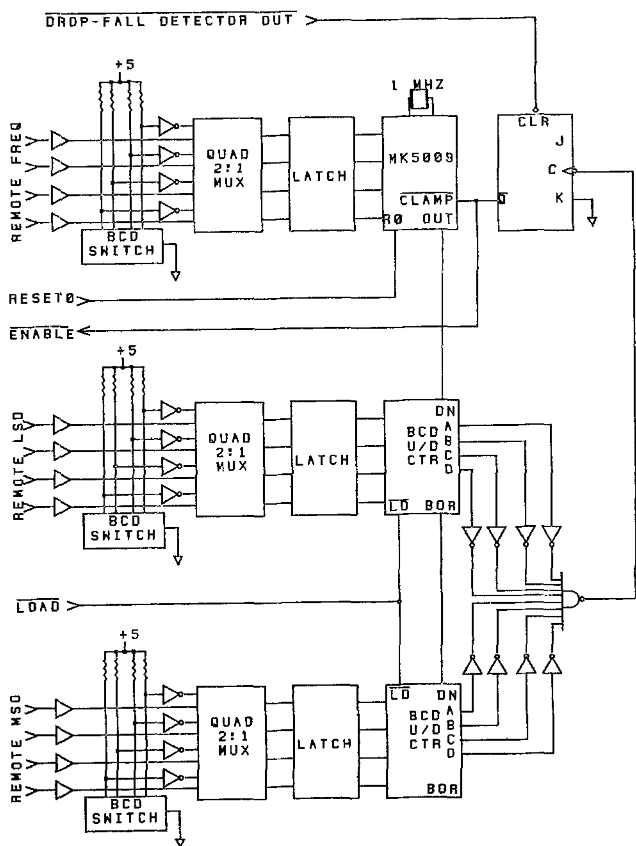

Fig. 1. Programmable timing circuit. Multiplexer (MUX) is 74157, latch is 7475, and BCD counter is 74192.

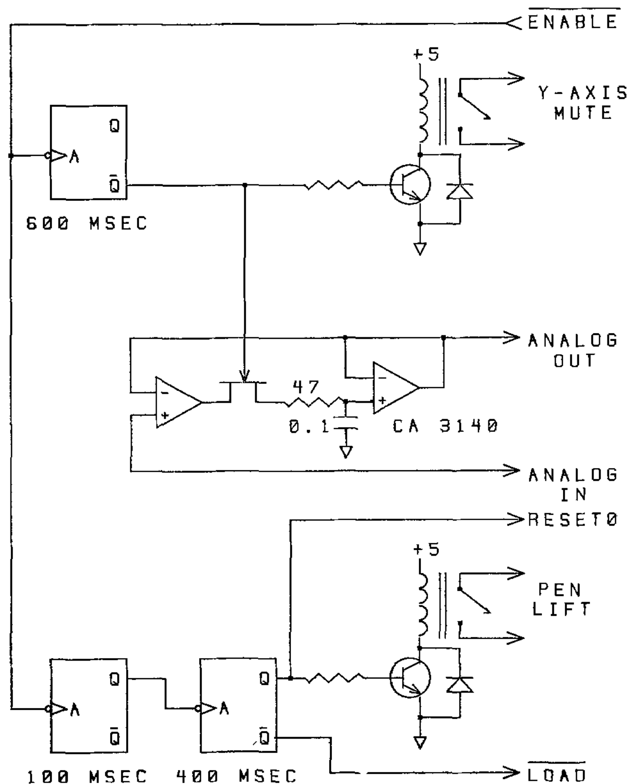

Fig. 2. Sample-and-hold sequencer. Monostables are 74121, and capacitor is a low-leakage type (polystyrene).

In order to synchronize the current-sampling with drop-fall, some sort of detection system is required. While many approaches have been taken on this aspect of the problem [see, for example, the citations in Ref. (6)], we initially chose the optical method of Hahn and Enke (6) based upon its lack of interaction with the potentiostat circuitry and simplicity of implementation; Fig. 3 presents a schematic diagram. The sudden change in light scattered up the capillary when the drop falls is converted to an electrical signal which is differentiated and amplified to provide a detector pulse which is compatible with transistor-transistor logic. Preliminary measurements produced rate constants which decreased monotonically as the sampling time increased and which were inconsistent with previously reported values (7), and efforts were undertaken to determine if systematic errors were introduced by any portion of the measurement system.

Upon closer scrutiny it was found that the signal produced by the drop-fall detector occurred no less than 80 msec following the fall of the drop. What appeared to be the source of the delay was that the original designers did not reckon with the inversion produced in the comparator stage of the level shifter [amplifier A4 in Fig. 2 of Ref. (6)]. The desired negative-going logic transition occurred only as the result of noise in the differentiator output on the trailing edge of its output spike. Once this level-inversion discrepancy was rectified, however, a nonreproducible 20 msec delay remained. Since one of our design goals was the capa-

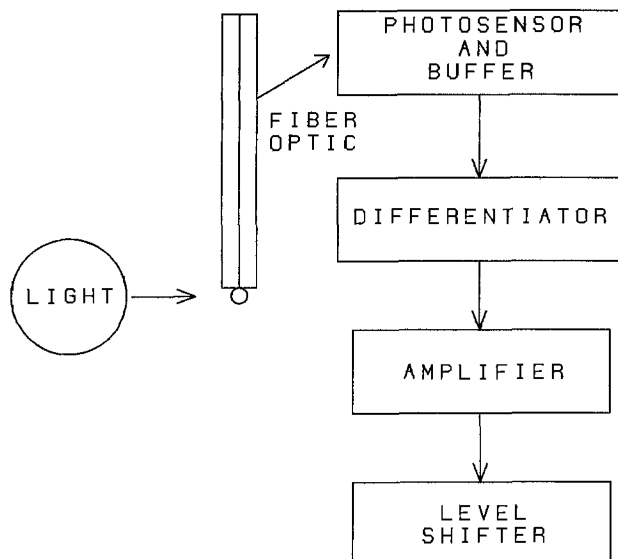

Fig. 3. Optical drop-fall detector [full details in Ref. (6)]

bility to sample currents after 50 msec, this performance remained unacceptable.

To meet this goal, it is necessary that the detector error be less than 1 msec. For it to be capable of this, however, it must have preferential frequency response in the 1-10 kHz region. Examination of the original passive components of the differentiator (6) showed that they limit frequency response to between 0.16 and 3 kHz (unity-gain limits), with maximum gain at 22.5 Hz and gain in excess of 10 at the archetypal noise frequencies 60 and 120 Hz. Even with more appropriate passive components, however, insufficient signal amplitude was present in the necessary frequency range; efforts to remove sources of stray light by optical shielding and to increase the gain of the amplification stage proved equally unsuccessful. Because the light is attenuated appreciably by the fiber optic system, even with the recommended polishing of the capillary groove and fiber optic ends, we tried attaching a more sensitive photodarlington transistor (2N5777) directly to the capillary groove with the die facing the Hg drop. The buffer amplifier in the detector was replaced by a current-to-voltage converter (10 μA/V); the a-c component of a typical differentiated output is shown in Fig. 4. While the signal-to-noise ratio would undoubtedly be increased if the current-to-voltage conversion were performed directly at the phototransistor, the necessary mounting considerations vitiate such an undertaking. Furthermore, inspection of Fig. 4 will reveal that the rise time of the differentiator spike produced by the fall of the drop is approximately 20 msec. This result is not surprising in view of the fact that the drop continues to reflect light after detachment until it falls below the light path, and a 20 msec delay corresponds to the time required for a 2 mm displacement of a freely falling object.

The inevitable conclusion is that the optical detection system is inappropriate for this or any other application where inaccuracies of 20 msec cannot be tolerated. It is still useful in systems such as its original utilization (8) where a precise albeit inaccurate time delay following the birth of the drop is all that is required. Subsequent measurements were made with an a-c tuned amplifier-based detection system to be described elsewhere (9). Features of the detector include a self-contained strobable oscillator and a response time of less than 150 μsec.

The large number and time-consuming nature of the experiments and data analysis required for the satisfactory scrutiny of this problem makes it an excellent candidate for automation. To place this and other DME studies under on-line control, a laboratory microcomputer based upon the Digital Equipment Corporation LSI-11 microprocessor[1] was constructed from commercially available modules and those of our own design, including a versatile, indirectly addressing digital interface which substantially reduces the number of ports required on the computer bus to service numerous digital devices (9).

Typical time-resolved polarograms of 2 m*M* $Cr(H_2O)_6^{3+}$ in 1*M* $NaClO_4$ at *p*H 4 and 24°±1°C with an Hg flow-rate *m* of 17.0 mg/sec are shown in Fig. 5. Kinetic parameters extracted from these data are less disparate from reported values (7) than those obtained above; a systematic decrease in calculated rate constant, although smaller than before, still occurs as the sampling time increases.

An important advantage of measurements at short sampling times is illustrated in the limiting current region. According to Koutecky theory (3), the currents at the top of the $Cr(H_2O)_6^{3+}$ wave due to $Cr(H_2O)_6^{3+}$ reduction vary as $t^{1/6}$ (diffusion-controlled), whereas those in the same region which result from proton reduction depend on $t^{2/3}$ (kinetically controlled). As the sampling time approaches zero (below 1 sec), the contribution from the kinetically controlled succeeding wave should become smaller relative to that from the wave which is diffusion-controlled, and this is borne out experimentally. The theory's assertion that the limiting current follows the Ilkovic equation does not work, however, at the large Hg flow rates necessary to make the area sufficiently large to assure reasonable signal-to-noise ratio at the shortest sampling times. In Fig. 6 plots are presented of limiting

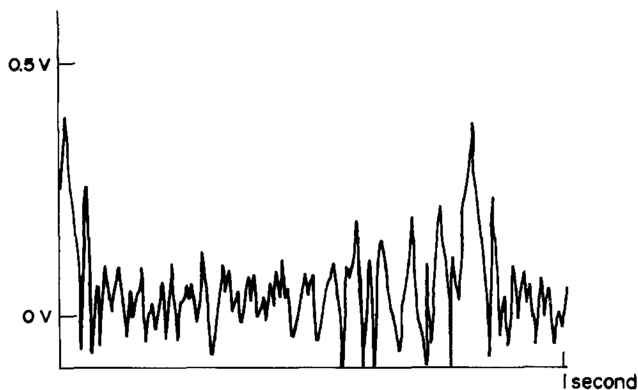

Fig. 4. Differentiated representation of photodarlington current

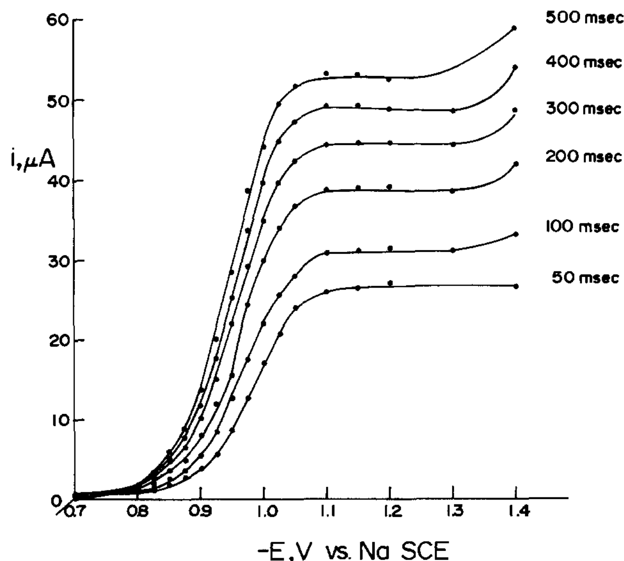

Fig. 5. Time-resolved polarograms of 2 m*M* $Cr(H_2O)_6^{3+}$ in 1*M* $NaClO_4$ at *p*H 4 and 24° ± 1°C; *m* = 17.0 mg/sec.

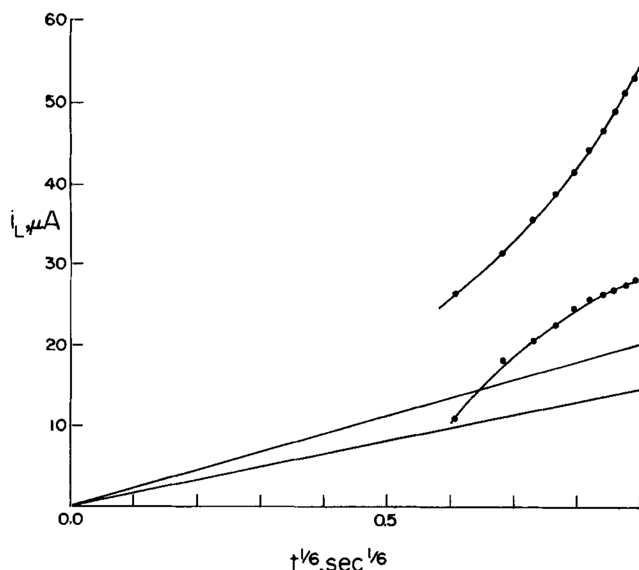

Fig. 6. Comparison of Ilkovic equation predictions (lines) and experimental results (curves). The upper line and curve are for $m = 17.0$ mg/sec, the lower ones for $m = 10.3$ mg/sec.

currents *vs.* $t^{1/6}$. The upper curve and line are the experimental data and theoretical prediction, respectively, for 2 m*M* $Cr(H_2O)_6^{3+}$ reduction for an Hg flowrate of 17.0 mg/sec; and the lower ones are for a flowrate of 10.3 mg/sec. That the limiting currents are substantially larger than what the Ilkovic equation predicts is reasonable when one considers that in the derivation of the Ilkovic equation one assumes that the mercury surface velocity has only radial components (10). However, it has been shown that Hg drops in 1*M* KCl solutions have appreciable tangential motion between −0.5 and −1.5V *vs.* SCE (11). This additional convection in the entrained solution enhances the current over and above that due to the convective diffusion phenomena which lead to the Ilkovic equation. Since Bond has demonstrated that under some conditions of natural drop fall at comparable flowrates the limiting current is less than that predicted by the Ilkovic equation (5), it should therefore be possible to determine the appropriate combination of flow-rate and drop-time where Ilkovic behavior should be observed. Further studies are in progress.

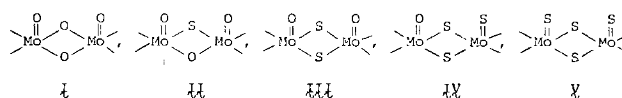
Mr. Faulkner III's report with his professor Dr. DeHayes is given below.

Electrochemical Studies of Oxo- and Sulfido-Bridged Molybdenum (V) Dimers

Dimeric molybdenum (V) complexes with cysteine (1), dithiocarbamate (2), and EDTA (3) ligands have been studied as reaction models for molybdenum-containing enzymes. EPR evidence indicates that the ligand field surrounding the molybdenum atoms at the active sites of these enzymes contains sulfur donors (4, 5). X-ray structural analyses have been performed on several dithiocarbamate complexes in which the terminal ligands bound to molybdenum and the bridging ligands between the molybdenums have been both oxygen and sulfur (6-10). Electrochemical studies in aprotic solvents have been performed on two diethyldithiocarbamate compounds (2) and aqueous studies have been carried out on both the EDTA and cysteine complexes of molybdenum (V) (1, 3). In addition, infrared studies have been made of di-μ-oxo-bis[N,N-dialkyldithiocarbamatooxomolybdenum (V)] and μ-oxo-μ-sulfido-bis[N,N-dialkyldithiocarbamatooxomolybdenum (V)] with the intent to observe and assign the bands due to the bridging oxygen and sulfur ligands (11). The present study summarizes the results of a systematic investigation of the influence of a sulfur *vs.* an oxygen ligand field on molybdenum (V) dialkyldithiocarbamate compounds. The groups that have been included in the investigation are



with diethyldithiocarbamate (dedtc) and di-n-butyldithiocarbamate (nbudtc) as the ligands.

Although infrared spectroscopy has been a major tool for the characterization of the compounds, the effects of the systematic substitution of sulfur for oxygen have been observed by cyclic voltammetry and u.v.-vis. spectroscopy for solutions of the compounds in dimethylformamide (DMF) and dimethylacetamide (DMA).

Experimental

Preparation of the complexes.—μ-Oxo-μ-sulfido-bis [N,N-di-n-butyldithiocarbamatooxomolybdenum (V)] and di-μ-sulfido-bis[N,N-di-n-butyldithiocarbamatooxomolybdenum (V)].—"Sulfurized molybdenum di-n-butyldithiocarbamate" was prepared according to the literature (12). TLC of the product exhibited two spots. 0.3g of this product yielded two bands on a dry-packed column (described below). After rotary evaporation of the solvent at 30°C and recrystallization the first band exhibited infrared peaks at 967, 955, 478, and 338 cm^{-1} [corresponding to $Mo_2O_2S_2(nbudtc)_2$], and the second band had peaks at 970, 951, 711, 513, 460, and 350 cm^{-1} [corresponding to $Mo_2O_3S(nbudtc)_2$].

Di-μ-sulfido-{[N,N-di-n-butyldithiocarbamatooxomolybdenum (V)]-[N,N-di-n-butyldithiocarbamatosulfidomolybdenum (V)]} and di-μ-sulfido-bis-[N,N-di-n-butyldithiocarbamatosulfidomolybdenum (V)].—10g of the "sulfurized molybdenum di-n-butyldithiocarbamato" was added to 8g of P_4S_{10} in 100 ml of xylene. The mixture was stirred for 15 hr at room temperature and then refluxed for an additional 2.5 hr. The xylene was removed by rotary evaporation. TLC of the product exhibited three spots. 1g of the product was eluted with benzene from a slurry-packed column (described below) to yield two bands. After rotary evaporation of the solvent and recrystallization the first band exhib-

ited peaks at 549, 533, 467, and 335 cm^{-1} [corresponding to $Mo_2S_4(nbudtc)_2$] and the second band exhibited peaks at 960, 538, 470, and 333 cm^{-1} [corresponding to $Mo_2OS_3(nbudtc)_2$].

Di-μ-oxo-bis-[N,N-diethyldithiocarbamatooxomolybdenum (V)].—The procedure used was a modification of that of Newton and Corbin (13). Under a nitrogen atmosphere, 4g of $MoCl_5$ (1.5×10^{-2} moles was dissolved in 25 ml H_2O. A solution of 1g of sodium diethyldithiocarbamate (5.8×10^{-3} moles) in 10 ml H_2O was then slowly added. The purple precipitate was refluxed for 2 hr, at which time it had changed to a brown color. The brown precipitate was isolated by vacuum filtration in air. Attempts at the synthesis of $Mo_2O_4(dedtc)_2$ with a 1:1 mixture of molybdenum pentachloride and sodium diethyldithiocarbamate as described by Newton and Corbin (13) yielded mainly $Mo_2O_3(dedtc)_4$. When the ratio was increased to 2:1 (molybdenum pentachloride to sodium diethyldithiocarbamate) the pure dioxobridged compound was obtained. The infrared spectrum of this compound is given in Table I and Fig. 1. The data agree well with that of Newton and McDonald (11).

Di-μ-sulfido-bis[N,N-diethyldithiocarbamatooxomolybdenum (V)] and di-μ-sulfido-{[N,N-diethyldithiocarbamatooxomolybdenum (V)]-[N,N-diethyldithiocarbamatosulfidomolybdenum (V)]}.—1g of $Mo_2O_3(dedtc)_4$ (13) was added to 50 ml $CHCl_3$. H_2S was bubbled through the solution for 20 min. The precipitate was then isolated and gave two spots upon TLC. 0.3g of this product was then added to the column. Elution with benzene dichloromethane solvent gave two bands. The infrared spectrum for the material in the first band had peaks at 955, 541, 470, and 335 cm^{-1} [corresponding to $Mo_2OS_3(dedtc)_2$] while the peaks for the second band were at 967, 953, 479, and 338 cm^{-1} [corresponding to $Mo_2O_2S_2(dedtc)_2$].

All of the compounds were recrystallized by slow evaporation of a CH_2Cl_2 solution except $Mo_2O_4(dedtc)_2$, which was recrystallized by adding petroleum ether (30°-60° bp) to a CH_2Cl_2 solution.

Materials and measurements.—TLC plates were prepared with EM Silica Gel A and spread to 0.25 mm thickness. The column used for separations measured 6.6 × 71.8 cm and was dry-packed with EM Silica Gel 60 except for the separation of $Mo_2OS_3(nbudtc)_2$ and $Mo_2S_4(nbudtc)_2$. For these latter EM Silica Gel 60 was slurry packed with benzene into the column and the mixture of complexes introduced as a solution. In the other separations the compound was rotary evaporated into a sample of silica gel that weighed 25-50 times more than the sample. This was then introduced at the top of the column prior to elution. In the case of $Mo_2S_4(nbudtc)_2$ and $Mo_2OS_3(nbudtc)_2$ the solvents were benzene and methanol for both the column and TLC separations. In all other cases the best solvent was found to be a 5:2 (vol:vol) mixture of benzene and CH_2Cl_2.

The electrochemical experiments were carried out with a PAR Model 173 Potentiostat/Galvanostat, Model 174 Digital Coulometer, and Model 175 Universal Programmer. A three-electrode system was utilized in all cases. The reference electrode was an Ag-AgCl electrode in aqueous tetramethylammonium chloride

(0.00V *vs.* SCE) in a capillary tube with a cracked-glass bead junction for contact with the solution. The auxiliary electrode was a Pt flag electrode, while the working electrode was a Beckman Pt inlay electrode for cyclic voltammetry and a Pt gauze electrode for coulometry. The supporting electrolyte, tetraethylammonium perchlorate, was synthesized and purified by established methods (14).

Cyclic voltammetric and coulometric studies of all the compounds were carried out in DMF and DMA. The electrochemical behavior was identical in both solvents with the exception of the $Mo_2O_4(dedtc)_2$ complex which seemed to decompose in DMA. Attempts were made to use DMSO and acetonitrile as solvents, but the compounds decomposed in DMSO and were too insoluble in acetonitrile to get reliable data. Reversibility of the first cathodic peaks was also determined as a function of scan rate.

Transfers of reduced species to airtight spectrometer cells were made inside a Vacuum Atmospheres Corporation Dry-Lab glove box. U.V.-vis. spectra were recorded on a Cary Model 14 spectrophotometer in quartz cells that ranged from 0.01 to 1.0 cm in path length. EPR spectra were recorded on a Varian Model 4500 X-band spectrometer by use of a Varian V-4548 solution cell. Infrared spectra were recorded with either a Perkin-Elmer 621 or Perkin-Elmer 283 spectrometer. All spectra were run as 0.3% KBr pellets. Dimethylformamide (DMF) was purified by refluxing 2 liters over 200g P_2O_5 for two days, followed by distillation at a pressure between 8-12 Torr. Dimethylacetamide (DMA) was purified by the same procedure.

Results

Infrared.—Two bands are obtained when "sulfurized molybdenum di-n-butyldithiocarbamate" is eluted from the column. The infrared spectrum of the first band displays a sharp doublet at 967 and 955 cm^{-1} and also contains stretches at 478 and 338 cm^{-1}. The spectrum from the second band also has a well-resolved doublet at 970 and 951 cm^{-1} as well as stretches at 711, 513, 460, and 350 cm^{-1}, with the stretches at 711 and 513 cm^{-1} not being observed in the spectrum of the first band. These two compounds are identified as $Mo_2O_2S_2(nbudtc)_2$ and $Mo_2O_3S(nbudtc)_2$.

The product of the reaction between P_4S_{10} and "sulfurized molybdenum di-n-butyldithiocarbamate" has three components. The first band eluted displays a finely resolved doublet at 549 and 533 cm^{-1} besides stretches at 467 and 335 cm^{-1}. The second band eluted has two strong singlet peaks at 960 and 538 cm^{-1} besides two stretches at 470 and 333 cm^{-1}. Finally, the third band eluted exhibits the same infrared spectrum as the first band of "sulfurized molybdenum di-n-butyldithiocarbamate." These three components are identified as $Mo_2S_4(nbudtc)_2$, $Mo_2OS_3(nbudtc)_2$, and $Mo_2O_2S_2(nbudtc)_2$.

The product of the reaction between H_2S and Mo_2O_3 (dedtc)$_4$ has two components. An infrared spectrum of the first compound has two strong stretches at 955 and 541 cm^{-1} besides the two stretches at 470 and 335 cm^{-1}. A spectrum of the second band exhibits four stretches, besides those associated with the ligand, a sharp doublet at 967 and 953 cm^{-1}, and stretches at 479 and 338 cm^{-1}. These two compounds are identified as $Mo_2OS_3(dedtc)_2$ and $Mo_2O_2S_2(dedtc)_4$.

Finally, the compound $Mo_2O_4(dedtc)_3$ prepared by a modified procedure (13) exhibited five stretches in the infrared spectrum not related to the ligand. The first two are a well-resolved doublet at 973 and 956 cm^{-1}, and the other three are at 730, 709, and 472 cm^{-1}. The infrared spectral data are displayed in Table I and Fig. 1.

U.v.-vis. spectra.—$Mo_2O_4(dedtc)_2$ exhibited a featureless u.v.-visible spectrum with a single peak at 268 nm ($\epsilon = 3.12 \times 10^4$). For compounds with the core structure, Mo_2O_3S and $Mo_2O_2S_2$, shoulders were exhibited at 370 and 350 nm, as well as peaks at 280 and 250 nm in DMF. The Mo_2OS_3 core exhibited peaks at 397 nm ($\epsilon = 3.37 \times 10^3$) and 260 nm ($\epsilon = 3.85 \times 10^4$ for $Mo_2O_2S_3(dedtc)_2$) while $Mo_2S_4(nbudtc)_2$ exhibits peaks at 441 nm ($\epsilon = 5.20 \times 10^3$) and 293 nm ($\epsilon = 4.33 \times 10^4$).

Electrochemistry.—Initial reduction scans showed all the compounds to be electroactive, but none of them exhibited peaks on an initial oxidation scan. A summary of the electrochemical results is contained in Table II.

Except for $Mo_2O_4(dedtc)_2$ and $Mo_2S_4(nbudtc)_2$, an oxidation peak is exhibited 80-150 mV more anodic than the reduction peak following reversal of the scan direction, *i.e.*, the reductions are quasireversible. Two compounds exhibit this reoxidation peak at scan rates slower than 100 mV/sec and they are $Mo_2O_2S_2(nbudtc)_2$ and $Mo_2O_2S_2(dedtc)_2$. $Mo_2S_4(nbudtc)_2$ behaves reversibly at scan rates of 200 mV/sec while the reduction peak for $Mo_2O_4(dedtc)_2$ seems to be totally irreversible, since there is no reoxidation peak exhibited at any scan rate. The first reduction peak for all the complexes is a one-electron reduction, except for $Mo_2O_4(dedtc)_2$ which is a two-electron reduction as shown by the coulometry and peak height data.

Two compounds exhibited a prominent second reduction peak in the voltammograms; $Mo_2O_2S_2(dedtc)_2$ displays a peak at −1.62V *vs.* SCE while $Mo_2O_2S_2$ (nbudtc)$_2$ displays a peak at −1.67V *vs.* SCE, which is shown to be a two-electron reduction by coulometric and peak-height data. $Mo_2OS_3(dedtc)_2$ has a second reduction peak at −1.72V *vs.* SCE, while Mo_2O_3S (nbudtc)$_2$ has a second reduction peak at −1.78V *vs.* SCE, and $Mo_2OS_3(nbudtc)_2$ has one at −1.75V *vs.* SCE. $Mo_2S_4(nbudtc)_2$ definitely exhibits a second, quasireversible reduction peak at −1.52 V *vs.* SCE but $Mo_2O_4(dedtc)_2$ exhibits no distinct reduction peaks following the one at −1.41V *vs.* SCE.

Coulometry performed at a potential just negative of the first cathodic peak indicated that the compounds are reduced by one electron. There is no evidence of the reverse oxidation peak for any of the complexes and all of the second reduction peaks exhibited by the compounds in the voltammograms prior to coulometry have disappeared. The color of the solutions after reduction by one electron per molecule is dark red, and u.v.-vis. spectra were featureless. Attempts were made, using both lithium amalgam and sodium amalgam, to chemically reduce the compounds on a larger scale in the hope of isolating the reduction product. However, the voltammetry of the chemically reduced product did not reproduce the voltammetry of the electrochemically reduced product. For all the complexes, except $Mo_2O_4(dedtc)_2$, initial anodic scans on the solutions after coulometry yield three peaks, one at +0.09V due to ligand oxidation, and small broad peaks at +0.65 and +0.90V. Coulometry at the potential of the ligand oxidation peak regenerates some of the starting material, while coulometry at +1.00V regenerates up to 60-80% of the starting material.

$Mo_2O_4(dedtc)_2$ is reduced by two electrons. An anodic scan of the reduced solution shows peaks at −0.24, +0.10 (due to ligand), +0.42, and a small broad peak at +0.80V. Coulometry at a potential just positive of the first oxidation peak yields about 25% regeneration of the starting material while oxidation at a potential just positive of the ligand peak yields about 50% regeneration of the starting complex.

The electrochemical data are displayed in Table II and Fig. 2.

Table II. Electrochemical data

Complex	$E_{p,c}$[a]	$E_{p,a}$[a]	n[a]
$Mo_2O_4(dedtc)_2$	−1.41		2
$Mo_2O_3S(nbudtc)_2$	−1.40	−1.30	1

$Mo_2OS_3(dedtc)_2$[b]	−1.00	−0.88	1
$Mo_2OS_3(nbudtc)_2$	−0.98	−0.87	1
$Mo_2S_4(nbudtc)_2$	−0.89	−0.83	1
$Mo_2S_4(nbudtc)_2$[c]	−1.52	−1.44	1

[a] $E_{p,c}$ cathodic peak potential. $E_{p,a}$ anodic peak potential at 200 mV/sec, n is the number of electrons per dimeric molecule after coulometry for the first reduction peak.
[b] Scan rate is 500 mV sec.
[c] Second reversible peak which is observed for $Mo_2S_4(nbudtc)_2$ before coulometry.

Discussion

Infrared spectra.—All the complexes in this study exhibit either C_S or C_{2V} symmetry, and these symmetry groups have been used to predict the number of expected infrared active bands. In all cases two terminal oxygen- or sulfur-molybdenum stretches are predicted to be infrared active, with an additional three or four infrared-active bridge stretches also expected.

$Mo_2O_4(dedtc)_2$ has C_{2V} symmetry, requiring two terminal and three bridge stretches. These are all observed and are in good agreement with those reported by Newton and McDonald (11). There is a lowering of symmetry to C_S in going from the Mo_2O_4 unit to the $Mo_2O_2(\mu\text{-}O)(\mu\text{-}S)$ unit. For this complex four bridge bands are predicted as well as the two terminal stretch bands. The four bridge bands are observed at 711, 513, 460, and 350 cm^{-1}, in good agreement with the results of Newton and McDonald (11). The $Mo_2O_2(\mu\text{-}S)_2$ unit exhibits C_{2V} symmetry, again requiring two terminal stretches and three bridge stretches. Only two bridge stretches are observed, however, the third

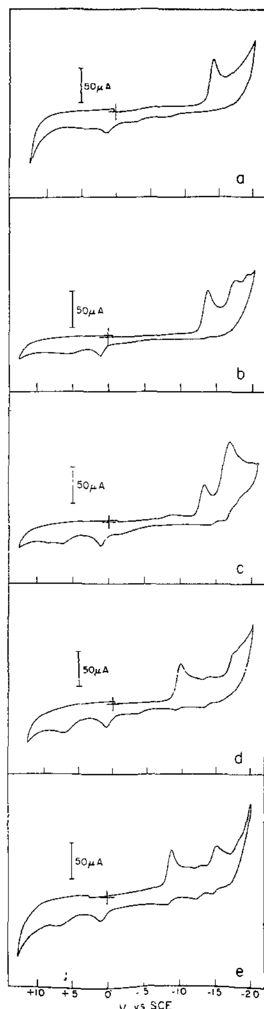

Fig. 2. Cyclic voltammograms at 200 mV/sec of 1 mF solutions of: (a) $Mo_2O_4(dedtc)_2$; (b) $Mo_2O_3S(nbudtc)_2$; (c) $Mo_2O_2S_2(nbudtc)_2$; (d) $Mo_2OS_3(nbudtc)_2$; (e) $Mo_2S_4(nbudtc)_2$.

one possibly coming below 300 cm^{-1} which is the limit of our spectra. The bridge stretches for $Mo_2O_4(dedtc)_2$, appearing at 730, 709, and 472 cm^{-1}, while those for $Mo_2O_2(\mu\text{-}S)_2$ appear at 478 and 338 cm^{-1}. Comparing these to the bridge bands observed for $Mo_2(\mu\text{-}O)(\mu\text{-}S)(nbudtc)_2$, it appears that the 711 and 513 cm^{-1} bands are associated mainly with the oxygen bridge atom, and that the bands at 460 and 350 cm^{-1} are associated mainly with the sulfur bridge atom, again in good agreement with Newton and McDonald (11). In all of the complexes so far the terminal molybdenum-oxygen stretch has been a doublet at approximately 970 and 955 cm^{-1}. The next unit of the series, $MoOS_3$, however, has a new terminal atom as well as a descent in symmetry to C_S. Two terminal stretching bands are required and observed, one at 960 cm^{-1} for the terminal molybdenum oxygen stretch, and one at 540 cm^{-1} for the terminal molybdenum sulfur stretch. Of the four predicted bridge stretches only two are observed, at 470 and 334 cm^{-1}, again presumably because two stretches may be of lower energy than can be observed in a KBr medium. The final complex in the series $Mo_2S_4(nbudtc)_2$ is C_{2V}. The two terminal stretches are represented by a doublet at 549 and 533 cm^{-1}. Only two bridge stretches, at 467 and 335 cm^{-1}, of the three required are observed.

Electrochemistry.—$Mo_2O_4(dedtc)_2$ is reduced by a two-electron process, in agreement with results published previously (2). The reduced species has lost one or more ligand molecules as evidenced by the presence of a ligand oxidation peak in the cyclic voltammograms after coulometry. The peak at +0.42V corresponds to the oxidation of $Mo^{IV}O(dedtc)_2$ (2). This implies that at least some of the binuclear molybdenum core has decomposed into a monomeric species which has then combined with free ligand to form $Mo^{IV}O(dedtc)_2$. This accounts for only 10% of the molybdenum in solution, however. Two possibilities exist for the oxidation peak at −0.24V. Either it is the oxidation of $[Mo^{IV}{}_2O_4(dedtc)_2]^{2-}$ to the starting material $Mo_2O_4(dedtc)_2$, or it is the oxidation of a species due to the decomposition of reduced $Mo_2O_4(dedtc)_2$. In this case after the decomposition product is oxidized it must somehow regenerate starting material, possibly by reaction with free ligand in solution. Oxidation at a potential positive of the ligand oxidation peak produces tetraalkylthiuramdisulfide (15). Regeneration of starting material after ligand oxidation is probably due to oxidative addition of the tetraalkylthiuramdisulfide to the major reduction product of $Mo_2O_4(dedtc)_2$.

Substitution of one sulfur into the Mo_2O_4 core causes a significant change in the electrochemical behavior. Although the reduction potential is not changed dramatically, the first reduction peak is only a one-electron process and it has become quasireversible. Introduction of the second sulfur atom into the bridge position causes a further change in the electrochemistry. The one-electron reduction product of this $Mo_2O_2S_2$ core is the most stable reduction product of all the complexes studied. Even at 50 mV/sec, it still exhibits a quasireversible reoxidation peak. The complex also appears to be capable of a further two-electron irreversible reduction, probably to a molybdenum (IV)-molybdenum (III) dimer which then decomposes. When these complexes are reduced by controlled potential coulometry, both the first and second reduction peaks disappear and a voltammogram for the resulting solution has three oxidation peaks in a positive scan.

Introduction of a sulfur into a terminal position of the binuclear molecules causes a further anodic shift in the potential of the first reduction peak to −0.99V. There is a second reduction peak observed at −1.75V which is also observed for $Mo_2O_3S(nbudtc)_2$, which is the size of the initial reduction peak. Because both of these compounds decompose at a much faster rate than the $Mo_2O_2S_2$ compounds, this peak at −1.75V may be a two-electron reduction of $Mo_2O_3S(dtc)_2^-$ and $Mo_2OS_3(dtc)^-$.

$Mo_2S_4(nbudtc)_2$ exhibits the most positive first-reduction potential and in this case it is reversible at a scan rate of 200 mV/sec. Also a second quasireversible one-electron reduction is observed at −1.52V (see Table II). In this case the first peak probably is due to reduction to $(Mo^VMo^{IV}S_4(nbudtc)_2)^-$ and the second peak is due to reduction to the dianion $(Mo^{IV}{}_2S_4(nbudtc)_2)^{-2}$. Coulometry after the first reduction peak causes the disappearance of both the first and second reduction peaks. A voltammogram on the resulting solution exhibits three oxidation peaks on an anodic scan which are discussed below.

On all complexes with sulfur substituted into the Mo_2O_4 core, coulometry after the first reduction peak yields a solution which is dark red. For the solutions containing the reduction products coulometry at a potential just positive of the ligand oxidation yields about 50% regeneration of the starting material. This probably is due to oxidative addition of tetraalkylthiuramdisulfide to the major reduction product. Since coulometry at +1.00V can regenerate 60-80% of the starting material, the peaks at +0.65 and +0.90V may be minor products of the decomposition which when oxidized produce starting material.

The sulfur-substituted core units do not appear to be broken up into monomeric units because the initial reduction does not exhibit catalytic behavior, even during coulometry, and no signal is observed by EPR. Further substantiation is provided by the fact that the reaction of coulometrically reduced product yields

only the original starting material and not a mixture of products.

U.V.-vis. spectra.—Perkins and Brown (16, 17) have shown that the $Mo_2O_2S_2$ core has more delocalization than the Mo_2O_4 core as well as a smaller formal positive charge on the molybdenum. This has been attributed to sulfur "d" orbitals allowing more delocalization in the $Mo_2O_2S_2$ unit than can be achieved in Mo_2O_4. The electrochemical data substantiate these results because $Mo_2O_2S_2(dedtc)_2$ is more easily reduced than $Mo_2O_4(dedtc)_2$. Introduction of additional sulfur into the terminal position appears to reduce the energy of the lowest unoccupied molecular orbital still further. This is consistent with the anodic shift in reduction potential of the Mo_2S_4 and Mo_2OS_3 cores with respect to the $Mo_2O_2S_2$ core [44 and 34 mV, respectively (see Table I]. Also the energy of the first electronic transition is lowered for those compounds that exhibit distinct peaks in the visual region specifically 397 nm for Mo_2OS_3 and 441 nm for Mo_2S_4.

The chromatographic elution of the compounds also is in accord with the reduction of the formal charge on the molybdenum upon replacement of oxygen by sulfur. The compound which elutes first is $Mo_2S_4(dtc)_2$, followed by Mo_2OS_3, $Mo_2O_2S_2$, and Mo_2O_3S. Apparently the more oxygens present the more polar the compound, with even the bridge oxygens having a significant effect.

Conclusions

The data in this paper indicate that there is little coupling between molybdenum terminal atom stretches and molybdenum bridge atom stretches as demonstrated by the constancy of the frequency of the infrared bands. Even when the bridge atoms are different, the bridge stretches appear almost independent of each other as can be seen by comparison of the infrared bands for $Mo_2O_4(dedtc)_2$, $Mo_2O_3S(nbudtc)_2$, $Mo_2O_2S_2(nbudtc)_2$, and $Mo_2O_2S_2(dedtc)_2$. These observations make it possible to determine both the number and the position of different atoms in binuclear molybdenum (V) compounds. The presence of two bridging sulfur atoms between the molybdenum (V) ions appear to be a requirement (at least in this system) for fast electron transfer with no subsequent decomposition of the complex. Additionally it is clear that binuclear molybdenum (V) complexes in an environment consisting mainly of sulfur donors can undergo reversible one-electron transfer reactions and that completely surrounding the molybdenum atoms with sulfur donors allows a binuclear molecule to undergo two consecutive one-electron transfers without appreciable decomposition. We conclude that an oxygen ligand field most likely could not support fast enzymatic redox reactions, and that the ligand field around the molybdenum atoms in redox enzymes, therefore most likely contains all sulfur donors.

Secondary Batteries: 1952-1977

A. J. Salkind,* D. T. Ferrell, Jr., and A. J. Hedges

ESB Technology Company, Yardley, Pennsylvania 19067

In the 25 years since the Society's 50th anniversary review, there have been many changes in the designs, manufacturing processes, and markets for secondary batteries. Some developments which were promising and disclosed in the Golden anniversary review in 1952 have been successful, while others failed. This paper will review briefly the major changes that have occurred and current research and development efforts that may lead to future progress in secondary batteries.

Review of the Industry

The secondary battery industry has grown greatly in the past 25 years; however, it is still dominated by the automotive starting, lighting, and ignition (SLI) battery. A major impetus for this growth has been the increase in popularity of internal combustion engine-powered automobiles and trucks. This is effectively illustrated in Table I which shows for the United States and for the free market countries of the world the growth in motor vehicle registrations and SLI battery shipments. These figures, in millions of units, are indicated in lines A and B. The dollar values of all major secondary battery shipments are shown in the subsequent lines. The data in Table I are based on the best available information from various sources; however, in some cases, the data had to be interpolated or estimated. The data are useful to illustrate trends and there are several interesting observations based on Table I. SLI battery shipment growth closely parallels the growth in vehicle registration and seems to have leveled off at about one battery annually for 2.2 to 2.4 vehicles registered. There has been a significant development since 1952 of consumer (nonautomotive) applications for secondary batteries; principally, small maintenance-free units for hand and garden tools, personal care products, calculators, and lighting devices. While inflation has contributed significantly to the dollar growth, normalization to constant dollars would still show substantial increase in shipments as evidenced by the SLI unit growth. Perhaps surprising to some is the indication that worldwide, alkaline secondary batteries have maintained a rather steady 8 to 10% of the total secondary battery business. This relatively constant market share, even with the development of new applications, reflects the limiting effect of the higher cost of the alkaline systems on market penetration.

Product and Process Changes, 1952-1977

From an over-all viewpoint, the general thrusts of the secondary battery industry can be summarized as follows:

Research—The research thrust has been largely devoted to the application of modern scientific methods and instrumentation for a better understanding of the reaction mechanisms which control performance and life.

Development—The development effort has been aimed at improvements in performance per unit weight and volume, reduction of maintenance, improved charge acceptance, and use of new materials.

Manufacturing—New and improved processes and equipment have permitted increased productivity through mechanization and automation. Recently, much attention has been paid to changing manufactur-

ing processing to minimize personnel and facility environmental problems.

The extent of what has been achieved is best understood by considering each of the secondary battery systems in production today.

Lead-acid system.—The published research activities in the lead-acid system up to 1970 are covered in detail in an excellent review article by Burbank, Simon, and Willihnganz (1). They point out a number of challenging questions that remain unanswered and to which the answers, unfortunately, are still being sought today. Auger, SEM, x-ray microprobe, and other modern techniques are beginning to delineate definite areas of attack for resolution of some of the questions; however, today many important questions remain unanswered. Typically, but in no way complete, the questions are:

1. The exact nature of the interface between positive active material and the grid, and the influence of grid composition, additives, etc., on the interface and the changes which occur when cycling.
2. How to improve active material utilization beyond the 25-35% typically experienced in commercial batteries and maintain or increase cycle life.
3. How to maintain particle morphology in positive active material to maximize performance and life.
4. The mechanism of expander action in the negative active material.

While these and other questions still occupy the scientist today, the last 25 years have seen significant changes in the product. Basically, the products described in the Society's 1952 review articles still exist today; however, most of them have undergone dramatic changes which are in some cases apparent and in other cases perhaps invisible but nevertheless equally as impressive.

Starting, lighting, ignition.—The 1952 review article by Willihnganz (2) indicates the typical SLI battery was 6V with a 20 hr discharge rating of about 100 A-hr. The average battery weighed about 40 lb (18 kg) and had a density of about 138 lb/ft³ (2.2 kg/liter). The battery was made in a hard rubber container with a soft asphalt cover seal. The grid alloys were high antimonial alloys (above 6% Sb), specific gravity of the electrolyte was 1.285, and there was a 50% or better chance that the separators were treated wood. The charger in the car of the period was a rotating generator which did not charge the battery below an engine rpm that was considerably above the idle speed.

A comparison of the features of the typical 1952 SLI battery with the ones found in the 1977 product is illustrated in Table II. Significant is the change during the period from rubber container and cover to battery cases that usually consist of thermoplastic polypropylene. Use of this material permits the container and cover to be heat-sealed together with a permanently bonded seam, eliminating most of the problems associated with the former asphalt compound sealing method.

Table II. SLI batteries: 1952-1977

Component or characteristic	1952	1977
Container	Rubber	Polypropylene
Cover	Rubber	Polypropylene
Seal	Asphalt	Heat-sealed
Intercell connector	Over cover	Thru-partition
Voltage	6V	12V
Specific gravity	1.285	1.260
Separators	Wood Treated paper Microporous rubber	Treated paper Microporous rubber Microporous plastic
Grid alloys	>6% Sb	<4% Sb or calcium
Weight	40 lb (18 kg)	35 lb (15 kg)
Density	138 lb/ft³ (2.2 kg/liter)	118 lb/ft³ (1.9 kg/liter)
Watering interval	7-30 days	6 months to several years
Charger	Generator	Alternator
Capacity (20 hr rate)	100 A-hr	48 A-hr*

* The 20 hr discharge rating which was in use in 1952 is no longer used for SLI batteries and the value shown for 1977 is for comparative purposes.

The use of polypropylene also allows the introduction of distinctive colors into SLI packaging to make the one-time, so-called "small black box" a far more attractive product and adding a new dimension to its marketability. The change, too, from exposed over-the-cover intercell connectors to concealed through-partition connectors, as well as the repositioning of terminal posts from the top to the side of the battery in late models of the period, also enhanced product appearance while reducing safety hazards that previously existed.

Perhaps most significant is the recent (1974) introduction of the maintenance-free (MF) SLI battery which theoretically requires no addition of water throughout its service life. Water loss in standard SLI batteries generally is the result of electrolysis during charging. Manufacturers of MF/SLI batteries have practically eliminated water loss by changes in the alloys used in the grids.

One approach is the use of a lead-calcium alloy grid (usually below 0.08% calcium), which not only results in lower self-discharge rates but also in an increase in the hydrogen evolution potential of the negative electrode. As a consequence, at the usual voltage regulator setting less current is available to decompose the water content of the electrolyte.

Water loss in standard SLI batteries also can be directly related to the buildup of antimony deposits on the sponge lead of negative plates during operation. Another approach to the MF/SLI battery is a reduction of the antimony content of grid alloys. Lowering the antimony content from 4-6% to 2-3% has cut the water loss drastically.

Another major development adopted nearly universally throughout the SLI battery industry during the 25-year period is the "dry charge" process. Basically, this involves the use of negative plates in which, after formation, the water content is reduced to a minimum without a corresponding increase in the oxygen content of the plates.

Since batteries can be stored for an extensive period in a dry charge condition without detrimental effect and then easily activated by the addition of standard electrolyte to the cells followed by a brief charging period, the process greatly simplifies the shipping and, in particular, the warehousing of SLI batteries.

The recently developed MF/SLI battery, however, now offers economic as well as practical advantage over the dry charge variety. Because of its much lower self-discharge rate, the MF/SLI battery can be shipped as well as stored in a wet, activated state for a relatively long time. This eliminates the cost of the dry charge process during manufacture and also the chore of adding acid electrolyte at the point of sale, an often unpleasant job not without danger.

One of the developments associated with the introduction of the MF/SLI battery has been the investigation of techniques for producing grids other than by the traditional casting method. At least one manufacturer is in large scale production using grids manufactured by expanding thin, continuously cast, lead-calcium alloy sheet. Techniques such as this offer the opportunity for continuous production of plates and significant reduction in the weight of the grid.

Industrial.—Lead-acid industrial storage batteries, which basically are larger, with stronger, better quality construction than SLI batteries, fall into three general application categories. Comprising about 55% of the industrial lead-acid market are the motive power types that propel material handling lift trucks, tractors, and motorized hand trucks; mining railcars, tractors, and specialized types of self-propelled mining vehi-

cles; industrial power sweepers and floor scrubbers; some electric street vans, buses, and autos (mostly experimental); and to a limited extent, golf carts and personnel carriers (the majority in service use automotive-type batteries).

Highlighting technological improvements in motive power batteries during the period is the development of improved sealing methods for cell covers and containers. Traditional in the industry has been the use of hard rubber cell covers and containers sealed together with an asphalt-like compound. Since this asphalt seal could be adversely affected by hot and cold ambient temperatures, internal cell stresses during battery operation, and physical shocks to which the vehicle was subjected, the leakage of acid electrolyte, with subsequent damage to both battery and vehicle, was not uncommon.

The first step in improvement of the sealing method came with the introduction of an epoxy sealant in the mid-1960's which proved to be an effective means of bonding cell cover and container together. It was, however, a time-consuming process in manufacturing. This was followed in the early 1970's by introduction of the faster, far more simplified (from the standpoint of manufacturing) heat bonded seal made possible by the use of thermoplastic polypropylene cell covers and containers.

The period also saw the phasing out of slotted plastic tubes in tubular-positive plate battery types. These have been replaced entirely by tubes made of woven glass fiber and synthetic polymer which are stronger, less costly, and offer greater porosity.

Another major application for lead-acid industrial batteries (approximately 30% of the market) is in stationary service: telecommunications systems; electric utilities, operating circuit breakers, switches, alarms, and other power distribution controls; emergency lighting, and fire, security, and similar standby power systems; and uninterruptible power systems (UPS) which have come into wide use in the past decade, providing precise a-c power to back up real-time computers and other critical processing and control equipment. Additionally, railroads use stationary-type lead-acid batteries for signals and track controls, in passenger car power systems for air conditioning and lighting, and to supplement axle-generator systems on caboose cars for lighting and communications. During the period, the use of tempered glass jars for stationary battery cell containers virtually ceased. These have been replaced by lighter, more durable and less costly units made from polystyrene, polycarbonate, and similar materials.

Another major application category for lead-acid industrial batteries is that of diesel locomotive engine starting. These rail diesel cranking batteries and similar units used for various engine starting chores in industry account for approximately 7% of the lead-acid industrial market. The so-called "unitized" container was brought out during the period for diesel locomotive batteries. Normally, such a battery consists of 32 cells in eight 4-cell hard rubber monoblock containers. The unitized container, however, holds 16 cells so that only two of these are required to make up a battery, greatly reducing handling and maintenance work. When first introduced in the late 1960's the unitized container consisted of a steel tray, usually with a plastic insulation coating, with hard rubber cell containers. This was followed by polypropylene trays and tray covers as well as cell covers and containers, the latter being heat-sealed.

Also in the railroad field, the period witnessed the debut of the lead-acid rapid transit battery to replace the waning nickel-iron-alkaline battery (see below) which at one time was used virtually 100% on rapid transit lines in the United States. To withstand the rigors of this service, the lead-acid rapid transit battery, introduced in 1975, utilizes a container made of polycarbonate and incorporates other features for additional physical strength.

Not to be overlooked is a miscellaneous group of lead-acid industrial batteries that include those for such applications as submarine service, miners' cap lamps, and reserve power in marine service. The demand for submarine batteries declined during the period with the diminishing use of diesel-battery boats; batteries, however, with smaller numbers of cells still are a necessity in nuclear submarines for reactor start-up and emergency power.

Lead-acid industrial batteries are available with three different positive plate configurations: tubular and pasted flat plate designs used in motive power, stationary and diesel cranking batteries, and Planté designs, characterized by active material areas that are formed from pure lead, found primarily in stationary-type batteries. Flat plate batteries additionally are classified as to whether the grids are cast from lead-antimony or lead-calcium alloys. The latter, however, are used mostly in stationary industrial batteries because of the inability of calcium alloy grids to withstand the rigors of the deep discharging associated with motive power and cranking service. It should be pointed out that the trend in recent years has been away from Planté-type batteries in stationary service, because of their higher initial cost, in favor of calcium-alloy units. Small maintenance-free lead-calcium alloy batteries have been available since the mid-1960's for emergency lighting and similar applications.

All of the above lead-acid batteries, including the SLI types, are prismatic in structure with flat, parallel plates. A new configuration, the "round cell," was developed for the telephone industry around the beginning of the present decade. Designed for a goal of trouble-free long life, this unique battery design features grids cast of pure lead in a shallow, conical shape which are stacked as finished positive and negative plates one above the other vertically in a cylindrical cell container.

Consumer.—Nonexistent in the marketplace 25 years ago, lead-acid consumer or "sealed" batteries have grown in United States sales from less than $1 million in 1960 to more than $10 million by the end of 1977. The worldwide sales of sealed lead-acid batteries reached a total exceeding $18 million by that year.

Sealed lead-acid batteries come in two general configurations, prismatically shaped units with parallel plate construction, ranging in capacity from 1 to 30 A-hr, and cylindrically shaped units, similar in physical appearance to several of the more popular dry cell types, having spirally wound grids and capacities ranging from 1 to 5 A-hr.

Although sealed lead-acid batteries can be operated in any position without danger of leakage, the term sealed is really a misnomer. The electrolyte is either in a gel form or as an aqueous solution absorbed in the plates and in highly porous separators. The batteries also make use of chargers that incorporate voltage-limiting circuitry to reduce water decomposition to a minimum. Too, the batteries have a one-way venting system that releases any gases that might possibly form only when a predetermined pressure is exceeded.

The grids employed in sealed lead-acid batteries generally are of lead-calcium alloy. Some cylindrical types, though, use grids of pure lead and have an internal design that successfully contributes to the recombination of any gases which might evolve. Sealed lead-acid batteries are used as power sources in emergency lighting equipment, cordless television sets, portable instruments and tools, and alarm and security systems.

In many respects the electrolyte retaining (ER) and charge retaining (CR) types of batteries reviewed in 1952 were the predecessors to today's sealed lead-acid batteries. Interestingly, usage of both ER and CR types declined during most of the last 25 years; however, in recent years there has been a resurgence of sales of the CR type for use with solar photovoltaic energy conversion systems.

Nickel-cadmium system.—Although nickel-cadmium batteries represent only slightly over 7% of the value of all secondary batteries produced in the noncommunist world, they comprise, nevertheless, a significant market. Nickel-cadmium battery sales in 1977 totaled more than $300 million or approximately 82% of the total value of all alkaline secondary batteries produced. The total world figure for nickel-cadmium batteries probably is as high as $600 million since they are known to be manufactured in large quantities in China (People's Republic), the U.S.S.R., and in other communist areas from which no confirming market data are presently obtainable.

Nickel-cadmium secondary batteries are available in a wide variety of electrode and cell design types as well as sizes. Most familiar, since its introduction at the beginning of the century, is the nickel-cadmium couple with its active materials contained in thin perforated, nickel-plated steel pockets. A modification of this is the use of perforated, nickel-plated steel tubes (actually the Edison-type positive with active materials consisting of metallic nickel flake and nickel hydrate) with standard pocket negatives.

Another electrode design is the sintered type that makes use of metal wire screens or perforated metal sheets which have sintered metal powder applied to the surfaces. Still another technique is to combine the active material with a conductive substance, such as carbon, and a plastic to serve as a binder. This mixture, after being heated or made fluid by addition of a solvent, is pressed into or pasted on a conductive grid. A more recent development is to make the plates by electrodepositing the active material on a conductive sheet or metallic fiber.

In addition to the variety of electrode structures, nickel-cadmium batteries are made with so-called "flooded and vented" cells and with "starved and sealed" cells, the latter containing only enough electrolyte to maintain the plates and separators in a saturated condition. Besides the conventional steel cell containers, nickel-cadmium batteries also are made with plastic containers, consisting of such materials as polyvinyl chloride, nylon polyamide, polystyrene, polyethylene, and polypropylene. Metal cell containers generally are used for batteries subject to the internal stresses of deep cycling operations or mechanical abuse.

In addition to prismatic cell configurations, nickel-cadmium batteries also are available in some of the familiar dry cell configurations, such as "AA," "C," and "D" shapes and sizes. These are sealed types having sintered plates that are spirally wound for insertion in the cylindrical containers. Nickel-cadmium batteries, additionally, are made in a button cell configuration to power cameras, calculators, and other electronic devices. These are generally made with electrodes consisting of pressed powder pellets.

The nickel-cadmium system has undergone three distinct periods in its evolution. The first period covered roughly the first 50 years of the present century and is the era of the nickel-cadmium battery as developed by Waldemar Jungner and his associates. This battery is constructed nearly entirely of nickel-plated steel with pocket-type plates. It is used primarily in heavy duty industrial applications such as motive power in material handling trucks, mining vehicles, and street delivery vans (the lattter two mostly in Europe), and for railway signals, emergency lighting, standby power, and diesel engine starting.

The second period of evolution began about 1950 with the development of sintered plates which resulted in significant increases in power delivery capability and specific energy content. Sintered nickel-cadmium batteries are used in aircraft engine starting, communications, and electronics.

The early 1960's ushered in the third period of nickel-cadmium evolution with introduction of the sealed cell. This is made possible by using a surplus of uncharged active material in the negative electrodes. This eliminates hydrogen gassing and permits controlled recombination of oxygen evolving from the positive electrodes. Additionally, the amount of electrolyte in sealed cells generally is lower than that which can normally be absorbed in the electrodes and separators.

Sealed nickel-cadmium batteries, which can be charged or discharged in any position, are used for portable power tools and appliances, emergency equipment, and small-engine starting, such as the recently introduced alternator-battery equipped, gasoline-powered lawnmower for example. The sintered, sealed type is by far the most widely produced nickel-cadmium battery at the present time.

Nickel-iron-alkaline systems.—From its introduction in 1908 until the cessation of its United States production in 1974, the nickel-iron-alkaline battery waged a losing contest in the marketplace, particularly whenever it came into direct competition with the industrial lead-acid system. Conceived originally by its inventor, Thomas A. Edison, as a power source for the early, but short-lived electric auto, the nickel-iron battery eventually saw service in material handling trucks, mining tractors, and other underground work vehicles, railway car lighting and air conditioning, rapid transit cars, and in stationary applications such as emergency lighting, circuit breaker control, and railway signal systems.

The nickel-iron battery, with major cell components of nickel-plated steel, is extremely durable in construction and exhibits basically stable thermodynamic reactions, both of which contribute to its long life. However, the nickel-iron system's lower emf (1.37 vpc) and lower specific energy (<0.8 W-hr/in.^{3}) along with its high cost of manufacture, in comparison with the lead-acid system, led to its ultimate decline in usage. As a result of the depressed market for the nickl-iron battery, the sole United States supplier recently terminated its production. The battery still is being manufactured on a limited basis elsewhere, notably in West Germany, and very possibly in the U.S.S.R. and other communist nations from which accurate information is not available.

Recent interest in electric vehicles has led to investigations of new approaches to the manufacture of nickel-iron batteries in the United States and in Europe. These approaches differ sigificantly from the Edison design and are based on sintering, pressing or thin-foil techniques for producing electrodes. Still experimental these designs offer promise of good performance and life; however, the cost of manufacturing may preclude their commercialization.

Silver-zinc and silver-cadmium systems.—The silver-zinc battery is noted for its high energy density, in fact, the highest attainable of any secondary system in use today. It also has a very low internal resistance (matched only by the sintered nickel-cadmium couple) with a very flat voltage discharge characteristic which is desirable in many high-rate applications. Among its shortcomings is the fact that the silver-zinc system has a somewhat limited cycle life, capable normally of less than 200 cycles of discharge and charge with an overall activated life of no more than two years. Most significant among its shortcomings, however, is the high cost of the silver.

Since the United States government removed controls on silver bullion prices in the late 1960's, silver has risen steadily from $1.35/troy ounce to as high as $5/troy ounce. Silver has since leveled off at about $4.50/troy ounce. This high cost of the active silver material, in addition to the high cost of manufacture associated with silver-zinc batteries, because of the preponderance of manual operations resulting from low production demand, has limited application of this system almost entirely to military and aerospace programs where the emphasis is on the performance rather than the economic factor. These include space satellites, missile power, submarine and torpedo pro-

pulsion, and some types of portable military communications.

Silver-zinc cells generally are prismatic in construction with flat parallel plates, using a restricted amount of electrolyte. They also generally make use of a pressure-type vent which permits the escape of gases but prevents continuous entry of the atmosphere.

Silver-zinc cells have silver electrodes with grids or substrates made exclusively of silver in the form of expanded sheet, wire mesh, or perforated silver sheet or, in some cases, made of silver-plated copper. The silver oxide active material is applied as a slurry pasting of fine particles followed by a sintering operation, by pressing the dry material into a grid structure and then sintering, or by incorporating a plastic bonding material with the silver powder particles, pressing this to the grid structure, heating to fire off the plastic, and then sintering.

Zinc electrodes utilize a substrate of either expanded metal, screen or perforated metal either of silver, which is preferred, or of silver-plated copper. The zinc oxide active material is applied as a dry powder and pressed, as a slurry paste which is then dried and pressed, or by a electroforming process in which zinc is deposited from solution.

Typical silver-zinc cells make use of a regenerated cellulose separator (unplasticized cellophane) which, while sufficient, has not been entirely successful. The cellophane is hydrated by the caustic electrolyte and expands. This, in turn, exerts a small internal pressure that helps to restrain the zinc anode material making it less available for dissolution. Since it is hydrated, the cellophane separator also is susceptible to oxidation and degradation which can lead to short circuits between positive and negative electrodes, often made worse by dissolved silver in the electrolyte forming conductive paths through the separators or by penetration of zinc nodules or dendrites.

Several approaches have been used in efforts to extend the life of silver-zinc separators. One is the use of a regenerated cellulose which includes a fibrous material that adds to the strength of the separator. Another is to impregnate the cellulose separator material with a silver salt which helps it to resist degradation.

The requirement of the aerospace program in the late 1960's for a heat sterilizable silver-zinc cell led to the development of an improved separator material. It was found that cellophane would degrade drastically with the application of sterilization temperatures of about 250°C. The new organic-inorganic separator, taken from fuel cell technology, consists of an asbestos mat base impregnated on one side with an organic resin and on the other side with a metal oxide such as zirconia or magnesium oxide. This separator is able to resist the high heat of sterilization and offers good zinc stopping characteristics. It does, however, have a relatively high resistance per layer that limits the system to medium or low rates of discharge. The separator also is expensive to manufacture which further adds to the high cost of the silver-zinc system.

Silver-cadmium.—Historically, the silver-cadmium battery goes back to the beginning of the century when Jungner conceived such a battery to power early electric autos. He soon dropped the idea because of the high cost of silver. The system lay dormant until the late 1950's when interest was revived in the silver-cadmium system as an energy source for appliances and power tools and for scientific satellites. Two factors made the silver-cadmium system promising for these applications: its relatively high energy density and its nonmagnetic property. The latter was particularly a requirement for the satellites which were constructed of nonmagnetic components since they carried magnetometers to measure radiation and the effects of magnetic fields of energetic particles. Also, sealed batteries were required by the satellites. Today the system has a very limited use in special applications which are not expected to increase.

Silver-iron.—Recently the silver-iron secondary system has been introduced in a special telecommunications application. As with the other silver systems, the cost and life considerations are expected to limit this system to very special applications (3).

New systems—The energy crisis that became painfully apparent to the public toward the mid-1970's has spurred an unparalleled interest in the development of new, more advanced secondary battery systems. The quest centers, in particular, on systems for electric road vehicles and electric utility load leveling.

The ubiquitous lead-acid system, despite its commercial dominance and its present (and, quite possibly, foreseeable) state of development, is not ideally suited to these applications. Lead-acid batteries have a low energy density that restricts the operating range of electric road vehicles; present lead-acid designs are too costly to be economically applied to load leveling.

Nevertheless, since the lead-acid system is the only commercially available system which comes close to meeting the load leveling and electric vehicle requirements, there are major development programs based on novel approaches to improving the performance and costs of the lead-acid system for these applications. Thus the potential of the lead-acid battery for these systems cannot be ignored in view of the problem of the new systems discussed below.

Advanced systems currently under study fall into two general groups. One consists of ambient temperature systems that make use of active materials which are stable to water, such as iron, zinc, and nickel, and can be utilized with aqueous electrolytes. The other group includes systems which use alkali metals as active materials that require a nonaqueous electrolyte for room temperature operation, either based on organic solvents or molten salt or ceramic electrolytes, operating at temperatures ranging from 200° to 600°C.

Included among the aqueous electrolyte types are the nickel-zinc, nickel-iron, zinc-air (oxygen), iron-air (oxygen), nickel-hydrogen, silver-hydrogen, and zinc-chlorine systems. The status of development of these systems has been described in some detail in many recent publications. Strictly speaking, the nickel-zinc and nickel-iron systems are not "new" systems; and the recent development programs involve new approaches to resolving old problems. There are many development problems which remain to be resolved before these systems can become significant commercial products.

The metal-air systems are limited in life as a result of the deterioration of the air electrode on the charging part of the cycle. The metal-hydrogen systems seem likely to be limited to space applications until a reliable, low cost method is established for storing hydrogen at low pressure.

The most promising of the aqueous systems for electric vehicles is the nickel-zinc system; however, the tendency of the zinc electrode to densify and to form dendrites has not been solved in the conventional approaches to cell design. A novel approach to cell design which eliminates both the separator and zinc electrode problems by vibrating the zinc electrode during the charging part of the cycle has recently been described (4). The cost of any of the systems using nickel electrodes will depend markedly on developing a high performance electrode with a high ratio of active material to nickel support.

Another aqueous system of promise is the zinc-chlorine system in which the chlorine is stored as a solid in chlorine hydrate (5). Because of the need for refrigeration, separation, and circulation systems, this system appears to be of most interest in large installations such as load leveling and perhaps the larger electric vehicle systems.

The nonaqueous secondary battery systems under development are those which operate at room temperature using an electrolyte dissolved in an organic sol-

vent or which operate at elevated temperatures and use either molten salt or ceramic electrolytes.

The room temperature systems appear likely to be limited to low rate applications in view of the low conductivity of the electrolyte and do not appear to be candidates for either electric vehicles or load leveling. There are several systems under investigation using lithium anodes (6, 7).

The high temperature systems receiving significant development are the lithium-molten salt-metal sulfide system which operates at 450°C (8), the sodium-ceramic electrolyte-sulfur system which operates at 300°-350°C (9), and the sodium ceramic-molten salt-metal chloride system operating at 200°C (10). If problems of seals, life, and scale-up can be resolved and low cost manufacturing methods are developed, these systems can be candidates for the electric vehicle and load-leveling applications.

Conclusion

While the next 25 years are likely to see the introduction of one or more advanced secondary battery systems, the lead-acid battery seems likely to remain the dominant system for most, if not all, of the period.

ABSTRACT

Properties of Corning thin-film SnO_2 electrodes in contact with 0.005-0.5*M* solutions of sulfuric acid in aqueous solvents containing 0-50 v/o CH_3CN were characterized. Schottky-Mott plots gave flatband potentials (E_{FB}) in the range 0-0.2V *vs.* SCE and charge carrier densities in the range 4-7 $\times$ 10^{20} cm^{-3} in 0.01*M* sulfuric acid, independent of solvent composition. Standard reduction potentials *vs.* SCE in 0.01*M* acid at room temperature were calculated from equilibrium compositions to be −0.04V for $TH^+/\cdot TH_2^+$, 0.33V for $\cdot TH_2^+/TH_4^{2+}$ and 0.14V for TH^+/TH_4^{2+} in water and −0.06V for $TH^+/\cdot TH_2^+$, 0.28V for $\cdot TH_2^+/TH_4^{2+}$ and 0.11V for TH^+/TH_4^{2+} in 50 v/v/o aq. CH_3CN. Voltammetric data show that establishment of protonic equilibrium is rapid compared with cathodic reduction of TH^+ at SnO_2 in water and in 50 v/o aq. CH_3CN. In contrast, protonic equilibration between the two electron-transfer steps is slow for thionine-1-sulfonic acid. Voltammetric data show that reduction of TH^+ and oxidation of TH_4^{2+} are kinetically controlled at both SnO_2 and Pt electrodes with reversibility greater at platinum than at SnO_2. Reversibility is slightly reduced by addition of CH_3CN to the solvent. Rectification (inhibition of oxidation of TH_4^{2+}) is not severe enough to prevent the use of SnO_2 as a selective anode but may reduce efficiency of photogalvanic conversion. Weak but persistent adsorption of TH^+ on SnO_2 activates photogalvanic conversion. Adsorption of TH_4^{2+} varied considerably from sample to sample of SnO_2 and was strong in some cases. Both oxidation and reduction of the Fe^{+3}/Fe^{+2} couple are much less reversible at SnO_2 than at Pt. Rectification (inhibition of oxidation of Fe^{2+}) is pronounced. Both oxidation and reduction on SnO_2 become more reversible with increasing fraction of CH_3CN; the major effect is enhancement of oxidation of Fe^{2+} but even with 50 v/o CH_3CN the couple is much less reversible than at Pt. Implications of the data with respect to efficiency of totally illuminated thin-layer iron-thionine photogalvanic cells are discussed.

A totally illuminated, thin layer iron-thionine photogalvanic cell has been described in recent publications (1-3). It differs from many other photoelectrochemical cells, which are essentially solid-liquid junction photovoltaic cells (4), because light is absorbed by solution species, initiating a photoredox reaction which produces high energy products. The energy conversion process is reversible, in the sense that the electrode reactions reform the photoredox reactants. Thus, the cell can be operated continuously.

The photogalvanic cell anode is a large bandgap n-type semiconductor with a high charge carrier density, which is transparent to the excitation radiation. Tin oxide is commonly used (1-3, 5), although highly reduced TiO_2 thin films have also proved suitable (6). As discussed in an earlier paper (1), the two photogalvanic cell couples discharge at the semiconductor electrode at widely differing rates. Consequently, under illumination a photopotential is established with respect to a metallic cathode.

Key words: photogalvanic, iron-thionine, electrodic, SnO_2.

Other means of establishing a photopotential difference between photogalvanic cell electrodes may be used. The earliest method (7, 8) involved illuminating only one electrode. The photopotential was thus a result of the difference in electrochemical potentials of the redox components at the two electrodes. A theoretical analysis for this type of cell has recently appeared (9). Gomer (10) has suggested that efficient operation of the cell should be achieved if the cell contains a membrane impermeable to one of the photochemically produced species, *e.g.*, allowing transfer of small inorganic cations but not of large dye molecules. Efficiency should be improved if a second membrane of opposite permeability is also used. However, the development of cells with suitable membranes has not been reported in the literature. Indeed, as Gomer points out, such an approach presents formidable technical problems. The selective semiconductor anode, while not without problems, is an effective and simple way to establish a potential difference in the iron-thionine cell. To date, it has produced the best energy

conversion efficiencies (1, 2) and also allows the design of simple, area-type cells.

Many aspects of thin layer cell performance can be related to the unique properties of the thin film semiconductor anode. The present paper, therefore, examines the electrodic phenomena in more detail. The electrode reactions of the thionine/leucothionine couple at SnO_2 are described. Additionally, the adsorption of dye species at the SnO_2 anode and consequent activation of thin layer cells is reported for the first time. The importance of solvent effects on the electrode reactions of thionine/leucothionine and Fe^{+2}/Fe^{+3} is discussed, and it is shown that when mixtures of acetonitrile and water are used as solvent, anode selectivity is highly dependent on the proportion of acetonitrile present in the photogalvanic cell electrolyte. Another publication currently in press reports the relationship of photostationary state solution composition and electrode phenomena to detailed current and potential measurements for iron-thionine cells and half-cells.

Experimental

Thionine was obtained as thionine acetate (99% purity, MCB) and was used without further purification or was converted to the free base form from the chloride salt and purified by recrystallization. Thionine-1-sulfonic acid was synthesized using the method of Havemann *et al.* (11). The dye content of solutions was analyzed spectroscopically. Reagent grade $FeSO_4 \cdot 7H_2O$ and $Fe_2(SO_4)_3 \cdot 9H_2O$ were used without further purification, and acetonitrile was u.v. grade, distilled in glass (Burdick and Jackson Laboratories).

Tin oxide (SnO_2) thin film electrodes on low alkali glass substrates were obtained from Corning Glass Works. These were cut to approximately 1×2 cm for electrochemical measurements. The active electrode area (≤ 1 cm^2) was obtained by masking off the remainder of the SnO_2 film with silicone rubber or pressure-fit Teflon masks. Electrical connections were made to the masked area of the electrode using conductive silver paint. Before using the SnO_2 electrodes to investigate electrode processes in the iron-thionine cell, several of them were characterized as follows. The flatband potential and charge carrier density were determined from capacitance *vs.* potential data, which were used to construct Schottky-Mott plots ($1/C^2$ *vs.* E) (12). The best straight-line fit was obtained by computer. The flatband potentials (E_{FB}) of the SnO_2 electrodes in $10^{-2}M$ H_2SO_4 varied from sample to sample, but were all near -0.1 to $-0.2V$ *vs.* SCE. This is, as expected, somewhat negative of E_{FB} values reported for SnO_2 with lower charge carrier densities (12), but positive of values recently obtained (13) for highly conducting SnO_2 films similar to those used in the present study. Charge carrier densities were mostly in the range $4\text{-}7 \times 10^{20}$ cm^{-3}. The values obtained were not greatly affected by addition of acetonitrile to the electrolyte.

The counterelectrode was a large platinum mesh and the reference electrode was a commercial saturated calomel electrode, against which all potentials are reported. The SCE was separated from the working solution compartment by a short salt bridge.

Current *vs.* potential measurements were made using a PAR Model 170 electrochemistry system. The internal resistance of the SnO_2 electrodes caused some distortion of voltammetric waves, giving erroneous results at the higher scan rates used. Accordingly, the feedback circuitry of Model 170 was used to compensate for ohmic losses where necessary in the data reported below. Photogalvanic cell short-circuit currents and open-circuit voltages were measured using the apparatus and methods described previously (1, 2). The photogalvanic cell assembly and solutions have also been described (1, 2).

Reactions of Thionine/Leucothionine at SnO_2

The equilibrium potential of the thionine/leucothionine (TH^+/TH_4^{+2}) [1] couple depends on solution pH. In acid media, the two-step reduction of thionine to leucothionine proceeds through a one-electron intermediate (semithionine, $\cdot TH_2^+$) and hydrogen ions are incorporated into the molecule. In neat water as solvent the equilibrium electrode potential fits Eq. [1] (14)

$$E_T = 0.321 - 0.09\,pH + 0.03 \log \frac{[TH^+]}{[TH_4^{+2}]} \quad [1]$$

The pH dependence has been explained in terms of the acid-base equilibria which obtain. We have found (14a) that in 50 v/v percent (v/v/o) acetonitrile/water in the pH range 1-3, $E^\circ = 0.321$ is replaced in Eq. [1] by $E^\circ = 0.29$.

The potential for each reaction step ($TH^+/\cdot TH_2^+$ and $\cdot TH_2^+/TH_4^{+2}$) can be determined if the equilibrium concentrations of TH^+, $\cdot TH_2^+$, and TH_4^{+2} are known. The case in which Fe^{+2}/Fe^{+3} is not present is considered to eliminate alternate pathways of converting one dye form to another via redox reactions with Fe^{+2}/Fe^{+3}. The equilibrium concentrations are obtained by considering the disproportionation of semithionine and the reverse process. At equilibrium, therefore

$$[\cdot TH_2^+]^2[H^+] = \frac{k_{-d}}{2k_d}[TH^+][TH_4^{+2}] \quad [2]$$

where k_d is the rate constant for disproportionation and k_{-d} is the rate constant for the reverse reaction. In aqueous sulfuric acid at $pH = 2.0$ the rate constants are $k_d = 1.0 \times 10^9$ M^{-1} sec^{-1} and $k_{-d}/[H^+] = 1.2 \pm 0.4 \times 10^3$ M^{-1} sec^{-1} (14a). In 50 v/v/o acetonitrile/water with $0.01M$ sulfuric acid, the solvent composition of recently reported photogalvanic cells (1, 2), we have found $k_d = 1.4 \times 10^8$ M^{-1} sec^{-1} and $k_{-d}/[H^+] = 7.5 \pm 2.5 \times 10^2$ M^{-1} sec^{-1} (10a). Inserting these values in Eq. [2] for an initial dye concentration of $10^{-3}M$ and 50% bleaching, the concentrations of the three dye species in water at pH 2 are $[TH_4^{2+}] = 5 \times 10^{-4}M$, $[\cdot TH_2^+] = 3.9 \times 10^{-7}M$, and $[TH_4^{2+}] = 5 \times 10^{-4}M$ while in 50 v/v/o acetonitrile/water at pH 2 $[TH^+] = 5 \times 10^{-4}M$, $[\cdot TH_2^+] = 8.2 \times 10^{-7}M$, and $[TH_4^{2+}] = 5 \times 10^{-4}M$. Thus almost all of the dye exists in either the totally oxidized or totally reduced forms.

The potentials for each of the reaction steps are

$$E_1' = E_1^{\circ\prime} + \frac{RT}{F} \ln \frac{[TH^+][H^+]}{[\cdot TH_2^+]} \quad [3]$$

$$E_2' = E_2^{\circ\prime} + \frac{RT}{F} \ln \frac{[\cdot TH_2^+][H^+]^2}{[TH_4^{+2}]} \quad [4]$$

where E_1' is the pH-dependent equilibrium potential of the first reaction step, etc. Combining [3] and [4] gives

$$E_1^{\circ\prime} - E_2^{\circ\prime} = (E_1' - E_2') + \frac{RT}{F} \ln \frac{[\cdot TH_2^+]^2[H^+]}{[TH^+][TH_4^{+2}]} \quad [5]$$

and at equilibrium, $E_1' = E_2'$. A similar treatment was used by Memming and Möllers for the quinone/hydroquinone system (15). Inserting the calculated concentrations of TH^+, $\cdot TH_2^+$, and TH_4^{2+} into Eq. [5] for the equilibrium condition at pH 2 gives $E_2^{\circ\prime} - E_1^{\circ\prime} = 0.37V$ in water and $E_2^{\circ\prime} - E_1^{\circ\prime} = 0.33V$ in 50 v/v/o acetonitrile/water. The value in water is substantially larger than an earlier estimate of 0.14V based on then-available solution kinetic data (16). The potential $E_T^{\circ\prime}$ for the TH^+/TH_4^+ couple is the average of the potentials for each step, $E_T^{\circ\prime} = (E_1^{\circ\prime} + E_2^{\circ\prime})/2$. Table I

[1] The symbol TH_3^+ has been used for leucothionine in earlier work (2) to represent a general protonated form of leucothionine in acidic media. However, in the following discussion it is necessary to consider that form of leucothionine predominating in the pH range 0-3.

summarizes values of $E_T°'$, $E_1°'$, and $E_2°'$ calculated from the data at *p*H 2. These potentials are compared to E_{FB} for SnO_2 in Fig. 1.

Protons are incorporated into the molecule during reduction, *i.e.*, the heterogeneous redox reactions involve electron transfers coupled with chemical steps. The protonations represent possible limitations in electrode reaction rate. For an ECE mechanism with a slow chemical step, for example, the function $i_{p,c}/v^{1/2}$, in which $i_{p,c}$ is the cathodic peak current and v is the potential sweep rate, decreases with increasing sweep rate (17). Table II shows that $i_{p,c}/v^{1/2}$ for thionine in acid media at SnO_2 increases with sweep rate, for reasons which are discussed below. Also the distinctive morphology of cyclic sweeps for E-slow C-E mechanisms with highly positive $\Delta E°$ was never observed, even when sweeps were extended >0.6V positive of the anodic peak. Rapid establishment of proton equilibria is also found in similar systems, *e.g.*, methylene blue (18) and quinone/hydroquinone (19).

Thus, the electrochemistry of thionine/leucothionine in protic solvents is, as expected, similar to that reported for methylene blue (18). In both cases, the reaction proceeds through an intermediate, with $E_2°'$ more positive than $E_1°'$. Under the conditions studied, $\Delta E°' = (E_2°' - E_1°')$ is considerably higher for thionine than for methylene blue (18) and hence the intermediate concentration is much lower. The proton exchanges are very rapid, so that the process can be described in terms of the E-E mechanism (20). The electron transfers for methylene blue at Pt are reversible. However, the reduction of thionine and the oxidation of leucothionine at Pt and SnO_2 electrodes are kinetically controlled. The anodic and cathodic waves are broader than reversible waves and there is a steady positive shift of $E_{p,a}$ and a negative shift of $E_{p,c}$ as the sweep rate is increased from 2 to 500 mV sec^{-1}.

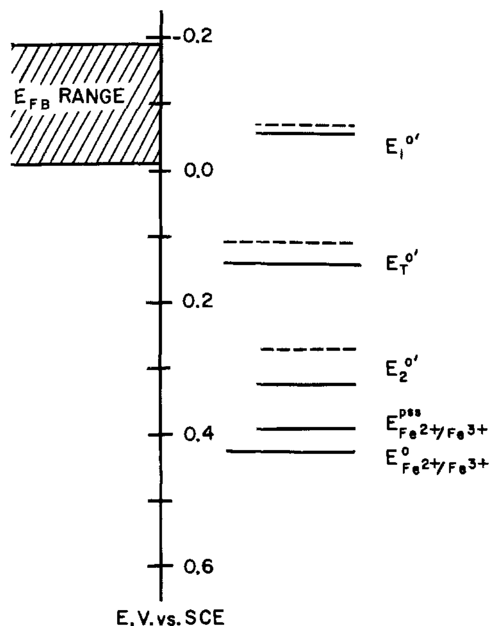

Fig. 1. Electron energy levels at the SnO_2 anode in the iron-thionine photogalvanic cell at *p*H 2. Solid lines, aqueous H_2SO_4; dashed lines, H_2SO_4, 50 v/v/o water/acetonitrile.

The voltammetry of thionine/leucothionine was examined in H_2SO_4 concentrations ranging from 5×10^{-3} to 0.5*M*, with CH_3CN present from 0 to 50 volume percent (v/o). In all cases, behavior was similar to that described above. The observed effect of changing [H_2SO_4] was a shift of the entire current-potential curve to more negative potentials with increasing *p*H, as predicted by Eq. [1]. The effects of acetonitrile are discussed below.

The thionine/leucothionine electrode reactions are less reversible at SnO_2 than at platinum, as seen from the greater shifts of $E_{p,c}$ and $E_{p,a}$ as a function of sweep rate (Table III). The potentials of dye couple reduction and oxidation waves (Fig. 2) *vs.* E_{FB} for SnO_2 are such that both processes are subject to tunneling limitations (21). Some degree of rectification is expected at SnO_2, because reduced states of the dye lie further below E_{FB} than oxidized states and, hence, overlap less favorably with the conduction band. The greater shift of $E_{p,a}$ than $E_{p,c}$ in Table III shows that the oxidation process is indeed more strongly affected by SnO_2. Since the anode reaction in the iron-thionine thin layer cell is leucothionine oxidation at SnO_2, the fact that rectification is not severe is critical to successful operation of the device. Ideally, a better match of the dye couple to the semiconductor conduction band would result in greater reversibility and the elimination of a possible efficiency loss at the photogalvanic cell anode.

The most efficient iron-thionine cells have used an aqueous sulfuric acid electrolyte with up to 50% acetonitrile by volume (1-2). Accordingly, cyclic potential sweeps were performed in aqueous H_2SO_4 containing 0, 20, and 50% acetonitrile to determine its effect on the reactions of thionine/leucothionine at SnO_2. A slight decrease in reversibility was noted as the fraction of acetonitrile was increased (Fig. 2). To determine whether the decrease in reversibility was perhaps caused by a negative E_{FB} shift associated with the presence of acetonitrile, E_{FB} was determined for SnO_2 electrodes in aqueous sulfuric acid solutions containing 0 and 50% CH_3CN. No significant shift in E_{FB} was seen. Thus, the decreased reversibility is apparently caused by the influence of CH_3CN on the properties of the dye couple.

The behavior of thionine-1-sulfonic acid illustrates the effect of poor dye reaction characteristics at SnO_2

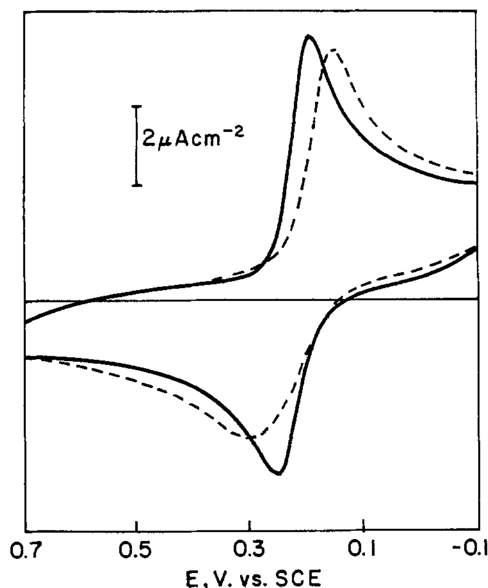

Fig. 2. Voltammetry of thionine acetate ($2.6 \times 10^{-5}M$) at SnO_2($n_D = 7.2 \times 10^{20}$ cm^{-3}, $E_{FB} = -0.16V$ vs. SCE). Sweep rate = 50 mV sec^{-1}. Solid line, aqueous 0.5M H_2SO_4; dashed line, 0.5M H_2SO_4, 50 v/v/o water/acetonitrile.

on thin layer cell performance. Although a previous investigation established that photochemical redox activity was similar to thionine (22), photogalvanic cells containing the sulfonic acid derivative produced much lower response. In identical aqueous cells ($10^{-2}M$ H_2SO_4 electrolyte), thionine produced open-circuit voltages of ~140 mV, while thionine-1-sulfonic acid gave V_{oc} ~75 mV. The difference was more pronounced in mixed solvent cells ($10^{-2}M$ H_2SO_4, 50% CH_3CN) in which V_{oc} ~150 mV for thionine and V_{oc} ~20 mV for thionine-1-sulfonic acid. Correspondingly lower short-circuit currents were also obtained with the sulfonic acid derivative in both cases. The explanation for reduced photogalvanic response is obtained from the cyclic voltammetry of thionine-1-sulfonic acid at SnO_2 (Fig. 3). The oxidation of leucothionine-1-sulfonic acid occurs via two well-separated waves, the second of which is very positive. This behavior is more pronounced in the presence of 50% CH_3CN, corresponding to the very low open-circuit voltages obtained in the mixed solvent photogalvanic cells. Peak potential shifts *vs.* sweep rate for the cathodic and first anodic waves were slightly greater than those of thionine/leucothionine. However, the positive shift of the second anodic peak was much greater, increasing as the fraction of CH_3CN in the electrolyte increased. The quantity $i_{p,c}/v^{1/2}$ decreased as the sweep rate increased, characteristic of a slow chemical step between charge transfer. Thionine-1-sulfonic acid is thus a poor candidate for the thin layer photogalvanic cell because of activation overpotential limitations.

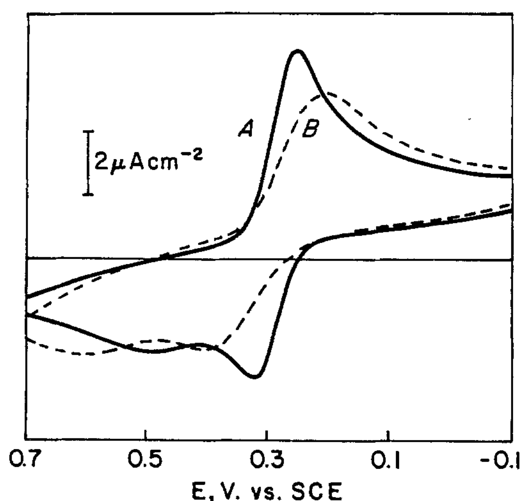

Fig. 3. Voltammetry of thionine-1-sulfonic acid ($1.1 \times 10^{-5}M$) at SnO_2. Sweep rate = 50 mV sec^{-1}. Solid line, aqueous 0.5M H_2SO_4; dashed line, 0.5M H_2SO_4, 50 v/v/o water/acetonitrile.

Reactions of Fe^{+2}/Fe^{+3} at SnO_2 in Photogalvanic Cell Electrolytes

The potentials of Fe^{+2}/Fe^{+3} in various acid electrolytes were measured by Miller (7) as part of an investigation of the limitations of the iron-thionine cell photopotential. Miller reported $E° = 0.426V$ *vs.* SCE for Fe^{+2}/Fe^{+3} in aqueous sulfuric acid. The anion concentration was reported to be not critical.

In the thin layer photogalvanic cell, the initial concentrations of Fe^{+2} and Fe^{+3} are typically 10^{-2} and $5 \times 10^{-4}M$, respectively. In a cell containing 1 mmole thionine which is 50% bleached under illumination, the photostationary state concentrations are $[Fe^{+2}]_{pss} = 9 \times 10^{-3}M$ and $[Fe^{+3}]_{pss} = 1.5 \times 10^{-3}M$. Using these concentrations, the photostationary state Fe^{+2}/Fe^{+3} potential is $E^{pss} = 0.39V$ *vs.* SCE (10a). This is very close to the 0.385V observed at the thin layer cell cathode in the photostationary state (1). A more rigorous study of the relationship between the photostationary state and half-cell potentials in the iron-thionine cell will be reported in a subsequent publication (23). The equilibrium and photostationary state potentials for Fe^{+2}/Fe^{+3} are compared to the dye couple potentials and E_{FB} for SnO_2 in Fig. 1.

A high degree of rectification for the Fe^{+2}/Fe^{+3} reactions at SnO_2 was found by Memming and Möllers (24). This was particularly true at lower SnO_2 charge carrier densities where the oxidation of Fe^{+2} was suppressed due to low tunneling probability. Raising the charge carrier density caused an increase in anodic current as the space charge layer became thinner and hence more penetrable to tunneling electrons. However, even at the highest charge carrier densities investigated (~5×10^{19} cm^{-3}) rectification was significant.

The present work with SnO_2 electrodes with high charge carrier density has shown that similar behavior is observed even at $n_D > 5 \times 10^{20}$ cm^{-3}. This result is consistent with the fact that tunneling probability changes less rapidly with n_D as the charge carrier density becomes large (21). Limiting anodic currents were eventually obtained in slow positive potential scans, but the current rise with departure from equilibrium was much more drawn out than for the cathodic process (Fig. 4, curve A). The effect of acetonitrile on the Fe^{+2}/Fe^{+3} reactions at SnO_2 is much greater than on thionine/leucothionine, and oppositely directed. A marked increase in reversibility was observed as the fraction of CH_3CN in the solvent was raised from 0 to 50% in 10% increments. Results for solutions containing 0, 20, and 40% CH_3CN are presented in Fig. 4. Both the oxidation and reduction became more reversible, but the major effect was a strong enhancement of the Fe^{+2} oxidation. A curious feature which emerged from the current-potential curves at SnO_2 electrodes with high charge carrier density was the structure of the anodic wave when CH_3CN was present. A well-defined reproducible current peak was observed to shift to more negative potentials with increasing acetonitrile content. Peak potentials are listed in Table IV. No attempt was made to explain the presence of current peaks or the wave structure in the limiting current region.

The cyclic voltammetry of Fe^{+2}/Fe^{+3} (Fig. 5) for solutions containing 0 and 50% CH_3CN also shows enhanced Fe^{+2} oxidation in the latter solvent, as seen from the large negative shift of $E_{p,a}$ and the large increase in anodic current. In addition, the ratio of

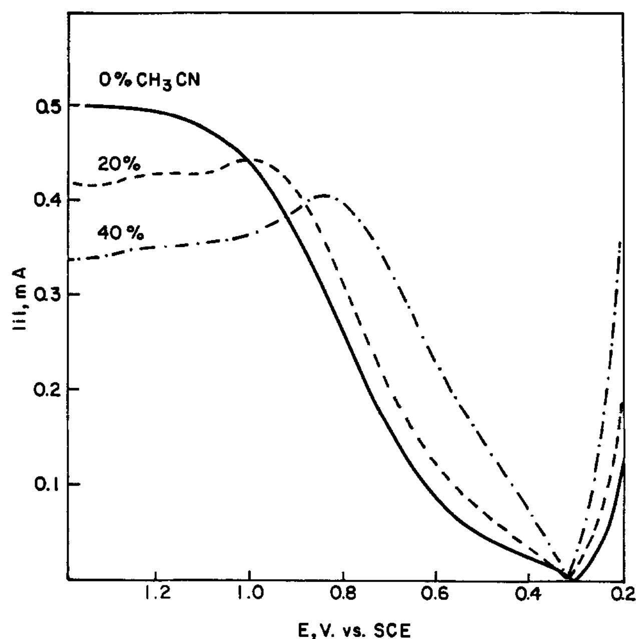

Fig. 4. Effect of fraction of acetonitrile in solvent on current vs. potential behavior of Fe^{2+}/Fe^{3+} at SnO_2. $[Fe^{+2}] = [Fe^{+3}] = 0.05M$; $[H_2SO_4] = 0.5M$; 0, 20, and 40 v/v/o acetonitrile/water. Sweep rate = 5 mV sec^{-1}.

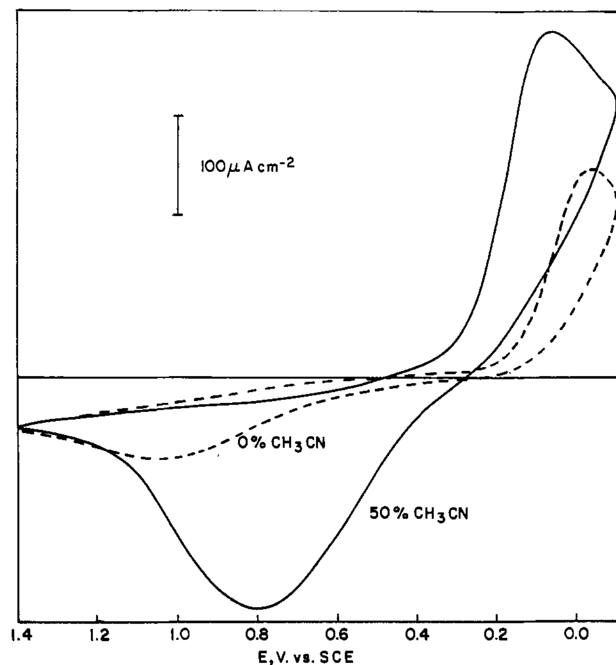

Fig. 5. Voltammetry of Fe^{2+}/Fe^{3+} at SnO_2, showing effect of fraction of acetonitrile in solvent. $[Fe^{2+}] = [Fe^{3+}] = 10^{-3}M$; $[H_2SO_4] = 0.5M$. SnO_2: $n_D = 7.4 \times 10^{20}$ cm^{-3}, $E_{FB} = -0.07V$ vs. SCE.

anodic to cathodic peak current increased as the fraction of CH_3CN in the solvent was raised. As with the slow scan current-potential curves, a smaller effect was also noted for the reduction wave. Even in 50% CH_3CN, however, the couple is much less reversible than at platinum electrodes, hence, considerable anode selectivity in the thin layer cell is still preserved.

In an earlier study, Miller (7) reported electrode activation in the iron-thionine cell, *i.e.*, prior exposure of platinum electrodes to thionine solution, increased photovoltages from those electrodes. Furthermore, the activation persisted even after the electrodes were washed and dried several times. Miller proposed that a layer of dye adsorbed on the electrode either enhanced leucothionine oxidation or suppressed the reaction of Fe^{+3}. A detailed study of dye adsorption was not made, however. It was also reported that activated electrodes were not able to generate a photopotential when exposed to an acidic solution of Fe^{+2} reducing agent.

Table IV. Peak potentials for Fe^{+2} oxidation at SnO_2

% CH_3CN	Potential of current peak (V *vs.* SCE)
0	No peak
10	1.08*
20	1.01
30	0.90
40	0.84
50	0.79

* Current was erratic near peak.
$[Fe^{+2}] = [Fe^{+3}] = 0.05M$, $[H_2SO_4] = 0.5M$.
SnO_2: $E_{FB} = -0.26V$, $n_D = 9.2 \times 10^{20}$ cm^{-3}, $A = 0.60$ cm^2.

Similar activation has been observed at SnO_2 electrodes in the iron-thionine thin layer cell. The possibility of markedly increasing the concentration of electroactive material in the vicinity of the anode, and thereby the efficiency of the thin layer cell, was pursued through a more detailed study of the adsorption of dye species at SnO_2. Evidence for the weak adsorption of thionine at SnO_2 is obtained from the increase of $i_{p,c}/v^{1/2}$ with sweep rate shown in Table II. This is consistent with thionine adsorption with a low free energy and its reduction in the same potential range as thionine from the bulk solution. The peak current function ($\alpha i_{p,c}/v^{1/2}$) is thus larger than predicted from diffusion limitations and increases with sweep rate due to the larger fraction of adsorbed dye participating in the reaction (25). The quantity of adsorbed thionine at equal bulk concentrations increases as the fraction of CH_3CN in the electrolyte is decreased, as shown in Table II by the greater increase in $i_{p,c}/v^{1/2}$. This is expected, because the addition of acetonitrile increases thionine solubility considerably.

Strong leucothionine adsorption occurred at some SnO_2 electrodes. A cathodic prewave (often poorly defined) was observed on negative potential sweeps (Fig. 6). A corresponding rise in anodic current positive of the principal oxidation wave was also observed on the reverse sweep. Adsorption peaks were greatly affected by the particular SnO_2 electrode used. Electrodes with nearly identical E_{FB} and n_D frequently showed large differences in leucothionine adsorption. The wide variation in leucothionine adsorption under thin layer cell conditions may explain the nearly two-

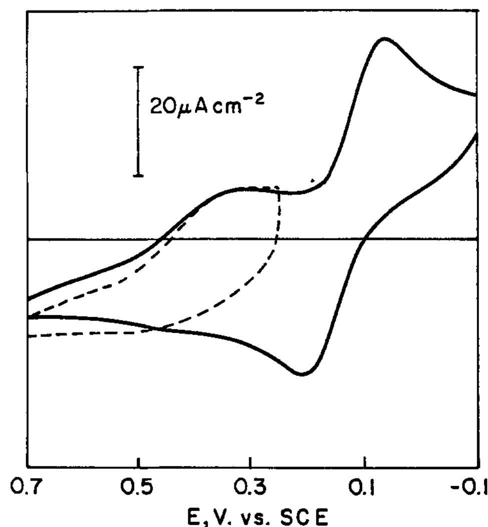

Fig. 6. Voltammetry of thionine acetate ($1.1 \times 10^{-4}M$) at SnO_2, showing strong adsorption of leucothionine. Sweep rate = 100 mV sec^{-1}. $5 \times 10^{-3}M$ H_2SO_4, 50 v/v/o water/acetonitrile.

fold variation in short-circuit current obtained from seemingly similar SnO_2 anodes (2).

Miller's observation (7) that platinum electrode activation persists is also true of SnO_2 electrodes. The adsorbed dye is very resistant to removal by water and a large portion survives washing with organic solvents such as isopropanol. This is shown in Fig. 7. After prolonged exposure to thionine solution, an SnO_2 electrode showed an increase in reversibility and peak current (curves A and B) which is characteristically obtained when a new hydrophobic SnO_2 electrode is wet by the solution (26). Part of the peak current increase can likely be ascribed to thionine adsorption. In addition, a prewave indicating strong leucothionine adsorption was obtained. The electrode was then removed from the solution, washed with isopropanol, and replaced in solution. Taken immediately following re-insertion, curve C shows that much of the adsorbed dye was retained. In a similar experiment, the washed electrode was inserted into electrolyte containing no thionine. At slow sweep rates, small reduction and oxidation waves of retained adsorbed dye were clearly seen.

The contribution of adsorbed dye to iron-thionine cell photogalvanic activity was substantiated in the following way. Three thin layer cells were constructed with new (previously unused) SnO_2 anodes. Initial measurements of V_{oc} and I_{sc} were made, exposing the SnO_2 electrodes to the photogalvanic cell solution for the minimum time necessary for steady-state outputs. The SnO_2 anodes were then removed and cleaned. One electrode was soaked in the photogalvanic solution, while a second was soaked in a similar solution containing no dye. The third electrode was soaked in distilled water. After 24 hr, the electrodes were dried and used to obtain new measurements of V_{oc} and I_{sc}. Electrodes 2 and 3 showed small ($<3\%$) increases in V_{oc} and I_{sc}, presumably due to increased wetting of the SnO_2 surface. Electrode 1, soaked in dye solution, showed much greater enhancement of photogalvanic activity. A 10% increase in V_{oc} and a 20% increase in I_{sc} were obtained.

In a second experiment, a tin oxide anode was used to make a preliminary measurement of V_{oc} and I_{sc} after prolonged exposure to photogalvanic solution (Table V). The cell was then taken apart, cleaned thoroughly with distilled water, and blotted dry. The cell was reassembled and filled with a photogalvanic blank solution, containing all components except thionine. As Table V shows, a photogalvanic response was obtained and furthermore, persisted over the course of the measurement (~5 min). The cell was then drained, dried, and filled again with blank solution. A smaller but still noticeable photogalvanic response was measured. These data are consistent with the retention of adsorbed thionine at SnO_2 reported above. Miller's observation that activated Pt electrodes were unable to generate a photogalvanic response by themselves is thus not supported by results with SnO_2 electrodes.

In several of the highest output thin layer cells, the photovoltage was established rapidly but I_{sc} rose slowly for 1-2 min or more, frequently to double the initial value. The current rise is much too slow to be ascribed to photochemical kinetics (27) and is not likely due to establishment of steady-state concentration gradients by diffusion, because most cells reached steady-state within a few seconds. It is possible that the current rise is caused by slow formation of the adsorbed dye layer at certain SnO_2 electrodes, as discussed above.

A film of adsorbed dye provides charge transfer species localized at the anode, which can be photochemically reduced and electrochemically oxidized without appreciable bulk motion. In addition, a more subtle effect is probably also present. For anodic band bending, the transition probability for tunneling depends not only on the band bending and energy positions of the donor electrons, but also on electronic coupling between the electrode surface and redox species. Thus, tunneling currents for the dye species should be enhanced relative to those for Fe^{+2}/Fe^{+3}. This factor operates in addition to those causes of selectivity which have been discussed previously (1, 2).

The use of aqueous acetonitrile in the thin layer cell may appear questionable on the basis of the results presented here. However, addition of acetonitrile prevents formation of photoinactive thionine dimers and increases the solubility of thionine, and hence the number of charge carriers in solution can be greatly increased. Enhancement of the efficiency of photochemical reduction of TH^+ by Fe^{+2} in bulk solution is also observed (27). The net result of using solvents containing CH_3CN is an increased cell efficiency arising almost entirely from greater current flow.

The most obvious factor determining the reversibility of the iron-thionine cell redox processes at SnO_2 is $E_{FB} - E_{redox}$. The redox potential difference between the dye and Fe^{+2}/Fe^{+3} couples is not large, however, and other redox couple pairs with similar potential separations and relationships to E_{FB} show smaller differences in reversibility at SnO_2 electrodes, even when n_D is much lower. The couple $Fe(CN)_6^{-4}$/$Fe(CN)_6^{-3}$, for example, has a redox potential nearly equal to Fe^{+2}/Fe^{+3} in sulfuric acid but is considerably more reversible at SnO_2 (24). The contribution of the large Fe^{+2}/Fe^{+3} rearrangement energy to the SnO_2 anode selectivity has been pointed out in previous publications (1, 2).

The Stability of the Secondary Lithium Electrode in Tetrahydrofuran-Based Electrolytes

V. R. Koch* and J. H. Young

EIC Corporation, Newton, Massachusetts 02158

ABSTRACT

The stability of tetrahydrofuran (THF)-based electrolytes toward bulk and electroplated Li has been assessed. Those electrolytes incorporating $LiAsF_6$ were least reactive to Li at elevated temperature and gave the best cycling efficiencies. These efficiencies could be further improved by aging the electrolyte at 71°C and by the addition of O_2 or N_2. Conversely, CO_2 degraded the performance of the secondary Li electrode. Small quantities of Na^+ and the variation of inert metal substrate had little, if any, effect on cycling efficiencies. Preelectrolyzing the electrolyte improved the cycling characteristics initially, but lengthy preelectrolysis resulted in electrolyte degradation. A recontact phenomenon, whereby previously isolated Li is recouped in subsequent cycles, was noted. The intervention of films is proposed to account for these observations.

Tetrahydrofuran (THF) is an aprotic cyclic ether with a variety of physical and chemical properties which favor its use in a secondary Li battery. It has, for example, a wide liquid range (−108° to +65°C at 1 atm), and low viscosity (0.461 cp at 25°C). It forms conductive solutions with Li salts, and THF itself is expected to manifest low chemical reactivity to reducing environments. With respect to the Li electrode, this last feature is of critical importance.

Aliphatic cyclic ethers like THF are very resistant to ring opening. The energy of the C—O bond is on the order of 85-91 kcal/mole, similar to that of an sp^3 C—C bond (1). While THF is routinely used as an inert solvent for dissolving metal reductions employing Li or Na (2) and reductions with $LiAlH_4$ (3), electrolytes prepared from it are known to anodically polymerize (4) and react with Li foil at elevated temperatures (5). In the latter instance, it was suggested that electrolyte reactions with Li were initiated by impurities.

The importance of eliminating (or at least minimizing) solvent impurities has been considered by Butler and co-workers (6). They determined that 1 ppm H_2O in 1 ml of solvent led to a 1000Å oxide film on 1 cm^2 of a clean Li surface; and in dimethylsulfoxide (DMSO),

Li_2O appears to promote solvent reduction. Work in these laboratories with methyl acetate (MA) (7) and propylene carbonate (PC) (8, 9) has established that the cycling efficiency and open-circuit stability of the Li electrode is intimately dependent on the kinds and quantities of reactive contaminants present. Usually this reaction leads to formation of a surface film which protects the metal from further attack (10). Such films confer practical stability in a number of primary batteries. With a secondary battery, the consequence of this filming reaction is more serious: If Li is not plated smoothly, the rate of filming will be enhanced, and the effects will be very damaging. Individual Li grains can become encapsulated by (insulating) film. This "encapsulated" Li cannot be discharged. Subsequently, Li tends to plate at places where there is no such encapsulated material. This causes dendritic growth, which enhances further encapsulation, and speeds up ultimate failure.

In this paper, we assess the stability of the Li electrode in THF-based electrolytes under a variety of static and dynamic experiments. Static tests involved the incubation of Li foil with electrolytes at 71°C. Dynamic conditions were achieved by galvanostatically cycling Li to and from an inert substrate at 25°C. The effects of various supporting electrolytes, purification procedures, metal substrates, and gaseous additives on the cycling efficiency of the Li electrode are also explored herein.

Experimental

General.—All purification procedures and the electrochemical experiments themselves were conducted at room temperature under an Ar atmosphere in a Vacuum/Atmospheres Corporation dry box equipped with a Model He-493 Dri-Train. The dry box atmosphere was continuously recirculated through a column containing molecular sieves and an activated Cu gettering material (BASF catalyst R3-11) which scavenged moisture and oxygen. The quality of this atmosphere was such that an exposed 25W light bulb filament burned for 3 days on line voltage. This is qualitatively indicative of O_2 concentrations of from 1-5 ppm (11).

Ultraviolet spectra were recorded with a Perkin-Elmer 124D spectrophotometer. Sodium analyses were carried out on a Perkin-Elmer Model 460 atomic absorption spectrophotometer.

Materials.—Tetrahydrofuran (THF) (Burdick and Jackson, distilled-in-glass), lithium hexafluoroarsenate ($LiAsF_6$) (U.S. Steel Agri-Chemicals, electrochemical grade), and lithium tetrafluoroborate ($LiBF_4$) (Foote Mineral Company) were used as received. Lithium perchlorate ($LiClO_4$) (Alfa, anhydrous) was dried *in vacuo* for 2 hr at 230°C prior to use. Lithium foil (15 mil) was obtained from Foote Mineral Company, sealed under Ar.

Ar (99.99%), CO_2 (bone dry, 99.8%), N_2 (99.999%), and O_2 (99.99%) were obtained in lecture bottles from Matheson Gas Products.

Activated neutral alumina (Fisher, Brockman Activity 1) and molecular sieves (Linde, 4Å) were used as received and exposed only to the dry box atmosphere. Approximately 1g desiccant per 5 ml of electrolyte was used in each purification procedure. The first 10% eluting through a column was always discarded.

Electrolyte preparation and storage.—All electrolytes were prepared with cooling (<0°C) to minimize possible decomposition. The following abbreviations are used to represent purification procedures: A, solvent through alumina, then the Li salt added in the cold; S, solvent through molecular sieves, then the Li salt added in the cold; APA, A followed by preelectrolysis, then passage through a thin plug of alumina to remove Li fines.

Storage tests were conducted in 16 × 100 mm culture tubes (Corning C9826) equipped with Teflon-lined screw caps. Lithium foil, 5.0 × 6.35 cm, was spiral wound after which 8 ml of electrolyte was added to the tube, yielding an area/volume ratio of 8 cm^{-1}. The outer surface of Li was scratched with a glass rod and immediately immersed in the electrolyte. This insured that a source of fresh Li was available to the electrolyte at the outset of the experiment. The Li was maintained below the surface of the electrolyte by weighting it with a 2 cm length of 6 mm diam glass rod. Teflon tape was wrapped around the culture tube threads prior to capping to insure a tight seal. These tubes were stored in a Blue M bacteriological incubator thermostated at 71° ± 2°C. The average rate of weight loss from this system was found to be 3.9 mg/day over a 30-day period.

Criteria for Li-electrolyte reaction were twofold: visual signs of corrosion on the Li ribbon, and coloration of the electrolyte was noted by comparison with a tube containing fresh electrolyte. In all cases, electrolyte stored in the absence of Li remained clear and colorless over the 30-day storage period.

Electrolyte aging was accomplished at 71°C in the culture tubes described previously. The Li, of course, was omitted during storage.

Cells and electrodes.—Glass rectangular cells (10 × 40 × 60 mm, Vitro Dynamics) were used for the galvanostatic plating and stripping of Li, as shown in Fig. 1. Spacers and tops were machined from polypropylene stock. The working electrode was a 5.5 cm × 3.8 cm × 5 mil strip cut from Ni 200 sheet (Roblinger). A Ni wire lead was spot-welded to the strip. The surface of the working electrode was cleaned by treatment with methanol followed by acetone. The degreased surface was then treated with dilute HCl, rinsed with twice distilled H_2O, and dried. This procedure was also employed for other substrate metals; Al, Cd, Cu, Fe, Nb, Mo, and Zr (Alfa-Ventron); cold-rolled steel, and stainless steel (Roblinger). With the exception of a 9 cm area, the rest of the electrode was masked with Teflon tape. The Teflon was bonded to the Ni substrate by pressing the assemblage at 16,000 psig on a Carver hydraulic press for 3-4 min between plates heated to 100°C. The counterelectrode was fabricated from 15 mil Li ribbon.

The reference capillary was constructed from 4 mm OD glass tubing through which a Li strip made contact with the electrolyte (volume ≃ 17 cm^3). All potentials are quoted *vs.* Li^+/Li.

Galvanostatic preelectrolysis was conducted in a 4 oz snap-cap bottle between two 15 mil Li electrodes. Both the anode and cathode had surface areas of about 20 cm^2. An electrolyte solution was electrolyzed with stirring for 16-24 hr at current densities of either 1.5 or 3.0 mA/cm^2 (*vide infra*). At the end of preelectrolysis the cathode was covered with dendritic Li, some of which had broken off and floated to the sur-

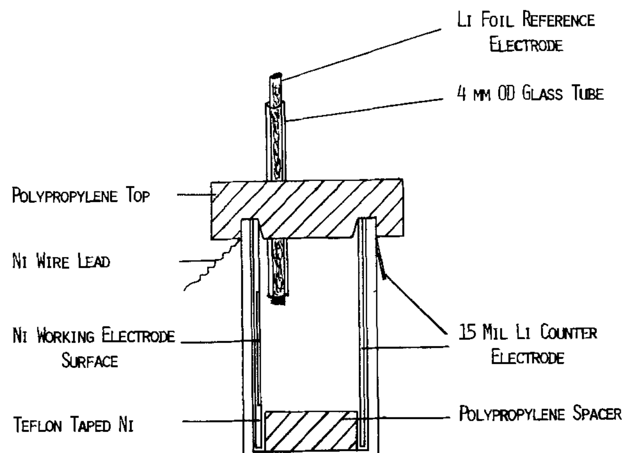

Fig. 1. Glass rectangular cell (10 × 40 × 60 mm) for coulometric cycling experiments. (Side view; not drawn to scale.)

face. The anode was smooth and uniformly brown in color. The electrolyte itself was clear and colorless.

Electrochemical instrumentation.—Chronopotentiometric plating and stripping were conducted with either a Wenking LT 73 potentiostat in the galvanostatic mode, or with a constant current power supply (constructed in-house). Long-term experiments utilized an automatic cycler (constructed in-house) which allowed plating for a given period of time, then stripped to a preset potential (+1.0V). Upon reaching this potential, stripping was terminated and the cell reverted to OCV until plating again commenced. Cycling experiments were conducted at 25° ± 2°C.

Results and Discussion

Cycling studies.—Cycling the Li electrode in a half-cell configuration mimics the charge and discharge characteristics of the negative in a secondary battery. In a given cycle, Li was plated and stripped galvanostatically. The over-all efficiency of a cycle was taken to be the ratio of charge stripped to charge plated (Q_s/Q_p). Each plate consisted of a 5 mA/cm^2 current for 225 sec, yielding a 1.125 C/cm^2 charge of Li. While ~1 C/cm^2 plates do not accurately reflect the amount of Li normally cycled in a secondary battery, they are useful in rapidly assessing the quality of a given electrolyte. Cycling of thin plates many times accelerates conditions leading to inefficiencies and failure. After a series of 1.125 C/cm^2 cycles, a final 30 C/cm^2 charge was plated and stripped.

All cycling experiments were conducted in the rectangular glass cell illustrated in Fig. 1. Typical Ni working electrode areas employed in this cell were 9 cm^2, as opposed to the 1 cm^2 area for the snap-cap vial cell used previously (7-9). It was found that for a given electrolyte, efficiency values decreased more rapidly in the vial cell than in the rectangular cell. Table I compares cycling efficiencies obtained in 1M $LiAsF_6$/MA for these two cells (12). Beyond the 6th cycle, efficiencies in the vial cell (A = 0.85 cm^2) rapidly fall off, while those in the rectangular cell (A = 9 cm^2) diminish at a more moderate rate.

Earlier work conducted in the snap-cap cell (13) revealed that edge effects played a significant role in terms of cycle inefficiencies. Thus, on going to thick (30 C/cm^2) plates most of the Li dendritic growth was found to occur along the perimeter of the Ni electrode. The perimeter to area ratio (P/A) for a 1 cm^2 Ni working electrode is 4 cm^{-1}; for a 9 cm^2 area, P/A = 1.3 cm^{-1}. Besides reducing P/A, the rectangular cell enforces the parallel placement of the Ni working and Li counterelectrodes. Carefully machined tops and spacers constrain the Ni and Li sheets flat against the walls of the glass cell. This leads to a more uniform electric field, and, therefore, a more uniform current density at any point on the working electrode surface.

The Li cycling efficiencies of three THF-based electrolytes were initially surveyed. Solutions 1M in either $LiAsF_6$, or $LiBF_4$ were prepared from THF passed through alumina (A electrolytes). As seen in

Table I. The effect of Ni working electrode area on Li cycling efficiency*

* $i_p = i_s$ = 5 mA/cm^2; Q_p = 1 C/cm^2; 1M $LiAsF_6$/MA.

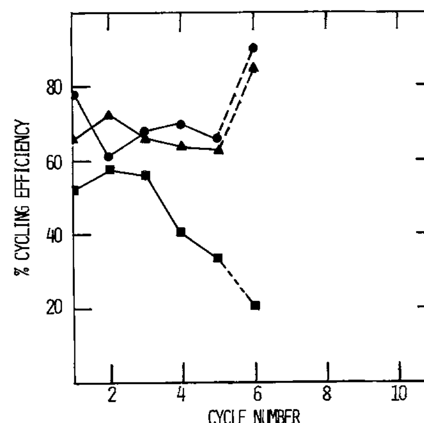

Fig. 2. Variation of efficiency with cycle number for $i_p = i_s = 5$ mA/cm^2, Q_p = 1.125 C/cm^2 (cycles 1-5); Q_p = 30 C/cm^2 (cycle 6). ●, 1M $LiAsF_6$/THF; ▲, 1M $LiClO_4$/THF; ■, 1M $LiBF_4$/THF; A— purification.

Fig. 2, somewhat higher values were achieved using the $LiAsF_6$ salt compared to those obtained with $LiClO_4$ as the supporting electrolyte. In both cases, the efficiency for the 30 C/cm^2 plates was markedly superior to that of the 1 C/cm^2 plates. Conversely, the $LiBF_4$ solution afforded very poor efficiencies. Data obtained over the first 10 cycles were reproducible to better than 5%. In parallel experiments involving $LiAsF_6$ and $LiClO_4$ electrolytes, the efficiency curves of the former salt were always higher than those of the latter.

Electrolyte storage with Li at 71°C.—The results of the cycling studies were complemented with data from static tests at 71°C. In Table II, the reactivities of THF and three THF-based electrolytes toward bulk Li are tabulated as a function of purification procedure. The first entry in each column represents the number of elapsed days after which Li corrosion was noted; the second entry in parenthesis represents the number of elapsed days at which solution coloration was detected. Corrosion invariably started on the scratched Li surface as well as on the edge of the freshly cut Li foil. All of the electrolytes yellowed with time.

We note that the static reactivity of A electrolytes toward Li roughly parallels their dynamic reactivity, as exemplified by decreasing cycling efficiencies (Fig. 2). Indeed, 1M $LiAsF_6$/THF-A is seen to be most resistant to Li-electrolyte degradation while electrolytes prepared from $LiBF_4$ are essentially insensitive to different purification procedures. While treatment with alumina helps stave off reaction with Li, electrolytes incorporating $LiClO_4$ or $LiAsF_6$ manifest a greater tendency to react when purified by the more elaborate APA procedure.

Variations of preelectrolysis time.—Earlier work (9) dealing with electrolyte purification procedures addressed itself to PC-based solutions. The effects of desiccants and preelectrolysis on the cycling efficiency of the Li electrode were noted. These efficiency values were highest and most long-lived when an alumina-

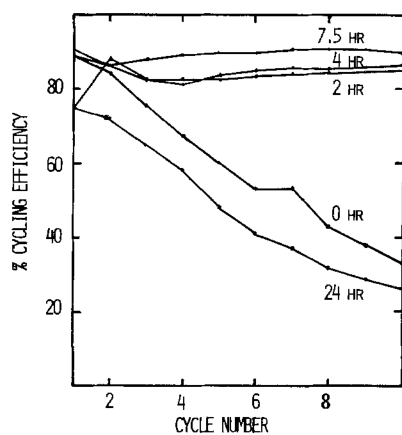

Fig. 3. Variation of efficiency with cycle number for $i_p = i_s = 5$ mA/cm^2, $Q_p = 1.125$ C/cm^2. 1M $LiAsF_6$/THF-APA aliquots taken at various preelectrolysis times.

preelectrolysis-alumina sequence was employed. In order to more fully understand the effect of preelectrolysis on electrolyte behavior, a variety of parameters was monitored as a function of preelectrolysis time. To this end, 100 ml of 1M $LiAsF_6$/THF was preelectrolyzed at our standard current density of 3 mA/cm^2. Aliquots were taken at various intervals and subjected to spectrochemical analysis as well as half-cell cycling studies. Figure 3 presents the cycling efficiency of the first ten 1.125 C/cm^2 cycles. The efficiency dramatically improved on going from no electrolysis to 2 hr of electrolysis. Small improvements are gained at 4 and 7.5 hr. The efficiency then decreased after 24 hr. On the basis of these data, subsequent preelectrolyses were run at current densities of 3 mA/cm^2 for 8 hr, or 1.5 mA/cm^2 for 16 hr. Loss of good cycling efficiency as the result of extended preelectrolysis is presumably due to electrolyte degradation. As electrolysis continues, the surface area of the cathode increases as Li dendrites build up. Dendritic growth is thought to arise from Li-impurity reactions, which proceed at a high rate, and Li-solvent reactions, which are somewhat slower (9). We believe that reaction of Li with THF itself eventually dominates on going to longer preelectrolysis times and therefore degrades the electrolyte.

Some evidence is available to support this hypothesis. Table III compares the u.v. cutoff and absorption intensity at 258 nm for electrolyte aliquots taken at several preelectrolysis times. Although the solvent cutoff limit increases only slightly after 7.5 and 24 hr, the intensity at 258 nm first decreases and then increases with time. The nature of the species absorbing in this region is unknown. However, its intensity seems to correlate with cycling efficiency, *i.e.*, higher concentrations are reflected in poorer cycling efficiencies (Fig. 3).

Since Foote Li is known to contain small amounts of Na, we sought to determine if Na^+ increased with preelectrolysis time. Duplicate samples from each aliquot were analyzed by atomic absorption spectroscopy and the results are shown in Table IV. After 2 hr of preelectrolysis, [Na^+] drops from about 8 to 5.5 ppm and remains essentially constant thereafter. Thus,

Table III. U.V. absorptions of 1M $LiAsF_6$/THF electrolyte as a function of preelectrolysis time

Na^+ is both a small and invariant contaminant in the electrolyte. Accordingly, we do not expect Na^+ to play a role in either solvent purification or electrolyte degradation on cycling.

The effect of different metal substrates on cycling efficiency.—To date, our cycling studies with the Li electrode have used Ni substrate exclusively. The following metals, representative of different groups in the Periodic Table, were surveyed: Nb, Mo, Fe, Cu, Cd, and Al. Two alloys were also tested: cold-rolled steel (CRS) and stainless steel (SS). These data are presented in Fig. 4 and compared with efficiencies achieved on Ni for 1M $LiAsF_6$/THF-APA electrolyte. Other than metals known to alloy with Li, *i.e.*, Al and Cd (14, 15), there were no dramatic changes in cycling efficiencies. In general, the efficiency plots paralleled each other, giving ~90% on the 1st cycle and between 60-73% on the 5th cycle. It would seem, therefore, that major improvements in both cycle efficiency and life must begin with the electrolyte itself.

Electrolyte aging at 71°C.—An effort was made to determine if exposure to elevated temperature would degrade $LiAsF_6$/THF electrolyte (yielding poorer cycling efficiencies). Thus, 10 ml of APA was stored in a screw-cap culture tube for 26 days at 71°C. When this electrolyte was brought into the dry box and cycled, the best results to date in this electrolyte were achieved. Figure 5 compares these data to those obtained for unstored APA electrolyte. Instead of rapidly decreasing to 50% on the 5th cycle, the cycling efficiencies of the stored APA electrolyte maintained values near 80% out to the 18th cycle. After a

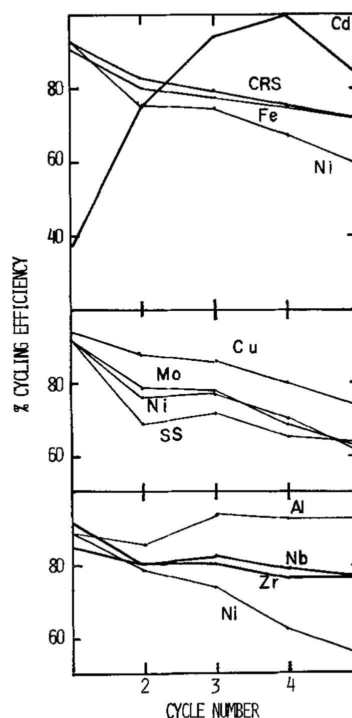

Fig. 4. Variation of efficiency with cycle number for $i_p = i_s = 5$ mA/cm^2, $Q_p = 1.125$ C/cm^2. 1M $LiAsF_6$/THF-APA at various working electrodes.

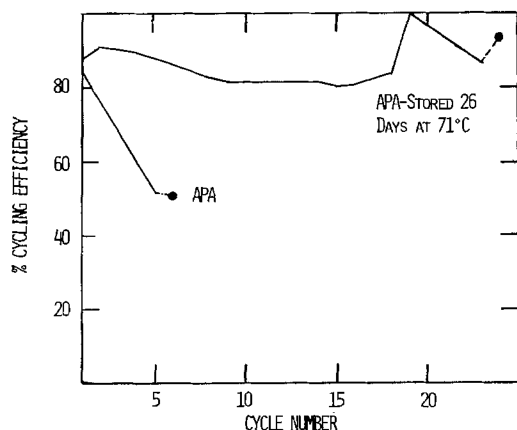

Fig. 5. Variation of efficiency with cycle number for $i_p = i_s = 5\ mA/cm^2$, $Q_p = 1.125\ C/cm^2$; $Q_p = 30\ C/cm^2$. 1M $LiAsF_6$/THF-APA.

60 min pause at OCV, the 19th cycle yielded 100% cycling efficiency. Subsequent cycles decreased in efficiency to 85% on the 23rd cycle. The 24th cycle gave a 94% efficiency for a 30 C/cm^2 plate, after which the cell was disassembled and the Ni working electrode examined. A very adherent and uniformly thin plate of residual Li remained. No gross dendritic growth was noted after a total of 54 C/cm^2 (28.6 C/cm^3) Li had been shuttled to and from the Ni. This is indeed a remarkable observation in that earlier results incorporating only 5 × 1 C/cm^2 cycles yielded highly dendritic residual Li.

A second batch of APA electrolyte was prepared and stored for 9 days at 71°C. The cycling results are shown in Fig. 6. After the 6th cycle, efficiency values remained nearly constant at 88% out to the 40th cycle. The 6th, 17th, and 26th cycles reflect slight improvements in efficiency due to pauses of 17, 15, and 30 min, respectively, between cycles. On the 41st cycle a 1.125 C/cm^2 charge of Li was plated onto the Ni, and the cell switched to OCV. After 44 min, the Li was stripped and an efficiency value of 73% was obtained. The 42nd cycle was run as usual and a 91% value was achieved. The 43rd cycle yielded the "baseline" value of 85%. On the 44th cycle 1.125 C/cm^2 was plated, and the cell switched to OCV overnight. Sixteen hours later the Li was stripped, yielding only 60% efficiency. The 45th cycle, however, gave a value of 107%! Clearly, some of the Li isolated from the Ni electrode on overnight stand was recouped on the 45th cycle. The 46th cycle gave 83%, after which the cell was disassembled and inspected. As in the earlier run with stored APA, the Ni electrode revealed compact, uniformly thin residual Li. The electrolyte solution itself was clear but very slightly tan in color, indicative of degradation products. A new Ni working electrode was inserted and a 30 C/cm^2 cycle yielded a 75% efficiency. The residual Li was dendritic in nature. Fresh

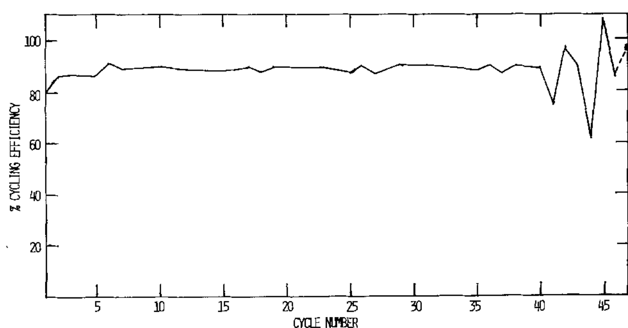

Fig. 6. Variation of efficiency with cycle number for $i_p = i_s = 5\ mA/cm^2$. $Q_p = 1.125\ C/cm^2$; $Q_p = 30\ C/cm^2$. 1M $LiAsF_6$/THF-APA stored 9 days at 71°C.

electrolyte and another new Ni electrode gave 95% efficiency on a 30 C/cm^2 cycle. This difference in cycling efficiencies clearly reflects the deleterious effect of degradation products on the Li electrode.

Lithium isolation rates calculated from the 41st and 44th cycles gave 57 $\mu A/cm^2$ over 44 min and 5 $\mu A/cm^2$ over 16 hr. These values are similar to those reported earlier for $LiAsF_6$/PC electrolytes (9) and reflect the initially rapid reaction of electrolyte with as-plated Li. The novelty of this result lies in the ability to recover some isolated Li in a subsequent cycle. This suggests a mechanism in which Li, electrochemically insulated from the Ni electrode, becomes reattached and thereby available for anodic dissolution.

Other investigators have invoked Li^+-conductive films to account for the behavior of the Li electrode in aprotic media. Dey (16) indicated that in PC the Li electrode is coated with a Li^+-conducting film composed of Li_2CO_3. More recently, Peled and Straze (17) have proposed a simple model of alkali and alkaline-earth metal/electrolyte films in terms of their ionic and electronic transport properties. A key component of these films is an insoluble metal salt, the cation of which migrates through the film on polarization. Others (18, 19) have compared corrosion and exchange currents of the Li electrode in a variety of media. They found that after initial Li-electrolyte contact, the corrosion rate became 1000 times slower than the rate at which the Li/Li^+ equilibrium was established. This implies the presence of a Li^+-conducting film which acts as a barrier to the reactive electrolyte. Finally, Besenhard (20) suggests that the conductivity of Li^+ through encapsulating films is enhanced when Li is electrodeposited in the presence of I^-. The I^- anion is presumed to be incorporated in the film thus providing high mobility for Li^+.

The effect of storage time at 71°C on cycling efficiency was assessed for APA electrolyte samples removed at 1, 3, 5, 7, 9, and 11 day intervals. The long-lived cycling efficiencies in Fig. 4 could only be reproduced when the electrolyte had been stored for 9 or more days. Electrolytes stored for shorter periods of time manifested initially higher efficiencies, which rapidly declined after the first few cycles. For example, the 5th cycle of APA-1, 3, 5, and 7 gave efficiencies of from 35-59%. The 5th cycle efficiencies of APA-9 and 11 were never less than 76%. The 71°C storage must chemically alter the electrolyte with time. Whether this alteration involves the formation of a stabilizing agent or the removal of an impurity is presently open to question.

The effect of various gases on electrolyte cycling efficiency.—Formidable efforts have been made to remove or minimize contaminants in the electrolyte. Distillation, adsorption of organic impurities on alumina, pre-electrolysis at the Li potential, and aging electrolyte in glass have dramatically improved the cycling efficiency of the Li electrode. Little attention, however, has been directed toward the presence of dissolved gases in the electrolyte. Burdick and Jackson u.v. grade THF used in all our THF-based electrolytes is packed under N_2 as received. Furthermore, when solvent is percolated through alumina, N_2, O_2, and CO_2 absorbed on the alumina particles surely dissolve into the THF. We set out to assess the effect of electrolyte perfused with Ar, CO_2, N_2, and O_2 on subsequent cycling experiments.

Gasification was achieved by passing the gas under study from a lecture bottle through an intervening Drierite column and then through a coarse glass frit immersed in electrolyte. Approximately 40 ml of electrolyte was perfused at any one time, and the gas under study was allowed to slowly bubble through the electrolyte for 5.0 min. Figure 7 presents the efficiencies of the first 10 cycles obtained in the presence of these gases. Each run was conducted on a new Ni electrode in freshly gasified electrolyte. Perfusion with Ar improved the cycle life of the Li electrode perhaps by

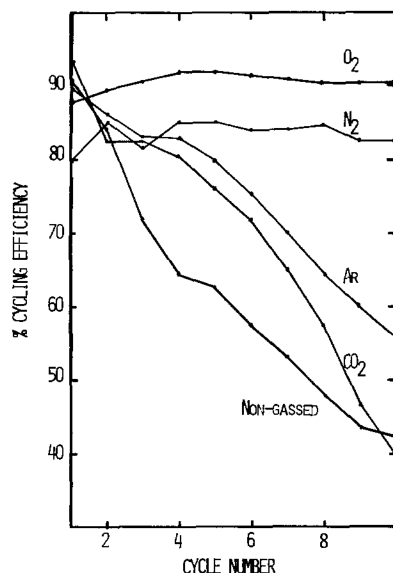

Fig. 7. Variation of efficiency with cycle number for $i_p = i_s = 5$ mA/cm², $Q_p = 1.125$ C/cm². 1M $LiAsF_6$/THF-APA perfused with various gases.

replacing other gases and/or volatile organic contaminants dissolved in the electrolyte. Oxygen and N_2 helped maintain cycle life relative to Ar while CO_2 and nongassified electrolyte did not. While dry O_2 does not readily react with Li at room temperature, dry N_2 and CO_2 form the nitride and carbonate (21). That N_2 was found to be superior to Ar is indeed surprising. We had thought that an Li_3N film would perturb the morphology of the electrodeposit so as to allow the rapid generation of dendrites. This would in turn lead to electrode failure. However, recent work with Li_3N single crystals has shown them to be pure Li-ionic conductors giving high conductivity at moderate temperatures (22). Polycrystalline Li_3N also manifests similar, though attenuated, conductivity values (22, 23). Thus the Li_3N film may partially protect Li from attack by residual impurities or THF itself, and there is some precedent for this hypothesis. Carbon dioxide in 1M $LiClO_4$/THF has been used to improve the self-discharge characteristics of Li primary cells (10). Apparently, CO_2 forms a protective (Li_2CO_3) which then allows Li^+ migration into solution on discharge. Oxygen afforded the highest cycling efficiencies over 10 cycles. While Li and O_2 are essentially inert on open circuit, protective oxide films could form as Li is plated down on Ni. Indeed, we observe that the OCV of Ni *vs.* Li in freshly oxygenated electrolyte is 300-400 mV higher than the OCV's in the other perfused electrolytes. The OCV is a mixed potential reflecting the midpoint between Li reduction and electrolyte oxidation. Thus, its shift to more positive OCV values (+2.60V → 2.95V) in the presence of O_2 suggests that O_2 can be reduced at potentials positive of Li. When Li is plated (reduced) on Ni, a concurrent reduction of O_2 to O^{-2} may occur. Subsequent reaction with freshly plated Li may then lead to a film which affords protection. If an oxide film is the source of higher cycling efficiencies and larger cycle life, its effect can only be short-lived. Li_2O cannot be electrochemically converted back to Li and O_2. Thus, after several cycles the film must ultimately perturb the Li morphology, leading to dendritic growth and subsequent electrode failure. In this regard, we note that cycling efficiencies in electrolytes perfused with O_2 and N_2 rapidly degrade beyond the 10th cycle.

Summary and Conclusions

The results of cycling and storage indicate that electrolytes incorporating $LiAsF_6$ are more stable to Li. This may be due to the high purity of this salt, or reflect a stabilizing property afforded by the AsF_6^- anion. In fact, we have found that THF and AsF_6^- react concurrently at a Li anode to form a brown coating (24). This film may provide some protection against further reaction. The storage tests also indicate that, on going to more stringent purification procedures, the reactivity of electrolyte to bulk Li increases. While some contaminants are known to degrade cycling efficiency, *e.g.*, CO_2 and organic electrolyte degradation products, others like H_2O (8), N_2, and O_2 help, albeit temporarily.

Preelectrolysis of the electrolyte improves its "inertness" with respect to the Li electrode, presumably by scavenging reactive impurities. However, continued preelectrolysis degrades the electrolyte, as evidenced by poor cycling efficiency and the appearance of contaminants in the u.v. spectrum. This suggests that impurities react with Li at a faster rate than electrolyte itself, as has been noted previously (9). Neither small Na^+ concentrations nor the use of different metal substrates have any significant effect on the cycling efficiencies of a given electrolyte. This indicates that solvent, salt, and impurities contained therein play a major role in determining the over-all reactivity of an electrolyte with Li.

Electrolyte aging at 71°C and the recontact phenomenon merit more study. Subtle changes in the electrolyte itself and in the structure of the encapsulating film dramatically affect the number of high efficiency cycles obtained. The understanding and subsequent control of these phenomena are required if a THF-based electrolyte is to be employed in a practical Li secondary battery.

The introduction of gases into the electrolyte dramatically alters the cycling efficiency. Apparently, the *in situ* generation of Li_3N and Li_2O films protects the underlying Li from parasitic electrolyte/impurity reactions. Conversely, a Li_2CO_3 film either affords no protection or seriously perturbs the plate morphology from the outset, leading to dendritic growth and rapid reaction with the electrolyte medium.

When taken together, these results point up the importance of films in ultimately determining the rate of Li/electrolyte reactivity. The specific nature of the reaction of Li with THF-based electrolytes, the kinds and distribution of products, and a mechanism accounting for their formation will be the subject of a forthcoming publication (24).

Thermodynamic Properties of Liquid Na-Sn Alloys by emf Measurements with Beta-Alumina Electrolytes

M. Rivier and A. D. Pelton

Département de Génie Métallurgique, Ecole Polytechnique, Université de Montréal, Montréal, Québec, Canada

ABSTRACT

The thermodynamic properties of liquid Na-Sn alloys have been measured over the temperature range $250° < T < 450°C$ and over the composition range $0 < X_{Na} < 0.3$ by means of concentration cells employing beta-alumina solid electrolytes. Compositions were varied by coulometric titration over the entire range from 0 to 30% Na. Enthalpies and entropies were obtained from the temperature dependence of the emf's. The results indicate that the alloys are strongly ordered and of partial ionic character.

Although a great deal of attention has been recently accorded to beta-alumina because of its importance in the development of the sodium-sulfur battery (1, 2), the applications of this solid electrolyte for thermodynamic measurements have only begun to be explored (3-7). To a large extent this has been due to the unavailability of an inexpensive source of impermeable tubes of beta-alumina.

A new, simple, and inexpensive slip-casting technique of making impermeable crucibles and tubes of beta-alumina has recently been developed in this laboratory (8). The crucibles used in the present investigation were made by this technique.

In the present study, the emf of the cell

Na (liquid) | beta-alumina | Na-Sn (liquid alloy)

has been measured. The transport number of Na^+ ions in the beta-alumina is unity. (This fact has been verified in the present study as is discussed below.) The emf of the cell is thus given by

$$E = -\frac{RT}{\mathbf{F}} \ln a_{Na} \quad [1]$$

where a_{Na} is the activity of Na in the alloy.

The high selectivity of the beta-alumina for conduction by Na^+ ions, as well as the completely sealed cell design used in the present study, enables highly reproducible and stable emf's to be obtained. In addition, the very low resistivity of the solid electrolyte ($\sim 1\Omega$ in the present study) permits the concentration of the alloy to be varied by coulometric titration over a composition range of 30 mole percent (m/o). This is to be compared to the composition variations of fractions of 1 m/o which are the maximum obtainable by coulometric titration with conventional solid electrolytes such as stabilized zirconia.

Key words: beta-alumina, sodium-tin system, liquid alloys—thermodynamics, liquid alloys—structure, alloy concentration cells.

The Na-Sn system was chosen for this study because of the interesting thermodynamic properties of these structurally highly ordered liquid alloys and the scatter in the reported data (9-15).

Experimental

The apparatus is shown in Fig. 1. A tube of beta-alumina (1 cm diam, 5 cm long, wall thickness 0.2 mm) is joined to a Pyrex tube by a Corning KOVAR 7056 graded seal. This joint can be used under vacuum to 450°C. In order to remove all traces of water, the beta-alumina is heated for 24 hr at 150°C in a vacuum oven. The tube is then filled with high purity[1] Sn, and this inner-electrode compartment is sealed under vacuum in order to avoid any oxidation of the alloy or any losses of Na from the alloy by volatilization. The outer reference electrode compartment contains pure[1] Na which has been prefiltered through a glass frit. During the course of the subsequent experiment, high purity argon gas is circulated over the sodium.

Emf measurements are made by a TACUSSEL millivoltmeter via tungsten electrodes. The temperature is measured by a thermocouple dipping into the Na.

The selectivity of the electrolyte for Na^+ ions, as well as its very low resistivity (the apparatus in Fig. 1 has a resistance of about 1Ω at 350°C), permits the composition of the alloy to be conventiently, accurately, and rapidly altered by the passage of a measured current (coulometric titration). The constant current (maximum 500 mA) is furnished by a Koslow Scientific coulometer.

The composition of the alloy was varied in this way from 0% Na up to more than 25 m/o Na and back again. Whenever the current was interrupted to make an emf measurement, the equilibrium emf was always attained within less than 10 sec. Figure 2 shows a measured curve of emf *vs.* composition at

[1] ALFA Inorganics Company.

constant $T = 360°C$. Some of the points shown were obtained upon increasing the composition and others upon decreasing it. The points obtained as the composition was increased were within ±0.5 mV of all those obtained as the composition was decreased. Furthermore, analysis of the sample by atomic absorption after the coulometric titration showed that the composition agreed with that given by the coulometry. Finally, at low concentrations of Na, the curve of emf *vs.* log X_{Na} is linear. Thus, Faraday's law is obeyed with a transport number of Na^+ of unity.

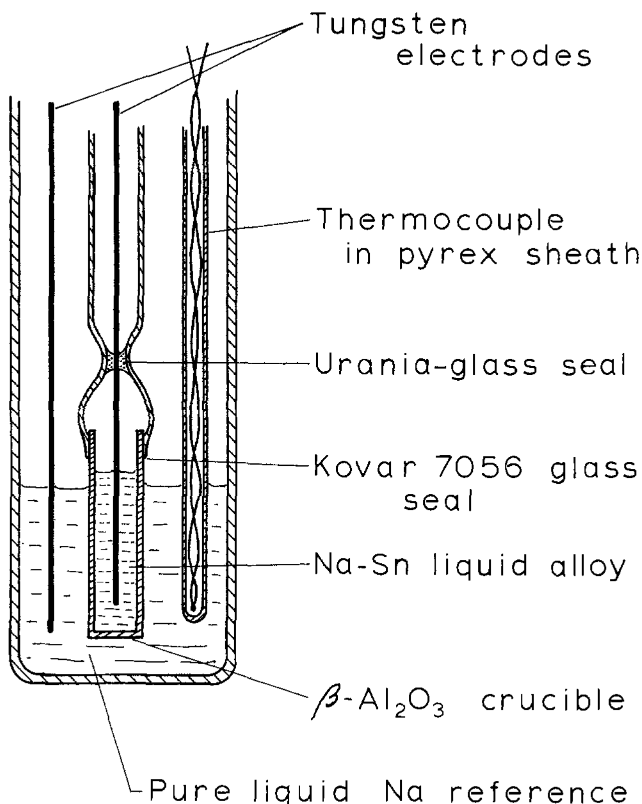

Fig. 1. Experimental apparatus

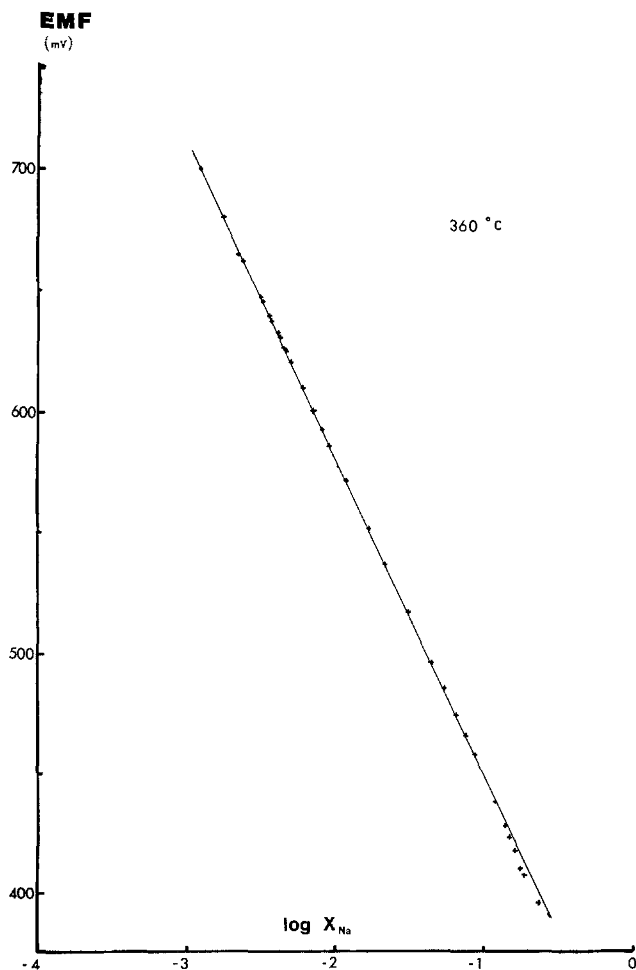

Fig. 2. Emf *vs.* log of sodium mole fraction in Na-Sn liquid alloys at 360°C. Composition varied by coulometric titration.

Three separate samples were studied over the range of temperature from 250° to 450°C and from 0% Na up to the phase boundary (20-30% Na). At all compositions and temperatures, emf's from the three samples were in agreement within ±0.5 mV.

During one week at 400°C, the emf was stable to within ±0.5 mV. This stability results from the fact that changes of composition by volatilization of the Na are prevented by sealing the inner electrode compartment near the meniscus of the alloy.

Results

Measurements were made at several compositions at 360°C. The excess free energy of Na, g_{Na}^E, at 360°C, calculated from the measured emf via the equation

$$g_{Na}^E = RT \ln a_{Na} - RT \ln X_{Na} = -\mathbf{F}E - RT \ln X_{Na} \quad [2]$$

(where X_{Na} is the mole fraction of Na in the alloy) is plotted in Fig. 3. Points shown are from all three samples.

At several composition, emf's were measured as a function of temperature over the range 250°-450°C. The curves of E *vs.* T deviated very slightly from linearity, thus indicating a slight temperature dependence of the entropy. However, for the temperature range 250°-450°C it was not deemed possible to determine the curvature with any precision. Hence, points obtained during both heating and cooling were fitted to straight lines by least squares regression. The resultant entropy and enthalpy values are thus "averages" for this temperature range. The equations of E *vs.* T and the root-mean-square deviations are listed in Table I, in which data obtained from all three samples are shown. Partial enthalpies, Δh_{Na}, and partial entropies, Δs_{Na}, of mixing of Na, calculated from the temperature dependence of the emf, are plotted in Fig. 4 and 5. The excess entropy of Na

$$s_{Na}^E = \Delta s_{Na} + R \ln X_{Na} \quad [3]$$

is plotted in Fig. 6.

Error limits may be estimated from the reproducibility (~ ±0.5 mV) and the temperature range (~200°C) of the measurements. The error in dE/dT is thus ~ ±2(0.5)/200 = 0.005 mV/K. The lower limits for random errors are thus ~0.5**F** or ±50J for

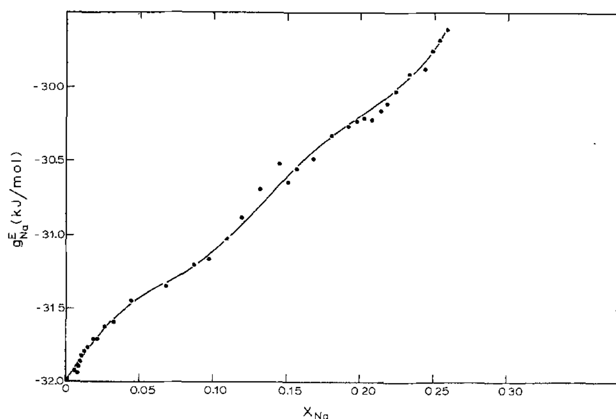

Fig. 3. Partial excess free energy of sodium in liquid Na-Sn alloys at 360°C calculated via Eq. [2] from experimental measurements. Curve is given by Eq. [10].

Discussion

A direct comparison of the present results with those of other workers (9-15) is difficult because of the widely different ranges of temperature and composition studied. Figure 4 shows the curve of Δs_{Na} calculated by Morachevskii and Lantratov (15) from the temperature dependence of the emf's of electrochemical cells containing Na-glass membranes for a

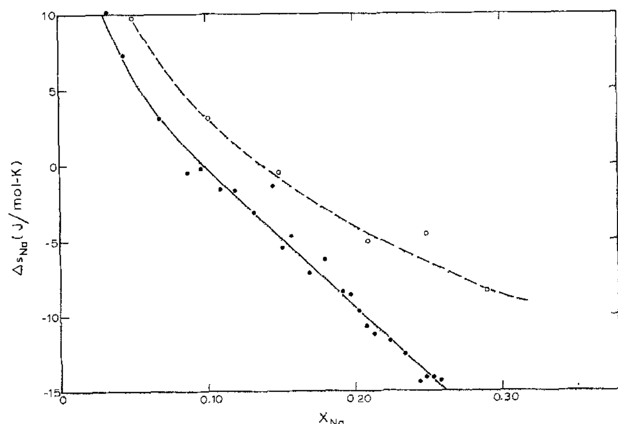

Fig. 4. Partial entropy of mixing of sodium in liquid Na-Sn alloys calculated from temperature dependence of emf's. —●—●— Present study; —○—○— Ref. (15), 600°C.

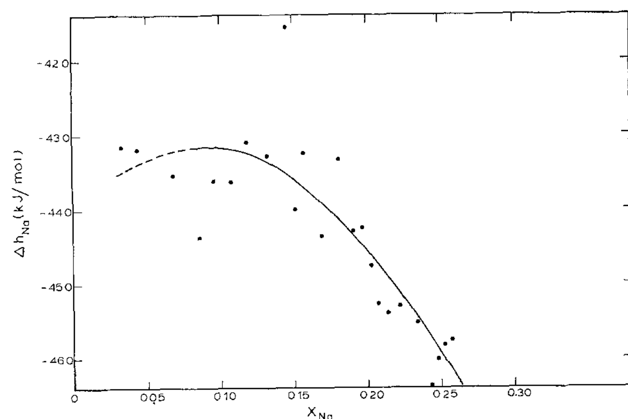

Fig. 5. Partial enthalpy of mixing of sodium in liquid Na-Sn alloys calculated from temperature dependence of emf's. Curve is given by Eq. [4]).

range of temperatures around 600°C. The curve is in qualitative agreement with the present results. As suggested by Bartlett and Crowther (12), the discrepancy may be due to attack on the Na-glass electrolytes, however, the difference could also be explained by a temperature dependence of the entropy.

The excess free energy, g_{Na}^E, and enthalpy, Δh_{Na}, of Na are both quite negative, indicating that the liquid alloys are very stable. The excess entropies are also very negative—so negative, in fact, that the partial entropy of mixing in Fig. 4 is negative for $X_{Na} > 0.1$. This indicates that the structure of these liquid alloys is highly ordered. Further information can be obtained from an examination of the partial properties of Sn and the integral properties of mixing which may be calculated from integration of the Gibbs-Duhem equation. To this end, the curves in Fig. 3, 5, and 6 were first fitted to analytical expressions. For the curves of Δh_{Na} and s_{Na}^E in Fig. 5 and 6, three coefficient equations were used. The equations obtained by least squares regression analysis of the experimental points are

$$\Delta h_{Na} = -77.282 + X_{Sn}^2(123.702 - 90.689\, X_{Sn}) \text{ kJ/mole} \quad [4]$$

$$s_{Na}^E = -82.429 + X_{Sn}^2(215.962 - 153.162\, X_{Sn}) \text{ J/mole-K} \quad [5]$$

Application of the Gibbs-Duhem equation then gives the following expressions for Δh_{Sn} and s_{Sn}^E which are plotted in Fig. 7

$$\Delta h_{Sn} = X_{Na}^2(78.358 - 90.689\, X_{Sn}) \text{ kJ/mole} \quad [6]$$

$$s_{Sn}^E = X_{Na}^2(139.381 - 153.162\, X_{Sn}) \text{ J/mole-K} \quad [7]$$

The curve for Δs_{Na} drawn in Fig. 4 was calculated by combining Eq. [3] and [5]. Figure 8 shows the integral molar entropy of mixing

$$\Delta s = -R(X_{Na} \ln X_{Na} + X_{Sn} \ln X_{Sn}) + (X_{Na}s_{Na}^E + X_{Sn}s_{Sn}^E) \quad [8]$$

where s_{Na}^E and s_{Sn}^E are given by Eq. [5] and [7]. Also shown in Fig. 8 is the integral enthalpy of mixing

$$\Delta h = X_{Na}\Delta h_{Na} + X_{Sn}\Delta h_{Sn} \quad [9]$$

where Δh_{Na} and Δh_{Sn} are given by Eq. [4] and [6].

For the curve of g_{Na} in Fig. 3, the precision of the results merits a 7-coefficient expansion. For an ordinary power series expansion with this many terms, about 13 significant figures would have to be retained in each coefficient in order to avoid round-off errors. This problem can be avoided through the use of an orthogonal series. The curve drawn in Fig. 3 is represented by the following 7-coefficient Legendre orthogonal expansion

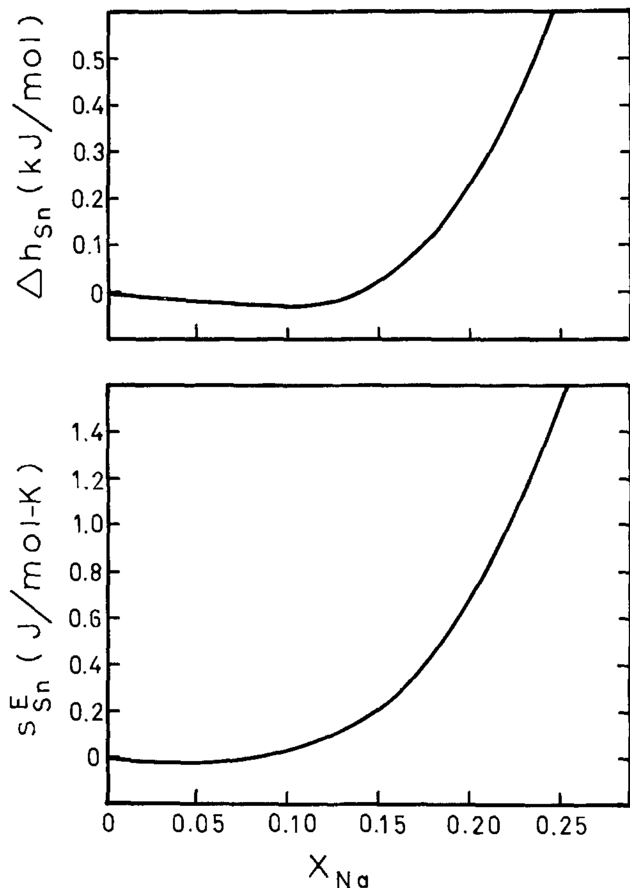

Fig. 7. Partial enthalpy of mixing and excess entropy of Sn in liquid Na-Sn alloys calculated by integration of the Gibbs-Duhem equation.

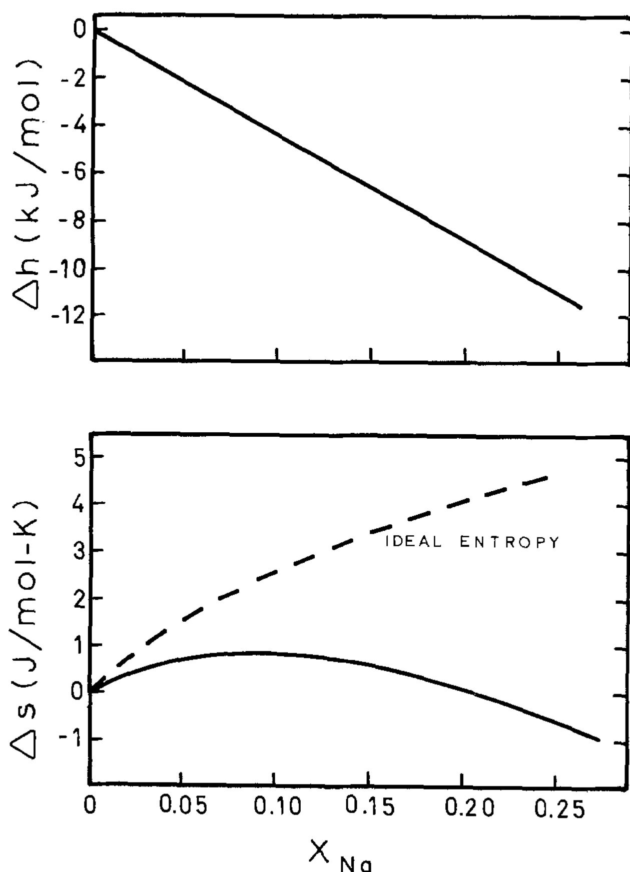

Fig. 8. Integral molar enthalpy and entropy of mixing in liquid Na-Sn alloys calculated by integration of the Gibbs-Duhem equation.

$$g_{Na}{}^{E} = X_{Sn}{}^{2} \sum_{n=0}^{6} a_n P_n(X_{Sn}) \qquad [10]$$

where the coefficients a_n are given in Table II and where $P_n(X_{Sn})$ is the nth orthogonal Legendre polynomial. The first few terms in the series are

$$a_nP_n(X_{Sn}) = a_0 + a_1(2X_{Sn} - 1) + a_2(6X_{Sn}{}^2 - 6X_{Sn} + 1) + a_3(20X_{Sn}{}^3 - 30X_{Sn}{}^2 + 12X_{Sn} - 1) + \ldots \qquad [11]$$

The general recursion relationship is

$$P_n(x) = \frac{(2n-1)(2x-1)}{n} P_{n-1}(x) - \frac{(n-1)}{n} P_{n-2}(x) \qquad [12]$$

The advantages of orthogonal Legendre series for representing thermodynamic solution properties have been discussed (16).

Integration of the Gibbs-Duhem equation then gives the following expansion for $g_{Sn}{}^{E}$

$$g_{Sn}{}^{E} = X_{Na}{}^{2} \sum_{n=0}^{6} b_n P_n(X_{Sn}) \qquad [13]$$

where the coefficients b_n are listed in Table II.

The integral enthalpy of mixing in Fig. 8 is nearly a straight line. The partial enthalpy of mixing of Sn in Fig. 7 is nearly zero (and even becomes very slightly positive at higher concentration of Na). The entropy of mixing in Fig. 8 deviates very negatively from ideality. Both the enthalpy and entropy are thus indicative of the formation of a liquid "compound" or "complex." That is, structural or electronic ordering is indicated.

Studies of binary alloy systems formed between two components with largely different electronegativities show that there may be electron transfer from one component to the other to form partially ionic species. Wagner (17) first suggested such behavior for molten Mg-Bi alloys. In this system there is an inflection point in $g_{Mg}{}^{E}$ near the composition Mg_3Bi_2 (18) as well as a deep minimum in the electrical conductivity near this same composition (19). Recent studies (20, 21) of the Cs-Au system have shown that at the 50-50 composition, the liquid "compound" CsAu has a very strong ionic character. The system Li-Pb exhibits a minimum in electrical conductivity and in molar volume (22, 23), and an inflection in $g_{Li}{}^{E}$ (24) near the composition Li_4Pb.

The ionic character, IC, of an alloy can be estimated using the empirical criterion of Pauling

$$IC = 1 - \exp(-0.25\, d^2) \qquad [14]$$

where d is the difference in electronegativities of the two metals. For Mg-Bi, Cs-Au, and Li-Pb, ionic characters of 11, 51, and 15%, respectively, are calculated. For Na-Sn, an ionic character of 18% is predicted. From the valencies of Na and Sn it would be expected that the anomalies would occur near the composition Na_4Sn which, however, is not within the range of the present study.

Table II. Coefficients of Legendre series expansions (Eq. [10] and [13]) for $g_{Na}{}^{E}$ and $g_{Sn}{}^{E}$ (kJ/mole)

n	a_n	b_n
0	7167	−32
1	−16872	−541
2	16871	1791
3	−10531	−2377
4	4241	1710
5	−1017	−671
6	110	110

In this model, then, the negative enthalpy of mixing results from the localization of electrons which occurs progressively as Na is added to molten Sn. This occurs approximately linearly with added Na, such that $\Delta h_{Na} \approx$ constant and $\Delta h_{Sn} \approx 0$ as observed. The negative deviations in entropy would result from short-range structural ordering (a preference of Na to have Sn as nearest neighbor and vice-versa as in an ionic melt) or from electronic ordering as the density of free electrons is decreased as Na is added. At low Na concentrations it would be expected that the decrease in free-electron density would occur approximately linearly with added Na. Hence, the electronic ordering would, at low Na concentrations, give $s_{Na}^E \approx$ constant and $s_{Sn}^E \approx 0$ as observed (Fig. 7 and 8). At higher concentrations of Na, localization of electrons on Sn atoms begins to occur. Electrons can then exist in localized bound states or in free-electron gas states. A positive entropy contribution arises from the distribution of the electrons between these two states, thus accounting for the positive values of s_{Sn}^E at higher Na concentrations observed in Fig. 7. Short-range structural ordering, on the other hand, would be expected to give negative values of s_{Sn}^E at all compositions. Hence, the results suggest that electronic ordering is occurring in these alloys.

A useful function for examining the thermodynamic behavior of melts is the stability function

$$\psi = 1 + \frac{X_{Na}X_{Sn}}{RT} \frac{d^2g^E}{dX_{Sn}^2} \quad [15]$$

which, as has been discussed by Darken (25), gives an indication of the stability of the melt and passes through maxima at compositions of particular stability (compositions where g^E has an inflection point). For example, ψ passes through sharp maxima at the approximate compositions Mg_3Bi_2 (18) and Li_4Pb (24) in the Mg-Bi and Li-Pb systems.

The stability function plotted in Fig. 9 was calculated for the Na-Sn system at 360°C from the Legendre series expansion for g_{Na}^E. As expected, ψ is very positive, and increases rapidly with X_{Na} at higher values of X_{Na}.

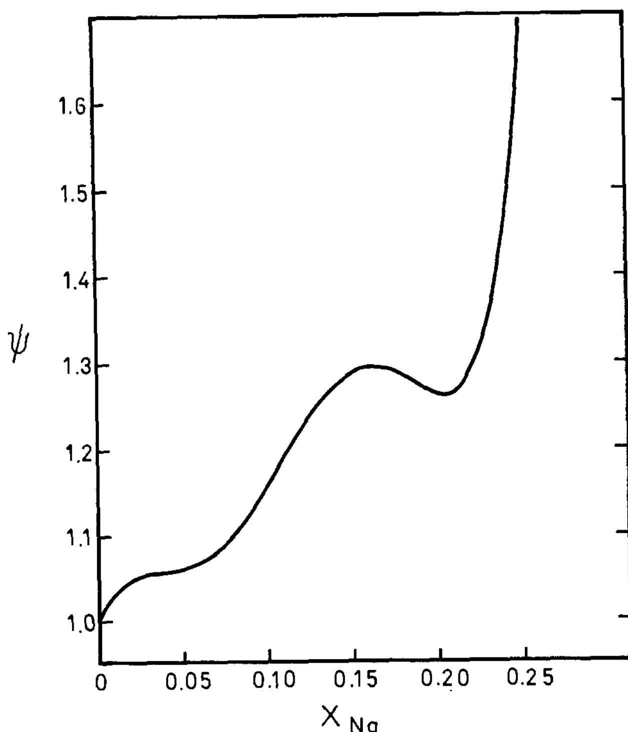

Fig. 9. Stability function $\psi = 1 + X_{Na}X_{Sn}/RT\ d^2g^E/dX_{Sn}^2$ at 360°C.

What is more interesting, however, is the small maximum in ψ observed around $X_{Na} = 0.16$, corresponding to the inflection point in the curve of Fig. 3. Resolution here is near the limit of precision of the measurements. The maximum in Fig. 9 occurs near the composition $NaSn_5(X_{Na} = 0.167)$ or $NaSn_6(X_{Na} = 0.143)$. There exists a solid intermetallic phase with the composition $NaSn_6$. It may be that in the liquid state short-range ordering at specific compositions is also energetically favored.

Conclusions

The beta-alumina solid electrolytes, which were fabricated in this laboratory in the form of impermeable tubes by a new slip-casting technique (8), have been shown to have a transport number of Na^+ ions equal to unity. This solid electrolyte works very well in a liquid sodium alloy concentration cell. Emf's are very stable and reproducible. The fact that impermeable tubes of the electrolyte are available permits the use of a sealed electrode compartment. This prevents Na losses by volatilization and contributes to the high stability and reproducibility of the measurements. The cells were sealed by a Pyrex-to-beta-alumina seal which is limited to temperatures below about 450°C. Aluminosilicate joints with much higher melting points are currently being developed, as are methods of fabrication of longer tubes of beta-alumina.

The very low resistivity and high selectivity for Na^+ ions of the beta-alumina permits the concentration of the alloy to be conveniently changed over a wide concentration range by the method of coulometric titration. Thus, one experimental cell can be used to study the entire composition and temperature range.

For the liquid Na-Sn alloys, the enthalpy of mixing and the excess free energy and excess entropy are all very negative, indicating a very stable ordered melt. The partial enthalpy of mixing and partial excess entropy of Sn, Δh_{Sn} and s_{Sn}^E, are very small and slightly positive. The results are interpreted in terms of a model of electron transfer from Na to Sn. Finally, a small maximum in the stability function is observed near $X_{Sn} = 0.16$, indicating short-range ordering near this composition.

Acknowledgments

The authors wish to thank Mr. Alain Dubreuil for his help and suggestions. Special thanks are also due to Mr. G. Sarfi for his expert assistance with the glass blowing, and to Dr. M. Gauthier for his understanding, and to Dr. M.-L. Saboungi for a critical reading of the manuscript. Financial assistance from the National Research Council of Canada and from a Cottrell grant from Research Corporation are gratefully acknowledged. One of the authors (M.R.) was supported by a France-Quebec graduate fellowship.

Manuscript submitted Aug. 3, 1977; revised manuscript received March 29, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Occurrence of Salt Films during Repassivation of Newly Generated Metal Surfaces

and Theodore R. Beck*

Electrochemical Technology Corporation, Seattle, Washington 98107

ABSTRACT

A mathematical model is developed to describe the processes by which transient appearance of salt films occurs during initial stages of corrosion of oxide-free metal surfaces. The model describes transport-controlled processes which lead to supersaturation by anodic dissolution, to precipitation of a salt film, and eventually to dissolution of the salt film after oxide passivation of the substrate material. Experimental observations on iron repassivation in $6N$ H_2SO_4 were used to test predictions of the model. Measurements of the lifetime of the salt film on the iron surface were in agreement with the model predictions; measurements of the extent of supersaturation prior to precipitation and of the moment of precipitation were in agreement with previous studies. In applying the model to predict the behavior of titanium in $3N$ HCl, calculations indicated that salt films of 20-100Å would be expected to form and then disappear within the time period of 10^{-5}-10^{-3} sec after generation of the oxide-free surface; during this period of time, the anodic dissolution rate of titanium would be expected to exceed 150 A/cm² if the salt film hypothesis is valid. The model presented here should be useful in guiding future experimental work into critical regions of parameter space.

During stress corrosion cracking, virgin metal surfaces are created and a sequence of electrochemical processes then takes place. In aqueous solutions, these processes would include metal dissolution, formation of a passive oxide film, and hydrogen ion reduction. While conducting fundamental investigations on repassivation processes, it has been found that, for some metals, the initial metal dissolution rate is so high that a salt film precipitates prior to oxide passivation. The investigation reported here uses a mathematical model to clarify conditions under which salt films may play a role in repassivation processes.

The awareness of salt films during metal passivation is not new. In 1927, Müller (1) reported observations on the existence of salt films during the passivation of iron and nickel. His work on these and other metals inspired a large number of investigations (2) which have continued for several decades (3). Various interpretations of passivation processes were reviewed by Hoar (4) in a work of broad scope and, more recently, by Galvele (5). Vetter and Strehblow (6) and Isaacs (7) have recently given persuasive evidence that pitting processes are closely related to the formation of salt layers at the interface.

For iron dissolution in sulfuric acid, the formation of a ferrous salt film was described by Serra and Feliú (8) who concluded that supersaturation of the electrolyte occurred prior to precipitation. Schwabe (9) indicated that a primary salt layer was a necessary precursor in the passivation of iron in sulfuric acid. More recently, Abakumova and Milyutin (10) suggested that the salt film creates conditions under which subsequent passivation by oxide films can occur.

For nickel passivation in sulfuric acid, early studies by Turner (11) and by Landsberg and Hollnagel (12) supported the view that pH changes occur in addition to accumulation of nickel ions in the anolyte. A number of authors (13-18) have used continuous mechanical scraping to study broader aspects of repassivation phenomena on bare surfaces of iron, nickel, chromium, gallium, and titanium. These studies, however, did not

* Electrochemical Society Active Member.

lend themselves to quantitative analysis because of the distribution of residence times exhibited by the continuously abraded rotating anode. An improved technique was developed by Ambrose and Kruger (19) who used triboellipsometry to investigate repassivation of freshly abraded titanium surfaces in NaCl; they concluded that the first monolayer of oxide was completed about 40 msec after cessation of abrasion. Using a different method to generate bare metal surface, *i.e.*, rapid fracture, Beck (20) showed that repassivation of titanium begins within 1 msec following fracture; the sequence of likely events following fracture would in this situation include formation and collapse of a cavitation bubble, charging of the electrical double layer, anodic dissolution of the bare metal (accompanied by hydrogen reduction), and eventually formation of a protective oxide film. Beck postulated that transient salt films were responsible for the primary passivation of bare titanium surfaces.

Salt films can also occur during the dissolution of nonpassivating metals (1). Lorenz (21) used unsteady-state experiments at constant current to demonstrate that supersaturation occurred prior to salt film precipitation; investigating several metals, he found that precipitation occurred with anolyte concentrations ranging between 1.4 and 5.0 times the saturation concentration. In a similar manner, Beck (22) reexamined the earlier data of Müller (1) and calculated supersaturation levels in the range of 1-5 times the saturation concentration for a variety of metal/salt systems. Alkire *et al.* (23) carried out dissolution experiments on artificial copper pits and observed precipitation when the anolyte concentration exceeded 2.2 times the saturation value.

Whereas the foregoing investigations were mostly carried out under diffusion-controlled transport, salt films have also been reported in the presence of convection past the anode. Ross *et al.* (24) studied anodic behavior of iron and steel in flowing sulfuric and hydrochloric acids and found that mass transfer behavior at high current densities was complex owing to a surface layer of ferrous precipitates. Kolotyrkin *et al.* (25) describe various salt film effects which accompany iron corrosion in phosphate solutions. Chin (26) reported precipitation on nonprotective anodic films during controlled mass transfer studies on electrochemical machining systems. Landolt and co-workers (27) studied the role of convective mass transfer on high rate iron and nickel dissolution under nonpassivating conditions and have emphasized the role of salt precipitation layers on system behavior.

The literature cited above indicates clearly that salt films play a major role in many transient repassivation processes as well as in both transient and steady-state nonpassivating processes. Accordingly, it seems reasonable that a more quantitative treatment of salt film precipitation phenomena under both diffusive and convective transport situations would be useful for the clarification of fundamental aspects of many anodic dissolution processes.

The purpose of this investigation is to develop a mathematical model for the formation and disappearance of salt films during early stages of diffusion-controlled metal passivation. An original objective was to determine whether primary passivation of titanium within 1 msec (20) could be attributed to formation of a salt film. As will be shown below, the model developed for this purpose predicts that the salt film, if formed on titanium, would develop and then disappear in the time period of about 10^{-5}-10^{-3} sec after formation of the bare surface. However, present experimental methods are unable to provide direct verification within this time scale. Therefore an additional objective of this work has been to test the theoretical model against experimental observations on metals which passivate more slowly than titanium. Experimental results on iron in 6*N* H_2SO_4, reported elsewhere (28), provided a convenient set of data for testing the mathematical model.

Experimental

The experimental procedures used in the investigation of iron repassivation (28) are summarized briefly here. Cylindrical and rectangular anodes of high purity iron were cast in epoxy resin so that only the end was exposed to electrolysis. Prior to study, the metal was recessed by 1-2 mm below the resin surface by means of anodic dissolution in chloride media. By recessing the anodic surface, the current distribution is nearly uniform over the recessed surface, and one-dimensional transport equations can thereby be used. The anode was positioned facing upward in the cell in order to minimize natural convection effects.

Experiments were performed in 6*N* H_2SO_4 containing various concentrations of ferrous sulfate. A potentiostatic power supply was programmed to apply a step change in electrode potential. Prior to the step change, the potential was held in the active region at low anodic current (−0.47V *vs.* SCE) under which conditions there is no surface film. Following the step change, the potential was held constant in a region where the metal eventually passivated (+0.4 to +1.0V *vs.* SCE). Current transients were recorded with a storage oscilloscope while simultaneously viewing the surface with a 60× binocular microscope.

Theoretical Model

The model developed below is designed to deal with diffusion-controlled salt film phenomena which might occur at bare metal surfaces exposed to electrolyte under an applied potential. The model is therefore capable of being used to inquire whether the proposed existence of salt films is consistent with experimental observations, as in the case of titanium investigated below.

The model does not deal specifically with the method by which bare metal is generated, common methods being abrasion, shearing or fracturing, stretching, and electrochemical reduction. Only anodic processes are taken into account; although it is clear that simultaneous cathodic processes occur during repassivation, it is assumed that such cathodic processes would not influence the course of the anodic processes other than by providing additional current for oxidation over and above the measured anodic current. Thus, for example, the model would not apply to situations where copious hydrogen evolution would stir the electrolyte and thereby influence diffusion processes which accompany anodic dissolution.

Following a sudden appearance of oxide-free metal, the sequence of events which is to be described by the model is:

1. Rapid metal dissolution under *IR*-limited constant current conditions causes an increase in metal salt concentration near the corroding surface.
2. Nucleation occurs on the surface of an adherent salt film which then grows by continued precipitation from the supersaturated electrolyte and also by continued anodic dissolution of the metal.
3. Growth of the salt layer is accompanied by a rapid decrease in the anodic current. Formation of a passive oxide layer occurs under the salt layer. (The precipitated salt layer is assumed to have an equilibrium quantity of water of hydration which is thereby available for oxide formation.) The region of supersaturated electrolyte becomes dissipated, and the salt film thereby attains a maximum thickness.
4. The salt film begins to dissolve, eventually to disappear altogether, leaving only the passive oxide film on the metal surface.

The period of time up to the instant of precipitation is denoted as stage I, and the period of time during which the salt film exists on the surface as stage II.

The experimental studies were designed to simplify the mathematical treatment as much as seemed rea-

sonable while still preserving the salient features of the corroding system. The assumptions which have been made are: (*i*) Only one electrochemical reaction is taken into account, *i.e.*, anodic metal dissolution; (*ii*) diffusion of the reaction product away from the surface obeys semi-infinite one-dimensional diffusion without migration or convection effects; (*iii*) the diffusion coefficient is constant; (*iv*) the anodic dissolution rate is constant prior to salt film precipitation, and decreases thereafter according to the empirical relation given by Eq. [9]; (*v*) precipitation of the salt films occurs onto the electrode surface and not homogeneously in the electrolyte phase. Concerning migration effects, Serra and Feliú (8) have provided strong evidence that proton and anion diffusion effects are negligible in iron passivation in sulfuric acid. Assumption (*iv*) implies that the current needed to form the passive film is negligible.

The diffusion of metal ions in the presence of excess supporting electrolyte obeys Fick's second law

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial y^2} \qquad [1]$$

Because the side conditions on Eq. [1] during stage I are different from those during stage II, it is convenient to discuss these stages separately.

Diffusion during stage I.—At the instant of generation of fresh surface, it is assumed that the electrolyte composition is uniform. The anodic dissolution process commences with a constant rate. The side conditions on Eq. [1] are therefore

$$\begin{aligned} c(\infty, t) &= c_b \\ c(y, 0) &= c_b \\ \frac{\partial c}{\partial y}(0, t) &= -\frac{i}{n\mathbf{F}D} \end{aligned} \qquad [2]$$

The well-known analytical solution of Eq. [1] and [2] is given by Carslaw and Jaeger (29)

$$c(y,t) = c_b + \frac{2i}{n\mathbf{F}}\sqrt{\frac{t}{\pi D}}\exp\left(-\frac{y^2}{4Dt}\right) - \frac{iy}{n\mathbf{F}D}\,\mathrm{erfc}\left(\frac{y}{\sqrt{4Dt}}\right) \qquad [3]$$

Stage I continues up to the moment of precipitation, denoted by t^*, at which time the concentration at the electrode surface is denoted by $c^s{}_{\mathrm{pptn}}$. At the instant of precipitation, Eq. [3] shows that

$$c^s{}_{\mathrm{pptn}} = c(0, t^*) = c_b + \frac{2i}{n\mathbf{F}}\sqrt{\frac{t^*}{\pi D}} \qquad [4]$$

Diffusion during stage II.—Following the instant of precipitation, the concentration distribution in the electrolyte is given by Eq. [3] except at the surface, where the precipitated salt film is in equilibrium with saturated solution. For stage II, the side conditions on Eq. [1] are therefore

$$\begin{aligned} c(\infty, t) &= c_b \\ c(y, t^*) &= c_b + \frac{2i}{n\mathbf{F}}\sqrt{\frac{t^*}{\pi D}}\exp\left(-\frac{y^2}{4Dt^*}\right) - \frac{iy}{n\mathbf{F}D}\,\mathrm{erfc}\left(\frac{y}{\sqrt{4Dt^*}}\right) \\ c(0, t > t^*) &= c_{\mathrm{sat}} \end{aligned} \qquad [5]$$

The analytical solution of Eq. [1] subject to side conditions of Eq. [5] is given in Carslaw and Jaeger (30)

$$c(y,t) = c_{\mathrm{sat}}\left[1 + \frac{1}{\sqrt{4\pi Dt}}\int_0^\infty f(y')\left(\exp\frac{-(y-y')^2}{4Dt} - \exp\frac{-(y+y')^2}{4Dt}\right)\right]dy' \qquad [6]$$

where

$$f(y') = -1 + \frac{c_b}{c_{\mathrm{sat}}} + \frac{2i}{n\mathbf{F}c_{\mathrm{sat}}}\sqrt{\frac{t}{\pi D}}\exp\left(-\frac{y'^2}{4Dt}\right) - \frac{iy}{n\mathbf{F}c_{\mathrm{sat}}D}\,\mathrm{erfc}\left(\frac{y'}{\sqrt{4Dt}}\right) \qquad [7]$$

Equations [3] and [6] provide a complete history of the concentration profile in the solution during stages I and II.

Salt film existence during stage II.—During stage II, a salt film appears on the metal surface. Growth of the salt film occurs via two routes by which metal ions arrive at the surface: (*i*) anodic oxidation of the metal by electrochemical reaction, and (*ii*) diffusion from supersaturated solution near the metal surface. The thickness of the salt film is therefore

$$d(t) = m\int_{t^*}^{t}\left(\frac{i(t)}{n\mathbf{F}} - D\frac{\partial c}{\partial y}\bigg|_{y=0}\right)dt \qquad [8]$$

The anodic reaction rate during stage II was experimentally observed (28) to decrease according to $(\mathrm{time})^{-s}$ where s has a constant value during the initial stages of decrease, that is

$$i\,(t > t^*) = i|_{t=t^*}\left(\frac{t}{t^*}\right)^{-s} \qquad [9]$$

Equation [8] has two terms within the integral, the first of which is always positive (anodic film growth) but which decreases in the course of time. The second term is initially positive (film growth by precipitation) but changes sign during the course of stage II (film dissolution). Because the film dissolution rate can eventually exceed the anodic formation rate, the salt film thins and eventually disappears.

Although the mathematical model takes specific account only of the salt film, it is tacitly presumed that additional passivation processes also occur during the existence of the salt film to such extent that, by the time the salt film dissolves, the surface is sufficiently passive that large anodic dissolution currents would not be observed. A mathematical treatment of the growth of oxide films would require consideration of the potential distribution in addition to the mass transfer aspects treated here.

Method of solution.—Equation [8] was integrated by a numerical procedure. It was found necessary to use different methods of integration over various ranges of time in order to avoid overflow and underflow difficulties.

$0 < t/t^* < 10^{-6}$: The complementary error function in Eq. [7] was approximated by

$$\mathrm{erfc}\left(\frac{x}{2}\right) \simeq 1 - \frac{x}{\sqrt{\pi}}$$

$10^{-6} < t/t^* < 1$: The derivative term in Eq. [8] was first rearranged with use of Leibnitz' rule, and the resulting integral (which extends to infinity) was evaluated with use of twelve-point Gauss-Laguerre quadrature. Equation [8] was then integrated with use of the trapezoidal rule.

$t/t^* > 1$: Equation [8] was integrated with use of the trapezoidal rule. The Leibnitz' integral, which extends to infinity, was truncated when the area of the final trapezoid was less than 0.01% of the accrued value of the integral.

Comparison of Experiments with Theory

Investigations were conducted with two different systems: iron in 6N H_2SO_4 and titanium in 3N HCl. In the iron system, the purpose of the investigation was to test model predictions in a system for which the parameters are reasonably well known. In the titanium system, the purpose was to predict conditions under which salt films might be expected and to compare those conditions with experimental observations reported to date. The parameters of both systems are listed in Table I.

Iron system.—Since the passive film on iron is reducible, oxide-free metal surfaces were obtained by controlling the metal potential at values at or slightly cathodic to its rest potential (−0.46V *vs.* SCE). The process of repair following rupture was simulated by suddenly changing the control potential from the above value to a more anodic potential (between +0.4 and +1.0V *vs.* SCE) at which passivity is eventually gained. A typical current-time response following a potential step to +0.5V *vs.* SCE is shown in Fig. 1. The current rapidly increased to a plateau level and then decreased. Light green crystals were first observed growing inward from the edges of the specimen at the time indicated by t^* on Fig. 1. Crystal growth continued inward until the sharp drop in current shown. At +0.4V, the entire iron surface became covered with green crystals; at +1.0V, approximately 20% of the surface was covered with green crystals at the time of the sharp drop in current. No other changes were visible until the crystals dissolved at t_p.

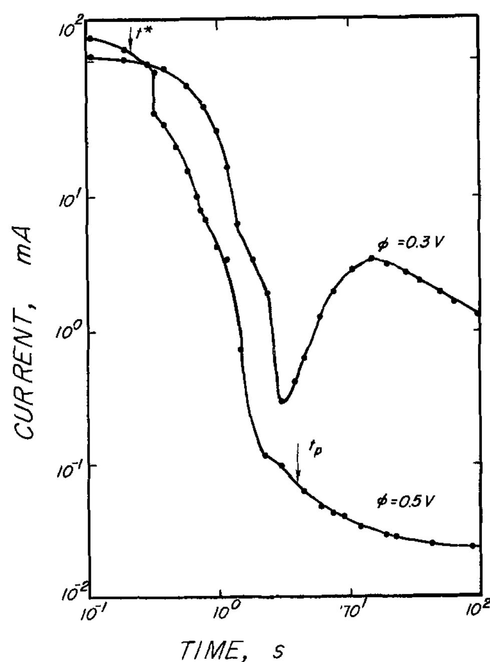

Fig. 1. Current decay curves for zone-refined iron in 6N H_2SO_4 at potentials below and above passivation potentials (anode area = 0.050 cm^2).

A transient current curve for a potential step to +0.3V, just below the passivation potential, is also shown in Fig. 1. For this condition a salt film forms but does not redissolve. The minimum in current for the +0.3V curve corresponds to a visible change in the salt crystal morphology. Flushing the pit with a jet of electrolyte for a period of 10 sec or longer reactivates the pit and repeats the sequence at +0.3V but has no effect at +0.5V. In the latter case the passive oxide film has formed.

The time during which lateral growth or dissolution of crystals occurred may be compared to the time constant characteristic of diffusion processes in the lateral direction, D/r^2. For pits of about 0.2 cm diam and for $D = 5.5 \times 10^{-6}$ cm^2/sec, one finds a time constant of roughly 10^4 sec. Since this time constant is much greater than the time during which repassivation events occur, it is proper to claim that the one-dimensional diffusion equation can be applied locally along the surface. That is, although the model does not account for crystal growth processes, it is still appropriate to compare the average time to film formation and average time to film dissolution to predictions based on a one-dimensional model.

In Fig. 1, the plateau region is identified as stage I. The plateau current density is taken to be i in Eq. [5], and the time at which the current decreases sharply is taken to be t^* in Eq. [5]. With these values, the supersaturation ratio at the moment of precipitation has been calculated with use of Eq. [8]. Figure 2 gives results for various magnitudes of potential jump and for various solutions. Each data point represents the average of about four separate measurements; measurements agreed among each other to within 2% of the value displayed. It is seen that the supersaturation ratio is slightly lower for the saturated solutions and for the larger potential jumps (higher plateau currents). These data support the interpretation that the initial plateau region in Fig. 1 corresponds to stage I.

Figure 3 gives the time at which dissolution of the salt film was observed in experiments on two unsaturated solutions. The initial plateau current was determined from the initial plateau region of the oscilloscope trace (see Fig. 1), and the dissolution process was observed with a microscope during the course of the experiment. It was difficult to see the surface salt as clearly at the highest current densities. Disappearance of the salt film did not occur uniformly over the surface at a particular instant. The salt film was observed to disappear from various parts of the surface over a range of time. In Fig. 3, each data point corresponds to the average of the beginning and the end of that time period; the vertical lines indicate the range of times over which disappearance was observed. Each data point is the average of about four separate experimental observations. In Fig. 3, it is seen that dis-

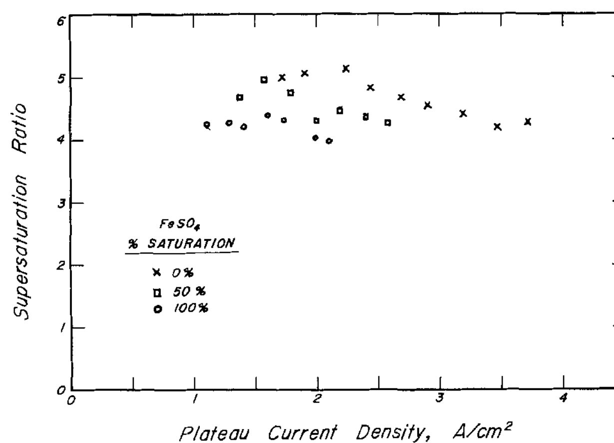

Fig. 2. Evidence for supersaturation processes during iron passivation in 6N H_2SO_4 containing various amounts of ferrous sulfate.

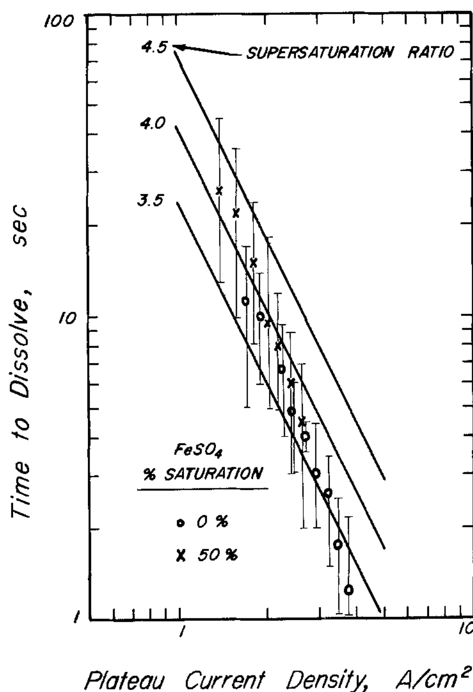

Fig. 3. Duration of existence of salt films during iron passivation in 6N H_2SO_4; solid lines give theoretical results with $s = 4$.

solution behavior in both solutions is correlated with use of the plateau current density.

In order to compare the data in Fig. 3 with calculations, it is necessary to specify the parameter s which appears in Eq. [9], and the parameter η which is proportional to the supersaturation ratio. For the iron system, the current decreased approximately at t^{-4} after the initial plateau period (28) as seen in Fig. 1. Calculations were therefore carried out with $s = 4$ and with various values of c^s_{pptn}/c_{sat} (supersaturation ratio): 3.5, 4.0, and 4.5. Calculated results are shown by the three diagonal solid lines in Fig. 3. By comparison with average experimental values (symbols) it is seen that data fall into a range of supersaturation ratios between 3.3 and 4.3, about 15% lower than the range found previously in Fig. 2. The data in Fig. 3 exhibit lower supersaturation ratios at larger values of plateau current density, in agreement with the trends seen in Fig. 2.

The theoretical model was also used to calculate the maximum salt film thickness which would be expected during stage II of dissolution in the iron system. Results are given in Fig. 4 for $s = 4$ and various supersaturation ratios. The maximum film thickness was found to vary inversely with the plateau current density. For the supersaturation ratios reported here (3.5-5.0) and for the observed range of plateau current densities (1.4-3.8 A/cm²), it was found that the maximum film thickness would be expected to be between 2 and 25 μm. The difficulties in observing films at the higher current densities may therefore be owing to the thinness of the film being less than the wavelength of light.

Titanium system.—The iron system is well poised for comparison between experimental data and theoretical calculations because the parameters which characterize the system are reasonably well known. On the other hand, making theoretical calculations for the titanium system is less satisfying since many of the system parameters are unknown. However, as indicated by the introductory remarks, it is nevertheless possible to estimate the range of several important parameters from experimental studies to date. The purpose of conducting theoretical calculations on the titanium system is, therefore, to determine whether or not, within reasonable constraints, it is possible for a salt film to form during initial moments of corrosion following generation of a virgin surface.

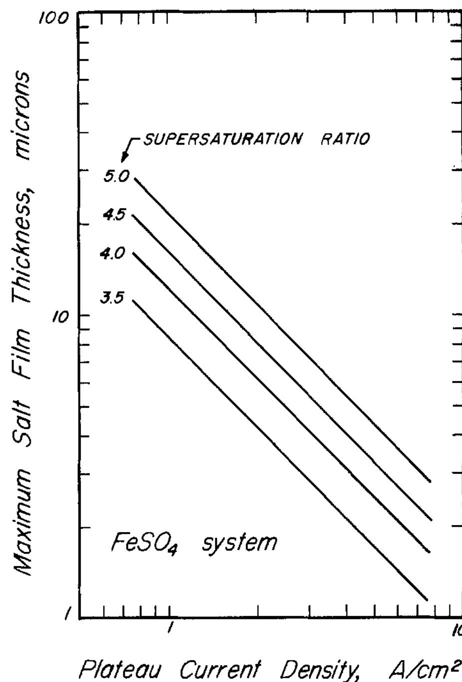

Fig. 4. Calculated results for iron system under study, with $s = 4$

In order to carry out theoretical calculations, it is necessary to specify the initial plateau current density, the supersaturation ratio at the moment of precipitation, and the parameter s in Eq. [9]. For the titanium system, rapid fraction experiments (20) have suggested that the initial anodic current density may be as high as 10^1-10^3 A/cm²; current decay was observed to begin at about 1 msec after fracture, and to decrease initially as t^{-2}. Because the supersaturation ratio had not been reported independently, calculations were carried out for various ratios between 1.0 and 3.0. Other values of parameters in the titanium system were given in Table I. Calculated results are given in Table II for $s = 2$, $10^2 < i < 10^3$, and $1.0 < c^s_{pptn}/c_{sat} < 2.82$.

Table II. Predicted behavior for titanium system for $s = 2$ and a range of parameter values

c^s_{pptn}/c_{sat}	100 A/cm²	200 A/cm²	500 A/cm²	1000 A/cm²

2.82	12,743	6,371	2,547	1,274

In the body of Part I of Table II, the time is given at which a salt film would form for each combination of supersaturation ratio and initial current density indicated. Since it is known that the initial current plateau does not persist for more than 1 msec, certain regions of parameter space clearly do not conform to experimental observations; these regions lie below the solid line drawn between entries in Part I. In Part II of Table II, the time at which dissolution is complete is listed for the various combinations of parameter values indicated. The ellipsometric measurements of Ambrose and Kruger (19) imply that if a salt film existed, it must already have disappeared within the 10 msec needed to initiate ellipsometric observations, since these authors did not observe salt films. The region below the solid line drawn in Part II corresponds to regions of parameter space which do not conform to the Ambrose and Kruger observation. Finally, Part III of Table II lists the maximum film thickness which may be expected for the different parameter values. Coulometric measurements during repassivation have indicated (20) that if a salt film exists, its thickness would range between 20 and 100Å. As seen in Part III of Table II, this criterion is by far the most stringent since it blocks out all but a narrow band of parameter space, contained between the solid lines.

By comparing the three parts of Table II, the view emerges that if salt films indeed form during the initial moments of titanium corrosion, then the initial plateau current density would exceed 150 A/cm², the supersaturation ratio would lie between about 1.1 and 1.3, and dissolution of the salt film would be complete within 0.03 to 1.0 msec following generation.

Discussion: Theoretical Model

A limiting case of behavior is encountered when all of the salt film originates by precipitation from the solution phase, that is, $s = \infty$. Pursuit of this limiting case provides a method for tabulating computer results so that users can, with simple algebra, estimate the salt film thickness and the lifetime of the film on the surface.

To achieve more general results, Eq. [8] will be cast into dimensionless form by defining

$$T = \frac{t - t^*}{t^*}$$

$$\theta = \frac{c}{c_{sat}}$$

$$\xi = \frac{y}{\sqrt{Dt^*}}$$

$$\delta = \frac{d}{\sqrt{Dt^*}}$$

$$M = mc_{sat}$$

By disregarding the anodic growth contribution to Eq. [8], the dimensionless form which results is

$$\frac{\delta(T)}{M} = -\int_0^T \frac{\partial\theta}{\partial\xi}(0, T)\, dT \qquad [10]$$

The right-hand side of Eq. [10] can be evaluated upon specification of the value of the parameter

$$\eta = \frac{i}{n\mathbf{F}c_{sat}}\sqrt{\frac{t^*}{D}}$$

The integration indicated by Eq. [10] has been carried out numerically, and dimensionless results are tabulated in Table III wherein the maximum value of the right-hand side of Eq. [10] is given for various values of η. As shown by the example calculation which follows, these results can be used to estimate the maximum thickness which a salt film will attain during its lifetime in any system which conforms to the model assumptions. If anodic film growth also occurs during precipitation, then the film will actually be thicker than the value computed from Table III.

Table III. Dimensionless salt film thickness and lifetime for the limiting case of $s = \infty$

η	$\frac{\delta_{max}}{M}(\eta)$	$T_p(\eta)$
0.9	0.00083099	1.0004
1.0	0.0053905	1.0263
1.2	0.035969	1.1630
1.5	0.116730	1.5842
2.0	0 30972	2.7444
2.2	0.40091	3.0932
2.5	0.54880	4.0143
3.0	0.81755	6.2089
3.2	0.93071	7.2506
3.5	1.1067	8.5007
4.0	1.4136	11.801

The dimensionless time at which the salt film dissolves completely, T_p, is that nonzero value for which

$$\int_0^{T_p} \frac{\partial\theta}{\partial\xi}(0, T)\, dT = 0 \qquad [11]$$

The integration indicated by Eq. [11] has been performed numerically for various values of η, and the resulting function $T_p(\eta)$ is tabulated in Table III. As illustrated by the following example, these results can be used to estimate the lifetime of the salt film on the surface for any system which the model describes. If anodic film growth also occurs after salt film precipitation, then the film will actually exhibit a longer lifetime than would be computed from data in Table III.

To demonstrate use of Table III, consider events for an iron system in which the electrolyte contains no iron salt ($c_b = 0$). For sake of example, suppose that experimental data indicate that the initial plateau current density is 2 A/cm² and that precipitation sets in 0.6 sec after polarization. By Eq. [4], one finds that the surface concentration at the moment of precipitation is 0.0039 gmole/cm³, or 4.0 times the saturation concentration. Also, η is found as

$$\eta = \frac{\sqrt{\pi}}{2}\frac{c^s{}_{pptn}}{c_{sat}} = 3.5$$

From Table III, find

$$\frac{\delta_{max}}{M} = 1.1067$$

where

$$d = 1.1067\,\frac{n\mathbf{F}c_s{}^2D\eta m}{i} = 2.83 \times 10^{-4}\text{ cm}, \quad \text{or } 2.83\ \mu\text{m}$$

This value may be compared with the value reported in Fig. 4 (4 μm). The difference corresponds to the effect of anodic film growth which is not considered in the limiting case under discussion.

From Table III, also find

$$T_p = 8.50$$

whence

$$t_p = (T_p + 1)\,\frac{\eta^2n^2\mathbf{F}^2c_{sat}{}^2D}{i^2} = 5.62\text{ sec}$$

This value may be compared with the experimental value reported in Fig. 3 (5-18 sec). The difference may be owing to anodic current flowing during precipitation.

Summary and Conclusions

A theoretical model has been developed to evaluate the hypothesis that salt films appear during repassivation of newly generated surfaces of certain metals. The model was tested by conducting experiments with iron in 6N H_2SO_4 under controlled ranges of system parameters. The model provided a correlation between the extent of supersaturation prior to salt precipitation,

the moment at which precipitation occurs, and the moment at which salt film dissolution occurs. The same model was then used to predict conditions under which a salt film would be expected on freshly generated titanium in 3*N* HCl, should such a film form. Comparison of calculated results with previously reported experimental observations indicates that the possible existence of salt films on titanium cannot be evaluated with data which are to date available. The investigation demonstrates how a mathematical model can be used to test hypotheses and to guide experimental work into regions of parameter space where definitive experiments can be carried out.

The model presented here does not include potential field effects or potential dependent aspects of charge-transfer or crystallization processes. To do so would require further clarification of various transport mechanisms which are incompletely understood at present.

The assumptions on which the model rests have been chosen primarily for the specific applications discussed here. The assumptions could be modified with relative ease to include additional effects such as convection, migration, hydrolysis, variable transport properties, and multiple reactions.

An Application of Coulostatic Method for Rapid Evaluation of Metal Corrosion Rate in Solution

Ken-ichi Kanno, Masayuki Suzuki, and Yuichi Sato

Tokyo Shibaura Electric Company, Limited,
Toshiba Research and Development Center, Saiwai-ku, Kawasaki 210, Japan

ABSTRACT

The coulostatic method was successfully applied to a rapid evaluation of metal corrosion rate in solution, where a known amount of small charge was supplied to the test piece, and the potential decay curve recorded was analyzed to obtain the corrosion rate. According to the theory developed, polarization resistances of mild steels in sulfuric acid and in distilled water were obtained, which agreed fairly well with resistances measured by usual methods. The coulostatic method developed in this study can be useful without ohmic drop correction, even in a high impedance solution. The time needed for measurement is considerably shorter, compared to the well-known linear polarization method.

The principal advantage of the polarization resistance technique (1-3) is its rapidity, compared to the weight loss method, in corrosion rate measurement. However, the measurements become markedly time dependent in the case of very low corrosion rate and the method involves a series problem in ohmic drop correction. Jones introduced a bridge circuit in order to correct the ohmic resistance of the solution (4). It is an excellent method, which we use regularly, but has several defects. For instance, it is useful only for galvanostatic measurement. It seems to be difficult, without several assisting devices, to apply the method to the solution of especially high ohmic resistance, such as distilled water or organic solvent. Further, the technique for detecting the balancing point by eliminating only the solution resistance from the polarization resistance requires a delicate, expert touch. To overcome this defect, an attempt was made to apply the coulostatic technique to the corrosion study. This was proposed by Delahay (5, 6) for the kinetic study of a usual electrode system, where redox species are in solution. In the coulostatic method, a known amount of small charge was applied to the test electrode at equilibrium state and the potential decay curve was recorded for analysis. In the present paper, the authors describe the coulostatic method applicability to a rapid metal corrosion rate evaluation from the theoretical point of view and its practical application to mild steels in 1N H_2SO_4 and in distilled water.

Theoretical

When a small amount of charge pulse is supplied to the electrical double layer of a metal test piece at a corrosion potential E_{corr}, the potential jumps to another potential E_m. It is assumed that the charging time is so short that leakage by the charge transfer reaction (corrosion reaction) can be neglected. Overvoltage η_0 of the test piece immediately after charging of the double layer is given by the equation

$$\eta_0 = E_m - E_{corr} \quad [1]$$

Assuming that the differential capacity per unit area of test piece C_d is essentially constant within a small voltage domain ($|\eta_0| < 5$ mV), the amount of charge density Δq_t consumed from time 0 to t, due to the corrosion reaction, is written by the equation

$$\Delta q_t = C_d(\eta_0 - \eta_t) \quad [2]$$

where η_t is the overvoltage at time t, namely the difference between the polarized potential and the corrosion potential. The increment of charge supplied to the electrode is consumed progressively by the corrosion reaction and the potential drifts back to its initial corrosion potential, E_{corr}. If it is assumed that the charge initially added is consumed only by the corrosion reaction of the test piece and that the concentration polarization is negligibly small in the corrosion process, the relation between overvoltage η_t and the faradaic current density I_t for discharge at time t is given by the next equation

$$I_t/I_{corr} = \exp\{(\alpha_+ n_+ \mathbf{F}\eta_t)/RT\} - \exp\{-(\alpha_- n_- \mathbf{F}\eta_t)/RT\} \quad [3]$$

where I_{corr} is corrosion current density, α_+ and α_- are transfer coefficients of anodic and cathodic reaction, and n_+ and n_- are the numbers of electrons concerning anodic and cathodic reactions, respectively. R, T, and $\mathbf{F}$ are gas constant, absolute temperature, and faradaic constant, respectively. When the absolute value of η_t is less than a few millivolts, Eq. [2] can be simplified to the following Stern-Geary equation (1-3)

$$I_t = 2.3\, I_{corr}\{(\beta_a + \beta_c)/\beta_a\beta_c\}\eta_t \quad [4]$$

where $\beta_a = 2.3\ RT/(n_+\alpha_+\mathbf{F})$, $\beta_c = 2.3\ RT/n_-\alpha_-\mathbf{F})$. The amount of charge density Δq_t defined by Eq. [2] is also expressed by using Eq. [4]

$$\Delta q_t = \int_0^t I_t dt = \int_0^t 2.3\ \{(\beta_a + \beta_c)/\beta_a\beta_c\}\eta_t \cdot I_{corr} dt \quad [5]$$

The combination of Eq. [2] and [5] yields the following differential equation

$$-C_d d\eta_t/dt = 2.3\{(\beta_a + \beta_c)/\beta_a\beta_c\}\eta_t \cdot I_{corr} \quad [6]$$

Solving Eq. [6] under the initial condition that $\eta_t = \eta_0$ at $t = 0$, the next equation is derived

$$\eta_t = \eta_0 \exp\{-2.3 I_{corr} \cdot t/(C_d K)\} \quad [7]$$

where $K = \beta_a\beta_c/(\beta_a + \beta_c)$.

Equation [7] suggests that overvoltage $\eta_t(t)$ decays exponentially with time t. Equation [7] is simplified by using polarization resistance R_p in place of $K/2.3I_{corr}$ (2)

$$\eta_t = \eta_0 \exp\{-t/(C_d R_p)\} \quad [8]$$

Polarization resistance R_p is considered to be one of the most important parameters concerning corrosion rate, which is inversely proportional to the corrosion current. If K values, namely the Tafel slopes for the anodic and the cathodic process, are known already or can be obtained by an appropriate method, corrosion current density I_{corr} is readily computed from R_p by the definition. Even if the Tafel slopes are un-

Key words: corrosion rate, rapid evaluation, coulostatic method.

known, the value of the reciprocal of R_p is useful as an indicator of the corrosion rate from a practical standpoint. Equation [8] is rewritten into a logarithmic equation

$$\log \eta_t = \log \eta_0 - t/(2.3C_dR_p) \quad [9]$$

which shows that a plot of log η_t against t is linear. By extrapolating log η_t plot to $t = 0$, η_0 can be obtained. Differential capacity C_d, which is needed in polarization resistance computation, is obtained simply from the next equation

$$C_d = \Delta q/\eta_0 \quad [10]$$

where Δq means a known amount of charge density supplied at first to the double layer of the test piece from capacitor C_1 of the equipment (see Fig. 1). Thus, polarization resistance R_p is calculated from Eq. [9] slope.

As C_d usually takes the value of 10^{-5}-10^{-4} F/cm^2, η_0 may be within 1-10 mV, if Δq is chosen as 0.1 μC/cm^2.

Experimental

Instrument.—The circuit of the instrument supplying known quantities of electric charge and recording variation of potential is shown in Fig. 1. This circuit is separated into two parts. One of them, the left side of the test cell, is composed of capacitor C_1, relay RL, battery B_1, battery B_3, and variable resistor VR_1 that acts as a source of known quantities of electric charge supply. The other is composed of battery B_2, variable resistor VR_2, operational amplifier OA, and voltage recorder D that follows potential variation of a test piece, called working electrode (WE). Before the measurement, a test piece was set with counter (CE) and reference electrodes (RE) in a test cell containing test solution. Measurement was made as follows: At first, capacitor C_1 was charged up to a certain voltage V_1, as was required to change the potential of the test piece a few millivolts from E_{corr}. Capacitor C_1 was then abruptly discharged across the cell by the action of relay RL, in order that the charge in C_1 was supplied to the test piece. In this equipment, three different capacitors are connected to a rotary switch so that the most suitable value can be selected. Capacitor C_1 is chosen sufficiently small, compared to the double layer capacity of the test piece, so that the almost whole charge stored in C_1 flows into the test piece.

The overvoltage (η_t)-time (t) curve shown in Fig. 2 was recorded with an Iwasaki SS-5003 Synchroscope, shown as D in Fig. 1. Before supplying the charge, the potential difference between WE and RE was canceled by the potentiometer composed of variable resistor VR_2 and battery B_2 in order to record only overvoltage η_t. The Teledyne Filbrick 1026 operational amplifier was used as a voltage follower.

Test pieces and other electrodes.—Commercially available mild steel plates (JIS SS41 and SB46), whose chemical compositions are given in Table I,

Table I. Compositions of mild steels tested in this work

Materials	C	Mn	S	P	Si
SS41	0.12	0.58	0.02	0.03	—
SB46	0.18	0.65	0.014	0.009	0.23

were used as test pieces. They were polished by 0.05 μm Al_2O_3 and were degreased in acetone. The surface of the specimen was coated with Parafilm (American Can Company) for an area of 9 cm^2 for SB46 and 5 cm^2 for SS41. About 10 cm^2 platinum plates, plated by platinum black, were used as counter and reference electrodes, respectively. Potential of the platinum plate as a reference electrode was sufficiently stable to observe the potential change in the test piece during measurement. A saturated calomel electrode was used for polarization curve measurement.

The solutions used in experiments were made from reagent grade chemicals with doubly distilled water. The conductance of distilled water was less than 1×10^{-6} Ω cm^{-1}. All measurements were carried out at a room temperature (28° ± 1°C) under atmospheric pressure without expelling dissolved oxygen in the solution.

Results and Discussion

Mild steel in 1N H_2SO_4.—The anodic overvoltage-time curve, resulting from the application of 5.82 μC of charge to the SB46 electrode immersed in 1N H_2SO_4 for 2 hr, is reproduced in Fig. 2. The corrosion potential E_{corr} of SB46, just before charging the double layer, is -0.5V *vs.* SCE and the end value of the potential decay curve coincided with the initial E_{corr} value. The log η_t-t plot, obtained from the potential decay curve of Fig. 2, indicates a good linearity in agreement with Eq. [9] (see Fig. 3). By extrapolating log η_t plot to $t = 0$, the value of η_0 was obtained as 3.0 mV, from which differential capacity C_d was calculated as 216 μF/cm^2. Although the value of η_0 was changed by changing the quantity of charge being supplied to the electrode the differential capacity, calculated by Eq. [10], is almost constant as long as η_0 is less than 10 mV. Polarization resistance R_p was deduced as 7.9 Ω cm^2 from the slope of log η_t plot, shown in Fig. 3, with the aid of C_d value.

For comparison, steady-state polarization curves were measured for the same test piece (Fig. 4), from which 2.8 mA/cm^2 and 50 and 128 mV were obtained as the values of I_{corr}, β_a, and β_c, respectively. From these parameters, R_p was computed as 5.6 Ω cm^2 by using the definition $R_p = K/2.3I_{corr}$, which agreed very closely with that obtained by the coulostatic method. The fact that the obtained C_d value is considerably larger, compared to that of a smooth electrode, such as mercury drop (7) (10-40 μF/cm^2), suggests an increase in the surface roughness of the test

piece due to corrosion reaction, pseudocapacitance caused by adsorption (8), and/or film formation (9).

Mild steel in distilled water.—The overvoltage-time curves for SS41 were also measured at various immersion times in distilled water. The relation between log η_t and t for the anodic process is shown in Fig. 5, which shows the case for 45 hr immersion. From Fig. 5, it is shown that the plots after about 200 msec indicate a fairly good linearity, while, at the initial stage of the decay curve, they deviate from the linear relationship. These deviations from the linear relationship may be due to the large resistance of distilled water. Since the charging process did not terminate instantaneously, due to the large resistance of the solution, it continued to proceed simultaneously with the discharge process at the initial part of the decay curve. Thus, during charging of the double layer, the overvoltage due to the ohmic drop between the reference and working electrodes was superimposed on the activation overvoltage due to the corrosion reaction which we wanted to measure. In such a case, the η_0 value was obtained by extrapolating the linear parts of the log η_t plots to $t = 0$.

The validity of this treatment and an interpretation of the deviation were confirmed by the following experiment, using the Graham-type equivalent circuit (Fig 6.) for the corrosion cell system composed of resistors, R_s', R_p', and capacitor C_d', which were solution resistance, polarization resistance, and double layer capacity, respectively. When charge Δq, stored in capacitor C_1 of the equipment, is transferred to capacitor C_d', current i, flowing through R_s', is given by

$$i = \frac{\Delta q}{R_s'C_1} \exp\left(-\frac{t}{R_s'C}\right) \quad [11]$$

where $C = C_1C_d'/C_1 + C_d'$). This equation explains that the time constant for charging capacitor C_d' becomes larger, with increasing R_s' values. For the discharging process in the equivalent circuit, the following relations also hold

$$V_t = V_0 \exp\left(-\frac{t}{C_d'R_p'}\right) \quad [12]$$

$$\Delta q = C_d'V_0 \quad [13]$$

where V_0 means the voltage difference in terminals (a and b in Fig. 6) immediately after charging the equivalent circuit by an external electricity source, V_t is voltage difference at time t, Δq is a known amount of charge stored in capacitor C_1. If a large resistor value, such as 97.7 kΩ, was used as R_s', deviation was observed, as expected, in log V_t plots of Eq. [12], while no deviation was observed in the case of $R_s' = 0$. These features are shown in Fig. 7 as plots a and b.

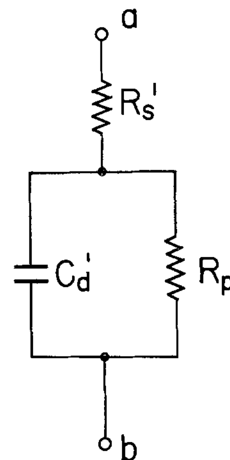

Fig. 6. Equivalent circuit for the test cell where R_s', R_p', and C_d' correspond to solution resistance, polarization resistance, and double layer capacitance, respectively.

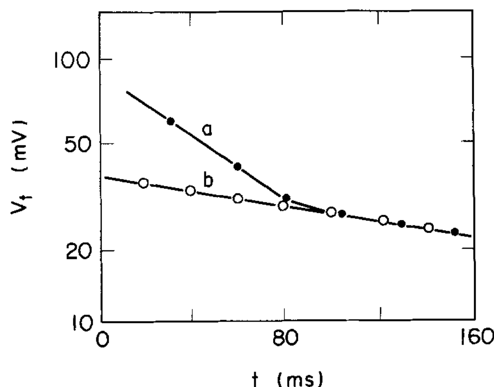

Fig. 7. Log V_t-t relationship for equivalent circuit. (a) $R_s' = 97.7$ kΩ, $R_p' = 29.5$ kΩ, $C_d' = 9.87$ μF; (b) $R_s' = 0$Ω, $R_p = 29.5$ kΩ, $C_d' = 9.87$ μF. Charge applied was 0.370 μC for both cases. Voltage values V_t were observed between terminals a and b in Fig. 6.

Table II. R_p' and C_d' data observed at various R_s' values

	Used values			Observed values			Reliability	
$\Delta q'$ (μC)	R_s' (kΩ)	R_p' (kΩ)	C_d' (μF)	V_0 (mV)	R_p' (kΩ)	C_d' (μF)	$(R_p')_{obs}/R_p$	$(C_d')_{obs}/C_d'$
0.128	0	2.94	7.40	16.3	2.95	7.87	1.003	1.064
0.370	0	1.29	7.40	48.2	1.35	7.68	1.046	1.038
0.370	0	29.5	9.87	37.4	28.4	9.90	0.963	1.003
0.370	0.509	29.5	9.87	36.9	28.9	10.0	0.980	0.993
0.370	3.00	29.5	9.87	37.1	28.8	9.98	0.976	1.011
0.370	97.7	29.5	9.87	37.0	28.7	10.0	0.973	1.013

The potential decay curve b in Fig. 7 can be regarded as being controlled by two different successive processes, indicated by $V_t = (\Delta q/C_1) \exp \{-t/(C_1R_s')\}$ and $V_t = V_0 \exp \{-t/(C_d'R_p')\}$, if $C_d' >> C_1$. The first equation corresponds to the C_1 discharging process, the second to the C_d' discharging process. As time constant $C_d'R_p'$ is from a few times to ten times larger than C_1R_s', the C_1 discharging process effect (R_s' effect) appears only at the initial part of the potential-time curve. Therefore, the latter part is controlled only by the large time constant $C_d'R_p'$, resulting in the latter part being unaffected by R_s'. In Table II, V_0 values obtained by extrapolating the linear parts of log V_t plots to $t = 0$ at various combinations of R_s', R_p', and C_d', C_d' values calculated by Eq. [13], and R_p' values calculated from the slope of log V_t plots by using Eq. [12] are tabulated in comparison with actual values of resistors and capacitors used. This table shows the observed values of C_d' and R_p' are nearly equal to the actual values used and are almost constant, even if the R_s' values are changed. From these results, it is shown that high resistance (R_s' in the equivalent circuit), in series to the leaky condenser, has virtually no effect in determining capacity C_d' and resistance R_p' values, although it delays the charging process. In an actual corrosion system with large solution resistance, the situation seems to be similar.

Thus, polarization resistances obtained in distilled water with high solution resistance seem to be correct. These values are tabulated in Table III with differential capacities at various immersion times. On the other hand, a value of 21 mdd was obtained by the weight loss method for the same test piece after 75 hr immersion. To confirm the validity of the coulostatic method, this 21 mdd (8.4 μA/cm^2) corrosion rate was transformed to an R_p value by using the following relations

$$\text{corrosion rate} = (M/n\mathbf{F}) I_{corr}$$

$$R_p = K'/I_{corr}$$

where M is atomic weight of iron, and $K' = \beta_a\beta_c/2.3(\beta_a + \beta_c)$. Constant K' used was 0.018V determined previously in this laboratory with a galvanostatic linear polarization method using Jones' circuit (4) and the corrosion rate by the weight loss method for nearly equal immersion time in distilled water. In the authors' experience, the K' value seems to be almost constant, even if the Tafel slopes changed to some extent with the immersion time. Although many combinations of β_a and β_c on the K' value of 0.018V may be possible, some reasonable combinations are 60 mV (β_a) and 134 mV (β_c) or 70 mV (β_a) and 105 mV (β_c), which are in good agreement with values reported in several papers (10-12). From this K' value (0.018V), the average R_p value was thus calculated to be 2.2 kΩ cm^2. This value seems to be in good agreement with the values tabulated in Table III, showing the usefulness of the coulostatic method.

Table III. Double layer capacity and polarization resistance for SS41 in distilled water for various immersion times $\tilde{t}$

$\tilde{t}$ (hr)	Δq (C/cm^2)	η_0 (mV)	C_d (μF/cm^2)	R_p (kΩ cm^2)
45	0.366	2.16	169	2.4
51	0.364	1.83	199	2.1
74	0.376	1.57	239	1.1

The C_d values given in Table III are also worth noting. Observed values are larger, compared to those for a smooth electrode (7), and tend to increase with increasing immersion time. Surface roughness, oxide film formation (9), adsorption of some charged species or hydrogen (8), etc., may be considered as factors that affect the C_d values. The stainless steel double layer capacity value is strongly affected by specimen pretreatment, such as pickling temperature, time, and precathodizing (8). Recently, Azzerri reported a large C_d value for mild steels covered by corrosion product layers (13). Though the physical meaning of the large C_d value is not clear at the present time, an increase in its value with increasing immersion time (Table III) may suggest that the surface roughness and the corrosion film formation of the test piece increase as the corrosion progresses.

From a practical standpoint, it is useful if the forms of corrosion are detectable, *e.g.*, general or localized. By using the coulostatic technique, it may be possible to determine whether it is general or pitting corrosion by comparing a pair of C_d and R_p values for each corrosion system. For instance, the C_d and R_p of Type 304 stainless steel in air-saturated $1N$ H_2SO_4 were 50 μF/cm^2 and 610 kΩ cm^2 after 54 hr immersion, while those of Type 304 stainless steel in 10% $FeCl_3$ solution after 19 hr were 40 μF/cm^2 and 0.14 kΩ cm^2, respectively. If the Tafel slopes in both solutions are not so different from each other, the corrosion rate is about 4000 times faster in $FeCl_3$ solution than in H_2SO_4, while the C_d values in both solutions are quite similar, and suggests that the metal surfaces are nearly equal in area, roughness, and/or state. Namely localized corrosion is expected to be occurring in $FeCl_3$ solution. In actuality, corrosion pits were observed on the test piece in $FeCl_3$ solution, while the surface, except the pits, maintained a metallic luster similar to that in H_2SO_4.

The advantage of the present method is that the overvoltage variation is measured without applying current between working and counterelectrodes. Therefore, the method is easily applicable to a high impedance solution, such as distilled water, without consideration of the ohmic drop correction. The coulostatic method is a sort of relaxation method, where measurement may be carried out within a much shorter time under more natural conditions, compared to the usual linear polarization method. To reduce the time-consuming defect of the linear polarization method, especially when measuring a low corrosion rate, Jones and Greene (14) derived a new charging curve analysis technique. In this method, however, the surface state of a specimen may change, owing to a constant current flow through the test piece surface. It is difficult to obtain a unique time constant and requiring much longer time, compared to the coulostatic method.

From the above results and discussion, it may be concluded that the coulostatic method is useful for a rapid corrosion rate evaluation for mild steel in sulfuric acid and in distilled water with high ohmic resistance. Experiments concerning other combinations of metals and solutions are in progress.

Inhibition of Corrosion of Iron in Acids by Thiourea and Derivatives

K. Chandrasekhara Pillai

National Metallurgical Laboratory, Jamshedpur, Bihar, India

and R. Narayan

Department of Chemistry, Indian Institute of Technology, Madras 600 036, India

ABSTRACT

The inhibition of corrosion of iron (0.13%C) in hydrochloric acid by thiourea and its derivatives has been investigated. Inhibition is due to adsorption of the molecular species. The maximum of efficiency with low concentrations of thiourea and its N-substituted derivatives is attributed to the protonation of the inhibitor with consequent acceleration of the hydrogen evolution process. Protonation is high with the simple thiourea and increases with the concentration of the inhibitor and hydrogen ion concentration. S-substituted derivatives show an increasing efficiency with concentration and are safe inhibitors.

Thiourea (TU) has been studied as a corrosion inhibitor by several groups of workers (1-14), and the reports are conflicting. Some workers finding TU to be a cathodic or anodic inhibitor depending on the concentration of TU (1, 7, 9) while others have observed a corrosion-stimulating effect by TU (4-6, 8). Where the TU is reported to be an inhibitor, it is a general observation that the effective inhibition is restricted to a small range of concentrations, the maximum efficiency being observed with 1-3 mM concentration of TU. No clear explanation is given for this maximum in efficiency. Several derivatives of TU have also been studied periodically and reported as moderately good inhibitors (15-18). Hence it was proposed to study TU and its derivatives for their inhibition of corrosion of a particular composition of the metal, varying other parameters like pH, oxygen content, etc. The objective was to correlate the structure of the inhibitor with its inhibiting action. Thiourea, tetramethyl thiourea (TMTU), and ethylene thiourea (ETU) as representatives of N-substituted derivatives, and S-methyl isothiourea (SMTU) and S-benzylisothiourea (SBTU) as S-substituted derivatives were chosen for the study.

Experimental

Corrosion rates were followed by gravimetric measurements and also by estimation of the Fe^{2+} in solution by spectrophotometry, as the complex of O-phenanthraline or dipyrydyl. Thin 0.2 mm plates (3.5 cm^2) were immersed in 150 ml of the corroding solution. Deaeration was carried out with deoxygenated nitrogen when necessary. The electrochemical studies were mainly measurements of the rest potentials and potentiostatic polarization using a 3 electrode combination of a platinum counter, a calomel reference with suitable bridge solution, and a test electrode with approximately 1 cm^2 circular face being exposed for corrosion. The mild steel test electrode had the following composition (percentage) 0.13 C, 0.032 S, 0.14 Si, 0.025 P, 0.48 Mn. All potentials are quoted with respect to the saturated calomel electrode. Tensammetric and drop times measurements were made with a dropping mercury electrode to observe the variation of the adsorption of the inhibitors at the metal solution interface.

Key words: metals, acid, corrosion, inhibition.

Results

The inhibition efficiency of the inhibitor is calculated as $(r_1 - r_2/r_1) \times 100$ where r_1 = corrosion rate in mg cm^{-2} without inhibitor and r_2 = corrosion rate in mg cm^{-2} with inhibitor, and r_1 and r_2 are the mean of four values. The mean deviation of the reported results is ±5%.

Figures 1, 2, and 3 show the variation of the inhibition efficiency with concentration of the inhibitor in 1 MHCl, 3 MHCl, and in a solution of pH 2.5 (KCl

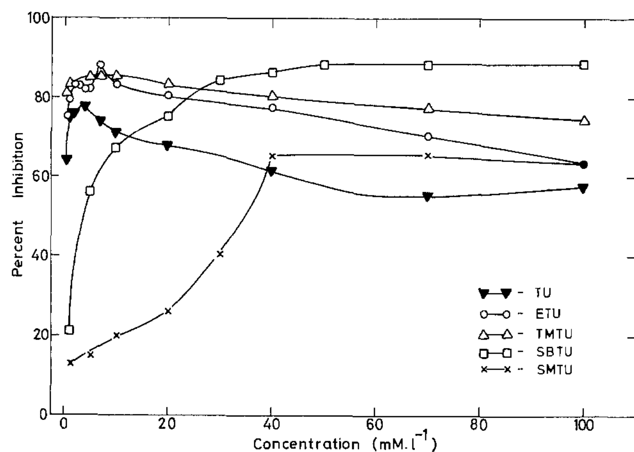

Fig. 1. Variation of inhibition efficiency with concentration of inhibitor in deaerated 1M HCl.

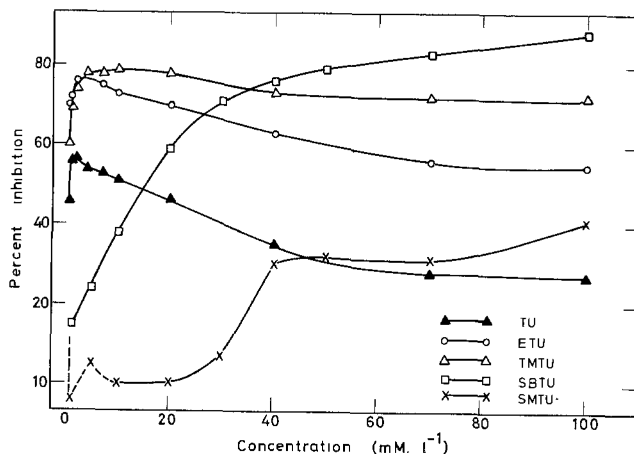

Fg. 2. Variation of inhibition efficiency of inhibitor in deaerated 3M HCl.

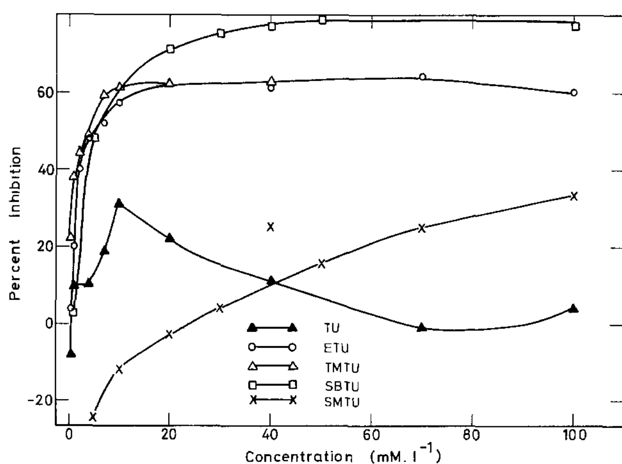

Fig. 3. Variation of inhibition efficiency in solution of pH_2

+ HCl). The efficiency goes through a maximum for TU, ETU, and TMTU while it increases continuously with concentration to a limit with SMTU and SBTU in deaerated 1M HCl and 3M HCl. TMTU shows a higher efficiency than TU and ETU at higher concentrations. The inhibition efficiencies are low in the solution of *p*H 2.5, low concentration of the inhibitors even stimulating corrosion. The sharp maximum in efficiency is observed only with TU.
