The I_{corr} has been obtained from the polarization curves at the E_{corr}, which is the point of intersection of the extrapolated linear regions of the cathodic and anodic curves. Where a linear cathodic Tafel region alone could be observed this has been extrapolated and the current corresponding to the E_{rest} has been taken as the I_{corr}. The inhibition efficiency is then calculated and the variation is generally similar to those observed with the gravimetric measurements. The E log i variations in 1M HCl are shown in Fig. 4-8.

The E_{rest} potentials (Tables I-III) show an initial negative shift with increasing concentration of TU, ETU, or TMTU and then a positive shift with higher concentrations. The concentrations corresponding to the maximum negative shift are the same as those which exhibit maximum inhibition efficiencies. The E_{rest} shifts continuously to cathodic values with increasing concentrations of SBTU. The E_{corr} values are more positive than E_{rest}, but changes in E_{corr} parallel the E_{rest} changes. Similar observations are made in deaerated 3M HCl solutions. The polarization of the cathodic process increases to a maximum with increasing concentration of TU, ETU, or TMTU and subsequently decreases with higher concentrations. The changes in the Tafel slopes are shown in Tables

I-III. The b_a or slope of the anodic Tafel region goes through a maximum with increasing concentration of TU, ETU, and TMTU. The polarization of the anodic process by TU, ETU, and TMTU is not very large. SBTU and SMTU polarize both the cathodic and anodic processes increasingly as their concentration is increased. SBTU has a greater polarizing effect than SMTU.

Discussion

Several workers have reported the maximum in corrosion efficiency with 1-2 mM thiourea in acid solution (8, 19, 20). The inhibition is ascribed to adsorption of thiourea. The initial increase in inhibition efficiency can be associated to the increased surface coverage by the adsorbed species, which appears to be a molecular form of thiourea (8). The fall in efficiency at higher concentrations should be the result of desorption of thiourea or due to modification in the adsorbed species. Other studies have shown that thiourea is adsorbed on several metals over a wide potential and concentration range (up to even 0.5M). Desorption is unlikely with iron at the corrosion potential (−0.25V) which is only a little positive to the pzc (−0.3V).

Stimulation of corrosion by H_2S obtained from the reduction of TU (8, 20) and through a negative ψ effect (5, 25) from the presence of HS^- have been suggested while Antropov (21) showed that H_2S actually increased the inhibition efficiencies of certain thiourea derivatives. H_2S could be detected presently only on prolonged contact of the iron with the solution while the high acid concentration used reduces HS^- concentration to negligible values.

We therefore propose that adsorbed thiourea undergoing a modification accelerates the hydrogen evolution reaction (HER) and hence exerts a lower inhibition effect. Polarographic studies show that the hydrogen overvoltage on mercury is lowered considerably by the presence of even small quantities of TU, ETU, or TMTU in solutions of pH less than 4 (Table IV). Mauree and Gierst (22) had shown that TU reduces the overvoltage of several reduction processes at mercury. These could generally be accounted for by a ψ effect, but they indicated that the much greater acceleration of the HER requires a different catalytic mechanism. The kinetic parameters of the HER on iron in the present studies follows the Volmer mechanism. Thus the discharge of H_3O^+ is the rate-determining step, both with mercury and iron electrodes, and this step is catalyzed by the adsorbed TU. Protonated thiourea is inferred to be the catalyst. The proton is attached to the sulfur and hence is brought closer to the metal since the adsorption of TU is through the metal sulfur interaction. The charge

Table IV. Decomposition potential (mV) of deaerated 1M HCl in presence of TU and derivatives, at a mercury electrode

60.0				−1105	−1035
100.0				−1095	−1025

transfer process can thus go through with a lower activation energy. The thiourea after adsorption may undergo protonation or may be protonated in the bulk and then adsorbed. With increasing concentration of TU in bulk, the interfacial concentration of the protonated species will increase at the cost of molecular thiourea. The former accelerates the HER while the latter inhibits the process. The two opposing effects lead to a maximum in the inhibition efficiency.

The concentration of the adsorbed thiourea and the protonated species will be higher at the mercury solution interface than with the iron solution interface for the following reasons: (*i*) the generally greater adsorption of organic compounds on mercury (23, 24); and (*ii*) the higher hydrogen overvoltage on mercury resulting in greater protonation process (23). Hence the acceleration of the HER is observed at mercury electrodes even with very small concentrations of TU.

The inhibition efficiency is a maximum with 10 mM TU in a solution of *p*H 2 with 4 mM in 1M HCl and with 2 mM in 3M HCl. The relative reduction in inhibition efficiencies are also greater in 3M HCl. These are due to the higher H_3O^+ concentrations resulting in greater protonation of TU in the more concentrated acids. However at any of the concentration studied, the concentration of molecular TU is apparently greater than that of the protonated species and net inhibition only is observed. The polarization curves show that the cathodic process is initially polarized by the molecular form. With higher concentrations, more and more of the protonated species take part in catalyzing the HER and the polarization becomes smaller.

The E_{rest} shift and cathodic polarization by ETU and TMTU are similar to those observed with TU. The polarizing effects are however greater while the accelerating effects on the HER by protonated species are much smaller. Similarly the anodic depolarizing effects are largest with TU. There are some depolarizing effects with ETU at 10 mM concentration while TMTU exerts at 20 mM or higher concentrations, a small part but a definite polarizing effect. The inhibition efficiency curve shows a clear maximum with TU while a flattening out of the curve is observed with TMTU (Fig. 1).

The drop-time potential curves which are similar in 1M HCl, 1M KCl, and in solution of *p*H 2 show that TU, ETU, and TMTU are specifically adsorbed at the mercury-solution interface. The negative shift of the pzc indicate the strong Hg-S interaction. The order of adsorption is TMTU > ETU > TU. The dipole moments calculated by the CNDO method is $\mu_{ETU} > \mu_{TU} > \mu_{TMTU}$ (Table V). The more extensive adsorption of TMTU causes a greater shift of the pzc. If this order of adsorption also holds good with iron [Antropov (26)], the inhibition effect will also increase in the order TMTU > ETU > TU. The protonation process, on the other hand, will be controlled by the electron density of the sulfur atom and availability of a proton adjacent to this atom, the latter

Table V. Dipole moments (μ) of TU, ETU, and TMTU calculated by "CNDO" method

Thiourea derivatives	$\mu_{calculated}$	Electron density on C	Electron density on N	Electron density on S	$\mu_{reported}$
TU	4.23	+0.2777	−0.1744	−0.4101	4.89[a]
ETU	5.98	+0.2853	−0.1297	−0.4101	5.51[b]
TMTU	3.69	+0.2688	−0.1209	−0.4086	

The dipole moments were computed by the "complete neglect of differential overlap (CNDO)" method proposed by Pople *et al.* (30), which is an approximate version of self-consistent Field (SCF)-LCAO-MO theory.

factor being important if the protonation is a surface process. Steric factors will thus come into play. The order of protonation will be TU > ETU > TMTU. Hence TMTU with the greatest adsorption and least protonation will have the maximum inhibition efficiency, while the relative lowering in efficiency will be largest with TU.

The near-symmetrical nature of the drop-time curves (Fig. 9) and the tensammetric studies (27) shows that both SBTU and SMTU are nonspecifically adsorbed over a wide range of potentials. The small positive shifts of the pzc are due to the adsorption of positively charged isothiouronium species. The adsorption increases continuously with the concentration. Studies with urea (27) showed very little adsorption and hence the absence of metal-nitrogen interaction. Thus SBTU and SMTU are adsorbed through the sulfur. This adsorption is not high, due to the substituent present on the sulfur. SBTU is more extensively adsorbed than SMTU, due to the metal-Π electron interactions and a probable flat orientation of the aromatic ring. The substitution will also reduce protonation of the sulfur. The proton is attached to the nitrogen as these are isothioureas. Hence catalysis of the HER is not to be expected as with the other thioureas. Very little lowering of the hydrogen overvoltage is observed on mercury while the cathode processes on iron are increasingly polarized (Fig. 7 and 8). Inhibition alone is expected and found.

The mechanism of anodic dissolution in the presence of protonated thioureas, the stimulation of corrosion with very small addition ($<10^{-4}$ Ml^{-1}) of the thioureas, and the influence of oxygen on these processes are to be dealt with separately.

Conclusion

The maximum in the inhibition efficiency of thiourea and N-substituted derivatives is the result of two opposing effects—an inhibition by adsorbed molecular species and an acceleration by adsorbed protonated species. The cathode polarization by these additives is greater than anode polarization. Substitution in the parent thiourea modifies metal-sulfur interaction and protonation. Alterations in the bulkiness, solubility, and symmetry of the structure due to substitution change the adsorption characteristics. TMTU with least protonation and with maximum adsorption thus is a better inhibitor than ETU and TU. SMTU and SBTU increasingly polarize the cathode and anode process and are safe inhibitors even at high concentrations.

Manuscript submitted Aug. 19, 1977; revised manuscript received Feb. 20, 1978. This was Paper 7 presented at the Philadelphia, Pennsylvania, Meeting of the Society, May 8-13, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

The Voltammetric Behavior of Some Viologens at SnO_2 Electrodes

J. Bruinink and C. G. A. Kregting

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The reduction peak of a linear potential sweep voltammogram of 1,1'-diheptyl-4,4'-dipyridinium dibromide in water, was found to be very steep with $E_p - E_{p/2} \approx 0.020$V at a scan speed less than 0.1 V/sec. This behavior was discussed on the basis of a model consisting of a reversible electron transfer and a coupled chemical reaction in analogy with reversible metal deposition. With modified viologens similar results have been obtained. The role of the coupled chemical reaction was underlined by the observed Nernstian dependence on cation and/or anion concentrations of both first and second reduction peak potential. The observed anodic peak of the first reduction step differs from the peak expected from the dissolution of a bulk deposit.

The use of viologens in redox chromic displays is well known (1-3). It has been demonstrated that with a suitable combination of viologen cation A^{2+} and anion X^-, *e.g.*, 1,1'-diheptyl-4,4'-dipyridinium dibromide, the first reduction step in water is followed by a chemical reaction causing a solid deposit on the electrode. The following reaction scheme in an aqueous solution has been proposed on the basis of polarographic and conductometric experiments (2, 3)

$$A^{2+} + e \rightleftarrows \dot{A}^{+} \quad \text{(first step)} \qquad [1]$$

$$\dot{A}^{+} + X^{-} \rightleftarrows AX\downarrow \qquad [2]$$

$$AX + e \rightleftarrows A\downarrow + X^{-} \quad \text{(second step)} \qquad [3]$$

The reaction product AX is deposited as a solid purple film on the electrode. The product A is also a solid deposit but with a yellowish-brown color.

Previous voltammetric measurements on tin dioxide electrodes revealed that the ratio of the charges involved in reduction and oxidation of heptyl viologen bromide is about unity for the first reduction step. Further, it was found that the first reduction step gives a very steep current peak, whereas the corresponding oxidation peak showed a very fast drop of the current after dissolution was completed (4).

The present study presents the results of some voltammetric investigations of the first reduction and oxidation steps of film-forming viologens on tin dioxide with the emphasis on 1,1'-diheptyl-4,4'-dipyridinium dibromide (HV-Br). The results are compared with a theoretical model.

Key words: deposition, nucleation, dipyridinium compound.

Theoretical

Cathodic current voltage curve.—The theory of linear potential sweep voltammetry (LSV) at solid electrodes for a reversible metal film deposition has been presented by Berzins and Delahay (5), whereas Nicholson and Shain described this theory for various other reduction schemes involving soluble reactants and products (6). When considering the redox reaction of viologens, it was necessary to extend this theory

to an electrochemical reaction with a coupled chemical reaction yielding an insoluble deposit on the electrode. In a simple approximation this can be done by considering reaction [1] as being reversible under the experimental conditions. This assumption is very reasonable, as appears from literature (7, 8). Further it is assumed that the precipitation reaction [2] proceeds fast and quantitatively thus yielding an equilibrium concentration of the monocation C_{A^+} equal to K_s/C_X (2, 9, 10), where K_s represents the solubility product of the viologen radical salt AX and C_X the anion concentration. All activity coefficients are assumed to be unity.

Semi-infinite diffusion to a plane electrode is assumed to be responsible for mass transport in the solution. For the cathodic sweep, $E = E_i - vt$, where v is the scan rate. The initial potential E_i at $t = 0$ is given by the equilibrium potential of the electrode covered with at least one monolayer of deposit

$$E_i = E_o + \frac{RT}{n\mathbf{F}} \ln (C^*_{A^{2+}} C_X/K_s) \quad [4]$$

where $C^*_{A^{2+}}$ represents the bulk concentration of A^{2+}.

The present situation is identical with that of reversible deposition of a metal film on a solid electrode, which was solved by Berzins and Delahay (5). The reduction current was given by them as

$$I = \frac{2n^{3/2}\mathbf{F}^{3/2}}{\pi^{1/2}R^{1/2}T^{1/2}} AC^*_{A^{2+}}D_{A^{2+}}{}^{1/2}V^{1/2}\Phi\left[\left(\frac{n\mathbf{F}}{RT}vt\right)^{1/2}\right] \quad [5]$$

where

$$\Phi(\alpha) = \exp(-\alpha^2) \int_0^\alpha \exp(z^2)\,dz \quad [6]$$

A is the surface area. The function Φ defined by [6] has a maximum value of 0.5410 at $\alpha = 0.9241$, as can be found in tables (11). The peak current at 25°C is then proportional to the square root of the scan rate

$$I_p = 367n^{3/2}AC^*_{A^{2+}}D_{A^{2+}}{}^{1/2}v^{1/2} \quad [7]$$

At the peak potential E_p, $vt = 0.022/n$ (V) at 25°C so that

$$E_p = E_i - 0.022/n \text{ (V)} \quad [8]$$

The concentration dependence of the first reduction peak potential of HV-Br at solid electrodes follows directly from Eq. [4] and [8], namely, at 25°C

$$E_p(1) = E_o(1) + 0.059 \log \{C^*_{A^{2+}} C_X/K_s\} - 0.022 \quad [9]$$

Further it is found that

$$E_{p/2} = E_i - 0.002/n \text{ (V)}$$

and

$$\Delta E = E_p - E_{p/2} = 0.020/n \text{ (V)} \quad [10]$$

From the simple model used it is clear that very steep reduction peaks are expected. They are shifted anodically in comparison with a reduction in which both reactant and product are soluble as follows directly from [4]. In the latter case I_p is also proportional to $v^{1/2}$, but ΔE is about $0.056/n$ (V) at 25°C (6). Deviations from this metal deposition theory such as a cathodic shift of the peak potential at increasing scan rate have been observed by Hills *et al.* (12). Their origin has been ascribed to the occurrence of nucleation effects.

These nucleation effects during electrochemical formation and growth of a metal deposit have been discussed by Fleischmann and Thirsk for the case where the depositing metal is the same as the electrode (13). An extension to nucleation and growth on inert substrates was presented by Astley, Thirsk, and Harrison (14). It was shown that if linear diffusion is the rate-controlling process in the three-dimensional growth of instantaneously formed hemispherical nuclei, the observed current-time transient due to a potentiostatic step has a dependence of the form

$$I \propto t^{1/2} \quad [11]$$

Anodic current-voltage curve.—The electrochemical dissolution of a bulk viologen radical salt deposit during the anodic sweep is considered to be a reversible oxidation process preceded by a fast chemical reaction as presented by [2] and [1]. In this case, too, the concentration of the deposit is assumed to have unit activity until complete dissolution occurs at t_{max}. With these assumptions, the dissolution can be compared with the anodic dissolution of a bulk metal deposit as discussed earlier by Nicholson (15). In the anodic case $E = E_i + vt$ in which E_i is given by [4]. The expression for the current is obtained after substitution of $\beta = -\frac{n\mathbf{F}}{RT} vt$ in [5]. The expression for the anodic current is then

$$I = -n\mathbf{F}AC^*_{A^{2+}}(\beta D_{A^{2+}})^{1/2}\exp(\beta t)\,\mathrm{erf}[(\beta t)^{1/2}] \quad [12]$$

The total charge q_o involved in the anodic dissolution is obtained by integration. As a result of this theory one obtains a rather steep anodic peak, while at $t = t_{max}$ the current drops abruptly to zero.

Experimental

The voltammetric experiments were performed with a PAR 173 potentiostat system and electronic *IR* compensation was used. A Hewlett Packard 7000 AM recorder and a Philips PM 3330 oscilloscope with a polaroid camera were used for signal monitoring. The electrode material employed was tin dioxide coated glass (10 Ω/□) made by pyrolitic decomposition of $SnCl_4$ in *n*-butylacetate using antimony as dopant.

The electrode area was 0.2 cm². All experiments were carried out in a vessel thermostated at 25°C. The electrolyte solutions were deoxygenated by passing argon through them (5 ppm O_2). The reference and counter-electrodes used were Ag/AgCl electrodes separated from the cell solution by Luggin capillary and glass frit, respectively. The 1,1′-diheptyl-4-4′-dipyridinium dibromide (HV-Br) and other dipyridinium derivatives were of the same purity as described in a previous paper (4).

Results and Discussion

Cathodic peak.—The LSV behavior of the first reduction step of HV-Br on tin dioxide is shown in Fig. 1, which is typical of this viologen at scan speeds less than 0.1 V/sec. The same figure gives theoretical values, calculated using Eq. [5]. The value of K_s used was calculated with aid of Eq. [9], while the value of the diffusion coefficient was obtained from the experimental value of I_p and Eq. [7]. It can be seen that the calculated values fit the experimental data very well, if at least one monolayer has been formed. In addition it is obvious that the voltammogram is very steep with $\Delta E \approx -0.02$V in agreement with the simple model.

An indication about monolayer completion can be deduced from Fig. 2 in which the charge involved in

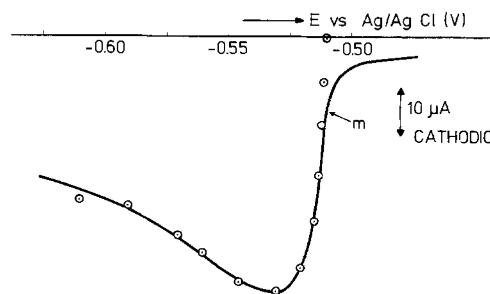

Fig. 1. Linear potential sweep voltammogram for 8.8 × 10^{-4}M diheptyl viologen dibromide in an aqueous solution of 0.3M KBr. Scan rate 0.1 V/sec. ⊙, Values calculated with $D = 6.4 \times 10^{-6}$ cm² sec^{-1} and $K_s = 6 \times 10^{-7}$. *m* indicates monolayer completion.

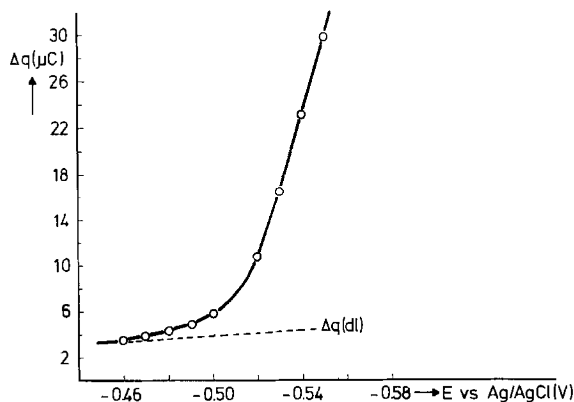

Fig. 2. Charge vs. potential of LSV for 8.8 × 10^{-4}M diheptyl viologen dibromide in an aqueous solution of 0.3M KBr. Scan rate 0.1 V/sec. Δq(d.l) is integrated charging current in 0.3M KBr. Starting point of the sweep 0V (Ag/AgCl).

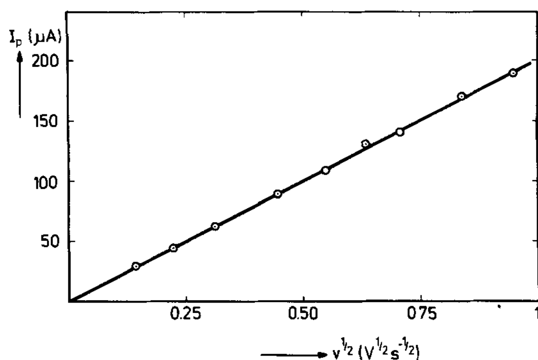

Fig. 3. I_p vs. $v^{1/2}$ plot for 10^{-3}M diheptyl viologen dibromide in an aqueous solution of 1M KBr.

film formation has been indicated. In general the predicted linear I_p — $v^{1/2}$ behavior is also found (Fig. 3). From this figure, and using the geometrical electrode surface area, a diffusion coefficient of 7.4 × 10^{-6} cm^2 sec^{-1} for the diheptyl viologen cation was calculated. In all experiments a reasonable agreement between the measured values of the diffusion coefficients was found, with values varying between 6 × 10^{-6} and 10^{-5} cm^2 sec^{-1} for HV-Br. Deviations from this ideal behavior have been observed at higher scan rates. In this respect it can be seen from Fig. 4 that the peak potential E_p varies with the scan rate if v is larger than 0.1 V/sec. In the same region (0.1 V/sec) it was found that $E_{p/2}$ was constant within the experimental error. This means that the value of ΔE varied from 0.02V at low scan speeds up to about 0.05V at 1 V/sec. Several reasons for this deviation from the simple model can be given. Since an uncompensated ohmic drop would be responsible for only a few millivolts deviation, other possibilities have

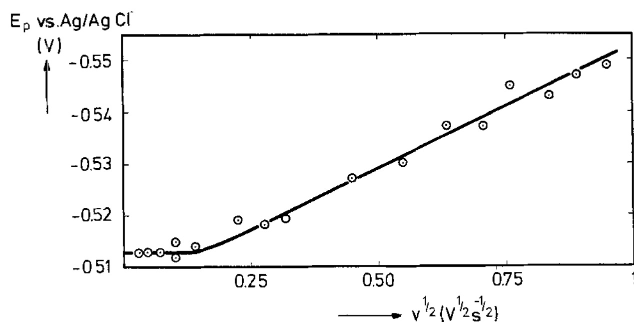

Fig. 4. Variation of the peak potential E_p with $v^{1/2}$ for 0.94 × 10^{-3}M diheptyl viologen dibromide in an aqueous solution of 1M KBr.

to be considered. Also the role of the film resistance can be neglected as followed from galvanostatic step measurements of films deposited with a charge density of 2 mC/cm^2.

A reason for the observed deviation can be the rate-determining character of the coupled chemical reaction at higher scan speed. This case is difficult to investigate since one has to make assumptions about the activity of the deposit at partial electrode coverage. Although some rate-determining role of the chemical reaction cannot be precluded, it is known that formation of a metal deposit on an inert electrode usually requires an overpotential, causing similar effects (12). Similarly, an explanation of the dependence of the peak potential on the scan rate is probably given by a rate-determining nucleation as mentioned earlier.

Nucleation phenomena during reduction.—The first stage in the electrodeposition of a heptyl-viologen bromide radical film was studied by applying a potential step to the electrode. After measuring the equilibrium potential of the radical film, the current-time dependency was determined at several small overpotentials. The results are represented in Fig. 5, which gives the $I - t^{-1/2}$ plot. At short times (milliseconds) the usual double layer charging is found (not indicated in the figure), followed by a rising part of the current which is proportional to $t^{1/2}$. After some time the usual $I - t^{1/2}$ diffusion behavior is observed as was reported in an earlier paper (16). The $I - t^{1/2}$ behavior can be observed only if small overpotentials are used and care is taken to avoid the presence of traces of radical film on the electrode. With very small amounts of radical film present, only the diffusional behavior is observed. As an explanation of the observed behavior it is proposed that a diffusion process controls the growth of nuclei formed by instantaneous three-dimensional nucleation in analogy with metal deposition. After some time overlapping of nuclei would occur and the $I - t^{-1/2}$ behavior is observed. It can also be seen from Fig. 5 that in the $I \propto t^{1/2}$ region, slopes as well as intercepts are dependent on the overpotential. An explanation of this dependence is thought to be that the number of active sites available for nucleation is potential dependent, while in addition some induction period for the formation of these sites must be considered. The cathodic shift of the peak potential (Fig. 4) at increasing scan rates might be due to these nucleation effects.

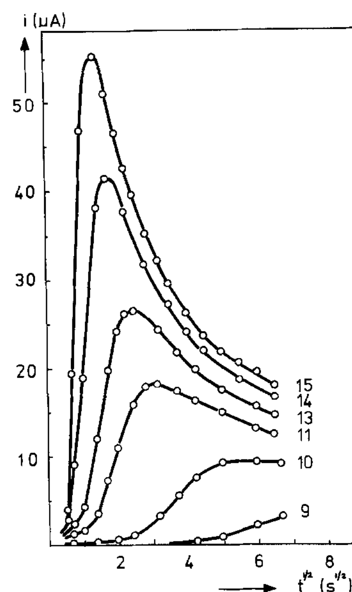

Fig. 5. Potentiostatic I — $t^{1/2}$ dependence for the deposition of diheptyl viologen radical bromide at tin dioxide. 0.01M diheptyl viologen dibromide in an aqueous solution of 0.3M KBr. Overpotentials (mV) indicated in figure.

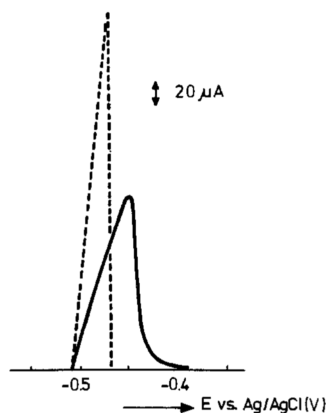

Fig. 6. Anodic peak due to the oxidation of a diheptyl viologen radical bromide film during a linear potential sweep voltammogram of 10^{-3}M diheptyl viologen dibromide in an aqueous solution of 0.3M KBr. Scan rate 0.1 V/sec. Total charge involved 0.679×10^{-4}C. Solid line, experimental curve; broken line, bulk theory. The value of the diffusion coefficient used was $D = 6 \times 10^{-6}$ cm^2/sec.

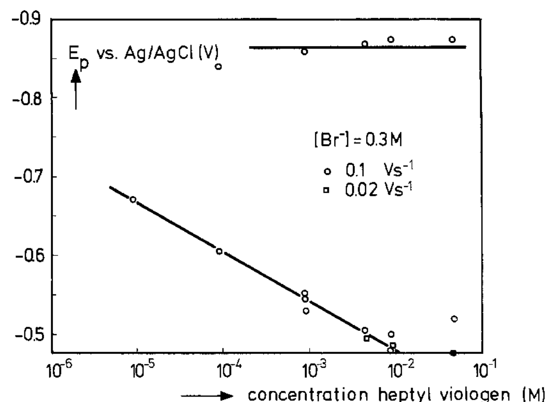

Fig. 8. Peak potentials of first and second reduction steps of HV-Br as a function of the diheptyl viologen concentration. Scan rates are indicated in the figure. The solid lines represent the Nernstian slope.

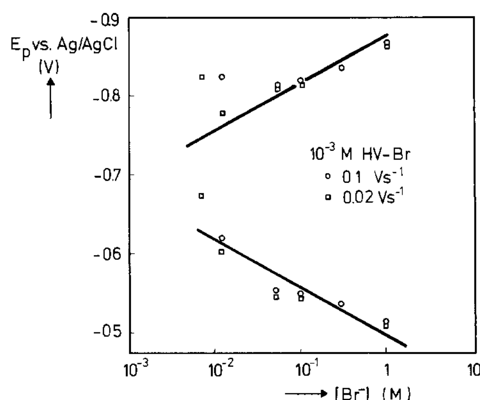

Fig. 9. Peak potentials of first and second reduction steps of HV-Br as a function of the bromide concentration. Scan rates are indicated in the figure. The solid lines represent the Nernstian slope.

Anodic peak.—The predicted dissolution behavior [12] of a bulk deposit is compared with experimental data in Fig. 6 for a diheptyl viologen radical bromide film deposited during a voltage sweep at 0.1 V/sec. It is clear that there is a considerable discrepancy between the theoretical dissolution behavior of the bulk film and the experimental curve although the current still drops very rapidly. It is likely that the observed discrepancy is due to a change in activity of the solid radical salt film just as occurs when dissolving metal films (15). With the viologen radical salt film dissolution this change in activity might be due to reorientation of the molecules as already mentioned in an earlier paper (4).

Reduction of modified viologens.—The experimental and calculated cathodic peaks of the two electron reduction of the modified viologen tetramethylen bis-[4(1-ethyl pyridin-4′-yl)pyridinium] perchlorate or ED-ClO_4 with $n = 2$ are shown in Fig. 7. The measured ΔE is about 0.013V which was found to be systematically larger than the 0.010V expected from theory. Also with this material nucleation phenomena were found comparable to those observed with heptyl viologen dibromide. Similar results were obtained with the modified viologen tetramethylen bis-[4(1-benzyl pyridin-4′-yl) pyridinium] tetrafluoroborate.

Concentration dependence of the reduction peak potentials of HV-Br.—The expression for the concentration dependence of the reduction peak potential [9] holds only at relatively low scan rates for which E_p is not much affected by nucleation effects. From Fig. 8 and 9 it can be concluded that the expected Nernstian dependence of both $C^*_{A^{2+}}$ and C_X is found experimentally. These results are in good agreement with those found at mercury electrodes (2). From the present

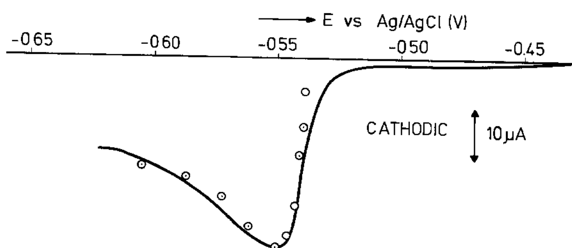

Fig. 7. Linear potential sweep voltammogram of 5×10^{-4}M of tetramethylene bis-[4(1-ethyl pyridin-4′-yl) pyridinium] perchlorate in an aqueous solution of 0.1M $NaClO_4$. Scan rate 0.02 V/sec. ⊙, Calculated with $D = 6.3 \times 10^{-6}$ cm^2/sec, $E_i = -0.539$V (Ag/AgCl), and $n = 2$.

experiment it can be concluded that the value of the solubility product of HV-Br is between 10^{-7} and 10^{-6}.

The expression for the second reduction peak potential of HV-Br is somewhat difficult to derive, since we are dealing here with the reduction of an insoluble deposit yielding an insoluble reaction product. At 25°C the equilibrium potential of the second reduction step product is equal to $E_0(2) + 0.059 \log(1/C_X)$, [see (2)], so it is expected that the second reduction step peak potential will also obey this dependence. From Fig. 8 it follows that $E_p[2]$ is indeed almost independent of $C^*_{A^{2+}}$ whereas Fig. 9 shows an anion dependence in agreement with theory. These results underline the role of the coupled chemical reaction and confirm the model proposed for the HV-Br reduction and oxidation.

Syntheses with Electrogenerated Halogens

Part III. Oxidation of Primary Alcohols to Acetals of 2-Haloaldehydes

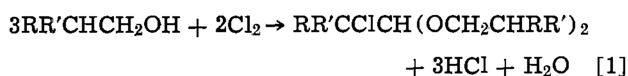
Donald A. White* and James P. Coleman*

Monsanto Company, St. Louis, Missouri 63166

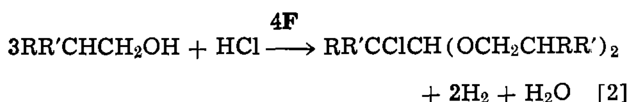
ABSTRACT

Electrolysis of primary alcohols having one or more β-hydrogen atoms in the presence of anhydrous hydrogen halides affords acetals of 2-haloaldehydes.

Direct electrochemical oxidation of anhydrous primary alcohols has been investigated by several workers (1-6) and affords aldehydes (1, 4, 6), acetals (1, 3, 6), or esters (6). Indirect oxidation has been investigated less extensively. With sodium iodide as the electrolyte, formate esters are obtained from methanol and ethanol (7) and oxidation of methanol containing anhydrous hydrogen chloride has been reported to give formaldehyde (8). The oxidation of alcohols containing anhydrous hydrogen chloride is also the subject matter of the present paper. The objective of this work has been the conversion of alcohols ($RR'CHCH_2OH$) having one or more β-hydrogen atoms to the acetals of the corresponding 2-chloroaldehydes [$RR'CClCH(OCH_2CHRR')_2$]. These acetals have been obtained previously by the reaction of alcohols with chlorine (9-13). This chemical reaction proceeds satisfactorily but produces three moles of hydrogen chloride per mole of acetal (1). Disposal of or recycle of this byproduct must be arranged. On the otherhand, the indirect electrochemical reaction offers the possibility of a process which consumes hydrogen chloride and gives innocuous coproducts, hydrogen, which may be burned to water, and water itself (2).



$$3RR'CHCH_2OH + 2Cl_2 \rightarrow RR'CClCH(OCH_2CHRR')_2 + 3HCl + H_2O \quad [1]$$



$$3RR'CHCH_2OH + HCl \xrightarrow{4F} RR'CClCH(OCH_2CHRR')_2 + 2H_2 + H_2O \quad [2]$$

Experimental

A Sorenson Model DCR 80-6B power supply (Raytheon Company, Manchester, New Hampshire), operating in its constant current mode, was used for the electrochemical reactions. The cell used was a 500 ml three-necked flask equipped with two graphite-rod (12 × 1/4 in. diam, Laboratory Supply and Equipment Company, Chevy Chase, Maryland) electrodes which were parallel and *ca.* 2 cm apart. The remaining necks were used for the attachment of a thermometer and a water-cooled condenser. The cell contents were stirred magnetically.

Anhydrous alcohols were obtained from Fisher Scientific Company, Fairlawn, New Jersey, or Mallinckrodt Chemical Works, St. Louis, Missouri, and anhydrous hydrogen halides from Matheson Gas Company, East Rutherford, New Jersey. They were used as supplied.

Reactions were followed and the product distributions (Table I) determined by observation of the NMR resonance due to the acetal proton [$RCH(OR')_2$] which could be easily observed in the acidic solutions and by GLC of neutralized (calcium carbonate) solutions. For the methanol reaction (Table I) the GLC column was a 7 ft × 1/8 in. stainless steel column packed with Porapak Q (40°-200°) and for the other reactions a similar 2 ft × 1/8 in. column packed with 5% OV101 on 100/120 Chromosorb G-HP (40°-200°). NMR spectra were recorded at 60 MHz on a Varian Model A56/60 or T60 machine.

The products from methanol oxidation (Table I, line 1) were determined by the NMR and GLC methods but were not isolated. The products from the other reactions were isolated by neutralization of the reaction mixture with excess calcium carbonate, filtration, and atmospheric-pressure distillation of the alcohol to give a mixture of the crude product and calcium chloride. This was partitioned between ether and water and the ether layer was separated, washed with water, dried over anhydrous calcium sulfate, filtered, and evaporated to give the crude product. This was distilled at atmospheric pressure (ethanol and *iso*butanol oxidations) or *in vacuo* (*n*-butanol oxidations).

The isolated haloacetals were identified via their NMR spectra, which, in the case of the ethanol oxidation products (Table I, line 2), were identical to published spectra (14). The spectra of *n*-butanol oxidation products (Table I, lines 3-7) are summarized in Table II. 2-Chloro*iso*butyraldehyde dimethyl acetal (from Table I, line 8) showed NMR bands at 1.50, 3.53, and 4.13 ppm downfield from internal $(CH_3)_4Si$ reference in $CDCl_3$ solution, due to C-methyl, O-methyl, and acetal protons, respectively.

The electrochemical reactions were carried out with the quantities shown (Table I) in the cell, which was

partially immersed in a bath of flowing cold water. In this preliminary work current density effects were ignored, and a current which would generate an electrolyte temperature in the desired range (30°-40°) was used. Since the expected anode (chloride discharge) and cathode (proton discharge) reactions tolerate a wide range of current densities, this approach may not be unreasonable. A typical example follows.

2-Chlorobutyraldehyde dibutyl acetal.—Electrolysis (1.0A for 13.4 hr ≡ 0.5**F**) of a solution of anhydrous hydrogen chloride (20g, 0.55 mole) in *n*-butanol (296g, 4.00 mole) afforded a clear, colorless solution containing the quantities of acetals shown in Table I, line 3. Butyl butyrate was also detected by GLC but not measured. Work-up, as described above, gave a colorless oil (28.5g) which was distilled *in vacuo*. Two fractions were collected: (*i*) a colorless liquid, bp 65°-70° (0.05 mm), 12.0g; and (*ii*) a colorless liquid, bp 72°-73° (0.04 mm), 13.5g. The latter was identified by its NMR spectrum (Table II, line 1) as 2-chlorobutyraldehyde dibutyl acetal. Found: C, 60.9; H, 10.9%. Calculated for $C_{12}H_{25}ClO_2$: C, 60.6; H, 11.0%. The presence of the chlorine substituent was evident from its mass spectrum, obtained via chemical ionization, which showed parent ion peaks at *m/e* = 236 and 238 in the expected 3:1 ratio. Fraction (*i*) was the same compound containing *ca.* 10 mole percent (m/o) of butyraldehyde dibutyl acetal. This impurity was identified by combined GLC/mass spectroscopy and measured using an authentic sample prepared by acetalization of *n*-butyraldehyde with *n*-butanol in the presence of anhydrous hydrogen chloride.

A portion (2.37g, 0.01 mole) of fraction (*ii*) was stirred with a solution (0.05*M*, 200 ml, 0.01 mole) of 2,4-dinitrophenylhydrazine in concentrated aqueous hydrogen chloride for 3 hr. The orange solid formed was removed by filtration, washed with water, and dried by suction on the filter. The dry solid (1.16g) was recrystallized from cyclohexane (100 ml) to give 2-chlorobutyraldehyde 2,4-dinitrophenylhydrazone as orange needles (0.75g), mp 93°-94°, liter[15] mp 93°-94°.

Results and Discussion

The electrolysis of some typical aliphatic primary alcohols containing anhydrous hydrogen chloride has been examined using a constant current in an undivided cell with graphite electrodes. Prior to examining its higher homologs the previously reported (8) reaction of methanol was reexamined. The products were found to be methylal and methyl formate, each in *ca.* 5% current efficiency. Throughout most of the electrolysis period the green color of anodically generated chlorine was evident in the solution. Its cathodic reduction explains the low current efficiencies and the drop, from the initial theoretical value, of the rate of cathodic hydrogen evolution observed by the previous workers (8). The discrepancy in the product formed may be an artifact of the different analytical methods used—GLC and NMR in the present work and reaction with ammonia to form hexamethylenetetramine in the previously reported work (8).

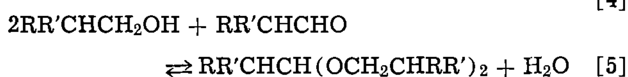
In contrast to the behavior observed with methanol, solutions of anhydrous hydrogen chloride in ethanol or *n*-butanol stayed absolutely colorless on electrolysis. The desired monohaloacetals were obtained with high current efficiencies (Table I, lines 2-5). Byproducts included the unsubstituted acetal and the dichloroacetal (also traces of the trichloroacetal from ethanol). The relative importance of these byproducts depends on reaction temperature, hydrogen chloride concentration, and alcohol conversion. Low temperatures (<30°) favor the unsubstituted acetal as do low hydrogen chloride concentrations (*cf.* Table I,

lines 3, 4a, 5). The effect of conversion is a little more complex. As it increases, selectivity to the monochloroacetal decreases due to increased dichloroacetal formation (Table I, lines 4a-4c). However, a constant selectivity is reached (Table I, lines 4c-4f) which, in the example shown, is still quite high (84%). However, there is a progressive decline in current efficiency (Table I, lines 4a-4f) which makes it desirable to use fairly low conversions. The corresponding ester, ethyl acetate, or butyl butyrate is also a minor byproduct. This became the major product when concentrated (37%) aqueous hydrogen chloride was substituted for the anhydrous material.

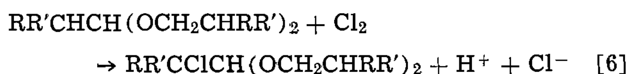
These results are consistent with a mechanism involving the anodic generation of chlorine (Eq. [3]), which oxidizes the alcohol to the aldehyde (Eq. [4]), acid-catalyzed conversion of the aldehyde to the acetal (Eq. [5]), and chlorination of the acetal (Eq. [6]).

$$4Cl^- \rightarrow 2Cl_2 + 4e^- \quad [3]$$

$$Cl_2 + RR'CHCH_2OH \rightarrow RR'CHCHO + 2H^+ + 2Cl^- \quad [4]$$

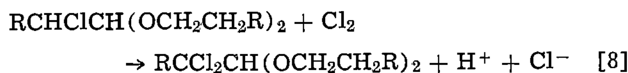


$$2RR'CHCH_2OH + RR'CHCHO \rightleftarrows RR'CHCH(OCH_2CHRR')_2 + H_2O \quad [5]$$

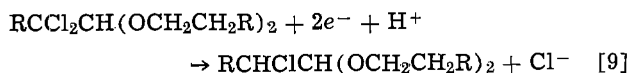


$$RR'CHCH(OCH_2CHRR')_2 + Cl_2 \rightarrow RR'CClCH(OCH_2CHRR')_2 + H^+ + Cl^- \quad [6]$$

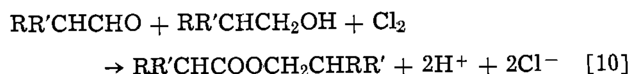
$$4H^+ + 4e^- \rightarrow 2H_2 \quad [7]$$



$$RCHClCH(OCH_2CH_2R)_2 + Cl_2 \rightarrow RCCl_2CH(OCH_2CH_2R)_2 + H^+ + Cl^- \quad [8]$$



$$RCCl_2CH(OCH_2CH_2R)_2 + 2e^- + H^+ \rightarrow RCHClCH(OCH_2CH_2R)_2 + Cl^- \quad [9]$$



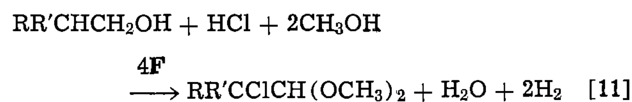
$$RR'CHCHO + RR'CHCH_2OH + Cl_2 \rightarrow RR'CHCOOCH_2CHRR' + 2H^+ + 2Cl^- \quad [10]$$

The cathodic reaction is hydrogen evolution (Eq. [7]), and the summation of these reactions [3-7] is the over-all reaction [2]. The dichloroacetal byproduct arises from further chlorination of the product (Eq. [8]). The fact that it builds up to a constant percentage of the acetal product mixture suggests that it may be cathodically reduced back to the monochloroacetal (Eq. [9]). Added water displaces equilibrium in Eq. [5] to the left. The aldehyde is then present in greater abundance and its oxidation (Eq. [10]) leads to ester formation. This becomes the major reaction when concentrated aqueous acid is used instead of the anhydrous material.

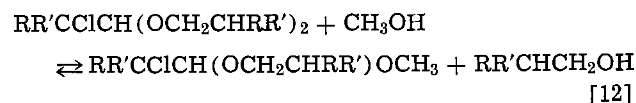
For satisfactory isolation of the acetals unreacted hydrogen chloride must be neutralized. This is conveniently done by stirring with calcium carbonate (sodium carbonate became coated with sodium chloride and was not so effective). If it is not done, the acetal is found to distill over with the solvent alcohol, even though its boiling point is much higher than that of the alcohol. In the case of ethanol, the "solvent" distilled at 77°-85° and chloroacetal (bp 157°) (13) was found in the distillate. The acetal may distill over in the form of chloroacetaldehyde (bp 85°) (13), which could be present in an acid-catalyzed equilibrium with the acetal (*cf.* Eq. [5]) and reform the acetal in the collected distillate. After neutralization, only normal, minor losses of the product into the solvent were found.

Electrolysis of *n*-butanol containing anhydrous hydrogen bromide has also been examined. In this case, bromine accumulated in the solution from the moment the current was turned on. In order to speed up the chemical reactions the temperature was allowed to rise to *ca.* 60°. In spite of this, bromine still remained in solution throughout the electrolysis period. As expected, the current efficiency was low and the product was a mixture of the bromo- and dibromoacetals (Table I, line 6).

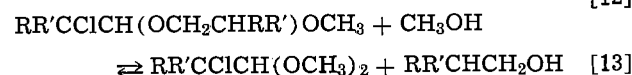
To extend the scope of the present reaction, the possibility of using a solvent other than excess alcohol has been examined. This would permit oxidation of higher molecular weight alcohols which have low dielectric constants and may be solids at appropriate reaction temperatures. Due to the presence of anhydrous hydrogen halides, several of the usual electrochemical solvents cannot be used, *e.g.*, amines, ethers, cyclic carbonates. Both dimethylformamide and acetonitrile reacted with a mixture of anhydrous hydrogen chloride and an alcohol. Methylene chloride, however, was usable and gave results comparable with those obtained when using excess alcohol as solvent (*cf.*, Table I, lines 4a and 7). Though its volatility is useful in work-up, the low dielectric constant of methylene chloride is a disadvantage. However, methanol has a high dielectric constant and, as shown (Table I, line 1), is oxidized only with difficulty by anodically generated chlorine. This suggested its use as a solvent for the oxidation of higher alcohols to dimethyl acetals (Eq. [11]). This reaction is exemplified by the



$$RR'CHCH_2OH + HCl + 2CH_3OH \xrightarrow{4F} RR'CClCH(OCH_3)_2 + H_2O + 2H_2 \quad [11]$$



$$RR'CClCH(OCH_2CHRR')_2 + CH_3OH \rightleftarrows RR'CClCH(OCH_2CHRR')OCH_3 + RR'CHCH_2OH \quad [12]$$



$$RR'CClCH(OCH_2CHRR')OCH_3 + CH_3OH \rightleftarrows RR'CClCH(OCH_3)_2 + RR'CHCH_2OH \quad [13]$$

oxidation of *iso*butanol (Table I, line 8). The formation of the dimethyl acetal depends primarily on the use of a large excess of methanol, but also on the acid-catalyzed equilibria Eq. [12] and [13] between the three acetals which may be formed. As the reaction progresses, consumption of the substrate alcohol will displace these equilibria to the right.

In summary, the present procedure offers a convenient route to acetals of 2-chloroaldehydes. High current efficiencies are obtained using a simple cell with inexpensive graphite electrodes. From the industrial point of view, the tendency, discussed above, of the product acetal to distill with the solvent alcohol is regrettable as it necessitates neutralization (or, perhaps, dehydration) of the reaction mixtures.

The Metal-Liquid Insulator Interface in Presence and Absence of an Applied Electric Field

Ikram Morcos*

Institute of Research of Hydro-Quebec, Varennes, Quebec, Canada J0L 2P0

ABSTRACT

The meniscus rise of different insulating liquids at a partially immersed copper rod and copper and gold plates was measured both in the absence and presence of different applied d-c voltages. Variations in contact angle in the absence of the field are qualitatively interpreted in the light of the Young and Duprée equation. Discrepancies between the experimentally observed meniscus height *vs.* voltage curves and theoretical curves calculated on the basis of an electrical-force mechanism are pointed out and a new mechanism envisaging the effect of interfacial forces is suggested.

The study of electric-field dependence of the interaction between a solid metal and an insulating liquid is complicated by the fact that the electrochemical parameters of the system are neither well defined nor accessible by presently available experimental techniques. Among the methods developed to study metal-liquid electrolyte interfaces, the meniscus-rise method (1-5) offers some promise in the study of metal-liquid insulator interfaces. The latter method has two criteria which make it attractive to use with liquid insulators notwithstanding the other problems with such systems. First, the method provides direct information on a single polarized interface which is essential for understanding the effect of electric field on the interfacial forces. Second, the meniscus height is measured by optical techniques which do not depend on the resistivity of the investigated system.

Observations on meniscus rise at high voltage electrodes date back to Faraday (6) who reported in 1836 that if two high voltages leads are dipped into a disk-containing turpentine, the liquid will rise along the positive electrode. The same phenomenon was rediscovered by Sumoto (7) who noted that the magnitude of rise and its dependence on the field direction are related to the type of liquid used The Sumoto effect was subsequently studied by Pickard (8), Middendorf and Brown (9), Krawinkel (10), and Pohl (11), and the subject has been more recently reviewed by Pickard (12).

Interpretations of the Sumoto effect have centered in the past around electrical-force mechanisms (12-15). In the present study the effect of interfacial forces, not dealt with in previous work, is considered. The study involves measurement of meniscus rise in both absence and presence of applied d-c voltage using insulating liquids of different chemical structure and test electrodes of two different geometries. In addition to its intrinsic scientific interest this problem was undertaken with two practical applications in mind. First, the data should be useful in the understanding of mechanisms of prebreakdown phenomena in transformer oils. Second, it is hoped that the measuring technique can be eventually developed into an analytical tool for detecting surface active impurities and/or degradation products.

Four insulating liquids were used in this study. These included the two alkylbenzene cable-insulants known as dodecylbenzene and decylbenzene, the transformer oil Voltesso 35 (chemical composition disclosed later), and polydimethylsiloxane which is a silicone oil known as the Dow Corning 200 fluid (electrical grade).

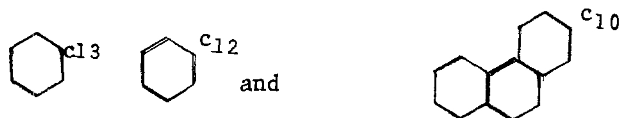
Both alkylbenzenes contain homologs with side chain ranging from C_9 to C_{12}. The main component, one with a side chain of C_{12} (dodecylbenzene) in one case and the other with C_{10} (decylbenzene) in the other case, constitutes only about 50% of the product. The dodecylbenzene is an electrical grade product commercially known as Chevron alkylate 21 (provided by Dussek Brothers) and is obtained by two vacuum distillations of the normal grade. The decylbenzene was provided by Pirelli Industries of Canada and was obtained from the normal grade by treating the latter product with Fuller's earth. Both the normal and electrical grades of decylbenzene but only the electrical grade of dodecylbenzene were used in this study. The dielectric constant and d-c resistivity of dodecylbenzene were 2.3 and 3.9×10^{14} Ω-cm, respectively. These alkylbenzenes are intrinsically stable compounds and impurities if present result from sources other than processes such as chemical rearrangement, degradation, or oxidation. Being good solvents for a wide variety of polar materials, these relatively low molecular weight alkylbenzenes are prone to contamination during transference from one container to another. The alkylbenzenes are produced by the Friedel-Krafts synthesis which involves the alkylation of benzene with the aliphatic chloro-derivatives of the hydrocarbons in the presence of aluminum trichloride as a catalyst.

Polydimethylsiloxane has the chemical structure $R_3SiO(R_2SiO)SiR_3$ where R is a $—CH_3$ radical. It is an extraordinarily stable product with a volume resistivity at 23°C and 500V d.c. of 1.0×10^{14} Ω-cm, dielectric constant at 23°C and 100 Hz of 2.7, and nominal viscosity at 25° of 20 centistates.

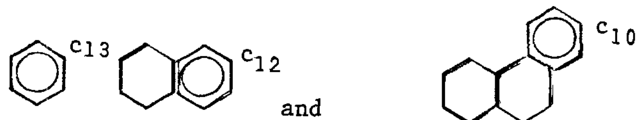
The Voltesso 35 is a mineral naphthenic-based oil in which the great majority of molecules are made up of one to three condensed cycloaliphatic and/or aromatic rings substituted with aliphatic side chains of variable lengths. Duval and Lamarre (16) studied the average molecular size distribution by liquid-solid chromatography (LSC) and gel permeation chromatography (GPC) of the Voltesso 35 oil and reported the following chemical constituents.

* Electrochemical Society Active Member.

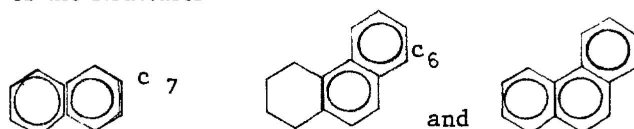
80% saturates with 25Å average molecular size with one or more of the structures



15% monoaromatics with 25Å average molecular size with one or more of the structures



5% diaromatics and triaromatics with 19 and 12Å average molecular size, respectively, with one or more of the structures



The Voltesso 35 contains a 0.08% by weight, 2,6-ditertiary butyl-p-cresol as an antioxidant. The Voltesso 35 has a volume resistivity of 10^{13} Ω-cm and a dielectric constant of 2.2. The Voltesso 35 was used without any further treatment.

Water contents are approximately 40, 30, and 110 ppm in dodecylbenzene, Voltesso 35, and polydimethylsiloxane.

Experimental Section

Experiments with each liquid were carried out with both cylindrically shaped and plate electrodes. The former electrode was in the form of a copper rod of 2.3 cm diam and the latter consisted of bright smooth 2 × 4 cm gold plate of 99.99% purity. Some experiments were also carried out with copper plates of 99.9% purity.

Surface roughness was measured by a Dekkak instrument provided by Sloan Instruments Corporation. The copper rods and plates were mechanically polished to produce a very bright surface with an average surface roughness of less than 0.1 μm. The plates were polished with aluminum oxide paste on a felt-covered wheel and the rod with a red-rouge polishing compound on a cotton-covered wheel. Prior to polishing the copper plates and rods were ground with different grade sandpapers. When the copper electrodes were not polished but chemically treated in a concentrated solution (1 part H_2O, 1 part HNO_3) of HNO_3 in water, their roughness was ~1.0 μm. Some experiments were also carried out with the latter electrodes. All electrodes were cleaned in methanol followed by drying at 110°C prior to the measurement.

Figure 1 shows a sketch diagram of the cell and type of electrodes used in the study. The measurement was made in a Teflon cell which has an ID of 12.3 cm and a height of 3.9 cm. The counterelectrode has the form of a cylindrical cage that consists of a 6 cm diam ring supported on four 4 cm long strips.

The level of the meniscus edge at the metal surface and the level of the liquid surface in the cell were measured with a cathetometer with a ± 0.001 cm sensitivity. To facilitate the measurement of the liquid surface level in the cell the latter was completely filled with the liquid until the liquid climbs forming a flat top. Before the measurement was started the electrode was lowered into and raised from the liquid several times to permit the establishment of equilibrium between the liquid vapor and the adsorption layer at the metal surface. With both gold and mechanically polished copper, the liquid meniscus forms a well-defined straight and horizontal edge with the metal surface (which is diagnostic of a surface free of macroscopic roughness or heterogeneity) and consequently its measurement could be carried out without much difficulty. In the case of chemically treated copper, however, the metal surface was observed to be covered above the proper meniscus with a liquid film which had probably resulted from the high surface roughness which by its capillary forces retains the liquid in the isolated depressions of the surface. The work with the latter electrodes was therefore discontinued.

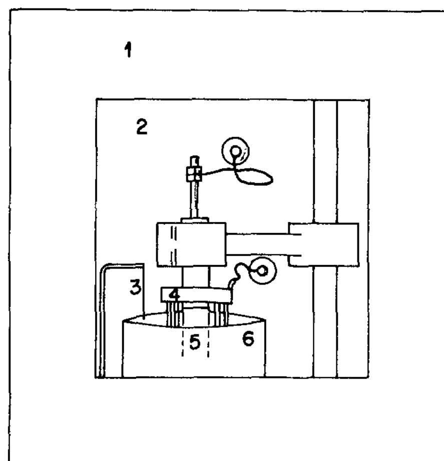


Fig. 1. Sketch diagram of cell and electrode. 1, Metal box; 2, glass window; 3, glass needle; 4, counterelectrode; 5, test electrode; 6, Teflon cell.

For the study of electric field dependence of the meniscus height, a high voltage power supply "LABTROL" provided by Universal Votronics Corporation was used. The voltage was increased in steps of 1 kV from 0 to the cathodic limit and from 0 to the anodic limit. Unless indicated otherwise, the voltage applied in each case ranged from 0 to ± 8 kV. No measurements were possible, however, at voltages higher than about 10-14 kV (depending on the liquid and polarity) because of the start of vibrations in the liquid meniscus. The equilibrium advancing meniscus height at a fixed voltage was measured after each voltage adjustment. After a series of measurements was completed between 0 and the cathodic or anodic limit, the voltage was reversed and a series of measurements for the receding meniscus height as a function of the decrease in voltage was carried out.

No attempt was made to measure the contact angle directly, but a technique used by Bascom *et al.* (17) was applied to determine whether zero and nonzero contact angles in the absence of the field remain or not as such in the presence of the electric field. This involved the use of monochromatic illumination and the same cathetometer used to measure the meniscus height. As indicated by Bascom *et al.*, a zero contact angle shows a diffuse wide zero-order fringe at the meniscus edge followed by narrow bands of higher order; a behavior that is not observed with a nonzero contact angle. This information was found to be useful in the discussion of the data as is demonstrated later.

Results and Discussion

In the absence of an externally applied voltage the meniscus height h at a partially immersed vertical plate is related to the contact angle θ by the exact equation

$$\sin \theta = 1 - (\rho g h^2 / 2\gamma_{LV}) \qquad [1]$$

where ρ and γ_{LV} are the liquid density and surface tension and g the acceleration of gravity. Equation [1] is derived (18) for an infinitely wide plate but the requirement of infinite width is experimentally satisfied if the plate width is only about 2 cm (19). There is no exact equation analogous to Eq. [1] for a partially immersed wire or rod but it has been experimentally demonstrated (20) that the meniscus height at a par-

Table I. Meniscus rise and contact angles for gold and copper in insulating liquids

tially immersed glass rod increases with the increase in the diameter of the rod until it asymptotically approaches the meniscus height observed at a plate 2 cm wide. The higher the surface tension of the liquid the larger will be the rod diameter required to provide conditions approaching that of a plate (20). But even with liquids with low surface tensions from 20 to 30 dynes/cm the conditions of infinite width are not approached until the rod diameter is considerably larger than 2 cm. If the rod diameter is only 2 cm the meniscus height will be less by about 15% than the corresponding meniscus height observed at a 2 cm wide plate. Consequently, under the present experimental conditions accurate value of θ can be only obtained from h measured at a plate.

Table I shows the meniscus height and corresponding contact angle data obtained with different systems in the absence of electric field. The contact angles are calculated by means of Eq. [1] from h values measured at metal plates. Both advancing and receding data are shown. With many systems several measurements were made to test the reproducibility. Each set of measurements has been obtained with one and the same metal plate but at different levels. The data are generally reproducible and exhibit very little hysteresis. Contact-angle magnitude vary between zero and 16.5° depending on the surface tension of the liquid, its chemical composition, and probably on whether or not the surface is covered with adsorbed oxygen or other impurities left over from the polishing process. A discussion of the manner in which these factors affect contact angles is given below.

The contact angle between a solid and a liquid is determined by the Young and Duprée equation (21)

$$\gamma_{LV} \cos \theta = \gamma_{SV} - \gamma_{SL} \quad [2]$$

where γ_{SV}, γ_{SL}, and γ_{LV} are the metal/vapor, metal/liquid, and liquid/vapor interfacial tensions, and

$$\gamma_{SV} = \gamma_S - \pi \quad [3]$$

where γ_S is the metal surface tension in vacuum and π is the film pressure (22) of the adsorbed vapor film. The system will exhibit a zero or nonzero contact angle depending on whether $\gamma_{SV} - \gamma_{SL}$ is $\geqq \gamma_{LV}$ or $< \gamma_{LV}$. A nonzero contact angle probably results from the presence at the metal surface of a liquid film which converts the high energy metal surface into a low energy surface with a lower γ_{SV} (23). In the presence of such film, a zero contact angle may be established only if the liquid (such as polydimethylsiloxane) has a very low surface tension (23). On the other hand, the effect of adsorbed films on the magnitude of γ_{SV} and consequently on θ will depend on the configuration of the film (23). Zieman (23) has concluded from extensive studies that the reduction in γ_{SV} will be more if the film comprises unbranched long-chain close-packed molecules terminating with groups such as $—CH_3$, $—CF_3$, or $—CF_2H$ than if the adsorbed molecules exhibit cyclic or branched structures. The adsorption of molecules of aromatic rings with aliphatic nonbranched side chains is probably responsible in the case of Voltesso 35 and the alkylbenzenes for the nonzero contact angle.

Adsorption layers of oxygen usually exist on all metal surfaces except that of gold. Such layers are known (24) to increase contact angles. This probably explains the larger θ observed with copper than with gold.

Smaller contact angles are observed with the normal-grade decylbenzene than with the same liquid after treatment with Fuller's earth. The difference must be due to the presence in the normal-grade sample of polar impurities which adsorb at the metal surface and decrease γ_{SL}.

The experimental meniscus height *vs.* voltage curves for different insulating liquids are plotted in solid heavy lines in Fig. 2-11. In most cases there is little hysteresis between the advancing and receding meniscus height. Figures 2-3 show the results with the vacuum-distilled dodecylbenzene, Fig. 4 and 5 with Fuller's earth-treated decylbenzene, and Fig. 6 for decylbenzene without the latter treatment. Figures 2 and 4 are for the copper rod electrode and Fig. 3, 5, and 6 are for the gold and copper plate electrodes. Figure 7 is for Voltesso 35 with a copper rod and Fig. 8 and 9 are for the same liquid with copper and gold plate electrodes, respectively. Figures 10 and 11 are for polydimethysiloxane with copper rod and gold plate, respectively.

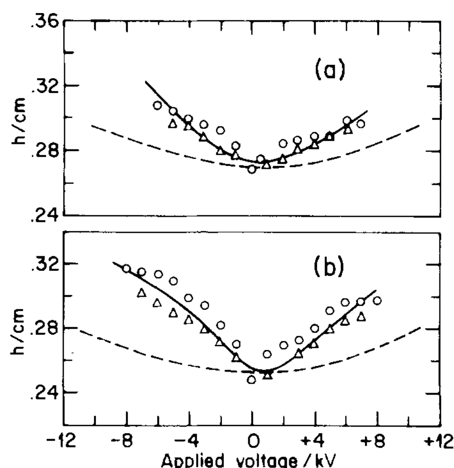

Fig. 6. Voltage dependence of meniscus height for normal-grade decylbenzene on (a) gold plate and (b) copper plate. ○ and △, Experimental advancing and receding curves and - - -, theoretical curve.

Figures 2-11 show that in the presence of electric field the meniscus height is a function of the applied voltage, the chemical composition of the insulating liquid, and the polarity of the field. With the alkylbenzene the voltage dependence of h appears to be a function of the technique applied to purify the oil before use. A smaller increase of h with voltage is observed with a dodecylbenzene sample treated with vacuum distillation than with a decylbenzene sample treated with Fuller's earth. A greater increase is observed with a decylbenzene sample not treated with Fuller's earth than with one subjected to such treatment. With the alkylbenzenes the increase in h with the applied voltage is larger with the rod than with the plate electrode. With Voltesso 35 and polydimethylsiloxane

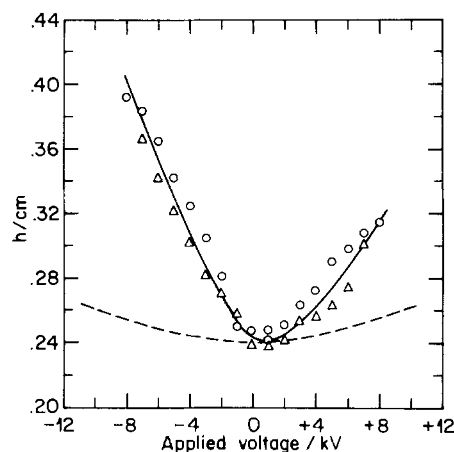

Fig. 9. Voltage dependence of meniscus height for Voltesso 35 on a gold plate. ○ and △, Experimental advancing and receding curves and - - -, theoretical curve.

h dependence on the voltage is slightly greater with the plate than with the rod.

There is experimental evidence that the change of meniscus height with the applied voltage is not accompanied by any significant change in the contact angle. The use of reflection microscopy and monochromatic illumination has indicated that the type of interference bands observed at the meniscus edge does not change with the electric field regardless of the

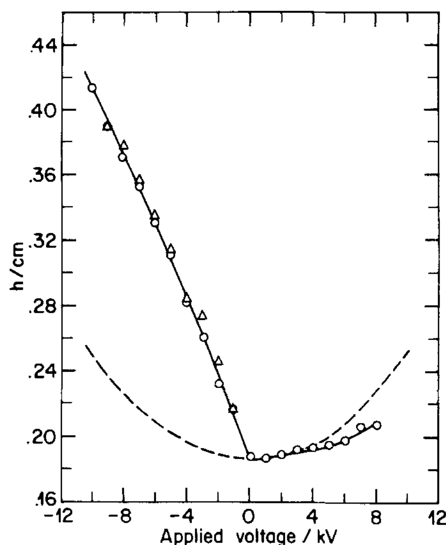

Fig. 10. Voltage dependence of meniscus height for polydimethylsiloxane on a copper rod. ○ and △, Experimental advancing and receding curves and - - -, theoretical curve.

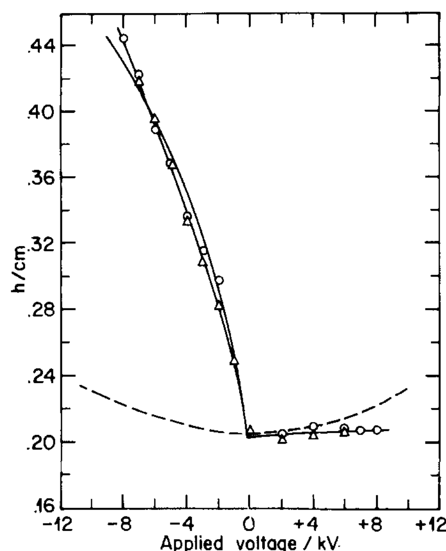

Fig. 11: Voltage dependence of meniscus height for polydimethylsiloxane on a gold plate. ○ and △, Experimental advancing and receding curves and - - -, theoretical curve.

initial value of contact angle in the absence of the field. For example, with a copper plate in Voltesso 35, the contact angle is 10.5°, in the absence of the field and the meniscus edge appears as a dark line. In the presence of the field such behavior does not change regardless of the increase in meniscus height. A gold plate in polydimethylsiloxane gives a zero contact angle in the absence of the field and the meniscus edge in both absence and presence of the field shows a diffuse wide zero order fringe followed by narrow bands of higher order.

The voltage dependence of meniscus height in the case of Voltesso 35 was found to be influenced by the time of exposure to light. This effect is negligible for a series of experiments carried out within the first few days after a fresh sample was taken from the metal-storage tank but becomes significant in a few weeks' time. Light is known to accelerate the oxidation process of the oil.

A linear variation of the current with the applied voltage was indicated (5) in the case of Voltesso 35. A similar current-voltage relationship was observed with the alkylbenzenes.

For interpreting the experimental curves of Fig. 2-11, it is appropriate to consider first the electrical-force mechanisms previously (13-15) mentioned. One may first assume that the insulating liquid is a perfect dielectric free of any space-charge zones. An electric field applied parallel to the liquid surface in the test cell will exhibit a mechanical stress directed normally to the liquid surface of the meniscus. Acting to minimize the mechanical potential energy of the system, the dielectrophoretic forces of the liquid will raise the meniscus upward. At equilibrium the vertical component of the mentioned mechanical force can be equated with the hydrostatic pressure due to the liquid head. The result (15, 25) will be

$$\Delta h = \frac{\epsilon - \epsilon_0}{2\rho g} E^2 \quad [4]$$

where Δh is the variation in meniscus height, E the field strength at the top of the meniscus, ρ the liquid density, g the acceleration of gravity, and ϵ and ϵ_0 are the permittivities of the liquid and the vapor. Theoretical plots for the variation of h with the voltage are given in dotted lines in Fig. 2-11. In each case h at a given voltage is obtained by adding Δh calculated by means of Eq. [4] to the experimentally measured h in the absence of the field. For a cylindrically shaped rod electrode E is calculated from the voltage V by means of

$$E = \frac{V}{a \ln b/a} \quad [5]$$

where a and b are the radii of the rod and coaxial cylindrical cage. For a rectangularly shaped (plate) electrode the field can be assumed to be elliptically shaped and is therefore calculated from

$$E = \frac{V}{f \ln c + d/f} \quad [6]$$

where the plate width is $2f$ and c and d are the semiaxes of the surrounding elliptically shaped outside electrode. For a cylindrically shaped outside electrode, the term $c + d$ can be approximately obtained from

$$b \sim \frac{c + d}{2} \quad [7]$$

The theoretical curves shown in Fig. 2-11 are both parabolically shaped and polarity independent. At a given E value Δh at the plate is approximately 38% its corresponding value at the rod. An examination of all the data of Fig. 2-11 shows however considerable discrepancy between the experimental and theoretical curves. The most marked discrepancy is observed with polydimethylsiloxane with which the experimental curves are strongly polarity dependent and contrary to theoretical predictions Δh is slightly higher with the plate than with the rod. A far smaller discrepancy is observed with the alkylbenzenes, where with both the vacuum-distilled dodecylbenzene and Fuller's earth-treated decylbenzene, the experimental curves are parabolically shaped and, as predicted by theory, Δh at a given voltage is greater with the rod than with the plate. However, normal-grade decylbenzene shows more deviation from theory than electric-grade decylbenzene. With Voltesso 35 the experimental curves are slightly asymmetric but as in the case of polydimethylsiloxane Δh is slightly greater with the plate than with the rod.

Pickard (8) reported a voltage dependence of meniscus height in excess of that expected on the basis of perfect-dielectric theory with a molybdenum wire cathode in acetone. This phenomenon was attributed (13) to the formation of an ionic specie charge zone with an associated potential drop near the cathode. In Pickard's view, the potential drop occurs only near the cathode because the ion responsible for its formation is a positively charged metal ion electrochemically produced by the anode. Expressed more

quantitatively, the presence of space-charge zone near the cathode means a larger E than that predicted at a given voltage by Eq. [5] or [6] and consequently a larger Δh. A larger E at the cathode reduces E at the anode which leads to a smaller Δh at the latter electrode. The interpretation provided by Pickard (13) may well be valid for the molybdenum/acetone system but it is doubtful that it can be generalized for other systems as well. First, the electrochemical mechanism suggested for producing the ions cannot explain similar phenomenon observed with other liquids such as chloroform at the anode (7) or as in the present work with Voltesso 35 at both the cathode and anode. Second, a space charge zone produced near the cathode implies that electrons are injected from the cathode but the linearly shaped current-voltage curves observed in the present work indicate that the conductance current is still ohmic in nature in the low field region (26). The explanation given by Pickard also suffers from the lack of experimental evidence that metal ions do indeed exist in the insulating liquids.

A more general mechanism based on interfacial forces may be used to explain the discrepancy between the experimental and theoretical curves of the present work. This is based on the assumption that an electric double layer probably exists between the metal surface and oriented liquid dipoles. The magnitude of dipole orientation depends on their dipole moment, the magnitude and polarity of the applied voltage, the nature of the solid substrate, and the strength of the intermolecular binding forces in the liquid. The effect of polarity should be particularly important with liquids whose molecules are naturally oriented at the phase boundary. An increase in the applied voltage will increase the potential drop across the double layer provided that the polarity of the field is favorable for the natural orientation of the dipoles. This increase in potential difference will be associated with an increase in the charge density at the metal surface (as in the case of an ideally polarizable electrode) and an increase in the orientation and polarization of the liquid molecules in the neighborhood of the liquid side of the double layer. The first effect causes a decrease in the metal/liquid interfacial tension (as indicated by the Lippmann equation) and the second causes an increase in the liquid surface tension. The increase in γ_{LV} results according to Eq. [1] in an increase in h. An increase in γ_{LV} alone should, according to Eq. [2], increase θ, but this does not take place because of the decrease in γ_{SL}.

The variation in γ_{SL} and γ_{LV} with the applied voltage should not depend on the geometry of the electrode and were it not for the conditions of infinite width required by Eq. [1], Δh caused by a change in γ_{LV} would be equal with both the rod and plate. However, as previously explained, the plate satisfies the conditions of infinite width and the rod does not and, therefore, the same increase in γ_{LV} causes a smaller Δh with the rod than with the plate.

The structural properties of polydimethylsiloxane appear to satisfy the requirements for the interfacial tension mechanism described above. First, the siloxane bond includes an appreciable polar component which is known (27) to interact with other surfaces by dipole or hydrogen bonding. Second, the molecule as a whole attains a helical conformation in which the siloxane dipole is internally compensated by another dipole of opposite polarity. The intermolecular binding forces are, therefore, particularly weak, a fact which enhances the affinity between polydimethylsiloxane molecules and other surfaces (27). This particular structure, however, probably results in strongly oriented molecules even in the absence of the field. On the basis of the present experimental data, this natural orientation is aided by the field direction at the cathode. A sterically hindered reorientatian process appears, however, to impede the formation of a double layer at the anode.

In the case of alkylbenzenes the results indicate that the double layer is formed by polar impurities rather than by any constituent of the pure liquid. Voltesso 35 has a very complex chemical nature and, therefore, it is difficult even to speculate on the nature of the species responsible for establishing the double layer.

A confirmation of the ideas suggested above would require some experimental knowledge of the potential drop across the metal/liquid interface and an independent study of the field dependence of the liquid surface tension. Unfortunately, however, the mentioned potential drop cannot be measured because reference electrodes conveniently used in electrochemical systems cannot be used in ion-free liquids. Wire probes which are occasionally used in the study of the distribution of charge carriers in insulating liquids cannot be placed with sufficient proximity from the electrode to detect the potential drop in the interfacial region. Information provided by these probes on charge distribution in the bulk have been both qualitative and subject to criticism (26). The resistivity of the insulating liquid also changes as a function of the field and, therefore, the original resistivity (in the absence of the field) cannot be used to calculate IR drops in the presence of the field. No definitive conclusions are available yet from studies of field dependence of liquid surface tensions (25, 28-30). The experimental data appear to depend on the technique applied probably because different techniques measure different parameters.

Conclusions

Contact angles between a sufficiently smooth solid metal surface and insulating liquids can be conveniently and accurately obtained from the liquid meniscus rise measured at a partially immersed plate in the liquid. Nonzero contact angles most probably result from the presence at the metal surface of a liquid film which converts the high energy metal surface into a low energy surface with a lower γ_{SV}. The liquid meniscus height at a partially immersed rod of a relatively small diameter ($\sim$2 cm) is less than the corresponding height at a plate, 2 cm wide, because the rod does not satisfy the conditions of infinite width required by Eq. [1].

Meniscus height *vs.* voltage curves measured with dodecylbenzene, decylbenzene, Voltesso 35, and polydimethylsiloxane show that the variation of h with the voltage depends on the magnitude of the voltage, the polarity, and the chemical composition of the insulating liquid. The variation of h with the voltage is not accompanied by any significant change in the contact angle. The variation of h with the voltage is discussed in the light of an electrical force mechanism and it is shown that such a mechanism can satisfactorily explain only those results obtained with vacuum-distilled dodecylbenzene. A mechanism based on the formation of a double layer between the metal surface and liquid dipoles and associated variation in γ_{SL} and γ_{LV} is suggested to explain the discrepancies between the experimental results with other liquids and theoretical predictions based on an electrical-force mechanism.

The Institute of Physical Chemistry, The USSR Academy of Sciences, Moscow, U.S.S.R.

ABSTRACT

The anodic oxidation kinetics and electrochemical properties of the passive surfaces of Ti, Ni, and Ti-Ni alloys (0.2-37.5 w/o) in 1*N* Na_2SO_4 (pH 5.6 and 10.6) solutions with and without redox couples have been investigated by electrochemical methods. Measurements have been made also on single crystals of TiO_2 (n-type) and NiO (p-type) with known electrophysical parameters. It was found that the passive surface of pure Ti and Ni electrodes having a thin-phase oxide film shows specific features of semiconductor electrodes. The electrochemical behavior of passive metal electrodes depends on the potential distribution at the passive metal/solution interface. The rate of anodic oxidation of Ti-Ni alloys is close to that of pure Ti. The solution ion oxidation reactions are greatly facilitated on the oxidized alloys as compared to Ti. To explain the results obtained a specific model of the alloy oxide layer structure has been adopted.

Today, one may consider it to be a proven fact that the starting metal passivation stage is associated with the adsorbed oxygen monolayers settling on the surface and drastically reducing the rate of electrochemical metal dissolution (1-5). The oxide layers formed during further passivation, however, produce a marked effect on the passive metal surface properties and, in many cases, determine the stability of passive metal condition.

The electrochemical properties of phase-oxide layers formed during anodic passivation have a big significance in developing commercial processes for producing controlled property surface oxide layers and in developing alloy compositions for cathodic protection or the electrolysis industry. The latter stimulates research to establish anodic oxide layer growth laws and to study anodic oxide layer structure and properties. Much attention has been focused on these problems at present with the major programs being deployed on iron, aluminum, titanium, and stainless steels (6-18).

The present work studies by electrochemical methods the growth kinetics of thin-phase oxide layers formed during anodic passivation of Ti, Ni, and Ti-Ni alloys, and also the redox reaction kinetics on these electrodes defined by the semiconductor properties of the passive surface. At the same time, measurements were made on single crystal compact oxides, *i.e.*, on TiO_2 (rutile, n-type conductance, $n = 5 \cdot 10^{18}$ cm^{-3}) and NiO (p-type, $p = 1.3 \cdot 10^{20}$ cm^{-3}), with known electrophysical parameters. The above oxides possess the properties of semiconductor electrodes and are a model to simulate the oxidized metals.

Key words: anodic oxidation kinetics, oxide films, Ti-Ni alloys.

Experimental

The measurements were made on rotating electrodes in an argon environment at 25° ± 0.1°C. Systems with one-electron transfer, *i.e.*, $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+}, were used as a redox system. The supporting solutions were 1*N* Na_2SO_4 with *p*H values of 5.6 for Ti and 10.6 for Ni. There was no anodic dissolution of Ti or Ni in these solutions. The electrodes were anodically oxidized in the supporting solution at a constant potential for 60-150 min, then redox substances were added to the solution and the electrode was immediately polarized in cathodic or anodic directions at a potential sweep rate of 60 V/min (Ti) or 4.8 V/min (Ni). The $Fe(CN)_6^{4-}$ or Fe^{2+} oxidizing current on Ti electrode was assessed from anodic *E*, *i* curves by the difference of the over-all anodic current (obtained in a reducing-agent solution) and the anodic current on Ti in the supporting solution.

The oxide layer increments were estimated by coulometric measurements and depending on the oxide formation potential changed in the range of 20-40Å.

Potential values are cited in relation to the NHE.

Results and Discussion

Figures 1 and 2 illustrate the potential, current density relationship for the oxidation reaction of $Fe(CN)_6^{4-}$ and Fe^{2+} on Ti and Ni passivated under different potentials.

The above processes occur on these electrodes in a radically different way. They tend to be strongly inhibited on the passive Ti electrode (the overvoltage of the $Fe(CN)_6^{4-} \rightarrow Fe(CN)_6^{3-}$ reaction is great and *E*, log *i* lines have unusually steep slopes).

The oxide formation potential shift in the positive direction increases the inhibition of the subsequent oxidizing reaction, and the *E*, log *i* line slopes become steeper. It should be noted that the *E*, log *i* curve slope for one and the same oxide film practically does not depend on whether $Fe(CN)_6^{4-}$ or Fe^{2+} is oxidized on the electrode. No oxygen is found to evolve on Ti up to ~3V.

For oxidized Ni, at the oxide layer thickness approaching that of Ti, the oxidizing anodic-reaction rate (the latter including oxygen evolution) is much greater, being close to that on Pt, and does not depend on the oxide forming conditions.

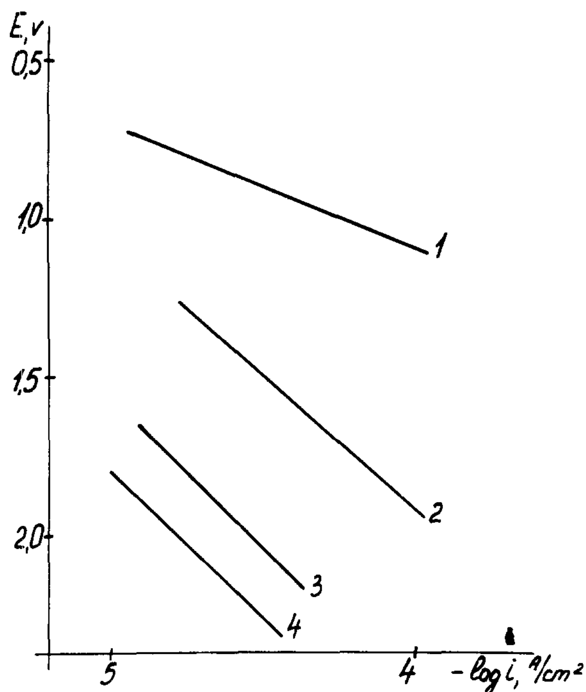

Fig. 1. Anodic *E*, log *i* plots in 1*N* Na_2SO_4 + 0.05*N* $K_3Fe(CN)_6$ + 0.05*N* $K_4Fe(CN)_6$ for Ti oxidized at curve (1) 0.25V; curve (2) 0.95V; curve (3) 1.40V; and in curve (4) 1*N* Na_2SO_4 + 0.05*N* $Fe_2(SO_4)_3$ + 0.05*N* $FeSO_4$ at 0.95V.

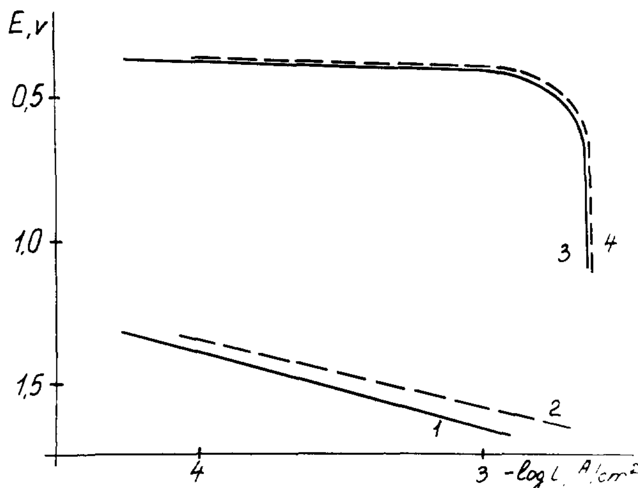

Fig. 2. Anodic *E*, log *i* plots in 1*N* Na_2SO_4 for curve (1) Ni oxidized at 0.50V; curve (2) for Pt; and in curve (3) 1*N* Na_2SO_4 + 0.005*N* $K_3Fe(CN)_6$ + 0.005*N* $K_4Fe(CN)_6$ for Ni oxidized at 0.50V; curve (4) for Pt.

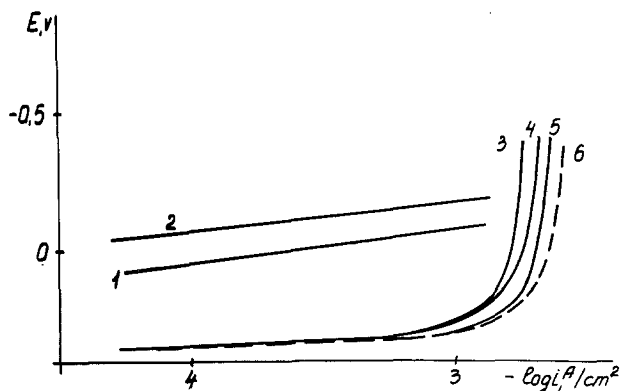

Fig. 3. Cathodic *E*, log *i* plots in 1*N* Na_2SO_4 + 0.05*N* $K_3Fe(CN)_6$ + 0.05*N* $K_4Fe(CN)_6$ for Ti oxidized at curve (1) 0.25V; curve (2) 0.95V; and in curve (3) 1*N* Na_2SO_4 + 0.005*N* $K_3Fe(CN)_6$ + 0.005*N* $K_4Fe(CN)_6$ for Ni oxidized at 0.30V; curve (4) 0.05V; curve (5) 0.70V; curve (6) for Pt.

The other relationships are observed for cathodic-reducing reactions (Fig. 3): normal *E*, log *i* curve slopes and their independence on the film-forming potential for Ti, and a marked reaction inhibition in the potential range of < 0.30V for Ni, showing the sooner, the less positive is the potential to form the film (19).

The *E*, log *i* curves shown in Fig. 4 for compact oxides point to the complete qualitative similarity of the electrochemical behavior of semiconductor (TiO_2 and NiO) and passive metal electrodes with a thin surface oxide layer.

Basing our consideration on the electron transfer theory for electrochemical reactions on semiconductors (20), we can explain the special features of redox-process kinetics on single crystal oxides, and primarily, abnormally steep *E*, log *i* curve slopes in a certain potential range in terms of potential localization in the solid phase, provided the electron exchange takes place through the conduction band for rutile[1] and valent band for NiO.

This fact finds an experimental proof in capacitance changes. Figure 5 shows that the linear relationship $1/c^2$, *E* indicating the presence of a space-charge region in the semiconductor, is valid in a broad range

[1] An indirect indication of this mechanism is the tendency to increased transfer coefficient of ferrocyanide reduction reaction (from 0.5 to 0.7) with the rise of the TiO_2-electrode polarization rate.

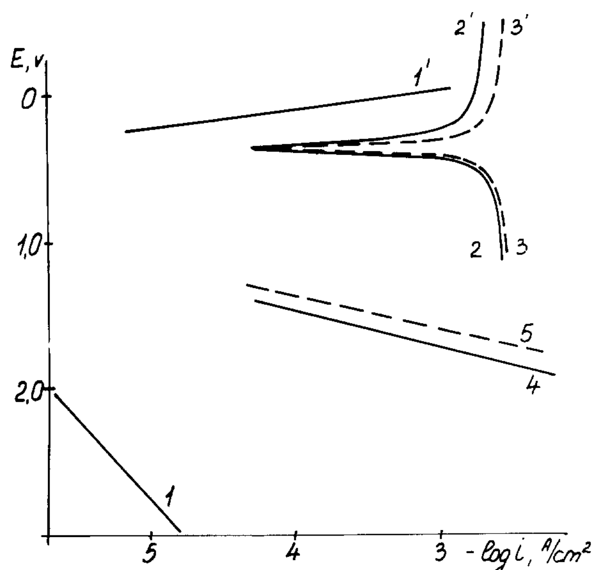

Fig. 4. Anodic and cathodic E, log i plots in curve (1.1') 1N Na_2SO_4 + 0.05N $K_3Fe(CN)_6$ + 0.05N $K_4Fe(CN)_6$ for TiO_2; curve (2.2') in 1N Na_2SO_4 + 0.005N $K_3Fe(CN)_6$ + 0.005N $K_4Fe(CN)_6$ for NiO; curve (3.3') for Pt; and curve (4) in 1N Na_2SO_4 for NiO; curve (5) for Pt.

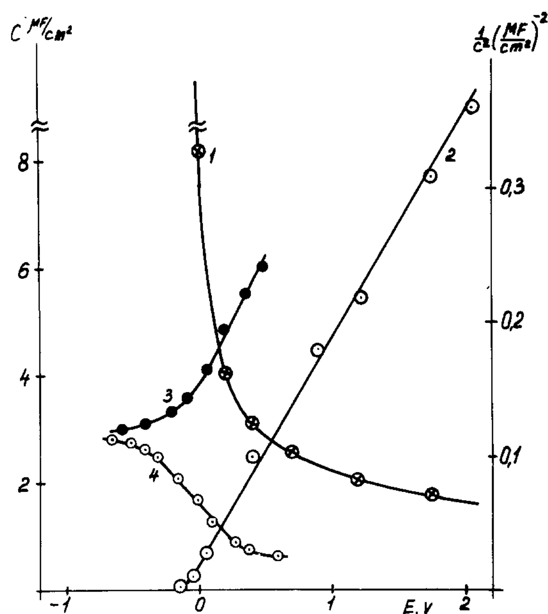

Fig. 5. The dependence of C and $1/C^2$ on potential in curves (1, 2) 1N Na_2SO_4 for TiO_2; curves (3, 4) and NiO, respectively.

of positive potentials for TiO_2 and in the potential range from about −0.35 to 0.30V for NiO, *i.e.*, at the very potentials where the redox reactions are inhibited on these electrodes.

Assuming the redox reaction mechanism for a passive metal surface and corresponding compact oxide to be the same, the distribution of the interfacial potential difference for the passive titanium electrode was estimated (20, 21) from the experimentally obtained E, log i curves slope for the oxidation reaction of $Fe(CN)_6^{4-}$ (Table I).

We can see that the potential drop part occurring in the oxide layer during anodic Ti polarization is fairly large and increases as E_f shifts in the positive direction. In the range of $Fe(CN)_6^{3-}$ reducing potentials, the main potential drop is probably concentrated in the Helmholtz layer. These data are in agreement with the results of study (22). The potential localization in the Helmholtz layer for Ni occurs at potential > 0.30V.

Table I. Estimation of interfacial potential difference distribution for TiO_2 and oxidized Ti

Electrode	pH	Oxide layer forming conditions E_f (V)	Oxide layer forming conditions t (min)	$Q_{oxid.}$ (mC/cm^2)	Potential drop part in oxide layer $\left(1 - \frac{2RT}{b_a \cdot F}\right) \cdot 100$ (%)
Ti	5.6	0.25	120	2.5	66
Ti	5.6	0.95	120	5.1	86
Ti	5.6	1.40	120	6.7	88
TiO_2	5.6	—	—	—	90

It is the different character of potential distribution that explains the differences in electrochemical properties of oxidized Ti and Ni surfaces.

To find out which of two factors—the film thickness or film nature—determines, for instance for Ti, the film/solution potential drop ratio, titanium was oxidized at two different potentials (0.25 and 0.95V) so as to maintain the amount of electricity spent for the surface oxidation (equivalent to film thickness) at a close level in both cases. The $Fe(CN)_6^{4-}$ oxidation rate at these electrodes was found to be different and the anodic E, log i slope describing potential localization in the oxide layer to be larger when the film was formed at a more positive potential (Fig. 6). Consequently, it is the oxide nature which depends on the oxide formation potential that in the given range of film thicknesses primarily controls the electrochemical properties of oxidized Ti. The more positive formation potential leads to a smaller concentration of oxygen vacancies. Since these act as electron donors, this, in turn, leads to a smaller free electron concentration, and hence, to a larger potential drop across the oxide film.

In contrast to Ti, the majority charge carriers in the surface oxide on Ni are holes. For the film formation potential shift in the positive direction (>0.30V) or during anodic polarization of electrode, the hole concentration increases, due to the increase in acceptor impurity (Ni^{3+}) concentration in the film. The latter factor decreases potential localization in the oxide layer and leads to the "metallization" of the passive nickel surface in relation to the anodic oxidation of solution ions.

Due to the different character of potential distribution for oxidized Ti and Ni electrodes, it was of interest to investigate the oxide growth kinetics on these metals. Figure 7 shows the change in the anodic

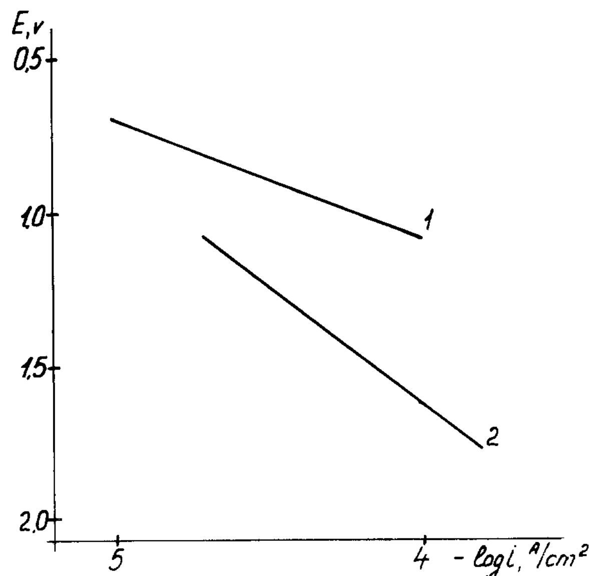

Fig. 6. Anodic E, log i plots in 1N Na_2SO_4 + 0.05N $K_3Fe(CN)_6$ + 0.05N $K_4Fe(CN)_6$ for Ti, E_f curve (1) 0.25V, $Q_{oxid.}$ 2.5 mC/cm^2; curve (2) 0.95V, $Q_{oxid.}$ 3.1 mC/cm^2.

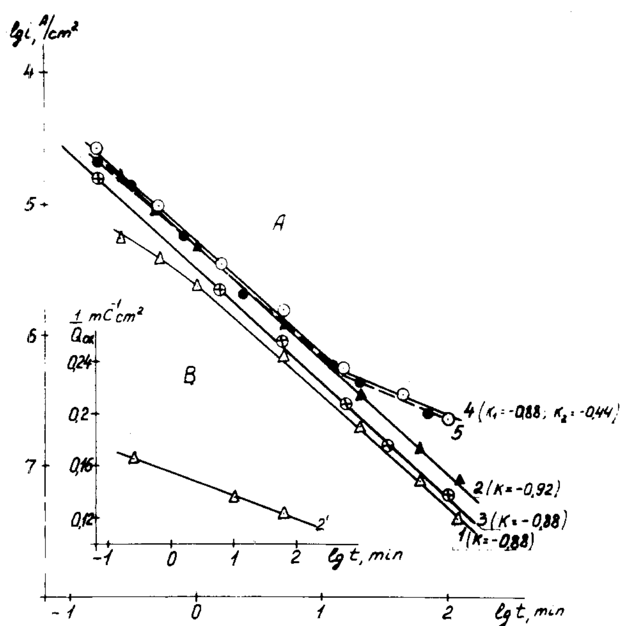

Fig. 7. A, The variation of Ti/Ni anodic oxidation current in 1N Na_2SO_4 with time: curve (1) Ti, E_f 0.25V; curve (2) 0.95V; curve (3) Ni, E_f 0.30V; curve (4) 0.70V; curve (5) 0.70V without agitation. B, $1/Q_{\text{oxid.}}$ — log t plot in 1N Na_2SO_4 for Ti E_f 0.95V curve (2′).

oxidation current of Ti and Ni surfaces in time under a constant potential in double logarithmic coordinates. The inverse logarithmic oxide film growth law, $1/Q_{\text{oxid}} = A - B \log t$, is valid for Ti oxidized in the given potential range. The latter is in agreement with the presence of electric field in the film and suggests the dominating role of ion generation and migration in the anodic surface oxidation processes (23). The time effect of Ni oxidation at film thicknesses approaching those of Ti depends on the oxide formation potential. At $E_f = 0.30$V, nickel oxidizes according to the logarithmic law.[2] For the oxidation at more positive potentials the logarithmic law is valid only during the first minutes of anodic oxidation, and then is replaced by the parabolic one, indicating the domination of free-particles diffusion in the film during its growth, since the solution agitation does not produce any effect on the oxidation rate. Oxygen evolves on the Ni electrode in the potential range >1.0V, and further thickening of the oxide film virtually stops.

Summing up the results, it is possible to conclude that the main difference in anodic behavior of oxidized Ti and Ni is caused by the difference in the interface potential drop distribution. The main potential drop for Ti under the conditions of developing anodic reactions is concentrated in the oxide layer, for oxidized Ni, in the Helmholtz layer. These differences are explained by the different nature of the majority carriers in the oxides formed and the change in their concentration when the oxide layer-forming potential is changed and, in some cases, too, in the process of anodic electrode polarization.

It was interesting to find out how the properties of the passive Ti electrode will change when it is gradually alloyed with Ni. To study this question representing also an independent interest (24-26), measurements were made on the Ti-Ni alloys containing different amounts of Ni changed from 0.2 to 37.5 w/o of Ni. The alloys were tested as annealed (600°C, 1 hr), and had a heterogeneous diphase structure (α + Ti_2Ni), excluding 37.5 Ni alloy corresponding to the monophase intermetallic compound Ti_2Ni. The test conditions were the same. The potential sweep rate during polarization measurements on the alloys was 4 V/min.

[2] We suppose that for Ni (or Ti-Ni alloys) the inverse logarithmic dependence in anodic oxidation may also be valid, but it was not specially tested.

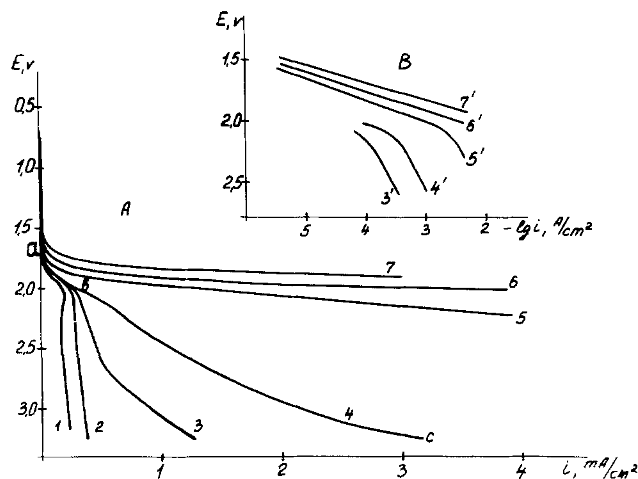

Fig. 8. Anodic polarization plots (A) and E, log i plots for the reaction of O_2 evolution (B) in 1N Na_2SO_4 for oxidized (at 0.95V) titanium curve (1) and Ti-based alloys with various nickel concentrations (w/o): curve (2) 0.2; curve (3.3′) 0.5; curve (4.4′) 1.0; curve (5.5′) 5.0; curve (6.6′) 11.0 and curve (7.7′) 37.5.

Figure 8 shows the anodic polarization curves for Ti and the alloys after film preforming at 0.95V in the supporting solution. In contrast to Ti, the oxygen-evolution reaction on Ti-Ni alloys can develop at rather significant rates, depending on Ni concentration. For the more Ni content in the alloy (5.0, 11.0, and 37.5% Ni) the O_2 evolution commences at potentials up to the secondary surface oxidation of the electrode and is rather facilitated. At low Ni concentration in the alloy (0.2, 0.5, 1.0%), oxygen evolves simultaneously with surface oxidation and the $H_2O \rightarrow O_2$ reaction is greatly inhibited in time. The O_2 evolution starting potential depends on Ni concentration in the alloy and shifts to the less positive values as Ni concentration increases. The clearest picture of the differences in the oxygen evolution kinetics on different alloys is obtained from the E, log i curves built from the over-all anodic current density/oxide growth current density difference, assuming that the oxide layer growth currents are the same for the alloys and Ti. For the Ti-0.5Ni and Ti-1.0 Ni alloys E, the log i curves slopes are rather steep and become even steeper during polarization.

For greater nickel concentration (5.0, 11.0, and 37.5%) the slopes of E, log i curves are much smaller, however, they, too, increase with the attainment of the secondary surface oxidation potential.

The results shown in Fig. 9 indicate that the $Fe(CN)_6^{4-}$ oxidation, not accompanied by the oxide film growth, is greatly facilitated as compared to the

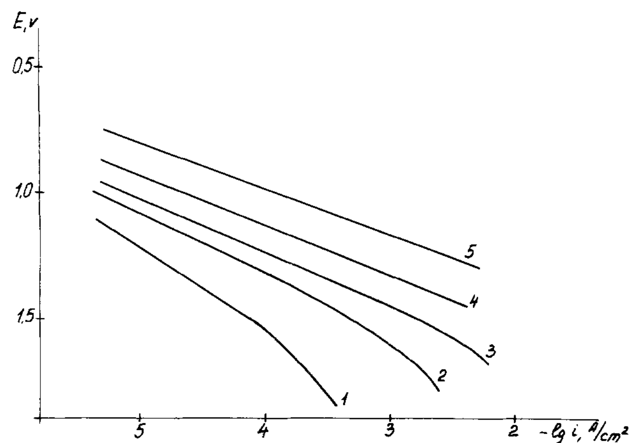

Fig. 9. Anodic E, log i plots in 1N Na_2SO_4 + 0.05N $K_3Fe(CN)_6$ + 0.05N $K_4Fe(CN)_6$ for oxidized (at 0.95V) Ti-based alloys containing Ni at: (1) 0.2; (2) 1.0; (3) 5.0; (4) 11.0; (5) 37.5%.

process of O_2 evolution, *e.g.*, on the Ti-1Ni alloy (curve 4 Fig. 9). For the less Ni content in the alloy (Ti-0.2 and Ti-0.5 Ni), this process facilitation covers only the potential range up to the secondary electrode oxidation. The overvoltage of the ferrocyanide oxidation reaction, in like manner to the overvoltage of the oxygen evolution process, depends on the Ni content in the alloy, having a tendency to diminish with the increased Ni concentration.

Figure 10 shows anodic polarization curves for pure Ti and alloys primarily oxidized at $E_f = 0.25$V. The film-forming potential shift to the less positive values makes it possible to divide the potential ranges corresponding to the oxide growth and oxygen evolution processes (sections ab and cd, respectively), thus providing additional information on the alloy surface oxidation kinetics. It follows that the secondary surface oxidation rate (Fig. 10, B) is not practically affected by the alloy composition. The dependence of the current for surface oxidation on the potential for both pure Ti and the various alloys has the same slope and, in fact, the curves virtually coincide. When plotted in double logarithmic coordinates the variation of current density with time (at a constant potential) gives a straight line with a slope close to -1. This indicates that the anodic oxide growth on Ti-Ni alloys proceeds by a law similar to that observed on pure Ti. Thus it follows that the law and the rate of anodic oxidation of the Ti-Ni alloys are identical to the oxidation of pure Ti, whereas oxidation reactions of solution ions are greatly facilitated on the alloys.

The similarity between the surface oxidation kinetics for the alloys and pure titanium suggests that in both cases a large part of the potential drop occurs through the surface oxide film.

In order to explain the results obtained, an alloy oxide layer structure model has been adopted including a provision for considerable oxide film composition variation across the film thickness. In agreement with this model Fig. 11 sketches the hypothetical changes in nickel content across the film thickness and interfacial potential drop distribution, depending on Ni concentration in the alloy at the same oxide-forming potential. The oxide zones adjacent to the metal (d_1, d_2 . . .) are assumed to be enriched in Ni, with the amount and penetration depth of the enrichment increasing with increasing Ni content in the alloy. At the film/solution interface, the film zone (d_1', d_2', . . .) is approaching TiO_2 in composition, its thickness correspondingly diminishing with the increase in Ni

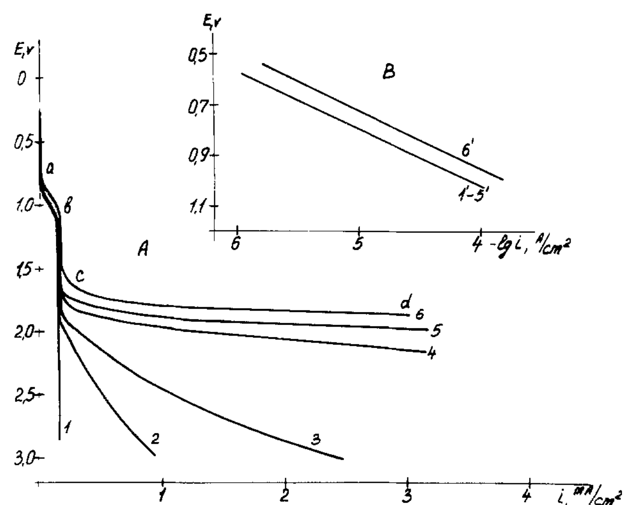

Fig. 10. A, Anodic polarization plots in 1*N* Na_2SO_4 for curve (1) preoxidized (at 0.25V) Ti; and curve (2) Ti-Ni alloys containing Ni (%) 0.5; curve (3) 1.0; curve (4) 5.0; curve (5) 11.0; and curve (6) 37.5.

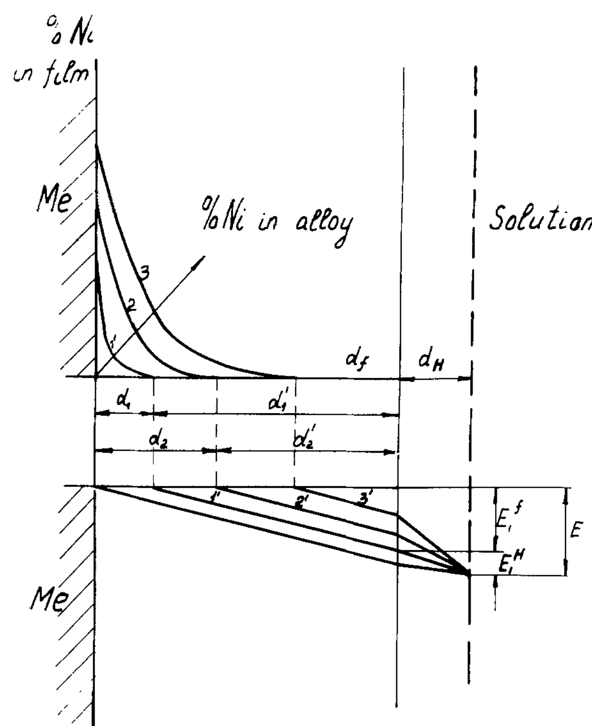

Fig. 11. Schematic presentation of Ni concentration variation across the film thickness and interfacial potential difference distribution depending on Ni concentration in the alloy (at the same E_f).

concentration in the alloy. The film composition variations across the film thickness may have resulted from the predominant Ti^{4+} ion migration as compared to that of Ni^{2+} to the outer surface during oxide formation. The outer film part composed of TiO_2 and having a thickness changing depending on the alloy composition is an energy barrier and probably determines the electrochemical properties of Ti-Ni electrodes. The facilitation of solution ions oxidation can be caused, for the more alloyed compositions, by both the increased potential drop part in the Helmholtz layer and the lowering of the outer barrier layer thickness and corresponding increase in the probability of electron tunneling through the oxide layer (27, 28). The oxide growth rate on the surface is independent of alloy composition since the electric field strength in the barrier film of varying thickness remains at a constant value (potential range up to the oxygen evolution is implied here).

Summing up the results obtained, it is possible to conclude that the passive surface of pure Ti and Ni electrodes having a thin phase oxide film possesses the peculiarities of the semiconductor electrodes. The dual electrochemical properties of the oxidized alloys are probably determined by their specific film structure.

Summary

1. The anodic oxidation kinetics and electrochemical properties of passive surfaces of titanium, nickel, and titanium/nickel-based alloys in sulfate solutions have been investigated.

The anodic oxidation of solution ions are strongly inhibited for oxidized titanium (at an oxide layer thickness of 30-50Å). The kinetics parameters of these reactions depend on the oxide layer-forming conditions. The kinetics of the oxidizing reactions for passive nickel does not practically differ from that of platinum electrode. The main potential drop under conditions of anodic polarization for Ti is concentrated in the oxide film, and for oxidized nickel, in the Helmholtz layer.

2. The rates of anodic oxidation of Ti-Ni alloys (0.2-37.5 w/o Ni) are identical to those of pure

titanium. A significant difference is observed in relation to the solution ion oxidation reactions which are greatly facilitated on the oxidized alloys as compared to Ti. The results are interpreted using an assumption that the oxide film composition on the alloy changes across the film thickness. The oxide zone adjoining metal is enriched with nickel, and the zone bordering on solution approaches TiO_2 in its composition and represents an energy barrier for the solution ion oxidation reaction. The reduction of the thickness of the outer film part with the increase of Ni content in the alloy results in a facilitated anodic solution ion oxidation on the Ti-Ni alloys with elevated nickel concentration.

Manuscript submitted Aug. 29, 1977; revised manuscript received Feb. 15, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

ABSTRACT

The time variation of current density at constant potentials for oxygen evolution on metals or alloys is one of the most difficult problems needing a solution in commercial water electrolyzers. The mechanism of this phenomenon on nickel electrodes was studied in 1*N* KOH using ellipsometry to analyze the nature of anodic oxide films. Effects of electrochemical pretreatment of oxide films on the kinetics of the oxygen evolution reaction were investigated. Nickel oxide films, formed potentiostatically at 1.5V, are more active than untreated nickel for this reaction. The time variation of current density for oxgen evolution at constant potentials (above 1.56V) is essentially due to the gradual conversion of Ni^{3+} to Ni^{4+} ions in the oxide film on the surface of the electrode. The electrocatalytic activities of aged electrodes are regained by rejuvenating the electrodes at 1.5V. The rejuvenation of aged oxide films is essentially attributed to the recovery of active sites on the very top layers of the films, rather than the diminution of the film thickness. The higher the electrolyte temperature the shorter the period of time required for approaching a stable current density. In addition, with increasing temperature, there is a more significant improvement of the electrocatalytic activity by rejuvenation on aged electrodes. Tafel plots for oxygen evolution on nickel preanodized or rejuvenated at 1.5V exhibit only one linear region with $b \approx 40$ mV, while dual Tafel regions are observed on nickel prepolarized at 1.8 or 2.0V: $b \approx 40$ mV at low η and $b \approx 170$ mV at high η. In comparison with the thickness of oxide films, the chemical identity of the very top layers of oxide films plays a more significant role in determining the kinetics of the oxygen evolution reaction.

One of the significant factors contributing to the performance degradation with time in water electrolysis cells is due to the increase of overpotential for oxygen evolution with time at a constant current density, which occurs over a period of two years or even more. This phenomenon has been observed on platinum in the potential range of 1.6-2.0V (1), on iridium (2), and on nickel (3). The authors of the work on iridium (2) and nickel (3) suggested that the decay of current with time is ascribed to the continuous growth of poorly conducting oxide films, which in return retard the electron transfer. Further confirmation of this suggestion, based on the nature of the oxide film, is needed.

According to thermodynamic data (4), the insoluble oxygen-containing species of the highest oxidation state of Ni, formed in the potential region for oxygen evolution, is hydrated NiO_2. Although x-ray crystallographic studies of nickel oxide films yield no direct evidence for the presence of NiO_2 in the films (5), many authors (6-9) have found oxides with ratios of O/Ni in the range of 1.7-1.9. Thus, further oxidation of Ni beyond the oxidation number of β-NiOOH (O/Ni = 1.5) is possible. The only direct evidence to demonstrate the existence of Ni^{4+} ions has been reported by Labat and Pacault (10, 11), who investigated the alteration of the magnetic susceptibility of $Ni(OH)_2$ subjected to electrochemical oxidation and reduction. It is generally accepted that, in the potential region for oxygen evolution, a certain number of Ni^{3+} ions in the β-NiOOH lattice is further oxidized to Ni^{4+} ions, thus, resulting in a nonstoichiometric oxide film essentially composed of Ni^{3+}, Ni^{4+}, OH^-, and O^{2-} ions (9, 12). The ratio of Ni^{3+} to Ni^{4+} ions is strongly dependent on the anodization potential (9). Similar results have also been reported for Pt anodes from ESCA measurements, which show that the amount of PtO_2 in oxide films increases with the polarization potential (13).

Oxide films on nickel in alkaline solutions have been extensively studied using ellipsometry (14-16), specular reflection spectroscopy (17), and x-ray photoelectron spectroscopy (18), only in the potential region for the formation and conversion of oxides. It is of interest to examine the nature of nickel oxide films, formed at higher potentials in the oxygen evolution region, using optical techniques. A possible explanation for the lack of such investigations is that at sufficiently high potentials, the vigorous generation of oxygen bubbles on an electrode surface may interfere with the measurement of optical parameters. Recently, Vinnikov and co-workers (19) have proposed a method to carry out ellipsometric measurements on oxide films formed in the oxygen evolution reaction. In this method, a platinum electrode was maintained in a potential region for oxygen evolution (about 2.0-2.3V) for a desired period of time. Ellipsometric measurements were then taken after decreasing the potential to 1.6V, under which conditions the rate of oxygen generation was low enough so as not to influence optical readings.

In spite of the extensive studies of nickel oxide films (14-18), information on the effect of the nature of the films on the kinetics of the oxygen evolution reaction from alkaline solutions is relatively sparse (12, 20). The present paper deals with this subject as well as the mechanism of the current decay for this reaction with time by an ellipsometric examination of the nature of oxide films formed on Ni at various potentials in the oxygen evolution region. Effects of electrochemical pretreatment of oxide films on the electrode kinetics of this reaction are also elucidated. In addition, efforts are made to develop methods for reactivating oxide films for oxygen evolution on aged nickel electrodes. It was recently proposed (21) that the electrocatalytic activity for oxygen evolution on aged Ir electrodes can be regained by applying a cathodic potential scan back to 0.25V and then returning to 1.50V.

Experimental

Electrode preparation.—The electrode was fabricated by mounting a nickel rod of purity 99.999% into a Teflon holder. Thus, only a single face with a geometric area of ~0.33 cm^2 was exposed to the electrolyte. Prior to each measurement, the electrode was mechanically polished to a mirrorlike finish as described elsewhere (22). The oxide film on the electrode surface, arising from the polishing process, was removed with dilute HCl solution. The electrode was then rinsed thoroughly with distilled water. Since oxide films on nickel electrodes are not removed by electroreduction (16, 17), the clean electrode surface could be obtained only by repolishing after each experiment. A cylindrical electrode made of platinum gauze was employed as the counterelectrode.

Electrolyte preparation and purification.—The 1*N* KOH solution was prepared from Baker analyzed reagent grade potassium hydroxide and triply distilled water. The electrolyte was purified by anodic preelectrolysis at a current density of 2 mA/cm^2 for at least 24 hr. Before each experiment, the electrolyte within the cell (about 120 ml) was deaerated by bubbling purified nitrogen.

Electrochemical measurements.—A cylindrical cell, made by inserting a Teflon sleeve into a brass envelop, was used to carry out the combined electrochemical and ellipsometric study. The electrochemical measurements were made using a PAR Model 173 potentiostat. Electrode potentials were measured with respect to the Hg/HgO electrode with KOH of the same concentration as the measuring solution. The potentials quoted in this paper are referred to the reversible hydrogen electrode (RHE) which is −926 mV *vs.* Hg/HgO electrode as determined in a previous study (23). Tafel plots for oxygen evolution on various pretreated nickel electrodes were determined by use of the steady-state potentiostatic method. In general, current density-potential measurements were made in the direction of decreasing current for the electrodes preanodized at 1.8 or 2.0V, and in the opposite direction for those pretreated at 1.5V. In all cases, the observed currents were reasonably stable at potentials below 1.56V. At higher potentials, readings were taken after the varying rate of current density was less than 0.2%/min. Ohmic overpotentials between the working and reference electrodes were determined using an interruptor technique (24).

Ellipsometric measurements.—*In situ* optical analysis of oxide films was conducted by use of a Rudolph Model RR2000 automatic ellipsometer. The combined ellipsometric and reflectometric measurements, as described in detail in the work of Gottesfeld and Srinivasan (21), were made at an angle of incidence (Φ) of 65° using a monochromatic light of wavelength (λ) 5461Å. The three-parameter (*i.e.*, Δ, ψ, and $\delta R/R$) method of solution was employed to determine the thickness (d_f) and optical constants (n_f, k_f) of oxide films. The optical readings of the bare surface were taken by maintaining a freshly prepared electrode at −50 mV for about 5 min. The ellipsometric and reflectometric measurements on oxide films grown in the oxygen evolution region were conducted by stepping the potential to 1.5V and then passing a stream of purified nitrogen gas over electrode surfaces to remove oxygen bubbles. A computer program, based on a system for function minimization (25), was used for the quantitative analysis of optical data. The film thickness observed under a fixed condition was ascertained by measuring a separate set of optical data with a light source of wavelength 6328Å.

Results and Discussion

Effects of electrochemical pretreatment on current density-time relations at constant potentials.—The influence of preanodization of nickel electrodes at 1.5V on the kinetics of the oxygen evolution reaction is shown in Fig. 1. On polarization at 1.8V, the initial current densities for oxygen evolution on preanodized electrodes are 4-5 times larger than on the freshly prepared electrodes. (The current density, recorded after the polarization of an electrode at 1.8V for 6 min, is referred to as the initial current density.) Similar results have been reported in the recent work of Shumilova and co-workers (26), who found that thermally oxidized nickel or cobalt oxide films are more active for oxygen evolution than pure metals.

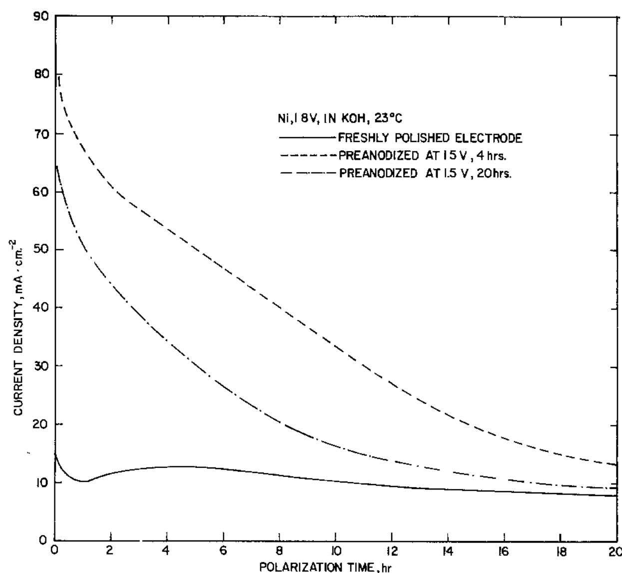

Fig. 1. Effect of preanodization at 1.5V on the current density for oxygen evolution on nickel electrodes in 1*N* KOH at 23°C.

Since oxide films on preanodized electrodes are thicker than on the freshly prepared one, it is extremely unlikely to correlate the considerable enhancement of initial current densities arising from preanodization (see Fig. 1) with film thickness. Instead, as it has been shown for the oxygen evolution reaction on iridium oxides (21) and on ruthenium oxides (27), the improvement of electrocatalytic activities for this reaction on preanodized nickel electrodes is apparently associated with the formation of the "right type of oxide." In the literature (15, 17, 28), it has been reported that preanodization of nickel at 1.5V yields oxide films essentially composed of β-NiOOH. On further oxidation at higher potentials, nonstoichiometric oxide films containing Ni^{3+} and Ni^{4+} ions are formed (6-9). The ratio of Ni^{3+} to Ni^{4+} ions in the films is dependent on the potential (9, 29) as well as the polarization time (29). Thus, the direct polarization of a freshly prepared nickel electrode at 1.8V produces an oxide film enriched in Ni^{4+} ions, which probably inhibit the oxygen evolution reaction, as discussed in a later section. Therefore, in comparison with the situation on the freshly prepared electrode, the significant increase of initial current densities on preanodized electrodes is essentially attributed to the presence of β-NiOOH, which is the so-called "right type of oxide" to activate the oxygen evolution reaction.

Further anodization of preoxidized nickel electrodes, by stepping the polarization potential from 1.5 to 1.8V, results in the gradual diminution of the concentration of Ni^{3+} ions in oxide films (9, 29). The current densities for oxygen evolution on these electrodes may thus be anticipated to decay with time, as supported by the experimental evidence shown in Fig. 1. Further, an increase of preanodization time at 1.5V causes an enhancement of the film thickness, which in turn produces an increase of resistance for the electron transfer. Consequently, as seen from Fig. 1, the performance for oxygen evolution on nickel preanodized

for 20 hr is poorer than that on the one preanodized for only 4 hr.

Despite the method of pretreatment, the oxygen evolution reaction on various electrodes exhibits approximately the same current densities after 20 hr of polarization at 1.8V (see Fig. 1). As illustrated in Fig. 2, however, the electrocatalytic activities of aged electrodes are rejuvenated by stepping the potential back to 1.5V. After maintaining aged electrodes at 1.5V for 2 hr, the initial current densities for oxygen evolution at 1.8V increase 3-7 times, but decrease with time again. The extent of improvement in electrocatalytic activities of oxide films is strongly dependent on the rejuvenation time as demonstrated in Fig. 2. Rejuvenation of an electrode at 1.5V for 12 min only doubles the initial current density. However, increasing the rejuvenation time to 2 hr results in an enhancement of about 7 times in the current density. Corresponding to the increase of rejuvenation time from 12 min to 2 hr, the period in which current densities on rejuvenated electrodes are higher than the initial current densities, increases from 2.2 to 11.5 hr.

Optical analysis of oxide films.—Figure 3 gives the variation of thickness (d_f) and optical constants (n_f, k_f) of oxide films with the electrochemical treatment applied to a nickel electrode. The complex refractive index ($\hat{n}_f$) on the bare nickel surface is 2.47-3.05i. Preanodization of the nickel electrode at 1.5V for 4 hr yields an oxide film with thickness of ~190Å and an absorption coefficient typical for semiconductors (n_f = 1.42-0.15i). It has been reported that, at $\Phi = 60°$ and $\lambda = 6328Å$, β-NiOOH film exhibits a complex refractive index of 1.6-0.117i in 5*N* KOH (15) and of 1.46-0.165i in 0.1*M* $Ni(NO_3)_2$ (30). From the observed optical constants in the present work, one confirms that the oxide film formed on nickel preanodized at 1.5V is β-NiOOH. The species β-NiOOH is a reasonably good electron conductor (20).

When this preanodized electrode is further oxidized at 1.8V for 20 hr, the film thickness increases to ~690Å with its $\hat{n}_f$ value[2] altering to 1.36-0.063i and the current density decreases from initial 79 to 13.3 mA/cm² (see Fig. 1). Further polarization of the preanodized nickel electrode results in the transformation of Ni^{3+} ions in the β-NiOOH lattice to Ni^{4+} ions (9, 12, 28). As has been pointed out by Vijh (31), the approximate relationship between the electronic conductivity (σ) and heat of formation per equivalent (ΔH_e) of intrinsic binary semiconductors may be represented by the equation

$$\sigma = \sigma_0 \exp(-\Delta H_e/kT) \quad [1]$$

where k is Boltzmann's constant, T is the absolute temperature, and σ_0 is the limiting electronic conductivity as T approaches zero. Apparently, Ni^{4+} oxide has a larger ΔH_e value than the Ni^{3+} oxide. Hence, the conversion of Ni^{3+} to Ni^{4+} ions may induce a decrease in the electronic conductivity of the oxide film and thus results in a considerable change in the k_f value of this film, as observed in the present work.

After polarization at 1.8V, the electrocatalytic activity of the aged electrode is rejuvenated by stepping its potential back to 1.5V.[3] As shown in Fig. 4, ellipsometric and reflectometric parameters remain approximately constant during the rejuvenation. After 2 hr of rejuvenation at 1.5V, the thickness of oxide film decreases slightly to ~680Å, having $\hat{n}_f$ = 1.36-0.065i. Apparently, the rejuvenation process causes no significant change in the thickness and optical constants of the oxide film. Subsequently, an increase of the potential of this rejuvenated electrode to 1.8V results in an enhancement of only ~15Å in the film thickness in the first 20 hr. However, the current density for oxygen evolution at this potential diminishes remarkably from initial 41 to 6 mA/cm² in the same period of time.

Influence of electrochemical treatment on Tafel parameters.—Tafel plots for oxygen evolution on various pretreated nickel electrodes are shown in Fig. 5. On electrodes which are preanodized at 1.8 or 2.0V, it always takes 1-2 hr to obtain a single current density with varying rate less than 0.2% per minute, particularly in the transition region between 1.56 and 1.7V. Above the potential 1.56V, Tafel plots for oxygen evolution on nickel electrodes preanodized or rejuvenated at 1.5V deviate from linear regions. For the oxygen evolution reaction on iridium in acid solution, a sharp break in the Tafel plot has been observed at 1.57V (2). Kinetics parameters for this reaction, as well as the thickness of oxide films, on various pretreated nickel electrodes are summarized in Table I.

Tafel plots for the anodic evolution of oxygen on the electrodes preanodized or rejuvenated at 1.5V exhibit only one linear region with $b \approx 40$ mV, while dual Tafel regions are observed on those preanodized at 1.8 or 2.0V: $b \approx 40$ mV at low η and $b \approx 170$ mV at high η (b and η represent the Tafel slope and oxygen overpotential, respectively). From optical analyses, the preanodization of nickel at 1.8 or 2.0V yields oxide films with low k_f (~ 0.06) values and thus poorer electronic conductivity. The films, in turn, lead to barrier-layer effects (32) on the reaction kinetics,

[2] By use of the three parameter method of solution, no difficulty was encountered in determining $\hat{n}_f$ value for a mixed oxide film containing Ni^{3+} and Ni^{4+} ions from the measured optical parameters.

[3] It may be more efficient to rejuvenate an aged electrode at less anodic potentials. However, it is found that the thickness of oxide films, grown at potentials above 1.56V, is greatly decreased when the potential is subsequently lowered below 1.35V, as shown by the significant reduction in the alteration of ellipsometric and reflectometric parameters with respect to the bare nickel surface. Also the conversion of Ni^{3+} to Ni^{2+} ions takes place below this potential (17). To eliminate the complications arising from these factors in the optical analysis of oxide films formed in the oxygen evolution region, the aged electrode is rejuvenated only at 1.5V.

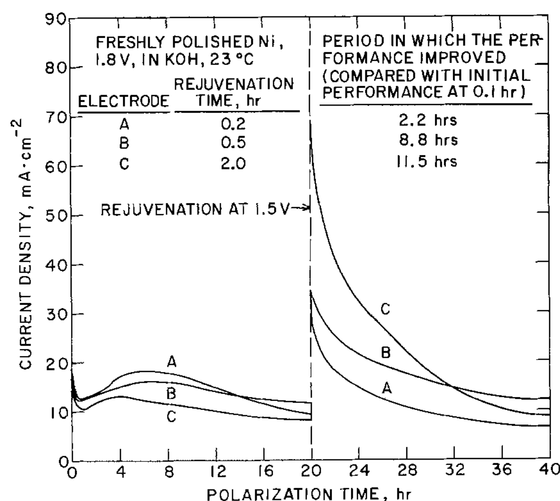

Fig. 2. The dependence of the extent of improvement in the electrocatalytic activity of oxide films for oxygen evaluation on the rejuvenation time.

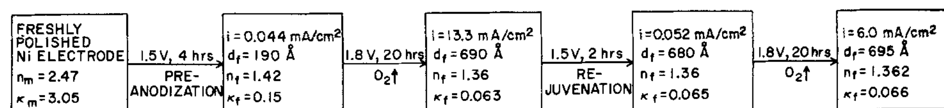
Fig. 3. Variation of the thickness (d_f), refractive index (n_f) and absorption coefficient (k_f) of oxide film with anodization potential in 1*N* KOH at 23°C ($\Phi = 65°$ and $\lambda = 5461Å$).



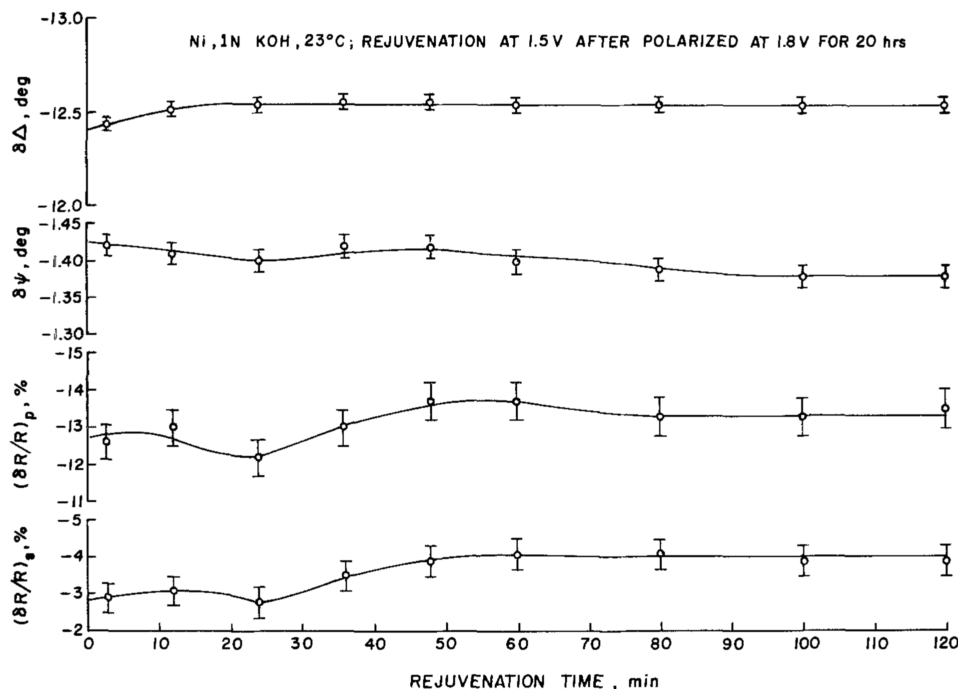


Fig. 4. Variation of ellipsometric ($\delta\Delta$, $\delta\Psi$) and reflectometric parameters [$(\delta R/R)_p$, $(\delta R/R)_s$] with the rejuvenation time.

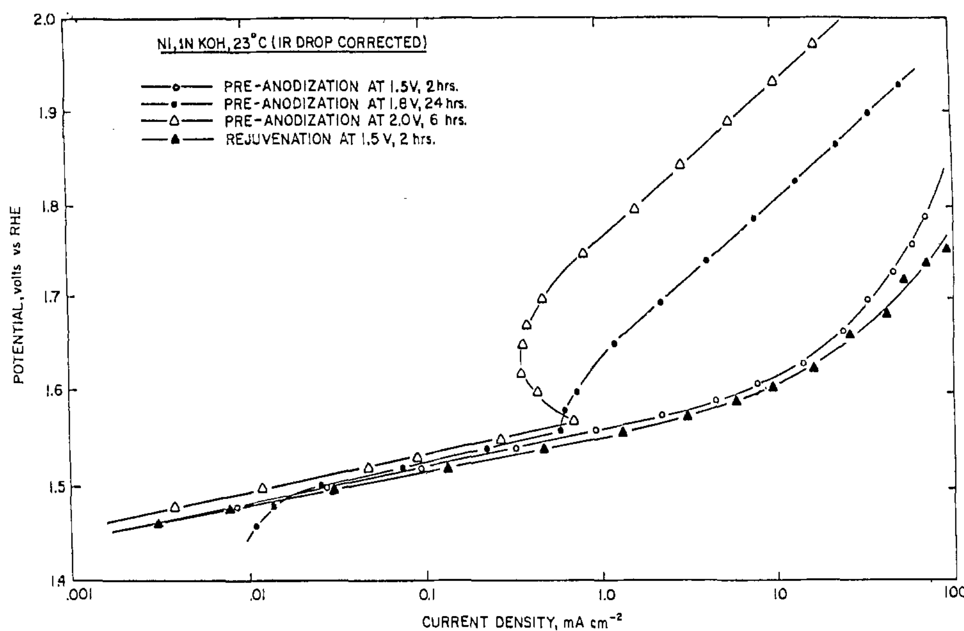

Fig. 5. Tafel plots for the oxygen evolution reaction on various pretreated nickel electrodes in 1N KOH at 23°C.

as further supported by the unusually high Tafel slopes of ~170 mV observed at high η.

In comparison with the case of pretreating nickel electrodes at 1.8V, preanodization of an electrode at a higher potential (*e.g.*, 2.0V) simply shifts the Tafel region at high η to a lower current density range in a parallel direction (see Fig. 5). Because the ratio of Ni^{3+} to Ni^{4+} ions in oxide films is dependent on the polarization potential (9, 29), the decrease in current density for oxygen evolution at high η can be attributed to the diminution of the concentration of Ni^{3+} ions in the films. Preanodization at 2.0V produces an oxide film of thickness ~1400Å,[4] which is much thicker than those formed on the electrode preanodized at 1.8V, being ~620Å in thickness. At potentials below 1.56V, however, Tafel plots for oxygen evolution on all the preanodized electrodes are in fair agreement with one another, in spite of the considerable difference in the electrode pretreatment.

As seen from Fig. 5, the Tafel plot for oxygen evolution on the rejuvenated electrode substantially coincides with that on the electrode preanodized at

[4] Actually, the electrode was first preanodized at 1.8V for 72 hr and then at 2.0V for 6 hr.

Table I. Kinetic parameters for oxygen evolution on pretreated nickel electrodes

Pretreatment	d_f, (A)	Tafel slope, b (mV) High η	Tafel slope, b (mV) Low η	Exchange c.d., i_o (A/cm²) High η	Exchange c.d., i_o (A/cm²) Low η
1. Preanodization at 1.5V, 2 hr	~230	—	39	—	3.8×10^{-12}
2. Preanodization at 1.8V, 24 hr	~620	170	43	4.2×10^{-6}	1.1×10^{-11}
3. Preanodization at 2.0V, 6 hr	~1400	167	40	6.2×10^{-7}	2.2×10^{-12}
4. Rejuvenation at 1.5V, 2 hr	~620	—	38	—	1.1×10^{-12}

1.5V. It is clear that the rejuvenation of an aged electrode causes the reappearance of the so-called "right type of oxide" in the film. Further, the film thickness on the rejuvenated electrode is much larger than that on the preanodized electrode (see Table I). However, the oxygen evolution reaction exhibits approximately equal Tafel slope and exchange current density on the two electrodes. These observations imply that the chemical nature of oxide films plays a more important role than the film thickness in the determination of the kinetic parameters for this reaction.

By intentionally extending the rejuvenation time to 12 hr, the influence of rejuvenation on Tafel plots for oxygen evolution on a nickel electrode is shown in Fig. 6. After preanodization of a freshly prepared nickel electrode at 1.8V for 4 hr, a Tafel plot for the anodic evolution of oxygen was determined. This aged electrode was then rejuvenated at 1.5V for 12 hr. Subsequently, the rejuvenated electrode was polarized at 1.8V for 20 hr, and a second Tafel plot for oxygen evolution was finally determined. The rejuvenation of a preanodized electrode results in the remarkable shift of the Tafel plot at high η to a higher current density range, in spite of the fact that the preanodization time has been increased from 4 to 20 hr. At potentials below 1.56V, however, the two Tafel plots are in excellent accordance with each other.

Effects of temperature on the rate of current decay.—The rate of the conversion of Ni^{3+} to Ni^{4+} ions in oxide films increases with increasing temperature. In general, higher oxides such as NiO_2 are less stable at higher temperature. Thus, if the time variation of currents under constant potential conditions is really associated with the further oxidation of Ni^{3+} ions. one is able to confirm this by investigating the variation of the rate of current decay with temperature.

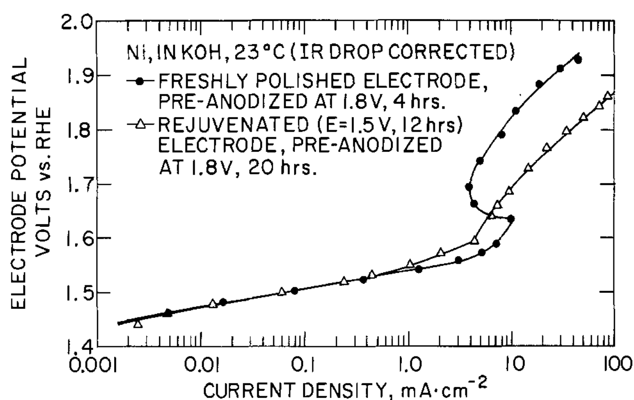

Fig. 6. Effect of rejuvenation (at 1.5V) on Tafel plots for the oxygen evolution reaction on a nickel electrode which is preanodized at 1.8V.

The initial current density varies significantly with the electrolyte temperature. With a view of comparing the rate of current decay at various temperatures, the ratios of the current density to its initial value rather than the apparent current densities, are plotted as a function of time in Fig. 7. The higher the electrolyte temperature, the shorter the period of time required for approaching a stable current. Also, the time variation of current density becomes a less serious problem at higher temperatures. For instance, after the polarization of preanodized electrodes at 1.8V for 20 hr, the current density diminishes to ~1/6 of its initial value at 23°C. Under the same conditions, however, the current density drops only about 50% at 80°C. After the rejuvenation of an aged electrode at 1.5V for 2 hr, the current density for oxygen evolution on this electrode at 1.8V regains 100% of its initial value at 80°C, but only 64% at 23°C. From these observations, it is obvious that the time variation of current for oxygen evolution is closely correlated with the chemical conversion of Ni^{3+} to Ni^{4+} ions.

Mechanism of current decay.—As has been confirmed in the present work, the preanodization of a nickel electrode at 1.5V yields β-NiOOH film, which is the "right type of oxide" providing active sites, *i.e.*, Ni^{3+} ions, for the oxygen evolution reaction. On further anodization of this electrode at potentials above 1.56V, it is assumed that some Ni^{3+} ions are converted to Ni^{4+} ions by an equation of the form

$$\beta\text{-NiOOH}_{(latt)} + OH^- \rightarrow NiO_{2(latt)} + H_2O + e^-_{(latt)} \quad [2]$$

where the formation of lattice, rather than intermediate, Ni^{4+} ions takes place in the bulk as well as on the surface layers of oxide films.

The oxygen evolution reaction occurs only at the surface of the films. For this reaction on nickel in alkaline solutions, the generally accepted mechanism (20), modified from the one suggested by Krasil'shchikov (33), involves the following steps

$$OH^-_{(ads)} \rightleftarrows OH_{(ads)} + e^-_{(latt)} \quad [3]$$

$$OH_{(ads)} + OH^- \rightleftarrows O^-_{(ads)} + H_2O \quad [4]$$

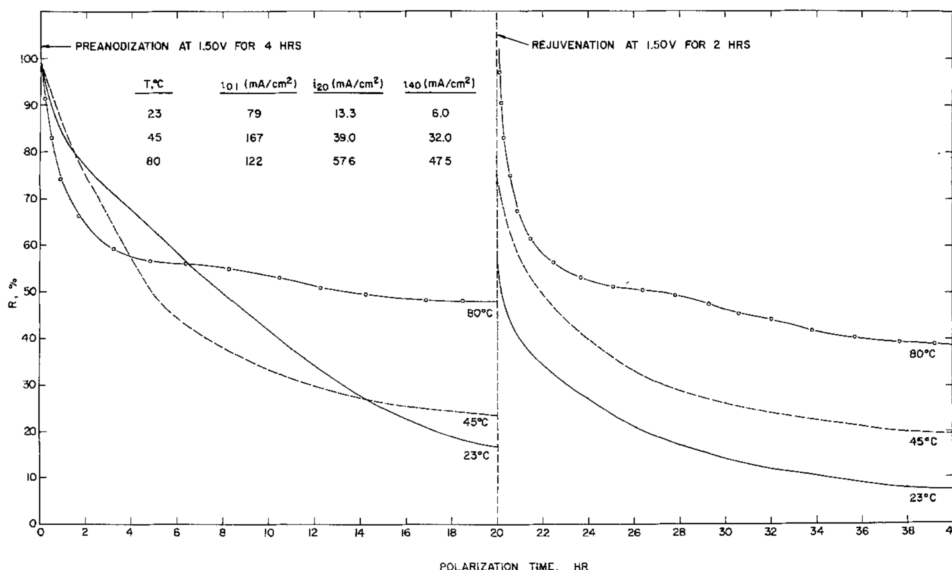

Fig. 7. Effect of temperature on the rate of current decay for the oxygen evolution reaction on preanodized and rejuvenated nickel electrodes.

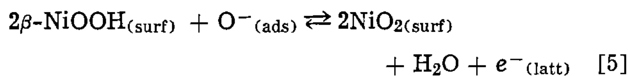

$$2\beta\text{-NiOOH}_{(surf)} + O^{-}_{(ads)} \rightleftarrows 2NiO_{2(surf)} + H_2O + e^{-}_{(latt)} \quad [5]$$

$$2NiO_{2(surf)} + H_2O \rightleftarrows 2\beta\text{-NiOOH}_{(surf)} + O_{(ads)} \quad [6]$$

$$O_{(ads)} + O_{(ads)} \rightleftarrows O_2 \quad [7]$$

Despite the pretreatment on each electrode, the observed Tafel slopes of $2RT/3\mathbf{F}$ (*i.e.*, ~40 mV, see Table I) at potentials below 1.56V support that Eq. [5] is the rate-determining step for oxygen evolution on nickel at low η. It is noted that NiO_2 formed via Eq. [5] is an intermediate species on the film surface only. According to thermodynamic data (4), the further anodization of NiO_2 to form insoluble solid species on the electrode surface is not possible. When an active species, *i.e.*, Ni^{3+} ion, on the film surface is anodized to Ni^{4+} ion, an intermediate step, similar to Eq. [5] cannot take place on the latter site and all the following steps in the over-all reaction for oxygen evolution may be completely inhibited. Thus, NiO_2, which is an intermediate in the oxygen evolution reaction, cannot function as an electrocatalyst for the over-all reaction. Therefore, the generation of each lattice Ni^{4+} ion on the film surface creates an inert site for oxygen evolution. On the other hand, the formation of lattice Ni^{4+} ions in the bulk of the oxide film, initially composed of β-NiOOH, results in a remarkable decrease in the electronic conductivity of the film itself as indicated by the significant drop of its absorption coefficient from 0.15 to 0.063 (see Fig. 3).

Figure 8 illustrates a possible mechanism for the loss and regain of electrocatalytic activities on oxide films. On further oxidation of one Ni^{3+} ion via Eq. [2], one proton migrates across the oxide-electrolyte interface accompanied by an electron transfer through the oxide-metal interface. The extent of the loss of electrocatalytic activity is dependent on the amount of protons ejected from the film into the electrolyte. Therefore, on polarization of pretreated nickel electrodes at 1.8V, the current decay with time is presumably attributed to the slow migration of protons from the oxide film into the electrolyte. In other words, the time variation of current density is essentially due to the gradual conversion of Ni^{3+} to Ni^{4+} ions in the bulk or on the surface of oxide films.

Possible reason for the rejuvenation of electrocatalytic activity.—As shown in Fig. 2, the current densities for oxygen evolution on nickel are considerably increased after rejuvenation of aged electrodes at 1.5V for different periods of time. The significant enhancement in current density, arising from the rejuvenation, is possibly ascribed to (*i*) the decrease of thickness of oxide films, and thus the diminution of resistance for the electron transfer; (*ii*) the alteration of microstructure of film surfaces, or more specifically, the increase of real surface area of oxide films; and (*iii*) the electrochemical reduction of Ni^{4+} to Ni^{3+} ion in oxide films.

During rejuvenation, the observed ellipsometric parameters are practically independent of time as shown in Fig. 4. After 2 hr of rejuvenation, the thickness of oxide film decreases slightly from ~690 to ~680Å (see Fig. 3). Furthermore, repolarization of this rejuvenated electrode at 1.8V for 20 hr results in a significant current decay, *i.e.*, from initial 41 to 6 mA/cm², but only a slight increase of ~15Å in the film thickness. Thus factor (*i*) hardly influences the current density for oxygen evolution at the potential of 1.8V.

The ellipsometric parameters, Δ and ψ, are sensitive to the variation of surface roughness of specimens (34). On rejuvenation of an aged electrode at 1.5V, these parameters remain substantially constant with time, as demonstrated in Fig. 4. Roughening of an oxide film causes an increase of real surface area and consequently results in a remarkable shift of Tafel plots for oxygen evolution on a rejuvenated electrode to a higher current density region. As shown in Fig. 6, however, intentional extension of the rejuvenation time to 12 hr causes no detectable shift of Tafel plots at low η. These observations strongly support that factor (*ii*) is unlikely to be the reason for the considerable enhancement of current density caused by the rejuvenation.

After the elimination of factors (*i*) and (*ii*) by the stated experimental evidence, chemical transformation of Ni^{4+} to Ni^{3+} ions, *i.e.*, factor (*iii*),[5] is the only possible reason for the increase of current density on rejuvenated electrodes. This transformation could induce two effects: (*i*) enhancement of active sites for oxygen evolution on the film surface; and (*ii*) increase of the electronic conductivity of the oxide film.

As demonstrated in Fig. 8, the electroreduction of Ni^{4+} to Ni^{3+} ions involves the migration of protons from the oxide-electrolyte interface onto the film surface and/or into the bulk of the film. Thus, at a constant potential, temperature and rejuvenation time are the essential factors controlling the extent of the electroreduction. Although the oxide film on the rejuvenated electrode exhibits no remarkable change in optical properties compared to that on the aged electrode (Fig. 3), the extent of improvement in the initial current density is strongly dependent on the length of rejuvenation time as well as on the temperature (see Fig. 2 and 7). Therefore, the electroreduction reaction does occur during rejuvenation in spite of the fact that no striking alteration of optical constants is detected. This peculiar phenomenon is elucidated below.

When an aged electrode is rejuvenated at such a high anodic potential (*e.g.*, 1.5V), it seems reasonable to assume that protons cannot migrate deeply through the oxide film because of the lack of sufficient field

[5] There is possibly an alternative explanation that, during rejuvenation, the lack of change in optical parameters is due to a compensating change in increased surface roughness for a decrease in film thickness. In this case, rejuvenation should arise due to decrease of film thickness. Figure 2 shows that the initial current densities on rejuvenated electrodes increase with the length of rejuvenation time. This result will then indicate that the film thickness decreases with increasing rejuvenation time. Certainly, thinning of oxide film could cause a surface roughening. However, it will be purely coincidental that, despite the length of rejuvenation time, changes in optical parameters, resulting from surface roughening, will always be equal to and thus compensate the change caused by the decrease in film thickness.

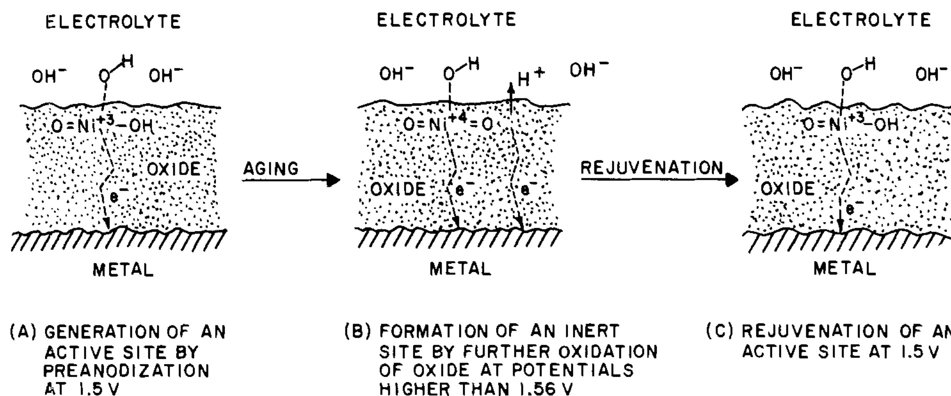

Fig. 8. Schematic illustration of deactivation and rejuvenation of active sites for oxygen evolution in the top few layers of nickel oxide films.

assistance. Thus, the electroreduction of Ni^{4+} ions possibly takes place only on the very top layers of the surface oxide. No significant change of the chemical identity in the bulk oxide is involved. The ellipsometry detects only the average properties of oxide films. Since thick films (~700Å) are present in the potential range for evolving oxygen, any possible change of optical properties in the top few layers of the films, arising from the electroreduction of Ni^{4+} ions, results in no detectable effect on the over-all film properties. Therefore, the rejuvenation of electrocatalytic activity is essentially attributed to the increase of active sites, *i.e.*, Ni^{3+} ions, on the very top layers of oxide films.

Conclusion

Nickel oxide films formed by the preanodization of the electrodes at 1.5V are more active than untreated nickel for oxygen evolution. This is essentially ascribed to the presence of the so-called "right type of oxide," *i.e.*, β-NiOOH, on the electrode surface. The β-NiOOH film with thickness of ~190Å exhibits an absorption coefficient typical for semiconductors ($\hat{n}_f$ = 1.42-0.15i). Further increase of potential on this preanodized electrode to higher values (say 1.8V) results in the gradual conversion of Ni^{3+} to Ni^{4+} ions on the surface layers of oxide films. Consequently, it causes a considerable enhancement of the film thickness and a remarkable drop in the electronic conductivity of the films, as determined using ellipsometric techniques. The time variation of current density for the oxygen evolution reaction at a constant potential above 1.56V is due to the continuous transformation of active (*i.e.*, Ni^{3+} ion) to inactive (*i.e.*, Ni^{4+} ion) sites.

From a practical point of view, the electrocatalytic activities of aged electrodes are regained by rejuvenating the electrodes at potentials below 1.56V. The rejuvenation of aged oxide films is substantially attributed to the recovery of active sites on the very top layers of the films. The time variation of current density for the oxygen evolution reaction at constant potential is less at higher temperatures. The higher the electrolyte temperature, the shorter the period of time required for approaching a stable current density and the more significant the improvement of the electrocatalytic activity of aged electrodes by rejuvenation.

Although the oxide film on the rejuvenated electrode is much thicker than that on the one preanodized at 1.5V, the Tafel plots for oxygen evolution on the two electrodes exhibit similar Tafel slopes (~40 mV) and exchange current densities (~10^{-12} A/cm^2). On the electrodes which are preanodized at 1.8 or 2.0V, dual Tafel regions are observed: $b \approx 40$ mV at low η and $b \approx 170$ mV at high η. It is concluded that the chemical nature of the top few layers of the films plays a more important role than the film thickness in the electrocatalysis of the oxygen evolution reaction on nickel. Methods to overcome the problem of performance degradation on anodes in water electrolysis cells include (*i*) increase of operating temperature to reduce the equilibrium ratio of Ni^{4+} to Ni^{3+} ions in the surface film, (*ii*) use of high surface electrodes to maintain the anode potential below the critical value of 1.56V at desired current densities, and (*iii*) introduction of a stable secondary cation into nickel oxide film (*e.g.*, $NiCo_2O_4$).

Electrogenerated Chemiluminescence

XXXIII. The Production of Excited States by Direct Heterogeneous Electron Transfer from Semiconductor Electrodes

J. D. Luttmer* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Electrogenerated chemiluminescence (ECL) arising from direct electron transfer from semiconductor electrodes to solution species was examined. The reduction of the oxidized forms of several luminescent species [$Ru(bipy)_3^{2+}$, thianthrene, 9,10-diphenylanthracene, and rubrene] on several n-type semiconductor electrodes (CdS, ZnO, TiO_2, SiC, GaP) was investigated. Only for reduction of rubrene radical cation on n-ZnO and n-CdS was unequivocal evidence found for production of an excited state (triplet) by direct heterogeneous electron transfer at potentials where homogeneous redox processes producing excited states were not possible. Current interruption techniques were employed to study the emission decay and an unusual emission at open circuit following a cathodic potential step was found. A model for direct triplet generation based on reduction via surface states within the bandgap region and quenching of excited states by the electrode is proposed and constraints on the experimental observation of direct excited state formation are suggested.

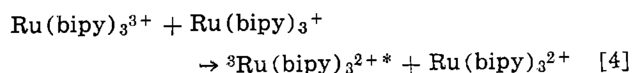
Many examples of the electrogenerated chemiluminescence (ECL) of aromatic molecules and rare earth chelates have been reported over the last decade and several reviews have been published (1-8). Usually these studies involve generating excited states (triplets and singlets) via homogeneous electron transfer between electrogenerated oxidized and reduced forms, frequently radical anions and cations ("radical ion annihilation"), *e.g.*, for rubrene (R)

$$R^{\dot{+}} + R^{\dot{-}} \rightarrow {}^3R^* + R \quad [1]$$

$$ {}^3R^* + {}^3R^* \rightarrow {}^1R^* + R \quad [2]$$

$$ {}^1R^* \rightarrow R + h\nu \quad [3]$$

or for $Ru(bipy)_3^{2+}$



$$Ru(bipy)_3^{3+} + Ru(bipy)_3^{+} \rightarrow {}^3Ru(bipy)_3^{2+*} + Ru(bipy)_3^{2+} \quad [4]$$

$$ {}^3Ru(bipy)_3^{2+*} \rightarrow Ru(bipy)_3^{2+} + h\nu' \quad [5]$$

Recent papers however have reported that excited states may also be formed by direct heterogeneous electron transfer at a semiconductor electrode surface (9, 10). Gleria and Memming (9) observed emission upon reduction of $Ru(bipy)_3^{3+}$ (bipy = 2,2'-bipyridine) at n-SiC and n-GaP semiconductor electrodes in H_2O or acetonitrile (ACN) solutions and proposed the reaction sequence

$$Ru(bipy)_3^{3+} + e^-(CB) \rightarrow {}^3Ru(bipy)_3^{2+*} \quad [6]$$

followed by [5], where $e^-(CB)$ represents an electron in the conductor band of the semiconductor. Yeh and Bard (10) reported singlet emission from rubrene produced by direct heterogeneous generation of the triplet state by reduction of $R^{\dot{+}}$ at an n-ZnO electrode followed by triplet-triplet annihilation in benzene-benzonitrile mixed solvent. *i.e.*

$$R^{\dot{+}} + e^-(CB) \rightarrow {}^3R^* \quad [7]$$

followed by [2] and [3]. In both studies it was proposed that the electron transferred from the conduction band to the oxidized solution species to form the excited triplet species. This is shown schematically in Fig. 1. Direct electron transfer to produce the ground state molecule should be less probable when the redox potential of the ground state molecule corresponds to an energy level within the bandgap of the semiconductor.

On a metal electrode an electron can be transferred from an isoenergetic state in the electrode to a lower orbital to produce the ground state of the molecule and no emission is expected. Moreover, excited state species are both more easily oxidized and more easily reduced at metal electrodes compared to the ground state species and metals are consequently good quenchers of excited states via electron transfer (11, 12). Quenching of excited state species by energy transfer to a metal is also well known (13). Although the direct heterogeneous production of triplet states at metal electrodes has been claimed (14), the emission observed in such cases has been attributed to a "preannihilation" type of ECL which involves reactions of impurities or electrogenerated products in the ECL solution (15, 16). Several other authors have been unable to observe evidence for the direct heterogeneous production of excited states on semiconductor

electrodes (17, 18). Moreover, in the studies reporting the direct heterogeneous production of excited states at semiconductors a rigorous examination of the possibility of preannihilation ECL contributing to the observed emission and of the extent of ECL arising from a homogeneous electron transfer involving inadvertently generated reduced forms of the emitting species was not undertaken. We report here a more detailed study of the ECL emission mechanism in these systems and examine other possible systems for excited state production by direct heterogeneous electron transfer from semiconductor electrodes.

Experimental

Acetronitrile (ACN) (Spectro Grade, Matheson, Coleman, and Bell; MCB) was purified by repeated vacuum distillation from P_2O_5 and freeze-pump-thaw cycles to remove O_2 as described by Park and Bard (19). Benzonitrile (BZN; MCB) was fractionally distilled under partial vacuum from $CaSO_4$ and again from P_2O_5. It was then refluxed over, and fractionally distilled from, CaH_2 under high vacuum. Oxygen was removed by three freeze-pump-thaw cycles and the solution was stored over activated neutral alumina. Benzene (Spectro Grade MCB) was stored over a sodium mirror for more than one week, then was vacuum distilled, and underwent four freeze-pump-thaw cycles to remove O_2.

Tris (2,2′ bipyridyl) ruthenium (II) perchlorate, $[Ru(bipy)_3(ClO_4)_2]$ was prepared by metathesis of $Ru(bipy)_3Cl_2 \cdot 6H_2O$ (G. F. Smith) with excess $NaClO_4$ in H_2O. The crystals were washed with H_2O, recrystallized once from ethanol and twice from ACN, and dried under vacuum at 90°C for 24 hr. Thianthrene (TH) (Aldrich) was recrystallized twice from benzene and sublimed. Rubrene (R) (Aldrich) was recrystallized three times from xylene-methanol under nitrogen in subdued light and dried under vacuum at 80°C. 9,10-Diphenylanthracene (DPA) (Gold Label, Aldrich) was recrystallized from xylene-methanol, sublimed, and zone refined.

Tetra-n-butylammonium perchlorate (TBAP) (Polarographic Grade, Southwestern Analytical Chemicals) was purified by filtering a warm ethanolic solution of the electrolyte containing activated carbon and repeated recrystallization from an ethanol-water mixture. A final recrystallization was done from benzene and the crystals were dried under vacuum at 50°C for 36 hr. All samples, solvents, and electrolytes were transferred to a Vacuum Atmospheres dry box in which the solutions were prepared and the electrochemical/ECL cells were filled.

The n-type single crystal semiconductor electrodes were prepared and mounted as previously described (20, 21). Ohmic contacts were made to them by electrodepositing indium on one side and attaching a lead with silver-epoxy cement. Silicone adhesive (Dow Corning) was used to insulate the electrical contact from the electrochemical solution. A platinum foil working electrode of similar area and geometry was fabricated in a similar manner. The electrodes were polished with 0.5 μm alumina and had geometric areas of 0.3-0.5 cm^2. N-CdS (National Lead) and n-GaP (Atomergic) were etched in 11M HCl for 30 sec. N-TiO_2 (National Lead) and n-SiC[1] were etched in an HF/HNO_3 mixture for 30 sec. N-ZnO (Atomergic) was first etched in H_3PO_4 and then in concentrated HCl, each for 15 sec. The flatband potentials of these semiconductor electrodes have previously been determined from the onset of the anodic photocurrent in ACN (9, 20, 21) and are given in Table I.

The electrochemical/ECL cell was of conventional design with the reference compartment separated by a porous Vycor (Corning Glass) glass plug and the auxiliary electrode separated by dual frits of medium porosity. The auxiliary electrode consisted of a very large piece of platinum foil or wire mesh. Controlled potential waveforms for ECL and cyclic voltammetry were obtained with a PAR Model 175 programmer and Model 173/176 potentiostat. Current-time and ECL intensity-time curves were obtained with a Nicolet 1090A digital oscilloscope and recorded on a Houston 2000 X-Y recorder. An Aminco-Bowman spectrophotofluorometer was used to obtain ECL and fluorescence spectra. The ECL and fluorescence detectors used were RCA 1P28 and RCA 4832 photomultiplier tubes incorporating an RCA 3140 operational amplifier as a current follower. The intensity response of the emission detectors was adjusted, as necessary, by the selected input sensitivity of the Nicolet oscilloscope or by expansion of the digitized data in the oscilloscope. The current interrupter, fabricated with a silicon p-channel field effect transistor (Archer, No. 276-2037) driven by a Wavetek Model 114 signal generator, had a switching time of less than 3 μsec. The oxidized form of the electroactive species studied was produced by partial (25-75%) *in situ* controlled potential bulk electrolysis of the solution (about 20 min) on a large platinum foil electrode prior to the ECL studies.

Results

Experimental approach.—In demonstrating direct excited state production via heterogeneous electron transfer at the electrode care must be taken to assure that the emission does not arise from the homogeneous radical ion annihilation path (Eq. [1]-[5]) or from a "preannihilation" or impurity pathway. In this latter case emission arises from the electrogeneration of a reactant from a small amount of impurity (X). For example, if X is reducible the following sequence is possible

$$X + e \longrightarrow X^- \quad [8]$$

$$X^- + R^{\overset{+}{\cdot}} \longrightarrow {}^3R + X \quad [9]$$

followed by reactions [2] and [3]. Because light levels 10^{-3}-10^{-4} times below the annihilation level are detected readily, impurity concentrations at the 10^{-6}-$10^{-7}M$ level can contribute appreciable preannihilation emission. X can represent either an impurity initially present or one generated from a small amount of decomposition of $R^{\overset{+}{\cdot}}$ (or other electrogenerated reactant in the ECL annihilation reaction). The possibility of these paths was not studied in depth in the previous investigation of ECL at semiconductor electrodes (9, 10).

The approach employed to distinguish the direct route from the annihilation and preannihilation paths involved examining the electrochemical behavior and emission observed with a platinum electrode (which we assume will not show direct excited state formation), under careful potential control, with that of the semiconductor electrode. A solution containing the oxidized precursor [*e.g.*, $R^{\overset{+}{\cdot}}$ or $Ru(bipy)_3^{3+}$] was prepared and the potential of the working electrode was scanned linearly in a negative direction at 2

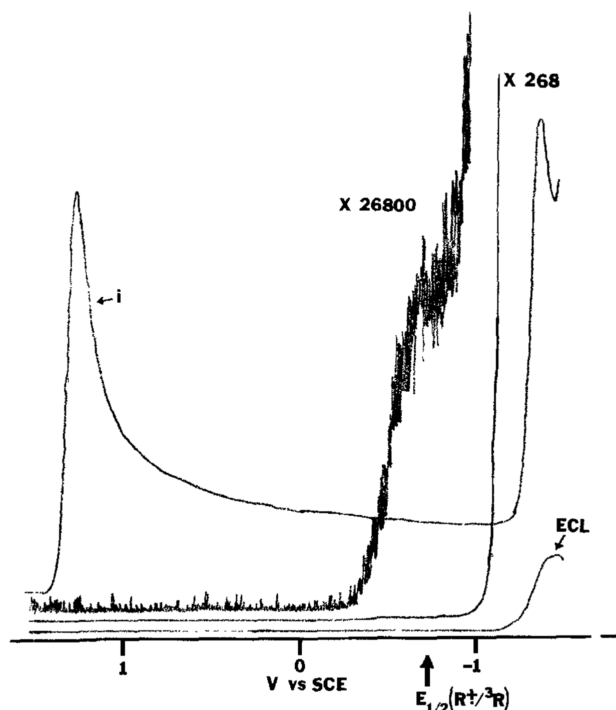

Fig. 2. ECL-potential and current-potential profiles obtained by cathodic potential scans at 2 V/sec 1.5 mmoles $Ru(bipy)_3^{3+}$ in 0.1M TBAP/ACN on platinum.

V/sec from potentials where the oxidized percursor was stable. Plots of the cathodic current (i) and the ECL intensity (I) as a function of potential (E) were thus obtained with different photomultiplier sensitivities. Typical results for a platinum electrode and $Ru(bipy)_3^{3+}$ in ACN/TBAP solution are shown in Fig. 2. The current scan shows two maxima, corresponding to the following electron transfer reactions at the electrode

$$Ru(bipy)_3^{3+} + e \rightleftharpoons Ru(bipy)_3^{2+} \ (E_p = +1.3V) \quad [10]$$

$$Ru(bipy)_3^{2+} + e \rightleftharpoons Ru(bipy)_3^{+} \ (E_p = -1.3V) \quad [11]$$

Homogeneous electron transfer between ionic species giving excited states occurs when the electrode potential becomes sufficiently negative to produce the reduced form of the ground state species; thus essentially all of the emission observed beyond $-1.0V$ *vs.* SCE in this system can be attributed to annihilation. Some residual emission is seen, however, at high sensitivities at potentials where the concentration of the electrogenerated +1 reduced species should be quite small. For example, the concentration of $Ru(bipy)_3^+$ at the electrode surface at $-1.3V$ *vs.* SCE is approximately 1.5 mmole; from the Nernst equation one calculates the concentration of $Ru(bipy)_3^+$ at the electrode surface at $-0.5V$. *vs.* SCE to be less than 2×10^{-13} mmole. This is too low to cause the residual emission observed at this potential. Thus this residual emission could not arise from homogeneous electron transfer but would necessarily arise from a preannihilation-type mechanism or conceivably, but not probably, by direct heterogeneous electron transfer at the metal electrode. Similar preannihilation emission was observed with all of the systems examined. Rigorous purification of solvent and supporting electrolyte would greatly reduce this emission but never entirely eliminate it, indicating at least some contribution to the ECL emission by impurities in the solvent and electrolyte.

Another possible approach to discriminate among the possible paths involves studying the time dependence of the ECL emission. Although attempts have been made to use the time dependence of the emission intensity during the potential step for this purpose (9, 10), the effects of possible quenching by radical ions and the complexity of the predicted annihilation results for triplet intermediates (2) suggest that unambiguous assignment by this approach may be difficult. An alternative method involves observation of the intensity decay following rapid current interruption. Qualitatively, under these conditions, the intensity would decay with the lifetime of the excited state for direct heterogeneous production. For homogeneous annihilation ECL the electrode would not reduce or oxidize the reactant ions at open circuit and the intensity decay should be governed by the rates of diffusion of the reactants.

Experimental results.—A summary of the results obtained using various compounds and semiconductor electrodes is given in Table II. For $TH^{\dot{+}}$, $DPA^{\dot{+}}$, and $Ru(bipy)_3^{3+}$, no emission which could be attributed unambiguously to direct heterogeneous production of excited states at the semiconductor electrodes was found. Either no emission was observed at potentials sufficient to produce excited states or the low levels of emission which were found at these potentials occurred at similar intensities and at the same potentials at a platinum electrode. Moreover, in these cases the decay times of the emission upon current interrup-

tion were much longer than those expected from the excited state lifetimes. These results suggest then that the observed emission at the semiconductor electrodes could be attributed mainly to preannihilation ECL rather than direct excited state formation. Different results were obtained upon reducing rubrene radical cation on n-CdS or n-ZnO, however. In these cases the behavior at platinum and at the semiconductors was very different and the ECL emission on current interruption showed unique and previously unobserved features. Details of these experiments are given below.

Because of the low solubility of R in ACN, ECL and electrochemical studies of R were carried out in benzonitrile (BZN) or in the mixed solvents benzene-BZN or benzene-ACN. A cyclic voltammogram of R in 0.1M TBAP/benzene-BZN is given in Fig. 3. R is reversibly oxidized and reduced in one electron transfer steps at 0.94 and −1.45V *vs.* SCE, respectively, in these solvent systems. Although phosphorescence of R has not been reported, energy transfer experiments indicate that the energy of the first triplet state is ~1.2 eV (23), approximately that of its parent molecule, naphthacene. Thus reduction of $R^{\cdot +}$ to the triplet state should occur at about −0.26V *vs.* SCE and n-TiO_2, n-ZnO, and n-CdS are suitable semiconductor electrodes to study the direct production of ^3R. Ideally the semiconductor electrodes should have a flatband potential, V_{fb}, negative of the potential needed to form the triplet, yet considerably removed from the thermodynamic potential for the reduction of R to $R^{\cdot -}$ to discriminate between reduction of $R^{\cdot +}$ to the excited triplet state and production of $R^{\cdot -}$ and annihilation ECL.

Current-potential curves for the reduction of $R^{\cdot +}$ at n-ZnO and n-CdS by linear single sweep voltammetry are given in Fig. 4. In the absence of intermediate levels or surface states within the bandgap region reduction of couples with redox potentials deep in the gap (*e.g.*, $R^{\cdot +}/R$ or $R^{\cdot +}/^3R$) should occur only at potentials near or negative of V_{fb}. However, studies of a number of redox couples in nonaqueous solutions at these semiconductors (20, 21) have shown reductions to occur significantly positive of V_{fb} at potentials characteristic of some intermediate levels or surface states. The current peak for the reduction of $R^{\cdot +}$ at about 0.5V *vs.* SCE (Fig. 4a) agrees quite well with the intermediate level proposed for n-ZnO (21). For potentials more negative than V_{fb}, the n-ZnO becomes degenerate, the electrode behavior approaches that of a metal (24) and reversible reduction of R to $R^{\cdot -}$ is observed.

The ECL intensity-potential profiles obtained during reduction of $R^{\cdot +}$ at Pt, n-CdS, and n-ZnO upon cathodic linear potential scans from potentials where $R^{\cdot +}$ is stable, well positive of the flatband potential of the semiconductor electrodes, are shown in Fig. 5. Note that reduction of $R^{\cdot +}$ on n-CdS and n-ZnO yields considerable emission at potentials positive of those where emission is observed on the platinum electrode. The potential sweep at the n-ZnO semiconductor electrode resulted in an emission peak at *ca.* −0.35V *vs.* SCE (in addition to the emission at *ca.* −1.5V due to the homogeneous ion annihilation reaction of $R^{\cdot +}$ and the $R^{\cdot -}$). Similarly, a peak at *ca.* −0.50V was obtained on the n-CdS semiconductor electrode. In both cases, the emission occurred at potentials where the triplet state is energetically just accessible yet at potentials positive of the flatband potential. This emission at rather positive potentials was quite reproducible over several hours and was found to be as large as 2-3% of the homogeneous annihilation

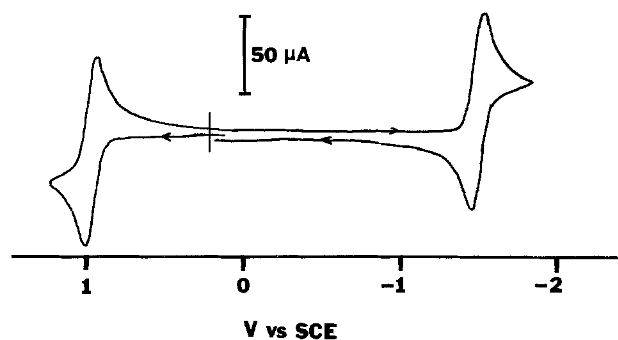

Fig. 3. Cyclic voltammogram of 1.5 mmoles R in 0.1M TBAP/benzene-BZN on platinum. Scan rate is 200 mV/sec.

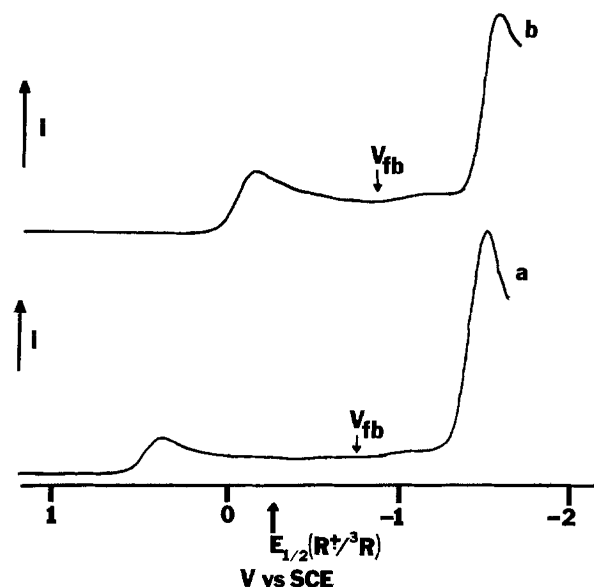

Fig. 4. Linear potential sweep voltammogram obtained with *ca.* 1 mmole $R^{\cdot +}$ in 0.1M TBAP/BZN on (a) n-ZnO, (b) n-CdS. Scan rate is 2 V/sec.

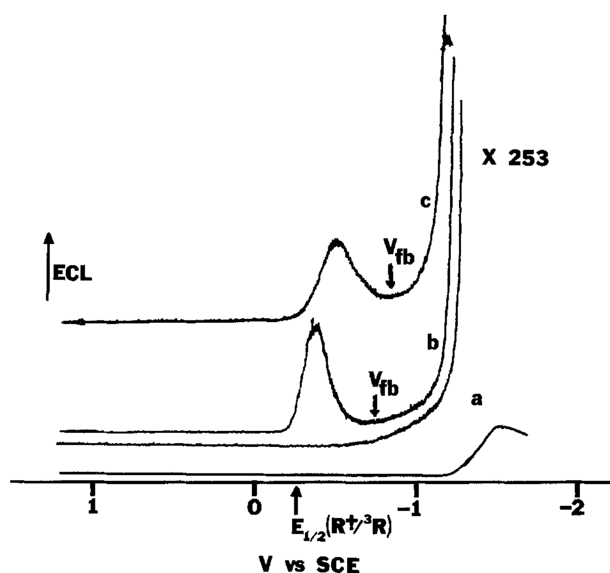

Fig. 5. ECL-potential profiles obtained with *ca.* 1 mmole $R^{\cdot +}$ in 0.1M TBAP solution at 2 V/sec. (a) Platinum electrode in benzene-ACN, (b) n-ZnO in benzene ACN, (c) n-CdS in BZN.

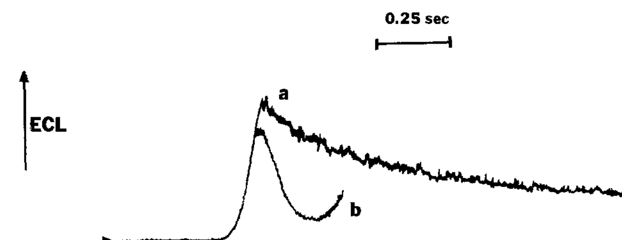

Fig. 6. ECL-time profile obtained concurrently with cathodic potential scan from 1.18V *vs.* SCE with *ca.* 1 mmole $R^{\cdot +}$ in 0.1M TBAP/BZN on n-CdS. Scan rate is 2 V/sec. (a) Potential ramp terminated at −0.5V *vs.* SCE (at curve maximum); (b) scan to −1.1V *vs.* SCE.

ECL emission produced at −1.5V under these conditions. That the peaked shape of the emission observed on the potential sweep at −0.35V (n-ZnO) and −0.50V (n-CdS) was caused by a potential, rather than a time, dependence was shown by the experiment of Fig. 6. When the potential ramp was stopped at potentials of the emission peak, the decay of the emission was rather slow (curve a). However, if the potential was scanned beyond the peak potential, the emission decayed abruptly (curve b).

To study the contribution to the emission by triplet states via triplet-triplet annihilation, the time dependence of the ECL emission was examined using a potential step excitation. Typical results obtained by stepping the potential from +1.1 to −0.7V *vs.* SCE at n-ZnO or to −0.62V at n-CdS are shown in Fig. 7. In both cases the cathodic current decay was proportional to $t^{-1/2}$, as expected for the diffusion-controlled reduction of $R^{\cdot +}$. The ECL intensity decay, however, was proportional to t^{-1}, or the square of the current, indicative of triplet generation followed by triplet-triplet annihilation (assuming a triplet lifetime controlled by quenching). Note that although a homogeneous annihilation production of ^3R could lead to a similar t^{-1} decay, the potentials employed in the step experiments preclude appreciable generation of $R^{\cdot -}$ and emission from the $R^{\cdot +}/R^{-}$ reaction route. In fact, potential steps to potentials where $R^{\cdot -}$ was generated at the semiconductor showed an emission decay with a dependence between $t^{-1/2}$ and t^{-1}.

Current interruption techniques were also informative and showed very different behavior for Pt and the semiconductor electrodes. ECL intensity time curves for a Pt electrode for potential steps of 30 msec to −1.1V (the presumed preannihilation region) are shown in Fig. 8. When the current was interrupted at the end of the step (curve a), the emission decay time was *ca.* 5 msec. In contrast, when the potential was stepped back to +0.0V after the cathodic step the emission decay was much faster (*ca.* 5 μsec) (curve b). In this case, bringing the electrode potential to positive potentials caused oxidation of the species responsible for emission and probably also ^3R; this result suggests that the emission occurs at or very near the electrode surface. Very different results were obtained upon current interruption with the semiconductor electrodes; typical results are shown in Fig. 9 and 10. When the initial potential step was to a potential, E_1, corresponding to the emission peak (Fig. 9c or 10a), the emission showed a slow decay during the peak and a decay in 0.4-3.6 msec to zero upon interruption. However, when the potential was stepped to values beyond the emission peak (but before potentials where preannihilation ECl is observed) a large peak which rapidly decays to low emission intensities during the step is

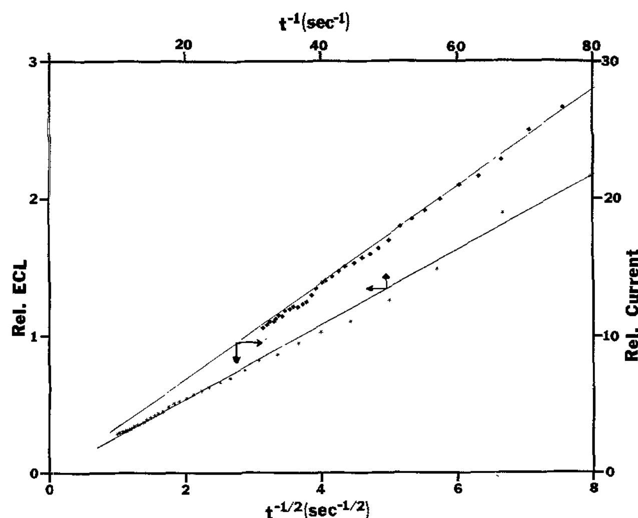

Fig. 7. ECL-time and current time profiles obtained with *ca.* 1 mmole $R^{\cdot +}$ in 0.1M TBAP/benzene-BZN by a cathodic potential step from +1.0V *vs.* SCE to −0.7V *vs.* SCE on n-ZnO. Current, ■; emission, *.

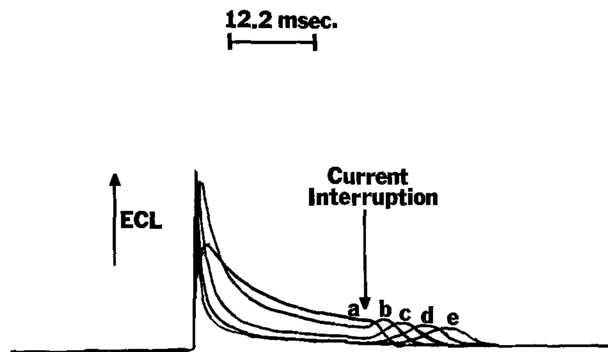

Fig. 10. ECL-time profiles obtained by cathodic potential steps on n-ZnO with $R^{+\cdot}$ in 0.1M TBAP/benzene-BZN. Current interruption was employed after 30 msec. Cathodic potential: (a) −0.3V *vs.* SCE, (b) −0.4V *vs.* SCE, (c) −0.5V *vs.* SCE, (d) −0.6V *vs.* SCE, (e) −0.7V *vs.* SCE.

observed (Fig. 9a and b, Fig. 10b-e). Upon interruption the emission decays or remains small for a time, but then a new emission peak, which occurs while the electrode is at open circuit, appears. This second, "echo" peak occurs at progressively later times after current interruption, the more negative is E_1. If, rather than using current interruption, the electrode was stepped to more positive potentials following the cathodic step, the emission would decay abruptly when the final potential was well positive of the emission peak potential (*e.g.*, 0.0V). However, when the second potential step was to a value at or near the emission peak, a second emission on the positive potential step occurred. Thus, for example, when $E_1 = -0.7$V on n-ZnO the effective decay time of emission on interruption was as long as 14 msec. However, when the potential was stepped to +1.1V, the emission decayed in about 95 μsec. Similar behavior was found with the semiconductor electrodes with triangular potential ramps (*i.e.*, cyclic voltammetry) (Fig. 11). When the scan direction was reversed following the emission peak, the emission again increased (although the cathodic current decreased on reversal) at potentials near the original emission maximum.

Discussion

The results obtained can be rationalized based on the known energetics of the rubrene system and the band structure of the semiconductors (Fig. 12). In this model there are different potential regions of the semiconductor electrode of interest. At positive potentials, just above the E° of the R^+/R couple, the number of electrons at the electrode-solution interface is small and no overlap between semiconductor levels and solution levels exists. Here no current flow or emission is observed. At somewhat more negative potentials the Fermi energy of the electrode is sufficient to populate an intermediate level or surface states, which leads to reduction of $R^{+\cdot}$ to the ground

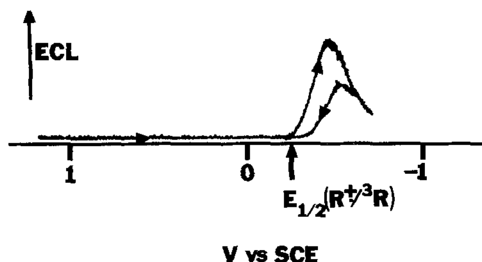

Fig. 11. ECL-potential profile obtained with concurrent cyclic voltammetry from +1.2V *vs.* SCE to −0.7V *vs.* SCE on n-CdS with *ca.* 1 mmole $R^{+\cdot}$ in 0.1M TBAP/BZN. Scan rate is 2 V/sec.

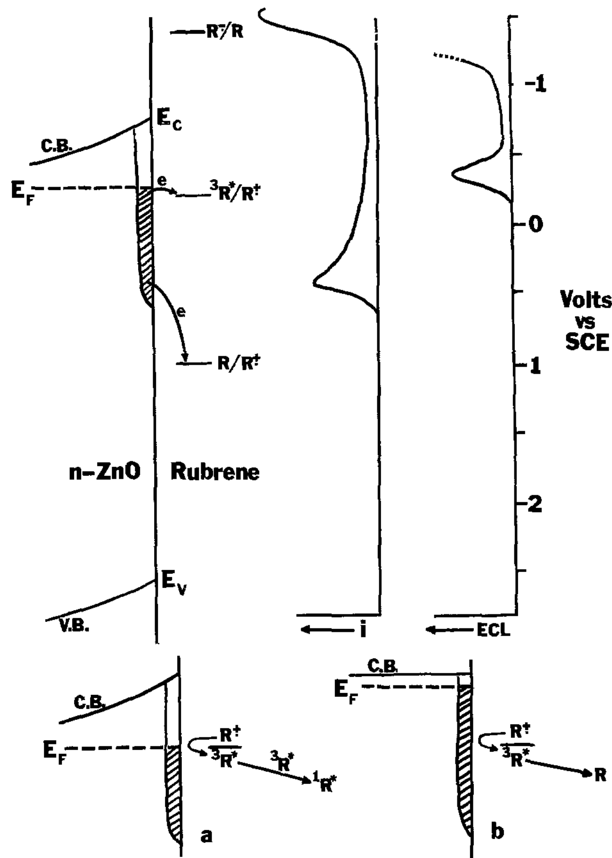

Fig. 12. Model for reduction of $R^{+\cdot}$ on n-ZnO. The current is proportional to the diffusion-limited reduction of $R^{+\cdot}$ to the ground state species and the ECL commences at potentials where $^3R^*$ is accessible (a) by electron transfer from the surface state. At more negative potentials (b) the excited states are more effectively quenched by the increased density of states at the electrode-solution interface.

state molecule, and a cathodic current is observed. The potential in this region is not sufficient to produce excited states, however. At more negative potentials the excited triplet species is thermodynamically accessible via surface states (the potential is still well positive of V_{fb}). Current continues to flow and is proportional to the flux of $R^{+\cdot}$ to the electrode. ECL emission is observed as the triplet species annihilate to yield the emitting singlet species. At still more negative potentials, however, as the surface states become more populated and the Fermi level approaches the conduction bandedge, the electrode becomes an effective quencher of the triplet states and the emission intensity increases. This explains the peak-shaped emission curve found on potential sweeps where the emission maximum occurs at potentials just at the $R^{+\cdot}/^3R$ potential. This model also explains the interruption experiments and the echo signals which appear at open circuit. Upon a potential step to potentials beyond the emission maximum the electrode is in a quenching mode and the emission decays to low levels. Upon interruption the Fermi level in the semiconductor begins to relax to that of the solution governed by the $R^{+\cdot}/R$ couple, by transfer of electrons to $R^{+\cdot}$ (coulostatic discharge). When E_F passes through the region of the $R^{+\cdot}/^3R$ potential, emission is observed. This potential drift was verified by independently monitoring the open-circuit potential of the n-ZnO electrode after a potential step to −0.93V *vs.* SCE followed by current

interruption. Thus, the time dependence of emission and the potential at open circuit monitors the rate of equilibration of the semiconductor electrode with the solution. The model further suggests that a semiconductor electrode can also act as an efficient quencher of excited states via surface or intermediate levels as well as via the conduction and valence band. The final potential region of interest is that well negative of V_{fb} where the electrode becomes degenerate. $R^{\overline{\cdot}}$ is produced and emission via annihilation ECL in the bulk solution well away from the quenching electrode surface is observed.

That ECL emission by direct heterogeneous production of excited states on semiconductor electrodes is not observed with the other systems examined can also be rationalized by this model. The critical restraints for excited state production and emission on semiconductor electrodes are (*i*) the oxidized form of the parent-emitting species must be reducible at a surface state at energies within the gap at a potential to provide sufficient energy to populate the excited state species and (*ii*) this reduction must occur at potentials well positive of the flatband potential where the electrode is not degenerate and quenching by the electrode is less favorable. Competitive reductions of the oxidized species to ground state species by surface states must also be considered in evaluating the lack of observable ECL emission by the direct heterogeneous production of excited states on semiconductor electrodes in some systems. Moreover, evidence for direct excited state production probably requires a sufficiently stable oxidized species which is reducible to a triplet state undergoing triplet-triplet annihilation to form the emitting singlet, since direct reduction to a singlet state will frequently occur at potentials negative to V_{fb} and near potentials where annihilation ECL is possible. We conclude that it will be difficult to find many examples of direct excitation although the process is possible and that the efficiency of emission via this route will be small.

We might comment on other possible explanations for the results presented here. One might suggest production of ^3R via a discrete surface level of energy, E_T, which is only rapidly filled when E_F is near this level. At more negative potentials one would have to invoke a slower filling of the level and hence decreased emission, even when $E_F > E_T$. However, this model does not agree with past results on reductions of couples with potentials located in the gap region (20, 21), with the observed reduction of R^+ to the ground state at more positive potentials, and with the lack of perturbation of the cathodic current for potential steps into this region.

A second possible explanation for the potential dependence of the emission invokes the electrogeneration of quenchers at potentials just negative of where the emission is observed. In this case, however, the quencher concentration would be expected to be large enough after the cathodic potential step to diminish significantly the emission upon a subsequent anodic pulse or sweep. This is contrary to experimental observations. Moreover, the generation of quenchers might shift the emission potential or alter the emission peak shape in separate experiments at different rubrene concentrations, but this was not observed.

The model predicts that the quenching of excited states at a semiconductor electrode should be potential dependent and this could probably be tested in photoexcitation experiments. Moreover, observation of the rate of relaxation of an electrode at open circuit following a potential step may be useful in determining the extent to which surface states mediate electron transfer at the liquid/semiconductor junction.

Acknowledgment

The authors wish to thank Professor H. Gerischer for his enlightening conversations concerning this work and Paul Kohl for the flatband potential measurements. The support of this research by the Army Research Office is gratefully acknowledged.

Electrogenerated Chemiluminescence

XXXII. ECL from Energy-Deficient Aromatic Hydrocarbon Acceptor and Tetrathiafulvalene Donor Systems

William L. Wallace and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The ECL emission from energy-deficient mixed aromatic hydrocarbon (AHC) acceptor and tetrathiafulvalene (TTF) donor systems has been investigated in acetonitrile. Radical ion annihilation involving TTF radical cations and AHC radical anions was found to result entirely in acceptor fluorescence emission. Energy considerations show that AHC triplet formation followed by triplet-triplet annihilation to produce the AHC first excited singlet state is the most probable mechanism for the observed ECL. The intermediacy of exciplexes in the ECL process was not observed experimentally.

Tetrathiafulvalene (TTF) has been the subject of intense investigation for its role as a donor in highly conducting one-dimensional solid-state complexes (1-3), such as, for example, its simple salt with tetracyanoquinodimethane (TTF-TCNQ) (4). These conducting salts form a class of ground state organic charge transfer complexes. Less is known about the potential of TTF as a donor in excited state reactions such as: (*i*) the formation of excited state complexes (exciplexes) via direct photoexcitation; and (*ii*) the formation of excited states via radical ion annihilation involving electron transfer from acceptor radical anions ($A^{\overline{\cdot}}$) to donor radical cations ($D^{\dot{+}}$), electrogenerated chemiluminescence (ECL). As judged from its ionization potential (6.95 ± 0.1 eV) (5) and oxidation potential (+0.33V *vs.* SCE, 0.1*M* TEAP in acetonitrile) (6) the donor strength of TTF should be comparable to that of amines (*e.g.*, IP = 6.86 eV for triphenylamine and 7.50 eV for triethylamine) (7) which as a donor class have been observed to form exciplexes efficiently in both the photoexcitation (8-11) and ECL (12-17) modes. Many examples of ECL generation in mixed systems using amines as donors have been investigated (12-15) and on a purely speculative basis, behavior similar to that using N,N,N',N'-tetramethyl-*p*-phenylenediamine (TMPD) as a donor ($E_{p,a}$ = +0.24V *vs.* SCE, 0.1*M* TBAP in DMF) (12) might be expected for TTF.

In addition a major goal in ECL studies has been to search for donors and acceptors which form highly stable radical ions in an attempt to extend the long-term lifetime of ECL systems (18, 19). The stability of the TTF radical cation by controlled potential reversal bulk coulometry on a time scale of a few hours has previously been observed (20) which makes it considerably more stable than amine oxidation in general [TMPD (16) and tri-*p*-tolylamine (TPTA) (17) are exceptions]. The stability of mixed TTF donor-acceptor ECL systems is therefore of interest. The following work represents a survey of mixed ECL systems consisting of TTF as the donor and various aromatic hydrocarbons as acceptors in acetonitrile solution undertaken as an initial effort to characterize TTF as a donor in excited state reactions.

Experimental

Chemicals.—Rubrene (Aldrich) was dissolved in hot xylene and precipitated with cold ethanol under nitrogen in subdued light twice. $Ru(bipy)_3(ClO_4)_2$ was prepared by metathesis with excess $NaClO_4$ in a water-ethanol mixture from $Ru(bipy)_3Cl_2 \cdot 6H_2O$ purchased from G. F. Smith Chemical Company. Further purification of $Ru(bipy)_3(ClO_4)_2$ was accomplished by two recrystallizations from acetonitrile. Anthracene (Matheson, Coleman, and Bell) was recrystallized once from benzene and sublimed twice. Diphenylanthracene (DPA; Aldrich) was sublimed twice and then zone-refined. Dimethylanthracene (DMA; Aldrich, 99%) was sublimed twice under vacuum at 120°C. *Trans*-stilbene was sublimed twice before use. Tetrathiafulvalene (Aldrich) was either sublimed twice under high vacuum at 60°C or was first recrystallized once from dry, degassed hexane and then sublimed twice. No difference in experimental results was observed between the two purification procedures. Tetra-*n*-butylammonium perchlorate (TBAP) purchased from Southwestern Analytical Chemical Company was used as received after drying under vacuum at 100°C for 24 hr. Benzonitrile and acetonitrile were both purchased from Matheson, Coleman, and Bell. A previously reported procedure was used to purify benzonitrile (21). Acetonitrile was dried and degassed by three transfers from dry P_2O_5 under vacuum. The solvent was stored under vacuum or in an inert helium atmosphere. Benzene (Fisher) and tetrahydrofuran (Matheson, Coleman, and Bell) were refluxed over sodium-benzophenone and subsequently distilled and stored in an inert nitrogen or helium atmosphere.

Apparatus and procedures.—Cyclic voltammetry and ECL experiments were carried out in the controlled potential mode using a Princeton Applied Research (PAR) Model 173 potentiostat and a Model 175 universal programmer. The voltage analog output from a PAR Model 176 current follower was either recorded directly using a Houston Instrument Model 2000 X-Y recorder or monitored and subsequently recorded via a Nicolet Model 1090A digital oscilloscope. Electrochemical cells of a conventional three-electrode design were used for cyclic voltammetry and ECL and were similar to ones previously described (22, 23). Emission spectra, fluorescence, and ECL were obtained using an Aminco-Bowman spectrophotofluorometer.

Solutions were prepared under an inert helium atmosphere in a Vacuum Atmospheres Model HE-43-2 dry box. Since TTF was found to undergo photodecomposition in dry degassed solutions of acetonitrile, ECL solutions were exposed to a minimum of room light. A background cyclic voltammogram was taken of the solvent-supporting electrolyte (0.1*M* TBAP) system before each study to insure the absence of residual oxygen and electroactive trace contaminants. ECL was generated in the pulse mode (cyclic double

potential step waveform) and in general ECL experiments were carried out on the same solutions previously characterized by cyclic voltammetry.

Results

Electrochemistry.—The electrochemical parameters listed in Table I show that except for the case of *trans*-stilbene and TTF, the interaction of donor and acceptor neutral and radical ion species on the cyclic voltammetric time scale is small. Values of E_p and ΔE_p, cyclic voltammetry peak potentials and peak separations, and i_{pc}/i_{pa} or i_{pa}/i_{pc}, peak current ratios for oxidation and reduction, respectively, were monitored for the acceptor in the presence and absence of TTF and show only slight variations. Deviations from ideal electrochemical behavior (*e.g.*, $\Delta E_p > 60$ mV) or slight shifts in values of E_p can be attributed to: (*i*) uncompensated cell resistance as in the case of using benzonitrile as a solvent; or (*ii*) the use of an unshielded Ag quasireference electrode in contact with the bulk electrochemical solution. For most of the systems examined, including *trans*-stilbene and TTF, values for ΔE_p and i_{pc}/i_{pa} for the two reversible one-electron oxidations of TTF were 70 mV and 1.00 ± 0.02, respectively, both in the absence and presence of the various acceptors. The only exception occurred for TTF in benzonitrile in which the second TTF oxidation wave overlapped with the first oxidation wave of rubrene and a large cathodic current spike was observed for dication reduction upon potential reversal. Large cathodic current spikes for the reduction of the TTF dication were frequently observed in nonpolar solvents and nonpolar solvent mixtures, such as tetrahydrofuran and benzene-acetonitrile (50:50). Unfavorable electrochemistry for TTF oxidation prevented ECL experiments in pure tetrahydrofuran. Under the experimental conditions of cell design and at a potential scan rate of 200 mV sec^{-1}, a value of 70 mV represents the peak separation expected for a reversible one-electron transfer in acetonitrile.

Examination of Table I reveals that in some cases values of i_{pa}/i_{pc} for reduction of the acceptor in the presence of TTF are significantly less than in the absence of TTF. Such behavior is represented in the extreme case by the *trans*-stilbene-TTF system in which increasing the concentration of TTF results in increasing values of i_{pc} and decreasing values of i_{pa}/i_{pc}. Limiting behavior for [TTF] > [*trans*-stilbene] is characterized by the complete absence of anodic current upon potential reversal following *trans*-stilbene reduction and by values of $i_{pc}/v^{1/2}$ which are approximately 2.8-3.0 times larger than those in the absence of TTF. A plot of $i_{pc}/v^{1/2}$ *vs.* log v was approximately linear (slight curvature was observed for extreme high and low values of v) for a solution consisting of $5.4 \times 10^{-3}M$ TTF, $1.2 \times 10^{-2}M$ *trans*-stilbene, and 0.1*M* TBAP in acetonitrile. The reaction(s) represented by these results have not been thoroughly investigated but the electrochemical data is consistent with a reaction of the *trans*-stilbene radical anion with TTF neutral as a first step forming a product which undergoes further reduction. A similar reaction may occur to a much lower degree in some of the other aromatic hydrocarbon acceptor-TTF systems.

Figures 1 and 2 illustrate the cyclic voltammograms resulting from the two extreme cases of electrochemical behavior observed in this investigation: (*i*) slightly interacting, anthracene-TTF; and (*ii*) strongly

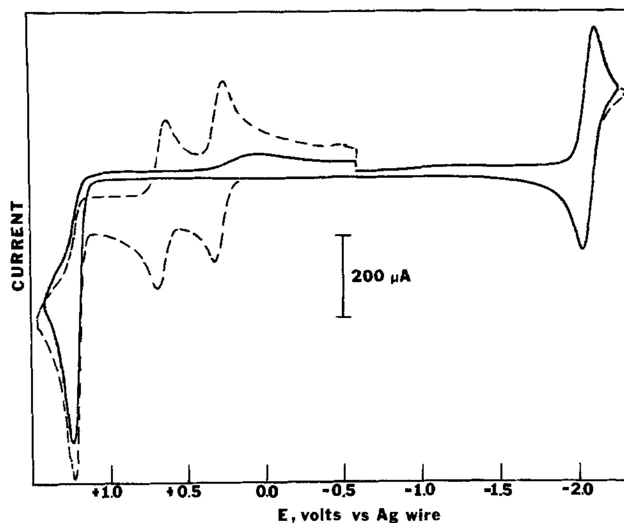

Fig. 1. First scan cyclic voltammograms of (———) $1.2 \times 10^{-2}M$ anthracene and (– – –) $1.2 \times 10^{-2}M$ anthracene and $7.1 \times 10^{-3}M$ TTF in a 0.1M TBAP-acetonitrile supporting electrolyte-solvent system using a scan rate of 200 mV sec^{-1}.

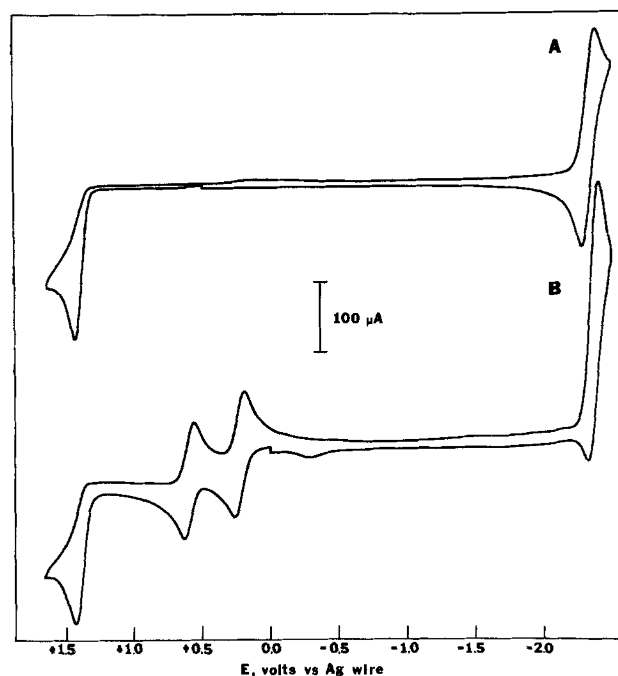

Fig. 2. First scan cyclic voltammograms of (A) $1.1 \times 10^{-2}M$ *trans*-stilbene; and (B) $1.1 \times 10^{-2}M$ *trans*-stilbene and $4.9 \times 10^{-3}M$ TTF in a 0.1M TBAP-acetonitrile supporting electrolyte-solvent system using a scan rate of 200 mV sec^{-1}.

interacting, *trans*-stilbene-TTF. In Fig. 1 and 2 a small cathodic wave in the range 0.0-+0.50V *vs.* Ag QRE is observed upon potential reversal following the anodic scan in the absence and presence of TTF. These waves can be attributed to the reduction of an oxidation product of the unstable anthracene and *trans*-stilbene radical cations. An anodic wave at −0.4V *vs.* Ag QRE found after potential reversal following *trans*-stilbene reduction is also observed for *trans*-stilbene in the presence of TTF. For all of the systems examined except *trans*-stilbene and TTF no additional product waves are observed when the applied potential limits are set to allow only the one electron oxidation of the donor (TTF) and the one electron reduction of the acceptor (AHC).

ECL.—Of the six donor-acceptor systems examined in this work, four exhibited ECL. The ECL was generated in the controlled potential mode employing a cyclic double potential step waveform alternately generating the acceptor radical anion and the donor radical cation. The ECL spectra obtained for three of the systems in Table II are shown in Fig. 3. The luminescence in all three cases can be attributed entirely to DPA, DMA, and rubrene fluorescence when reabsorption at the appropriate donor-acceptor concentrations is taken into account. In the case of DMA an additional component due to excimer emission contributes to the ECL spectrum. The observed spectral distributions, relative peak intensity ratios, and peak energies compare well with previously published ECL spectra of the isolated acceptors (12, 24, 25). The ECL spectra also essentially match the fluorescence spectra taken of the original electrochemical bulk solutions either at full concentration or diluted by a factor of 1/10 in a 1.00 cm path length fluorescence cell taken using a right angle illumination geometry. In addition fluorescence spectra of the bulk electrochemical solutions compare well in spectral distribution and peak energies with fluorescence spectra of the isolated acceptors taken in acetonitrile or other solvents (24, 26). The ECL spectrum of TTF and DMA was also taken in a relatively nonpolar acetonitrile-tetrahydrofuran (40:60) solvent mixture, and within experimental error it was identical in spectral distribution with the spectrum obtained in pure acetonitrile. A complete ECL spectrum of anthracene-TTF could not be obtained due to rapid decay of the ECL emission; however, emission was observed at a wavelength of 400 nm when the working electrode was pulsed between potential limits corresponding to the generation of $TTF^{+\cdot}$ and the anthracene radical anion.

In all cases where ECL is observed, emission is clearly the result of TTF radical cation-acceptor radical anion annihilation as the anodic potential is varied from a point where no faradaic oxidation processes occur toward more positive potentials. The onset of spectrophotofluorometric detection of ECL always corresponded to the onset of anodic current for TTF oxidation. Extending the anodic potential limit to values which cause TTF dication or acceptor radical cation formation resulted in either a rapid decrease in the peak ECL intensity as a function of potential, as in the case of DPA-TTF, or in a gradual decrease in ECL intensity, as in the case of DMA-TTF. Intensity enhancements at potentials more positive than $TTF^{+\cdot}$ production were never observed.

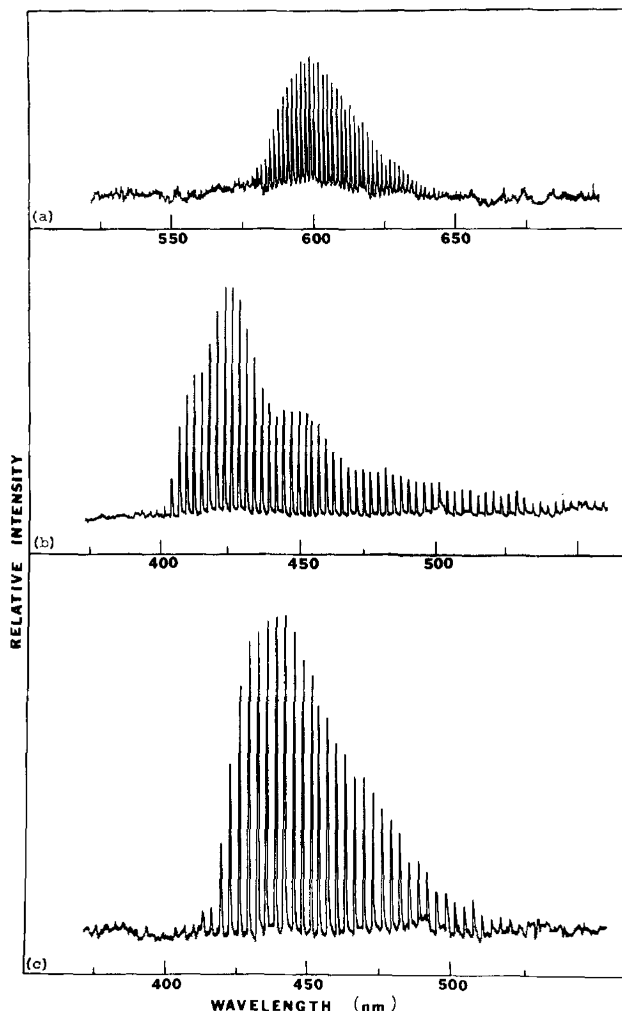

Fig. 3. ECL spectra of (a) $5.0 \times 10^{-3}M$ rubrene and $2.2 \times 10^{-3}M$ TTF, pulse width = 500 msec; (b) $2.4 \times 10^{-3}M$ DMA and $1.9 \times 10^{-3}M$ TTF, pulse width = 500 msec; and (c) $4.3 \times 10^{-3}M$ DPA and $5.9 \times 10^{-4}M$ TTF, pulse width = 500 msec; all in acetonitrile containing 0.1M TBAP; spectrophotofluorometer bandpass = 5 nm.

Peak ECL intensities for all the TTF-aromatic hydrocarbon systems monitored under continuous pulsing conditions on a time scale of a few minutes to 1 hr

decayed to zero intensity in a few hundred pulses or less. ECL emission in these mixed systems in acetonitrile was always observed to occur on only one pulse polarity which was usually, but not consistently, anodic. Emission could not be observed on the opposite polarity pulses except under the most sensitive spectrophotofluorometric conditions. Observation of emission only on anodic pulses might be attributed to instability of the TTF radical cation relative to that of the aromatic hydrocarbon radical anion; however, on the cyclic voltammetric time scale such instability is not observed. Only the aromatic hydrocarbon radical anions exhibited significant instability as judged by peak current ratios (see Table I). Correlated to the decrease in ECL intensity with time under continuous pulsing conditions was the buildup of a layer of colored material in the solution surrounding the working electrode. Cyclic voltammetry showed no new peaks or product waves associated with the colored material and presumably it arises from the accumulation of excess stable radical ion ($TTF^{\dot{+}}$ or $AHC^{\dot{-}}$) with time. Prolonged pulsing resulted in product formation observed as a gray precipitate of unknown composition in the TTF-DMA and TTF-DPA systems.

Discussion

Listed in Table II are the cyclic voltammetric peak potentials for the first oxidation and reduction waves of several acceptor compounds deemed suitable for study in this work. Also tabulated are the acceptor singlet and triplet energies and the enthalpies for radical ion annihilation for the reaction between the TTF radical cation and the acceptor radical anion to produce ground state products. The calculated enthalpies for radical ion annihilation are based on experimental data obtained in this work and represent the maximum excess energy available for donor or acceptor excited state production in the radical ion annihilation reaction.

Examination of the data in Table II reveals several important aspects of ECL production using TTF as a donor. Note that the cyclic voltammetry peak potentials for the first oxidation wave of all the acceptors fall well outside the first oxidation wave for TTF; therefore, no interference is to be expected from the acceptor in generating $TTF^{\dot{+}}$. In only one case (TTF-rubrene) does overlap occur between the acceptor first oxidation and TTF second oxidation waves. In addition, TTF is not reduced within the potential range available for the acetonitrile-TBAP solvent-supporting electrolyte system and therefore cannot interfere with acceptor reduction. These conditions insure that with the appropriate selection of potential limits the reaction between the donor radical cation and the acceptor radical anion may be probed exclusively.

Comparison of ΔH° values with the excited state energies listed in Table II shows that in no case is the energy release during radical ion annihilation sufficient to populate the acceptor excited singlet state; however, in most systems (the first five in Table II) the acceptor first excited triplet state may be attained. The situation for TTF is less clear since the excited state singlet and triplet energies for this molecule are not well defined. To our knowledge fluorescence and low temperature phosphorescence studies of TTF are absent in the literature. Our own fluorescence studies at room temperature show weak emission from 10^{-3} to $10^{-4}M$ deaerated acetonitrile solutions of TTF in the range 300-500 nm. The spectral distribution of this emission was dependent on excitation wavelength and irradiation time (photolysis of $10^{-4}M$ acetonitrile solution via the unfiltered output of a 450W Xe lamp) and can be attributed predominantly to impurity fluorescence. The disappearance of TTF as a function of irradiation time can be followed by absorption spectroscopy and correlates with increasingly efficient Rayleigh scattering and formation of cloudy photolysis solutions. Results of a low temperature phosphorescence study of $10^{-4}M$ TTF in methyltetrahydrofuran at 77°K were similarly inconclusive. Although phosphorescence was observed, the spectral distribution of the emission was again a function of excitation wavelength and irradiation time. It should be mentioned that the fluorescence observed in TTF solutions was too weak to contribute significantly to fluorescence spectra of mixed TTF-acceptor solutions and was never observed in ECL spectra.

Attempting to estimate the singlet energy of TTF from its absorption spectrum also presents problems. The longest wavelength low molar absorptivity coefficient band of TTF at 450 nm has been variously assigned to: (*i*) an $n \rightarrow \pi^*$ transition of the sulfur lone pair electrons (27); (*ii*) a symmetry forbidden singlet-singlet $\pi \rightarrow \pi^*$ transition of B_{1g} symmetry (28); and (*iii*) a composite of two weakly allowed spin-forbidden singlet-triplet $\pi \rightarrow \pi^*$ transitions of B_{2u} and B_{3u} symmetry (29). Self-consistent statistical exchange multiple-scattering calculations also lead to the prediction of a spectroscopically unobserved triplet state at approximately 1.7 eV (29). The discrepancy in the assignments for the low energy TTF absorption band has so far not been resolved by spectroscopic means.

If indeed the lowest lying excited singlet state in TTF can be correlated with the lowest energy absorption band (E_s = 2.58-2.8 eV), then the TTF singlet will be inaccessible in all the ECL systems examined in this study. The TTF triplet, which has been estimated to be 0.20-0.68 eV lower than the singlet by $X\alpha$-scattered wave calculations (30), could be accessible in several systems. If, however, the lowest energy TTF absorption band correlates with the lowest energy triplet, then neither the TTF singlet or triplet states could be populated in the systems examined. Population of a TTF excited state cannot be probed by ECL since no emission which could be attributed to TTF (or an impurity) was ever observed in the ECL spectra monitored in acetonitrile solution.

The observed ECL behavior for the six systems in Table II can be divided into two categories: (*i*) ECL is observed and corresponds entirely to emission from the aromatic hydrocarbon acceptor (first four systems); and (*ii*) ECL is not observed [TTF-*trans*-stilbene and TTF-Ru(bipy)$_3$(ClO$_4$)$_2$]. Of the systems in the first category the absence of emission other than acceptor fluorescence in the ECL rules out the formation of stable emitting excited state complexes (exciplexes) (although not exciplex formation itself). Exciplex emission in the long wavelength region of the TTF-DMA ECL spectrum in acetonitrile can be ruled out by the observation that within experimental error the spectral distribution is identical to that in the ECL spectra of DMA alone in acetonitrile and DMA-TTF in an acetonitrile-tetrahydrofuran (40:60) solvent mixture. An enhancement in the exciplex/monomer intensity ratio and a blue shift in exciplex emission would otherwise be expected in the less polar solvent (ϵ = 7.4 for tetrahydrofuran and ϵ = 36.7 for acetonitrile) (15). Excimer emission is considerably less affected by solvent polarity. The DMA excimer emission observed in the TTF-DMA ECL spectra is produced probably via triplet-triplet annihilation of $^3DMA^*$ as in the previously studied $DMA^{\dot{-}}/TPTA^{\dot{+}}$ (15) and $DMA^{\dot{-}}/TMPD^{\dot{+}}$ (16) systems. In addition, fluorescence studies of 10^{-3}-$10^{-4}M$ aromatic hydrocarbon solutions containing 10^{-3}-$10^{-1}M$ concentrations of TTF in acetonitrile, benzene, and tetrahydrofuran failed to produce definitive evidence for exciplex emission. Although apparent long wavelength emission was observed in solutions containing the highest TTF concentrations, reabsorption of acceptor fluorescence emission by TTF, not exciplex emission, was found to be

responsible. Both competitive absorption and reabsorption caused serious experimental difficulties in carrying out energy transfer studies in these systems.

Since the acceptor excited triplet states are accessible in all systems exhibiting ECL triplet-triplet annihilation is adequate to account for acceptor fluorescence in every case. Numerous investigations, including the study of magnetic field effects and energy deficient systems, have demonstrated the intermediacy of triplets in the ECL of rubrene (31, 32), DPA (31, 33), DMA (13, 16), and anthracene (31, 33) mixed systems. An over-all mechanism for ECL emission can be represented as follows

$$A^{\overset{-}{\cdot}} + D^{\overset{+}{\cdot}} \rightarrow {}^3A^* + {}^1D \quad [1]$$

$$A^{\overset{-}{\cdot}} + D^{\overset{+}{\cdot}} \rightarrow {}^1A + {}^3D^* \quad [2]$$

$${}^3A^* + {}^3A^* \rightarrow {}^1A^* + {}^1A \rightarrow 2{}^1A + h\nu \quad [3]$$

Again note in Eq. [1] that the formation of acceptor excited singlet states can be omitted on the basis of energy considerations. Equation [2] necessarily includes the possibility of forming donor triplets; however, formation of TTF singlets cannot occur in the four systems exhibiting ECL.

The relatively rapid degradation of ECL intensity over a period of time under continuous pulsing conditions makes it amply clear that the reactions in Eq. [1]-[3] are not the only pathways available for donor-acceptor interaction. Numerous possibilities exist for chemical reactions leading to ECL degradation including: (*i*) direct interaction of neutral donor and acceptor molecules to form ground state complexes or other products; (*ii*) chemical reaction of radical ions either by first-order degradation processes or by reaction with neutral donor and acceptor molecules or other solution constituents including impurities; (*iii*) chemical reactions via radical ion annihilation; and (*iv*) photochemical reactions of donor and acceptor excited states produced by radical ion annihilation. The formation of ground state complexes incorporating TTF as a donor are well known and as previously mentioned form an important and highly studied class of conducting solid-state DA complexes. Formation of such DA complexes commonly occurs via reaction of the neutral substituents but can also occur as a radical ion reaction as, for example, in the reaction of electrogenerated $TTF^{\overset{+}{\cdot}}$ with X^- to form TTF halide salts (34, 35). Ground state complex formation by either method, however, or any other reaction between neutral donor and acceptor molecules is unsupported in the systems examined in this study by the electrochemical evidence. In addition, formation of strong DA complexes with the acceptors in this study is unlikely due to their relatively weak electron accepting ability. Furthermore, electrochemical data show that donor radical cations in the presence of neutral acceptor and acceptor radical anions in the presence of neutral donor are stable on a cyclic voltammetric time scale, with the one exception of *trans*-stilbene$^{\overset{-}{\cdot}}$ in the presence of TTF neutral. However, even though evidence for a chemical reaction cannot be observed in initial mixed donor-acceptor solutions, product formation is observed after electrochemistry, possibly indicating the contribution of radical ion reactions on a long-time scale. The possible contribution of photochemical reactions to over-all ECL degradation cannot be easily probed; however, the reactivity of TTF excited state(s) appears to be established in this and other studies (5, 36) and must be taken into account. An analysis of the products formed in the ECL systems examined in this study will be necessary to elucidate precisely the specific pathway(s) involved in the observed degradation behavior. It should be noted that in general studies defining the stabilities of radical ions on a cyclic voltammetric or even bulk coulometric time scale will not necessarily be of use in predicting the stability of ECL systems.

Of the two systems which did not exhibit ECL the TTF-*trans*-stilbene system was chosen as a possibility for exhibiting exciplex emission. Observation of exciplex emission in the ECL from *trans*-stilbene radical anion and amine radical cation annihilation has been observed (15) enhancing the possibility of observing exciplex emission using TTF as a donor. The complete absence of emission from the *trans*-stilbene-TTF system seems to rule out the formation of a stable emitting exciplex. The *trans*-stilbene triplet state is accessible in this system; however, the short triplet lifetime at room temperature in fluid solution (37) is adequate to explain the absence of stilbene fluorescence via triplet-triplet annihilation. The most compelling reason for not observing ECL is the extreme reactivity of the *trans*-stilbene radical anion in the presence of TTF. A new product-forming route is opened for the radical anion which competes with radical ion annihilation and excited state formation. As stated previously, the evidence at this point indicates a reaction of the stilbene radical anion with neutral TTF forming a further reducible product

$$A^{\overset{-}{\cdot}} + D^\circ \rightarrow P \xrightarrow{e^-} P' \quad [4]$$

The $Ru(bipy)_3(ClO_4)_2$-TTF system was chosen as a test case. No ECL was expected for reaction with the TTF radical cation, although reaction with TTF^{+2} would just barely be energetic enough to produce the Ru(II) triplet state. No ECL is observed, however, pulsing between potential limits sufficiently anodic to produce $TTF^{\overset{+}{\cdot}}$, TTF^{+2}, or the Ru(III) complex. The lack of emission from the Ru(I)-Ru(III) reaction in the presence of TTF indicates that efficient quenching of either the Ru(I)-Ru(III) radical ion annihilation and/or of the Ru(II) excited triplet state takes place. A possible explanation for the lack of emission in the TTF^{+2}-Ru(I) annihilation reaction is the presence of the TTF radical cation in the solvent cage complex immediately after electron transfer leading to efficient quenching

$$D^{+2} + A^- \rightarrow (D^{\overset{+}{\cdot}} \ldots {}^3A^*) \rightarrow D^{\overset{+}{\cdot}} + A \quad [5]$$

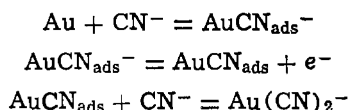
A Study of Anodic Dissolution of Gold in Aqueous Alkaline Cyanide

D. W. Kirk,* F. R. Foulkes,* and W. F. Graydon*

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

The rate of dissolution of gold in aqueous alkaline cyanide solutions was studied as a function of potential within the range -0.9 to $+0.4$V *vs.* SCE. The dissolution rate was found to exhibit three maxima at -0.65, $+0.04$, and $+0.38$V *vs.* SCE. These maxima corresponded to three current peaks found in anodic potential sweep measurements. Data from weight loss measurements were used for the determination of the stoichiometry of the electrochemical dissolution reaction and showed that for the region -0.9 to $+0.6$V *vs.* SCE, $n = 0.85 \pm 0.01$; for the region -0.1 to $+0.15$V *vs.* SCE, $n = 0.95 \pm 0.01$; for the region $+0.2$ to $+0.38$V *vs.* SCE, $n = 1.05 \pm 0.06$. The dependence of the dissolution rate on the concentration of potassium hydroxide and potassium cyanide was determined in the two more anodic regions. At $+0.38$V *vs.* SCE the dissolution was directly proportional to the cyanide concentration and independent of hydroxide concentration. At $+0.04$V *vs.* SCE the dissolution rate was approximately linear with cyanide for low concentrations (<0.1M) and decreased with increased hydroxide concentration. At moderate hydroxide concentrations (0.1M) the dissolution rate decreased for cyanide concentrations greater than 0.2M. Several of the mechanisms suggested in the literature to account for the reactions in these two regions were shown to be incorrect in some way; instead, the following sequence was proposed



$$Au + CN^- = AuCN_{ads}^-$$

$$AuCN_{ads}^- = AuCN_{ads} + e^-$$

$$AuCN_{ads} + CN^- = Au(CN)_2^-$$

The dissolution rate was controlled by step 2 in the region of -0.1 to $+0.15$V *vs.* SCE and by step 3 in the region of $+0.2$ to $+0.38$V *vs.* SCE. The above reaction sequence appeared to account for the dissolution over the complete potential region investigated. The decrease in current between the peaks in the potential sweep measurements was discussed in terms of the formation of films which interrupt the dissolution process. At potentials anodic to $+0.38$V *vs.* SCE dissolution by the above sequence was suppressed by a gold oxidation reaction with $n > 1$.

The use of an alkaline cyanide electrolyte for gold plating was recorded in 1840 with a patent filed by Elkington (1). Since that time, this medium has been used extensively for gold electrodeposition, refining, and cyanidization. The latter remains the most important process for gold recovery (2). Despite the widespread use of alkaline cyanide, the electrochemistry of gold in this medium has not been studied extensively. Some disagreement exists in the literature concerning the nature of the complex gold dissolution process (3, 4). The potential sweep and weight loss experiments reported below were undertaken to study the electrochemical reactions of gold in alkaline cyanide, which is of interest in both the electrochemical recovery and the refining of gold.

Experimental

Solutions, prepared from analytical grade reagents and doubly distilled water, were deoxygenated by bubbling with oxygen-free nitrogen during the experiments. Pure gold foil was used for both the working and the counterelectrodes. The experimental cell is shown in Fig. 1. The working electrode, spot welded to a gold wire, was suspended 0.2 cm below the surface of the electrolyte. Two counterelectrodes set 1.25 cm to either side of the working electrode were contained in glass fritted tubes. The reference electrode was a microsaturated calomel electrode. A Luggin capillary housing the reference electrode was positioned with the 0.1 cm diam capillary tip located 0.17 cm from the electrode. This configuration has been shown to distort the current density at the point of measurement by less than 1% (5, 6). The data were

not corrected for *IR* drop. The calculated maximum *IR* drops for peaks 1, 2, and 3 were 0.3, 5, and 22 mV, respectively. The absence of a visible skew at the top of peak 3 (greatest *IR* drop) indicates that the actual *IR* drops were even less than the above values.

The Pyrex beaker used to hold the electrolyte (60 cm^3) was fitted with either a machined Teflon cap or a No. 11 rubber stopper which had provisions for holding the electrodes and a glass fritted tube for nitrogen bubbling. No difference could be found in the potential sweep curves using either the rubber stopper or the Teflon cap. The solution was stirred by a magnetic stirrer located beneath the cell.

Experiments to determine the effect of stirring rate on peak height showed that the stirring rate had no effect on peak 2, whereas peaks 1 and 3 increased at higher stirring rates. With the aid of a digital tachometer it was shown that the reproducibility of the stirring rate used was such that all measured peak heights were reproducible to within less than ± 1%. The temperature of the electrolyte was found to vary less than ± 1°C during an experiment.

The electronic components consisted of a Wenking potentiostat (70TS1), voltage scan generator (VSG72), and an integrator (SS170). A Hewlett-Packard 70004Bx4 recorder was used for the potential sweep measurements.

Gold dissolution rates were determined from weight losses and electrode surface areas. Each experimental run was continued for sufficient time to allow a minimum weight loss of 200 μg, which was measured using a semimicrobalance with an accuracy of ± 10 μg. The shortest run was 1 min and the longest 2 hr. The surface area of the electrode was determined from potential scan measurements, using the linear relation between the current peak height and the square root of the voltage scan rate for the oxidation of $Fe(CN)_6^{-4}$. The relation given by Nicholson and Shain (7) is

$$\frac{i_p}{n\mathbf{F}AC_o\left(D_o\frac{n\mathbf{F}v}{RT}\right)^{1/2}} = 0.4463$$

where C_o is the concentration of $Fe(CN)_6^{-4}$ (mole · dm^{-3}), D_o is the diffusion coefficient of $Fe(CN)_6^{-4}$ ($cm^2 \cdot sec^{-1}$), i_p is the peak current (A), A is the area of the electrode (cm^2), n is the number of electrons transferred in the oxidation, v is the scan rate (V · sec^{-1}), and **F**, R, and T have their usual meanings. The electrode area was found not to change during an experimental run.

A standard pretreatment of the electrode was necessary to achieve reproducibility. The electrode was first heated to redness in air, then etched in hot aqua regia for 10 sec, washed in doubly distilled water, dried, and weighed. It was immediately given a further treatment consisting of a 5 min reduction period in the electrolyte at −1.2 V.[1] This latter procedure was found to improve the reproducibility of the weight loss and potentiodynamic measurements but did not affect the measured weight of the electrode. At the end of an experiment, the electrode was thoroughly washed in doubly distilled water, dried, and weighed.

Results and Discussion

Figure 2 shows the potentiodynamic sweep profiles for three electrolyte compositions. Within the potential range of −1.2 to +0.6V, it can be seen that there are three current peaks referred to in the figure as peak 1, peak 2, and peak 3. Three current maxima were also observed for gold in aqueous cyanide by Cathro and Koch (3) using a potentiostatic technique. Their three current maxima corresponded to the three peak regions found in our work, although the relative magnitudes of the peak current densities were different. In our work, at concentrations comparable to those used

[1] All potentials are reported *vs.* the saturated calomel electrode.

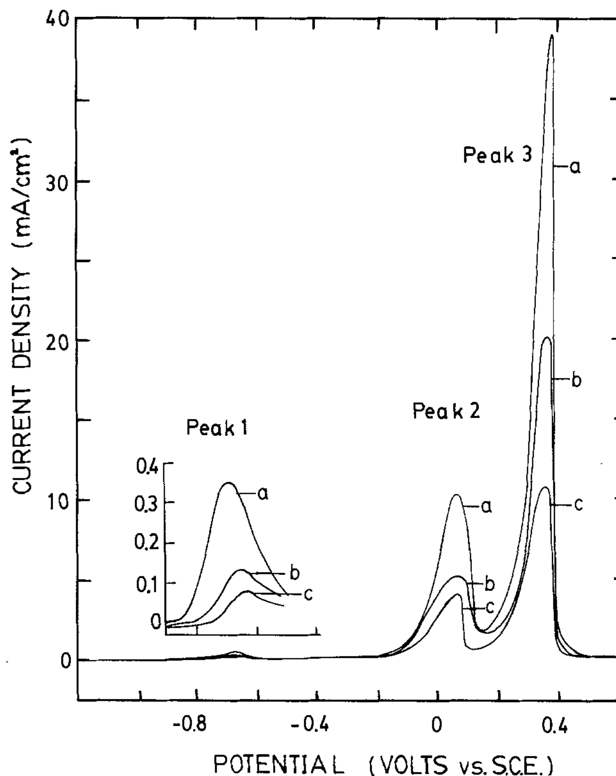

Fig. 2. Potentiodynamic anodic sweep profile in aqueous alkaline cyanide. a, 0.1M KOH + 0.2M KCN; b, 0.1M KOH + 0.1M KCN; c, 0.1M KOH + 0.05M KCN. Scan rate 1.0 mV · sec^{-1}, temperature 23.5°C.

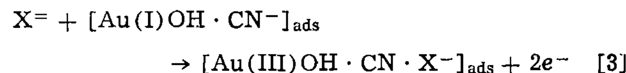
by Cathro and Koch, peak 1 had a much smaller current density (0.096 mA · cm^{-2}) than peak 2 (5.0 mA · cm^{-2}) or peak 3 (11 mA · cm^{-2}) for the 0.05M CN^- + 0.1M KOH electrolyte. In the work of Cathro and Koch, peak 1 assumed a much greater significance relative to peaks 2 and 3, with a current maximum of 1.2 mA · cm^{-2} compared with 1.5 mA · cm^{-2} for peak 2 and 4 mA · cm^{-2} for peak 3 for a 0.038M CN^- + 0.063M KOH solution. The difference could result from the different measurement technique and the lower concentration of cyanide.

For the first peak region, Cathro and Koch proposed the following reaction scheme

$$Au + CN^- \rightleftarrows AuCN_{ads} + e^- \quad [1]$$

$$AuCN_{ads} + CN^- \rightleftarrows Au(CN)_2^- \quad [2]$$

At low surface coverage, using Tafel data, step [1] was identified by them as the rate-determining step. Anodic to the current maximum, the formation of a basic cyanide film ($Au(I)(OHCN)_x$) was considered to cause passivation. The conversion of the $Au(I)\ (OHCN)_x$ basic cyanide film to an Au(III) basic cyanide film, according to the following reaction scheme, was thought to cause peak 2



$$X^= + [Au(I)OH \cdot CN^-]_{ads} \rightarrow [Au(III)OH \cdot CN \cdot X^-]_{ads} + 2e^- \quad [3]$$

where $X^=$ is any anion except OH^-.

No reaction scheme was proposed for peak 3, but anodic to peak 3 passivation was considered to arise from the formation of a surface layer of Au_2O_3. In a more recent work, McIntyre and Peck (8) have also observed three peaks in the region of our study but did not discuss these peaks in detail.

In a study of gold reduction and oxidation in aqueous solutions, MacArthur (4) observed two peak regions for gold in alkaline cyanide electrolytes, using a cyclic voltammetric method. The first current peak was associated with the peak 1 of Cathro and Koch's

work, although the potential of the peak occurred at −0.3V rather than the −0.6V observed by both Cathro and Koch and ourselves. The reaction in the region of −0.6 to −0.3V was considered to occur via reaction scheme [1] and [2] with step [2] being the rate-determining step. An identical dissolution process had also been proposed earlier by Maja (9). The second peak observed by MacArthur, which corresponded in magnitude and potential to our peak 3 was stated to be of a complex nature, perhaps composed of two overlapping peaks. It was thought to be the result of a reaction involving either the direct oxidation of gold to a soluble species ($Au(CN)_2^-$) or the oxidation of Au to an Au(III) complex which then reacted with CN^- to give $Au(CN)_2^-$, either reaction being complicated by the formation of gold oxide which caused eventual passivation. Based on the work of Cathro and Koch, and more recently McIntyre and Peck (8), which showed three peaks, and that of MacArthur, which showed two peaks, it is not clear whether gold exhibits two or three potential regions where significant electrochemical reactions take place. In addition, the reactions corresponding with peaks 2 and 3 have not been adequately described. Therefore, experiments to measure directly the dissolution rate of gold in alkaline cyanide as a function of potential and electrolyte composition were conducted, as previously described in the experimental section. The results, weight loss per unit area per unit time ($mg \cdot m^{-2} \cdot sec^{-1}$) as a function of potential for three electrolyte compositions, are shown in Fig. 3. During the measurements, a very slight darkening of the gold surface was noted near peak 1. In the region of peak 2, a film was formed which grew darker in color as the the voltage became more anodic. This film could not be due to surface roughening, since electrode area did not vary. Attempts to measure the weight of the film in a manner similar to that made by Frankenthal and Thompson (10) in the case of gold hydroxide films in acid media were not successful, apparently because of insufficient surface product. The weight loss measured for the dissolution rate determination includes a small error (<10 μg) resulting from the weight of the film, since the film was not removed during the wash with doubly distilled water. No change in the color of the surface was noted during gold dissolution experiments in the region of peak 3.

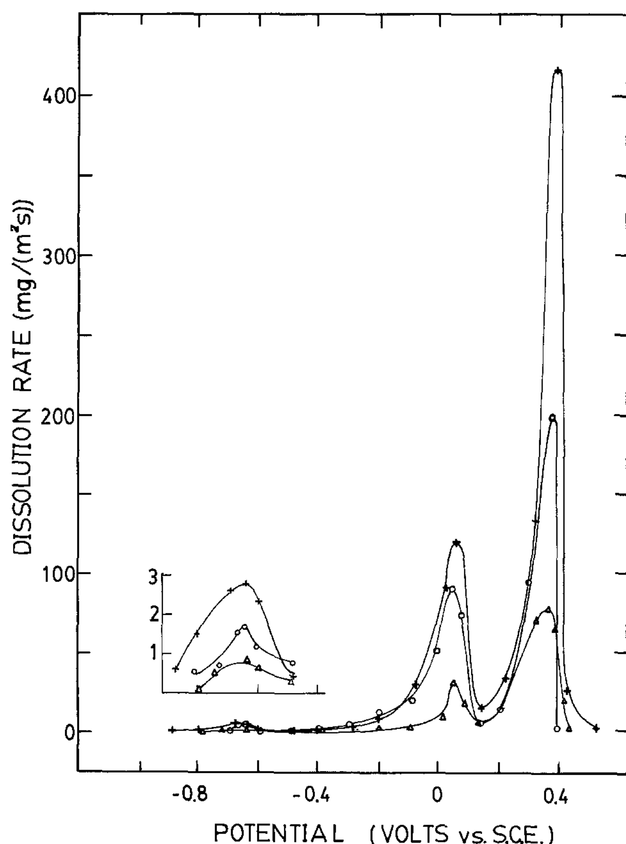


Fig. 3. Dissolution rate in aqueous alkaline cyanide. + 0.1M KOH + 0.2M KCN, ○ 0.1M KOH + 0.1M KCN, △ 0.1M KOH + 0.05M KCN. Temperature 23.5°C.

From Fig. 3 it can be seen that there are three regions of high dissolution rate and that these regions correspond, both in relative magnitude and potential range, to peaks 1, 2, and 3 found in the potential sweep measurements (Fig. 2). Thus, the current measured in the potential sweep experiments is the result of charge transfer in a gold dissolution process. In order to identify the dissolution process, the number of coulombs passed during each dissolution experiment was measured and combined with the weight loss of the electrode to give the number of Faradays per mole of gold dissolved. The results are presented in Table I as a function of potential. As can be seen from the table, the values of n range from somewhat less than 1 at potentials near −0.9V to values slightly greater than 1 at potentials near 0.3V. The averages for the regions of peak 1, peak 2, and peak 3 are 0.85, 0.95, and 1.05, respectively.

In the region of peak 1, most of the dissolution occurs by a one-electron transfer step. The n values in this region are less than 1 so that it is possible that some gold might dissolve chemically, perhaps by a reaction such as

$$Au + HCN + CN^- \rightarrow \tfrac{1}{2} H_2 + Au(CN)_2^- \quad [4]$$

Free energy calculations (see Appendix) indicate that such a reaction is just barely thermodynamically possible under the prevailing experimental conditions.

In the region of peak 2, the dissolution process is clearly the result of a one-electron transfer step. Therefore, the reaction at peak 2 cannot be the conversion of a Au(I) salt to a Au(III) salt via reaction [3], as suggested by Cathro and Koch.

In the region of peak 3, the dissolution process also involves a one-electron transfer step; and, in addition, appears to show the onset of a dissolution process with $n > 1$ at more anodic potentials. Indeed, the few measurements taken at potentials greater than +0.4V indicate an $n = 3$ electron transfer reaction. Thus the dissolution occurring in the region of peak 3 is the oxidation of gold to Au(I) and not to Au(III). At

potentials more anodic than +0.4V an oxidation process involving a three-electron transfer appears to dominate. The formation of Au(III) oxide is known to occur at anodic potentials (11-13). In acid media, the potential of Au(III) oxide formation on a polycrystalline gold surface was found to be close to +1.2V (14), which corresponds to +0.33V in 1M KOH. The form of this oxide recently has been shown (10) to be $Au(OH)_3$. This oxide peak, corresponding to the reaction

$$Au + 3\,OH^- \rightarrow Au(OH)_3 + 3e^- \quad [5]$$

can be readily seen in Fig. 4, which is a potentiodynamic sweep profile in an alkaline electrolyte with no cyanide present. Thus, at potentials anodic to peak 3, the dissolution reaction is most likely superceded and terminated by the formation of a passivating gold hydroxide layer via reaction [5], which would correspond to $n = 3$. The fact that the n values were slightly greater than 1 in the region of peak 3 may indicate that some $Au(OH)_3$ was already starting to be formed at the more positive potentials.

Peak 3.—In order to determine the effect of cyanide and hydroxide concentrations on the reaction occurring at peak 3, the dissolution rate was determined for four concentrations of cyanide, each at three concentrations of hydroxide. The results, shown in Fig. 5, clearly demonstrate that the reaction is first order with respect to cyanide concentration and independent of hydroxide concentration. Linear regression analysis yielded a correlation coefficient of 0.99 for the data. Direct oxidation, as suggested by MacArthur

$$Au + 2CN^- \rightarrow Au(CN)_2^- + e^- \quad [6]$$

must, therefore, be ruled out, because such a reaction would be expected to be second order with respect to cyanide.

In addition, the effect of diffusion on the dissolution process was studied. Figure 6 shows two anodic potential sweeps in an alkaline cyanide solution with a 1.0M KCl supporting electrolyte added to ensure diffusion control. One sweep was conducted with the electrolyte unstirred, the other with rapid stirring. It can be seen that the dissolution rate for peak 3 was enhanced by stirring; hence, in the unstirred case, the diffusion of the cyanide ion plays a significant role in the reaction rate for peak 3. The same results were obtained when KNO_3 was used as the supporting electrolyte.

Since the dissolution process involves the reaction of gold and cyanide through a one-electron transfer step and since the Au(I) cyanide complex is extremely stable ($K_{dissociation}$) $= 2.5 \times 10^{-29}$) (15), the following mechanism is proposed

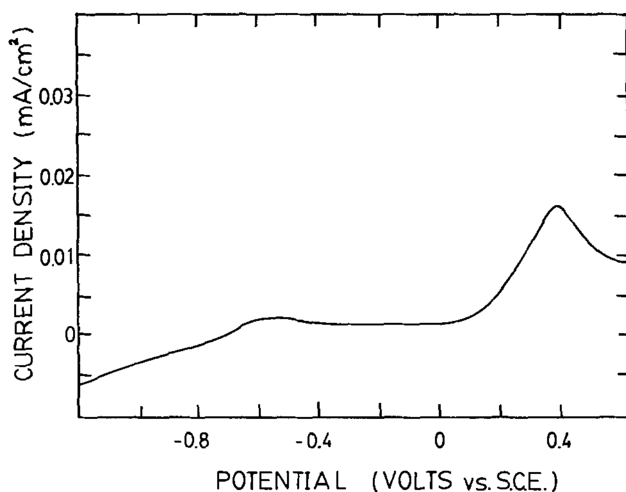

Fig. 4. Potentiodynamic anodic sweep profile in an aqueous alkaline electrolyte without cyanide. 1.0M KOH. Sweep rate 0.1 V · sec^{-1}, temperature 23.4°C.

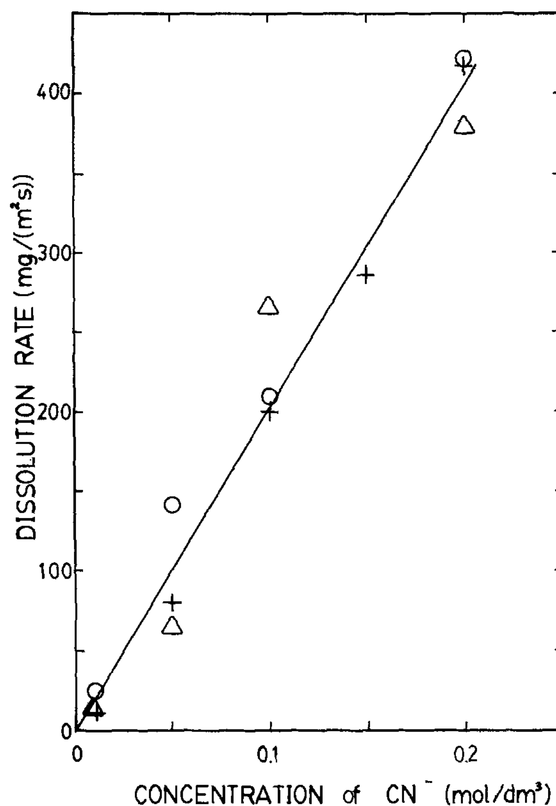

Fig. 5. Dependence of dissolution rate on cyanide and hydroxide concentration for peak 3. ○ 1.0M KOH, + 0.1M KOH, △ 0.01M KOH. Temperature 23.5°C.

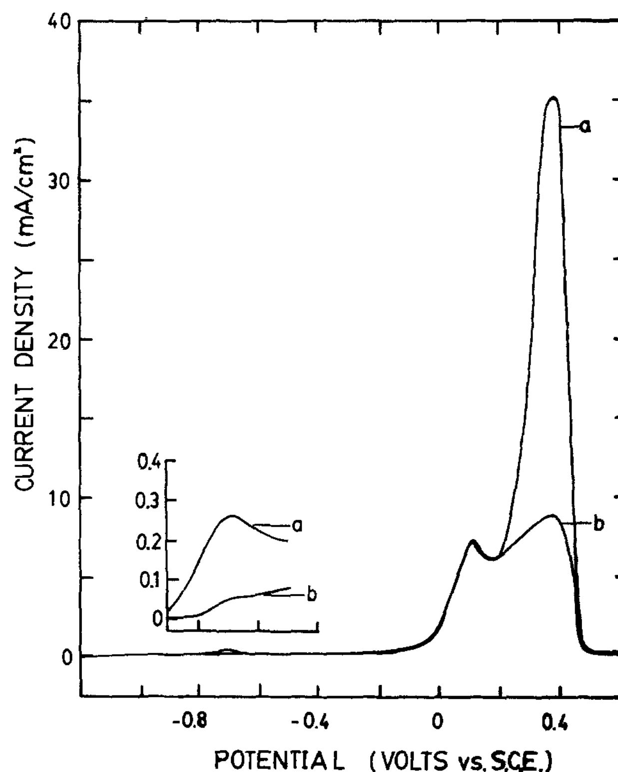

Fig. 6. Effect of stirring on reaction rate in aqueous alkaline cyanide. 0.1M KOH + 0.1M KCN + 1.0M KCl. *a*, Well stirred electrolyte; *b*, nonstirred electrolyte. Sweep rate 2 mV · sec^{-1}, temperature 23.6°C.

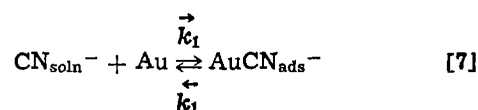
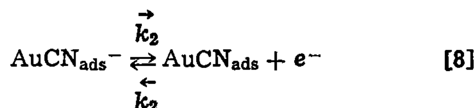
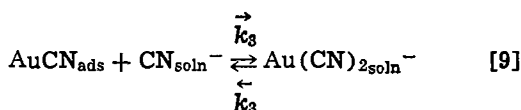


$$CN_{soln}^- + Au \underset{\overleftarrow{k_1}}{\overset{\overrightarrow{k_1}}{\rightleftarrows}} AuCN_{ads}^- \quad [7]$$



$$AuCN_{ads}^- \underset{\overleftarrow{k_2}}{\overset{\overrightarrow{k_2}}{\rightleftarrows}} AuCN_{ads} + e^- \quad [8]$$



$$AuCN_{ads} + CN_{soln}^- \underset{\overleftarrow{k_3}}{\overset{\overrightarrow{k_3}}{\rightleftarrows}} Au(CN)_{2soln}^- \quad [9]$$

For each step of the reaction sequence, the dependence of the reaction rate on the bulk cyanide concentration can be calculated and is presented in Table II (see Appendix for derivations).

From Table II it can be seen that for step [7] as the rate-determining step, the reaction rate increases linearly with cyanide concentration and decreases with hydroxide concentration.

For step [8] as the rate-determining step, the reaction rate increases linearly with cyanide concentration only for low surface coverage of $AuCN_{ads}^-$. Since the surface coverage (θ') of $AuCN_{ads}^-$ should follow an adsorption isotherm, and since the reaction rate is proportional to the surface coverage, deviation of the reaction rate from linearity with cyanide concentration is expected at high cyanide concentrations. The concentration of hydroxide ion, according to

$$Au + OH^- \rightleftarrows AuOH_{ads}^- \quad [10]$$

also affects the reaction rate because of the competition for surface sites on the gold electrode (θ'' increases with $[OH^-]$).

For step [9] with low surface coverage, $(1 - \theta - \theta') \simeq 1$, and the reaction rate is second order with respect to cyanide concentration. At high surface coverage, the reaction rate is directly proportional to cyanide concentration and, since θ is high and approximately constant, there is no dependence of the reaction rate on hydroxide concentration.

In view of the above, it reasonably can be concluded that for peak 3, step [9] is the rate-determining step, since from Fig. 5 the reaction rate at peak 3 is linear with cyanide concentration and independent of hydroxide concentration. Step [9] would also account for the influence of stirring on the reaction rate at peak 3, observed in Fig. 6.

Peak 2.—The effect of cyanide and hydroxide concentration on the dissolution rate for the reaction at peak 2 was studied using six levels of cyanide and four of hydroxide. The results, shown in Fig. 7, demonstrate that at low cyanide concentrations the dissolution rate

Table II. Theoretical dependence of gold dissolution rate on cyanide concentration

Rate-determining step	
[7]	$i \simeq \overrightarrow{i_1} = \overrightarrow{k_1}[CN^-][Au] \simeq \overrightarrow{k_1}[CN^-](1 - \theta'')$
[8]	$i \simeq \overrightarrow{i_2} = \overrightarrow{k_2}\,\theta' \exp\left[\frac{\beta F \Delta\phi}{RT}\right] = \frac{\overrightarrow{k_1}\overrightarrow{k_2}[CN^-](1 - \theta - \theta'')}{\overleftarrow{k_1} + \overrightarrow{k_2}[CN^-]} \exp\left[\frac{\beta F \Delta\phi}{RT}\right]$
[9]	$i \simeq i_3 = \overrightarrow{k_3}[CN^-]\theta = \frac{\overrightarrow{k_1}\overrightarrow{k_2}k_3[CN^-]^2(1 - \theta - \theta'')}{\overleftarrow{k_1} + \overrightarrow{k_1}[CN^-]} \exp\left[\frac{F\Delta\phi}{RT}\right]$

Where θ = fractional surface coverage of $AuCN_{ads}$, θ' = fractional surface coverage of $AuCN_{ads}^-$, and θ'' = fractional surface coverage of $AuOH_{ads}^-$.

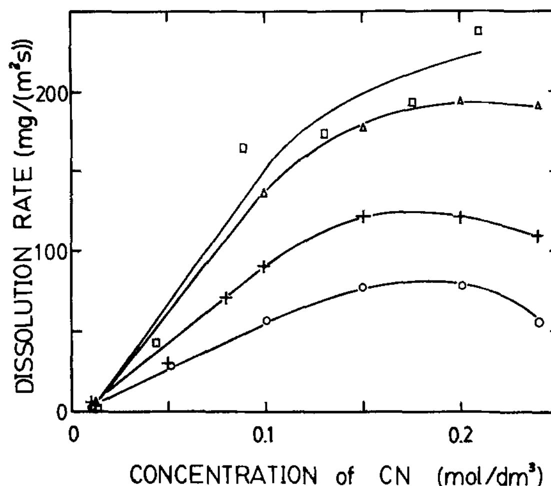


Fig. 7. Dependence of dissolution rate on cyanide and hydroxide concentration for peak 2. ○ 1.0M KOH, + 0.1M KOH, △ 0.01M KOH, □ 0.0001M KOH. Temperature 23.5°C.

is approximately linear with cyanide concentration and that the dissolution rate decreases with increasing hydroxide concentration. At moderate hydroxide concentrations, the reaction rate decreases for cyanide concentrations greater than 0.2M. In addition, the voltage scans in Fig. 6 indicate that the reaction rate is not influenced by stirring and hence is not affected by cyanide diffusion.

The reaction at peak 2 is a dissolution reaction involving a one-electron transfer step and should follow the reaction scheme [7], [8], and [9]. Although each of the steps can exhibit a reaction rate which is linear with cyanide concentration, only step [8] can account for the decrease in the reaction rate at high cyanide concentrations and for the lack of dependence of the reaction rate on the diffusion of cyanide ions. As seen from Table II, the reaction rate, if step [8] is the rate-determining step, depends on the concentration of $AuCN_{ads}^-$ on the surface and would, therefore, account for the lack of dependence of the reaction rate with stirring. At low surface coverage (θ, θ' small) the concentration of $AuCN_{ads}^-$ can be shown to be $\overrightarrow{k_1}/\overleftarrow{k_1}$ $[CN^-](1 - \theta'')$ when step [7] is in pseudoequilibrium, and thus the reaction rate is directly proportional to the cyanide concentration. An increase in hydroxide concentration causes a decrease in the reaction rate as a result of the term $(1 - \theta'')$ decreasing.

At higher cyanide and hydroxide concentrations the expression given in Table II for $\overrightarrow{i_2}$ can be shown to have a maximum if the concentration of $AuCN_{ads}$ increases with cyanide concentration. In the potential region near peak 3 the surface concentration of $AuCN_{ads}$ is known to be high (from previous discussion of peak 3); also, from the fact that surface concentrations of adsorbed species tend to follow Langmuir-type adsorption isotherms, it is reasonable to assume that the surface concentration of $AuCN_{ads}$ will increase with cyanide concentration. Therefore, at sufficiently high cyanide concentrations, the term $(1 - \theta - \theta'')$ begins to decrease and causes a lowering of the reaction rate. It is concluded that reaction [8] is the rate-determining step for peak 2.

Peak 1.—The reaction at peak 1 has been found to be a dissolution process with $n = 0.85$. The voltage scans in Fig. 6 show that the dissolution rate is affected by stirring; hence, the diffusion of the cyanide ion influences the reaction rate in the unstirred electrolyte. These data and the work of Cathro and Koch and MacArthur indicate that the electrochemical dissolution proceeds via sequence [7], [8], and [9]. Further

work is currently being conducted to identify the rate-determining step and additional processes taking place.

From the data presented, it is evident that throughout the potential range -0.9 to $+0.4$V in alkaline cyanide, gold dissolution rate are consistent with the reaction sequence [7], [8], and [9]. The rate-determining step for the dissolution process depends on potential, with step [9] controlling the reaction rate in the region of peak 3, and step [8] controlling in the region of peak 2. Despite the fact that the dissolution proceeds by the reaction sequence [7], [8], and [9] throughout the potential region investigated, the presence of the three peaks in the potentiodynamic sweep profiles (Fig. 2) as well as in the potential-dissolution rate determinations (Fig. 3) indicates that the dissolution process must be complicated by surface blockage or by the formation of a passivating surface film.

The change in color of the electrode surface observed in our work in the regions of peak 1 and peak 2 and a corresponding change in reflectance measurements of a gold surface in alkaline cyanide presented by Cathro and Koch are clear indications of film formation. The formation of simple oxides or hydroxides generally may be ruled out, because calculations made using standard electrode potentials (16) indicate that in alkaline media (1M KOH) AuOH should form at ±1.26V, AuO at $+0.302$V, $Au(OH)_3$ at $+0.382$V, and AuO_2 at $+0.682$V. These potentials generally are inconsistent with the potential regions where surface coloration was observed. There is, however, the possibility of formation of more complex species involving adsorbed hydroxide and cyanide ions, since both species can be adsorbed on a gold surface (17, 18).

The potential of zero charge for gold in alkaline solutions is known to be $\simeq 0$V (19) and independent of hydroxide concentration (20, 21). Therefore, anion electrosorption in the region of peak 1 will be relatively weak and the passivating layer need not be strongly bonded to cause interference with the dissolution reaction. At potentials near peak 2, the electrosorption of anions is much stronger and competition for surface sites between cyanide and hydroxide ions takes place. This can be seen from Fig. 7 since the reaction rate decreases with an increase in hydroxide concentration. At still more anodic potentials, the dissolution rate decreases and this decrease coincides with the formation of a dark surface film. Therefore, it would appear that this surface film is the passivating layer. Work is now being carried out to identify the surface product. At potentials near peak 3, the electrode is strongly positive, and the cyanide ion is preferentially adsorbed and, as either $AuCN_{ads}^-$ or $AuCN_{ads}$, occupies most of the available sites on the gold surface. The concentration of hydroxide has no effect on the reaction rate in this region (Fig. 5) and the dissolution is controlled by step [9], as discussed earlier. Anodic to peak 3, the formation of $Au(OH)_3$ becomes favored and the cyanide reaction is terminated.

Conclusions

1. Dissolution of gold in alkaline cyanide was found to occur via a one-electron transfer step in the potential range -0.4 to $+0.38$V *vs.* SCE. At less anodic potentials the dissolution proceeds with $n < 1$.

2. The peaks found in potentiostatic weight loss measurements and potentiodynamic sweep experiments at low sweep rates are the result of a single over-all dissolution reaction with different rate-controlling steps.

3. The reaction at peak 3 ($+0.2$ to $+0.38$V *vs.* SCE) is consistent with the sequence [7], [8], and [9] with step [9] as the rate-determining step. It cannot be the direct oxidation by reaction [6] as suggested in the literature.

4. The reaction at peak 2 (-0.1 to $+0.15$V *vs.* SCE) involves the same dissolution scheme as for peak 3, but with step [8] as the rate-determining step. It cannot be explained as the conversion of an Au(I) to an Au(III) salt as suggested by previous workers.

5. The formation of peaks in the potentiostatic weight loss measurements and potentiodynamic measurements arises because of blockage of the dissolution reaction by adsorption or the formation of passivating surface species.

6. The dissolution of gold in alkaline cyanide by the reaction sequence [7], [8], and [9] is terminated at potentials more positive than $+0.38$V (peak 3) by the formation of $Au(OH)_3$.

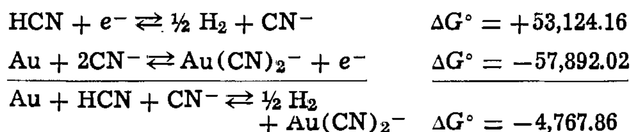
$$= +57{,}892.02J$$

$$\therefore \text{for anodic direction, } \Delta G° = -57{,}892.02$$



$HCN + e^- \rightleftarrows \frac{1}{2} H_2 + CN^-$	$\Delta G° = +53{,}124.16$
$Au + 2CN^- \rightleftarrows Au(CN)_2^- + e^-$	$\Delta G° = -57{,}892.02$
$Au + HCN + CN^- \rightleftarrows \frac{1}{2} H_2 + Au(CN)_2^-$	$\Delta G° = -4{,}767.86$

spontaneous reaction under standard conditions [A-5]

$$\Delta\epsilon° = -\frac{\Delta G°}{nF} = \frac{-(-4767.86)}{(1)(96{,}486.7)} = 0.049415V$$

$$\Delta\epsilon = \Delta\epsilon° - 0.59157 \log \frac{P_{H_2} \cdot a_{Au(CN)^-}}{a_{HCN} \cdot a_{CN^-}} \qquad [A\text{-}6]$$

Typical solution composition is 0.10M KOH + 0.10M KCN

Total ionic strength is $\simeq \frac{1}{2} \sum_i M_i z_i^2 = \frac{1}{2}(0.1 + 0.1 + 0.1 + 0.1) = 0.20$

Modified Debye-Hückel-Güntelberg-Davies equation (23)

$$\log \gamma_\pm = -\frac{A/z_1z_2/\sqrt{I}}{1+\sqrt{I}} + 0.1/z_1z_2/I$$

$$= \frac{-0.50841(1)\sqrt{0.2}}{1+\sqrt{0.2}} + 0.1(1)(0.2)$$

$$= -0.13711$$

$$\gamma_\pm = 0.729 \simeq \gamma_{H^+} \simeq \gamma_{CN^-} \simeq \gamma_{Au(CN)_2^-} \qquad [A\text{-}7]$$

$$\therefore \Delta\epsilon = 0.049415 - 0.059157 \log \frac{P_{H_2} \cdot [Au(CN)_2^-]}{\gamma_\pm[HCN][CN^-]} \qquad [A\text{-}8]$$

From K_A

$$[HCN][CN^-] = (4.93 \cdot 10^{-10}) \frac{[HCN]^2}{[H^+]}$$

At pH 13

$$\frac{[CN^-]}{[HCN]} = \frac{K_A}{[H^+]} = \frac{4.93 \cdot 10^{-10}}{10^{-13}} = 4.93 \cdot 10^3$$

$$\therefore [CN^-] = 4.93 \cdot 10^3 [HCN]$$

mass balance

$$[HCN] + [CN^-] = 0.10$$

$$[HCN] + 4.93 \cdot 10^3 [HCN] = 0.1$$

$$[HCN] = 2.028 \cdot 10^{-5}$$

$$\therefore [HCN][CN^-] = \frac{(4.93 \cdot 10^{-10})(2.028 \cdot 10^{-5})^2}{10^{-13}}$$

$$= 2.0276 \cdot 10^{-6} \qquad [A\text{-}9]$$

Substituting [A-7] and [A-9] in [A-8]

$$\Delta\epsilon = 0.049415 - 0.059157 \log \frac{P_{H_2} \cdot [Au(CN)_2^-]}{(0.729)(2.0276 \cdot 10^{-6})}$$

$$= -0.29549 - 0.059157 \log (P_{H_2} \cdot [Au(CN)_2^-])$$

Hydrogen will be formed at $P_{H_2} = 1$ atm, therefore the criterion for spontaneous chemical dissolution according to reaction [A-5] is that $\Delta\epsilon \leqq 0$, *i.e.*

$$\log [Au(CN)_2^-] \leqq \frac{-0.29549}{0.059157} \leqq -4.995$$

$$[Au(CN)_2^-] \leqq 1.01 \cdot 10^{-5} \text{ mole/dm}^3$$

$$\leqq 2 \text{ mg Au/dm}^3$$

The maximum dissolved gold concentration at the end of a potentiostatic dissolution run was 4 mg/dm^3, so that the concentration of $Au(CN)_2^-$ was <2 mg/dm^3 for a considerable time during a run, hence chemical dissolution was thermodynamically possible.

LIST OF SYMBOLS

- A electrode area
- C_o concentration of $Fe(CN)_6^{-4}$
- D_o diffusion coefficient of $Fe(CN)_6^{-4}$
- F the Faraday
- i_p peak current
- $\vec{k}$ rate constant of forward reaction
- $\overleftarrow{k}$ rate constant of backward reaction
- K equilibrium constant $= \vec{k}/\overleftarrow{k}$
- n number of electrons transferred in over-all reaction
- R gas constant
- T absolute temperature
- v voltage scan rate
- β anodic symmetry factor
- $\Delta\phi$ potential difference across electrode/solution interface
- θ fractional coverage of $AuCN_{ads}$
- θ' fractional coverage of $AuCN_{ads}^-$
- θ'' fractional coverage of $AuOH_{ads}^-$

An Impedance Interpretation of Small Amplitude Cyclic Voltammetry

I. Theoretical Analysis for a Resistive-Capacitive System

Digby D. Macdonald*

SRI International, Materials Research Center, Menlo Park, California 94025

ABSTRACT

The transient response of an equivalent circuit for an electrode/solution interface to a small-amplitude triangular potential excitation is derived by use of transform analysis. The response consists of both transient and steady-state contributions. The predicted steady-state response yields a hysteresis loop that is qualitatively similar to those exhibited by real systems under small-amplitude cyclic voltammetric conditions. Numerical analysis illustrates the dependence of the response on the voltage sweep rate, and the analysis of experimental data for corroding 90:10 Cu:Ni alloy in flowing seawater is described.

Small-amplitude cyclic voltammetry (SACV) (1), in which a triangular potential excitation function is imposed across an electrode/solution interface, has been used for both fundamental studies of the structure and capacitance of the double layer and for evaluating the corrosion rates of metals in condensed systems. At high voltage sweep rates, the capacitive components

* Electrochemical Society Active Member.

Key words: cyclic voltammetry, linear polarization, equivalent circuit, impedance, transform analysis.

frequently dominate the interfacial impedance, and the observed current response can be used to estimate the capacitance of the surface (1). Conversely, at low sweep rates the capacitive current is usually negligible compared with the faradaic contribution. In this case, the SACV response is principally determined by the charge-transfer (polarization) resistance of the interface.

The SACV technique is used extensively in corrosion research for estimating the polarization resistance of a metal-solution interface at the corrosion potential (2). Typically, a 10-20 mV peak-to-peak triangular excitation is imposed across a corroding interface by use of a potentiostat. The current response is then recorded over one or more cycles, and the polarization resistance is estimated from the gradient of the potential (E) *vs.* current (I) plot at the corrosion potential. The E *vs.* I plot is frequently nonlinear, but more important for the present analysis, the plot may exhibit considerable hysteresis. The nonlinear response has been discussed (2, 3), and it appears that this phenomenon can be used to obtain information on the nature of the corrosion process. On the other hand, little attention has been focused on the origin of the hysteresis, even though this property plays a central role in the interpretation of data from the closely related a-c impedance technique (1).

In this paper, the origin of the hysteresis in current *vs.* potential as observed under SACV conditions is analyzed in terms of the impedance of an equivalent electrical circuit. It is shown that the degree of hysteresis is sensitive to the potential sweep rate, and that the observed current response can be used to estimate values for the resistances and capacitances at the interface.

Impedance Operators

Provided that the amplitude of the excitation voltage is sufficiently small, the components of the impedance at a metal/solution interface can be regarded as linear; that is, the impedances of the individual components are independent of voltage. Accordingly, the interface may be represented by an equivalent electrical circuit consisting of linear components only, and the response of the system to an excitation signal $E(t)$ can be obtained by application of Eq. [1]

$$I(t) = E(t)/Z(p) \quad [1]$$

where p is the impedance operator defined as

$$p = d/dt \quad [2]$$

$$1/p = \int dt \quad [3]$$

The impedance function $Z(p)$ is chosen so that $Z(p) \times I(t)$ is equal to the voltage drop across the device in question. For instance, the drops in voltage across resistive, capacitive, and inductive components are given by

Resistive: $E(t) = RI,\ Z(p) = R$ [4]

Capacitive: $E(t) = (1/C) \int I dt,\ Z(p) = 1/pC$ [5]

Inductive: $E(t) = L(dI/dt),\ Z(p) = Lp$ [6]

Furthermore, the total voltage drop across a series combination of components is given by

$$E(t) = \sum_i E_i(t) \quad [7]$$

whereas the total current through a parallel network is

$$I(t) = \sum_i I_i(t) \quad [8]$$

Accordingly, the impedance functions for series and parallel combinations of components are given by Eq. [9] and [10], respectively

$$Z(p) = \sum_i Z_i(p) \quad [9]$$

$$1/Z(p) = Y(p) = \sum_i [1/Z(p)] = \sum_i Y_i(p) \quad [10]$$

The parameter $Y(p)$ is commonly termed the admittance function for the circuit under consideration.

Inspection of Eq. [1], [4]-[6], [9], and [10] shows that if the impedance (or admittance) operator of a complex circuit is known, then prediction of the current response to a specified excitation voltage function $E(t)$ will involve solution of one or more integral/differential equations. One of the most effective methods for handling this type of problem is by use of Laplace (or Fourier) transforms. The application of these integral transforms for predicting the transient responses of electrical circuits is known as transform analysis. Although Pilla (4) and others (1, 5, 6) have used numerical transformation techniques in the analysis of the a-c impedance characteristics and potentiostatic responses of electrochemical systems, transform analysis of either experimental data or equivalent electrical circuits does not appear to have been employed extensively in the study of SACV.

Transform Analysis

It can be shown (7) that upon transformation of Eq. [1] into Laplace space, that is

$$\overline{I}(s) = \overline{E}(s)/Z(s) \quad [11]$$

with

$$\mathcal{L}[f(t)] = \overline{f}(s) = \int_0^\infty f(t)e^{-st}dt \quad [12]$$

the impedance function $Z(s)$ has the same analytical form as $Z(p)$ with the impedance operator, p, replaced by the Laplace variable, s. This convenient property permits the straightforward derivation of an expression for the Laplace transform of the current in terms of the variable s. Inverse transformation (analytically or numerically) therefore yields the required current response in terms of real time.

By way of illustration, we consider a simple series R-C circuit. The impedance operator for this circuit is obtained from Eq. [4] and [5] as

$$Z(p) = R + 1/pC \quad [13]$$

The current response to a voltage step applied at $t = 0$ is therefore given in Laplace space as

$$\overline{I}(s) = EC/(1 + sRC) \quad [14]$$

where the Laplace transform of $E(t)$ is (8)

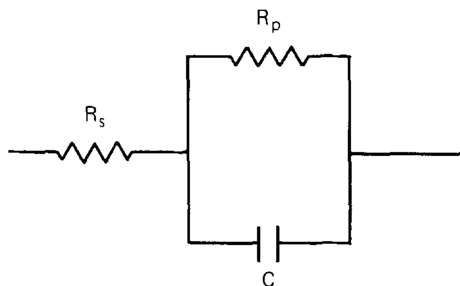
$$\mathcal{L}[E(t)] = E/s \quad [15]$$

Inverse transformation of Eq. [14] is straightforward by use of standard tables (8) to yield the familiar exponential decay of current with time

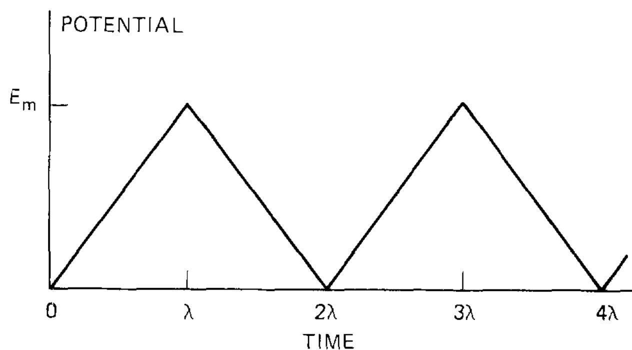
$$I(t) = (E/R)e^{-t/RC} \quad [16]$$

Simulated Metal/Solution Interface

The simplest general electrical equivalent circuit for a metal/solution interface is a parallel combination of a resistor (R_p) and a capacitor (C) in series with a second resistor (R_s) as shown in Fig. 1a. The resistance R_p may be identified with the charge-transfer (or polarization) resistance, whereas R_s is commonly associated with any pure resistance (*e.g.*, from the solution or low capacitive films) between the metal and the tip of the reference electrode probe. Although at first sight this equivalent circuit may appear to be unrealistically simple, it can frequently simulate the relaxation behavior of a real interface, particularly if a single relaxation process dominates the electrochemical behavior over the range of frequency of interest. In the complex plane representation of the impedance, this behavior is characterized by a single first quadrant semicircle centered on the real axis. Although other relaxation processes may exist at other frequencies, their contributions to the over-all impedance of a



(a) EQUIVALENT CIRCUIT FOR THE METAL-SOLUTION



(b) TRIANGULAR VOLTAGE EXCITATION FUNCTION

Fig. 1. Equivalent circuit and voltage-excitation function for the model considered for the metal-solution interface.

series combination of elements of the type shown in Fig. 1a will be small, provided that the relaxation times are sufficiently well separated.

With these limitations in mind, the impedance of the interface under linear conditions is given by

$$Z(p) = R_s + \frac{R_p}{1 + pR_pC} \qquad [17]$$

The excitation voltage applied in the controlled potential mode across the interface is in the form of the triangle shown in Fig. 1b and is represented mathematically by Eq. [18]

$$E = \begin{cases} E_m\left[\frac{t}{\lambda} - 2n\right] & 2n\lambda < t < (2n+1)\lambda \text{ (forward sweep)} \\ E_m\left[2(n+1) - \frac{t}{\lambda}\right] & (2n+1)\lambda < t < (2n+2)\lambda \text{ (reverse sweep)} \end{cases} \qquad [18]$$

where E_m is the maximum value of the excitation voltage, λ is the time of reversal of the voltage scan, and $n = 0, 1, 2, \ldots$ is the cycle number. The Laplace transform of Eq. [18] is given in transform tables (8) as

$$\overline{E}(s) = E_m(1 - e^{-\lambda s})/\lambda s^2(1 + e^{-\lambda s}) \qquad [19]$$

Substitution of Eq. [17] and [19] into Eq. [11] with $p = s$ therefore yields the Laplace transform of the response current as

$$\overline{I}(s)/E_m = [(1 - e^{-\lambda s})/b\lambda s(1 + e^{-\lambda s})] \times \left[1/s\left(s + \frac{a}{b}\right) + R_pC/\left(s + \frac{a}{b}\right)\right] \qquad [20]$$

where

$$a = R_s + R_p \qquad [21]$$

$$b = R_sR_pC \qquad [22]$$

Inverse transformation may be accomplished by use of the convolution theorem (7, 8)

$$\mathcal{L}^{-1}[\overline{I}(s)/E_m] = \int_0^t F(x)G(t - x)dx \qquad [23]$$

where $F(x)$ and $G(t - x)$ are the inverse transformations of $f(s)$ and $g(s)$ given below

$$f(s) = (1 - e^{-\lambda s})/s(1 + e^{-\lambda s}) \qquad [24]$$

$$F(x) = \begin{cases} +1 & 2n\lambda < x < (2n+1)\lambda \\ -1 & (2n+1)\lambda < x < (2n+2)\lambda \end{cases} \qquad [25]$$

$$g(s) = 1/s\left(s + \frac{a}{b}\right) + R_pC/\left(s + \frac{a}{b}\right) \qquad [26]$$

$$G(t - x) = b/a + Ke^{ax/b} \qquad [27]$$

with

$$K = (R_pC - b/a)\, e^{-at/b} \qquad [28]$$

Substitution of Eq. [25] and [27] into Eq. [23], followed by integration over successive forward and reverse sweeps, yields

$$I^f(t) = (E_m/a\lambda)\left\{ t - 2n\lambda - (R_pC - b/a) \times \left[2\sum_{m=0}^{2n} (-1)^m e^{-a(t-m\lambda)/b} - e^{-at/b} - 1 \right]\right\} \qquad [29]$$

for the current on the forward sweep with $2n\lambda < t < (2n + 1)\lambda$, and

$$I^r(t) = (E_m/a\lambda)\left\{ 2(n+1)\lambda - t + (R_pC - b/a) \times \left[2e^{a\lambda/b}\sum_{m=0}^{2n} (-1)^m e^{-a(t-m\lambda)/b} - e^{-at/b} - 1 \right]\right\} \qquad [30]$$

for the reverse sweep with $(2n + 1)\lambda < t < (2n + 2)\lambda$. The summations contained in Eq. [29] and [30] are geometric progressions. Summation over the indicated limits therefore yields

$$I^f(t) = (E_m/a\lambda)\{t - 2n\lambda - (R_pC - b/a) \times [2e^{-at}(1 + e^{(2n+1)a\lambda/b})/(1 + e^{a\lambda/b}) - e^{-at/b} - 1]\} \qquad [31]$$

and

$$I^r(t) = (E_m/a\lambda)\{2(n+1)\lambda - t + (R_pC - b/a) \times [2e^{-(t-\lambda)a/b}(1 + e^{(2n+1)a\lambda/b})/(1 + e^{a\lambda/b}) - e^{-at/b} - 1]\} \qquad [32]$$

for the forward $[2n\lambda < t < (2n + 1)\lambda]$ and reverse $[2n + 1)\lambda < t < (2n + 2)\lambda]$ sweeps, respectively.

It is convenient to redefine the time scales so that zero time for the forward sweep coincides with $2n\lambda$ (*i.e.*, with the start of the nth forward sweep) and with $(2n + 1)\lambda$ for the reverse sweep. This is accomplished by use of the following transformations

$$t' = t - 2n\lambda \qquad [33]$$

$$t'' = t - (2n + 1)\lambda \qquad [34]$$

Thus, substitution for t in Eq. [31] and [32] using Eq. [33] and [34], respectively, yields the following expressions for the current transients for the forward and reverse sweeps

$$I^f(t') = (E_m/a\lambda)\{t' - e^{-at'/b}(R_pC - b/a) \times [2(e^{-2na\lambda/b} + e^{a\lambda/b})/(1 + e^{a\lambda/b}) - e^{-2na\lambda/b}] + (R_pC - b/a)\} \qquad [35]$$

$$I^r(t'') = (E_m/a\lambda)\{\lambda - t'' + e^{-at''/b}(R_pC - b/a) \times [2(e^{-2na\lambda/b} + e^{a\lambda/b})/(1 + e^{a\lambda/b}) - e^{-(2n+1)a\lambda/b}] - (R_pC - b/a)\} \quad [36]$$

Equations [35] and [36] demonstrate that the current response contains both steady-state and transient components. Of principal interest in this work is the steady state that is established when $na\lambda/b \to \infty$. Under these conditions $e^{-2na\lambda/b}$ and $e^{-(2n+1)a\lambda/b} \to 0$, so that Eq. [35] and [36] reduce to

$$I_{ss}^f(t') = (E_m/a\lambda)\{t' - (R_pC - b/a) \times [(2e^{a(\lambda-t')/b}/[1 + e^{a\lambda/b}]) - 1]\} \quad [37]$$

$$I_{ss}^r(t'') = (E_m/a\lambda)\{\lambda - t'' + (R_pC - b/a) \times [(2e^{a(\lambda-t'')/b}/[1 + e^{a\lambda/b}]) - 1]\} \quad [38]$$

Because SACV experiments are normally carried out with potential sweep rate as the independent variable, a further transformation of Eq. [37] and [38] is necessary. Thus, substitution of $\lambda = E_m/v$, where v is the potential sweep rate, into Eq. [37] and [38] yields

$$I_{ss}^f(t') = (v/a)\{t' - (R_pC - b/a) \times [(2e^{a(E_m-vt')/vb}/[1 + e^{aE_m/vb}]) - 1]\} \quad [39]$$

$$I_{ss}^r(t'') = (v/a)\{E_m/v - t'' + (R_pC - b/a) \times [(2e^{a(E_m-vt'')/vb}/[1 + e^{aE_m/vb}]) - 1]\} \quad [40]$$

Equations [39] and [40] therefore give the complete steady-state response of the equivalent circuit shown in Fig. 1a as a function of time and sweep rate as the independent variables.

Numerical Analysis

Equations [39] and [40] show that the steady-state response of the equivalent circuit shown in Fig. 1a to a triangular voltage excitation is a complex function of the resistances and capacitances of the circuit elements, the maximum voltage, E_m, and the voltage sweep-rate, v. The relationships given are sufficiently complex that the dependence of the response on the independent variables is best illustrated by numerical analysis; that is, the current on the forward and reverse sweeps is calculated from Eq. [39] and [40] for selected values for R_s, R_p, C, E_m, and v.

Typical steady-state current-voltage curves as a function of voltage sweep rate are shown in Fig. 2. In general, the polarization curves exhibit hysteresis between the forward and reverse sweeps, with exponential-type decays at the start of both sweep directions. The curves plotted in Fig. 2 show that the degree of hysteresis is sensitive to the voltage sweep-rate, and only at the lowest sweep-rate considered is the degree of hysteresis negligible. The amount of exponential decay at the start of both the forward and reverse sweeps depends upon the value for the series resistance R_s. Thus, if the series resistance is not present or has been compensated for by positive feedback, no exponential decay is predicted as can be shown from Eq. [39] and [40]. These calculated voltammograms are similar in both form and response to the independent variable, v, as those frequently observed for real systems (see next section).

In practice, it is possible to obtain reasonably precise data for the gradient of the current/voltage curve at the end of both the forward and reverse sweeps. Furthermore, the hysteresis current, ΔI, defined as

$$\Delta I = I_{ss}^f(t' = \lambda/2) - I_{ss}^r(t'' = \lambda/2) \quad [41]$$

is also conveniently measured from the observed current response (see Fig. 2). Differentiation of Eq. [39] and [40] with respect to t' and t'', and substitution of $t' = t'' = \lambda$, therefore yields

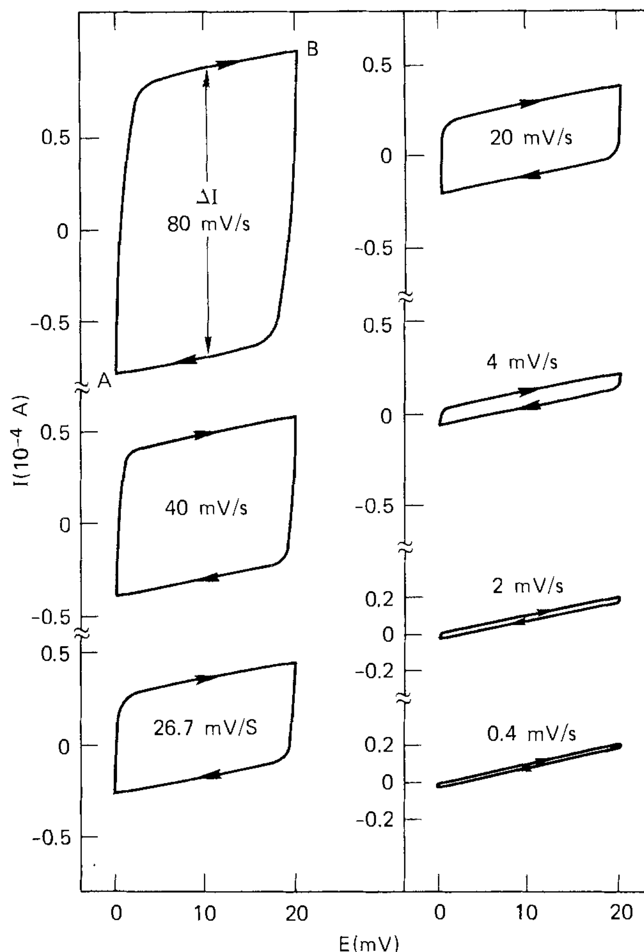


Fig. 2. Cyclic voltammograms for the electrical equivalent circuit shown in Fig. 1(a) as a function of voltage sweep rate. $R_s = 10\ \Omega$, $R_p = 1000\ \Omega$, $C = 1000\ \mu F$, $E_m = 20$ mV.

$$1/R_{app} = 1/(R_s + R_p) + 2R_p/R_s(R_s + R_p)(1 + e^{aE_m/vb}) \quad [42]$$

where the apparent polarization resistance, R_{app}, is equal to $(\partial E/\partial I_{ss})_{t=\lambda}$; that is, it is equal to the slope of the polarization curve at $t' = \lambda$ for the forward sweep and at $t'' = \lambda$ for the reverse sweep. Similarly, substitution of Eq. [39] and [40] into Eq. [41] yields the following expression for the hysteresis current

$$\Delta I = 2R_p^2C\{1 - 2e^{aE_m/2vb}/(1 + e^{aE_m/vb})\}v/(R_s + R_p)^2 \quad [43]$$

A third equation may be derived by noting that the diagonal resistance, R_d, is given by

$$1/R_d = [I_{ss}^f(t' = \lambda) - I_{ss}^r(t'' = \lambda)]/E_m \quad [44]$$

This parameter is determined experimentally as the gradient of the line joining points A and B of the voltammogram shown in Fig. 2 for a sweep rate of 80 mV/sec. Substitution of Eq. [39] and [40] into Eq. [44] therefore yields

$$1/R_d = 1/(R_s + R_p) + \{2R_p^2C(e^{aE_m/bv} - 1)/E_m(R_p + R_s)^2(e^{aE_m/bv} + 1)\}v \quad [45]$$

The variation of $1/R_{app}$ and $1/R_d$ with voltage sweep rate (or frequency $v/4E_m$) for the indicated values for R_s, R_p, C, and E_m is shown in Fig. 3. At low sweep rates, both R_{app} and R_d tend toward the total d-c resistance of the circuit, that is $R_s + R_p$. This limit is also approached at low frequency for sinusoidal excitation as used in the a-c impedance technique (1). At very high voltage sweep rates both curves approach the value for the series resistance, R_s. This expected

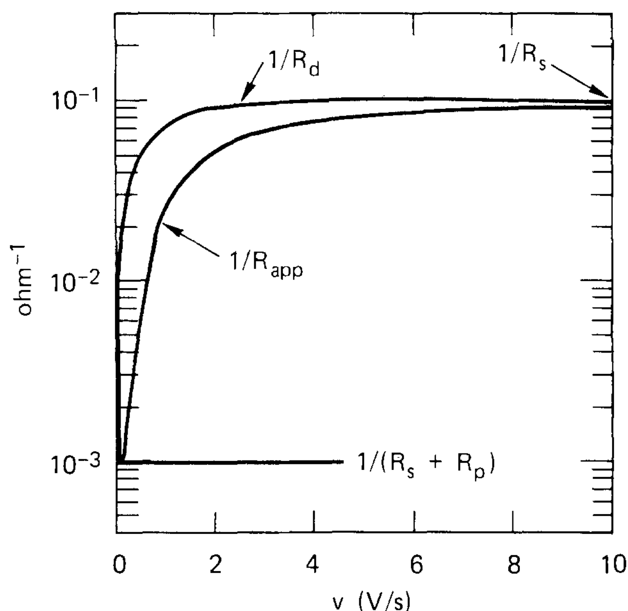

Fig. 3. Variation of $1/R_{app}$ and $1/R_d$ with voltage sweep rate for SACV. Note the two limits given by $1/R_s$ and $1/(R_s + R_p)$. $R_s = 10\ \Omega$, $R_p = 1000\ \Omega$, $C = 1000\ \mu F$, $E_m = 0.020V$.

result also parallels the well-known high frequency behavior under sinusoidal excitation (1).

The sweep rate dependence of the hysteresis current plotted in Fig. 4 shows that ΔI at first increases with v due to the increased conductance of the parallel capacitor. At higher sweep rates, however, the impedance of the interface becomes increasingly determined by the series resistance so that the hysteresis current decreases. At very low sweep rates (in the range for most linear polarization resistance measurements), ΔI is predicted to vary monotonically with v with a limiting gradient equal to $2CR_p^2/(R_p + R_s)^2$ as shown by the expanded scale plot in Fig. 4. This property is used later in this paper for the analysis of experimental data.

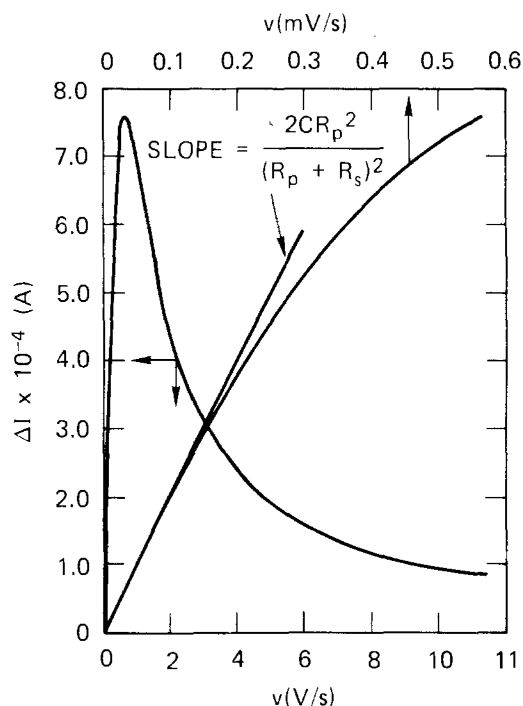

Fig. 4. Dependence of the hysteresis current (ΔI) on voltage sweep rate (v) for SACV. The arrows indicate the appropriate sweep rate axes. $R_s = 10\ \Omega$, $R_p = 1000\ \Omega$, $C = 1000\ \mu F$, $E_m = 0.020V$.

Analysis of Experimental Data

The essential features of the procedure for analyzing experimental data are illustrated by reference to the SACV's for corroding 90:10 Cu:Ni alloy in flowing seawater shown in Fig. 5. The experimental details of this work will be published in a subsequent paper (9). Comparison of these curves with those calculated theoretically (Fig. 2) shows that the responses are qualitatively similar, in that both exhibit hysteresis between the forward and reverse sweeps, and both show exponential-type relaxation phenomena at the start of the scans in both directions.

Plots of $1/R_{app}$ and $1/R_d$ against sweep rate for 90:10 Cu:Ni alloy in flowing seawater are shown in Fig. 6. These curves agree with the theoretical prediction that the plots should be approximately parabolic (Eq. [42] and [45]), and that $1/R_d$ is more dependent on sweep rate than is $1/R_{app}$. In both cases, extrapolation to zero sweep rates yields the same value of $1316 \pm 25\Omega$ for $R_s + R_p$. The dependence of the hysteresis current, ΔI, on sweep rate, is shown in Fig. 7. Again, the theoretical prediction of an approximately parabolic function that extrapolates to $\Delta I = 0$ for vanishingly small sweep rates is observed. The gradient of the ΔI *vs.* v plot at v $= 0$ is related to the values of the equivalent circuit components through Eq. [46]

$$(d\,\Delta I/dv)_{v\to 0} = 2R_p^2C/(R_p + R_s)^2 \quad [46]$$

Assuming that $R_p >> R_s$ (see below), this expression yields an interfacial capacitance of $2500 \pm 200\ \mu F$.

The validity of the values for R_p and C as determined by SACV can be assessed by comparison with data obtained by the more conventional a-c impedance technique (1). Typical impedance diagrams for 90:10

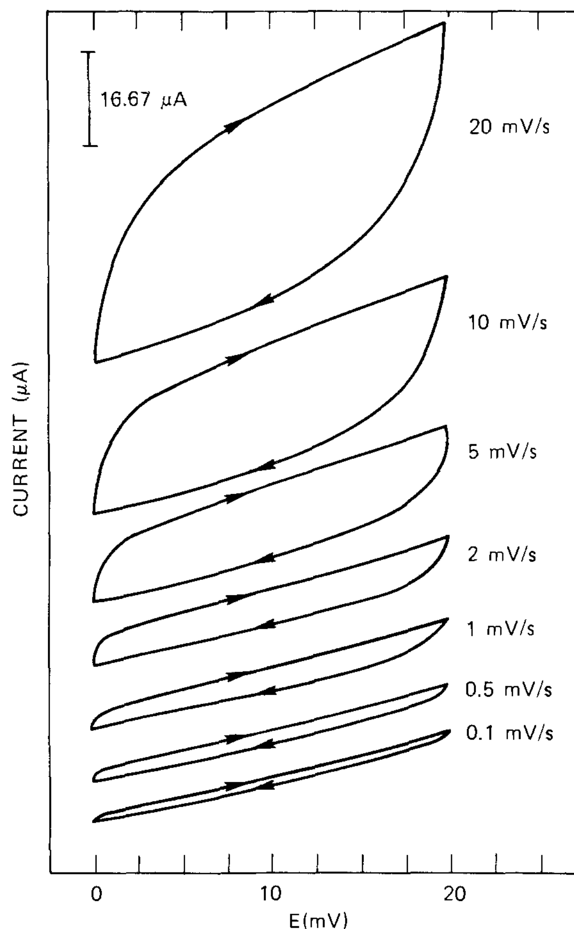

Fig. 5. Small-amplitude cyclic voltammograms for 90:10 Cu:Ni alloy in flowing seawater. Flow velocity = 1.62 m/sec; $[O_2]$ = 0.045 mg/liter; specimen area = 11.05 cm^2; T = 26°C; exposure time = 50 hr.

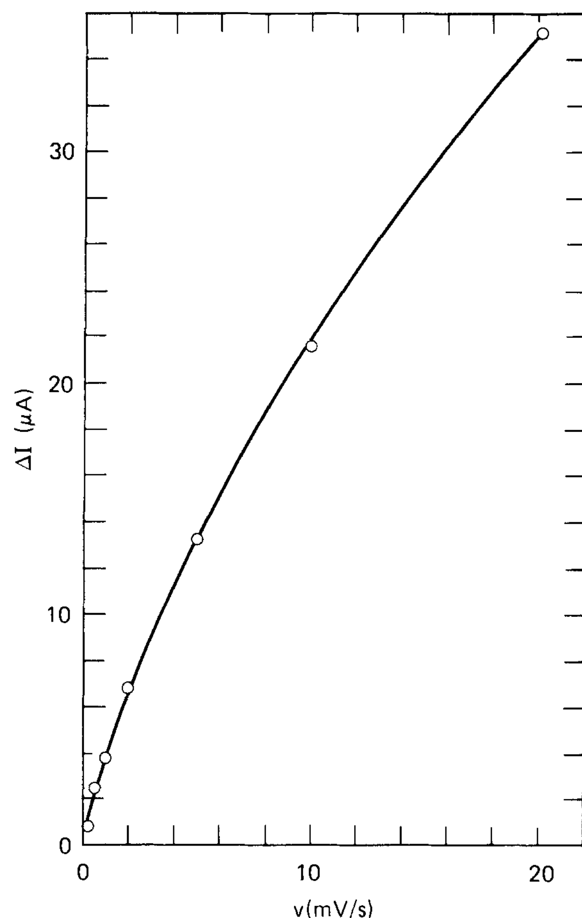

Fig. 7. Plot of Eq. [43] for 90:10 Cu:Ni alloy in flowing seawater. Experimental conditions as listed in Fig. 5.

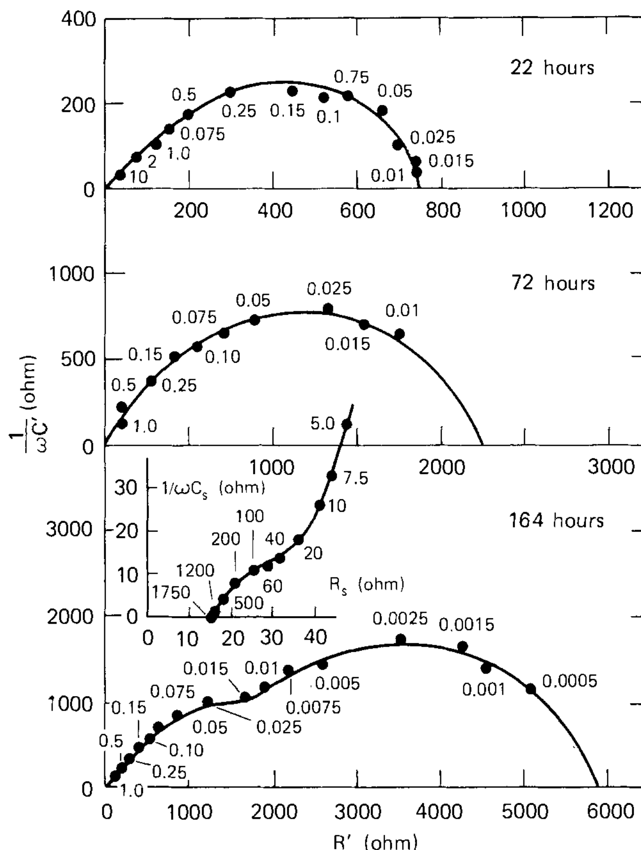

Fig. 8. Complex plane-impedance diagrams for 90:10 Cu:Ni alloy in flowing seawater as a function of exposure time. Experimental conditions as listed in Fig. 5. Numbers next to each point refer to frequency in Hz.

Cu:Ni alloy in the same experiment at three different exposure times are shown in Fig. 8. These data were obtained by analysis of the Lissajous figures generated by simultaneously imposing the sinusoidal excitation voltage and response current across the X and Y axes, respectively, of an oscilloscope (frequency > 1 Hz) or fast-response X-Y recorder (frequency < 1 Hz) (1, 9). For all three exposure times, the impedance plots take the form of distorted semicircles, or combinations of semicircles. At sufficiently low frequency, all the impedance diagrams exhibit partially resolved semicircular plots, as expected for dominance of the impedance by a single relaxation process having an equivalent circuit of the type adopted in this theoretical analysis (Fig. 1a). Other relaxation processes are evident at higher frequencies, as shown clearly by the impedance diagram for the longest exposure time. Thus, semicircles with maxima at $\sim$ 0.025 and $\sim$ 60 Hz are evident, in addition to the low frequency semicircle with its maximum at $\sim$ 0.0025 Hz. We have obtained extensive impedance data for both 90:10 and 70:30 Cu:Ni alloy in flowing seawater as a function of oxygen and sulfide concentrations. The analyses of these diagrams will be presented in a later publication (9).

In all three cases shown in Fig. 8, the impedance plots extrapolate at high frequency to very small values for the real component R', as expected for small values for the series resistance, R_s. The low frequency intercept with the real axis is equal to the impedance of the d-c path; that is, equal to $R_s + R_p$. Furthermore, the frequency (ω) at which the semicircle is at a maximum is given by

$$\omega = 1/R_pC \qquad [47]$$

Thus, substitution for R_p in Eq. [47] using the low frequency intercept with the real axis permits an estimate to be made of the interfacial capacitance.

A comparison of the values for $R_s + R_p$ and C, as derived by use of the a-c impedance and the SACV techniques is shown in Fig. 9. Excellent agreement is obtained between both experimental methods, thereby demonstrating the usefulness of SACV for investigat-

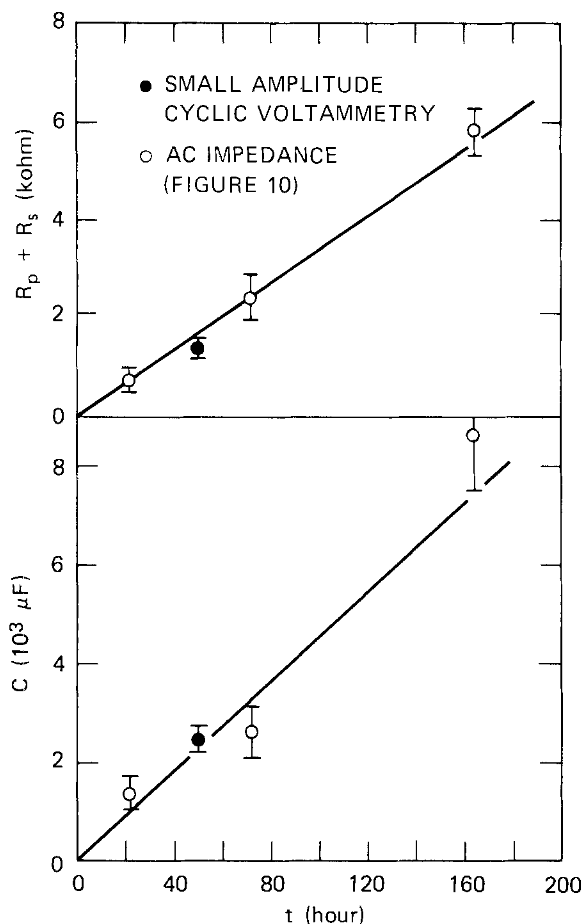

Fig. 9. Variation of $R_p + R_s$ (upper plot) and C (lower plot) with exposure time for corroding 90:10 Cu:Ni alloy in flowing seawater. Experimental conditions as listed in Fig. 5.

ing the impedance properties of a metal/solution interface. Interestingly, the capacitances measured in this work for 90:10 Cu:Ni alloy in flowing seawater are much larger than the expected double layer capacitance (200-400 μF for a specimen area of 11 cm^2) and increase with time. The observed values presumably reflect pseudocapacitance associated with the deposition of a surface film (1).

At this point it is worthwhile to comment upon the relative merits of the SACV and a-c impedance techniques for measuring corrosion rates for metals in condensed media. Although the SACV technique is used extensively in corrosion research, and indeed forms the basis of an ASTM recommended practice for measuring polarization resistance, the present work demonstrates that a full impedance interpretation of the data is very complex, even if only a single relaxation is assumed to occur at the interface. Contrariwise, the a-c impedance technique provides a powerful method for not only estimating the polarization resistance, but also for mechanistic investigations by analysis of the form of the complex plane plot (10). Nevertheless, it is likely that the SACV technique will continue to be used extensively for routine measurement of polarization resistance because of the experimental simplicity and because for many systems the SACV response at low voltage sweep is almost entirely resistive in character.

ABSTRACT

The hydrolysis of chromium (III) in molten LiCl-KCl eutectic has been studied by varying the ratio of H_2O to HCl vapor pressure in equilibrium with the melt using cyclic voltammetry at a glassy carbon indicator electrode. The initial process is a reversible hydrolysis to form an electroactive species, believed to be $CrCl_5(OH)^{-3}$, followed by slower polymerization reactions culminating in the irreversible formation of an insoluble phase. Raising the temperature from 450° to 500°C causes the initial reversible hydrolysis to be less pronounced, and to increase the rate of the subsequent irreversible processes.

In view of the difficulty of completely dehydrating molten LiCl-KCl eutectic, the behavior of water is of special interest. Hydrolytic decomposition during melting according to the reaction

$$H_2O + Cl^- \rightleftharpoons HCl + OH^- \quad [1]$$

is suppressed by gaseous HCl and promoted by substances such as metal ions or acidic oxides which react with OH^- or $O^=$ ions to form soluble species or insoluble phases. Fusion of a moist salt mixture in glass or silica vessels leads to an instantaneous etching, which can be prevented by pumping off most of the water from the solid salts and fusing under dry HCl atmosphere (1). Previous studies of water in LiCl-KCl melts have been concerned with measurement of its dissociation constant (2) and with the effect of moisture on the mechanism of the cathodic reduction of chromate (3, 4). In the latter work, it was found that no etching of glass occurred in the presence of moisture if excess HCl was present.

Previous studies of the chromium (III)-chromium (II) system have included a measurement of the reversible potential (5), steady-state voltammetry (6), and cyclic voltammetry (7). In the latter study, the first reduction step was interpreted in terms of a rapid charge-transfer reaction

$$Cr^{+3} + e^- \rightleftharpoons Cr^{+2} \quad [2]$$

followed by a slow precipitation of $CrCl_2$

$$Cr^{+2} + 2Cl^- \rightarrow CrCl_2 \quad [3]$$

This mechanism appears implausible, in view of the fact that our previous potentiometric and voltammetric work (5, 6) had been carried out with solutions of chromium (II).

Spectrophotometric studies of $CrCl_3$ have indicated an octahedral coordination to produce $CrCl_6^{-3}$ in LiCl-KCl eutectic at temperatures of 392° and 444°C (8) and also in molten CsCl at temperatures of 650°-750°C (9). Divalent ions such as Ni(II), Co(II), Cu(II) were found to have tetrahedral coordination, corresponding to $MCl_4^=$. Gruen and McBeth (10) found that V(III) and V(II) in LiCl-KCl melts showed octahedral coordination at 400°, while at higher temperatures a transition to tetrahedral coordination took place. Accordingly, it appeared probable that the first step of electroreduction should best be written

$$CrCl_6^{-3} + e^- \rightleftharpoons CrCl_6^{-4} \quad [4]$$

and the second, slow step as the dissociation reaction

$$CrCl_6^{-4} \rightarrow CrCl_4^{-2} + 2Cl^- \quad [5]$$

The simplest hydrolysis reaction of Cr(III) may be written

$$H_2O + CrCl_6^{-3} \rightleftharpoons CrCl_5(OH)^{-3} + HCl \quad [6]$$

By equilibrating an inert carrier gas with aqueous HCl solution, a variable ratio of p_{HCl}-p_{H_2O} could be maintained in the gas phase, and correspondingly the concentration ratio of HCl to H_2O could be varied in the solution phase.

The present investigation was carried out using cyclic voltammetry to monitor the progress of reaction [6] and subsequent polymerization reactions to produce an insoluble product.

Experimental

Reagents.—The LiCl-KCl eutectic was obtained from Anderson Physics Laboratories, Incorporated, Urbana, Illinois, where it was prepared and purified by the method outlined by Laitinen *et al.* (1).

Anhydrous $CrCl_3$ was prepared by heating $CrCl_3$ (Research Organic/Inorganic Chemical Corporation) to 650°C in a stream by CCl_4 vapor (11). The product was refined further by sublimation between 700°-750°C in an anhydrous HCl gas (12). The other chemicals were used without further purification.

Electrodes.—Platinum reference electrodes and spectroscopic grade graphite counterelectrodes were used as in previous studies (13).

Glassy carbon electrodes (Beckwith Carbon Corporation) were used as working electrodes. Rods of 3 mm (1/8 in.) diam were sealed into Pyrex by two techniques which were evaluated by measurements of double layer capacity and steady-state residual currents and by cyclic voltammetry of the purified solvent. For comparison, measurements of the same type were carried out with a platinum flag electrode having a geometrical area of about 16 mm^2. The glassy carbon

* Electrochemical Society Active Member.

Key words: chromium, molten salts, hydrolysis.

electrodes, designated as GCE-I and GCE-II, were prepared as follows.

GCE-I.—A glassy carbon rod, provided with a knotted platinum contact wire at one end, was placed in a Pyrex glass tube, closed at one end, and provided with a thin-walled section slightly larger than the carbon rod. By lowering the pressure at the open end and heating the thin-walled section to the softening point, the rod was coated with glass, taking care to avoid bubbles at the carbon-glass interface. The thin-walled section was strengthened by welding it into a commercial glass tube, again under reduced pressure, and pulling off the thick-walled tube in the flame. After cooling in an oven maintained at 160°C, the end was cut off to expose the flat circular cross section of the glassy carbon which was polished to a mirror finish using fine alumina powder on a glass plate. The electrode was stored in an oven regulated at 160° until its use in electrochemical experiments, because glassy carbon has a coefficient of thermal expansion close to that of Pyrex glass at temperatures above 100°C (14).

GCE-II.—To improve the seal between glassy carbon and Pyrex glass, the rod was first treated with a silica coating, prepared by soaking in 20% sodium silicate solution, drying in an oven at 160°C, exposing it to dry HCl gas at 200° for 30 min, washing with deionized water several times to remove NaCl, and dehydrating by heating to red heat. The rod was treated in this manner five times and then sealed into Pyrex using the same technique as described above for GCE-I.

Apparatus.—Double layer capacity measurements were made with a Wayne Kerr Universal Bridge B221 using 1000 Hz signal source. A Universal Programmer Model 175 (Princeton Applied Research Corporation) was used as a potential source, a 241 A Oscillator (Hewlett-Packard) as an a.c. sine wave source, and a Type 1232, A Tuned Amplifier and Null Detector (General Radio Company) as a zero detector were used.

Cyclic voltammetric scan waves were obtained with a Polarographic Analyzer Model 174A (Princeton Applied Research Corporation) coupled to a Universal Programmer PAR (Model 175), and the current-voltage curves were recorded on a Moseley Model 7000 AM X-Y Recorder (Hewlett-Packard).

Procedure.—All electrochemical experiments were performed at 450°C. A Hevi-Duty MK 3012-S Vertical Split Tube Furnace (Hevi-Duty Electric Company) was used. The temperature was regulated with a Wheelco Panel-Mount Capacitrol Temperature Controller (Wheelco Instrument Company). The procedures employed for cleaning glassware and handling the molten salt with special glass devices were described in detail by Johnston (15). The melt solution of Cr(III) was prepared by dissolving a known weight of anhydrous $CrCl_3$ in the molten LiCl-KCl eutectic saturated with dry HCl gas.

Moist HCl gas was prepared by passing Ar gas through a series of two gas washing bottles fitted with fritted glass dispersion tubes to assure equilibrium between aqueous HCl and carrier gas (3). Concentrations of H_2O and HCl were expressed in terms of their partial pressures in Ar gas, using tabulation of the partial pressures in equilibrium with aqueous solutions at various temperatures (16). For the three aqueous HCl concentrations, 12, 11, and 10*M*, the values of p_{H_2O}/p_{HCl} were, respectively, 0.0173, 0.0467, and 0.134 at 30°C.

After replacing the gas in the cell containing the melt with moist HCl gas by blowing at least 30 min, it was bubbled into the melt for the desired time. After termination of an electrochemical experiment, the salt was dissolved in deionized water. The volume of melt was calculated from the amount of chloride ion determined by argentometry and the density.

Research and Discussion

Evaluation of glassy carbon electrodes.—Measurements of double layer capacity revealed that GCE-I showed an apparent differential capacitance of the order of 100 ± 20 $\mu F/cm^2$ over a potential range of 0–−1.6V *vs.* 1*M* Pt(II)/Pt. At more negative potentials the capacitance gradually increased several-fold evidently because of faradaic processes. In comparison, GCE-II showed a much lower capacitance, of the order of 40 ± 10 $\mu F/cm^2$ over the same potential range, once more increasing without apparent limit at potentials more negative than −1.6V.

Cyclic voltammetry and steady-state residual current measurements likewise indicated lower blanks for GCE-II, presumably because the silica layer provided superior bonding to glass. Both types of measurements indicated a useful potential range of 0–−1.8V for GCE-II. The residual current was slightly anodic at potentials near zero *vs.* Pt, presumably because of a slow anodic oxidation of the carbon surface, in agreement with the observation of Levy and Reinhardt (7).

Cyclic voltammetry of chromium(III) in dry HCl.—Cyclic voltammetry experiments were carried out at 450°C at three concentrations of Cr(III) prepared by the addition of anhydrous $CrCl_3$ to melts saturated with HCl gas at seven voltage scan rates ranging from 1.000 to 0.010 V/sec. Typical voltammetric curves are shown in Fig. 1.

Plots of the cathodic peak current *vs.* square root of the voltage scan rate were linear through zero. The diffusion coefficients of Cr(III) calculated from the slopes of these plots ranged from 0.8 to 1.0 × 10^{-5} cm^2 sec^{-1}, somewhat larger than those reported by Levy and Reinhardt (7).

The ratios of cathodic to anodic peak currents were measured for each scan, using the empirical expression developed by Nicholson (17)

$$i_a/i_c = i_{ap}/i_{cp} + 0.485\, i_{sp}/i_{cp} + 0.086 \qquad [7]$$

when i_{ap} and i_{cp} are the measured anodic and cathodic

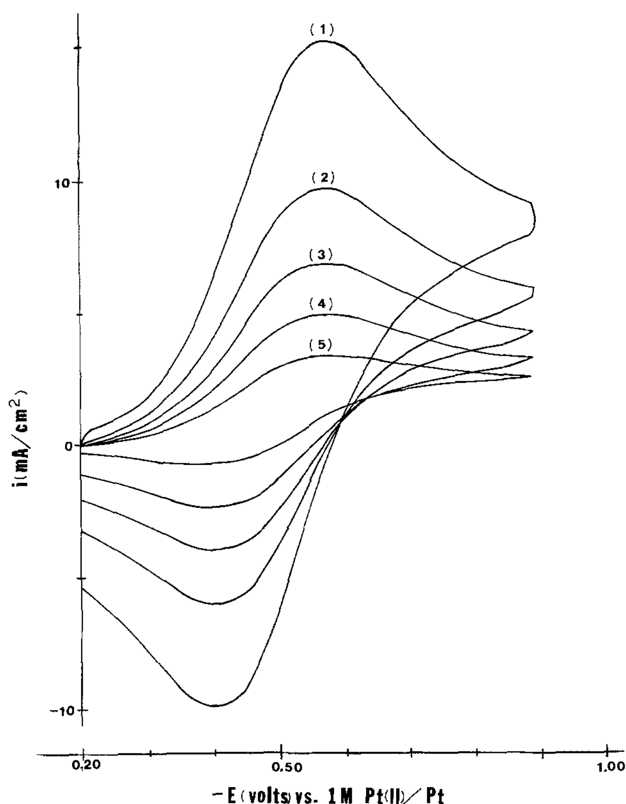

Fig. 1. Cyclic voltammograms for reduction of Cr(III) to Cr(II) in melt solution saturated HCl gas. Curve (1) Voltage scan rate of 0.500 V/sec; curve (2) 0.200 V/sec; curve (3) 0.050 V/sec; curve (4) 0.020 V/sec; curve (5) 0.010 V/sec.

peak currents and i_{sp} is the cathodic current at the switching potential. The values of i_a/i_c plotted against voltage scan rate are shown in Fig. 2. In agreement with the observations of Levy and Reinhardt (7), the ratio i_a/i_c is near unity at high scan rates ($0.10 < V < 1.00$) and decreases with decreasing scan rate at lower scan rates ($0.01 < V < 0.10$). The peak separation ΔE_p between cathodic and anodic peaks was close to the theoretical value of 140 mV, indicating a reversible charge transfer reaction. The variation of i_a/i_c indicates a relatively slow chemical step following charge transfer. This slow step was interpreted by Levy and Reinhardt in terms of the formation of "insoluble" $CrCl_2$, with a rate constant of 0.028 sec^{-1} at 500°C. In view of the spectrophotometric evidence cited above, and in view of our experience in preparing solutions of Cr(II) by electrochemical reduction of Cr(III), we prefer to write Eq. [4] and [5] to represent the electrode process in a dry melt.

Confirmation of a soluble Cr(II) species in dry melts was provided by carrying out a coulometric titration of Cr(III) by electrolytic reduction at constant current (5, 18), using a glassy carbon electrode as a cathode and interrupting the current periodically to register a potentiometric titration curve. Such a titration curve, for 26 mM Cr(III), in comparison with the theoretical curve, is shown in Fig. 3.

The two curves show close similarity during the first 2/3 of the titration, but no endpoint could be detected.

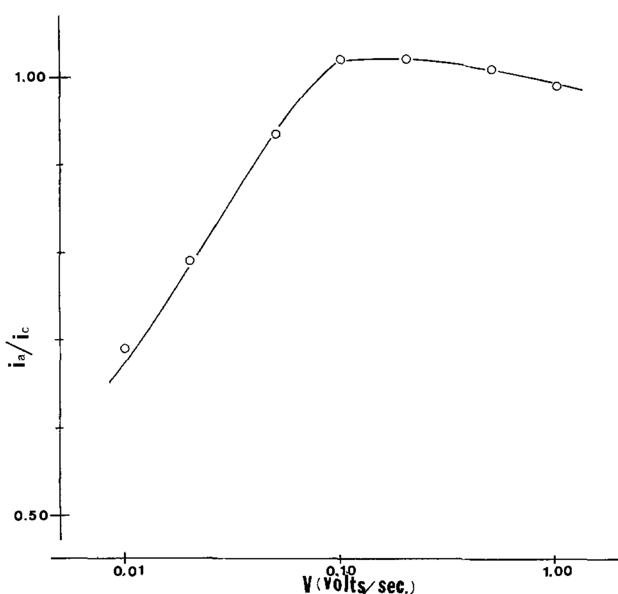

Fig. 2. Anodic to cathodic peak current ratio (i_a/i_c) vs. voltage scan rate (V) for melt solution saturated HCl gas.

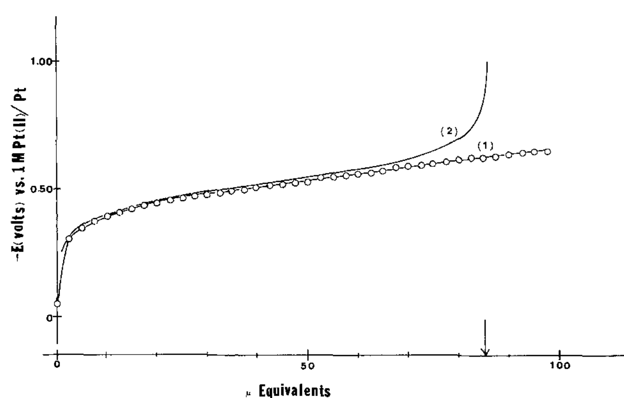

Fig. 3. Potentiometric titration curve for reduction of Cr(III) to Cr(II). Amount of Cr(III) added shown by arrow. Curve (1) Titration curve of 85.3 μequiv. Cr(III) in 3.3 ml melt solution; curve (2) Titration curve calculated theoretically.

To ensure that no hydrolysis of Cr(III) could occur, the melt was continuously stirred by a stream of HCl gas bubbles during the titration. The lack of an endpoint is no doubt due to the fact that the reduction potential of HCl is close enough to that of Cr(III) (5, 19)

$$Cr(III) + e^- \rightleftarrows Cr(II),$$

$$E^\circ = -0.525V \text{ vs. } 1M \text{ Pt(II)/Pt} \quad [8]$$

$$2HCl + 2e^- \rightleftarrows H_2 + 2Cl^-, \; E^\circ = -0.694V \quad [9]$$

so that quantitative reduction of Cr(III) could not be achieved before some HCl reduction took place. A color change corresponding to reaction [8] could be observed near the equivalence point although the potential change was obscured by mixed potential behavior.

Cyclic voltammetry of chromium(III) in moist HCl. —To determine the effect of moisture on the electrochemical behavior of the Cr(III)-Cr(II) couple, a series of cyclic voltammograms was run, varying the ratio of p_{H_2O}/p_{HCl} by equilibrating the Ar carrier gas with 12, 11, and 10*M* aqueous HCl, and using dry HCl gas as a comparison. The curves shown in Fig. 4 were run after bubbling for 20 min in each experiment. It is evident that the principal change is a marked lowering of the peak currents of both the cathodic and anodic branches.

By varying the voltage sweep rate, it was found that the cathodic peak current was proportional to the square root of sweep rate (Fig. 5), as would be expected for an essentially reversible mass-transport controlled process. We are led to the conclusion that an increasing fraction of the electroactive Cr(III) species is converted to an electrochemically inactive species by hydrolysis. We believe that the first step of hydrolysis

$$CrCl_6^{-3} + H_2O = CrCl_5(OH)^{-3} + HCl \quad [10]$$

is reversible and does not lead to an electroinactive species, but that subsequent polymerization reactions

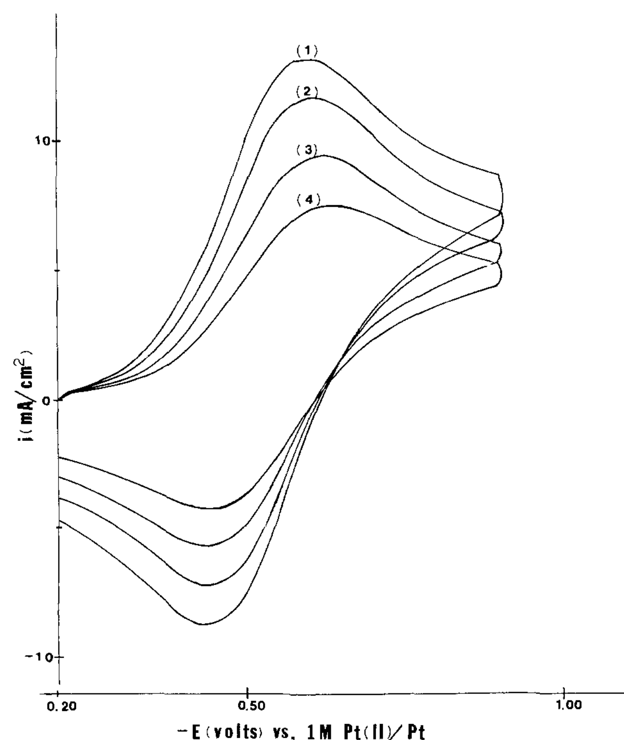

Fig. 4. Cyclic voltammograms for reduction Cr(III) to Cr(II) in melt solution equilibrated with dry HCl gas and moist HCl gas for 20 min. a) Voltage scan rate of 0.500 V/sec. Curve (1) Bubbling dry HCl gas; curve (2) bubbling moist HCl gas-I (12*M* HCl); curve (3) bubbling moist HCl gas-II (11*M* HCl) curve (4) bubbling moist HCl gas-III (10*M* HCl).

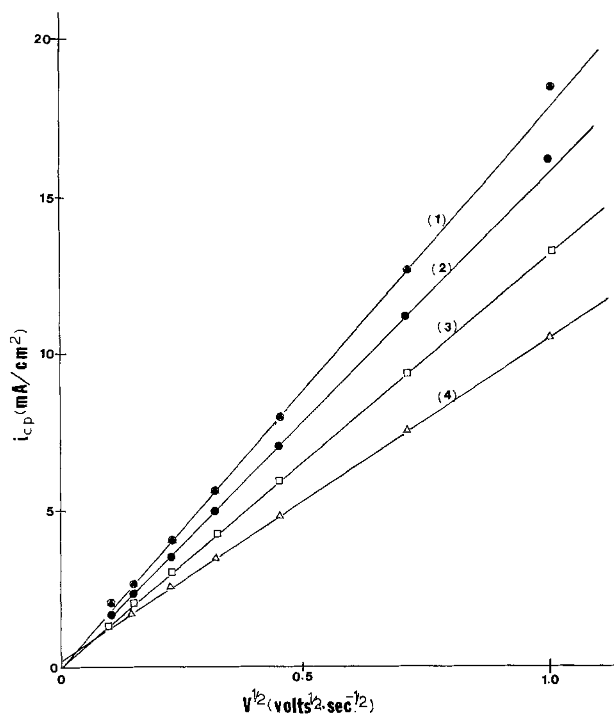

Fig. 5. Cathodic peak current (i_{cp}) vs. square root of voltage scan rate ($v^{1/2}$) for melt solution equilibrated with dry and moist HCl gases. Curve (1) Dry HCl gas; curve (2) moist HCl gas-I (12*M* HCl); curve (3) moist HCl gas-II (11*M* HCl); curve (4) moist HCl gas-III (10*M* HCl).

form bridged species such as through irreversible reactions

$$2CrCl_5(OH)^{-3} \rightarrow [Cl_5Cr\text{-}O\text{-}CrCl_5]^{-6} + H_2O \quad [11]$$

The final product would be an insoluble oxychloride of Cr(III).

To look for evidence for a slower charge-transfer reaction such as

$$CrCl_5(OH)^{-3} + e^- = CrCl_5(\dot{O}H)^{-4} \quad [12]$$

in a moist solution, we calculated the charge transfer rate constant k_s as well as a first order rate constant k_f for the homogeneous chemical reaction subsequent to the primary charge transfer (reaction [4]). These parameters, calculated for four melt treatments are presented in Table I. The apparent decrease in D actually reflects a decrease in concentration, as mentioned above, whereas the changing k_s indicates a slower effective charge-transfer rate due to a greater participation of Eq. [12] as compared with Eq. [4] with increasing moisture content.

It was of interest to run a few experiments at 500°C, to allow a direct comparison with the work of Levy and Reinhardt (7) and to compare the hydrolysis effects at the two temperatures. Preliminary experiments showed a relatively rapid precipitation upon equilibration with 10*M* HCl, so this condition was omitted. The results are presented in Table II.

Comparing the two tables, we can conclude that the first hydrolysis reaction is less pronounced at 500° than at 450°C, evidently because of the lower solubility of water in relation to HCl. However, the subsequent irreversible polymerization reactions are more rapid at 500°C. This is illustrated by the effect of a short Ar flush, which results in a rapid change in calculated D and k_s due to the removal of HCl.

Table I. Calculated parameters of Cr(III) reduction in LiCl-KCl eutectic treated with dry and moist HCl gases for 20 min at 450°C

Treatment	$D \times 10^5$ (cm²/sec)	k_f (sec⁻¹)	k_s (cm/sec)
dry HCl	0.81	0.009	0.052
12*N* HCl	0.72	0.012	0.050
11*N* HCl	0.52	0.013	0.026
10*N* HCl	0.33	0.014	0.022

Table II. Calculated parameters of Cr(III) reduction in LiCl-KCl eutectic treated with dry HCl and moist HCl gas for 30 min at 500°C

	$D \times 10^5$ (cm²/sec)	k_f (sec⁻¹)	k_s (cm/sec)
dry HCl	0.92	0.021	0.098
12*N* HCl	0.85	0.018	0.022
11*N* HCl	0.85	0.014	0.095
dry Ar flush, 10 min	0.33	0.016	0.039

Comparing the data with dry HCl treatment at 500°C with those of Levy and Reinhardt, we observed a k_f value close to theirs, but larger D and k_s values. These differences imply that their experiments were done in the presence of a trace of moisture.

The polymerization reaction.—At 450°C in moist melts, it was found that a relatively rapid change in peak current and kinetic parameters occurred during the first 20 min, as described above, and that subsequent changes occurred much more slowly. These changes ultimately lead to the appearance of a solid phase, at a rate increasing with moisture content. The irreversible nature of this slow reaction was demonstrated by returning from the moist HCl to dry HCl bubbling. Instead of the voltammetric curves returning to their original heights, the peak continued to decrease in height.

A similar experiment at 500°C, in which the solution that had been flushed with dry Ar after equilibration with 11*M* HCl was treated with dry HCl gas, showed increased calculated values of D and k_s, but the recovery was not complete even after 2 hr. We conclude that the hydrolysis reactions can be reversed at higher temperature but the reverse reactions are quite slow.

The Electrochemical Behavior of Selenium and Selenium Compounds in Sodium Tetrachloroaluminate Melts

J. Robinson and R. A. Osteryoung*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

The electrochemistry of selenium and various selenium compounds in $AlCl_3$:NaCl melts has been investigated by a variety of techniques including pulse and cyclic voltammetry, coulometry, and the rotating-disk electrode. It was found that selenium can be reduced, in both acid and basic melts, by a single two-electron step to selenide which exists in the melt as either AlSeCl or $AlSeCl_2^-$ (or their analogous solvated species $Al_2SeCl_5^-$ and $Al_2SeCl_6^{2-}$) depending upon the acidity. The mechanism for the oxidation of selenium to Se(IV) was found to be dependent upon the melt acidity. In basic melts, selenium was first oxidized by a two-electron step to an Se(II) species and then by a further two-electron step to Se(IV). In acid melts the oxidation was a single quasireversible four-electron step. The reduction of Se(IV) to selenium was a single four-electron step at all melt acidities. The kinetics of these oxidation and reduction processes were investigated extensively. From studying $SeCl_4$ solutions, it was found that there were two Se(IV) species in the melt, $SeCl_6^{2-}$ and $SeCl_5^-$, linked by the acidity-dependent equilibrium

$$SeCl_5^- + Cl^- \rightleftarrows SeCl_6^{2-}$$

for which the equilibrium constant was calculated to be $6.0 \pm 1.0 \times 10^3$ on the mole fraction scale.

In recent years there has been considerable interest in the use of fused-salt media as electrolytes for high energy density batteries and fuel cells. In view of this, there have been several papers dealing with the electrochemical behavior of chalcogens and their compounds in these systems. Sulfur has been studied in a variety of these molten salts including most recently sodium tetrachloroaluminate, both in this laboratory (1) and by Mamantov and co-workers (2, 3). Studies of selenium are, however, much fewer. Bodewig and Plambeck (4) have investigated its electrochemistry in fused LiCl-KCl melts and observed that it undergoes oxidation and reduction to Se_2Cl_2 and Se^{2-}, respectively, while Shimotake and Cairns (5) have investigated a Li/Se battery using a ternary eutectic of LiF, LiCl, and LiI as the electrolyte. Recently, while screening cathode materials for use in an $AlCl_3$:NaCl battery, Marassi *et al.* (2) studied the electrochemistry of Se. They ran cyclic voltammograms on a saturated solution of Se in a 63-37 mole percent (m/o) $AlCl_3$:NaCl melt at a platinum electrode and observed a quasireversible oxidation couple close to the anodic limit of the melt and a reduction process at about 1V *vs.* an Al wire in the melt. They also observed a second, irreversible, reduction wave that appeared only on platinum electrodes. No coulometric studies were undertaken in this study; therefore, it is unknown what the reaction products were.

This latter paper appears to be the only published electrochemical study of Se in tetrachloroaluminates. There have, however, been a few studies of stabilization of low oxidation states of Se in these melts. It has been established that the large anions, $AlCl_4^-$ and $Al_2Cl_7^-$, present in acid tetrachloroaluminates are capable of stabilizing low oxidation states of metals such as Cd_2^{2+}, Sn_2^{2+}, Pb^+, and cluster cations of Te (6, 7), and recently Bjerrum *et al.* (8) identified a variety of low oxidation state species of Se such as Se_4^{2+}, Se_8^{2+}, Se_{12}^{2+}, and Se_{16}^{2+}. These were observed spectrophotometrically in mixtures of Se and $SeCl_4$ in acid tetrachloroaluminate melts and the natures of the species were found to be dependent upon the relative amounts of Se and Se(IV) present. Corbett *et al.* (9) have also studied similar systems, Se-($SeCl_4$ + $AlCl_3$) mixtures, and have identified the species Se_4^{2+} and Se_8^{2+} as being present.

Selenide anions are known to exhibit interesting chemistry in $AlCl_3$:NaCl melts. Metal oxides and chalcogenides have been observed to react with $AlCl_3$ in closed tubes at temperatures around 300°C to yield the species AlOCl (10), AlSCl (10), AlSeCl (11), and AlTeCl (12) as the products of reactions such as

$$AlCl_3 + ZnSe \rightleftarrows AlSeCl + ZnCl_2 \quad [1]$$

In a recent study in this laboratory (13), it was shown that similar reactions occur in acidic $AlCl_3$:NaCl melts where the oxide and chalcogenide ions behave as tribases reacting with the melt to yield the same species. In basic melts these anions were shown to be dibases and the product of reaction with the melt was then a species such as $AlSeCl_2^-$. The relative strengths of the tribases were found to be

$$Te^{2-}, Se^{2-} < S^{2-} < O^{2-}$$

The papers discussed above are the only published studies of selenium and its compounds in tetrachloroaluminate melts. This paper is concerned with the electrochemistry, principally at 175°C, of these species with particular attention being given to its acidity de-

pendence. In order to examine this the acid-base properties of the solvent must be fully understood. The three principal equilibria linking the major species present are (14)

$$2AlCl_3(l) \rightleftarrows Al_2Cl_6(l) \quad K_o = 2.86 \times 10^7 \quad [2]$$

$$AlCl_4^- + AlCl_3 \rightleftarrows Al_2Cl_7^- \quad K_2 = 2.4 \times 10^4 \quad [3]$$

$$2AlCl_4^- \rightleftarrows Al_2Cl_7^- + Cl^- \quad K_m = 1.06 \times 10^{-7} \quad [4]$$

where K_o, K_2, K_m are the mole fraction equilibrium constants at 175°C. The dominant acid-base equilibrium is that described by Eq. [4] with Cl^- as the Lewis base and $Al_2Cl_7^-$ the Lewis acid. The pCl$^-$ of the neutral melt, 50 m/o $AlCl_3$, is 3.5 on the mole fraction scale; however, a melt of any desired acidity can be made (15) by anodizing an Al wire into the melt until the desired value, as indicated by an aluminum wire electrode, is reached.

Experimental

Melt preparation and purification.—The preparation of pure NaCl-saturated $NaAlCl_4$ melts by the preelectrolysis of a molten mixture of $AlCl_3$ (A. G. iron-free Fluka) and an excess of NaCl(A. C. S. Fisher) between two aluminum electrodes has been described elsewhere (15). After purification, a sample of the melt was filtered through a medium porosity frit to remove any excess NaCl or suspended aluminum particles and was then transferred to the small Pyrex glass experimental cell.

The melt preparation and all subsequent electrochemical experiments were performed in a dry box (Vacuum Atmospheres Company) under an argon atmosphere. This dry box was fitted with a purification system (Vacuum Atmospheres dri-train HE 193-2) that recycled the atmosphere through activated copper and molecular sieves to remove oxygen and water, respectively. The level of oxygen in the atmosphere was determined by burning a 25W tungsten lamp filament (General Electric Company) exposed to the atmosphere (16). A bulb lifetime of several days, indicating an atmosphere containing around 1 ppm of oxygen, was considered satisfactory.

Experimental cells and electrodes.—The cells were made of Pyrex glass, with a volume of approximately 75 cm^3, and had a fitted Teflon cap. This cap was drilled to facilitate the mounting of the secondary- and reference-electrode compartments, which consisted of fine porosity frits mounted on Pyrex glass tubes, the thermocouple well, and the working electrode. The working electrode compartment could readily be stirred using a glass-coated magnetic stirrer bar. The assembly was mounted in a tube furnace and the temperature was maintained within ± 1°C by a controller (Thermo-Electric Model 32422) in conjunction with a Chromel-Alumel thermocouple.

For all experiments, the reference electrode was a coiled aluminum wire (Alfa Inorganics m5N) immersed in an NaCl-saturated melt at 175°C. Throughout this paper, all potentials are referred to this electrode. The secondary electrode was also a coiled aluminum wire.

The electrodes in the voltammetric studies were either tungsten (1/8 in. diam Alfa Inorganics m3N8) or vitreous carbon (3 mm diam Atomergic Chemetals V25 or 2.5 mm diam Tokai GC 30), mounted in Pyrex glass. These were ground flat on an emery wheel and then polished to a mirror-like finish using alumina (Type B Fisher). Rotating-disk studies were carried out on a vitreous carbon disk electrode (5 mm diam Tokai GC 30) mounted and prepared in the same way as the above electrodes. This electrode was rotated by a servocontrolled motor-tachometer (Pine Instrument Company Type ASR 2), the rotation rate of which could be controlled between 50 and 10,000 rpm with an accuracy of greater than 1%.

Exhaustive controlled potential coulometry was carried out in either a tungsten crucible (Research Organic/Inorganic Chemical Corporation W120) or a vitreous carbon crucible (Atomergic Chemetals Company V25-16) used both as the cell and working electrode. Adequate mass transport was achieved by stirring with a glass-coated magnetic stirring bar and the total charge passed in these experiments was measured by a coulometer (Acromag Incorporated).

Electrochemical instrumentation.—All cyclic voltammetry and rotating-disk studies were made with a multipurpose instrument (17) constructed in this laboratory and the data were recorded on an X-Y recorder (Hewlett Packard Model 7046A). Pulse voltammetric studies were performed on a pulse polarograph (PARC Model 174), modified (18) to permit parametric studies. The melt acidity was adjusted by the anodization of an aluminum wire (Alfa Inorganics m5N) into the melt using a constant current source (Sargent Model IV coulometric current source) as has been discussed previously (13).

Chemicals.—Na_2Se (Cerac Pure, Incorporated), Na_2SeO_4, Na_2SeO_3, $SeCl_4$, and Se_2Cl_2 (Alfa Inorganics) were all used without further purification. The most readily soluble type of selenium was found to be the red amorphous form, presumably due to its structure, long chains, as compared to the ring structure of the vitreous form. This was prepared by reducing a solution of Na_2SeO_3 in 9M HCl with SO_2 (Matheson Gas Products) (25). The red precipitate was then filtered and washed, dried with diethyl ether, and finally dried under a vacuum.

Results and Discussion

A cyclic voltammogram of 1.18×10^{-3}M selenium in an NaCl saturated melt at 175°C is shown in Fig. 1. It can be seen that there is a reduction peak at 0.880V on the cathodic going sweep from the electrode rest potential. On the return sweep there is a very slight shoulder at about 0.950V followed by a peak at 1.140V; there are then two oxidation peaks close to the anodic limit of the melt, at 1.88 and 2.02V. Finally, on the return sweep there is a peak at 1.80V. Successive sweeps are identical to the first. Figure 2 is a cyclic voltammogram of a solution of sodium selenide, also in an NaCl saturated melt, showing the same features as Fig. 1. As the acidity is increased, Fig. 2b and 2c, the behavior changes significantly. The peaks previously seen at 0.880 and 1.140V in an NaCl-saturated melt move together and also in an anodic direction while the features close to the anodic limit of the melt change considerably. The cyclic voltammogram in the most acid

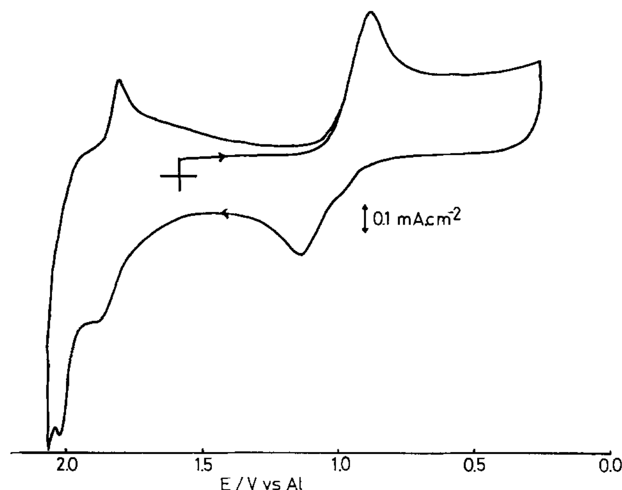

Fig. 1. Cyclic voltammogram of Se in NaCl-saturated melt (pCl = 1.9) at a glassy carbon electrode. Temperature = 175°C; sweep rate = 100 mV sec^{-1}; concentration of Se (as monomer) 1.18 mM.

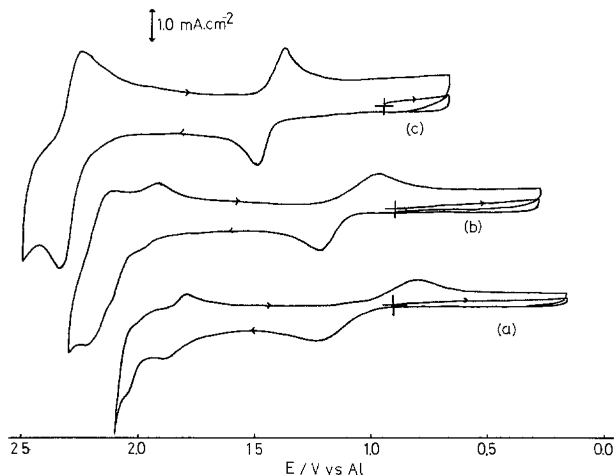

Fig. 2. Cyclic voltammogram of 3.6 mM Na_2Se at a glassy carbon electrode. Temperature = 175°C; sweep rate = 200 mV sec^{-1}. Melt pCl. (a) 1.9; (b) 2.9; and (c) 5.2.

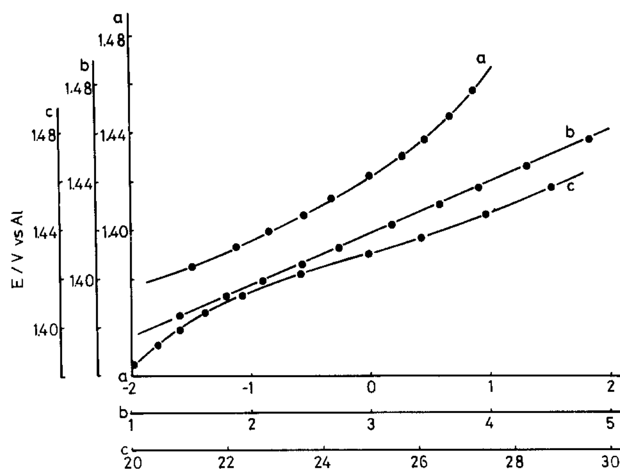

Fig. 3. Nernst plots for various Se/Se^{2-} redox couples at a pCl of 5.7 and at 175°C using a glassy carbon electrode. The units of the abscissa are (a) $\log_{10}[Se]/[Se^{2-}]$; (b) $\log_{10}[Se_2]/[Se^{2-}]^2$; and (c) $\log_{10}[Se_8]/[Se^{2-}]^8$.

melt, Fig. 2c, closely resembles that observed by Marassi *et al.* (2) for selenium on a platinum electrode in an acid melt, except that the second selenium reduction peak seen on platinum is not seen here, either for a vitreous carbon or tungsten electrode. The voltammograms shown here were all made with a vitreous carbon electrode. The behavior of a tungsten electrode was, however, very similar except that selenium, as evidenced by the shape of the cyclic voltammetric peak, appeared to adsorb strongly. For this reason all subsequent work was carried out at a vitreous carbon electrode.

To facilitate this discussion the electrochemistry of selenium is considered in two parts. The first deals with the selenium reduction, observed at 0.880V in an NaCl-saturated melt, and the subsequent oxidation of the product, which, as is shown later, is the selenide ion. The second part considers the oxidation of selenium to selenium cations and their reduction back to selenium.

The selenium-selenide couple.—Exhaustive constant potential coulometry was performed on a solution of selenium in both basic and acidic melts at a potential corresponding to the diffusion plateau of the reduction peak. It was found that for basic melts (pCl = 1.9) 2.03 ± 0.05 electrons/selenium atom were passed, while the corresponding value in an acidic melt (pCl = 6.0) was 1.99 ± 0.05. A cyclic voltammogram of the resulting solution was identical to that of a solution of sodium selenide. In the same way, sodium selenide was oxidized by a two-electron step to give a solution behaving like a solution of selenium. It can therefore be concluded that selenium is reduced by a two-electron step to selenide which itself can be oxidized back to selenium, again by a single two-electron transfer.

To obtain more information about the nature of the selenium and selenide species in the melt, the dependence of the equilibrium potential of a vitreous carbon indicator electrode on the concentrations of selenium and selenide ion present was investigated. A solution of known concentration of sodium selenide was prepared in a vitreous carbon crucible. A small amount of the selenide ion was then oxidized to selenium using the crucible as a working electrode and the rest potential of the indicator electrode was measured. The concentrations of selenium and selenide ion were readily determined from the number of coulombs passed. This procedure was repeated many times until all the selenide had been oxidized to selenium. The potential of the crucible was then changed and the selenium was reduced, in a stepwise fashion, back to selenide with equilibrium potential measurements again being made.

Figure 3 shows three attempts at fitting this data to possible redox reactions. Curve (a) corresponds to the plot for the equilibrium

$$Se + 2e^- \rightleftarrows Se^{2-} \quad [5]$$

curve (b) to

$$Se_2 + 4e^- \rightleftarrows 2Se^{2-} \quad [6]$$

and curve (c) to

$$Se_8 + 16e^- \rightleftarrows 8Se^{2-} \quad [7]$$

It can immediately be seen that while plots (a) and (c) are curved, plot (b) is a straight line and furthermore, its slope is 22 mV which is in agreement with the value predicted, 22.3 mV at 175°C, by the Nernst equation for this process

$$E = E^\circ + 2.303 \frac{RT}{3\mathbf{F}} \log \frac{[Se_2]}{[Se^{2-}]^2} \quad [8]$$

This implies that the potential determining selenium species is the dimer Se_2, as was observed previously for the sulfur-sulfide couple (1). The above data were obtained in an acidic melt (pCl = 5.7); however, similar results, indicating the Se_2 dimer to be the potential determining species, were obtained for all the melt acidities investigated (pCl = 1.9-6.0). This is perhaps surprising in view of the fact that Se_2 is not normally stable except as a vapor at temperatures greater than 900°C. The thermodynamically stable form of selenium at 175°C is the gray form, which consists of long chains (15) between 10^3-10^4 units long. This is not, however, known to be soluble in any solvents. At room temperature there are two unstable allotropes, both of which consist of puckered Se_8 rings. These forms, which are soluble in several solvents such as CS_2, rapidly convert to the gray form on heating. Since the temperature of the melt is above this transition temperature, any Se added will rapidly convert to the gray form; the melt must then have the effect of splitting off Se_2 groups which it stabilizes. This probably explains the very slow solubilization of Se observed in this present work.

These potentiometric experiments were carried out at a range of melt acidities and it was found that the standard potential for the couple showed a very strong dependence on the pCl. This observation has been discussed in an earlier paper (13), and, as outlined in the introduction to this study, is due to the basic properties of the selenide ion. In melts more acidic than a pCl of 3.5, on the mole fraction scale, the selenide ion behaves as a tribase and reacts with the acid species in the melt, $Al_2Cl_7^-$, to form the species AlSeCl, or, more probably, the solvated species $Al_2SeCl_5^-$. Similarly, in basic melts the selenide ion behaves as a dibase and is present either as $AlSeCl_2^-$ or $Al_2SeCl_6^{2-}$. The redox reaction should therefore be written as

$$Se_2 + 4e^- + 2AlCl_4^- \rightleftarrows 2AlSeCl + 6Cl^- \quad [9]$$

in acid melts, and

$$Se_2 + 4e^- + 2AlCl_4^- \rightleftarrows 2AlSeCl_2^- + 4Cl^- \quad [10]$$

in basic melts.

It has been shown (1) that the basic properties of the sulfide ion result in very high solubilities of metal sulfides, for example CuS, in acidic melts. Very similar behavior was observed for selenides; in a 60 m/o $AlCl_3$:NaCl melt the solubility of CuSe was found to be 0.32M. Oxides and tellurides were also found to be solubilized to the same degree, which suggests that acidic tetrachloroaluminate melts may have some application in the processing of metal ores.

The oxidation of selenide ions, or more precisely the species AlSeCl and $AlSeCl_2^-$, to selenium was investigated initially by pulse voltammetry. Figure 4 shows such a pulse voltammogram in an NaCl-saturated melt. The first wave is due to the oxidation of selenide to selenium and there is also a slight indication of waves due to the oxidation of selenium, as observed in cyclic voltammetry (Fig. 1 and 2a). These latter waves, however, are very small. The first wave, when analyzed by the method of Oldham and Parry (20), yielded a linear plot from which αn_α was calculated to be 0.59. The limiting current for the wave also showed a linear dependence on selenide ion concentration, and the diffusion coefficient of the diffusing species, probably the solvated form of $AlSeCl_2^-$, was calculated to be $2.3 \pm 0.2 \times 10^{-6}$ cm^2 sec^{-1}. While the position of the wave was strongly dependent upon the pCl of the melt, the values of αn_α and D were, despite the change in the nature of the selenide species, independent of the acidity.

Pulse voltammetry proved to be a fairly successful technique for investigating the kinetics of the oxidation process; however, the method of choice is the use of the rotating-disk electrode (RDE). Very large currents are obtained for low concentrations of electroactive material and, since the measurements are made at a steady state, there is no charging current adding to the background.

Figure 5 shows some results of a series of RDE experiments carried out on a solution of sodium selenide. These plots were obtained by sweeping the electrode potential at a rate of 2 mV sec^{-1} at various fixed rotation rates. A plot of the diffusion current, measured at a steady state, as a function of the square root of the rotation rate, $\omega^{1/2}$, is a straight line at all melt acidities, indicating that the oxidation of selenide is diffusion controlled. The diffusion current also varies linearly with the concentration of sodium selenide. From the i vs. $\omega^{1/2}$ plots, the diffusion coefficient of the selenide species is readily calculated (21) and values at a range of melt acidities are shown in Table I. These are in close agreement with the values obtained earlier from the pulse voltammetry and are independent of the melt acidity.

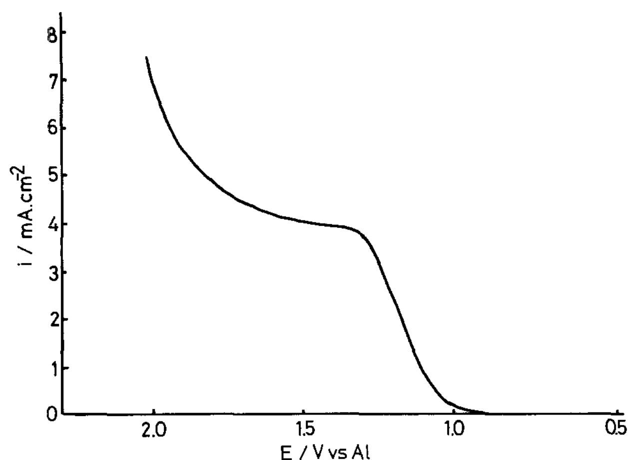

Fig. 4. Normal pulse of 5.2 mM Na_2Se at a glassy carbon electrode. Melt pCl = 1.9; pulse width 48 msec; sweep rate 5 mV sec^{-1}; temperature = 175°C.

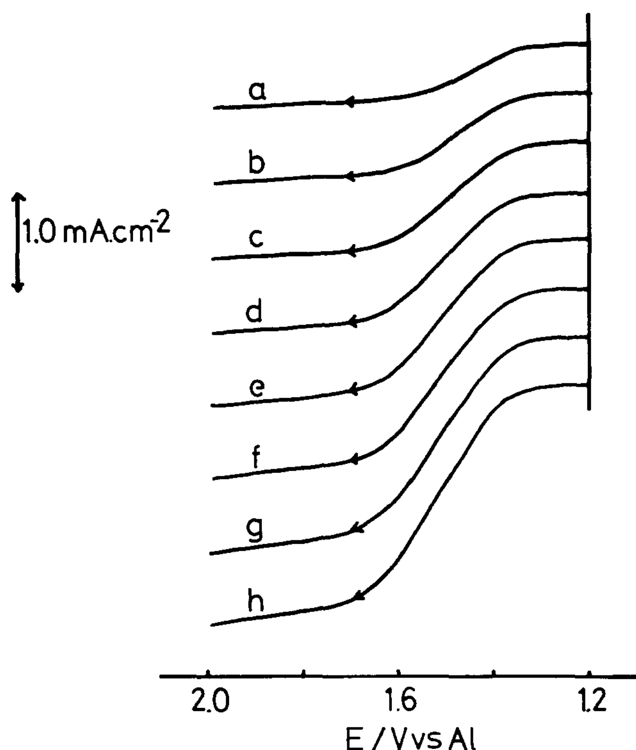

Fig. 5. RDE experiment for 2.06 mM Na_2Se at a glassy carbon electrode. Melt pCl = 4.5; rotation rates are (a) 400; (b) 900; (c) 1600; (d) 2500; (e) 3600; (f) 4900; (g) 6400; and (h) 8100 rpm; temperature = 175°C.

The rising portions of the plots in Fig. 5 are fairly drawn out; this behavior is typical of a process for which the rate is being controlled by a slow electron transfer, and the rate constant for this step can be determined (21). Figure 6 shows a kinetic plot ($1/i$ vs. $1/\omega^{1/2}$) for a sodium selenide solution under the same conditions as Fig. 5, the steady-state currents at various potentials within the rising portion of the waves being determined for a range of rotation rates. The plots are a series of parallel lines as would be expected for a slow electron-transfer step. If these lines are extrapolated to where $\omega^{-1/2}$ equals zero, that is to an infinite rotation rate, the intercept on the y-axis then corresponds to the pure kinetically controlled current since the rate of mass transfer is infinite. From these intercepts the forward rate constant can be calculated, and Fig. 7 shows a plot of $\log_{10} \vec{k}$ vs. potential. This plot is a straight line and the value of αn_α can be calculated from the slope. Knowing the value of the standard potential, E_o, from potentiometry, the standard rate constant, $k_o^\ominus$, can be determined. The values of $k_o^\ominus$ and αn_α obtained

Table I. Kinetic parameters and diffusion coefficients, obtained from RDE experiments, for oxidation of Na_2Se at 175°C

at various pCl's are given in Table I. The values of αn_α are independent of pCl and are in good agreement with those calculated from pulse voltammetry. The values of k_0^Θ show a slight increase with melt acidity.

It was observed earlier on the cyclic voltammograms of sodium selenide (Fig. 2) that the peaks corresponding to the reduction of selenium and the subsequent reoxidation of selenide moved closer with increasing pCl; that is, the reaction appeared to become more reversible. The RDE experiments, however, show that changing the pCl has only a slight effect on the rate of oxidation of selenide, certainly not enough to account for the apparent increase in reversibility. The observed decrease in peak separation must, therefore, be due to the increased acidity affecting the reduction of selenium. Both pulse voltammetry and RDE experiments were attempted as a means of investigating this, but no kinetic information could be obtained as selenium was found to adsorb slightly at the vitreous carbon electrode. This adsorption, which is greatest in basic solutions, can also be seen on cyclic voltammograms (Fig. 1) where the reduction peak for selenium is higher and sharper than the corresponding oxidation peak.

Interesting qualitative information was, however, obtained from the temperature dependence of the cyclic voltammetry of selenium solutions. Figures 8a, 8b, and 8c show cyclic voltammograms at 175°, 225°, and 275°C, respectively, of a selenium solution with all the potentials adjusted to the same reference electrode; an Al wire in an NaCl-saturated melt at 175°C. The melt used was of fixed composition, that of an NaCl-saturated melt at 175°C. The increase in temperature, therefore, caused a reduction in the melt acidity due to the increased dissociation of $AlCl_4^-$. These pCl changes were, however, much too small to account for the gross changes observed on the cyclic voltammograms. The selenium reduction potential changes from approximately 0.840V at 175°C to 0.985V at 225°C and to 1.090V at 275°C. The corresponding selenide oxidation potentials are 1.16, 1.13, and 1.15V. Thus, it can be seen that, within experimental error, the position of the selenide oxidation peak hardly changes with temperature, while the selenium reduction potential moves anodically 250 mV for a temperature increase of 100°C, the peak separation decreasing from 320 to 60 mV, which is close to the value for a two-electron reversible process at 75°C (54 mV). The most probable explanation for this behavior is that there is a chemical step involved in the reduction, the rate of which is greatly affected by temperature. One such possible chemical step could be the monomerization of the selenium dimer. The apparent increase in reversibility as the pCl is increased, Fig. 2a, 2b, and 2c, may also be explained by the increased rate of the same chemical step.

At this point, it should be mentioned that the nature of the slight shoulder seen at about 0.950V on an anodic going sweep of a selenium solution, Fig. 1 and 8a, is uncertain, though it may be associated with the selenium adsorption discussed earlier. It only appears on cyclic voltammograms in the most basic melts and disappears as the temperature is increased, Fig. 8b and 8c.

The electrochemical oxidation of selenium and the behavior of selenium cations.—From Fig. 1 and 2 it can be seen that the oxidation of selenium and the reduction of the products of this oxidation are fairly

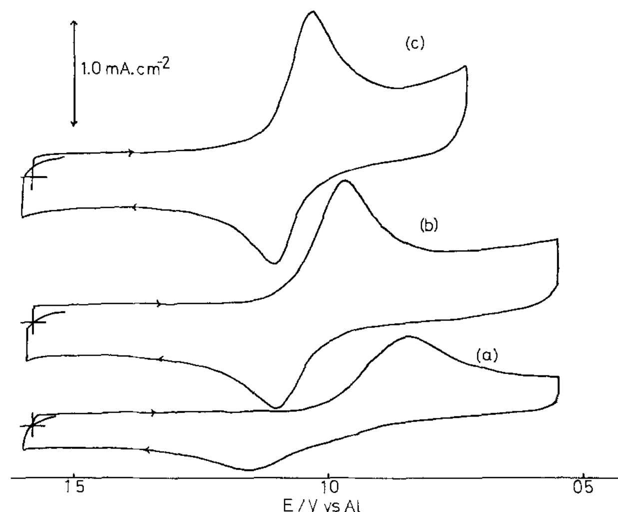

Fig. 8. Cyclic voltammogram of 1.18 mM Se (as monomer) in a basic melt (NaCl saturated at 175°C) at a glassy carbon electrode. Sweep rate = 200 mV sec^{-1}. Temperature (a) 175°C; (b) 225°C; (c) 275°C.

complex in these melts. Considering first the behavior in the most basic solutions, there are two rather poorly defined oxidation peaks for selenium at 1.88 and 2.02V with a corresponding reduction wave at 1.79V. If the potential scan is reversed after the first oxidation peak, there is still a single reduction wave at 1.79V. In order to determine the over-all stoichiometry, exhaustive coulometry was carried out on a selenium solution in a vitreous carbon crucible. If the coulometry was performed at about 1.9V in an NaCl-saturated melt (pCl = 1.9) a total of 2.03 ± 0.05 electrons/selenium atom were passed to yield an Se(II) species. Continued coulometry at about 2.05V gave a further two electrons, after correction for the background current which was rather large due to the proximity of the anodic limit of the melt. The final oxidation product, therefore, appears to be an Se(IV) species. These coulometry experiments could be carried out fairly rapidly (about 15 min each), and therefore no problem of product volatility was encountered. When potentiometric measurements were made on these couples, it was found that both the Se(IV) and Se(II) species were slowly lost from the melt, the latter being lost more rapidly. It was, therefore, not possible to make any Nernst plots. As it was found the Se(IV) was the highest oxidation state of selenium as formed $SeCl_4$ was added to the melt. A cyclic voltammogram of a solution of this showed all the same features as one of selenium or sodium selenide, and coulometry at about 1.7V showed that 4.1 ± 0.05 electrons were passed for each molecule of $SeCl_4$ added. Sodium selenite behaved in exactly the same way as $SeCl_4$, showing the high affinity of the melt for oxide ions (13). Sodium selenate, when added to the melt, first evolved chlorine and then behaved as $SeCl_4$ while Se_2Cl_2 appeared to decompose when added to the melt.

As the pCl is increased, Fig. 2b, the situation becomes more complex. The oxidation peaks formerly at 1.88 and 2.02V and the reduction peak at 1.79V are all still present but have shifted in the anodic direction and there is now a new oxidation wave at 2.19V with its corresponding reduction wave at 2.14V. As the acidity is increased further, Fig. 2c, the picture simplifies, there being a single oxidation peak and corresponding reduction peak. Coulometry at such an acidity shows that both the oxidation and reduction are four electron steps. It is therefore clear that, as in basic melts, the highest oxidation state formed is Se(IV), but the oxidation of selenium to Se(IV) now goes by a different route.

The cyclic voltammetry of an $SeCl_4$ solution of intermediate pCl, such as the pCl of Fig. 2b (pCl = 2.9) shows two reduction waves. However, if coulometry is carried out on the first wave at about 2.1V four electrons/$SeCl_4$ molecule are passed with the formation of a solution of selenium. It therefore appears that there are two Se(IV) species in the melt linked by a pCl-dependent equilibrium. This is supported by the fact that the more anodic wave grows at the expense of the other as the melt is made more acidic. The equilibrium constant for this equilibrium is calculated later from RDE results. The oxidation of selenium in very basic melts can therefore be summarized as the oxidation to Se(II) and then to an Se(IV) species followed by the subsequent four-electron reduction back to selenium. This changes in acid melts to a single quasireversible four-electron oxidation to a different Se(IV) species while at intermediate acidities both mechanisms are seen to operate.

Attempts to investigate more closely the oxidation of selenium in basic melts by either pulse voltammetry or RDE's proved fruitless. This was due in part to the proximity of the waves to the anodic limit of the melt but principally to the fact that the currents observed for these processes were very much less than would be predicted for a diffusion-controlled process. It can be concluded from this that either a very slow electron-transfer step is occurring or more probably that there are chemical steps involved in these processes. From the cyclic voltammetry it can be seen that the peaks for the Se-to-Se(II) and Se(II)-to-Se(IV) oxidations both move in an anodic direction as the acidity increases, indicating that chloride ions are involved in both these steps. It is a reasonable assumption, therefore, that both the Se(II) and Se(IV) species are chloro-complexed. It was observed that the cyclic voltammetry peak potentials for the reduction of solutions of Se(IV) and Se(II) (prepared by potentiostatic oxidation of a Se solution) were identical (1.79V at a pCl of 1.9). This suggests that the Se(II) species undergoes a chemical step prior to reduction, either a disproportionation into Se(IV) and Se or, alternatively it is a polymeric species that undergoes decomposition to Se(IV) and Se. Such a chemical step is supported by the observation that the acidification of Se(II) solution with $AlCl_3$ results in the formation of Se and Se(IV) by either a disproportionation or decomposition mechanism. Similar instability of the Se(II) ion to disproportionation is observed in fluoroacetic acid solutions (22).

In contrast to the behavior of basic melts, the oxidation of selenium in acid melts is readily studied, and Fig. 9 shows a normal pulse voltammogram at a pCl of 5.23 at three pulse widths. Plots of the diffusion current *vs.* $1/t^{1/2}$ and concentration are both linear, indicating the process to be diffusion controlled, and the diffusion coefficient of selenium was calculated to be $3.0 \pm 0.3 \times 10^{-6}$ cm^2 sec^{-1}.

The reduction of Se(IV) was studied using an RDE, and Fig. 10 shows a series of slow voltage scans, at fixed rotation rate, for three pCl values. In the most basic melt there is a very small wave followed by a much larger one, but as the acidity is increased the first wave grows at the expense of the other until in the most acid melts there is only one wave. This type of behavior is identical to that seen in the cyclic voltammetry and is attributed to there being two Se(IV) species in an acid-dependent equilibrium. At all pCl's the relative heights of the two waves are independent of the rotation rate and of the Se(IV) concentration, which indicates that the interconversion of the two species is slow and that there is no difference in the degree of polymerization between them. The diffusion current for the wave in the most acid melt varies linearly with $\omega^{1/2}$ and Se(IV) concentration, showing the reduction to be diffusion-controlled and the diffusion coefficient of the Se(IV) species was calculated to be 6.9 ± 10^{-6}

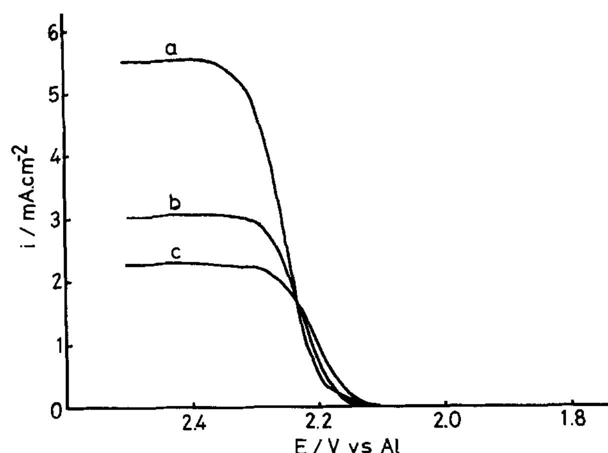

Fig. 9. Normal pulse voltammograms for the oxidation of 1.78 mM Se (as monomer) at a glassy carbon electrode in an acid melt (pCl = 5.25); temperature = 175°C. Pulse widths (a) 20 msec; (b) 50 msec; (c) 100 msec.

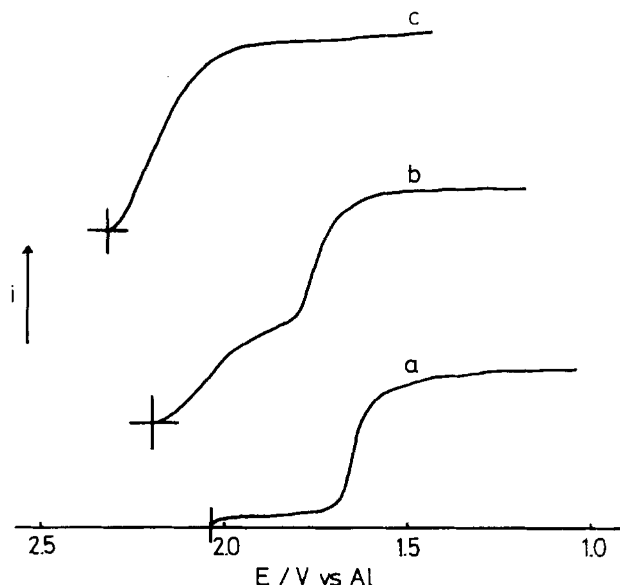

Fig. 10. RDE experiments for the reduction of Se (IV) at a glassy carbon electrode. Rotation rate = 4900 rpm; temperature = 175°C; pCl = (a) 1.9; (b) 3.5; (c) 5.8.

$cm^2\ sec^{-1}$. The reduction wave was analyzed in the same way as the oxidation of Na_2Se and αn_α was calculated to be 0.70. The standard potential for the process is not known, so k_o^Θ could not be calculated. The rate constant at the rest potential, 2.32V, was, however, determined and was found to be 4.8×10^{-4} cm sec^{-1} at a *p*Cl of 5.8. The reduction process in a basic melt was analyzed in the same way. The process was found to be diffusion controlled and by assuming that the value of *D* calculated for the acid-favored Se(IV) species did not vary with *p*Cl. The diffusion coefficient of the species favored in basic melts was found to be 1.94×10^{-6} $cm^2\ sec^{-1}$, αn_α was calculated to be 0.36, and the rate constant at the rest potential (2.04V) in an NaCl-saturated melt (*p*Cl = 1.9) was determined to be 3.8×10^{-4} cm sec^{-1}.

Knowing the diffusion coefficients for both Se(IV) species and the heights of the two waves at various *p*Cl's it was possible to fit the data to various equilibria and the one that appears to operate is shown below

$$Se(IV)(Cl)_z{}^{(4-z)+} + Cl^- \rightleftarrows Se(IV)(Cl)_{z+1}{}^{(3-z)+} \quad [11]$$

with an equilibrium constant of $6.0 \pm 1.0 \times 10^3$ on the mole-fraction scale. From other studies in chloride-rich media (23) it was found Se(IV) is usually present as the hexachloro complex. The probable equilibrium in the present case is therefore

$$SeCl_5^- + Cl^- \rightleftarrows SeCl_6^{2-} \quad [12]$$

though comparable equilibria between $SeCl_5^-$ and $SeCl_4$ or $SeCl_5$ and $SeCl_3^+$ cannot be ruled out.

The stoichiometry of the electrochemical oxidation of selenium and reduction of selenium cations in $AlCl_3$:NaCl melts can be summarized as follows

(a) In acid melts

$$Se_2 + 10Cl^- \rightleftarrows 2SeCl_5^- + 8e^- \quad [13]$$

(b) In basic melts

$$nSe_2 + 2yCl^- \rightarrow 2Se_nCl_y{}^{(y-2n)-} + 4ne^- \quad [14]$$

$$Se_nCl_y{}^{(y-2n)-} + (6n-y)Cl^- \rightarrow nSeCl_6^{2-} + 2ne^- \quad [15]$$

$$2SeCl_6^{2-} + 8e^- \rightarrow Se_2 + 12Cl^- \quad [16]$$

where the values of *n* and *y* are either zero or integral.

It is interesting that no evidence is found for the formation of polymeric selenium cations during the oxidation of selenium in acidic melts where they have been observed spectrophotometrically (7). This may be due to the much lower concentrations used in the present work; in this present study the solubility of selenium (as the monomer) was found to be about 3×10^{-3}M, whereas in Bjerrum's study (8) the combined Se and $SeCl_4$ concentration was 10-100 times greater than this. It is, however, possible that the species of formal oxidation state +2 formed during oxidation of Se in basic melts is polymeric, though electrochemical studies of the reduction of Te(IV) in similar melts (24) suggest that $TeCl_3^-$ and $TeCl_2$ are the predominant Te(II) species present in this case and Se(II) might be expected to behave in a similar manner.

Mass Transfer to an Impinging Jet Electrode

D-T. Chin* and C-H. Tsang

Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

A study has been made of mass transfer to a circular disk electrode located in the stagnation region of an impinging jet. A semiempirical solution of a convective diffusion model is presented in the form of an asymptotic series to permit an estimate of the transfer rate for $0.7 \leq Sc < \infty$. Experimental results reveal that the electrode possesses a property of "uniform accessibility" to the diffusing species if the electrode radius is less than 1 nozzle diameter for turbulent jet and ½ nozzle diameter for laminar jet. Within this region, the mass transfer is relatively independent of radial positions, and the semiempirical correlations are presented for both laminar and turbulent flows over a range of nozzle heights from 0.2 to 6 nozzle diameters. The result indicates that the impinging jet electrode is a feasible tool for electroanalytical applications. This geometry can be easily adopted in process streams and closed systems at a pressure other than the ambient atmosphere.

The impinging jet electrode is commonly used in electrochemical machining, erosion corrosion, and other industrial processes. It is composed of a submerged circular jet of electrolyte incident on a flat plate normal to the direction of flow. The electrode is a circular disk embedded on the flat plate at the stagnation point as shown in Fig. 1. This geometry is attractive because of a high mass transfer rate.

The flow characteristics of the impinging jet has been extensively studied in the past two decades. A literature survey of the subject can be found in Ref. (1). When a submerged jet collides perpendicularly with a flat plate in a stationary electrolyte, there forms four distinct flow regimes as illustrated in Fig. 1: Region I is called the potential core region in which the velocity profile of the jet changes from pipe flow to a free jet flow. As the flow discharges from the submerged nozzle, the electrolyte in the jet starts to mix with the surrounding fluid. The mixing zone grows in width along the downstream direction of the jet. This leaves a conical potential core wherein the fluid property and the velocity are relatively constant. This core length varies from 4.7 to 7.7 nozzle diameters (1). Region II is the established flow region in which the velocity profile is well developed. In this region, the centerline velocity of the jet starts to decrease; its magnitude is inversely proportional to the distance from the nozzle exit and becomes zero near the stagnation point. This region covers a distance from the apex of the potential core to a height of 1.6 ~ 2.2 nozzle diameters from the surface of the flat plate (2). Region III is the stagnation region. This is a layer of fluid, about 1.6 ~ 2.2 nozzle diameters thick and 0.6 ~ 1.4 nozzle diameters in radius, on the flat plate in which the jet is deflected from the axial direction to a radial flow. The flow in this region is of an axisymmetric inviscid irrotational type, and the thickness of the boundary layer is relatively independent of the radial position near the stagnation point (2-3). According to Homann (4), the axial and the radial velocity components in the region can be described by $v = -2az$ and $u = ar$, respectively, where a is a hydrodynamic constant. Region IV is called the wall jet region. This is a region adjacent to the flat plate at some distance from the stagnation point where the radial velocity starts to decay and the thickness of the boundary layer increases with radial positions. The flow in this region can be divided into two sublayers. They are the inner layer where the flow is influenced by the wall and the outer layer where the flow is influenced by the surrounding fluid. The maximum velocity occurs at the boundary of the two sublayers; its magnitude is inversely proportional to the radial distance from the stagnation point (5).

Heat and mass transfer from the impinging jet to the flat plate has been studied by a number of investigators (6-19). Works published before 1973 were reviewed by Livingood and Hrycak (20). Most of these studies were confined to the low Schmidt numbers of less than 2.45. The local transfer rate at the flat plate has been found to depend on the nozzle Reynolds number of the fluid, Re, the Schmidt number of the diffusing species, Sc, the dimensionless nozzle height, H/d, and the dimensionless radial position from the stagnation point, r/d. In the wall jet region (7, 9-10, 16) the transfer rate is proportional to the nozzle Reynolds number raised to a power of 0.75 and is inversely proportional to the dimensionless radial position. In the stagnation region, the mass transfer rate depends on $Re^{1/2}$ (7-8, 14-16, 18, 20). Several experiments with evaporation of naphthalene to an air jet (6, 8) and dissolution of *trans*-cinnamic acid to a water jet (7, 10-11) have found that the local mass transfer rate in the stagnation region is relatively independent of the radial position for $r/d < 1$. The evidence is supported by the analyses of Sparrow and Lee (19), and Scholtz and Trass (8), who confirmed that mass transfer rate should be constant in the neighborhood of the stagnation point. This property is similar to mass transfer to a rotating disk where the local mass transfer rate is independent of the radial position in laminar flow (21). It appears that if one limits the electrode radius to less than 1 nozzle diameter, the

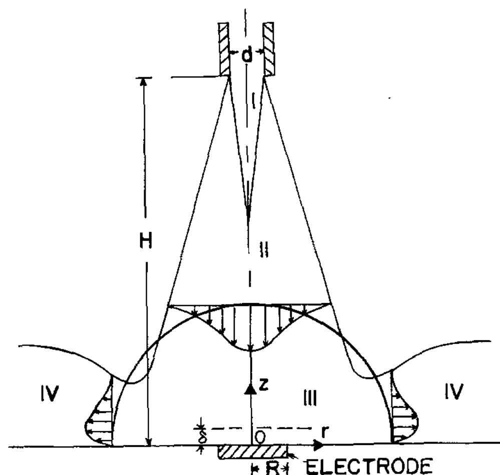

Fig. 1. The impinging jet electrode

* Electrochemical Society Active Member.

Key words: convective diffusion, limiting current, uniform accessibility.

system would possess a "uniform accessibility" to the diffusing species in the electrolyte, and a constant surface concentration could be maintained throughout the electrode. This particular feature would make the impinging jet electrode a useful tool for electroanalytical applications. It has the advantage over the rotating disk electrode that there is no mechanical movement and the electrode can be easily adopted to monitor the concentration of ionic species in a process stream.

Electrochemical study of the impinging jet has been made by Yamada and Matsuda (22) and Coeuret (23). Yamada and Matsuda measured the limiting current for the reduction of ferricyanide ions in the wall jet region. Coeuret's experiment was confined to an electrode size of $r/D = 0.5 \sim 3$; his empirical correlation basically confirmed the concept of uniform accessibility near the stagnation point.

In this study, a mathematical model is presented for mass transfer to a circular disk electrode located within the stagnation region of an impinging jet. The convective diffusion equation is solved with a perturbation method. The resulting rate equation expressed in the form of an asymptotic series of the Schmidt numbers is shown to be valid over a range of Sc from 0.7 to infinity. To determine precisely the region of uniform accessibility, a potassium ferricyanide/ferrocyanide system has been used to measure the limiting current density at the electrode for the reduction of ferricyanide ion. Mass transfer rates with both laminar and turbulent impinging jets are presented for a range of electrode radii varying from 0.02 to 6 nozzle diameters and for the nozzle heights from 0.2 to 6 nozzle diameters.

Analysis

This analysis is concerned with mass transfer to a circular disk electrode located within the stagnation of the impinging jet. Since there is a strong interaction between mass transfer and fluid flow, the latter is briefly considered here.

A mathematical solution describing the boundary layer flow in the stagnation region of a uniform flowing field incident on an infinite plate was first obtained by Homann (4). Homann's solution has been extended to the case of a uniform impinging jet by Schrader (24), who showed that there existed a boundary layer of a constant thickness having a radius of approximately 1.1 nozzle diameter in the stagnation region. The experiments with evaporation of naphthalene and dissolution of *trans*-cinnamic acid (6-11) also demonstrate that the mass transfer rate at the impinged surface is relatively uniform for $R/d < 1$. The measurements of velocity and pressure distributions (8, 25) have confirmed the existence of an inviscid flowing field just outside the boundary layer. According to Homann's axisymmetric stagnation flow (4), the radial and the vertical velocity components in this inviscid flowing field can be described by $u = ar$ and $v = -2az$, respectively. Here, the constant a is an unspecified hydrodynamic constant. For a nonuniform impinging jet (8), the radial velocity component in the inviscid flowing field becomes $u = ar + br^3 + \ldots$; however, in the neighborhood of the stagnation point, the series can be simplified to $u \sim ar$. Thus, Homann's inviscid solution is valid in the neighborhood of the stagnation point for both uniform and nonuniform impinging jets. Also, experimental evidences have indicated that Homann's solution is true whether the flow at the nozzle exit is laminar or turbulent. These different flow conditions are reflected by the different values of the hydrodynamic constant, a; they will not affect the mathematical derivation in this analysis.

Mathematical modeling.—For the simplicity of the analysis, we shall make the following assumptions: (*i*) The diffusion domain is confined to a region in which the boundary layer thickness is uniform; (*ii*) the cell diameter is large enough so that the effect of the cell wall on the flow boundary layer is negligible; (*iii*) the electrolyte flowing through the nozzle has the same physical properties as the surrounding electrolyte; (*iv*) the solution has sufficient inert salt to insure that the migration flux of the diffusing ion in the electric field can be neglected; (*v*) physical properties of the electrolyte are constant; and (*vi*) the effect of the gravitational force on the diffusion field is negligible. For a steady-state axisymmetric impinging jet, the system can be described by a cylindrical coordinate system with the origin located at the stagnation point as shown in Fig. 1. The coordinate, r, is the radial distance from the stagnation point, and z is the perpendicular distance from the electrode surface. Under the assumption of a uniform boundary layer thickness in the neighborhood of the stagnation point, there is no concentration variation in the radial direction. The steady-state convective diffusion equation for mass transfer in the diffusion domain takes the form

$$v\frac{dC}{dz} = D\frac{d^2C}{dz^2} \qquad [1]$$

with boundary conditions

$$\left.\begin{array}{ll} z = 0 & C = C_0 \\ z \to \infty & C = C_\infty \end{array}\right\} \qquad [2]$$

Here, v is the velocity component of the boundary layer flow in the z-direction; C and D are the concentration and the diffusivity of the diffusing ion.

To solve Eq. [1] and [2], v must be known. As mentioned in the foregoing paragraph, Homann's axisymmetric stagnation flow exists just outside the boundary layer in the stagnation region where the velocity components in the radial and the axial directions are given as $u = ar$ and $v = -2az$, respectively. For the flow inside the boundary layer, Homann (4) made an assumption that

$$u = ar\phi'(\eta), \qquad v = -2\sqrt{a\nu}\,\phi(\eta) \qquad [3]$$

Here, a is the unspecified hydrodynamic constant having a dimension of $\sec^{-1}$, u and v are the velocity components in the radial and axial directions, respectively; $\eta = \sqrt{a/\nu}\, z$ is a dimensionless variable; $\phi'(\eta)$ is the first derivative of a stream function $\phi(\eta)$ with respect to η; and ν is the kinematic viscosity of the electrolyte.

A dimensionless concentration may be defined as

$$\overline{C} = \frac{C - C_\infty}{C_0 - C_\infty} \qquad [4]$$

where C_∞ is the bulk concentration of the diffusion ion, and C_0 is the concentration at the electrode surface. Substituting Eq. [3]-[4] into Eq. [1]-[2], the convective diffusion equation can be reduced to a second-order ordinary differential equation

$$\frac{d^2\overline{C}}{d\eta^2} + 2\mathrm{Sc}\,\phi(\eta)\frac{d\overline{C}}{d\eta} = 0 \qquad [5]$$

with the boundary conditions

$$\left.\begin{array}{ll} \eta = 0 & \overline{C} = 1 \\ \eta \to \infty & \overline{C} = 0 \end{array}\right\} \qquad [6]$$

Here, Sc is the Schmidt number defined as $\mathrm{Sc} = \nu/D$.

To solve Eq. [5]-[6] analytically, one needs a mathematical expression for the stream function $\phi(\eta)$. Homann (4) obtained a power series solution of $\phi(\eta)$. An improved numerical solution was obtained by Froessling (26) and was tabulated in Schlichting (4). Using Froessling's results, the Taylor series expansion of the function $\phi(\eta)$ near the electrode surface, *i.e.*,

$\eta = 0$, can be found as

$$\phi(\eta) = 0.656\eta^2 - 0.16667\eta^3 + 3.6444 \times 10^{-3}\eta^6 - 3.9682 \times 10^{-4}\eta^7 + \ldots \quad [7]$$

Asymptotic solution.—The Schmidt numbers for electrochemical applications are high. In order to find a simple solution for the convective diffusion, Eq. [5]-[6], we carry out successive perturbations of the parameter, Sc. The procedures have been illustrated by Chin (27-31). Following the procedures, the concentration profile can be represented by an asymptotic series in the descending powers of Sc

$$\overline{C} = \overline{C}_0 + \frac{1}{Sc^{1/3}}\overline{C}_1 + \frac{1}{Sc^{2/3}}\overline{C}_2 + \frac{1}{Sc}\overline{C}_3 + \frac{1}{Sc^{4/3}}\overline{C}_4 + \frac{1}{Sc^{5/3}}\overline{C}_5 + \ldots \quad (\text{for } Sc >> 1) \quad [8]$$

Here, $\overline{C}_0, \ldots, \overline{C}_4$ and $\overline{C}_5$ are called the zeroth, ..., the fourth and the fifth-order concentrations, respectively. They are functions of a stretched coordinate, Z, defined as

$$Z = Sc^{1/3}\eta = Sc^{1/3}\sqrt{a/\nu}\,z \quad [9]$$

Substituting Eq. [7]-[9] into Eq. [5]-[6], and equating the terms having the like powers of Sc in the resulting equation, we have

$$\frac{d^2\overline{C}_0}{dZ^2} + 1.312Z^2\frac{d\overline{C}_0}{dZ} = 0 \quad [10]$$

$$\frac{d^2\overline{C}_1}{dZ^2} + 1.312Z^2\frac{d\overline{C}_1}{dZ} = 0.33333Z^3\frac{d\overline{C}_0}{dZ} \quad [11]$$

$$\frac{d^2\overline{C}_2}{dZ^2} + 1.312Z^2\frac{d\overline{C}_2}{dZ} = 0.33333Z^3\frac{d\overline{C}_1}{dZ} \quad [12]$$

$$\frac{d^2\overline{C}_3}{dZ^2} + 1.312Z^2\frac{d\overline{C}_3}{dZ} = 0.33333Z^3\frac{d\overline{C}_2}{dZ} \quad [13]$$

$$\frac{d^2\overline{C}_4}{dZ^2} + 1.312Z^2\frac{d\overline{C}_4}{dZ} = 0.33333Z^3\frac{d\overline{C}_3}{dZ} - 0.007288Z^6\frac{d\overline{C}_0}{dZ} \quad [14]$$

$$\frac{d^2\overline{C}_5}{dZ^2} + 1.312Z^2\frac{d\overline{C}_5}{dZ} = 0.33333Z^3\frac{d\overline{C}_4}{dZ} - 0.007288Z^6\frac{d\overline{C}_1}{dZ} + 0.00079365Z^7\frac{d\overline{C}_0}{dZ} \quad [15]$$

with the new boundary conditions

$$\left.\begin{array}{ll} Z = 0 & \overline{C}_0 = 1, \overline{C}_1 = \overline{C}_2 = \ldots = \overline{C}_5 = 0 \\ Z \to \infty & \overline{C}_0 = \overline{C}_1 = \ldots = \overline{C}_5 = 0 \end{array}\right\} \quad [16]$$

This set of simultaneous linear ordinary differential equations can be integrated to give the following solutions

$$\overline{C}_0 = 1 - 0.85002\int_0^Z e^{-0.43733Z^3}\,dZ \quad [17]$$

$$\overline{C}_1 = \int_0^Z e^{-0.43733Z^3}(-0.070835Z^4 + 0.071906)\,dZ \quad [18]$$

$$\overline{C}_2 = \int_0^Z e^{-0.43733Z^3}(-0.0029515Z^8 + 0.0059922Z^4 + 0.013913)\,dZ \quad [19]$$

$$\overline{C}_3 = \int_0^Z e^{-0.43733Z^3}(-8.1986 \times 10^{-5}Z^{12} + 2.4968 \times 10^{-4}Z^8 + 1.1594 \times 10^{-3}Z^4 + 4.879 \times 10^{-3})\,dZ \quad [20]$$

$$\overline{C}_4 = \int_0^Z e^{-0.43733Z^3}(-1.708 \times 10^{-6}Z^{16} + 6.935 \times 10^{-6}Z^{12} + 4.8309 \times 10^{-5}Z^8 + 8.85 \times 10^{-4}Z^7 + 4.0658 \times 10^{-4}Z^4 - 1.2145 \times 10^{-3})\,dZ \quad [21]$$

$$\overline{C}_5 = \int_0^Z e^{-0.43733Z^3}(-2.8467 \times 10^{-8}Z^{20} + 1.4449 \times 10^{-7}Z^{16} + 1.3419 \times 10^{-6}Z^{12} + 7.4053 \times 10^{-5}Z^{11} - 6.7386 \times 10^{-5}Z^8 - 7.4873 \times 10^{-5}Z^7 - 1.0121 \times 10^{-4}Z^4 - 1.1125 \times 10^{-3})\,dZ \quad [22]$$

Equations [17]-[22] give the concentration profile in the diffusion layer.

The local mass transfer rate, j, is related to the concentration gradient at the surface by

$$j = -D\left(\frac{\partial C}{\partial z}\right)_{z=0} = k(C_0 - C_\infty) \quad [23]$$

where k is the local mass transfer coefficient. The concentration gradient at the surface can be obtained by differentiating Eq. [8] and Eq. [17]-[22]. Since the concentration is independent of r due to the assumed uniform boundary layer thickness, the average mass transfer coefficient over the electrode surface is essentially equal to the local value of k

$$K = k = 0.85002\,D\sqrt{a/\nu}\,Sc^{1/3}g(Sc) \quad [24]$$

Here, the function $g(Sc)$ is an asymptotic series of Sc

$$g(Sc) = \left[1 - \frac{0.084593}{Sc^{1/3}} - \frac{0.016368}{Sc^{2/3}} - \frac{0.0057398}{Sc} + \frac{0.0014288}{Sc^{4/3}} + \frac{0.0013088}{Sc^{5/3}} + \ldots\right] \quad [25]$$

The Sherwood number, Sh, defined as Kd/D, can be calculated from the following equation

$$Sh = 0.85002d\sqrt{a/\nu}\,Sc^{1/3}g(Sc) \quad [26]$$

where d is the nozzle diameter. At large Sc, the function $g(Sc)$ is one and Eq. [24] can be simplified to

$$Sh = 0.85002d\sqrt{a/\nu}\,Sc^{1/3} \quad [27]$$

Comparison with numerical solutions.—By solving Eq. [5] and [6], the exact concentration profile can be expressed as

$$\overline{C} = 1 - \frac{\int_0^\eta \exp\left[-2Sc\int_0^\eta \phi(\eta)d\eta\right]d\eta}{\int_0^\infty \exp\left[-2Sc\int_0^\eta \phi(\eta)d\eta\right]d\eta} \quad [28]$$

The numerical solutions of Eq. [28] for different Schmidt numbers have been obtained with a fourth-order Runge-Kutta method and a six-points Gaussian quadrature formula on a digital computer. Figure 2 shows a comparison between the asymptotic concentration profiles calculated from Eq. [8] and [17]-[22] and the numerical concentration profiles calculated from Eq. [28]. For $Sc \geqq 2.45$, their agreement is within 8% for $\overline{C} \geqq 1.0 \times 10^{-3}$. Figure 3 is a log-log plot of $Sh/d\sqrt{a/\nu}$ *vs.* Sc for the asymptotic solution of Eq. [26] and the numerical solutions calculated from

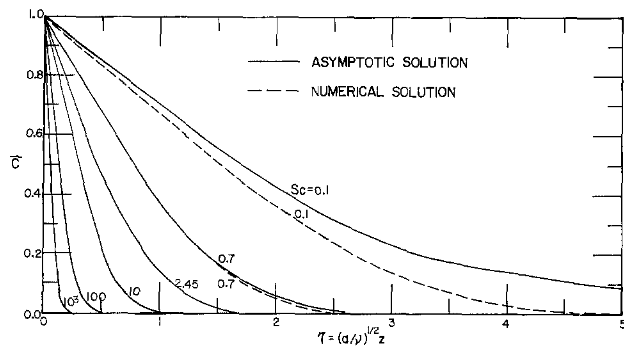

Fig. 2. Concentration distributions on the impinging jet electrode

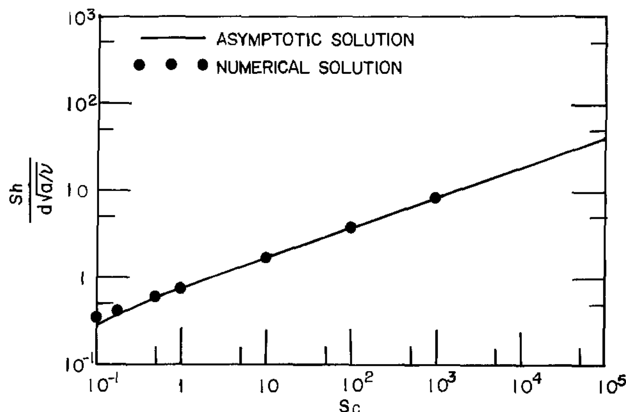

Fig. 3. Comparison for the mass transfer rate between the asymtotic and the numerical solutions.

Eq. [28]. Table I presents the numerical values for the comparison. The present asymptotic solution is based on Sc >> 1; however, at Sc = 0.7 and 1, the asymptotic solutions agree with the numerical solutions to within 0.6 and 0.3%, respectively. The slope of the curve is 1/3 at large Schmidt numbers.

Evaluation of hydrodynamic constant.—For practical application of Eq. [24]-[27], the hydrodynamic constant, a, must be known.

For a circular disk immersed perpendicularly in a uniform flow, Lamb (32) has found that the velocity component of the potential flow along an infinitely thin disk surface with radius R can be expressed as

$$u = \frac{\pi r}{8R} U' \quad [29]$$

Here, U' is the bulk velocity of the uniform flow. The hydrodynamic constant, a, for this system is essentially $\pi U'/8R$. Substituting the value of a into Eq. [24], the mass transfer rate equation becomes

$$Sh_R = \frac{KR}{D} = 0.5327 Re'^{1/2} Sc^{1/3} g(Sc) \quad [30]$$

Here, Re' is the Reynolds number defined as $U'R/\nu$. For large Schmidt numbers, g(Sc) becomes 1, and Eq. [30]

Table I. Values of $Sh/d\sqrt{a/\nu}$ at different Schmidt numbers

	$Sh/d\sqrt{a/\nu}$		
Sc	Asymptotic solution of Eq. [26]	Numerical solution of Eq. [28]	% difference

agrees with the analysis of Matsuda and Yamada (33) who obtained a numerical coefficient of 0.5325.

For the case of an impinging jet, the potential flow field outside of the boundary layer depends not only on the nozzle exit flow but also on the nozzle height, H. Introducing a dimensionless hydrodynamic constant defined as

$$a^* = ad/\bar{U} \quad [31]$$

Eq. [26] becomes

$$Sh = 0.85002 Sc^{1/3} Re^{1/2} \sqrt{a^*} \cdot g(Sc) \quad [32]$$

where Re is the Reynolds number, $\bar{U}d/\nu$, based on the nozzle diameter, d, and the average nozzle exit velocity, $\bar{U}$. According to the published data, the dimensionless hydrodynamic constant, a^*, is only a function of the dimensionless nozzle height, $\bar{H}$, defined as H/d. In this study, an attempt has been made to correlate several theoretical and empirical results (2, 6, 8, 13, 17, 19) of a^* with a least squares curve fitting method. The results are tabulated in Table II for various ranges of H/d. The flow conditions at the nozzle exit, as reported in the corresponding reference, are indicated in column 4. Since this analysis is similar to that of the impinging rectangular-slot jets, the table also lists a number of correlations of a^* obtained from the slot geometry. The range of H/d for the a^*'s given in the table varies from 0.05 to ∞. Substituting these a^*'s into Eq. [32], the corresponding rate equations for mass transfer near the stagnation point are tabulated in Table III. In this way, a total of 13 equations have been obtained for various ranges of H/d; they are numbered from [III-1] to [III-13] in the last column of Table III. As it can be seen, the rate equations have a general form

$$Sh = \alpha Re^{1/2} Sc^{1/3} g(Sc) f(H/d) \quad [33]$$

where α is a constant coefficient. Figure 4 is a log-log plot of $Sh/Re^{1/2} Sc^{1/3} g(Sc)$ *vs.* H/d for the equations in Table III and the experimental data reported in Ref. (6, 8, and 23). The numbers in the figure represent the equation numbers in Table III. It is noted that there is no single equation which satisfies the measured transfer rate over the entire range of H/d. For $0.1 \leq H/d \leq 0.5$, Eq. [III-1] shows a fair agreement with the data obtained by Scholtz and Trass for the evaporation of naphthalene to a nonuniform laminar jet. For high Schmidt numbers, Coueret's electrochemical measurements with an impinging jet electrode of a radius $r/d = 1.4$, agrees fairly with the predictions of Eq. [III-2] and [III-3] at $H/d = 1.1$. However, his result with a smaller electrode of $r/d = 0.45$ is twice higher than the prediction. For $1.0 < H/d < 10$, the data of Chia *et al.* (6) at Re = 34,000 fall into the region predicted by Eq. [III-5], [III-8], and [III-9]. It seems that there is no satisfactory agreement between the correlations and the reported experimental

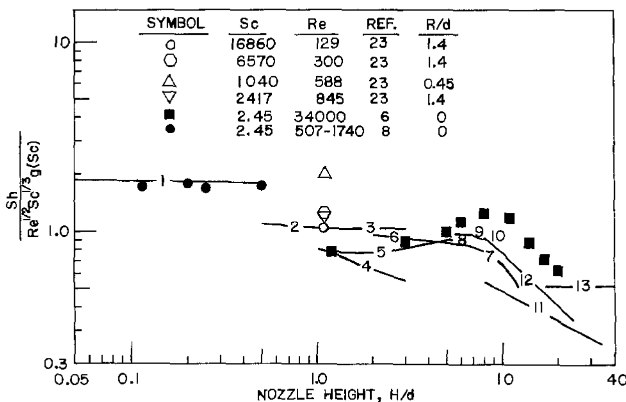

Fig. 4. Comparison between the mass transfer correlations listed in Table III and the published experimental data.

† The width of the slot jet is replaced by the diameter of the circular jet.

data over the entire region of the dimensionless nozzle heights. The discrepancy is probably due to an inaccuracy in the reported dimensionless hydrodynamic constants, a^*, as well as the experimental faults. The mass transfer experiments with dissolution of a *trans*-cinnamic acid disk or evaporation of a naphthalene disk tend to roughen and deform the surface. Coueret's electrode of a radius $r/d = 1.4$ was greater than the stagnation region, and the measured mass transfer rate must be influenced by the flow in the wall jet region. It seems that more elaborate experimental work is needed to determine the hydrodynamic constant required for the transport equations.

Experimental

The purpose of the present experimental work is to determine the region of "uniform accessibility" on the impinged surface and to investigate the feasibility of the impinging jet electrode for electroanalytical applications. It also intends to further contest the rate equations listed in Table III with an electrochemical mass transfer experiment.

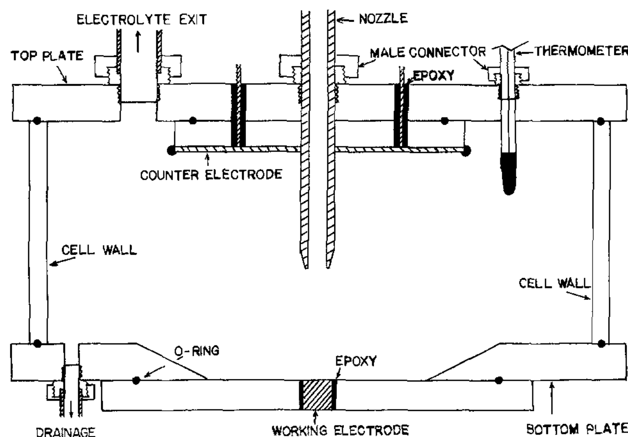

Fig. 5. The experimental cell used in this study

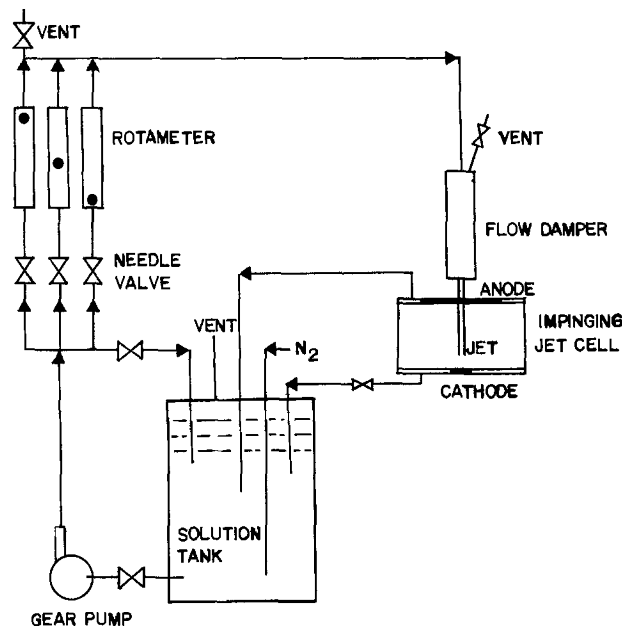

Fig. 6. The flow system used in this study

The experimental cell used is shown schematically in Fig. 5. It consisted of a section of a Plexiglas pipe, 20.3 cm ID by 7.6 cm long, and a set of Plexiglas top and bottom plates of 25.4 cm diam. They were bolted together at the circumferences of the top and the bottom plates and were sealed with O-rings.

The impinging jet electrode (or the working electrode) was located on the bottom plate; it was a circular nickel disk embedded on a replaceable Plexiglas electrode disk attached to the underside of the bottom plate as shown in Fig. 5. Eight different sizes of the impinging jet electrode were prepared; the radii of these electrodes were: 0.0127, 0.0495, 0.0787, 0.157, 0.265, 0.634, 1.27, and 1.91 cm. The electrodes with radius smaller or equal to 0.634 cm were made of either a nickel wire or a cylindrical nickel rod inserted through the central hole on the Plexiglas electrode disk and held in place with an epoxy glue. For the larger electrodes, a circular nickel foil was cemented to a shallow dent at the center of the electrode disk. The disk was then machined and smoothed until the nickel surface became flush with the Plexiglas surface. The counterelectrode was a circular nickel foil of 10.2 cm diam glued on the underside of the top plate. It had a very large surface area compared to the working electrodes to ensure that the over-all cell reaction was controlled by the reaction at the working electrode under the limiting current conditions.

The electrolyte nozzle was a Plexiglas tube inserted perpendicularly through a central hole on the top plate and held in place with a male tube connector. Two different nozzle sizes were used in the experiment; they had an inside diameter of 0.635 and 0.318 cm, respectively. Both nozzles were either 20.3 or 63.5 cm long. The nozzle height, which is the distance between the nozzle exit and the surface of the working electrode, could be adjusted by moving the nozzle tube up and down through the top plate and by tightening up the nut of the male tube connector. A micrometer depth gauge was used to measure the nozzle height when the cell was assembled.

There were two other tube connectors on the top plate. One was for accommodating a thermometer in the cell and the other was connected to an electrolyte exit tube. A small tube connector on the bottom plate was used for drainage. While in operation, the assembled cell was mounted on a sturdy bench to avoid any mechanical vibrations.

The flow system used in this experiment is shown in Fig. 6. It consisted of a solution tank, a gear pump, a set of rotameters, a flow damper, and the impinging jet cell. These components were connected together with ½-in. polypropylene tube and ½-in. nylon tube fittings. The solution tank was an 11 liter PVC tank, and an epoxy gear pump with a Hastelloy-C shaft and a Buna-N impeller was used to circulate the electrolyte. A bypass nylon needle valve and three other nylon needle valves in the upstream of three rotameters were used to control the flow rate of the electrolyte. Three Gilmont F-1500 shielded rotameters were used to measure the flow rate; they were composed of a glass tube and a glass ball to avoid the corrosion problems. The Plexiglas flow damper in the downstream of the rotameters was used to eliminate any turbulences in the electrolyte before it flowed into the impinging jet cell. The electrolyte flowed into the cell through the nozzle tube. It impinged normally on the working electrode and then returned to the storage tank via the exit on the top plate of the cell. All the components in the flow system were rigidly fastened on an aluminum rack to avoid vibrations.

The reduction of ferricyanide ion at the working electrode was used for the limiting current measurement. The solution used was composed of 0.01M potassium ferricyanide, 0.01M potassium ferrocyanide, and 1.0M sodium hydroxide. An iodimetric titration method was used to determine the ferricyanide concentration. An Ostward viscometer was used to determine the viscosity of the electrolyte. The density of the electrolyte was measured with a specific gravity bottle and the diffusivity of ferricyanide ion was determined with a rotating disk electrode. The typical properties of the solution with 9.774×10^{-4}M ferricyanide ion at 23°C were as follows:

density: 1.042 g/ml
viscosity: 1.06 cp
diffusivity of ferricyanide ion: 6.54×10^{-6} cm^2/sec
Stokes-Einstein parameter: $D\mu/T = 2.34 \times 10^{-10}$ cm^{2}poise/sec°K

The above Stokes-Einstein parameter agreed with the measurement by Gordon *et al.* (34), who obtained a value of $2.36 \pm 0.05 \times 10^{-10}$ cm^{2}poise/sec°K.

To obtain reproducible limiting current data, the working and the counterelectrodes were polished with 600 grade emery paper before the run. They were further degreased in methanol and cathodically activated in a 5% NaOH solution for 15-30 min before putting into the impinging jet cell. The solution was bubbled with nitrogen gas for at least 2 hr to remove any dissolved oxygen before the experiment. During the run, a nitrogen atmosphere was maintained in the storage tank. A Lambda LT-2095 d-c power supply was used as a d-c source for the cell reaction. The applied potential drop across the cell was controlled by a 10-turn potentiometer. The cell current for the reduction of ferricyanide ion at the working electrode

was obtained by measuring the voltage drop across a standard resistor with a Hewlett-Packard 3476A digital multimeter. To obtain the limiting current at a specific flow rate, a complete curve of cell current *vs.* cell voltage was measured by increasing the applied voltage across the cell. As the applied voltage increased, the current flowing through the cell first increased, then leveled off to form a plateau, and finally increased sharply. The current plateau was taken as the limiting current for the reduction of ferricyanide ion. The present system had a negligible background current and a wide limiting current region which existed over the cell voltages varying from 0.3 to 1.2V. All the runs were made at a constant room temperature of 23° ± 1°C. The details of the experimental setup and procedures are given in Ref. (35).

Results and Discussion

Uniform accessibility.—To determine the region of "uniform accessibility" at the impinging jet electrode, the limiting current density for the reduction of ferricyanide ion was measured as a function of electrode radius. The results for $H/d = 1$ are presented in Fig. 7 for four different nozzle Reynolds numbers. The curves represent the typical behavior observed in this study. The results with other nozzle heights exhibited the same characteristics. It is seen that for each curve there is a region where the limiting current density was relatively constant. This uniform mass transfer region varies from $R/d = 0.1$ to 1.0 for turbulent jets and from 0.1 to 0.5 for laminar jets; within this region, the variation in the limiting current density for different electrode sizes was less than ±10% of the average value. At the radial positions greater than the uniform accessible region, the limiting current density started to decrease with increasing electrode radius. A surprise feature revealed by this study is the nonuniformity in mass transfer for $R/d < 0.1$. Each curve reached a maximum value at the stagnation point as represented by the smallest electrode with $R/d = 0.02$. It (except at Re = 1210) also exhibited a minimum at $R/d = 0.078$. This particular behavior has not been reported in any previously published literature. The high mass transfer rate at the smallest electrode ($R = 0.0127$ cm) can probably be attributed to the mass transfer enhancement of the edge effect. The fact that it might be located slightly away from the centerline of the impinging jet, because of mechanical misalignments in the cell assembly, could also contribute to the higher rate at the smallest electrode (36). However, the result of a minimum mass transfer rate for the electrode with $R/d = 0.078$ cannot be explained. This minimum did not occur for all the nozzle heights tested; it gradually disappeared with increasing nozzle distance. At $H/d = 6$, the limiting current density for this electrode became consistently higher than that in the uniform accessible region. Since there have not been any published data showing the variation of mass transfer rate for $R/d < 0.1$, this problem will be left to future studies.

Effect of nozzle flow rates.—The limiting current densities at the eight working electrodes were measured for five different nozzle heights over a range of the nozzle Reynolds numbers from 500 to 16,000. This covered the laminar, the transitional, and the turbulent flow conditions in the impinging jet. Since the limiting current density for the reduction of ferricyanide ion is related to the average mass transfer coefficient by $i_{\lim} = KFC_\infty$, according to Eq. [32] a plot of $i_{\lim}$ *vs.* $\sqrt{Re}$ should result in a straight line passing through the origin with a slope equal to $0.85\, FDC_\infty Sc^{1/3} a^{*1/2}/d$. Figure 8 is the typical of such a plot obtained with a 0.635 cm diam nozzle at $H/d = 1.0$. Also shown in the figure are two vertical lines which separate the nozzle flow into the laminar and the turbulent flow regimes. The behavior of the data points can be classified into three categories according to whether the electrode radius was smaller, within, or greater than the uniform accessible region shown in Fig. 7:

(*i*) For R/d less than 0.1, the typical behavior can be represented by the limiting current at $R/d = 0.02$. For this electrode, a straight line passing through the origin can be drawn through the data points located in the transitional and the turbulent regimes. The laminar data at the lower end of the Reynolds numbers can also be correlated with a straight line through the origin; however, its slope is greater than that at the higher Reynolds numbers.

(*ii*) For the electrode radii located within the uniform accessible region, the data points for three different size electrodes ($R/d = 0.124$, 0.247, and 0.417) fall together as a single curve. An attempt has

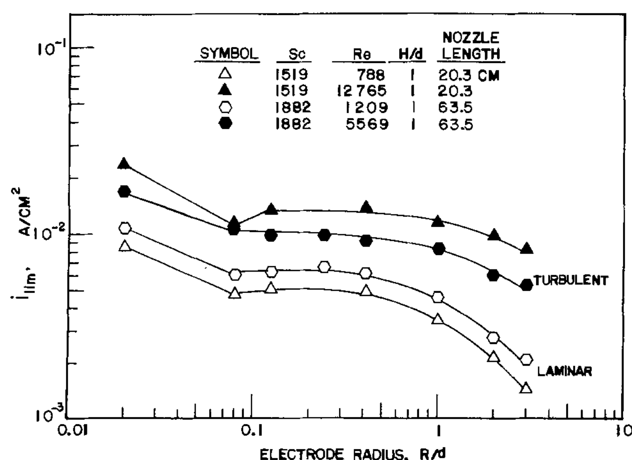

Fig. 7. Variation of the limiting current density with the dimensionless electrode radius.

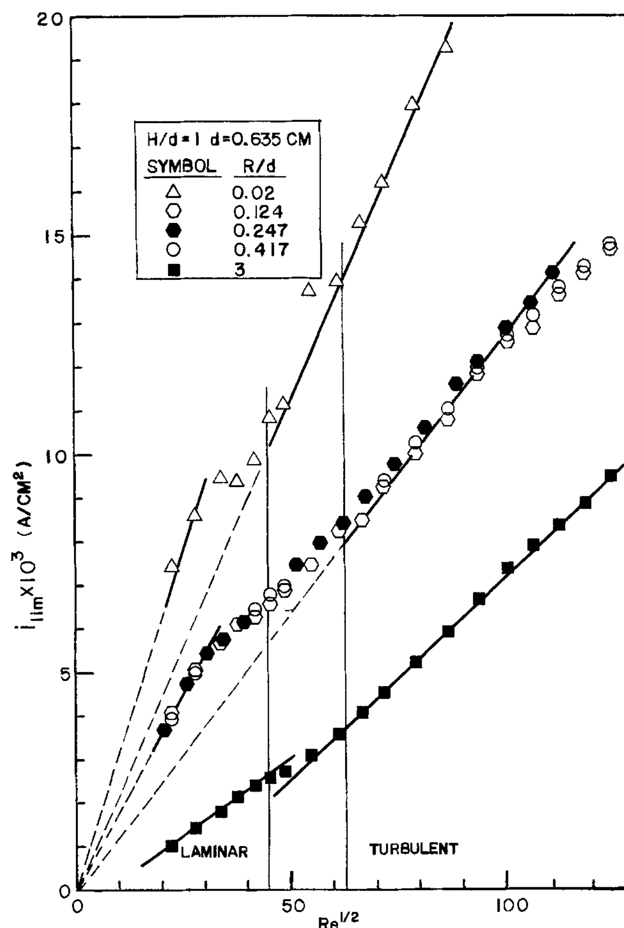

Fig. 8. Typical behavior of the limiting current density vs. the square root of the nozzle Reynolds numbers.

also been made to correlate these data with a straight line passing through the origin at the lower and the higher ends of the Reynolds numbers. It is seen that there is an excellent correlation for the data in the laminar region. The turbulent data can be correlated to within ±10% with a straight line passing through the origin. Again, the slope of the straight line in the laminar region is greater than that in the turbulent region. At the moment we do not have any suitable explanation of this phenomenon. Probably it was caused by a difference in behavior of the hydrodynamic constant, a^*, between the laminar and the turbulent impinging jets.

(*iii*) For the electrodes whose radii are greater than the outer limit of the uniform accessible region ($R/d \approx 0.5$ for laminar jet and 1.0 for turbulent jet), the limiting current density started to decrease with increasing electrode radius. The behavior in this region can be typically represented by the data obtained with $R/d = 3.0$. For this electrode, the data points in the laminar and the turbulent regimes can also be correlated with two separate straight lines; however, they cannot be extrapolated to the point of origin as shown in Fig. 8.

During the measurements, the limiting current was found to fluctuate. For the smallest electrode, the fluctuation was ±2% of the average limiting current in the laminar flow regime, ±5% in the turbulent region, and was ±20% in the transitional regime. The fluctuations decreased with increasing electrode sizes. The reproducibility for the smallest electrode with $R/d = 0.02$ was about ±8%. For the larger electrodes, the reproducibility of the limiting current measurement was better than ±3%.

To further contest the one-half power dependence of the mass transfer rate on the nozzle Reynolds numbers, the limiting current densities were converted to the Sherwood number, Kd/D, and the results were plotted against the Reynolds number in a log-log scale. Two such plots for $H/d = 1.0$ with two different nozzle sizes (one with a 0.318 cm diam nozzle and the other with a 0.635 cm diam nozzle) are given in Fig. 9 and 10, respectively. Again, the general feature of the data depends on the electrode sizes. For the smallest electrode and the electrodes located within the uniform accessible region, the data can be represented

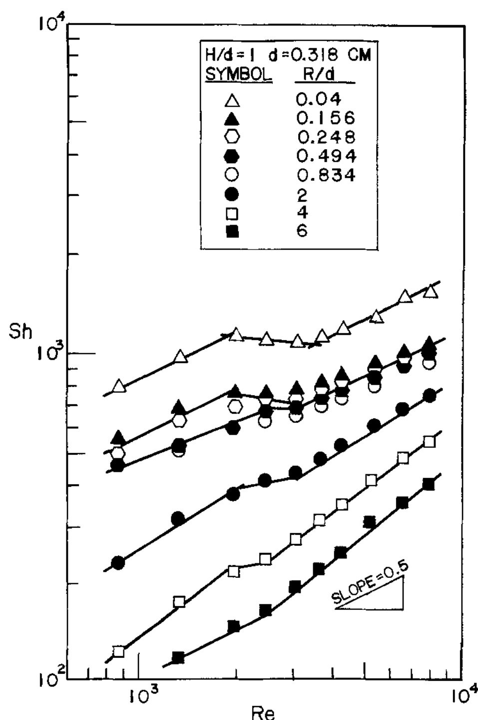

Fig. 9. Sh vs. Re for a 0.318 cm diam nozzle

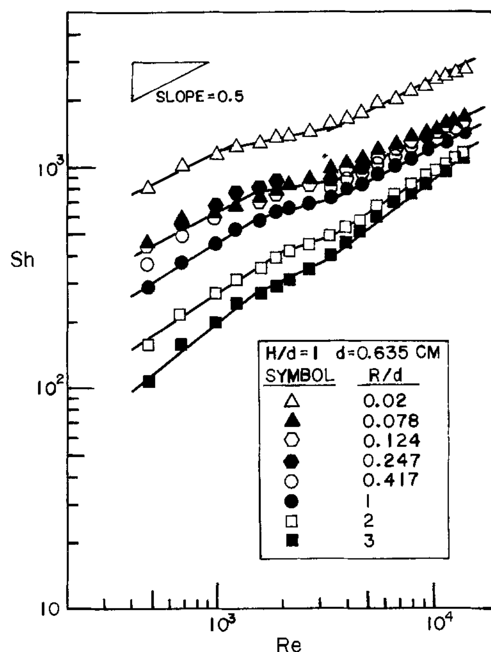

Fig. 10. Sh vs. Re for a 0.635 cm diam nozzle

by the three straight-line segments. The two breakpoints at the intersections of the segments correspond more or less to the point of instability (Re ~ 1500) and the transitional Reynolds number (Re ~ 3500) of pipe flow. The slopes of the straight lines in both laminar and turbulent flow were approximately equal to one-half. This result agrees with those of Scholtz and Trass (8), Giralt and Trass (7), and Belove *et al.* (14). These authors found that the one-half power dependence on the Reynolds number was true for both laminar and turbulent jets. The data points for different size electrodes located within the uniform accessible region ($0.1 < R/d < 0.5$ for laminar flow and $0.1 < R/d < 1$ for turbulent flow) have a tendency to merge together even though there is still a slight variation with the radial position. In general, these data could be correlated to within ±10% with a straight line of slope one-half.

For the electrodes with R/d greater than the uniform accessible region, there is a strong dependence of the Sherwood number on the dimensionless radius. For each electrode, the data points can also be correlated with three separate linear segments representing laminar, transitional, and turbulent flows. However, the slopes in the laminar and the turbulent regimes are greater than one-half. Also the break points become less distinguished and the width of the transitional regime seems to diminish with increasing electrode radius. For $R/d = 6$, for instance, the transitional regime completely disappeared, and the flow seemed to change directly from laminar to turbulent flow. An attempt has been made to correlate the data in this region with the following empirical equation

$$\mathrm{Sh} = l\mathrm{Re}^m \mathrm{Sc}^{1/3} \quad [34]$$

where the proportional constant, l, and the exponent, m, depend upon the electrode sizes. The results of a least squares curve fitting for Re greater than 4000 and H/d between 0.2 and 6 are listed in Table IV. It is

Table IV. Summary of the least squares curve fittings for the data with $R/d \geq 2$, $\mathrm{Re} \geq 4000$, and $0.2 \leq H/d \leq 6$

Empirical equation: $\mathrm{Sh} = l\,\mathrm{Re}^m\,\mathrm{Sc}^{1/3}$

R/d	l	m
2	0.342	0.59
3	0.133	0.68
4	0.0635	0.73
6	0.0316	0.77

seen that the value of l decreases with increasing R/d. On the other hand, the exponent m increases asymptotically with R/d; the values at $R/d = 4$ and 6 are seen to agree with the work of Yamada and Matsuda (22), who obtained an exponent of 0.75 for mass transfer in the wall jet region. This result clearly demonstrates that the wall jet region begins approximately at $R/d = 4$. Between $R/d = 1$ and 4, there is an intermediate region, where the turbulent impinging jet changes from the stagnation flow to the wall jet flow.

Mass transfer correlation for the uniform accessible region.—To compare the experimental data with the predictions of the equations listed in Table III, the values of $Sh/Re^{1/2}Sc^{1/3}$ were calculated for the electrodes located in the uniform accessible region for both laminar and turbulent jets. The results are plotted in Fig. 11 against the dimensionless nozzle height, H/d. Each data point represents the average value of several electrodes in the uniform accessible region over a range of Reynolds numbers indicated in the figure. Two different nozzle diameters and two different nozzle lengths were used to collect the data. Also plotted in the figure are the 13 equations listed in Table III. They are represented by the thin curves and identified by the corresponding equation numbers. It is seen that the present experimental results fall into the general area predicted by the equations. The agreement is poor for most equations. Only Eq. [III-1] is close to the laminar data; however, the prediction is at least 20% higher than the experimental value. For the turbulent data there is a satisfactory agreement between the data points and those predicted by Eq. [III-2] and [III-3] even though they were based on an analysis of a nonuniform rectangular laminar jet (19).

The data in Fig. 11 can be correlated in the form of Eq. [33]. A least squares curve fitting of the results gives the following equations:

(*i*) for the laminar data ($Re < 2000$, and $0.1 < R/d < 0.5$)

$$Sh = 1.51 Re^{1/2} Sc^{1/3} g(Sc) (H/d)^{-0.054} \quad [35]$$

(*ii*) for the turbulent data ($4000 < Re < 16{,}000$ and $0.1 < R/d < 1$)

$$Sh = 1.12 Re^{1/2} Sc^{1/3} g(Sc) (H/d)^{-0.057} \quad [36]$$

where the asymptotic series $g(Sc)$ is given by Eq. [25]. Equations [35] and [36] are plotted in Fig. 11 as the thick solid lines; the standard deviation of these correlations from the experimental data is ±10%. It should be noted that these equations are valid for $0.2 \leq H/d \leq 6$.

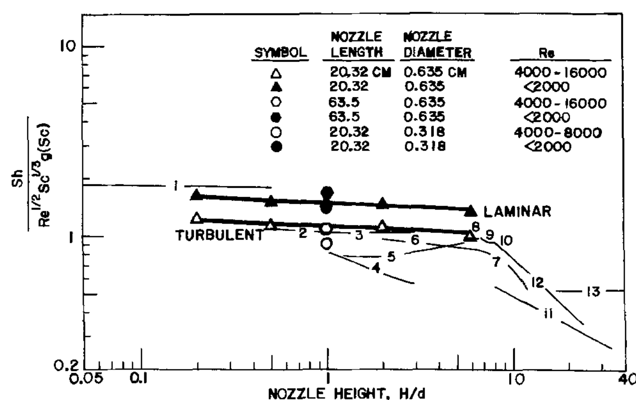

Fig. 11. Mass transfer rate as a function of the dimensionless nozzle height. For comparison the equations listed in Table III are also plotted as the thin curves; they are identified by the corresponding equation numbers. The thick solid lines are the least squares correlations of the present experimental results, Eq [35]-[36].

Electrochemical applications.—This result has proved that the impinging jet electrode is a feasible tool for electrochemical applications because of the existence of a uniform accessible region. This geometry can be adopted for the process streams and the closed systems requiring a pressure other than the ambient atmosphere. Since the electrode can be used for both laminar and turbulent flows, the upper limit in kinetic measurement is determined only by the pump size. At a nozzle Reynolds number of 10^8, for instance, Eq. [36] indicates that a first-order rate constant on the order of 1 cm/sec can be determined with the impinging jet. This is about one order of magnitude higher than the rotating disk electrode. It is suggested that a cell with a fixed ratio of nozzle height to nozzle diameter, H/d, be constructed, and the radius of the electrode be limited to less than 1 nozzle diameter. A convenient choice for the electrode size is $R/d = 0.5$, for which the nonuniform central core of $R/d < 0.1$ constitutes less than 4% of the total surface area; this is an acceptable error for most experimental work. In view of the complexity of mass transfer at the impinging jet electrode, the semiempirical equation in the form of Eq. [33] should be used for any kinetic, diffusivity, and concentration measurements. For a cell with fixed H/d and R/d ratios, the quantity $\alpha f(H/d)$ in Eq. [33] becomes a simple empirical cell constant which may be calibrated with a known redox reaction such as the reduction of ferricyanide to ferrocyanide ions. The present results of Eq. [35] and [36] can be used as a guideline to check the accuracy of the calibrations.

Conclusions

A theoretical and experimental study has been made of mass transfer to a circular disk electrode located within the stagnation region of an impinging jet. Using the method of perturbation, an asymptotic series is presented for the Schmidt number corrections over the range of Sc from 0.7 to ∞. The maximum deviation of the asymptotic series from the numerical solution is less than 0.7%. It is found that the electrode possesses a "uniform accessibility" to the diffusing ions within a range of dimensionless electrode radius, r/d, from 0.1 to 1.0 for turbulent nozzle flow and from 0.1 to 0.5 for laminar nozzle flow. Within this uniform accessible region the mass transfer rate is relatively independent of the electrode size, and the semiempirical correlations are presented in both laminar and turbulent flow regimes for $0.2 \leq H/d \leq 6$. Beyond the uniform accessible region, the mass transfer rate decreases with the radial position, and the wall jet region is found to begin approximately at $R/d = 4$.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

LIST OF SYMBOLS

a — a hydrodynamic constant, sec^{-1}
a^* — dimensionless hydrodynamic constant, defined as $ad/\bar{U}$
C — concentration of the diffusing ion, g-mole/cm^3 or kg-mole/m^3
C_0 — concentration of the diffusion ion at the electrode surface, g-mole/cm^3 or kg-mole/m^3
C_∞ — bulk concentration of the diffusing ion, g-mole/cm^3 or kg-mole/m^3
$\bar{C}$ — dimensionless concentration of the diffusing ion
$\bar{C}_0 \ldots \bar{C}_5$ — the zeroth order, ..., 5th order concentration, dimensionless
D — diffusivity of the diffusing ion, cm^2/sec or m^2/sec
d — diameter of the circular nozzle or the width of the rectangular slot nozzle, cm or m

F	Faraday constant, 96,487 C/g equiv.
$f(H/d)$	an empirical function of H/d, see Eq. [33]
g(Sc)	a series expression of Sc given by Eq. [27]
H	nozzle height, cm or m
$\overline{H}$	dimensionless nozzle height, H/d
i_{lim}	limiting current density, A/cm^2 or A/m^2
j	local mass transfer flux at the electrode surface, g-mole/cm^2 sec or kg-mole/m^2 sec
K	average mass transfer coefficient, cm/sec or m/sec
k	local mass transfer coefficient, cm/sec or m/sec
n	number of electrons transferred in the electrode reaction, g-equiv./g-mole
R	radius of the disk electrode, cm or m
r	radial coordinate measured from the stagnation point, cm or m
$\overline{U}$	average velocity at the nozzle exit, cm/sec or m/sec
U'	bulk velocity of the uniform flow, cm/sec or m/sec
u	velocity component in the radial direction, cm/sec or m/sec
v	velocity component in the axial direction, cm/sec or m/sec
Z	a stretched coordinate for the diffusion boundary layer defined as $Sc^{1/3}$ η or Sc^{3} $\sqrt{a/\nu}\, z$, dimensionless
z	a coordinate perpendicular to the electrode surface, cm or m

Greek letters

α	an empirical constant in Eq. [33], dimensionless
γ	the adiabatic exponent in Table I, dimensionless
δ	boundary layer thickness in Fig. 1, cm or m
η	a dimensionless variable defined as $\sqrt{a/\nu}\, z$
μ	viscosity of the electrolyte, poise or Pa · sec
ν	kinematic viscosity of the electrolyte, cm^2/sec or m^2/sec
ϕ	stream function, dimensionless

Dimensionless groups

Re	Reynolds number, $d\overline{U}/\nu$
Re'	Reynolds number, RU'/ν
Sc	Schmidt number, ν/D
Sh	Sherwood number, Kd/D or kd/D
Sh_R	Sherwood number, KR/D

Reversibility and Growth Behavior of Surface Oxide Films at Ruthenium Electrodes

S. Hadzi-Jordanov,[1] H. Angerstein-Kozlowska, M. Vuković,[2] and B. E. Conway

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5

ABSTRACT

Experiments are described in which the nature of surface oxidation processes at Ru electrodes are investigated and compared with those of other noble metals. Surface oxidation of Ru is much more irreversible than at Pt, Au, or Rh and the oxide formed in sweeps taken to 1.4V can only be reduced in the H region, usually with some coevolution of H_2. However, surface oxidation already begins at potentials in, or close to, the H region; this behavior is somewhat similar to that of Pt in alkaline solutions. Upon repeated cycling into the oxide region up to 1.4V E_H, a new state of the oxidized Ru surface is generated which exhibits remarkable reversibility of the *i-V* profile in anodic and cathodic sweeps taken to any potential in the range 1.4V. This effect is associated with a reversible redox process in the oxide film, probably between Ru(IV) and Ru(III), but reduction back to the metallic surface does not occur as it does in the initial sweeps. The behavior is somewhat similar to that previously observed with Ir. Time-dependent growth of the oxide film at Ru is observed, as at other noble metals, and the direct logarithmic law applies. Similarities to the surface oxidation behavior of other noble metals, especially iridium, are pointed out and depend on anion adsorption.

Ruthenium is of current interest as an electrocatalyst material, especially in combination with an oxidized Ti substrate, as an anode material for Cl_2 evolution (1-3). From an electrochemical point of view, this metal has, however, been less well characterized than most other noble-metal materials, especially with regard to the state of adsorbed H at its surface near the reversible H_2/H^+ potential and the nature of surface oxidation processes that occur at more positive potentials. In the case of Pt, Rh, Ir, and Au, the general surface oxidation characteristics were studied in some detail by Breiter *et al.* in a number of papers (4-6) using the potentiodynamic sweep method of Will and Knorr (7), and by Vetter and Berndt (8), and Schultze and Vetter (9), using galvanostatic conditions. Apart from the literature quoted in an earlier preliminary communication on Ru (10), relatively little work has been carried out on the surface oxidation behavior of Ru. An extended abstract (11) of a paper presented at the same meeting as that at which the present paper was given, reports comparisons between the properties and electrochemical behavior of oxide films on Ru and Ir and confirms the main features of the results given in our preliminary communication (10) in 1975.

In the previous short communication (10) we showed (*i*) that a region of H deposition and re-ionization could be distinguished at Ru electrodes, (*ii*) that a region of surface oxidation occurred over a broad potential range, and (*iii*) that the processes of formation and reduction of surface oxide showed much more hysteresis than at Ir (12), Pt (13), Rh (13), or Au (14), depending on the positive potential limit in the anodic sweep (13) in cyclic voltammetry experiments.

It is the purpose of this paper to give an account of further work [cf. (10)] that has been carried out in order to characterize more fully the formation and reduction of thin oxide films at Ru electrodes and to relate the observed behavior in a general way to that of Pt, Ir, and Au.

Experimental

Method.—Cyclic voltammetry experiments were carried out by well-known procedures. Anodic and cathodic sweeps at various rates could be applied to the electrode in a repetitive mode or individually after holding the potential for a controlled time [cf. (13)] at a particular value.

In the cyclic voltammetry experiments, it is found to be useful to take the potential successively to a series of increasing or decreasing values in the anodic or cathodic sweeps and thus generate a family of *i-V* profiles which illustrate the progressive changes of properties of the electrode, or oxidized electrode, surface in relation to the reversibility of the processes involved, as was done previously (13, 15) at Pt.

All experiments were conducted in solution bubbled with O_2-free N_2 as described previously (16).

Electrode preparation.—Most experiments were conducted at ruthenized Pt or Au, or a ruthenized Ru electrode prepared by the electroplating of the substrate metal from a recrystallized ammonium ruthenichloride solution. The Ru layer was electrodeposited at *ca.* 100 mA initial apparent current density at 300°K until an average Ru loading of *ca.* 5×10^3 atoms Ru per substrate Pt, Au, or Ru atom was obtained, as described previously (10). Some experiments were conducted on the ground and polished surface of a 2.5 mm diam $\times$ 2 cm long zone-refined Ru rod supplied by Research Organic and Inorganic Chemical Corporation, Sun Valley, California. The behavior of an electroplated layer on the Ru itself was not different from that on Pt or Au.

The real/apparent area ratio of the electroplated electrodes was initially *ca.* 100 after plating but in some experiments (see below) the real areas became diminished due to electrode dissolution upon cycling. Exact real areas cannot, however, be electrochemically determined, *e.g.*, through electrodeposited H accommodation measurements, as at Pt, due to the appreciable absorption of H that occurs simultaneously with H adsorption as described elsewhere (10, 17).

In other experiments, a chemically formed Ru electrode was prepared by painting a strong solution of $(NH_4)_2RuCl_6$ on a cleaned glass tube and firing it, in air, at *ca.* 723°K. A Pt contact had previously been sealed into the side of the tube.

Solutions.—0.1 or 1*N* aq. H_2SO_4 (B.D.H. Aristar grade) solutions, made up in pyro-distilled water (18), were employed as electrolytes. The cell was periodically washed with pure H_2SO_4 and then with the pyro-distilled water.

Key words: metals, electrode, charge, adsorption.

Potential scales and reference electrodes.—Measured potentials were referred to an H_2/Pt (reference) electrode in the same solution as that used for the working electrode and are referred to as E_H in the text which follows.

Currents and current densities.—Owing to the problem of defining real areas of electrodes in the case of Ru by H accommodation, because of H absorption [as we (17) and others (19) have found previously], it will not be possible to give real current densities on most of the graphs in this paper. Similar problems arise in evaluations of charges per unit area. However, for convenience and possible comparison with other published data, current densities and charges are recorded per geometric square centimeter of substrate electrode or the initial geometric area of an electrode. The time dependence of electrode areas upon anodic/cathodic cycling, mentioned above, is a further complicating aspect of this question.

Results and Discussion

Processes in the H region at ruthenium.—In previous papers (10, 17), it was demonstrated that a potential range (0.05-0.2V E_H) exists at Ru electrodes over which processes of H deposition and ionization arise, as at Pt, Rh, and Ir. In order to be able to describe and interpret the surface oxidation behavior which is observed at more positive potentials, it is first necessary to recapitulate briefly the conclusions (10, 17) regarding the H processes at Ru since at Ru, unlike Pt, there can be appreciable overlap between the processes of surface oxide formation and reduction with those of H ionization and deposition, respectively; also appreciable absorption as well as adsorption of H occurs.

Several aspects of the behavior at Ru indicate that the processes in the H region do not correspond simply to underpotential deposition of H in a series of four or five multiple states below monolayer coverage, as at polycrystalline Pt (20). The situation is complicated on the cathodic side by overlap with irreversible surface-oxide reduction processes in or near the H deposition region and facile H_2 evolution, and on the anodic side by H_2 reoxidation and reformation of a surface oxide species already at low positive potentials (17), 0.2 ~ 0.3V E_H.

A number of characteristics of the process in the H region indicated that H deposition and sorption into Ru, as well as adsorption onto its surface, occurs. H diffusion into Ru, as at Pd, is, *e.g.*, mentioned in early literature (21), and was demonstrated in a previous paper (17) by (*i*) cyclic voltammetry experiments where currents in the H region were shown to be dependent on square root of sweep-rate, *s*, rather than on its first power as for a surface process, *e.g.*, at Pt. Similar conclusions were reached by Bagotskii and co-workers (19); and (*ii*) by microcurrent-efficiency measurements for H_2 evolution at bulk Ru electrodes. These results indicate that a substantial fraction, if not all, of the H deposition/ionization charge measured in the H region at Ru electrodes is to be associated with H absorbed into the metal near its surface.

The general current-potential profile for formation and reduction of surface oxide at Ru.—Figure 1a shows

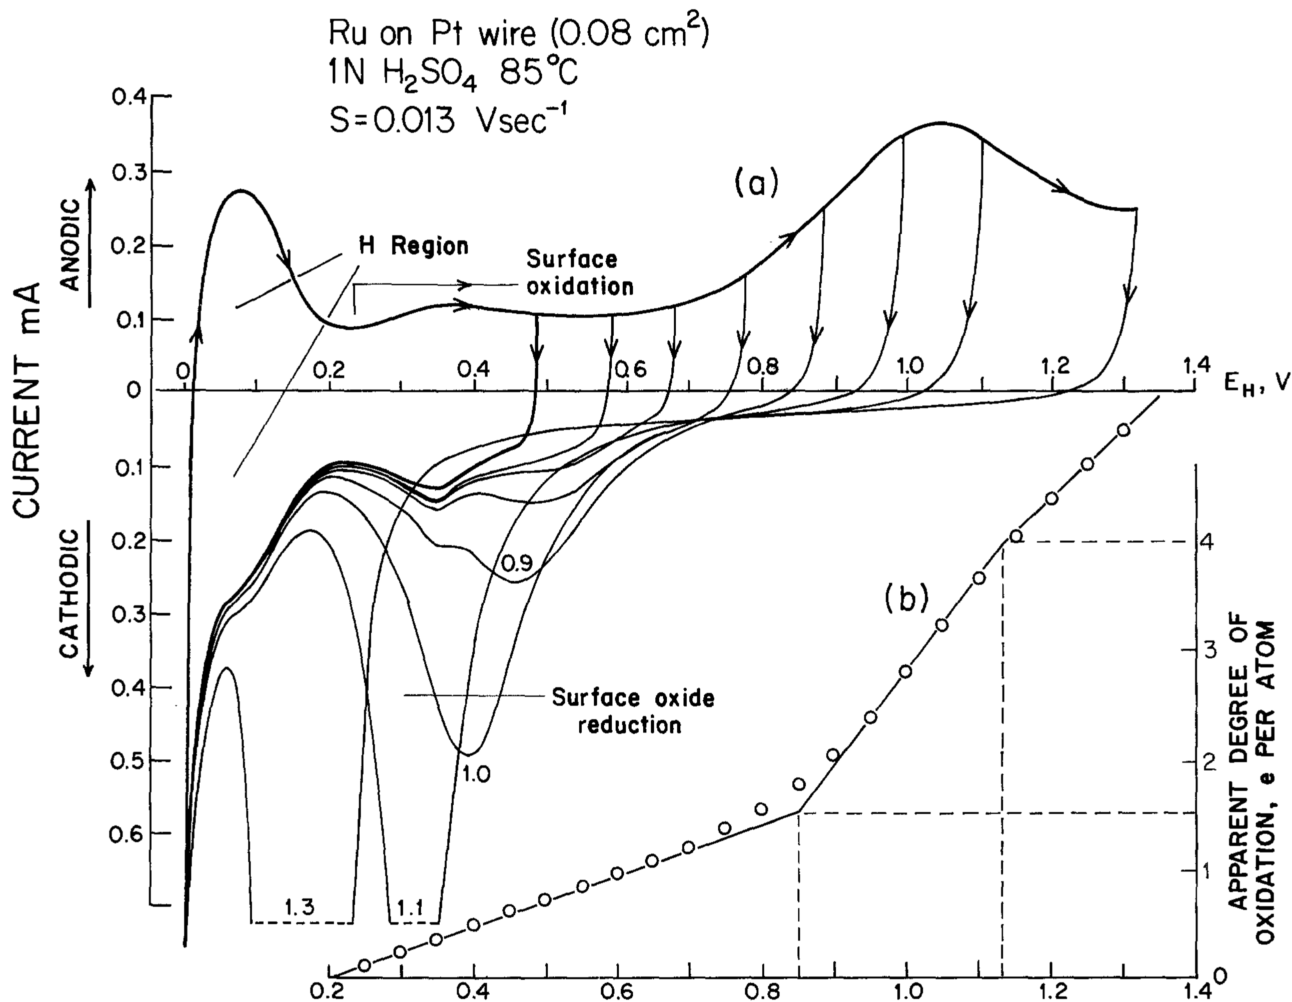

Fig. 1. (a) Cathodic and anodic potentiodynamic *i-V* profiles taken up to various potentials at ruthenized Pt, showing the H region and the progressive irreversibility between formation and reduction of surface oxide. Sweep-rate 13 mV sec^{-1}; 0.5M H_2SO_4; 358°K. Figures on cathodic curves indicate positive potential limit of previous anodic sweep. (b) Inset shows charge vs. potential profile obtained by integration of the *i-V* curves giving apparent degree of surface oxidation in e per atom.

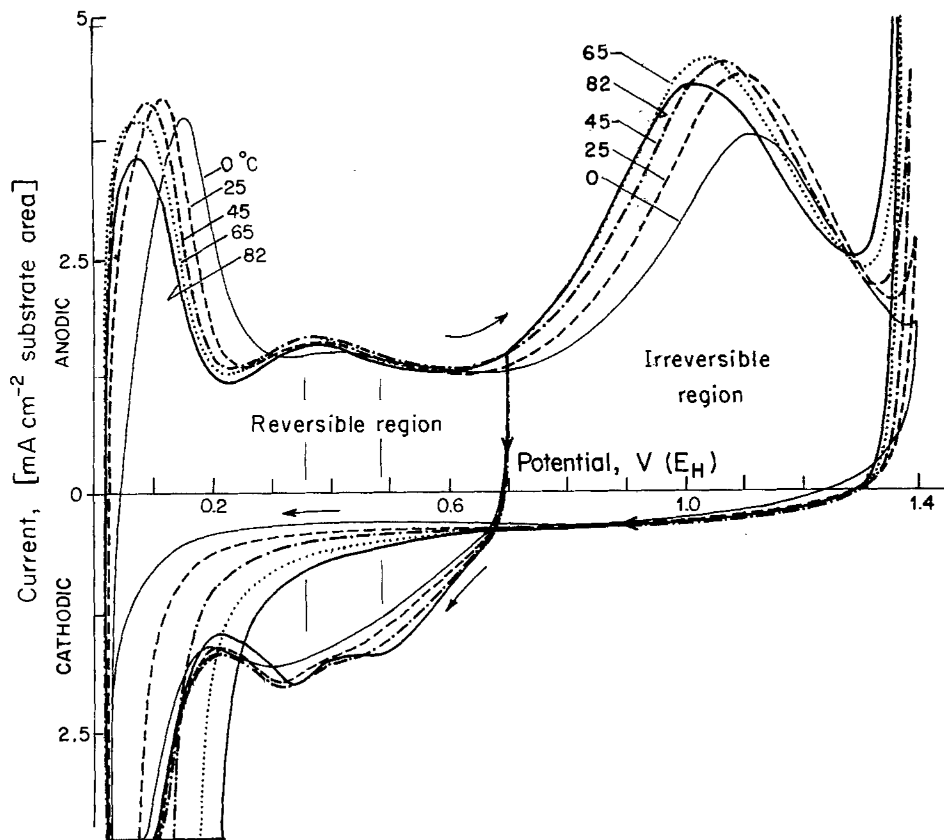

Fig. 2. Comparison of a series of potentiodynamic i-V curves for ruthenized Pt in 1N aq. H_2SO_4 taken over a range of 0.05-1.4 and 0.05-0.7 E_H, illustrating the region of almost reversible oxide formation and reduction if the anodic potential limit is < 0.8V. Temperatures 273°, 298°, 318°, and 355°K; sweep rate 13 mV sec^{-1}.

the general behavior of Ru surfaces subjected to a small number of anodic and cathodic sweeps. The characteristic features to be emphasized are (*i*) the early onset of surface oxidation, overlapping with the H region as mentioned above; (*ii*) a more or less reversible behavior in the processes of formation and reduction of the surface oxide when the extent of oxidation of the Ru surface is small (Fig. 2) [cf. the behavior of Pt (15)], (*iii*) development of a stage of higher oxidation of the Ru surface beyond 0.8V E_H (Fig. 1), and (*iv*) increasing hysteresis, much more than at Pt, Pd, Rh, or Au, between the processes of surface oxide formation and reduction when the potential of Ru has been taken above *ca.* 0.6V E_H and especially in the range 1.1 ~ 1.4V E_H (Fig. 1).

From current-potential profiles, such as those in Fig. 1a, the integrated charge for surface oxidation can be obtained as a function of potential as shown in Fig. 1b. Similar data at four temperatures are shown in Fig. 3. The second main region has a slope twice that of the first, suggesting that an oxide film involving twice the valence change of Ru compared with that in the first region is involved.

The true extents of surface oxidation per square centimeter up to any given potential cannot be reliably evaluated, as they can at Pt, owing to the uncertainty (10, 17) of the significance of the charge measured in the H region on account of substantial H absorption mentioned earlier. However, relative estimates, based on a fast sweep in the H region, are shown in the inset of Fig. 1 (marked b). The apparent degree of surface oxidation attained at 1.4V would then correspond nominally to "RuO_2" but this should be taken only as an approximate figure, not reliable to better than 30%.

From various i-V profiles similar to Fig. 1a but taken on a more sensitive current scale, it appears that the region between *ca.* 0.2 and 0.65V E_H corresponds to at least two broadly overlapping stages of surface oxidation, which are resolvable with difficulty below 0.65V in the anodic and cathodic sweeps. This region is evidently comprised of at least two-non-Langmuir peaks [cf. (22, 23)] for the initial stages

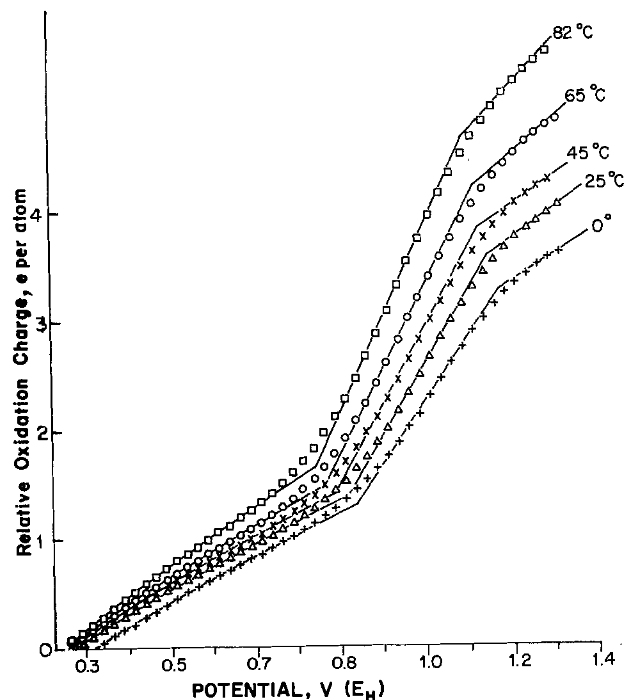

Fig. 3. Charges for surface oxide formation beyond 0.25V E_H showing the two or three principal stages of oxidation (the first region is probably resolvable into two overlapping components; see Fig. 1a and 2).

of surface oxidation of Ru, but these stages are better resolved in the cathodic sweeps (Fig. 1a).

Irreversibility in formation and reduction of the oxide film at Ru.—The hysteresis observed between the i-V profiles of Fig. 1a for the anodic and cathodic sweeps increases with the positive potential limit in the anodic sweep, as it does at other noble metals (7, 13), but the effect is much greater than at Pt or Au.

From Fig. 1 it is evident that the surface oxide formed when the potential of a Ru electrode is taken progressively to values > 0.8V E_H in the anodic sweep is only incompletely reduced in the cathodic sweep. In fact, in repetitive sweeps between 0.05 and 1.4V, the surface oxide formed is never reduced so that the full currents for its reformation are not required on a following anodic sweep. Then an unstructured i-V profile, of the kind reported in earlier work[3] (10, 24), over a 1.4V range at pure bulk Ru is observed. In a restricted range cycling experiment (0.05-0.7V E_H) on bulk Ru, the H region can be resolved after some cycling.

The slow process of reduction of surface oxide formed at appreciable positive potentials (1.1-1.4V E_H) can be followed by bringing the sweep back in a cathodic direction to the H region (to 0.05V E_H) and then holding the potential constant. During this potential-hold, the current can then be recorded as a function of time; it corresponds to slow reduction of the oxide film formed on the previous anodic sweep. In fact, the oxide film reduction is only completed in the H region or with H_2 evolution as at some other metals, *e.g.*, in the reduction of NiO, and the experimental behavior observed is shown in Fig. 4a and b.

Figure 4a shows the current-potential and current-time responses of a ruthenized Pt wire in 1*N* H_2SO_4 to the potential program shown in the inset of Fig. 4a: The potential of the electrode is swept at 0.1 V sec^{-1} to 0.7, 1.0, or 1.35V and then returned to 0.05V at which it is then held constant. The subsequent current-time transient is then recorded as shown to the right of the zero of time on the X axis of Fig. 4a.

After oxidation of the Ru to 0.7 or 1.0V, the cathodic sweep already shows a normal peak corresponding to oxide film reduction. Then the following cathodic current-time transients at 0.05V E_H are almost identical and extend over *ca.* 25 sec. However, when the electrode has been oxidized to ≳ 1.35V, there is almost no main oxide film reduction peak on the cathodic sweep and the reduction occurs on the cathodic current-time transient. This exhibits a maximum which may correspond to a nucleation-controlled reduction of the oxide film with codeposition of H.

In Fig. 4b, the results of a somewhat different but related experiment are shown. For this case, the potential program is as shown below the X axis. The potential is swept from 0.05 to 1.5V and then held for 0, 10, or 100 sec in successive experiments at that potential. The potential is then returned to 0.05V in a cathodic sweep at 0.1 V sec^{-1}, held at 0.05V, and then the cathodic current-time transient is recorded as shown to the right of the 0 on the X axis of Fig. 4b. Longer anodic holding (0 → 10 → 100 sec) produces a longer delay in the cathodic current-time transient corresponding to slower reduction of the oxide film in the H region. After 100 sec holding at 1.5V, the oxide film requires about 90 sec to become fully reduced. Hence, in repetitive sweeps between 0.05 and 1.35 ~ 1.5V, the oxide film is only incompletely reduced in the cathodic sweeps, unless very low sweep rates (<0.01 V sec^{-1}) are employed.

The reversibility of the process of formation and reduction of the oxide is illustrated in another way by the ratios, Q_A/Q_C, of charges Q measured in the anodic (A) and the cathodic (C) sweep, respectively. Q_A/Q_C remains almost equal to unity (Fig. 5) up to a potential of *ca.* 0.8V. If the sweep is taken beyond this potential, then $Q_A/Q_C > 1$ as seen in that figure. The effect is due mainly to incomplete reduction of the oxide in the cathodic sweep but also significantly to some dissolution (see below) of Ru toward the positive end of each anodic sweep.

Induction of a reversible process in oxide film formation and reduction upon multiple cycling.—Very interesting behavior arises at Ru after many (~25-50)

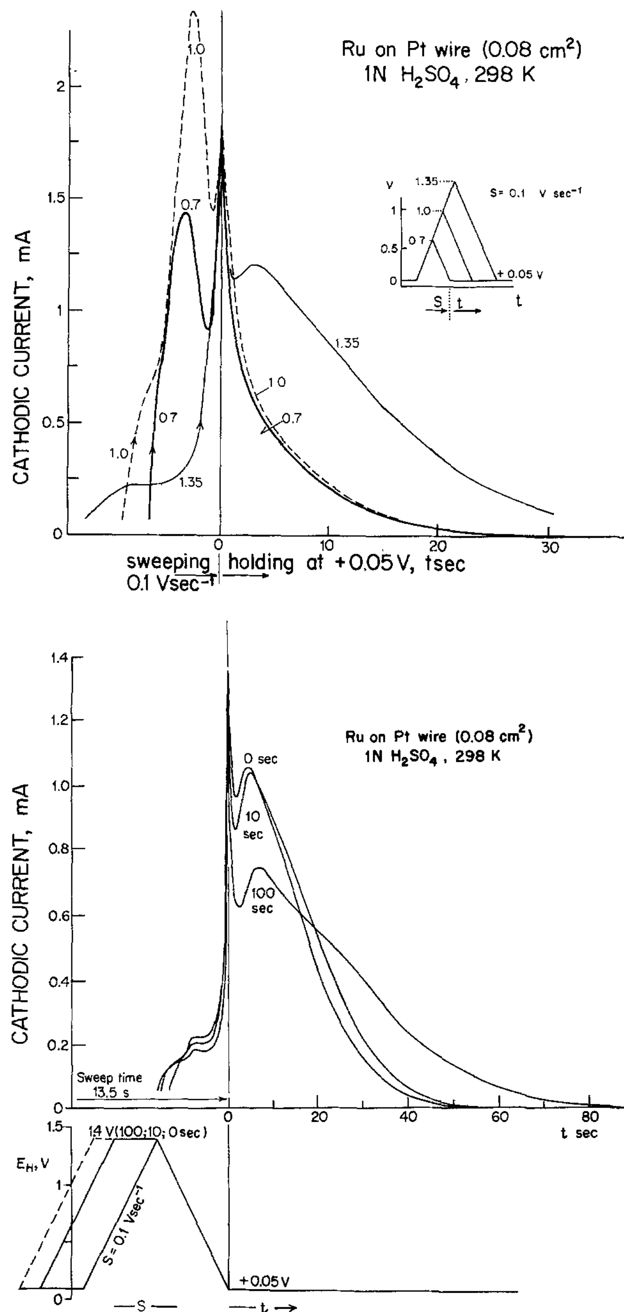

Fig. 4. Current-time transients for potentiostatic completion of reduction of oxide films on Ru after an anodic potentiodynamic sweep: (a, top) for sweeps to 0.7, 1.0, and 1.35V; (b, bottom) for sweeps to 1.4V with 0, 10, and 100 sec holding.

anodic/cathodic cycles up to 1.4V E_H. Initially, the behavior is as in Fig. 1 with much hysteresis between the processes of formation and reduction of the oxide; unless the potential is held at *ca.* 0.05V at the end of the cathodic cycle, the oxide formed in the previous anodic sweep will not be completely reduced, as was indicated with respect to Fig. 1, 2, and 4a and b.

However, upon repeated cycling, the behavior shown in Fig. 6 develops where, at any potential in the sweep, an almost reversible behavior is observed (25) as the direction of the sweep is changed. This is characterized by a sudden change of direction of current, from anodic to cathodic, at a magnitude almost the same as that on the immediately previous anodic sweep. The kinetic relaxation characteristics [cf. (26)] are then those of an almost reversible process, like the behavior of H at Pt (20, 26) or of the initial stage of surface oxidation of Pt (15), especially in alkaline solution. The changed state of the surface is initiated when sweeps are taken beyond

[3] In a paper just published by Trasatti *et al.* (48), similar behavior is found.

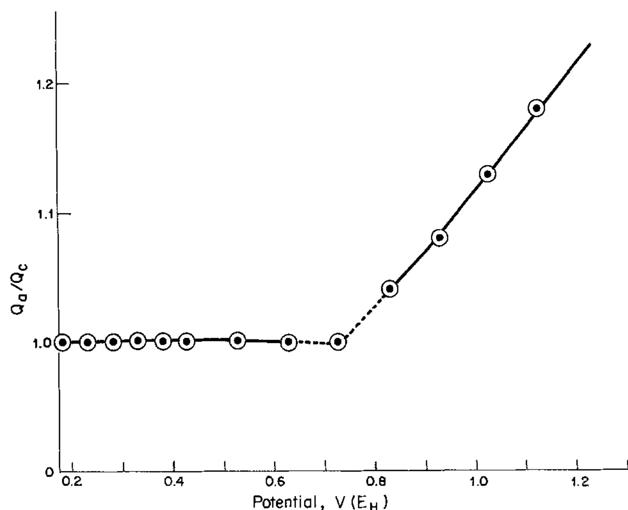

Fig. 5. Values of Q_A/Q_C as a function of the reversal potential in the anodic sweep at ruthenized Pt. Sweep rate 18 mV sec^{-1}. (Compare oxidation charge isotherms of Fig. 3.)

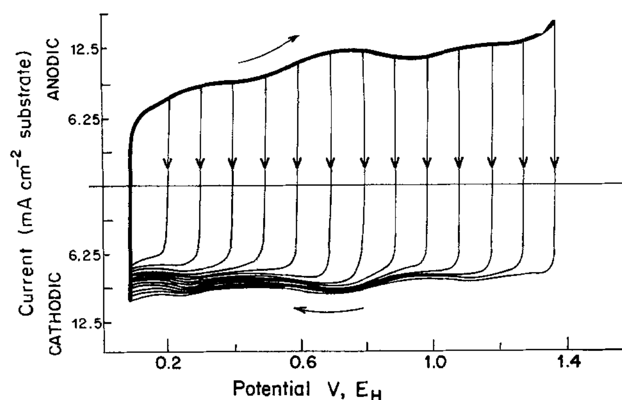

Fig. 6. Behavior of a Ru electrode in anodic and cathodic sweeps taken to various potentials after repetitive cycling ($\geqq$ 50 cycles); (note development of almost reversible cathodic and anodic sweep behavior but absence of reduction peaks or H deposition region shown in Fig. 1a). Sweep-rate 200 mV sec^{-1}.

the 0.8V potential where the higher stage of oxidation sets in (Fig. 3).

During repetitive cycling at a ruthenized electrode, some material is lost by dissolution (see below). This results in some diminution of currents at a given sweep rate but coupling with the effect mentioned above, gives *i-V* profiles (Fig. 6) with much increased reversibility at any potential. An electrode which has reached this state of surface conditioning no longer exhibits (Fig. 6) a resolvable region of H deposition and ionization, as it did initially (Fig. 1). This is because cycling to 1.4V produces the irreversibly oxidized surface that is not reduced in the H region in cathodic sweeps. At Ir, ellipsometric experiments (27) show that the oxide film which is similarly generated upon cycling (12) and which exhibits (12, 13) reversible redox behavior like oxidized Ru, is also not reducible to Ir metal in the H region [cf. (11)].

We have suggested (25) that the remarkable reversibility within the *i-V* profile at any potential, as demonstrated by Fig. 6, is due to establishment of an oxide film in which a rapid redox process,[4] *e.g.*, formally $2RuO_2 + 2H^+ + 2e \rightleftharpoons Ru_2O_3 + H_2O$, can occur with kinetic facility. This process is probably, in reality, more complex involving Ru-O-Ru bridges (28, 29) dependent on the valence state of Ru and on protonation (30, 31). The special state of the surface is only generated, however, by repetitive cycling without reduction of the anodically generated oxide back to the metal at the end of each cathodic sweep. In this respect, the behavior is similar to that of Ir in the experiments of Visscher (12) and of Rand and Woods (32), where an oxide film grows on cycling and exhibits remarkably reversible behavior as noted first by Stonehart, Kozlowska, and Conway (13). Even at Pt, somewhat similar effects of cycling have been reported (33).

Presumably, in the state of oxidation generated by cycling, there is a mixed valency [Ru(III) and Ru(IV)] oxide on the Ru surface at all potentials but the Ru(III)/Ru(IV) ratio, which characterizes the oxide film, evidently depends in a continuous way on the potential of the electrode. In this respect, the surface-oxide redox behavior is analogous to the titration behavior of a polyelectrolyte or ion-exchange resin where the ionizable groups, although having the same individual *p*K values, give rise to a broad titration curve over a wide *p*H range without the inflections characteristic of titration of di- or tribasic acids. The reason for this behavior is that interaction effects destroy the individuality of the *p*K value. Similarly, in a redox system involving two or more charged (ionic) states, interaction effects will broaden the electrode potential degree of oxidation (reduction) relation. Addressing an oxide redox system with a linear potential sweep is analogous to effecting a redox titration of the surface oxide material. We suggest that this is what is observed in Fig. 6, where the individual stages of surface-oxide formation and reduction, which are resolved in initial sweeps (Fig. 1a), are no longer observable in the multiply repeated *i-V* profile.

It is interesting that a similar state of reversibly reducible/oxidizable oxide can be generated on the surface of Ru by thermally forming a Ru film on glass in air at *ca.* 450°C from $(NH_4)_3RuCl_6$. The behavior of this kind of film is illustrated in Fig. 7 and is to be compared with that generated on cycling the nonthermally formed film (Fig. 6).

Film growth behavior.—At the noble metals, holding the potential at a value where surface oxidation can occur results in growth of the oxide film and/or change in the state of oxidation of the metal in the film. The growth is conveniently measured by the charge, Q_C, recovered in a slow cathodic sweep. Q_C is usually (34, 35) a direct logarithmic function of the duration, *t*, of the growth period, although direct and inverse log laws of film growth are sometimes

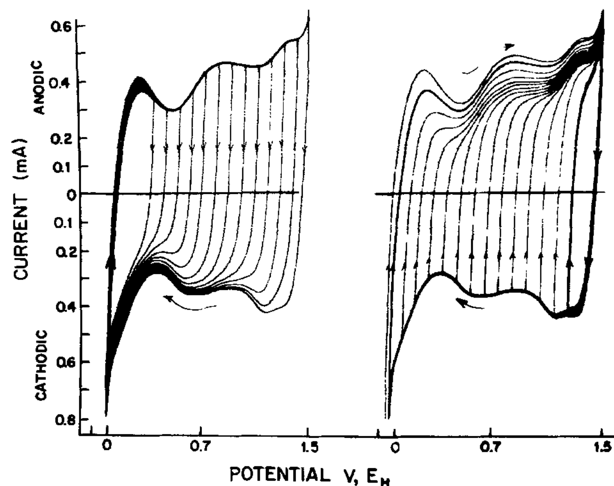

Fig. 7. Reversible anodic/cathodic *i-V* profiles for a Ru film (presumably oxidized) formed by thermal decomposition of $(NH_4)_3RuCl_6$ on glass in air at 450°C. (Compare Fig. 6.) Sweep-rate 200 mV sec^{-1}.

[4] The species shown in this reaction are intended only to represent the probable well-known valence states involved [Ru(IV) and Ru(III)]. The formulas probably do not correspond to bulk compounds for the case of the thin films.

difficult to distinguish unless data over a wide range of time is available. The initial oxidation, *e.g.*, of Pt, in an anodic sweep is a fast process as indicated by the large value of its reversibility parameter, s_0 (36, 37); [s_0 is the maximum value of sweep rate, s, up to which a surface process remains reversible, *i.e.*, peak potentials for electrodeposition of O-species, or of H, remain independent of s. When $s > s_0$, Tafel-type behavior arises, viz., peak potentials are displaced logarithmically in s, see Ref. (23) and (34)]. The growth process, logarithmic in t, is associated with a slow rearrangement of the film in a step following the initial deposition of OH/O species, by place-exchange (38-40) between Pt and OH or O species. The continuing deposition of OH and O species is made possible at the holding potential by the rearrangement process, as discussed in more detail below.

At Ru, very similar behavior to that at Pt (34) is observed; both at the bulk Ru rod (Fig. 9) and at ruthenized Pt (Fig. 9), the oxide film growth is logarithmic in time (except at short times), with a slope $dQ_C/d \log t$ which increases with the holding potential E_A, as shown in the inset of Fig. 9; also Q_C, measured after a given holding time (100 sec), is almost linear in E_A (inset of Fig. 8). Results for two temperatures are shown in Fig. 8.

An interesting characteristic of the growth process, found first at Pt (41), is that if the potential is held for a short time (1 ~ 100 sec, for example) during the anodic sweep, and then the sweep is continued, the resulting i-V profile will fall on the fast continuous-sweep profile determined previously, after an interval in the potential scan, dependent on the time of holding during the sweep. This behavior is also found for Ru as shown in Fig. 10a and b for various holding potentials. Figures 10a and b show that this behavior commences at Ru already at quite low potentials, *ca.* 0.35V E_H.

The behavior of Ru shown in Fig. 10a and b appears to be a general feature of initial stages of oxide film growth at noble metals as it is also found at Au, Pd, and Rh as well as at Pt (41). The following pro-

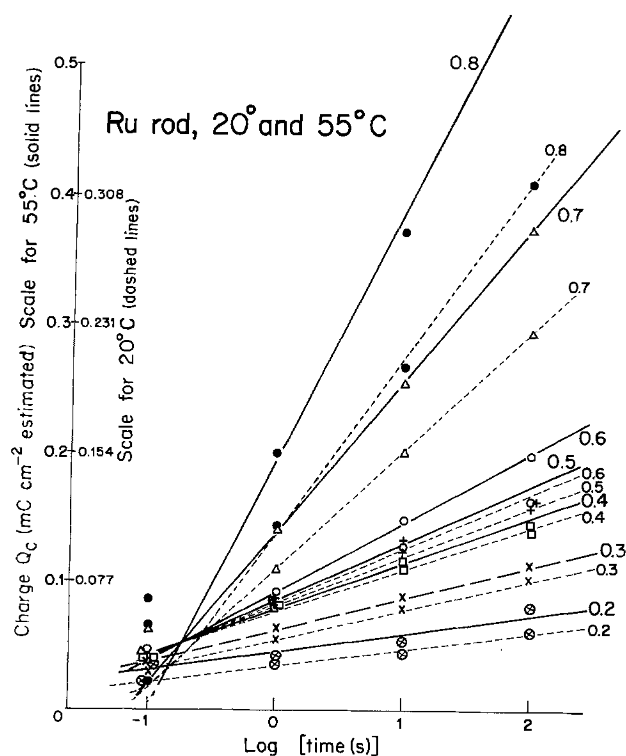

Fig. 8. Plots of increase of degree of surface oxidation (measured as cathodic charge Q_C for reduction of the anodically formed film) of a Ru rod electrode at 293° and 328°K as a function of the log of the growth time.

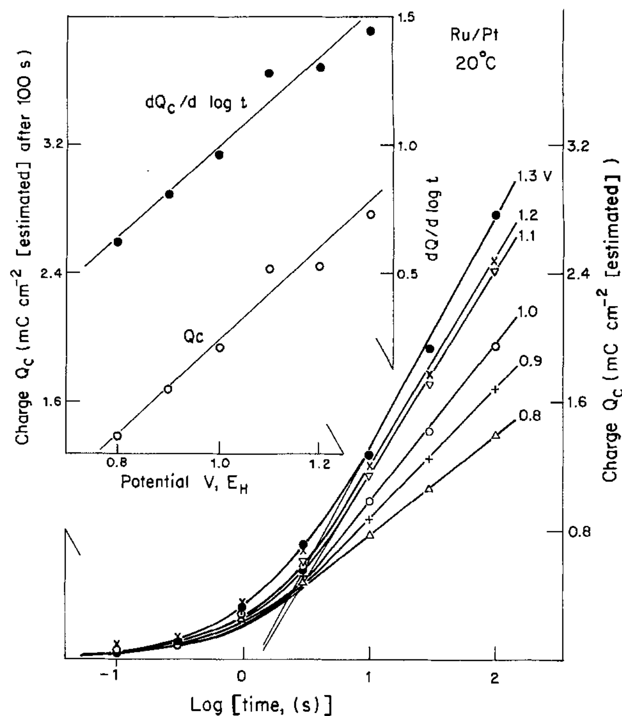

Fig. 9. As in Fig. 8, but for ruthenized Pt at 293°K. Inset shows other functions of Q_C.

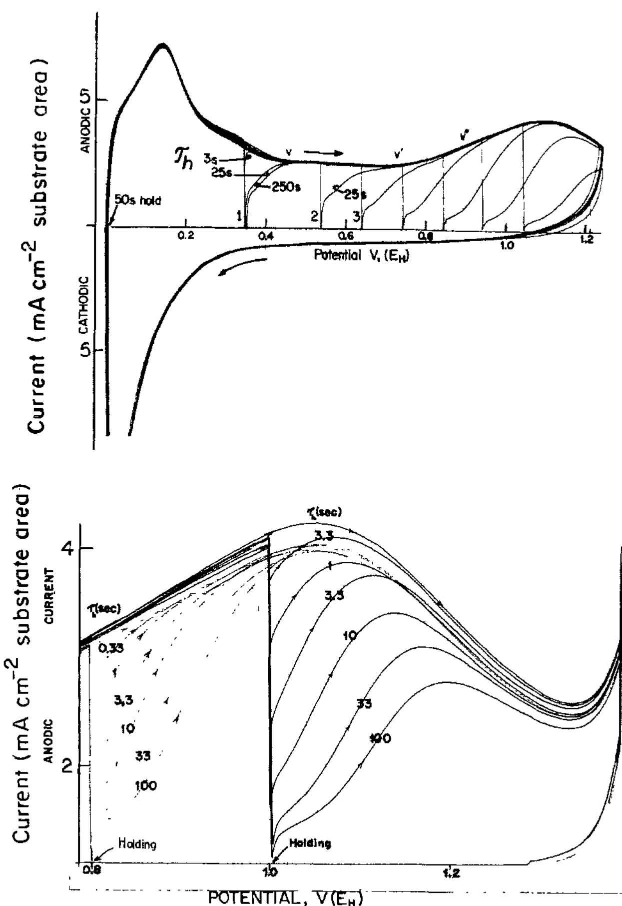

Fig. 10. (a, top) Anodic i-V profiles for a ruthenized Pt electrode with and without holding at various potentials for the indicated times τ_h during the potential sweep. (b, bottom) As in 10a, but at higher potentials of 0.80 and 1.0V.

posal for the origin of this behavior can be made. Although of a tentative nature, it provides a basis for understanding a number of features of the initial stages of oxidation of Ru and other metals, and the irreversibility between oxide film formation and re-

duction processes which is notable characteristic of films formed at coverages $\theta > ca.$ 0.15.

In a fast anodic sweep, rapid (high s_o) underpotential deposition of OH and O species first occurs[5] on noble metal surfaces and at low extents of oxidation, *e.g.*, $\theta \leq ca.$ 0.75, the coverage θ at any potential in a fast sweep over this range of surface oxidation is a reproducible function of that potential. Relatively successful attempts have been made to represent this behavior by an additive combination of two or three electrochemical isotherms of the form [1], *e.g.*, at Pt (23, 40)

$$\theta/(1-\theta) = K \exp(-g\theta)\cdot C \exp VF/RT \quad [1]$$

where g is an interaction parameter, V the potential, and C the reactant concentration, *e.g.* of OH^- or H_2O. Usually, for electrodeposited OH and O films with $\theta_{OH/O} < 0.75$, the isotherms contain repulsive terms, *i.e.* $g > 0$ [cf. Ref. (23, 42)], so that occupancy of the surface by OH and O species is spread over a wider range of potentials than in the Langmuir case ($g = 0$). Usually, distinguishable multiple states of adsorption (*i.e.*, ranges of θ with different K values) can be resolved below monolayer coverage, as at Pt (15), and probably also here with Ru.

As potential and time progress in the anodic sweep, it has been proposed (40) that a relatively slow process of place-exchange between metal atoms and OH/O species in the surface occurs. This is directly indicated by the results of Arvia (43) on open-circuit time-effects in the change of state of oxide films at Pt and by effects of holding the potential constant in the film formation region, followed by cathodic reduction (13, 15).

As the place-exchange process progresses, repulsive interactions existing between the initially electrodeposited OH/O species in the developing monolayer (due to the "MOH" or "MO" surface dipoles) can become locally relieved due to MOH or M-O dipole inversion, so that further deposition of OH or O can occur at a potential below that which would be defined by a $\theta \sim V$ relation such as Eq. [1] for deposition of OH or O species in a regular monolayer on the metal surface. Thus a greater coverage can be attained by holding at some potential E_h in the sweep in the surface oxidation potential region than the equivalent coverage attained in a continuous sweep. Coupled desorption of previously adsorbed anions occurs as the film growth continues.

Eventually, (see Fig. 10a and b) as the continued sweep, after holding at a potential E_h, progresses to sufficiently high potentials E_s in the sweep s, the same coverage and state of the surface is reached after holding as in the regular continuous sweep. This is because the same state of surface oxidation is achieved by holding the potential at E_h for a time τ_h as in a continuous sweep up to the potential E_s, where $E_s > E_h$ to an extent dependent on τ_h (see Fig. 10a and b).

That the same degree of surface oxidation is attained when this condition obtains, is indicated experimentally [cf. (41)] by the fact that the cathodic i-V profile following the anodic sweep is identical for the continuous sweep as for the sweep with intermediate holding at E_h for time τ_h provided that the anodic i-V curve for the continued sweep, after holding, has reached a potential where the i-V profile coalesces with that for the continuous sweep, *e.g.*, at points V, V', V" in Fig. 10a for Ru oxidation.

These results lead to the conclusion, as at Pt, that a given extent of oxide film growth at Ru can be achieved in a "holding" experiment at a potential E_h, as in a continuous sweep to higher potentials, $E_s > E_h$, where the field for continuing oxidation by place-exchange at E_s is larger than that at E_h in the holding experiment. During the holding time, τ_h, the growth of the film is logarithmic in τ_h as described earlier.

Some place-exchange always occurs, of course, in a continuous sweep due to lateral interaction and field effects; the extent of this naturally depends on the sweep rate. The holding effects are hence best observed when $\tau_h >> \Delta t$ where $\Delta t = \Delta V/s$ is the time interval in a sweep at rate s for traversal of a potential excursion ΔV in the surface oxidation region.

Unlike the behavior of Pt or Au in acid solution, however, the growth of surface oxide at Ru commences already at potentials around 0.2 $\sim$ 0.3V E_H. This is apparent in Fig. 10a as well as in the logarithmic plots in Fig. 8.

In order to investigate the growth of the surface oxide film at low potentials, the effect of holding the potential in the range 0.4-0.2V E_H was investigated at a ruthenized Pt electrode that had been subjected only to a few initial conditioning cycles, as for the electrode which gave the results in Fig. 1a. The behavior is shown in the oscilloscope photographs of Fig. 11. Even at these low potentials, the extent of surface oxidation of Ru increases with τ_h as indicated on the successive cathodic i-V profiles of Fig. 11.

Bagotskii *et al.* (19) observed a cathodic peak at 0.27V similar to those in Fig. 11, but attributed it to deposition of H which became sorbed into the Ru.[6] Since the charge under these i-V profiles increases with increasing τ_h at 0.45V E_H (*i.e.*, at a potential where adsorbed or absorbed H would be readily oxidized) it seems that the observed cathodic current peak must be assigned to growth of surface oxide in the early stages of development of the oxide film at Ru rather than to H deposition. This is confirmed by the observation (Fig. 11) that there is constancy of the anodic i-V profiles following the cathodic sweeps after various holding times at 0.45V. This seems to support the conclusion that the cathodic process at these potentials is surface oxide reduction since if the cathodic currents and the current during holding were associated with H deposition in a sorbed state, then more H should be available for the following anodic sweep, which is not the case. This question has been dealt with in more detail elsewhere (17) in a paper on the state of electrodeposited H at Ru.

Relation to surface oxidation behavior of other noble metals.—While the oxidation behavior of Ru surfaces is in some respects unusual, it is useful to point out some of the features which are basically similar to those for other metals. The hysteresis between forma-

[6] Other evidence, *e.g.*, the sweep-rate dependence of the anodic peak current in the H region, does indicate (17) H diffusion from the bulk of Ru. However, such evidence is not obtained from the cathodic sweep behavior at 0.27V.

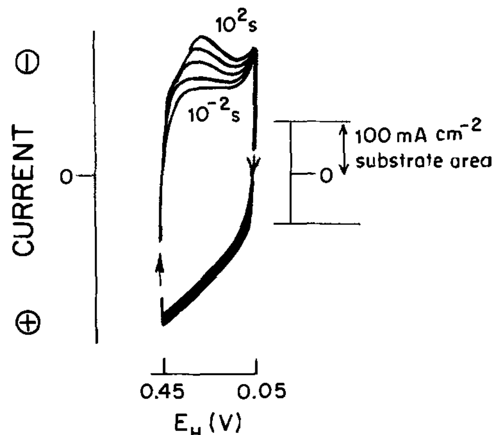

Fig. 11. Oscilloscope i-V profiles for cathodic sweeps from 0.45V E_H after various holding times τ_h from 10^{-2} to 10^2 sec. Anodic and cathodic sweep rates 20 V sec^{-1}.

[5] This reaction itself is found kinetically to be highly reversible (15). However, as shown elsewhere (34), the over-all process of surface oxidation of Pt always exhibits hysteresis due to transformation of the "PtOH" species into a place-exchanged oxide film. This is equivalent to an irreversible chemical step following the reversible electrodeposition process of OH or O species (37).

tion and reduction of surface oxide in initial sweeps is greater than at Pt, Rh, or Au but similar to that at Pd. It increases, as at most metals (13), with increasing potential in the anodic sweep, *i.e.*, with increasing extent of surface oxidation and consequently greater place-exchange (13, 15). Almost reversible surface oxidation of Ru in aq. H_2SO_4, we have shown, already commences at, or close to, the H region. While this is different from the behavior of Pt in acid (15), it is similar to that of Pt in alkaline (NaOH) solution where a reversible region of surface oxidation is already observable at *ca.* 0.4V E_H. This is illustrated for comparison in Fig. 12 for fast anodic and cathodic sweeps at Pt in NaOH solution. Under these conditions, the H region is moved to appreciably more positive potentials in the anodic sweep and to appreciably more negative ones in the cathodic sweep due to irreversibility of H ionization and deposition processes in alkaline solution (36). The surface oxidation and reduction processes are more reversible in alkaline than in acid, so are observed in a well-resolved way as seen in Fig. 12.

The difference between the acid and alkaline solution behavior is due in part to the lack of anion adsorption in the latter case because the potential of surface oxidation (relative to the H_2 electrode potential for the same solution) is much less positive with respect to the potential of zero charge than in acid solution (44). Thus, in acid media, it is known that SO_4^{2-} concentration has a substantial effect at Pt and especially at Au on the potential for onset of surface oxidation. This is because, in the deposition of OH species in the initial stages of surface oxidation of Pt and Au, previously adsorbed anions must be displaced. At Ru, SO_4^{2-} anion adsorption is evidently less competitive with regard to surface oxidation. Despite conclusions (45) that Cl^- does not depress oxygen adsorption at Ru very much, we find that in strong Cl^- solutions (5M NaCl), anion adsorption effects at Ru become more comparable to those at Pt with SO_4^{2-}; then the H region becomes displaced cathodically and the initial surface oxidation region anodically [as is well known at Pt (44)], so that a "double-layer" charging region with a smaller and more normal capacitance becomes revealed in the potentiodynamic *i-V* profile which then is seen to be more similar to that at Pt in aq. H_2SO_4 where strong SO_4^{2-} adsorption prevails. These results illustrate the importance of anion adsorption in determining the shapes of the *i-V* profiles for H deposition and surface oxidation at noble metals, as shown in the early work of Breiter (46).

In other respects, *e.g.*, effects of cycling, Ru behaves somewhat like Ir, as we have shown above and as was noted by Rand, Woods, and Michell at the 1977 Spring Electrochemical Society meeting (11).

Dissolution accompanying surface oxide formation and reduction.—The stability of oxidized Ru surfaces is of interest in relation to the performance of continuous anodic reactions, *e.g.*, Cl_2 evolution, at such electrodes. A number of experiments were conducted at oxidized bulk Ru rod electrodes in order to evaluate rates of dissolution in 1*N* aq. H_2SO_4 and NaCl solutions under steady-state and cyclic anodic polarization. Weight losses were determined directly by withdrawing the electrode periodically from the cell, washing and drying it, and then recording weight changes by means of a microbalance.

The experiments on extents of dissolution were conducted in two ways: (*i*) by cycling the electrode for various numbers of cycles up to various anodic potentials E_a = 0.7, 0.9, 1.1, and 1.3V E_H and recording the losses of weight after 5, 10, 15, 20, 25, and 30 cycles as shown in Fig. 13a, and (*ii*) by establishing an anodic current in the range 6-16 mA and following weight changes, if any, over a period of 4 hr. None was observed (Fig. 13b). The same electrode was then subjected to anodic/cathodic cycling over the range 0.05-1.3V E_H at 16 mV sec^{-1} for 55 min. During this time, a substantial loss of weight occurred as shown in Fig. 13b. The electrode was then returned to a continuous anodic polarization mode at 8-14 mA. The rate of weight loss was then much diminished in comparison with that in the cyclic mode but significant further weight loss did occur over the next 5 hr (Fig. 13b) and more than in the first 4 hr prior to cycling.

After the period of intermediate cycling (Fig. 13b), a change of state of the electrode had evidently taken place, as described earlier. The electrocatalytic properties for anodic reactions are then found to be changed although the real area of the material is, in the short term, not diminished by more than 5%.

It is to be concluded that the stability of a Ru electrode in acid is much less under cyclic polarization conditions than under continuous anodic current operation. This is probably due to the repetitive reorganiza-

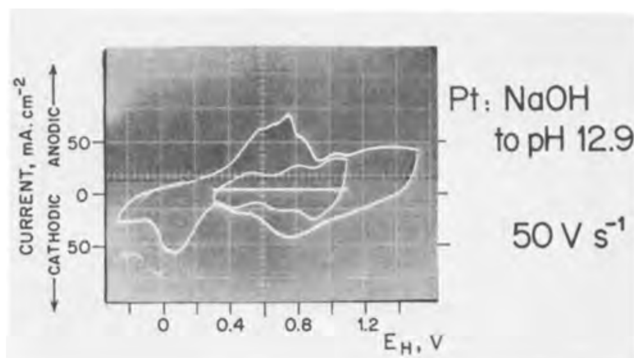

Fig. 12. Resolution of reversible regions of Pt surface oxide formation and reduction near the H region for alkaline solution conditions by displacement of the H oxidation and deposition profiles at a high sweep rate. 1*N* NaOH at 298°K. Sweep rate 50 V sec^{-1}. Outer profiles for full potential range with displaced H region. Inner profiles for the same sweep rate, but over a restricted potential range revealing regions of reversible surface oxide formation and reduction at low anodic potentials.

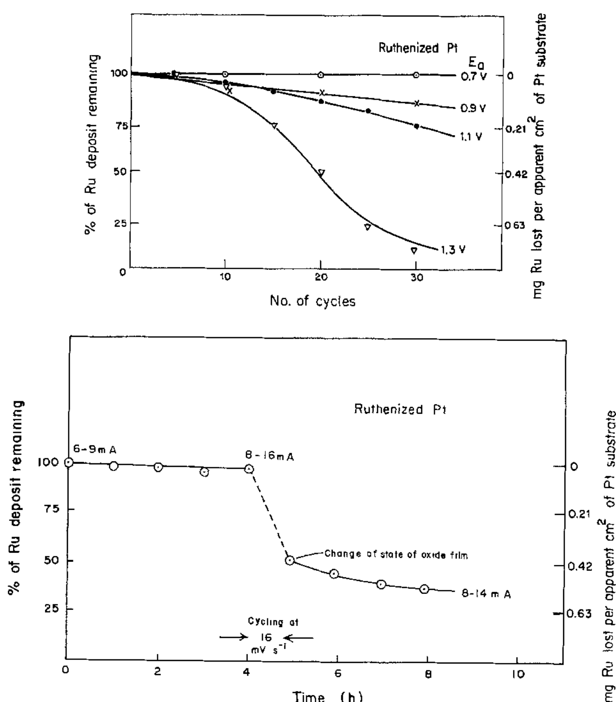

Fig. 13. (a, top) Relative and absolute extents of dissolution of Ru from a ruthenized Pt electrode by cycling to various potentials E_a in the anodic sweep. (b, bottom) Relative and absolute extents of dissolution of Ru from a ruthenized Pt electrode under steady-state and cyclic anodic polarization conditions.

tion of the surface which accompanies cyclic polarization and is associated with the place-exchange processes referred to earlier and with possible accompanying deprotonation and reprotonation (31). Generally, it seems that dissolution depends on: (*i*) the positive potential in the anodic sweep (Fig. 13a); (*ii*) the number of sweep cycles to which the electrode has been subjected (Fig. 13b), and (*iii*) whether the electrode has been polarized only in continuous anodic current mode or otherwise in a cyclic regime (Fig. 13b).

The dissolution is found to be quite appreciable, especially during an anodic/cathodic cyclic treatment, when the anodic potential limit exceeds 0.8V. This is the potential at which a higher state of surface oxidation begins to arise (see Fig. 1b and 3). The effect of Cl^- ion is to enhance the dissolution rate in comparison with that in aq. H_2SO_4 alone. On account of the dissolution which occurs on repetitive cycling, a Ru rod electrode will become "autoruthenized" and will suffer significant increase in real area. On the other hand, a ruthenized Pt electrode progressively loses Ru by dissolution under such conditions, with a decrease of real area, as mentioned earlier.

The extents of dissolution are substantially greater than those which are found at Pt (47) and Ir (32). In alkaline solution, electrochemical oxidation leads directly to dissolution of Ru as solution-soluble ruthenate which can be easily observed on account of its dark red color.

These results emphasize the importance of stabilizing RuO_2 electrode materials by combination, *e.g.*, with a TiO_2/Ti substrate.

Conclusions

Studies on the formation and reduction of surface oxide on Ru lead to the following conclusion: (*i*) At low potentials (0.2-0.4V E_H) initial stages of surface oxidation arise which are almost reversible and overlap with the process of H (absorbed and adsorbed) ionization. (*ii*) Beyond *ca.* 0.8V, a higher state of oxidation of the surface arises and its formation and reduction is progressively more irreversible the more positive is the potential. Formation of oxide at 1.3-1.4V results in a film that is only slowly reducible in the H region. (*iii*) Repetitive cycling to $\geq$ 1.3V causes an irreversible transformation of the behavior of the surface oxide to a state in which the film apparently undergoes a remarkable redox process over a wide range of potentials yet is not reducible back to the metallic state. The role of a Ru(III)/Ru(IV) redox couple in the oxide film is suggested. (*iv*) Appreciable anodic dissolution of Ru occurs on cycling over a potential range >0.7V from 0.05V E_H, especially to higher positive potentials. Dissolution on steady-state anodic polarization is much less rapid. (*v*) In the presence of strongly adsorbed anions, *e.g.*, Cl^-, the current-potential profiles for Ru become more like those of Pt in aq. H_2SO_4. (*vi*) The over-all behavior of Ru is more like that of Ir than that of Pt or Rh, although some important similarities to the latter metals are apparent.

Acknowledgments

Grateful acknowledgment is made to Hooker Chemicals and Plastics Corporation, Niagara Falls, New York for support of this work. Helpful discussions with Drs. Emery, Pouli, Stephens, and Tilak of Hooker have been much appreciated.

Manuscript submitted July 12, 1977; revised manuscript received April 17, 1978. This was Paper 336 presented at the Philadelphia, Pennsylvania, Meeting of the Society, May 8-13, 1977.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Recently, ultramicrotomy (1) and ion beam thinning of films (2), allied with transmission electron microscopy and secondary ion mass spectrometry (SIMS) (3), have provided greater resolution of film morphology and composition. Furthermore, the completeness of the apparently neat but simple explanation of steady-state porous film formation involving field-assisted dissolution (4,5) has now been questioned and an additional mechanism involving direct loss of Al^{3+} ions to solution proposed (6). A model of film growth has been developed (7) which considers solid-state growth of relatively pure alumina at the metal/oxide interface, together with the deposition of microcrystalline, acid anion-incorporated film material at the film/solution interface. This outer layer of film material is derived from impure, colloidal alumina which results from the ejection of Al^{3+} ions, not consumed in solid-state film formation, at the film/solution interface. The two types of film material (distinguished by acid anion incorporation) have been detected by SIMS for barrier (3) and porous films (8). Cell boundary bands, possibly depicting the relatively pure alumina region, have been observed by transmission electron microscopy of ion beam thinned porous anodic films formed in oxalic and phosphoric acids (2). The purpose of this note is to distinguish further between the relatively pure alumina boundary bands and the outer, pore-adjacent acid anion-incorporated material [observed using conventional transmission and scanning transmission microscopy (STEM) allied with energy dispersive x-ray analysis (EDAX)].

Key words: anion, anode, x-rays, sputtering.

The porous anodic films were formed for 10 min on electropolished aluminum at a constant voltage of 150V in vigorously stirred 0.4M phosphoric acid. The films were stripped from the substrate in the usual manner (5) and ion beam thinned from both sides until a suitable thickness for transmission electron microscopy was achieved. The films were generally examined in a Philips 301 electron microscope and analyzed in a Philips 400 electron microscope with scanning transmission and energy dispersive x-ray analysis facilities.

The conventional transmission electron micrograph of the ion beam thinned film shows a distorted cell pattern and the pore section shapes appear to follow the irregular cell morphology (Fig. 1). The cell boundary bands are readily apparent from the onset of examination but become more sharply defined with exposure to the electron beam. With continued exposure to the electron beam, remarkable changes in the film material substructure are observed and are probably related to a drying out process, sintering, or agglomeration and crystallization in the electron microscope (2). The micrograph illustrated in Fig. 1 was taken as soon as possible to avoid the changes discussed above, but some change in appearance is likely since the specimen was exposed, under the vacuum, to the electron beam.

For STEM analysis a nominal probe diameter of 25 nm was selected in order to optimize spatial resolution and count rate for x-ray analysis. The x-ray spectrum from the cell material remote from the cell boundary band and that from an area associated with the junc-

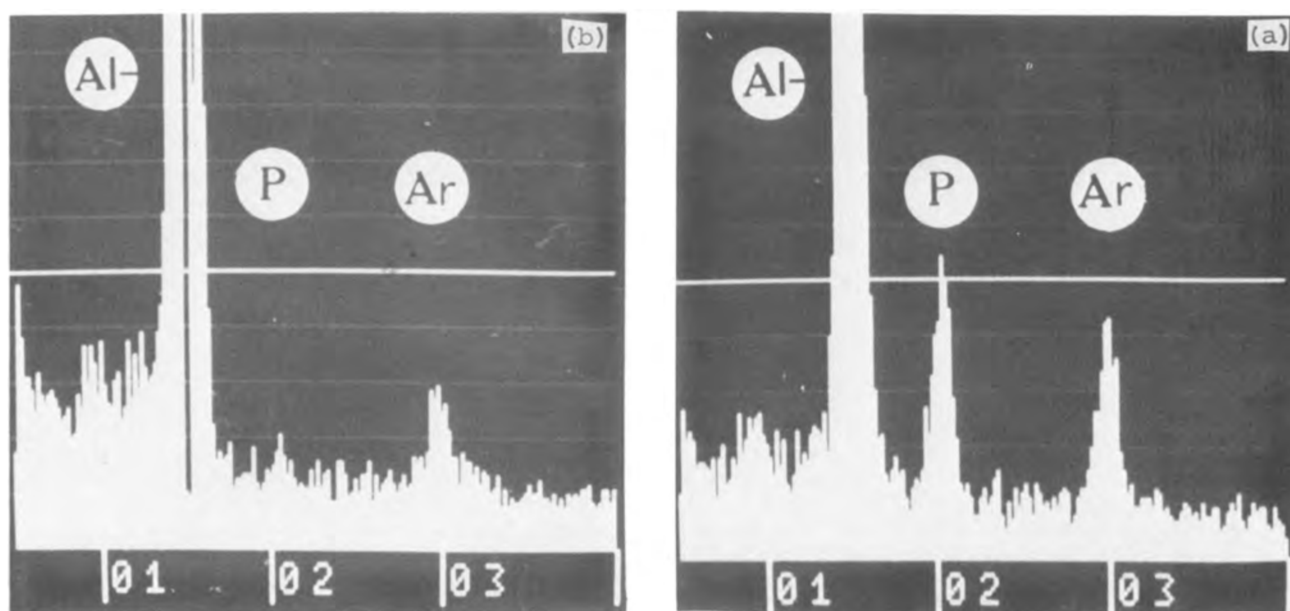

Fig. 2. Typical x-ray spectra (a) for the film material away from the cell boundary band and (b) for the film material associated with the cell boundary band.

tion of the cell boundary bands are displayed in Fig. 2a and 2b, respectively. The energy-dispersive analysis shows aluminum, phosphorus and argon, a much larger phosphorus yield being detected in the cell material away from the cell boundary bands than that associated with the cell boundary bands.

A similar analysis was carried out on several microareas of the cell material between two pores, and the results are shown in Table I. Position 1 represents an area adjacent to one pore and positions 2-5 represent successive probe areas moving inwards from the pore. The probe positions are shown with respect to a comparable pore in the conventional transmission electron micrograph of Fig. 1. X-ray spectra obtained from positions 2 and 6 are shown in Fig. 2a and 2b, respectively. The results indicate that the P/Al ratio decreases as the probe area moves inwards from the pore to the cell boundary band and increases beyond the cell boundary band. The cell boundary band is located between the probe positions 3 and 5.

The detection of a low phosphorus yield within the cell boundary band may be genuine or may be due to x-ray source overlap into the adjacent anion-incorporated material. The distribution of phosphate may

Table I. Comparison of the x-ray counts for aluminum, phosphorus, and argon

Position	Aluminum	Phosphorus	P/Al ratio × 10^3	Argon	Ar/Al ratio × 10^3
1	2,232	207	93	364	163
2	4,951	359	73	368	74
3	7,811	395	51	325	41
4	10,902	149	14	236	22
5	11,206	318	28	175	16
6	11,385	37	3	265	23

also be shifted during ion beam thinning and associated heating of the anodic film.

Argon and silicon were detected for probe areas very close to the pores. Argon ion beams were employed for ion beam thinning and so the detection of argon may be anticipated; silicon may arise from contamination from vacuum greases during ion beam thinning or from the glassware during specimen preparation.

The Ar/Al ratio decreases as the probe area moves inwards from the pore to the cell boundary band (as does the P/Al ratio). This variation is thought to reflect the degree of "openness" of the film across the cell material. The film material adjacent to the pore (formed originally by deposition of impure colloidal alumina) and in contact with the aggressive electrolyte is more hydrated than the film material comprising the cell boundary band (formed originally by ionic migration through an existing film). Thus, as the probe area moves inwards the compactness of the cell material increases in addition to the compositional changes, with respect to acid anion-incorporation recorded.

The results of the present investigation confirm that the cell boundary bands are composed of relatively pure alumina, whereas the cell material adjacent to the bands contains incorporated phosphate species from the anodizing electrolyte. These direct results are in general agreement with the work of Takahashi and Nagayama (9), who determined the distribution of the phosphate species indirectly by dissolution in sulfuric acid of the porous anodic film formed in phosphoric acid.

Corrosion of the Ruthenium Oxide Catalyst at the Anode of a Solid Polymer Electrolyte Cell

J. L. Weininger* and R. R. Russell

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

New and significant developments in ion-exchange technology have been reported recently in a symposium on fluorocarbon ion exchange membranes (1). Nafion[R,1] membranes have also found application as the solid polymer electrolyte (SPE) in fuel (2) and electrolysis cells (3). Clearly, prospects for hydrogen production by electrolysis of water will be enhanced if the cost of the electrocatalysts and their loading in the electrode structures can be reduced (4). For this reason, it is of interest to study the behavior of the electrocatalyst, especially at the anode. As an example, in electrolysis iridium anodes experienced slow corrosion during oxygen evolution (5). Similar behavior of a ruthenium oxide (RuO_x) anode in an SPE cell prompted the present work, in which the electrode and electrolyte structure was examined by electron microscopy and other analytical techniques.

Structure of the Electrocatalyst and SPE Cell

The structures of the electrocatalysts and of the electrode/SPE interface were examined by microscopic means, especially electron microscopy, and by energy dispersive analysis (EDA) and optical microscopy.

Figure 1 is a micrograph of the SPE cell, which consists of a 0.010 in. thick Nafion[R] membrane, covered respectively by a RuO_x powdered anode and Pt cathode. The figure represents the cross section of a microtomed, approximately 2000Å thin, sample of a SPE cell at the end of life test. Folds in the sample on the cathode side and the torn appearance of the RuO_x catalyst (anode) are artifacts of sample preparation. Important observations, which were further explored in electron microscopy, are: (*i*) A sublayer "skin," about 10 μm into the SPE from the electrode interface. This skin has no particles or foreign inclusions; (*ii*) Beyond this sublayer, particles appear at the anode side. Those closest to the interface are largest. They decrease in number as well as size as they go into the interior of the membrane (see electron microscopy below); (*iii*) Some catalyst is torn away from the interface, but there is no smearing so that the subsurface particles are real, not artifacts. These features as well as a porosity in the surface layer of the SPE are brought out by electron microscopy.

Electron Microscopy

In the preparation of the SPE cell, catalysts produced by the Adams method (6) were used in combination with the Nafion[R] membrane as a Pt cathode and a RuO_x anode. Samples of the cells were examined at the start and end of the life test. The latter corresponded to the time at which the oxygen overvoltage had increased approximately 10%. A standard

[1] Sulfonated perfluoro polyethylene (du Pont).

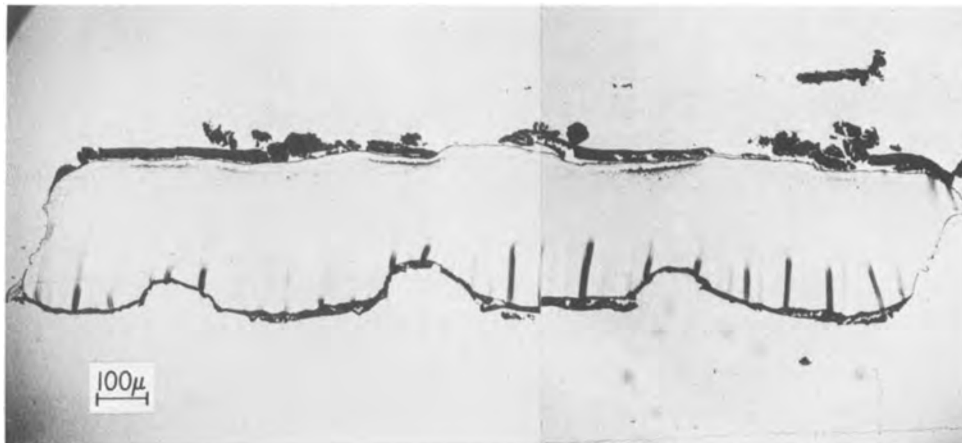

Fig. 1. Optical micrograph of SPE cell. Top electrode, RuO_x; bottom electrode, Pt black.

procedure utilizing ultramicrotomy for preparing electron microscopic samples was used (7).

The SPE/electrode interface of a new cell is shown in Fig. 2. The membrane immediately below the interface is free of foreign particles but contains pores which are 1 μm in diameter or smaller. Although the total porosity may be only 1-5%, the pores are numerous. They were seen on all samples, new and old, and at both sides. At the anode side the location of the pores corresponded to the site of the later formation of particles in the SPE (Fig. 3).

All further electron micrographs of SPE cell components deal with used cells. Thus, in the used SPE cell (Fig. 3) there are foreign inclusions at the anode side, starting at a distance of about 2 μm from the interface. Particles appear at that distance, becoming progressively smaller and fewer for a distance of about 22 μm into the interior of the membrane. Structural details of the particles are shown in Fig. 4. The largest ones, 1 μm in diameter, are agglomerates of smaller entities.

Many more electron micrographs of the SPE cell could be shown, but for the purpose of this report it may suffice to show the overview of the cathode (Fig. 5) and details of the Pt catalyst/cathode (Fig. 6) and RuO_x catalyst/anode (Fig. 7). Note that there is a difference in magnification between Fig. 6 and 7 of 165,000 and 15,000 times, respectively, with the Pt hav-

ing such fine structure that the smallest discernible Pt grain has a dimension of approximately 10Å. That this is the case for a sample at the end of life test proves that no SPE deterioration occurs at the cathode. This deterioration is due to the increasing oxygen overvoltage at the anode, which in turn can be traced to corrosion and subsequent sintering of the RuO_x structure. As for sintering, the RuO_x electrode of Fig. 7 shows several large rhombohedral crystals as well as fine particle structure down to about 150Å. A comparison with the original powder, prepared by the Adams method, indicates that some of the fine particles are identical with those of the original preparation (Fig. 8), but on the average there is some increase in size in the old sample and there are also more of the rhombohedral, large particles, all of which may be the result of sintering.

Energy Dispersive Analysis

In EDA, an electron beam hits a sample and produces x-rays which are converted to voltage pulses in a detector. As in the case of transmission electron microscopy (TEM), many combined SEM views and EDA measurements were obtained on the SPE samples. Figures 9 and 10 are characteristic of these, the former being an SEM of the anode area, the latter giving the fluorescence spectrum from particles 1 and 2 in Fig. 9. There are 1 μm large inclusions in the membrane. The spectra (Fig. 10) show peaks only for Ru and Cu, the latter arising from the copper grid which supports the SPE sample in the microscope. The Ru

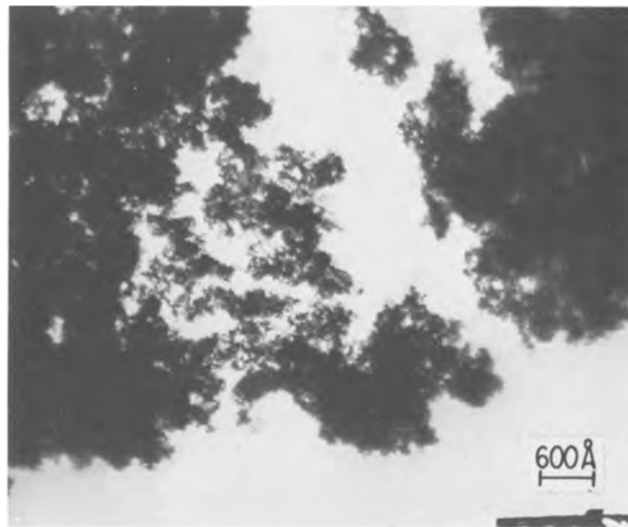

Fig. 6. Electron micrograph of a Pt cathode.

Fig. 7. Electron micrograph of RuO_x catalyst.

spectra are identical to the spectrum coming directly from the electrocatalyst. It could arise either from Ru particles or, more likely, from a Ru oxide or salt. The possibility of the presence of RuO_x particles in the membrane cannot be excluded by EDA analysis.

Other EDA observations were: (*i*) In the old cell, the Ru spots were clearly identified by short x-ray counts; (*ii*) Longer counts over larger areas show with greater instrumental sensitivity the presence of trace amounts of Ca, Si, Mg, Al, Fe, Ti, S, and Cl near the Ru particles and in the bulk of the membrane. Their sources are not visible either in SEM or TEM and must be assumed to be part of the ion-exchange polymer; (*iii*) In contrast to the above, a new SPE cell shows neither multivalent ions nor Ru particles in its membrane.

Summary of Experimental Observations

New cell. —(*i*) The new membrane has a clear appearance, without impurities, but there is a surface region, about 20 μm wide, which differs in texture and porosity from the bulk of the membrane; (*ii*) The porosity is estimated to be about 1%, with pore sizes ranging up to 1500Å, average pore size about 100Å; (*iii*) There are a few large rhombohedral particles in the RuO_x catalyst prepared by the Adams procedure.

Old cell.—(*i*) The new and old SPE cathode and its Pt catalyst appeared to be identical, including the remaining surface layer porosity; (*ii*) On the anode side, the RuO_x particle size, on the average, appeared to be slightly increased over its original condition, roughly 150-100Å; (*iii*) Ru-containing particles appear in the membrane at a distance of 2-8 μm from the interface. The subsurface area is clear of Ru; (*iv*) Beyond the

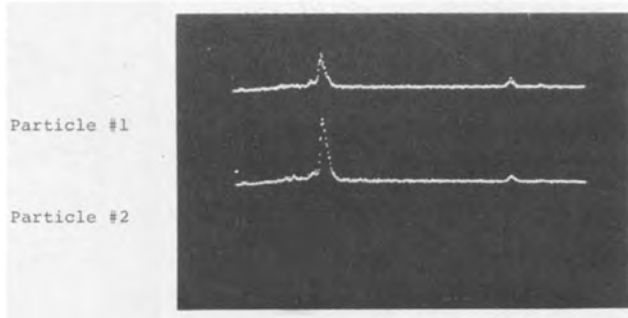

Fig. 10. X-ray spectra from particles 1 and 2, identified as Ru

subsurface region the Ru particles are located in the membrane with a rapidly decreasing distribution, in terms of size and number, toward the interior of the membrane; (*v*) Other multivalent metals (Ca, Mg, Al, Si, Fe, and Ti) and nonmetals (S and Cl) also appear in a qualitatively homogeneous distribution in the membrane.

Interpretation of Observations

A speculative interpretation, consistent with the above observations, is based on regular ion-exchange processes plus the corrosion of the RuO_x catalyst, as follows: (*i*) The membrane interacts with contaminant cations (other than H^+) and retains them to some extent particularly multivalent ions, by exchange with H^+ ions at counter-ion sites; (*ii*) By contrast, Ru dissolves slightly under the acidic conditions of the anode, produced by the electrode reaction

$$H_2O = 2H^+ + \frac{1}{2} O_2 + 2e^-$$

Ru precipitates on the catalyst particles or finds its way, either in ionic form or by electrophoretic action, into the membrane where it is also precipitated and deposited; (*iii*) Ru^{+x} ions which may be complexed, even to the negative ionic form, back-diffuse from the cathode, either dissolved in the swollen membrane or in cracks or gas passages. The latter are exemplified by the porous structure of the membrane adjacent to the electrodes. These gas passages can facilitate access of hydrogen gas from the cathode to the diffusing Ru^{+x} species in the water-filled pores. These pores are in the region where large and most numerous Ru particles are located. They must be distinguished from the "capillaries" of the ion exchange membrane, with sizes of the order of 10Å, which are the site of the electrolyte in the membrane; (*iv*) Once Ru is nucleated at a pore wall, the reaction

$$Ru^{+x} + x/2\ H_2 = Ru + xH^+$$

will proceed autocatalytically, leading to the observed large particles. These inclusions are similar to the calcium precipitates in Nafion[R] membranes used in electrolysis of brine which contains calcium impurity (8); (*v*) RuO_x is known to corrode in acid (9). Although the rate of this process may be very small, elevated temperature should increase it. There also exists a pH gradient from greater acidity at the RuO_x particle reaction site to lesser acidity in the membrane. If the solubility of the Ru-containing species is an inverse function of pH, it will come out of solution at a line parallel to the electrode/SPE interface, where the concentration exceeds its solubility. At that place and time, reduction processes may also take place.

Thus, the deterioration of the RuO_x catalyst is due to corrosion and sintering. The Ru particles in the membrane, per se, may not be deleterious but point up the corrosion process. More or less uniform deposition of other metal ions, in a distribution dictated by the electroneutrality of the membrane, will increase the *iR* drop in the SPE, hence lead to poorer cell performance.

Acknowledgments

We wish to thank S. Hayashi and S. Alessi for the SEM and optical microscopy of the SPE cells. Valuable discussions with M. W. Breiter, W. T. Grubb, and L. W. Niedrach are also acknowledged.

SEAT: Simulated Environment Accelerated Test

Newton Schwartz*[,1] and D. D. Bacon

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The guidelines are established for conducting an accelerated environmental test at 75% RH and 85°C with a set of multiple known pollutants from the atmosphere. The conditions for such a test are based on atmospheric upper limits (AUL) based on measured pollutants and meteorological conditions in the continental U.S. The actual concentration of the test pollutant is increased above the AUL by considering the temperature dependence of the adsorption of each pollutant. The latter is approximated at 75% RH to be similar to the temperature dependence of the solubility of each specific gas in water.

Many forms of tests are utilized to evaluate the long-term reliability of electronic materials or devices or subsystems (labeled M/D/S in this paper). Conventionally when these tests have been chemically or corrosion oriented, they have relied mainly on elevated temperature and high humidity, with the test at 85°C and 85% RH being the prime example for many device studies (1).

In recent years, chemically oriented testing has started to include individual or combinations of chemical gases to evaluate the sensitivity of the M/D/S to known environmental pollutants. Such testing for electronic M/D/S had earlier been concentrated on films, starting with the dynamic testing with about 1 ppm chlorine at low relative humidities in the temperature range of 100°-300°C (2). Static testing in sealed bulbs with water and a pollutant also has been used extensively (3). A British Post Office test for contacts is based on the dynamic SO_2 test to simulate London smog conditions (4). More recently, other tests (5, 6) have been developed using multiple pollutants in flow systems while simultaneously controlling the humidity and with the temperature being in the range of 25°-60°C. The latter workers (6), in particular, have observed that synergistic effects exist in the tarnishing of silver and copper when SO_2, NO_2, and Cl_2 are added to the active H_2S agent. Experiments of this sort have also been a part of a long term program (7), which has also concentrated on the study of aerosols (8), on which the adsorption of pollutants may be predominant. More recently, dynamic single pollutant testing at 85°C and 85% RH on thin and thick films has been performed (9, 10) utilizing the permeation tube technique for generating low concentration pollutants (6).

Table I lists some of the conditions used in previous studies (5, 6) in tests primarily oriented to metallic contact performance. In many of these studies it is not completely clear what guidelines determined the particular set of conditions used or how stated acceleration factors (6) were obtained.

The present paper is meant to state the conditions and general equipment design for a multiple pollutant environmental test for M/D/S. The philosophy of such a test, called SEAT (simulated environment accelerated test), and the assumptions on which the testing conditions are based are given.

* Electrochemical Society Active Member.

Key words: corrosion, pollutants.

Normal Ambient Conditions

In order to realistically establish test conditions, it is first necessary to evaluate the average environment that the M/D/S will be exposed to in a 10-30 year life interval. The test is intended to simulate the design life and not temporary exposure to excessive adverse conditions. Considerable effort, therefore, has been involved in establishing normal AUL (*i.e.*, atmospheric upper limits) for a variety of atmospheric pollutants (10). Table IIA lists these AUL values as well as the stable components of the atmosphere. These values may change with time as various measures to change the environment become effective, but they represent the best evaluation at the present time of the maximum average concentration of these pollutants that the M/D/S will be exposed to in a 10-30 year life. These AUL are based on outdoor measurements but good reasons exist, in many instances, to expect these to reflect indoor air quality (10).

Accelerated Testing

Temperature.—The best known factor associated with the acceleration of almost all fundamental chemical reactions is temperature, which is characterized by the Arrhenius function

$$k_p = P' e^{-\Delta E/kT} \quad [1]$$

where k_p is the rate constant of the process, P' is the preexponential, ΔE is activation energy, k is the Boltzmann constant, and T is the absolute temperature,

There may be hesitancy in basing acceleration on a rise in temperature alone (*i.e.*, utilizing Eq. [1]), because the basic mechanism may change over large temperature intervals or P' may be temperature dependent. However, if these latter two factors can be eliminated, then Eq. [1] represents the best description of the change in rate of a process with respect to temperature.

Table IIA lists 23.3°C as the AUL for temperature. Since much M/D/S testing has already been performed at 85°C (1), an arbitrary "small" temperature acceleration interval is to be contrasted with some "large" intervals of 75°-225°C that have been used in some earlier tests (2, 3).

It is instructive to try to relate the significance of a positive or negative result in an 85°C test to the basic activation energy of the degradation process, the length of the test, the time dependence of the degradation process, and the predicted life at 23.3°C. A degradation process, P, can be considered which starts as some virgin state, P_o, at time equal to zero, t_0, and ends up at some failed state, P_f, at some later time, t_f. Equation [2] gives a general equation for this process

$$P_f - P_o = k_p \pi (\overline{C}_i)_s^{n_i} (\overline{C}_{H_2O})_s \int_{t_0}^{t_f} f'(t) \quad [2a]$$

$$= A_o \pi (\overline{C}_i)_s^{n_i} (\overline{C}_{H_2O})_s \, e^{-\Delta E/kT} \int_{t_0}^{t_f} f'(t) \quad [2b]$$

where A_o = temperature independent preexponential; $(\overline{C}_i)_s^{n_i}$ = product of the average concentration of individual pollutants adsorbed in the surface, each raised to some chemical reaction order; $(\overline{C}_{H_2O})_s$ = similar function for the adsorbed water on the surface; and $\int_{t_0}^{t_f} f'(t)$ = unknown time dependence of the process.

In order to use temperature acceleration as a significant tool, it is imperative that the factors $(\overline{C}_i)_s^{n_i}$ and $(\overline{C}_{H_2O})_s$ remain constant as the temperature is raised. If these factors change markedly, as they surely will because of the heats of adsorption associated with the process, then there is no clear way to evaluate the acceleration factor, which is difficult under any circumstances. The temperature dependence of $(\overline{C}_i)_s^{n_i}$ and $(\overline{C}_{H_2O})_s$ is discussed in the next section.

In many diffusion, corrosion, and oxidation processes between a gas and solid phase, the time dependence[2] of the reaction may be either directly proportional to time (associated with spalling of the separating grown phase) or proportional to the logarithm of time (associated with the separation of charge in the separating phase). Other time dependences can exist, but these will be considered as examples in attempting to evaluate the significance of a result on an 85°C test. Equation [2b][3] will be used with these different time dependencies, where the design life will be assumed to be 20 years, and where the test time at any elevated temperature will be 200 to 1000 hr. With these assumptions, the results in Table III are calculated. Table III indicates that it takes a 10,000+ hour test at 85°C to eliminate processes down to 0.4 eV for a linear time dependence.

It is obvious from this simple analysis that an 85°C-200 hr test is most effective for a (log t) process, since there are not many degradative processes with activation energies below about 0.1 eV. Table IV lists some typical activation energies for a variety of processes.

This discussion indicates that for important M/D/S intended for final manufacture and use, some effort should be devoted to determining the time dependence and activation energies of the failure process. In a general test at 85°C, however, the absence of a failure in test times of 200-1000 hr has a high probability of eliminating processes with activation energies of 0.5 eV or higher.

SEAT assumption I: Temperature will be used as the acceleration factor. The temperature interval will be relatively "small" in order to encompass the same mechanism.

Testing time.—In the previous section, it was stated that 200-1000 hr is a reasonable test time, and these

[2] The time dependence discussed here is the integrated function

$$f(t) = \int_{t_o}^{t_f} f'(t)$$

[3] For the present calculations, the concentration factors are presumed to be constant with a change in temperature.

Table III. Activation energies of the degradation process eliminated for 20 year life at 23.3°C in tests at 85°C

Time dependence of process	Activation energies, eV			
	200 hr test	1000 hr test	5000 hr test	10,000 hr test
t	≥1.0	≥0.8	≥0.54	≥0.44
$t^{1/2}$	≥0.5	≥0.4	—	—
log t	≥0.12	—	—	—

Table IV. Activation energies for different processes*

Process	ΔE, eV
Diffusion limited corrosion (solution)	0.1-0.2
Grain boundary diffusion	0.25-0.50
Hopping transport on dry surfaces	1-2
Electron transfer at surfaces	0.7-1.5
Oxidation of metals	0.75-2
Bulk diffusion	1-3

* Values not to be taken too literally; obtained by discussion with various individuals knowledgeable in the field.

times are to be contrasted to "short" intervals (*i.e.*, 20-60 min) and "long" intervals (*i.e.*, year). The latter time is more suitable for a product which has a definite commitment to manufacture, but it is impossibly long during the active development of a M/D/S. For such activities, there is a strong pressure for immediate information and "short" times are considered. Degradation can be accomplished under these latter conditions only by applying excessive elevated temperatures, fields, or pollutants. Under these conditions there may be a serious danger of studying degradation processes which normally might not be pertinent during the design life of the M/D/S. Moreover, in reliability testing, there is the well-known phenomenon of very early failures, perhaps associated with manufacturing sports, followed by a slower fallout due to various slow failure mechanisms. In "short" time testing, there may be a tendency to detect only the early fallout, without being able to detect the later failures.

Times of the order of 200-1000 hr are an arbitrary compromise to the above "short" and "long" times. However, if the information portrayed in Table III is considered, there is a definite relationship, for such "intermediate" test times, of the absence or presence of a failure to the activation energy of the process. If some prior- or post-insight is available on the process involved, then some qualitative judgments can be made on the reliability of the M/D/S, based on 200-1000 hr testing.

SEAT assumption II: A reasonable time for an accelerated test is 200-1000 hr.

Humidity.—It is well established that humidity is an aggressive agent in corrosion processes and accelerates most degradation at a given temperature. This property is associated with the adsorbed layer on surfaces, which acts as a medium for electrolytic and electrochemical processes.

In Eq. [2], the surface water factor is given as $(\bar{C}_{H_2O})_s$, which might be expressed as the weight of the adsorbed layer per unit area of exposed surface. In any general test, where many different materials might be exposed, this factor is specific for the individual material mechanism. In order to establish absolute reliability criteria for a particular M/D/S, then the entire mechanism has to be determined, and the temperature dependence of the adsorption isotherms must be considered. These same comments apply to the pollutant concentration factors, $\pi(\bar{C}_i)_s^{n_i}$, of Eq. [2].

Another semiquantitative approach is utilized in this study in order to establish a general test for a wide variety of M/D/S. In this approach, an attempt is made to hold the surface concentration of these species relatively constant as the temperature is raised to accelerate the process. In order to achieve such a minimization of the change in chemical surface concentrations with a rise in temperature, it is necessary to introduce some other simplifying assumptions.

An illustration of the dependence of the adsorbed water surface concentration on electroplated gold with respect to the gas phase pressure and temperature is given in Fig. 1 (11). The weight of the water adsorbed is determined by the shift in frequency of a quartz crystal balance (Fig. 1, left-hand side), which can be converted directly into a mass gain (Fig. 1, right-hand side); if a density of about 1 is assumed for the adsorbed water, then a nominal thickness can be determined (Fig. 1, right-hand side). The dashed vertical line indicates how the water surface concentration varies with temperature with an arbitrary choice of pressure of 10 Torr. With a change in temperature from 15.5° to 39°C, the surface concentration decreases by a factor of ~7. This change in surface concentration is equivalent to an enthalpy change of about 0.6 eV/mole, which is probably composed of a small adsorption energy and a much larger heat of condensation of water when the results are analyzed

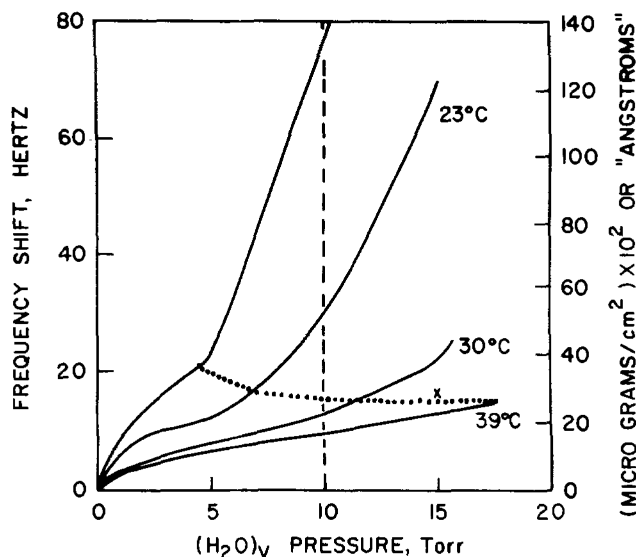

Fig. 1. Adsorption of water vapor on electroplated gold (11)

according to the BET equation (11). Any failure process, as defined in Eq. [2b] and linearly dependent in $(\bar{C}_{H_2O})_s$, with a real activation energy, E, of about 1 eV, would demonstrate an apparent activation energy of 0.4 eV when investigated near the test temperature of about 85°C if the process were investigated at a constant water vapor pressure of 10 Torr.

It is instructive to consider how these numbers might affect the extrapolation of failure data from higher temperature accelerated testing. Assume that the desired failure rate is 1% in 20 years[4] at the AUL temperature and humidity of 23.5°C and 75% RH, respectively, and that the actual E in Eq. [2b] is 1 eV. For the same surface coverage of water at the test temperature of 85°C, the calculated expected failure rate in 200 hr would be 1.1×10^{-3}%. The actual failure rate would be lowered to a value of 1.9×10^{-5}%, since the water surface coverage would be decreased by a factor of 1.76×10^{-2} because of the 0.6 eV/mole enthalpy change. This observed failure rate when combined with the 0.4 eV/mole activation energy would lead to a predicted time of 300 years to achieve the desired 1% failure rate. If such a result did not lead to a change of design, then the M/D/S would have the expected reliability in service, with no safety margin. If due to economic penalties for such a conservative design, the M/D/S were altered to give an extrapolated failure rate of 1% in 40 years, then the M/D/S will eventually be underdesigned from a reliability viewpoint.

The immediate above discussion is only illustrative, since most accelerated testing is done at constant relative humidity. The minimization of the error, due to varying surface water concentration as the temperature is raised when tests are performed at constant relative humidity, is demonstrated in Fig. 1 by the approximately horizontal dotted line. This line is calculated for a RH of 32% and indicates that the water concentration changes by only 40% in the same temperature interval that resulted in a 700% change at a constant pressure of 10 Torr.

This sort of result might indicate that the sorbed water layer has something "liquid-like" about its structure since the relative constancy in its concentration as a function of temperature depends on the equilibrium liquid water vapor pressure. This possible assumption is verified to some extent by the "thickness" axis of Fig. 1, which indicates on gold at 23°C (*i.e.*, the AUL) and 15 Torr (*i.e.*, ~70% RH, close to the AUL) that the water layer has a nominal thickness of 120Å or about 40 monolayers. This water may

[4] This assumes a $f(t)$ which is linear.

be condensed in pores or at hygroscopic impurities, but these may also act as "liquid water sinks" for corrosion processes.

SEAT assumption III: Accelerated testing will be done at a constant relative humidity and from Table II, this value will be 75% RH.

Gas phase pollutant concentrations (single additions).—The same considerations about adsorption energies discussed for water in the previous section apply to the adsorption of pollutant gases to account for the $\pi(\bar{C}_i)_s^{n_i}$ term in Eq. [2]. It will be assumed, considering the possible "liquid-like" character of the adsorbed water, that the solubilities of gases in water can be used to make corrections as the temperature is raised.

SEAT assumption IV: Pollutant gas pressures at any test temperature will be increased over the AUL by a factor proportional to the decrease in solubility of that gas in water.

It is assumed that, as the surface concentration of the adsorbed pollutant decreases as the temperature is raised, the decrease can be compensated for by an appropriate increase in gas phase pressure, similar to the Henry's law pressure dependence of the solubility of gases in liquids (12). Moreover, the magnitude of the pressure compensation as a function of temperature can be estimated from the known temperature dependence of the solubility of that gas in water. This procedure will minimize the error associated with a change of temperature but will not correct for it absolutely. Again in any critical application, specific studies will have to be performed to evaluate these factors.

The application of SEAT assumption IV will be illustrated first with the stable components of air: nitrogen (78.1%), oxygen (20.9%), argon (0.93%), carbon dioxide (0.033%), methane (2000 ppb), hydrogen (500 ppb), and nitrous oxide (500 ppb) (13).

The solubilities of all of these gases are given in terms of Henry's law (14)

$$K_a^{T_i} = P_a^{T_i}/X_a^{T_i} \quad [3]$$

where $K_a^{T_i}$ is the Henry's law constant for a particular gas at a given temperature, T_i; $P_a^{T_i}$ is the partial pressure of the gas at T_i; and $X_a^{T_i}$ is the mole fraction of the dissolved gas at T_i. For illustrative purposes, T will be taken as 23.3°C (296.5°K) the AUL, while T_i will be any elevated temperature. SEAT assumption IV requires that at any elevated temperature $X_a^{T_i}$ will remain constant relative to its value at T, so that

$$P_a^{T_i} = P_a^T \frac{K_a^{T_i}}{K_a^T} \quad [4]$$

where P_a^T is the value of the AUL at 23.3°C, $P_a^{T_i}$ is the increase in temperature and $K_a^{T_i}/K_a^T$ ratio of Henry's law constants to be used as correction factors.

These ratios of Henry's law constants are given in Fig. 2 for all of the relatively stable components of air and in Fig. 3 for all of the pollutants in air. The slopes of this ratio should be proportional to the heat of solution according to Eq. [5]

$$\log \frac{K_a^{T_i}}{K_a^T} = -\frac{\Delta H_s}{2.303R}\left[\frac{1}{T_i} - \frac{1}{T}\right] \quad [5]$$

Because of the expected dependency of Eq. [5], Fig. 2 and 3 are plotted as semilogarithmic with respect to the reciprocal absolute temperature, although the upper ordinate is given in degrees centigrade. The solid vertical line gives the results for the assumed test temperature of 85°C, and all values start at one at the AUL of 23.3°C.[5] The values at 85°C are used to calculate, according to Eq. [4], the test temperature values given in Table IIB. Figures 2 and 3 show a high degree of nonlinearity, indicating that the heat of solution is not constant over this temperature range.

[5] The dotted lines in Fig. 2 and 3 are extrapolations of known data given by the solid lines at lower temperatures.

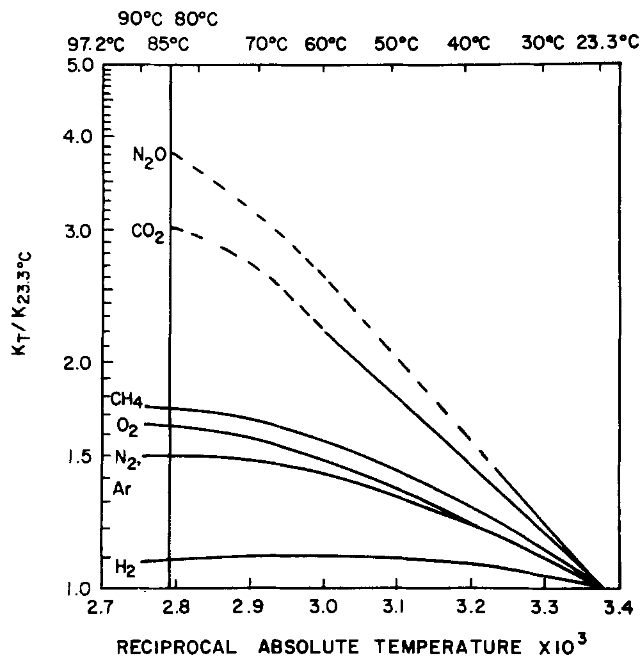

Fig. 2. Ratios of Henry's law constants for the solubilities in water of the stable components of air as a function of temperature.

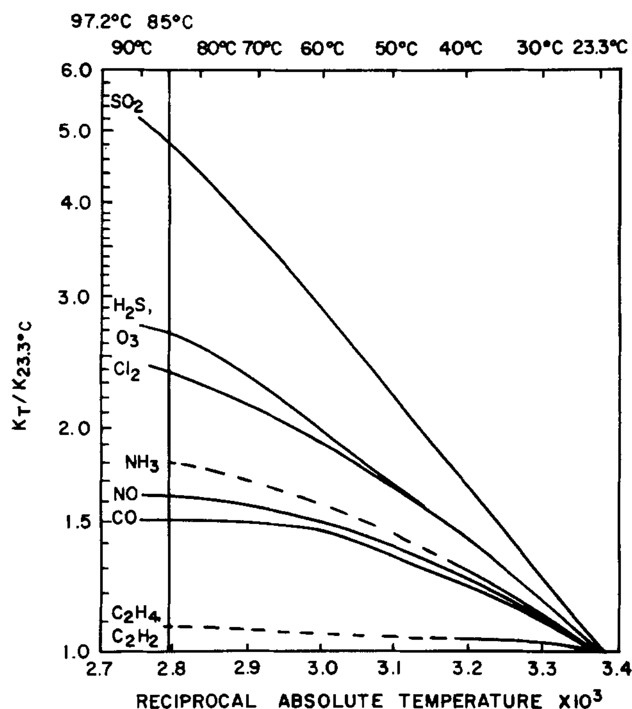

Fig. 3. Ratios of Henry's law constants for the solubilities in water of the pollutants in air as a function of temperature.

In Fig. 2, the pressure correction factor at 85°C is rather insignificant for H_2 (*i.e.*, 1.08), moderate for CH_4, N_2, Ar, and O_2 (*i.e.*, ~1.6), and rather large for N_2O and CO_2 (*i.e.*, ~3.5). For trace gases, Fig. 3, the corrections for NH_3, NO, CO, C_2H_4,[6] and C_2H_2[6] are small to moderate while those for Cl_2, O_3, H_2S, and SO_2 in particular, are quite large.

In general, the temperature dependence of these gas solubilities are related to simple heats of solution where not too strong interactions exist with water, although some heat of reaction occurs for SO_2 and Cl_2 due to the formation of acids. NO_2 represents a

[6] These were chosen as perhaps being typical of NMHC (non-methane hydrocarbons).

special case since no tabulated solubility data exist because of the formation of nitric acid. Many studies (15) indicate that in flow systems the solubility of NO_2 in water is kinetically slow, presumed to be associated with the need to form the dimer, N_2O_4. At the parts per billion levels of the NO_2 AUL, it can be calculated that N_2O_4 does not exist and NO_2 conceivably may be very slow to dissolve in water. Another report (16) exists, however, which indicates that although at moderate concentrations the solution of NO_2 is slow and incomplete, there is a tendency for NO_2 to dissolve more completely at low partial pressures. In this paper we assume that the latter observation is pertinent and that the equilibrium reactions take place at the AUL.

The reaction (17) when NO_2 dissolves in water is given by Eq. [6], and the equilibrium constant by Eq. [7]

$$3NO_{2(g)} + H_2O_{(l)} \rightarrow 2HNO_{3(aq)} + NO_{(g)} \qquad [6]$$

$$K_{T_i} = [HNO_3]_{T_i}^2 \frac{(P_{NO})_{T_i}}{(P_{NO_2})_{T_i}^3} \qquad [7a]$$

$$[HNO_3]_{T_i}^2 = K_{T_i}\,(P_{NO_2})_{T_i}^3/(P_{NO})_{T_i} \qquad [7b]$$

The left-hand side of Eq. [7b] is a function of the partial pressures of both NO_2 and NO, and, making the same assumption as previously that the concentration of the species in solution (or adsorbed) must remain constant as the temperature is raised, then Eq. [8] results

$$\frac{(P_{NO_2})_{T_i}^3}{(P_{NO})_{T_i}} = \frac{(P_{NO_2})_T^3}{(P_{NO})_T}\frac{K_T}{K_{T_i}} \qquad [8]$$

where T is the value at the AUL, T_i is any elevated test temperature, and $(P_{NO_2})_T$ and $(P_{NO})_T$ are the AUL values.

The ratio K_T/K_{T_i} can be evaluated from the usual Eq. [9]

$$\log\frac{K_{T_i}}{K_T} = \frac{-\Delta H^\circ}{2.303R}\left[\frac{1}{T_i} - \frac{1}{T}\right] \qquad [9]$$

where the enthalpy, ΔH°, is calculated from the standard heats of formation (18), and the value of $-31{,}000$ kcal (*i.e.*, -1.34 eV) is calculated for this reaction.

Values of the partial pressure of NO_2 to be used at any elevated temperature can be calculated using Eq. [8] and [9], but only for given values of the partial pressure of NO at the test temperature. Figure 4 shows the value of NO_2 to be used at different temperatures for three fixed values of NO: 70 (AUL), 100, and 200 ppb. It is assumed that the middle value of 100 ppb of NO will be easy to control at any test temperature, and for this concentration the partial pressure of NO_2 at 85°C is about 1700 ppb. This is the largest correction for all the pollutants listed in Table IIB, since the AUL for NO_2 is only 72 ppb.

Gas phase pollutant concentrations (multiple additions).—The above discussion represents semiquantitative corrections for the addition of single gaseous components, or at most pairs of components such as NO_2/NO. There are various complications to be considered when multiple additions are made. Some illustrations are:

(*i*) Catalytic conversion of SO_2 in the presence of NO_2

$$2SO_2 + O_2 \xrightarrow{NO_2} 2SO_3$$

(*ii*) Catalytic disappearance of O_3 with H_2O or NO

$$O_3 + H_2O \rightarrow H_2O_2 + O_2$$

$$NO + O_3 \rightarrow NO_2 + O_2$$

(*iii*) Neutralization reactions

$$2NH_3 + 3NO_2 + H_2O \rightarrow 2NH_4NO_3 + NO$$

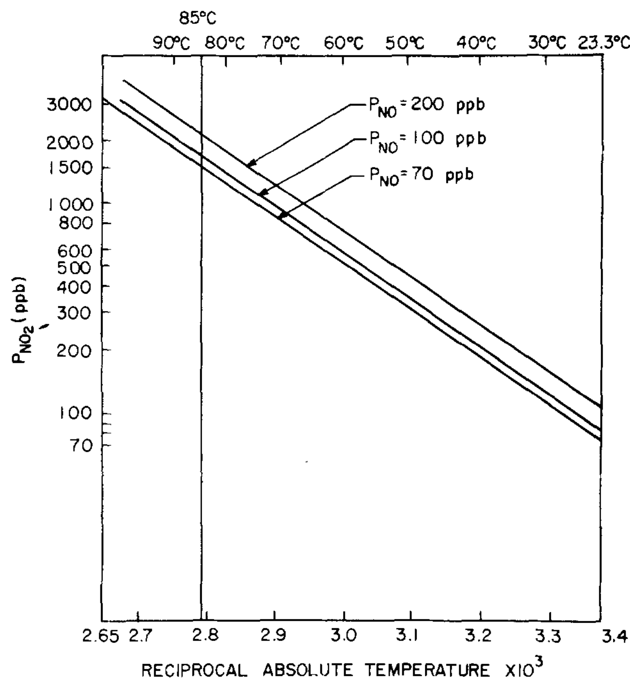

Fig. 4. Calculated partial pressure of NO_2 to be used at various test temperature for fixed NO partial pressures.

All of these chemical reactions, and others, can potentially change the temperature dependence associated with elevated temperature testing. However, these represent such a sophisticated degree of analysis and specification that no consideration will be attempted until future experiments indicate the degree to which they exist.

Initially all of these tests will be performed in the dark to avoid photochemical complications. Eventually, however, they can easily be performed in the presence of visible and ultraviolet light.

Operation of the System

The basic control factors associated with a SEAT facility are temperature, humidity, and pollutant concentrations.

Temperature and humidity.—It was desired to have a relatively large facility to allow the simultaneous testing of large numbers of M/D/S, and in common with another test (6), a commercial temperature-humidity cabinet was chosen. A single pass temperature-humidity oven (Fig. 5) was quite appropriate, since the air stream is first humidified over a heated water pan, then heated to the test temperature, then passed into the test chamber, and then exhausted. The air does not recirculate, and the pollutants can be added just before entering the test chamber.

Due to the corrosive nature of some of the potential pollutants, a Teflon box is therefore utilized inside of the test chamber. To get the most efficient evaporative cooling of the wet and dry bulb thermometer, air flows in the range of 100 to 200 slpm were used. Such high gas flows are also desirable since a previous study (19) showed that the tarnishing of metals in H_2S is dependent on the cube root of the gas flow.

Pollutant concentral control.—Permeation tube rates (6, 7, 9, 10) are not quite high enough for total flow rates of 100-200 slpm, and it was decided to use 0.75% of the pollutant in nitrogen in standard gas tanks at 700-2400 psi. Such a concentration can be made quite accurately by a gas supplier and is high enough that possible reactions with the walls of the tank represent an insignificant change in concentration.

In order to accurately meter multiple gases in the range of 0.2-20 sccm each, a gas blender consisting of electronic mass flow controllers was selected.

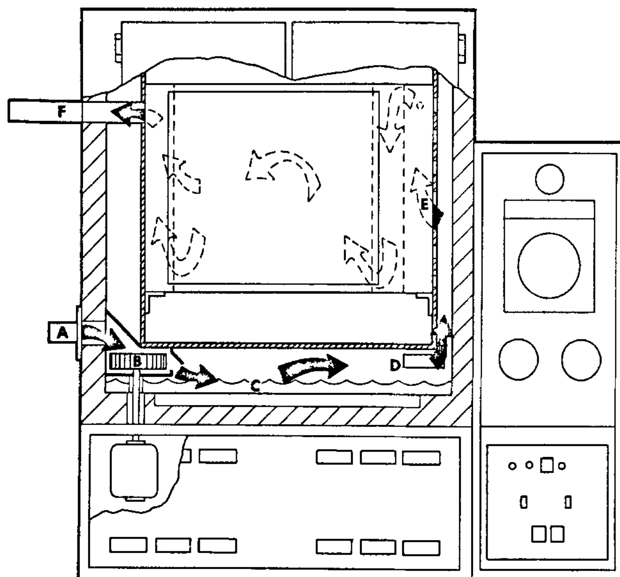

Fig. 5. Over-all diagram of Teflon box in humidity oven. Arrows show single pass air flow from inlet (A), pass blower motor (B), oven humidity tray (C), oven dry bulb heaters (D) into Teflon box (E), and out exhaust (F).

SO_2-air dilution characteristics.—The SEAT system was operated with an original source in the tank of 4.9% SO_2/nitrogen and at various flow rates of clean air. The concentration of SO_2 in the Teflon box was measured by extraction with a pump and then optically analyzed.[7] The solid curve in Fig. 6 shows the SO_2 concentration as a function of the clean air flow rate, while the dashed line is the calculated concentration based on the known SO_2 concentration and known gas flow rates. At very high air flow rates, the calculated and measured concentrations are identical, but at flow rates below about 120 slpm they depart markedly. This data can be interpreted to mean that at the selected operating condition of 100 slpm, the actual dilution air consists of about 80% of added clean air and about 20% of ambient air. This latter factor is of no great concern since this ambient air has been measured to have a low particulate content and very low SO_2 and NO_2 levels compared to the levels controlled within the SEAT system.

SO_2 concentration at different humidities.—Figure 7 shows the concentration of SO_2 inside of the Teflon box at different flow rates of the 4.9% SO_2/N_2 mixture

[7] SO_2 Pulsed Fluorescence Optical Monitor, Thermoelectron Corporation, Waltham, Massachusetts.

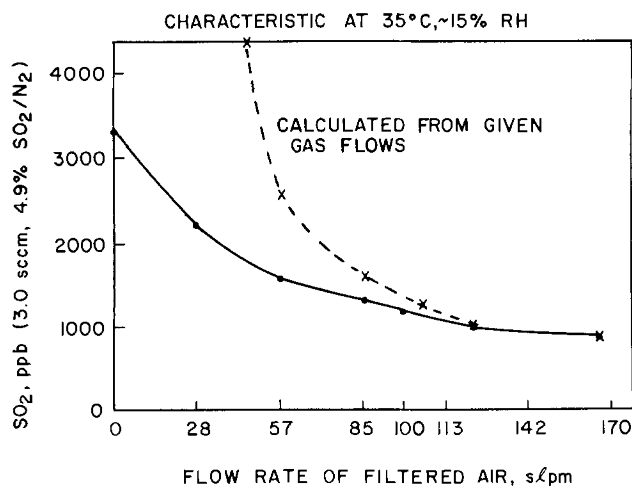

Fig. 6. Measured SO_2 concentration in SEAT facility as a function of the air flow rate.

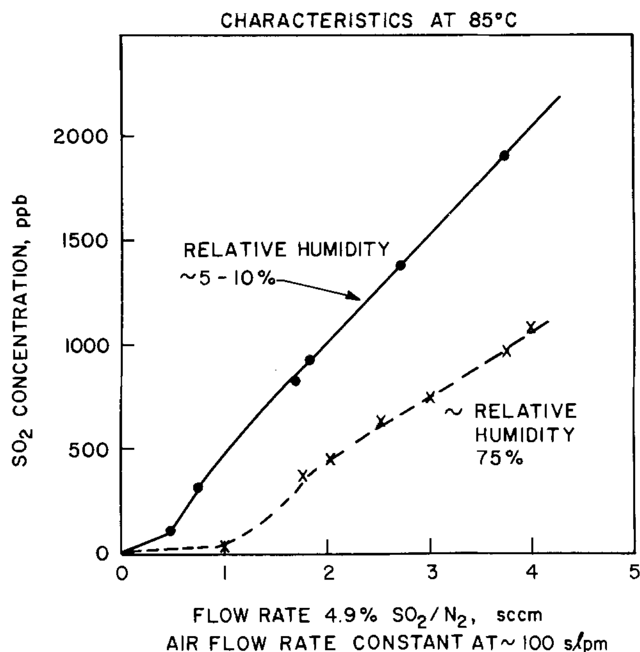

Fig. 7. Measured SO_2 concentration in SEAT facility at 85°C with and without water, as a function of the SO_2/N_2 flow rate.

with a constant flow rate of 100 slpm of air. The solid curve is for measurements at 85°C with no water in the humidifying tray, and the relative humidity was about 5-10%. The concentrations of SO_2 are essentially linear, as expected, with SO_2 flow rate; an essentially identical line was obtained for measurements at about 30°C.

A major difference appears when the same set of measurements was made in the presence of moisture (*i.e.*, dashed line, Fig. 7, 85°C, 75% RH). The same flow rate of SO_2 yields gas phase concentrations which are from 10 to 30% of the values measured in the absence of moisture. In order to protect the optical SO_2 monitor from moisture, a condenser is put in to trap out the water from the air sample. Some SO_2 is known to condense with the moisture and it is likely that this is a major cause of the discrepancy. Further tests must be made to obtain SO_2 concentrations. These over-all effects demonstrate concretely that pollutant monitors are necessary in such a system to accurately define the conditions of the test.

There are many mechanisms that can be proposed for the net equilibrium decrease of SO_2 with the addition of moisture such as a reaction to form SO_3 or a reaction with the Teflon walls or trapping in the condensate. Further characterization of this process will be deferred to another paper when more analyses have been taken.

Summary

What has been described in this paper are the general principles and assumptions underlying a proposed test of M/D/S with respect to their life of 10 to 30 years in an average high polluted environment. Other tests will have to be utilized to evaluate short time exposure to aggravated conditions of temperature, humidity, and specific high pollutant levels.

It is recognized that many subsystems and systems are not designed to survive at 85°C test for even 216 hr (9 days) at 75% RH. It is possible that these systems will require another sort of test where more moderate temperature acceleration is utilized, but compensated for with some pollutant concentration acceleration. Future work in the proposed SEAT system may provide the guidelines for establishing such a test.

It is also recognized that many *ad hoc* assumptions have been utilized in establishing the guidelines for a SEAT program. Some tests in the past have been ini-

tiated, where subsequent users were not quite aware of what guidelines determined the conditions and what assumptions were implicit in the test. This paper, at a minimum, is a source of such statements with respect to the SEAT mode of testing.

Selective Site Laser Excitation and ESR Studies of Nd^{3+} Ions in $Ca_5(PO_4)_3F$

F. M. Ryan,* R. W. Warren, R. H. Hopkins, and J. Murphy*

Westinghouse Research and Development Center, Pittsburgh, Pennsylvania 15235

ABSTRACT

Single crystals of $Ca_5(PO_4)_3F$ activated with Nd^{3+} were studied by high resolution selective site laser spectroscopy. The optical properties of Nd^{3+} ions located at various inequivalent sites were correlated with Nd^{3+} site symmetries obtained from electron spin resonance (ESR) measurements and also with the polarizations predicted by group theory. Two types of Nd^{3+} sites were observed with C_3 site symmetry, two with C_{1h}, and one with no symmetry. Models for these centers are proposed, and the effect of growth conditions on the distribution of Nd^{3+} among these various sites is discussed.

Calcium fluorophosphate is of interest because of its use as a fluorescent lamp phosphor and as a laser host. In its phosphor application it is activated with Sb^{3+} and for laser applications it is activated with Nd^{3+}. There are two inequivalent Ca^{2+} sites in the structure, denoted Ca(I) and Ca(II). The Ca(I) site is axially symmetric, C_3, with each calcium ion surrounded by six oxygen nearest neighbors forming a slightly twisted triangular prism. Three Ca(II) sites form an equilateral triangle centered on an F^- ion with reflection symmetry C_{1h} (C_s) perpendicular to the crystalline C axis. Sb^{3+} and Nd^{3+} substitute for Ca^{2+} in the apatite lattice with charge compensation required to preserve neutrality. The two calcium sites and the variety of possible compensation models make the analysis of the optical properties of trivalent activator ions in this structure very difficult. The most useful technique for determining site symmetries of activator ions is electron spin resonance (ESR), which unfortunately is useful only in studying paramagnetic ions like Nd^{3+}, although in certain cases the location of the nonparamagnetic ion Sb^{3+} can be deduced from its superhyperfine interaction with nearby paramagnetic defects of known configuration (1). However, Nd^{3+} and Sb^{3+} probably form the same types of centers so that identification of Nd^{3+} centers should by analogy yield information on Sb^{3+} centers.

In earlier work Ohlmann *et al.* (2) suggested that Nd^{3+} ions occupy only Ca(II) sites in calcium fluorophosphate because no strongly polarized fluorescent or excitation transitions were observed. Group theory predicts 100% polarization for many of the transitions of Nd^{3+} located on a site of symmetry C_3 while none of the transitions of Nd^{3+} on a site of symmetry C_{1h} (C_s) would be strongly polarized. The crystals studied in that work were grown from stoichiometric melts and the neodymium was introduced as Nd_2O_3. Eaglet *et al.* (3) conducted x-ray structure and optical investigations on crystals pulled from stoichiometric melts. They concluded that almost all of the neodymium would locate on Ca(II) sites with a compensating oxygen replacing an adjoining fluorine

* Electrochemical Society Active Member.

ion. If neodymium was introduced as NdF_3, however, they indicated that both Ca(I) and Ca(II) sites were likely to be occupied. However, no evidence was given to support these conclusions. Daraseliya *et al.* (4) observed the ESR spectrum of Nd^{3+} located on a site of C_{1h} (C_s) symmetry. Growth conditions of the crystals were not stated in their paper. Kaplyanskii and Kuzminov (5) performed piezospectroscopic measurements on crystals pulled from stoichiometric melts with neodymium added as Nd_2O_3. They also concluded that the neodymium preferentially located on a Ca(II) site with the probable method of compensation being an oxygen substituting for an adjacent fluorine.

Since these earlier studies were completed a useful new tool has been developed for studying the optical properties of ions in crystals containing multiple sites, the technique of selective site excitation with a tunable laser (6). In this paper we have combined selective site laser spectroscopy with ESR to identify the site symmetries and optical properties of Nd^{3+} in calcium fluorophosphate crystals and also the effect of melt composition on the distribution of Nd^{3+} among these sites.

Experimental Details

Crystal preparation.—The single crystals of Nd^{3+}-activated $Ca_5(PO_4)_3F$ for this work were pulled from the melt by a technique reported previously (7). Nd^{3+} was introduced as Nd_2O_3 and crystals were grown from melts with both stoichiometric and nonstoichiometric composition. The crystals studied are listed in Table I which indicates the Nd melt doping and melt stoichiometry; the Nd^{3+} incorporated into the crystals was approximately half that added to the melt.

The melts were made by combining various properties of Luminescent Grade CaF_2, $CaHPO_4$, and $CaCO_3$. The $CaCO_3$ is equivalent to CaO since CO_2 evolves during melting. Variations in melt stoichiometry may be expressed as excesses or deficiencies of CaF_2, CaO, or $CaHPO_4$. In previous work (1, 8-11) it was found that crystals pulled from stoichiometric melts are deficient in fluorine, producing large numbers of fluorine vacancies which are occupied by various configurations of electrons and substitutional oxygen ions. The concentration of substitutional oxygen ions can be greatly reduced by growing crystals from melts deficient in CaO; the number of fluorine vacancies is increased when the melts are deficient in CaF_2 (9). It was not possible to study an extended series of crystals in which only one parameter had been changed at a time (*e.g.,* Nd^{3+} concentration and stoichiometry) because of the crystals available, many contained Nd^{3+} concentrations too high to permit the separation of individual centers by ESR.

The crystals were oriented by Laue photography, cut, and optically polished. ESR and optical measurements were performed on the same piece of crystal for each boule.

ESR.—The ESR measurements were performed with a conventional x-band apparatus. To achieve adequate resolution measurements were performed at both 77° and 4.3°K. The apparatus was constructed to allow rotations of the crystals relative to the external magnetic field. This permitted a precise determination of the symmetry of each neodymium site in the crystal. No details of the ESR spectra are shown because they are not important to this work.

Selective site laser excitation.—Selective site laser excitation permits unraveling the optical properties of ions located on each of a number of inequivalent crystallographic sites (6). The composite optical spectrum of these inequivalent ions is normally very complex and the separation into the individual components quite difficult. The selective site laser technique uses a tunable dye laser as an excitation source to excite the luminescence of the ions. The energy emitted in the narrow line-width of the dye laser is very large compared to that of more conventional excitation sources, so that the signal/noise ratio is greatly enhanced, and ultrahigh resolution excitation spectroscopy becomes possible. In previous work (6) the ion studied was Er^{3+} and the fluorescent emissions of Er^{3+} at various sites were resolvable, allowing the individual excitation spectra to be easily obtained. The comparatively broad ($\sim$1 nm) linewidth of Nd^{3+} in calcium fluorophosphate leads to a more confusing overlap of the fluorescent emissions of the various site contributions. By obtaining a series of excitation spectra when viewing at various portions of the fluorescence envelope, and by varying the polarization of the excitation source and the fluorescence detector, it was still possible to sort out the individual site contributions.

The experimental arrangement used in performing our selective site excitation is shown on Fig. 1. A 1 MW Molectron Model U-V 1000 pulsed nitrogen laser is used as a u.v. excitation source for a tunable dye laser. The nitrogen laser produces 10 nsec long pulses at a repetition rate of 50 Hz to allow rapid scanning of the dye laser output for obtaining excitation spectra. The tunable dye laser used was a Molectron Model DL-20 which produced an output tunable between 570 and 590 nm of approximately 25 kW peak, consisting of 7 nsec long pulses. The FWHM resolution of the dye laser output was 0.01 nm and Rhodamine 6G was used as the dye. The output of the tunable laser passes through a polarizer to the crystal which is immersed directly in the refrigerant in the optical cryostat. The measurements were performed at 77°K in order to sharpen the optical spectra as an aid in separating the spectra of the various inequivalent neodymium sites. Further cooling of the crystal to 1.8°K gave no measurable improvement over 77°K.

The infrared Nd^{3+} fluorescence passes through an *IR* polarizer to a 0.25m Jarrell-Ash monochromator. An S-1 photomultiplier cooled to 77°K was used as a detector and coupled to a Princeton Applied Research Box Car Integrator to increase the signal/noise ratio of the fluorescence pulses. Due to the relatively slow decay time of the Nd^{3+} centers ($\sim$0.25 msec) gate widths in the order of 1 msec or longer were required. All of the Nd^{3+} centers studied had approximately identical decay times so that no site discrimination by decay times was possible.

The Site Symmetry Dependence of the Transitions of Nd^{3+} in $Ca_5(PO_4)_3F$

A partial energy level diagram of Nd^{3+} is shown on Fig. 2. Nd^{3+} has three 4f electrons which form a $^4I_{9/2}$ ground state. The fluorescence studied in this

SELECTION RULES

Fig. 4. The character table for transitions involving Nd^{3+} ions located on sites of C_{1h} symmetry.

work is at 1.06 μm and is an electric dipole transition from the $^4F_{3/2}$ level to the $^4I_{11/2}$ level (2). This is also the laser transition for Nd^{3+}. Fluorescence excitation was between 17,000 and 17,500 cm^{-1}, the useful range of the dye Rhodamine 6G. Nd^{3+} has four $^2G_{7/2}$ and three $^4G_{5/2}$ levels in this energy range. Transitions from the ground state $^4I_{9/2}$ levels to the $^2G_{7/2}$ are spin forbidden so that to first order only the three transitions to the $^4G_{5/2}$ levels should be observable in the excitation spectra for each inequivalent Nd^{3+}.

The selection rules for the allowed electric dipole transitions in the Ca(I) and Ca(II) sites are determined from the character tables in Fig. 3 and 4. Since the higher symmetry (C_3) of the Ca(I) site leads to a table with more structure, it will be instructive to analyze the consequences of C_3 symmetry after which the properties of the Ca(II) table will be self-evident.

The symmetry operations E, C_3, C_3^2, R, RC_3, RC_3^2 are the transformations performed on the crystalline axes that leave the environment of the Nd^{3+} ion unchanged. The origin of coordinates is taken to be at the Nd^{3+} center. E is the identity operation and amounts to no operation at all. Its presence is required in order that the group be complete. C_3 and C_3^2 represent rotations through 120° and 240°, respectively, about the crystalline C axis. The operation R represents a rotation through 360° about the C axis. Its effect is the same as the identity operation when one is dealing with the transformation properties of (*i*) the states of systems with an even number of electrons, *e.g.*, Pr^{3+} and Eu^{3+}, or (*ii*) the operators that represent the interaction energies between systems, *e.g.*, electron-photon, electron-crystalline field. On the other hand, for the states of a system with an odd number of electrons, R changes the sign of the state function. Therefore, whenever one is dealing with an odd electron system, such as Nd^{3+}, the operation R must be included in the point group.

The eigenstates of any system must transform as one of the representations of the group of operations that leave it invariant. The functions with which we are concerned are (*i*) the three components of the electric dipole moment of Nd^{3+} ion since that is what couples to the electric field through an interaction of the form

$$-e\mathrm{E}\cdot r = -e(\mathrm{E}_x x + \mathrm{E}_y y + \mathrm{E}_z z) = -e\{(\mathrm{E}_x + i\mathrm{E}_y)(x - iy) + (\mathrm{E}_x - i\mathrm{E}_y)(x + iy) + \mathrm{E}_z z\} \quad [1]$$

where plane polarized and circular polarized descriptions of the interaction are given; and (*ii*) the angular momentum wave functions of the Nd^{3+} ion which are various linear combinations of functions of the form $e^{im\phi}$, m being the component of the total angular momentum along the C axis. The quantum mechanical expression for the transition probability includes a factor of the form

$$|\langle\psi_f|H'|\psi_i\rangle|^2 \quad [2]$$

where $H' = -e\mathrm{E}\cdot r$ and ψ_i and ψ_f are the initial and final Nd^{3+} wave functions.

Since the transition probability is just a number, its value cannot depend on any transformation of the crystal that leaves the crystal in exactly the same condition. If we carry out all of the symmetry operations on the functions contained in the matrix element, some piece of it must remain unchanged, otherwise the transition described by that matrix element is zero. There is always one representation of a group that is invariant under all of the operations and it is conventionally labeled A_1 (Γ_1 in some circles).

The previous paragraph requires that the matrix element remain unchanged under all symmetry operations. Therefore

$$<Op\psi_f|Op(-eE\cdot r)|Op\psi_i> = <\psi_f|-eE\cdot r|\psi_i> \quad [3]$$

where Op is any symmetry operation. But the character table in Fig. 3 tells what happens to the states of Nd^{3+} for all Op's.

For all states that have z components of angular momentum given by $m = 1/2 \pm 3n$, $n = 0, 1, 2, 3$, etc., the effect of the symmetry operators in Fig. 3 are

$$Ee^{im\phi} = e^{im\phi}$$

$$C_3e^{im\phi} = e^{im(\phi+2\pi/3)} = e^{i\pi/3}e^{im\phi} = -w^2e^{im\phi}$$

$$C_3^2e^{im\phi} = e^{im(\phi-2\pi/3)} = e^{-i\pi/3}e^{im\phi} = -we^{im\phi}$$

$$Re^{im\phi} = e^{im(\phi+2\pi)} = e^{i\pi}e^{im\phi} = -e^{im\phi}, \text{ etc.} \quad [4]$$

where

$$w = e^{2\pi i/e}$$

Therefore the states with $m = 1/2 \pm 3n$ transform as the first row of the representation $D_{1/2}$ in Fig. 3.

The Hermitian conjugate states, *i.e.*, those with $m = -1/2 \pm 3n$ can be shown by the same procedure as in Eq. [4] to transform as the second row of $D_{1/2}$. Those states that have $m = \pm (3/2 + 3m)$ transform as the representation S in Fig. 3.

Using the table in this way we derive the selection rules illustrated in Fig. 3 and 4 for Nd^{3+} in Ca(I) (C_3) sites and Ca(II) (C_s) sites, respectively. The set of equations corresponding to Eq. [3] with $\psi_i = e^{i\phi/2}(D1/2)$, $\psi_f = e^{3i\phi/2}(S)$ coupled together by $(E_x - iE_y)(x + iy)$

$$E: \quad <e^{3i\phi/2}|x + iy|e^{i\phi/2}> = <e^{3i\phi/2}|x + iy|e^{i\phi/2}>$$

$$C_3: <-e^{3i\phi/2}|w(x + iy)|-w^2e^{i\phi/2}> = <e^{3i\phi/2}|x + iy|e^{i\phi/2}>$$

$$C_3^2: <-e^{3i\phi/2}|w^2(x + iy)|-we^{i\phi/2}> = <e^{i\phi/2}|x + iy|e^{i\phi/2}>$$

$$R: \quad <-e^{3i\phi/2}|x + iy|-e^{i\phi/2}> = <e^{3i\phi/2}|x + iy|e^{i\phi/2}>$$

$$RC_3: \quad <e^{3i\phi/2}|w(x + iy)|\, w^2e^{i\phi/2}> = <e^{3i\phi/2}|x + iy|e^{i\phi/2}>$$

$$RC_3^2: \quad <e^{3i\phi/2}|w^2(x + iy)|we^{i\phi/2}> = <e^{3i\phi/2}|x + iy|e^{i\phi/2}>$$

Every operation leaves the matrix unchanged and therefore the transition is allowed from $e^{i/2\phi}$ to $e^{3/2i\phi}$ with a right circular polarized photon traveling parallel to the C axis.

It is not necessary to write out the transformations as indicated, we can get the answer by multiplying the corresponding table entries for the three quantities in the matrix element being careful to use the complex conjugate of the final states representation. If the product of the representations carried out in this way contains the A_1 representation, the transition is allowed, if not it is forbidden.

The result of this group theoretical treatment is, therefore, the following. A Nd^{3+} ion located on a Ca(I) site will exhibit some strongly polarized transitions such as the unmixed σ($\perp$ to C axis) and π($\|$ to C) transitions shown on Fig. 3. Charge compensation for the Ca(I) Nd^{3+} ion which is located on the trigonal axis will not alter the site symmetry or polarization. A Nd^{3+} ion located on a Ca(II) site will exhibit the polarized transitions shown on Fig. 4.

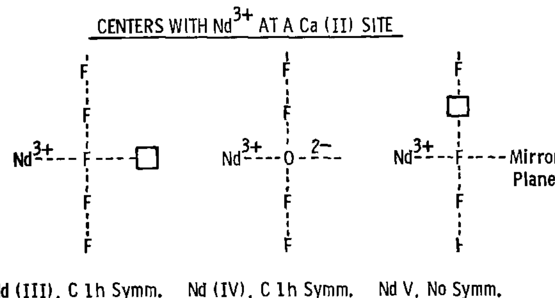

Fig. 5. Proposed models for Nd^{3+} centers located substitutionally at a Ca(II) site.

A Nd^{3+} center formed with charge compensation for the Ca(II) Nd^{3+} located out of the reflection plane (thus destroying the C_{1h} (C_s) symmetry) would also be unpolarized and would be undistinguishable from an $C_{1h}Nd^{3+}$ center from polarization measurements.

Experimental Results and Discussion

The relative ESR concentrations of the various Nd^{3+} centers observed in our crystals are listed in Table I. In the "stoichiometric melt" sample only one Nd^{3+} center was observed in ESR, labeled the Nd(IV) center. It has C_{1h} symmetry which means that it consists of a Nd^{3+} ion replacing a Ca(II) ion presumably with charge compensation, (O^{2-} replacing F^-) located in the reflection plane. The most probable model for this center is shown on Fig. 5. The corresponding fluorescence and excitation spectra of the Nd(IV) center are shown on Fig. 6 and 7 and show the lack of strong polarization expected for a C_{1h} symmetry Nd^{3+} center. What is not expected in the excitation spectrum of Nd(IV) on Fig. 7 is the appearance of at least five energy levels between 17,000 and 17,500 cm whereas only three are expected for a single type of Nd^{3+} center (see Fig. 2). All of the crystals we studied showed such "extra" energy levels with as many as 20 levels observed in one case. One explanation for these "extra" lines could be that we are observing spin forbidden transitions to the $^2G_{7/2}$ levels. An excitation spectrum does not weigh heavily against weak absorptions as does an optical

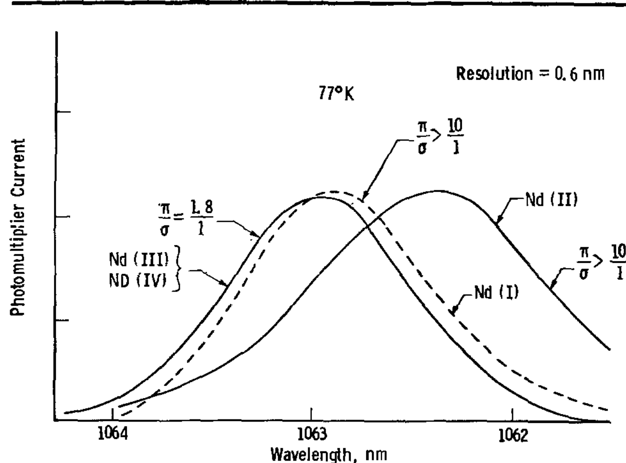

Fig. 6. The fluorescence envelopes of the Nd(I), Nd(II), Nd(III), and Nd(IV) centers.

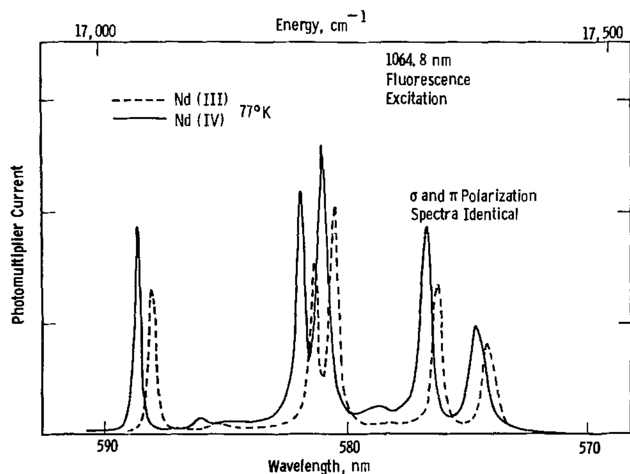

Fig. 7. The fluorescence excitation spectra of the Nd(III) and Nd(IV) centers.

absorption measurement. Unfortunately, our signal/noise did not permit optical absorption data to be taken as a check of this point. However, a more probable explanation for these "extra" lines is that while ESR is capable of identifying only one C_{1h} type of Nd^{3+} center in the "stoichiometric melt" crystal, selective laser excitation shows that indeed more than one related type of Nd(IV) center exists. We have been unable to sort out the excitation levels of each of these centers due to the broad 1 nm fluorescence envelope of Nd^{3+}. Excitation into each of the five energy levels on Fig. 7 yielded fluorescence envelopes indistinguishable from one another. In this respect an ion exhibiting much sharper fluorescence, such as Er^{3+}, is a more suitable candidate for a selective laser excitation experiment than Nd^{3+} and ambiguities of this type should not arise.

In the "10% CaO deficient" sample the Nd(IV) center was no longer observed in ESR or optically. In its place ESR displayed four distinct types of Nd^{3+} centers labeled Nd(I), Nd(II), Nd(III), and Nd(V). Selective laser excitation resolved three sets of Nd^{3+} centers which we have correlated with the Nd(I), Nd(II), and Nd(III) centers seen in ESR. It has been observed if one grows $Ca_5(PO_4)_3F$ crystals from a melt deficient in CaO that oxygen no longer locates substitutionally for fluorine vacancies (9). The disappearance in this crystal of the Nd(IV) center (attributed to a Nd^{3+} substitutional for a Ca(II) with an adjacent oxygen compensator) is consistent with this observation. In its place ESR shows a different type of C_{1h} center labeled Nd(III). As this center possesses reflection symmetry the charge compensator for the Nd^{3+} must either be very distant from the Nd^{3+} or located in the reflection plane (such as an adjacent Ca(II) vacancy as suggested in Fig. 5). The fluorescence envelope of the Nd(III) center is shown on Fig. 6. It is indistinguishable from the Nd(IV) center and is not strongly polarized, typical of a C_{1h} neodymium center. The excitation spectrum of the Nd(III) center is shown on Fig. 7. It is very similar in appearance to the Nd(IV) spectrum but is displaced slightly to higher energy.

In addition to this C_{1h} type of Nd^{3+} center, two distinct types of Nd^{3+} centers of C_3 symmetry are observed, labeled Nd(I) and Nd(II). Models for these centers are shown on Fig. 8 and involve the substitution of Nd^{3+} for a Ca(I) on the 3-fold rotation axis (C_3) with various types of on-axis charge compensation. In Fig. 8 the Nd(II) center is pictured as one for which charge compensation is achieved by an adjacent Ca(I) vacancy while the Nd(I) has more distant charge compensation. Justification for the assignment of "distant compensation" for the Nd(I) center and "nearby compensation" for the

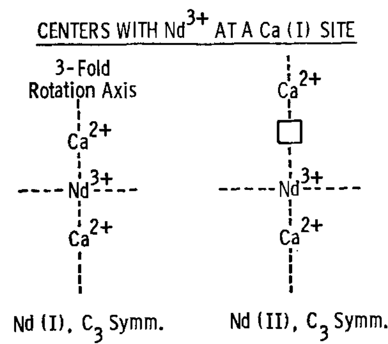

Fig. 8. Proposed models for Nd^{3+} centers located substitutionally at a Ca(I) site.

Nd(II) center will be given in the discussion of the "2% CaF_2 deficient" crystal. The correlation between the centers labeled Nd(I) and Nd(II) in ESR and the corresponding optical properties is exact as the absence of the Nd(I) center and presence of the Nd(II) in the "2% CaF_2 deficient" crystal permitted on unambiguous assignment.

The fluorescent emissions of the Nd(I) and Nd(II) centers are shown on Fig. 6 and their respective excitation spectra on Fig. 9 and 10. Both fluorescences are highly polarized parallel to the crystal C axis. In the absence of crystalline imperfections and if perfect alignment had been achieved it is likely that 100% fluorescence polarization would have been observed for these C_3 centers. The excitation spectra of both centers show some strongly polarized transitions as well as some that are relatively unpolarized,

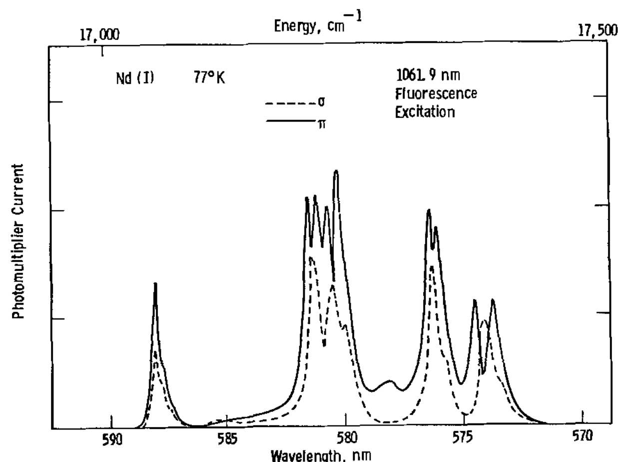

Fig. 9. The fluorescence excitation spectra of the Nd(I) center

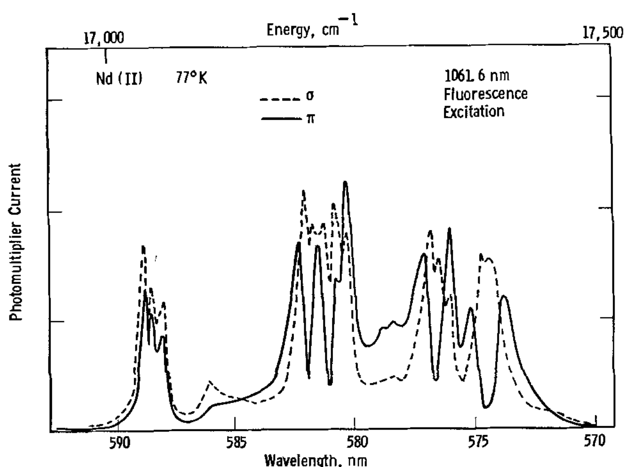

Fig. 10. The fluorescence excitation spectra of the Nd(II) center

exactly what one would expect for Nd^{3+} in C_3 symmetry. Both spectra are very complex, again indicating that the centers we have labeled Nd(I) and Nd(II) are in fact two families of Nd^{3+} centers involving a variety of similar but distinct axial compensation mechanisms.

The final type of center seen in ESR in the CaO deficient crystal has no symmetry and is labeled Nd(V). A typical model for such a center is shown in Fig. 5 where an (unspecified) charge compensator for Nd^{3+} is located nearby and out of the reflection plane, destroying the C_{1h} symmetry. We have been unable to separate the optical spectra of this center probably because (*i*) it is present in relatively low concentrations and (*ii*) it would exhibit unpolarized spectra very similar to the C_{1h} centers.

The third crystal studied was grown from a melt deficient in CaF_2 and containing a high neodymium concentration. One would expect several modifications to occur in the distribution of Nd^{3+} among the various possible sites in such a crystal. One would expect again to observe the Nd(IV) center, since oxygen compensation centers are no longer discriminated against as they were in the CaO deficient crystal. At this higher concentration of Nd^{3+} and of calcium vacancies one would also expect that centers such as the Nd(I) center might disappear as the higher Nd^{3+} concentration would decrease the average Nd-Nd and Nd-Ca vacancy separation and decrease the probability of forming isolated Nd^{3+} centers with accompanying distant Ca vacancy compensation. The disappearance that we do observe of the Nd(I) center in this crystal and the accompanying increase in Nd(II) is in fact the best argument for the relative assignment of models between the Nd(I) and Nd(II) centers previously given. The optical properties of the Nd(II), Nd(III), and Nd(IV) centers were obtained by selective laser excitation in this crystal and were identical to their counterparts observed in the other crystals. Consistent with the ESR measurement, no Nd(I) was observed. For reasons mentioned previously, no Nd(V) could be identified optically.

Conclusions

When calcium fluorophosphate crystals are grown from stoichiometric melts containing low Nd_2O_3 concentrations ($\sim$0.01%), the neodymium locates on the Ca(II) site and forms a center that preserves the local C_{1h} site symmetry. We label this the Nd(IV) center. The most likely model for this center involves Nd on the Ca(II) site and a charge compensating oxygen located on the adjacent fluorine site in the reflection plane. This center has been observed in ESR and its optical excitation and fluorescence spectra were obtained. The Nd^{3+} transitions of this center are essentially unpolarized, in agreement with the selection rules expected for this C_{1h} site. This model is consistent with the assignments given in previous work (2-5).

If crystals are pulled from a melt deficient in CaO, formation of the Nd(IV) center is suppressed and four new types of Nd^{3+} centers are observed in ESR: the Nd(III) center which has C_{1h} symmetry but differs from the Nd(IV) center, the Nd(V) center which has no symmetry, and two centers with C_3 symmetry, the Nd(I) and Nd(II). Probable models for the centers are: Nd(III), a Nd^{3+} ion substitutional for a Ca(II) with an adjacent Ca(II) vacancy in the reflection plane, Nd(V), a Nd^{3+} ion substitutional for a Ca(II) with nearby charge compensation located out of the reflection plane, Nd(I), a Nd^{3+} ion substitutional for a Ca(I) with a distant on axis charge compensating Ca(I) vacancy, and Nd(II), a Nd^{3+} ion substitutional for a Ca(I) with an adjacent charge compensating Ca(I) vacancy. The excitation and fluorescence spectra of the Nd(I), Nd(II), and Nd(III) centers were obtained and the Nd(I) and Nd(II) centers exhibit strongly polarized transitions as expected for Nd^{3+} in a C_3 site. No optical spectra could be obtained for the Nd(V) center.

When a crystal is pulled from a melt which is deficient in CaF_2 and contains a much higher Nd^{3+} concentration ($\sim$0.1%), the formation of the Nd(I) center is suppressed as Nd(I) type centers are converted to the Nd(II) type.

The effect of the growth conditions on the Nd^{3+} distribution occurred in a very predictable fashion in our crystals. A deficiency of oxygen makes oxygen compensation for Nd^{3+} more difficult, and high concentrations of Nd^{3+} reduces the concentration of isolated centers involving distant compensation. Although the electronic configurations of Sb^{3+} and Nd^{3+} are different it is very likely that analogous Sb^{3+} centers would be formed in $Ca_5(PO_4)_3F$ under similar growth conditions.

Grain Growth Mechanism of Heavily Phosphorus-Implanted Polycrystalline Silicon

Yasuo Wada and Shigeru Nishimatsu*

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Grain growth phenomena of heavily phosphorus-implanted polycrystalline silicon films owing to high temperature annealing are investigated by transmission electron microscope. Phosphorus doping in excess of 4×10^{20} cm^{-3} is found to enhance grain growth. This growth is broken down into primary and secondary recrystallization. Isochronal annealing reveals the activation energies for these as 2.4 and 1.0 eV, respectively. The driving force of the primary recrystallization is found to be the interface energy. Therefore, the elementary process behind the primary recrystallization is attributed to silicon diffusion across the grain boundary region.

Polycrystalline silicon (poly Si) is commonly used as gate materials of MOS LSI's (1). In particular, recent progress in fine pattern lithographic technology has made it indispensable to control the pattern definition as well as to lower the resistivity of the material.

However, these two requirements have been found to be paradoxical. This is because lower resistivity, which requires heavy impurity doping, inevitably brings about an increase in poly Si grain diameter and degrades the delineation. Although variation of poly Si gate length arising from grain growth is less than 10% in today's MOS LSI's (2), it might become more than 40% in the coming submicron gate MOS LSI's (3). Therefore, from the process design viewpoint, it is necessary to quantitatively make clear the impurity-doping effect on the growth phenomena.

Grain growth phenomena owing to high temperature (above 1200°C) annealing of thick poly Si film (about 100 μm) for solar cell usage (4) as well as sintering phenomena of poly Si at more than 1200°C for high temperature material (5) have been reported. They showed that the final grain size is about the same as the film thickness or the final material density depends on the initial poly Si grain size.

On the contrary, concerning thin poly Si film, only the dependence of poly Si diameter on the growth conditions (6) and the crystalline state dependence of poly Si resistivity (7) have been reported. The impurity doping effect of grain growth or the growth mechanism itself have yet to be clarified.

This paper quantitatively reports the grain growth phenomena of heavily phosphorus-doped poly Si as functions of doping concentration, annealing conditions, and film thickness. It also aims to propose a possible growth mechanism of poly Si grains.

Experimental Procedure

Poly Si deposition and doping.—A 0.4 μm thick poly Si layer was deposited by thermal decomposition of silane (SiH_4) at 630°C onto a 0.6 μm thick SiO_2 layer, thermally grown on a p-type (100) oriented 10 Ω-cm silicon wafer. Phosphorus ions were implanted at a 50 keV accelerating energy to a dose of between 1×10^{15} and 5×10^{16} cm^{-3} in order to dope quantitatively at low temperature. Radiation damage arising from the heavy doping had no effect on the grain growth phenomena, as is shown in the experiment. The target-heating effect is experimentally ascertained to be less than 100°C since the dose rate was in the order of 0.1 W/cm^2 under these implantation conditions (8).

Doping concentration was defined as (dose/poly Si thickness); therefore, a 1×10^{15} cm^{-2} dose refers to a 2.5×10^{19} cm^{-3} doping concentration, etc.

Annealing in a dry N_2 atmosphere was carried out between 500° and 1200°C to a duration of between 20 min and 64 hr. Impurity outdiffusion was negligible since the sheet-carrier number measured by Hall effect was unchanged under these experimental conditions.

Transmission electron microscope sample preparation and grain diameter measurement.—Transmission electron microscope (TEM; Hitachi HU-12A Type) observation was used to measure grain diameter and to estimate the crystalline state of poly Si. The samples provided for TEM observation were prepared as follows: (*i*) The 400 μm thick silicon substrate was etched from the back side to the 0.6 μm thick oxide layer with $HF:HNO_3 = 1:3$ solution; and (*ii*) Samples were immersed in a dilute HF solution to remove the oxide layer.

The finished sample diameter ranged from 0.1 to 1 mm, and was ladled out by copper mesh for observation. The accelerating voltage of the TEM was 100 kV, and magnification was between 2000 and 20,000 times.

Mean grain diameter $\bar{r}$ was calculated from the following equation (9)

$$\bar{r}' = 1.5 \times l/(n \times m) \quad [1]$$

where, m is the micrograph magnification, l is the line length on the micrograph, n is the number of grains crossed by the line, and 1.5 is the parameter assuming sphere grains.

Brief Explanation of Crystallization Phenomena

Recrystallization phenomena are classified into three stages; nucleation, primary recrystallization, and secondary recrystallization. This paper describes the possible grain growth mechanism of primary recrystallization. Therefore, prior to stating the experimental results, the mechanism of primary recrystallization is briefly explained here (11, 12).

The primary recrystallization mechanism can be classified into three types:

(*i*) In strain-induced growth, the main driving force of growth is the stored strain energy (by cold-work ion implantation or by such effects) within the crystal. The growth follows the equation

$$\bar{r} = k_1 \cdot t \quad [2]$$

which indicates that linear growth on annealing time is expected.

(*ii*) In interface energy-induced growth, the main driving force is the interface energy. The growth follows the equation:

$$\bar{r} = k_2 \cdot t^{1/2} \quad [3]$$

which indicates that grain growth corresponds to the square root of annealing time.

* Electrochemical Society Active Member.
Key words: ion implantation, recrystallization, polycrystalline silicon.

(*iii*) With the impurity drug effect, although the main driving force of growth is the interface energy, impurity included in the grain boundary retards growth. The growth follows the equation

$$\bar{r} = k_3 \cdot t^{1/3} \quad [4]$$

Therefore, the mechanism can be determined by measuring the annealing time dependence of grain growth.

Experimental Results

Doping concentration dependence of grain growth.—Doping concentration dependence of grain growth was examined first. Annealing temperature was 1000°C and annealing time was 20 min. Phosphorus concentration was between 1.2×10^{19} and 7.5×10^{20} cm^{-3}. Some typical TEM micrographs are shown in Fig. 1. These results indicate that grain growth is superlinearly enhanced with impurity concentration. This is contrary to the well-known impurity doping effect on growth phenomena of metals, where "impurity drug" effect is normally observed (10).

The grains were mostly inclined to (110) orientation detected by electron diffraction measurements. This tendency was enhanced with higher annealing temperature. Phosphorus solid solubility in silicon has been reported by Trumbore (11), Kooi (12), and Sunami (13), and is schematically shown in Fig. 2. They indicate that at 1000°C, the solid solubility is around 1×10^{21} cm^{-3}, therefore, these experiments were performed well within the single phase solid solution.

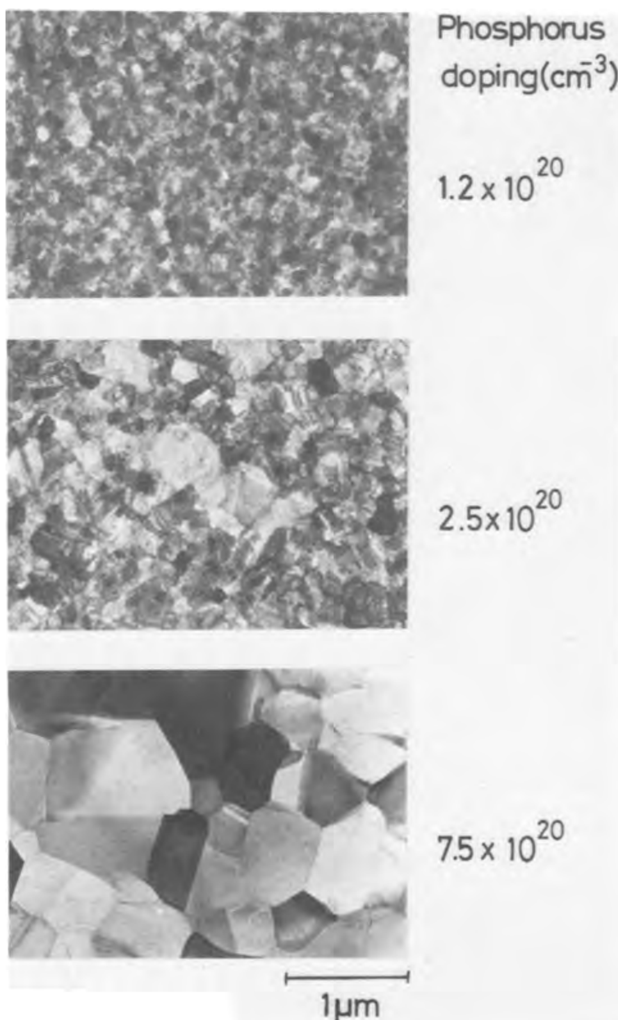

Fig. 1. TEM micrograph of 0.4 μm thick poly Si grains; phosphorus doping concentration is a parameter. Annealed at 1000°C for 20 min.

Annealing temperature dependence of grain growth.—Poly Si doped with 7.5×10^{20} cm^{-3} phosphorus was isochronally annealed for 20 min between 500° and 1100°C. Resulting TEM micrographs between 800° and 1100°C are shown in Fig. 3. Below 700°C, no grain growth was observed as the 800°C case. These results indicate a drastic increase in grain diameter between 800° and 900°C. They also show that there are two stages of grain growth above 1000°C. These, as in the case of metal, are called primary and secondary recrystallization. The former is a growth from initially less than 0.1 μm grains to about 0.8 μm in mean diameter. The latter is a growth of particular grains to more than 2 μm diam, as shown at the right of the 1100°C case in Fig. 3.

Mean grain diameter was calculated using Eq. [1], and the temperature dependence is shown in Fig. 4. The activation energy of primary recrystallization between 800° and 900°C was 2.4 eV, and the secondary recrystallization above 1000°C was 1.0 eV. The horizontal line below 800°C denotes that the mean grain diameter is the same as the as-deposited film in this temperature range. The horizontal line above 1000°C represents the termination of primary recrystallization.

Annealing time dependence of grain growth.—Poly Si doped with 7.5×10^{20} cm^{-3} phosphorus was isothermally annealed for between 20 min and 30 hr at 700°, 800°, and 1100°C. The resulting TEM micrographs are shown in Fig. 5. These results indicate that in both 700° and 1100°C cases, no additional growth as in the 20 min case was observed for longer annealing durations. On the contrary, the 800°C isothermal annealing caused a marked increase in grain diameter, which is classified as primary recrystallization. The mean grain diameter $\bar{r}$ is shown to depend on the square root of annealing time, as depicted in Fig. 5. This indicates that the relationship cited in Eq. [3] stands in these experimental conditions. An 850°C isothermal annealing also showed grain growth following Eq. [3]. These results clearly show that the main driving force of the primary grain growth phenomenon is the interface energy of

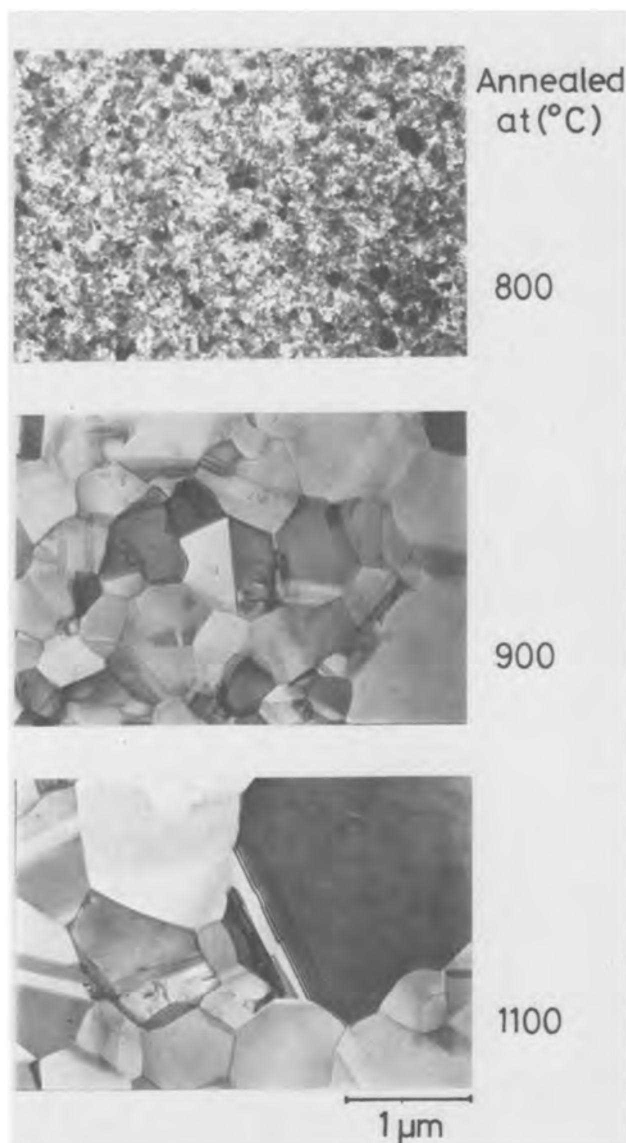

Fig. 3. TEM micrograph of 0.4 μm thick poly Si grains; annealing temperature is a parameter. The phosphorus-doping concentration is 7.5 $\times$ 10^{20} cm^{-3} and it is annealed for 20 min at each temperature.

the grains, not strain energy stored in the thin film nor radiation damage arising from heavy ion implantation (14). Thus, radiation damage is effectively removed in the initial stage of heat-treatment and does not contribute to the grain growth. The results also suggest that the elementary process of primary grain growth can be silicon diffusion across the grain boundary region (14, 15) (single boundary migration).

Although 1 μm thick samples were also examined under the same experimental conditions, almost the same results were obtained. This indicates that poly Si thickness between 0.4 and 1.0 μm has little, if any, effect on the grain boundary energy.

In addition to phosphorus, the arsenic- or boron-doping effect on the poly Si was also examined. Almost the same phenomena were observed on these three impurity dopings.

Discussion

Impurity-concentration dependence of grain growth.—The impurity-concentration dependence of primary grain growth phenomena are discussed first. As mentioned, impurity doping generally decreases the grain growth rate, and is called "impurity drug" in the metal cases (10). In our experiments, contrary to the cases

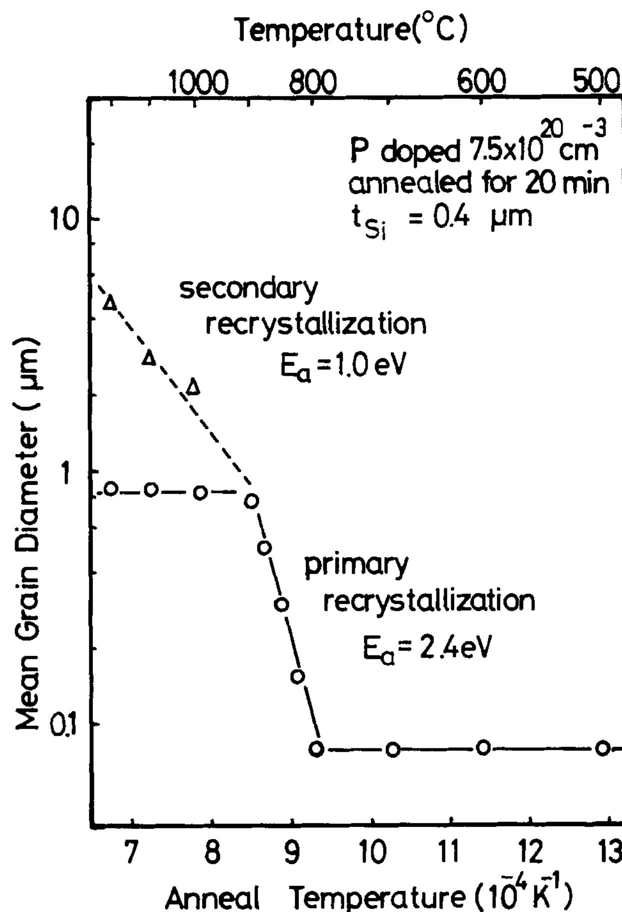

Fig. 4. Annealing-temperature dependence of the mean grain diameter derived from the results shown in Fig. 3.

of metals, impurity doping extremely enhances grain growth. There are two possible reasons for the marked increase in grain diameter, depending on impurity concentration.

One possible reason is the "liquid phase growth" (16), in which low temperature eutectic liquid phase appears in the grain boundary region. However, the Si-P phase diagram (17) shows no low temperature eutectic below 1100°C. In addition, the TEM micrograph depicted in Fig. 1 indicates no such trace of liquid phase. Therefore, this kind of growth mechanism cannot be valid in these experiments.

Another possible reason is the diffusion-enhanced growth, in which an increase in diffusion coefficient enhances grain growth. An impurity concentration-dependent diffusion coefficient has been reported on As (18) and P (19) in silicon, as well as a silicon self-diffusion coefficient under heavily As- or P-doped conditions (20). These results are shown in Fig. 6. They indicate that more than 4 $\times$ 10^{20} cm^{-3} impurity doping greatly enhances the diffusion coefficient. As will be shown later, the silicon self-diffusion coefficient has relations with a grain boundary diffusion coefficient, which in turn is related to grain growth. Therefore, impurity concentration dependence of grain growth is also shown in Fig. 6 by a solid line. A good coincidence with the diffusion-coefficient enhancement was obtained. These results indicate that the origin of grain-growth enhancement is the silicon self-diffusion coefficient enhancement with impurity concentration.

Grain boundary migration rate of primary recrystallization.—The grain boundary migration rate is calculated and compared with the experimentally obtained results to support the aforementioned single boundary migration mechanism.

The grain boundary migration rate was derived from the experimentally obtained results, shown in Fig. 3 and 5. Assuming the relationship in Eq. [3] is valid be-

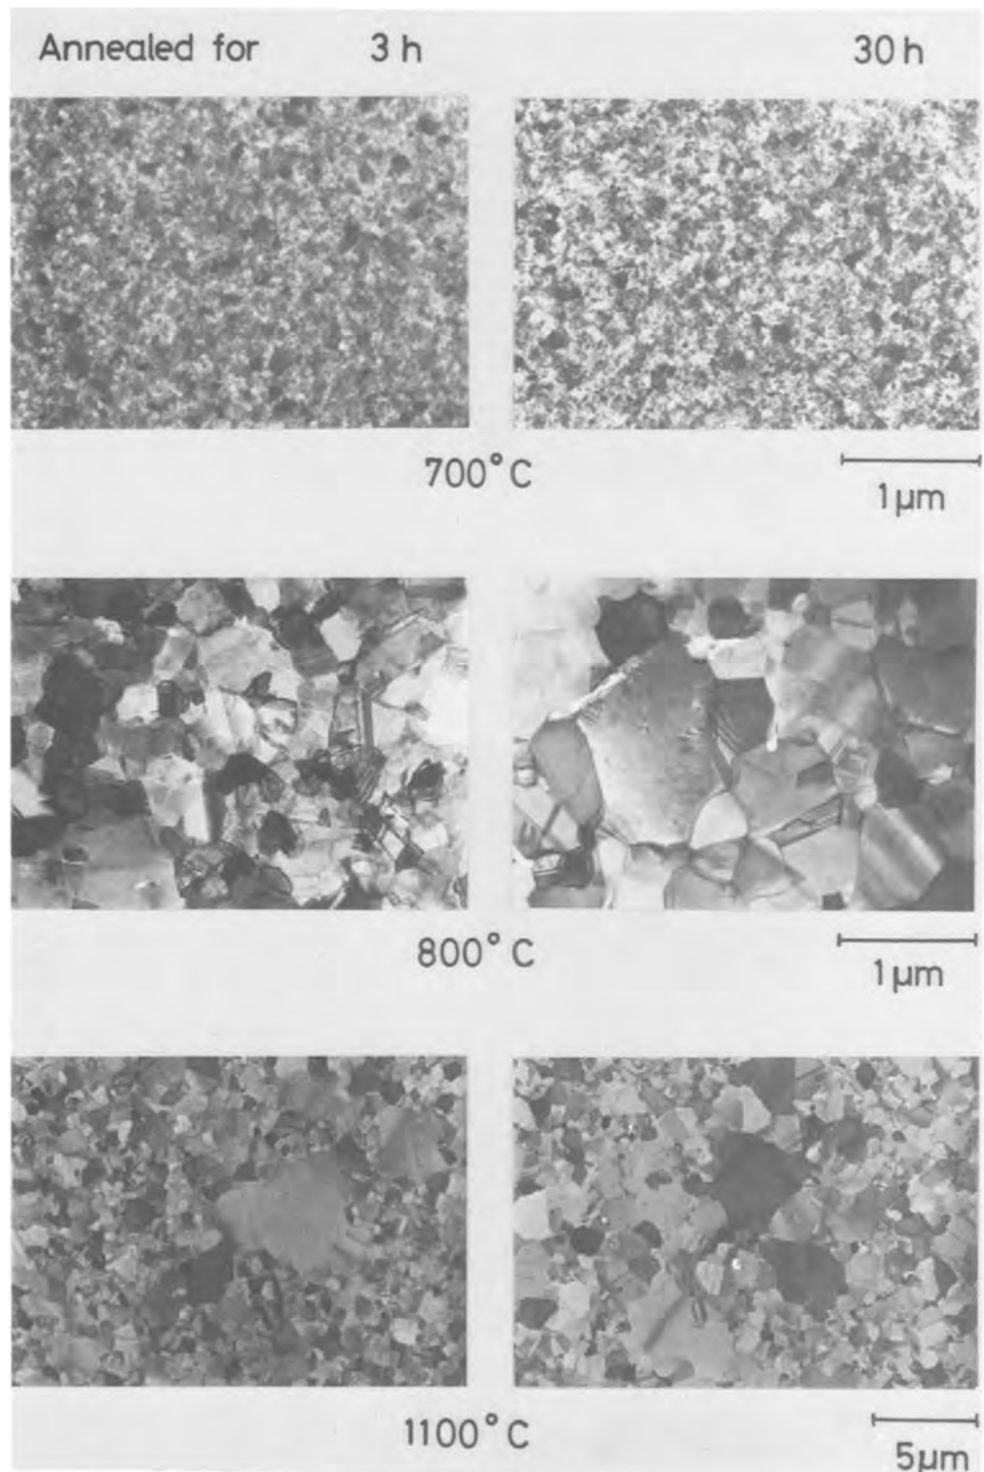

Fig. 5. TEM micrograph of 0.4 μm thick grains; annealing time is a parameter. The phosphorus-doping concentration is 7.5 × 10^20^ cm^−3^ and annealing temperatures are 700°, 800°, and 1100°C.

tween 800° and 900°C, as shown in Fig. 7, the results listed in Table I are obtained. The temperature dependence is shown in Fig. 8, in which both 0.3 and 0.5 μm cases showed the same dependence.

Assuming the migration of grain boundary is attributed to silicon diffusion across the grain boundary, the grain boundary migration rate was calculated and compared with the experimental results. According to Turnbull's equation (14)

$$G = M \cdot F \quad [6]$$

where notations and values are listed in Table II. Grain boundary mobility is expressed as follows

$$M = D_g/kT \quad [7]$$

Driving force is derived from the following equation

$$F = \lambda\sigma/\nu \cdot N_A \quad [8]$$

In these equations the only unknown parameter is the grain boundary diffusion coefficient D_g. Assuming single boundary migration, D_g can be replaced by the grain-boundary silicon diffusion coefficient D_b. D_b is expressed by D_s and D_p through the equation (21)

$$D_p = (D_p - (1 - \alpha) D_s)/\alpha \quad [9]$$

Assuming D_p is proportional to D_s through the equation

$$D_p = kD_s \quad [10]$$

the experimentally obtained grain boundary migration rate was fitted with the calculated results, with k in Eq. [10] as a parameter. The mean grain diameter used in the calculation was 0.3 and 0.5 μm, and the results

are shown in Table I. Almost the same k values were obtained in this temperature range. That is, if the diffusion coefficient in single crystal is about two orders of magnitude smaller than that in polycrystal, quantitative agreement is obtained between experiment and calculation. This D_p-D_s relationship is reported including the impurity concentration effect (22).

The results shown here indicate that the doping-concentration dependence, annealing-temperature dependence, and annealing-time dependence of primary recrystallization can be explained by the single boundary migration mechanism. That is, the elementary process of the poly Si grain growth is attributed to silicon diffusion across the grain boundary region.

Termination of primary recrystallization.—As shown in Fig. 4, the primary grain growth terminated when the 0.4 μm thick poly Si layer was singly crystallized throughout the thickness and the mean grain diameter reached around 0.8 μm. Although thickness (d_{Si}) dependent final grain size ($\bar{r}_f$) has been reported (23)

$$\bar{r}_f = k_f d_{Si} \quad [11]$$

the results obtained here showed no such evidence between 0.4 and 1.0 μm. This indicated a faster vertical grain growth than horizontal growth. The growth termination is explained by the disappearance of driving force, when three grain boundaries meet at a certain point at 120° (14). Nevertheless, it was not clarified yet why the mean final grain diameter was 0.8 μm.

Secondary recrystallization.—The final grain diameter of secondary recrystallization was found to depend only on annealing temperature between 900° and 1200°C. In addition, the poly Si thickness between 0.4 and 1.0 μm had no effect on the final grain diameter. Therefore, the activation energy of the secondary recrystallization of 1.0 eV shown in Fig. 4 can be temperature-dependent on interface energy. Notwithstanding, these peculiar phenomena were not clarified quantitatively in this report.

Although it has been reported that the final grain diameter is almost the same as the film thickness (4), it was more than 10 times as large in our experiment. The largest grain obtained was around 20 μm in diameter, which was annealed at 1200°C. This indicates the latent possibility of realizing thin single crystal films on amorphous substrates. This might lead to a new era of coming high density LSI's.

Summary

Grain growth phenomena of heavily phosphorus-doped poly Si were investigated as functions of doping concentration, annealing temperature, annealing time, and poly Si thickness. The results obtained are summarized as follows.

1. Grain growth was superlinearly dependent on phosphorus-doping concentration and was shown to be almost proportional to the dependence of silicon diffusion coefficient on phosphorus concentration.

2. Isochronal annealing revealed that the recrystallization phenomena are broken down into two stages. These, as in the case of metal, are called primary and secondary recrystallization. The former is the growth to about 0.8 μm grain diam, while the latter is the growth of particular grains to much larger diameter. The obtained activation energies were 2.4 and 1.0 eV, respectively.

3. Isothermal annealing of 7.5×10^{20} cm^{-3} phosphorus-doped poly Si showed that the driving force of the primary grain growth is the interface energy and that the elementary growth process is attributed to silicon self-diffusion across the grain boundary region.

4. The secondary recrystallization showed irregular behavior, and could not be explained in this report.

Zinc Ion Implantation as a Predeposition Process in Gallium Arsenide

M. C. Boissy and D. Diguet

RTC La Radiotechnique Compelec, BP 6025 14001 Caen, France

ABSTRACT

Ion implantation of zinc into n-type GaAs substrates at room temperature is used as a process of predepositing a solid source from which impurities may be thermally diffused during a postannealing treatment at high temperature (830° or 900°C). The implantation is performed through a Si_3N_4 layer (about 700Å thick) deposited on the crystal surface, in order to prevent the dissociation of the lattice and the out-diffusion of doping atoms. Due to this fact, the total implanted dose is shared between the superficial nitride layer and the semiconductor. High doses are used around 10^{15}-5×10^{15} ions implanted in the substrate per square centimeter to give rise to a deep junction depth ($\sim$10 μm) required for electroluminescence. Such a deep junction is easily obtained by using a high total dose (10^{16} cm^{-2}) and a high dose inside the GaAs substrate (5×10^{15} cm^{-2}). This paper intends to point out that a high junction depth may also be performed with a high total dose (10^{16} cm^{-2}) and a weak amount of ions implanted in the semiconductor (10^{15} cm^{-2}) which comes from the use of a weak implantation energy. This very case is found favorable to good quality doped material. Diodes obtained by this process exhibit good electrical characteristics; evidence of the quality of the resulting p-n junction. Finally, this method leads to light emission efficiency about 1.5 times greater than the standard vapor-phase diffusion, which proves both the efficient injection of minority carriers and the good quality of the implanted and annealed material.

Ion implantation used for doping of semiconductors is an attractive method compared to vapor-phase diffusion, particularily as far as the control, the reproducibility, and the purity of the dopant are concerned. However, ion implantation of p-type impurities in III-V compounds does not give very satisfactory results (presence of a semi-insulating layer between the p-type region and the n-type region, p-n junction with a low light-emission efficiency) when the subsequent annealing is carried out at a low temperature or when the protection of the surface is inefficient (1-6). Indeed radiation damage such as lattice disorder or vacancies which occurs during ion implantation is more difficult to anneal in III-V compounds than in silicon. This fact arises from the values of the binding energies of crystal lattice with regard to those of the defect generation energies. Thus the initial electronic quality is not completely recovered after a thermal treatment: the forbidden bandgap of the implanted material contains a large amount of deep energy levels (1) which have influence both on electrical properties (free carrier concentration and mobility) and on optical properties (photon absorption and light-emission efficiency).

This paper deals with the use of zinc ion implantation as a means of "predepositing" p-type dopant atoms in GaAs, this process being completed by a subsequent annealing at high temperature. In this method the heat-treatment at 800° or 900°C allows both a more efficient annealing of defects and the activation of the thermal diffusion of impurities from the solid source created by the implantation. The implantation is performed through a dielectric layer deposited onto the surface of the material in order to prevent the superficial dissociation of the crystal and the out-diffusion of the dopant during implantation or annealing.

Experimental

Sample preparation.—The GaAs substrates were obtained from ingots grown by the gradient freeze method with silicon-doping concentration ranging from 2×10^{17} to 10^{18} cm^{-3} and with a dislocation density of around 10^3-10^4 cm^{-2}. Substrate wafers about 500 μm thick were lapped and subsequently chemically polished. Their surfaces were oriented in the (100) plane. These surfaces were then coated with a layer of Si_3N_4 about 700Å thick obtained by chemical vapor deposition at 750°C from a SiH_4-NH_3 reaction. This surface protection was carried out before implantation to avoid out-diffusion of implanted dopant during Si_3N_4 deposition. Si_3N_4 was chosen in preference to SiO_2 because it has been shown that out-diffusion of gallium can occur from the substrate through silicon oxide (7) and that such a generation of gallium vacancies induces a substitutional diffusion mechanism of dopant atoms near the SiO_2-GaAs interface, thus reducing the zinc diffusivity in the semiconductor.

Implantation.—Implantation was performed with singly ionized 100-150 keV zinc ions into substrates held at room temperature with a misorientation of 7° to avoid channeling. The implantation energy was calculated using data given by LSS theory (8) in order to obtain the desired penetration depth in the material, taking into account the thickness of the superficial dielectric layer. The ion dose has been varied in the range 10^{13}-10^{16} cm^{-2}.

Assuming that the implantation profile is approximately gaussian (8) the distribution of the dopant between the nitride layer and the semiconductor may occur in three different ways, as shown on Fig. 1: (a) most of the dose is implanted in the GaAs substrate, (b) the maximum of the gaussian curve is located at the dielectric/material interface; (c) most of the dose is contained in the nitride layer. Samples with these three configurations were investigated.

Heat-treatment.—Following implantation, samples were annealed in a nitrogen atmosphere at 830° or 900°C. The properties of the resulting p-doped region were first investigated on a stained cleavage plane.

Device preparation.—Then the dielectric layer was removed with a CF_4 plasma: An ohmic contact pattern was deposited on the implanted layer by evaporation of Au + 1% Be through a metallic mask. The resulting metallic dots were 400 μm in diameter. Tin evaporation was performed on the back face to ensure the n^+-type

ohmic contacts. The processed samples were diamond scribed and diced in order to obtain 750 μm square chips which were then soldered onto TO 18 headers. Finally, a gold wire was bonded on the top metallization (Fig. 2). This simple but rapid process was chosen in order to allow fast assessment of the p-n junction properties during the optimization phase of each parameter. The analysis of the devices was carried out by assessment of the electrical (current-voltage) and optical (light emission power) characteristics.

Results

In the case of GaAs electroluminescent diodes, most of the radiative recombination takes place in the p layer. Therefore, in order to obtain the best efficiency, its thickness has to be greater than the electron minority carrier diffusion length Le. In practice for the usual p-type doping level ($p \sim 10^{19}$ cm^{-3}), Le is about 5 μm so that the junction depth xj has to be of that order of magnitude. When the p-n junction is obtained by normal zinc vapor-phase diffusion techniques, it is experimentally shown that the optimized xj is as great as 10 μm (9). Therefore, optimization of implantation conditions (dose and energy) and post annealing treatments (temperature and duration) were carried out with this aim.

Two annealing temperatures were used: 830° and 900°C. Figure 3 exhibits the evolution of the junction depth with annealing duration. This curve, in its first part, shows the expected proportionality of xj with the square root of the annealing time. Then the slope of the curve decreases for longer annealing times due to the depletion of the finite zinc source created by the implantation. So for given implantation parameters, the annealing condition can be adjusted to obtain the desired p-type region thickness.

In addition, the junction depth strongly depends on implantation conditions. Firstly, the influence of the ion-implanted dose is presented in Fig. 4. We have represented the variations of the junction depth with the zinc dose implanted in the semiconductor. In this figure the points refer to experiments carried out in the same configuration: for each sample the implantation energy is chosen so that the total dose is equally shared between the nitride layer and the GaAs substrate. In these conditions the junction depth quickly increases beyond a threshold when the dose implanted in the substrate increases, for constant annealing treatment. The thermal diffusion of impurities is slight when the dose incorporated in the material is less than 10^{15} ions cm^{-2}; the junction depth is too shallow to give an efficient light-emitting diode. This is the reason why

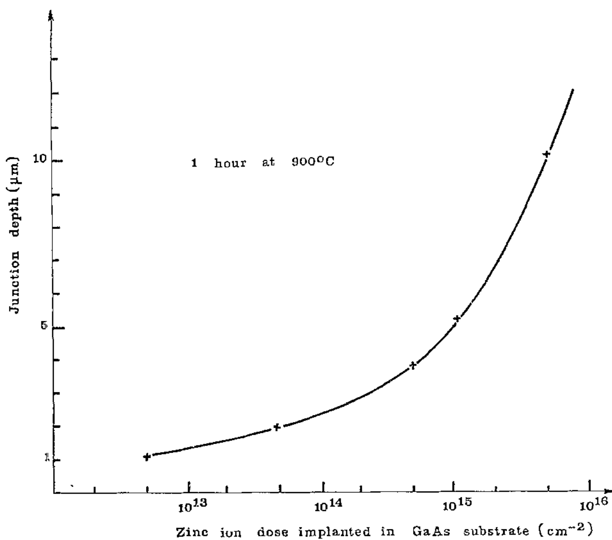

Fig. 4. Influence of the dose implanted in the substrate on the junction depth after annealing [the implantation energy is such that (Zn in GaAs = (Zn) total/2].

high doses are used for the following study, *i.e.*, 10^{15}-5×10^{15} zinc ions cm^{-2} implanted inside GaAs substrates.

Within this reduced range of values, differences can be noticed as far as the shape of the diffusion front is concerned. Thus Fig. 5 compares two samples in which the junction line is located at the same depth and results from two implantations carried out with the same total dose but with doses implanted in the semiconductor differing with a ratio of five. (The annealing conditions were chosen so that they induced about the same junction depth in the range of the optimized depth for electroluminescence). The junction lines thus obtained are straight for 10^{15} ions cm^{-2} implanted in the GaAs (Fig. 5a) but wavy and distributed for the higher doses (Fig. 5b). In the latter case the introduction of a large amount of doping atoms in the semiconductor at a few hundred angstroms from its surface induces perceptable disorder and stresses which affect the diffusion mechanisms initiated there.

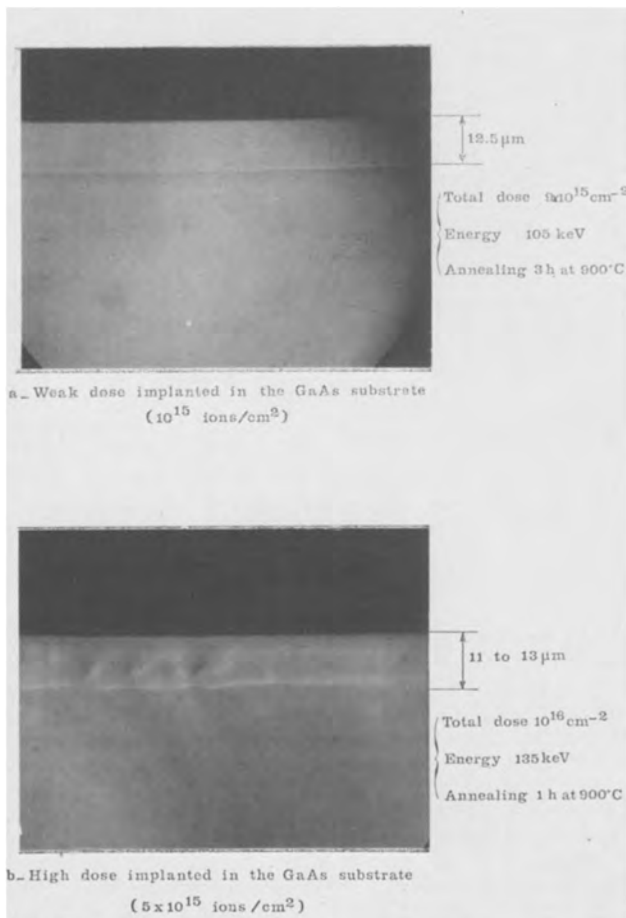

Fig. 5. The shape of the diffusion front

The influence of the dose implanted in the semiconductor itself being thus clarified, this parameter is fixed and the others are now reviewed. Data are summarized in Table I for samples processed under the same conditions: Si_3N_4 thickness (~ 600Å); implanted dose in the semiconductor (10^{15} cm^{-2}); annealing temperature and duration (3 hr at 900°C), except for the configuration of the sharing of the dose between the nitride and the semiconductor as shown in the first column of the table.

These three different configurations in which the dose implanted in the substrate is kept constant are performed by varying the value of the implantation energy and so the value of the total dose too. Indeed when one of the three parameters of implantation, total dose, dose implanted in the semiconductor, energy, is fixed, the two others are interacting. Thus, with a constant dose in GaAs, a high implantation energy implies a small total dose and inversely.

In this way the table shows that zinc diffusivity strongly increases when the implantation energy decreases and consequently the total dose increases. It can be concluded that, for a given dose implanted into the semiconductor, the diffusion coefficient is somewhat higher when the majority of the dose is located in the Si_3N_4 overlayer. Two interpretations of this behavior can be proposed.

Firstly, when the nitride layer contains a large concentration of dopants, the out-diffusion of zinc is less probable from the substrate to the dielectric than from the dielectric to the substrate and all the zinc atoms introduced in the semiconductor diffuse inside the substrate.

Besides, it is known that implantation defects are mostly generated at the start of the ion penetration into the crystal and then are found in the first part of the implantation profile (10, 11). Thus, radiation defects will be confined within the nitride layer when most of the dose is implanted in this overlayer. Thus the concentration of defects in GaAs which could trap zinc atoms in the vicinity of the semiconductor surface

Table I. Influence of the configuration of implantation (sharing of the total dose) on the zinc diffusivity after annealing

Implantation profile	Total implanted dose (cm^{-2})	Dose implanted in GaAs (cm^{-2})	Implantation energy (keV)	Junction depth (µm)
	1.4×10^{15}	10^{15}	155	2
	2×10^{15}	10^{15}	125	3.5
	9×10^{15}	10^{15}	105	13

Annealing 3 hr at 900°C.

is lowered and the concentration of zinc diffusing-in is increased.

The analysis of properties of the implanted p-type regions is also carried out by measurement of the zinc concentration profile after annealing, using a colorimetry method (12). This method consists of an electrolytic etching of the doped material introducing the zinc in solution; a colored complex of zinc is then formed which is analyzed by optical absorption. A typical measured zinc profile is given in Fig. 6. It can be seen that high zinc concentrations are present close to the surface (2×10^{19} cm^{-3}) and that the zinc concentration profile is gradual. Just such a profile gives rise to a good light-emission efficiency since it favors the injection of minority carriers. Indeed it induces a high concentration of majority carriers, to which the injection efficiency is directly proportional (13, 14).

Although the device geometry is not yet optimized, electrical measurements give satisfactory results, the characteristics being similar to that of standard light-emitting diodes. The forward current-voltage characteristics are compared in Fig. 7 with that of a vapor phase diffused device with the same structure. It should be noticed for these two kinds of devices that the variation of the current with the applied bias follows the law $I = I_{SC} \exp(qV/2\,kT)$, evidence of the predominance of space-charge recombination mechanisms. This fact proves that the junction obtained by this predeposition process is a p-n junction, unlike the p-i-n structures obtained by several authors (1-6). Hunsperger (4) attributed the existence of the intermediate semi-insulating layer to the generation of localized defects, such as arsenic vacancies, produced by ion bombardment and to their diffusion inside the lattice during annealing. During the diffusion these localized defects associate with substrate dopants to form more stable complexes. Therefore strong electrical compensation is present when the concentration of defects equals the substrate impurity concentration. In our case, it can be supposed that the nitride layer through which ion implantation is carried out prevents superficial dissociation.

Finally the light power emitted by the devices at a current of 500 mA is measured. As shown in Fig. 8, light power up to 10 mW/A is thus obtained corresponding to an external quantum efficiency about 0.7%. This figure also proves that the optimum value for the junction depth xj is around 10 μm, evidence of the high minority carrier diffusion lengths coming from the good quality of the diffused material. When comparing devices produced under different implantation conditions but having the same xj value, higher efficiencies are found for diodes in which most of the dose was implanted in the nitride layer. Indeed as the substrate contains a smaller amount of implanted ions than when the total dose is equally shared between the dielectric and the material, it is less disturbed by stresses and localized defects.

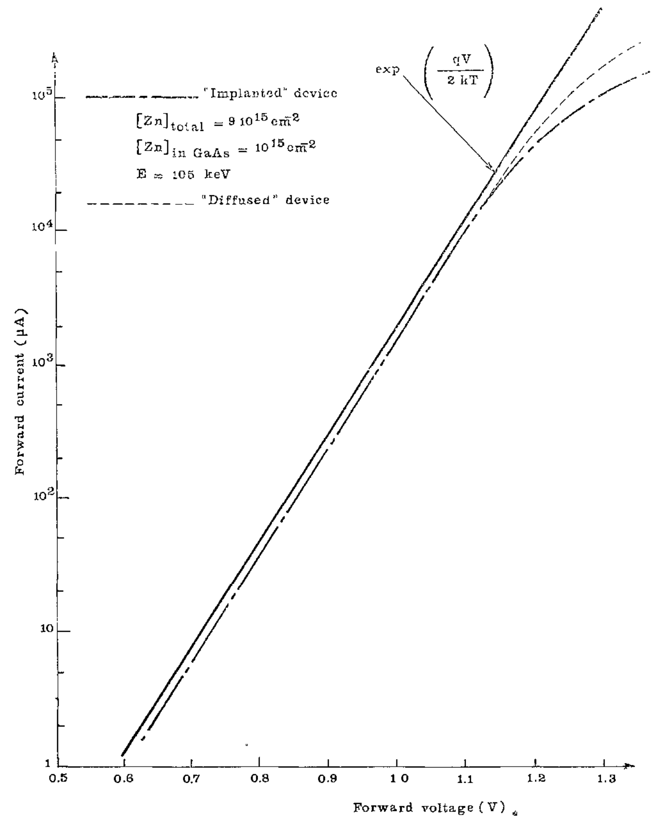

Fig. 7. Forward current-voltage characteristics

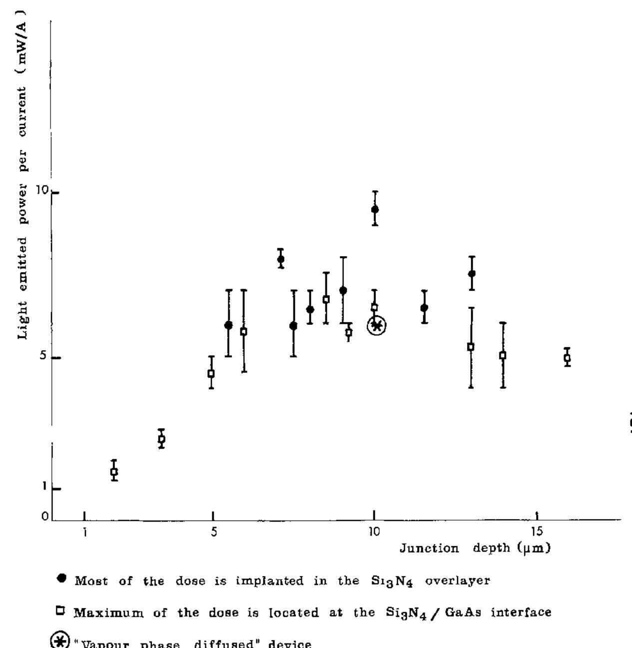

Fig. 8. Light-emission efficiency vs. junction depth

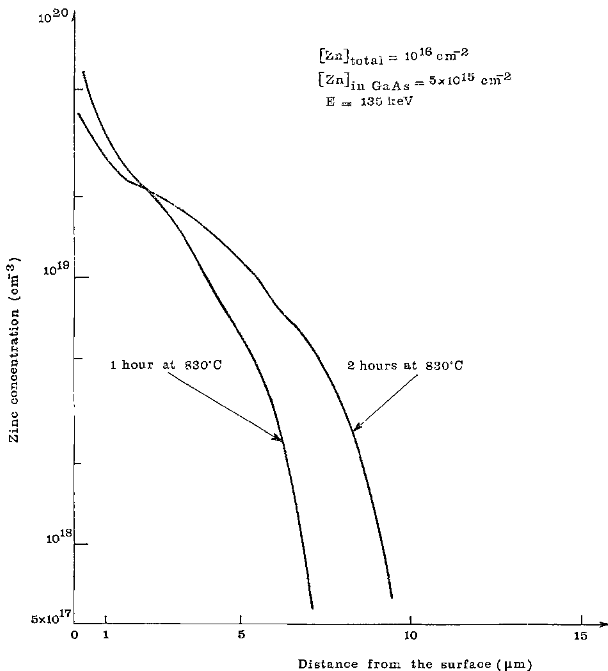

Fig. 6. Zinc concentration profile after annealing

To prove interest of this method of doping, its results are compared with those of the vapor phase thermal diffusion. For that purpose, a 3 μm-thick layer was chemically removed after implantation from part of a sample, the other part of which was processed as described previously. This first piece was then diffused with the vapor phase diffusion process, the heat-treatment conditions being approximately the same as for postimplantation annealing. So the results of both the treatments may be compared on the same material for a constant junction depth. The light-emitting power is found to be 1.5 times greater for the "implanted" diode than for the "diffused" diode. The higher efficiency of the "implanted" device is thought to be due to a better minority carrier injection coming from the gradual shape of zinc concentration profile.

Discussion

In summary, the junction depth observed after annealing is firstly determined by the amount of zinc atoms implanted within the semiconductor itself, as proved by Fig. 4. This behavior is consistent with the well-known dependence of the diffusion coefficient on the impurity concentration during zinc diffusion in III-V compounds.

Then, for a given dose in the semiconductor, the penetration depth of ions during implantation is found to play an important role since it induces the sharing of the total implanted dose between the nitride layer and the semiconductor, which has a strong influence upon the diffusivity of the doping impurities during annealing. Thus, to obtain a high diffusion depth ($\sim$ 10 μm) after annealing, high total dose (10^{16} cm^{-2}) and high implantation energy ($\geqq$ 155 keV) can be used; in such a case the deep diffusion is mainly due to the high amount of zinc atoms contained inside the substrate ($\sim 5 \cdot 10^{15}$ cm^{-2}). But, as shown in Table I, a deep junction may also be performed with a high total dose and a weak energy and this very case is favorable to good quality doped material (see photos on Fig. 5) and consequently to efficient electroluminescent devices (Fig. 8).

In conclusion, the main advantages of ion implantation, *i.e.*, the control and the reproducibility of doping, are shown to be kept in this method of predeposition. Moreover, other advantages are induced by performing the implantation through a dielectric layer, which plays a multiple role: it avoids the out-diffusion of doping atoms during the postannealing; it prevents superficial dissociation and especially generation of arsenic vacancies so that the junction formed after heat-treatment is a p-n junction with high injection efficiency; it allows most of the radiation defects to be confined within this layer by implanting most of dose there.

Due to this last point, this sharing of the dose between the dielectric and the substrate appears to be attractive for several reasons: with a constant dose implanted in the substrate, deep diffusion is easier; with a constant total dose, the diffused region is of better quality and the concentration profile is gradual.

We shall proceed with the extension of the method to other III-V's such as GaP, GaAlAs, GaAsP, and the optimization of the device processing by localizing the implanted surfaces.

Acknowledgments

The authors would like to express their thanks to M. Garcia from Leti, Grenoble, for carrying out the implantations.

They are also indebted to R. Chanu for his very capable technical assistance, to J. Lebailly for enlightening discussions, and to G. Kerr for reading the manuscript.

A New Etching Solution System, H_3PO_4-H_2O_2-H_2O, for GaAs and Its Kinetics

Yoshifumi Mori and Naozo Watanabe

Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240, Japan

ABSTRACT

A new solution system consisting of H_3PO_4, H_2O_2, and H_2O was found useful for etching GaAs wafers. This solution system can be divided into four regions a-d, according to etching characteristics. The boundaries between the regions are given by a mole ratio $(m \cdot r)$ of H_2O_2 to H_3PO_4 of about 2.3 and a mole fraction $(m \cdot f)$ of H_2O of about 0.9 at room temperature. Rate-limiting processes are: a, adsorption of H_2O_2 $(m \cdot r \lesssim 2.3,\ m \cdot f \gtrsim 0.9)$; b, diffusion of H_2O_2 $(m \cdot r \lesssim 2.3,\ m \cdot f \lesssim 0.9)$; c, dissolution of oxidized products $(m \cdot r \gtrsim 2.3,\ m \cdot f \lesssim 0.9)$; and d, adsorption of H_3PO_4 $(m \cdot r \gtrsim 2.3,\ m \cdot f \gtrsim 0.9)$. Solutions in region a have a reproducible etching rate of 0.01-0.1 μm/min, which is useful for MESFET processing. Crystallographic etching is also available with solutions in region c.

In the fabrication of microwave GaAs devices with sufficient reliability and reproducibility, the thickness of the active layer must be controlled. Depth profiles of impurity concentrations and mobility must be measured accurately to correlate device characteristics with material properties. An etching technology using electrochemical reactions such as an anodic oxidation, followed by dissolving the oxide (1-3) or an anodic dissolution (4) has been proven a useful way for accurate GaAs dissolution. An etching technology using chemical reactions with sufficient accuracy and reproducibility however, has not yet been established.

GaAs field-effect transistors are usually fabricated by a lift-off and self-align techniques (5) in which the gate regions of the active layer are etched accurately through windows in protective masks. For this purpose, the chemical etching is more favorable technology than the electrochemical etching because the former way does not need ohmic contacts. However, in the selective etching through windows in protective masks, an anomaly of etching rate such as enhanced etching rate near the edge of the masks (6) is undesirable.

We have found that etching rates of less than 0.1 μm/min without this anomaly are reproducibly attainable using a new solution consisting of H_3PO_4, H_2O_2, and H_2O within a specific composition range. The etching rate is reproducible to within an accuracy of several tens of angstroms.

There is a specific composition range in which the etching rate depends strongly on crystallographic orientation. We report in this paper the etching characteristics of GaAs in this new solution and its etching kinetics.

Experimental

The solution was prepared by mixing 85 weight percent (w/o) H_3PO_4, 30 w/o H_2O_2, and deionized water. The etching studies were generally performed on Te-doped n-type (100), (110), (111)A, and (111)B-oriented GaAs wafers with net donor concentration of $\sim 10^{18}$ cm^{-3}. Etching rate was not affected by all kinds of dopants and by conductivities of wafers. Photoresist AZ-1350 and sputtered SiO_2 films were used as masks for selective etching. Etching was carried out in a temperature range of 0°-40°C without stirring and illumination with temperature control of ±0.5°C. The etched depth was measured from a step height between etched and unetched surfaces using an interference microscope.

Key words: etching, gallium arsenic, phosphoric acid, kinetics.

Results

Composition dependence of etching rate.—Figure 1 is a ternary diagram of the experimental results on a (100) surface obtained at 30°C. The basic components in the three corners in this figure correspond to H_2O, 85 w/o H_3PO_4, and 30 w/o H_2O_2. Concentrations are expressed by volume percent. The numbers within the triangle of the figure refer to etching rates in μm/min. For a given H_2O content, a maximum rate of etching is attained for a mole ratio of H_2O_2 to H_3PO_4 $(m \cdot r)$ of about 2.3. The ternary diagram of the etching rate can roughly be divided into four regions a, b, c, and d corresponding to specific etching characteristics. The etched depth depends linearly on etching time for various surface orientations in regions a, c, and d, as shown in Fig. 2. The rate in region b, on the other hand, depends roughly linearly on the square root of etching time. The etching rate in region b is considered to be limited by the diffusion of H_2O_2 in the solution. The increase in the viscosity for increasing the H_3PO_4 concentration supports this mechanism (1, 2). Figure 3 shows the dependence of the etching rate on the con-

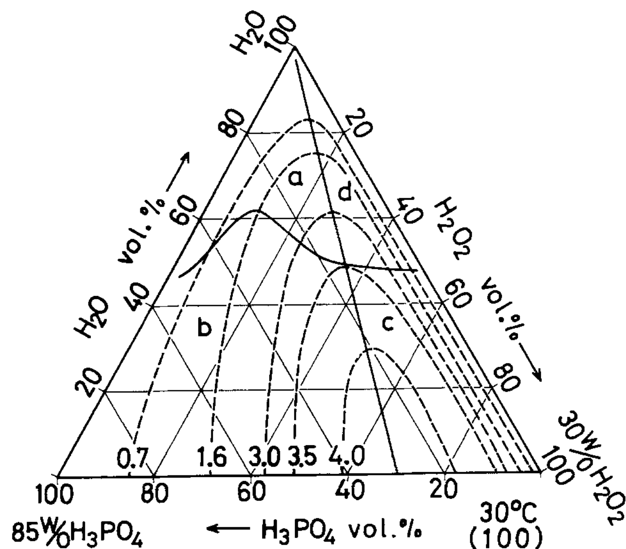

Fig. 1. Dashed lines are constant etching rate contours on (100) surface as a function of the composition of the solution. The numbers represent etching rates in μm/min obtained at 30°C. Solid lines divide ternary diagram in 4 regions: a, b, c, and d.

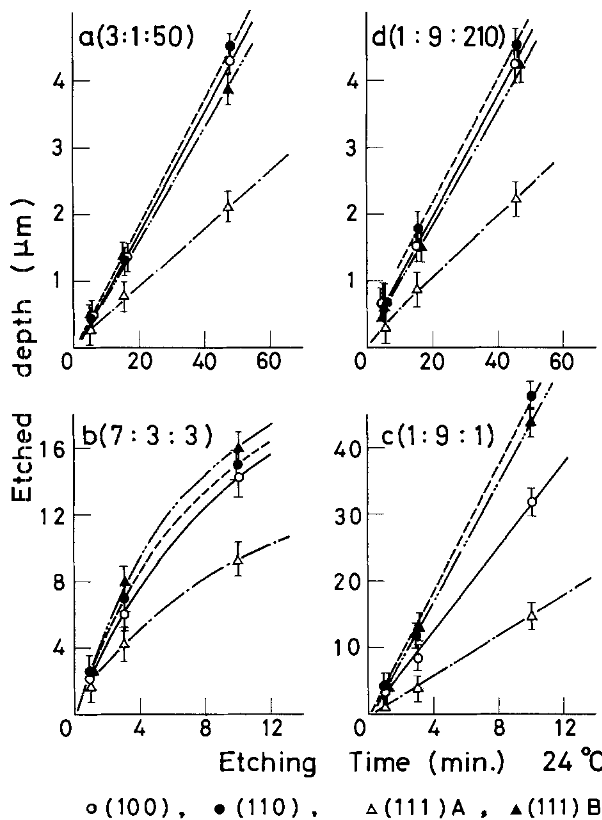

Fig. 2. Relation between etched depth and etching time for various surfaces. Composition of each region is expressed by volume ratio of 85 w/o H_3PO_4 to 30 w/o H_2O_2 to H_2O.

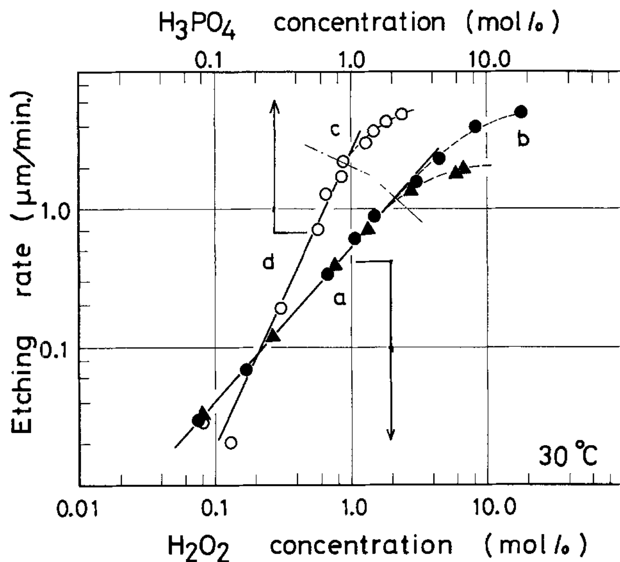

Fig. 3. Composition dependence of etching rate on the concentration of H_2O_2 for regions a and b and of H_3PO_4 for regions c and d. Open circles correspond to $[H_2O_2/H_3PO_4]$ mole ratio $(m \cdot r) = 9.1$ and closed circles and triangles correspond to 1.02 and 0.43, respectively. Concentrations are expressed by mole percent.

centrations of minority reactants, H_2O_2 and H_3PO_4, in solutions obtained on the (100) surface, *i.e.*, regions a and b, and c and d, respectively. Concentrations are expressed by mole percent. The abscissa is scaled by the percentages of minority reactants, that is, H_2O_2 in regions a and b, and H_3PO_4 in regions c and d.

Data in region a lie on an identical straight line for two series of solution having different $m \cdot r$'s, but they differ in region b. This fact indicates that the etching rate in region a is determined by and is proportional to H_2O_2 (minority reactant) concentration. A flat-bottomed hole is always obtained. In region d, the rate is proportional to the square of H_3PO_4 concentration. The etched surface frequently becomes cloudy due to formation of an oxidized film with small pits. The rate tends to saturate in region c. V-shaped and reverse mesa-shaped holes are clearly observed, as will be shown later.

Temperature dependence of the etching rate.—Temperature dependences of the etching rate for various surface orientations in each region are shown in Fig. 4. Values of activation energies are also given in the figure. The activation energy is the same in regions a and d and takes a value of about 10 kcal/mole, independent of surface orientation. In regions b and c, however, it depends on the surface orientation. These results suggest that the rate-determining process is different in each region, as is discussed later.

Slow and reproducible etching.—Stable etching is attainable using the solution in region a. The etching rate in this region is independent of H_3PO_4 concentration and of etching time. The activation energy is independent of surface orientation. Figure 5 shows changes of etching rates on repeated use of etching solutions. Vertical scales refer to the etching rate normalized to the initial rate. In the H_2SO_4-H_2O_2-H_2O system, the etching rate was not stable after about 100 min from its preparation. It sometimes increased by 50% of the initial value and then decreased gradually afterward. Fluctuation of the etching rate for repeated use is the largest in this system. The rate decreased gradually in the KOH-H_2O_2-H_2O system. Etching was not attainable after a storage time of a few months in H_2SO_4 and KOH systems. In the H_3PO_4-H_2O_2-H_2O system, on the other hand, a slow etching rate with excellent reproducibility was maintained over several months. In the H_2SO_4 system, heat evolves upon mixing the reactants and water. The solution is essentially unstable. Bubbles are generated by decomposition of H_2O_2 on the surface of a GaAs wafer while etching in the KOH system. The concentration of H_2O_2 changes with repeated use. The mixing of reactants is nonexothermic in the H_3PO_4 system. H_2O_2 is not exces-

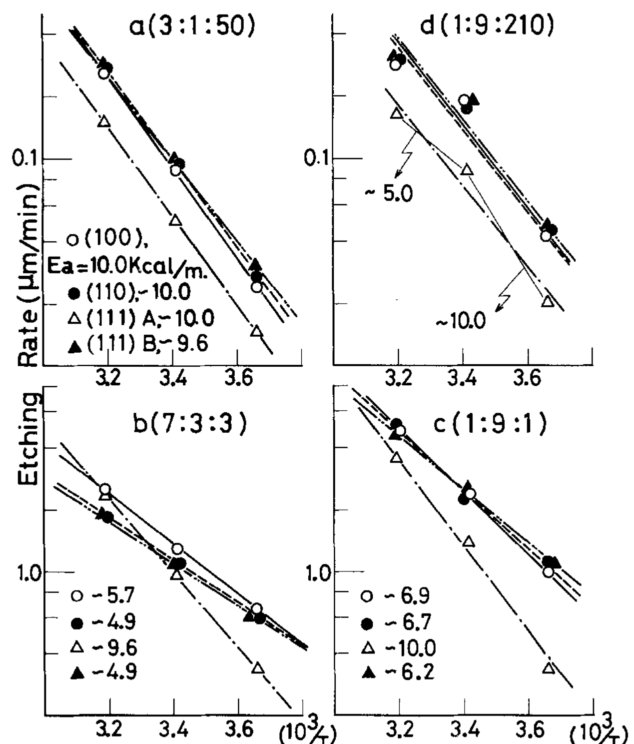

Fig. 4. Temperature dependence of etching rate on various surface orientations.

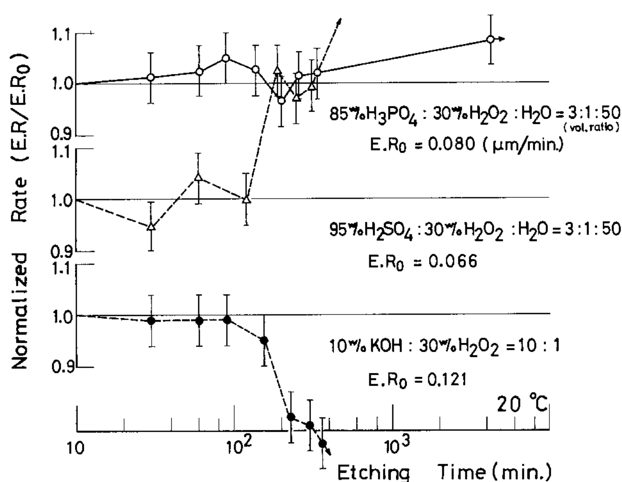

Fig. 5. Change of etching rates on repeated use of etching solutions obtained at 20°C. Every time etching was done for 5 min.

sively consumed in the etching reaction (no bubbles were observed). This is one reason why the H_3PO_4 system is the most stable of the three solutions.

Crystallographic etching.—The ratios of etching rates on the (111)B to (111)A surfaces as a function of H_2O_2 concentration at three different temperatures are shown in Fig. 6. Temperature dependence of this ratio is larger for larger H_2O_2 concentrations. This is a result of the difference in the temperature dependences of the etching rate for different surface orientations in each region (see Fig. 4). Crystallographic etching can be performed by control of temperature and of solution composition in region c. Figure 7 shows pictures of the $(0\bar{1}\bar{1})$ cleavage plane of the selectively etched (100) surface using a photoresist mask (AZ-1350). The upper pictures are for the case where $m{\cdot}r$ is 3.05 and the mole fraction of H_2O ($m{\cdot}f$) is 0.89. The lower pictures are for the cases of 9.15 and 0.83, respectively. Correlation between the etched shape and the etched depth in the case of $(01\bar{1})$ cleavage plane can be seen in Fig. 8. The etching temperature and etching time (t) are given in each photograph.

Discussion

We formulated a rate equation for GaAs etching to determine a rate-limiting process in each region. The etching process was assumed to consist of the following five steps: (i) adsorption of m molecules of H_2O_2 on an active center; (ii) formation of oxidized products; (iii) adsorption of n molecules of H_3PO_4 on oxidized product; (iv) dissolution of oxidized products; and (v) desorption of dissolved complex into solution.

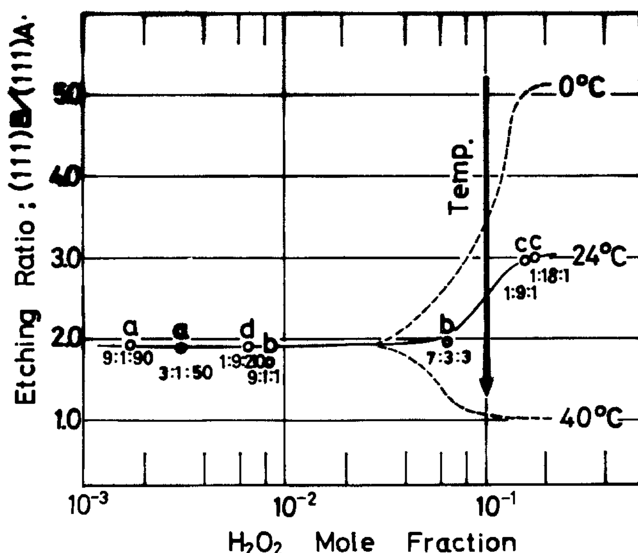

Fig. 6. Ratio of etching rate on (111)B to (111)A surface as a function of mole fraction of H_2O_2. Volume ratios of 85 w/o H_3PO_4, 30 w/o H_2O_2 to H_2O are shown in the figure.

The reaction processes are assumed to proceed at specific active centers on a GaAs surface. The active centers are in different states as the reaction proceeds through the above-mentioned five steps. The total number of active centers in these states is assumed to be constant. Solving the simultaneous rate equations for the five reaction steps, the etching rate, R, under a steady state is obtained as follows

$$1/R = 1/k_1[H_2O_2]^m + 1/k_2[H_3PO_4]^n + 1/k_3 \quad [1]$$

where k_1 and k_2 are rate coefficients for the steps (i) and (iii), and $1/k_3$ is the summation of inverse rate coefficients of each of the other steps. These parameters include temperature, activation energy, partition functions of the activated species, and the reaction frequency factor. For diluted solutions, the k_3 term can be neglected. Exponents m and n can be determined from experimental data of the concentration dependence of etching rate, as was shown in Fig. 3

$$m \simeq 1.0$$

$$n \simeq 2.0$$

Equation [1] is then reduced to the following simple relation

$$R \simeq \frac{[H_2O_2][H_3PO_4]^2}{[H_2O_2]/k_2 + [H_3PO_4]^2/k_1} \quad [2]$$

This equation corresponds to the case where the adsorption steps of reactants, (i) and (iii), are rate limiting. Equation [2] is reduced to the relation, $R \simeq k_1[H_2O_2]$, when $[H_2O_2] << [H_3PO_4]$. This corresponds to the rate equation for the H_2O_2 adsorption process. R is equal to $k_2[H_3PO_4]^2$ when $[H_2O_2] >> [H_3PO_4]$, which corresponds to the rate of H_3PO_4 adsorption. The H_3PO_4 adsorption is bimolecular.

Curve fitting was carried out using Eq. [2], which is shown in Fig. 9. Concentrations in this ternary diagram are expressed by mole percent. Solid and dashed lines represent calculated and experimental results. The calculated results in most parts of regions a, d, and a part of region c agree well with the experimental results. The etching rate in these regions can be considered to be limited by the adsorption processes. Agreement is not good in region b and in the concentrated portion of region c. The rate-limiting process in region b was presumed to be the diffusion of H_2O_2 in the solution. Therefore, the disagreement is a natural consequence. Disagreement in region c may be caused by the contribution of other surface reaction processes such as dissolution of oxidized products. It was concluded that the rate-limiting processes in regions a to d are the adsorption of H_2O_2 on the active centers of GaAs surface, diffusion of H_2O_2 in solution, dissolution of oxidized products, and the adsorption of H_3PO_4 on the oxidized products, respectively. The results are summarized in Table I.

A general concept for GaAs etching is given through the above study. The etching rate is determined by effective densities of reactants and of active centers on the GaAs surface, when the rate-limiting process is the adsorption of a reactant in diluted solutions. The temperature dependence of the etching rate on various surface orientations must be equal. In concentrated solutions, the rate-limiting process is the formation and/or dissolution of oxidized products. The etching rate is affected by the surface activities of GaAs. Temperature dependence of etching rate is different on various orientations.

Summary

A newly found solution, which consists of H_3PO_4, H_2O_2, and H_2O, is presented as a GaAs etchant. This

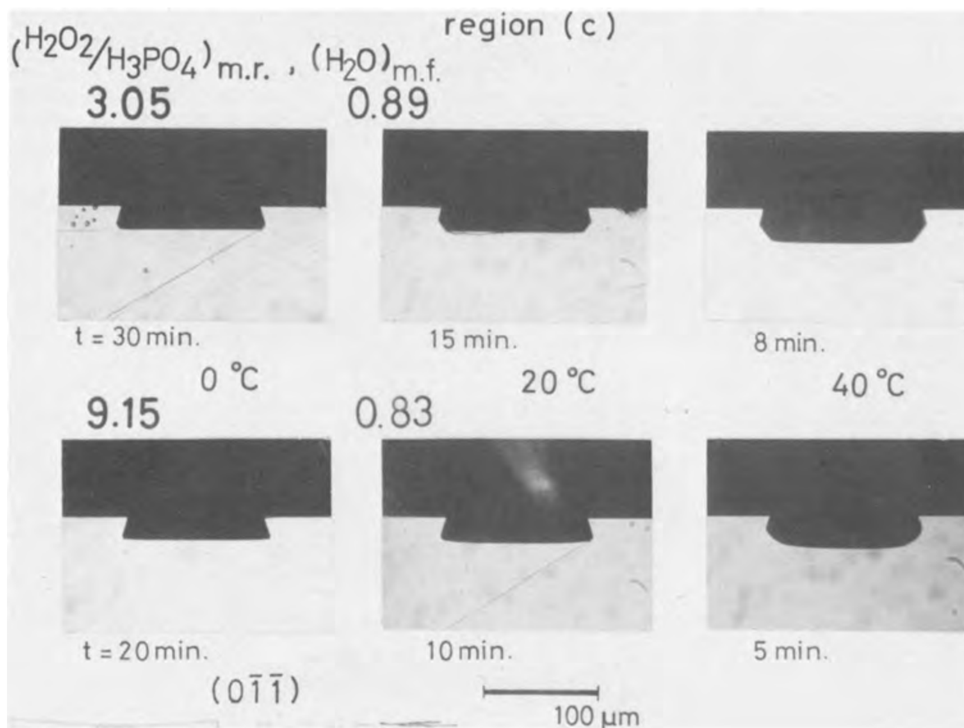

Fig. 7. Pictures of (01̄1̄) cleavage plane of selectively etched (100) surface in the solution in region c.

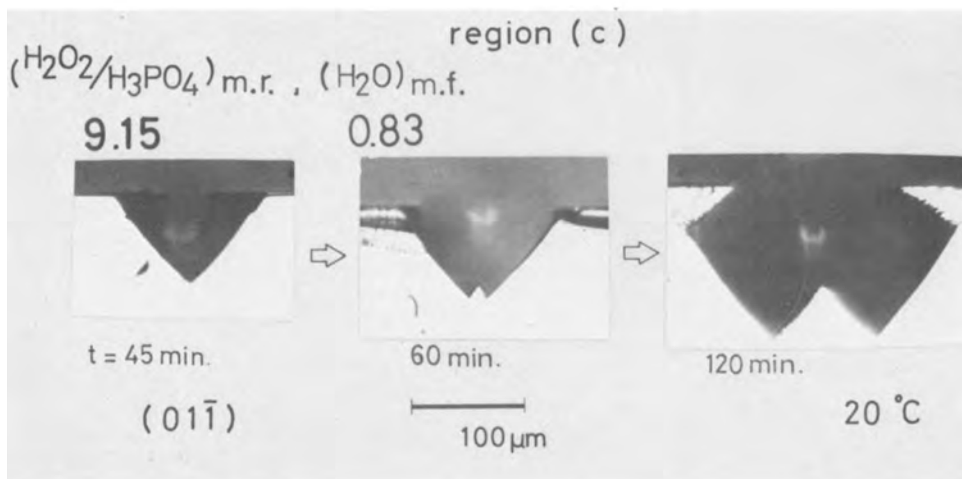

Fig. 8. Correlation between the etched shape and etched depth. Pictures are (011̄) cleavage plane.

solution system was divided into four regions a-d. The boundaries between the regions are given by a mole ratio of H_2O_2 to H_3PO_4 ($m{\cdot}r$) of about 2.3 and a mole fraction of H_2O ($m{\cdot}f$) of about 0.9 at room temperature. The activation energy in diluted solutions: regions a, $m{\cdot}r \lesssim 2.3$ and $m{\cdot}f \gtrsim 0.9$; and d, $m{\cdot}r \gtrsim 2.3$ and $m{\cdot}f \gtrsim 0.9$, is independent of crystallographic orientation. The rate-limiting process is determined as the adsorption of minority reactant in a solution, that is H_2O_2 in region a and H_3PO_4 in region d. We confirmed that the solutions in region a were useful for slow, stable, and accurate GaAs etching.

The rate-limiting process is the surface reaction, such as dissolution of oxidized products in concentrated solutions: in region c, $m{\cdot}r \gtrsim 2.3$ and $m{\cdot}f \lesssim 0.9$. A solution composition in this region c is useful for crystallographic etching. The etching rate is affected by the surface activities.

Table I. Summary of the experiments in Fig. 7 and 8

Region	a	b	c	d
H_2O_2/H_3PO_4 Mole ratio	$\lesssim 2.3$	$\lesssim 2.3$	$\gtrsim 2.3$	$\gtrsim 2.3$
H_2O Mole frac.	$\gtrsim 0.9$	$\lesssim 0.9$	$\lesssim 0.9$	$\gtrsim 0.9$
Depth *vs.* time	$\propto t$	$\propto t^{1/2}$	$\propto t$	$\propto t$
Ea (surf. orient.)	Ind.	Dep.	Dep.	Ind.
Rate-limiting process	H_2O_2 adsorption	H_2O_2 diffusion	Surface reaction	H_3PO_4 adsorption
Useful for	Accurate reproducible slow etch	Sub. surface treatment	Preferential etching	—

Improved Theoretical Predictions for the Steam Oxidation of Silicon at any Elevation

Don L. Kendall,* Marcelo García C., and Mariano Aceves

Instituto Nacional de Astrofísica, Optica y Electrónica, Puebla, Puebla, Mexico

ABSTRACT

The steam oxidation of {111} Si at an altitude of 2160m is studied between 800° and 1200°C. The oxidation time to obtain a given thickness is shown to be 30% longer than that required near sea level. The data are in general agreement with the theoretical formulation of Deal and Grove (1) who showed that the oxide thickness X in μm could be related to the time of oxidation t in minutes by the expression $X^2 + AX = Bt$ for oxidation in steam. It is found that this expression is valid over a wide range of temperature and pressure for values of $A = 6.2 \times 10^{-6} \exp(1.16 \text{ eV/kT})$ and $B = 6.7(P/760) \exp(-0.776 \text{ eV/kT})$, where A is in μm, B is in μm^2/min, and P is in Torr. These values lead to thickness corrections of about 10% at 900°C and 6% at 1000°C as compared to the original formulation of Deal and Grove.

The work of Deal and Grove (1) on the oxidation of silicon in dry and wet oxygen is widely accepted as the standard at atmospheric pressure at sea level, namely 760 Torr. We have repeated these experiments over a wide range of temperatures for steam oxidation at an altitude of 2160m where the atmospheric pressure is only 586 Torr.

As expected, the same type of behavior is observed in these experiments as in those of Deal and Grove; namely the thickness is proportional to time at short times and to the square root of time at long times. However, by obtaining data over a wide range of temperatures, we show that the mathematical predictions of Deal and Grove are not precise enough to allow extrapolation to temperatures below about 1050°C.

In view of the importance of obtaining precise thickness estimates over a wide range of temperatures, for example, for computer-aided process simulations, we have calculated new activation energies and pre-exponentials for the steam oxidation of silicon. By suitable adjustment of the pre-exponentials, these expressions can be used at any altitude and with any value of atmospheric pressure.

Key words: silicon, steam oxidation, reduced pressure, process control.

Experimental

Chemically polished silicon slices grown by the Czochralski method were used in these experiments. They were n-type, the resistivity was 5 Ω-cm, and the orientation was {111}.

The silicon slices were placed horizontally on a quartz boat during the oxidation. Steam was provided to the slices by boiling deionized water. Condensation in the connecting tubing was avoided by wrapping the tubing with heating tape. The laboratory is in Tonantzintla, Puebla, near the city of Puebla, Mexico, where the altitude is approximately 2160m. The atmospheric pressure at this altitude is 586 Torr.

The day-to-day variation in pressure was typically 1-3 Torr, which is too small to be of significance in these experiments. The boiling point of water at this altitude is 92.9°C.

Incidentally, in this work no distinction is made between steam oxidation and oxidation in wet oxygen, since Deal and Grove found little difference in their data whether oxygen or argon was bubbled through 95°C water, therefore implying that the oxidizing species is water. In addition, they found that their data after suitable adjustment to 760 Torr was in good agreement with the data of Flint (2), using atmospheric steam oxidation.

The oxide thicknesses were estimated by comparing the colors of the films to the color descriptions given by Burger and Donovan (3). This method is precise to about 0.005-0.02 μm, depending on which range of thickness is being studied. It should be noted that the data of Deal and Grove should be more accurate than ours at thicknesses below 0.3 μm. They used an interferometric method and hence their data below 0.2 μm are believed to be accurate to about 0.0025 μm. We have assumed that their stated oxidation times are also reasonably precise. The latter comment regarding oxidation time is not trivial at times between 2 and 10 min. However, such times can be meaningful if a low mass boat is used, or better yet if the slices are inserted into the furnace without a boat.

Before concluding this discussion, the assumptions inherent in the determination of thickness by the colorimetric method should be discussed. The colorimetric method depends heavily on the color descriptions of Ref. (3). The present work also depends on the refractive index and the density of the oxide film remaining constant to within at least 1% for steam oxidations between 800° and 1200°C. The water content in the SiO_2 films might be thought to vary measurably over such a temperature range and therefore the density and refractive index also. However, Hetherington and Jack (4) show that neither parameter suffers large changes for considerable variations in water content. For example, they found the density of "wet" vitreous SiO_2 (containing almost $10^{20}/cm^3$ of water) to be 2.197 and for "dry" vitreous SiO_2 (with less than $10^{18}/cm^3$ water) to be 2.203. Furthermore, they found the refractive index at a wavelength of 0.5893 μm to be 1.4584 in wet SiO_2 and 1.4582 in dry SiO_2. In any case, Moulson and Roberts (5) showed that the solubility of water in vitreous SiO_2 was essentially constant over the temperature range 900° to 1200°C.

The data of Fig. 1 were obtained by careful comparison between samples oxidized at various temperatures and times. In analyzing the data we have made use of both our data and the data of Deal and Grove. The latter data was taken at a pressure of 640 instead of the 586 Torr typical of our altitude, so we have increased their oxidation times by the factor 640/586. In addition, we have taken the liberty of adjusting the 920°C data of Deal and Grove to 900°C so we could make direct comparison with our data. These adjustments were made using our theoretical curves at 900° and 920°C. In the section to follow an additional set of oxidation experiments at 898°C is described in which oxide thicknesses were measured using both interferometric and colorimetric methods.

Discussion

The theory of Deal and Grove for the oxidation of silicon is well described in their article (1) and we will only summarize the points relevant to this work. They establish that the oxide growth proceeds from the oxide-silicon interface rather than the oxide-vapor interface, and hence is dependent on the diffusion of an oxidizing species through the growing oxide film. In the presence of pure dry oxygen, the diffusing species is evidently the molecule O_2. This model is supported by the similarity between the the temperature dependence of 1.24 eV for the rate constant in the parabolic region and the literature value (5) of 1.17 eV for the activation energy for the diffusion of oxygen in fused silica.

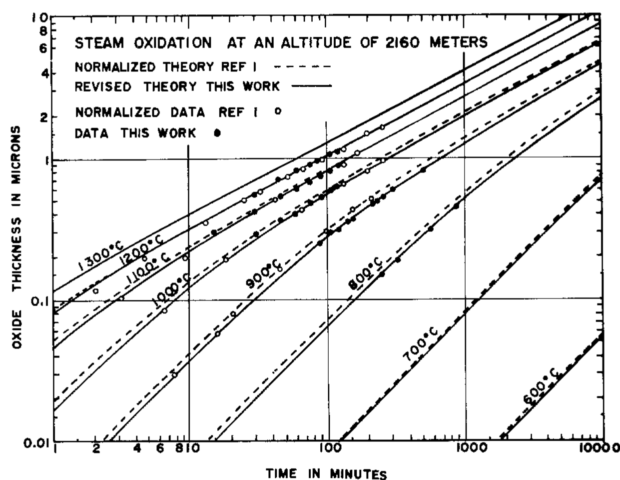

Fig. 1. Combined steam oxidation data of this work at an altitude of 2160m and that of Deal and Grove adjusted to the equivalent pressure of 586 Torr along with the revised theoretical formulation for oxide thickness as a function of oxidation time at various temperatures. The 920°C data of Deal and Grove has also been adjusted to 900°C for purposes of comparison.

Similarly, during steam oxidation, Deal and Grove found that the parabolic (diffusion limited) rate constant had a temperature dependence of 0.707 eV. The literature value (5) of 0.794 eV for the activation energy of diffusion of H_2O through fused silica is not inconsistent with this value. In this work the parabolic constant gives an activation energy of 0.776 eV. This close agreement with the diffusion data for water in SiO_2 gives even stronger support to such a model.

The general expression found by Deal and Grove for the steam oxidation of silicon is

$$X^2 + Ax = Bt \quad [1]$$

where X is the oxide thickness, t is the time of oxidation, and A and B are constants that depend on temperature. At small values of X and t, this reduces to the linear expression

$$X = (B/A)t \quad [2]$$

At large values of X and t, Eq. [1] becomes quadratic, namely

$$X^2 = Bt \quad [3]$$

In addition, the model suggests that A is independent of partial pressure of the oxidizing species and that B is directly proportional to the partial pressure. Note that Bt appears as a simple product in Eq. [1]. Thus at a given temperature, if the pressure is reduced, the constant B is reduced proportionally. Further, in order to obtain an equivalent value of X at the reduced pressure, one must increase t proportionally so that the product Bt remains constant. This is obvious in the linear Eq. [2] above, but can also be shown to be true for Eq. [1] and [3]. As an example of this behavior, one can calculate the time to grow a given thickness oxide in Tonantzintla, Puebla in Mexico, as compared to the time required at sea level. The time is increased by the reciprocal ratio of the atmospheric pressures, namely 760/586 = 1.297, in agreement with the observation that it must be 30% larger to grow a given thickness at the higher altitude. As a corrollary, one can predict the times required to grow equivalent thicknesses at sea level from the data of Fig. 1 by merely shifting all of the

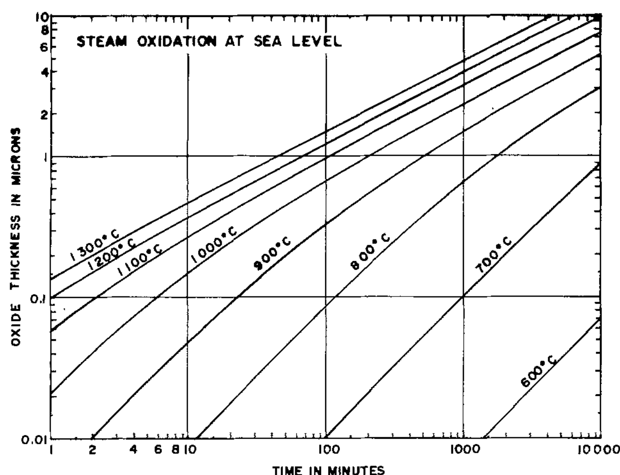

Fig. 2. The expected thickness of an oxide film on silicon grown in steam at sea level at various temperatures using the revised theoretical predictions of this work.

curves to shorter times by the factor of 1.297. This is done in Fig. 2 for purposes of reference for those working at or near sea level.

We have done a least squares analysis on the combined data of this work and that of Deal and Grove. To find the value of A and B at a given temperature, Eq. [1] can be rewritten in the form

$$X = B(t/X) - A \quad [4]$$

Thus in a graph of X *vs.* t/X, B is the slope of a straight line and $-A$ is the intercept with the X axis. The constant B is typically more precise than A since small variations in the slope B cause relatively large variations in the intercept $-A$. In order to fit the combined data over the wide temperature range of 800° to 1200°C we have chosen to exclude the 920°C data of Deal and Grove. We will explain this later. We also found it necessary to give double weight to the data points of Deal and Grove at short times at the temperatures of 1000°, 1100°, and 1200°C. Thus we give double weight to the data points at each of these temperatures when the oxide thicknesses are 0.2 μm or less. As discussed earlier, due to the interference method of measurement used by Deal and Grove, these data points should be quite accurate. In addition, however, these data points are critical in the determination of the constant A. The data at longer times do a credible job of determining the parabolic rate constant B, but it is the data at short times that gives the additional precision to the slope B needed to give an accurate value for the intercept $-A$. It should also be noted that the data in the parabolic region (long times), in addition to being less precise on average, are heavily over-represented at these three temperatures as compared to the data for shorter oxidation times.

Using the above method of weighting in a standard least squares analysis program, the values of A and B shown in Table I were determined at various temperatures. A further least squares analysis of the logarithms of these constants as a function of T^{-1}

Table I. Rate constants for the steam oxidation of silicon at an atmospheric pressure of 586 Torr. The calculated values of A and B are from Eq. [5] and [6], where A is in μm and B is in μm²/min

T (°C)	A (exp.)	A (calc.)	B (exp.)	B (calc.)
800	1.8254	1.7617	0.00118	0.00118
900	0.6025	0.6042	0.00235	0.00241
1000	0.2372	0.2451	0.00455	0.00440
1100	0.1025	0.1134	0.00723	0.00736
1200	0.0645	0.0583	0.01146	0.01149

using single weighting gave the following values for A and B at a pressure of 586 Torr

$$A = 6.2 \times 10^{-6} \exp(1.16\ \text{eV}/kT) \quad [5]$$

$$B = 5.2 \exp(-0.776\ \text{eV}/kT) \quad [6]$$

where A has units of μm and B has units of μm²/min. In this analysis the values of the correlation coefficient r were 0.998 for A and 0.9997 for B. These values are very close to unity, therefore showing that the logarithmic dependence of both A and B on T^{-1} is quite certain, with the precision of B being especially high on such a scale.

For purposes of comparison, the values chosen by Deal and Grove (1) (after adjustment to a pressure of 586 Torr) are shown as A^1 and B^1 below

$$A^1 = 2.4 \times 10^{-6} \exp(1.258\ \text{eV}/kT) \quad [7]$$

$$B^1 = 4.0 \exp(-0.707\ \text{eV}/kT) \quad [8]$$

Thus the activation energies for A and B in the revision, Eq. [5] and [6], differ by 8-9% from those of Ref. (1). However, the activation energy for the revised linear constant B/A of 1.936 eV is in good agreement with the value 1.965 eV obtained by Deal and Grove.

Finally, using the formulation of this work in Eq. [1], a general expression for the oxide thickness at any value of atmospheric pressure (or vapor pressure of water) can be obtained from Eq. [5] and [6] using the following expressions for A and B

$$A = 6.2 \times 10^{-6} \exp(1.16\ \text{eV}/kT) \quad [9]$$

$$B = 6.7(P/760) \exp(-0.776\ \text{eV}/kT) \quad [10]$$

where P is the atmospheric pressure in Torr (if the water is allowed to reach the boiling point) or is the vapor pressure of the water at the control temperature of the water, and A and B have the same units as before.

The theoretical curves shown in Fig. 1 were calculated using Eq. [1] with the parameters A and B calculated from Eq. [5] and [6]. They are seen to be in very good agreement with the experimental data of this work at all temperatures, as well as with the data of Deal and Grove at 1000°, 1100°, and 1200°C. The data of Deal and Grove in the range of 900°C are in poor agreement with these predictions, as well as with our data. Taking all of the above into account, we are led to the conclusion that the great majority of the experimental data in both sets of work is correct. However, the five upper data points of Deal and Grove at 920°C (adjusted here to 900°C) evidently suffered from some experimental problem. For example, the furnace temperature may have been inadvertently about 10°C too high. However, this is perhaps less likely than another temperature-control problem, namely the control of the water temperature at 95°C. If during these five runs, the water temperature were allowed to reach 100°C, the vapor pressure of the water in the oxidation furnace would be raised from 640 to 760 Torr. As discussed earlier, such a change in vapor pressure can be accounted for by shifting the data points to longer times by the ratio of 760/640 = 1.19. Such a shift brings these points almost exactly into line with our data. However, it is important to note that the revision in the parameters suggested here does not rest on the experimental data in one narrow temperature range. The revised theoretical predictions are also in much better agreement with both sets of data at all thickness values at 1000° and 1100°C, as well as the new data at 800° and 900°C. The 800°C data are especially valuable in establishing the linear constant B/A which is important for extrapolation to lower temperatures. On the other hand, the 900°C data are crucial to establishing both the temperature dependence of the constant B in the quadratic range of behavior, and that of B/A in the linear range.

Table II. Predicted oxide thicknesses after 100 min compared to the original formulation of Deal and Grove (at 586 Torr). The values also apply to 130 min at 760 Torr

T (°C)	X (this work) (μm)	X^1 (Deal and Grove) (μm)	$(X - X^1)/X$ (%)
700	0.00790	0.00828	−4.8
800	0.0646	0.071	−9.9
900	0.274	0.302	−10.2
1000	0.552	0.585	−6.0
1100	0.803	0.825	−2.7
1200	1.044	1.045	−0.1
1300	1.286	1.261	+2.0

The difference between the values of oxide thickness predicted by the two formulations at a time of 100 min at various temperatures is shown in Table II. For this particular period of oxidation, the maximum difference between the two formulations is about 10% and it occurs between 800° and 900°C. Deal (6) has also recently observed variations of the order of 10% between the experimental results and the earlier predictions at 900°C. It will be appreciated that the differences between the two predictions are not trivial in the semiconductor device fabrication business.

Finally, as a check on the accuracy of the predictions above, and as confirmation of some of the color descriptions in Ref. 3, it was decided to make independent measurements of the thicknesses obtained in the critical range of 900°C, since this is where the data of Deal and Grove are believed to be the least precise. This was done using both the optical-interference method of Tolansky (7) and the colorimetric method. In these experiments, windows of 200 μm width were opened in the oxides using standard photolithographic methods. These slices were then coated with an opaque layer of silver (approximately 0.3 μm). A thin microscope slide was then coated with a semitransparent film of silver until the transmission was reduced to 10-15%. This microscope slide was then placed in contact with the previously silvered slice which contained the etched windows. The combination was viewed by reflected light from a beam-expanded He-Ne laser projected through a vertical illuminator of a metallurgical microscope. When the slide was suitably adjusted on the slice surface, the interference fringes could be made approximately perpendicular to the etched windows. The photographic width of the fringes was typically λ/100 under these conditions and the center of the fringe could easily be located with a precision of about λ/500, or about 0.0012 μm. However, due to local flatness variations on these slices, the oxide thickness measurements are estimated to be precise to only about 0.0025-0.0050 μm.

The results of these experiments, along with estimates based on color, as well as predictions based on Eq. [1], [9], and [10], are shown in Table III along with the error between the predicted and measured thicknesses. The agreement between the interferometric and colorimetric methods is very good. Furthermore, the measured values are also in excellent agreement with the predicted values. On the basis of these results, as well as similar interference measurements made at 800° and 1100°C, we expect that the predicted thicknesses using Eq. [1], [9], and [10] should be precise to at least 3% over a wide range of temperatures (800°-1300°C), times, and atmospheric pressures and/or water vapor pressures.

Table III. Thickness measurements of films grown at 898°C using interference method ($X_{int.}$), colorimetry (X_{color}), and thickness calculated ($X_{calc.}$) from Eq. [1], [9], and [10] for a pressure of 586 Torr. Colorimetry is used only above 0.2 μm. The error calculations make use of $X_{int.}$ except for the 520 min sample, for which no interference measurement was made

Time (min)	$X_{int.}$ (μm)	X_{color} (μm)	$X_{calc.}$ (μm)	$\Delta X/X_{calc.}$ (%)
10	0.0365	—	0.0368	−0.8
30	0.101	—	0.100	+1.0
60	0.170	—	0.180	−5.6
120	0.316	0.31	0.310	+1.9
240	0.520	0.51	0.510	+2.0
520	—	0.84	0.848	−0.9
557	0.878	0.88	0.886	−0.9

Conclusion

In this work, the general behavior of the theory of Deal and Grove for the oxidation of silicon has been very well substantiated. The predicted pressure dependence was found to explain the 30% increase in time required to grow a given oxide thickness at an altitude of 2160m. The extensive data taken at 800° and 900°C were used to make important corrections to the original theoretical parameters of Deal and Grove. For Si of {111} orientation, these corrections lead to thickness predictions that differ by 6-10% at 1000° and 900°C, respectively, as compared to the original formulation of Deal and Grove. Similar corrections must be made in laboratories nearer sea level.

Acknowledgments

The authors would like to express their appreciation to Dr. Jorge Agraz and Ramón Nuño Z. for starting this work, and to Consejo Nacional de Ciencia y Tecnologia (CONACYT) of Mexico for supporting it. Thanks are also due Dr. David Stevenson of Stanford University for numerous helpful suggestions during the writing of the manuscript.

Implanted As Redistribution during Annealing in Oxidizing Ambient

Kunio Nakamura and Mototaka Kamoshida

Nippon Electric Company, Limited, IC Division, 1753 Shimonumabe, Nakahara-ku, Kawasaki, 211 Japan

ABSTRACT

Carrier distribution in 150 keV, $10^{16}/cm^2$ $^{75}As^+$-implanted Si layer after steam oxidation in the 850°-1000°C temperature range has been measured by the spreading-resistance probe technique. When the oxidation temperature is below 1000°C, the carrier distribution shifts toward the surface at the initial stage of oxidation due to the Si-SiO_2 interface movement, and sheet resistance increases correspondingly. After the initial stage, the carrier distribution then spreads gradually, corresponding to a slowing down in the oxidation rate. In contrast, when the oxidation temperature is above 1000°C, As diffusion effects dominate, and the carrier distribution spreads into Si and sheet resistance decreases monotonically with increasing oxidation time. These behaviors have been explained by simple numerical calculations.

Implantation of As ions has been extensively used for formation of source and drain regions in short-channel MOSIC's (1) or emitter regions in shallow junction bipolar IC's (2). Generally, a subsequent annealing process is required after implantation to recover crystallinity. This annealing process is often carried out in an oxidizing atmosphere to allow the growth of a passivating oxide layer simultaneously. In regard to implanted As redistribution during oxidation, Fair and Tsai reported detailed data at temperatures above 1000°C (3), however, there is little data reported in the case where temperatures are below 1000°C. Muller *et al.* only reported backscattering data after steam oxidation at 850°C (4).

Kudoh *et al.* recently developed a simple method for profiling the impurities within a shallow p-n junction by spreading-resistance probe technique (5). In the present study, this newly developed technique has been applied to obtain carrier distributions in $^{75}As^+$-implanted layers after steam oxidations at temperatures below 1000°C and thus to provide processing data for short-channel MOS or shallow junction bipolar IC's.

Experimental Procedure

Polished p-type silicon wafers oriented nearly in the <100> direction with 1.4Ω cm resistivity were used as starting materials. Arsenic ($^{75}As^+$) implantations were performed at 150 keV with a dose of $1 \times 10^{16}/cm^2$. The wafers were initially at room temperature. Thermal oxidations were performed in steam at 850°, 900°, 950°, and 1000°C for time periods ranging from 15 min to 8 hr. The thicknesses of the oxides formed on the implanted layers were determined by ellipsometry measurements. Carrier distributions after oxidation were measured using the spreading-resistance probe technique (5). Irvin's curve was used to convert the resistivity into the carrier concentration (6). Sheet resistances were also measured after removal of the oxide layers by using the four-point probe technique.

Results and Discussion

Figure 1 shows thickness of SiO_2 formed on the $^{75}As^+$-implanted layer during steam oxidation as a function of oxidation time at each temperature. Curves are plotted in log-log scale. It is evident that oxide growth can be divided into two stages. At the initial stage of oxidation, the slope of each growth curve is steeper than 0.5. The slopes become larger and also the periods of the initial stage increase at lower temperatures. After a certain period, oxide growth reaches the second stage, where diffusion effects dominate and growth is governed by parabolic law.

Key words: arsenic ion implantation, arsenic redistribution during oxidation, profile measurement, spreading-resistance probe.

Figure 2 shows the carrier distribution measured by the spreading-resistance probe technique after oxidation at 850°, 900°, 950°, and 1000°C. Figure 2(A) shows the carrier distribution after oxidation at 850°C. The calculated As distribution just after implantation is also shown in this figure, assuming a Gaussian distribution using projected range and projected standard deviation reported by Gibbons *et al.* (7). After 15 min oxidation, the carrier distribution spreads about 500Å. This might be due to the enhanced diffusion caused by ion-implantation-induced damage or the effect of As-diffusion tail (8). After this initial stage, the carrier distribution becomes shallower with increasing oxidation time. Diffusion effects of As can be almost neglected at 850°C; therefore, As distribution shifts toward the surface due to the Si-SiO_2 interface move-

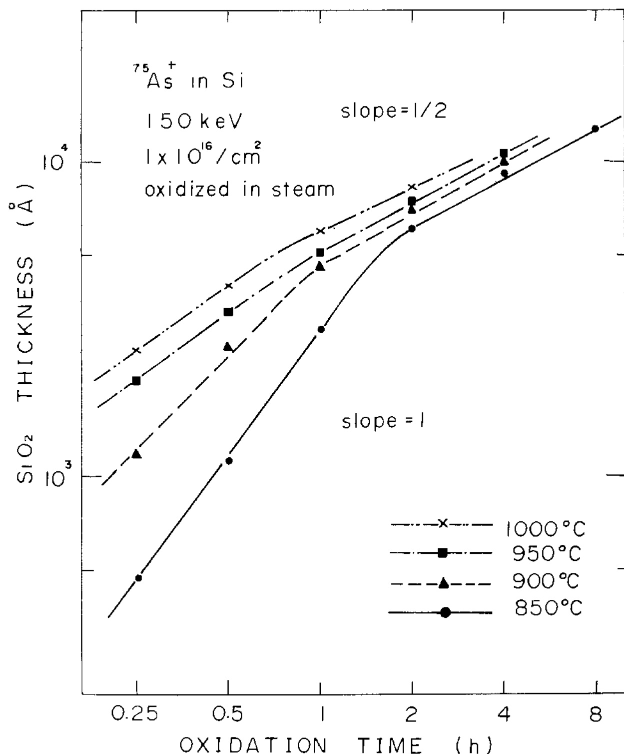

Fig. 1. Thickness of SiO_2 formed on the $^{75}As^+$-implanted layer during steam oxidation at 850°, 900°, 950°, and 1000°C as a function of oxidation time.

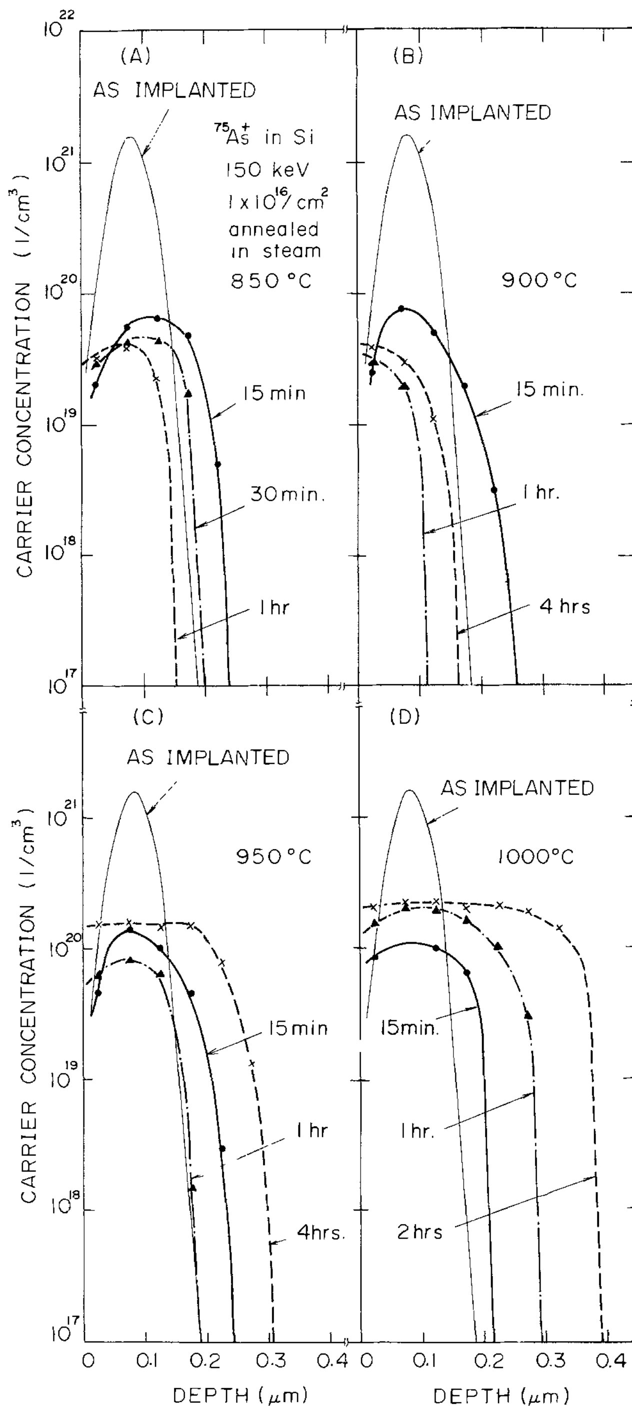

Fig. 2. Carrier distribution measured on the $^{75}As^+$-implanted layer using the spreading-resistance probe technique after oxidation at (A) 850°; (B) 900°; (C) 950°; and (D) 1000°C.

ment. In fact, during steam oxidation for between 15 and 30 min, the carrier distribution shifts toward the surface by about 800Å, which corresponds to the thickness of Si consumed during oxidation. After oxidation for 2 hr, the carriers seem to disappear according to spreading-resistance probe measurement. However, if one takes into account the fact that the segregation coefficient of As at $Si-SiO_2$ interface is quite large (3), this apparent As disappearance is not due to As segregation into the growing SiO_2 film, but to As pileup at the $Si-SiO_2$ interface. Muller *et al.* reported that the pileup region is about 200Å thick and As in this region is highly unsubstitutional (4). Therefore, the As in the pileup region is undetectable by spreading-resistance probe measurement since the pileup region depth is shallower than the 250Å resolution which corresponds to the minimum probe pitch.

At 850°C, the slope of the oxide growth curve is more than 1 as shown in Fig. 1. This might be due to the fact that interface reaction is enhanced with time by the accumulation of As in the $Si-SiO_2$ interface as described above.

Figure 2(B) shows carrier distribution after oxidation at 900°C. The carrier distribution shifts toward the surface for oxidation time up to 1 hr and then spreads gradually into the silicon substrate. From the data in Fig. 1, one can determine that oxide growth rate at 900°C slows down after 1 hr. Therefore, the gradual spread in carrier distribution after 1 hr is due to the fact that As diffusion velocity exceeds the $Si-SiO_2$ interface moving velocity.

Figure 2(C) shows carrier distribution after oxidation at 950°C. The behavior of carrier distribution after oxidation can be explained qualitatively according to the same reasons as were pertinent for Fig. 2(B).

Figure 2(D) shows carrier distribution after oxidation at 1000°C. The diffusion of As is prominent even for short oxidation time. The carrier distribution spreads deeper monotonically with increasing oxidation time. Carrier distribution after oxidation for 2 hr shows a typical feature of As-diffused layer with an abrupt p-n junction. The maximum carrier concentration measured here is about $3 \times 10^{20}/cm^3$, which agrees with the result reported by Fair and Tsai (3).

Figure 3 shows junction depth obtained from carrier distribution measurement as a function of oxidation time. For oxidation temperatures below 950°C, the junction depth decreases during the initial oxidation stage and thereafter increases gradually with time in periods corresponding to the slowing down of the oxidation rate. On the other hand, above 1000°C, junction depth increases monotonically with increasing oxidation time.

Figure 4 shows sheet resistance as a function of oxidation time. The results in this figure closely correspond to the results described above. Below 950°C, sheet resistance increases with increasing oxidation time, corresponding to the decrease in junction depth, and it reaches a maximum value when junction depth reaches a minimum. Thereafter, the sheet resistance decreases gradually. On the other hand, above 1000°C, the sheet resistance decreases monotonically with oxidation time, corresponding to the monotonic increase in junction depth.

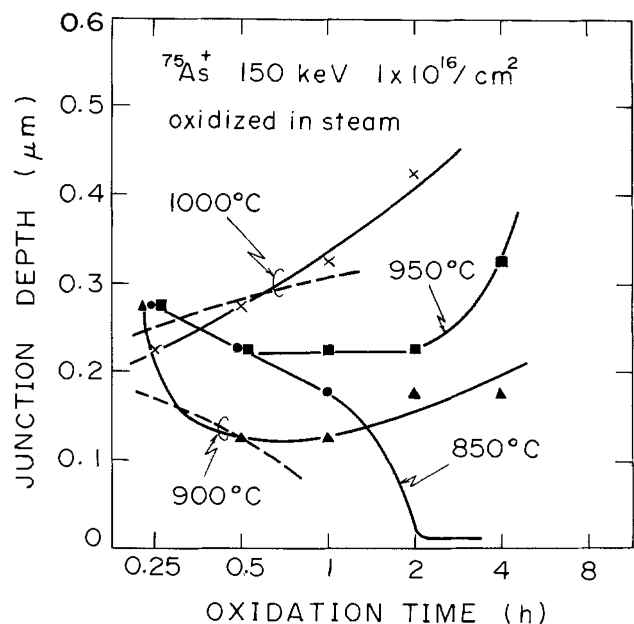

Fig. 3. Measured (solid line) and calculated (dashed line) junction depth as a function of oxidation time at 850°, 900°, 950°, and 1000°C.

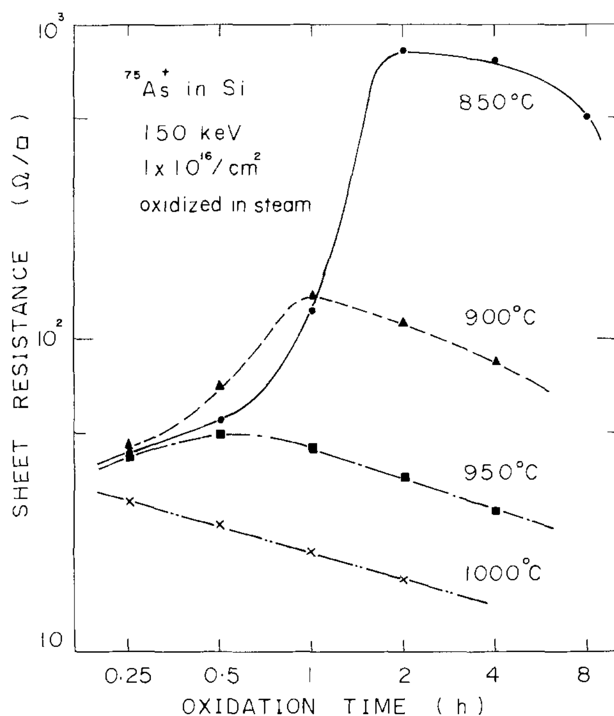

Fig. 4. Sheet resistance on the $^{75}As^+$-implanted layer after oxidation at 850°, 900°, 950°, and 1000°C as a function of oxidation time.

Results described above show that As carrier-distribution behavior depends on relative speed of As diffusion and $Si\text{-}SiO_2$ interface movement. To discuss the above results more quantitatively, diffusion equations were solved numerically. The diffusion equation in oxidizing ambient is expressed (9)

$$\frac{\partial}{\partial t} N(x,t) = \frac{\partial}{\partial x}\left[D \frac{\partial}{\partial x} N(x,t)\right] + \alpha \frac{dX}{dt} \frac{\partial}{\partial x} N(x,t)$$

and boundary condition is

$$D \frac{\partial}{\partial x} N(x,t)|_{x=0} = \left(\frac{1}{m} - \alpha\right) \frac{dX}{dt} N(0,t)$$

where the origin of the χ axis is the moving $Si\text{-}SiO_2$ interface, $N(x,t)$ is impurity concentration, D is diffusion coefficient, α is the ratio of the consumed Si thickness to the SiO_2 thickness during oxidation ($\alpha = 0.45$), X is the SiO_2 thickness, and m is the segregation coefficient. It is well known that the As diffusion coefficient depends on its concentration (3). In the present case, however, effective As diffusion coefficient data obtained from junction depth measurement by Murase *et al.* was used to simplify the calculation (10). In addition, the oxide growth rate was approximated by linear growth rate during oxidation, *i.e.*, dX/dt is constant. Their values were taken from the oxide growth curves in Fig. 1. The segregation coefficient obtained by Fair and Tsai ($m = 800$) was used (3). Initial As distribution was assumed to be Gaussian, using projected range and projected standard deviation reported by Gibbons *et al.* (7). The use of a Gaussian approximation does not necessarily give a precise profile where diffusional broadening does not wash out details of the initial profile. In the present case, junction depths calculated on the Gaussian approximation (no oxidation and no appreciable diffusion) are 0.22 μm, while including third-moment corrections yields 0.28 μm. The results, however, are qualitatively the same even if one takes into account third-moment corrections in the initial profile. Therefore, a Gaussian approximation was used for simplicity of the calculation. Calculations were performed by sectioning time and depth axes into equal intervals and by using a simple finite-difference method.

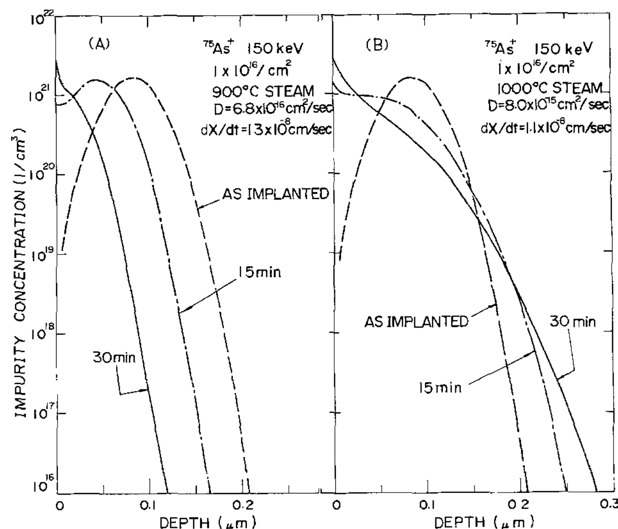

Fig. 5. Calculated distribution of As after initial oxidation stage at (A) 900°; and (B) 1000°C.

Figure 5(A) shows the calculated distribution after initial oxidation stage at 900°C. Values of the parameters used in the calculation are shown in the figure. It is evident that diffusion effect is almost negligible at this temperature, and As distribution shifts toward the surface due to the $Si\text{-}SiO_2$ interface movement during oxidation.

Figure 5(B) shows the calculated results at 1000°C. In contrast to the case of oxidation at 900°C, the diffusion effect can be observed. In both cases, As pileup at the $Si\text{-}SiO_2$ interface occurs. This is due to the fact that the As segregation coefficient is extremely high, and supports the speculation described in Fig. 2. Junction depth obtained from this calculation is shown in Fig. 3. Although good agreement was not obtained due to the rough approximation used, a general tendency in the initial stage of oxidation is evident.

Conclusions

Arsenic ions were implanted into Si and subsequent annealing was performed in an oxidizing ambient. The carrier distributions were measured by the newly developed spreading-resistance probe technique. When oxidation temperature is below 1000°C, As carrier distribution becomes shallower during the initial oxidation stage because the $Si\text{-}SiO_2$ interface moving speed is faster than the As diffusion speed. Thus, sheet resistance increases with increasing oxidation time. After this initial stage, the oxide growth rate slows down and As carrier distribution spreads. Sheet resistance then decreases correspondingly. On the other hand, when the temperature is above 1000°C, diffusion effects dominate and carrier distribution spreads into the substrate. Therefore, sheet resistance decreases with increasing oxidation time. These behaviors have been explained by simple numerical calculations. Above results provide information to design the As profile more precisely for shallow junction formation.

ABSTRACT

An investigation of the Si_xB_y compound formed when silicon is doped from B_2O_3 in the 950°-1100°C temperature range has been carried out. Depending on the composition, four main regions have been analyzed by different techniques: ionic analysis, x-ray diffraction, microsonde, electron diffraction, and infrared spectroscopy. Results showed that the Si-B phase crsytallizes on the cubic system with a 6.20Å parameter and the composition closely resembles SiB_5.

It is well known that the diffusion of impurities in silicon depends on the gas composition in the reactor, temperature, time of the diffusion, and on the initial resistivity of the sample.

Various authors have studied the diffusion of boron into silicon in an attempt to find an analytic law for the diffusion profile at temperatures ranging from 950° to 1200°C (1-7). Arai *et al.* (8) studied the interface reactions of B_2O_3-Si system and reported that the compound produced in the glass-silicon interface for high boron doping was SiB_4 and/or SiB_6, these compounds having been previously described in the literature (9-14). Recently, Moore *et al.* (15, 16), using standard B_2H_6 gas source, have investigated the distribution of B in SiO_2/Si with Auger electron spectroscopy. These authors found that the resulting film consisted of ~100Å B_2O_3 layer on a B-doped SiO_2 region separated from B-doped Si by a Si-B phase and this phase formed already at short deposition times, reaching a maximum B concentration of $(4 \pm 2) \times 10^{22}$ cm^{-3}. The width of the phase increased and grew into a lamellar structure, with the number and amplitude of lamellae depending on deposition time. Kiewit *et al.* (17) also investigated boron glass layers formed on silicon at high diffusion temperatures (1150°C). These authors also found an HF insoluble layer which was characterized as a Si-B phase according to Busen *et al.* (18) and by use of Auger electron spectroscopy they obtained the boron, silicon, and oxygen profiles.

In this paper we discuss the results of a study of the Si-B compound produced in the SiO_2/Si interface at 900°-1100°C by using B_2O_3 as diffusion source. In this study ionic analysis, x-ray diffraction, EDAX microsonde, electron diffraction, and infrared techniques were used in order to determine the structure and chemical composition of the compound.

Key words: B_2O_3-Si system, Si-B compounds, SiB_5, borosilicates, boron diffusion.

Experimental

Silicon used in this study was n-type and (111) surface oriented into which boron had been diffused. Samples were in the form of circular slices of 300 μm thickness and 37 mm diam.

Boron depositions were made in a ±0.5°C planar controlled furnace in the 900°-1100°C temperature range. The B_2O_3 diffusion source was of high purity (99.999) and was in an ultrapure (99.999) diffusion alumina boat at the same temperature as the silicon sample. In order to eliminate the oxygen in the reactor, a 10^{-3} mm Hg vacuum was pulled before the diffusion boat with the samples was introduced. The gas flow used was N_2 (99.999) with a water vapor content less than 5 ppm and an O_2 content less than 1 ppm. The flow rate was 0.7 liter/min.

The chemical composition measurement was made by means of ion analysis, where the primary beam consisted of Ar^+ ions with an energy of 5.5 keV and a current density of 1 μA/mm. The bombarded area was 1.5 mm diam and the analyzed one was 60 μm. Oxygen gas was introduced during the process to saturate the surface. Analyses were made by measuring the electric intensity of the B^{+11}, Si^{+30}, and O^{+17} ions.

In order to analyze the silicon on the different zones, an EDAX energy-dispersive x-ray analysis system attached to a Philips scanning electron microscope PSEM 500 was used. The sample was placed parallel to the incident beam which had a 3 keV energy.

The crystalline structure analysis was carried out with a Philips PW 1050 diffractometer using Ni-filtered Cu_α radiation (40 kV, 10 mA). In order to see a

possible structural difference between the substrate and the intermediate layer, transmission electron diffraction was also performed.

Transmission infrared measurements were made in pressed KBr disks using a Perkin-Elmer spectrophotometer, Model 457. The reflectivity curves were taken using a 30° fixed angle of incidence specular reflectance attachment. Some measurements were also made with an attenuated total reflectance (ATR) accessory.

Discussion and Results

In Fig. 1-3 and on a semilogarithmic scale, the boron and silicon concentrations *vs.* thickness are shown for three different samples studied by ionic analysis. Temperatures were 960°, 1000°, and 1100°C and the diffusion times 1200, 2350, and 345 min, respectively.

In Fig. 4 and for the 345 min, 1100°C diffused sample, the collected O^{+17} ionic intensity is plotted *vs.* depth on a semilogarithmic scale.

From the above graphics the existence of four main regions is deduced:

I $SiO_2 + B_2O_3$

II $Si_xB_yO_z$

III Si_uB_v

IV $Si + B$

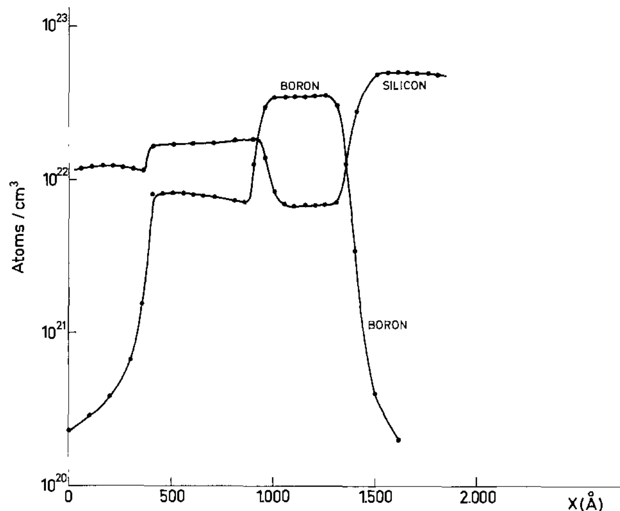

Fig. 1. Measured boron- and silicon-doping profiles in (111) surface-oriented silicon wafer after boron diffusion at 960°C for 1200 min.

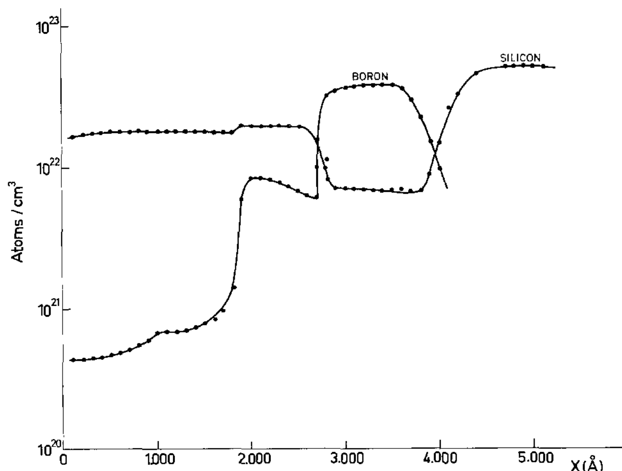

Fig. 2. Measured boron- and silicon-doping profiles in (111) surface-oriented silicon wafer after boron diffusion at 1000°C for 2350 min.

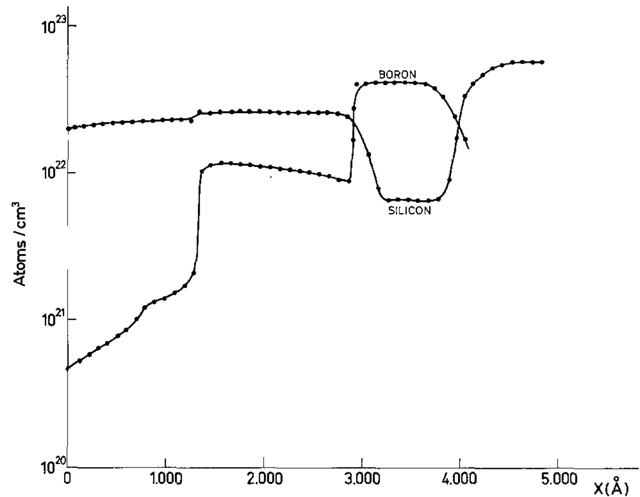

Fig. 3. Measured boron- and silicon-doping profiles in (111) surface-oriented silicon wafer after boron diffusion at 1100°C for 345 min.

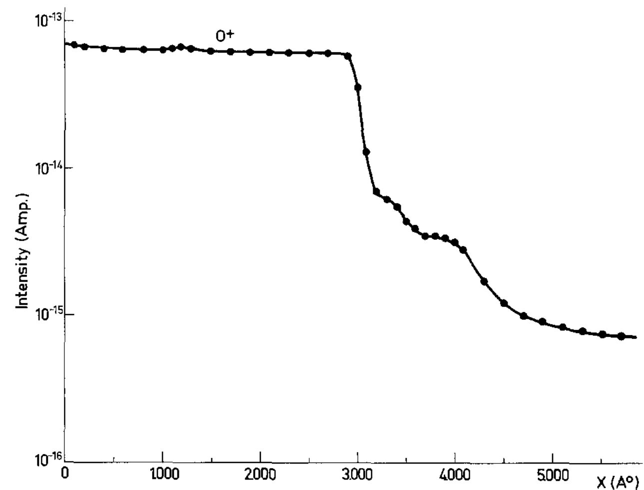

Fig. 4. O^{+17} ion intensity profile for the 345 min 1100°C diffused sample.

Table I shows the results obtained by means of the EDAX microsonde technique for three different zones, the first one comprising I and II obtained from ionic analysis. Silicon composition of zone III approximately corresponds to SiB_5.

Figure 5 shows the x-ray diffraction diagrams for three samples: a) Oxidized (111) surface-oriented sample. A wide band due to the SiO_2 is observed at $d(Å) = 10.8$; b) Boron diffused (in $N_2 + O_2$ atmosphere) (111) surface-oriented sample. Characteristic bands of the Si-B compound at $d(Å) = 6.10$ and $d(Å) = 6.20$ appear on the diagram; c) Boron diffused in N_2 atmosphere (100) surface-oriented sample. A peak at $d(Å) = 6.20$ is observed. The band decreasing is attributed to epitaxy in the (100) direction.

The Si-B layer insoluble in a HCl + HF mixture was studied by electron diffraction. Both the electron diffraction diagram and surface state micrograph are given in Fig. 6. Results reveal the existence of a crystalline compound where the growth has been rather homogeneous.

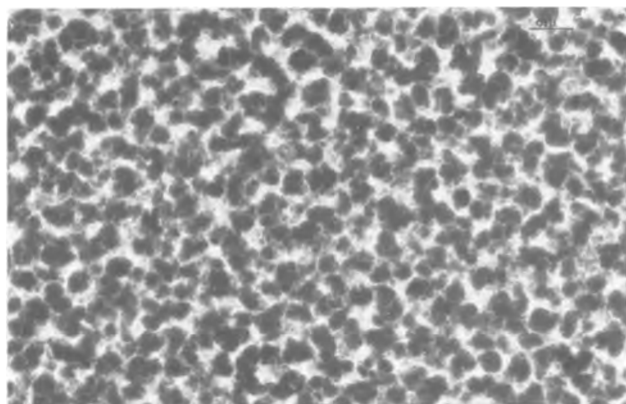

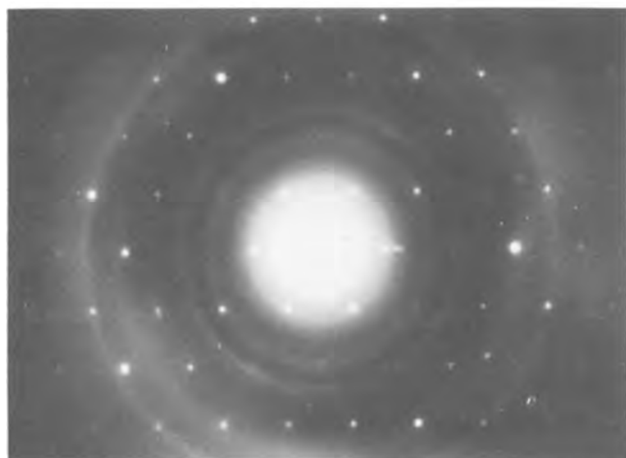

Fig. 6. Electron diffraction diagram and micrograph of Si-B compound.

Table II shows the crystallographic data corresponding to the diffraction diagram.

By use of the method given by Jamard *et al.* (19) the data of Table II are interpreted in terms of the Si-B phase having a cubic structure of 6.20Å parameter in agreement with the x-ray diffraction results. On the other hand, the x-ray and electron diffraction values measured in the present work do not coincide with the data of the literature for SiB_4 or SiB_6 (9-14).

The above results were confirmed by infrared spectroscopy as follows. Figure 7 shows the infrared absorption spectrum of powder obtained by light scraping from samples previously submitted to boron diffusion in nitrogen atmosphere for 20 hr. A complex absorption band is observed in the 9 μm region (1100 cm^{-1}) with maxima at 8.7 μm (1150 cm^{-1}), 9.1 μm (1100 cm^{-1}) and 9.35 μm (1070 cm^{-1}) which are related with Si-O vibrations. A second band centered at 7.25 μm (1380 cm^{-1}) points out to the existence of B-O bonds. A weaker band at 10.87 μm (920 cm^{-1}) might be due to Si-O-B bonds according to data of literature (20). Finally, the shoulder at 8.33 μm is attributed to O-H deformation vibrations of B-OH groups. Although the predominant bands of spectrum of Fig. 7 can be related with the compounds of the first and second layer as revealed by microsonde results, it must be borne in mind that the infrared spectrum of the insoluble compound produced in the B_2O_3-Si interface in our experiments must be similar to the spectrum of SiB_6 reported in the literature (21) and the characteristic bands could be overlapped by the stronger B-O and Si-O bands.

The reflectance curves for oxidized (26 hr, 900°C), and oxidized (4 hr, 90°C) and boron-diffused (48 hr, 900°C, N_2 atmosphere) samples are given in Fig. 8. In the first case the characteristic peaks of SiO_2 (22) are observed. In the second case changes arise in the 7.27 μm (1375 cm^{-1}) region related with the presence of B-O bonds and at 10.75 μm (930 cm^{-1}) attributed to Si-O-B bonds. With increasing boron deposition time a peak at 7.97 μm (1255 cm^{-1}) and a shoulder at 8.6 μm (1165 cm^{-1}) are observed in the reflectance spectra, these new peaks corresponding to the Si-B phase.

When the boron diffusion takes place in the presence of oxygen ($N_2 + O_2$ atmosphere) the SiO_2 bands may be predominant and an additional absorption at 11.36 μm (800 cm^{-1}) has been observed in some cases probably due to some interaction between B_2O_3 and SiO_2 compounds. These results confirm the conclusion of other authors (8) that the growth rate of the Si-B compound is depressed as the oxygen concentration in the atmosphere increases according to the reaction

$$\text{Si-B compound} + O_2 \rightarrow SiO_2 + B_2O_3$$

However, at higher diffusion temperatures (1000°C) in N_2 (94%) + O_2 (6%) atmosphere a great propor-

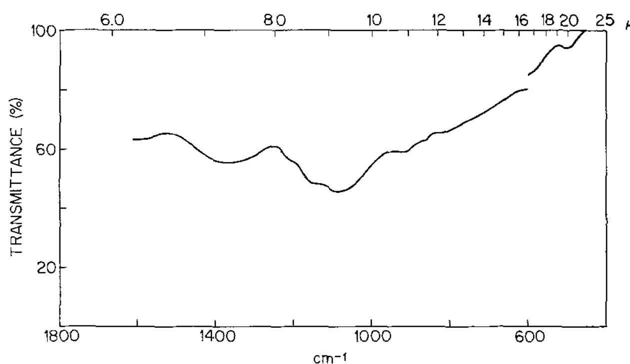

Fig. 7. IR spectrum of powder obtained by light scraping of boron-diffused sample (900°C for 20 hr, N_2 atmosphere).

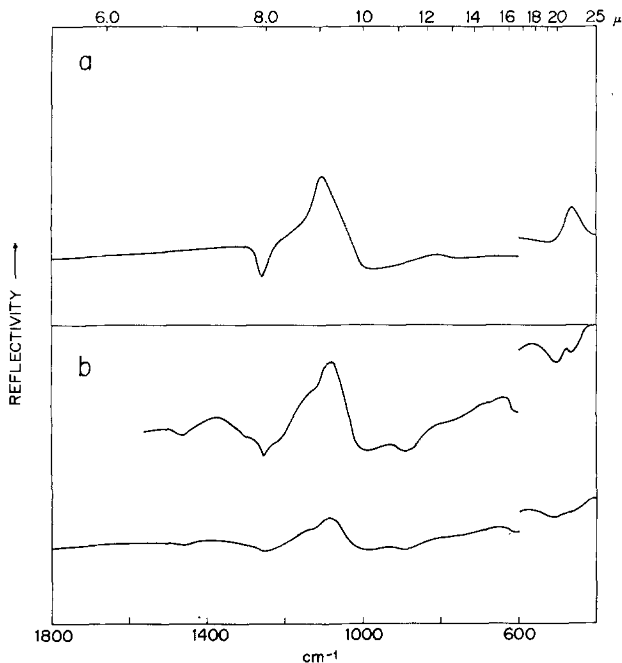

Fig. 8. Reflectance curves. a) Oxidized sample (at 900°C for 26 hr); b) heat-treated sample at 900°C, first in wet N_2 for 4 hr, and after that submitted to boron diffusion in N_2 for 48 hr.

tion of the Si-B phase was observed at 15 hr diffusion time.

Figure 9 gives the reflectance curves of two samples diffused in a N_2 atmosphere at 900°C for 48 and 90 hr, respectively, and for another boron-diffused sample after two days treatment with HF (48%). The peaks at 7.97 μm (1255 cm^{-1}), 8.55 μm (1170 cm^{-1}) are related to the Si-B phase. Another peak or inflection at 8.93-9.01 μm (1120-1110 cm^{-1}) is attributed to SiO_2.

The spectra of samples with low diffusion times show bands at 7.1 μm (1400 cm^{-1}), 8.2 μm (1220 cm^{-1}), 9.5 μm (1050 cm^{-1}), and 10.99 μm (910 cm^{-1}) related to B-O, Si-B, Si-O, and Si-O-B vibrations, respectively, according to the above results.

Conclusion

From the above experimental results it is concluded that when B_2O_3 is diffused into silicon in an N_2 atmosphere the compound produced at the B_2O_3-Si interface at 900°-1100°C is neither SiB_6 nor SiB_4 but most probably resembles SiB_5 composition.

ABSTRACT

Noncrystalline Si_3N_4 layers are grown at low temperatures by the chemical reaction of silane and ammonia, and at extremely high deposition rates (120Å/sec) which is 50 times higher than the usual deposition rates. Correlations between growth conditions and layer properties are studied. The growth conditions for obtaining the most suitable encapsulant layers for the annealing of ion-implanted GaAs are: gas feed rates of silane, ammonia, and nitrogen carrier gas of 5, 200, and 1500 ml/min, respectively, and a growth temperature of 700°C. Layers formed under these conditions have a refractive index of 1.95 and an etch rate of 500 Å/min in 50% HF solution. These values are nearly equal to that of conventional Si_3N_4 layers deposited at lower deposition rates. Auger electron spectroscopic analysis shows an oxygen concentration below the detection limit (<0.1 atom percent) and a uniform Si/N ratio along the thickness direction. Out-diffusion of Ga and As into the layer does not occur on 900°C annealing. No cracks are formed when thin Si_3N_4 layers, less than 1200Å thick, are deposited on GaAs substrates. These layers are useful as encapsulant films for the annealing of GaAs.

Chemical vapor deposited noncrystalline Si_3N_4 layers have been extensively applied to silicon devices for surface passivation, diffusion masking, and MNOS devices, because of their chemical stability. Recently, Si_3N_4 layers have been frequently used as an encapsulant film for the annealing of ion-implanted GaAs (1-4).

In ion-implanted GaAs, annealing at above 800°C is necessary to eliminate radiation damage and to achieve high electrical activation of implanted species. Therefore, good encapsulant layers are required. An effective encapsulant should reduce thermal decomposition of the GaAs surface and the out-diffusion of Ga, As, and implanted species during high temperature annealing. However, encapsulation effects on GaAs annealing are significantly affected by layer quality and deposition conditions, as reported previously (1-4).

As there is a relatively large difference in thermal expansion coefficient between Si_3N_4 (2.6×10^{-6} °K^{-1}) (5) and GaAs (6.9×10^{-6} °K^{-1}) (6), a large strain is formed at the Si_3N_4-GaAs interface. Therefore, cracking and lifting of the Si_3N_4 film occurred when the film was annealed at temperatures above 800°C (7). Although GaAs decomposition increases at temperatures above 600°C (8, 9), the decomposition can be reduced by shortening the high temperature exposure of GaAs surfaces before deposition. To meet these requirements, the deposition of thin Si_3N_4 layers must be carried out at high temperatures with extremely high deposition rates. The heating of substrates up to the deposition temperature within an extremely short time is also important.

Recently, Donnelly *et al.* have reported on high rate deposition of Si_3N_4 (2, 10). They have demonstrated that this layer is a good encapsulant film for the annealing of ion-implanted GaAs. However, detailed features of growth conditions and layer properties have not been reported. It is well known that the properties of Si_3N_4 can be varied over a wide range depending on the deposition technique and conditions. Therefore, optimum growth conditions for obtaining good encapsulant layers must be established.

This paper describes the growth conditions of high deposition rate Si_3N_4. The properties of layers deposited under different conditions are also described.

Key words: silicon nitride, chemical vapor deposition, gallium arsenide, ion implantation, encapsulation film.

Results and Discussion

Deposition.—Silicon nitride films were deposited on GaAs wafers using the chemical reaction between NH_3 and SiH_4. A cold wall type vertical reactor with 150 mm diam was manufactured using stainless steel. Special care was taken to eliminate slow leaks in the gas tubing system and reaction chamber by using stainless steel fittings. Chemomechanically polished GaAs substrates were cleaned with organic solvents and dipped in 35% HCl to remove residual surface oxides just prior to deposition.

After GaAs substrates of 10 × 10 mm were placed on the graphite strip heater in the reactor chamber, the reactor system was evacuated to mid-10^{-5} Torr in order to prevent oxide layer depositions. The substrates were then heated to 200°C in N_2 gas flow. This preheating procedure permits shortening the substrate heating time prior to deposition and prevents the predeposition of oxide layers (10). Reactant gases, SiH_4 and NH_3, were introduced into the reactor together with the N_2 carrier gas. High purity NH_3 gas (99.999%) was used to obtain oxygen-free Si_3N_4 layers. Then the substrate was heated rapidly from 200°C to a predetermined deposition temperature, for instance 700°C, within 5 sec by increasing the heater current. As a result, the deposition of the Si_3N_4 layer occurred at an extremely high growth rate. Silane flow rate was constant at 5 ml/min throughout this experiment, while the NH_3 and N_2 gas feed rates were varied. When deposition was carried out at the gas feed rates of SiH_4 = 5 ml/min, NH_3 = 200 ml/min, and N_2 = 1500 ml/min,

we denoted the ratio as $SiH_4:NH_3:N_2 = 1:40:300$, for simplicity. The thickness of Si_3N_4 layers deposited at different deposition times was measured using an ellipsometer.

The layer thickness variation with deposition time is shown in Fig. 1, where deposition was made at 700°C with gas feed rate ratio of $SiH_4:NH_3:N_2 = 1:40:300$. This figure shows that the layer thickness increases linearly with time and that deposition rate is nearly constant at 120 Å/sec in the range studied here (<30 sec). This deposition rate is much higher than that of conventional Si_3N_4 grown at higher temperatures (>800°C) and lower gas feed rates (11-13). High deposition rate Si_3N_4 is abbreviated as HR Si_3N_4 in the following discussion.

Depositions were carried out at various temperatures ranging from 500° to 800°C, where the gas feed ratio of $SiH_4:NH_3:N_2$ was fixed at 1:40:300, and the layer thickness was fixed at around 1000Å. The deposition rate is shown as a function of deposition temperature, T, in Fig. 2. As seen in this figure, the deposition rate of HR Si_3N_4 increases markedly with increasing T and becomes relatively temperature insensitive at temperatures above 700°C. Temperature variations at below 700°C suggest that the chemical reaction is a rate-limiting process and the deposition rate follows an exponential law. The apparent activation energy of the growth is about 10.6 kcal/mole, which is smaller than the value of 17 kcal/mole reported for conventional Si_3N_4 growth (12). Above 700°C mass transfer process is dominant as shown in Fig. 3, where NH_3 to SiH_4 feed ratios of 30, 40, and 50 are used. The deposition rate decreases sharply with increasing N_2 flow rate, for instance, from 250 Å/sec at a N_2 flow rate of 250 ml/min to 70 Å/sec at 2250 ml/min. Similar tendencies are seen for different NH_3 to SiH_4 ratios. It is clear from these results that high rate deposition should be attained if the N_2 flow rate is lowered and the SiH_4 feed rate is increased. However, layer thickness uniformity within the wafer improves significantly at higher N_2 flow rates, the best uniformity (within 12%) was attained at a N_2 flow rate of 1500 ml/min with a gas feed ratio of $SiH_4:NH_3:N_2 = 1:40:300$, and deposition temperature of 700°C. In this case, a deposition rate of around 120 Å/sec was obtained. This value is about 50 times higher than that for conventional Si_3N_4 layers.

Layer properties.—Evaluation of layer properties for HR Si_3N_4 grown under different conditions was carried out to obtain desired encapsulant layers. Refractive indexes of the layers deposited at different temperatures were measured with an ellipsometer. The refractive index as a function of deposition temperature is shown in Fig. 4 for deposits at a gas feed ratio of $SiH_4:NH_3:N_2 = 1:40:300$. The refractive index is nearly constant for depositions at above 600°C and increases slowly with decreasing deposition temperature below 600°C. Reduction of the refractive index

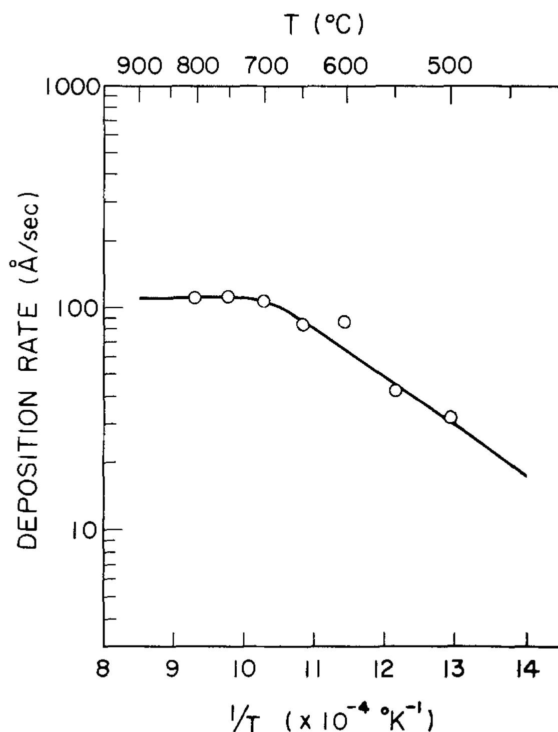

Fig. 2. Deposition rate of HR Si_3N_4 as a function of deposition temperature. Gas feed ratio, $SiH_4:NH_3:N_2 = 1:40:300$.

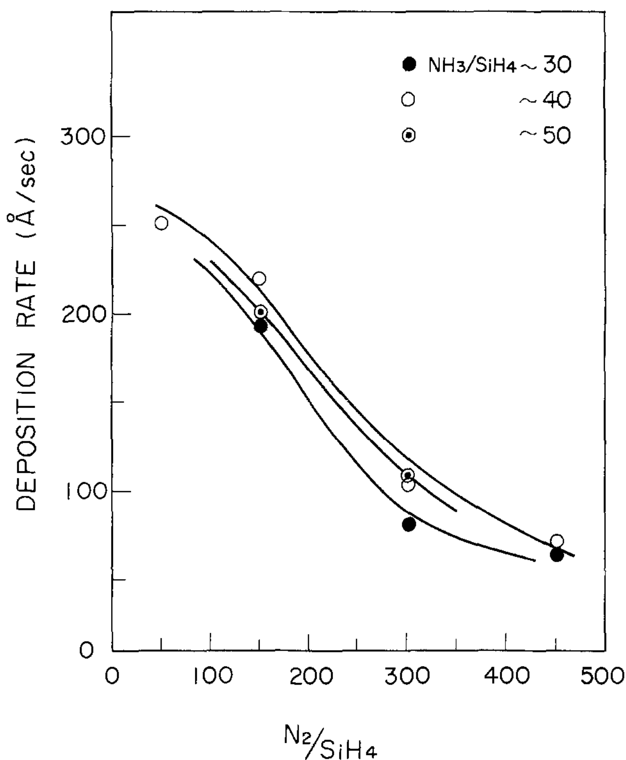

Fig. 3. Deposition rate of HR Si_3N_4 as a function of N_2 carrier gas at different NH_3/SiH_4 ratios where deposition temperature was 700°C.

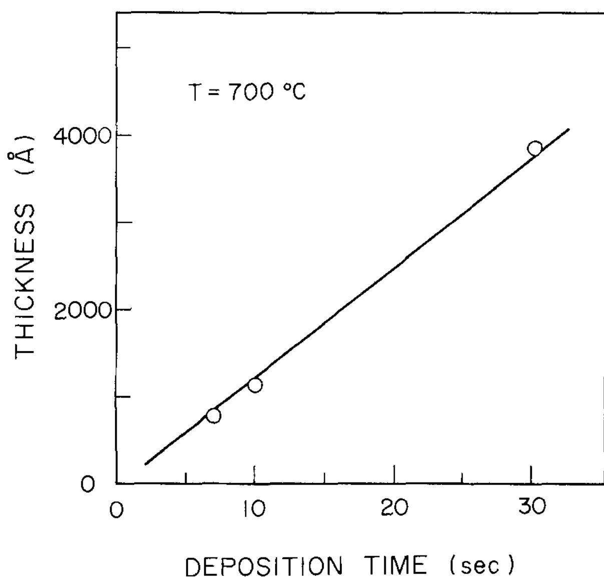

Fig. 1. Thickness variation of Si_3N_4 layers with deposition time, where the deposition was made at gas feed ratio of $SiH_4:NH_3:N_2 = 1:40:300$, and a deposition temperature of 700°C.

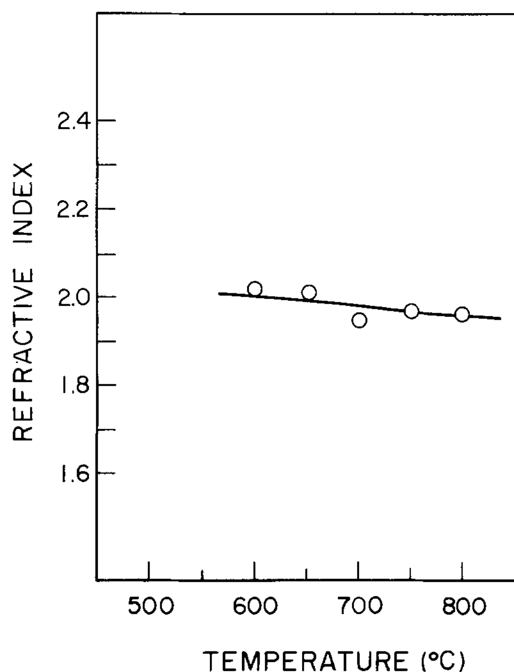

Fig. 4. Refractive index of HR Si_3N_4 as a function of deposition temperature. Gas feed ratio, SiH_4:NH_3:N_2 = 1:40:300.

by the incorporation of oxygen in the film has been demonstrated (14), although the refractive index is affected with deposition parameters such as temperature and NH_3 to SiH_4 ratio. The refractive index of 1.95 for HR Si_3N_4 grown at 700°C is nearly equal to that of conventional Si_3N_4 (15).

The etch rates of the deposited layer were measured by dipping specimens into 50% HF solution at 20°C without stirring. The layers could be removed completely from GaAs surface in this manner. The etch rates of layers deposited at a gas feed ratio of SiH_4:NH_3:N_2 = 1:40:300 are plotted in Fig. 5 as a function of deposition temperature, *T*. The etch rate decreases drastically with increasing *T* and becomes constant at about 500 Å/min for temperatures above 600°C.

Chu *et al.* (12) have reported that the etch rate of conventional Si_3N_4 deposited at 800°C is approximately 700 Å/min. As shown in Fig. 5, the etch rate of HR Si_3N_4 deposited at and above 600°C is around

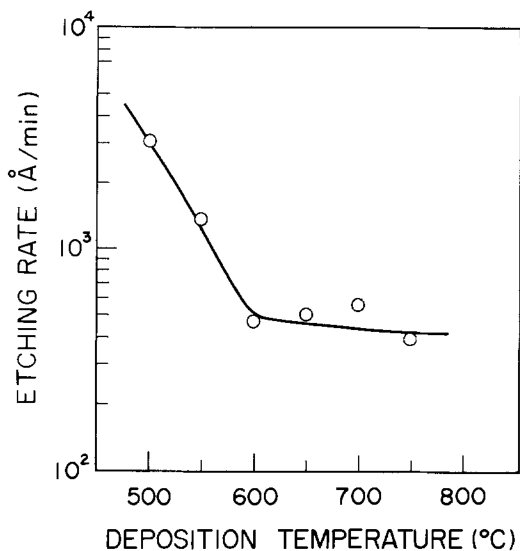

Fig. 5. Etch rate of HR Si_3N_4 in 50% HF at 20°C as a function of deposition temperature. Gas feed ratio, SiH_4:NH_3:N_2 = 1:40:300.

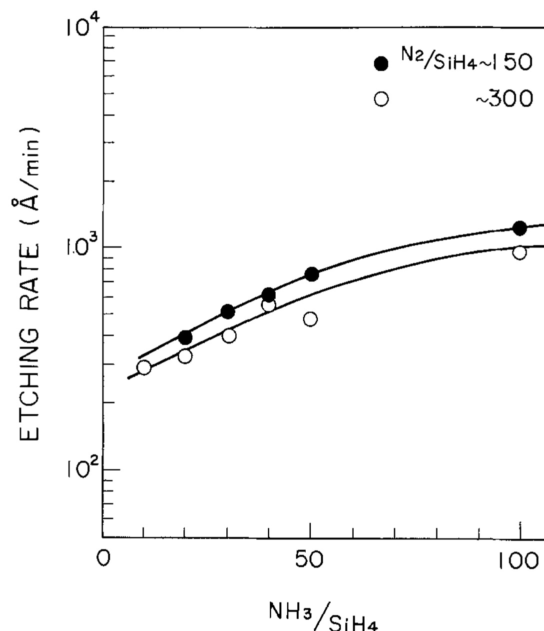

Fig. 6. Etch rate of HR Si_3N_4 layers in 50% HF at 20°C as a function of NH_3/SiH_4 ratios where deposition temperature was 700°C.

500 Å/min. The etch rates of layers deposited at different NH_3/SiH_4 ratios are shown in Fig. 6. The etch rates decrease gradually with decreasing NH_3 concentration.

Typical infrared absorption spectra are given in Fig. 7, where curves A and B are for 1000Å thick layers grown on Si substrates at a gas feed ratio of SiH_4:NH_3:N_2 = 1:40:300 and 1:40:50, respectively. The main Si-N absorption appears at around 12 μm as observed in conventional Si_3N_4 layers (14). Infrared absorption study of other layers indicates that the magnitude of this absorption is independent of both deposition temperature and gas feed ratios in the range studied here. Although the N-H absorption band at 2.97 μm was not found in layers typical of conditions shown for curve A, this band appeared in layers grown with extremely high NH_3 concentrations, as shown in curve B.

The absorption coefficient as a function of the mole fraction of NH_3 to total gas is shown in Fig. 8, where the 2.97 μm band grows rapidly with increasing NH_3 fractions in the range above 30%. The absorption peaks at 4.6 μm due to Si-H bonds, which have been reported for glow discharge Si_3N_4 (16), were not detected. Since the Si-O band at 9.2 μm was not

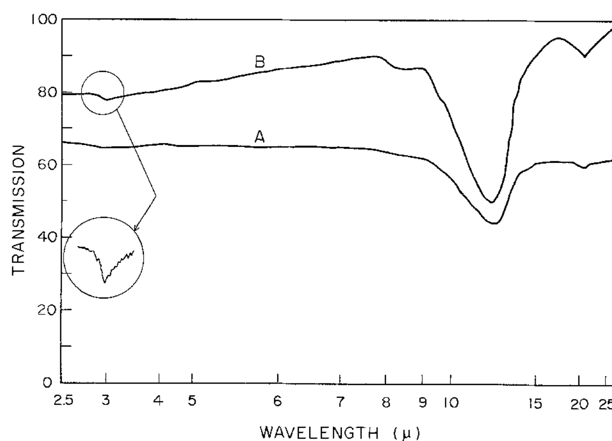

Fig. 7. Infrared absorption spectra of HR Si_3N_4 deposited at 700°C. Gas feed ratio, SiH_4:NH_3:N_2 = 1:40:300 (curve A) and 1:40:50 (curve B).

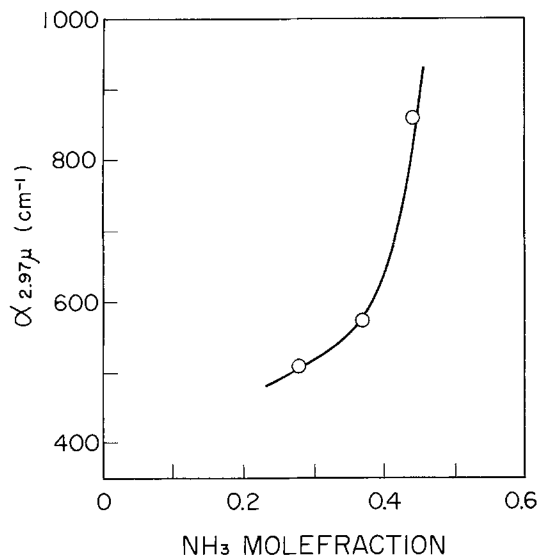

Fig. 8. Percent absorption at 2.97 μm (N-H bonds) of HR Si_3N_4 as a function of ammonia mole fraction, ($NH_3/SiH_4 + NH_3 + N_2$), where deposition was made at 700°C.

observed, these layers are regarded as low in oxygen concentration.

Auger electron spectroscopic analysis of HR Si_3N_4 was performed using a JEOL type JAMP-3, where measurement was made at $E = 5$ keV and $I = 10^{-7}$A. Depth profiles of N, Si, and O in as-deposited layers show that the distribution profile of the N/Si composition ratio was uniform along thickness direction, and that the oxygen concentration is below the detection limit (<0.1 atom percent) (17). The layer examined was deposited at 700°C and at a gas feed ratio of SiH_4:NH_3:N_2 = 1:40:300. However, trace amounts of oxygen were detected at the Si_3N_4-GaAs interface, although residual surface oxide layers were removed from the GaAs surface before growth. The origin of this oxygen is not clear at this time.

Gyulai *et al.* (18) using the MeV He ion backscattering method, have shown that out-diffusion of Ga into encapsulant Si_3N_4 film occurs when a sample is heated to 750°C. The amount of out-diffusion from the substrate seems to be affected by layer quality, for instance, growth conditions and oxygen concentration in the Si_3N_4 layer (19). The layer was annealed at 900°C for 15 min in a N_2 gas flow. Distribution profiles of N, Si, and O were then examined by Auger electron spectroscopy. Neither Ga nor As atoms diffused into the HR Si_3N_4 layer during 900°C annealing, because the oxygen concentration is below the detection limit, as shown in Fig. 9. An oxygen peak is observed at the GaAs-Si_3N_4 interface as seen in the as-deposited layers (17).

Doo *et al.* (11, 13) and others (12) have reported that cracks are often observed in as-deposited thick Si_3N_4 layers grown on Si substrates and that crack density increases with increasing growth rates. There is a much larger difference in thermal expansion coefficients between Si_3N_4 (5) and GaAs (6) compared with the Si_3N_4-Si interface. Therefore, cracks should form more easily on the Si_3N_4 layers deposited on GaAs. In order to obtain good encapsulant layers for annealing of ion-implanted GaAs, the conditions under which cracks do not appear even for annealing at 900°C must be established. To establish these conditions, layers with different thicknesses were deposited. No cracks were found in as-deposited HR Si_3N_4 layers when the layer thickness was in the range between 500 and 4000Å. Pin holes disappeared in the layer thicker than 800Å. These layers were annealed at 900°C for 15 min. A scanning electron microscope photograph of a 1100Å thick annealed Si_3N_4 layer is shown in Fig. 10. No cracks are seen in this layer.

After Si_3N_4 films were removed using an HF solution, the GaAs surface was examined by SEM. There were no cracks or damage when the thickness of the HR Si_3N_4 layer was below 1200Å. However, when thicker layers were deposited, for instance > 1500Å, cracks were formed during this annealing process. Typical cracks, which appeared on GaAs surfaces when annealing was carried out using 3000Å thick encapsulant layers, are shown in Fig. 11. It should be noted that the cracks on the GaAs seem to run along the cleaved surface. It is concluded that the HR Si_3N_4 layer thickness should be less than 1200Å for annealing GaAs.

This study on refractive index, etch rate, and Auger electron spectroscopy indicates that the HR Si_3N_4 is a good encapsulant layer and low in oxygen concentration.

Peak carrier concentrations of 4.5×10^{18} cm^{-3} have been obtained using this layer as an encapsulant film for the annealing of Si ion-implanted GaAs (17). Detailed features of the electrical properties of ion-implanted GaAs annealed with an HR Si_3N_4 encapsulant will be reported in the near future.

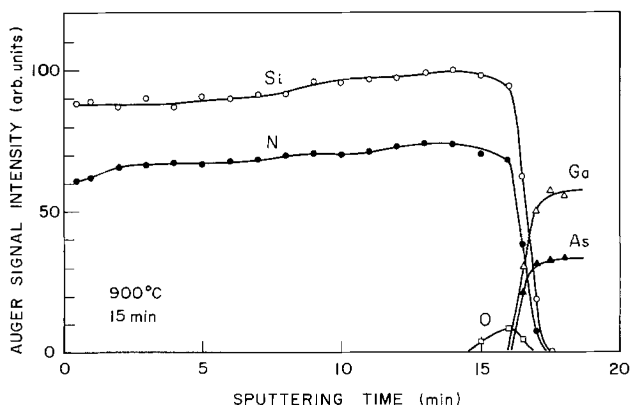

Fig. 9. Auger electron in-depth profiles of annealed HR Si_3N_4 layers deposited on GaAs substrates, where annealing was carried out at 900°C for 15 min.

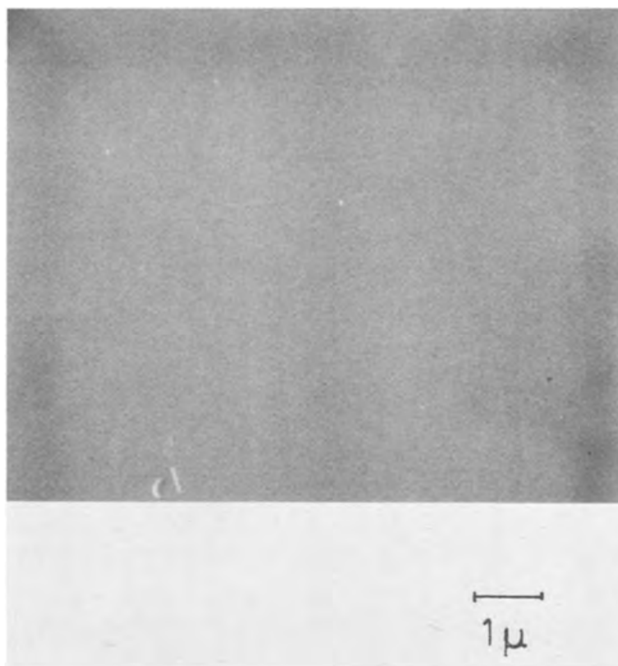

Fig. 10. Scanning electron microscope photographs of a 1100Å thick HR Si_3N_4 layer, which was deposited on a GaAs substrate and annealed at 900°C for 15 min.

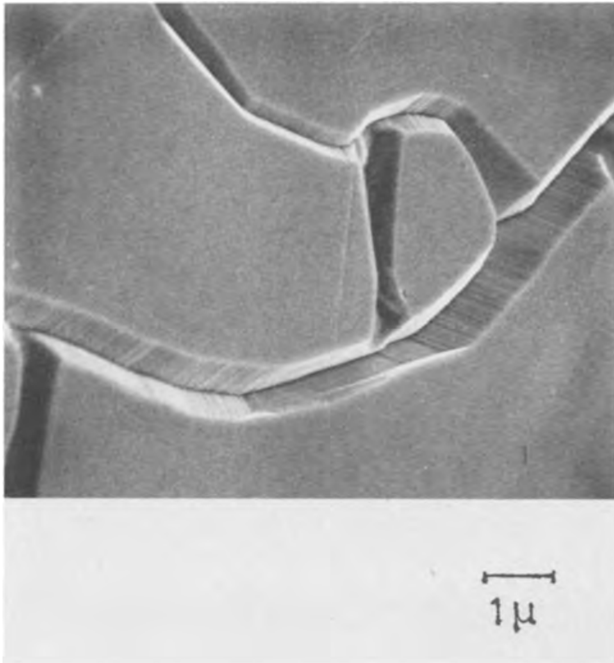

Fig. 11. Scanning electron microscope photograph of surface cracks formed on GaAs substrates under the following annealing procedure: 3000Å thick Si_3N_4 layers were deposited on GaAs. After annealing at 900°C for 15 min in N_2 flow, Si_3N_4 layers were removed by etching from GaAs surface. Cracks were formed on the GaAs surface.

Conclusion

Deposition conditions of high deposition rate Si_3N_4 were studied. From results of layer property evaluation, it is clear that good encapsulant layers for annealing GaAs can be grown by the chemical reaction of SiH_4 and NH_3 in N_2 gas flow under the following conditions: growth temperature 700°C; gas feed rates of SiH_4 5 ml/min, NH_3 200 ml/min, and N_2 carrier gas 1500 ml/min. In this case, the deposition rate was 120 Å/sec and about 50 times larger than that of conventional Si_3N_4. Properties of layers deposited at these conditions were an etch rate in 50% HF of 500 Å/min and a refractive index of 1.95. High deposition rate layers were essentially free from oxygen contamination and out-diffusion of Ga and As into the encapsulant layers did not occur during the annealing at 900°C with the layers deposited on GaAs substrates. No cracks were formed during 900°C annealing when thin layers, below 1200Å, were deposited. Pin holes could be eliminated when thick layers, above 800Å, were deposited. From these results, it can be concluded that the HR Si_3N_4 layers with around 1000Å thick are promising encapsulant films for the annealing of ion-implanted GaAs.

Diffusion Properties of Cadmium in Indium Antimonide

A. Kolodny and J. Shappir

Faculty of Electrical Engineering, Technion-Israel Institute of Technology, Haifa, Israel

ABSTRACT

Diffusion profiles of cadmium in indium antimonide were measured by a modified C-V technique and were found to exhibit anomalous behavior, as commonly found in III-V compounds. The general shape of the diffusion profile on a logarithmic scale is characterized by a concave region close to the surface followed by a steep front. The steep front is explained by the interstitial-substitutional diffusion mechanism. The concave region is theoretically shown to be related to a decrease of the diffusion coefficient near the surface. This decrease is assumed to be the result of the surface proximity rather than the result of a nonmonotonic concentration dependence of the diffusion coefficient. This surface effect is physically explained by an extension of the interstitial-substitutional model. Computer simulations based on this model give profiles similar to those experimentally measured.

Cadmium diffusion profiles in n-type indium antimonide exhibit a steep front near the p-n junction and a concave region (when plotted on a logarithmic scale) near the surface (1, 2). Such anomalous diffusion is commonly found in III-V compounds (3) and has been reported for zinc in GaAs (3, 4), InP (1), and InAs (1), phosphorus in GaAs (5), and other diffusion systems.

The basic interstitial-substitutional diffusion mechanism (6), which is usually invoked to interpret the steep front of the profiles, does not explain the concave region in the profiles, because it leads to profiles which are convex with a steep front. The concentration dependence of the diffusion coefficient, obtained from experimental profiles by applying the Boltzmann-Matano analysis (3), is nonmonotonic, exhibiting a maximum at intermediate diffusant concentrations (4, 5). Furthermore, the behavior near this maximum varies with diffusion time. This result, which is clearly unphysical, contradicts the monotonic dependence of the diffusion coefficient on the diffusant concentration as predicted by the interstitial-substitutional model. Consequently, the validity of the Boltzmann-Matano analysis for this type of diffusion has been doubted by some authors (4, 5), since the profiles cannot be expressed in terms of a single variable $x/\sqrt{t}$ (diffusion depth divided by the square root of diffusion time). The concave region in the profiles, which causes a peak in the results of a Boltzmann-Matano analysis, is assumed to be related to a surface effect on diffusion. A qualitative explanation of this phenomenon, relating it to a nonequilibrium of vacancies, has been given by Tuck (3).

The anomalous behavior described above was observed on a cadmium diffusion profile which was measured by means of a "graded *C-V*" technique described in the experimental section.

In the theoretical section, we present a generalization of the Boltzmann-Matano formula for the case of a diffusion coefficient dependent upon depth, diffusant concentration, and diffusion time. By means of this formula, phenomenological conclusions about the behavior of the diffusion coefficient are reached, showing that it decreases near the surface. Numerical results showing good qualitative agreement with experiment are presented, and suggestions are made about the physical reasons for the phenomenon.

Graded *C-V* Profiling Method

The profile of electrically active cadmium diffused into the InSb was found from *C-V* measurements on MOS capacitors in several depths along the profile. This "graded *C-V*" technique is preferable to the well-known radiotracer and resistivity methods because it eliminates the necessity for removal of successive thin layers. The method is based on gradual immersion of a long diffused sample in an etching solution so that the surface becomes a slightly slopy plane, along with which the impurity concentration is gradually changing. The surface type is changed from p to n where the wedge crosses the junction plane. A thin insulating layer is deposited on the sample, and a series of small electrodes are placed upon it to form MOS capacitors as shown schematically in Fig. 1.

From *C-V* measurements on a MOS capacitor at high frequency, the type of impurities in the crystal below it may be determined, and their concentration may be calculated from the ratio of minimum-to-maximum capacitance. Similar methods have been used for shallow implanted layers, but in those, the varying bias voltage controls the measurement depth, and the derivative dC/dV of the measured curve is required to obtain the profile (7). In our experimental process, cadmium was diffused for several hours at 400°C into samples of tellurium-doped InSb with donor concentration of about 10^{15} cm^{-3}, cut along <111> plane and polished on the In face. After the diffusion, a slice about 2.5 cm long was gradually etched, so that a height difference of about 2 μm was obtained. A narrow strip along the sample had been protected by photoresist before the etching so that a step was formed, and the distance from every point on the wedged surface to the original surface could be determined by measuring the step height. A 1000Å pyrolitic SiO_2 layer was then deposited on the sample, and a series of 0.6 mm diam capacitors were formed on it by Cr-Au evaporation. *C-V* curves of these capacitors at 1 MHz were measured at 77°K.

The measured capacitance is equivalent to that of three capacitors in series: oxide capacitance C_{ox}, depletion capacitance C_{dep}, and the p-n junction capacitance C_j. The junction area is almost equal to the area of the whole sample, so that C_j is large and thus may be neglected. One is left with the simple structure of a MOS capacitor at high frequency, and the ionized

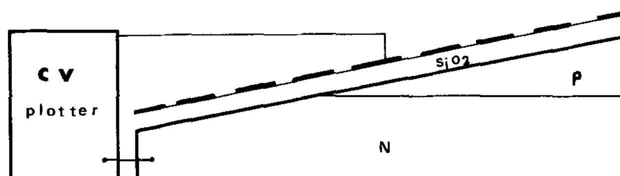

Fig. 1. Schematic setup for measurement of a diffusion profile by the graded *C-V* method. The impurity concentration below each MOS capacitor is found from the *C-V* curve.

Key words: Boltzmann-Matano analysis, C-V profiling method, concave diffusion profiles, interstitial-substitutional mechanism.

impurity concentration N_o may be readily obtained from the value of C_{min}/C_{ox} which is a function of the oxide thickness and substrate doping level, by solving

$$\frac{N_o}{\phi_F} = \frac{4C_{ox}^2}{q\epsilon_{InSb}\epsilon_o A^2} \left[\frac{\frac{C_{min}}{C_{ox}}}{1 - \frac{C_{min}}{C_{ox}}} \right]^2 \quad [1]$$

C_{min} is the minimum of the C-V curve, ϕ_F is the Fermi potential, A is the capacitor area, and the other symbols have their usual meaning.

The accuracy of the graded C-V method is determined by the following factors: (*i*) Variation of impurity concentration in the depletion region; (*ii*) variation of impurity concentration along the sloped surface under the metal electrode; (*iii*) minority-carrier generation by background illumination; (*iv*) magnification of capacitance-measurement error as $C_{min}/C_{ox} \rightarrow 1$ (see Eq. [1]; (*v*) inhomogeneity of the slope-etched surface; (*vi*) errors in the etching depth measurement.

For impurity densities above 5×10^{16} cm^{-3}, the depletion layer width is less than 0.1 μm, so that the impurity concentration may be assumed to be constant throughout the depletion layer. Making a moderate slope on a long substrate eliminates the effect of concentration variation under the metal electrode. The effect of background illumination was found to be negligible from C-V measurements on an n-type substrate with a known impurity concentration.

The minimum detectable change in capacitance is obtained for impurity concentrations below 10^{19} cm^{-3}. It may thus be concluded that the graded C-V method is applicable for measurements of diffusion profiles in InSb for the range of impurity concentrations 5×10^{16} cm$^{-3} \leq N \leq 10^{19}$ cm^{-3}.

Application of the graded C-V method to our cadmium-diffusion process gave the profile shown in Fig. 2. The measured profile of active cadmium impurities is very similar to profiles measured by radiotracer methods. Hence, the results may be analyzed assuming that all the cadmium atoms are ionized. The surface concentration was too high to be measured by this technique, so the initial part of the profile may be extrapolated to the maximum solid solubility which is in the range of 4×10^{19}-2.5×10^{21} cm^{-3} (8, 9). The spread of the measured values is believed to be mainly due to the nonuniformity of the etched surface, which was observed visually.

Inspection of the resulting profile motivated an investigation of the mathematical properties of the diffusion equation corresponding to such a diffusion profile. The treatment is given in the next section.

Analysis of Diffusion Profiles

We assume that the diffusion process obeys Fick's law with an effective diffusion coefficient, D, which accounts for the detailed transport mechanism. For fixed temperature, surface concentration, and vapor pressures, D may depend on the diffusant concentration C, the distance to the surface x, and the time t. The diffusion equation is

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x} \left[D(C, x, t) \frac{\partial C}{\partial x} \right] \quad [2]$$

The initial conditions are $C(x) = 0$ for $x > 0$, and the boundary conditions (constant source diffusion) are

$$\left. \begin{aligned} C(\mathrm{o}, t) &= C_o \\ C(\infty, t) &= 0 \end{aligned} \right\} \quad [3]$$

It is usually assumed in the literature that D is a function of C only.

These are the conditions for application of the standard Boltzmann-Matano analysis, which gives the

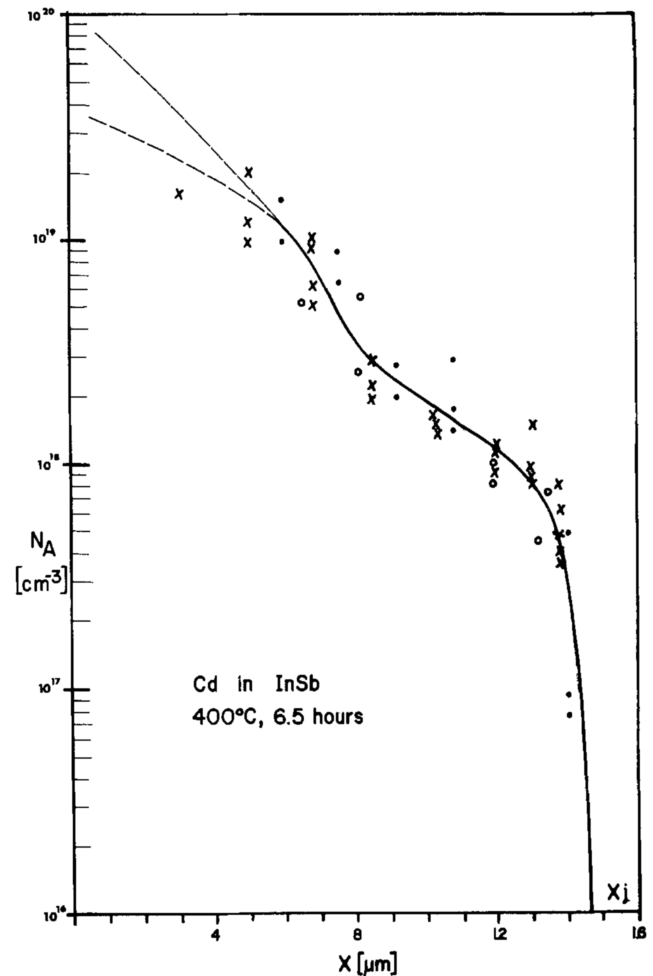

Fig. 2. Diffusion profile of Cd in InSb, measured by the graded C-V method. Experimental points represent several capacitors on three samples. The surface concentration was too high to be measured by this technique.

value $D(C_1)$ at any concentration C_1 on an experimentally-measured profile $C(x)$ as (5)

$$D(C_1) = -\frac{1}{2t_1} \left(\frac{dx}{dC} \right)_{C_1} \int_0^{C_1} x dC \quad [4]$$

where t_1 is the diffusion time used in the experiment.

Functions $D(C)$ that were obtained by applying Eq. [10] on profiles measured by us and by others (1, 9), are given in Fig. 3. Functions of similar behavior were calculated in GaAs for Zn (4) and P (5). The increase in $D(C)$ with increasing C at the low concentrations range is a consequence of the steepness of the experimental profile at the diffusion front and is physically explainable by the interstitial-substitutional diffusion mechanism (7).

The peak in $D(C)$ at intermediate concentrations reflects the existence of a concave region in the profiles. The fact that the peak of $D(C)$ is time-dependent (4) leads to the conclusion that the validity of the results is in doubt. The peak in $D(C)$ is physically unfeasible: it is the outcome of applying Eq. [4] near the surface, and probably is not representative of bulk diffusion (5). In fact, the diffusion depth of such profiles, plotted *vs.* square root of diffusion time, is not a straight line through the origin (4), indicating that a diffusion coefficient which depends only on the diffusant concentration as in Eq. [2] does not represent the actual diffusion process. It is reasonable to assume that in the actual process there is a dependence of D on x which is responsible for special behavior near the surface, and our previous assumption that a concentration dependence may account for it led us to an unphysical result.

In a more general case, $D(C)$ in Eq. [2] may be replaced by a function $D(x, C, t)$, dependent on depth, diffusant concentration, and diffusion time.

Following the steps for derivation of the Boltzmann-Matano formula (3) without any restricting conditions on D, we obtain

$$D(x_1, \hat{C}_1, t_1) = -\frac{1}{2t_1} \frac{\int_0^{\hat{C}_1} x dC}{\left.\frac{\partial \hat{C}}{\partial x}\right|_{C=\hat{C}_1}} \quad [5]$$

where $\hat{C}(x, t_1)$ is a known profile at a certain time t_1.

This is a generalization of the Boltzmann-Matano formula, giving the local value of D in a single point of a three-dimensional space. If D depends only on C, all the information about $D(C)$ may be extracted from a single experimental profile by means of Eq. [5], but an infinite number of profiles is required for doing so in the general case. Hence, Eq. [5] is not very useful without further assumptions.

With the aid of Eq. [5] we can now prove that a concave region of the diffusion profiles on a logarithmic scale indicates that D is increasing in that region from the surface toward the bulk.

The fact that the profile is concave may be expressed by (see Fig. 4)

$$-\frac{\partial}{\partial x} (\ln C)|_{x_1} > -\frac{\partial}{\partial x} (\ln C)|_{x_2} \quad [6]$$

where (x_1, C_1) and (x_2, C_2) are two points on the profile, and $x_1 < x_2$.

By Eq. [5], the ratio of the values of D in these points is

$$\frac{D_1}{D_2} = \frac{\left.\frac{\partial C}{\partial x}\right|_{x_2}}{\left.\frac{\partial C}{\partial x}\right|_{x_1}} \cdot \frac{\int_0^{C_1} x dC}{\int_0^{C_2} x dC}$$

$$= \frac{\left.\frac{\partial C}{\partial x}\right|_{x_2}}{\left.\frac{\partial C}{\partial x}\right|_{x_1}} \left[1 + \frac{\int_{C_2}^{C_1} x dC}{\int_0^{C_2} x dC}\right]$$

$$< \frac{\left.\frac{\partial C}{\partial x}\right|_{x_2}}{\left.\frac{\partial C}{\partial x}\right|_{x_1}} \left[1 + \frac{(C_1 - C_2)x_2}{C_2 x_2}\right]$$

$$= \frac{\left.\frac{\partial C}{\partial x}\right|_{x_2}}{\left.\frac{\partial C}{\partial x}\right|_{x_1}} \cdot \frac{C_1}{C_2} = \frac{\frac{\partial}{\partial x} (\ln C)|_{x_2}}{\frac{\partial}{\partial x} (\ln C)|_{x_1}} \quad [7]$$

From inequality [6] it follows that

$$\frac{\frac{\partial}{\partial x} (\ln C)|_{x_2}}{\frac{\partial}{\partial x} (\ln C)|_{x_1}} < 1 \quad [8]$$

and by substituting Eq. [8] in Eq. [7] we have

$$\frac{D_1}{D_2} < 1 \quad [9]$$

Discussion

By inspection of diffusion profiles having a concave region near the surface and a steep front, in light of the previous section it may be concluded that: (*i*) Deep in the bulk (where the cadmium concentration is low), the local diffusion coefficient is decreasing along the x direction, causing a profile with a steep front; (*ii*) Near the surface, the local diffusion coefficient is increasing along the x direction, causing a concave region in the profile.

It is physically reasonable to relate the first phenomenon to a concentration dependence of D (6), and the second to the variable x (*i.e.*, to an effect of the surface proximity on D). Ignoring any possible variations of the model in time, the behavior of D may be explained qualitatively by a family of curves as shown in Fig. 5, describing a function $D(x, C)$ that increases with C and increases with x for small values of x. If we mark a decreasing series of concentrations (representing a diffusion profile) on the curves, we get a distribution $D(x)$ with a maximum somewhere below the surface. A plot of this distribution *vs.* C will exhibit the same properties as the curves in Fig. 3. This explains the existence of a maximum in the $D(C)$

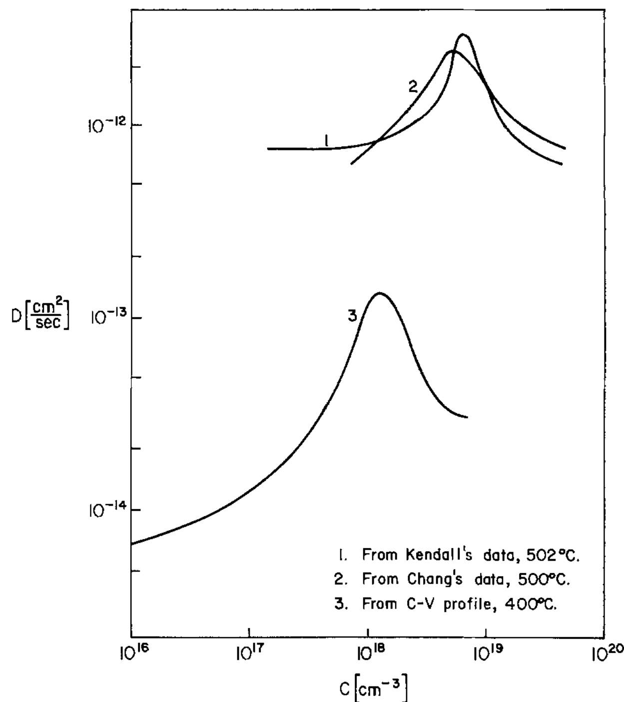

Fig. 3. Concentration dependence of the diffusion coefficient resulting from Boltzmann-Matano analysis of experimentally measured Cd profiles in InSb.

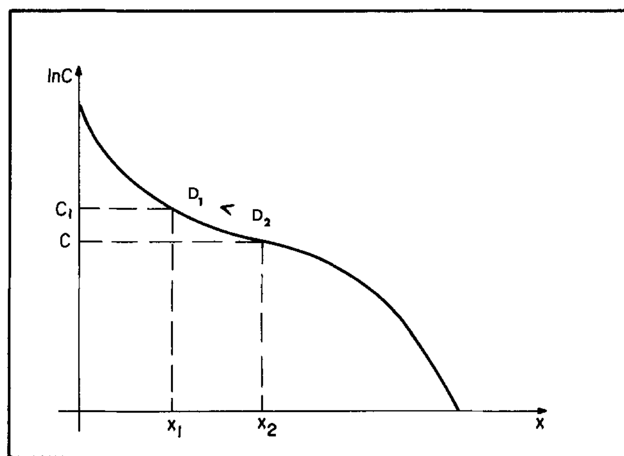

Fig. 4. Two points in the concave region of a diffusion profile. The diffusion coefficient increases with increasing depth in this region.

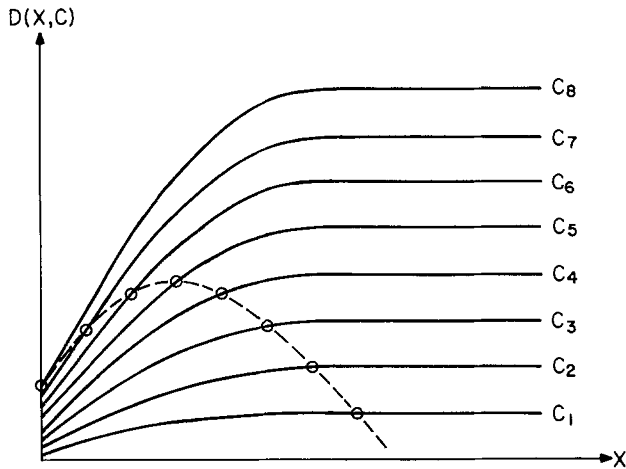

Fig. 5. Curves representing a diffusion coefficient $D(x, C)$ which increases with C and increases with x near the surface. By plotting $D(x)$ along a diffusion profile a peak is obtained.

curve calculated by the standard Boltzmann-Matano method.

The concentration dependence of D is usually explained by the interstitial-substitutional diffusion mechanism with charged interstitial species (6, 3). Another mechanism, based on charged vacancies, has also been proposed for diffusion of Cd in InSb (9). The dependence on x may be explained by an extention of the interstitial-substitutional model.

Following the derivation of the standard interstitial substitutional model (3, 6), it may be shown that

$$D(C) = K\frac{D_i}{C_v}C^n \qquad [10]$$

where D_i is the interstitial diffusion coefficient, C_v is the vacancy concentration, n depends on the interstitial charge, and K is a constant. In the derivation of Eq. [10], C_v was assumed to be constant throughout the sample. Now, if we assume that the surface supplies vacancies to the bulk during the diffusion process, so that the vacancy concentration C_v is decreasing from the surface towards the bulk, D might be expressed in an extended form of Eq. [10]

$$D(x, C, t) = KD_i\frac{C^n}{C_v(x, t)} \qquad [11]$$

In Eq. [11], $C_v(x, t)$ is the vacancy profile which diffuses simultaneously with the cadmium. Each of the curves depicted in Fig. 5 is proportional to the reciprocal of the vacancy profile. Our assumption about the vacancies implies that the interstitial-to-substitutional ratio increases along the x direction near the surface, causing a corresponding increase in diffusion coefficient. Since the incoming vacancies are consumed by interstitials going substitutional, it is reasonable to make a first-order assumption that a stationary vacancy profile is established, thus obtaining a model which does not depend on time. Numerical experiments with the model also support this assumption.

A computer routine for solving a general quasilinear parabolic partial differential equation, of which Eq. [2] is a special case, has been written, such that all the coefficients are parameters and may depend on x, C, and t. The program is based on a stable three-time-level method described by Mitchell (10), and uses Richardson's extrapolation for automatic stepsize control. Computational experiments with that program actually served as motivation for a part of the theory described above. Figure 6 shows theoretical profiles obtained for a diffusion coefficient of the form (10) where n was chosen to equal 1, and $C_v(x, t)$ was arbitrarily assumed to be of the form $1 + K_1 \cdot \exp(-x/L)$, where L is a "vacancy diffusion length" and K_1 is a constant. A qualitative agreement with experiment was clearly obtained: the profiles have a steep front (caused by C^n) and a concave section appears after a certain diffusion time. An exact quantitative agreement with experiment in InSb could not be obtained, due to lack of data, so that n could not be picked optimally, and it was impossible to fit the function C_v exactly.

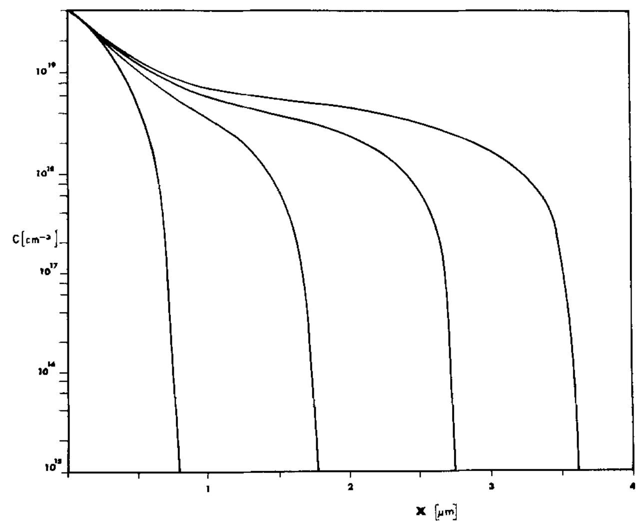

Fig. 6. Diffusion profiles calculated by the computer using the $D(x, C)$ model, for $t = 3, 6, 9, \ldots$ hr.

Figure 7 shows diffusion depth vs. $\sqrt{t}$, as obtained from the computer results. The junction depth is observed to grow slowly in the initial stage, then continues in a straight line that does not cross the origin.

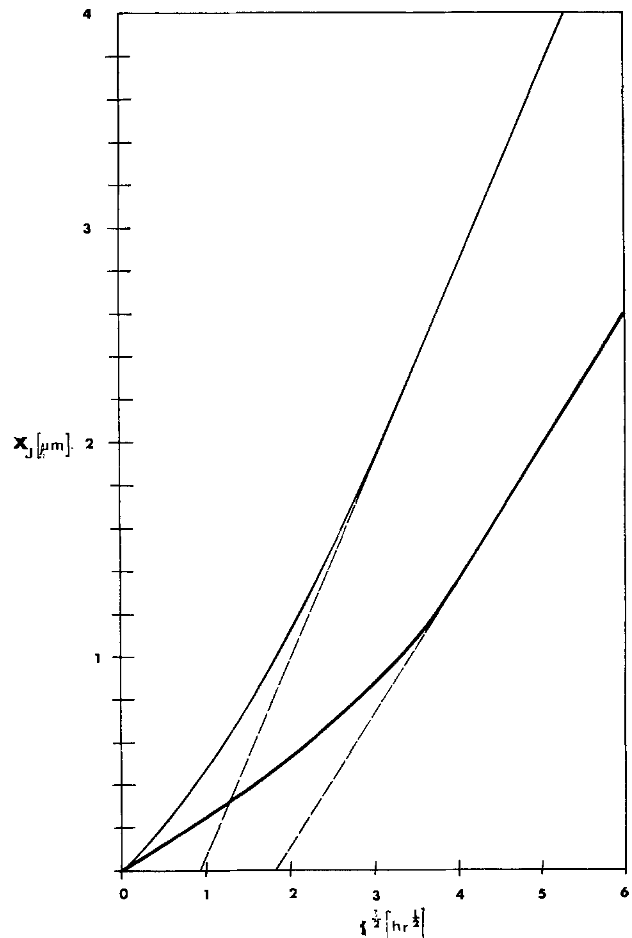

Fig. 7. Diffusion depth vs. square root of diffusion time, calculated using the $D(x, C)$ model for two different parameter sets.

Experimental results of exactly the same nature were published by Ting and Pearson (4) for zinc in GaAs.

Conclusions

A generalization of the Boltzmann-Matano analysis for diffusion profiles has been presented. As a corollary, it has been shown that a concave region in constant-source diffusion profiles (on a semilogarithmic scale) indicates that the diffusion coefficient is increasing in that region toward the bulk. By analysis and synthesis of constant-source diffusion profiles, it has been shown that the outstanding properties of diffusion of various impurities in III-V compounds may be characterized by a nonlinear diffusion coefficient which depends both on the diffusant concentration and the distance from the surface. Time dependence of the diffusion coefficient seems to be negligible. Such a diffusion coefficient may represent an interstitial-substitutional diffusion mechanism with a surface-effect that reduces the diffusion constant at small depths. An extension of the interstitial-substitutional model, assuming an enhanced vacancy concentration near the surface, has been suggested to explain this effect. The model has been implemented on a computer, and theoretical profiles that have been produced show a good qualitative agreement to experiment in shape and time dependence of the diffusion depth.

Kinetics of Tungsten Deposition by the Reaction of WF_6 and Hydrogen

W. A. Bryant*

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania 15235

ABSTRACT

Experimental rate data from a number of investigations on the chemical vapor deposition of tungsten by the hydrogen reduction of WF_6 were analyzed to determine the reaction mechanisms which controlled the process under experimental conditions in which mass transport limitiation was absent. Rate-controlling mechanisms were identified by comparing reaction orders obtained from the experimental data with those obtained from rate equations derived for each possible rate-controlling step. Where the reactant stream was expected to remain streamlined and only slightly heated through contact with the tungsten substrate, the rate-controlling mechanism was determined to be the dissociation of H_2 molecules adsorbed on the substrate. The activation energy for this process step was 67,000 J/mole. The reaction orders with respect to WF_6 and H_2 were zero and one-half, respectively. With experimental conditions more conducive to gas stream turbulence and stream heating, deposition rate was controlled by homogeneous gas phase reactions also having an activation energy of about 67,000 J/mole. The reaction order for this mechanism was 2 with respect to both reactants.

Although a considerable amount of work has been reported on the kinetics of tungsten deposition by the H_2 reduction of WF_6 according to the over-all reaction

$$WF_6 + 3H_2 = W + 6HF \quad [1]$$

the rate-controlling mechanism(s) is still not completely understood. Carlton and Oxley (1) have demonstrated that the rate of tungsten deposition from WF_6 could be predicted within the regime of mass transport control. Later investigations further established that mass transport is rate controlling in this system at relatively high temperature-high pressure combinations (2, 3).

At lower temperature-pressure combinations, other processes control the deposition rate. However, the identity of the processes has not been firmly established. Haskell (4) concluded that a model based on HF desorption from the tungsten substrate was able to describe the rate data of Holman and Huegel (5). Some support for this mechanism was provided by other correlations (2) of rate data (6), however, that analysis did not provide a strong enough test of the data correlations to completely rule out other rate-controlling mechanisms. Cheung (7) has shown

* Electrochemical Society Active Member.

that a model based on the dissociation of hydrogen adsorbed on the tungsten substrate was able to explain both his data and that of Holman and Huegel. Huegel *et al.* (8), using their results of experiments in which small amounts of HCl were added to the reactant stream to serve as a deposition retardant, concluded that the Cheung model rather than the one of Haskell best described their results. Brecher's analysis (9) of the data of Berkeley *et al.* (10) did not provide identification of a rate-controlling mechanism since the analysis combined data obtained both from the regime of substrate surface process control and mass transport control.

It was the purpose of the present work to critically examine all available rate data obtained under controlled conditions for this chemical vapor deposition reaction and to definitively establish the rate-controlling mechanism(s) outside the regime of mass transport control.

Procedure

Mass transport control of a chemical vapor deposition reaction is favored by relatively high pressure and temperature and relatively low reactant flow rate. Thus correlations between these parameters and tungsten deposition rates were used to establish the boundaries separating mass transport controlled and nonmass transport controlled regimes. Only data from the latter regime were further analyzed to determine rate control mechanisms. These data included those in which the reactants were diluted with either argon or HF. [The work of Huegel *et al.* demonstrated that the influence of HF was one of dilution rather than substrate surface poisoning.]

Plots were made of deposition rate as a function of the reciprocal of substrate temperature for essentially constant pressure and gas composition and with reactant flow rates great enough as to not significantly affect deposition rate. In the region of maximum slope the deposition rate varies exponentially with temperature. However, as the extent of mass transport control becomes significant at higher temperature, the slope decreases. At the highest temperatures, the slope eventually corresponds to square root dependence on temperature as dictated by boundary layer theory. Figures 1 through 3 are examples of this type of data plot.

From Fig. 1 only the data of Berkeley *et al.*, corresponding to H_2/WF_6 of 3 and 4 and a temperature

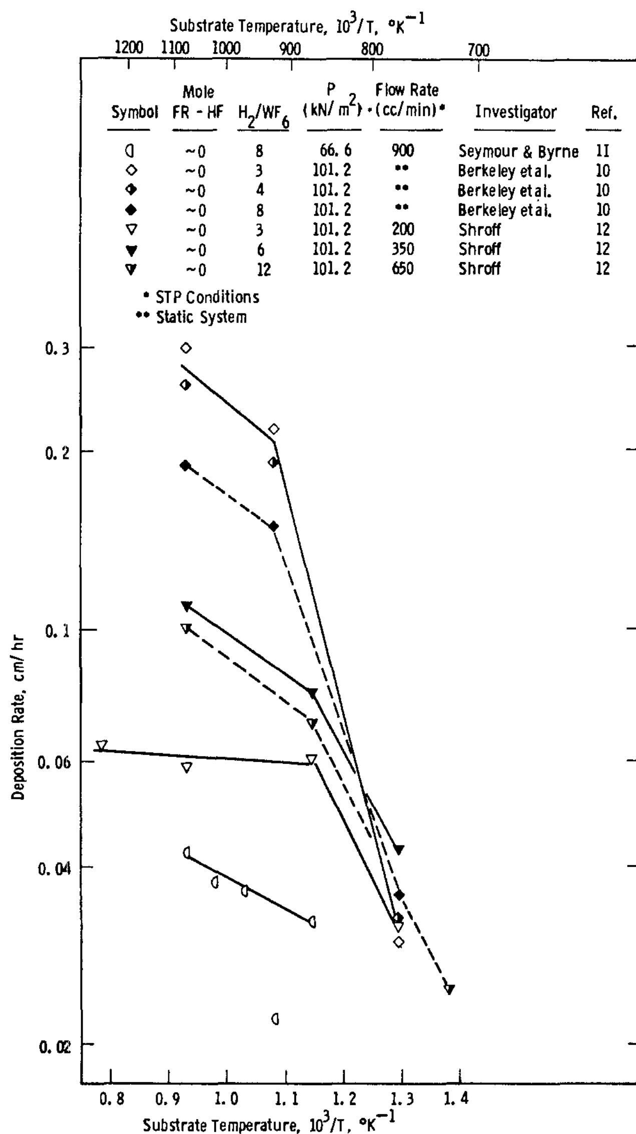

Fig. 1. Temperature dependence of tungsten deposition rate for high pressure (66.6-101.2 kN/m²).

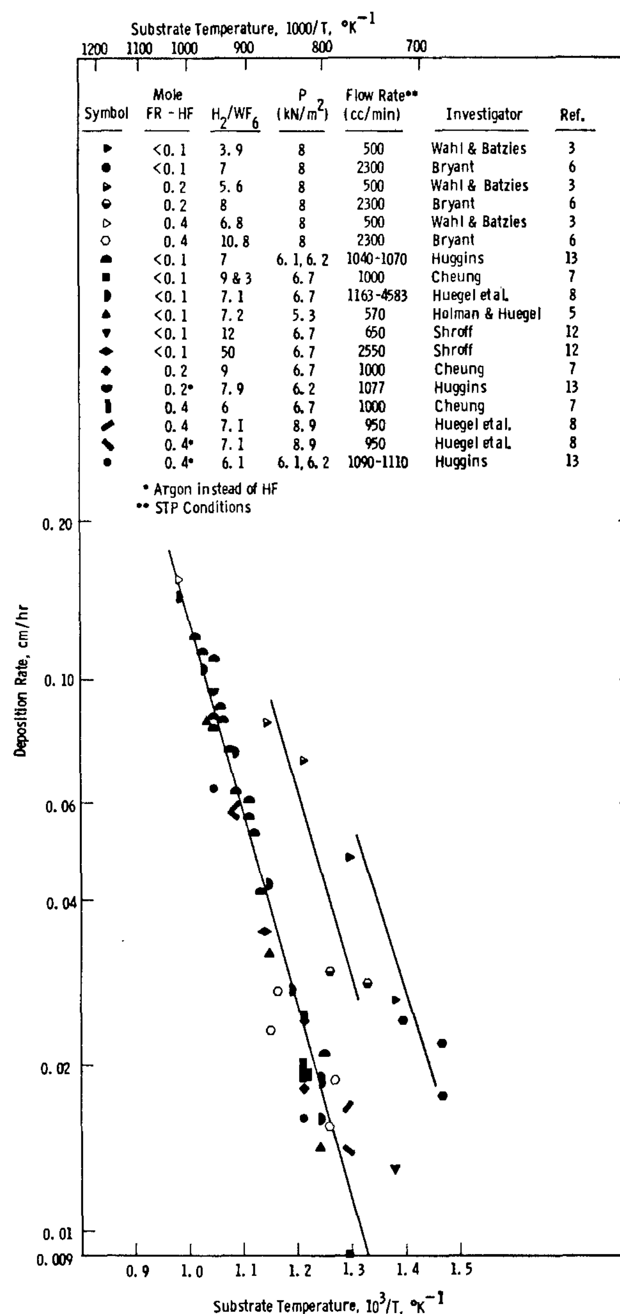

Fig. 2. Temperature dependence of tungsten deposition rate for various levels of dilution and for intermediate pressures (5.3-8.9 kN/m²).

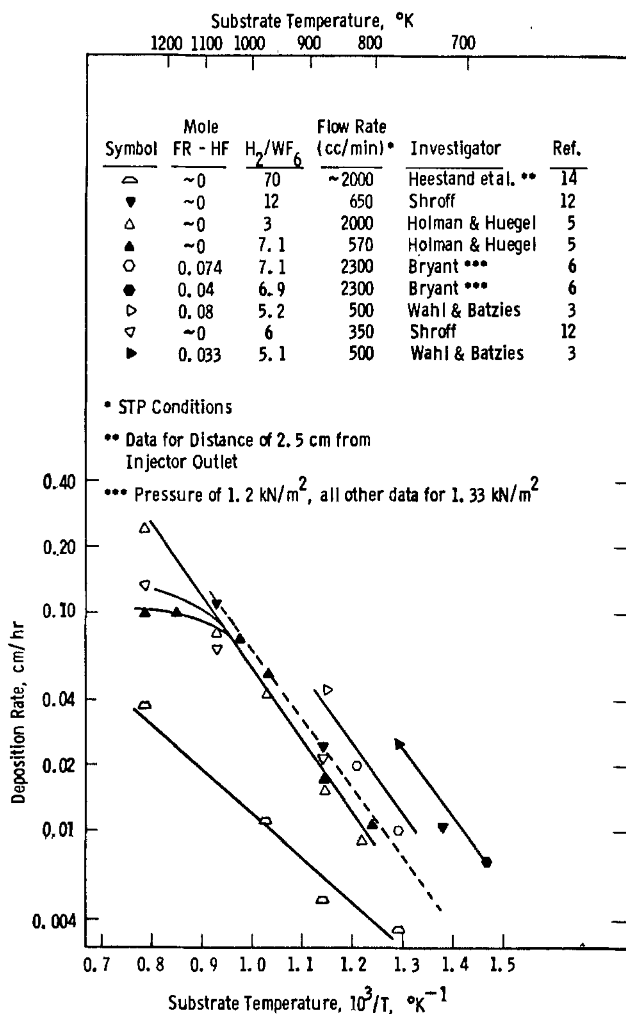

Fig. 3. Temperature dependence of tungsten deposition rate for little or no HF dilution and for low pressures (1.2-1.33 kN/m²).

of 773°K, were considered to be free of significant mass transport control. All the Fig. 2 data were judged to have been little influenced by mass transport. The data of Heestand *et al.* (14) in Fig. 3 were felt to have been obtained under conditions of excessive control by mass transport. All data for temperatures greater than 873°K were not considered further (even though some of them were undoubtedly associated with insignificant mass transport resistance) since they were too few in number to warrant the effort involved in their analysis.

Plots of deposition rate as a function of pressure (for example, Fig. 4) were constructed from data taken at essentially constant temperature and gas composition and at sufficient flow rate to minimize, as much as possible, resistance from mass transport. In these plots the onset of significant mass transport control was taken to be the pressure at which the deposition rate became essentially pressure independent. Therefore to eliminate data influenced by mass transport control, all data for pressures greater than 20 kN/m² were eliminated from further analysis. The data point of Berkeley *et al.* was not eliminated since it was previously accepted by the analysis of Fig. 1.

The onset of significant mass transport control was also indicated by a pronounced dependence of deposition rate on flow rate as the flow rate was reduced and the other parameters were held essentially constant. This criterion is in keeping with film theory (or boundary layer theory) since, as flow decreases, film thickness increases to an eventual value at which diffusion through the film completely controls the rate of deposition. In determining the cutoff point for onset of significant mass transport resistance, it

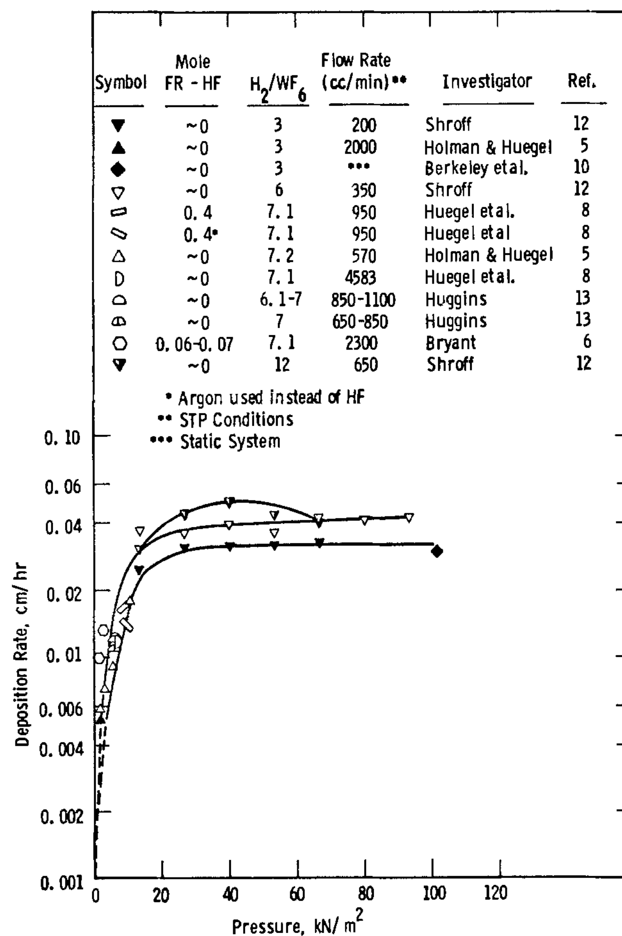

Fig. 4. Pressure dependence of tungsten deposition rate at 773°K for various gas compositions and flow rates.

was necessary that, as much as possible, each investigator's data be analyzed separately. This precaution was taken since, as observed by Chin (15), differences in experimental setups could be sufficient to influence the data. This influence was most noticeable in evaluation of flow rate data. In each curve of Fig. 5, for example, the data point corresponding to the lowest flow rate of Huggins (13) was considered

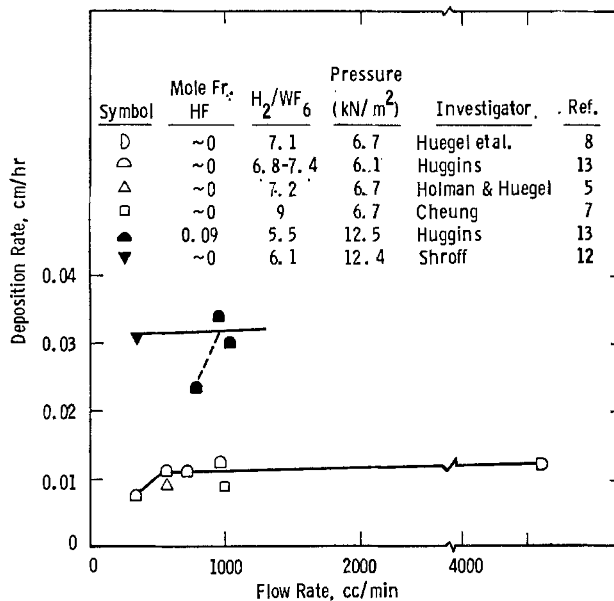

Fig. 5. Flow rate dependence of tungsten deposition rate. Data are for 773°K.

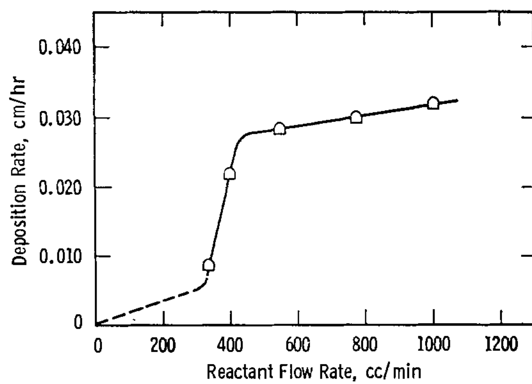

Fig. 6. Flow rate dependence of tungsten deposition rate using data of Huggins for 853°K, pressure of 6.1 kN/m² and H_2/WF_6 of 7.

to involve partial mass transport control even though in one case (nominal 12.5 kN/m² pressure) a data point of another investigator, at lower flow was not eliminated from further evaluation.

Even with the precautions taken, it is doubtful that the influence of mass transport on deposition rate was completely eliminated for data selected for further analysis. In Fig. 6 are plotted tungsten deposition data obtained under conditions which are fairly typical of those corresponding to the data of the present study. Flow rates between about 300 and 500 cm³/min define the region of mass transport control. Below 300 cm³/min convective transport effects are appreciable. Flow rates greater than about 500 cm³/min are required to essentially eliminate mass transport resistance for the subject conditions. A condition of zero transport resistance is reached only where no dependence of deposition rate on flow is indicated. However, since this dependence is asymptotic, only the use of intolerably high flow rates would eliminate this resistance altogether.

Other data, in addition to those given in Fig. 1-5, were used in the kinetic analysis. Some of these were obtained by interpolation or extrapolation. Where this was necessary, only data from a single investigator were used and extrapolations were made only to lower pressure or temperature.

HF mole fractions in the gas stream were calculated from weight change data for the investigations of Huggins (13), Wahl and Batzies (3), and Bryant (6). Since the substrate surface areas for the remaining investigations were no greater than the least of the above, it was assumed that the amount of HF formed was also no greater. Thus in many cases an assumption of essentially no HF formation was warranted. Where this assumption was not warranted and the HF concentration could not be calculated because of insufficient information, the corresponding kinetic data were not included in the study.

Deposition rate data obtained in fluidized bed systems [Oxley *et al.* (16) and Sump and Howard (17)] were also eliminated since, with the attendant very high substrate surface area and WF_6 utilization, different processes can control within different portions of the bed. [It is for this reason that Oxley *et al.* (16) determined an over-all activation energy of 30,600 J/mole for their process rather than either a much smaller value associated with mass transport (2) or a much larger value associated with the absence of mass transport (3, 5, 13, 18, 19)].

Using only the rate data found to be essentially without influence from mass transport, reaction orders with respect to each reactant were determined from log-log plots of deposition rate as a function of partial pressure of the reactant for three levels of temperature (773°, 823°, and 873°K). Care was taken to hold essentially constant the partial pressure of the other reactant and the temperature.

By comparing the experimentally determined reaction orders with respect to both reactants to those determined from Langmuir-Hinshelwood type rate equations for various possible rate-controlling mechanisms (Table I), the actual rate-controlling mechanisms were identified. Details of the procedure used to formulate these rate equations are given in Appendix A.

Results

In both Fig. 2 and 3 it was noted that for the condition of little or no presence of diluent (HF or A) the deposition rate was greater for comparable deposition parameters for the data of both Wahl and Batzies and Bryant. This suggested a reaction mechanism for these data which was different from the one for the data of the remaining investigators. This

Table I. Rate equations and reaction orders derived for study of kinetics of tungsten formation by chemical vapor deposition

Kinetic step	Rate equation: Full expression	Rate equation: Simplified form	Reaction order with respect to reactant: Hydrogen	Reaction order with respect to reactant: WF_6
1. WF_6 adsorption	$R = \dfrac{K_r p_{ai} M/\rho_w}{\left[1 + \dfrac{K_a p_{ci}^6}{K_{eq} p_{bi}^3} + (K_b p_{bi})^{1/2} + K_c p_{ci}\right]}$	$R = K_r p_{ai}$	0	1
2. H_2 adsorption	$R = \dfrac{K_r p_{bi} M/\rho_w}{\left[1 + K_a p_{ai} + \left(\dfrac{K_b p_{ci}^2}{K_r p_{bi}^{1/2} M/\rho_w}\right) + K_c p_{ci}\right]^2}$	$R = K_r p_{bi}$	1	0
3. H_2 dissociation	$R = \dfrac{K_r p_{bi}^{1/2} M/\rho_w}{\left[1 + K_a p_{ai} + \left(\dfrac{K_b p_{ci}^2}{K_{eq}^{1/3} p_{ai}^{1/3}}\right)^{1/2} + K_c p_{ci}\right]^2}$	$R = K_r p_{bi}^{1/2}$	1/2	0
4. Chemical reaction	$R = \dfrac{K_r K_a K_b \left[p_{ai} p_{bi}^3 - \dfrac{p_{ci}^6}{K_{eq}}\right] M/\rho_w}{[1 + K_a p_{ai} + (K_b p_{bi})^{1/2} + K_c p_{ci}]^n}$	$R = K_r' p_{ai} p_{bi}^3$	3	1
5. HF desorption	$R = \dfrac{K_r[(K_{eq} p_{ai} p_{bi}^3)^{1/6} - p_{ci}] M/\rho_w}{[1 + K_a p_{ai} + (K_b p_{bi})^{1/2} + K_c (K_{eq} p_{ai} p_{bi}^3)^{1/6}]^n}$	$R = K_r'' p_{ai}^{1/6} p_{bi}^{1/2}$	1/2	1/6
6. Homogeneous reaction a	$R = K_r \left[p_{ai}^2 p_{bi}^2 - \dfrac{p_{di}}{K_{eq}}\right] M/\rho_w$	$R = K_r p_{ai}^2 p_{bi}^2$	2	2
6. Homogeneous reaction b	$R = K_r \left[p_{ai}^2 p_{bi}^2 - \dfrac{P_{ci}^2 p_{di}}{K_{eq}}\right] M/\rho_w$	$R = K_r p_{ai}^2 p_{bi}^2$	2	2
6. Homogeneous reaction c	$R = K_r \left[p_{ai}^2 p_{bi} - \dfrac{p_{di}}{K_{eq}}\right] M/\rho_w$	$R = K_r p_{ai}^2 p_{bi}$	1	2

same segregation was found in the plots of experimental data for determination of reaction order with respect to each reactant (Fig. 7 through 12) where the data have also been grouped by partial pressure of the other reactant, *i.e.*, partial pressure of the reactant whose order is not being determined.

The reaction orders determined from the experimental data are listed in Table II. Reaction orders other than 2 could have been assigned to the data of Wahl-Batzies and Bryant. However the value adopted is most compatible with the findings of Huggins (13) whose work provided experimental evidence for reactions [2] and [3]. Comparison of these values with those obtained from the derived rate equations (Table I) indicate that the deposition data of Wahl-Batzies and Bryant represent control by a homogeneous reaction, specifically one of the following

$$2WF_6 + 2H_2 = W_2F_{10}\cdot H_2 + H_2F_2 \quad [2]$$

$$2WF_6 + 2H_2 = W_2F_8 + H_2F_2 + 2HF \quad [3]$$

From this comparison it is further indicated that the deposition data of the other investigators represent deposition control by H_2 dissociation on the tungsten surface.

Further evidence for the existence of two rate-controlling mechanisms in the nontransport controlled regime was provided by data concerning the influence on deposition rate of diluents added to the reactant stream (Fig. 2). The deposition rates of both Wahl and Batzies and Bryant were strongly influenced by the presence of diluent. This is the result to be expected for a homogeneous, gas-phase process since the concentration dependence of the deposition rate was large, as shown by a value of 2 for the reaction order with respect to each reactant. In contrast, the deposition rate at constant temperature for the controlling substrate surface reaction would be expected to be only slightly dependent on the reactants' partial pressures at the substrate. This conclusion follows from the determination of low reaction orders for the mechanism of H_2 dissociation.

The influence of HF on the rate of deposition controlled by the homogeneous process is one of dilution only. With the combined partial pressures of the reactants held nearly constant, the deposition rate was independent of HF concentration in the gas stream (Fig. 13).

An activation energy of 67,000 J/mole was determined for both the homogeneous, gas-phase process and the dissociation of H_2.

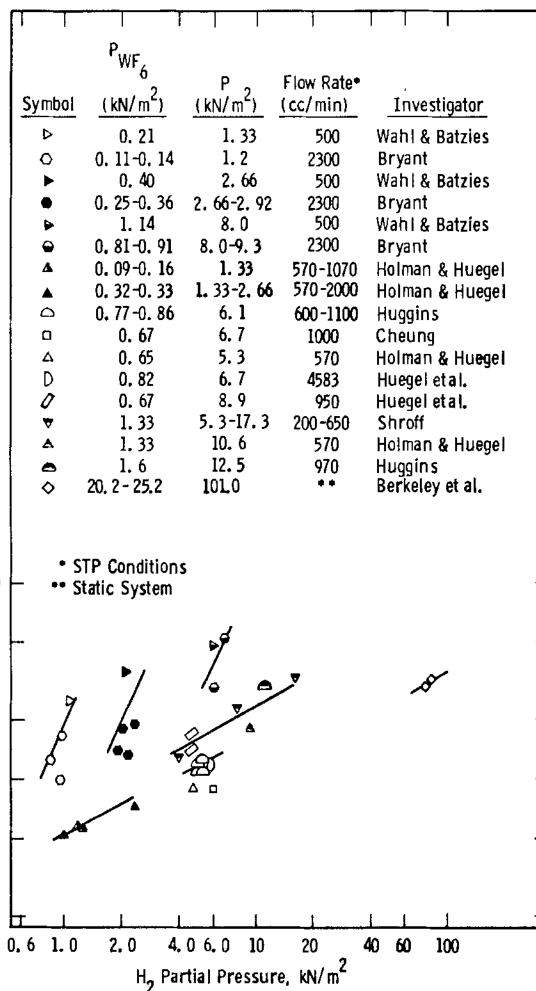

Fig. 8. Plots to determine reaction order with respect to hydrogen at 773°K.

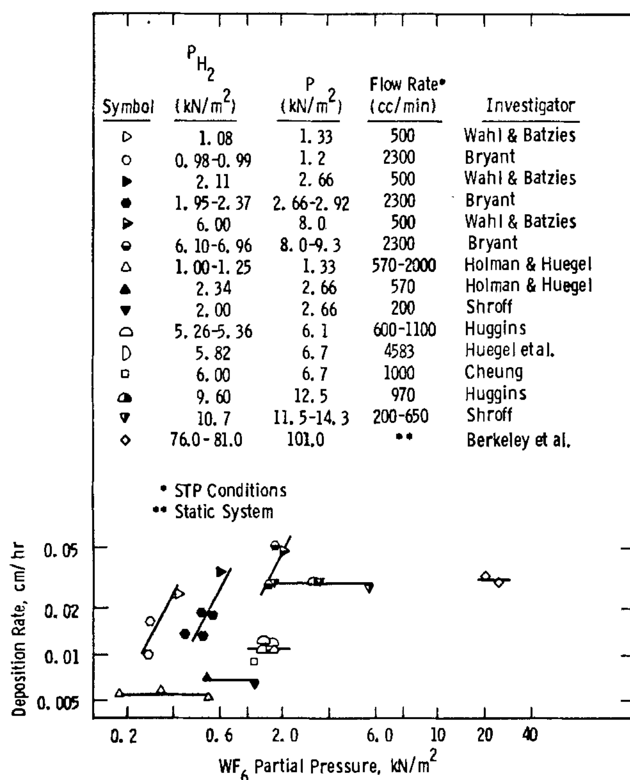

Fig. 7. Plots to determine reaction order with respect to WF_6 at 773°K.

Discussion

Identification of the rate-controlling surface reaction as H_2 dissociation agrees with the earlier result of Cheung. Further evidence supporting this mechanism as rate controlling is provided by the activation energy of 67,000 J/mole determined from the appropriate data of Fig. 1 through 3. The dissociation is

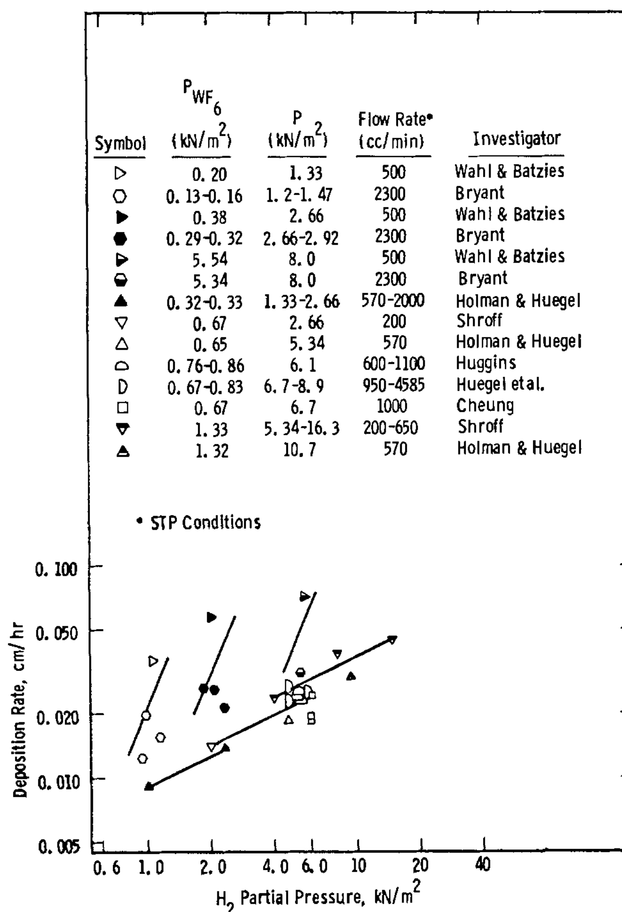

Fig. 10. Plots to determine reaction order with respect to hydrogen at 823°K.

completed by the jumping of one of the H atoms to a neighboring lattice site (7). The reported values for H_2 surface diffusion on tungsten are also 67,000 J/mole (20, 21).

The activation energy for the H_2 dissociation mechanism is in good agreement with the separate values for surface processes obtained by Holman and Huegel (67,000 J/mole), Shim and Byrne (18) (67,000 J/mole), Haskell and Byrne (19) (63,000 J/mole), and Huggins (65,400 J/mole).

A mechanism of homogeneous reaction finds support in the observations of both Huggins and Wahl and Batzies. The former found the compound W_2F_9 condensed in the cold trap of his experimental setup. A combination of the two tungsten-bearing molecules formed by reactions [2] and [3] would yield a product having the same ratio of fluorine to tungsten. The latter investigators observed, at low pressures of about 1.0 kN/m² or less, a strong dependence of growth rate on pressure (R proportional to $P^{1.8}$ to R proportional to $P^{3.3}$). [At higher pressures this dependence is less owing to effects produced by partial mass transport control (22)]. From the results of the present work, the exponent was 0.5 for rate control by the surface process. Mass transport control would also be expected to exhibit a much lower dependence of deposition rate on pressure.

It is suggested that the gas phase reactions do not stop with the formation of monomers, but instead proceed to form particles larger in size than the thermodynamically stable size. According to the theory of homogeneous gas-phase nucleation (23), the rate of formation of critical-sized nuclei, given by Eq. [4], is an exponential function of temperature

$$J = \frac{\alpha \Pi r^{*2} P C}{(2 \Pi m k T)^{1/2}} e^{-\Delta F^*/kT} \quad [4]$$

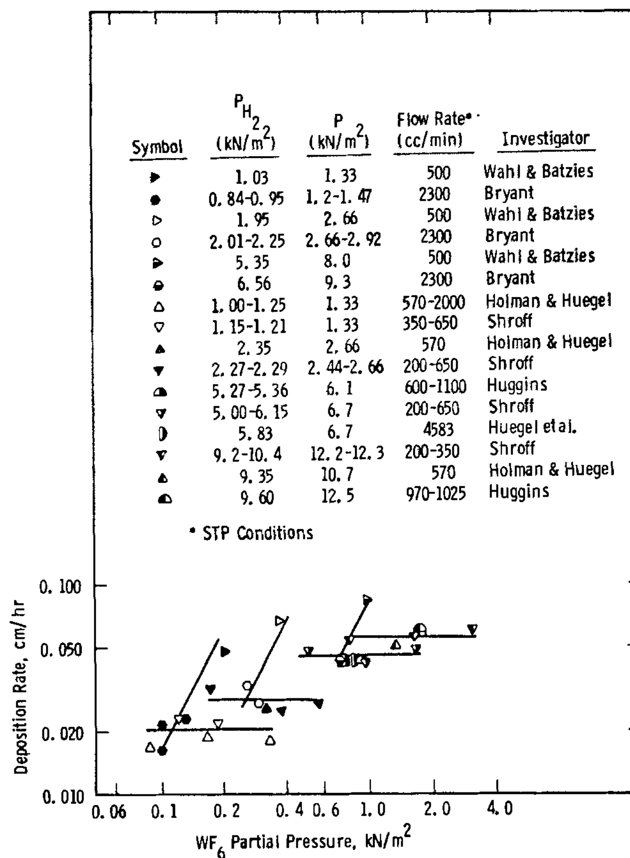

Fig. 11. Plots to determine reaction order with respect to WF_6 at 873°K.

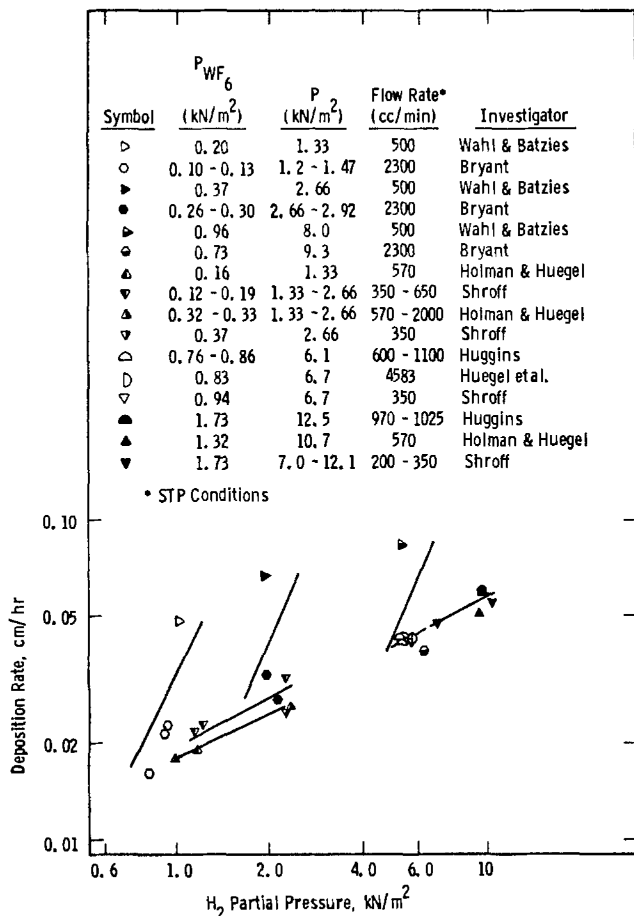

Fig. 12. Plots to determine reaction order with respect to hydrogen at 873°K.

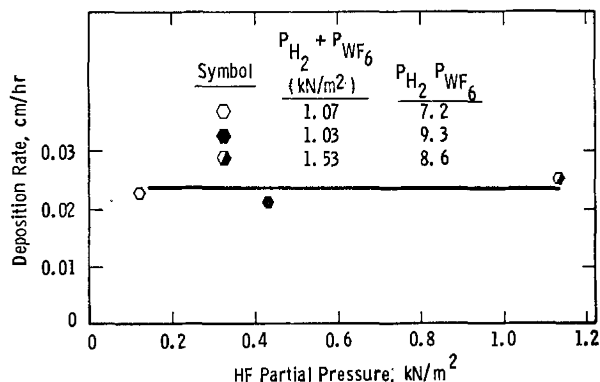

Fig. 13. HF partial pressure dependence of tungsten deposition rate for process control by homogeneous gas-phase reaction. Data are for 873°K and flow rate of 2300 cm^3/min [Ref. (6)].

It was this form of temperature dependence that was found in the present work for the data of Wahl and Batzies, and Bryant, rather than the $T^{1/2}$ dependence which would have been found if only monomers had been formed according to the collision frequency suggested by kinetic gas theory (24).

Further support for the Wahl and Batzies, and Bryant, data conforming to control by homogeneous reaction is provided by the observed linear dependence of deposition rate on the concentration of HF diluent (Fig. 14). This same linear dependence is found in relation [4] where the concentration term occurs to the first power.

Under seemingly very similar experimental conditions two modes of reaction rate control were found to occur outside the regime of mass transport control. Two conditions would favor homogeneous reaction

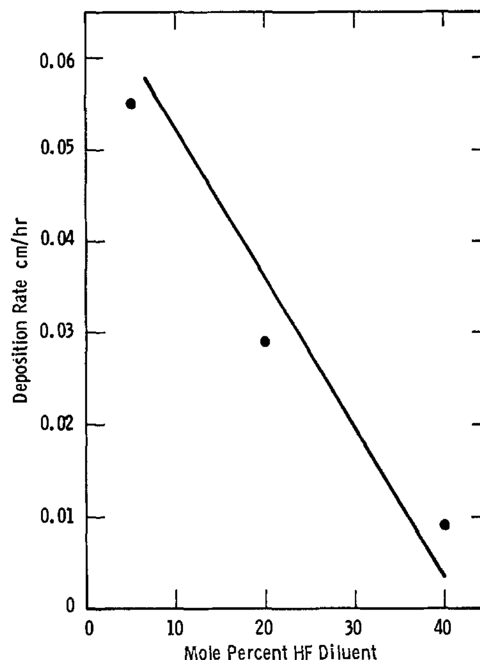

Fig. 14. Influence of HF dilution on deposition rate for the data of Wahl and Batzies, and Bryant (Data were taken from Fig. 2 for a temperature of 770°K. A value of 5 mole percent was assigned to the data corresponding to 10 mole percent diluent or less.)

over heterogeneous reaction control. Higher gas temperature and greater turbulence of the gas would both favor a homogeneous process, the former by increasing the equilibrium concentration of critical-sized nuclei and the latter by increasing the frequency of interparticle collisions.

To see if any of the experimental investigations could have produced a relatively higher gas temperature, the relative heat transfer rates for each investigator's experimental setup were calculated for representative experimental conditions by the procedure of Appendix B. The heat transfer data (Table III) show that a higher gas temperature would be expected for the work of the present author and thus reaction in the gas phase would be more favored in that experimental setup.

The second condition favoring a homogeneous process (increased molecular collisions resulting from gas turbulence) would be expected for the experimental arrangement of Wahl and Batzies where the linear velocity of the gas stream was, relatively, very high (Table III). Impingement of the stream on the flat substrate disk would produce little streamlined flow past the substrate whose diameter (2 cm) was greater than the diameter of the reactant gas nozzle (0.65 cm) located only 1.5 cm from the substrates. The stream velocities of the experimental arrange-

* Static system.

ments conducive to surface process control were much lower. Additionally, more streamlined flow would be expected for these arrangements since the substrate dimension normal to the gas flow direction was small relative to the stream diameter.

The deposition rates observed for the homogeneous process (in the absence of dilution) were greater than those found for the heterogeneous process under identical experimental conditions. It is suggested that residual mass transport resistance was lessened for the two investigations involving the homogeneous process. The greater degree of gas turbulence in the work of Wahl and Batzies would decrease the reactive film thickness as would the greater gas temperature determined for the work of Bryant.

The activation energy found for the homogeneous, gas-phase process of 67,000 J/mole is not in agreement with the value of 56,000 J/mole obtained by Wahl and Batzies for their data. This discrepancy is possibly the result of these authors' failure to account for the effect of HF dilution on deposition rate.

Conclusions

Under experimental conditions of minimal influence by mass transport control, the deposition of tungsten by the H_2 reduction of WF_6 is controlled either by the dissociation of H_2 on the substrate or by homogeneous, gas-phase reactions. The degree of gas stream turbulence and heating determines which of the two processes is rate controlling. An activation energy of 67,000 J/mole was found for each process.

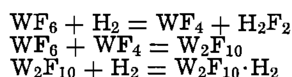
APPENDIX A

Formulation of Rate Equations

The method of Yang and Hougen (25) was used to formulate rate equations for each possible step in the over-all reaction sequence. This methodology is based on Langmuir-Hinshelwood models for competitive adsorption by reactants. Many of the reaction steps suggested by Yang and Hougen were eliminated from further consideration by the knowledge that WF_6 would be expected to strongly adsorb on tungsten (26, 27) (the deposit substrate after the first few minutes of deposition) and that hydrogen would be readily atomically adsorbed (28).

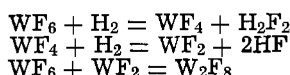
The following reactions remained as possible rate-controlling steps. All but the last are surface processes.

1. Adsorption of WF_6
2. Adsorption of H_2
3. Dissociation of H_2
4. Chemical reaction between WF_6 and H_2
5. Desorption of HF
6. Homogeneous, gas-phase reactions as follows[1]



$$WF_6 + H_2 = WF_4 + H_2F_2$$
$$WF_6 + WF_4 = W_2F_{10}$$
$$W_2F_{10} + H_2 = W_2F_{10}\cdot H_2$$

a. $$2WF_6 + 2H_2 = W_2F_{10}\cdot H_2 + H_2F_2 \qquad [A\text{-}1]^2$$



$$WF_6 + H_2 = WF_4 + H_2F_2$$
$$WF_4 + H_2 = WF_2 + 2HF$$
$$WF_6 + WF_2 = W_2F_8$$

b. $$2WF_6 + 2H_2 = H_2F_2 + 2HF + W_2F_8 \qquad [A\text{-}2]^3$$

$$WF_6 + H_2 = WF_4 + H_2F_2$$
$$WF_6 + WF_4 = W_2F_{10}$$

c. $$2WF_6 + H_2 = H_2F_{10} + H_2F_2 \qquad [A\text{-}3]$$

[1] These reactions have been suggested by Huggins.
[2] Equation [A-1] is the same as Eq. [2].
[3] Equation [A-2] is the same as Eq. [3].

As shown by Yang and Hougen the net rate of a reaction can be written in the form

$$\text{rate} = \frac{(\text{kinetic term})\,(\text{potential term})}{(\text{adsorption term})^n} \qquad [A\text{-}4]$$

where n equals the number of substrate surface sites involved in the reaction. For the purpose of illustration, the rate equation for HF desorption was developed as follows, with the subscripts a, b, and c used to designate respectively the gases WF_6, H_2, and HF.

The kinetic term includes factors for the total number of active surface sites, the number of adjacent sites, an effectiveness factor, and a rate constant. These separate terms were combined into a single reaction rate constant K_r.

The potential term is the difference between the actual surface concentration (activity) and the equilibrium activity of HF gas. With these interfacial activities replaced by partial pressure values and by employing the definition of the equilibrium constant, the potential term was written as

$$(\text{potential term}) = [(K_{eq}P_{ai}P_{bi}^3)^{1/6} - P_{ci}] \qquad [A\text{-}5]$$

The general term for adsorption (all reactants and products adsorbed under equilibrium conditions and without dissociation) is given by the reaction

$$(\text{adsorption term}) = [1 + K_aP_{ai} + K_bP_{bi} + K_cP_{ci}]^n \qquad [A\text{-}6]$$

Again the equilibrium value of P_{ci} was placed in terms of the partial pressures of the reactants. Replacement in the general adsorption term was made from Table III of the subject reference to account for the dissociation of H_2. A value of unity was assigned to the exponent n according to the instructions of Table IV of the subject reference.

By making the appropriate substitutions into Eq. [A-4] and multiplying by a term consisting of the molecular weight of tungsten divided by its density, the final rate equation for the deposition rate, R (in centimeters per hour), as controlled by HF desorption was obtained

$$R = \frac{Kr[(K_{eq}P_{ai}P_{bi}^3)^{1/6} - P_{ci}]M/\rho_w}{1 + K_aP_{ai} + (K_bP_{bi})^{1/2} + K_c(K_{eq}P_{ai}P_{bi}^3)^{1/6}} \qquad [A\text{-}7]$$

The remaining rate equations were derived in similar manner. Considerable simplification was permitted by the very large value of the equilibrium constant and by the assumption of low surface coverage (and hence low adsorption constant values) by the gases.

The assumption of low surface coverage was justified in the following manner. The reported very rapid adsorption of hydrogen on tungsten (25) suggests low surface coverage by hydrogen. Because of its similarity to oxygen adsorption (27), WF_6 adsorption is expected to be essentially nonactivated (26). Thus surface coverage by WF_6 would also be expected to be slight.

APPENDIX B

Relative Heat Transfer Rates for Various Experimental Investigations

The conditions representing those most frequently used in the various experimental investigations were a H_2 to WF_6 ratio of 6.0, a substrate temperature of 823°K, a system pressure of 6.7 kN/m^2 and a stream-substrate interface concentration of HF of 5%. These conditions and the most commonly used reactant flow rates (Table IV) were employed in the calculations.

The relative rate of steady heat flow was calculated from the relation

$$q = hA\Delta T = \frac{k}{d}N_{Nu}A\Delta T \qquad [B\text{-}1]$$

Upon reaching the vicinity of the substrate, the gas stream in each experimental system would be expected to be at about the same temperature. Therefore the temperature gradient, ΔT, was assumed con-

† This equation is recommended by the authors (35) for Reynolds numbers greater than 1600. However Nusselt numbers calculated from it for both the Wahl and Batzies and the Shroff data, for respective Reynolds numbers of 110 and 161, are in good agreement with the values determined by Gardon and Akfirat (36) for the same system-flow geometry and comparable Reynolds numbers.
N.A. Not applicable.

stant. The thermal conductivity of the gas mixture, k, was not calculated since it would be constant and only relative values for the heat transfer rates were desired.

With each value of the substrate surface area, A, and characteristic system dimension, d, known (Table IV), it remained to calculate the Nusselt number for each system. The equations for determining Nusselt numbers are also given in Table IV. In several instances it was necessary to adapt the appropriate equation from a corresponding mass flow equation by making use of the Chilton-Colburn analogy (29). A constant value of 0.73 was assigned to the Schmidt number on the basis that a narrow range of values, centering about this value, exists for a great number of gases. Based on information from the literature (30), a value of 0.65 was assumed for the Prandtl number.

K	adsorption constant, $(kN/m^2)^{-1}$
$K'(K'')$	combined forms of over-all rate constant, variable units
n	integer corresponding to number of surface sites involved in surface reaction
N_{Nu}	Nusselt number, hd/k
N_{Sc}	Schmidt number, $\mu/\rho\ \overline{D}_{eff}$
N_{Re}	Reynolds number, $dV\rho/\mu_f$
N_{Gr}	Grashof number, $d^3\rho_f{}^2 g\Delta\rho/\mu_f{}^2\rho_b$
N_{Pr}	Prandtl number, $Cp\ \mu/k$
d	characteristic dimension of system, cm
L	length or effective length of substrate, cm
V	linear velocity, cm/sec
μ	viscosity, g/cm·sec
$\overline{D}_{eff}$	over-all effective binary diffusivity for gases, cm²/sec
g	gravitational constant, 1.27×10^{10} cm/hr²
$\Delta\rho$	$\rho_b - \rho_i$, g/cm³
k	thermal conductivity, cal/sec·°K·cm
Q	activation energy, J/mole
h	heat transfer coefficient, cal/sec·°K·cm²
ρ	density of gas, g/cm³
A	area of substrate, cm²
T	temperature, °K
D	nozzle diameter, mm
t	nozzle to plate distance, mm
q	rate of heat flow, cal/sec
Cp	specific heat at constant pressure, cal/g·°K
J	rate of formation of nuclei of critical size, number/cm³·sec
α	condensation coefficient, dimensionless
γ^*	radius of nucleus of critical size, cm
P	vapor pressure, g/cm·sec²
C	monomer concentration, number/cm³
m	molecular mass, g
ΔF^*	free energy of formation of nucleus of critical size
k	Boltzmann's constant

Subscripts

a	WF_6
b	hydrogen
c	HF
d	H_2F_2
i	value taken at gas stream-substrate interface
b	value taken in bulk gas stream
f	value taken in film adjacent to substrate

Thermodynamics of the Gaseous Zirconium Iodides

P. D. Kleinschmidt, D. Cubicciotti,* and D. L. Hildenbrand

SRI International, Menlo Park, California 94025

ABSTRACT

The gaseous zirconium iodides ZrI_4, ZrI_3, ZrI_2, and ZrI, generated by the reaction of HI(g) with Zr(s) at elevated temperatures, were identified and characterized thermochemically by Knudsen cell mass spectrometry. Gaseous ZrI_4 was the major reaction product up to about 1300°K; above this temperature, atomic I became the major product, with minor amounts of the lower Zr iodides appearing as the temperature was progressively raised. From an analysis of equilibrium data, the following enthalpies of formation were deduced; $\Delta Hf°_{298}(ZrI_3, g) = -30.8 \pm 1.5$ kcal/mole, $\Delta Hf°_{298}(ZrI_2, g) = 32.6 \pm 4.0$ kcal/mole, and $\Delta Hf°_{298}(ZrI, g) = 96.3 \pm 2.8$ kcal/ mole. Individual bond dissociation energies evaluated from the enthalpy data are close to the average value in ZrI_4. The new thermochemical data are consistent with observations on the iodide process for refining impure zirconium whereas earlier estimates are not.

Information about the chemistry of the gaseous iodides of zirconium can have an important bearing on the technology of the metal. The iodide process for refining zirconium (1) is based on vapor transport of the gaseous iodides, and iodine-induced stress corrosion cracking (SCC) of zirconium alloys has been thought (2) to involve gaseous iodide transport of zirconium. Understanding of the mechanisms of those processes has been hindered for lack of reliable data on the stabilities of the vapor species. Prior to the present work, experimental thermochemical data were available only for the tetraiodide, ZrI_4. To our knowl-

edge, none of the other gaseous iodides had been identified by a spectroscopic technique or had been otherwise characterized experimentally.

In the iodide process for zirconium refining, impure metal is heated to 500°-600°K in a container where it reacts with gaseous iodine species at pressures of 10^{-4}-10^{-2} atm. The gaseous zirconium iodides produced are decomposed on a heated filament at 1500°-1700°K on which purified zirconium deposits. Shapiro (1) considered the chemistry of the iodide decomposition process using the thermochemical information available at that time (almost all estimated) and found that rather than clarifying the mechanism, the analysis only confused the situation. His analysis indicated that ZrI_2 was the principal gaseous Zr-containing species. We have used literature estimates (3) to calculate the partial pressures shown in Fig. 1. Those estimates also indicate that ZrI_2 should be the principal gaseous species in an iodide process cell. However, the information in Fig. 1 is obviously in error because it indicates that decomposition of gaseous ZrI_2 should not occur below about 1700°K, whereas, in the iodide process, deposition of Zr on the hot filament occurs at temperatures above about 1300°K.

In the work described below, gaseous equilibria among the zirconium iodides were studied by high temperature mass spectrometry, and thermochemical data for ZrI, ZrI_2, and ZrI_3 were derived. Our new data on the gaseous zirconium iodides show that the estimated thermochemical values are seriously in error; a recalculation of vapor composition in the iodide cell using the new results makes the process understandable.

Experimental

The equilibrium studies on the Zr-I system were carried out by high temperature mass spectrometry, using the magnetic sector instrument and experimental technique described in previous publications (4). Effusion cell beams containing a distribution of the gaseous Zr iodides were generated by the reaction of HI(g) with elemental Zr; HI was admitted to the cell via an inlet tube in the base. A rolled strip of Zr foil was placed in the bottom of the cell, covered by a thin molybdenum partition to increase the number of reactive collisions and promote equilibration. Graphite cells were used for studies of the species ZrI_4, ZrI_3, and ZrI_2 at 1100°-1500°K, while molybdenum cells were used for the corresponding studies on Zr and ZrI at 2200°-2400°K.

All ion intensities used in the equilibrium calculations were corrected for any background contributions by noting the change in signal level resulting from misalignment of the neutral beam defining slit. Background levels were generally negligible. Ion abundances were measured by pulse counting for some of the equilibrium studies and by the standard electrometer method for the remainder. The two methods are, of course, equivalent, although each has certain advantages in a given situation. For the one Zr-I reaction studied by both methods, the derived equilibrium data were in good agreement.

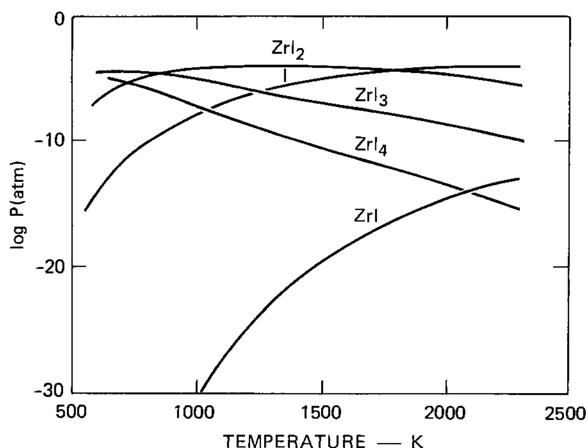

Fig. 1. Partial pressures of species in equilibrium with Zr(s) calculated from literature estimates for P(total I) $= 10^{-4}$ atm. P(total I) $=$ total iodine equivalent pressure $\equiv \Sigma np(ZrI_n) + \Sigma np(I_n)$.

In order to evaluate the absolute equilibrium constants for reactions requiring a pressure calibration, the instrument sensitivity constant was determined by using gold as a vapor pressure standard. Gold was vaporized from a graphite cell, and Au^+ abundances were observed at several temperatures, and for several ionizing energies, using both pulse counting and electrometer detection. From the abundance data and known vapor pressures (5), the sensitivity constant k in the expression

$$P = \frac{kTA^+}{\sigma} \quad [1]$$

was evaluated at several fixed values of the excess ionization energy; in this expression A^+ is the observed positive ion abundance of a species with partial pressure P at an effusion source temperature T, and with ionization cross section σ. For atomic species, values of σ were taken from the compilation by Mann (6), while values for molecular species were calculated by assuming additivity of atomic cross sections. In electrometer applications, the ion multiplier sensitivity was assumed to be mass independent, as indicated by many multiplier gain measurements with our instrument over a wide mass range. The instrument sensitivity proved to be constant over long time intervals. A subsequent check on the calibration using KCl(s) as a vapor pressure standard, monitoring the KCl(g) pressure with K^+/KCl fragment and KCl^+ parent ions, gave a KCl monomer pressure agreeing with the tabulated value (3) to within 20%. An uncertainty of about 50% is attached to the derived equilibrium constants, stemming largely from the estimated ionization cross sections.

The zirconium foil sample, obtained from Alfa/Ventron Corporation, had a minimum purity of 99.9%. Gaseous HI was taken from a Matheson commercial sample and was used without further purification.

Results

The distribution of gaseous Zr iodides in the effusion cell beam changed markedly with temperature. These species were identified from the masses, isotopic distributions, and threshold appearance potentials of the ions produced by electron impact. A summary of the appearance potentials observed for various cell temperatures, together with the neutrals inferred from the threshold values is given in Table I; these thresholds were evaluated by the vanishing current method. Only ZrI_4(g) was observed as a

Table I. Threshold appearance potentials of observed ions in the Zr-I system and the assigned neutral precursors

Ion	Appearance potential (eV)*	Neutral precursor
Zr^+	6.5 ± 0.3 (2200°K)	Zr
	18.0 ± 0.5 (1200°K)	ZrI_3
	21.5 ± 0.5 (700°K)	ZrI_4
ZrI^+	7.0 ± 0.7 (2200°K)	ZrI
	10 ± 1 (1500°K)	ZrI_2
	14.0 ± 0.5 (1200°K)	ZrI_3
	17.8 ± 0 5 (700°K)	ZrI_4
ZrI_2^+	10.3 ± 0.3 (1100°K)	ZrI_3
	14.0 ± 0.3 (700°K)	ZrI_4
ZrI_3^+	7.5 ± 0.3 (1100°K)	ZrI_3

product of the $HI(g) + Zr(s)$ reaction below about 1000°K; above that temperature, ZrI_3 appeared, then $ZrI_2(g)$, and finally $ZrI(g)$ and $Zr(g)$ above 2000°K. The total pressure within the cell was kept below 10^{-4} atm, in order to maintain molecular flow conditions.

Unambiguous identification of gaseous Zr, ZrI, ZrI_3, and ZrI_4 was provided by the lowest threshold energies of the corresponding positive ions. One would expect that the ionization potential of ZrI_4, in which all of the Zr valence electrons are involved in bonding, would approach that of atomic I (10.45 eV), while those of the lower iodides, which have nonbonded Zr valence electrons, would tend toward the ionization potential of Zr (6.84 eV). The lowest threshold energies for ZrI_4^+, ZrI_3^+, and ZrI^+, which we assign to the ionization potentials of the parent neutrals, do indeed follow this pattern, corroborating the interpretation. (Ionization potentials have not been reported previously for these species.) The diiodide ZrI_2 was the least abundant of the gaseous iodides, and it was identified through observation of the fragment ion ZrI^+/ZrI_2 appearing at 10 eV.

The low abundance of ZrI_2, and of the other gaseous Zr iodides as well, compared to the considerably higher abundances of the fluorides and chlorides observed in similar studies of Zr and other metals, is a consequence of the weaker metal-iodine bonds. Quite high pressures of atomic I, approaching the molecular flow limit, were needed to generate workable Zr-I ion signals at the usual low electron energies used. It was nevertheless possible to observe all the gaseous Zr iodides and to characterize them thermochemically within certain limits. It is worth noting that there is a marked shift in the vapor phase chemistry as a result of the decrease in metal-halogen bond strength with increasing halogen atomic number. In consequence, experimental studies of the lower valent metal iodides are considerably more difficult than those of the other metal halides.

$ZrI_3(g)$.—Studies of the two reaction equilibria

$$1/4\,Zr(s) + 3/4\,ZrI_4(g) = ZrI_3(g) \qquad [2]$$

and

$$ZrI_4(g) = ZrI_3(g) + I(g) \qquad [3]$$

were carried out over the range 1100°-1400°K using the corresponding parent ions measured at 2 eV above threshold to monitor the neutral abundances. Reaction [2] was studied in two separate experiments with different Zr samples, one with ion counting detection and one with the usual electrometer analog detection. For third law calculations, it was necessary to account for the rather extensive fragmentation of ZrI_4 and ZrI_3. Measurements of ion fragmentation showed that at an ionizing electron energy 2 eV above the respective parent and fragment ion thresholds, the total ion yield from ZrI_3 was 5.3 times that of $A(ZrI_3^+)$, while that of ZrI_4 was 2.2 times $A(ZrI_4^+)$. The ion abundance data were coupled with the fragmentation corrections, the estimated ionization cross sections, and the pressure calibration constant to yield the equilibrium constants, K_{eq}, given in Table II. At 1300°K, the I^+, ZrI_3^+, and ZrI_4^+ parent ion abundances at 2 eV above threshold were in the approximate ratio 220/1/36, respectively. In checking on the attainment of chemical equilibrium, the value of K_{eq} for reaction [2] was found to be unchanged with HI flow rate at 1305°K when the ZrI_3^+ and ZrI_4^+ signals varied by factors of 2.0 and 2.6, respectively. The good agreement in derived properties of $ZrI_3(g)$ from the data of reactions [2] and [3] is also a strong indication of equilibrium behavior.

Thermodynamic functions of the various species used in the analysis of these and other equilibria were taken from sources summarized in the Appendix. The two studies of reaction [2] yielded the third law values $\Delta H°_{298} = 32.3 \pm 1.5$ and 32.9 ± 1.5 kcal/mole, with corresponding second law values of 32.0 ± 0.6 and 30.5 ± 1.0 kcal/mole. For reaction [3], the derived second and third law values are $\Delta H°_{298} = 79.5 \pm 1.1$ and 79.8 ± 1.5 kcal/mole, respectively. The agreement between second and third law heats for reactions [2] and [3] and between the two different determinations of reaction [2] is quite good. Since the properties of $I(g)$, $Zr(s)$, and $ZrI_4(g)$ are known from other sources (3, 7) two independent determinations of the thermochemical properties of $ZrI_3(g)$ can be made. Using the average of the third law values, one derives $\Delta H_f°_{298}(ZrI_3,g) = -31.1 \pm 1.9$ kcal/mole from reaction [2] and -30.6 ± 2.1 kcal/mole from reaction [3]. A "best value" of $\Delta H_f°_{298}(ZrI_3,\ g) = -30.8 \pm 1.5$ kcal/mole is selected from the results of this research. The close accord between second and third law enthalpies shows that the estimated molecular constants and thermodynamic functions of $ZrI_3(g)$ are quite reliable.

$ZrI_2(g)$.—At temperatures slightly higher than those used in studies of reactions [2] and [3], it was possible to investigate the isomolecular reaction

$$ZrI_4(g) + ZrI_2(g) = 2ZrI_3(g) \qquad [4]$$

using parent ZrI_4^+, and fragment ZrI_2^+/ZrI_3 and ZrI^+/ZrI_2 measured at 2.5 eV above threshold as indicators of the ZrI_4, ZrI_3, and ZrI_2 pressures. Fragment ZrI_2^+/ZrI_3 was used rather than parent ZrI_3^+ to monitor $ZrI_3(g)$, in order to gain sensitivity; there was no discernible ZrI_2^+ ion current below 10 eV, showing that there could be no parent ion contribution at the higher energies to interfere with evaluation of the ZrI_3 abundance. Likewise there was no detectable ZrI^+ current below 10 eV, eliminating any possible interference from neutral ZrI. At the selected electron energies used, the neutral procursors of ZrI_4^+, ZrI_2^+, and ZrI^+ are clearly defined as ZrI_4, ZrI_3, and ZrI_2.

At 1450°K, the ion signals ZrI_4^+, ZrI_2^+, and ZrI^+ measured at 2.5 eV above threshold were in the ratio 716/245/1. Despite the low ZrI^+/ZrI_2 signal levels, it was possible to obtain a fair degree of precision in the determination of K_{eq} for reaction [4] by using

Table III. Derived thermochemical data for the reaction

$ZrI_4(g) + ZrI_2(g) = 2ZrI_3(g)$ [4]

T (°K)	K_{eq}	$\Delta H°_{298}$ [4] (kcal/mole)
1339	48.3	−9.0*
1431	48.7	−9.6
1452	57.1	−10.2
1468	43.1	−9.5

1478	47.4	−9.8
	Avg. (Third law)	−9.4 ± 3.5
	Second law	−4.6 ± 6.8

* Third law enthalpies derived from information given in the Appendix.

ion pulse counting detection. Pulse counting is somewhat tedious at low signal levels (0.5 to 1 counts/sec) but it does provide more reproducible results than the electrometer method. Because of the low ZrI_2 signal levels, however, it was not possible to obtain meaningful second law (slope) data, and all of the derived results are based on third law analysis. Appropriate corrections for the parent-fragment ion distributions in ZrI_3 and ZrI_4 were applied. No pressure calibration was required because reaction [4] was isomolecular. The equilibrium constants and derived reaction enthalpies are summarized in Table III, leading to $\Delta H°_{928}[4] = -9.4 \pm 3.5$ kcal/mole and $\Delta H_f°_{298}(ZrI_2, g) = 32.6 \pm 4.0$ kcal/mole.

If a nonlinear structure with apex angle of 120° is assumed for ZrI_2, rather than the linear configuration adopted as noted in the Appendix, then the derived enthalpy change at 298°K for reaction [4] will be 3.2 kcal/mole more negative, and the 298°K enthalpy of formation of $ZrI_2(g)$ will be more positive by the same amount. The difference arises because the Φ function calculated for the linear form is about 2.3 cal/deg mole smaller than for the bent form at 1500°K. For a wide range of temperatures centered about the measurement temperatures, the free energies of formation of ZrI_2 calculated from $\Delta H°_{298}$ and Φ for the linear model will be the same as those calculated from the $\Delta H°_{298}$ and Φ for the bent model, within the quoted uncertainties. The present measurements give no indication of which structure is correct.

ZrI(g).—Gaseous ZrI was observed only at relatively high temperatures, above 2000°K, when a measurable level of Zr(g) was also present. Consequently, it was possible to characterize ZrI(g) through studies of the equilibrium

$$ZrI(g) = Zr(g) + I(g) \quad [5]$$

in the range 2200°-2400°K. Again, the ZrI^+ parent signal was relatively weak when measured a few electron volts above threshold (<count per second). Several comparisons showed that values of K_{eq} evaluated from parent ion abundances measured at 3 eV above threshold differed by less than a factor of two from those derived from 50 eV ion abundances. The comparison establishes that the use of 50 eV ionizing energies to gain additional sensitivity in the study of reaction [5] introduces no extraneous signals that would complicate the interpretation. Therefore, in the equilibrium studies of reaction [5], parent Zr^+ and ZrI^+ were measured at 50 eV, while the intense I^+ parent signal was measured at 15 eV and an accurate correction was applied to normalize all signals to 50 eV ionizing energy. At 2300°K, the Zr^+, ZrI^+, and I^+ abundances were in the approximate ratio 200/1/4.6 × 10^4. The ZrI^+ signals varied from about 1 to 20 counts/sec, while the atomic I pressure was about 5 × 10^{-5} atm under these conditions. A series of measurements at various HI flow rates and at constant temperature showed the derived equilibrium constant of reaction [5] to be independent of pressure when the I pressure was varied by a factor of 13.

The equilibrium constants and derived thermochemical data for reaction [5] are summarized in Table IV. The second and third law values of $\Delta H°_{298}$ are 67.9 ± 6.6 and 72.6 ± 2.5 kcal/mole, respectively; the latter leads to $\Delta H_f°_{298}(ZrI, g) = 96.3 \pm 2.8$ kcal/mole.

The reaction thermochemistry and derived thermochemical data are summarized in Table V.

Discussion

Application to the iodide process.—The pressures of Zr-I species calculated from our experimental thermochemical data are shown in Fig. 2 for a total iodine equivalent pressure of 10^{-4} atm, typical of iodide refining process conditions. These results lead to a simple interpretation of the deposition of Zr in the iodide process, based on the thermodynamic data. At low temperatures the major gaseous species is ZrI_4, whereas at temperatures above 1300°K the major species is atomic I. Therefore, in the iodide process gaseous ZrI_4 is formed from reaction of impure Zr with iodine at low temperatures. The ZrI_4 diffuses to the hot filament and is decomposed to solid Zr and gaseous I atoms. The temperature above which deposition occurs on the hot filament is about 1300°K from the thermodynamic data in Fig. 2, in reasonable agreement with experience in the iodide process. Therefore, the data indicate that in the iodide process the only important gaseous species are ZrI_4 and I.

The effect of pressure of total iodine-containing species can be seen in Fig. 3 and 4. The major species

Table V. Summary of derived thermochemical data

Reaction	$\Delta H°_{298}$ (III)* (kcal/mole)	Derived enthalpies of formation (kcal/mole)
3/4 $ZrI_4(g)$ + 1/4 Zr(s) = $ZrI_3(g)$	32.6 ± 1.1	$\Delta H_f°_{298}(ZrI_3, g) = -31.1 \pm 1.9$
$ZrI_4(g) = ZrI_3(g) + I(g)$	79.8 ± 1.5	$\Delta H_f°_{298}(ZrI_3, g) = -30.6 \pm 2.1$
$ZrI_2(g) + ZrI_4(g) = 2ZrI_3(g)$	−9.3 ± 3.5	$\Delta H_f°_{298}(ZrI_2, g) = 32.6 \pm 4.0$
$ZrI(g) = Zr(g) + I(g)$	72.6 ± 2.5	$\Delta H_f°_{298}(ZrI, g) = 96.3 \pm 2.8$

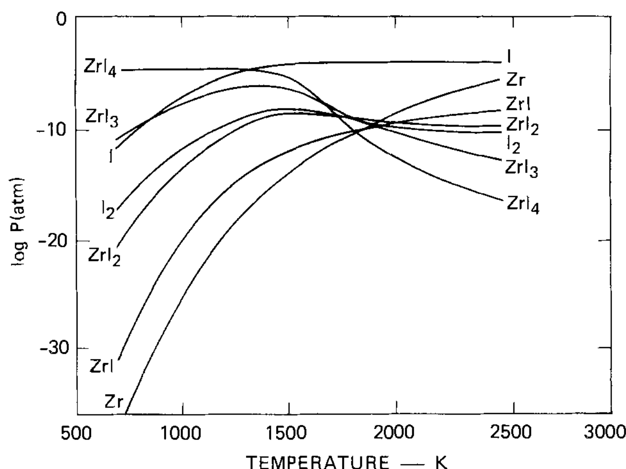

Fig. 2. Partial pressures of species in equilibrium with Zr(s) from present data for P(total I) = 10^{-4} atm. P(total I) = total iodine equivalent pressure $\equiv \Sigma np(ZrI_n) + \Sigma np(I_n)$.

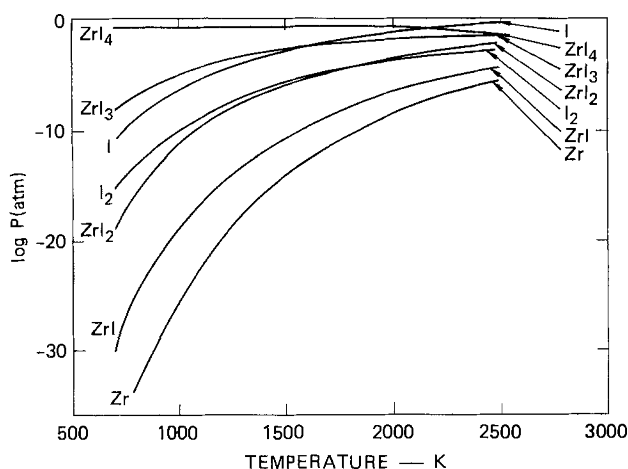

Fig. 3. Partial pressures of species in equilibrium with Zr(s) from present data for P(total I) = 1 atm. P(total I) = total iodine equivalent pressure $\equiv \Sigma np(ZrI_n) + \Sigma np(I_n)$.

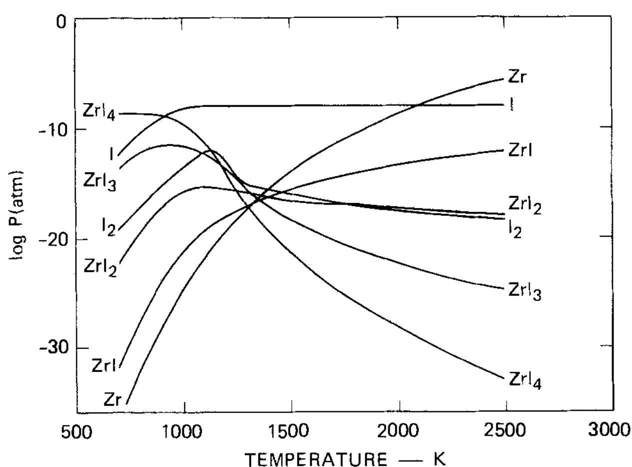

Fig. 4. Partial pressures of species in equilibrium with Zr(s) from present data for P(total I) = 10^{-8} atm. P(total I) = total iodine equivalent pressure $\equiv \Sigma np(ZrI_n) + \Sigma np(I_n)$.

under most conditions are either ZrI_4 or I. For 1 atm total iodine equivalent pressure, shown in Fig. 3, the temperature at which the ZrI_4 and I pressures cross is about 2200°K. That is, deposition of Zr would occur only at filament temperatures higher than 2200°K. For total iodine equivalent pressures of 10^{-8} atm, shown in Fig. 4, the cross-over temperature is about 900°K. Therefore as the pressure of total iodine-containing species in the system is increased, the minimum temperature for decomposition of ZrI_4 increases.

In the iodide process it has been observed (8, 9) that as the temperature of the impure zirconium was increased the rate of deposition of Zr first increased then decreased. That behavior can be related to the effect of pressure on the decomposition temperatures shown in Fig. 2-4. The initial increase in rate occurs because increasing the temperature of the impure Zr increases the partial pressure of ZrI_4 and thus its rate of arrival at the filament. As the impure Zr temperature is further increased, the fraction of the ZrI_4 arriving at the filament which is decomposed decreases, in accord with Fig. 2-4, and the decomposition rate falls off largely because that fraction decreases. Shelton (10) discussed the maximum in the rate of the process in terms of changes in the iodine diffusivity and the change in fraction decomposed is implicit in his treatment.

The composition profiles shown in Fig. 2-4 illustrate clearly the reason for the experimental difficulties in studying the lower Zr iodides alluded to earlier. The lower iodides are minor species under all practical experimental conditions, and there is no way to increase their abundances relative to ZrI_4 and I at temperatures below 2500°K.

Bond dissociation energies.—From the enthalpies of formation in Table V, one can evaluate the individual bond dissociation energies in ZrI_4 as follows: $D(I_3Zr\text{-}I)$ = 80 kcal, $D(I_2Zr\text{-}I)$ = 92 kcal, $D(IZr\text{-}I)$ = 86 kcal, and $D(Zr\text{-}I)$ = 73 kcal. These values differ only slightly from the average bond energy in ZrI_4, 83 kcal. Each of the first three bond dissociation reactions is assumed to yield an iodine atom plus a zirconium iodide molecule in which the zirconium valence electrons not used in bonding are unpaired. For ZrI_3, ZrI_2, and ZrI, these electronic configurations are those of the ground states of the gaseous ions Zr(IV), Zr(III), and Zr(II). The ground state of Zr(I), $4d^25s^2$, contains two paired and two unpaired electrons, however; the first excited state of Zr(I) in which all of the valence electrons are unpaired ($4d^35s^1$) lies 13.9 kcal above ground. Thus the comparable bond dissociation reaction for ZrI, ZrI $\rightarrow$ Zr ($4d^35s^1$) + I has an energy of 73 + 14 = 87 kcal, not greatly different from all the others.

Relevance to iodine attack and SCC of Zr.—The chemical attack of zirconium alloys by gaseous iodine at temperatures near 600°K causes pitting of the metal surface (11). Pitting probably occurs by vapor transport removal of material. The present results show (Fig. 2-4) that the predominant vapor species under those conditions is ZrI_4, which must then be the species responsible for any vapor transport of Zr. Pitting implies that some metal surface sites are more reactive so that localized removal of material is favored over uniform corrosion.

Stressed samples of zirconium alloys can also crack in iodine vapor and vapor transport has been suggested as a mechanism which maintains the sharp crack tip required for crack propagation. The validity of that mechanism has been questioned (11) because pitting, the apparently favored mode of attack would blunt the crack tip rather than sharpen it. Zirconium tetraiodide can induce the stress corrosion cracking of Zircaloys as readily as iodine (11, 12). The present work shows that the partial pressures of reduced Zr-I species are very small under conditions of ZrI_4-induced Zircaloy cracking so that the removal of zirconium by vapor transport of lower iodides is not a likely mechanism.

Thus SCC of zirconium alloys in iodine and iodides apparently occurs by mechanisms other than vapor transport.

APPENDIX

Sources of Auxiliary Thermochemical Information

Thermodynamic functions and auxiliary thermochemical data used in the analysis of the equilibrium measurements were taken from sources listed below. The equilibrium internuclear distances in gaseous ZrI, ZrI_2, and ZrI_3 were assumed to be the same as the measured value for ZrI_4, 2.66Å. For ZrI, ZrI_2, and ZrI_3, the estimated moments of inertia (I), symmetry numbers (σ), electronic ground state statistical weights (g_0), and vibrational frequencies (ω) are listed in Table VI. Values of the Φ function (the tempered Gibbs energy function, formerly called free energy function) calculated from these spectroscopic constants are given in Table VII. The estimated uncertainties in the calculated Φ functions at the temperatures of the equilibrium measurements are ± 1, ± 2.3, and ± 1 cal/deg mole for ZrI, ZrI_2, and ZrI_3. These uncertainties are consistent with the observed agreement between second and third law heats. These uncertainties are coupled with those in the derived equilibrium constants to give the over-all estimated uncertainties attached to the third law heats.

I(g).—All data were taken from the JANAF Tables (3).

Zr(s, g).—Thermodynamic functions were taken from the JANAF Tables (3), while the enthalpy of formation of Zr(g), $\Delta H_f°_{298} = 143.4 \pm 1.2$ kcal/mole reported by Ackermann and Rauh (13), was adopted.

ZrI(g).—The vibrational frequency was estimated from the stretching frequency in ZrI_4. A $^4\Sigma$ ground state was assumed, as in ZrCl.

$ZrI_2(g)$.—A linear structure was assumed, in view of structural trends in the neighboring alkaline earths. Vibrational frequencies were estimated by analogy with those of SrI_2 and ZrI_4. The ground state was assumed to be a triplet.

$ZrI_3(g)$.—A planar symmetric structure with doublet electronic ground state was assumed. Vibrational frequencies were estimated by comparison with those of related molecules such as AsI_3.

$ZrI_4(g)$.—The thermodynamic functions, based on accurately known spectroscopic and molecular constants, were taken from the JANAF Tables (3). We have adopted the enthalpy of sublimation and enthalpy of formation of the gas, $\Delta H_f°_{298} = -84.9 \pm 1.5$ kcal/mole, given by Cubicciotti *et al.* (7).

Dates of JANAF Tables used were as follows: I(g), 6-74; Zr(s, g), 12-67; and ZrI_4(g), 6-75.

Investigation of Cation-Transport Processes during Anodic Oxidation of Duplex Layers of Tantalum on Niobium by the Use of Rutherford Backscattering and Nuclear Microanalysis

J. Perrière, S. Rigo, and J. Siejka*

Groupe de Physique des Solides de l'Ecole Normale Supérieure, Université Paris VII, 75221 Paris Cedex 05-France

ABSTRACT

It has been shown that, during anodic oxidation of superimposed metallic films of tantalum on niobium, a regime exists in which the growth laws of niobium substrate oxidation are the same as those found during pure niobium oxidation. Using ^{4}He Rutherford backscattering techniques we have shown that the order of cations is partially inverted in the oxide films. A pure niobium oxide region near the metal is covered by a layer in which both cations (Ta and Nb) are present. The fraction F_t of niobium atoms present in this last region was measured as a function of oxidation potential, tantalum deposit thickness, current density, and temperature. It was found that, for sufficiently high oxidation potentials, F_t is voltage independent and lies around 25%. F_t increases with increasing current density or decreasing temperature, while F_t is independent of tantalum layer thickness for thicknesses above 6 nm. Possible cation transport mechanisms corresponding to these observations are proposed and discussed.

The study of anodic oxide growth mechanisms consists in determining the moving species (metal or oxygen or both), and in elucidating their microscopic transport mechanisms. Studies of the migration of the atomic constituents of the oxide films have given rise to numerous publications (1-12). Data obtained from noble gas markers indicate that both metal and oxygen migrate during the anodic oxidation of Al (3, 5), Ta (3, 4), and Nb (3). The main difficulty in determining the microscopic transport mechanism is due to the fact that it is not possible to observe directly the movement of the constituent species during anodic oxidation since all experimental methods only give a picture of the final macroscopic situation. In order to find out how oxygen and metal move, it soon appeared that a suitable method is isotopic tracing. Thus, oxygen movements were studied by analysis of the ^{18}O distribution in duplex films obtained by successive oxidation in natural (^{16}O) and ^{18}O-enriched solutions. Results have shown that the order of oxygen atoms is on the average conserved during anodic film formation on Al (1) and on Ta (10), *i.e.*, the new oxygen atoms are incorporated at the oxide-solution interface. Isotopic tracing of metal was used in 1958 by Verkerk *et al.* (11) for Ta oxidation, but the results were not clear enough and gave rise to contradictory interpretations.

An alternative to isotopic tracing which is not always easy to carry out for studying cation movement could be the use of "substitute tracers," *i.e.*, tracer atoms whose movement with respect to the matrix is assumed to be well known. If these atoms move during anodic oxidation under the influence of electric field, with the same mechanism as the corresponding oxide constituent, they are equivalent to isotopic tracers. In the study of cation movements during oxidation of a metal M_1, this role might be played by atoms of another metal M_2 with similar properties. An oxidation of superimposed metallic films is hence carried out, in which a metal M_1 is covered by a thin film of metal M_2 (system $M_1|M_2$), and the change of cation distribution is studied after anodization. Such an approach was first used by Amsel and Samuel (1) and recently by Rigo and Siejka (12); the latter have studied cation movements during anodic oxidation of tantalum covered with a thin niobium film (Ta|Nb) and of niobium simliarly covered with tantalum (Nb|Ta). Tantalum and niobium (which are in the same column of the periodic table) are completely miscible and form the same kind of oxide with a faradaic efficiency near 100% and the ionic radii of Ta^{5+} and Nb^{5+}, and are generally listed as equal (13). It was thus initially assumed as a working hypothesis that each metal could be used with respect to the other as a practical equivalent of an "isotopic tracer." The results have shown (12) that, in the first case of (Ta|Nb), a moderate cation mixture appears in the oxide, while in the second case (Nb|Ta), a fraction of oxidized niobium atoms migrates through the oxide and fixes oxygen atoms at the oxide-solution interface. Furthermore, it was found that the cation movements seem to depend on tantalum deposit thickness (12). Differences in the anodic oxidation behavior of Ta and Nb have also been observed by Khoo *et al.* (14) in the study of the anodization of alloys. It appeared, thus, that although they are very similar in many aspects, Ta and Nb cannot be considered as equivalent to isotopic tracer for each other. This might be due, among other reasons, to the large difference in the corresponding electric fields of formation. Nevertheless, it also appeared that the study of anodization of superimposed metallic films is by itself a fruitful method to study cation migration mechanisms, shedding light on the basic transport mechanisms involved. In addition, practical applications of mixed oxide films grown in this way may be interesting in microelectronic device technology and in corrosion protection problems.

In this paper, we present results dealing with cation movements during anodic oxidation of niobium substrates covered with tantalum. The variations of the cation distribution in the oxide as a function of oxidation potential were studied for various current densities, temperatures, and tantalum layer thicknesses. A first report of these results was presented by Perrière (15).

A second purpose of this work was to elucidate the role played by the presence of tantalum at the various stages of the oxidation process of niobium. The number of tantalum atoms is always conserved during oxi-

* Electrochemical Society Active Member.
Key words: anodic oxidation, tantalum, niobium, transport mechanisms.

dation, but their depth concentration changes as a function of oxidation potential (16). Thus, the possible influence of tantalum oxide on niobium oxidation mechanism could depend on the tantalum atom distribution in the oxide. In fact, the number of niobium and tantalum atoms per unit oxide volume is practically the same in tantalum and niobium oxide. Hence, the penetration of niobium atoms in the tantalum oxide, due to cation movements, must be associated with the formation of an equivalent portion of new oxide at the oxide-solution interface. Thus the questions arise whether the microscopic transport mechanisms are conserved in tantalum oxide in spite of the penetration of niobium atoms into it, and whether they depend on niobium and tantalum atom concentration. This work was an attempt to provide at least partial answers to these questions.

Oxygen movements in these superimposed layers have been also studied. The results of these investigations are presented elsewhere (17).

Experimental

Preparation and analysis of samples.—The superimposed metallic films were tantalum layers deposited either on chemically polished bulk niobium (18), or on niobium layers deposited on aluminum. The same results were obtained (12) whatever the type of samples used. The metallic layers were obtained by d-c triode sputtering in an argon plasma at a 0.13 Pa pressure, with 2.5 kV cathode potential and a 60 mA current. The cathode diameter was 13 cm, and the cathode to substrate distance was 7 cm. Tantalum and niobium used as bulk substrates or as sputtering targets were supplied by Kawecki Berylco Industries with a 99.98% purity for tantalum and 99.9% for niobium.

As we have shown previously (12) that various electrolytes like ammonium citrate solutions, glacial acetic acid, and ammonium pentaborate solutions give the same results, we chose to use in this work aqueous solutions of ammonium pentaborate (0.5% by weight, pH kept at 9 by ammonium hydroxide additions). Such solutions do not dissolve aluminum and this insured compatibility with future work. The anodic oxidations were carried out at constant current density.

Nuclear microanalysis by the direct observation of nuclear reactions and of backscattered particles were used to study samples before and after oxidation. The experiments were carried out using the 2 MeV Van de Graaff accelerator of the laboratory.

Using nuclear microanalysis as described by Amsel *et al.* (19), the ^{16}O content of the films was obtained through the $^{16}O(d,p)^{17}O^*$ nuclear reaction. The absolute values were obtained by comparison with an oxygen reference target known to within ±3%. The preparation of such references is described in Ref. (20).

Rutherford backscattering was employed to analyze the depth distribution of cations in the superimposed films and in their anodic oxides; lateral homogeneity was assumed for the interpretation of the spectra. The basic concepts and equations related to Rutherford backscattering spectrum interpretation have been fully described (21, 22). Absolute amounts of niobium and tantalum atoms expressed in atoms/cm^2, in the deposits, and in their oxide were obtained (assuming validity of the Rutherford law), by comparison with a tantalum film containing $(525 \pm 10) \cdot 10^{15}$ at. Ta/cm^2, taken as a standard. The preparation of such standards is described in detail in Ref. (23). For convenience, the film thicknesses will also be given in nanometers, the equivalence atoms/cm^2 · thickness being practically the same for both Ta_2O_5 and Nb_2O_5, *i.e.*, 10^{15} at./cm^2 = 0.46 nm assuming the densities 8.04 and 4.74, respectively (24).

$^4He^+$ ion beams in the 1.6-1.9 MeV energy range were used according to the experiments with currents of about 80 nA on a 1 mm diam spot. The incident beam was normal to the targets and backscattered particles were detected at 165° or 150° angle by means of an Ortec silicon barrier detector of 25 mm^2 area with a 1 mm^2 diaphragm. The distance between target and detector was 59 and 50 mm, respectively, for the 165° and 150° detecting angle. With these conditions, the energy resolution (FWHM) was equal to about 14 keV and corresponds to a depth resolution of about 20 nm for tantalum and niobium oxides as calculated from Bragg's additivity rule for stopping power and using stopping power values of Ziegler and Chu (25) (see next section).

Analysis of MeV helium backscattering spectra.—As a simple initial test, the energy spectra backscattering of 1.6 MeV $^4He^+$ on a niobium sample covered by $8 \cdot 10^{16}$ tantalum atoms/cm^2 (about 15 nm assuming a density equal to 16 for tantalum) layer before oxidation (a) and after oxidation (b) were measured: They are shown on Fig. 1. The arrows Ta and Nb indicate the calculated energy values of particles backscattered by tantalum and niobium atoms located at the sample surface. In Fig. 1a, the niobium edge is shifted 20 keV with respect to its surface position. This effect is due to the energy loss in the tantalum film undergone by ^4He particles which are eventually backscattered from the niobium substrate. The tantalum peak, well separated from the niobium spectrum, is closed up against the Ta arrow, and so is the tanta-

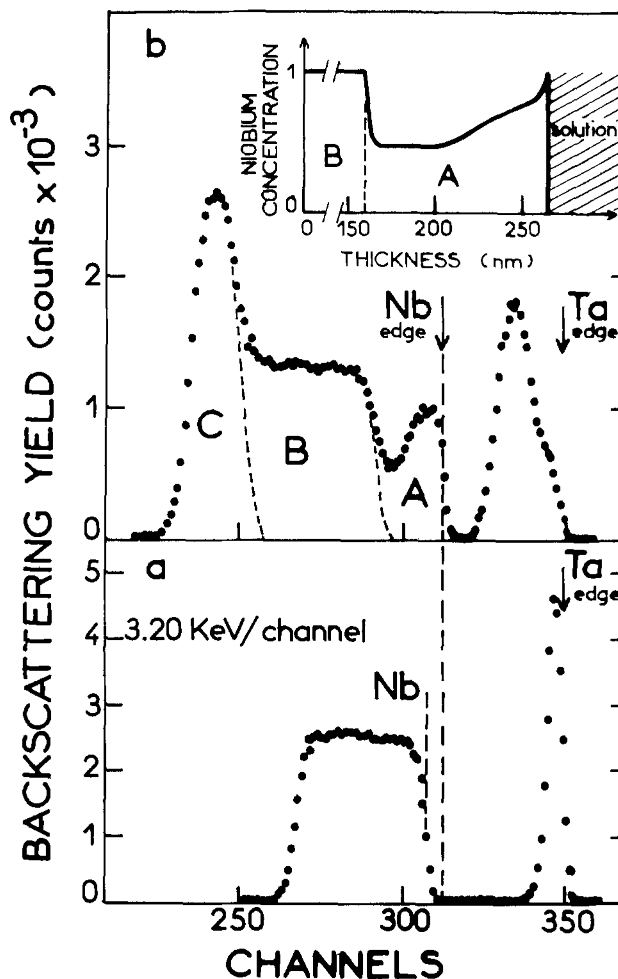

Fig. 1. Backscattering spectra of 1.6 MeV ^4He ions for a 15 nm thick tantalum film superimposed on a 120 nm thick niobium substrate on Al support. (a) Before oxidation; (b) after oxidation V = 150V; T = 23°C; i = 5 mA/cm^2. Channel 0 corresponds to E = 1.12 MeV. For the insert, see text.

lum at the surface. In Fig. 1b, the niobium edge appears at the surface energy position. Regions A and B of the niobium spectrum are related to the depth distribution of niobium atoms in the oxide; region C corresponds to unoxidized pure niobium. The tantalum spectrum is still well separated from that of the niobium; its shape is typical of tantalum atoms distributions encountered in this work. In fact, on the tantalum spectrum, a shoulder appears toward high energies; it indicates that some tantalum atoms remain in the near surface region of the oxide, mixed with niobium atoms, while the majority appears deeper in the oxide. From the spectrum, we may conclude that a niobium-rich layer is formed at the oxide surface, corresponding to the surface peak in the niobium spectrum. Thus a simple analysis of these spectra allows us to get an insight on cation movements during the anodic oxidation of this system. The atomic concentration ratio of niobium and tantalum in the two oxide mixtures is given with a good approximation (26) by $N_{Nb}/N_{Ta} = Y_{Nb}/Y_{Ta}[\sigma_{Ta}/\sigma_{Nb}]^2$ where Y_{Nb} and Y_{Ta} are the scattering yields per energy width for same energy particles before scattering (same depth), σ_{Ta} and σ_{Nb} are the elastic cross section for tantalum and niobium. Furthermore, stopping power values of niobium and tantalum oxide, as calculated from Bragg's additivity rule and Ziegler and Chu values (25), are very similar (the percentage difference is less than 4% in the 1-1.8 MeV energy range). So their differences were neglected, and we could determine a single energy-depth relationship for the tantalum and niobium oxide mixture.

The insert in Fig. 1b shows schematically the depth profile of niobium atoms in the oxide deduced from the spectrum. This niobium profile exhibits a pure niobium oxide layer (region B) covered by a tantalum and niobium oxide mixture (region A). The niobium atom concentration is constant (about 50%) in the internal part of the A region and then increases in the external part of the A region.

In this paper we present measurements of the number of niobium atoms n_A and n_B present in the parts A and B of the oxide. n_A and n_B represent, respectively, the number of niobium atoms in mixed oxide (which have crossed the inner edge of the tantalum atom distribution) and in pure niobium oxide, and we call F_t the ratio $n_A/(n_A + n_B)$. Since n_A and n_B are proportional to the areas N_A and N_B (corrected for cross section effects) of the regions A and B of the spectra, F_t can also be represented by the ratio $N_A/(N_A + N_B)$. Errors on these measurements depend on the precision with which we can establish the boundary lines between A and B, and B and C regions in the spectra. The shape of these separations was experimentally established by measuring the energy width of a niobium-niobium oxide interface. These measurements were carried out on pure niobium oxides the thicknesses of which were similar to those of A and A + B regions. So, the numbers of niobium atoms present in A and B regions were determined with an accuracy better than 5% for thick films (Nb consumption equivalent to more than 200 nm oxide) and equal to 20% for thin films (Nb consumption equivalent to less than 50 nm oxide).

Results

In order to describe and discuss our results in terms of microscopic transport mechanisms, we use the concepts of cationic events and of oxide network (27, 28). By the term of cationic events, one means the sequence of elementary jumps of one or more metallic cations which result, on the one hand in a transport of charges from their creation point to that of their recombination, and on the other hand in oxide growth. The elementary jumps can be of various types (29) such as long range (interstitial), or short range like interstitialcy, vacancy (assuming that such point defects can be defined in amorphous oxides), or Dignam lattice point defects movement (30). The term of network is meant in the sense of the continuous random network theory of amorphous media, as the spatial distribution of the atomic sites and bonds (the oxide being considered, under this concept, as mainly covalent), which is organized progressively as the oxide grows. We shall speak of "niobium or tantalum oxide networks," meaning that these two oxides may be organized in two well-defined, possibly different network types, keeping their nature even if some niobium or tantalum atoms are replaced by tantalum or niobium atoms, respectively.

Relationships between oxidation potential V and time t: $V = f(t)$.—Figure 2 shows some typical curves obtained by recording oxidation potential as a function of time during the anodic oxidation of pure niobium (curve a), of pure tantalum (curve b), and of a 15 nm thick tantalum layer superimposed on niobium substrate (curve c). All these experiments were performed at 5 mA/cm² current density and at 23°C temperature.

Three regions can be distinguished in curve c, these being regions 1 and 3 where $V = f(t)$ is linear. The slopes of these straight lines are identical to those observed for pure tantalum and pure niobium oxide growth (curves a and b). Region 2 is a transition region, between 25 and ~ 80V, where an undershoot of dV/dt is observed (see insert of Fig. 2). The intercept of the straight lines in regions 3 and 1 determine an oxidation potential V_1 which is relative to the potential drop in tantalum oxide obtained by anodization of a 15 nm thick tantalum layer. The value of the potential drop in tantalum oxide (37 nm) is 24.4V, calculated using a value of the slope of the kinetic of tantalum oxide growth equal to 1.54 nm/V [deduced from Ref. (31)]. This potential drop is in reasonable agreement with V_1 equal to about 25V.

These results confirm that tantalum oxide is formed in region 1 as expected, and strongly suggest that usual niobium oxide is formed in region 3, in spite of the presence of the tantalum oxide already formed. No clear explanation for the existence of the transition region 2 can be presented.

Oxide stoichiometry.—The total number of oxidized metallic atoms, tantalum plus niobium (the number of tantalum atoms per cm² was constant and equal to $8 \cdot 10^{16}$), as related to the number of oxygen atoms

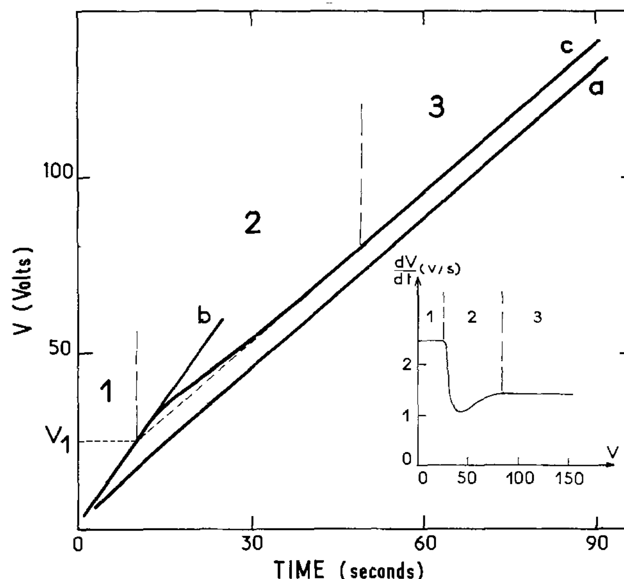

Fig. 2. Oxidation potential V as a function of time during anodic oxidation at a 5 mA/cm² current density and at a 23°C temperature for: (a) pure niobium; (b) pure tantalum; (c) 15 nm thick tantalum film on niobium substrate.

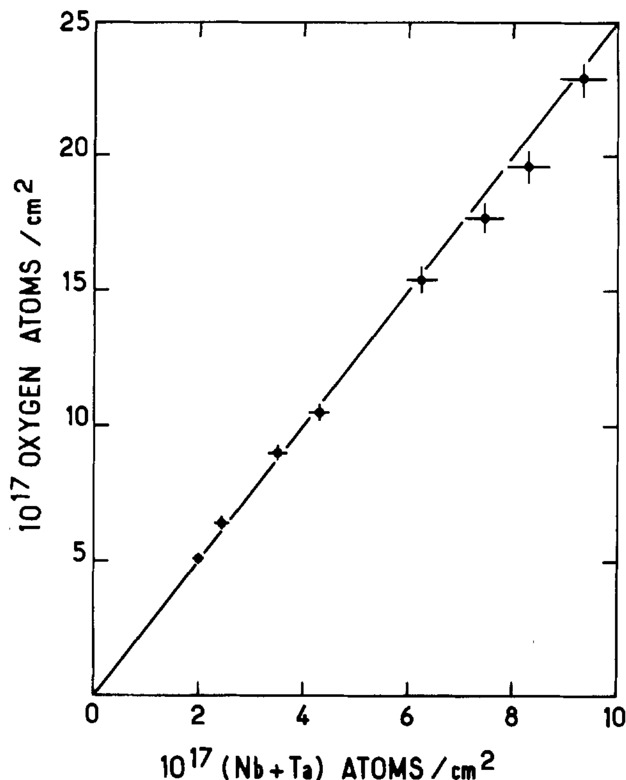

Fig. 3. Number of oxygen atoms in the oxide as a function of the total number of oxidized niobium plus tantalum atoms (the number of tantalum atoms per cm² is equal to $8 \cdot 10^{16}$ for each point). The absolute errors on each point are shown by the error bars.

fixed in the oxide for oxidation potentials lying between 60 and 220V, is presented on Fig. 3. These results were obtained using nuclear microanalysis as described above. The full line represents the theoretical curve corresponding to stoichiometric composition, *i.e.*, to the M_2O_5 formula (M for metal). Within our experimental precision (about 5%), Fig. 3 shows that for this oxidation potential range, this oxide is stoichiometric. For oxidation potentials lower than 60V, the errors on the measurements of the total number of oxidized niobium atoms increase as oxidation potential decreases; this precludes precise stoichiometry measurements in this region.

Cationic movements.—We have investigated the change of cation distribution in the oxides as a function of oxidation potential, tantalum layer thickness, and electric field.

Influence of oxidation potential.—Samples with a 15 nm thick tantalum deposit on niobium substrate were oxidized at 5 mA/cm² current density and at 23°C temperature. Oxidation potentials were chosen so that the various regimes observed in the $V = f(t)$ relationship could be studied. These oxidation potentials were chosen between 25V (total oxidation of tantalum deposit) and 220V. Figures 4 and 5 show backscattering spectra obtained on these samples. On all the spectra where the tantalum peak is well separated from the niobium spectrum, the peak area, corrected for differential cross-section effects, is constant within our experimental precision. This indicates that the number of tantalum atoms in the oxide is constant, and therefore excludes any dissolution process during oxide growth. So, even when the tantalum peak overlaps the niobium spectrum (at very high oxidation potentials), we can determine the number of oxidized niobium atoms mixed with tantalum atoms in the oxide. This is done by subtracting the tantalum peak area, obtained on the last spectrum where it is isolated, from the integral of the whole spectrum. Similar experiments were performed with double deposits on aluminum backing with a 120 nm thick niobium layer and 15 nm thick tantalum film. These latter results indicate that no appreciable dissolution of niobium occurs during anodization of superimposed layers, similarly to tantalum.

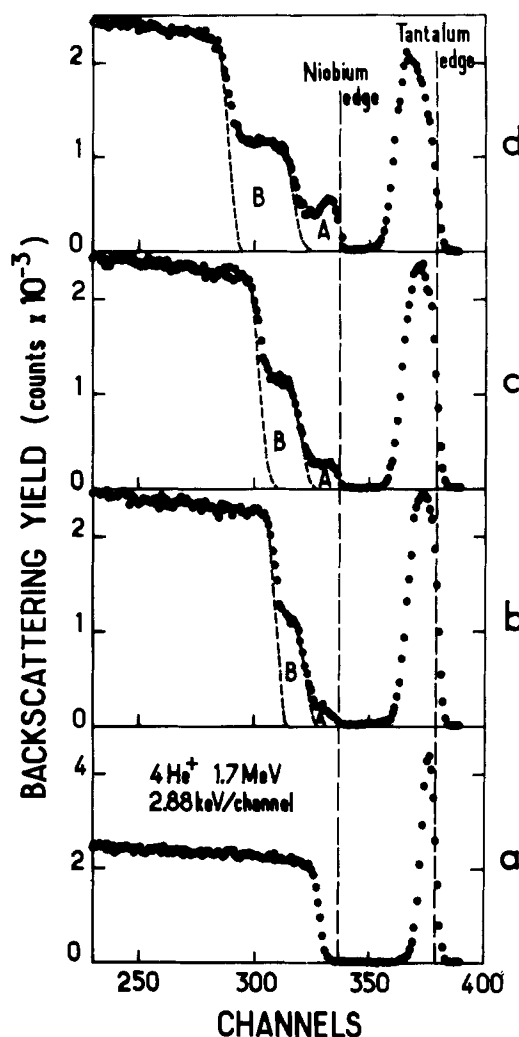

Fig. 4. Backscattering spectra of 1.7 MeV ⁴He ions for 15 nm thick tantalum film on niobium substrate: (a) before oxidation; (b) after oxidation at 23°C, $i = 5$ mA/cm², $V = 50$V; (c) 60V; (d) 80V.

The backscattering spectra are presented and discussed assuming lateral uniformity of the tantalum and niobium oxide mixture. In order to check this assumption, experiments are presently being carried out to study the lateral uniformity of tantalum distribution by using an electron probe with a resolution of about 4 μm. Preliminary results indicate that the tantalum concentration appears homogeneous with such a resolution, except in some localized defects (diameter equal to about 20 μm) with an over-all area below 1% of the whole surface.

Figure 4a represents the backscattering spectrum obtained on a sample before oxidation, and Fig. 4b, 4c, 4d, and 5 correspond to oxidized samples. Analysis of Fig. 4a shows that no mixing occurs between niobium and tantalum atoms to within 10 nm during the deposit. For an oxidation potential V equal to 25V, only the tantalum layer is oxidized. For higher oxidation potentials, the niobium substrate begins to be oxidized, and for various oxidation potentials, the changes in cation distribution appear as follows:

With 50V (Fig. 4b), a tail towards high energy appears in the niobium spectrum. It indicates a progressive penetration of niobium atoms in the tantalum

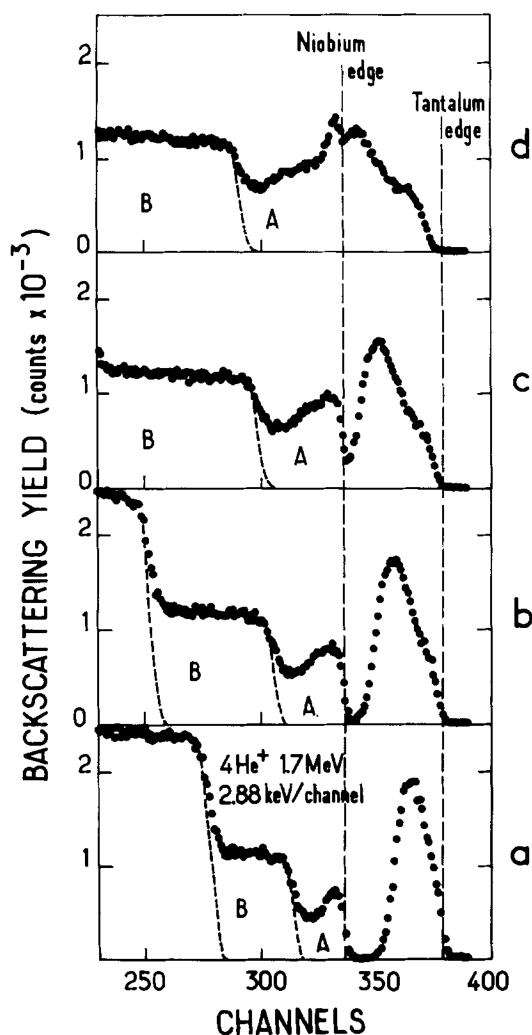

Fig. 5. Backscattering spectra of 1.7 MeV ^{4}He ions for 15 nm thick tantalum film on niobium substrate: (a) after oxidation at 23°C, i = 5 mA/cm^2, V = 100V; (b) 140V; (c) 180V; (d) 220V.

oxide network which is already formed. The presence of niobium atoms in this part of the oxide proves that niobium cations take part in cationic events, since movement of tantalum atoms against the field may be neglected.

With 60V (Fig. 4c), the niobium spectrum exhibits two clearly resolved steps. The first, corresponding to the oxide-solution interface, shows a tantalum and niobium oxide mixture over about 50 nm. In this mixture, the roughly uniform niobium concentration is about 30%. The second one corresponds to pure niobium oxide underlying the oxide mixture.

With 80V (Fig. 4d) and 100V (Fig. 5a), they correspond to the end of the transition region appearing in the $Vf(t)$ relationship (see Fig. 2). A surface peak in the niobium spectrum, and a shoulder toward high energies in tantalum spectrum begin to appear. This shows that niobium concentration increases in the near-surface region of the oxide mixture. This niobium concentration goes from 30% at 60V to about 60% for 100V oxidation potentials, and it is clearly higher than in the bulk of the oxide mixture (about 40%) where the niobium atom distribution is rather uniform.

With 120-200V (Fig. 5b-5d), oxidation potentials exist at which dV/dt is constant at the level expected for anodization of pure niobium (see Fig. 2). These spectra show that the niobium concentration first increases in the bulk of the oxide mixture: it goes from 40% to 55% as oxidation potential goes from 100 to 160V. Above, this niobium concentration remains constant within our experimental precision. The increase of the surface peak in the niobium spectrum indicates an increase of the niobium contents in the near-surface region of the oxide mixture. The tantalum spectrum is shifted towards lower energies and broadened as a function of oxidation potential, and finally, its rear edge overlaps the niobium spectrum (Fig. 5c and 5d). The shoulder on the tantalum spectrum is more and more resolved as oxidation potential increases. This fact shows that the tantalum and niobium atom ratio distribution in the surface region is steadily changing. For oxidation potentials higher than 120V, the front edge of the tantalum spectrum is shifted toward lower energies. This fact is explained by the formation of a pure niobium oxide layer at the oxide-solution interface. Its thickness increases with oxidation potential since the tantalum spectrum shift also increases, and reaches about 20 nm for a 220V oxidation potential.

In Fig. 6 we have presented schematically the depth profiles of niobium in the anodic oxides formed at 60, 100, 160, and 220V. The tantalum profile is not presented since it is the complement of that of niobium. We may distinguish a pure niobium oxide region (B) and the remainder of the oxide formed (A), *i.e.*, a tantalum-niobium oxide mixture region followed at high potentials by a pure niobium oxide region near the oxide solution interface. The sharp boundary between A and B was taken as the origin of the depth scale in Fig. 6. A region X of thickness equal to that of the oxide formed by the oxidation of the tantalum film alone has been represented on all figures by vertical dashed lines. It appears that for given potential, the niobium concentration in region X is practically constant and known with high enough relative precision (±10%). For oxidation potential higher than 160V, the niobium concentration in region X remains

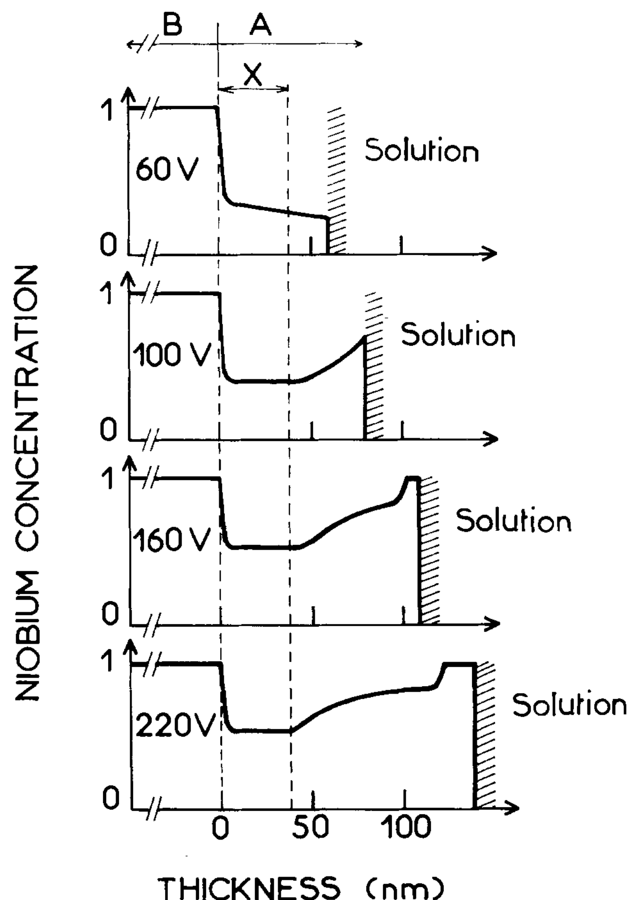

Fig. 6. Schematic representation of depth profiles of niobium for various oxidation potentials, deduced from the spectra of Fig. 4 and 5.

stationary reaching 55% ± 5%. On the other hand, the figures show that beyond region X the shape of the niobium profiles goes on changing with potential, the thickness of the mixed region as well as that of the pure surface oxide region increasing steadily.

Let us recall, as stated above, that this analysis is based on the assumption of lateral homogeneity of niobium and tantalum atoms in the oxide. As pointed out, the behavior of the niobium profile (as a function of oxidation potential) in the X region is different from that in the external part of the oxide mixture. The most likely explanation of this fact seems to be that the tantalum atoms present in the region X do not take part in cationic events for potentials higher than 160V. If we assume that these tantalum atoms have never taken part in cationic events during all the niobium substrate oxidation, one can conclude that region X can be associated to the tantalum oxide network formed during the anodic oxidation of the tantalum film alone.

From the spectra presented on Fig. 4 and 5 we have calculated F_t defined above as $F_t = n_A/(n_A + n_B)$ or $N_A/(N_A + N_B)$, *i.e.*, the fraction of oxidized niobium atoms which have crossed the inner edge of the tantalum atom distribution.

In Fig. 7, we have presented the F_t values as a function of the total number of oxidized niobium atoms n_{Nb}. For low values of n_{Nb}, the F_t measurements are not precise. It seems, however, that F_t values increase with niobium substrate consumption until about $3 \cdot 10^{17}$ Nb·at/cm^2 are oxidized (~75V of niobium oxidation). For higher oxidation potentials, the precision on F_t measurements is more satisfactory (about 10%), and F_t takes a constant value (F_t max), independent of oxidation potential and equal to 0.25 ± 0.02. Note that F_t is constant while (*i*) the distribution of tantalum and niobium atoms in the oxide mixture undergoes strong changes; and (*ii*) dV/dt is constant at the level expected for niobium anodization (see Fig. 2).

The analysis of the backscattering spectra has shown that, for oxidation potentials higher than 120V, there is a layer of pure niobium oxide at the oxide-solution interface. The thickness of this layer reaches about 20 nm for a 220V oxidation potential, while the increase, after the appearance of pure Nb_2O_5 surface layer (about 120V), of the total oxide thickness is equal to 200 nm. The pure niobium oxide layer represents then a fraction F_s equal to 0.10 ± 0.03 of the increase in total oxide thickness.

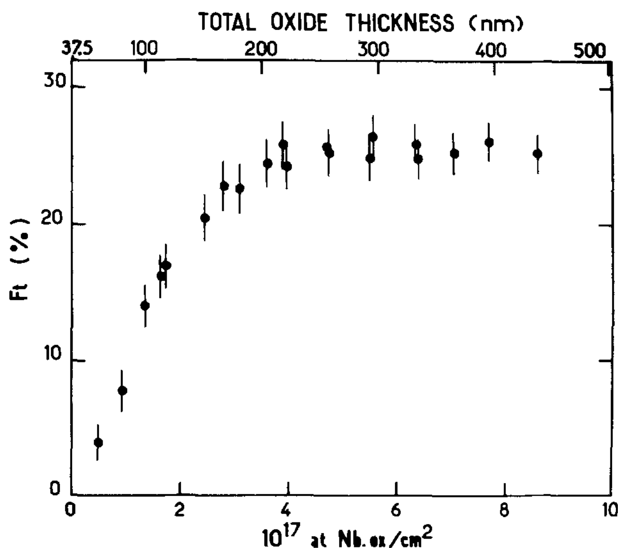

Fig. 7. Variation of F_t with niobium consumption for 15 nm thick Ta films on niobium oxidized at $T = 23°C$ and $i = 5$ mA/cm^2. The absolute errors on each point are shown by the error bars.

Note that F_s and F_t are a measure of the rate of burying of the tantalum atoms present in the surface region or in the tantalum network (region X) respectively. The difference between the values of F_s and F_t (0.10 and 0.25) is too high to be explained by measurements errors. Thus we may deduce that tantalum atoms present in the external part of the oxide mixture take part in cationic events whatever the oxidation potential.

Influence of the electric field.—F_t max was measured as a function of electric field. These experiments were performed on samples, with a 15 nm thick tantalum deposit, oxidized at 140V. During anodic oxidation of pure niobium or tantalum, an exponential-type relationship exists between the electric field, temperature, and current density. We may reasonably assume that the same relationship exists when we oxidize the niobium substrate at oxidation potentials corresponding to the linear region 3 of the $V = f(t)$ curve, regime in which dV/dt has the level expected for pure niobium anodization (see Fig. 2). Moreover, in this regime, F_t is constant and equal to F_t max (see influence of oxidation potential). Thus, the oxidation potential in these experiments (140V) was such that this regime was reached, and this was checked for each sample by recording the oxidation potential as a function of time during anodization.

Two kinds of experiments were carried out to study the influence of the electric field. The F_t max values were measured as a function of current density for constant temperature (23°C) and as a function of temperature for constant current density (5 mA/cm^2).

Figures 8 and 9 show that F_t max values increase linearly with the logarithm of current density and decrease with temperature. F_t max varies from 21 to 26% when the current density changes from 0.1 to 10 mA/cm^2 and from 23 to 27% when temperature decreases from 50° to 0°C. The relationship between F_t and current density seems to indicate that F_t is a linear function of electric field. The decrease of F_t with temperature is also likely to be due to the corresponding variation of the electric field, in the range of electric field studied in these experiments.

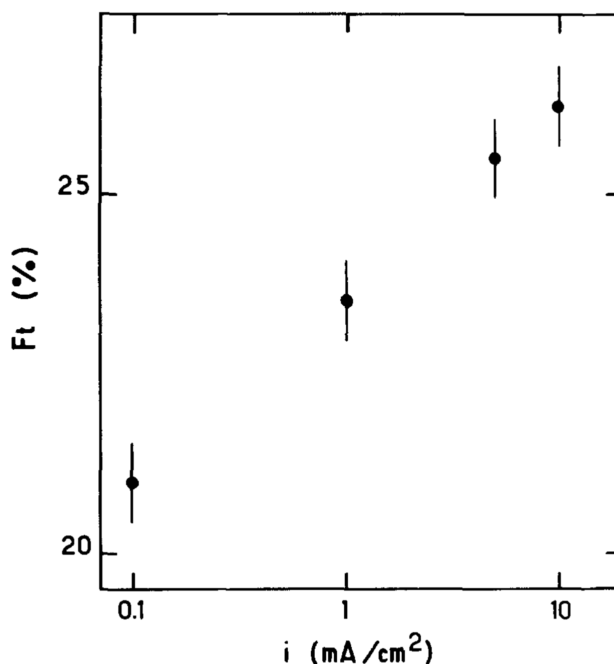

Fig. 8. Variation of F_t as a function of current density for 15 nm thick tantalum films on niobium oxidized at $T = 23°C$ and $V = 140V$. The relative errors from one point to another are shown by the error bars.

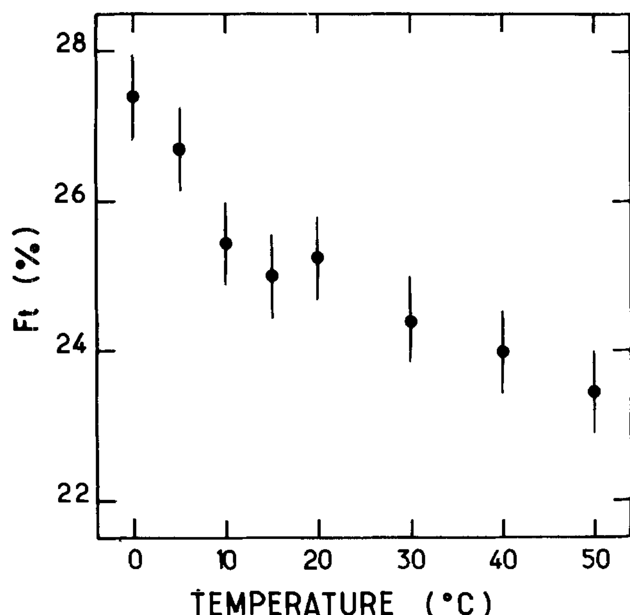

Fig. 9. Variation of F_t as a function of temperature for 15 nm thick tantalum films on niobium oxidized at $i = 5$ mA/cm^2 and $V = 140$V. The relative errors from one point to another are shown by the error bars.

Influence of tantalum deposit thickness.—Three kinds of samples were distinguished as a function of tantalum deposit thickness: (*i*) 6-40 nm. One may reasonably assume that a continuous metallic film covers the niobium substrate (32); (*ii*) (10^{14}-10^{15} at./cm^2) equivalent to the order of 0.1 nm. One may assume that anodic oxidation of this kind of samples is similar to that of pure niobium and that niobium oxide network is formed, tantalum being present as traces; and (*iii*) 1-4 nm. This is too small to ensure the presence of a continuous metallic film on the substrate (32), and too high to be considered as traces.

The experiments were carried out at a constant current density (5 mA/cm^2) and at 0°C temperature. For samples (*i*), oxidation potentials were chosen so that constant values of F_t (F_t max) as a function of oxidation potential were reached (see influence of oxidation potential). Oxidation potentials were such that the number of oxidized niobium atoms was the same for all samples (*i*). All the other samples, *i.e.*, (*ii*) and (*iii*), were oxidized at oxidation potentials where the number of oxidized niobium atoms was the same as that chosen for samples (*i*), *i.e.*, $5 \cdot 10^{17}$ at./cm^2 and in all cases, these potentials corresponded to the linear region 3 of the $V = f(t)$ curve (see Fig. 2). This was checked for each sample by recording the oxidation potential as a function of time during anodization. The results of these experiments are presented on Fig. 10.

For samples (*i*) they are expressed by the F_t max values, and for a 15 nm thick tantalum deposit a value of F_s is also presented. One can see that F_t max values are constant, equal to 27%, independently of the thickness of the tantalum deposit.

For samples (*ii*) the burying of the tantalum atoms in the oxide was determined by the shift of the position of the tantalum peak on the backscattering spectra (12). Note that this peak has a practically constant width, indicating that the tantalum atoms remain grouped to within 10 nm (limited by the depth resolution of our measurements). We can express this burying as a ratio $R = L_s/L_{Tot}$, where L_s is the oxide thickness corresponding to the energy shift of tantalum peak, and L_{Tot} is the total oxide thickness. The value of tantalum atoms burying was found equal to 10 ± 3%. Furthermore, experiments were carried out at various oxidation potentials and similar R values

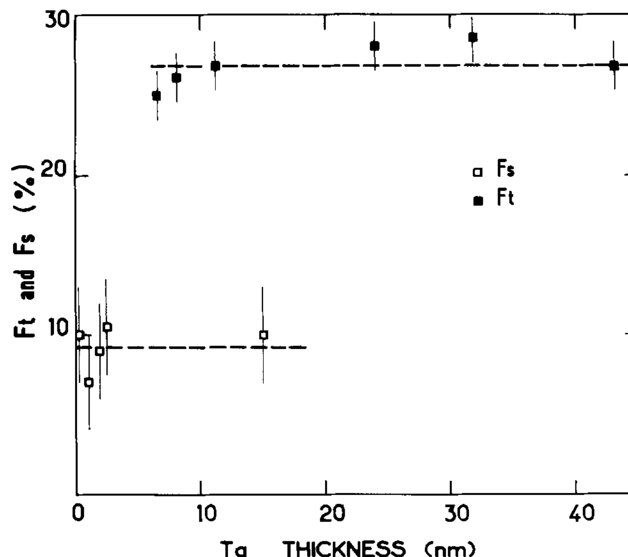

Fig. 10. Variation of F_t and F_s as a function of tantalum deposit thickness. The absolute errors on each point are shown by error bars.

were found in all cases. One can see that R has the same value as F_s for samples with a continuous tantalum deposit (15 nm).

For samples (*iii*), F_s values were measured and are presented on Fig. 10. The F_s values, so determined, appear near to that found for a 15 nm thick uniform tantalum deposit. Furthermore, one can notice that in all cases, F_s is equal to the R value defined for tantalum traces. This strongly suggests that, for a continuous tantalum film, tantalum atoms in the near surface region of the oxide move in the same way as tantalum traces in niobium oxide. Hence it is reasonable to assume that, in this case, the niobium oxide network is formed at the oxide solution interface before a pure niobium oxide layer appears there.

Discussion and Conclusion

We have shown that the anodic oxidation of a niobium substrate covered by a thin tantalum oxide takes place, for oxidation potential higher than 100V, with the same kinetics and leads to the formation of the same stoichiometric oxide (Nb_2O_5) as for pure niobium oxidation. The fraction F_t of niobium cations which crosses the inner edge of the tantalum atom distribution during anodization reaches its saturation value (25% with $i = 5$ mA/cm^2 and $T = 23$°C), for an oxidation potential equal to about 100V, and then F_t is constant for higher oxidation potentials. The F_t values increase with increasing current density and decreasing temperature.

We discuss our results using the concepts previously defined (see results); moreover we assume that the cationic events preserved their identity through the whole oxide. Let us recall that, by cationic events one means the sequence of elemetary jumps, of one or more metallic cations, which result in a transport of charge through the oxide and in oxide growth. This assumption means, thus, that the cationic events, which are initiated at the metal-oxide or oxide-solution interface (depending on the microscopic transport mechanism), result in a transport of charge to the other interface involving only the elementary jumps of metallic cations through the whole oxide. We exclude therefore *a priori*, creation of cationic events in the bulk of the oxide or the transformation of cationic events in anionic events in the bulk of the oxide.

One may notice that, with this assumption, and as any movement of tantalum or niobium atoms against the electric field may be neglected, one may write that F_t represents the minimal fraction of niobium oxide grown by cation migration. The term minimal

means that the possible movement of tantalum atoms under the influence of the electric field is not *a priori* neglected. Moreover, t_m being the transport number of niobium, since F_t is defined as the minimal fraction of niobium oxide grown by cationic movements, the relationship $F_t \leq t_m$ holds. It is interesting to compare the value of F_t with that of t_m measured during pure niobium anodization in comparable experimental conditions. According to Davies *et al.* (3) the value of t_m for niobium is equal to 27%. Let us recall that in the interpretation of our experimental results we have assumed that some tantalum atoms in region X (see Fig. 6) do not take part in cationic events. With this assumption, region X could be used as a reference frame to measure the transport number of niobium implying $F_t = t_m$. Comparison of F_t with the transport number of niobium given by Davis *et al.* (3) shows that F_t is practically equal to t_m (27%), *i.e.*, oxidation of niobium (in the presence of tantalum oxide) takes place with the same value of t_m as for pure niobium oxidation. Although the validity of this conclusion will have to be checked by other more detailed studies of the transport number of pure niobium (as a function of current density and temperature), the present work establishes that the transport number of niobium substrate covered by thin tantalum oxide is equal at least to 25% (at $i = 5$ mA/cm^2 and $T = 23°$C), assuming the preservation of cationic events.

In this work, the description of the results was based on the hypothesis of lateral uniformity of the tantalum and niobium oxide mixture, and was made by using the R, F_s, or F_t measurements. R describes the burying of tantalum traces in niobium oxide as a function of oxidation potentials. One can assume that the anodic oxidation leads in this case to the formation of practically pure niobium oxide network (Ta concentration ~0.5-5 a/o), and that we have measured the value of Ta burying in niobium oxide network in the case of isolated tantalum atoms. It was found that $R = 10 \pm 3\%$. This value is much lower than F_t (25%) and lower than the reported t_m value for pure niobium, 27% (3). This means that in this case, all tantalum atoms in the niobium oxide participate in the growth. As no movement of tantalum atoms in not growing oxide has ever been observed, we can assume that the movement of tantalum atoms is due to cationic events which take place during oxide growth. As a large spread is not observed in the tantalum distribution, we may assume that the tantalum atoms move by a neighbor-to-neighbor jump process. Hence there are two possibilities for niobium atoms: (*i*) all the movements of niobium cations are also of the neighbor-to-neighbor jump process type; or (*ii*) a fraction of niobium cations move by long-range migration (12).

(*i*) In this case, the burying of the tantalum atoms would be due to the difference between jump probabilities of tantalum (P_{Ta}) and niobium (P_{Nb}) atoms during oxide growth. We may write $P_{Ta}/P_{Nb} = (t_m - R)/t_m$, getting the value 0.6 (with $t_m = 0.25$). Let us notice that such an hypothtsis means that the order of cations would be conserved during the anodic oxidation of pure niobium and that no burying of niobium isotopic tracer would be obtained in an isotopic tracer experiment.

The F_s measurements describe the burying of the tantalum atoms in the surface layer of the mixed oxide during anodic oxidation of a niobium substrate covered by a continuous tantalum film (15 nm). It was found that the value of F_s is practically equal to R. So we can assume that these tantalum atoms take part in the ionic current in the same way as tantalum traces in niobium oxide with the same microscopic transport mechanism and that the network formed would be of the niobium type. The formation of pure niobium oxide at the oxide solution interface would be due to the fact that the jump probability P_{Ta} is smaller than P_{Nb} in this part of mixed oxide. One may conclude from these assumptions that the network formed beneath the pure surface Nb_2O_5 region is also of the niobium oxide network type although it contains more than 20% of tantalum atoms.

The F_t measurements describe the burying of the tantalum atoms present in the region X which is assumed to be the tantalum oxide network (Fig. 6). It was found that tantalum concentration (C_{Ta}) in region X is constant ($C_{Ta} = 45\%$) and independent of oxidation potential for potentials higher than 160V. This would mean that P_{Ta} is nearly zero in the tantalum oxide network for $C_{Ta} = 45\%$. However, for oxidation potentials lower than 160V ($C_{Ta} > 45\%$), some tantalum atoms take part in cationic events, *i.e.*, $P_{Ta} > 0$. One may conclude that P_{Ta}, in the tantalum network, is a function of the concentration in tantalum and niobium atoms and changes from $P_{Ta} = 1$ ($C_{Ta} = 100\%$) to $P_{Ta} = 0$ ($C_{Ta} = 45\%$). On the other hand, values of P_{Ta} higher than zero are found in the niobium network for tantalum concentrations equal to about 20% or in the case of traces. These results suggest that the jump probability of tantalum (or niobium) atoms during oxide growth depends not only on tantalum concentration but also on the type of oxide network. Note that the same results could be observed in a slightly different situation: some tantalum atoms would be rigidly locked to the network and would never participate in the cationic movements, their presence being needed to insure the stability of the tantalum oxide network; others would move freely and may be replaced by niobium atoms, the network still keeping its "tantalum network" character. In this case there would exist two different types of cationic sites in the network, in nearly equal proportions; however, this does not seem likely in an amorphous medium. As such a process would lead to a partial reversal of the order of the tantalum atoms during pure tantalum oxide growth, a precise radioactive tracer experiment could allow one to draw definite conclusions.

(*ii*) If we assume that the microscopic transport mechanism of niobium cations is not only of the neighbor-to-neighbor jump process type, the burying of the tantalum atoms would not be due to a difference in jump probabilities, but to the fact that a fraction of the cationic events are of long-range migration type (12). The progressive change in niobium profile with oxidation potential suggests that long-range migration would take place in several jumps. Hence, niobium cations could move in interstitial position, jumping over 2, 3, or more sites, the substitutional jumps of increasing length occurring with decreasing probability. Such an hypothesis should lead to an inversion of the order of cations during the anodic oxidation of pure niobium.

Although our experimental results do not permit a choice between these two possibilities, it seems to us that (*ii*) is less probable since it needs two different microscopic transport mechanisms for niobium and tantalum atoms.

Let us recall that the above discussion is based on lateral uniformity of the oxide, as suggested by preliminary results obtained by electron probe measurements (see above). However, heterogeneity of the oxide structure cannot be excluded in the dimension range lower than our experimental resolution (~4 μm). For example, tantalum oxide could form some islands of microscopic dimensions. The cationic events would pass round them, involving only the niobium atoms. Our present results do not allow us to rule out completely nonuniformity effects.

Acknowledgments

The authors wish to thank Dr. G. Amsel for his numerous comments and suggestions during this work and for his help in writing this paper. The technical assistance of Messrs. J. P. Enard and A. Laurent was much appreciated. The authors are grateful to Dr. C.

Bahezre of the "Laboratoire de Physique des Matériaux" (C.N.R.S. Bellevue) who has carried out the preliminary experiments with the electron probe, and to E. d'Artemare, E. Girard, and M. Vidal for their help in the use of the nuclear microanalysis facility of our laboratory.

The use of vapor-deposited silicon nitride films has been an essential part of the fabrication process for several types of integrated circuits for a number of years (1-3). Hot-wall silicon nitride vapor deposition systems have emerged as a means of meeting the increasing throughput requirements of semiconductor manufacturers.

Generally, hot-wall-type systems utilize a diffusion furnace or similar apparatus. The carrier reactant gases are heated and chemical reactions initiated prior to their reaching the wafers located in the hot zone. Significant variations in film growth rates and in structure can be expected for small changes in operating parameters such as gas species concentration, flow rates, wafer location, temperature, etc. However, the temperature control of a modern diffusion furnace is very precise with temperature variations of less than ¼°C over periods of months. Therefore, in any given system, temperature is the easiest parameter to control. The objectives of the study then were a characterization of silicon nitride film growth rates and properties as a function of gas parameter variations for fixed temperature operations at atmospheric pressures.

Key words: CVD, diffusion, circuits.

Equipment and Procedure

The hot-wall diffusion furnace used in this series of experiments was a single zone, Lindberg Heavy Duty model with 2 in. diam quartz tube. The furnace was set at 875°C and profiled (see Fig. 1). All experiments

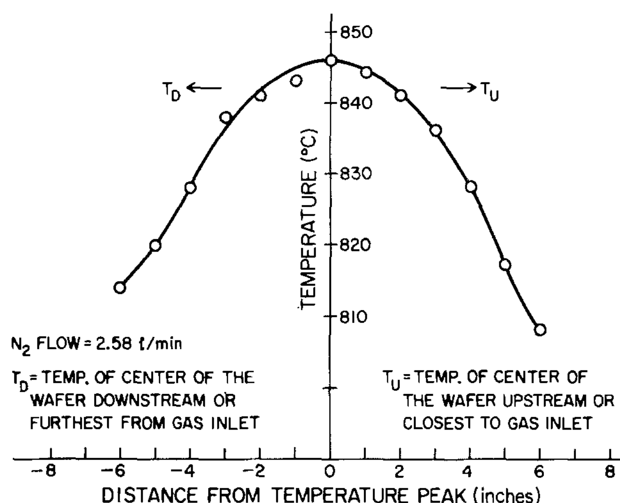

Fig. 1. Temperature profile of Si_3N_4 diffusion furnace with a 6 in. quartz boat centered at the peak temperature.

were conducted with two 1 in. diam <111> polished silicon wafers laid flat (polished side up) on a 1.5 × 6 in. quartz boat. A wafer was placed at each end of the boat on the center line. The boat was placed in the furnace at the thermal and physical center. The maximum temperature gradient across a wafer was determined to be 1.4°C. All furnace operations included a 5 min warm up period. Gas flow rates through the furnace were monitored and controlled using Brooks flowmeters. Nitrogen was obtained from the boil off of liquid nitrogen and the silane and ammonia were electronic grade.

The refractive index of the films grown on the silicon test wafers was determined using an Applied Materials ellipsometer, and the film thicknesses were determined both optically and mechanically. The optical technique used monochromatic light (Sodium-D) and involved counting interference fringes at steps between grown film areas and portions of the silicon slice from which the film had been removed. The mechanical method used a Sloan Corporation DekTak. Film thicknesses as measured by the two methods were within ±5%.

Experimental Results

Based on a number of earlier experimental runs, not reported on here, a set of flow rates for the silane ($SiHy_4$), ammonia (NH_3), and the carrier gas (N_2) which produced "satisfactory" silicon nitride films existed in our laboratory. These values were selected as a starting point. The time of growth in the furnace was then varied, with the results as shown in Fig. 2. The refractive indexes of all films were between 1.90 and 1.95. The data of Fig. 2, when linearly extrapolated to zero thickness, indicate an approximate nucleation period, before growth, of between 15 sec (for upstream wafers) and ½ min (for downstream wafers). Here upstream refers to those wafers between the gas inlet and the furnace center.

The growth period was then fixed at 5 min, and the flow rate of the carrier gas (N_2) was varied while maintaining the SiH_4 and NH_3 flow rates constant. These data are presented in Fig. 3. Note that for upstream wafers a maximum exists in the film thickness as a function of a nitrogen flow rate, and that the growth rate for wafers closest to the gas inlet is much higher than that for wafers downstream. The refractive index of all films grown in this portion of the investigation lay between 1.85 and 1.95.

The next experiment, as shown in Fig. 4, held the growth time, nitrogen flow rate, and ammonia flow rate fixed, as specified. The silane flow rate was varied so as to vary the ammonia-to-silane ratio. The data for the upstream wafers indicate that the process has

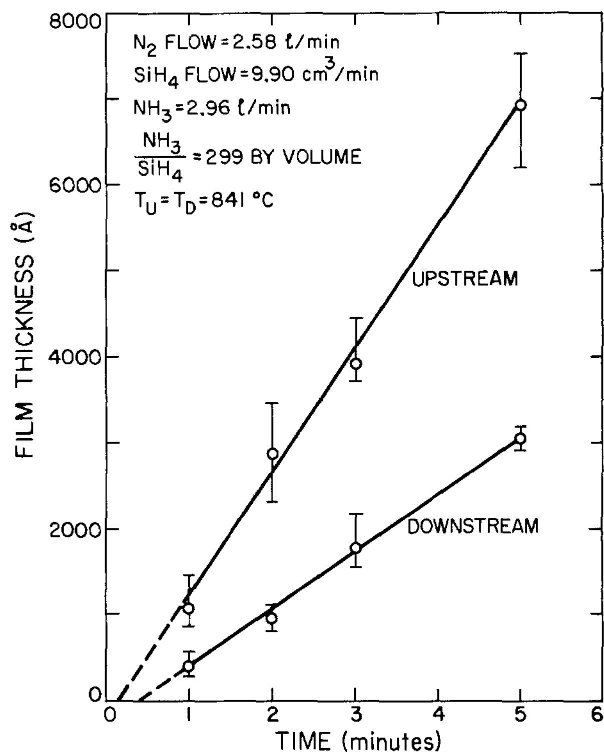

Fig. 2. Silicon nitride film thickness *vs.* time. Bars on data points indicate degree of uncertainty of data. Circles indicate average data.

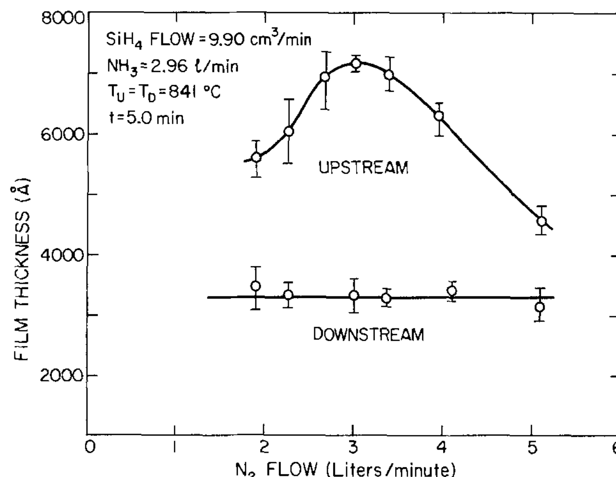

Fig. 3. Film thickness *vs.* nitrogen flow rate. Bars on data points indicate degree of uncertainty of data. Circles indicate average data.

several "type" reactions. For low ammonia-to-silane ratios, the growth rate is high. At intermediate ratios (region II) the growth rate is stable over a wide range (3/1) of flow ratios. This is attributed to a combination of the availability of the required chemical constituents at the wafer surface and the rate at which their reaction and the subsequent "siting" of the silicon nitride on the surface of wafer is carried out. In region III the ammonia-to-silane ratio is in excess of 300 and the reaction decreases, owing to a deficiency of silane. The data for the downstream wafers indicates that the process in this region remains in a "silane deficient condition" reaction for all silane: ammonia ratios. In regions I and II the bulk of the silane is reacting upstream, the silane reaction gradually shifting towards the downstream end as an increasing percentage of the silane is swept past the upstream wafer before it can react. In region III the entire tube is "silane deficient" and thus cannot support rapid silicon nitride growth.

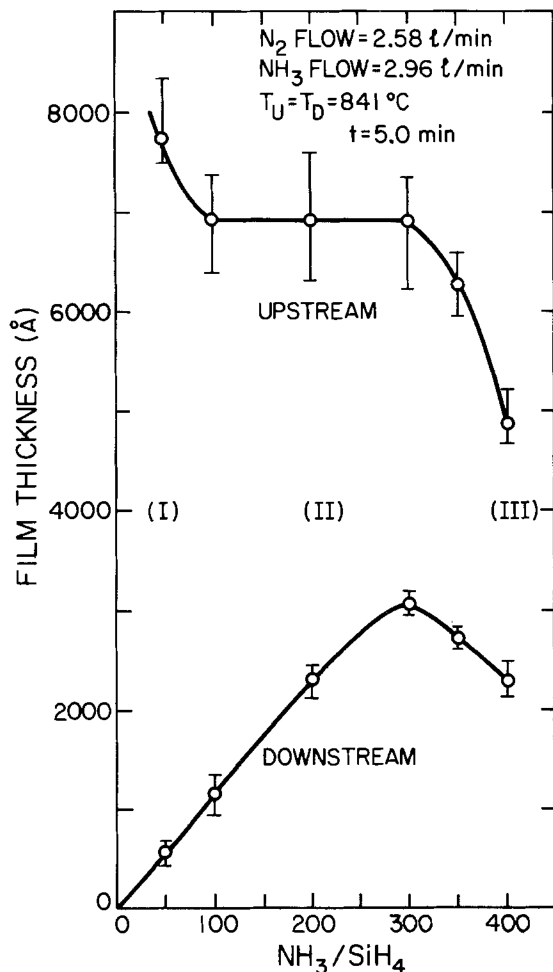

Fig. 4. Film thickness vs. ammonia:silane ratio. Bars on data points indicate degree of uncertainty of data. Circles indicate average data.

Refractive index measurements on all films were between 1.86 and 1.95 for this phase of the experiments.

The final growth rate variations, as shown in Fig. 5, involved fixing the carrier gas (N_2) flow rate, the ammonia-to-silane flow ratio (NH_3/SiH_4), and varying the total volume of ammonia and silane. Again the growth period was 5 min. The refractive index of all films was checked and found to vary between 1.90 and 1.95.

A major use for silicon nitride in semiconductor processing is as a mask against silicon oxide growth. Representative silicon nitride films from this collection of experiment, of thickness 750, 1000, and 2000Å, were placed in an oxidation furnace. An oxidation, employing oxygen saturated with water vapor at 95°C, was carried out at 950°C for a period of 6 hr. After stripping the silicon nitride film in hot phosphoric-acid, no sign of an oxide on any of the silicon wafers was detected, either optically or chemically.

Discussion and Conclusions

As stated previously, excellent agreement (within ±5%) was found for silicon nitride film thickness measurements made both mechanically and optically. In addition, the variation in uniformity of the deposited film across any individual wafer was within ±3% in all cases. However, the variation in film thickness from run to run for wafers in the same location and under measurably identical conditions was within ±15%, in-

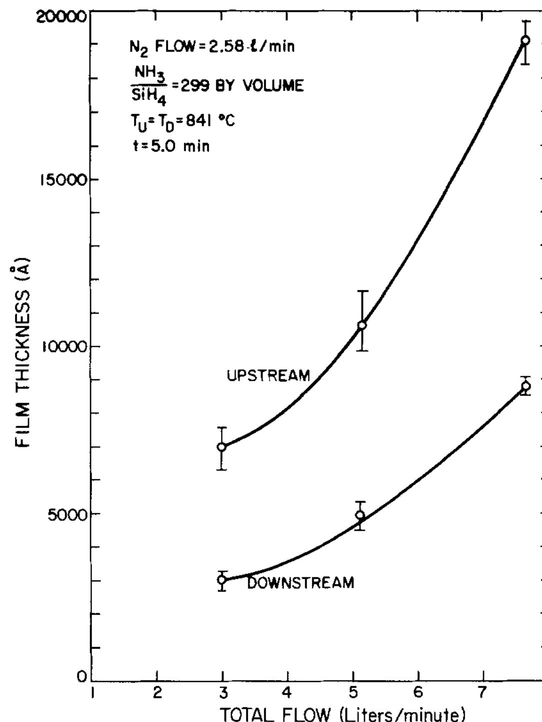

Fig. 5. Film thickness vs. total gas flow. Bars on data points indicate degree of uncertainty of data. Circles indicate average data.

dicating system instabilities. An attempt was made to correlate film thickness to chemical etch rate, employing a chemical etch of hot phosphoric acid. No correlation in etch rate for any of the samples was obtained even for samples grown under the "same" conditions. Since the etch rate of the silicon nitride films depends strongly on the structure of the film, and since the film structure depends on minute variations in gas flow patterns as well as gas composition, the results suggest that the films may possess significant difference in structure and composition.

Analysis of the refractive index measurement data revealed small variations of the index within individual wafers but significant variations among wafers of the same run and of different runs. Due to these variations it is likely that the films have considerably different structural properties. The slices closest to the gas inlets tend to have higher film growth rates and a wider range of film thickness for any given set of conditions. This is indicative of a strong "deficiency mechanism" in which most of the silane has prereacted prior to reaching downstream wafers. Even though individual film characteristics vary, hot-wall process silicon nitride films as thin as 750Å are effective in blocking oxidation of the underlying silicon surface for periods in excess of 6 hr at 950° in wet ambients.

Surface Morphology of GaAs Layers Grown by Electroepitaxy and Thermal LPE

Y. Imamura,[1] L. Jastrzebski, and H. C. Gatos*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

It was found that terraces commonly present on GaAs layers grown by standard (thermal) LPE were not present on layers grown by electroepitaxy. A comparison of the surface morphology obtained by the two methods was based on layers of the same thickness grown in the same apparatus, with the same average growth rates, on substrates having the same orientation (and electrical properties) and from solutions equilibrated at the same temperature. Growth in thermal LPE is induced by a temperature decrease; in electroepitaxy growth is initiated and sustained by passing electric current across the growth interface while the temperature of the growth system is maintained constant (1).

In electroepitaxy the growth process is controlled by electromigration of solute toward the growth interface and the contribution of the Peltier effect is negligible when appreciable convection in the solution is not present (2). Since the origin and nature of supersaturation in thermal LPE and in electroepitaxy are different, a comparision of the surface morphology of layers obtained by the two methods could elucidate the dependence of surface morphology on parameters of the growth process. The comparison is confined to epitaxial layers with the commonly used (100) crystallographic orientation.

Electroepitaxial growth was carried out in a standard LPE apparatus modified to permit controlled flow of electric current across the growth interface (3). Semi-insulating Cr-doped substrates were used. They were prepared by a standard procedure described elsewhere (4); their orientation was (100) within less than 0.1°. A uniform electrical contact on one side of each substrate was made employing a thin layer of Ga (3). The growth area was 0.5 cm^2. Interference of convection in the solution with the growth process was eliminated as described elsewhere (3). Consistent with the criteria for electromigration-controlled growth (2), the microscopic growth rate was found to be the same in experiments carried out at the same current density but employing substrates with a large difference in thickness (*i.e.*, 250 and 2500 μm).

The surface morphology of a 10 μm thick, Ge-doped ($p \simeq 2 \times 10^{18}/\text{cm}^3$) layer, grown in 11 min on a 450 μm thick substrate at 900°C from a solution with a height of 1 cm at a current density of 20 A/cm^2 is shown in Fig. 1. The layer exhibits no terracing (Fig. 1a) commonly encountered on layers grown by thermal LPE (5-8). The only detectable defects on the layer of Fig. 1a are small pits of very low density. As seen from the interferogram in Fig. 1b, that layer is flat.

A number of parameters which might affect the surface morphology were studied, such as thermal gradients in the solution, thickness of the epitaxial layer, solution height, and current density. Only one parameter was varied at a time; the other parameters, unless otherwise specified, were as indicated for the growth of the layer shown in Fig. 1. Thus, the vertical thermal gradient in the solution was varied from 0.3° to 2.7°C/cm, by varying the thickness of the substrate from 250 to 2500 μm for a current density of 10 A/cm^2 (cooling at the interface increases with substrate thickness) (9). Prior to current flow the vertical thermal gradient in the solution was less than 0.15°C/cm and the horizontal less than 0.1°C/cm. Growth was initiated either after the substrate and the solution, equilibrated at 900°C, were brought into contact (as in the case of the layer shown in Fig. 1) or after the solution, thermally equilibrated at 901.5°C (over a dummy substrate), was brought into contact with the substrate which was equilibrated at 900°C (in this case the substrate was partially backmelted). The thickness of the grown layers was varied from 8 to 70 μm. The solution height was varied from 1 to 1.4 cm. Finally, the current density was varied from 5 to 50 A/cm^2, corresponding to a growth rate variation from 0.4 to 4.5 μm/min.

The surface morphology of the layers grown under all of the above experimental conditions was essen-

Fig. 1a. Nomarski interference contrast photomicrograph of the surface of a GaAs layer 10 μm thick, grown at 900°C under 20 A/cm^2; (290 times).

Key words: surface morphology, GaAs, electroepitaxy, LPE.

tially indistinguishable from the surface morphology of the layer shown in Fig. 1. The occasional appearance of defects such as dishes or hillocks were invariably related to defects in the electrical contact of the substrate (3). It is, thus, concluded that, over a broad spectrum of growth conditions, GaAs layers grown by electromigration-controlled electroepitaxy are flat and exhibit no terracing or other morphological defects.

For the growth of layers by thermal LPE, the same apparatus, experimental conditions, and procedures were used as for electroepitaxial growth. After equilibration at 900°C the temperature was decreased at a controlled rate so that the average growth rates were comparable to those obtained by electroepitaxy. The surface morphology of a layer grown from 900°C by lowering the temperature is shown in Fig. 2. The layer, as the one shown in Fig. 1, is Ge-doped ($p \simeq 2 \times 10^{18}/cm^3$), 9 μm thick, and was grown in 10 min from a solution with a height of 1 cm, on a 450 μm thick substrate cut from the same wafer used for substrate of the layer shown in Fig. 1. It is seen that the surface of the layer shown in Fig. 2a exhibits terracing and is not flat as shown in the interferogram in Fig. 2a.

As in electroepitaxy, a number of parameters were varied in studying the surface morphology of layers grown by thermal LPE. Thus, layers were grown on partially melted substrates and on substrates which were not backmelted (as in the case of the layer shown in Fig. 2). The thickness of the grown layers was varied from 9 to 70 μm and the solution height from 1 to 1.4 cm. Finally, the growth rate was varied from 0.3 to 4 μm/min. The surfaces of all layers exhibited terracing similar to that shown in Fig. 2a; small (but not systematic) variations in the spacing of the terraces were observed among some layers.

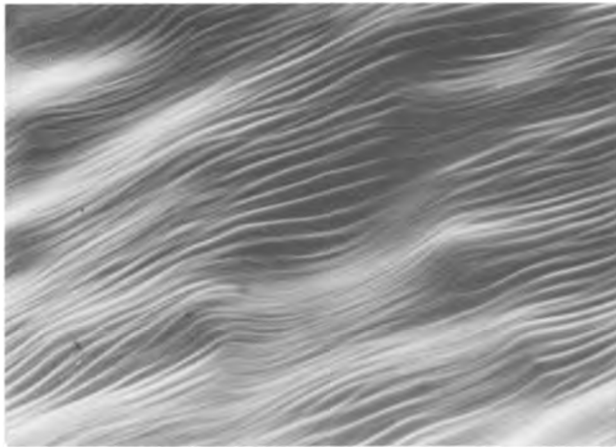

Fig. 2a. Nomarski interference contrast photomicrograph of the surface of GaAs layer 9 μm thick, grown by temperature decrease (thermal LPE); orientation of substrate was identical to that of substrate used for layer shown in Fig. 1 (growth conditions given in text); (290 times).

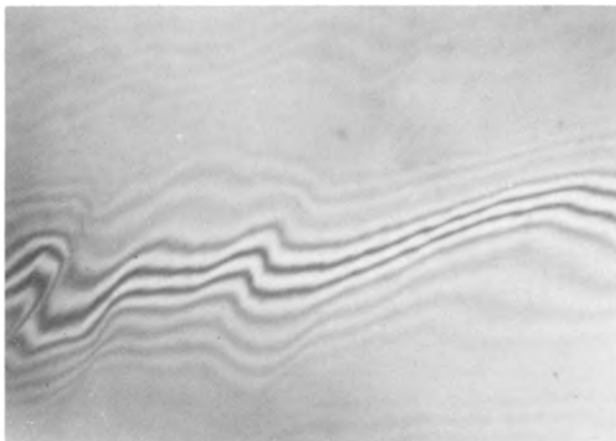

Fig. 2b. Interferogram of the same area shown in Fig. 2a

In view of the above results, the pronounced differences in the surface morphology of the layers grown by electroepitaxy and of those grown by thermal LPE cannot be attributed to specific growth conditions. Rather they must be associated with fundamental differences in the growth mechanisms involved in the two growth methods. Since quantitative models of nucleation and growth have not been established for these methods, the present results are considered in the light of some general features characterizing the methods.

In electroepitaxy supersaturation takes place in the immediate vicinity of the growth interface and growth is controlled by the rate of transfer of solute, under an electric field, to the interface (electromigration-control); the contribution of the Peltier effect is negligible (2). In fact, for a given temperature, the growth rate is directly proportional to the current density (*i.e.*, to the electric field). Under these conditions growth must take place under nearly equilibrium (isothermal) conditions and interface instabilities due to constitutional supercooling cannot occur. On the other hand, in thermal LPE supersaturation is induced throughout the solution and nucleation takes place not only on the substrate but, to some extent, also on the walls of the solution container. Unless special precautions are taken (10), random nucleation, fluctuations in solute concentration, and/or temperature gradients and constitutional supercooling are potential causes of nonuniform growth leading to terraced surface morphology.

In conclusion, in electromigration-controlled electroepitaxy, the steady-state and uniform transfer of solute to the growth interface under isothermal conditions leads to uniform growth and flat terrace-free surface morphology.

Dynamic X-Ray Diffraction

R. R. Chianelli, J. C. Scanlon, and B. M. L. Rao*

Exxon Research and Engineering Company, Linden, New Jersey 07036

ABSTRACT

The discharge of a TiS_2 electrode in an ambient temperature Li/TiS_2 organic electrolyte cell has been investigated by dynamic x-ray diffraction. The new technique involves a continuous *in situ* measurement of x-ray diffraction simultaneous with electrochemical polarization. The investigation has provided additional information on electrolithiation of TiS_2. These include: (*i*) the onset of changes in 101 peak position right from the start of discharge, (*ii*) correspondence of x in Li_xTiS_2 to state-of-charge from coulombic balance; and (*iii*) details of changes in the c axis during discharge, especially during the first 30% of discharge capacity. The results are discussed along with the cell design, operational details, and merits and limitations of the technique.

X-ray diffraction is a well-known technique for the analysis of composition and structure of electroactive solids used in batteries. Most of the previous work involves isolating the electrode from the environment before and after electrochemical polarization and subjecting the sample to x-ray analysis. In so doing, there is always the possibility that some details may be lost during the isolation of the electrode from the electrochemical environment and/or during the treatments needed for preparation of the sample for x-ray diffraction. This limitation could be overcome if *in situ* x-ray diffraction analysis could be carried out on electrodes in an operating cell. This would also have the advantage of gaining insight into intermediates and/or products formed during the dynamic conditions of current flow.

In this report, we have developed procedures for *in situ* x-ray diffraction of electrodes in an operating cell. We have termed the new technique dynamic x-ray diffraction (DXD) to signify x-ray diffraction measurements under dynamic conditions in which changes in micro- or macrocrystallinity, stoichiometry or composition of the electroactive material occur due to electrochemical polarization.

Recently there has been growing interest in intercalation compounds as positive active materials for lithium-nonaqueous electrolyte cells. In this context, TiS_2 has been the subject of intense investigation on physical, chemical, and electrochemical (1-6) properties. In an effort to gain further insight into the intercalation mechanism of lithium in TiS_2, we have undertaken the dynamic x-ray diffraction studies. The experimental set-up, cell design, and the technique is general enough to be applicable to similar investigations on other systems.

Experimental

Setup and operation.—The experimental setup consisted of an x-ray diffraction unit operating in conjunction with an electrochemical polarization circuit, as shown in Fig. 1. Copper-K_α radiation from a Phillips powder diffractometer was collimated onto the test electrode of an electrochemical cell mounted in a specially designed sample holder. The diffracted wave was received by x-ray electronics and analyzed in the usual manner. For the dynamic measurement the test cell was rotated to continuously scan between predetermined Bragg angles $2\theta_1$ and $2\theta_2$, back and forth, while carrying out the electrochemical measurement. Thus the changes in the position and intensity of the peaks followed as a function of coulombs of electrochemical change identified the changes in nature and concentration of the species undergoing the electrochemical reaction.

Specific materials and procedures.—The dynamic x-ray diffraction of a TiS_2 electrode in a cathode limiting Li/TiS_2 cell was investigated. In a typical experiment, the 100, 002, and 101 peaks of TiS_2 were scanned. These three peaks provided (7) a convenient check on the "a" and "c" lattice parameter as a function of state of charge during the electrochemical polarization of the cell. The scanning was performed in a 15 min/cycle at a rate of 1°/min in an automatic repeat sequence starting from 28° ($2\theta_1$) until 35° ($2\theta_2$).

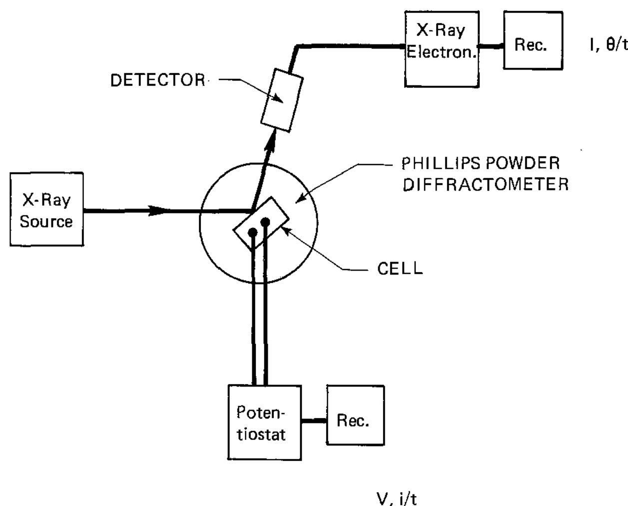

Fig. 1. Experimental arrangement

* Electrochemical Society Active Member.

Key words: lithium anode, TiS_2 cathode, organic electrolyte, *in situ* x-ray diffraction.

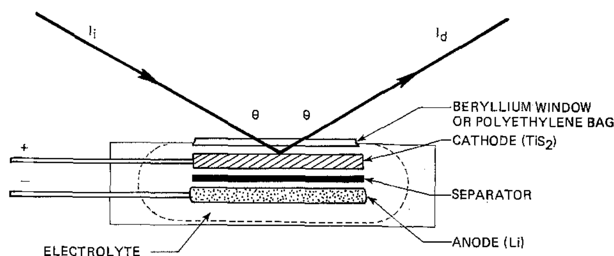

Fig. 2. Schematic of x-ray diffraction cell

Figure 2 gives a schematic representation of the Li/TiS_2 cell used in parallel plate configuration. The anode was 200 mA-hr lithium foil and the cathode was a pasted-plate TiS_2 electrode of 80-160 mA-hr loaded on 5 cm^2 nickel grid. The TiS_2 used was prepared from the elements and the electrodes contained 10 w/o polytetrafluoroethylene binder. The cells contained 65% porous fiber glass separator (0.0375 cm thick) and 0.5-1.0 ml 2M $LiClO_4$ in dioxolane electrolyte. The cell casing was either a polyethylene bag or an aluminum and polytetrafluoroethylene casing, as described later. The cells were assembled in a helium dry box and then mounted in a specially designed cell holder that would enable alignment of the test electrode in the optical path of x-ray in the diffractometer.

In the case of the polyethylene bag cell, the x-ray radiation impinged on the TiS_2 electrode by penetrating polyethylene film (0.005 cm) and the surrounding electrolyte, both of which are noncrystalline. With this cell, the polyethylene film contributes intense scattering in the region 15°-28° (2θ), making observation of the Bragg peaks difficult. However, preliminary experiments did permit observation of the 101 reflection as a function of electrochemical state of charge.

To overcome these difficulties, a second cell was designed (Fig. 3) with a beryllium x-ray window which permitted TiS_2 Bragg peaks to be analyzed with greater precision than the polyethylene bag cell. In this design, the Li/TiS_2 was an integral part of the cell holder. The cell holder comprised an aluminum (bottom) and polytetrafluoroethylene (top) casing which housed the electroactive elements, *i.e.*, Li/TiS_2 cell, and contained an electrolyte fill port. The top and the bottom were held under compression with an EPR gasket and set screw assembly, as shown: The polytetrafluoroethylene top had cemented to it a 50 μm thick beryllium window that is transparent to x-ray beam in the region of 10°-35° 2θ. We recognize that although the sharp beryllium metal peaks did not interfere with TiS_2 lines in this experiment, there might be a problem in other investigations based on this technique. Appropriate modification of x-ray window is recommended in such cases.

It is to be noted that at high discharge rates, nonuniform discharge may occur. The relationship between dynamic x-ray data and the electrochemical discharge may then represent quasi-equilibrium under this condition.

Prevention of electrolyte leakage from the cell, alignment of the test electrode in the optical path of the x-ray beam, and proper shielding of the dynamic x-ray arrangement to prevent radiation leakage to avoid hazards to the operating personnel needed special attention in these studies.

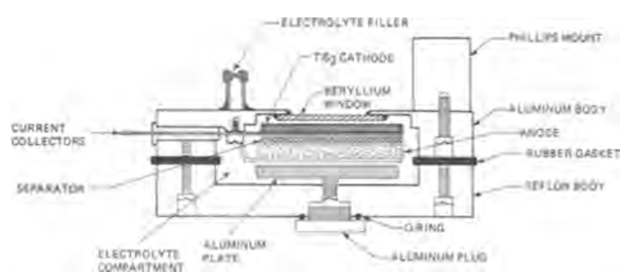

Fig. 3. Schematic of x-ray diffraction cell with beryllium window

Results and Discussion

The depth of penetration of CuK_α radiation is assessed to be ~ 50 μm of the 700 μm thick TiS_2 electrode used in test cell. Thus, the changes in Bragg peak position and intensity observed during the dynamic x-ray diffraction measurements reflected the changes in the composition and crystal structure occurring in ~10% depth in thickness as measured from the position away from the lithium electrode, *i.e.*, back side of the electrode. The x-ray spectra taken prior to switching on of the electrochemical circuit served as internal standard for the calibration of the cell.

Figure 4 represents the 101, 002, and 100 Bragg peaks of a TiS_2 electrode as measured before and after discharge of a positive limiting Li/TiS_2 cell at 1 mA/cm^2. The observed continuous variation of lattice spacings as x in Li_xTiS_2 changes from 0 to 1 during the chemical reaction (1)

$$x\text{Li}^+ + \text{TiS}_2 + xe \rightarrow \text{Li}_x\text{TiS}_2, \quad 0 \geqq x \leqq 1$$

is represented in Fig. 5. Data in Fig. 5 indicate that 002 has the greatest variation with state-of-charge of TiS_2 and 100 the least. The 101 has intermediate variation, but is the most intense line and provided greater ease of measurement. Consequently, all analyses of the results are presented with reference to varia-

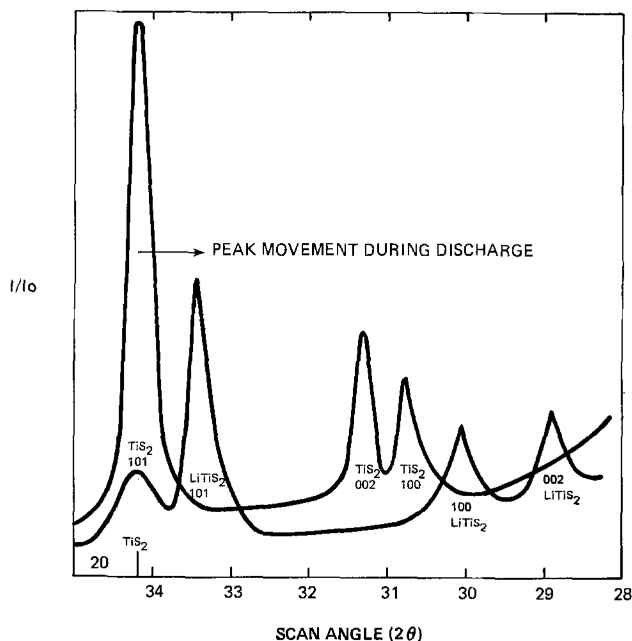

Fig. 4. Movement of Bragg peaks observed during discharge of TiS_2 to form $LiTiS_2$.

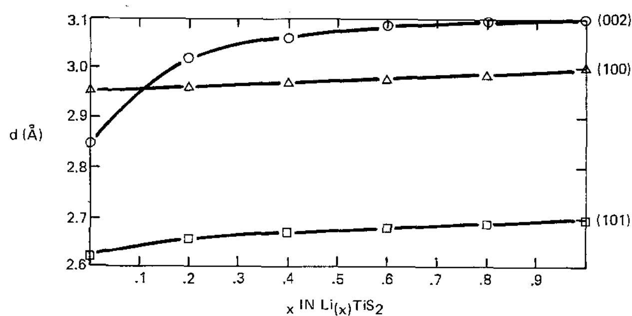

Fig. 5. Variation of 002, 001, and 101 Bragg peaks as a function of x in Li_xTiS_2 ($0 \geqq x \leqq 1$).

tions in the 101 line from 2.62A for TiS_2 to 2.69A for $LiTiS_2$.

Figure 6, curve a, illustrates the discharge data for a TiS_2 electrode of 156 mA-hr and 4.83 cm^2 area at 1 mA/cm^2. Figure 6, curve b, is a plot of the position of the 101 line measured during the discharge. The test electrode exhibited 90% depth of discharge with an open-circuit voltage of 1.84V after 10 hr of rest following discharge. The position of the 101 line was determined by measuring the relative distance between the position of the 101 line on the up θ scan, and the same line on the down θ scan, as indicated in Fig. 7. This technique permitted the determination of relative line shifts with an accuracy of 0.0015A. Thus, each point in the curve of c axis expansion *vs.* x in Li_xTiS_2, indicated by the percentage depth of discharge in Fig. 6, consists of an average of two points which are approximately 3-4° 2θ apart.

Figure 8 gives the details of the variation of 101 peak as a function of depth of discharge. The 101 line

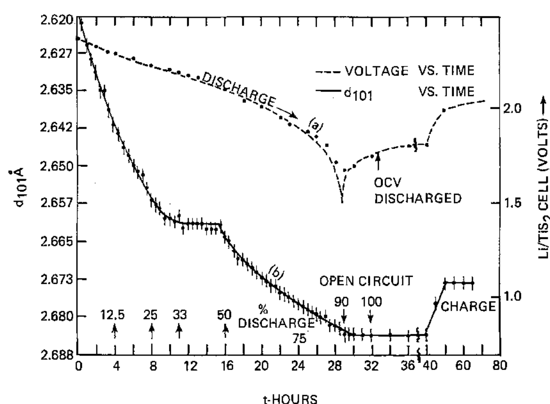

Fig. 6. Comparison of variations in Li/TiS_2 cell voltage with movement of Bragg peaks (d 101) observed during dynamic x-ray diffraction.

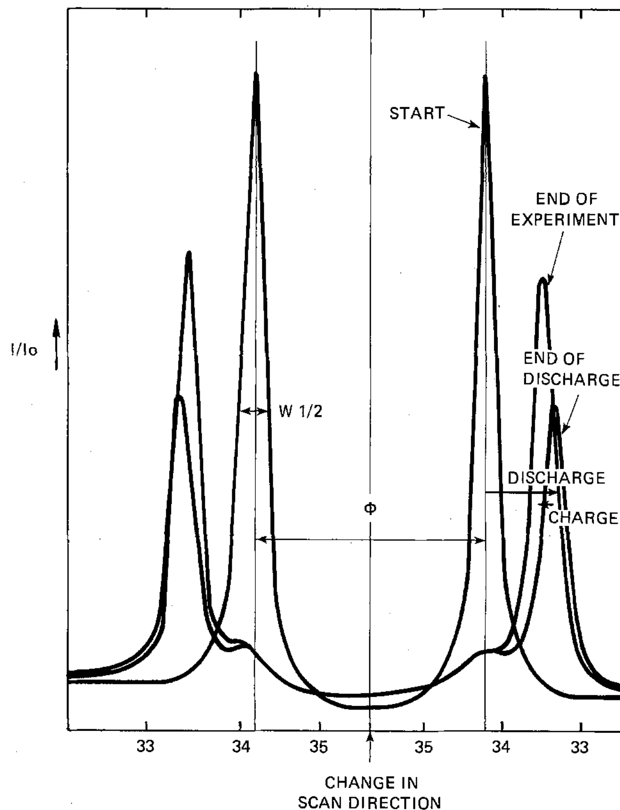

Fig. 7. Dynamic x-ray diffraction scan data used in analysis

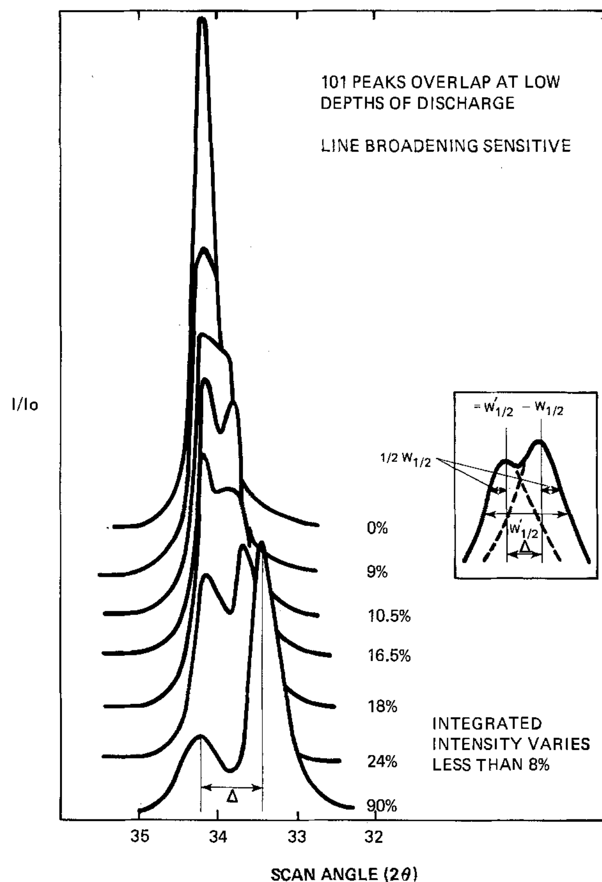

Fig. 8. Variation of Bragg peaks as a function of depth of discharge of TiS_2.

position reflects a change in composition of the test electrode as soon as discharge began. As crystallites of Li_xTiS_2 are nucleated, their contribution to the 101 line begins, resulting in an apparent decrease in intensity and line broadening until splitting of the peaks is noticeable at ~15% depth of discharge. Only after this splitting could the previously described method for determining 101 position be used. Determination of the line position *vs.* state-of-discharge at low depths of discharge was possible from the continuous scan data by measuring the half-height width (W' ½) of combined peaks (*i.e.*, resolved + unresolved) and applying the formula

$$2\theta_{101}(Li_xTiS_2) = 2\theta_{101}(TiS_2) - \Delta, \quad \Delta = (W'\,½ - W\,½)$$

where W ½ is the half-height width of the resolved TiS_2 or Li_xTiS_2 peak, as exemplified in Fig. 7.

One can see from Fig. 9 that up to $x = 0.3$, *i.e.*, 30% depth of discharge, the variation in c-axis expansion is approximately linear. The point of inflection in the region of 12-18% may be attributed to lithium ordering an effect recently reported (9).

Throughout the experiments, the width of the 101 line for a given x in Li_xTiS_2 did not change, but the intensity of the peak decreased. This decrease cannot be explained by calculating the intensity of the 101 line for various compositions in Li_xTiS_2. Because of the low scattering power of lithium atoms, no more than 10% variation is expected in the intensity of the 101 line, whereas a decrease of more than 50% is observed, as seen in Fig. 10(a). Experiments indicated that upon standing on open circuit for 10 hr, this intensity is regained almost to the original value, as indicated in Fig. 10(b). We propose that the observed intensity loss during the discharge is due to intercalated layers which are wrinkled or bent, and therefore do not contribute to the intensity of Bragg peaks. This effect occurs in TiS_2 crystals during chemical lithiation with n-butyl lithium, and has been previously re-

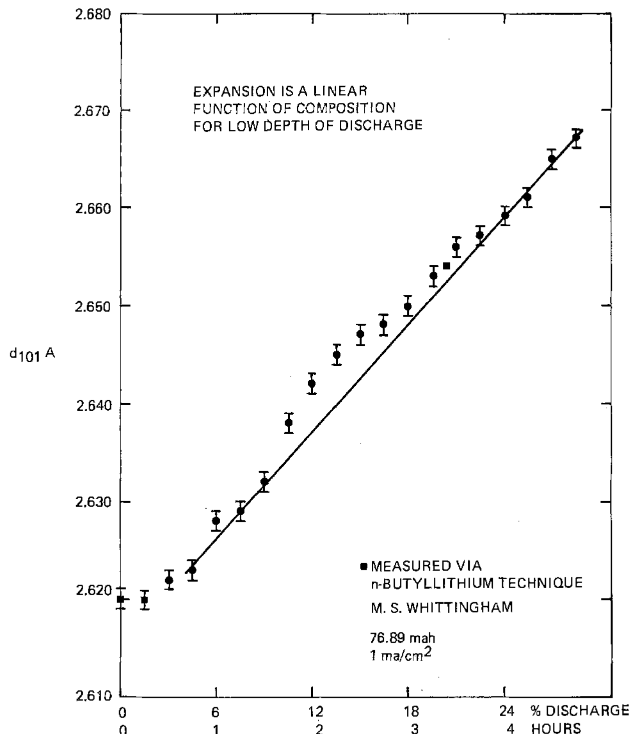

Fig. 9. Lattice expansion data for low depths of discharge

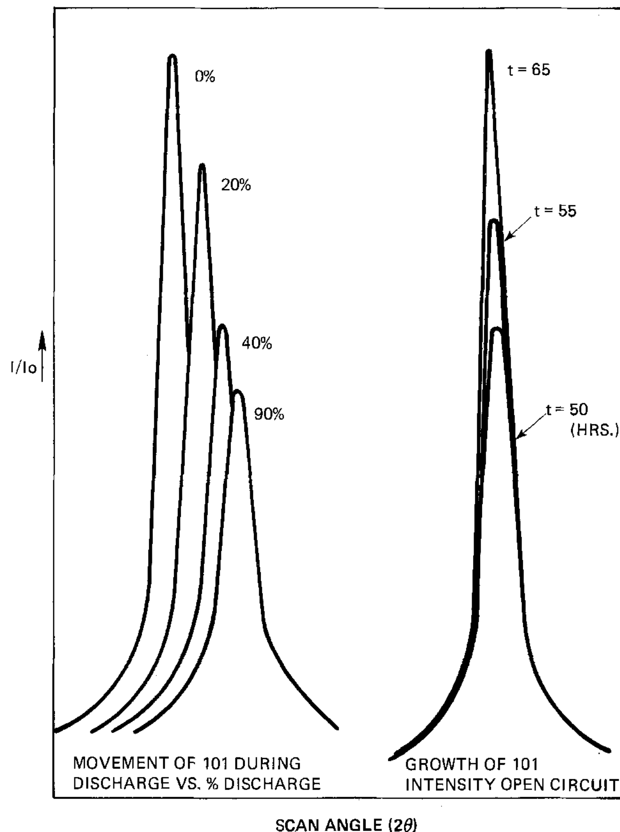

Fig. 10. Movement of 101 Bragg peaks of TiS_2 and growth of 101 peak intensity on open-circuit stand.

ported (8). Upon standing on open circuit, the stressed TiS_2 layers anneal and realign themselves, causing the intensity to be regained.

The charge used for the discharge of the TiS_2 electrode corresponded reasonably well to that expected from an estimate of the electrode composition determined by the x-ray spectrograph presented in Fig. 6. The data indicated that approximately 10 w/o of TiS_2 is left undischarged at the end of the experiment. Unavailability of this material for discharge may be traced to electrode configuration, and is also associated with the technique of preparation, a feature that is commonly encountered in battery electrodes.

A striking feature of the variation of the 101 line position is the pronounced plateau which begins at ¼ discharge and ends at about ½ discharge, as seen in Fig. 6. We believe this to be due to lithium ordering in the TiS_2 layers, and will be discussed in detail in a future publication (9).

Conclusions

The dynamic x-ray diffraction technique is an effective and sensitive method for studying bulk morphology and stoichiometry in solid electrodes. It permits accurate measurement of topochemical structural changes which take place during electrochemical polarization.

The TiS_2 cathode undergoes structural disordering during discharge and shows lattice parameter anomalies which are thought to be due to lithium atom ordering.

Solubility Products of Metal Sulfides in Molten Salts:

Measurements and Calculations for Iron Sulfide (FeS) in the LiCl-KCl Eutectic Composition

Marie-Louise Saboungi,* Jane J. Marr, and Milton Blander*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

An electrochemical titration technique is used to determine the solubilities of Li_2S and the solubility products of FeS in the molten LiCl-KCl eutectic composition in the temperature range from 673° to 773°K. The solubility products of FeS are, on an ion fraction basis, $K_{SP} = 0.44 \times 10^{-12}$, 2.3×10^{-12}, and 1.3×10^{-11} at 673°, 723°, and 773°K, respectively. These values are in good agreement with values calculated *a priori* from an exact thermodynamic cycle; at 723°K, we deduce a value of -38.36 kcal $mole^{-1}$ (or -160.50 kJ $mole^{-1}$) for $RT \ln K_{SP}$, as compared with an experimentally derived value of -38.50 kcal $mole^{-1}$ (or -161.11 kJ $mole^{-1}$). During the operation of the cells at relatively high sulfide compositions, the complex phases Li_2FeS_2 ($\equiv$X phase) and $LiK_6Fe_{24}S_{26}Cl$ ($\equiv$J phase) are formed, as established by x-ray and metallographic analyses. A discussion of their chemical stability in the electrolyte in the temperature range of this study is presented. A moderate change in the activities of LiCl and KCl can influence the formation of the J phase.

In the development and testing of high temperature batteries utilizing iron disulfide (FeS_2) as electrodes and the molten LiCl-KCl eutectic as the electrolyte, some problems have been encountered in cells that have been subjected to extensive charging and discharging cycles (1), namely, lithium sulfide (Li_2S) and iron particles are deposited in the separator, which may lead to a loss of performance or even to cell failure. The mechanism of the formation of the deposits is not yet well understood; one of the hypotheses relates this effect to chemical transport through dissolution in the electrolyte. However, it should be noted that such deposits do not occur in cells having iron monosulfide (FeS) as the active electrode material. To resolve these problems, determinations of the solubilities of Li_2S, FeS, and FeS_2 in the LiCl-KCl eutectic are needed.

We report on an experimental and theoretical investigation of the solubilities of Li_2S and FeS in the molten LiCl-KCl eutectic in the temperature range of operation of the battery (T = 673°-773°K). The experimental method used was an electrochemical titration based on the following reaction

$$Li_2S + FeCl_2 \rightarrow FeS(\downarrow) + 2LiCl \quad [1]$$

During our experimental study, we found that the above reaction is not the only chemical reaction occurring in the solution. More complex sulfide phases (designated as J and X phases) were formed identical to those identified in engineering-scale cells (2, 3). The thermodynamics of FeS, as well as those of X phase ($\equiv Li_2FeS_2$) and J phase ($\equiv LiK_6Fe_{24}S_{26}Cl$), are derived from our data. The solubility product of FeS in the molten LiCl-KCl eutectic is evaluated from the electromotive force measurements (emf) under two different assumptions. In the first, reaction [1] is supposed to occur with no solid solutions involving FeS. In the second, the probable existence of a limited solid solution (4) in the Li_2S-FeS system is taken into consideration; consequently, the precipitate would no longer be FeS but a solid solution of FeS and Li_2S. We find that the solubility product does not vary significantly with either hypothesis. Finally, an exact calculation of the solubility product of FeS is made *a priori*. The value obtained is in good agreement with experiment.

Experimental

Materials.—Anhydrous purified LiCl-KCl eutectic was supplied in 200g ampuls by the Anderson Physics Laboratory, Champaign, Illinois. Lithium sulfide was provided by Eagle-Picher as unsintered powder. Its lithium and sulfur contents determined by chemical analysis were 30.33 (theoretical 30.21) and 69.57 (theoretical 69.79) in weight percent (w/o), respectively; a spectrochemical analysis showed less than 0.4 w/o impurities. Silver chloride of 99.9% typical purity was purchased from Cerac. Finally, anhydrous iron chloride ($FeCl_2$) was prepared on request by the Anderson Physics Laboratory by synthesis from 99.999% purity iron. The slugs were fused in quartz vials sealed under argon. A typical chemical analysis gave 44.44 w/o of Fe^{2+} (theoretical, 44.06 w/o), 44.54 w/o of total Fe (theoretical, 44.06 w/o), and 55.84 w/o of Cl (theoretical 55.94 w/o). At first, after opening a vial, $FeCl_2$ was used without further purification. The remaining $FeCl_2$ was slowly doubly sublimed under vacuum at about T = 773°K to remove Fe^{3+} and any trace of possible contamination by moisture. The distilled product was sealed in fused silica tubes until used.

Experimental procedure.—The cell used in this investigation can be schematized as follows

$$Ag|AgCl\text{-}LiCl\text{-}KCl||LiCl\text{-}KCl(eut)\text{-}FeCl_2\text{-}Li_2S|Fe \quad [2]$$

An outer high purity alumina crucible contained the electrolyte, the eutectic LiCl-KCl, to which were added known amounts of $FeCl_2$ and Li_2S. Alumina proved to be resistant to corrosion by Li_2S provided that no traces of water were present in the melt. The reference electrode consisted of a high purity silver wire (>99.9999%) immersed in a dilute solution [8.4×10^{-3} mole per cent (m/o)] of silver chloride in the LiCl-KCl eutectic melt. The AgCl-LiCl-KCl solution was contained in a Pyrex tube with asbestos fibers sealed in at the bottom. The diaphragm was made by shrinking the Pyrex tubing (½ in. OD) on to a very few asbestos fiber bundles. Electrolytic contact between the Ag electrode and the outside melt was effected through the wetting of the interstices between the fibers by the salt whereas the diffusion of dissolved AgCl was insignificant. The Pyrex tubing was con-

* Electrochemical Society Active Member.

Key words: thermodynamic properties, lithium-sulfur batteries, electrochemical titration, solubilities, solubility products.

tained in a high purity porous beryllia cup to avoid any possible attack and decrepitation of the Pyrex in contact with the sulfides. Results of chemical and spectrochemical analyses showed no evidence of silver leaking from the reference electrode.

The second electrode consisted of an iron rod (1/8 in. diam). Prior to use, the metal was filed in an inert atmosphere in order to remove any oxide coating present on the surface. Both electrodes were connected to a digital voltmeter (input resistance greater than $10^{10}\Omega$) by tantalum leads.[1] For each run, the temperature was held constant within a degree and was measured with a stainless steel (s.s.)-sheathed calibrated (Pt-Pt 10% Rh) thermocouple. The melt was constantly stirred at a uniform speed using a s.s. stirrer. The stirring was extremely important to insure complete and relatively fast dissolution of all added chemicals. Finally the emf's and the temperature were continuously recorded.

Due to the dissimilarities of the electrode materials, a thermoelectric voltage was created. In order to obtain the true electrochemical voltage, the measured voltage of cell [2] should be corrected by subtracting the thermoelectric voltage at the temperature of the experiments (−2.57 mV at $T = 673°K$, −3.03 mV at $T = 723°K$, and −3.55 mV at $T = 773°K$).

The cells were operated by making successive additions of $FeCl_2$ and Li_2S. When only $FeCl_2$ was the solute, the equilibration of the cell with respect to temperature and voltage was rapidly attained, usually in less than 5 min (or 300 sec). Upon addition of Li_2S, solid FeS precipitated and the equilibration of the cells required several hours [as much as 12 hr (43,200 sec)], particularly near the equivalence point. An increase in the temperature by about 50°-100°K helped in achieving faster equilibration. The emf's measured were steady and stable to less than 1 mV for overnight observation periods. The thermal reversibility of cell [2] was checked by temperature cycling. All the operations were carried out inside a glove box filled with helium purified by passage through molecular sieves. The levels of oxygen and water were monitored constantly; there was always less than 1 ppm water and oxygen in the helium.

Results

In all that follows, unless specified differently, the true electrochemical voltage corrected for the thermoelectric potential of cell [2] is reported.

Dilute solutions of $FeCl_2$ in LiCl-KCl eutectic.—Each experiment was initiated by checking the behavior of the iron electrode since the silver-silver chloride electrode has proved to be reversible (5, 6). Tests of the Nernst law were carried out at constant temperature. For dilute solutions of $FeCl_2$ in the LiCl-KCl eutectic, the emf's vary with composition according to the relation

$$E = E°_2 - \frac{RT}{2\mathbf{F}} \ln a_{FeCl_2} \quad [3]$$

where E is the true electrochemical voltage of cell [2]; R, the gas constant; $\mathbf{F}$, the Faraday constant; a_{FeCl_2}, the activity of iron chloride in solution; and $E°_2$, the limiting potential of $FeCl_2$ in the LiCl-KCl eutectic melt *vs.* the silver-silver chloride electrode. In Fig. 1, some typical emf's as read (without the thermoelectric effect correction) are plotted as a function of the ion fraction of Fe^{++} in solution together with the calculated Nernst slopes: $2.3026\ RT/2\mathbf{F}$ where the 2 in the denominator takes into consideration the two-electron process. For each temperature, a least squares fit of the data leads to slopes in excellent agreement with the theoretical slopes (Table I). At $T = 723°K$, combining our value for $E°_2$ with that of the standard formation potential of AgCl in the LiCl-KCl eutectic

[1] The connections Ag-Ta and Fe-Ta were made outside of the crucible, at glove box temperature.

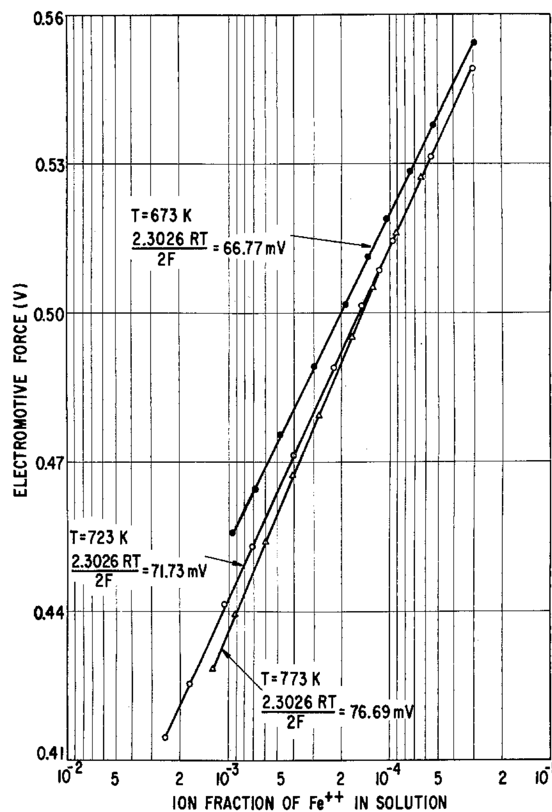

Fig. 1. Electromotive forces of the cell:

Ag|AgCl-LiCl-KCl||LiCl-KCl-$FeCl_2$|Fe (eut.)

for dilute concentrations of $FeCl_2$ at $T = 673°$, 723°, and 773°K. The slopes of the lines are equal to the calculated Nernst slopes: 66.77, 71.73, and 76.69 mV.

as obtained by Laitinen and co-workers (5, 6) and making the appropriate correction for the concentration of AgCl in the reference electrode and the thermoelectric effect, we calculate 1.382V for the standard formation potential of $FeCl_2$ in the LiCl-KCl eutectic melt. This value is in reasonable agreement with that of 1.387V as measured by Laitinen and Liu (6). The difference of 5 mV can easily be ascribed to uncertainties related to the composition of silver chloride in our reference electrode combined with uncertainties in the measurements of Laitinen and Liu (6).

Titration of $FeCl_2$ with Li_2S.—After reaching the desired composition of $FeCl_2$ in the molten LiCl-KCl eutectic, successive additions of Li_2S were made to precipitate sulfides. Around the equivalence point ($X_{Fe} = X_S$ where X_i refers to the total ionic fraction of the ith ion added to the solution), the emf's increase steeply with the concentration of Li_2S. Beyond the equivalence composition ($X_S > X_{Fe}$), the emf's keep increasing but not as steeply. Finally, when the solution is saturated with Li_2S, the emf's reach a final plateau with a constant voltage.

For each temperature, at least three independent experiments were carried out with either a different or the same initial concentrations of iron chloride. In Fig.

Table I. Least squares fitted equation of the true electrochemical voltage of cell [2] for dilute $FeCl_2$ and no Li_2S: $E = E°_2 - m \log X_{Fe^{++}}$

T (°K)	m (theor.) = $\frac{2.3026\ RT}{2\mathbf{F}}$ (mV)	m (exp.) (mV)	$E°_2$ (mV)
673	66.77	66.43 ± 0.13	256.66 ± 0.50
723	71.73	71.18 ± 0.18	231.58 ± 0.67
773	76.69	76.95 ± 0.22	209.09 ± 1.85

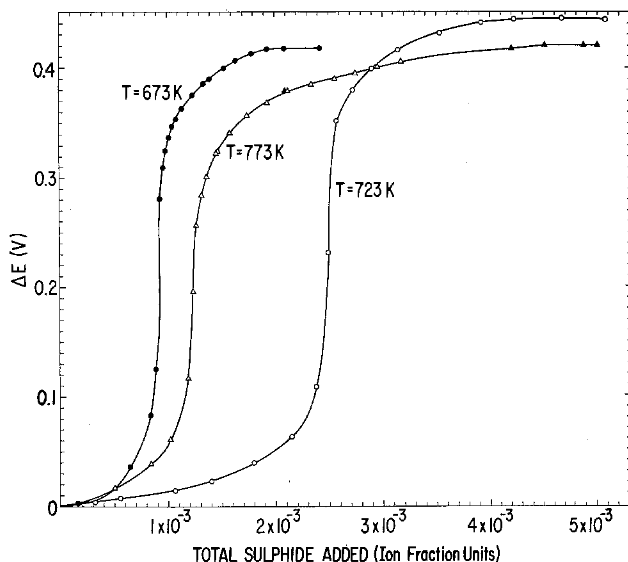

Fig. 2. Variations of the difference between the emf's of cell [2] with and without Li_2S with the total amount of added sulfides, X_S. The two symbols (△, ▲) at $T = 773°K$ refer to results collected from two different experiments. The initial concentrations of $FeCl_2$ are 9.274×10^{-4}, 2.413×10^{-3}, and 1.236×10^{-3} at $T =$ 673°, 723°, and 773°K, respectively. (Note: Saturation was not achieved in the measurements shown at 723°K.)

2, the differences in the emf's emf of cell [2]) − emf of cell [2] with $X_S = 0$) are plotted *vs.* the total sulfide added; the three titration curves shown at 673°, 723°, and 773°K are typical of those from 18 separate experiments. At $T = 773°K$, data collected in two independent experiments with the same initial $FeCl_2$ concentration are plotted to show the reproducibility of the measurements (Fig. 2). In Table II are listed some of the data measured at 673°, 723°, and 773°K.

In order to identify the black precipitate which was formed, separate samples were prepared by the following method. Carefully weighed amounts of the eutectic, $FeCl_2$, and Li_2S were melted and vigorously stirred for several days. They were rapidly cooled and submitted to x-ray and metallographic analysis. Three different phases were reported depending on the temperature and the composition of the solution. Well before the solution became saturated with Li_2S, FeS was the only precipitate to be identified in the temperature range of this study. Therefore, reaction [1] occurs and FeS is formed chemically. As the solution approaches saturation, two other sulfide phases designated by J and X, were identified.

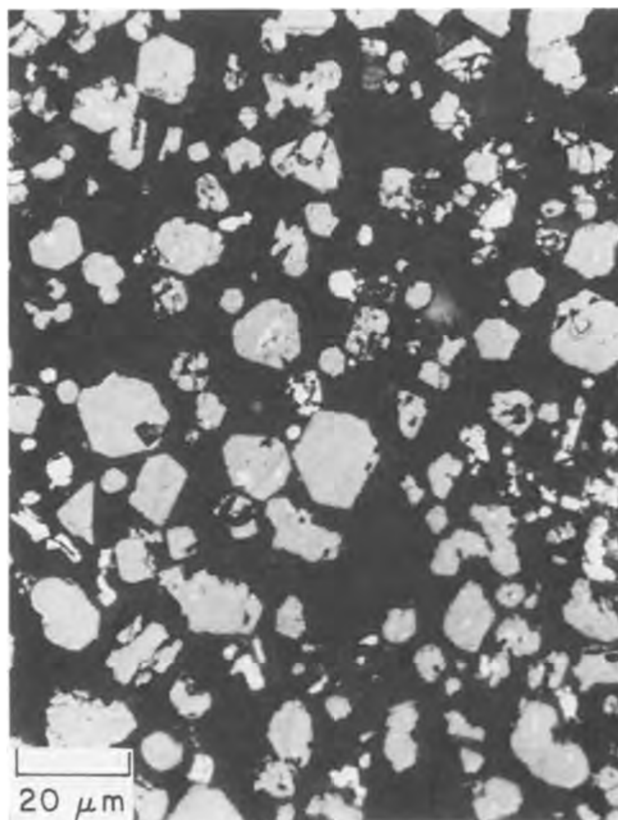

Fig. 3. Typical polished section of material collected at $T = 673°K$ showing the euhedral crystals of the J phase. (Courtesy L. Fuchs.)

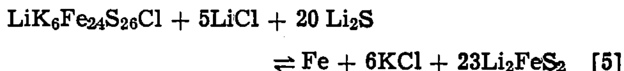
The J phase refers to the mineral djerfisherite with a composition tentatively described as $LiK_6Fe_{24}S_{26}Cl$.[2] A typical polished section of this material is shown in Fig. 3. A possible reaction occurring in the solution is

$$23FeS + 3Li_2S + 6KCl + Fe \rightleftharpoons LiK_6Fe_{24}S_{26}Cl + 5LiCl \quad [4]$$

This complex compound which forms on the iron sulfide electrode in the engineering-scale cells is highly undesirable since it slows the kinetics of the cell reaction to a considerable extent (2). As expected, it has been found that if the electrolyte is replaced by another molten salt mixture such as LiF-LiCl, the J phase does not form.

The X phase refers to the compound Li_2FeS_2 formed in solution according to the reaction



$$LiK_6Fe_{24}S_{26}Cl + 5LiCl + 20\ Li_2S \rightleftharpoons Fe + 6KCl + 23Li_2FeS_2 \quad [5]$$

A typical polished section exhibiting the X phase is given in Fig. 4.

In the temperature range of this investigation, the J phase did form as a precipitate in Li_2S-rich solutions. Except at $T = 673°K$, as the concentration of sulfide in solution increased, a conversion of J phase to X phase (Eq. [5]) occurred. According to metallographic and x-ray analyses, this conversion was noticed in essentially sulfide-saturated solutions at $T = 723°K$ or at relatively high sulfide concentrations at $T = 773°K$.

Results of metallographic and x-ray analyses of numerous samples allowed us to derive, for each tem-

[2] Differences in the analyzed composition of the mineral djerfisherite are given in Ref. (3b). The composition given in this work is commonly used for the J phase formed chemically.

Fig. 4. Typical polished section of material collected at 773°K exhibiting platelets of the X phase. (Courtesy A. E. Martin.)

perature, the concentrations of sulfide ions in solution, N_S^J and N_S^X, above which J and X phases exist respectively.[3] At $T = 673$°K, we have $N_S^J = 1.9\ (\pm 1.0) \times 10^{-4}$ (in mole fraction units); there was no evidence for the existence of X phase even in solutions in which the amount of sulfide exceeded by far the saturation limit. At $T = 723$°K, we have obtained, $N_S^J = 3.8\ (\pm 0.2) \times 10^{-4}$ and $N_S^X = 15.0\ (\pm 1.0) \times 10^{-4}$ and at $T = 773$°K, $N_S^J = 5.4\ (\pm 1.0) \times 10^{-4}$ and $N_S^X = 17.6\ (\pm 2) \times 10^{-4}$. The uncertainties are related to the interval in the composition of samples where either one phase or two coexisting phases were detected.

Finally, at relatively high concentrations of sulfides, we have noticed a progressive appearance of a red-burgundy color, which increases in intensity with the temperature. At low concentrations of sulfides, the solution has no color except for the black precipitate.

Calculations from the Data

The data collected from our titration experiments can be utilized to calculate the solubility products of FeS and the solubility of Li_2S in the LiCl-KCl eutectic solvent. In addition, with the auxiliary data on the concentrations of dissolved Li_2S where the J and X phases first form in equilibrium with FeS, we can also deduce the Gibbs free energies of formation of these phases. As will be seen, the J phase has a marginal stability so that a decrease in the activity ratio of KCl/LiCl in the solvent can prevent the formation of this undesirable phase in the battery electrode.

The solubility products of FeS.—In principle, the solubility products of FeS in the LiCl-KCl eutectic mixture, K_{SP}, can be directly derived from the titration curves such as those shown in Fig. 2. However, in this specific case, we must take into consideration the fact that FeS is not the only precipitate. Therefore, calculations of K_{SP} can be made when no other phases such as J or X are present.

If Henry's law holds for $FeCl_2$, Eq. [3] can be used to calculate, N_{Fe}, the concentration of $FeCl_2$ in solution, ($a_{FeCl_2} = N_{Fe}$). The concentrations of sulfides in solution, N_S, are given by the relation

$$N_S = X_S - r(X_{Fe} - N_{Fe}) \qquad [6]$$

where r is unity, 2 or (26/23) depending on whether the precipitating phase is FeS, X phase, or J phase, respectively. Equation [6] is valid for compositions where N_S is much larger than N_{Fe}, even if Henry's law is not accurately obeyed. (Obviously, one has $X_{Fe} = N_{Fe}$ only when no sulfide ion is present in solution.)

Near the equivalence point, the values calculated for K_{SP} are very sensitive to small uncertainties in the concentration of sulfides in solution. Beyond this point, K_{SP} is not as much affected. In most of the experiments, the experimental equivalence point did not coincide with the theoretical one, indicating a ratio of (X_S/X_{Fe}) slightly greater than unity. A possible interpretation would be the presence of small amounts of sulfide-forming impurities in the electrolyte or from the iron electrode. The measurements indicate impurity levels of 2 to 4×10^{-5} mole fraction in the melts which reacted with Li_2S to form a sulfide precipitate. The apparent impurity level increased by more than a factor of three when about 200g of fine grained iron powder prefired in a hydrogen-helium atmosphere for more than 24 hr was added to the melt. Thus, the values of N_S calculated from Eq. [6] must be corrected for the estimated amounts of impurities which are given for the three experiments listed in Table III. The impurity level was estimated from the change in the amount of sulfide necessary to achieve the theoretical equivalence point. The derived values of K_{SP} (in ion fraction units) for the three listed experiments are also reported in Table III. Our combined data lead to values of $K_{SP} = 0.44 \times 10^{-12}$, 2.3×10^{-12}, and 1.3×10^{-11} at $T = 673$°, 723°, and 773°K, respectively, with the standard Gibbs free energies of solution being 38.05, 38.50, and 38.51 kcal mole^{-1} (or 159.2, 161.1, and 161.1 kJ mole^{-1}) at these three temperatures. As will be seen, our values are in close agreement with exact theoretical predictions made *a priori* from thermodynamic considerations. The standard en-

[3] N_S^J and N_S^X were calculated neglecting, N_{Fe}, the concentration of Fe^{++} left in solution since N_{Fe} was less than 10^{-9}. Therefore the values given for N_S^J and N_S^X are given by (X_S − 26/23 X_{Fe}) and (X_S − $2X_{Fe}$), respectively.

tropy of solution is very small, −3 cal deg^{-1} mole^{-1} (or −12J deg^{-1} mole^{-1}); the standard enthalpy of solution is 36 kcal mole^{-1} (or 151 kJ mole^{-1}). This thermodynamic behavior is similar to that observed for solutions of silver halides in molten salts, where the standard Gibbs free energies and enthalpies of solution of relatively insoluble solids are almost equal (7).

The solubility of Li_2S.—The apparent concentration of Li_2S, X_S, at which the last plateau of each titration curve begins (Fig. 2 for $T = 673°$ and 773°K), when corrected for the amount and the chemical nature of the precipitate, yields the solubility of Li_2S in the LiCl-KCl eutectic, N_S(sat). The correction depends on the temperature of the experiments. At $T = 723°$ and 773°K, it is $2X_{Fe}$ since the X phase (Eq. [5]) is the second solid phase present at saturation, while at $T =$ 673°K it is (26/23) X_{Fe} since the J phase (Eq. [4]) coexists with solid Li_2S. The results thus derived, together with those obtained by an *in situ* generation of sulfide from a nickel-nickel sulfide eutectic electrode (8) are listed in Table IV. (Note that the level of impurities as estimated in Table III was taken into account.) Although there is a difference in the absolute values, the temperature dependence of the two sets of data in Table IV is essentially the same and leads to an enthalpy of solution $\Delta H_{Li_2S} = 10.22$ kcal mole^{-1} (or 42.78 kJ mole^{-1}). Our results are in agreement with our yet unpublished measurements in a lead sulfide system saturated with Li_2S.

On the stabilities of X and J phases.—Values for the standard Gibbs free energies of formation of X and J phases can be derived from data on the solubility of Li_2S, N_S(sat), combined with data on $N_S{}^X$ and $N_S{}^J$.

The standard Gibbs free energy of formation of Li_2FeS_2, from solid Li_2S and FeS, $\Delta G°_X$ is given by

$$\Delta G°_X = \frac{\Delta G°_4 + \Delta G°_5}{23} = \frac{3}{23} RT \ln (N_S{}^J/N_S(\text{sat})) + \frac{20}{23} RT \ln (N_S{}^X/N_S(\text{sat})) \quad [7]$$

where $\Delta G°_4$ and $\Delta G°_5$ refer to the standard Gibbs free energy changes for reactions [4] and [5], respectively. We have obtained, $\Delta G°_X = -0.33$ (±0.20) kcal mole^{-1} (or −1.38 ± 0.84 kJ mole^{-1}) at $T = 723°$K and $\Delta G°_X = -0.72$ (±0.20) kcal mole^{-1} (or −3.01 ± 0.84 kJ mole^{-1}) at $T = 773°$K.

Preto and Roche [see Ref. (1), p. 58] have performed slow-scan voltametry experiments, using LiAl as a reference electrode and FeS as positive electrode. From a typical voltamogram obtained at 700°K, one can estimate the standard Gibbs free energy of formation of the X phase from the peak separation assuming that Li_2FeS_2 did form during the charging cycle, $\Delta G°_X = -0.46$ kcal mole^{-1} (or −1.93 kJ mole^{-1}).

Using the phase diagram of the Li_2S-FeS system (9) and assuming that the liquid solution is ideal (*i.e.*, $a_{FeS} = X_{Fe}X_S$ and $a_{Li_2S} = X_{Li}{}^2X_S$) we have estimated, at $T = 1158°$K, $\Delta G°_X = -1$ kcal mole^{-1} (or −4 kJ mole^{-1}). The values thus derived (cyclic voltametry and phase diagram) are in consonance with our results.

The standard Gibbs free energy of formation of the J phase, $\Delta G°_J$ may be expressed in several ways depending on the choice of the reference state. If the LiCl-KCl eutectic composition is the standard state for LiCl and KCl, $\Delta G°_J$ is then identical to the standard Gibbs free energy change for reaction [4], $\Delta G°_4$

$$\Delta G°_J = 3RT \ln \left(\frac{N_S{}^J}{N_S(\text{sat})} \right) \quad [8]$$

where Li_2S and FeS have solids for their standard states. We have calculated for $\Delta G°_J$ values of −6.2 ± 1.8 kcal mole^{-1} (or −25.9 ± 7.5 kJ mole^{-1}), −6.1 ± 0.3 kcal mole^{-1} (or −25.5 ± 1.2 kJ mole^{-1}), and −6.9 ± 0.6 kcal mole^{-1} (or −28.9 ± 2.5 kJ mole^{-1}) at $T = 673°$, 723°, and 773°K, respectively.

If we chose solids as the standard states for all reactants and products for reaction [4], we have then to account for the relative activities of LiCl and KCl; the standard Gibbs free energy of formation of the J phase, $\Delta G_J{}^*$, is given by

$$\Delta G_J{}^* = 3RT \ln \left(\frac{N_S{}^J}{N_S(\text{sat})} \right) - 5RT \ln \left(\frac{a_1}{a_1(\text{sat})} \right) + 6RT \ln \left(\frac{a_2}{a_2(\text{sat})} \right) \quad [9]$$

where a_1 and a_2 are activities of LiCl and KCl, respectively, at the eutectic composition, and a_1(sat) and a_2(sat) are those at the liquidus composition. Using activities calculated from the phase diagram and from thermodynamic data reviewed by Lumsden (10, 11), we have obtained $\Delta G_J{}^* = -5.8 \pm 1.8$ kcal mole^{-1} (or −24.3 ± 7.5 kJ mole^{-1}), −6.7 ± 0.3 kcal mole^{-1} (or −28.0 ± 1.2 kJ mole^{-1}), and −8.1 ± 0.6 kcal mole^{-1} (or −33.9 ± 2.5 kJ mole^{-1}) at $T = 673°$, 723°, and 773°K, respectively. To our knowledge, these data constitute the only thermodynamic data available on the stability of the J phase.

A consideration of the values of $\Delta G°_X$ and $\Delta G°_J$ and of the metallographic and x-ray results allows us to draw some conclusions on the relative stabilities of the X and J phases as a function of temperature and of the electrolyte composition:

1. As mentioned previously, the X phase did not form at 673°K; it is marginally stable at 723°K since $N_S{}^X/N_S(\text{sat}) \sim 1$. We can deduce that, in our cells, the X phase does not form at temperatures that are very slightly lower than 723°K.

2. In Li_2S-rich melts at temperatures of 723° and 773°K, we have obtained a conversion of the J phase to the X phase. The conversion depended on the temperature of the measurements and on the sulfide concentration in solution. From thermodynamic considerations, we can estimate that this conversion can be made to occur at lower temperatures by (*i*) altering the electrolyte composition, and (*ii*) keeping the melts at saturation with repect to sulfides. The electrolyte should be changed in such a way that the activity of LiCl is increased and that of KCl is decreased. This can be done either by enriching the LiCl-KCl mixture in LiCl or by adding a third or perhaps, if necessary, a fourth constituent. The key factors are to keep the Li_2S and LiCl activities as high and the KCl activity as low as is practical. Therefore, in the operation of high temperature lithium batteries, one can ultimately eliminate the formation of the undesirable J phase (1) and be in a regime where the X phase would form instead. From our present data and Eq. [4] and [5], we have estimated that the J phase will not form in Li_2S-saturated melts with a change in the ratio of $(a_{LiCl}{}^5/a_{KCl}{}^6)$ of a factor of 7 at 698°K and 160 at 673°K.[4]

It is important to emphasize that, in the study of the stabilities of the X and J phases, we have assumed that they are line compounds. If the stoichiometries of

[4] Independent measurements of the solubility of Li_2S in the eutectic LiCl-LiF have shown that the solubility is considerably increased. Thus, if one changes the electrolyte composition, one has to be aware that the solubility of Li_2S in this new medium is consequently modified.

these phases do change significantly with temperature, our conclusions will have to be corrected.

Finally, it is worth mentioning that careful metallographic analyses combined with x-ray measurements are being undertaken to pinpoint the temperature-range and other factors which define the range of stability of the J phase (4).

Discussion

Firstly, calculations of the solubility product of FeS are carried out based on an exact thermodynamic cycle. Secondly, the presence and influence of associating species between Fe^{2+} and S^{2-}, on the solubility of FeS are examined. Thirdly, the possibility of the existence of limited solid solutions between Li_2S and FeS is considered.

A priori calculations of the solubility product of FeS.—The solubility product of FeS in the molten LiCl-KCl eutectic can be independently calculated *a priori* from thermodynamic considerations. The dissolution of FeS in the electrolyte can be written as

$$FeS(s) + 2LiCl(eut) \rightleftharpoons FeCl_2 + Li_2S \quad [10]$$

If one chooses as standard states, solid for FeS, liquid for LiCl, and a reference state so that the activity coefficients of $FeCl_2$ and Li_2S are unity at infinite dilution in the eutectic, the standard Gibbs free energy change for reaction [10], $\Delta G°$, is expressed as follows

$$\Delta G° = -RT \ln \left(\frac{a_{FeCl_2} a_{Li_2S}}{a_{LiCl}^2} \right)$$
$$= -RT \ln K_{SP} + 2RT \ln a_{LiCl} \quad [11]$$

The quantity $\Delta G°$ is also given by

$$\Delta G° = \Delta G_{FeCl_2}{}^* + \Delta G_{Li_2S}{}^* - \Delta G_{FeS}{}^\square - 2\Delta G_{LiCl}{}° \quad [12]$$

where the superscript * denotes the standard state defined at infinite dilution, the superscript □ denotes the solid, the superscript ° denotes the liquid, and the ΔG_i's are the standard Gibbs free energies of formation of the ith compound, at the temperature of reaction [10].

By combining our data with those of Laitinen and Pankey (5), $\Delta G_{FeCl_2}{}^*$ can be derived from the standard formation potential of $FeCl_2$ in the eutectic LiCl-KCl at 723°K. The quantity $\Delta G_{Li_2S}{}^*$ is calculated from the expression

$$\Delta G_{Li_2S}{}^* = \Delta G_{Li_2S}{}^\square - RT \ln N_S(\text{sat}) \quad [13]$$

where $\Delta G_{Li_2S}{}^\square$ is the Gibbs free energy of formation of solid Li_2S from pure liquid Li and pure sulfur in the gaseous state and under 1 atm pressure (12, 13). Similarly, $\Delta G_{LiCl}{}°$ can be derived from the standard Gibbs free energy of formation of solid LiCl as tabulated in JANAF (13) and the activity of LiCl at the liquidus composition (10, 11)

$$\Delta G_{LiCl}{}° = \Delta G_{LiCl}{}^\square - RT \ln a_{LiCl}(\text{sat}) \quad [14]$$

Finally, $\Delta G_{FeS}{}^\square$ at 723°K is calculated by extrapolating values selected by Robie and Waldbaum (14). The solubility product of FeS can be calculated *a priori* from known data combining Eq. [10]-[14]. At T = 723°K, we deduce a value of −38.36 (±3.0) kcal mole^{-1} (or −160.50 kJ mole^{-1}) for $RT \ln K_{SP}$ compared to −38.50 kcal mole^{-1} (or −161.11 kJ mole^{-1}) as derived experimentally. The good agreement between these calculations and the experiments serves as an independent confirmation of our measurements.

Influence of ionic associations.—As mentioned earlier, Eq. [6] has been derived under the assumption that Henry's law is obeyed for $FeCl_2$ and Li_2S. If this is not the case, then the solubility product is expressed as follows

$$K_{SP} = (a_{FeCl_2})(a_{Li_2S})$$
$$= N_{Fe} N_S \gamma_{FeCl_2} \gamma_{Li_2S} \quad [15]$$

where the activities, a, and the activity coefficients, γ, are defined so that the solution is ideal at infinite dilution of both solutes. Formation of associated solution species, such as the ion pair FeS or larger species, leads to deviations from Henry's law. In the event that such species exist, both γ_{FeCl_2} and γ_{Li_2S} would always be less than unity and the apparent $K_{SP} = (N_{Fe}N_S)$ would be larger than the true K_{SP} as given by Eq. [15]. In the present investigation, there is no significant difference between the true and the apparent K_{SP} since (*i*) the emf of the cell is a direct measure of a_{FeCl_2} ($= N_{Fe}\gamma_{FeCl_2}$) which was used in our calculations, and (*ii*) the calculations were made at concentrations of sulfide such that $N_S >> N_{Fe}$. Therefore, if such associated species exist, their concentrations must be much lower than N_S. Consequently, in the concentration range of this study, Li_2S should obey Henry's law closely.

The solubility of FeS cannot be unambiguously derived from the solubility product unless information is available on any significant associations between Fe^{2+} and S^{2-}. For example, if the only associated solution species is FeS with an association constant K, then the solubility of solid FeS in an equimolar solution of Fe^{2+} and S^{2-} would be $KK_{SP} + \sqrt{K_{SP}}$. For $K << K_{SP}{}^{-1/2}$ the solubility is not enhanced significantly and for $K >> K_{SP}{}^{-1/2}$ the solubility can be considerably enhanced. It seems probable that values of K would be large since both Fe^{2+} and S^{2-} are doubly charged leading to very large negative coulombic energy (in addition to possible noncoulombic energy) contribution(s) in favor of forming this ion pair. Coulomb repulsions tend to make species such as $(Fe_2S)^{2+}$ and $(FeS_2)^{2-}$ relatively unstable in this specific medium and they would tend to form only if they had some very special type of bonding that overcame the net coulomb repulsions of the two divalent ions of like charge. An experimental investigation of these considerations is being considered.

Solid solutions and solubility products.—Recent careful studies of the Li_2S-FeS binary phase diagram have indicated that limited solid solutions of Li_2S in FeS (up to 5 mole percent) might occur (4). The influence of such solid solutions on the interpretation of the present data have to be investigated.

The major effect of solid solutions would be to lower the activity of FeS by dilution, thus leading to calculated values of the apparent K_{SP} that are somewhat smaller than those of the true K_{SP}. If the solutions are dilute enough so that the Li_2S component in the solid solution obeys Henry's law and FeS Raoult's law, then one has

$$a_{FeS} = \overline{X}_{Fe}$$

and

$$\overline{X}_{Li} = 1 - \overline{X}_{Fe}$$
$$= \alpha\sqrt{N_S} \quad [16]$$

where a_{FeS} refers to the activity of FeS in the solid solution; $\overline{X}_{Fe}$ and $\overline{X}_{Li}$ are the cation fractions of Fe and Li in the solid, respectively, and α is a proportionality factor which can be calculated from the extent of the solid solution and the solubility of Li_2S. (For a maximum value of $\overline{X}_{Li} = 0.1$ at saturation with Li_2S, α would be 2.6). The true solubility product of FeS can be written as

$$K_{SP} = \frac{(a_{FeCl_2})(a_{Li_2S})}{\overline{X}_{Fe}} \quad [17]$$

where the activities of $FeCl_2$ and Li_2S are measured at saturation with the solid solutions. The activity of Li_2S can be approximated by the concentration of unassociated S^{2-} calculated from the expression

$$N_S = X_S - (X_{Fe} - N_{Fe}) \left(\frac{1 - 0.5\overline{X}_{Li}}{1 - \overline{X}_{Li}} \right) \quad [18]$$

We have computed the true solubility products of FeS

at different temperatures using Eq. [16]-[18] for a variety of possible values of α. The average values of K_{SP} increased very slightly; for example, at $T = 723°K$, this increase was less than 3%. Thus, the over-all effect of such solid solutions on the calculations of K_{SP} is negligible. Finally, the accuracy of our measurements cannot lead to a clear distinction between the effect of a small nonstoichiometry of the FeS phase or a small amount of solid solution. One must therefore, as we have, rely on the known phase diagrams of Fe — S (15) to ascertain that FeS is stoichiometric and that some solid solution with Li_2S is present (4). Until accurate measurements on the extent of solid solution are available, the small corrections to our reported values of K_{SP} cannot be attempted.

Conclusions

Values of solubility products of FeS in molten LiCl-KCl eutectic composition as measured by an emf technique are in excellent agreement with independent theoretical calculations made *a priori* based on exact thermodynamic relations. At relatively high concentrations of sulfide, phases identified as Li_2FeS_2 (X phase) at 723° and 773°K, and $LiK_6Fe_{24}S_{26}Cl$ (J phase) at 673°, 723°, and 773°K were formed in solution. These phases which occur in the full-scale engineering molten-salt batteries are shown to have marginal stabilities in the LiCl-KCl electrolyte; furthermore, the undesirable J phase can be eliminated by using an Li_2S-saturated electrolyte in which the LiCl activity is increased and the KCl activity decreased by an amount calculable from our results. The solubility of FeS in the LiCl-KCl eutectic can be determined accurately when information on the existence of associated species between Fe^{2+} and S^{2-} and their equilibrium constants becomes available.

Acknowledgments

We are indebted to A. E. Martin for the extensive metallographic analyses and all the information he generously shared with us. We are grateful to M. Roche for stimulating discussions. We also wish to acknowledge B. Tani for performing the x-ray analyses, L. Fuchs for metallographic analyses, L. Gutzman and W. Schulze for the glass-blowing, and K. Jensen and colleagues for the chemical analyses. This work was performed under the auspices of the Division of Basic Energy Sciences of the U.S. Department of Energy.

Primary Li/SOCl$_2$ Cells

IV. Cathode Reaction Profiles

A. N. Dey* and P. Bro

P. R. Mallory & Company Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The reaction profiles of the Teflon-bonded carbon cathode of the Li/SOCl$_2$-1M LiAlCl$_4$-SOCl$_2$ inorganic electrolyte battery were determined by sectioning the discharged cathodes and analyzing for LiCl which is formed quantitatively based on the charge passed according to the reaction

$$2Li + SOCl_2 \rightarrow 2LiCl + SO$$

The profiles show that LiCl precipitates preferentially near the cathode surface, and the interior of the cathode remains underutilized at high current density. The cathode also expands nonlinearly with the increase in the specific capacity. The longitudinal profiles of the cathodes of high rate D cells indicate that the current distribution is controlled by the electrical resistance of the cathode grid. This in turn causes the cell wall to be the hottest part of the cell on shorting.

The Li/SOCl$_2$ inorganic electrolyte system (1-4) is one of the highest energy density systems known to date. The system consists of a Li anode, a porous carbon cathode, and an LiAlCl$_4$-SOCl$_2$ electrolyte; SOCl$_2$ acts both as a solvent and as a cathode-active material. The Li anode is prevented from reacting with the SOCl$_2$ by virtue of the formation of an LiCl protective film (5) on the Li as soon as it contacts the LiAlCl$_4$-SOCl$_2$ electrolyte according to the reaction

$$2Li + SOCl_2 \rightarrow 2LiCl + SO \quad [1]$$

We proposed (6) this to be the primary cell reaction. The biradical SO is unstable and usually dimerizes and then decomposes to S + SO$_2$ according to

$$2SO \rightarrow (SO)_2 \quad [2]$$

$$(SO)_2 \rightarrow S + SO_2 \quad [3]$$

SO may undergo other possible chemical reactions to produce other byproducts (7). It was demonstrated experimentally (8) that all the Li dissolved from the anode precipitated quantitatively as LiCl on the porous carbon cathode. Furthermore, we showed (9) that the utilization of SOCl$_2$ in optimized D cells approached 100% asymptotically based on reaction [1] at low current densities. The energy densities delivered by these cells reached 20 W-hr/in.^{3} (1.24 W-hr/cm^3) and 300 W-hr/lb (661 W-hr/kg) at low current densities. At high current densities and low temperatures the energy densities were reduced significantly because of the premature passivation of the porous carbon cathode. Thus, from an energy density standpoint, the performance-limiting electrode is the porous carbon cathode. Attempts were made (9, 10) to mitigate this limitation by developing two types of D cells having a low and a high rate capability (Fig. 1). The low rate cells have shorter and thicker electrodes, thus having more active materials than the high rate cells which have longer and thinner electrodes and necessarily longer separators and current collectors which occupy space otherwise used by active materials. The object of this investigation was to determine the reaction profiles (both cross-sectional and longitudinal) of the porous carbon cathodes used in the Li/SOCl$_2$ D cells to assess its performance-limiting characteristics in some detail. The ultimate objective of these studies is to improve the porous carbon cathodes so that they may perform efficiently at high current densities, thus possibly eliminating the need of two types of cells for high and low rate applications.

Experimental

Cross-sectional reaction profiles.—The reaction profiles were determined by sectioning the porous carbon cathodes which were made by hot pressing a mixture of Shawinigan Black and Teflon on a layer of expanded Ni prewelded on a stainless steel stud. The cross-sectional view of the cathode is shown in Fig. 2. The extent of reaction in the cathode slices was determined by analyzing for LiCl which was found (8) to precipitate quantitatively based on the charge passed according to reaction [1]. The carbon cathodes were approximately 0.1 cm thick and had a diameter of 1.27 cm, which coincided with the inner diameter of the cylindrical test cell, shown in Fig. 3, to provide a relatively uniform current distribution on the cath-

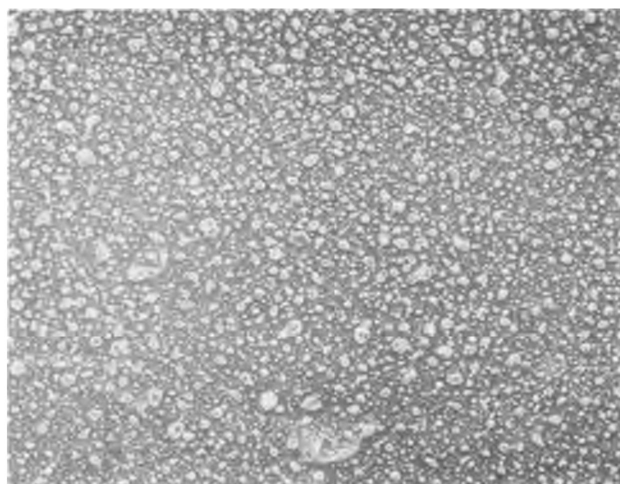

Fig. 4. SEM photograph of the cathode surface after discharge showing the LiCl precipitates (50 times).

ode. The SEM photograph (Fig. 4) of a discharged cathode surface at 50 times magnification showing the LiCl precipitation demonstrates the uniformity of current distribution. The Li counterelectrode was of the same size as the carbon cathode.

The cathodes were discharged in an excess of 1M $LiAlCl_4$ in $SOCl_2$, [the preparation and purification of which have been described elsewhere (10)] to several depths of discharge at various currents and temperatures. After the discharge, the electrodes were washed thoroughly in excess $SOCl_2$ to remove $LiAlCl_4$ and then dried under vacuum to remove $SOCl_2$. The thicknesses of the cathodes were measured before and after discharge in order to determine the cathode expansion. For analysis, a central section was cored from the cathode to eliminate edge effects on the current distribution. The central core was mounted on a microtome, as shown in Fig. 5, and the cathode was sectioned into thin slices that were leached with distilled water to recover the LiCl. The extracted LiCl was determined by analyzing the lithium in the extract by atomic absorption spectrometry. The leached cathode slices were dried and weighed.

Longitudinal reaction profiles.—The high rate Li/$SOCl_2$ D cells (10) were made by winding together Li anodes and carbon cathodes (with glass separators) having the following dimensions: carbon cathode, 20 × 1.75 in.; Li anode, 20 × 1.50 in. The wound elec-

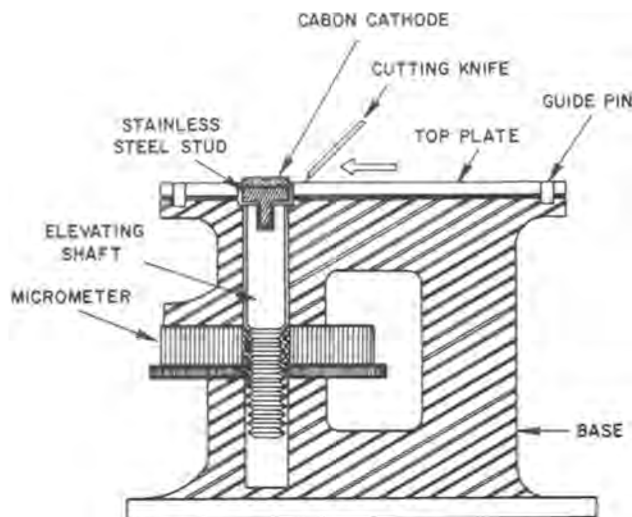

Fig. 5. Cathode-sectioning apparatus

trode assembly fit snugly into the Ni can, (OD, 1.30 in.; length, 2.38 in.). The cathode terminal in the form of an Ni tab (prewelded to the expanded Ni current collector of the porous carbon cathode) was located near the interior wall of the can and connected to the Ni can wall by welding. The Li anode was short by approximately 0.5 in. in covering the cathode on the outer wrap of the electrode assembly. The Li anode terminal in the form of a Ni tab was located at the center of the wound electrode assembly and was connected to the feedthrough of the G/M seal terminal. The longitudinal reaction profile of the cathode was determined by washing the cathode of the discharged D cell with excess $SOCl_2$ and then punching out circular disks from the cathode at various locations with respect to the tab. The LiCl content of these disks and their weights after the leaching was determined as before.

Results and Discussion

Cross-sectional reaction profile.—The histograms of the experimental results are shown in Fig. 6-9 for the various discharge conditions. The electrode depth is expressed in cumulative weights of the cathode slices starting from the electrode-electrolyte interface toward the interior of the cathode. The depth of dis-

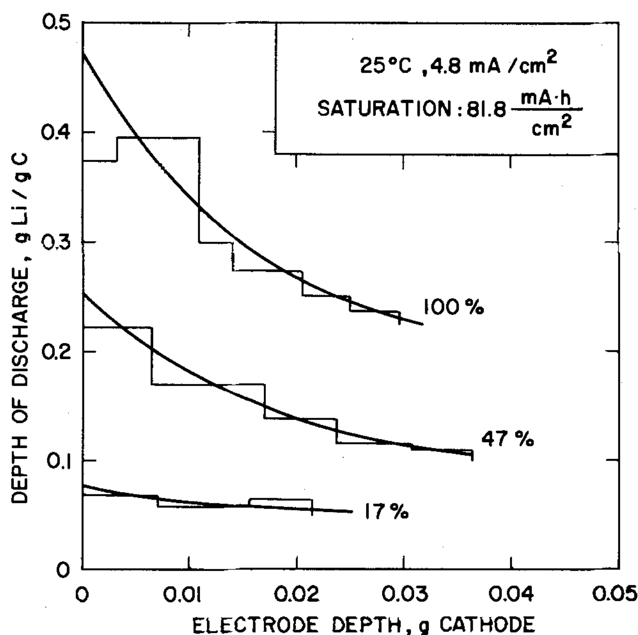

Fig. 6. Reaction profiles of the cathode discharged at 25°C, at 4.8 mA/cm².

charge is expressed in weight of Li (in the form of LiCl) per unit weight of the cathode slice. The smooth curves drawn through the histograms represent the reaction profiles. The reaction profiles of the cathode discharged at 25°C at a current density of 4.8 mA/cm^2 are shown in Fig. 6. The specific capacity of the fully discharged (100%) cathode was 81.8 mA-hr/cm^2 under the above condition. The reaction profiles were obtained at three different states of discharge *viz.* 17, 47, and 100%. At 17% depth of discharge, the profile is fairly flat, indicating a uniform precipitation of LiCl throughout the cathode. At higher states of discharge the profiles become nonuniform and the precipitation of LiCl occurs preferentially near the cathode-electrolyte interface. At 100% depth of discharge, the precipitation in the interior of the cathods is approximately 50% of that near the surface.

The reaction profiles of the cathode discharged at 9.4 mA/cm^2 at 25°C are shown in Fig. 7. The specific capacity of the fully discharged cathode decreased to 29.5 mA-hr/cm^2 at this higher current density. The reaction profiles become increasingly nonuniform. The precipitation of LiCl occurs primarily near the front of the cathode. The precipitation in the interior is only 14% of that near the front surface. Thus, the interior of the carbon cathodes remain underutilized at high current densities.

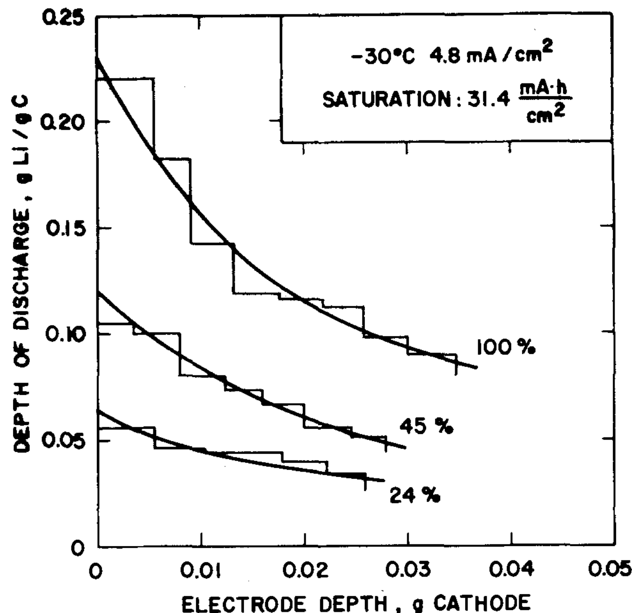

Fig. 9. Reaction profiles of the cathode discharged at —30°C, at 4.8 mA/cm^2.

The reaction profiles of the cathodes discharged at —30°C at current densities of 2.4 and 4.8 mA/cm^2 are shown in Fig. 8 and 9. The specific capacities of the fully dicharged cathodes were 44.3 and 31.4 mA-hr/cm^2 for the two current densities. The shape of the reaction profiles at 25° and —30°C at the same current density (4.8 mA/cm^2) are similar, only the specific capacities are reduced drastically at the lower temperature. Lowering of the current density to 2.4 mA/cm^2 at —30°C results in an increase of the specific capacity to 44.3 mA-hr/cm^2, although the profiles remain relatively unchanged. The cathode appears to be less efficient at low temperature.

The results suggest that the carbon cathodes are mass-transport limited, and the diffusive choking of the cathode by the precipitation of the reaction products (LiCl, S) is the likely cause of the polarization of the cathode. Therefore, the rate capability of the cathode can be improved by (*i*) increasing the porosity of the cathode to improve the mass-transport characteristics; and (*ii*) reducing the thickness of the cathode. The latter approach has been examined (9) and found to cause an energy-density penalty.

The maximum capacity predicted from the design calculations (11) of Li/$SOCl_2$ D cells having a specific electrode geometry was 11.62 A-hr, whereas the experimentally realized (9) maximum capacity of D cells having a similar electrode geometry was found to be approximately 16 A-hr. This discrepancy between the calculated and the experimental values indicates the importance of experimental characterization of the cathode in regard to the reaction profile.

Cathode expansion.—The Teflon-bonded carbon cathodes were found to expand during the discharge. The expansion of cathodes discharged under various conditions in a D cell is shown in Fig. 10. The cathode expansion depends on the specific capacity irrespective of the discharge conditions. This may be attributed to the expansion being caused by the precipitation of LiCl which is quantitatively related to the specific capacity according to the cell reaction [1]. The initial expansion of the cathode as a function of the specific ca-

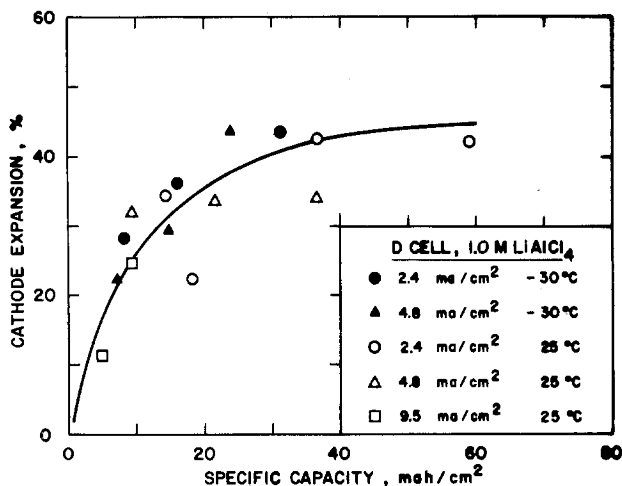

Fig. 10. Cathode expansion on discharge

pacity is rapid and levels off during the later stages of discharge. This may be attributed to the fact that the cathodes are soft and pliable during the early part of the discharge but become increasingly rigid as the precipitation of LiCl continues. Thus, the modulus of elasticity of the cathodes is dependent upon the specific capacity. It will be interesting to study the rheology of the cathode as a function of its composition.

Longitudinal reaction profile.—The longitudinal reaction profiles of a high rate D cell cathode on a 2.0A discharge at 25°C is shown in Fig. 11. The profiles were obtained at three depths of discharge, 2.5, 5.4, and 10.3 A-hr, the latest corresponding to the complete passivation of the cathode. Note that at the early stage of the discharge, most of the cell reaction occurs near the Ni tab of the cathode. This indicates that at high rates (2A) the electrical resistance of the Ni grid controls the current distribution of the cathode. It is expected that at higher currents, most of the cell reaction will be restricted to the cathode area near the tab which is welded to the cell can, and in our design this cathode area happens to be adjacent to the cell wall as shown at the top of Fig. 11. This particular longitudinal reaction profile results in an interesting internal temperature profile of the high rate D cells on shorting. The short-circuit current of these cells was approximately 20-30A. At that current, it is expected that almost all the reaction will occur right near the tab and hence near the cell wall, thus making the cell wall temperature higher than that of the cell interior. We measured the internal as well as the wall temperature of high rate D cells by means of thermocouples, as shown in Fig. 12, after externally shorting the cell. The voltage current and the temperature profiles are shown in Fig. 13. The three thermocouples located on the wall, halfway between the wall and the center, and at the center are referred to as TC-1, TC-2, and TC-3, respectively. The cell was equipped with a low pressure vent which was automatically activated at an internal pressure of 100-130 psi. We found that the cell wall temperature was substantially higher than that of the interior temperatures, as expected. This particular electrode design imparts additional safety characteristics to the cell by ensuring that the hottest point of the cell is the wall which can be cooled more easily than can the cell interior.

Conclusions

1. Cross-sectional reaction profiles of the carbon cathodes show that mass transport through the porous carbon is the limiting feature of the cathodes. At high

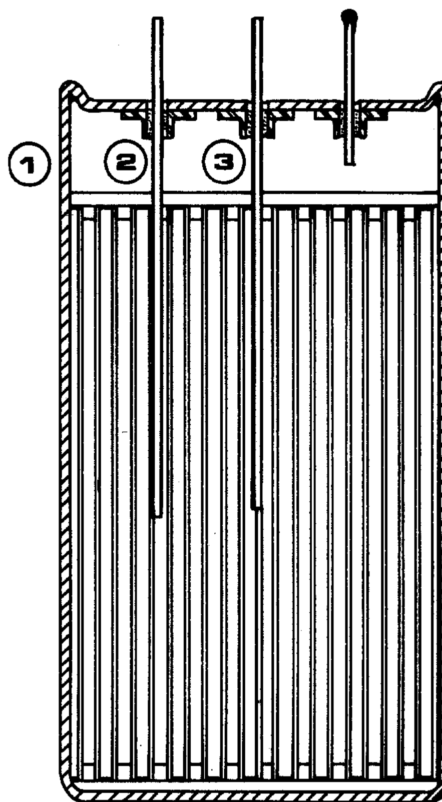

Fig. 12. Cross-sectional view of a D cell with thermocouple feedthroughs.

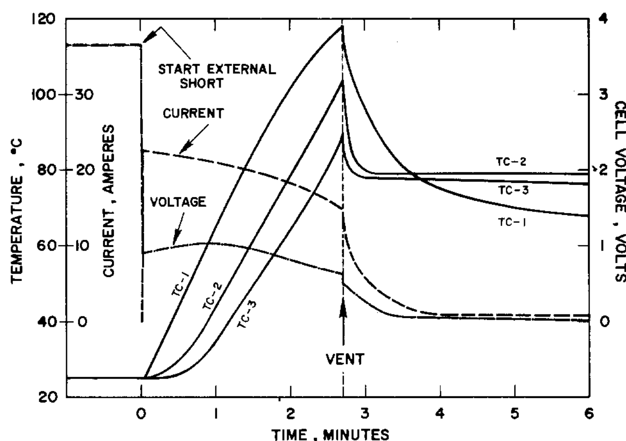

Fig. 13. Temperature profiles on shorting a high rate D cell. Wall temperature (TC-1); halfway between wall and the center (TC-2); center (TC-3).

currents the interior of the cathode remains virtually unutilized.

2. The cathodes expand nonlinearly with the specific capacity, and the expansion is independent of the current density and the discharge temperature. The expansion is rapid at first and then levels off as the cathode becomes increasingly stiff.

3. The longitudinal current distribution of the cathode is controlled by the electrical resistance of the expanded Ni grid. At high currents most of the reaction is localized near the cathode tab, thus making the cell wall the hottest part on cell shorting.

Rate Processes Related to the Hydrated Nickel Hydroxide Electrode in Alkaline Solutions

R. S. Schrebler Guzmán, J. R. Vilche, and A. J. Arvía*

ABSTRACT

The potentiodynamic response of the Ni/alkaline aqueous solution interface in the region of the hydrated $Ni(OH)_2$ to β-NiOOH electrochemical reaction reveals that both species undergo phase transformations. The anodic product from the $Ni(OH)_2$ species involves the formation of three species energetically different which are detected during the electroreduction process. Under well-defined perturbation conditions, a reasonable set of kinetic parameters pertaining to the anodic process is obtained which is formally interpreted through a consecutive three-step mechanism of reaction involving a charge transfer, a chemical reaction, and a charge transfer and a proton transfer process. Side reactions involving water take into account the various aging processes of the reaction products.

It is well established that a nickel electrode immersed in concentrated aqueous alkaline hydroxide solutions is spontaneously covered with $Ni(OH)_2$ layers while the potential increases slowly with time (1-3). In 1*M* KOH solution the layer increases to a thickness of up to 15 atom units at open circuit during 16 hr (4, 5).

The electrochemical characteristics of nickel in alkaline solutions in the potential range preceding the O_2 evolution are related to the hydrated nickel hydroxide electrode (6-15). Its kinetics have been particularly considered in relation to the Ni-Cd battery, hence, most of the works refer to large surface area electrodes. As is well known, the reduced system consists of a variety of hydrated $Ni(OH)_2$ forms and the oxidized system is generally related to the NiOOH species. Both species exist in two structural modifications which are called α and β for the former species and γ and β for the latter (14). The α-$Ni(OH)_2$ structure is unstable on standing in an open circuit and cycling (7). In KOH solution, for a limited time, it is possible to cycle between the α-$Ni(OH)_2$ and the γ-NiOOH structure (7, 10, 11). The conversion of α-$Ni(OH)_2$ to β-$Ni(OH)_2$ has been related to the aging characteristics of the film, which correspond to the shift in potential of about 50 mV moving to higher potential as the electrode is cycled or is allowed to stay in KOH solution (7, 10).

There is evidence that the hydrated $Ni(OH)_2$ to β-NiOOH electrochemical oxidation follows a composite pattern, which still poses important unresolved questions and considerable controversy, particularly when the different authors advance explanations in terms of different stoichiometries of isolated nickel compounds (16). Apparently the amount of adsorbed oxygen on Ni changes with the ionic composition and alkali concentration (17, 18). In alkaline solution it increases on passing from LiOH to CsOH (19).

The structural changes of the $Ni(OH)_2$ species have been electrochemically observed and they were assigned to the conversion of α-$Ni(OH)_2$ into β-$Ni(OH)_2$ (7, 10, 11, 20-22). Recent reports (3, 23-25) indicate that the cathodic current peak potential recorded either with a triangular potential sweep or with trapezoidal pulses shifts toward the cathodic potential as the anodic switching potential becomes more anodic. This confirms also that the product anodically formed is partially transformed into a more stable species (24, 25). This aspect of the problem is

Key words: nickel hydroxides, anodic oxidation, film formation, aging processes.

certainly not clear, and to draw definite conclusions from the kinetic response of electrochemical systems involving different amounts of active material on the electrode seems excessively optimistic. The present work refers to the potentiodynamic response of the Ni/alkaline solution interface in the potential range of the hydrated nickel hydroxide electrode under different potential perturbation conditions involving amounts of charge at most of the order of a few monolayers of reactant and product. After the systematic change of the perturbation conditions, different straightforward relationships involving the various kinetic parameters are obtained which are meaningful in terms of a relatively simple reaction pathway. The over-all electrochemical behavior of nickel in alkaline solutions is, in principle, interpreted through various film forming $Ni(OH)_2$ and NiOOH species. Although these species in bulk are apparently poor electron conductors, they appear to be good proton conductors. Therefore, the conclusions of the present work are particularly interesting for a preliminary understanding of the early stages involved in the passivity of nickel and certainly they apply to nickel electrodes as employed in alkaline batteries.

Experimental

The experimental procedure including the electrolysis cell and electrode materials are practically the same as already described in previous publications (24, 25). The following electrolyte solutions were employed: 1.00*N* KOH (solution A); 0.10*N* KOH (solution B); 0.10*N* KOH + 0.60*N* K_2SO_4 (solution C); 0.01*N* KOH + 0.66*N* K_2SO_4 (solution D). They were prepared from triply distilled water and analytical grade (Merck) reagents. Experiments were made under N_2 gas saturation at 25°C using repetitive triangular potential scans (RTPS) and other different potential/time perturbation functions which are indicated for each particular run. The latter were programmed to normalize the average structure of the reactants at the electrode surface in order to derive from each run comparable kinetic data.

After a certain number of RTPS at a particular potential sweep rate (v) the electrode attained a reproducible *E/I* contour. In the following text, these electrodes are referred to as "stabilized electrodes." The potentials are referred to the NHE scale.

Results

E/I characteristics obtained with triangular potential sweep perturbations.—RTPS run at $v = 0.1$ V/sec, between the switching potentials $E_{\lambda,c} = -0.96$V and $E_{\lambda,a} = 0.74$V, just exceeding the potential range of the electrochemical stability of water are shown in Fig. 1. The complex *E/I* contour is obtained using a polished electrode immersed in solution A, which was previously cathodized at $E_{\lambda,c}$ for 5 min. The initial anodic scan exhibits an anodic current peak at −0.44V (peak I), followed by an appreciable anodic current in the −0.4 to 0.4V range, and another anodic current peak (peak II) in the potential range just preceding the net oxygen evolution. The immediately returning scan presents a cathodic current peak (peak III) which, in principle, is complementary to current peak II. The following successive potential sweeps show practically no trace of current peak I and a net decrease of the anodic current in the −0.4 to 0.4V range. The first anodic scan exhibits the anodic current peak II located at potentials slightly more anodic than in the following successive cycles. Furthermore, there is a slight contour change of both current peak II and III, and, after a relatively large number of sweeps, a new cathodic shoulder (peak IV) on the left side of current peak III is definitely recorded. The stable *E/I* profile is only reached in this case after 50-60 potential scans. The reactions occurring in the potential range of current peak I concern the hydrated $Ni(OH)_2$ film formation. The corresponding kinetic and mechanistic interpretations have been considered in a previous publication (25).

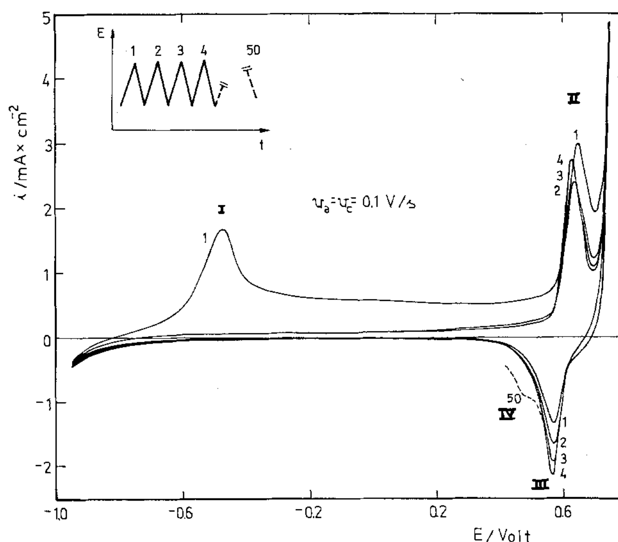

Fig. 1. Potentiodynamic displays obtained under RTPS at 0.1 V/sec. Solution A.

The passivation current recorded during the first anodic potential sweep in the −0.1 to 0.4V range fits at constant potential a linear log *i*/log v relationship (Fig. 2), with a slope equal to 1.

Current peaks II, III, and IV are better defined when $E_{\lambda,c}$ is closer to the potential of current peak II. The limiting *E/I* contours or current peaks II and III resulting after the nth RTPS between $E_{\lambda,c} = 0.34$V and $E_{\lambda,a} = 0.68$V are characterized by a high degree of symmetry as defined by the peak height to peak width at one-half of peak height (Fig. 3). Otherwise, the cathodic side of current peak III is influenced by current peak IV which, under the present conditions, actually appears as a net current plateau. The RTPS profiles run within fixed $E_{\lambda,c}$ and $E_{\lambda,a}$ yield reasonably good linear current peak height $(I_p)/v$ relationships. Once the stable *E/I* profiles are attained there is only a very small shift of the potentials of current peaks II and III on changing v. Moreover the half-wave potential of peak IV remains practically independent of v at least for $6 \leq v \leq 30$ mV/sec. The amount of charge involved on both the anodic (Q_a) (after baseline correction for the electrochemical oxygen-evolution reaction) and the cathodic scans (Q_c) decreases as v increases, approaching a charge of the order of one monolayer thickness at high v (Fig. 4). The Q_a/Q_c ratio at a constant v is practi-

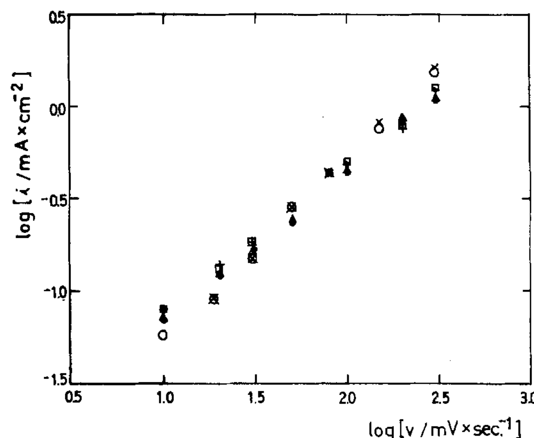

Fig. 2. Potential sweep rate dependence of the anodic current recorded during the first potential scan. Read at different fixed potentials. Solution A, −0.06V (×) and 0.04V (○); Solution C, 0.14V (□) and 0.04V (+); Solution D, 0.24V (△) and 0.14V (●).

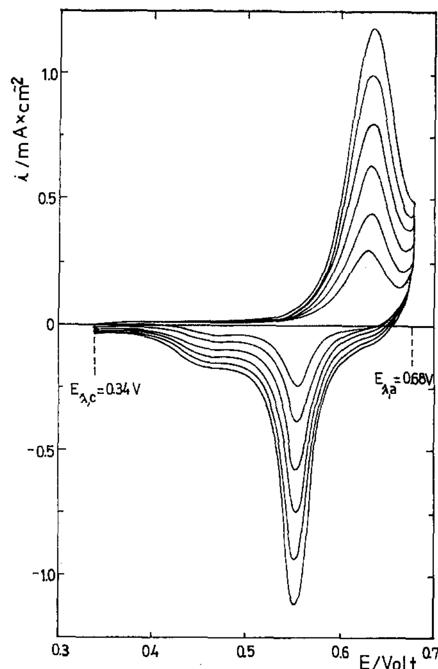

Fig. 3. E/I displays run with a stabilized electrode and symmetrical triangular potential scans at different potential sweep rates. Solution A. v = 6, 10, 15, 20, 25, and 30 mV/sec.

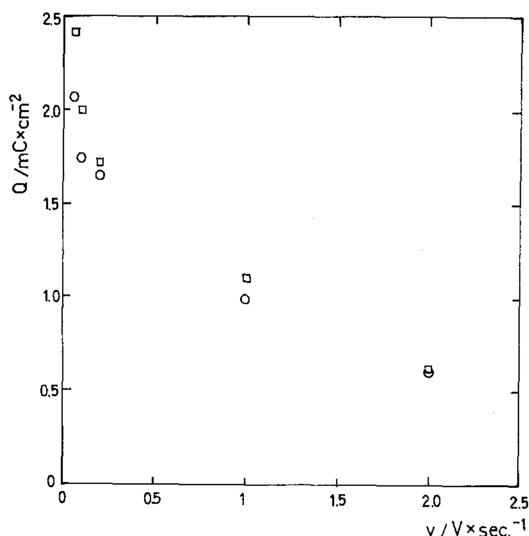

Fig. 4. Potential sweep dependence of the charge involved in the RTPS run between 0.44 and 0.79V. Solution C. (□) Anodic charge; (○) cathodic charge.

cally equal to one. The E/I profiles recorded with asymmetric repetitive triangular potential perturbations (either v_a, v_c = constant or v_c, v_a = constant), covering the potential region of current peaks II and III (Fig. 5) are influenced by the products of the reaction related to current peak III. They are probably not completely removed during the cathodic scan when $E_{\lambda,c}$ is not sufficiently cathodic. As the $E_{\lambda,c}$ becomes more anodic than the potential of current peak IV, the anodic charge decreases and simultaneously one observes that the initial part of the E/I line related to current peak II shows an appreciable depolarization as compared to that depicted in Fig. 8. On the other side, as v_a increases the contour of current peak III appears flatter and an increasing current contribution is also noticed at the anodic side of current peak III, while the corresponding current peak potential turns more anodic. The over-all effect resembles an aging-type process of the passivating species. The decrease of Q_c as v_a increases is obviously

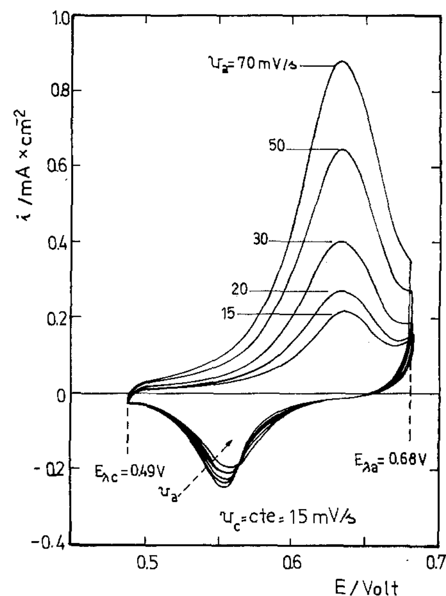

Fig. 5. Potentiodynamic E/I displays run at v_c = 0.015 V/sec and 0.015 V/sec ≤ v_a ≤ 0.070 V/sec. The dashed arrow indicates the shift of the cathodic profile as v_a increases. Solution A.

derived from the dependence of Q_a on v_a already referred to.

The shape of the stabilized electrode E/I profile depends on the $E_{\lambda,a}$ value (Fig. 6). Thus, at constant $E_{\lambda,a}$, the charge associated with current peak IV is practically constant for any potential scan. Nevertheless, it further increases as $E_{\lambda,a}$ increases because of the baseline shift of current peak III. This result indicates that the species electroreduced within the potential range of the current peak IV are those anodically produced at the lower anodic potential region of current peak II.

The E/I profile shown in Fig. 7 has been stabilized under a RTPS between $E_{\lambda,c}$ = 0.49V and $E_{\lambda,a}$ = 0.695V (E/I curve 9) covering a relatively large potential range of the O_2-evolution reaction. After the stabilized profile has been obtained the cathodic E/I profiles numbered from 1 to 8 are recorded by switching the anodic potential at different values. Thus, those cathodic scans initiated from switching potentials overlapping to a relatively larger extent the po-

tential range of the O_2-evolution reaction imply Q_a/Q_c ratios increasing with the switching potentials values (Table I). In spite of this any surface species which might be involved in the O_2-evolution reaction produce apparently no particular change in the E/I characteristics.

An equivalent influence of $E_{\lambda,c}$ on both current peaks II and III are seen (Fig. 8). When the potential sweep covers the range between 0.675 and 0.600V, the E/I characteristics approach a highly reversible behavior as is immediately deduced from the fast response of the current to the both anodic and cathodic potential switchings. Under these circumstances only a small fraction of the total charge is periodically removed from and reformed on the surface. As $E_{\lambda,c}$ decreases, the charge fraction which is involved in the over-all process increases. Moreover, the over-all process becomes more irreversible as evidenced by the decrease of the anodic current at a given potential in the initial portion of the anodic profile. Furthermore, when $E_{\lambda,c}$ is more cathodic than the potential range of current peak IV, the potential of current peak III becomes progessively more anodic, attaining a constant value when $E_{\lambda,c} = 0.4$V. When the region of current peak IV is not included, the rest of the electrochemical reactions occurring on the covered electrode surface show a faster response to the electrical perturbation. But when those species related to current peak IV are involved in the perturbation process, their formation reaction occurs with appreciable irreversibility although this situation produces an apparent activation of the process related to current peak III.

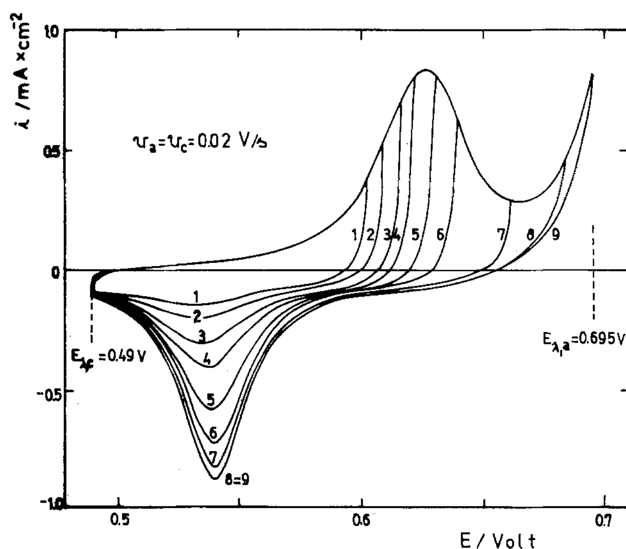

Fig. 7. Influence of the anodic switching potential on the Q_a/Q_c ratio. Each run is made from $E_{\lambda,c}$ upward after a previous RTPS at 0.02 V/sec between 0.49 and 0.695V, to attain a stable E/I profile. Solution A.

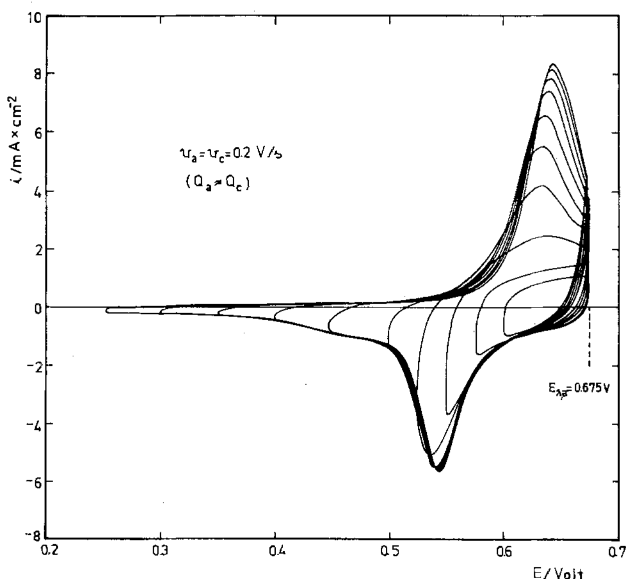

Fig. 8. Influence of the cathodic switching potential on the E/I profiles recorded with RTPS at 0.2 V/sec. Solution A.

The E/I characteristic referred to are maintained within the range $11 \leq pH \leq 14$ (Fig. 9). Under constant perturbation conditions, the potentials of current peaks II, III, and IV shift equally toward more positive potentials as the pH decreases. The charges involved in the E/I displays are practically the same in the covered range of pH although the current peaks extend over a larger potential range as the pH decreases. As a matter of fact, the relative charge contributions of current peaks III and IV in the cathodic profile change with pH. It appears as if the contribution of the former is larger as the pH of the solution decreases. This is probably related to the wider region covered by the anodic current peak. Furthermore, the contribution of the O_2-evolution reaction at $E_{\lambda,a}$ is increasingly important at lower pH.

At any pH reasonable linear log I_p/log v relationships with the slope close to 1 are obtained under the range of experimental conditions indicated in the present work (Fig. 10-13). Nevertheless, for the anodic current peak II the best straight line is obtained through the log (I_p/Q_a)/log v plot.

The potentials of current peaks II and III change linearly with log v (Fig. 14 and 15). Their corresponding slopes, as well as the remaining kinetic parameters, are assembled in Table II. The difference between the potentials of current peaks II and III, $\Delta E_p = E_{pII} - E_{pIII}$, increases linearly with v. After the extrapolation at $v \rightarrow 0$ one obtains $\Delta E_p \approx 0.080$V.

under the perturbation program depicted in Fig. 16 show the influence of τ, the potentiostatting time at 0.655V, a potential at which there is practically no net current flow. Under these circumstances, for the same anodic charge, as τ increases the cathodic charge remains constant but the shape of the current peak III extends over a wider potential range, its height decreasing and the corresponding current peak potential becoming more cathodic. On the other side, the current peak IV remains independent of τ, its apparent increase being only due to the changes of current peak III. These runs are indicating that during the rest time there is no appreciable chemical dissolution of the product anodically formed, but certainly the latter undergoes a chemical transformation without any likely detectable stoichiometric change through the electroreduction process.

The E/I profiles (Fig. 17) obtained with a stabilized electrode which is potentiostatted during a constant τ but at different potentials confirm that the cathodic charge of current peak IV is unaffected by the perturbation conditions. Furthermore, as $E_{\lambda,a}$ decreases, the species left on the surface after a 3 min potentiostatting are those which require the largest electroreduction potential. Therefore, from these results one deduces that at least two different species are involved in the electroreduction process occurring in the potential range of current peak III. This is also confirmed when the stabilized interface is perturbed with a fast RTPS within a range of potential where only a fraction of the surface covering species is involved in the removal and reformation processes (Fig. 18 and 19). It is clear that as τ increases and the cathodic charge remains constant (0.5 min $\leq \tau \leq$ 10 min) the cur-

rent peak III splits into two current peaks. The splitting of current peak III depends also on the potential limits of the past RTPS as well as the fraction of the surface covering species participating in the fast RTPS. The splitting effect is clearly established for the various solution compositions employed in the present work.

Discussion

Most of the experimental work made with the Ni/KOH interface concerns electrode structures ap-

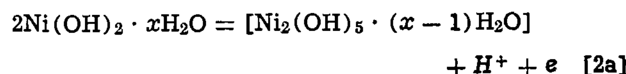
proaching the conditions prevailing in the alkaline nickel batteries. In this case, relatively large charges take part in the potentiodynamic perturbation of the interface, and, consequently, the kinetic interpretation is perhaps more complex than that resulting when charges of the order of a few monolayer thickness are involved.

The present results correspond to a surface $Ni(OH)_2$ species which is formed during relatively fast potential cycling and the charges taking part in the over-all electrochemical processes are smaller than those of previous works. In these circumstances the repetitive potentiodynamic *E/I* characteristics imply not only a single anodic *E/I* profile which just precedes the electrochemical O_2 formation but also a multiple current peak display during the reduction of the product of the anodic reaction. But the over-all reaction taking place during each periodic perturbation is completed since the Q_a/Q_c ratio is always practically one. The interpretation of the charge magnitude in terms of the actual surface area is, however, ambiguous. As a matter of fact there are two possibilities, either the metal roughness factor is one and the film thickness corresponds to a multilayer thickness or the latter is of the order of the monolayer thickness and its roughness factor changes during cycling and depends on v.

Kinetics of the anodic reaction.—Probable reaction path when the structural changes of the reactant are negligible.—Within a certain range of the perturbation variables the anodic reaction exhibits an apparent simpler response to the RTPS potentiodynamic perturbation than to the cathodic process. Consequently a set of reasonable kinetic parameters is derived for this process. Provided that the over-all anodic process under potentiodynamic conditions is expressed by the over-all reaction

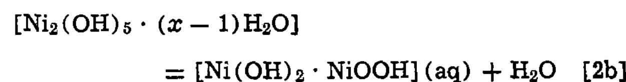
$$Ni(OH)_2 \rightarrow NiOOH + H^+ + e \quad [1]$$

a possible reaction path which may account for the kinetic behavior should imply a series of single electron transfer and chemical steps as follows. The initial stage is the proton release from the hydrated $Ni(OH)_2$ lattice on the positively charged nickel surface



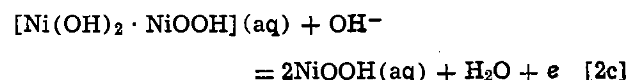
$$2Ni(OH)_2 \cdot xH_2O = [Ni_2(OH)_5 \cdot (x-1)H_2O] + H^+ + e \quad [2a]$$

The proton diffusion out of the electrochemical interface is assisted by the electrical field located there. Step [2a] involves a partially hydrated intermediate which undergoes a structural rearrangement through a chemical reaction



$$[Ni_2(OH)_5 \cdot (x-1)H_2O] = [Ni(OH)_2 \cdot NiOOH](aq) + H_2O \quad [2b]$$

and finally



$$[Ni(OH)_2 \cdot NiOOH](aq) + OH^- = 2NiOOH(aq) + H_2O + e \quad [2c]$$

The formation of the NiOOH-species is equivalent either to the accumulation of Ni(III) species or to the creation of 3-d holes in the film (26). Whatever the case, the reaction path [2a]-[2c] implies an increasing deprotonation of the insoluble film, so that the Ni/O atomic ratio remains constant, the H/O ratio decreases, and the Ni/H ratio increases in passing from the hydrated $Ni(OH)_2$ to the NiOOH species. Ellipsometry (12, 27) and impedance measurements of the resistive layers formed during nickel anodization in 1*N* KOH (2, 28) indicate the presence of those species.

The sequence of reactions [2a]-[2c] can be analyzed either as a reversible or as an irreversible electrochemical system assuming that the same reactions hold for the cathodic processes. Thus, when one attempts to correlate the kinetic characteristics of the nickel hydroxide electrode with its fast response one finds some apparent contradictions. For a reversible conjugated electrochemical system implying a monolayer formation, the corresponding anodic and cathodic current peaks must occur at the same potential and this potential is independent of the potential sweep rate. The latter is certainly obeyed, but, in contrast, the difference between the potentials of the anodic and cathodic main current peaks as revealed by the RTPS experi-

ments is *ca.* 0.08V. Therefore, the simple three-step reversible mechanism is unsatisfactory.

Let us consider the possibility that the rate process is determined by the rate of one partial reaction. From previous stationary measurements of the nickel electrode in different alkaline solutions, step [2c] can be supposed as the rate-determining step. Then, if the reaction proceeds in only one direction, the stationary current density derived in the conventional way yields the following expression

$$i_a = k a_{Ni(OH)_2}{}^2 a_{H^+}{}^{-2} \exp\left[\frac{(1+\alpha)FE}{RT}\right] \quad [3]$$

where the a_i's are the activities of the i species at the reaction interface, k is the formal rate constant, α is the transfer coefficient assisting the reaction [2c] in the anodic direction, and E is the potential applied to the electrochemical interface.

A kinetic equation formally similar to Eq. [3] was derived from a mechanism involving Ni(IV) species and ionic nickel-oxygen surface species (16). There is, however, no firm evidence of the former species although magnetic susceptibility measurements coupled to electrochemical processes revealed the presence of Ni(IV) (26). A further oxidation in the β-NiOOH lattice may convert Ni(III) into Ni(IV), leading to the formation of very stable nonstoichiometric oxides (14, 20-22).

If Eq. [3] is valid, the corresponding potentiodynamic E/I profile related to the change of electrode coverage from the $Ni(OH)_2$ monolayer to the NiOOH monolayer derived according to the Srinivasan and Gileadi procedure (29) gives the following parameters

$$\left(\frac{\partial \ln i_p}{\partial \ln v}\right)_{pH} = 1; \qquad \left(\frac{\partial \ln i_p}{\partial \ln a_{H^+}}\right)_v = 0$$

$$\left(\frac{\partial E_p}{\partial \ln v}\right)_{pH} = \frac{RT}{(1+\alpha)F}; \qquad \left(\frac{\partial E_p}{\partial \ln a_{H^+}}\right)_v = \frac{2RT}{(1+\alpha)F}$$

Now the tentative reaction mechanism explains only three out of four kinetic parameters (Table II) leaving unclear the important one related to the apparent independence of the anodic current peak potential on the potential sweep rate. Then, the interpretation of the reaction in terms of step [2c] or any other equivalent step as the rate-determining step seems unlikely. Therefore, the sample three consecutive reaction mechanism, neither under reversible nor under irreversible conditions, is able to explain the kinetic data derived from the RTPS E/I profiles. The partial discrepancies suggest, however, that the interpretation of the over-all reaction is even more complex.

The influence of structural changes.—The experimental data revealed that the reactions related to current peaks II, III, and IV are closely connected and that the characteristics of the electrochemical processes are even more complex than earlier believed because not only the nickel hydroxide species involves structural changes (aging) as already known (14, 20-22) but also the products of its anodic oxidation undergo a similar type process.

The dependence of the experimental results on the potential perturbation conditions indicates that the anodic and cathodic processes as seen through the RTPS E/I profiles can be considered as fast reactions. But in contrast with reactions [2a]-[2c] the cathodic reactions are not exactly represented by the reverse reactions. This occurs if both reactants and products undergo structural transformations simultaneously during the electrochemical processes which alter their corresponding surface activities. Under these circumstances the over-all stoichiometry is maintained in the course of the reaction, but at least three different and fast conjugated redox couples involving proton transfer should be involved.

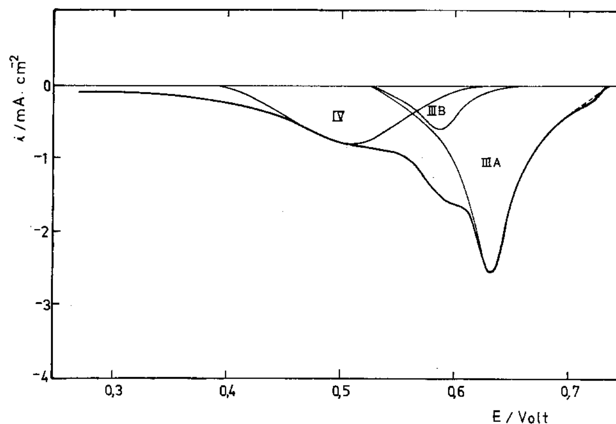


Fig. 20. Evaluation of the over-all cathodic *E/I* profile in terms of three cathodic reactants. Data correspond to profile 3 of Fig. 19.

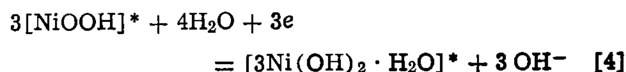
It is clear the cathodic E/I curve can be resolved at least into three current peaks, drawn in terms of three Gaussian distribution functions (Fig. 20) with well separated current peak potentials (Table III). This is perhaps the simplest attempt for separating the contributions of the three anodically formed nickel surface species quite likely involving the same oxidation state of the metal (Ni(III)) but different energetic configurations. Each species can be assigned to a particular electroreduction process. For current peaks III-A and III-B the following reactions are tentatively proposed, without compromising any particular hydrated structure or definite configuration



$$3[NiOOH]^* + 4H_2O + 3e = [3Ni(OH)_2 \cdot H_2O]^* + 3\,OH^- \quad [4]$$

$$[NiOOH]^{**} + H_2O + e = [Ni(OH)_2]^{**} + OH^- \quad [5]$$

For current peak IV one assumes that β-NiOOH is the species more difficultly reducible out of the three

$$3\beta\text{-}NiOOH + 5H_2O + 3e = 3Ni(OH)_2 \cdot 2H_2O + 3\,OH^- \quad [6]$$

where the structure of the reaction product may be α-$Ni(OH)_2$, according to Bode (10, 11). The reactant and product involved in reaction [6] probably belong to the innermost portions of the electrode film. The extent of each reaction for a particular set of the perturbation variables is given by the corresponding cathodic charge as already indicated in Table III. The three different reactants appearing, respectively, in reactions [4], [5], and [6], two of them identified with asterisks, undergo structural changes which are represented by the following reactions

$$[NiOOH]^{**} \rightleftarrows [NiOOH]^* \rightleftarrows \beta\text{-}NiOOH \quad [7]$$

The chemical transformations of the various species schematically represented by reaction [7] probably involve structural changes related to the β-NiOOH and γ-NiOOH species discussed in the literature by different authors (13-15). These transformations, which are revealed both in the anodic and in the cathodic potentiodynamic profiles, are likely related to a change in the water content and the cation concentration in the oxy-hydroxide nickel lattice. The cation contribution to build up certain structural configurations of the lattice may involve an ionic mass transfer toward the reaction interface in an opposed electrical field.

Table III. Data derived from the cathodic current peaks

Peak number	III-A	III-B	IV
Current peak potential/V	0.630	0.585	0.510
Charge/mC × cm⁻²	1.67	0.33	0.96

Chemical reactions such as [7] should be related to the so-called aging process of the anodic reaction product.

These results can explain how three out of four transition times recorded at the four arrests of the galvanostatic E/time display the electroreduction of the oxidized nickel electrode without the assumption of dubious surface compounds (16). The fourth transition time may be related to the presence of O_2.

The anodic profile should correspond to the sum of various anodic processes, as can be deduced from potentiodynamic data previously reported (7). Therefore, the apparent independence of the potential of the anodic current peak on the potential sweep rate is difficult to interpret unless the structural transformations of the different film components at the electrode surface are taken into account. Thus, the average film composition should depend, under constant switching potentials, on the potential sweep rate. So the activity ratio of the more reactive to the more stable species increases just as the potential sweep rate does. This means that the current contribution at the cathodic side of the anodic current peak should increase accordingly so that the over-all effect is to depict an E/I profile which on the whole shifts toward the cathodic potential region. In this way if there is any shift of the current peak potential toward more anodic values as v increases, it might be either partially or totally compensated. The situation is, then, to some extent similar to that encountered in the electroreduction of oxygen-containing film monolayers on Pt (30) and Au (31).

Under the present experimental conditions the proton diffusing out of the film, as step [2a] implies, exerts no appreciable influence on the reaction rate. The reported proton diffusion coefficient in the nickel hydroxide lattice covers the range 2×10^{-7}-2×10^{-9} cm^2/sec (7, 32, 33). Therefore, this process is fast enough to be in equilibrium during the potentiodynamic sweep unless the potential perturbation is so short that the $\sqrt{Dt}$ is of the order of the layer thickness. Under the present circumstances this would require a potential sweep rate of the order of 10^3 V/sec. The situation, however, is different when thicker hydrated hydroxide films are involved. When step [2a] occurs in a multilayer it induces a proton transfer mechanism through the existing film and the proton neutralization at the solution side of the electrical double layer.

When thin films are involved under relatively fast perturbation conditions it seems rather arbitrary to assign to the ill-defined material present at the working electrodes only one particular and constant structure participating in the over-all electrochemical processes. The conclusion is that at least three anodic reaction products are formed as revealed by the three well-defined cathodic current peaks. Furthermore, depending on the number of potential sweeps there is good evidence that only two current peaks are seen during the anodic reaction under conventional triangular potential sweep perturbations, although the triangularly modulated potential sweep technique reveals the occurrence of at least three well-distinguished processes (34). Therefore, three nickel hydroxide species and three nickel oxy-hydroxide species are participating in these processes.

Crystal-structure analysis of the following pure crystalline phases has been undertaken, namely, β-$Ni(OH)_2$, α-$Ni(OH)_2$, β-NiOOH, and γ-NiOOH (11, 14). The existence of the two forms of the α-$Ni(OH)_2$ and γ-NiOOH are also reported (10, 11, 14). There is, therefore, a good correspondence between the number of species which are required for the three different electrochemical processes. The proper configuration of the species indicates that the first species to be electrooxidized is α-$Ni(OH)_2$, while the electrooxidation of β-$Ni(OH)_2$ should occur at more positive potentials. On the other hand, β-NiOOH should be elecrtoreduced at the more cathodic potentials, provided that the double cathodic current peak placed at more anodic potentials may belong to the electroreduction of the two γ-NiOOH forms. Whatever the case, caution needs to be exercised at present in assigning a particular redox system to the pairs of current peaks potentiodynamically recorded.

The suggested reaction pathway, although it must be considered without structural compromises, is more general than any of those previously discussed. As a matter of fact it contrives the idea of having a rate-controlling proton transport process as earlier suggested (7, 33), and it includes chemical side reactions to explain the aging effect of the film anodically formed.

Polarization and Corrosion in Sodium/Sulfur Cells

Roger J. Bones and Trevor L. Markin

A.E.R.E. Harwell, Materials Development Division, Didcot, Oxon, OX11 ORA, England

ABSTRACT

In a previous publication (1) we showed that stainless steel undergoes corrosion in a sodium polysulfide melt when polarized cathodically (*i.e.*, at the end of discharge in a Na/S cell). This basic electrochemical study of the sulfur/polysulfide cathode has been extended using specially designed electrochemical cells incorporating potential probes in the cathode. The apparent accumulative loss in capacity on cycling of Na/S cells is explained in terms of increasing polarization which, in turn, is related to the steel corrosion phenomenon.

The general principles of operation of sodium/sulfur cells, first developed by Kummer and Weber (2) are well known. An early favored sulfur cathode current collector, used in the form of an outer case, was stainless steel. However, it has been shown that on deep cycling, such a current collector can undergo severe corrosion during the operation of cells; also the cells in turn can suffer considerable loss of useful capacity—typically 50% in <200 cycles. In recent years workers in the U.K. have favored the central sulfur cell design (3); this circumvents the problem of cell case corrosion but the electrochemical behavior of the central cathode is similar to that of the cathode in the central Na cell. For convenience the discussions in this paper refer to a central Na cell.

The sulfur electrode itself typically consists of a sulfur/polysulfide melt distributed within a carbon felt matrix bounded on one side by the βAl_2O_3 electrolyte and on the other side by the electronic conducting current collector. There are several publications (4-6) dealing with the fundamental studies of the operation of the sulfur electrode. A relationship has also been shown to exist between cathode polarization and cell case corrosion (5) which can lead to progressive capacity loss on cycling. This paper describes an extension to the previous study; experiments have been performed to measure the electronic and sodium potentials within an actual working cathode in order to gain further insight into the factors limiting the operation of the electrode. The results are related to the corrosion phenomena observed in practical Na/S cells.

It is not possible to advance unambiguous explanations of the complete mode of operation of such a complicated electrode from these experiments alone. Rather, the results should be considered together with other studies in order to obtain a more complete picture.

Experimental

Experiments referred to previously (1) showed that when stainless steel (Type AISI 316) was immersed in sulfur or sodium polysulfide (Na_2S_5-$Na_2S_{3.6}$) a protective sulfide film formed on its surface. It was also shown that when an external potential was applied across a cathode matrix (containing $Na_2S_{3.6}$) sandwiched between two such sulfided electrodes, it was possible under certain conditions to strip off this protective film. This occurred when the particular electrode was sufficiently negatively polarized. The clean shiny metal surface remaining was rapidly resulfided on current reversal. Repeated cycling in this manner lead to progressive corrosion of the electrode and to a buildup of a crust of corrosion products adjacent to the steel electrodes, similar to that observed in the postoperative examination of tubular sodium/sulfur cells which had stainless steel cases and had suffered considerable capacity loss.

It was postulated that the imposition of an applied potential across the mixed ionic/electronic electrode matrix causes partial electrolysis of the ionically conducting molten phase, giving rise to localized sulfur/polysulfide compositions (Na/S ratios) in the vicinity of the electrodes, which can be significantly different from the bulk equilibrium composition.

In order to investigate this, the experiment was repeated using a specially constructed twin electrolyte experimental cell shown in Fig. 1.

The twin electrolyte experimental cell.—An electrochemically prepared sulfur electrode specimen was sandwiched, under compression, between two platinum gauze electrodes which were in turn strapped to two identical βAl_2O_3 tubes containing liquid sodium. The platinum electrodes could serve as both active electrodes and electron potential probes. The liquid Na/electrolyte assemblies served as similar sodium potential reference electrodes for measurement of Na potentials at the extremes of the cathode. The cell was operated at 350°C in an enclosed argon gas environment.

A range of potentials was applied across the cathode specimen between electrodes 3 and 4 in a stepwise manner. Na potential measurements were made of the melt in the vicinity of these electrodes, using a high impedance digital voltmeter, between electrodes 1 and 2 and between 4 and 3. By reference to the well-known dependence of cell OCV of Na/Na polysulfides composition shown in Fig. 2, the local Na/S ratios of the melt adjacent to the βAl_2O_3 tubes were derived.

Key words: battery, cathode, corrosion, electrode.

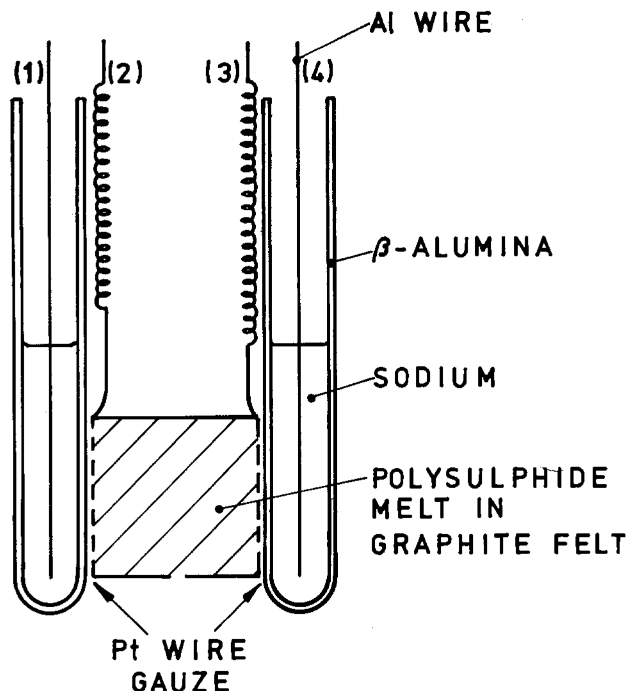

Fig. 1. Twin electrolyte experimental cell for studying the electrochemistry of the cathode melt.

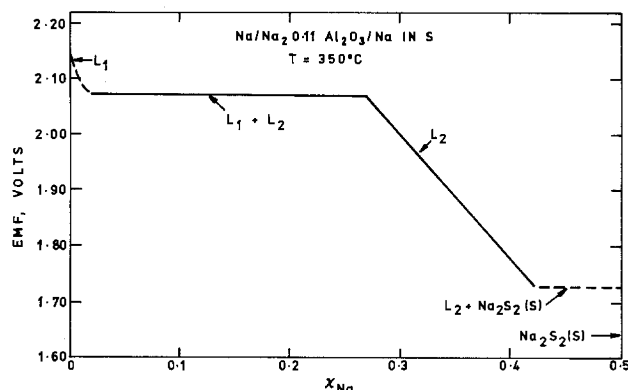

Fig. 2. Reversible emf of the Na/S cell as function of cathode composition.

Figure 3 shows the results obtained for three such experiments starting with initially different bulk Na/S melt compositions—Na_2S_4, $Na_2S_{3.45}$, and Na_2S_3. The extent of the polarization caused within the cathode matrix can be seen to increase as the applied potential IR increases. The positive electrode becomes richer in sulfur (higher OCV with respect to bulk melt equilibrium composition) whereas the negative electrode experiences a relative Na enrichment (lower OCV). Stable readings were obtained in most cases in 1-2 min, although unstable, rapidly falling values were observed at the negative electrode for values of <1.73V, indicating a rapidly increasing polarization situation.

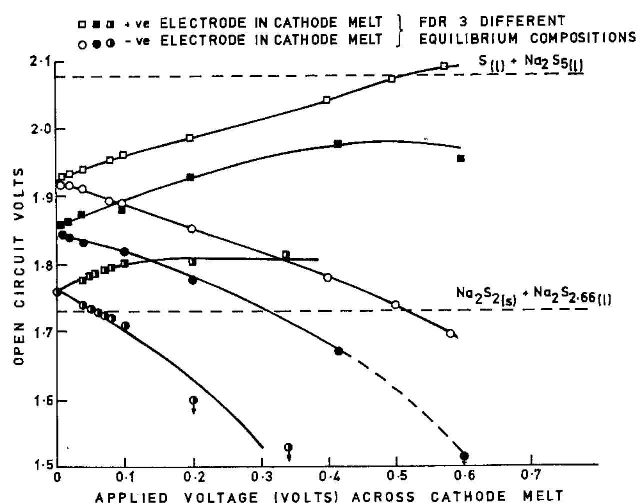

Fig. 3. OCV at positive and negative electrodes as the applied voltage across the cathode increased stepwise.

In repeat experiments, using presulfided stainless steel electrodes instead of platinum, it was found that the dark protective sulfide layer was removed when these OCV measurements of the melt at the negative electrode was less than 1.73V.

From Fig. 3 it can be seen that this occurs for example at an applied potential of 50 mV for a starting composition of Na_2S_3 (OCV = 1.78) and at an applied potential of 300 mV for an equilibrium bulk composition having an OCV of 1.85.

Thus a relationship exists between corrosion (or more exactly corrosion film stripping) of stainless steel and high imposed negative potentials. Further experiments were carried out using the same apparatus, in different modes, in order to relate this further to actual cathode behavior in a working electrode. In this series of experiments one of the Na-containing electrode tubes was used as a conventional Na electrode of a Na/S cell, transferring Na to and from the cathode matrix. The two platinum gauze electrodes were used as cathode current collector and electron potential probe, respectively, in attempts to monitor electronic potentials actually developed across a working cathode.

The later stages of a normal discharge half-cycle were studied by connecting a load between electrodes 1 and 3 and allowing the cathode specimen to complete a normal constant current discharge from an initial OCV of 1.86. During this discharge the electronic potential difference across the cathode between electrodes 2 and 3 was recorded continuously as was the change in Na potential at both the working and nonworking electrolyte surfaces. The discharge was terminated when a massive decrease in cell voltage occurred, leading to a situation when a constant current condition could no longer be maintained.

Figure 4 shows the actual voltage discharge curve between electrodes 1 and 3 simulating normal cell discharge between the sodium electrode and the cell case. The monitored Na potential close to the working electrolyte (*i.e.*, potential 1-2) showed only slight deviation from calculated equilibrium OCV values, whereas that at electrode 3 changed dramatically, indicating rapidly changing Na/S composition at the surface of electrode 3.

The potential difference monitored across the cathode 2-3 during this discharge is shown in Fig. 5 where it can be seen that over most of this range the potential drop is fairly constant (~50 mV), but this increases rapidly close to the end of discharge, leading to the low cell operating voltage. Additional platinum wire potential probes, evenly spaced across the cathode thickness, confirmed that this rapid nonohmic behavior occurred only close to the interface between the metal current collector and the cathode matrix. It is important to realize that the polarity of this developed potential is opposite to that of the cell terminals. That is to say, the cell case is negative with respect to the remainder of the cathode, even though it is the positive pole of the cell. It follows that close to the end of discharge the cell case becomes highly negatively charged with respect to the sulfur electrode. The previous applied potential experiments showed this can lead to severe progressive electrochemical corrosion (erosion) of the cell case if the extent of the polarization is not controlled.

Any change in the system which reduces the potential developed across the cathode would reduce the

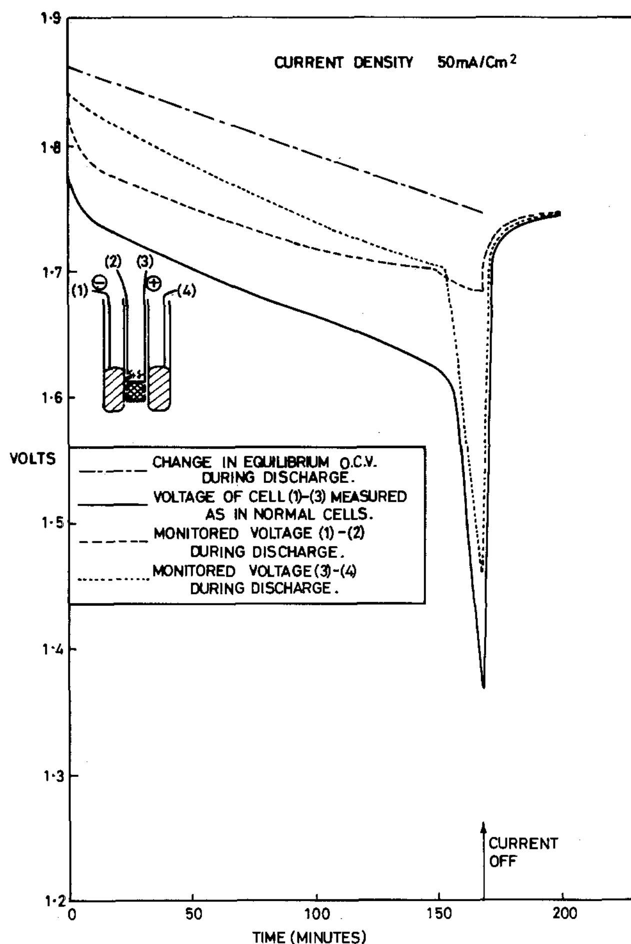

Fig. 4. Cell discharge between electrodes 1 and 3 at constant current, and sodium potentials monitored at edges of sulfur electrode.

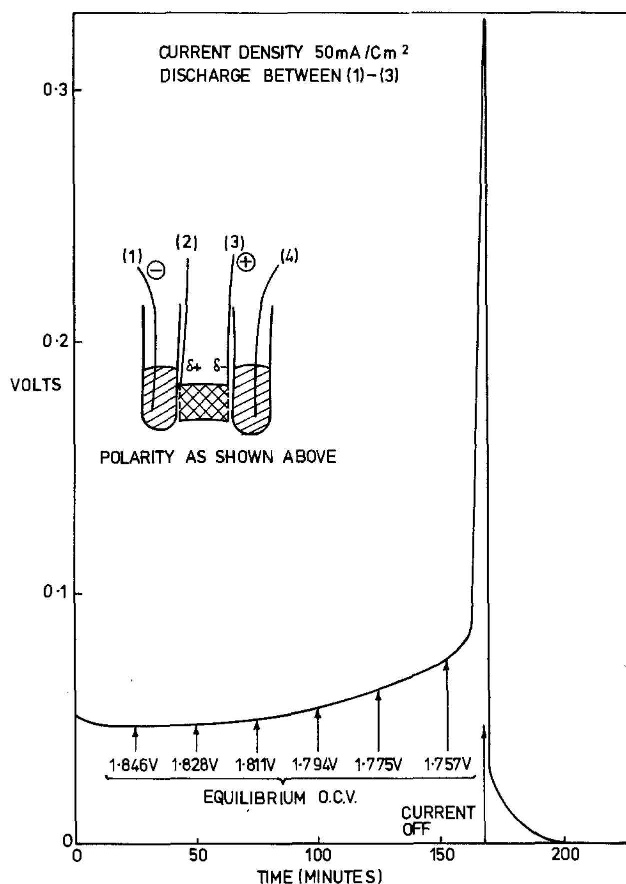

Fig. 5. Potential developed between electrodes 2 and 3 (across cathode) during cell discharge at constant current.

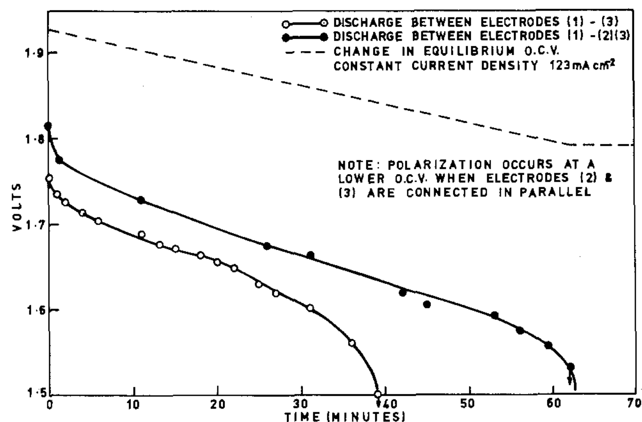

Fig. 6. Normal cell discharge 1-3, and discharging with electrodes 2-3 in parallel.

polarization and, therefore, any change within the structure of the cathode which reduces its electronic resistance R would be beneficial. The discharge experiments were repeated at different current densities, initially using electrodes 1-3 and secondly by connecting electrodes 2-3 in parallel and discharging between electrodes 1-2 and 3. One result obtained is shown in Fig. 6 for a current density of 123 mA cm^{-2}. It can be seen that the parallel coupling discharge gives a higher operating voltage on discharge than the normal electrode 1-3 discharge at the same current density. The IR voltage loss has been decreased—the cell resistance was lower due to the increased electron injection capabilities of electrode 2. The equilibrium OCV at which polarization occurred, shown by a rapid change in V, was 1.84V for normal discharge, but advantageously lower at 1.79V for the cathode with the additional current collector. The effect of coupling electrodes 2 and 3 is to reduce the potential difference across the cathode extremities to zero and to reduce significantly the internal polarization within the cathode.

If a permanent change in the cathode structure is contemplated, to reduce corrosion on discharge the effect of such a modification on the recharge must be considered.

The previous experiment was repeated for the charge half-cycle. It was found that when electrodes 2 and 3 were connected in parallel, this was not detrimental to the recharge at 50 mA cm^{-2}.

Having demonstrated practically the conditions under which polarization can be generated by applying suitable potentials across the cathode specimen and by monitoring actual potentials developed inherently in a working cathode, it was decided to use the twin electrolyte cell to study an aged cathode sample from a Na/S cell.

A radial segment was cut from a recovered cathode of a cell which had apparently lost practically all of its reversible capacity on cell cycling. The specimen was well impregnated and had a thin brown crust on the outside surface where it had been in contact with the steel cell case. The specimen was assembled into the cell between electrodes 2 and 3 with the outer surface against electrode 3 simulating the cell case.

At 350°C, under a similar compression to that employed in the cell, the OCV of the sample monitored both with reference to electrode 1 and 4 was 1.87V. By connecting an external load it was possible to discharge the cathode sample at ~100 mA cm^{-2} by using electrodes 1-2. However, a discharge current of only 3 mA was obtained when discharge was attempted between electrodes 1 and 3 and this was accompanied

by massive polarization—the potential developed across the cathode 2-3 rose rapidly to >1V.

From Fig. 3 one can see that for such massive polarization to occur on discharge with this initial composition and such a low current, the resistance R in the cathode/electrode junction must be very high. It appears that the hard outer crust (probably formed via corrosion of the can) has a very high resistance to electrons and, furthermore, its continuity prevents the carbon fibers from contacting the cell case.

This was confirmed subsequently by grinding away the hard crust from this and similar samples and replacing the cathode samples in the cell. The cathode then behaved normally when discharging with either electrode 2 or 3; it cycled readily and developed anticipated potentials of only 50-100 mV across the cathode. It appears that the high resistance to electron flow from the cell case to the cathode matrix had been interpreted as a capacity loss. In fact it has now been shown that the charge/discharge capacity of the bulk of the polysulfide cathode was far from being exhausted.

Variable compression of graphite felt.—All the previously described experiments have been carried out with a constant degree (25%) of compression of the graphite felt compared with its fully expanded state. In order to study the effect of the extent of the compression used, the compression of the graphite was varied from nil to 50% while the cell was discharged. The cell output and the potential developed across the cathode 2-3 were monitored.

The cell output improved and, as can be seen from Fig. 7, the potential across the cathode decreased as the degree of compression was increased. The 50% compression led to irreversible contraction of the graphite felt. The developed potential across the cathode seems least sensitive to degree of compression at levels of 25-33% (*i.e.*, that normally used in Na/S cells).

It can be implied that, even at optimum compression, with this cell construction one is going to be forced to tolerate potentials of >50 mV close to the end of discharge at commonly used current densities of 100 mA/cm^2. This is intrinsic to the graphite felt and is additional to potentials resulting from corrosion of the container. A current collector of lower resistance would be desirable.

Na/S cell incorporating extra potential probe.—The above experiments were repeated (and extended to study the recharge process) in a purpose-built, tubular sodium/sulfur cell. The cell (Fig. 8) incorporated an additional potential probe within the cathode consisting of a wire mesh strapped to the electrolyte tube. This probe was insulated from the cell case via a special seal.

The cell was cycled to establish stable operating characteristics. It was then subjected to several discharge cycles at different current densities during which the actual potential developed across the cathode was monitored. The results, shown in Fig. 9, confirm those obtained earlier with the small cell; over most of the range ohmic behavior is observed, but a sharp rise in cathode potential difference occurs towards the end of discharge limiting the extent of constant current discharge available.

Similar experiments on the recharge process were then carried out at a variety of current densities (Fig. 10). It should be noted that the starting OCV of the cell was different in each case. It can be seen that at charging current densities of up to 130 mA cm^{-2} the monitored potentials across the cathode are approximately ohmic throughout the entire range. There is no tendency for the potential to rise close to cell polarization on charge; in fact a slight tendency to decrease by a few millivolts is noticed. Charging the cell at 190 mA cm^{-2} caused considerable premature polarization of the cell itself, leading to nonohmic

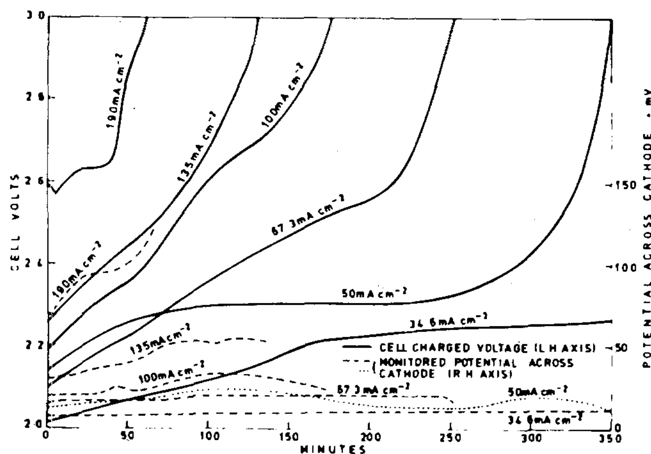

Fig. 10. Electronic potential drop across cathode and cell voltage during charge at different current densities.

behavior across the cathode. The shape of the potential curve also suggests that it is in some way directly related to the cell polarization.

For all charge current densities up to 135 mA cm^{-2}, some alternative explanation is required for the polarization often observed on charge not related to the potential as measured across the cathode. The most likely explanation for this behavior on recharge is the buildup of a sulfur insulating layer on the surface of the electrolyte.

Discussion

The onset of polarization in a working cathode has been studied in a miniature and an engineered sodium/sulfur cell. It has been shown that over the entire charge cycle and most of the discharge cycle an AISI 316 stainless steel cathode current collector forms a protective sulfide layer. Furthermore, it is only the polarization which occurs at the end of discharge that is instrumental in removal of the protective layer, a process which if repeated continuously during each cycle leads to severe thinning of the steel. For such high chromium steels as AISI 316 (17 w/o Cr) the principal protective effect arises from the formation of Cr_2S_3 and the spinel compound $FeCr_2S_4$, through which the diffusion of Fe^{++} is very much slower than either FeS or FeS_2. Since it can be shown that these chromium phases form only slowly, repeated removal of the sulfide film prevents the formation of a satisfactory barrier.

The polarization of a working cathode is primarily a function of the structure and operating conditions of the felt/melt matrix .Any change which can be made to reduce a rising potential difference across the cathode at the end of discharge will reduce the polarization and hence corrosion. Typical changes which can be made are to lower the effective resistance of the matrix, to use two or more current collectors electrically connected, to restrict the depth of discharge to, say, an OCV of 1.85 instead of Na_2S_3 (OCV 1.78), or to reduce the discharge current close to the end of the cycle. In the event of restricting the depth of discharge one would have to assess the penalty of an immediate loss in capacity initially compared with a higher initial capacity which decreased at a much faster rate. The operation of a Na/S cell in which all of the above-mentioned variables were changed favorably led to a considerably reduced capacity loss in 200 cycles from 50% to <10%.

Whether sufficient improvement can be achieved for steel to be used in an unprotected state as a cathode current collector remains to be seen. If protective coatings are found to be necessary such control of operating conditions may still be necessary if the coatings do not provide 100% protection over the entire life of the battery.

The Behavior of the Zinc Electrode in Alkaline Solutions

I. The Effect of Ionic Strength at the Equilibrium Potential

T. P. Dirkse*

Calvin College, Grand Rapids, Michigan 49506

ABSTRACT

The exchange current densities of the zinc electrode in KOH solutions were determined under a variety of conditions. Special attention was given to the total ionic strength of the solutions. While the exchange current density does depend on the total ionic strength of the solution, there is no evidence that the water molecule enters directly into the electrode reaction. Instead, the ionic strength appears to influence the mobility of the reacting species and in this way modifies the exchange current density.

Previous work on the determination of the exchange current density for the zinc electrode in strongly alkaline solutions showed that this electrode process was sensitive to the ionic strength of the electrolyte (1). It was suggested at that time that his sensitivity could account for the maximum observed in the i_0 *vs.* KOH

* Electrochemical Society Active Member.
Key words: electrolyte, electrode, current density, kinetics.

concentration data. It was also suggested that this sensitivity indicates that water plays a role in the zinc-electrode processes although the role of the water could not be unequivocally determined.

The present work is a report on a further and more systematic investigation of the effect of the ionic strength of the electrolyte on the zinc-electrode processes in an effort to determine more precisely the role of the water molecule in these processes. This study is limited to the behavior of the zinc electrode near the equilibrium potential. A later report will deal with the effect of ionic strength on the zinc-electrode processes in the Tafel region.

Experimental

Stock solutions of KOH, KOH + Zn(II), and KF were prepared by using analytical grade solids and doubly distilled deionized water. The Zn(II) was introduced by dissolving ZnO in a KOH solution. These stock solutions were then used to prepare the working solutions. This was done by taking prescribed volumes of the stock solutions and quantitatively diluting them. The ionic strength of the solutions was controlled by the addition of KF or other indifferent electrolytes.

The exchange current densities were measured galvanostatically by obtaining $\eta - i$ data within 7 mV of the equilibrium potential (2). All work was carried out at room temperature, 21° ± 1°C.

Results and Discussion

The results that were obtained are shown in Fig. 1-4. At lower ionic strengths, Fig. 1, it was possible to use indifferent electrolytes other than KF, but at higher ionic strengths only KF was sufficiently soluble to obtain the desired ionic concentrations. Consequently, the ionic strength was maintained with KF. This has the added advantage that the F^- and OH^- ions are isoelectronic and thus likely have similar hydration numbers. Figures 3 and 4 show the effect of varying ionic strength at constant OH^- ion concentration: Figure 3 shows the effect on that part of the curve where i_o is increasing with increasing KOH concentration, while Fig. 4 shows the same effect on that part of the curve where i_o decreases as the KOH concentration increases.

Because the OH^- ion and the Zn(II) concentration were held constant in a given series of solutions and because the zinc electrode was 99.999% pure, a plot of log i_o *vs.* log μ should give a line whose slope is the reaction order with respect to the ionic strength. Such a plot of the data in Fig. 4 is given by the solid line on Fig. 5. The slope of this line is −1. It is tempting to ascribe this to the influence of water on

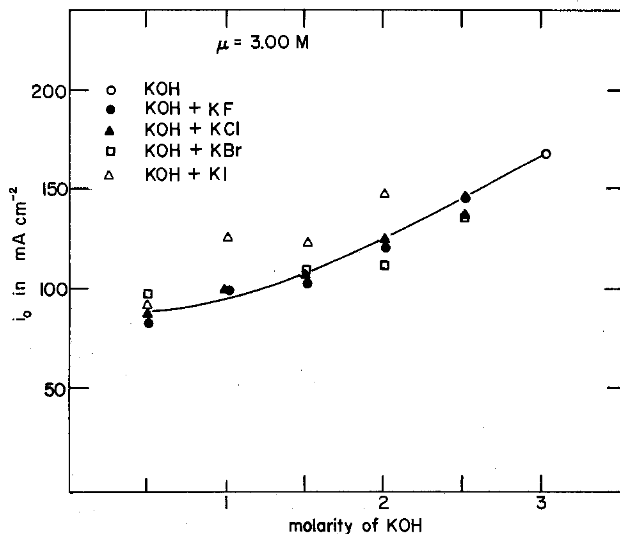

Fig. 1. Exchange-current densities of the zinc electrode in solutions of 3M total ionic strength.

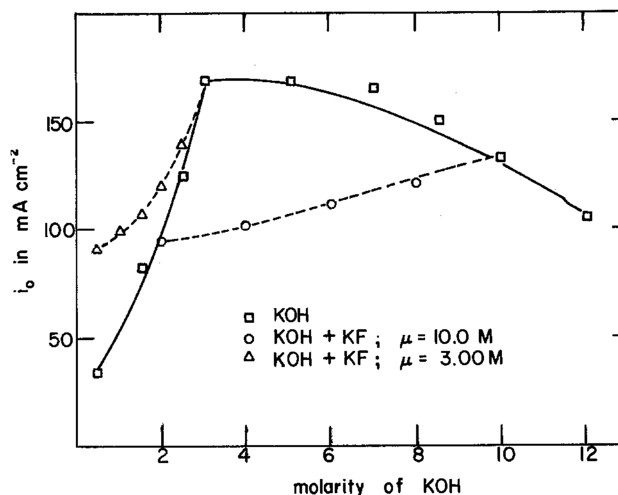

Fig. 2. Exchange-current densities of the zinc electrode as a function of OH^- ion concentration at room temperature.

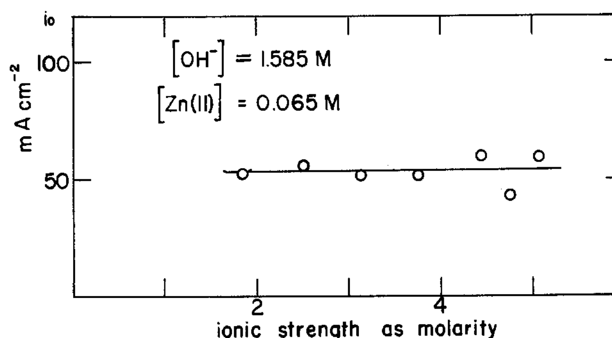

Fig. 3. Exchange-current densities of the zinc electrode as a function of total ionic strength with low OH^- ion concentration.

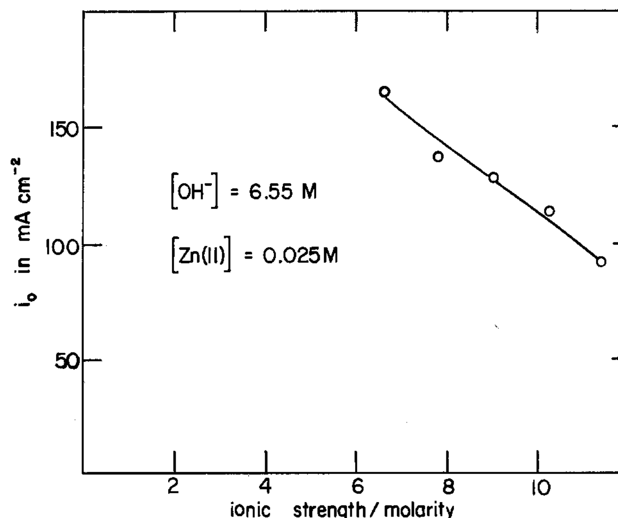

Fig. 4. Exchange-current densities of the zinc electrode as a function of total ionic strength with high OH^- ion concentration.

the electrode reaction. However, because of the uncertainty of the relationship between the ionic strength of the solution and the activity of the water, the exact significance of this result is in doubt.

An alternate way of approaching this is to assume that the activity of water is a function of the ionic strength of the solution. Then it may be possible to use the data for the activity of water in KOH solutions (3). If it assumed further that the activity of water in KOH solutions is the same as that in KOH + KF solutions having the same ionic strength then the dashed line in Fig. 5 represents the log i_o − log a_{H_2O}

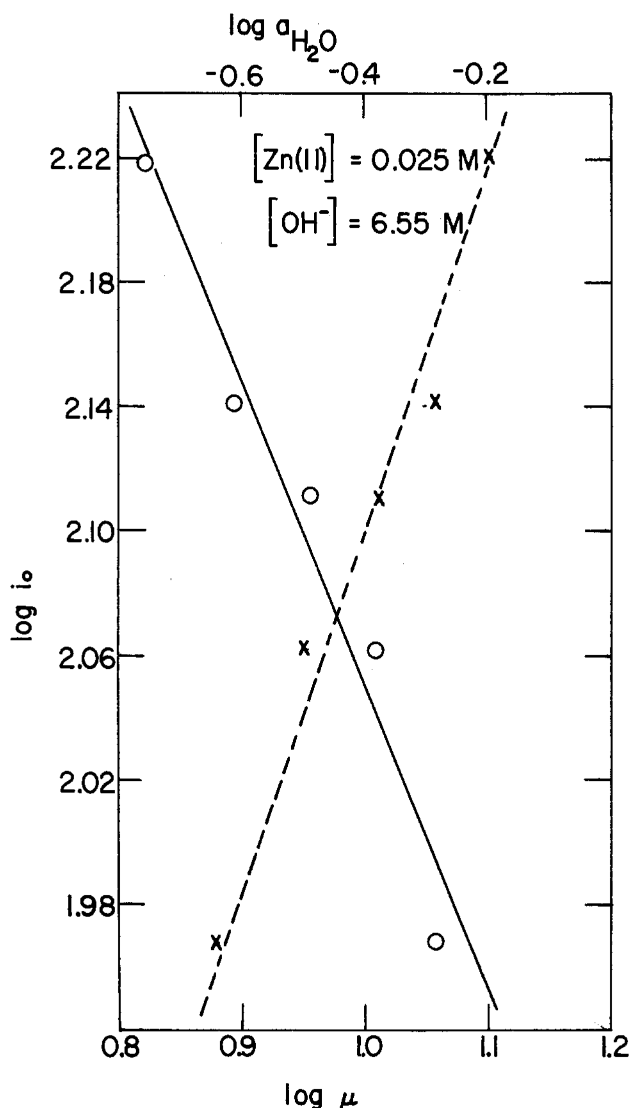

Fig. 5. Plot to determine the reaction order of the ionic strength

relationship. In this case the slope of the line is 0.54. These results indicate that the water molecule does play a role in the zinc-electrode process at equilibrium but the precise nature of this role cannot be assigned from this information.

Moreover, a log i_0 *vs.* log μ plot for the data in Fig. 3 gives a line with a slope of zero. Obviously, it is necessary to assume that the effect of ionic strength (and perhaps the role of the water molecule) depends on whether one is considering the region of ascending or descending i_0 in Fig. 2.

Solutions about 3-5M in KOH appear to be some sort of watershed so far as the characteristics of KOH solutions are concerned. In solutions less than about 3M the activity coefficients of the OH^- ion are less than one, but become larger than one at concentrations greater than 3M (3). Also, a solution that is about 3M in KOH appears to separate those solutions for which the specific conductance increases with increasing pressure and those for which the specific conductance decreases with increasing pressure (4). Lown and Thirsk account for this by suggesting that the mechanism of specific conductance is twofold: a hydrodynamic and a proton-transfer mechanism. The latter requires so-called "unbound" or "free" water molecules, *i.e.*, water molecules not dominated by proximity to an ion. As the ionic strength increases there are more ions, fewer "free" water molecules, and the proton-transfer mechanism makes a smaller contribution to the specific conductance of the electrolyte.

Using this suggestion of Lown and Thirsk for the solutions described on Fig. 1 then, as a first approximation, the amount of "free" water molecules should be the same for all the solutions because all have the same ionic strength. Then any change in the exchange current density on Fig. 1 is most likely due to the change in the concentration of the OH^- ion. Even when the total ionic strength is 10M, i_0 increases with OH^- ion concentration, Fig. 2.

The decrease in exchange current density, Fig. 4, could be attributed to a decrease in the amount of "free" water. However, if that is the cause then a decrease in i_0 should also have been observed on Fig. 3. The fact that this is not observed strongly suggests that the water molecule is not directly involved in the electrode reaction. This is further substantiated by the fact that when water was used as the electrolyte, the current flow was extremely small (less than 10^{-4} A cm^{-2} for overpotentials up to 400 mV). Further, practically no current could be obtained up to overpotentials of 235 mV in a 6.12M KF solution, indicating that neither the K^+ ion nor the F^- ion was a contributor to the exchange reaction in any of these solutions.

It appears from all this that i_0 for the zinc electrode does depend on the OH^- ion concentration and not on the water molecule directly. However, in some way the effect of changing ionic strength masks the effect of the OH^- ion concentration.

A reasonable explanation for this is suggested by the work of Lown and Thirsk (4). An increase in ionic strength causes a decrease in the amount of "free" or "unbound" water. This also means a decrease in the mobility of the OH^- ion and a decrease in the exchange current density if the OH^- ion is directly involved in the exchange reaction.

Comparing Fig. 3 and 4, it is obvious that when the OH^- ion concentration is held constant, the effect of changing ionic strength is different for solutions in which i_0 is increasing with KOH concentration, Fig. 3, than for solutions in which i_0 is decreasing with increasing KOH concentration, Fig. 4. For the solutions represented in Fig. 4 the concentration of KOH is such that there is relatively little "unbound" water and hence the effect of increasing ionic strength on decreasing the mobility of the OH^- ion is the dominant factor. On the other hand, the solutions represented on Fig. 3 are those for which the concentration of "unbound" water is larger and the effect of increasing ionic strength on the mobility of the OH^- ion is not large enough to mask the effect of the OH^- ion on the electrode process. Furthermore, as the ionic strength increases to about 4M, Fig. 3, the results become more erratic, suggesting that in this region the effect of ionic strength is beginning to make itself felt.

Conclusions

The water molecule does not take part directly in the zinc-electrode process at the equilibrium potential. The reaction does involve the OH^- ion and as the concentration of this ion increases, so does i_0. However, the ionic strength does determine the concentration of "free" water molecules in the solution and as this concentration of "free" water decreases, the mobility of the OH^- is also decreased resulting in a decreased exchange-current density. This becomes significant and increasingly dominant in KOH solutions more concentrated than about 3-5M.

As a practical matter, then, any effort to determine the role or reaction order of the species involved in the electrode reaction should give careful consideration to the ionic strengths of the electrolytes that are used. It would be well to carry out such work at constant ionic strength to minimize the effect of changing concentration of "free" or "unbound" water molecules on the mobility of any reacting species.

Localized Corrosion on Slip Steps of Aluminum Straining

I. A. Maier and J. R. Galvele*

Comisión Nacional de Energía Atómica, Departamento de Materiales, Av. Libertador 8250, Buenos Aires, Argentina

ABSTRACT

The initial steps of localized corrosion of aluminum strained in aggressive solutions were studied by electron microscopy of oxide replicas. Aluminum samples were strained at a constant potential in the following deaerated solutions: 1M NaCl (pH 7); 4M NaCl (pH 11); and 1M $NaNO_3$ (pH 7). No pitting was found on the aluminum strained in those solutions below the pitting potential; the slip bands showed the same substructure as that found on aluminum strained in air. At, and above, the pitting potential, pitting was found on the surface of the strained aluminum. Pitting nucleated on the whole surface in neutral NaCl solutions. In 4M NaCl solution (pH 11) and in 1M $NaNO_3$ solution pitting nucleated preferentially on the slip bands, leading to semicylindrical pits. It was also concluded that mechanical film breakdown is not a sufficient condition for pit initiation. Another process, such as localized acidification, must be assumed to explain pit initiation at pitting potential.

Pitting is a form of very localized corrosion found on corroding metal surfaces. From a mechanistic point of view, three different types of pitting have been described (1). They are: (*i*) electrochemical depassivation, which appears in neutral and alkaline solutions and is characterized by the existence of a pitting potential; (*ii*) chemical depassivation, which is observed mainly in acid solutions and in which no pitting potential is found; and (*iii*) HCl-stainless steel type, which is observed in acid solutions and which shows a pitting potential, but this potential is not affected by alloying elements as is the case with electrochemical depassivation.

The pitting initiation process in electrochemical depassivation could follow different paths, and there is no clear description yet about the detailed mechanism of pit initiation. In one line of thought (2, 3) it is considered that a very important step for pit initiation is the contamination of the oxide film by the aggressive anions. This contamination increases the conductivity of the oxide film, leading to enhanced localized dissolution (pitting). On the other hand, several authors (4-7) have suggested that the oxide film acts as an inert barrier with no effect on the mechanism of pitting. According to them pitting starts either at flaws already in the oxide film (4, 5) or at defects resulting from a continuous process of passivity breakdown and repassivation (1, 6-8).

Since the existence of such flaws or defects is questioned by some authors (2, 9), in the present work those flaws were produced by straining the metal, so as to study the changes observed on the metal surface by electron microscopy. The metal chosen was aluminum, which carries an air-formed oxide film of the order of 2.5×10^{-9}m (9). Thomas and Nutting (10) have shown that plastic deformation of annealed aluminum produces various kinds of slip bands containing slip steps at least 6×10^{-8}m high. Since the aluminum oxide film is very fragile (11), in deformation the film breaks easily, and the bare metal is exposed to the solution.

NaCl solutions and $NaNO_3$ solutions were chosen as aggressive media because aluminum shows a big difference in the rate of pit nucleation and in pit morphology in those solutions. In neutral 1M NaCl solutions pitting nucleates very easily, and the pits develop the {100} crystallographic planes (12). In 4M NaCl solution, *p*H 11, hemispherical pits have been reported (13). Hemispherical pits have also been found when aluminum is exposed in $NaNO_3$ solutions above the pitting potential (12). Pitting of aluminum in $NaNO_3$ solutions was found to develop more slowly than in neutral NaCl solutions, and it was also reported to be accelerated by straining the metal (6). The pitting potential of straining aluminum, in both solutions, was found to be equal to the pitting potential of static aluminum. From potentiostatic straining experiments Wexler and Galvele (6) concluded that semicylindrical pits should be formed on the slip steps of aluminum strained in $NaNO_3$ solutions. No direct proof of such supposition had been so far available.

During the present work no pitting was found to nucleate on aluminum strained in aggressive solutions at potentials below the pitting potential. Pits were observed only at, or above, the pitting potential. It was concluded that the mechanical breakdown of the passive film was not a sufficient condition for pit initiation, and that some electrochemical reaction should be assumed to take place at the pitting potential.

Experimental

Coupons 11.0 × 0.6 cm were cut from a 1 mm thick sheet of 99.99% aluminum. The coupons were pickled in a 10% NaOH solution, rinsed with a 10% HNO_3 solution, washed with distilled water, and dried. The coupons were annealed for 1 hr at 600°C, obtaining

* Electrochemical Society Active Member.
Key words: metals, anode, SEM, dissolution.

samples with about 1 mm diam grain size. Before being strained, the specimens were electrolytically polished for 8 hr in a 90% Butilcellosolve plus 10% perchloric acid solution, at 28V and 0°C. A metallic cell (14) internally lined with cured epoxy resin was used for the straining experiments. The joints between the parts of the cell and between the sample and the cell were sealed with silicon rubber gaskets. A platinum wire was used as a counterelectrode inside the cell, and the electrode potential was measured through a Luggin capillary.

The potential was measured against a saturated calomel electrode for the chloride-containing solutions, and against a saturated mercurous sulfate reference electrode for the $NaNO_3$ solutions. All the potentials are reported in the normal hydrogen electrode scale (NHE). The solutions were prepared with analytical-grade reagents and distilled water and were deaerated with 99.99% nitrogen. The measurements were performed at room temperature (20°C). The solutions used were neutral 1M NaCl solution, 4M NaCl solution (*p*H 11), and neutral 1M $NaNO_3$ solution. The alkalinization of the 4M NaCl solution was performed by addition of a NaOH solution. No buffers were used for these solutions.

The cell containing the sample was mounted on a straining machine and connected to a reservoir containing the test solution. Nitrogen was bubbled through the solution and the cell until deaeration was completed (about 90 min). Then the solution was let into the cell and the samples were polarized with a Tacussel PRT-20-2X potentiostat at a potential in the passive zone until the anodic current reached a quasistationary value. Then the potential was switched to the desired value and the specimen was strained at a strain rate of 5%/min and up to a total elongation of 10%.

In separate experiments the pitting potential of the samples in the different solutions was measured. The measurements were performed by increasing the potential in steps of 20 mV and recording the current until a quasistationary state was reached.

The corrosion morphology of the strained samples was studied by means of aluminum oxide replicas. The replicas were prepared (15) by anodizing the corroded samples in a 3% tartaric acid solution, partially neutralized with ammonium hydroxide, to *p*H 5.5. Good oxide replicas were obtained by anodizing the samples for 20-30 min at 28-30V. The surface of the anodized samples was scratched to obtain oxide replicas of the size of the grids for the electron microscope. The scratched samples were immersed for 1 min in a saturated mercurous chloride solution, washed with alcohol, and immersed in distilled water until the oxide replicas were detached from the metal surface. The oxide replicas were washed in a 10% HCl solution, then in distilled water, and finally in alcohol. The oxide replicas were observed either in a Philips EM 300 electron microscope or in a Hitachi HK-3AM electron microscope.

The profile of some of the corroded slip bands was measured by electron-stereomicroscopic techniques (16). By tilting the oxide replicas in the electron microscope, two pictures with a tilting angle difference of 12° were taken. These pictures were taken to a Hilger Watts SB 190 stereoscope, and from the parallax difference, the tilting angle, and the magnification, the depth profile in the pictures was calculated.

Results

Air-strained aluminum.—Figure 1 shows the electron micrograph of a sample strained to 10% elongation in air. Slip bands were found on the strained samples. The slip-line substructure of the slip bands, as described by Thomas and Nutting (10), was found on about 50% of the observed slip bands. No slip lines could be resolved on the remaining 50% of the slip bands. The absence of resolution of slip lines is probably due to the fact that the slip line separation in those bands was too small to be resolved by the oxide replica technique. By stereoscopic observation a smooth slope change is found on the sample surface across the slip band.

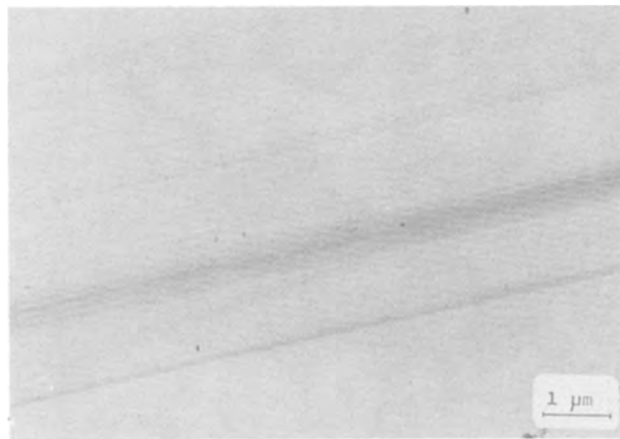

Fig. 1. Slip band substructure on aluminum strained to 10% elongation in air. Oxide replica observed by transmission electron microscopy.

Aluminum strained in pH 7, 1M NaCl solution.—The pitting potential measured for aluminum in deaerated 1M NaCl solution, *p*H 7, was found to be −0.53V. No pitting was observed on samples exposed for 5 hr at −0.70, −0.65, and −0.57V. At these three potentials the current density remained below 10^{-6} A/cm^2 during the experiments.

For the electron-microscope observations, aluminum samples were strained in the NaCl solution at the following potentials: −0.60, −0.57, −0.55, −0.53, −0.50, and −0.48V. At least two samples were strained at each potential.

The samples strained below the pitting potential showed a slip band structure similar to that found on air-strained aluminum. The main difference between the air-strained samples and the samples strained in 1M NaCl solution, below the pitting potential, was the partial disappearance of the slip line substructure, Fig. 2. While 50% of the slip bands showed slip lines on the air-strained samples, only 10% of the slip bands showed those lines on the aluminum strained in NaCl solutions below the pitting potential. One possible explanation is that the oxide film formed in NaCl solutions is thicker than the air formed film; therefore the slip line microstructure would be not so clear as in the air-strained samples. No evidence of corrosion was

Fig. 2. Slip band substructure on aluminum strained to 10% elongation in deaerated 1M NaCl solution, below the pitting potential (E = −0.55V). Oxide replica observed by transmission electron microscopy.

found on the slip bands of the samples strained in NaCl solutions below the pitting potential. No pitting was detected on the metal surface either. Besides, the stereoscopic observations gave the same profiles as those found on the air-strained samples.

At a potential 30 mV above the pitting potential some areas of the samples showed intensive pitting, as in Fig. 3. Other areas showed a disappearance of the slip lines on the slip bands, suggesting a further thickening of the oxide film. At higher potentials intense attack was observed on the slip bands and on the whole surface of the samples.

Aluminum strained in 4M NaCl solution (pH 11).—As reported by Kaesche (13), the pitting potential of aluminum in 4M NaCl solution (pH 11) is −0.56V, and the pits have a hemispherical shape. Straining experiments, most of them by duplicate, were performed at the following potentials: −0.60, −0.58, −0.56, −0.54, −0.52, and −0.50V.

Specimens strained below the pitting potential did not show localized corrosion. Beginning at the pitting potential, and up to a potential 40 mV above, the attack took the shape of hemispherical pits and was localized mainly on the slip bands (Fig. 4 and 5). At higher potentials pitting was more extensive and was localized also outside the slip bands. The pitting localization on the slip bands at potentials close to the pitting potential confirms previous observations made by Galvele *et al.* (12). According to these authors, when straining aluminum in 4M NaCl solutions (pH 11) the current density increase followed a square root law. This was interpreted as the result of nucleation of hemispherical pits on the slip bands, leading to semicylindrical pits. The microscopical observations made in the present paper confirm such supposition.

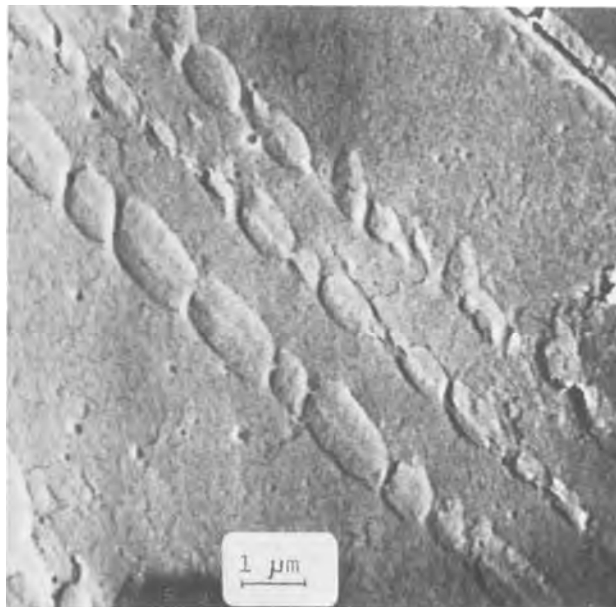

Fig. 5. Semicylindrical pits on slip bands of aluminum strained to 10% elongation in deaerated 4M NaCl solution (pH 11), above the pitting potential ($E = -0.52V$). Metallized plastic replica observed by scanning electron microscopy.

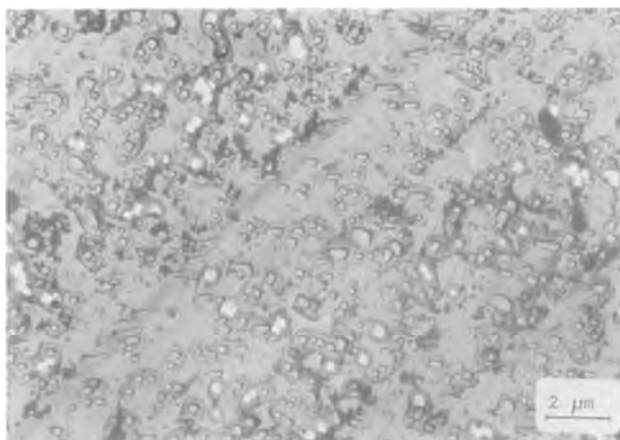

Fig. 3. Generalized pitting distribution on aluminum strained to 10% elongation in deaerated 1M NaCl solution, above the pitting potential ($E = -0.50V$). Carbon replica observed by scanning electron microscopy.

Aluminum strained in a neutral 1M $NaNO_3$ solution.—The pitting potential of aluminum in 1M $NaNO_3$ solution was found to be 1.70V, in agreement with previous publications (6). Samples exposed for 2 hr at 1.69V did not show pitting when observed under the optical microscope. There was no pitting either on samples exposed up to 5 hr at 1.0 and 1.5V. On the other hand, pitting was found on samples exposed for 2 hr at 1.71 and 1.74V.

Straining experiments were performed at least twice in neutral 1M $NaNO_3$ solutions at the following potentials: 1.69, 1.72, 1.74, 1.78, 1.79, 1.80, and 1.84V. The surface morphology of the samples strained at a potential below the pitting potential was similar to that observed on air-strained samples, Fig. 6. Above the

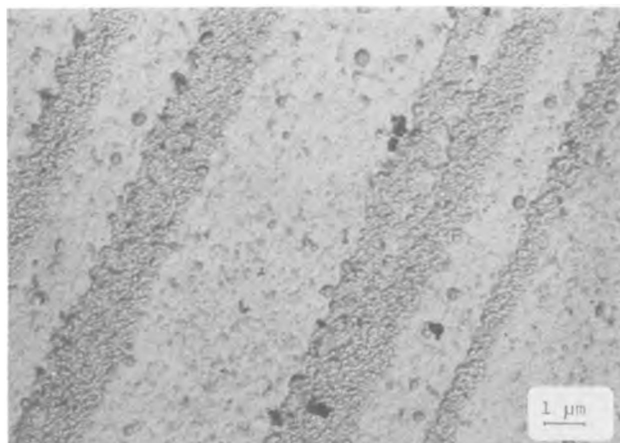

Fig. 4. Incipient hemispherical pits on slip bands of aluminum strained to 10% elongation in deaerated 4M NaCl solution (pH 11), at the pitting potential ($E = -0.56V$). Oxide replica observed by transmission electron microscopy.

Fig. 6. Slip band substructure on aluminum strained to 10% elongation in deaerated 1M $NaNO_3$ solution below the pitting potential ($E = 1.69V$). Oxide replica observed by transmission electron microscopy.

pitting potential and up to 1.80V, a disappearance of the slip steps from the slip bands was observed and incipient corrosion was detected on the slip bands. At 1.84V intensive pitting was found on the slip bands, Fig. 7, 8, and 9. No pitting was detected outside the slip bands. The extension of the pitting on the slip bands was not equal on all the bands, and three different degrees of attack could be detected. About 20% of the slip bands showed extensive, semicylindrical pits along the bands, Fig. 7 and 8. Another 20% of the slip bands showed small hemispherical pits, Fig. 9. The remaining 60% of the slip bands showed a rough surface and an absence of slip lines Fig. 9.

By stereomicrographic observation deep grooves were observed along the pitted slip bands. The semicylindrical pits appear to be the result of hemispherical pits that merge into a single semicylindrical pit after nucleating on a slip band.

Discussion and Conclusions

The present work confirms the assumptions made by Wexler and Galvele (6) that semicylindrical pits are formed on aluminum when strained in $NaNO_3$ solutions.

The present results are also relevant from the point of view of the mechanism of pitting. The straining of aluminum in NaCl solutions and in $NaNO_3$ solutions below the pitting potential produces a slip band substructure similar to that found on air-strained aluminum. Except for the effects attributed to film thickening, no other changes were found on the strained metal. No evidence of localized corrosion was found. The nucleation of pits could be seen only above the pitting potential. Above the pitting potential under conditions of easy pit nucleation, as with aluminum in NaCl solutions, pits nucleated on all the metal surface. Under conditions of difficult pit nucleation, on the other hand, as is the case with aluminum in $NaNO_3$ solutions, pits nucleated preferentially on the slip bands.

Fig. 7. Semicylindrical pits on slip bands of aluminum strained to 10% elongation in deaerated 1M $NaNO_3$ solution above the pitting potential (E = 1.84V). Oxide replica observed by transmission electron microscopy.

Fig. 8. Semicylindrical pits on slip bands of aluminum strained to 10% elongation in deaerated 1M $NaNO_3$ solution above the pitting potential (E = 1.84V). Oxide replica observed by transmission electron microscopy.

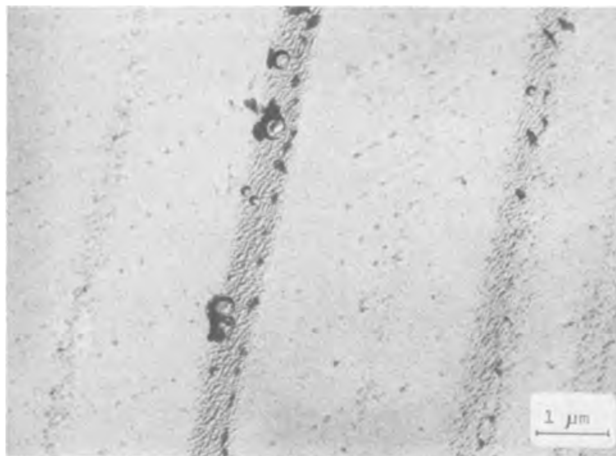

Fig. 9. Incipient hemispherical pits on slip bands of aluminum strained to 10% elongation in deaerated 1M $NaNO_3$ solution above the pitting potential (E = 1.84V). Oxide replica observed by transmission electron microscopy.

The absence of pitting on the strained metal below the pitting potential was also reported for zirconium in NaCl solutions (17, 18). It was observed that the zirconium oxide film, broken by straining below the pitting potential, was reformed by repassivation. The same conclusions were reached through surface-scratching techniques on zinc (7), cadmium (19), iron (20), and nickel (20). When the metal was scratched at a potential below the pitting potential, repassivation of the scratched surface was found. Only at potentials above the pitting potential pits were nucleated.

It is concluded that mechanical film breakdown, even in the presence of aggressive anions is not a sufficient condition for pit initiation. Assuming the presence of flaws in the film, as suggested by Wood and co-workers (4, 5), or the existence of a continuous process of film breakdown, as suggested by other authors (1, 6-8) the fact must be accepted that at the pitting potential there is some electrochemical change at the metal-solution interface that leads from repassivation to localized corrosion. As shown in other publications (1, 6, 7, 21) the conditions for pitting initiation and propagation are related to the appearance of localized acidification on the metal-solution interface. When a metal is strained below the pitting potential, no localized acidification can take place on the bare metal. In this case only repassivation will take place. At the pitting potential and above, localized acidification is formed on the bare metal surface and the repassivation process is hindered, leading to localized corrosion.

Photopotentials on Copper and Copper Alloy Electrodes

Ugo Bertocci*

National Bureau of Standards, Metallurgy Division, Washington, D.C. 20234

ABSTRACT

The effect of white light illumination on the current-potential relationships of pure copper and of Cu-Ni and Cu-Al alloys in neutral solutions was examined, both under galvanostatic and potentiostatic conditions. The results obtained show that the photoresponse is only weakly affected by the addition of alloying elements to copper, but that it is influenced by the method of formation of the oxide film on the metal surface. Depending on whether or not the Cu_2O film was formed by reaction with a copper solution, the amplitude of the signal response could be strongly affected and the sign of the photopotential at open circuit reversed, indicating a change in the nature of the majority carriers. Polarization of the electrode can also vary the photoresponse, but its rapid following of the potential does not support the view that the structure of the oxide film is altered. Impedance measurements on electrodes under illumination and in the dark indicate that the charge-transfer reactions, rather than the resistivity of the oxide film, are affected by light.

Photopotentials have been used in corrosion research in order to obtain information on the nature and characteristics of surface films, mainly oxides, which are often formed on metals in a corrosion environment (1, 2). Such studies have been carried out under galvanostatic or potentiostatic conditions and from the variations in photoresponse, conclusions were drawn on changes in the properties of the surface film with electrode potential or as a consequence of the adsorption of corrosion inhibitors, and correlations made with changes in corrosion resistance.

The present study was undertaken to investigate the usefulness of photopotential measurements as a tool in corrosion research by studying the effects of alloy composition and different methods of producing the surface films.

In this work the materials investigated were pure copper and some copper alloys in the presence of an oxide film. Copper was chosen because information is available on its oxide films (3) and because the photosensitivity in the visible light range is such that the measurements are simplified.

* Electrochemical Society Active Member.

Key words: alloys, photovoltaic, photopotentials.

Experimental Methods

The experiments were carried out on electrodes of pure Cu and Cu alloys prepared by casting with 10 and 30 atom percent (a/o) of Ni and with 6% Al. All of these alloys are single phase. The electrodes in the form of disks 1-2 cm diam and about 1 cm thick were embedded in lucite, so as to leave only a flat circular surface exposed to the solution. Electrical contact was made through a threaded stainless steel rod in a glass tube with a Teflon gasket (4). The electrode surface was mechanically polished.

The solutions used in this work were 0.25M sodium acetate, at pH 5 and 8, the same solution plus 0.01M copper acetate with a pH adjusted to 5, and a 1:1 mixture of saturated H_3BO_3 and $Na_2B_4O_7$ with a pH close to 8. Some experiments were also carried out in a solu-

tion 0.1M both in potassium ferro- and ferricyanide plus 0.2M sodium acetate, at pH close to 8.

Measurements were taken on electrodes covered by the oxide film formed by exposure to the solution under study, or on electrodes which prior to introduction in the cell were immersed for various lengths of time in neutral (pH $\simeq$ 5) copper acetate solution. By this treatment a relatively thick layer of Cu_2O is formed by attack of the metallic copper on the part of the Cu^{++} ions in solution.

Copper acetate was chosen over other salts because the oxide film formed in this solution is more uniform and adherent than that formed in the presence of other anions (5). However, films formed in neutral copper sulfate and nitrate did not show significant differences in the light response, as shown in Fig. 1.

The light source was a tungsten-iodine lamp. The light entered the cell through a Pyrex window and traversed about 2 cm of solution before striking the electrode. The light intensity on the electrode surface was found to be approximately 150 mW/cm^2, as measured by putting a light power meter in the place of the cell. The light could be modulated by means of a rotating wheel with a slot. The frequency of rotation could reach about 50 Hz. The angular width of the slot was 12°, giving a duty cycle (time of illumination over period of rotation) of 1/30.

The cell, except for the flat window, was of conventional design, with provisions for controlling the atmosphere. Stirring was accomplished by means of a magnetic stirrer. The Pt counterelectrode was separated from the electrode compartment by a coarse glass frit. The cell was fitted with two reference electrodes, a saturated calomel electrode (SCE) which was used in most instances, and a Pt sheet electrode, employed when low impedance was necessary to prevent excessive noise pickup.

Measurements were carried out both under current and potential control. In a number of experiments, a small (a few μA/cm^2) constant a-c current was superimposed on the constant d-c current and the a-c voltage across the electrode monitored with a tracking generator. When both the real and the imaginary part of the a-c impedance were measured, a lock-in amplifier was used.

Experimental Results

Light response as a function of the method of oxide film preparation and of electrode potential.—The most important parameter in determining the photoresponse of the electrode was found to be the method of preparation of the oxide film. When the electrode was immersed in copper acetate prior to the measurements (or if the measurements were taken in copper acetate), the photopotential signal at open circuit was negative and often quite large, reaching more than 500 mV in some instances. Within the limits of current and potential in which the oxide film was not severely altered or destroyed, cathodic polarization tended to decrease the negative photopotential signal, and eventually to invert it, while anodic polarization tended to increase it.

The results obtained on a Cu alloy with 10% Ni in copper acetate are shown in Fig. 2. The two curves marked A and B shown on the cathodic side without illumination correspond to the initial values and to the steady-state condition where copper deposition has begun, and, therefore, the overvoltage decreases.

The exact value of the potential at which the sign of the photopotential is reversed is uncertain, since the light signal shows transient peaks which can be opposite to the steady-state value. Such complex transients have been reported previously (6).

The behavior of the electrode potential under illumination described here is observed on all alloys examined as well as on copper, if the electrode, after the formation of Cu_2O by reacting with copper acetate, is transferred into a neutral solution. In Fig. 1 the potential under illumination is plotted *vs.* the potential in the dark under galvanostatic conditions for a number of specimens. The open-circuit potential in this solution is close to -50 mV *vs.* SCE. The magnitude of the photopotential signal and the potential at which the signal reverses varies with the composition of the electrode and the length of time of immersion in the copper solution. This behavior, in a rough qualitative way, points to a correlation between the thickness of the oxide film and the amplitude of the signal, although this is obscured by changes in photoresponse caused by prolonged polarization of the electrode, which tends to alter the characteristics of the Cu_2O film. Nevertheless, the largest signals were observed on specimens which had been immersed for long times. Since pure copper reacted more rapidly than the alloys, short immersions produced films on Cu which exhibited large photopotentials.

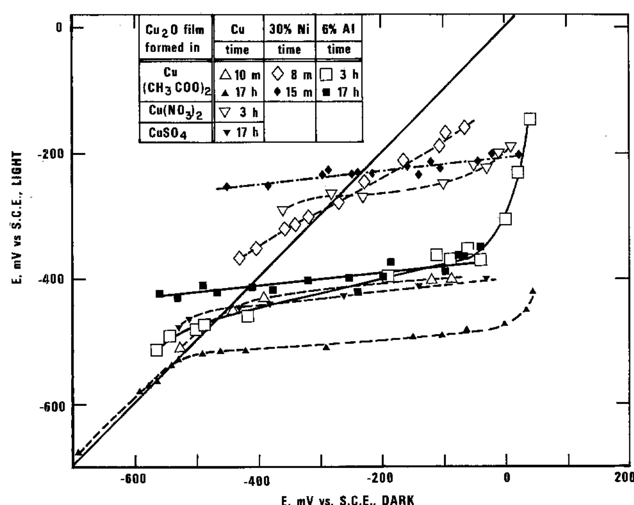

Fig. 1. Potential under illumination *vs.* potential in the dark for various electrodes with Cu_2O film formed in different copper solutions. Measurements taken in 1:1 H_3BO_3-$Na_2B_4O_7$.

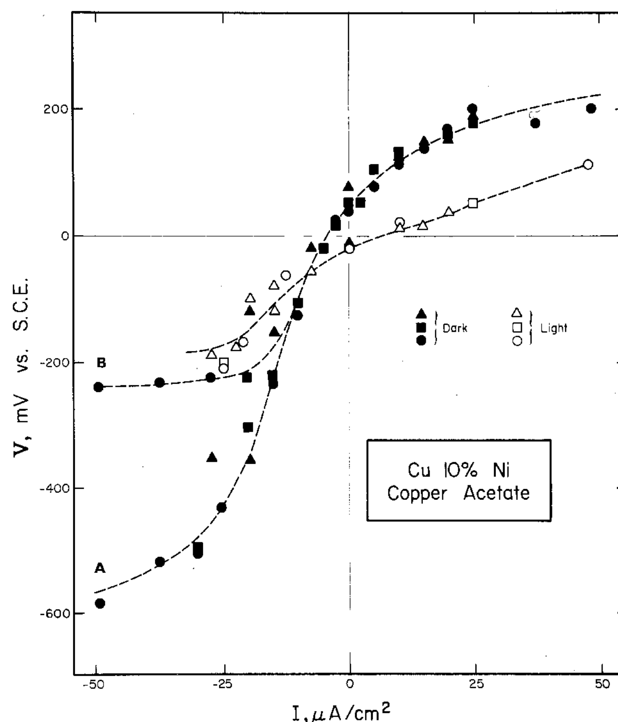

Fig. 2. Effect of light on galvanostatic current-potential curves for Cu 10% Ni in 0.05M Cu acetate. Different mark shapes correspond to different runs. Curve A, initial values. Curve B, steady state.

If the oxide film, on the contrary, is produced by exposing the metal to air or to a neutral solution not containing copper, the photoresponse is similar to that of bulk, melt-grown Cu_2O, in that it is positive at open-circuit and more cathodic potentials, with reversal to a negative signal occurring by anodic polarization. The results on bulk Cu_2O are shown in Fig. 3. The potential changes with illumination are, however, much larger on bulk Cu_2O than on film-covered metal specimens, where, typically, the signal is of the order of a few millivolts. Transient peaks, particularly in the region where signal reversal occurs, are observed on this kind of oxide also, making uncertain the determination of the potential for signal reversal.

If the experiments are carried out under potentiostatic conditions, the light current signal has, of course, a sign opposite to that of the voltage signal under galvanostatic conditions. Figure 4 shows a potentiodynamic scan on a Cu_2O-covered copper electrode in borate solution. Light produces large increases in cathodic current below the inversion point which occurs at about −400 mV. Around this value, the transients show complex shapes. On the anodic side the signal is smaller, and it is undetectable above about 600 mV.

It was found that the photoresponse could be eliminated both by reduction at very low potentials, when hydrogen evolution, or in Cu acetate solution, copper deposition occurred, or by strong anodic polarization at about + 1V *vs.* SCE. The photosensitivity, however, could be detected over a wide range of potentials, typically from −700 mV to +700 mV and, if destroyed tended to reappear within times of the order of 1 min at open circuit even before the potential had decayed back to its final open-circuit value.

Behavior in redox solution.—Measurements have been taken on some electrodes in solutions of $K_4[Fe(CN)_6]$ and $K_3[Fe(CN)_6]$, both 0.1M, plus 0.2M sodium acetate. The *p*H of the solution was 8 and the potential of a Pt electrode was about +230 mV *vs.* SCE. The purpose of the measurements was to establish the n- or p-character of the surface film from its current-potential and photoresponse behavior. Unfortunately there is a strong tendency to form layers of insoluble copper ferro- and ferricyanide, so that the reproducibility of the results is poor. Nevertheless, the behavior observed is in agreement with the assumption that the oxide film formed by reaction with copper acetate is an n-semiconductor and that formed by anodic oxidation is a p-semiconductor.

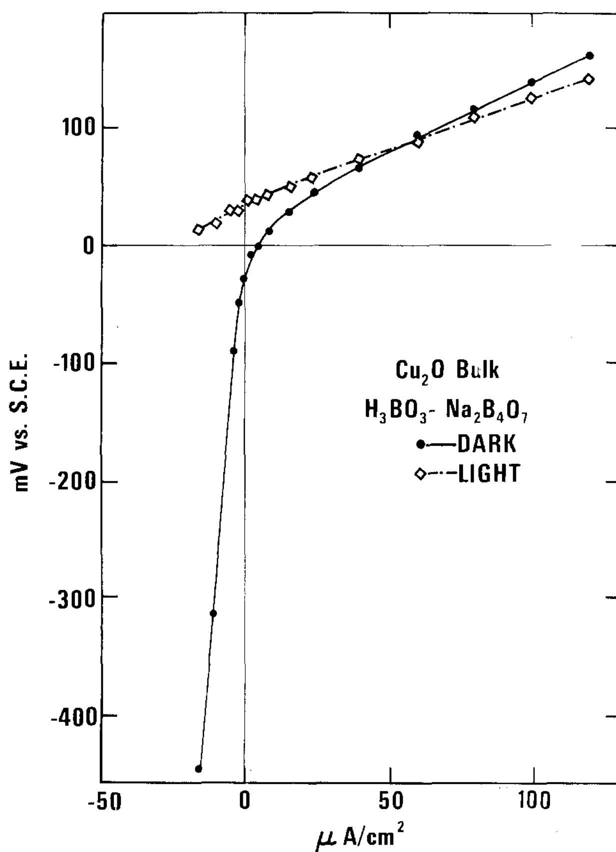

Fig. 3. Effect of light on galvanostatic current-potential curve for bulk Cu_2O in 1:1 H_3BO_3-$Na_2B_4O_7$.

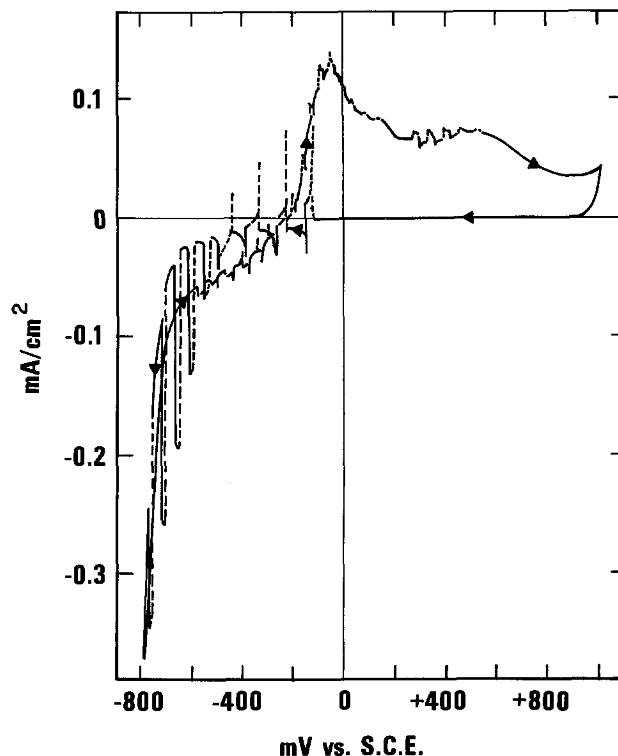

Fig. 4. Effect of light during potentiodynamic scan for Cu with Cu_2O film formed in Cu acetate. Solution, 1:1 H_3BO_3-$Na_2B_4O_7$; scan rate, 8 mV/sec; solid line, dark; dotted line, light.

Figure 5 shows a potentiodynamic scan of a 30% Ni Cu alloy which had been passivated at +700 mV *vs.* SCE in borate buffer. The anodic-cathodic dissymmetry is quite striking, pointing to a p-character in the film. Similar curves taken on pure copper and Cu-Al alloy have given rather confusing and irreproducible results, indicating a tendency for the electrode to react forming a reddish tarnish. Ferrocyanide films were detected on the electrode surface. However, the anodic branch always showed current densities five to ten times larger than the cathodic branch. The rest potential tended to be about 100 mV more negative than the equilibrium redox potential, again indicating a mixed potential.

The potentiodynamic scans of electrodes covered with Cu_2O film resembled those obtained in borate and acetate. The ferrocyanide/ferricyanide reaction did not seem to play an important role. The effect of light on one of these electrodes is shown in Fig. 6. Negative photopotentials were observed at open circuit (about +20 *vs.* SCE). The inversion of the steady-state photopotential signal occurs approximately at −250 mV, but if the initial spike is observed with an oscilloscope, the inversion occurs at about −400 mV.

A-c impedance measurements.—Cuprous oxide is a material that exhibits photoconductivity. It was interesting, therefore, to see if some of the effects observed could be attributed to a decrease in the ohmic drop in the oxide film under illumination. For this purpose, a small constant 200 Hz a-c current (of the order of 1 $\mu A/cm^2$) was passed through the cell during galvanostatic photopotential measurements, and the absolute value of the electrode impedance was recorded as a function of time. In the case of the

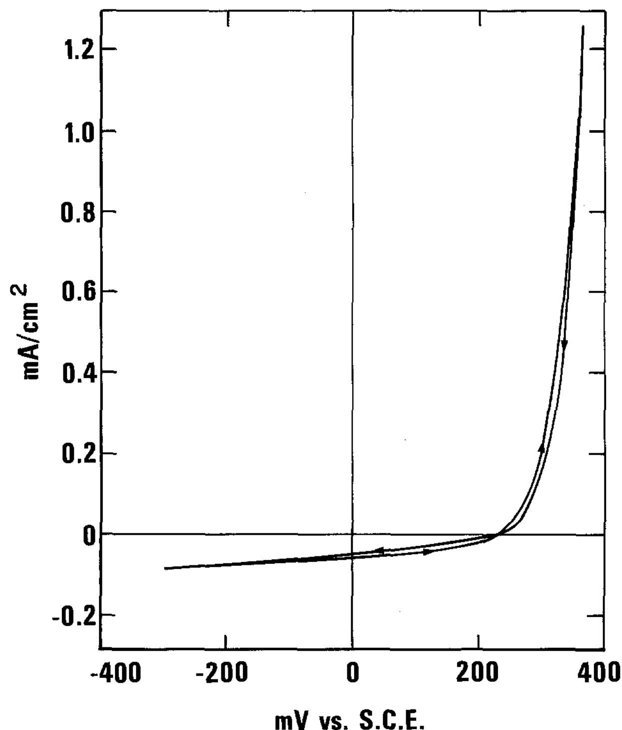

Fig. 5. Potentiodynamic scan for Cu 30% Ni in 0.1M $K_3[Fe(CN)_6]$ + 0.1M $K_4[Fe(CN)_6)]$ + 0.2M $NaCH_3COO$. Scan rate, 1.6 mV/sec. The electrode had been passivated in boric-borate solution at +700 mV *vs.* SCE.

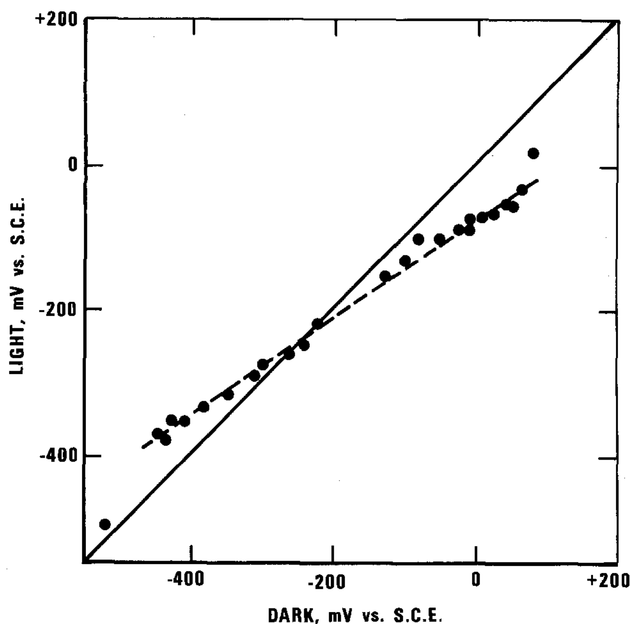

Fig. 6. Potential under illumination *vs.* potential in the dark for Cu 30% Ni with Cu_2O film formed in Cu acetate. Solution: 0.1M $K_3[Fe(CN)_6]$ + 0.1M $K_4[Fe(CN)_6]$ + 0.2M $NaCH_3COO$.

anodically produced film, the impedance was small and the decrease under illumination was hardly detectable. For the case of a film formed by reaction with Cu acetate, the effect was quite large. Figure 7 shows both a-c impedance and d-c potential for pure copper, where both light and dark transitions were quite sharp. Similar results were obtained on the other materials studied, but for the 30% Ni alloy the recovery of the dark value was much slower.

In order to establish, however, whether the impedance changes were due to a change in ohmic drop or to a decrease of charge-transfer resistance, some experiments were carried out using a phase-sensitive

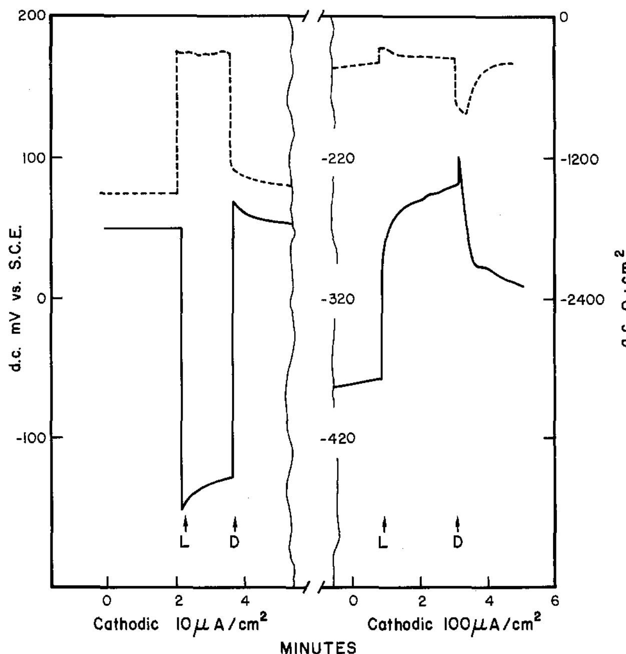

Fig. 7. Effect of light on electrode potential and on impedance at 200 Hz for Cu in 0.05M copper acetate. Solid line and left scale d-c potential; dotted line, and right scale, a-c impedance.

lock-in amplifier so as to measure both the real and imaginary part of the impedance. The measurements were done at open circuit, spanning a frequency range from about 30 KHz to as low as 5 Hz. The curves obtained in the dark and under illumination for Cu_2O covered copper in borate, and for bulk Cu_2O in copper acetate are shown in Fig. 8 and 9. The results show clearly that no change in ohmic drop resistance occurred under illumination since the high frequency limit of the real component was not affected by light. In the case of Fig. 9, for a system where the electrode is substantially in equilibrium for the Cu^+/Cu^{++} transition it appears clearly that the charge-transfer resistance decreases considerably with light, whereas the ohmic drop does not.

Discussion

The interpretation of photogalvanic effects on semiconductor electrodes has been based on the general

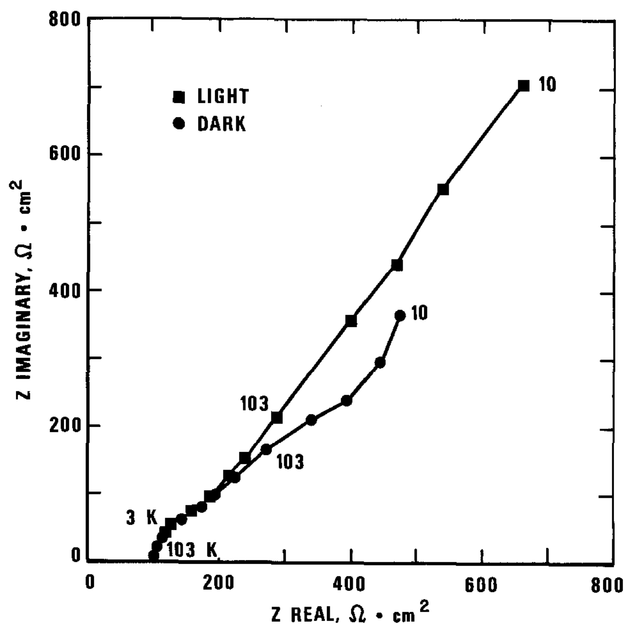

Fig. 8. Imaginary impedance *vs.* real impedance for Cu with Cu_2O film formed in Cu acetate, under illumination and in the dark. Open cirruit. Solution: 1:1 H_3BO_3-$Na_2B_4O_7$. Frequency as parameter.

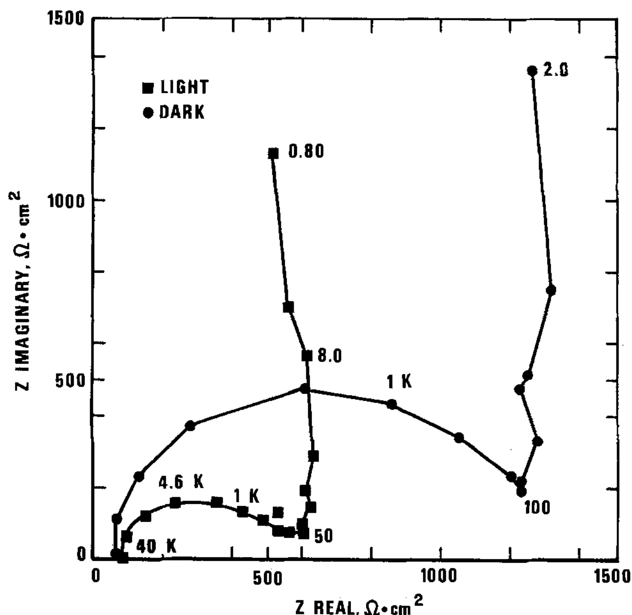

Fig. 9. Imaginary impedance vs. real impedance for bulk Cu_2O in 0.05M Cu acetate, under illumination and in the dark. Open circuit. Frequency as parameter.

treatment of semiconductor electrochemistry. The same principles, therefore, ought to be applied in the case of oxide films, although complications can be expected due to the fact that, in the case of the films, light could penetrate to the semiconductor-metal interphase, and also that the thickness of the film would be very often less than the thickness of the space-charge region in a bulk semiconductor.

The sign of the photopotential as a function of the sign of the majority carrier at or close to equilibrium can be obtained from the treatment given by Dewald (7). More recently Oshe and Rozenfeld (8, 9) have obtained the same conclusion, that is, a negative photopotential for n-semiconductor and a positive one for a p-semiconductor by assuming that, upon illumination, diffusion transport and electromigration would compensate each other and that deviations from stoichiometry in the oxide film would provide the recombination centers for the charge carriers. According to this interpretation the photopotential can become a tool for probing the composition of the oxide film.

The results presented here, as far as open-circuit conditions are concerned, confirm the usefulness of photopotential for obtaining information on the characteristics of the oxide film.

On the basis of the results presented here, it has to be concluded that alloying copper with Ni or Al, although it affects the corrosion resistance of the metal, has little influence on the semiconducting properties of the surface film. On the contrary, the method of preparation of the oxide film is much more important, as shown by the large negative potential shown by the cuprous oxide produced by reaction with Cu^{++} ions in solution. That alloying changes the photoresponse of Cu-based alloys only in minor ways is perhaps understandable, since other workers have found very small concentrations of the alloying metal in tarnish films (10).

The amplitude of the photopotential signal on these films is quite interesting since it can bring the potential of the electrode below the value of the Cu_2O/Cu equilibrium, and causes, therefore, the destruction of the oxide film under illumination. This result might have implications for the corrosion behavior of copper and copper alloys. It is, for example, known that copper can exhibit stress corrosion cracking in the dark, but not in the light (11).

The photopotential response has been used in probing the properties of the oxide film not only at open circuit, but also under polarization (2, 9). Reversal of the signal of the photopotential in these conditions, an effect already described many years ago (12), has been interpreted as caused by a change in the defect structure of the film. In light of the present results, considering how rapidly the photoresponse can be modulated by polarizing the electrode, it is very unlikely that this interpretation is correct, even if care is taken to observe the sometimes complex transients occurring when the light is switched on and off. However, as this study shows, the examination of the effect of polarization on the photosignal can give useful information on the range of stability of the semiconducting oxide and on the rate of its formation, once it has been destroyed.

EMF Measurements on Electrochromic Amorphous Li_xWO_3 Films

Sarat K. Mohapatra*[,1] and Sigurd Wagner*[,2]

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

We report the electromotive force of cells with amorphous lithium tungsten bronze film cathodes. The cathodes were incorporated in electrochromic cells of the type Au|Li|1M $LiClO_4$ in propylene carbonate|Li_xWO_3|Au. Li-concentrations, $0 < x < 0.54$, were established by coulometric titration. Up to $x = 0.4$ the films consist of a single phase with a strongly concentration-dependent emf. A constant emf of 2.0V at $x > 0.4$ suggests the existence of an intermediate Li-WO_3 phase.

Electrochromic cells incorporating lithium tungsten bronze films are being considered for passive display applications (1). The emf measurements reported here are part of a quantitative study of the rate-determining processes and the stability of such cells. In an earlier publication the kinetics of coloration and of bleaching were presented (2). In coloration, transfer of Li^+ from the electrolyte into the WO_3 constitutes the slowest step. The over-all cycle time is determined by the rate of bleaching that depends on a space-charge limited current of Li^+ and e^- within the WO_3 film. This current is proportional to the mobility of Li^+ (μ_{Li^+} (WO_3) $= 5.3 \times 10^{-9}$ cm^2 V^{-1} sec^{-1}) which is an order of magnitude lower than μ_{H^+} (WO_3). Therefore, the coloration/bleaching cycle of Li_xWO_3-based cells takes about ten times longer than that of H_xWO_3 cells. Thus longer cycle duration appears to put Li_xWO_3 at a disadvantage to H_xWO_3. However, Li_xWO_3 is in certain respects more stable than H_xWO_3, *e.g.*, against oxidation and therefore might offer better long-term stability.

1 cm^2 WO_3 films 0.3-0.9 μm thick were electron-beam evaporated onto In_2O_3-coated glass substrates (PPG Nesatron). The film thickness at steps to the substrate was determined by interference microscopy ($\lambda = 0.589$ μm) after evaporation of a reflective Ag layer. Across samples the thickness varied by less than 7%. The electrolyte consisted of a solution of 1M $LiClO_4$ (dried at 100°C in air for 7-8 hr) in propylene carbonate (twice vacuum-distilled at 100°C and 1 Torr). The glass cell of the type employed for coloration studies was assembled in a dry box. During the experiments the space over the electrolyte was kept exacuated.

The Li concentration was adjusted in steps by coulometric titration with 50-100 mC of Li^+ apportioned by means of a Keithley 225 constant current source. After titration the external circuit was switched to a Keithley 602 electrometer for emf measurement. Steady emf values were reached within 15 min when $x < 0.4$. While the titration was always carried out at 23°C, measurements were also taken at 2° and 36°C, all temperatures being established in a water bath.

Emf and $\Delta\overline{G}_{Li}$ as a function of x are plotted in Fig. 1 for three cells at 23°C. Emf's for 2° and 36°C, respectively, lay within 5 mV of the 23°C values for each cell. The differences in the emf between the cells probably arise from different oxygen activities in the three WO_3 films (3). The standard free energy of formation $\Delta G(x\text{Li} + WO_3 = Li_xWO_3)$ obtained from a Gibbs-Duhem integration is shown in Fig. 2.

The leveling off at 2.0V of the emf for $x > 0.4$ suggests coexistence of $Li_{0.4}WO_3$ with a Li-rich WO_3 phase. This interpretation corroborates the earlier observation (2) of irreversible coloration at $x > 0.4$. While Li_xWO_3 layers are blue at $x < 0,4$, they turn

Key words: electrochromism, tungsten bronze, display.

pink at $x > 0.4$. Crystalline tungsten bronzes normally change color from blue to red with increasing alkali content (4). In the present case the shift of the principal absorption band from the infrared (700-1100 nm) to the ultraviolet (<350 nm) is so drastic that it may also be taken as indication for the formation of a new phase. The equilibration times in the two-phase region were found to be much longer than those at $x < 0.4$.

The existence of an intermediate phase constitutes one distinction between electrochromic Li_xWO_3 and H_xWO_3 films. In H_xWO_3-based cells (5) the emf varies continuously up to the highest hydrogen concentration reported, $x = 0.4$ (Fig. 3). However, amorphous $H_{0.35}WO_3$ is in equilibrium with H_2 at atmospheric pressure. Films with $x > 0.35$ are metastable against decomposition to $H_{0.35}WO_3$ and H_2 gas. Thus any intermediate phase with $x > 0.35$ will not be stable. The low stability of amorphous H_xWO_3 films is not surprising in view of the marginal stability of crystalline $H_{0.18}WO_3$ (tetragonal B phase) and $H_{0.35}WO_3$ (tetragonal A phase) (6).

A marked dependence of the emf on x distinguishes the amorphous tungsten bronze films from their crystalline counterparts. The data cannot be fitted to either a linear dependence of the partial excess free energy

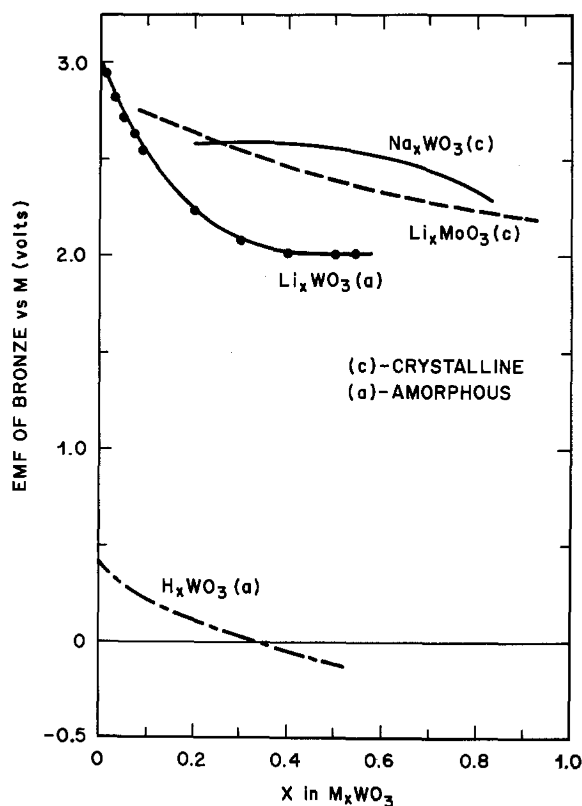

Fig. 3. Emf vs. pure component M at atmospheric pressure of amorphous H_xWO_3 [Crandall *et al.* (5)], Li_xWO_3 (this study) and crystalline Li_xMoO_3 and Na_xWO_3 [Whittingham (3)].

of Li on the mole number, x_{Li} (5), as formulated by Crandall *et al.* (5), or to the square of the mole fraction of the solvent $1/(1 + x_{Li})^2$, the well-known Bragg-Williams model. One might argue that this failure arises from improper formulation of the entropy of mixing. The linear presentation (5) assumes random distribution of one Li^+ and one electron per WO_3. As pointed out by Ramanarayanan and Worrell (7), this implies unit Li activity for the composition $LiWO_3$ which most likely is not the case. On the other hand, a mixture of Li and WO_3 in any proportion, as assumed in the quadratic formalism, disregards the filling of the cubic interstitial sites that has been observed in crystalline tungsten bronzes. In any case a simple pairwise interaction for the enthalpy is not an adequate formulation. While the question of the ideal entropy of mixing is of fundamental importance, it is of little consequence in the present case since the emf is determined by the large partial molar enthalpy of Li. The highest observed variation of the emf with temperature was 5 mV in the range from 2° to 36°C This corresponds to a partial molar entropy of Li of 14 JK^{-1} $mole^{-1}$.

Emf data for crystalline Li_xWO_3 are not available. For comparison with the emf of amorphous Li_xWO_3 films we have plotted (Fig. 3) emf's of crystalline Na_xWO_3 (3) and Li_xMoO_3 (8) as presented by Whittingham (3). The cubic "interstitial" sites in the crystalline bronzes are highly degenerate so that the emf is nearly independent of x. The marked dependence of the emf on composition for amorphous Li_xWO_3 films suggests a large spread in energy of the sites in amorphous WO_3 that accommodate Li. Only a small fraction of these sites lies at energies (emf's) as low as might be expected for crystalline Li_xWO_3, *i.e.*, ~3 eV. Our measurements also show that the partial excess entropy of Li is negligible. Therefore, the Li sites are distributed at random.

Wettability of Some Carbon Surfaces by Molten Sulfur and Polysulfides

G. J. Janz* and R. M. Murphy

Rensselaer Polytechnic Institute, Cogswell Laboratory, Troy, New York 12181

ABSTRACT

The present communication reports a study of the wetting properties at moderately high temperatures (~350°C) using a modified wicking technique. Strong preferential wetting of bare carbon surfaces by molten sulfur is confirmed through the adhesion tension ratios and the thereby-derived contact angles. The effect of various metal oxide deposits on such properties was investigated and, specifically, the wettability of alumina-treated carbon surfaces by molten polysulfides. A technique for coating the carbon surfaces with metal oxide deposits of good adherence is reported. Some results are reported for the polysulfide transport properties of such treated carbons.

Information on the wetting properties of molten sulfur and polysulfides for carbon surfaces has followed largely from cyclic voltammetry and related techniques in the studies of the processes occurring during the charge-discharge cycling of the sulfur electrode in Na/S cells (1-5). Direct experimental investigations, based on molten salts contact angle measurements (6-8), present a number of difficulties, and with the exception of some provisional measurements for sulfur and polysulfides by Ludwig (4), have not been pursued with molten polysulfides. Capillary penetration of porous materials may also be investigated by wicking (9, 10), a technique in which the substrate is dipped into the liquid and the wetting properties are observed by the liquid rise in the porous "wick." In the present communication we report an investigation of the wetting properties of molten sulfur and polysulfides at Na/S cell operating temperatures (350°C) by this approach. The purpose was to gain insight on the relative wetting properties of these two fluids for various carbon surfaces and to investigate these with modified carbon surfaces, *e.g.*, metal oxide deposits. The preparation of a series of treated carbon surfaces was undertaken and is reported, together with the results of a series of wicking measurements with molten sulfur and polysulfides.

Experimental

Polysulfides.—Na_2S_4 (Alfa-Ventron) was used both "as received" and after toluene extraction. Last traces of toluene were removed at ~ 150°C and 10^{-2} Torr dynamic vacuum. In the latter step small amounts of sulfur sublimed (identified by mp and Raman spectra); we attribute this to the small but finite sulfur pressures reported for polysulfides (11) rather than trace impurities. Sulfur (Fisher, reagent grade) was used in the limited series of sulfur-wetting measurements. It was used "as received," except for predrying (85°C, 10^{-4} Torr dynamic vacuum). All transfers were effected in dry N_2 atmospheres.

Carbons.—Electrographitic rod (Arco Speer Grade 580) and WDF Graphite Felt (Union Carbide Corporation) were used for the wettability measurements. The pore size distributions, gained from Hg intrusion porosimetry, are summarized in Table I, together with the results for massive graphite (block) and vitreous carbon (foam) for comparison. Prior to the wetting measurements, the carbons were acid washed and baked-out at reduced pressures and elevated temperatures (~ 500°C, 10^{-3}-10^{-5} Torr dynamic vacuum).

Metal oxide deposits on carbons.—The decomposition of metal nitrates (12-15) to the oxides, *e.g.*, for a divalent salt

$$M(NO_3)_2 \rightarrow MO + 2NO_2 + \tfrac{1}{2} O_2 \quad [1]$$

offers a method for the deposition of a variety of oxides on carbon surfaces. The following procedure was therefore adopted for the surface treatment of the carbon surfaces: (*i*) Aqueous soak: The carbon specimens are immersed in aqueous solutions of metal nitrates; the soaking period is extended for a time sufficient for penetration of the porous carbons. (*ii*) Nitrate decomposition: The water is removed from the soaked carbons at reduced pressures and moderate temperatures (25°-150°C), and the temperature is increased with the specimens under dynamic vacuum until the nitrate decomposition is complete (*i.e.*, no further evolution of nitrogen oxides). The temperature range for this step must be determined for each metal nitrate; for aluminum nitrate it was in the range of 450°-600°C. (*iii*) Thermal "bake-out": The temperature of the carbon specimens is further increased under reduced pressures to well above the nitrate decomposition temperatures, and the specimens are "baked-out," *e.g.*, in the present work, 10^{-5} Torr; ~ 900°-1000°C.

The weight of the sample on completion of this procedure was noted to gain the amount of the metal oxide thus deposited. The adherence of the deposit was tested after the bake-out, using aliquots with an ultrasonic adhesion test (16).

The surfaces were characterized by scanning electron microscopy (SEM) and x-ray fluorescence. Some illustrative results for a series of alumina deposits on WDF graphite felts are in Fig. 1. The porosity of such treated surfaces was found to decrease ~20% relative to the untreated carbons (Hg intrusion porosimetry). For a series of alumina-coated samples the nature of the surface deposit was analyzed by atomic absorption spectroscopy; the results are summarized in Table II. The agreement with the weight analysis (based on complete decomposition of the nitrate to alumina) provides support for this procedure as a method for the deposition of metal oxides on carbon surfaces.

Table I. Porosity and pore spectra for various carbons

		Pore size distribution		
Sample	Porosity ϵ (%)	Median diam (μm)	Smallest diam (μm)	Diam range for 90% pore space

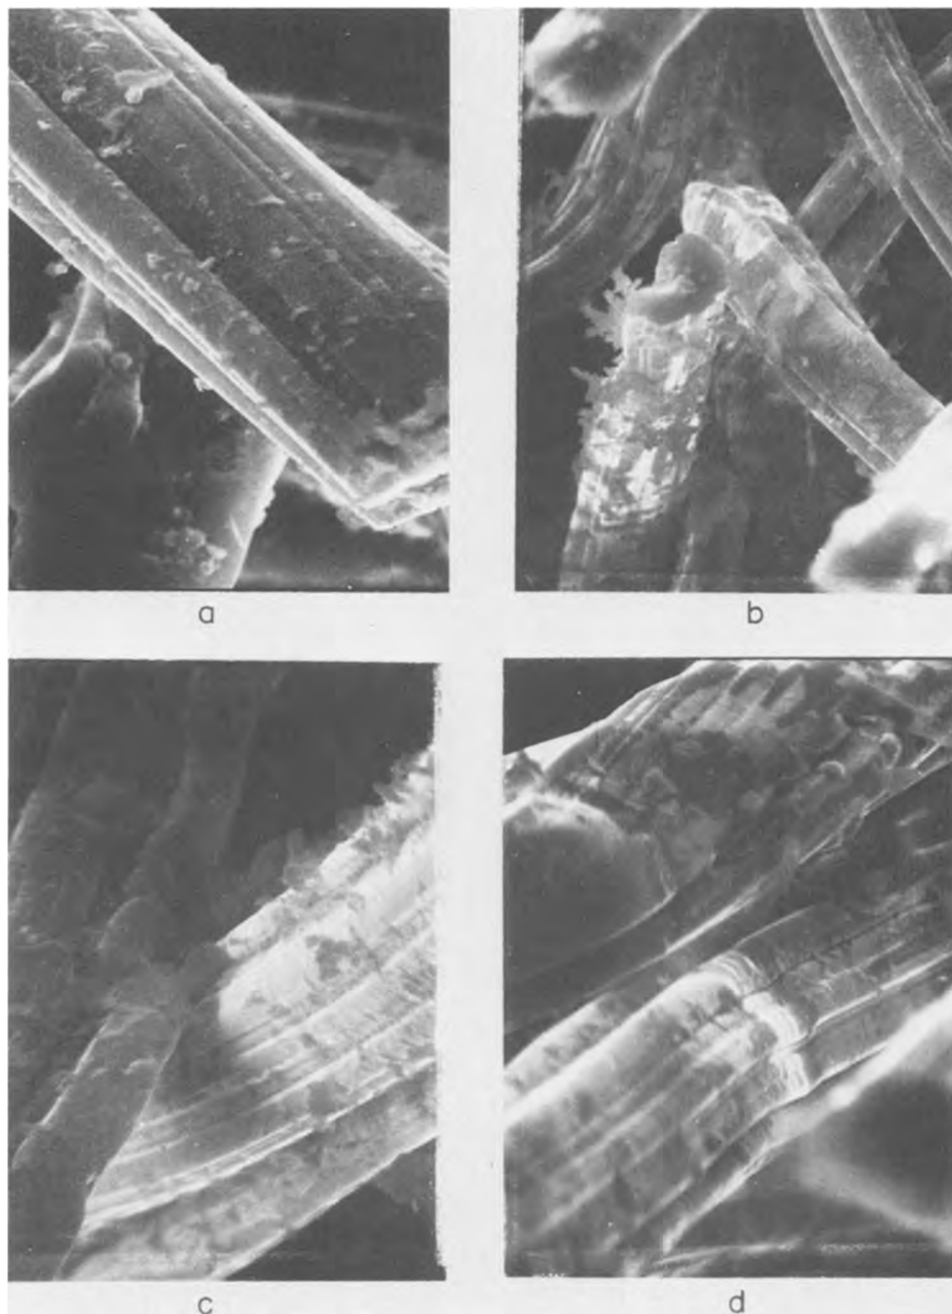

Fig. 1. Alumina-treated graphite felts—SEM photomicrographs. (a) Moderately loaded felt [4.43 w/o $Al(NO_3)_3 \cdot 9H_2O$ soak solution], 5000 times; (b) heavily loaded felt [9.27 w/o $Al(NO_3)_3 \cdot 9H_2O$ soak solution], 2000 times. Both (a) and (b) exhibit a coating of alumina, but (b) has a significant number of dendritic clusters emanating from the fiber axis. (c) Moderately loaded felt, intersection of two fibers, 5000 times; (d) heavily loaded felt, intersection of two fibers, 5000 times. X-ray fluorescence analyses at the felt fiber junctions in (c) and (d) indicate a much higher concentration of Al for (d) than for (c).

Wetting measurements.—The capillary-penetration technique was adapted for the present measurements as follows. For small carbon samples (~ 5 cm length), the experimental assembly is illustrated in Fig. 2. The under-the-pan suspension and analytical balance ensures a vertical alignment for the wicking sample and provides a sensitive detection for the contact of the wick and wicking fluid as the crucible is raised. The temperature gradient in the hot zone at 350°C was ±20° in the arrangement illustrated (Fig. 2). With molten polysulfides (*i.e.*, Na_2S_4) no difficulties were encountered due to vapor transport/condensation on the sample suspension, and the observed weight change correlated well with the amount "wicked." Owing to the high sulfur vapor pressures and consequent recondensation on the suspension, this procedure was modified with molten sulfur. For the latter, the amounts wicked were gained after the sample had been removed from the assembly. To extend the measurements to longer wicks (*e.g.*, 25-30 cm lengths), a second arrangement was used in which the wicking chamber was a sealed long-necked round-bottom flask. The sulfur (or polysulfide) was loaded through a sidearm near the lower part of the wick to minimize contact prior to the wicking measurements. Loading the wicking chamber was done under a dry Argon atmosphere. The chamber was next evacuated to 0.5 Torr and sealed off with a torch. The chamber was vertically positioned in a larger furnace already at the wicking temperatures. The temperature flat zone was ±4° at 350°C over a 32 cm length. The amounts of polysulfide

Table II. Characterization of the coated carbon surfaces

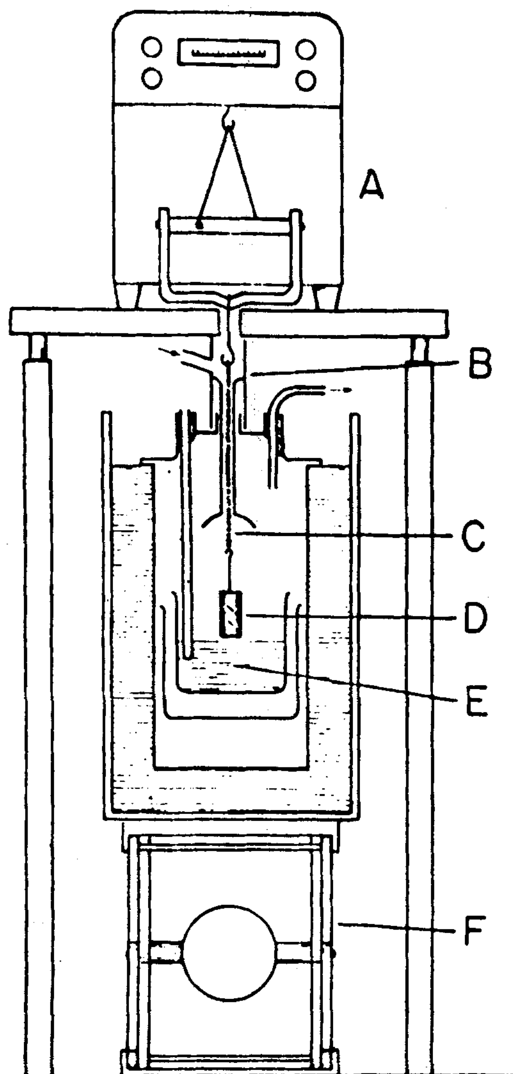

Fig. 2. Small wicking assembly. The porous wick (D) is suspended from an analytical balance (A) with a gold chain (C). The wicking liquid (E) is in a double container (for safety), and a variable height platform (F) is used to raise the liquid until contact with the wick is established. The manifold (B) enables one to maintain an inert and dry atmosphere throughout.

wicked in this series of measurements were gained by sectioning the wick for weight analysis, using a soaking technique to leach out the water soluble polysulfide.

The wetting studies undertaken were as follows: (*i*) Wettability studies of carbon surfaces (bare), with molten polysulfides and molten sulfur; (*ii*) an exploratory series of wettability studies, using a variety of metal oxide deposits on carbon surfaces (in trace amounts); (*iii*) wettability studies, with increasing amounts of metal oxide surface deposits; and (*iv*) some measurements of wettability for carbon surfaces prepared with incompletely decomposed nitrates. The nitrates of cobalt, iron (III), silver, nickel, aluminum, and mixtures (*e.g.*, Co, Al; Ni, Al; Ag, Al; and Fe, Al) were used in the exploratory series at soak solution concentrations from 0.1 to 2 M; for the later follow-up series, the studies were largely limited to alumina-treated surfaces.

Results and Discussion

The results of the wetting measurements with molten polysulfide and molten sulfur and carbon surfaces, the influence of added metal oxides on these surfaces, and the further studies with alumina-treated carbon substrates are discussed.

Carbon surfaces.—Using the electrographitic carbon (rod), a series of wetting measurements with both molten polysulfide (Na_2S_4) and molten sulfur at 350°C were undertaken to investigate the preferential sulfur wettability of such surfaces. The results of this series of measurements are in Table III, and the appearance of the specimens in Fig. 3. It is apparent that the carbon surfaces are readily wetted by molten sulfur, and that, at 350°C, molten polysulfides are relatively nonwetting. With WDF graphite felt wicks, it was observed that sulfur wicked virtually over the complete specimen length (5 cm); by contrast, the polysulfide, as shown in Fig. 3, was found not to wick to any appreciable extent. It is seen that a polysulfide residue "clings" to the porous system; this surface excess was removed mechanically with care prior to the weight analysis (Table III). Nevertheless an uncertainty is imposed on the quantitative nature of the results since it is very difficult to discriminate between a very small capillary rise and the liquid that may cling to the porous substrate (for molten polysulfides). It is of interest, nevertheless, to examine the results from viewpoints of adhesion tension and contact angle.

The adhesion tension, defined as $\gamma \cos \phi$, has been used as measure of the wettability of a substrate surface (17). Here ϕ is the contact angle and γ, the interfacial (surface) tension. The adhesion tension may be calculated from a knowledge of the equilibrium height, h_1 and the classical capillary rise equation, *viz.*

$$\gamma \cos \phi = \rho g r/2 \qquad [2]$$

where r is the average pore radius, and ρ and g are as defined conventionally. Correspondingly the volume of liquid wicked at equilibrium would be $v_e = N\pi r^2 k h_e$, where N is the number of capillaries, and k, the tortuosity factor for the wicking substrate. The equilibrium weights would be $w_e = \rho v_e$. Comparing the results for two fluids (sulfur, s; polysulfide, ps) and the same wicking material, it follows that the adhesion tension ratio is given, simply, by

$$\frac{(\gamma \cos \phi)_s}{(\gamma \cos \phi)_{ps}} = \frac{(w_e)_s}{(w_e)_{ps}} \equiv \frac{(h_e\rho)_s}{(h_e\rho)_{ps}} \qquad [3]$$

and that either measurements of the equilibrium weights or equilibrium heights may be used. In the present work the observed results (Table III) may be taken as equilibrium wicking results; the measurements were under vapor-saturated atmospheres (18, 19), and little, if any, evaporation would be expected from the liquid contents of the felts. The data in Table III show a factor of 10 difference in the weights of liquid wicked. From the adhesion tension criterion, the wettability of the carbon surface at 350°C by molten sulfur would appear as much as 10 times greater than by the molten polysulfide.

Provisional results for the contact angles, by direct observations, have been reported by Ludwig (4). Under a helium atmosphere and short-time measurements, the observed values of ϕ were 20°-30° and 100°,

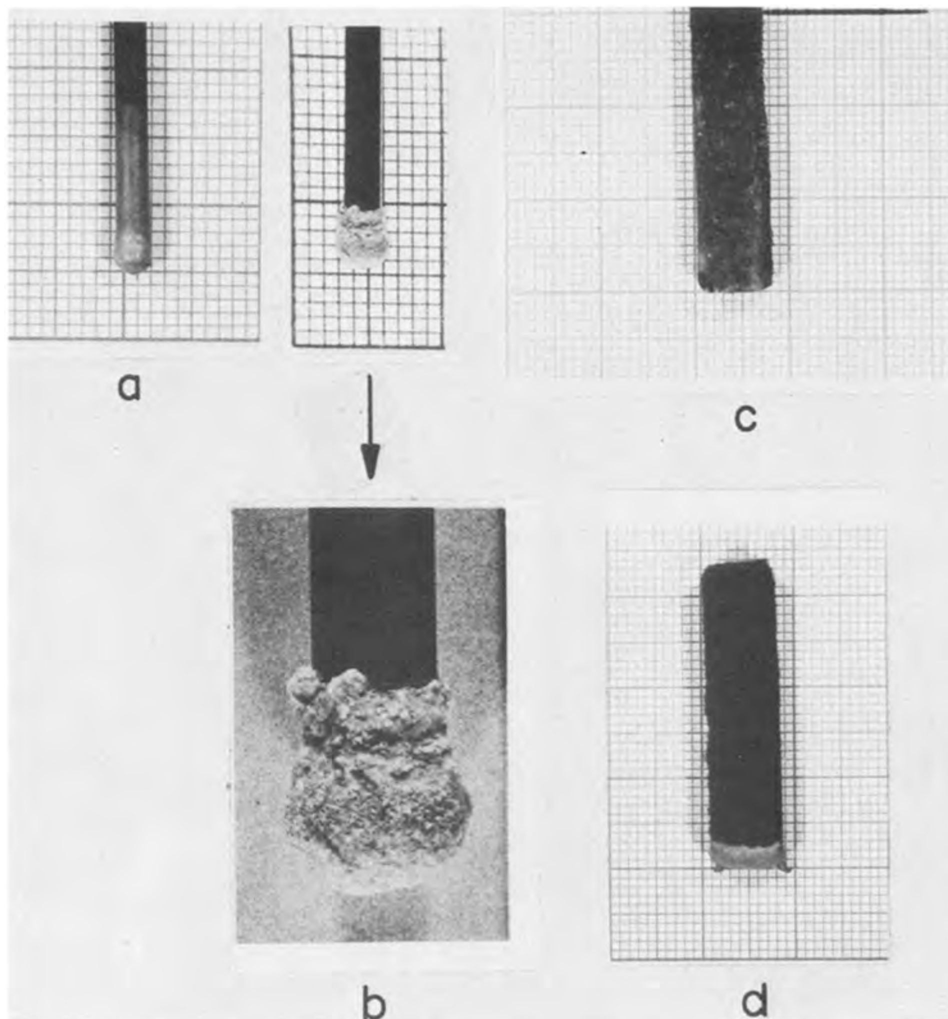

Fig. 3. Wettability of carbon surfaces at 350°C with molten sulfur and molten polysulfide. Bare electrographitic carbon (rod) contacted with (a) molten sulfur and (b) with molten polysulfide. The close-up shows a "nonwetting" globule of molten polysulfide (after solidification). Bare WDF felt wicks, after contacted with molten sulfur and polysulfide at 350°C, are shown in (c) and (d), respectively.

respectively, for molten sulfur and polysulfide at 318°C on graphite surfaces. Taking 25° as a probable value for molten sulfur, and values of the surface tensions for molten sulfur (20) and polysulfide (21) as 46 and 128 dyne cm^{-1} (at 350°C), respectively, it follows from Eq. [3] and the present wicking data (Table III), that a value of 91° is predicted for ϕ_{ps}, *i.e.*, the molten polysulfide is thus predicted to be nonwetting on bare carbon surfaces.

The difficulties of the present technique in discriminating between a very small capillary rise (for ϕ slightly less than 90°) and the liquid residue that may cling to the wick (for ϕ slightly greater than 90°) should be noted relative to the preceding calculations of adhesion tensions and contact angles. The significant result is the observation that porous carbon is much more wettable by molten sulfur than by molten polysulfide. The observations of preferential wetting of carbon graphite surfaces by molten sulfur from cyclic voltammetry and related measurements (1-5) and contact angle measurements (4) are clearly supported by the preceding observations at 350°C.

Metal oxides.—The effects of various metal oxides deposited on both the electrographitic carbon rod and WDF graphite felt were investigated with the small wicking assembly (5 cm length wicks). The amount retained by the wick (after 30-60 min contact with the molten polysulfide) relative to the amount wicked by the untreated (bare) carbon wick provides a measure of the changes in adhesion tensions. With the exception of two metal oxides, aluminum and cobalt, the various metal oxides did not markedly improve the wettability of the carbon surfaces by molten polysulfides. Some of the results for the cobalt oxide and alumina treated surfaces are in Table IV. The amount wicked is given both as weight and weight percent (w/o) (relative to the wick weights prior to the measurements). A quantitative comparison of the relative effectiveness of the various metal oxides is thus shown. It is clear that alumina (either through the thermal decomposition of the nitrate, or as a hydrosol of a dispersable form of alumina, *i.e.*, Dispal) markedly promotes the wettability of the carbon surfaces by molten polysulfides. Inspection of these specimens after the measurements showed that the polysulfide had penetrated the full 5 cm length of the felt wicks. By contrast, the bare felts showed virtually no penetration; the amount "wicked" on the bare carbons (Table IV) can be accounted for as the polysulfide retained as a pendant drop after wick detachment from the molten polysulfide.

To investigate the polysulfide transport properties of alumina-treated graphite surfaces, a series of felt

* $Al(NO_3)_3 \cdot 9H_2O$.

wicks were prepared from increasingly more concentrated soak solutions [4-40 w/o $Al(NO_3)_3{\cdot}9H_2O$]. Because of the increasingly larger alumina loadings, the resiliency of the felt matrix is largely lost; the ultrasonic tests for adherence, however, indicated that ~90% of the surface-deposited alumina was adherent at the higher felt loadings. Inspection of the surface morphologies (see, for example, Fig. 1) showed dendritic deposits, with increasing buildups at fiber intersections as the alumina loadings were increased. The polysulfide transported as a function of wick length was gained quantitatively by weight analysis of the felts sectioned into aliquots after each measurement. The results for the limiting felt loadings ("wicked" to equilibrium conditions) are summarized in Table V. The equilibrium heights attained for the two alumina-treated felts were, respectively, 4 and 5 cm for the felts loaded with the 4.43 and 40 w/o nitrate soak solutions; inspection of the amounts wicked shows that the polysulfide transport is almost in the ratio of the soak concentrations, *i.e.*, approximately a nine-fold increase.

Some "exceptionally high" wicking heights were observed in the course of this part of the investigation, *i.e.*, 10 cm and higher, with alumina-treated felts, relatively heavily loaded (soaking concentration, ~ 20 w/o). It seemed possible that these correlated with the felts for which there had been a change in preparative procedure. Such felts had been maintained at ~350°C for the thermal decomposition of the nitrate and had not been subjected to further bake-out at higher temperatures. The studies of the thermal transformation of aluminum salts (13-15) show that $Al(NO_3)_3{\cdot}9H_2O$ decomposition to amorphous Al_2O_3 is not complete at temperatures below 500°-700°C; lower temperatures would lead to markedly different surface deposits. This was confirmed through the preparation of a series of loaded felts with 350°C as the terminal temperature and some subsequent wicking measurements. The results were as follows. With a 20 w/o soak solution, a wicking height of 10 cm was observed after 4 hr, and this had increased to 25 cm after 100 hr (350°C). Samples of this surface-treated felt, prior to wicking measurements, were found to have strong tendencies to rehydrate, *e.g.*, a continuing weight gain was observed. With further heating under dynamic vacuum (500°C, 10^{-5} Torr), both H_2O and nitrogen oxides were evolved.

The very effective transport properties of such alumina-treated felt surfaces may be undoubtedly attributed, in part, to the trace amounts of H_2O inherent with the surface deposits and the consequent species from the following chemical reactions with molten polysulfides at 350°C, but the possibility of the alumina also being in a more "reactive" morphology for polysulfide transport, *e.g.* boehmite, is not ruled out. This is being investigated further, and discussion is deferred until additional results are in hand.

Acknowledgments

The studies reported in this publication were part of a program supported at Rensselaer Polytechnic Institute by a National Science Foundation-RANN contract with Ford Motor Company for sodium-sulfur battery research. We particularly acknowledge with pleasure the discussions with F. A. Ludwig (Ford) on matters that led to the selection of metal nitrates and the long wicking techniques reported in this communication.

Manuscript submitted Feb. 27, 1978; revised manuscript received April 26, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Film Growth on Dilute Noble Metal Alloys

S. P. Sharma* and J. H. Thomas, III*

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

A general mathematical model for solute segregation to the surface and subsequent oxide or film development on thin (finite layer) binary noble metal alloys has been formulated. Fick's second law has been solved in a general formalism for time varying boundary conditions, thus coupling corrosion kinetics with the solute diffusion in the alloy. Closed form solutions are presented for the specific cases of linear and parabolic kinetics. Numerical results for parabolic corrosion kinetics are presented along with a procedure for determining the diffusion coefficient for the solute in the alloy if the concentration at the interface is known.

Film growth on noble metal alloys due to solute diffusion to the metal surface and subsequent reaction with a corrosive or oxidizing environment has been the subject of a number of experimental and theoretical investigations (1-7). Interest in this subject is generated primarily by the possible failure mechanisms encountered in dilute noble metal alloys due to substrate or impurity (solute) diffusion (6). For example, experiments have been performed on hard gold electroplates and analytical models developed to describe the formation of oxides of cobalt (4, 5) and copper (8) on electroplated hard gold on copper. In deriving the diffusion coefficients from experimental data, it is generally assumed that the concentration at the film-alloy interface is zero (the "infinite sink" model) (4). However, in experiments, the concentration at this interface is hardly ever measured as zero. This model may hold true in specific cases but its general validity is questionable. Tompkins and Pinnel (8) find that in the Cu-Au system, the presence of chlorine in the environment increases the amount of film formation on the surface. The rate of corrosion, therefore, plays a significant role in diffusion problems. Wagner (3) has studied noble metal alloys (*e.g.*, Au-Ni) and developed an analytical model which assumes that the alloy-film interface varies in position with film growth. Wagner's model coupled film growth kinetics for a parabolic film growth rate with the concentration gradient in an infinite thickness alloy.

In this paper, we present a mathematical analysis in which the rate of film growth has been coupled to diffusion of a solute from dilute noble metal alloys of finite thickness. The diffusion of substrate materials through the noble metal will be the subject of another paper. Our analysis employs Duhamel's (9) theorem to obtain a solution for the solute concentration for a time varying boundary condition in a general case. Closed form solutions have been obtained for parabolic and linear growth kinetics. The diffusion coefficient of the solute in the noble metal is related to the solute concentration at the interface. For the case of parabolic film growth kinetics, numerical solutions are presented. These solutions can be used to compute the solute diffusion coefficient with a knowledge of the film growth kinetics and the solute concentration at the film-alloy interface.

Model Development

The impurity diffusion from a noble metal can be be described by Fick's second law

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial X^2} \quad [1]$$

where C and t represent concentration and time and D is the diffusion coefficient, assumed independent of concentration. It is assumed that diffusion occurs only in the thickness direction of the medium which is bounded by two planes at $X = 0$ and $X = l$ (Fig. 1).

Initially the concentration of the impurity is uniform throughout the noble metal. The initial condition therefore is

$$C(X,0) = C_B \quad [2]$$

As discussed by Goel and Bader (6), the impurity content present nearer to the metal surface at $X = l$ will diffuse out at a faster rate than that present nearer to the medium at $X = 0$. Consequently, we can assume that the concentration gradient at $X = 0$ is zero, *i.e.*

$$\frac{\partial C}{\partial X}(0,t) = 0 \quad [3]$$

As the diffusion proceeds, the impurity on the surface chemically reacts with the environment. In air or an oxygen environment, the impurity is oxidized. The film growth rate and the film thickness can be experimentally determined using Auger/ESCA depth profiling techniques or microbalance measurements. It is important to realize that the mathematical analysis presented in this paper is applicable to the particular situation of a binary alloy where solute is the only reacting specie, that is, the solvent is a noble metal.

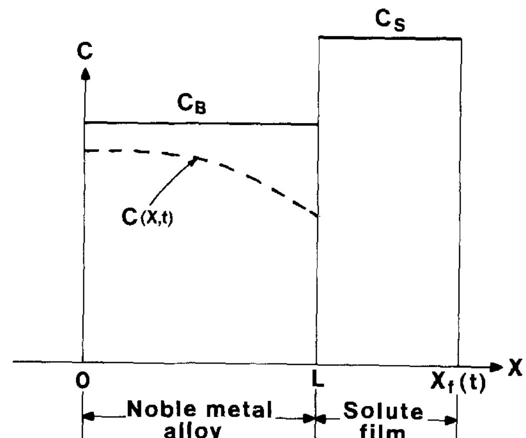

Fig. 1. Diagram of the mathematical model. C_B = bulk solute concentration, $C(X,t)$ = solute concentration at X,t for $0 \leq X \leq L$, C_S = solute concentration in the surface film, X_f = surface film thickness at t, and L = alloy thickness.

* Electrochemical Society Active Member.

Key words: diffusion, solute segregation, corrosion kinetics, oxide films.

Modern analytical techniques (ESCA/Auger, etc.) can also provide the chemical composition of the surface film. The amount of solute in the film (weight percent or atomic percent) can thus be calculated. Therefore, it is assumed in this analysis that the solute concentration in the film is known either from the stoichiometry or from other experimental measurements.

The second boundary condition needed to solve Eq. [1] is derived from the conservation of the solute (10), *i.e.*, the total amount of solute, Q, in the system remains constant

$$Q = \int_0^l C(X,t)\,dX + \int_l^{l+X_f} C(X,t)\,dX \qquad [4]$$

where X_f is the thickness of the corrosion film.

A further mathematical simplification is made by assuming the concentration of solute in the film to be a constant equal to C_s. This assumption is reasonable since the film generally is homogeneous (one phase), and, to first order, the concentration gradient effect (*e.g.*, due to diffusion of cations through the film) is small. Thus

$$Q = \int_0^l C(X,t)\,dX + \int_l^{l+X_f} C_s dX \qquad [5]$$

Using Leibniz's rule of differentiating integrals (11), for Eq. [5] and utilizing Eq. [1] and [3] we get the following boundary condition at $X = l$

$$D\frac{\partial C}{\partial X}\bigg|_{X=l} = -\frac{dX_f}{dt}C_s$$

or

$$\frac{\partial C}{\partial X}\bigg|_{X=l} = -\frac{1}{D}\left(\frac{dX_f}{dt}\right)C_s \qquad [6]$$

Equation [6] is the second boundary condition needed to solve Eq. [1]. This in fact is a time-dependent flux boundary condition at $X = l$, linking the solute flux with the film growth. Initially the growth rate is faster and therefore the impurity flux is higher. As the film growth rate reduces (film thickens), the flux at $X = l$ also reduces. This is physically a very plausible boundary condition and represents the real life diffusion processes more accurately than the infinite sink model or concentration-dependent flux conditions.

The general solution of Eq. [1] subject to initial condition [2] and boundary conditions [3] and [6] is given by Eq. [A-11] as shown in Appendix A, *i.e*,

$$C(X,t) = C_B - \frac{C_s}{D}\int_0^t \frac{\partial}{\partial t}\left\{\frac{dX_f(t-\lambda)}{dt}\right\}F(X,\lambda)\,d\lambda + \frac{C_s}{D}\cdot\frac{dX_f(o)}{dt}F(X,t) \qquad [7]$$

where F is given by Eq. [A-12] in Appendix A.

In order to use Eq. [7] for determining the concentration profiles, a simple computer program utilizing an integration subroutine has been developed. The program consists of ~30-40 instructions and is relatively simple and very inexpensive to use. The film growth rate kinetics is experimentally derived and the rate of film growth dX_f/dt is inserted into Eq. [7]. The resulting concentration profiles can be utilized to derive D and are discussed later.

Equation [7] is the most general solution applicable to any corrosion kinetics. Some of the important film growth rate laws encountered in practice are summarized in Appendix B. Closed form solutions can be obtained in specific cases and two such solutions are discussed below.

Parabolic Growth Rate Model ($X_f^2 = kt$) [8]

The boundary condition [6] in this case becomes

$$\frac{\partial C}{\partial X}\bigg|_{X=l} = -\frac{1}{D}\left(\frac{\sqrt{k}}{2\sqrt{t}}\right)C_s \qquad [9]$$

The Laplace transform of Eq. [9] is

$$\frac{\partial f}{\partial X} = \frac{-\sqrt{k}\sqrt{\pi}}{2D\sqrt{s}}C_s \qquad [10]$$

The solution to Eq. [1] in the transform space in this case is

$$f = \frac{C_B}{s} - \frac{\sqrt{k}\sqrt{\pi}}{2s\sqrt{D}}C_s\frac{\cosh gX}{\sinh gX} \qquad [11]$$

or

$$f = \frac{C_B}{s} - \frac{\sqrt{k}\sqrt{\pi}}{2\sqrt{D}\,s}C_s\sum_{n=0}^{\infty}\{e^{-g[(2n+1)l-X]} + e^{-g[(2n+1)l+X]}\} \qquad [12]$$

Taking the inverse Laplace transform of [12] yields the solution

$$C(X,t) = C_B - \frac{\sqrt{k}\sqrt{\pi}C_s}{2\sqrt{D}}\sum_{n=0}^{\infty}\left\{\operatorname{erfc}\frac{(2n+1)l-X}{2\sqrt{Dt}} + \operatorname{erfc}\frac{(2n+1)l+X}{2\sqrt{Dt}}\right\} \qquad [13]$$

where erfc is the complementary error function. The above solution converges quite rapidly except for large values of (Dt/l^2). At large values of (Dt/l^2), Eq. [7] can be used.

In situations where the value of l is so large that the system can be considered semi-infinite, a simpler solution given by Thomas (5) can be used instead. (Equation [13] reduces by suitable manipulation to his solution by using a coordinate system where $X' = l - X$ and $l \rightarrow \infty$.)

Linear Growth Rate Model ($X_f = k_1t$)

The solution in this case can be shown to be

$$C(X,t) = C_B - \frac{2k_1\sqrt{t}}{D}\sum_{n=0}^{\infty}\left\{\operatorname{ierfc}\frac{(2n+1)l-X}{2\sqrt{Dt}} + \operatorname{ierfc}\frac{(2n+1)l+X}{2\sqrt{Dt}}\right\} \qquad [14]$$

where

$$\operatorname{ierfc} X = \int_X^{\infty}\operatorname{erfc}\xi\,d\xi \qquad [15]$$

Results

Many important film growth processes encountered in practice obey the parabolic growth rate. Thomas (5) in an earlier paper has shown that Co diffusing out of gold oxidizes according to parabolic rate. Wagner (3) has shown that Ni diffusing out of Pt follows parabolic oxidation kinetics. It has been shown in the literature that a substantial number of solutes (used in noble metals) follow parabolic oxidation when they are not in solution. It may therefore be expected that even in solution, the diffusing specie may oxidize according to parabolic growth rate law. For this reason, we discuss this case in detail.

In order to understand the time development of the solution $C(x,t)$, we will first discuss a specific example as shown in Fig. 2a-c. Assume that corrosion proceeds with a rate $k = 10^{-18}$ cm²/sec for parabolic growth kinetics and $C_S/C_B = 50$. The ratio $C_S/C_B = 50$ is representative of the Co-Au system (5). Equation [13], for this case, is solved numerically for various values of k/D (3×10^{-4}, 10^{-4}, and 10^{-6}) and $C(x,t)$ is plotted for various times as a function of x/l in Fig. 2. In Fig. 2a and b, $C(l,t)$, the concentration at the interface, remains constant for times up to ~10^6 sec. As time increases, $C(l,t)$ decreases and eventually becomes zero (with a finite concentration in the alloy layer). In Fig. 2c, $k/D = 10^{-6}$, $C(l,t)$ varies continuously after 10^4 sec. For shorter times, $C(l,t)$ is also fixed at some value close to C_B for $k/D \sim 10^{-6}$.

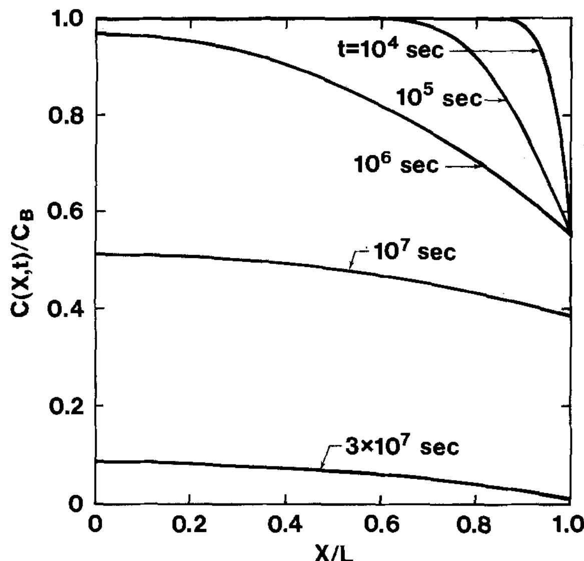

Fig. 2a. $C(X,t)$ is plotted as a function of X/l for $k/D = 10^{-4}$ for various times.

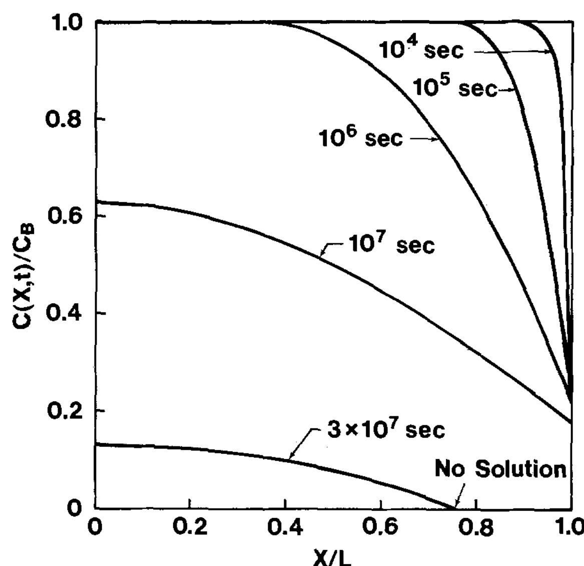

Fig. 2b. $C(X,t)$ is plotted as a function of X/l for $k/D = 3 \times 10^{-4}$ for various times.

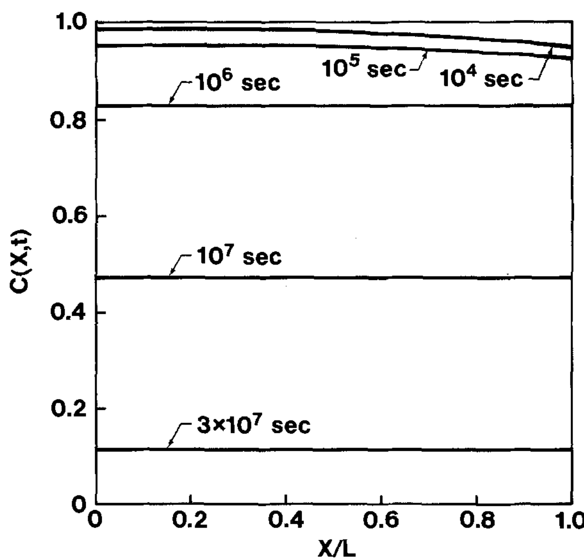

Fig. 2c. $C(X,t)$ is plotted as a function of X/l for $k/D = 10^{-6}$ for various times.

From Eq. [13], $C(x,t)$ at $x = l$ reduces to the following expression

$$C(l,t) = C_B - \sqrt{\frac{\pi k}{4D}} C_s \left\{ 1 + \sum_{n=1}^{\infty} 2 \operatorname{erfc}\left(\frac{nl}{\sqrt{Dt}}\right) \right\} \quad [16]$$

It can be shown from [16] that for $t = 0$ or $l = \infty$

$$C(l,o) = C_B - \sqrt{\frac{\pi k}{4D}} C_s \quad [17]$$

This expression is identical to the expression for $l \to \infty$ in Ref. (5). Therefore, for small times (limit $t \to 0$), the interface concentration is fixed (see Eq. [17]). This is due to the fact that the time-dependent part of Eq. [16] (erfc argument) is much smaller than unity for very large arguments. As the argument of the error function decreases (with increasing Dt), $C(l,t)$ starts decreasing as observed in Fig. 2. Physically, this is a result of finite thickness of the alloy. The error function contribution becomes significant when material (solute) from surface $x = 0$ begins to reach the surface $x = l$. Since D for $k/D = 10^{-6}$ is larger than D for $k/D = 10^{-4}$, the time at which the interface concentration begins to vary is smaller for $k/D = 10^{-6}$ (10^5 sec for $k/D = 10^{-6}$ and 10^7 sec for $k/D = 10^{-4}$). For smaller values of k/D, $C(l,t)$ is approximately equal to C_B initially, and for larger times a uniform depletion of material occurs with $C(l,t)$ decreasing continuously with time. If the diffusion coefficient is much larger than $k(>k(C_s/C_B)^2)$, there is enough time available for the diffusion of material to take place from the interior. Thus at smaller values of k/D (*e.g.*, $k/D = 10^{-6}$ in Fig. 2) no sharp concentration gradient is observed, instead a more or less uniform depletion of material from the entire thickness takes place. At some time the entire solute will be depleted. At smaller k/D values, diffusion is not rate determining. As k/D increases (10^{-4}), *i.e.*, D comparable to $k(C_s/C_B)^2$, it is seen that initially (shorter times) most of the solute material which reacts comes from near the boundary at $X = l$. With increasing time more and more solute material arrives from inside. A sharp concentration gradient exists for these higher k/D values. The concentration profile is very steep initially. As t increases the steepness of the profile decreases. Physically this is very plausible. Since k is larger, the material which arrives on the surface is quickly corroded and diffusion plays a significant role in the over-all process. It is also observed from Eq. [16] that the concentration at $X = l$ reduces with t and at a certain instant of time, $C(l,t)$ becomes zero. The condition for $C(l,t)$ to be zero is

$$\frac{C_B}{C_s} = \frac{\sqrt{\pi}\sqrt{k}}{2\sqrt{D}} \left\{ 1 + \sum_{n=1}^{\infty} 2 \operatorname{erfc} \frac{nl}{\sqrt{Dt}} \right\} \quad [18]$$

The mathematical model breaks down at this time, since the solution after this time predicts a negative concentration at the interface $X = l$, a physically impossible situation. When C becomes zero at the interface, the physical process becomes diffusion controlled and does not explicitly depend on the corrosion rate constant, k. This predicts that when the physical corrosion rate constant is measured, k will be a direct function of D as shown in Eq. [18] rather than independent of D as was the initial premise. At this time, the flux at the interface will depend only on D.

Finally, it is observed that the slope of $C(X,t)$ at the interface becomes very large for times approaching zero. This effect is a manifestation of the model used, that is, $X_f^2 = kt$. Since $dX_f/dt \propto 1/\sqrt{t}$ and when $t \to 0$, dX_f/dt (and thus $dc/dX)_{x=l}$ becomes large ($\to \infty$).

Figure 3 represents the generalized solutions, $C(X,t)$ normalized with respect to C_B (*i.e.*, $C(X,t)/C_B$) plotted as a function of X/l for various values of $l/\sqrt{kt}$ (or l/X_f) and k/D (Fig. 3a is for $C_s/C_B = 50$ and Fig. 3b is for $C_s/C_B = 10$). For a given value of l and k, the high values of l/X_f represent shorter time periods and as t increases, l/X_f decreases. Smaller

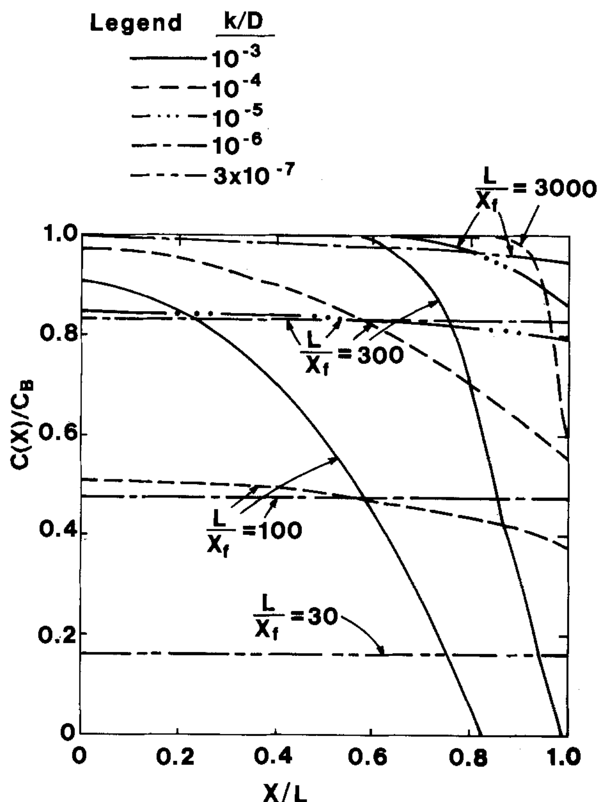

Fig. 3a. Normalized solute concentration is shown as a function of X/l with l/X_f as a parameter for $C_s/C_B = 50$.

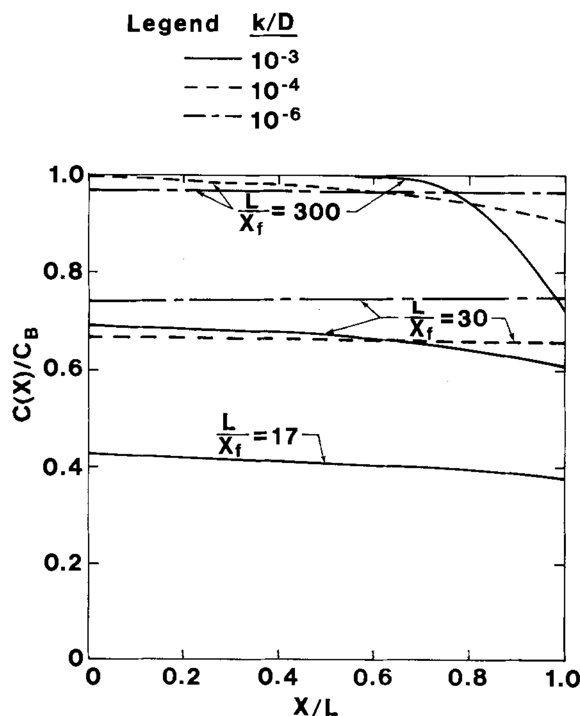

Fig. 3b. The same as Fig. 3a except $C_s/C_B = 10$. l is the alloy thickness, X_f is the solute film thickness, C_s is the solute concentration in the film, and C_B is the bulk solute concentration. For parabolic kinetics $X_f = \sqrt{kt}$.

k/D represents the situation where the oxidation rate (or film growth rate) is slow and the diffusion constant is higher. If the k value increases and/or the value of D decreases (higher k/D ratio), the system may reach a diffusion-controlled situation. The more general case is where the process is controlled by both k and D. It is seen from Fig. 3 that when $D > k(C_s/C_B)^2$, no sharp concentration gradient is observed and a more or less uniform depletion of material takes place. At higher k/D values the concentration profile is very steep initially, that is, its gradient is large as explained above. The slope of the concentration, $C(l,t)$ decreases with time. [This situation is similar to the one discussed in our specific example (Fig. 2) and need not be elaborated further.]

In actual measurements of concentration profiles by AES depth profiling, for example in the case of cobalt-hardened gold, the concentration at the interface can be measured. We believe that in most situations, film growth is not diffusion controlled and, hence, a depth profile would show nonzero concentration at the interface.

Because the concentration at the interface is most significant and can be used to determine material parameters, k, D, etc., a plot of $C(l,t)/C_B$ has been generated as a function of time. Equation [13] can be easily nondimensionalized using the following parameters which are functions of the material system constants, that is

$$(a)\ \frac{X_f}{l}\frac{C_s}{C_B} \text{ and } (b)\ \frac{k}{D}\left(\frac{C_s}{C_B}\right)^2$$

where (a) is basically $\sqrt{t}$ dependence for fixed C_s, C_B l, and k. Figure 4 shows the concentration at the interface, $C(l,t)/C_B$, as a function of X_fC_s/lC_B with $(C_s/C_B)^2\ k/D$ as a parameter. For values of $k/D \times (C_s/C_B)^2$ near unity, the ratio $C(l)/C_B$ remains constant until X_fC_s/C_Bl approaches unity then $C(l)/C_B$ rapidly goes to zero. For a specific case of $l = 3\ \mu$m, and $C_s/C_B = 50$, the concentration at $X = l$ remains constant until the film grows to 200Å. For thicknesses greater than 200Å, the concentration $C(l,t)$ goes rapidly to zero. This behavior holds true for $k/D\ (C_s/C_B)^2 > \sim 10^{-2}$. For smaller values of $k/D(C_s/C_B)^2$ (*e.g.*, 2.5×10^{-4} in Fig. 4) the $C(l,t)$ goes very slowly to zero with time (or film thickness). Figure 5 presents a plot of $C(l,t)/C_B$ as a function of $k/D(C_s/C_B)^2$ for various parameters of C_s/C_B and X_f/l and provides similar information as in Fig. 4.

Figure 6 shows a nomograph from which the parabolic rate constant, k, can be computed knowing the film thickness X_f developed in time t. Figure 6 in conjunction with Fig. 4 or Fig. 5 can be used to compute the diffusion coefficient, D, for known C_s, C_B,

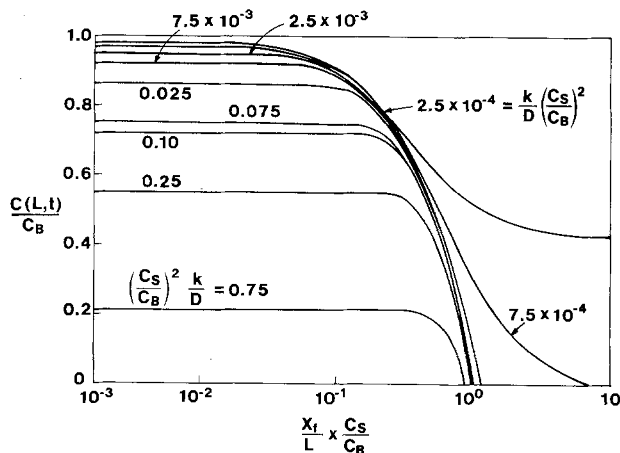

Fig. 4. Normalized solute concentration at $X = l$ is shown as a function of the nondimensional parameter $X_f/l\ C_s/C_B$ with $(C_s/C_B)^2\ k/D$, (also nondimensional) as a parameter.

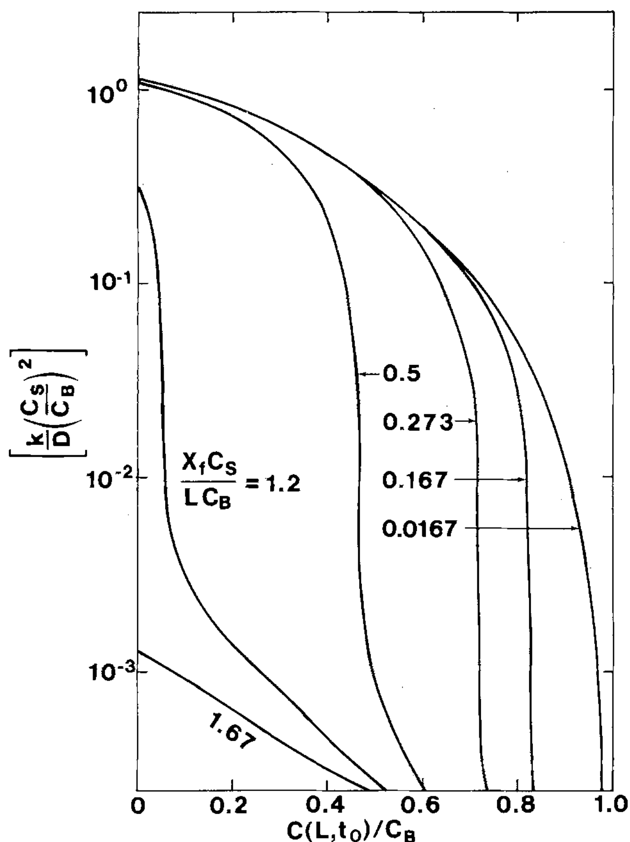

Fig. 5. This plot is similar to Fig. 4 with coordinates and parameters changed. k/D $(C_s/C_B)^2$ is shown as a function of $C(l)/C_B$ with X_f/l C_s/C_B as a parameter.

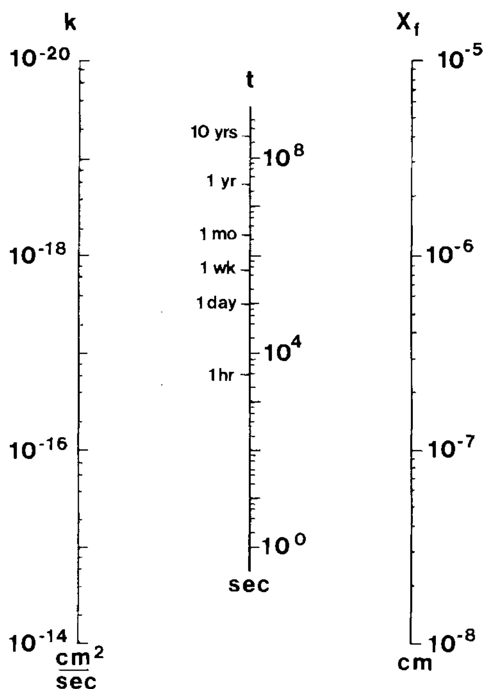

Fig. 6. This nomograph provides a means of computing the parabolic rate constant from film thickness, X_f and time, t.

$C(l)$, and film growth kinetics. Experimentally $X_f(t_o)$ and $C(l,t_o)$ are measured. The parameter $C_s/C_B(X_f/l)$ is then computed. Using Fig. 4 or 5, k/D $(C_s/C_B)^2$ is then obtained. One then computes k from Fig. 6 and proceeds to calculate D. As an example, it is assumed that $C_s/C_B = 50$, $l = 3 \times 10^{-4}$ and that a film thickness $X_f = 80$Å in 1.8×10^6 sec is produced in a certain experiment. For parabolic growth kinetics, k is found to be $\sim 5 \times 10^{-19}$ cm²/sec. If, by measurement, $C(l)/C_B$ is 0.4, the parameter X_f/l (C_s/C_B) can then be calculated as 0.134. From Fig. 5, k/D $(C_s/C_B)^2$ is found to be 0.5. The value of D is calculated to be 2.5×10^{-15} cm²/sec.

Conclusions

In calculating the solute diffusion coefficient from dilute noble metal alloys, the concentration at the alloy-film interface is often assumed to be zero (infinite sink model). Experimentally, the concentration at this interface is seldom zero. We have used a time-dependent flux boundary condition at the film-alloy interface as derived by conserving the total solute in the system. By utilizing this boundary condition, the kinetics of solute film growth has been coupled to the solute diffusion from the alloy. A general mathematical analysis has been presented for different film growth rate laws using Duhamel's theorem. Two specific closed form solutions for parabolic and linear growth rate kinetics have been derived. A method for calculating the diffusion coefficient by measuring the corrosion rate constant and the solute concentration at the film-alloy interface has been outlined for parabolic kinetics. Numerical results for the solute concentration have been presented for this case. It is observed that at low k/D values, no sharp concentration gradient occurs along the thickness of the alloy, *i.e.*, an almost uniform depletion of solute occurs in the entire thickness as a function of time. As the k/D value increases, the concentration changes sharply along the alloy thickness. At some time, $C(l) = 0$, a diffusion-controlled situation is reached. The concentration at the interface has been plotted as a function of the nondimensional parameter $(X_f/l\ C_s/C_B)$ for various values of $k/D(C_s/C_B)^2$. By knowing the concentration at the interface and other material parameters, D can be calculated. Numerical calculations have been shown as an example.

APPENDIX A

In order to solve Eq. [1] subject to initial condition [2] and boundary conditions [3] and [6], the Laplace transform techniques can be used. The Laplace transform of Eq. [1] with the initial condition [2] is

$$D\frac{\partial^2 f}{\partial X^2} - sf + C_B = 0 \qquad [A\text{-}1]$$

Where s is the Laplace transform variable and $f(s)$ is Laplace transform of $C(X,t)$. The solution of Eq. [A-1] is

$$f = E\cosh gx + F\sinh gx + \frac{C_B}{s} \qquad [A\text{-}2]$$

where

$$g = \sqrt{(s/D)}$$

In order to solve a general problem with time-dependent flux boundary condition, we proceed as follows (9, 13). We first solve an auxiliary problem with the following boundary condition at $X = l$

$$\frac{\partial C}{\partial X} = 1 \text{ at } X = l \qquad [A\text{-}3]$$

In transform form this boundary condition is

$$\frac{\partial f}{\partial X} = \frac{1}{s} \text{ at } X = l$$

We also take the transform of boundary condition [3], *i.e.*

$$\frac{\partial f}{\partial X} = 0 \text{ at } X = 0 \quad \text{[A-4]}$$

Utilizing Eq. [A-3] and [A-4] in Eq. [A-2], we get

$$f(s) = \frac{\cosh gx}{sg \sinh gl} + \frac{C_B}{s} \quad \text{[A-5]}$$

The solution in the time domain is obtained by taking the inverse Laplace transform of Eq. [A-5]

$$C = C_B + \frac{1}{2\pi i}\int_{\gamma - i\infty}^{\gamma + i\infty} \frac{e^{st}\cosh gx}{sg \sinh gl} ds \quad \text{[A-6]}$$

The integral, by Cauchy's theorem, is equal to $2\pi i$ times the sum of the residues at the poles of its integrand. We also assume that γ is so large that all the singularities of $f(s)$ lie to the left of the line $(\gamma - i\infty, \gamma + i\infty)$. There is a double pole at $s = 0$ and the residue at $s = 0$ is

$$\underset{s \to 0}{\text{Limit}} \frac{d}{ds} \left\{ \frac{De^{st} g \cosh gX}{\sinh gl} \right\} = \frac{Dt}{l} + \frac{3X^2 - l^2}{6l} \quad \text{[A-7]}$$

The other poles of $f(s)$ are

$$g = \frac{n\pi i}{l},\ n = 1, 2, 3, \ldots \quad \text{[A-8]}$$

and the residues at $g = n\pi i/l$ (or $s = -n^2\pi^2 D/l^2$) are

$$= (-1)^{n+1}\frac{2}{n^2\pi^2} e^{-(n^2\pi^2 Dt/l^2)} \cos\frac{n\pi X}{l} \quad \text{[A-9]}$$

The solution of Eq. [1] subject to boundary conditions [3] and [A-3] and initial condition [2] is

$$C = C_B + \frac{Dt}{l} + \frac{3X^2 - l^2}{6l} - \frac{2l}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} e^{-(n^2\pi^2 Dt/l^2)} \cos\frac{n\pi X}{l} \quad \text{[A-10]}$$

The above solution is similar to that given in Carslaw and Jaeger (13). In order to obtain the solution of the problem for time-dependent flux boundary condition [6], we use Duhamel's theorem following Churchill (9) (with the aid of convolution property) for the flux boundary conditions. The solution is

$$C(X,t) = C_B - \frac{C_s}{D}\int_0^t \frac{\partial}{\partial t}\left\{\frac{dX_f(t-\lambda)}{dt}\right\} F(X,\lambda)\, d\lambda + \frac{C_s}{D}\cdot\frac{dX_f(0)}{dt}\cdot F(X,t) \quad \text{[A-11]}$$

where $dX_f(t - \lambda)/dt$ is the time varying function of the variable $(t - \lambda)$ and $dX_f(0)/dt$ is the value of dX_f/dt at $t = 0$. The function $F(X,t)$ is the solution of the Eq. [1] with boundary conditions [3] and [A-3] but with zero initial condition and is therefore given by

$$F(X,\lambda) = \frac{D\lambda}{l} + l\left\{\frac{3X^2 - l^2}{6l^2} - \frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} e^{-(n^2\pi^2 Dt/l^2)} \cos\frac{n\pi X}{l}\right\} \quad \text{[A-12]}$$

Equation [A-11] together with [A-12] represents the solution of Eq. [1] to appropriate boundary conditions [3] and [6] and initial condition [2].

APPENDIX B

Film Growth Kinetics—Laws (14, 15)

Linear growth rate.

$$X_f = k_l t \quad \text{[B-1]}$$

where k_l is the linear growth rate constant. The rate of growth of the film in this case is constant

$$\frac{dX_f}{dt} = k_l \quad \text{[B-2]}$$

Parabolic growth rate.—The most general parabolic growth rate can be described by

$$\frac{1}{k_{p1}} X_f^2 + \frac{1}{k_{p2}} X_f = t \quad \text{[B-3]}$$

where k_{p1} and k_{p2} are the rate constants in appropriate units. The rate of growth dX_f/dt is given by

$$\frac{dX_f}{dt} = \left[\sqrt{\left(\frac{1}{k_{p2}}\right)^2 + \frac{4t}{k_{p1}}}\right]^{-1} \quad \text{[B-4]}$$

In a special case of simple parabolic growth rate we get

$$X_f^2 = kt$$

and

$$\frac{dX_f}{dt} = \frac{\sqrt{k}}{2\sqrt{t}} \quad \text{[B-5]}$$

Asymptotic growth rate.—If the film growth rate approaches some constant thickness X_c in the course of time, the growth rate law may be described by

$$X_f = X_c[1 - e^{-k_a t}] \quad \text{[B-6]}$$

Where k_a is the appropriate rate constant describing the growth characteristic. In this case

$$\frac{dX_f}{dt} = X_c k_a e^{-k_a t} \quad \text{[B-7]}$$

Logarithmic growth rate.—The film growth rate in this case is described by

$$X_f = k_n \log(at + b) \quad \text{[B-8]}$$

and

$$\frac{dX_f}{dt} = \frac{k_n a}{at + b} \quad \text{[B-9]}$$

Inverse logarithmic growth rate.—The growth rate in this case is

$$\frac{1}{X_f} = k_1 - k_2 \log t \quad \text{[B-10]}$$

and

$$\frac{dX_f}{dt} = \frac{k_2}{t(k_1 - k_2 \log t)^2} \quad \text{[B-11]}$$

In addition to above analytical expressions describing the oxidation (film growth) processes which begin at the time $t = 0$, there are many cases where experimental data reflect an over-all result for which two or more independent physical mechanisms are responsible (15). Most of these cases can be judiciously reduced to the above expressions. For example, if one of the processes is described by a linear rate and the other by parabolic

$$X_f = k_l t + \sqrt{k_p t} \quad \text{[B-12]}$$

It may be shown that the resultant curve is a skewed parabola. If there are two simultaneous parabolic processes involved in film growth, *i.e.*

$$X_f = \sqrt{k_{p3} t} + \sqrt{k_{p4} t} \quad \text{[B-13]}$$

the resultant curve is a parabola $X_f^2 = kt$, where

$$k = (\sqrt{k_{p3}} + \sqrt{k_{p4}})^2 \quad \text{[B-14]}$$

Various other situations where some process controls oxidation to certain time $t = \tau$ and at that instant another mechanism takes over, can also be reduced to above cases by suitably choosing the coordinate systems.

The Application of Pulsed Current Electrolysis to a Rotating-Disk Electrode System

II. Electrochemical Kinetics

K. Viswanathan* and H. Y. Cheh**

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

ABSTRACT

A new method which was based on a combination of pulsed electrolysis and stirring to study fast electrode reactions was developed. Theoretical expressions were derived for a first-order reversible reaction. Experimental investigation was carried out in a ferri-ferrocyanide system. Good agreement on the results was obtained between the new method and the d-c measurements.

Methods for studying fast electrode reactions can be grouped generally into two types. The first type involves the application of transient technique to an unstirred electrochemical system. Techniques such as chronopotentiometry, chronoamperometry, cyclic voltammetry, etc. all fall into this group. Theoretical analyses involve solving the diffusion equation subject to boundary conditions in accordance with the applied technique. There is a wealth of information concerning this approach in the literature in terms of research papers, review articles, and books. Major reviews on the subject include the early summary by Delahay (1) and subsequent books by Vetter (2), Adams (3), and most recently, Macdonald (4). The second type involves the application of direct current or potential to a stirred system. Theoretical analyses involve solving the convective diffusion equation under d-c boundary conditions. The rotating-disk electrode (RDE) due to its well-known mass transfer behavior, is the most prominent tool in this approach. Levich (5), Adams (3), Albery and Hitchman (6), Pleskov and Filinovskii (7), and Opekar and Beran (8) have written extensive reviews on the RDE system.

A common principle for both types of methods is that in order to study fast electrode reactions, mass transfer limitations must either be negligible or be quantitatively accounted for. The RDE system possesses both the practical advantage of effective stirring and the theoretical advantage of being a relatively simple system to analyze mathematically. A combination of the two methods, *i.e.*, the application of transient techniques to a RDE system, would in principle enable one to study quantitatively the rate of fast electrode reactions. In this paper we develop such a method by applying pulsed current electrolysis to an RDE system. Theoretical analysis on the determination of kinetic parameters is presented. Experimental investigation by using a ferri-ferrocyanide system is then reported. It is important to note here that a major advantage of pulsed current electrolysis is that the surface concentration of the reacting ion can be calculated solely from mass transfer considerations by solving the convective diffusion equation subject to Fick's first law of diffusion as a boundary condition. In other words, the surface concentration of the reacting ion depends on the transport characteristics of the system and the applied current density. It is independent of reaction kinetics.

Theoretical

The theoretical analysis is based on an RDE system with the same assumption as described in part I of our paper (9). Assume also that the following reaction may occur at the RDE

$$O + ne^- \rightleftharpoons R \quad [1]$$

where O and R represent the molecular formula of the oxidized and reduced species, respectively, and n is the number of electrons transferred during reaction. The Butler-Volmer equation is assumed to represent adequately the rate of the reaction when a pulsed current is applied

$$i_p = i_{o,\infty}\left[\frac{c_{R,i}}{c_{R,\infty}}\exp\left\{\frac{\alpha n\mathbf{F}\eta}{RT}\right\} - \frac{c_{O,i}}{c_{O,\infty}}\exp\left\{-\frac{(1-\alpha)n\mathbf{F}\eta}{RT}\right\}\right] \quad [2]$$

where i_p is the applied pulsed current density, $i_{o,\infty}$ is the exchange current density at the bulk concentration, $c_{R,i}$ and $c_{R,\infty}$ are the concentration of R at the electrode surface and in the bulk, respectively, $c_{O,i}$ and $c_{O,\infty}$ are the concentration of O at the electrode surface and in the bulk, respectively, α is the transfer coefficient, η is the overpotential, and $\mathbf{F}$, R, and T have their usual meaning.

Consider the case of applying a cathodic current and assume that the ratio, $c_{R,i}/c_{R,\infty}$, is close to unity. Equation [2] can be rewritten as

$$i_p = i_{o,\infty} \exp\left\{\frac{\alpha n F \eta}{RT}\right\}\left(1 - \frac{c_{O,i}}{c_{O,\infty}} \exp\left[-\frac{nF\eta}{RT}\right]\right) \quad [3]$$

The concentration of O at the electrode surface can be calculated by the following equation which has been derived by Cheh (10)

$$\frac{(c_{O,i} - c_{O,\infty}) nFD_O}{i_p \delta_O} = 1\text{-}2 \sum_{n=1}^{\infty} \frac{1}{\mu_n^2} \cdot \left\{ \frac{\exp[-\mu_n^2 \tau_{O,l}] - \exp[-\mu_n^2 \tau_{O,c}]}{(1 - \exp[-\mu_n^2 \tau_{O,c}])} \right\} \quad [4]$$

where

$$\mu_n = (2n - 1)\frac{\pi}{2} \quad [5]$$

$$\tau_O = D_O t / \delta_O^2 \quad [6]$$

and D_O is the diffusion coefficient and δ_O is the thickness of the Nernst diffusion layer, $\tau_{O,l}$ and $\tau_{O,c}$ are the dimensionless pulse and cycle time, all referred to species O, and t is time.

Since the RHS of Eq. [4] is equal to the ratio of the d-c cathodic limiting current density $(i_{d\text{-}c})_{l,c}$ and the pulsed cathodic limiting current density $(i_p)_{l,c}$ (9, 10) and since $(i_{d\text{-}c})_{l,c}$ is related to δ_O by Eq. [5]

$$(i_{d\text{-}c})_{l,c} = -\frac{nFD_O c_{O,\infty}}{\delta_O} \quad [7]$$

Equation [4] can be rewritten as

$$\frac{c_{O,i}}{c_{O,\infty}} = \frac{(i_p)_{l,c} - i_p}{(i_p)_{l,c}} \quad [8]$$

By substituting Eq. [8] into [3] and rearranging, one obtains

$$\ln \left\{ \frac{i_p}{\left[1 - \left(\frac{(i_p)_{l,c} - i_p}{(i_p)_{l,c}}\right) \exp\left\{-\frac{nF\eta}{RT}\right\}\right]} \right\} = \ln i_{o,\infty} + \frac{\alpha n F\eta}{RT} \quad [9]$$

Similarly, if the applied pulsed current is anodic, the following equation can be derived

$$\ln \left\{ \frac{i_p}{\left[\left(\frac{(i_p)_{l,a} - i_p}{(i_p)_{l,a}}\right) \exp\left\{\frac{nF\eta}{RT}\right\} - 1\right]} \right\} = \ln i_{o,\infty} - \frac{(1-\alpha) nF\eta}{RT} \quad [10]$$

Equation [9] and [10] are the basic equations for the analysis of kinetic parameters by the pulsed current technique.

Experimental

The same experimental setup as described in our previous paper (9) was used in this work. In order to avoid possible poisoning of Pt in ferri-ferrocyanide solution, an Au disk electrode of 0.461 cm² area was used. The electrolyte consisted of 0.01M ferricyanide, 0.01M ferrocyanide, and 0.5M K_2SO_4. K_2SO_4 instead of KCl was chosen to eliminate possible anodic dissolution of Au. All experiments were carried out at 22° ± 1°C.

The kinematic viscosity of the electrolyte was measured by an Ostwald viscometer and the value was found to be 0.00976 cm²/sec. The diffusion coefficients of the ferri- and ferrocyanide ions were obtained by d-c limiting current density measurements. The values were 6.9×10^{-6} and 5.7×10^{-6} cm²/sec, respectively.

For comparison purpose, the kinetic parameters for the ferri-ferrocyanide reaction system were first determined by using the d-c method developed by Jahn and Vielstich (11). These authors showed that the exchange current density and the transfer coefficient for the reaction could be determined from a knowledge of the intercept and slope of a 1/(applied d-c current density) *vs.* 1/(rotation speed)$^{1/2}$ plot. Experimental results are shown in Fig. 1. The exchange current density and transfer coefficient were found to be 4.3 mA/cm² and 0.5, respectively.

Pulsed experiments were carried out at rotation speeds of 400, 900, and 1600 rpm, with a pulse time of 10^{-4} sec and a cycle time of 10^{-3} sec. The overpotential of the RDE was measured as a function of the applied pulsed current density. Results are shown in Fig. 2. Equations [9] and [10] were used to calculate the

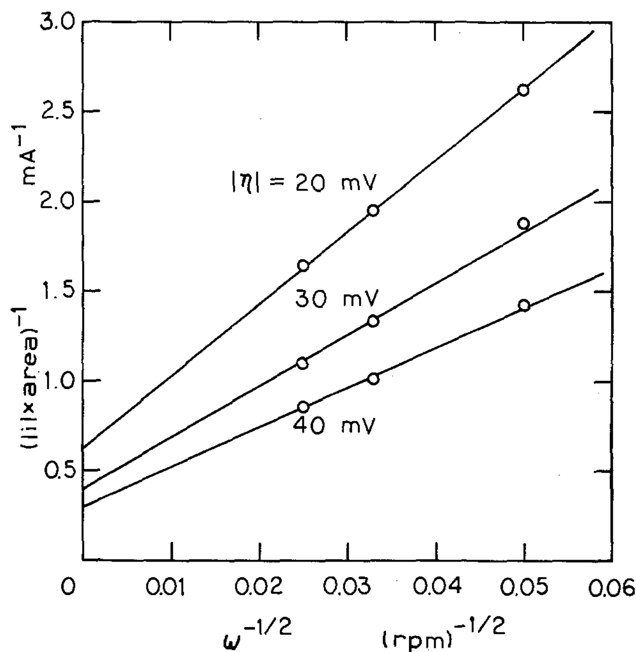

Fig. 1. Current-potential plot for the determination of kinetic parameters by the method of Jahn and Vielstich (11).

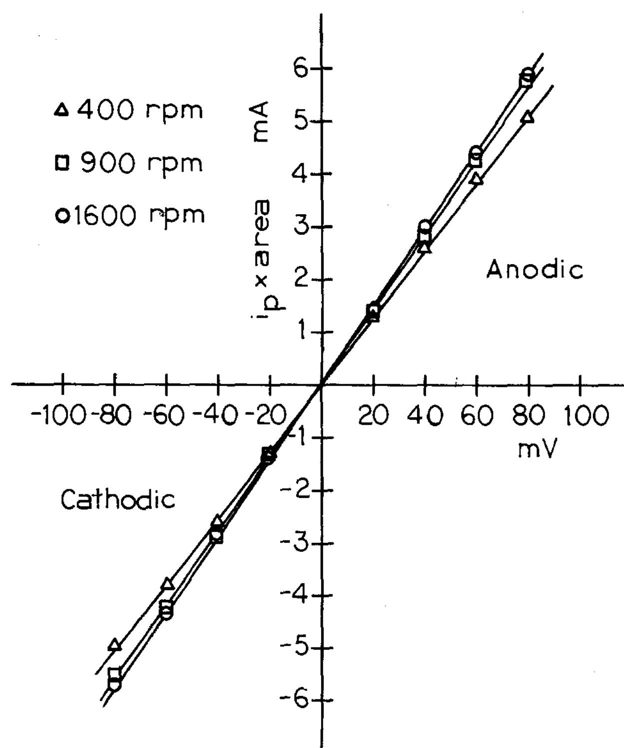

Fig. 2. Current-potential behavior of the ferri-ferrocyanide system under pulsed current conditions.

kinetic parameters. $(i_p)_{l,a}$ and $(i_p)_{l,c}$ were first calculated for the experimental conditions. The LHS of Eq. [9] and [10] were plotted as a function of overpotential. Results are shown in Fig. 3 and 4. The line in both figures was drawn so that a transfer coefficient of 0.5 would result from the slope. The exchange current density was found to be 4.3 mA/cm^2 for cathodic reduction of ferricyanide from Fig. 3, and 4.5 mA/cm^2 for anodic oxidation of ferrocyanide from Fig. 4. Comparing these results with those obtained by d-c measurements, the agreement can indeed be considered very good.

Conclusions

A new technique which is based on pulsed current electrolysis in a stirred system is developed to study fast electrode reactions. Theoretical expressions were derived for reversible first-order reaction on an RDE system. The technique was applied to determine kinetic parameters for a ferri-ferrocyanide reaction system. Good agreement was obtained between the results based on the present approach and those from d-c measurements.

The new technique is in principle capable of studying much faster reactions than the experimental system chosen for this work. This can be accomplished by a combination of applying shorter pulses with low duty cycles and increased stirring. The method can also be easily extended to reactions other than first order.

n-Heptylviologen Radical Cation Films on Transparent Oxide Electrodes

Raymond J. Jasinski*,[1]

Texas Instruments Incorporated, Dallas, Texas 75265

ABSTRACT

The cosmetic and kinetic properties of n-heptylviologen dihydrogenphosphate radical cation films deposited on transparent oxide electrodes, in particular tin oxide, are dependent upon the initial condition of the oxide-electrode surface. The implication is a strong interaction of the electrode surface with the first layer(s) of radical cation film deposited.

"Viologens" are dialkyl and diaryl 4,4' bipyridinium compounds (1). They are stable in water below pH 8-10; the water solutions are colorless, or pale yellow, depending on the substituent group. These compounds are readily synthesized in high yield, from reaction of dypiridyl and the appropriate alkyl or aryl halide (1). Other synthetic routes are also available (2-5).

Chemical and cathodic reduction of the short-chain viologens in water solutions (*e.g.*, the dimethyl and diethyl compounds) generate blue-to-violet colors which have been shown due to stable radical cations (6-8). Mild oxidation with air, for example, restores the parent dication. In 1973 it was pointed out (9) that cathodic reduction of viologens with alkyl side chains containing more than five carbon atoms resulted in deposition of colored films on the reducing electrode surfaces rather than forming soluble blue material. Furthermore, in the absence of air, these films remained adherent to the electrode surface, and on anodization yielded the parent dication.

It was also suggested that this phenomenon could be the basis for an alphanumeric display. Since that time, a number of papers and patents have discussed the use of viologens in this context. Most of these have dealt with generating viologen films onto metal electrode surfaces, and although the mechanisms involved in film growth and oxidation are not totally understood, the phenomenology appears to be relatively straightforward. Such is not the case with viologen redox reactions on transparent oxide electrodes which are of considerable importance in practical display technology.

This paper discusses properties of one viologen radical cation film (that from n-heptylviologen dihydrogenphosphate) on commercially available transparent tin oxide and on tin-doped indium oxide. The contention is made that the differences in electrode performance, vis-à-vis metal electrodes, must arise from chemical interactions of the electrode surface with the radical cation film, as well as from the higher ohmic resistance of the oxide electrode.

Experimental

The experimental techniques were substantially as described elsewhere (10), but with a few modifications. The apparatus included the following: Wenking Potentiostat, Wenking VSG 72 Scan Generator, PAR Digital Coulometer, Corning Model 101 Electrometer, TI No. 341 and Servoriter recorders, Lab Con Company glove box. The glass cell was of the standard three-compartment design; a glass frit separated the counter-electrode compartment from the working electrode; a capillary, within 1 cm of the working electrode isolated the Orion double junction reference electrode (Model 90-02-00, with 10% KNO_3 as the "outer" solution). The test cell and glove box were deaerated with nitrogen which had been passed over copper filings at 580°C.

Open-circuit ("equilibrium") potentials were recorded 7 min after depositing a nominal 3 mC/cm^2 of radical cation film at potentials positive to those required to reduce the radical cation. No attempt was made to control cell temperature precisely during these studies.

N-heptylviologen dibromide was synthesized in-house by reaction of dipyridyl and 1-bromoheptane. Recrystallization was from methanol with acetone. The dihydrogenphosphate derivatives were prepared from the bromide salt via ion exchange on Amberlite IRA-400. It was determined that the residual halide concentration was less than 5×10^{-5}M. The supporting electrolyte was molar phosphate, pH 4.

Deaerated n-heptylviologen solutions were stored in the glove box (under fluorescent lamps) with no obvious decomposition over a 12 month period. Solutions stored in air developed a pungent odor within a few days, unless contained in "actinic" glass.

The oxide electrodes (1 cm^2) studied were the commercially available "NESA," "Nesatron 20" and "Nesatron 100" from PPG Industries, as well as SnO_2 from Corning. A few measurements were made with "Electropane" from Libby-Owens-Ford. Sheet resistances for these materials were measured routinely by a two-point probe method (11), calibrated by the four-point probe method of van der Pauw (12). The cathodic limits were established by exhaustive electrolysis (13), *i.e.*, potentiostating the electrode for prolonged periods of time at the appropriate values and measuring changes in sheet resistance, usually accompanied by visible changes in the film. This technique sees" only electrode decomposition, rather than reduction of trace oxygen, hydrogen evolution, or plating of trace metal ions. Techniques for conditioning and cleaning the transparent oxide surfaces are discussed in the text.

Electrical contact to the oxide electrode was made via a direct clip to the slice, 0.5 cm above the solution level. Although poor current distribution can be expected, it was the only electrode-mounting scheme which did not perturb the electrode surface. Bonding conductive oxide-coated glasses over small apertures with epoxy did improve current distribution, however, flowing of epoxy during the sealing operation and/or simultaneous contamination of the surfaces made the technique valueless for the purposes of this work.

Surface elemental analyses were made with the PHI Model 548 Auger Spectrometer and the JEOL 3 Scanning Auger Spectrometer. The oxygen/metal ratios were calibrated by assuming that the measured signals for sputtered surfaces corresponded to a 2:1 atom ratio for tin oxide, and 3:2 for the indium oxide-based materials (14). The O/Sn calibration factors so obtained agreed to within ±2% standard deviation for 15 samples of commercial and in-house prepared tin oxide. The surface carbon contents are reported as C/metal

* Electrochemical Society Active Member.

[1] Present address: Occidental Research Corporation, Irvine, California 92713.

Key words: viologens, electrochromics, transparent electrodes, tin oxides, indium oxides.

peak height ratios, since a reasonable calibration procedure was not readily available for carbon.

Results

The bulk characteristics of the electrode materials used in this study are shown in Table I. The variations listed in sheet resistances and thicknesses are standard deviations for a minimum of 12 pieces from one shipment each. It was not possible to generate quantitative atom ratios for the dopant levels of the tin oxide samples due to the lack of fluoride and antimony standards. The dopant values listed for the Nesatron 20 samples are bulk values. The surface Sn/In ratios (*e.g.*, 0.12-0.16) were suspect due to the inevitable surface carbon contamination (see below).

Most of the electrochemical measurements were carried out with the first three materials listed because of the lower sheet resistances. The cathodic limits (at pH 4) given in the table are conservative in that all samples tested survived these potentials without change; some samples were stable at an additional -50 mV.

Films of radical cation formed on as-received electrodes were almost always "patchy" and nonuniform in appearance. The rates of cathodic decomposition and, in particular, anodic erasure of the radical cation film, were slow; 3-5 min, for example, were required to anodize completely a 3 mC/cm^2 film.

It was presumed that the nonuniformity of the film was due, at least in part, to the carbonaceous materials on the electrode surface indicated by the Auger spectra (Table II). Oxidative and extractive procedures reduced this carbon to minimal levels. Those surfaces Soxhlet-extracted 4 hr each with xylene, isopropanol, methanol, and water, as well as those surfaces treated with alcoholic caustic, subsequently yielded uniform viologen radical cation films. Films formed onto surfaces that had been subjected first to highly oxidative treatments, both wet and dry, were routinely nonuniform, being darkest around the edges and light in the center.

This relationship between carbon content and film uniformity is not particularly surprising, however the pretreatment procedure had an additional effect, that of altering the erasure kinetics. Shown in Fig. 1 are plots of the amounts of charge remaining on a tin oxide electrode surface *vs.* time after application of a constant $+100$ mV for three clean-up procedures. Each electrode had been first coated with 3 mC/cm^2 radical cation film at -525 mV and then held on open circuit

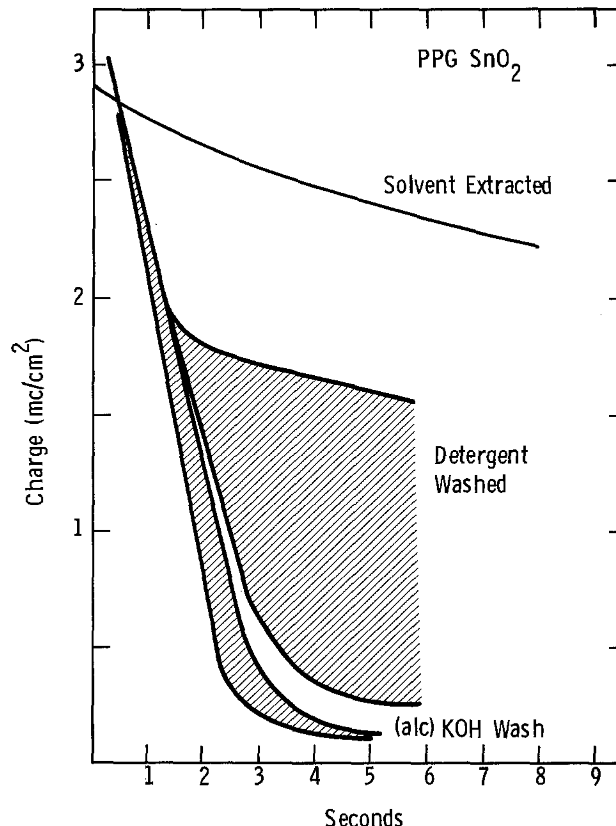

Fig. 1. Quantity of charge remaining on a PPG tin oxide sample as a function of time after application of a constant + 100 mV.

for 1 min. Obviously a uniform deposit does not correlate with fast erasure, nor did a nonuniform deposit correlate entirely with a slow erasure (the detergent-treated samples (14) were almost always nonuniform in appearance, but sometimes gave fast erasures). A rationalization of this effect is offered below after a discussion of additional phenomenology involved in film formation and erasure.

The caustic-treated and solvent-extracted samples were always wettable; the as-received samples were not. This effect has generally been ascribed to hydrolysis of the surface [*e.g.*, (14, 15)], which according to theory (19, 20) is not accompanied by an increase in O/Sn ratio.

Table I. General properties of conductive oxide electrodes

Item	C. SnO_2	NESA	Nesatron 20	N. 100	L.O.F.

Extract in (xylene/IPA/H_2O)/buffer	0.01	0.09	3.2	4.0

The measured surface O/Sn atom ratios are also given in Table II. As found by others (14), the surface ratios were always larger than the bulk atom ratios, with a ratio of nominally 2.5:1 as the lower limit, *i.e.*, when the samples had not been treated chemically and were not substantially contaminated with carbon. There is precedence in the literature [e.g., Ref. (16)] for excess surface oxygen due to compensation of bulk vacancies by adsorbed gaseous oxygen. Much, although not necessarily all, of this oxygen should be removed by pump down in the Auger chamber (17). Some oxygen is likely the result of contamination from the same source as the large amount of carbon found on the surface, particularly for the as-received PPG samples (both the carbon and oxygen signals were high and the tin signal was low). Samples simply contacted with water could be slightly "hydrated," yielding an increased oxygen signal. With one exception, both low carbon contents and increased O/Sn ratios were obtained for electrodes treated with alcoholic caustic + buffer, peroxide/sulfuric acid, and xylene extraction + buffer. This could be due to incorporation of substantial water into the tin oxide with one or more of the electrolyte constituents. (The significance of "+ buffer" is discussed below.)

An attempt was made to study the hydrolysis of the surface in a more direct fashion by correlating organosilane subsequently bonded to the surface hydroxyl groups (16) with the pretreatment procedure. As-received Corning tin oxide samples, kept from contact with bulk water, did not bond significant amounts of organosilane (specifically hydrogen triethoxysilane). Such samples soaked in buffer solution subsequently bonded considerable organosilane. Drying the surface by heating in air decreased but did not eliminate the reaction with organosilane. However samples of PPG tin oxide simply exposed to water during the glass-cutting operation bonded considerable organosilane. These samples were not visibly "wettable" (hence the surface was not hydrolyzed appreciably); the surface was contaminated with considerable carbon (Table II). Identical results were obtained with as-received Nesatron 20 and Nesatron 100 samples treated in the same manner, and these were also highly contaminated with carbonaceous material. The dry oxygen glow discharge essentially eliminated the uptake of organosilane by the Corning tin oxide and, as shown in Table II, essentially eliminated the carbon residue on the surface. The same glow discharge applied to the PPG samples decreased but did not eliminate the carbon residue on the surface. The interpretation which must be given to these results then is that the organosilane can bond to water incorporated into the surface and more incorporation takes place during extended contact with water solutions. However the organosilane can also bond to functional groups which are part of the surface contamination on the as-received samples.

Cleaned oxide electrodes were equilibrated in *p*H 4 phosphate buffer at least 12 hr before testing in viologen solution. This was a nontrivial step for the tin oxide electrodes, but was less important for the Nesatron 20. If omitted for SnO_2, the radical cation films formed nonuniformly (including this step but omitting the cleaning stage gave the same poor performance). A possibly analogous effect has been reported in the literature (15), whereby soaking the tin oxide electrode in electrolyte increased the subsequent activity for adsorption of iodide ion. The mechanism was interpreted as an increase in the hydration/ion exchange capacity of the tin oxide, a phenomenon well known with bulk cassiterite (10). Since, in the present case, surface hydroxyl groups were probably present before the equilibration, it is assumed that the dominating reaction was ion exchange. Indeed phosphorus was found on the tin oxide electrode surfaces with the scanning Auger (avoiding areas of the surface containing particulate matter). This then was the surface on which the following electrochemistry was carried out.

Shown in Fig. 2 are erasure curves for PPG tin oxide, cleaned with alcoholic caustic, onto which had been nominally deposited 1, 2, 3, 4, and 5 mC/cm^2 of radical cation film. Obviously the bulk of the film erased at a constant rate which was independent of coverage. The "tail" initiated at about 0.05 mC/cm^2. Figure 3 shows a similar plot, but with erasure potentials varied for a constant initial coverage of 3 mC/cm^2 ($\pm$ 10%). The conclusion here is that the "fast" erasure section is more potential dependent than the "tail" section. The "tail" section was less pronounced with Nesatron 20 than with the tin oxide samples.

Both the "tail" and "fast" sections were independent of the length of time after deposition and erasure of the film (between 1 and 7 min). Accumulation of color on the electrode was not observed after 10^{+3} repetitive cycles of minimal 6 sec each; the charge in the "tail" did not increase.

Cyclic voltammograms on the tin oxide electrode were of the same form as previously reported for metals (10, 13) except for the distortion due to the ohmic resistance of the electrode materials. A definite peak corresponding to deposition or removal of the "tail" section could not be distinguished from the major Faradaic processes. However, those electrode/electrolyte combinations leading to tailing on anodic erasure also lead to "drawn out" anodic peaks on cyclic voltammograms.

Shown in Table III are the cathodic peak currents observed on the three oxide electrodes, for a constant cathodic potential of −550 mV. Nesatron 20, with the lower sheet resistance, did give a higher peak current

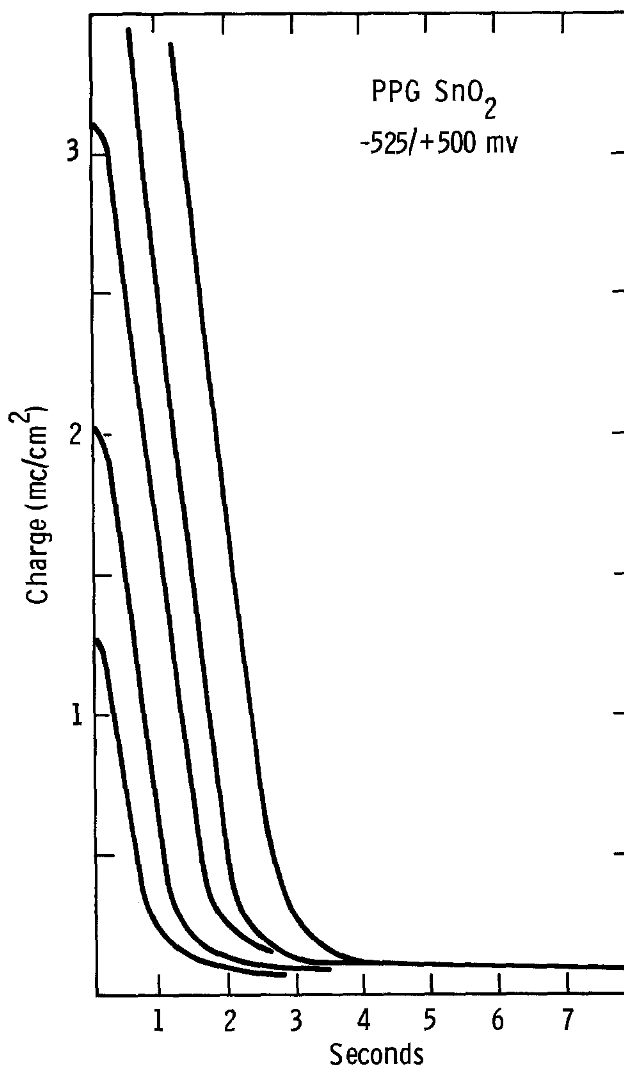

Fig. 2. Erasure curves with initial coverages of 1.3, 2, 3.1, 4.2, 5 mC/cm^2, respectively.

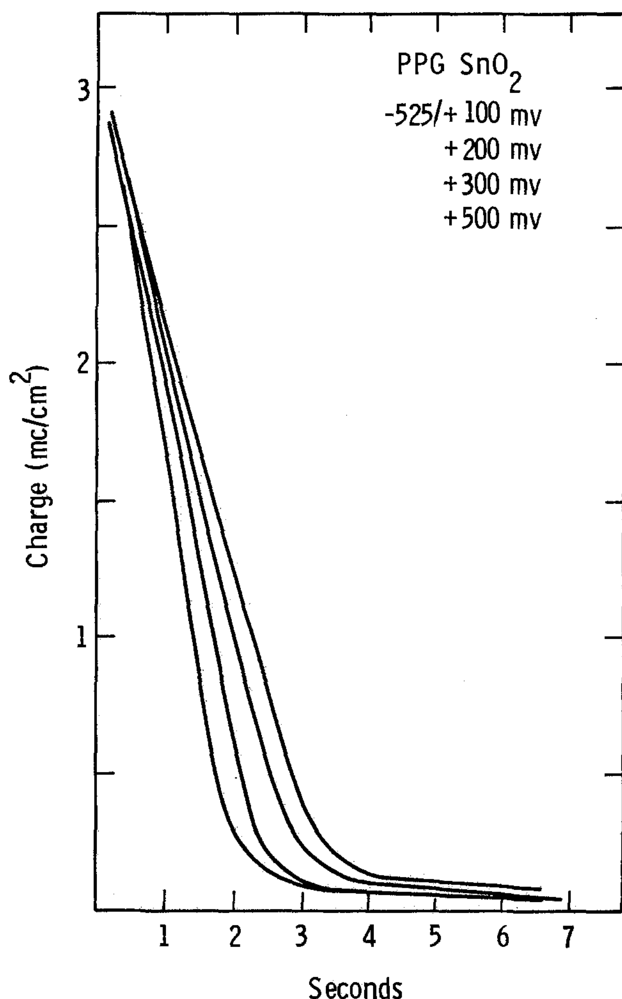

Fig. 3. Erasure plots as a function of erasure potential. The fastest erasure corresponds to the most positive potential (+ 500 mV) applied.

than the SnO_2 electrode, but not in direct proportion to the sheet resistance. For a given electrode material, however, the application of more negative potentials increased the cathodic current proportionately in the range -475--600 mV.

Discussion

The reaction sequence shown in Table IV is inferred from these results as a working model for redox processes of n-heptylviologen dihydrogenphosphate (R-V^{+2}) on transparent tin oxide electrodes.

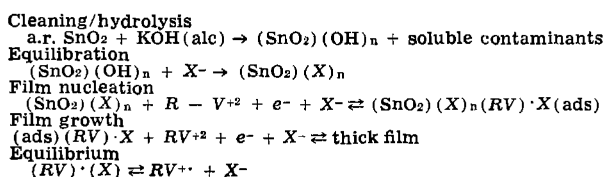
Table III. Effect of sheet resistance

Deposition of n-heptylviologen phosphate (-550 mV)

Electrode	Sheet resistance (Ω/□)	i_{peak} (mA)
Corning SnO_2	99 ± 13%	0.36
PPG SnO_2	100 ± 18%	0.54
Nesatron 20	27 ± 10%	0.65
Gold		>3

Table IV. Viologen salts on tin oxide electrodes

Working model



Cleaning/hydrolysis
a.r. SnO_2 + KOH(alc) → $(SnO_2)(OH)_n$ + soluble contaminants
Equilibration
$(SnO_2)(OH)_n + X^- \rightarrow (SnO_2)(X)_n$
Film nucleation
$(SnO_2)(X)_n + R - V^{+2} + e^- + X^- \rightleftarrows (SnO_2)(X)_n(RV)\cdot X(\text{ads})$
Film growth
$(\text{ads})(RV)\cdot X + RV^{+2} + e^- + X^- \rightleftarrows$ thick film
Equilibrium
$(RV)\cdot(X) \rightleftarrows RV^{+\cdot} + X^-$

The need to remove surface contaminants (step **1**) and expose conductive oxide is logical and the necessity for this step has been demonstrated herein. The simultaneous generation of surface hydroxyl groups (step 1) is consistent with the literature (15) and the wettability character of the so-treated surfaces.

It has been demonstrated that a surface equilibration with electrolyte is required before uniform radical cation films can be generated on the tin oxide electrodes. This is shown (step 2) as an ion-exchange process. Auger analysis did find phosphorus on the surface after excluding particulate residual salts from the analytical beam. Higher O/Sn ratios were also found. There is precedence in the literature for cassiterite-exchanging hydroxyl groups for dihydrogenphosphate (19). This step is apparently less important with indium oxide electrodes since uniform radical cation films could be generated and erased rapidly on nonequilibrated Nesatron 20.

The reactions of this modified oxide surface with the viologens dication (21) and/or the first layer of cathodically formed radical cation are grouped in step 3. It is this first layer which must, logically, provide for the adhesion of the subsequently deposited bulk film. The label of "nuclei" is used for this first layer on oxide electrodes to be consistent with observations on the electrodeposition of metals and metal oxides onto the same type of material [*e.g.*, Ref. (22, 23)]. It is apparent from the data presented in Fig. 2 and 3 that the last nominal 0.03 mC/cm^2 of radical cation to be anodized off the electrode surface must have different properties than the bulk of the radical cation film. This quantity of charge is consistent with that required to form nuclei from silver on tin oxide, with due allowance made for the difference in size of the viologen molecule and the silver atom.

To explain the data of Table III, *i.e.*, the less-than-expected increase in cathodic currents from oxide electrodes of lower sheet resistances, and the increase in current from increasing the overpotential applied to a given material, it is proposed (*i*) that the number of nuclei formed on an electrode surface are a function of material, pretreatment, and possibly potential; and (*ii*) only these nuclei act as electronically conducting channels for delivery of charge from the electrode to the growing film. A variation in nucleus concentration with pretreatment also would explain the erasure curves shown in Fig. 1 whereby speed was a distinct function of electrode pretreatment.

The bulk film must grow (step 4) by reduction of the dication from the solution. It is not known whether this is actually a two-stage process, *i.e.*, cathodic formation of the soluble radical cation which eventually precipitates as a salt [as has been claimed many times, *e.g.*, Ref. (9, 13)] or whether the two steps are concurrent, as implied in Table IV. As with metals, the film must be relatively nonporous since undercutting and peeling of the film are not found on anodic oxidation.

Step 5 implies an equilibrium between radical cation in the bulk film with radical cation in solution. It has been shown (10, 20) that the concentration dependences of the equilibrium potentials for such films on metals obey the Nernst equation modified for the solubility product relationship. Identical potentials were found with films on transparent oxide electrodes, so it is reasonable to assume that this equilibrium applies here as well.

S/Se Substitution in Polycrystalline CdSe Photoelectrodes

Photoelectrochemical Energy Conversion

and Gary Hodes* and Joost Manassen

Plastics Research Department, The Weizmann Institute of Science, Rehovot, Israel

ABSTRACT

On the basis of x-ray photoelectron spectroscopy (XPS) studies of polycrystalline CdSe electrodes, the occurrence of S/Se substitution in these electrodes, when immersed in polysulfide solution, is verified. The substitution process is enhanced considerably when the electrode is illuminated as part of a photoelectrochemical cell. The mechanism of the S/Se exchange is discussed, as well as the consequences of such an exchange for electrode stability. The resulting presence of a thin (several tens of angstroms) layer of CdS on top of the CdSe is taken into account in constructing a rough band scheme for the system. The CdS layer is shown to influence the photovoltage and, to a lesser extent, the photocurrent obtainable from this kind of photoelectrochemical cell. Its relation to the slow deactivation of highly crystalline CdSe photoelectrodes is discussed.

Since the discovery that Cd-chalcogenide photoelectrodes can be stabilized considerably in aqueous solutions by the addition of sulfide ions to the solution (1-3), several hypotheses have been forwarded to explain this stabilization. These include the low redox potential of the $S/S^=$ redox couple, the fast kinetic behavior of the $S/S^=$ redox reaction, and the preferential absorption of sulfide ions on CdS (4), although it is quite possible that no single one of these is solely responsible and that the explanation must include a combination of these factors. An investigation of the changes occurring in Cd-chalcogenide electrodes when they are used as photoelectrodes in a photoelectrochemical cell (PEC) might shed some light on the stabilization mechanism. It is noteworthy that different degrees of stabilization have been obtained for single crystal, sintered disk, and thin layer polycrystalline electrodes (1, 3). In an earlier report we mentioned the occurrence of S/Se substitution, when CdSe is used in polysulfide (S/S^{2-}) solution as a photoelectrode (1). In this report we present results, obtained by x-ray photoelectron spectroscopy (XPS), which show the occurrence of this substitution both in the light and in the dark. Additional evidence is given which supports such a substitution and the resulting effect of it on the conversion efficiency and stability of CdSe electrodes in polysulfide solutions. The mechanism of the substitution is discussed and on the basis of these data we present a band scheme for the polysulfide electrolyte-CdS-CdSe system in which the CdS layer is considered as essentially an insulator. Therefore, in analogy to solid state MIS systems this junction can be looked upon as an EIS (electrolyte-insulator-semiconductor) one. Also, on the basis of the substitution phenomenon, we explain the difference in behavior between polycrystalline and single crystal electrodes and the short- and long-term changes in photovoltage and photocurrents obtained from such a PEC.

Experimental

XPS (ESCA) spectra were obtained on an AEI ES200 spectrometer, using Al Kα radiation (1486.3 eV, ~0.9 eV linewidth). The samples to be investigated were handled in a glove box attached to the spectrometer. Powdered samples (CdS, CdSe) were ground in the glove box, which was previously made oxygen and water free by cooling a Cu coil, situated inside the

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, energy conversion, XPS, photocorrosion.

glove box, with liquid N_2 until no more condensation was observed. The freshly ground powders were then pressed into previously cleaned In foil.

The polycrystalline electrodes (5 × 16 mm) were investigated as prepared (1), although contact with air was minimized to avoid oxidation of the surface. Electrodes which had been immersed in S/S^{2-} solution were washed twice in Na_2S solution to prevent precipitation of elemental S from adsorbed electrolyte and then washed several times thoroughly in deionized water to remove adsorbed Na_2S, prior to analysis. Both wide scans [1-1000 eV binding energy (B.E.)] and narrow scans (20-40 eV) were made.

Etching of the surface was achieved using an Ar ion gun situated in the analyzing chamber at a glancing angle of 60° with respect to the substrate. The probe current was 6.6 μA for a beam voltage of 1000V. An etching time of 10 min corresponds, under these conditions, to an etched layer of 80 ± 20Å, *i.e.* 30 ± 6 atomic layers of Cd-chalcogenides (5). Pure CdS and CdSe powders (99.99% Alpha Inorganics) were used as standards. The CdS electrode consisted of a chemically vapor deposited CdS layer on In-SnO_2 conducting glass. The CdSe electrodes were prepared electrolytically on Ti-metal (1). CdSe electrodes were illuminated in a photoelectrochemical cell as described previously (1) using C/CoS counterelectrodes (6). Both sides of the Ti substrate were plated with CdSe. One side was insulated by painting with a solution of tar in benzene (which we have found to form a stable coating over long periods of time in the sulfide electrolyte), except in experiments where the two sides were compared, as in illuminated and nonilluminated sides for the XPS measurements. Illumination at ~ AM1 intensity (for higher than bandgap energy photon flux) was obtained from a conventional tungsten-iodine projector lamp, yielding short-circuit currents of 5-7 mA/cm^2 and open-circuit voltages of ~ 0.5V for samples used in XPS experiments. In these experiments samples were illuminated for 24-36 hr continuously under near short-circuit conditions. n-CdSe crystals were purchased from Cleveland Crystals Corporation (specific resistivity 1-10 Ω-cm, ~ > 10^{16} cm^{-3} donor concentration). Ohmic contact was made to the CdSe crystals by an In-Ga alloy to which a wire (Cu or Ta) was connected by silver epoxy and covered with an insulating epoxy.

XPS Results

Preliminary wide scans of the electrodes showed the presence of Cd, Se(S), C, some O, and Ti (for CdSe electrodes only). Ar^+ etching decreased the relative intensities of the Ti 2p, Cls, and Ols peaks considerably. Narrow scans were made of the S 2s, Se3s region (Fig. 1), S2p, Se3p region (Fig. 2), Se3d, Se $L_2M_{4,5}M_{4,5}$ Auger peak, S KLL Auger peak, and Cd 3d regions. The clearest evidence for the presence of S in illuminated CdSe electrodes was obtained from the Auger peak at ~ 151 eV kinetic energy (K.E.), because no Se peaks are present in this region. Because of the width of this peak no attempt was made to use it for the determination of the amount of S present; however, in a qualitative way, it proved unequivocally the increased presence (see below) of S in previously immersed and illuminated electrodes. For analysis of the relative amounts of S and Se in the samples the S2s/Se3s and S2p/Se3p peaks were used. The Cd3d peaks showed no significant change before and after illumination, which is to be expected as the peak positions of Cd3d in CdS and CdSe (both powders and electrodes) are identical (405.0 and 411.7 eV B.E.); ~ 1.40 eV FWHM). The Se $L_2M_{4,5}M_{4,5}$ Auger peak (~1307 eV K.E.) was monitored to show the (dis)appearance of Se in the electrode top layer. Again, because of the width of this peak it was used as a qualitative guide only. Figure 1 shows the region of the S2s and Se3s peaks. For comparison pure CdS is included as well. The spectrum of the nonilluminated side of a CdSe electrode after submersion is included because it shows behavior intermediate between that of an electrode prior to and after illumination. Although the S and Se peaks overlap somewhat, the strong S presence in the illuminated electrode is clear from the figure. Also the spectrum shows the presence of some S in an electrode prior to illumination. The source of this S is probably in the SeO_2 and/or H_2SO_4 used for the electrolytic preparation of the CdSe electrode (1), as this sample had not been in contact with the $S/S^=$ solution. After prolonged etching (35 min) the peak profile resembles that of an electrode prior to illumination rather closely. Even after 10 min etching a strong decrease in the S peak is observed and the peak profile is closer to that of

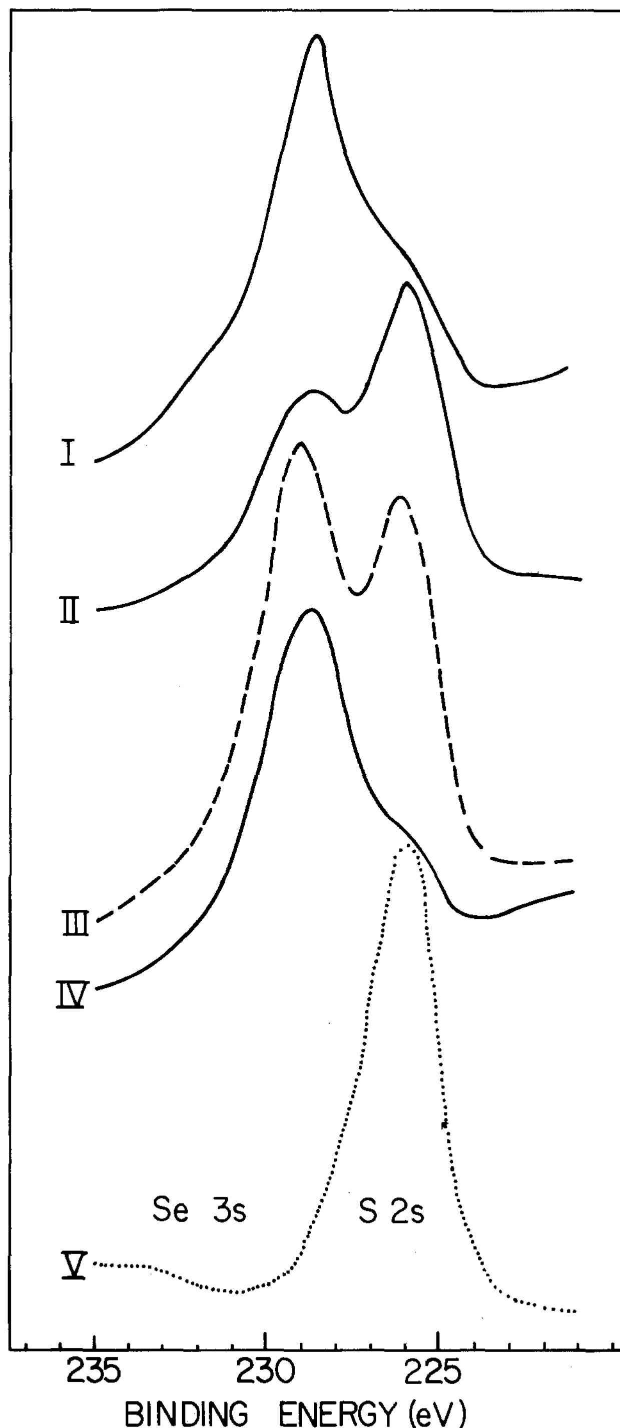

Fig. 1. Photoelectron spectra of CdSe electrodes. I, New electrode before immersion and illumination in polysulfide solution; II, same electrode after 36 hr of illumination as photoelectrode in photoelectrochemical cell (short circuit); AM1 equivalent light intensity; illuminated side; III, same as II, nonilluminated side; IV, same as II, after Ar ion sputtering for 35 (10 + 10 + 15) min; V, CdS.

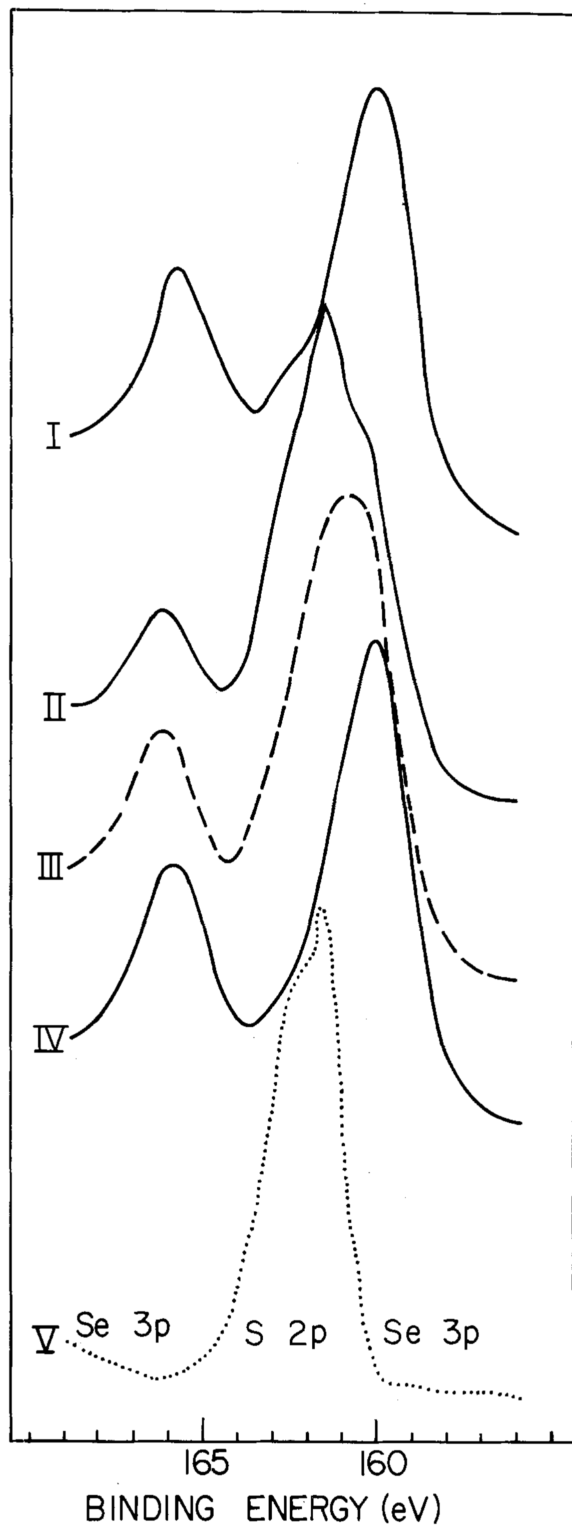

Fig. 2. As Fig. 1. Splitting of Se3p and asymmetry of S2p peaks is due to L-S coupling.

the electrode prior to illumination than to that of an illuminated one. (The continued presence of some residual S, even in nonilluminated samples, seems to argue against differential sulfur etching.) For the nonilluminated side a 10-min etching period is sufficient to make the S peak return nearly to that obtained for the electrode before illumination. Figure 2 shows the region of the S2p and Se3p peaks. The change in these peaks is parallel to that observed for the S2s/Se3s peaks. The change in relative intensity of the Se3p½ peak especially, shows the course of the S/Se substitution clearly. On the basis of the data, shown partly in Fig. 1 and 2 and those obtained for the Cd3d peaks, a rough depth profile can be obtained, using the relative intensities given in Ref. (7) for Cd3d, S2p, and Se3p. As a check on this profile, which gives the Cd/Se (Cd/S) ratio, the S2s and Se3s peaks were used to estimate the S/Se concentration ratio. In the case of overlapping peaks, manual deconvolution was used to estimate individual peak intensities. The results of these calculated estimates are shown in Fig. 3. It should be noted that the exact course of the initial decrease in the Cd/Se and S/Se ratio in the top layer is uncertain, because only points for zero and 10 min etching are used. This uncertainty in the decrease is indicated by the dashed lines in the graphs. The units used for the Cd/Se ratio were calculated using the data of Ref. (7), while in the case of the S/Se ratio arbitrary units are used.

Discussion

Exchange mechanism.—The XPS results show that a chemical exchange occurs both under illumination and in the dark. Under illumination the exchange is enhanced considerably and results in deeper penetration, *i.e.* the resulting sulfide-rich layer extends deeper into the semiconductor. It seems probable that this photoenhanced exchange occurs via hole oxidation of CdSe in the following fashion (8)

$$2h\nu \xrightarrow{\text{CdSe}} 2e^- + 2h^+ \quad [1]$$

$$2h^+ + \text{CdSe} \rightarrow \text{Cd}^{2+} + \text{Se} \quad [2]$$

$$\text{Se} + \text{S}^{2-} \rightarrow \text{SSe}^{2-} \text{ (in solution)} \quad [3]$$

$$\text{Cd}^{2+} + (\text{S}^{2-})_{\text{ads}} \rightarrow \text{CdS}\downarrow \quad [4]$$

Thus, following oxidation of CdSe to Cd^{2+} and Se [2],

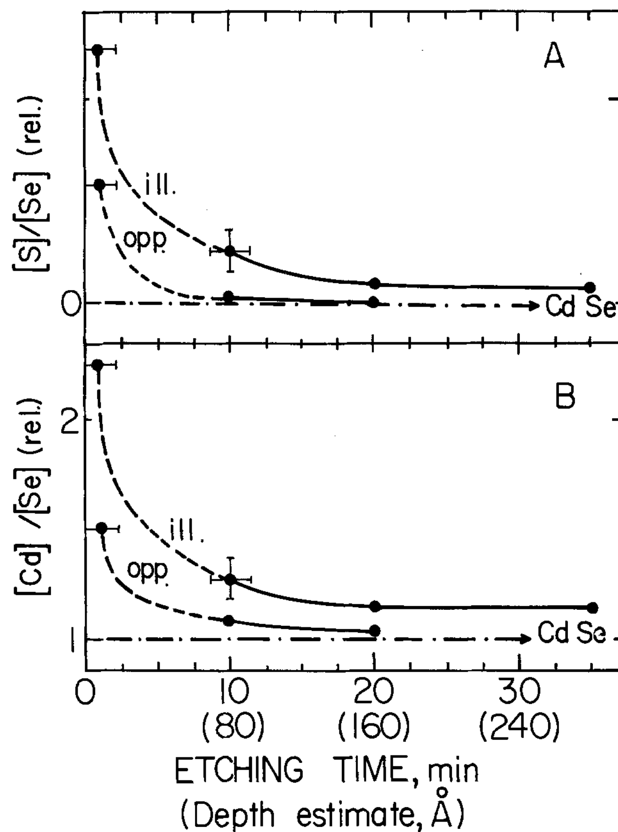

Fig. 3. Depth profile of illuminated and nonilluminated sides of CdSe photoelectrodes in photoelectrochemical cell. A, relative [S]/[Se] ratio derived from the Se3s and S2s peaks; B, [Cd]/[Se] ratio derived from the Cd3d, Se3p and S2p peaks, using the relative photoelectron signal intensities tabulated in Ref. (7). Horizontal error bars reflect the sampling depth (~ 20Å), vertical ones reflect uncertainty in peak intensities. Because of the polycrystalline nature of the surface the depth estimate in angstroms should be considered as a rough guide only. Lines labeled CdSe refer to new nonimmersed, nonilluminated CdSe electrodes.

the Se can dissolve in the sulfide-rich solution [3]. At the same time, because of the high surface concentration of sulfide ions, the Cd^{2+} ion will react to give CdS within a very short time of its formation [4]. In a way this sequence of reactions can be thought of as a reprecipitation of CdS on the CdSe surface, although not in the usual sense, *i.e.*, from the bulk solution.[1]

The presence of a polycrystalline CdS layer and the mechanism for its formation as outlined above is capable of explaining several observations, namely, (*i*) the difference in stability between single crystal and polycrystalline electrodes, (*ii*) the increase in stabilization with increase in sulfide concentration or decrease in photocurrent, (*iii*) the gradual loss of signal when a single crystalline electrode, immersed in polysulfide solution, is measured by ellipsometry, (*iv*) the increase in bias voltage dependence of the short-circuit current on single crystal electrode deactivation, and (*v*) the initial increase in photovoltage observed when immersing a clean (freshly etched) poly or single crystalline CdS electrode in polysulfide solution and illuminating it. In the following we explain these observations in more detail. From reactions [1]-[4] we expect a highly crystalline electrode of CdSe to degrade at its surface by the formation of a more polycrystalline CdS layer.[2] This then suggests a deactivation of CdSe with time, as reported by Miller *et al.* for sintered disks (3b) and single crystals [referred to in (3c)] and verified by us for single crystals. The deactivation can be dramatic indeed for electrodes with high initial (solar energy peak) efficiencies ($\sim 6\%$). Decreases to $\sim 30\%$ of the initial power output have been observed by us for single crystal electrodes in 1M [OH^-], 1M [S^{2-}], and 1M [S] solutions after a period of 7 hr, while in an electrolyte of 2M [OH^-], 2M [S^{2-}], and 2M [S], over the same period of time, the power dropped only to 80% of its initial value, and after 20 hr continuous illumination to $\sim 45\%$ ($\sim$ AM1). For our polycrystalline electrodes the deactivation is much less pronounced and proceeds very much slower if at all. For electrodes having an initial efficiency of $\sim 1\%$, complete stability, in 1M each of NaOH, Na_2S, and S, has been routinely found over many months of use in actual weather conditions. In earlier experiments, electrodes with an *initial* efficiency of 2.5-3.0% fell in efficiency by typically $\sim 15\%$ after six days under the same conditions as above, and in recent experiments, using improved techniques of preparation of the electroplated photoelectrodes, photoelectrodes with 2.5-3.0% conversion efficiencies have shown no deactivation whatever after periods up to one month of use in predominately clear sky conditions (AM2).

If we accept the hypothesis that the gradual deactivation observed for single crystal and polycrystalline sintered disk CdSe electrodes is due to a degradation of the crystallinity at tthe surface due to CdS formed, this implies a migration of cadmium (in some form) from its original lattice position. Such a migration follows from reactions [2] and [4] above, if CdS formation is not rapid enough to prevent it. Clearly an increase in S^{2-} concentration at the semiconductor surface may minimize the time free Cd^{2+} can exist, and so can a decrease in Cd^{2+} concentration. A decrease in free Cd^{2+} concentration can be obtained by working at low current densities (reaction [2] above). Miller *et al.* have indeed reported an increase in stability of sintered disk, polycrystalline CdSe electrodes with increasing S^{2-} concentration and decreasing current density (3b). The differences in stability between polycrystalline thin film, sintered disk, and single crystal electrodes can be correlated with the real surface areas of the electrodes, as they will affect the real current densities at the surface (9a). Thus, our electroplated CdSe layers, with grain size of a few microns or less (as measured by SEM techniques) will have a larger surface area than the sintered polycrystalline CdSe [with reported grain sizes of 10-20μ (3b)], or single crystals, and hence a lower local current density (for the same apparent current density) at the surface. Preliminary results from ellipsometry experiments support this hypothesis (9b). These measurements show that an initially highly polished CdSe crystal, when immersed in S/S^{2-} solution, becomes rough when illuminated and on flow of photocurrent.

Before discussing the effect of the S/Se exchange and deactivation on the open-circuit voltage and short-circuit current, we will use the XPS results to construct a rough band diagram of the system.

Band diagram.—From the depth profile (Fig. 3) and the preceding discussion it is evident that a band scheme of the $CdSe/S\text{-}S^{2-}$ semiconductor-liquid junction must take into account the presence of a sulfur-rich CdS_xSe_{1-x} layer near the surface and a surface layer which is probably pure CdS. In order to arrive at a plausible band diagram several points should be taken into consideration:

1. The thickness of the CdS layer on our CdSe electrodes is of the order of tens of angstroms (Fig. 3). While some substitution occurs even into a depth of hundreds of angstroms, the value of x in CdS_xSe_{1-x} falls sharply in the direction of the interior of the semiconductor. For simplicity's sake we shall assume an abrupt junction between a CdS layer tens of angstroms thick and the bulk CdSe. The gradual transition from CdS to CdSe will modify the band picture somewhat, but should not change its salient features (10).

2. The n-type behavior of these CdSe electrodes is due to Cd excess and/or Se vacancies. Substitution of surface layers of Se by S from polysulfide present in the electrolyte will lead to considerable compensation of previously occurring Cd excess and/or Se vacancies, because of the excess sulfur (as polysulfide) present at the surface. This means that the donor concentration, N_d, in the CdS layer would be expected to be considerably less than in the CdSe bulk. The CdS layer can then be treated as relatively electrically insulating with the Fermi level further from the conduction band than in the original CdSe.

3. The width of the space charge layer in a semiconductor is given by the equation (11) $L = (\epsilon\epsilon_0 V/qN_d)^{1/2}$ where V is the potential drop across the space charge layer in volts, N_d is the donor concentration in cm^{-3}, and the other symbols have their usual meaning. From this equation, assuming $N_d \sim 10^{16}$ cm^{-3} and with $\epsilon \sim 9$ we see that a layer of some tens of angstroms of CdS cannot support a potential drop of more than $\sim$1 mV. Because of point 2 above N_d will probably be much less than $\sim 10^{16}$ cm^{-3}, and this will reduce the maximum possible potential drop in the CdS layer even further. Therefore, the voltage drop across the CdS can be ignored compared to the hundreds of millivolts of voltage difference which exist across the CdSe space charge layer, *i.e.*, ΔV (CdS) $<< \Delta V$ (CdSe).

In view of these three points, namely that the CdS layer is very thin, relatively insulating, and unable to support a large voltage drop, we feel that it is appropriate to consider the band diagram of the $CdSe/CdS/S\text{-}S^{2-}$ system as an analogue of a metal-insulator-semiconductor (MIS) system, rather than a metal-composite abrupt isotype heterojunction system. It could be more appropriately referred to as an electro-

[1] The possibility suggested by Ellis *et al.* (2b) that the stabilization mechanism for polycrystalline and single crystal electrodes operating at different current density is different, *viz.*, rapid precipitation of CdS by reaction [4] and fast oxidation of added S_n^{2-}, respectively, does not seem to be a probable one. The presence of CdS is indeed the stabilizing factor in polysulfide solution, and chemical S/Se exchange is the cause for its formation. Stabilization will result *inter alia* from the combined effect of CdS formation and rapid kinetics for S^{2-} oxidation on the CdS surface. We see no reason why in this respect a polycrystalline electrode should behave differently from a single crystal one.

[2] Recently Gerischer has noted the possibility of destruction of a CdS single crystal photoelectrode in polysulfide solution by CdS deposition on the decomposing crystal surface, as, according to his thermodynamic arguments, the possibility for photoanodic dissolution exists (8c). Such a conclusion can be drawn also using the similar thermodynamic approach of Wrighton and Bard (8d). If we accept this possibility, it will depend on the kinetics of the system, whether in fact stability is achieved, or not. Our arguments here are concerned only with the kinetic aspects of the problem.

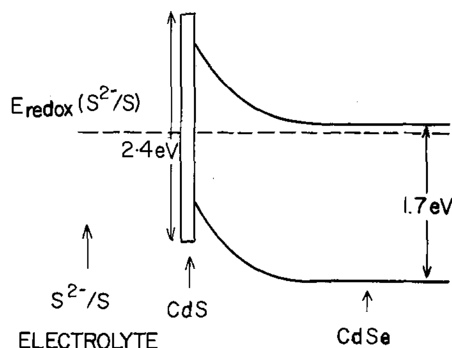

Fig. 4. Schematic idealized band scheme of polysulfide/CdS/CdSe EIS system. Because of uncertainties in the electron affinities for CdS and CdSe slight variations in the relative positions of the bandedges are possible. Presence of interface states between CdS and CdSe (due to lattice mismatch) is neglected.

lyte-insulator-semiconductor (EIS) system. A schematic of such a system is shown in Fig. 4. In this figure we have neglected interface states between CdS and CdSe, which are expected to occur because of the 4% lattice mismatch between these two chalcogenides.

From experiments with metal-semiconductor (Schottky) solar cells it is known that the presence of an insulating layer between the metal and the semiconductor can increase the photovoltage, obtainable from such a cell (12, 13). This effect is at present not fully understood. Several workers have stressed the importance of interface states between the insulator and the semiconductor in shaping the electrical field in the semiconductor (14) and in decreasing the majority carrier tunneling probability (15). Such a decrease has been explained also by considering the MIS cell as a nonequilibrium minority carrier device (16, 17). Here we shall accept the existence of the effect without further explanation and assume that similar or analogous causes can lead to an increase in photovoltage in our EIS system.

We have indeed, in a consistent way, observed increases in the photovoltage of new, or freshly etched single crystal as well as polycrystalline CdSe electrodes (18). These increases can be quite considerable (typically 20% of the initial value for polycrystalline electrodes and somewhat less for single crystal electrodes over a period of 5-10 min).

The way in which the existence of the larger bandgap CdS on top of the smaller bandgap CdSe influences the photovoltage can be considered in phenomenological terms as well. In photovoltaic cells and in photoelectrochemical cells for a given redox system, and where there is no gross deleterious chemical change at the semiconductor surface junction, materials with larger bandgaps generally yield larger photovoltages. Therefore the presence of CdS on top of CdSe can lead to a higher photovoltage than would be expected for CdSe alone as E_G (CdS) > E_G (CdSe) by ~ 0.7 eV (19). Also the photovoltage is determined by the position of the redox potential of the electrolyte with respect to the edges of the energy bands. In an n-type semiconductor the smaller $| E_{redox} - E_v \text{ (surface)} |$ the larger the photovoltage can be. In the case of chemisorbed species, which is that considered here for sulfide on CdS (4), this position should be at least partly determined by the strength of sulfide adsorption on CdS, since increased adsorption lowers the energy of the sulfide ion and thus brings it closer to the valence bandedge, E_v (surface). As the surface of a CdSe electrode in sulfide electrolyte is CdS, it will determine the adsorption properties of the sulfide ion on the electrode and, thus, can lead to an increase in photovoltage.[3]

[3] Recently Noufi *et al.* (20), reporting on CdS/CdSe solid solution photoelectrodes in polysulfide solutions, suggested that the variation in flatband potential and corresponding change in open-circuit voltage observed with change in S/Se ratio, could be brought about by changes in electron affinity or specific adsorption. From our argument it would be expected that the specific adsorption for all these systems is similar.

The last effect, which we discuss here, is the behavior of the short-circuit current upon deactivation and its changing dependence on bias voltage. The short-circuit current values which are obtainable from both single crystal and polycrystalline photoelectrodes (routinely between 10 and 15 mA/cm² for AM1 equivalent illumination) show that the current is not limited by the CdS layer, as it is impossible to create that many photons in CdS by AM1 radiation, even if we assume a quantum yield of unity, according to

$$I_{sc} = E_G \int^{\infty} A(E)\, N(E)\, d(E)$$

Here $A(E)$ is the absorption coefficient of CdS and $N(E)$ is the number of photons per unit energy in the solar spectrum. Under the same conditions, an etched CdS crystal gives a short circuit current of $\lesssim$~1 mA/cm². This low value is due mainly to absorption of light in the orange polysulfide solution. This then excludes the possibility of looking upon the system as a normal heterojunction such as the n-CdS/n-GaAs photoanode, recently investigated by Wagner and Shay (19). The possibility that the surface layer is some Cd hydroxide/oxide is rather unlikely as well, not only because in this case a much more precipitous decrease in I_{sc} (or at least some decrease, in the case of the stable polycrystalline photoelectrodes) would be expected, but also because the ESCA results do not show any evidence for it. We cannot exclude the possibility that some part of the surface is indeed Cd hydroxide/oxide, but its presence does not seem to influence the physical behavior of the electrode.

Another argument in favor of the increase in polycrystallinity (mosaicity) of the surface of illuminated photoelectrodes is found in the increasing influence of a forward bias on I_{sc}, when a single crystalline electrode deactivates. When a new or freshly etched single crystal electrode is immersed and illuminated in polysulfide solution, little increase in I_{sc} is found when a forward bias voltage V_F is applied. This indicates that recombination losses are small. Upon deactivation, I_{sc} decreases and applying V_F leads to a considerable increase in current (18). Such a behavior follows logically out of the preceding discussion. Increasing polycrystallinity leads to increasing recombination losses at newly formed grain boundaries. If now V_F is added to V_{photo} the recombination probability is decreased and thus I_{sc} increases correspondingly.

Summary

Based on a sulfide depth profile derived from x-ray photoelectron spectroscopy data, and using the analogy between the metal-semiconductor and electrolyte-semiconductor junction, we have derived a rough electron energy band picture for the CdSe/S-S⁼ junction. A possible mechanism for S/Se exchange on the surface of the CdSe electrode has also been presented. The consequences of this exchange especially for the photovoltage and electrode stability have been discussed.

Elsewhere we will deal in more detail with the short and long term behavior of the CdSe photoelectrode, polycrystalline and single crystal, especially as far as this is influenced by the presence of CdS on the surface (9, 18). Also, in collaboration with Prof. A. Bard, XPS studies similar to the ones described here, are being continued both on single crystal and polycrystalline materials, in order to obtain a more accurate picture of the S/Se substitution process.

Acknowledgments

We thank Dr. G. Sawatzky for his extensive guidance and assistance with the experimental part of this work and Ir. A. Heeres for technical assistance. D.C. thanks them and the University of Groningen for their hospitality during the performance of the XPS experiments. We thank S.O.N. and Z.W.O. for use of the Dutch National Photoelectron Spectroscopy Facility in Groningen. D.C. and G.H. thank Prof. A. Rose for help-

ful discussions. We are indebted to Dr. D. Lasar and Z. Har-Zion for their cooperation in performing the ellipsometry experiments. Part of this work was supported by Grant No. 1314 from the U.S.-Israel Binational Science Foundation to G.H. and D.C.

Electrode Processes of Lead Halides

Part 2: β-PbF_2

R. W. Bonne[1] and J. Schoonman*

Department of Solid State Chemistry, Physics Laboratory, State University of Utrecht, Utrecht, The Netherlands

ABSTRACT

Electrode reactions have been studied in the cell arrangements Pb|β-PbF_2|Pb and Pb|β-PbF_2|M (M = C, Pt) by means of cyclic voltammetry, scanning electron and optical microscopy, and x-ray analysis. At cathodic potentials *vs.* the reversible lead electrode lead deposit is observed, irrespective of the electrode material employed. Dependent on the oxygen content of the surrounding ambient the lead deposit can be converted partly into lead oxides, *i.e.*, PbO and Pb_2OF_2. At anodic potentials *vs.* the lead electrode, Pb reacts to form α-PbF_2, while decomposition of the lead oxides is observed. The decomposition voltage of β-PbF_2 in the cell Pb|β-PbF_2|M is well below the theoretical decomposition voltage. The decomposition is ascribed to the reaction $2PbF_2 \rightarrow PbF_4 + Pb$. X-ray analyses that support the electrode reactions are included.

In recent years the electrical properties and conduction mechanism of β-PbF_2 have attracted much attention (1-10). At elevated temperatures an unusually high temperature-independent ionic conductivity has been observed (2, 6). This has been ascribed to a liquid-like behavior of the anion sublattice (2). At low and moderate temperatures the ionic conductivity can be described by classical ionic motion theories. Intrinsic point defects are thermally generated according to the antiFrenkel mechanism (1). Kennedy *et al.* (3) verified Tubandt's finding that β-PbF_2 is a pure anion conductor. The present authors (10) have studied the conductivity of nominally pure, and AgF- and LaF_3-doped β-PbF_2 and arrived at a consistent description of the defect chemistry of β-PbF_2. Both the interstitial fluoride ions and the fluoride ion vacancies are mobile. At low and moderate temperatures the fluoride ion vacancies constitute the more mobile species.

In addition to a-c conductivity measurements, d-c polarization studies of asymmetric cells of the type $-$Pb|β-PbF_2|M+, known as Wagner polarization cells, have been reported (3, 6, 8, 11). Several authors (6,

* Electrochemical Society Active Member.
[1] Present address: Philips Research Laboratories, Eindhoven, The Netherlands.
Key words: solid electrolyte, charge, voltammetry.

8, 11) obtained plateau-type current-potential characteristics for applied d-c voltages up to 1V; these results indicate conduction by electrons. In these polarization cells graphite was used as the ionically blocking electrode. Kennedy *et al.* (3) studied the polarization behavior of this cell in the 1-1.5V range at 423°K with a vacuum-evaporated gold electrode. The slope of the reported current-potential curve, plotted at ln i *vs.* V, was about three times less than the value predicted theoretically. The electronic (presumably hole) conductivity was calculated to be less than 10^{-4}% of the total conductivity at 423°K. The observed behavior, however, was attributed to the possibility that the gold electrode was partly blocking the ionic current. The authors proposed as cell reaction

$$\tfrac{1}{2}O_2(g) + 2PbF_2 \rightarrow PbF_4 + PbO \qquad [1]$$

From the free energies of formation, Kennedy *et al.* have calculated a cell voltage of −1.59V at 423°K (3). It was very near to this voltage that the current increased dramatically.

It has been emphasized (12) that cyclic voltammetry is a useful tool in studying electrode reactions in symmetric and asymmetric all-solid cells. The electrode reactions in cells with lead chloride and lead bromide as solid electrolyte have been reported in the literature (12). Since the nature of the mobile species in β-PbF_2 is now well established, we have used cyclic voltammetry, scanning electron and optical microscopy, together with x-ray analysis to elucidate electrode reactions and their products in cells of the type Pb|β-PbF_2/Pb and Pb|β-PbF_2|M (M = C, Pt).

Experimental

A detailed description of the preparation of crystalline material of nominally pure β-PbF_2 has been given elsewhere (10). Specimens with thickness 0.2-0.5 cm and surface area 0.3-0.5 cm^2 were cut from the crystalline pieces. The polished surfaces were covered with either graphite (Aquadag) or platinum paint (Leitplatin 308) or they were covered with evaporated lead. The prepared cell systems were springloaded between two platinum disks in evacuable conductivity equipment. A potential ramp of known variable sweep rate was applied across the cell, and the current through the cell system was measured with a picoammeter (Keithley).

More details of cell preparation and a detailed description of the electrical equipment used have been reported in the literature (12). Scanning electron and optical micrographs referred to here were taken with a Stereoscan S4 scanning electron microscope and with Olympus optical microscopes. The x-ray analyses were performed on a Philips diffractometer, using Cu-Kα radiation.

Results and Discussion

Symmetric cell of the type Pb|β-PbF_2|Pb.—This cell arrangement reveals a linear behavior between the applied voltage and the measured current, the slope being equal to the frequency-independent a-c conductance, which is known to be a bulk property (9). The lead electrode is reversible at anodic and cathodic potentials, thermodynamically as well as kinetically.

Scanning electron micrographs of the lead anode demonstrate the formation of new material. The anode reaction can be represented by

$$Pb + 2F_F^x \xrightarrow{\text{anode}} (PbF_2)_{surface} + 2V_F^{\bullet} + 2e' \qquad [2]$$

since at low and moderate temperatures fluoride ions carry the current via fluoride ion vacancies (10). Here, and throughout this paper the defect notation of Kröger is used (14).

The deposits have been studied by means of x-ray analysis. It was observed that β-PbF_2 partly converts into α-PbF_2 while the surfaces are polished prior to electrolysis. The increased intensity of the lines of α-PbF_2 in the x-ray diagram of the lead anode compared to that of the lead cathode, however, confirmed the deposit to be α-PbF_2 in accord with observations reported by Kennedy and Miles (8). A marked decrease in the intensity of the lines of metallic lead was observed on the anode side, in accord with reaction [2].

Scanning electron micrographs of the cathode surface demonstrate only a shrinkage of the crystal. The reaction

$$Pb_{Pb}^x + 2V_F^{\bullet} + 2e' \xrightarrow{\text{cathode}} Pb \qquad [3]$$

accounts for this behavior. The growth of lead dendrites from the cathode is readily observed with an optical microscope. The dentritic growth of lead occurs perpendicular to the current flow and is located in a thin region of the electrolyte at the interface electrode-electrolyte. Although similar current-potential curves and electrode reactions were observed for lead chloride and lead bromide (12), dendritic lead growth in these halides proceeds along the current flow, ultimately leading to an electrical short circuit.

Asymmetric cells of the type Pb|β-PbF_2|M (M = C, Pt).—In Fig. 1 we have gathered typical voltammograms of the cell Pb|β-PbF_2|Pt. The voltammograms were recorded in nitrogen and were strongly dependent on the electrolysis duration at cathodic potentials

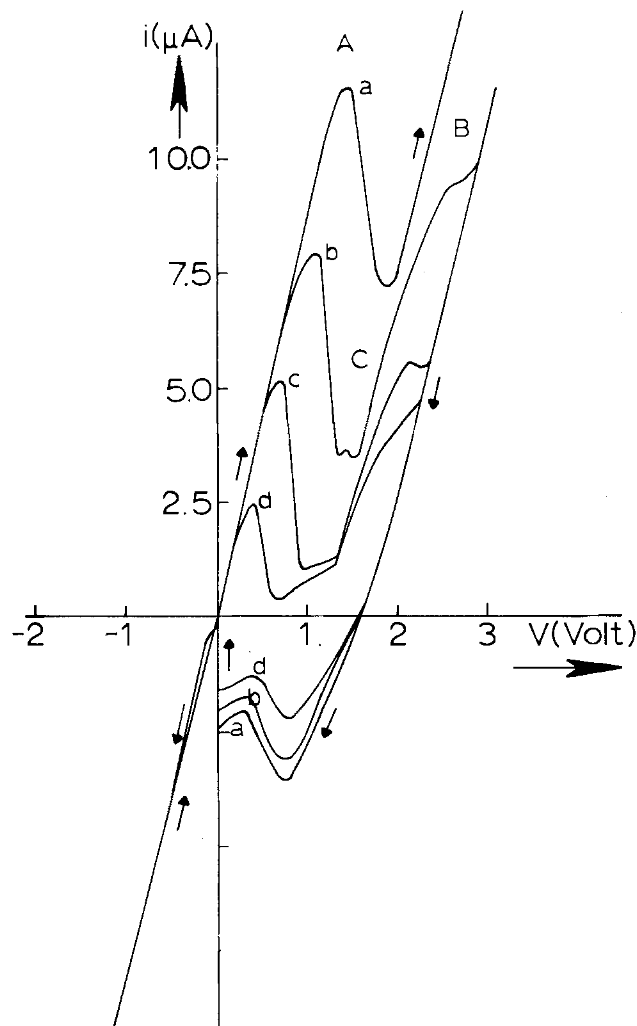

Fig. 1. Voltammograms of the cell Pb|β-PbF_2|Pt in air at 390°K for different electrolysis times. Sweep rate 83 mV sec^{-1}. Curve a, 4.0 × 10^{-4}C; curve b, 2.3 × 10^{-4}C; curve c, 1.0 × 10^{-4}C; curve d, 5.9 × 10^{-5}C. The sweep direction has been marked with arrows. For the meaning of the designations A, B, and C, see the text. The voltages indicated are measured *vs.* the reversible lead electrode.

vs. the reversible lead electrode. Analogous voltammograms were observed for cells with painted Pt or C-electrodes in nitrogen, air, and oxygen atmosphere, in the temperature range 300°-600°K. For voltages above about 2V the current varies directly with the potential, with a slope equal to the bulk conductance.

In general current-potential curves reveal two main anodic waves (A and B in Fig. 1). In several cases there is an indication of a third anodic wave (C). The waves A, B, and C appear only when the blocking electrode has been operated before at cathodic potentials (Fig. 2). The shape of the voltammogram is typical of that observed for the formation, oxidation, and reduction of reaction products (12).

According to reaction [3] a lead deposit on the blocking electrode is expected to occur during electrolysis with electrode M operating at cathodic potentials. A cell system with two reversible lead electrodes readily results. On reversing the potential, the lead deposit reacts to form α-PbF_2 (reaction [2]). Thermodynamically, the total cell reaction hardly requires any energy. The first anodic wave (A), which is also observed for lead chloride and lead bromide in identical cell arrangements (12), has been ascribed to this process. Other reactive species, however, must be responsible for the other waves, and they are to be correlated with oxidation of the reaction products formed at the blocking electrode during electrolysis at cathodic potentials.

Bonne *et al.* (12) derived a simple equation for the amount of charge transported during electrolysis and deduced an equation for the amount of charge transported in the waves. The ratio of these amounts gives the fraction x of the amount of charge transported in the wave. In Fig. 3 this inferred fraction x is plotted *vs.* the total amount of charge passed during the electrolysis at cathodic potentials. It is observed that the oxidation waves A and B account for almost all the transported charge, the major fraction being found in wave B. From these data it is concluded that a large fraction of the initial lead deposit at the blocking electrode is converted into another lead compound which acts as an electroactive compound responsible for wave B.

In Fig. 4 voltammograms recorded in a nitrogen and in an oxygen atmosphere are presented for the cell Pb|β-PbF_2|Pt. Similar voltammograms were obtained for graphite paint electrodes. A remarkable decrease in wave height is observed for the anodic wave A, when oxygen is used as ambient, while the reverse is true for the wave B. In Fig. 5 the fraction of charge transported in the wave A is plotted *vs.* the total amount of charge transported during electrolysis at cathodic potentials in nitrogen, air, and oxygen. From these observations it is evident that the freshly deposited amount of lead on the blocking electrode reacts partly with oxygen from the ambient to form an oxide. The observed waves B and C can be ascribed to the decomposition of the oxides formed on the blocking electrode. The observed voltages at

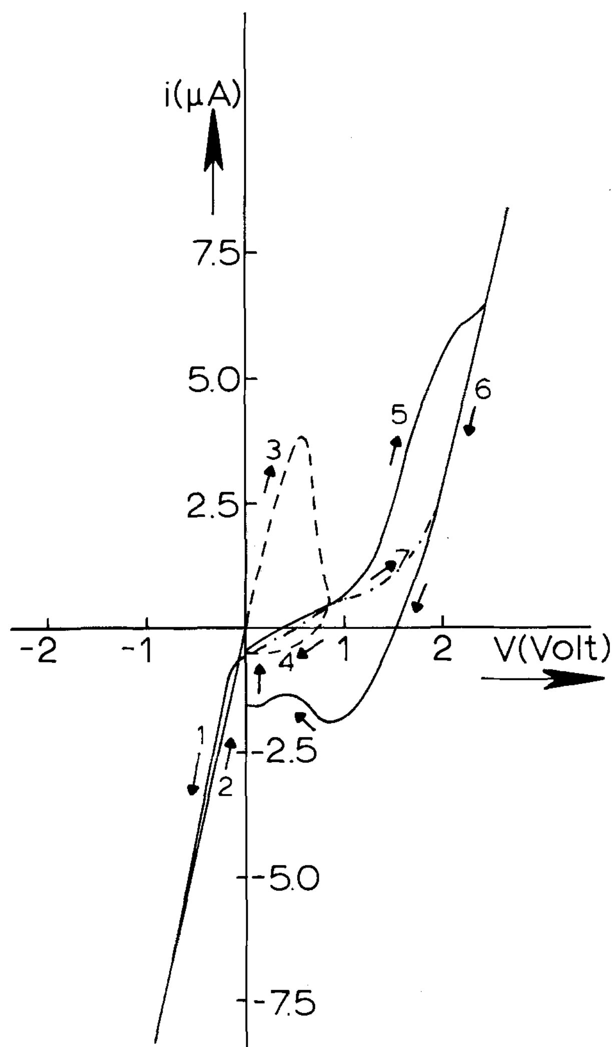

Fig. 2. Voltammograms of the cell Pb|β-PbF_2|Pt in air at 390°K. Different sweeps in the positive voltage region are shown. Their sequence is indicated by the No. 1-7. Sweep rate 83 mV sec^{-1}.

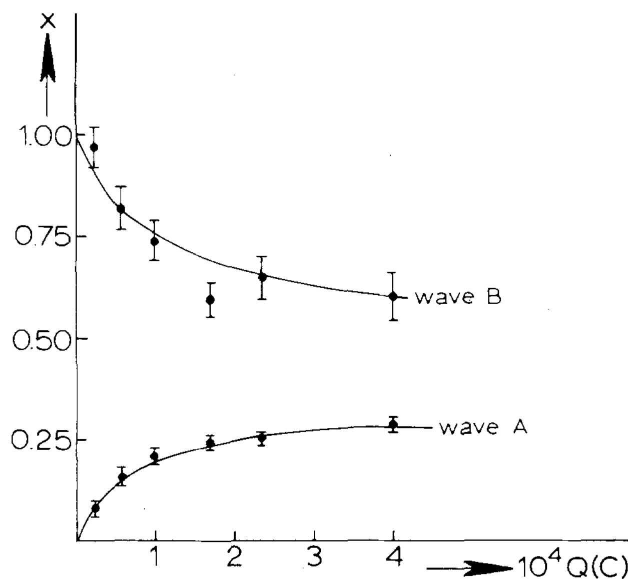

Fig. 3. The fraction x of the amount of charge transported in the wave A and B as a function of the total amount of charge passed during electrolysis of the cell + Pb|β-PbF_2| Pt — at 390°K in air.

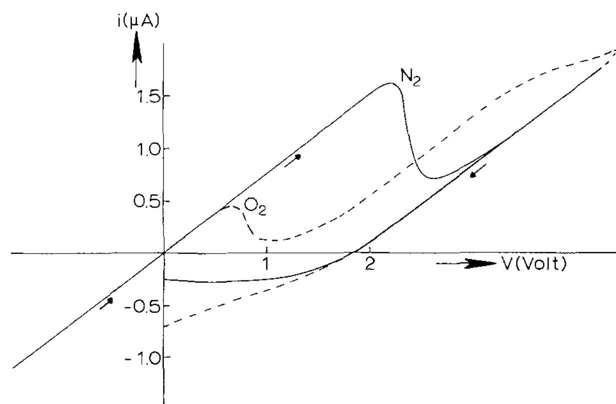

Fig. 4. The influence of the ambient on voltammograms of the cell Pb|β-PbF_2|Pt. T = 390°K, sweep rate 83 mV sec^{-1}.

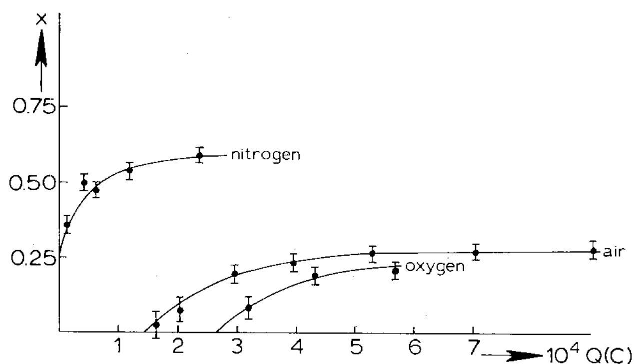

Fig. 5. The fraction x of the charge transported in wave A as a function of the total amount of charge passed during electrolysis at cathodic potentials of the cell Pb|β-PbF_2|Pt in different ambients at 390°K.

which these waves start are (1.12 ± 0.08)V, and (0.50 ± 0.15)V, respectively, at 473°K. These values are hardly dependent on temperature. The decomposition voltages of PbO_2 and PbO at 473°K are calculated to be 0.482 and 0.893V, respectively. These values are close to the voltages observed experimentally. For the anodic wave C we therefore propose the electrode reaction

$$PbO_2 + 2F_F^x \xrightarrow{\text{anode}} PbF_2 + O_2(g) + 2V_F^{\bullet} + 2e' \quad [4]$$

whereas for the wave B the electrode reaction

$$PbO + 2F_F^x \xrightarrow{\text{anode}} PbF_2 + \tfrac{1}{2}O_2(g) + 2V_F^{\bullet} + 2e' \quad [5]$$

is proposed. The first wave was already ascribed to reaction [2]. The minimum total cell voltage required for reaction [4] or [5] is almost equal to the decomposition voltages of the respective oxides. For PbO the observed voltage is slightly higher than the theoretical value. The experimental observations, however, do not indicate any overpotential. Kennedy and Miles (8) reported the presence of Pb_2OF_2 on the anode after electrolysis of the cell Pb|β-PbF_2|Pb. Thermodynamic data relating to this compound are not available in the literature. If wave B can be related to the reaction

$$Pb_2OF_2 + 2F_F^x \xrightarrow{\text{anode}} 2PbF_2 + \tfrac{1}{2}O_2(g) + 2V_F^{\bullet} + 2e' \quad [6]$$

instead of reaction [5], then the formation enthalpy of Pb_2OF_2 is calculated to be about 192 kcal/mole at 473°K.

Figure 6 shows cyclic voltammograms for the cell Pb|β-PbF_2|C in air taken at a constant sweep rate in the cathodic direction, the sweep rate being varied from 167 to 8.3 mV sec^{-1} in the anodic portion. The peak currents of the waves can be expressed by (12)

$$i_p(A) = (2vxQ)^{1/2}R_b^{-1/2} \quad [7]$$

with v the sweep rate (V sec^{-1}), xQ the actual amount of charge transported in the wave, and R_b the bulk resistance. For the two main waves A and B, this square root dependence was observed. In Fig. 7 the fraction of charge transported during the wave is plotted *vs.* the sweep rate. At low sweep rates the voltammogram shows that almost all the lead deposit has been oxidized by the ambient. The oxide formation does not occur instantaneously, but only after some time has elapsed.

The observed deposition voltage of about 2V at 473°K is well below the theoretical decomposition voltage of β-PbF_2, *i.e.*, 3.082V (13). This deposition voltage is practically independent of temperature in the region 320°-450°K; it is not dependent on the electrode paint employed.

Kennedy *et al.* (3) observed a dramatic increase in current in the cell −Pb|β-PbF_2|Au+ above about 1.5V. If not all the faradaic processes were blocked, then the observed steady-state current would still contain an ionic contribution. As over-all cell reaction the authors proposed reaction [1]. Instead of the reported value of −1.59V at 423°K (3), we found by recalculation a cell voltage of −1.04V. The PbO is formed at the cathode-electrolyte interface, while PbF_4 is formed at the anode-electrolyte interface. If this reaction occurs, a rapid increase in current above 1.0V is to be expected. We expect to find not

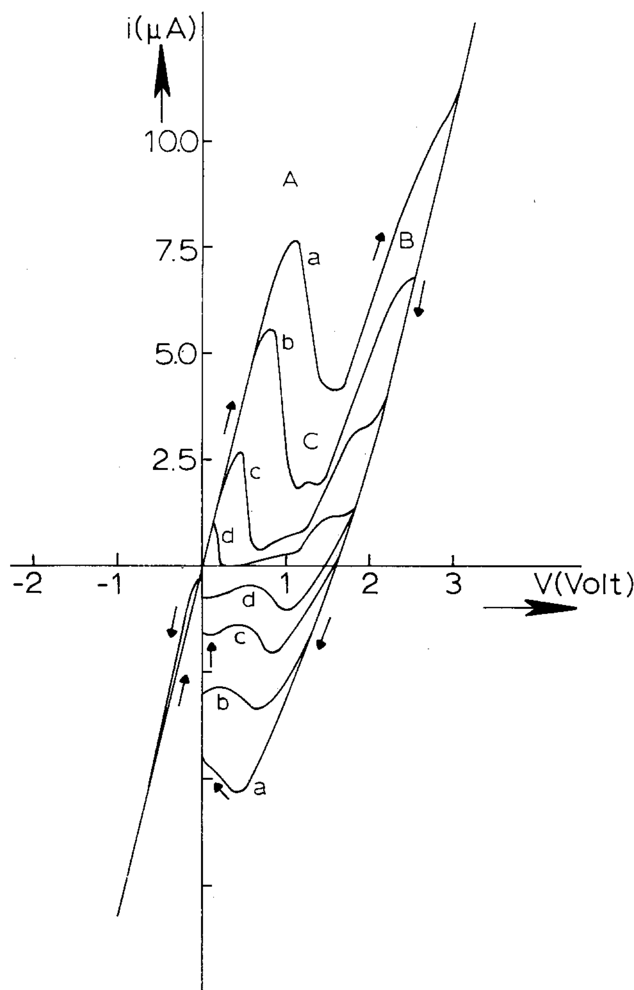

Fig. 6. Voltammograms of the cell Pb|β-PbF_2|C in air. Charge transported during electrolysis 1.0 × 10^{-4}C. Curve a, sweep rate 167 mV sec^{-1}; curve b, sweep rate 83 mV sec^{-1}; curve c, sweep rate 33 mV sec^{-1}; curve d, sweep rate 8.3 mV sec^{-1}.

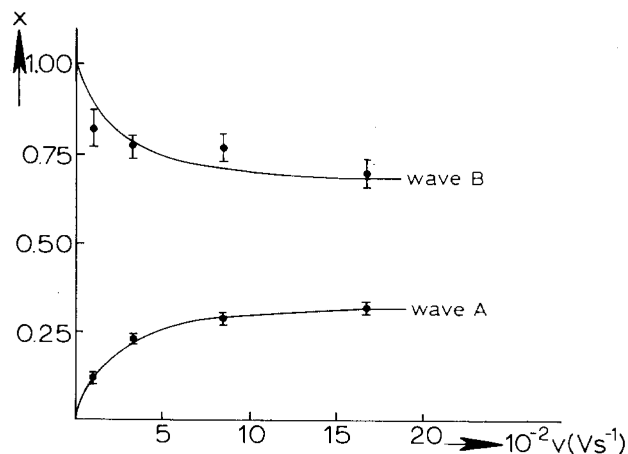

Fig. 7. The fraction x of the charge transported during the waves A and B as a function of the sweep rate for the cell Pb|β-PbF_2|Pt.

a wave but a current that varies directly with the applied voltage. In this study the wave that starts at about 1.1V is ascribed to the decomposition of PbO because the wave is clearly dependent on the amount of PbO present on the electrode surface. With an optical microscope lead dendrite formation is observed at the cathode-electrolyte interface. There is no evidence of an electrochemical reaction of oxygen with lead. From these observations cell reaction [1] is not likely for the present cell system. The slope of the current-potential curve above about 2V equals, however, the bulk conductance. The presence of a faradaic process is, therefore, established.

As total electrolysis reaction we propose the reaction

$$2PbF_2 \rightarrow PbF_4 + Pb \quad [8]$$

The cell voltage calculated from free energies of formation is -1.95 at 423°K. Lead will be deposited on the cathode-electrolyte interface, whereas PbF_4 forms at the anode-electrolyte interface.

In order to find evidence for this cell reaction x-ray analyses of the electrode surfaces were carried out after electrolysis. In this case electrolysis was performed at 2.5V on a β-PbF_2 single crystal between two platinum mesh electrodes at 493°K in air. The mesh electrodes behave in the same way as the paint electrodes. X-ray analysis of the cathode-electrolyte surface revealed the presence of β-PbF_2, α-PbF_2, Pb_2OF_2, and Pb when electrolysis times were short. After long electrolysis times the presence of PbO in the red modification was detected as well. These data indicate that the lead deposit on this electrode is oxidized into Pb_2OF_2 and PbO, and that the oxidation wave B can be related to the decomposition of Pb_2OF_2 rather than that of PbO. In the x-ray diagram of the anode-electrolyte surface the lines of α-PbO_2, β-PbF_2, α-PbF_2, and PbO (red) were observed, while, for long electrolysis times, only the lines of Pb_2O_3 were observed. The PbF_4 formed is known to react very rapidly with traces of H_2O (15). The following reaction can result

$$PbF_4 + 2H_2O(g) \rightarrow PbO_2 + 4HF(g) \quad [9]$$

especially when the crystal is removed from the conductivity cell. The PbO_2 formed is partly converted into PbO or into other lead oxides. The x-ray data therefore indicate indirectly the occurrence of the proposed cell reaction [8].

From the above results it is evident that Wagner polarization studies of cells of the type Pb|β-PbF_2|M (M = C, Pt) should at least be restricted to voltages below 1.95V, because above this voltage β-PbF_2 decomposes electrolytically.

Acknowledgments

The authors are grateful to Prof. Dr. G. Blasse for discussing the text in detail and for offering valuable criticism in the course of the preparation of the manuscript. We are indebted to Mr. J. Pieters of the Molecular Cellbiology Department of this University, who recorded the scanning electron micrographs, and to Dr. H. A. Harwig of the Inorganic Chemistry Department of this University, who kindly made available the potentiostat and optical microscopes.

Manuscript submitted July 18, 1977; revised manuscript received May 24, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Technical Note

Lithium-Boron-Silicon Alloy Lithium Electrodes

Anthony F. Sammells*,[1]

Rockwell International, Atomics International Division, Canoga Park, California 91304

Lithium/metal sulfide batteries are presently under development at the Atomics International Division of Rockwell International (1), General Motors (2), and Argonne National Laboratory (3) for their application in utility load leveling systems and electric vehicles. In recent years there have been several candidate lithium electrode materials considered for this battery system. From an energy density consideration,

* Electrochemical Society Active Member.

[1] Present address: Institute of Gas Technology, Chicago, Illinois 60616.

Key words: lithium-boron-silicon alloy, silicon migration, molten salt, secondary battery.

liquid lithium is most attractive for its low equivalent weight and high cell voltage. However, recent evidence (4) has shown that lithium can be lost by the reaction

$$\underset{\text{(melt)}}{KCl} + Li \rightarrow LiCl + \underset{\text{(melt)}}{K}$$

followed by potassium vaporization. This, together with correspondingly increased cell component corrosion and difficulties with containment of liquid lithium, has dictated that a variety of lithium alloys be investigated to avoid these problems. Binary alloys can either be formed electrochemically by charging a metal such as Bi, Pb, Sn, (5) or Al with lithium or they can be synthesized directly from the ingredients, *e.g.*, LiB (6). However, only two of the binary alloys have been found, at this time, to possess utility in secondary molten salt batteries.

The two binary lithium alloys presently under development for the lithium-metal sulfide battery include lithium-aluminum (7, 8) which has an open-circuit potential 303 mV positive to liquid lithium at 400°C and lithium-silicon (9, 10) which, in the fully charged state, has a composition approximating Li_5Si. The latter can be discharged through a series of voltage plateaus at 48, 158, 280, and 336 mV *vs.* liquid lithium at 400°C. The theoretical Faradaic capacity of Li_5Si is 2.12 A-hr/g compared to 0.8 A-hr/g for LiAl. The high capacity of Li_5Si together with excellent capacity retention over long cycling periods (11) and favorable electrochemical performance (12) has provided a strong incentive to develop this material as a lithium electrode for lithium/iron-sulfide batteries.

During the course of extended cycling tests, it has become apparent that migration of silicon to the metal substrate can occur at cell operating temperatures. This effect manifests itself by loss of capacity at the negative electrode and eventual embrittlement of the electrode structure, which can lead to electrode rupture. Silicon migration proceeds slowly at normal cell operating temperatures (425°C) but is much accelerated as the temperature approaches 550°C. Several approaches to arrest such silicon migration into the electrode substrate are being pursued at Atomics International.

This communication discusses some preliminary findings from one of these approaches, notably the use of lithium-boron-silicon ternary alloys as an active material in the electrode. The use of these alloys has been found to markedly reduce silicon attack of ferrous substrates. Thermodynamic data for one group of lithium-boron-silicon alloys are presented here together with some preliminary corrosion results.

A preliminary phase diagram for the boron-silicon system (13) indicates the existence of two compounds with the compositions B_4Si and B_6Si. The existence of the phase BSi_2 has been indicated by metallographic and microhardness data (14), but x-ray data do not appear to be conclusive at this time (15). The solubility of boron in silicon is temperature dependent but occurs by a substitutional mechanism with a silicon lattice parameter contraction from 5.430 to 5.425Å upon substitution of 1 atomic percent (a/o) boron or more as measured at room temperature.

For BSi_2 synthesized at 1310°C for 2 hr from elemental boron and silicon, the lattice parameter was observed to contract from 5.431Å for pure silicon to 5.417Å for BSi_2. Upon sectioning of the material, two phases could be seen which may possibly correspond to the alpha and beta phases of this material referred to by other workers (16).

Experimental

Chemicals.—Highly prepurified LiCl-KCl eutectic (mp 352°C) was purchased from Anderson Physics Laboratories, Incorporated, Urbana, Illinois. Silicon powder, 99.5% pure, was obtained from Atomergic Chemetals Company, Carle Place, New York. Boron metal, 5 μm amorphous type, 96% pure, was obtained from Cerac/Pure, Milwaukee, Wisconsin. Lithium metal was obtained from the Foote Mineral Division of Newmont Mining Company.

Preparation of alloys.—Lithium-containing alloys were first synthesized by the addition of silicon to molten lithium at 700°C. This molten mixture was then chill-cast to optimize the grinding procedure. Ternary alloys with compositions corresponding to BSi_2Li_4, BSi_2Li_8, BSi_2Li_{10}, and $B_{2.64}SiLi_4$ have been synthesized in this manner. The synthesis of BSi_2 was performed by thoroughly mixing boron and silicon powders, pressing these into a green slug at 15,000 psi, and heating to 1350°C under an argon atmosphere using an induction heater.

Experimental measurements and cell operations with lithium were performed in a Vacuum Atmospheres dry box equipped with a Ni-Train purifier. Concentrations of oxygen, nitrogen, and water were removed to below the parts per million level.

Apparatus.—Cell voltage measurements were made on a Sargent Recorder, Model MR. Constant current was supplied to the cell between voltage measurements by an Electronic Measurements, Model C633, constant current power supply. Temperature measurements were made with a chromel alumel thermocouple with a floating hot junction connected to a Westronics strip chart recorder. The test cell consisted of a 250 ml stainless steel beaker with appropriate electrically insulated feed-throughs to accommodate the lithium reference electrode (titanium felt metal impregnated with liquid lithium), the counterelectrode (aluminum wool), the working electrode (BSi_2Li_{10} on titanium felt), and the chromel-alumel thermocouple (not shown in Fig. 1).

Procedure.—The open-circuit temperature dependencies of the voltage plateaus of the ternary Li-B-Si alloy *vs.* liquid lithium were determined in the thermally controlled constant temperature molten salt bath. The working electrode having an initial charge state composition BSi_2Li_{10} was discharged at 5 mA/cm^2 into an aluminum wool counterelectrode. Voltage and temperature measurements were made during slow (approximately 0.2°C/min) cooling of the molten salt bath to minimize any thermal gradients between the electrodes and thermocouple. Repeated measurements using this technique gave reproducible results.

Results and Discussion

A typical *IR*-free discharge curve at 400°C for the ternary alloy having all initial stoichiometry BSi_2Li_{10} is shown in Fig. 2. As with the binary lithium-silicon alloy, the discharge occurs via five voltage plateaus. Similar discharge curves were obtained from material initially prepared in the discharged state and charged electrochemically to the same stoichiometry. BSi_2, if ground to a suitably fine powder, could be charged close to theoretical capacity. In such experiments, BSi_2 active material was contained in a honeycomb-type electrode structure shown in Fig. 3, and had a typical,

Fig. 1. Laboratory investigation cell

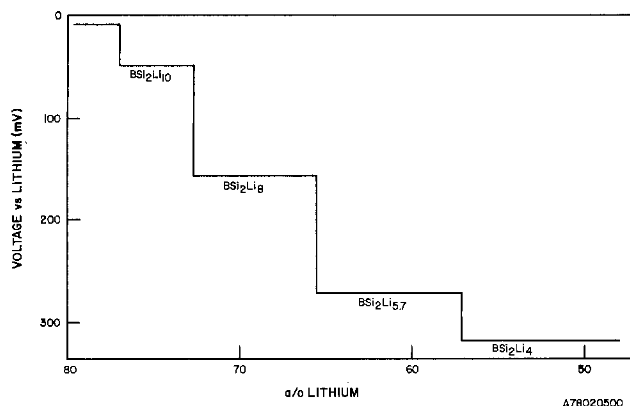

Fig. 2. *IR*-free discharge curve for BSi_2Li_{10}

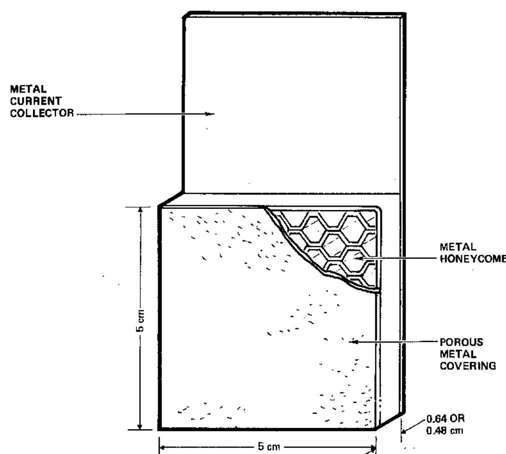

Fig. 3. Honeycomb electrode structures

average particle size of 3 μm. Particle sizes significantly larger than this exhibited a lower Faradaic capacity during charge, presumably due to the apparent unavailability of the silicon in the boron-silicon matrix. At each voltage plateau, the voltage temperature dependency was determined, typically between 650° and 730°K, from which a straight line relationship could be written, using the least squares method. The accuracy of the measurements was estimated to be ±2%. The voltage temperature dependencies and voltage plateaus at 400°C are shown in Table I. The Faradaic capacity of this ternary alloy is 1.97 A-hr/g which compares to the 2.12 A-hr/g for Li_5Si and 0.8 A-hr/g for LiAl. The voltage temperature dependencies allowed calculation of the relative partial molar entropies of lithium, $\overline{\Delta S}_{Li}$, using the thermodynamic relationship

$$\overline{\Delta S}_{Li} = n\mathbf{F}(\Delta E/\Delta T)_p \quad [1]$$

where $\overline{\Delta S}_{Li}$ = relative partial molar entropy; $\mathbf{F}$ = Faraday's constant; n = number of equivalent per mole; ΔE = voltage change; ΔT = temperature variation; and p = indicated constant pressure. After determination of $\overline{\Delta S}_{Li}$, the relative partial molar-free energy $\overline{\Delta G}_{Li}$ and enthalpy $\overline{\Delta H}_{Li}$ could be calculated from

Table I. Temperature dependency of voltage of lithium-boron-silicon alloys *vs.* lithium metal

Voltage plateau at 400°C (mV *vs.* lithium)	Temperature dependency (mV *vs.* °K)
49.79	188.9-0.2067T
156.66	270.6-0.1693T
271.44	313.5-0.0625T
318.73	350.4-0.04706T

Table II. Thermodynamic data for lithium-boron-silicon alloys at 400°C

Alloy-composition range	$\overline{\Delta S}_{Li}$ (cal/°K mole)	$\overline{\Delta G}_{Li}$ (kcal/mole)	$\overline{\Delta H}_{Li}$ (kcal/mole)
BSi_2Li_{10}-BSi_2Li_8	−9.53	−2.30	−8.71
BSi_2Li_8-$BSi_2Li_{5.7}$	−8.98	−8.31	−14.35
$BSi_2Li_{5.7}$-BSi_2Li_4	−2.45	−10.64	−12.29
BSi_2Li_4-BSi_2	−4.34	−29.4	−32.32

the relationships

$$\overline{\Delta G}_{Li} = -n\mathbf{F}E \quad [2]$$

and

$$\overline{\Delta H}_{Li} = \overline{\Delta G}_{Li} + T\,\overline{\Delta S}_{Li} \quad [3]$$

The results obtained from these calculations are shown in Table II. The composition was chosen by analogy to other metal silicides of this composition. It should be emphasized that BSi_2 is probably not a compound but a solid solution. Alloys of lower boron content (*e.g.*, BSi_4) would be expected to be equally electrochemically active.

X-ray measurements are in agreement with earlier work (15) which shows some degree of lattice parameter contraction upon substitution of boron into silicon lattice sites. This is to be expected from the 25% smaller tetrahedral covalent radii in boron when compared to silicon (17).

Accelerated 4 week tests using BSi_2Li_8 indicate that silicon migration into 1010 low carbon and 304 stainless steel electrode substrate materials can be reduced by a factor of five relative to that observed with Li_8Si_2 at 550°C in a LiCl-KCl molten salt eutectic, as determined using microprobe analysis techniques. At this time, it is difficult to determine what the corrosion-inhibiting mechanism or mechanisms might be. Whether the silicon penetration into the metal substrate electrode is reduced by the formation of a metal boride diffusion barrier or is minimized by a reduction in the activity of silicon or a combination of both is, as yet, uncertain.

Further work is in progress to determine the electrochemical and long-term corrosion-inhibiting characteristics of boron-silicon alloys in metallic honeycomb-type substrate electrodes. Such information will be used to optimize the boron to silicon ratio of the ternary alloy.

Boron presently costs around $25/lb in large quantities (2000 lb). The cost of boron per kW-hr in the lithium-iron sulfide battery will depend upon both the final alloy stoichiometry and the charge state capacity chosen for the alloy. For BSi_2, the cost penalty introduced by the boron content, assuming a final charged state composition BSi_2Li_{10}, would be around $1.80/kW-hr. It is expected that silicon migration into the negative electrode current collector structure will be inhibited to an acceptable degree by the use of lower boron containing ternary alloys and will thereby provide a cost-effective solution to achieving both an electrochemically and mechanically stable long life lithium electrode for the lithium-metal sulfide battery.

Manuscript submitted Oct. 27, 1977; revised manuscript received March 15, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by Rockwell International.

ERRATA

In reference to the paper "Reactive Plasma Deposited Si-N Films for MOS-LSI Passivation," by A. K. Sinha, H. J. Levinstein, T. E. Smith, G. Quintana, and S. E. Haszko, which appeared on pp. 601-608 in the April 1978 JOURNAL, Vol. 125, No. 4, the following additional information should be noted.

The stated range of stresses in Table I is based upon data in Fig. 2-5 which indicate a value of approximately 5×10^9 dynes cm^{-2}, and upon data in Fig. 6 which indicate a stress of approximately 1×10^9 dynes cm^{-2}. The abrupt drop in stresses, shown in Fig. 6, was observed after certain modifications were made to the substrate table and the rf-tuning network. Prior to the modification, the wafer capacity on the substrate table was eight 2 in. diam Si wafers which were placed in cutouts on a stainless steel substrate table and heated by direct exposure from the quartz lamps. After the modification, the usable wafer capacity was 22 2 in. diam Si wafers which were placed on a solid aluminum plate heated by quartz lamps from underneath. At this point in time, the impedance matching network was also modified by increasing the tunable load capacitor. This greatly improved the tuning of the plasma at 1 Torr pressure. Data presented in Fig. 6-10 were taken after the above modifications—they show substantially lower tensile stresses and lower etch rates in buffered HF. The exact mechanism for these changes in film properties is not understood. However, the above observations further highlight the importance of machine-related effects in addition to the process variables discussed in the paper.

In reference to the paper "Breakdown and Efficiency of Anodic Oxide Growth on Titanium," by C. K. Dyer and J. S. L. Leach, which appeared in the July 1978 JOURNAL, Vol. 125, No. 7, pp. 1032-1038, one error should be noted. The word "interrupted" in the caption of Fig. 4, p. 1035, should be "continuous." Thus, the caption should read, "Ellipsometric film thickness during continuous anodization at 1 mA/cm^2 in 0.1M Na_2CO_3 + 0.1M $NaHCO_3$. $\lambda = 546.1$ nm, $n_f = 2.008 \pm 1\%$, $k_f = 0$. $V_B \sim 5.2V$."

High Temperature Reaction Kinetics of Tungsten with Sulfur Dioxide

Paul Meubus*

Applied Sciences Department, Centre de Recherche du Moyen Nord, Université du Quebec à Chicoutimi, Chicoutimi, Quebec, Canada G7H 2B1

ABSTRACT

The kinetics of reaction for the tungsten-sulfur dioxide system has been studied within the temperature range 1600°-2100°K and sulfur dioxide concentrations up to 15% in helium. The reaction rate for tungsten attack shows a maximum around 1870°K, the latter temperature being nearly independent of sulfur dioxide concentration. Experimental data lead to a reaction rate model implying a first-order reaction, becoming second order for particular conditions. Parameters defining the reaction rate equation are calculated and a $W\text{-}SO_2$ chemical reaction equation is discussed.

As part of a study of the high temperature behavior for refractory metals in adverse surroundings, the reaction for the system tungsten-sulfur dioxide has been investigated at temperatures above 1600°K. Studies of this kind are useful, for instance, in the case of tungsten electrodes in plasma industrial reactors, where corrosive gases are generated by solid-gas reactions.

Little information is available in the literature on the high temperature reactions of tungsten with sulfur dioxide. Early qualitative observation described the sulfurization of tungsten in the presence of sulfur dioxide at "red hot" temperatures (1), while oxidation of the metal is observed at higher temperatures (2). Kinetics of synthesis and structure of sulfides including tungsten sulfide are described in a recent Soviet work (3). However, the latter is related to the sulfurization of the metal by a gaseous mixture of sulfur in helium.

In view of the scarcity of information on the subject, the present work was undertaken to study the kinetics of reactions of W with SO_2 at high temperatures. In this respect, it has been shown that a maximum rate of attack does occur around 1870°K. The experiments were carried out in a reactor described in the experimental section. Mixtures of helium and up to 15% sulfur dioxide were used at various temperatures within the range 1600°-2100°K.

Experimental

The reactor used in the present study is partly shown in Fig. 1. It is made of a 6 cm long alumina or thoria tube, following the temperature to be attained, the inside diameter being 3 mm. The tube ends are connected to stainless steel lengths, tightness between the alumina and stainless steel tubes being ensured by means of Teflon O-rings. The reactor ends are provided with small quartz windows which allow a longitudinal view from the outside into the reactor. The refractory oxide tube is surrounded by a graphite electrical resistance with cooled electrical connections at both ends which also provide a thermal protection for the O-rings. The complete experimental assembly is shown in Fig. 2. Electrical current is supplied from the secondary wiring of a transformer whose primary circuit is controlled by a variac of appropriate power. The maximum power applied to the graphite heater is of the order of 6500W, with a voltage drop of about 3V across the resistance.

The reactor and heater are enclosed in a cooled vessel connected to a vacuum pump and a helium

DIFFERENTIAL REACTOR

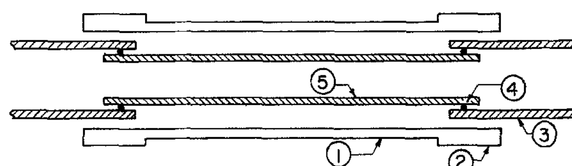

Fig. 1. Partial view of differential reactor with graphite resistance

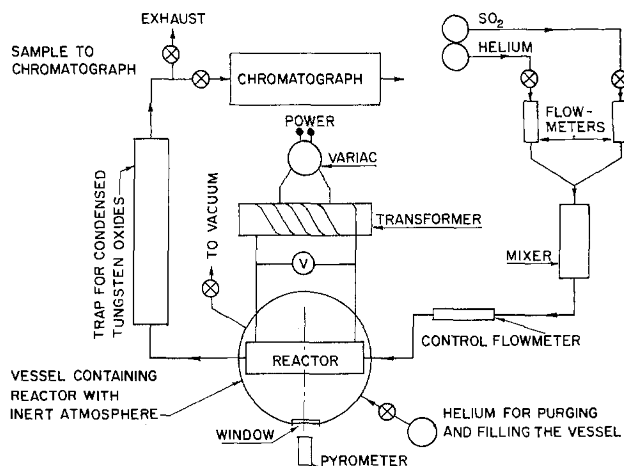

Fig. 2. Experimental layout

* Electrochemical Society Active Member.

Key words: tungsten, corrosion, sulfur dioxide, high temperature.

cylinder so that an inert atmosphere can be introduced within the vessel, thus providing an adequate protection against the graphite oxidation. The remainder of the assembly is made of conventiontal equipment consisting of a mixer for the incoming gases (helium and sulfur dioxide), a separator for products of reaction, flowmeters, etc.

In view of the temperatures to be attained in the reactor, alumina tube only was used in the course of this study. Prior to the experiments, the temperature inside the differential reactor was calibrated by means of a small piece of pure tungsten located at the required position in the refractory tube. The tungsten sample surface temperature was measured with a pyrometer (Leeds and Northrup, 1000°-6000°C) at an effective wavelength of 685 mm. The reading was corrected for blackbody deviation by means of the emission coefficient for tungsten at the considered wavelength and for the temperature obtained. The reactor inside temperature was then correlated with the temperature recorded at the middle of the outside surface of the surrounding electrical heater. The latter temperature was readily accessible during the experiments through the window provided for this purpose in the enclosing vessel, so that the inside temperature was known also from the relationship already obtained. The graphite was replaced when its electrical resistance did change. Figure 3 represents an example of the inside temperature distribution starting from the middle of the reactor.

The method of calibration used was checked by observation in the reactor of the fusion point obtained for pure alumina (FP 2323°K) which was found equal to 2300°K. Pure iron was also tested and melted at 1790°K, the theoretical FP being 1808°K. These measurements were made using a helium atmosphere. It can be shown from Fig. 3 that the temperature discrepancy is about 60°K within ±5 mm from the center of the reactor, when defined as

$$\Delta T = \frac{\int_0^5 T dx}{x} \quad [1]$$

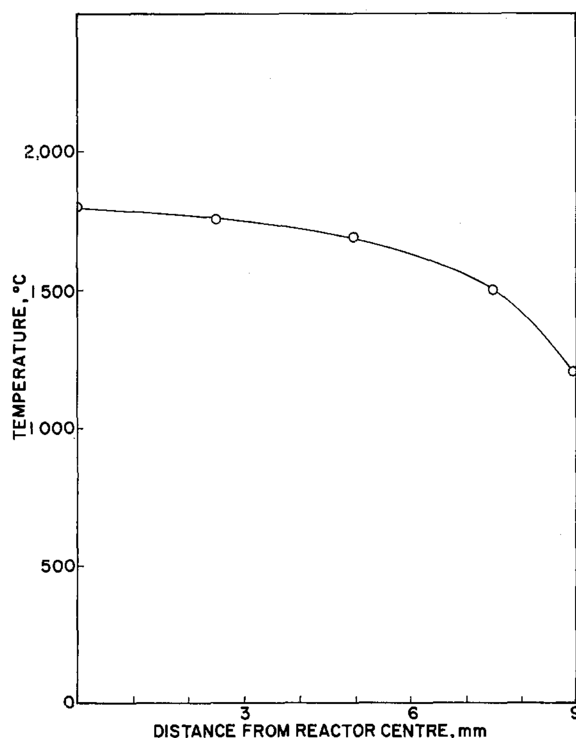

Fig. 3. Example of temperature distribution inside the differential reactor.

This situation was nearly the same for the whole temperature range used in the experiments. Equation [1] was taken into account for temperature correction and the temperature determined at the reactor center was decreased by 30°K, so that the corrected temperature did not differ by more than 30°K from the extreme temperature values as obtained from Eq. [1]. This temperature was chosen as representative of the reaction temperature. It should be noted that 5 mm on each side of the reactor center delineates the position of the tungsten samples used for the SO_2 reaction experiments.

The metal used for the rate-of-attack determination was made of 99.9% pure tungsten (Metal Werk, Plansee, AG., Reute, Tyrol) wire 0.07 cm diam, resulting in a weight of 0.0742 g/cm. The tungsten samples used for the experiments were shaped from given lengths (~2 cm) of wire in the form of small springs, the length of which was reduced down to the length of reactor available at the required operating temperature, say around 1 cm. Prior to the experiments, the tungsten samples were treated for 1 hr under an atmosphere of hydrogen at 1173°K.

The experiments were carried out at atmospheric pressure, with sulfur dioxide concentrations up to 15% in helium and temperatures ranging from 1600° to 2100°K, the choice for these temperatures being justified under the heading "Discussion." The gas velocity was chosen equal to 250 ml/min. Further increase in velocity did not affect the tungsten rate of attack, being an indication that boundary layer effects were no longer important and that pure chemical kinetics was involved. In this respect it was found that for the chosen conditions the initial sample weight did not seem to have any effect on the reaction rates observed since similar duplicate points were obtained from tungsten samples with an initial weight difference as high as 30%.

The chromatograph used for analysis of the initial gas mixture was of the Fisher Hamilton 20 type, with a sulfur dioxide and oxygen detection column 3m long and 6 mm diam, containing 10% Di-N-Decyl-phthalate on Chromosorb T(40-60 mesh). The reacted gas was analyzed for O_2 and SO_2. No attempt was made to establish an O and S balance since SO_2 and O_2 could have been absorbed with condensing WO_3 or a number of reactions could occur between the main reaction site and the cooling section of the reactor. However, it was interesting to know whether O_2 was present or not for the purpose of speculations about the main reaction with W, while the SO_2 analysis in the issuing gas was used for calculating an average pressure for SO_2 in the reactor, the issuing SO_2 gas being by all means in large excess (inlet and outlet concentrations did not differ by more than 20% in all cases). The carrier gas was helium, flowing at a rate of 40 ml/min.

The chemical inertness of the reactor was verified by carrying out blank experiments at high temperatures. The issuing gas was checked for SO_2 depletion and oxygen presence and the reactor was examined for possible alteration. No change was observed in the reaction gas composition after passage through the reactor when the highest SO_2 concentration (up to 20%) and the highest temperature (2100°K) considered for the experiments were used for the blank controls. Also, no visible alteration was found in the reactor. The sulfur dioxide used was 99.9% pure (Canadian Liquid Air).

To start a run, the hydrogen-treated tungsten sample was weighed to the nearest 0.1 mg and introduced into the reactor. By means of a three-way valve giving access to either helium or the required helium-sulfur dioxide mixture, the reactor and gas circuit were first flushed with helium and the sample was heated up to the desired experimental temperature. Connection was then established with the helium-SO_2

mixture and the reaction time was started when visible fumes evolution was observed through the small quartz windows provided at the ends of the differential reactor. The starting of visible fumes could also be predicted by calculating the time required for the reaction gas to reach the tungsten sample after opening of the three-way valve, knowing the flow rate (250 ml/min) as well as the length and diameter of the gas line. The sulfur dioxide content was then determined in the outlet gas, and after a predetermined reaction time was elapsed, the electrical power was cut off, the gas circuit was flushed, and the tungsten sample was weighed again. The average wire surface was obtained from

$$A_m = \frac{\pi l (d_1 - d_2)}{\ln \frac{d_1}{d_2}} \quad [2]$$

The average wire diameter after attack was calculated from the relationship

$$d_2 = (4P/19.3\, l\pi)^{1/2} \quad [3]$$

and the average sulfur dioxide concentration could be written

$$C_{AV} = \frac{C_{in} + C_{out}}{2} \quad [4]$$

$$p = \frac{p_{in} + p_{out}}{2} \quad [5]$$

and p_{AV} was taken as a representative value for the SO_2 partial pressure. The partial pressures p_{in} and p_{out} did not differ by more than 20% even in extreme cases of tungsten rate of attack.

The tungsten rate of attack was obtained from

$$\frac{dW}{dt} = \frac{\Delta P}{184\, A_m \Delta t} \quad [6]$$

Results and Discussion

Figure 4 shows the linearity of tungsten weight loss as a function of time for given sulfur dioxide concentrations and temperatures, no layer of reacted product being observed, at least on the macroscopic scale, in all cases covered by this study. As a result, the rate of tungsten attack in Eq. [6] could be considered constant at a given temperature for a given sulfur dioxide concentration and could be measured from the slope of lines similar to those appearing on Fig. 4. These results were observed for temperatures between 1600° and 2100°K.

Interpretation of data.—If it is assumed that the reaction rate constant for the tungsten attack by SO_2 follows the Arrhenius law behavior then one obtains

$$-\frac{dW}{dt} = e^{-E/RT}C \quad [7]$$

at constant sulfur dioxide partial pressure. In the case of Eq. [7], one can also write

$$\log\left(-\frac{dW}{dt}\right) = -0.434\frac{E}{R}\frac{1}{T} + \log C \quad [8]$$

and [7] is the equation of a straight line with slope $-0.434\, E/R$.

Figure 5 shows the tungsten rate of attack variation between 1600° and 2100°K, log $(-dW/dt)$ being represented as a function of $1/T$, and it is observed that the rate of attack is maximum around 1870°K and that on each side of the maximum the representative lines are indeed straight lines within the experimental temperature limits, showing the validity of application of Eq. [8]. In this respect, a rather small number of experimental points are required for defining the phenomena involved.

Figures 6 and 7 are derived from Fig. 5 and describe the rate of attack for tungsten as a function of sulfur dioxide partial pressure for given temperatures. They suggest a reaction rate of the kind

$$r = \frac{ap^2}{1 + bp} \quad [9]$$

being parabolic, or second order, for $bp << 1$ and becoming first order when bp is comparable to 1 or higher than 1. Exponents higher than 2 for p in Eq. [9] are not considered since reaction orders higher than 2 are very unlikely.

If a reaction rate law of the kind indicated in Eq. [9] is obtained, one may write

$$\frac{p^2}{r} = \frac{b}{a}p + \frac{1}{a} \quad [10]$$

and p^2/r is a linear function of p. Figures 8 and 9 show straight lines, representative of p^2/r variation as a function of p, for various temperatures below (Fig.

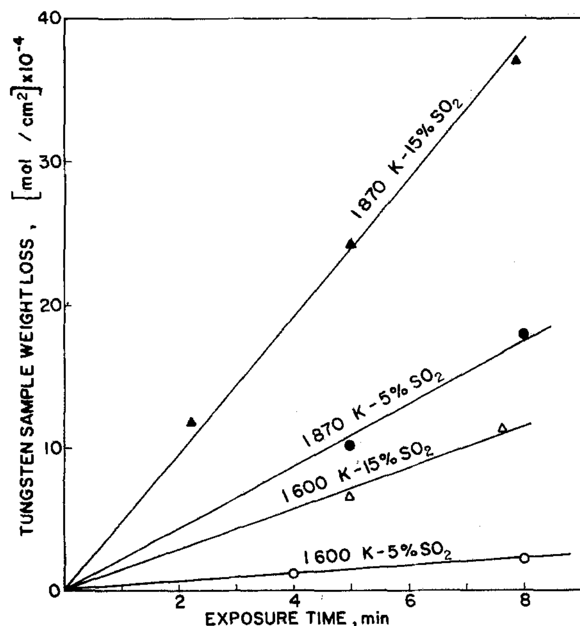

Fig. 4. Tungsten rate of attack as a function of time at given temperature and sulfur dioxide concentration.

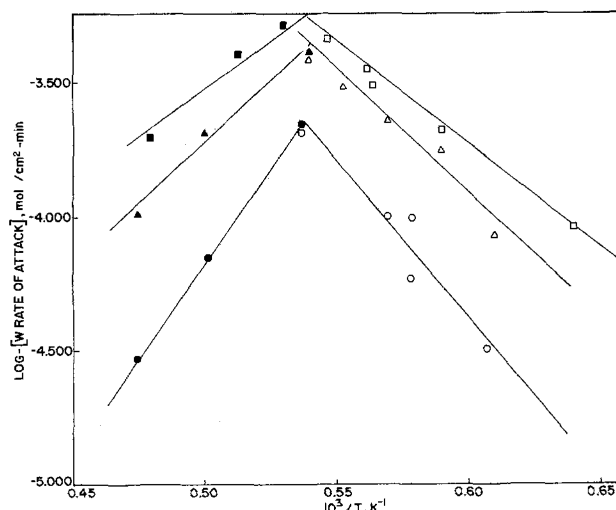

Fig. 5. Linear relationship of $\log_{10}$ [— W rate of attack] as a function of $\frac{1}{T}$. 5% SO_2, ● and ○; 10% SO_2, ▲ and △; 15% SO_2, ■ and □.

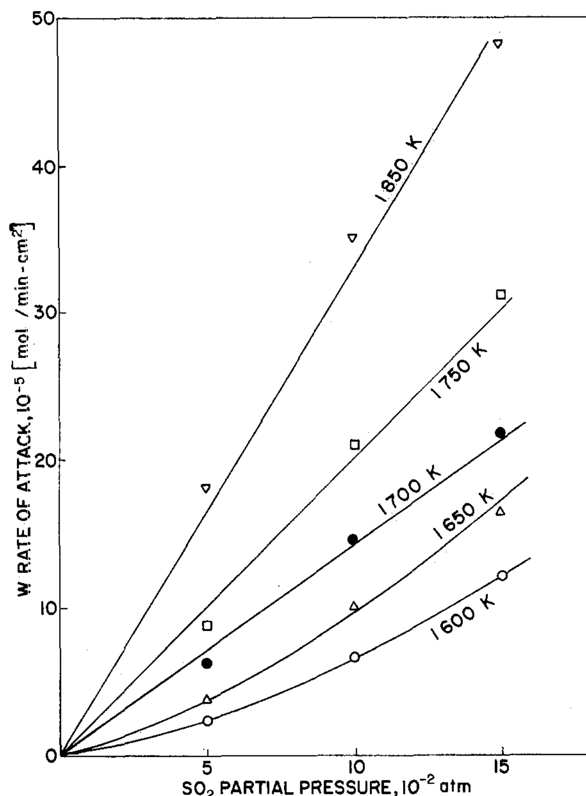

Fig. 6. Tungsten rate of attack as a function of sulfur dioxide concentration and given temperature (temperature range 1600°-1850°K).

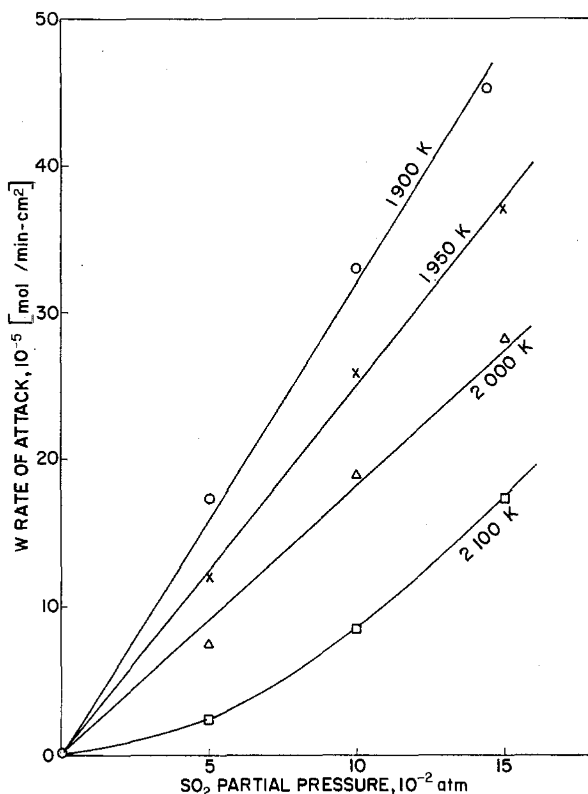

Fig. 7. Tungsten rate of attack as a function of sulfur dioxide concentration and given temperature (temperature range 1900°-2100°K).

8) and above (Fig. 9) 1870°K temperature for which a maximum rate of attack does take place. As a result, a and b may be calculated at various temperatures using the straight lines on Fig. 8 and 9. Indeed, b/a is deduced from the slope of these lines, while $1/a$ is

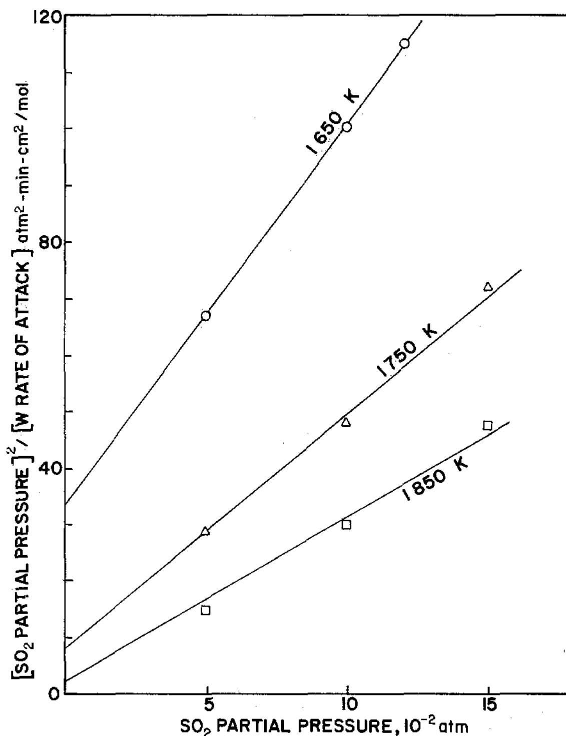

Fig. 8. Linear relationship between [sulfur dioxide partial pressure]^2/—[rate of tungsten attack] and sulfur dioxide partial pressure, for the temperature range 1600°-1870°K.

the limiting value in Eq. [10] when $p \to 0$. A number of values obtained for a and b at various temperatures are shown in Table I. Using Eq. [10] and classical error calculation methods, one obtains a relative error of $\pm 15\%$ on a and $\pm 30\%$ on b, this implying 1% error on, respectively, p, t, T, and 0.5 on W.

Equation [9] implies a number of reaction steps which include a gaseous reaction with an adsorbed species, the surface reaction being the controlling step (4, 5). The resulting over-all reaction is now discussed

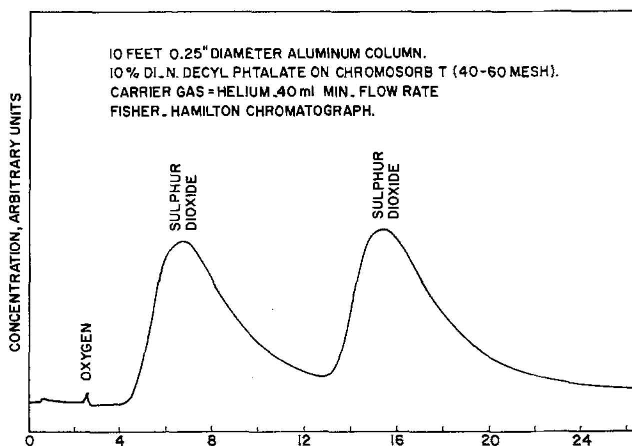

Fig. 10. Typical chromatogram for residual gases after reaction with tungsten.

in the light of experimental observations and thermodynamic constraints.

Reaction model for the system tungsten-sulfur dioxide.—Figure 10 shows an average chromatogram related to the experiments, indicating traces of oxygen and the two characteristic curves for sulfur dioxide which also appear for this gas prior to reaction. These are not due to water presence since the gases used are dried. The reaction products consisted of tungsten oxides, for which $WO_{2.9}$, in effect $W_{20}O_{58}$, was the major constituent. This dark blue oxide was identified by x-ray analysis. No tungsten oxide or sulfide was detected on the tungsten surface which, by all means,

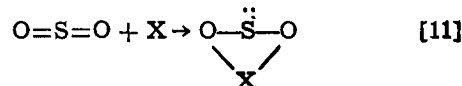
Table I. Values of the parameters a and b at various temperatures in rate Eq. [9]. SO_2 concentration between 0 and 15%

Temperature (°K)	Parameters in rate Eq. [9] a (moles/min-cm²-atm²)	b (atm⁻¹)
1650	3.6×10^{-2}	2.3×10
1750	1.9×10^{-1}	7.3×10
1850	7.2×10^{-1}	1.9×10^{2}
1950	3.3×10^{-1}	1.1×10^{2}
2000	10^{-1}	4.8×10
2100	2.7×10^{-2}	1.8×10

did not show any visible layer, but elemental sulfur was present in the reactor tube. It is possible that free oxygen or SO_2 were absorbed during condensation of tungsten oxide vapor.

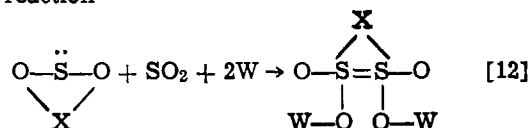
Considering the observations made and the interpretation of the experimental data which lead (Eq. [9]) to the description of a classical sequence of steps, the following model is proposed, the surface reaction being the controlling step (4, 5)

Absorption step



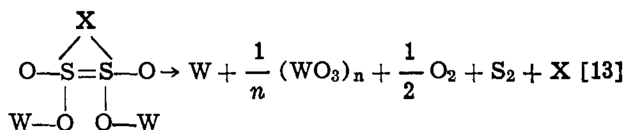
$$O{=}S{=}O + X \rightarrow O{-}\ddot{S}{-}O \text{ (bridged by X)} \quad [11]$$

Surface reaction



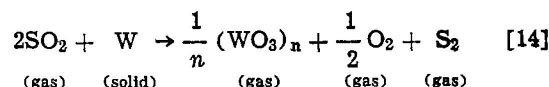
$$O{-}\ddot{S}{-}O \text{ (bridged by X)} + SO_2 + 2W \rightarrow O{-}S{=}S{-}O \text{ (S–S bridged by X; W–O, O–W)} \quad [12]$$

Desorption process



$$O{-}S{=}S{-}O \text{ (bridged by X; W–O, O–W)} \rightarrow W + \frac{1}{n}(WO_3)_n + \frac{1}{2}O_2 + S_2 + X \quad [13]$$

The over-all reaction is then



$$\underset{(gas)}{2SO_2} + \underset{(solid)}{W} \rightarrow \underset{(gas)}{\frac{1}{n}(WO_3)_n} + \underset{(gas)}{\frac{1}{2}O_2} + \underset{(gas)}{S_2} \quad [14]$$

The volatile tungsten oxide product WO_3 has been written in the more general form $(WO_3)_n$ since the species $(WO_3)_n$ with $n = 2, 3, 4$ is generated by WO_2 (solid) between 1300°-1600°K (6) and probably above. In the latter case, solid WO_3 is formed, which vaporizes and changes into $(WO_3)_{2,3}$ while vaporizing at a given temperature. The validity of Eq. [14] has been determined by means of data found in the literature for $(WO_3)_n$ (6), SO_2 (7), and S_2 (8), which are reported in Table II. The information in Table II has been used to calculate $\Delta F_T°$ for reaction [14] when the various oxides $(WO_3)_n$ are involved. The results appear in Table III together with the equilibrium constants for this reaction at various temperatures.

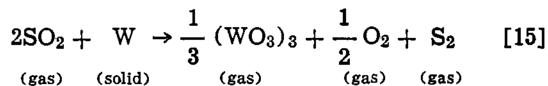
2100	+183	3×10^{-5}	+29.2	0.2	+20	0.3	+24	0.4		

From the heat of formation for the various $(WO_3)_n$ species appearing in Table II, the free energy of reaction for reaction [14] has been calculated with the assumptions of, respectively, $(WO_3)_1$, $(WO_3)_2$, $(WO_3)_3$, and $(WO_3)_4$ being present. Table III shows that the species $(WO_3)_2$, $(WO_3)_3$, and $(WO_3)_4$ are those most likely to occur at the considered temperatures. For the sake of simplicity, $n = 3$ has been retained in Eq. [14] which can then be written



$$\underset{(gas)}{2SO_2} + \underset{(solid)}{W} \rightarrow \frac{1}{3}\underset{(gas)}{(WO_3)_3} + \frac{1}{2}\underset{(gas)}{O_2} + \underset{(gas)}{S_2} \quad [15]$$

Table II shows that the free energy of formation of S_2 from 2S is highly negative in the whole range of temperatures involved in the present study, thus ensuring the presence of the species S_2 in Eq. [14] and [15].

At first sight, the following reaction could also be responsible for tungsten attack by sulfur dioxide

$$\underset{(solid)}{W} + \underset{(gas)}{2SO_2} \rightarrow \underset{(solid)}{WS_2} + \underset{(gas)}{2O_2} \quad [16]$$

Table III shows that this reaction is very unlikely to occur in view of the free energy of reaction found at 1400° and 1523°K, using information from Table II (9). By all means WS_2 decomposes at 1523°K (10).

Although $(WO_3)_n$ does vaporize, it could leave a solid layer of WO_3. However, if this were the case, the partial pressure of WO_3 (solid) should be the controlling step for reaction [15] at a given temperature and the rate of evolution should be independent of SO_2 concentration. This is not observed and it is concluded that the WO_3 rate of vaporization (which is possible for thermodynamic reasons) is such that no accumulation of solid oxides is possible within the experimental conditions.

Finally, in order to explain the presence of blue tungsten oxide identified as $WO_{2.9}$ by x-ray diffractometry, which was found in the cooler part of the reaction tube, the following reaction is considered

$$\frac{x}{4}S_2 + WO_3 \rightarrow WO_{(3-x)} + \frac{x}{2}SO_2 \quad [17]$$

the species $(WO_3)_n$ having receded to the state WO_3 and the reaction occurring downstream from the tungsten specimen. In the present case, $x = 0.1$ in Eq. [17].

Summarizing the development made on a possible model for the W-SO_2 reaction, the type of rate, Eq. [9], found leads to an over-all reaction Eq. [14]. The latter equation is then completed on the basis of thermodynamic considerations, thus leading to the reaction Eq. [15]. This equation also explains the experimental observations made like: (*i*) presence of sulfur and $WO_{2.9}$ in the cooler part of the reaction tube; and (*ii*) absence of a reacted layer of tungsten oxide or sulfide.

Conclusions

The kinetics of reaction for the tungsten-sulfur dioxide system has been studied within the temperature range 1600°-2100°K and sulfur dioxide concentrations up to 15% in helium. The tungsten rate of attack shows a maximum around 1870°K, this temperature being independent of sulfur dioxide concentration.

Experimental data lead to a first-order reaction rate model of the form $r = ap^2/(1 + bp)$, becoming second order when the product $bp << 1$. The parameters a and b related to the rate equation have been calculated and they have been found functions of the temperature. The rate equation leads to a W-SO_2 chemical reaction equation which has been completed on the basis of thermodynamic constraints and which explains the experimental observations made.

LIST OF SYMBOLS

A_m	logarithmic average surface of tungsten wire exposed to sulfur dioxide attack, cm^2
a	constant in Eq. [9] and derived equations, moles/min cm^2-atm^2
b	constant in Eq. [9] and [10]
C	sulfur dioxide concentration in helium, moles fraction. Also, constant in Eq. [7] and [8], moles/cm^2-min
d_1	initial tungsten wire diameter, cm
d_2	final tungsten wire diameter, cm
e	base of naperian logarithms
$\Delta F_T°$	free energy of formation or reaction
l	length of tungsten wire exposed to attack, cm
n	coefficient of $(WO_3)_n$ in Eq. [14], under the form of $1/n$, dimensionless
p	sulfur dioxide partial pressure, atm
P	tungsten weight, g
ΔP	tungsten weight variation, g
r	tungsten rate of attack, moles/min-cm^2
R	gas constant, kJ/mole-K
t	reaction time, min
T	temperature, °K
ΔT	temperature discrepancy between center and ±5 mm from center for reactor in Eq. [1]
W	moles tungsten
x	coefficient in Eq. [17]. Also, distance from center of reaction in Eq. [1]

Subscripts

A_v	average
in	at inlet of the reactor
out	at outlet of the reactor
m	logarithmic average
n	designates the degree of polymerization for WO_3
$(1 - x)$	designates the amount of oxygen tied up to W in Eq. [17]

Abbreviations

log	log in base 10

Fabrication Processes for a Silicon Substrate Package for Integrated Gallium Arsenide Laser Arrays

Michael J. Brady

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Single crystal silicon substrate chips with preferentially etched V-groove structures have been fabricated to accurately hold optical fibers for efficient output coupling of integrated gallium arsenide laser arrays. In addition, the substrate contains individually addressable drive electrodes electrically isolated by reversed biased p-n junctions. This paper discusses the required fabrication and processing techniques necessary to achieve the silicon package utilizing batch-processing technology found in the manufacture of microelectronic devices.

Anisotropic etching of single crystal silicon has become a standard processing step in silicon technology (1, 4). Utilization of the preferentially etched grooves with smooth-walled topology has also been applied to the fabrication of integrated optical devices such as channel waveguides (5, 6). Recent interest in optical communications utilizing gallium arsenide light-emitting diodes and gallium arsenide-gallium aluminum arsenide double heterostructure lasers as optical sources (7) has increased due to fabrication of a high radiance and high power source. Since the output characteristics differ between an LED and a laser, various techniques have been proposed (8) to capture the highly divergent emitted beam and effectively couple it into a low numerical aperture fiber waveguide.

We present here a fabrication technique that allows precisely grooved crystalline silicon to serve as a miniature optical bench that provides highly efficient coupling of a GaAlAs laser through a lens into a fiber guide. A common glass cylindrical lens and an array of fiber lightguides are self-aligned to the optical sources' optic axis. The preferentially etched grooves provide kinematic support for both a cylindrical lens and the fiber waveguides, and allow predetermined placement of the fibers with respect to the source axis and the silicon surface. Because the etching process is self-terminating, when the characteristic V-shape is formed, grooves of different depth can be etched simultaneously into the same substrate in one fabrication step, thus allowing one to align a different diameter lens to waveguides.

In addition, individual thin film driving electrodes, consisting of titanium, palladium, and gold are evaporated on the silicon surface and photolithography delineated. To provide electrical isolation between adjacent lasers, individual p-n junctions are fabricated below the silicon surface in line with the drive electrodes. The surface topology of the silicon optical bench provides a smooth oxidation-free metallized surface for bonding of the laser arrays. The silicon bench also acts as a good thermal heat sink for the lasers, and minimizes the strain due to the closer matching of the thermal expansion coefficients between silicon and gallium arsenide. Figure 1 shows a schematic of the assembled laser array package consisting of 13 devices spaced on 200 μm centers. The lasers are fabricated from double hetrostructure material grown using standard liquid phase epitaxy techniques. The laser cavities are 575 μm long and have an active region between 0.2 and 0.3 μm and a 12 μm wide oxide stripe on the p-type side to provide current confinement and limit the active region width. Contact metallurgy on the p-side of the laser consists of 500Å of chromium and 5000Å of gold, while a gold-germanium-nickel mixture is alloyed into the n-type side. The laser is bonded to the metallurgy on the silicon substrate with indium solder. A cross section of the package in Fig. 1 is shown in Fig. 2.

Key words: optical bench, alignment grooves, optical fibers, multichannel optical links.

Processing Steps

While many steps employed in silicon device technology were utilized to fabricate the miniature optical bench several deviations were required. The specifications for the substrates, shown in Table I, were necessary to obtain precise straight walls in the <110> directions and defect-free {111} faces. The orientation flat (<110>-major flat) is required so that the photolithographic masking patterns can be aligned to the wafer with a precision of $\pm 1°$ or better in order to get the straight-wall grooves.

The fabrication steps were performed in the following sequence:

(*i*) The wafers were chemically cleaned using H_2O:H_2O_2:NH_4OH (5:1:1) and H_2O:H_2O_2:HCl (6:1:1) solutions, blown dry in oil-free N_2, and immediately

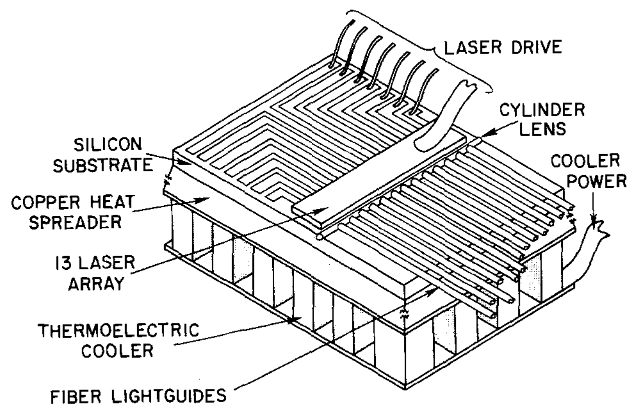

Fig. 1. Schematic of assembled substrate-laser array package with optical fibers, using a thirteen laser array as an example.

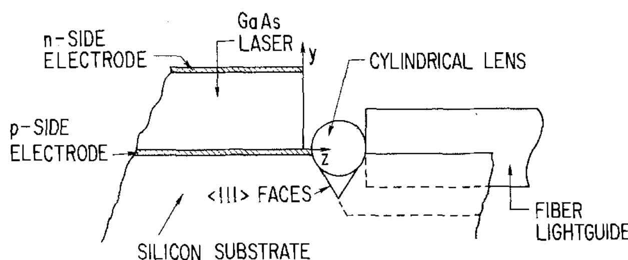

Fig. 2. Sectional view in the y-z plane showing the position of the lasers end facet (z direction) with respect to the lens groove.

Table I. Specifications required for the silicon wafers to ensure good quality optical benches

Specifications	
Single crystal silicon wafers	
Type	P
Dopant	Boron-noncompensated
Orientation	<100> Surface orientation ± 1°
Resistivity	1-2 Ω-cm ± 20%
Diameter	1.250 in. ± 0.010 in.
Thickness	Nominal 8 mils, with a thickness uniformity per wafer ± 1.0 mil
Parallelism	Within 0.5 mil
Primary flat	0.500-0.625 in. long oriented along (110) direction ± 0.5°
Secondary flat	0.250 in. long at 90° to primary flat
Dislocation density	Less than 500 per cm²
Note	Lap both sides and etch to remove damaged silicon. Chemechanically polish both sides. Periphery should be smooth, with no cracks, fractures, or sharp indents.

oxidized utilizing an open-tube steam apparatus at 1050°C to form a silicon dioxide film 1 μm thick in approximately 250 min.

(*ii*) The oxidized wafers were then coated with AZ 1350 Shipley photoresist (at 4000 RPM for 20 sec) on the front and back side, and prebaked at 70°C for 30 min. The back side protection is necessary to maintain the protective oxide layer during the isotropic etching of the windows.

(*iii*) The lens and waveguide pattern and the 75 μm junction windows (Fig. 3) were then exposed and developed. The wafers are then postbaked for 30 min at 100°C. Using the photoresist stencil, the openings are etched in the SiO_2 using buffered hydrofluoric acid at a rate of approximately 1000Å/min. The photoresist is stripped from both sides in an acetone solution that is ultrasonically agitated and the samples are then "ashed." The ashing process utilizes a plasma discharge in a Freon gas atmosphere. RF power of approximately 50W for 20 min appeared to be sufficient to remove any residual organic photoresist. At this point the samples are ready for open-tube diffusion to form the p-n junctions. A liquid n-type dopant was used, *i.e.*, phosphorous oxychloride ($POCl_3$) in a carrier gas (5500 ppm) at 870°C.

(*iv*) The junction fabrication procedure is as follows: The wafers are cleaned again using step (i). Diffused junctions are generated by depositing a blanket layer of phosphosilicate glass on the wafers, fol-

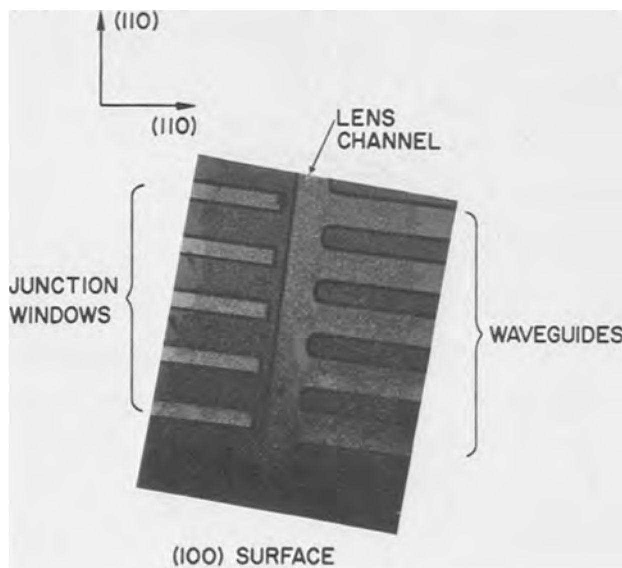

Fig. 3. Lens, waveguide, and junction patterns aligned to the {110} directions with dimensions of 125, 125, and 75 μm, respectively.

lowed by a drive-in of the phosphorous, to a depth of approximately 2 μm, in a dry oxidation atmosphere (O_2 flowing) at 1050°C for 200 min with approximately 0.3 μm of SiO_2 growing during the drive-in.

(*v*) Contact windows 50 × 550 μm are then optically positioned, centered, and photolithographly delineated in the 75 μm window and etched through the 0.3 μm layer over the N^+ diffusion area, using buffered hydrofluoric acid. This step is necessary in order to reduce the thermal resistance between the laser arrays and the heat sink, resulting in direct contact between the metal and the silicon and providing good ohmic contact. After the contact windows are opened, an additional layer of photoresist is deposited on the front surface and the resist is hardened for 30 min at 100°C. The oxide layer is then stripped from the back side by dipping in buffered HF for 15 min. The photoresist is again ultrasonically removed in an acetone solution, and after a further ashing, wafers with the freshly etched 50 × 550 μm contact regions are mounted in an electron beam evaporator and maintained at a pressure of $\leq 10^{-6}$ Torr.

(*vi*) The layered structure that was chosen for the metal electrodes was a combination of titanium, palladium, and gold. The selection of titanium was based on several parameters. Titanium has a high oxygen activity, forms a self-passivating oxide, and has a high surface bonding strength. The top layer of gold was chosen because of its high conductivity, resistance to corrosion, and ease of bonding. To prevent the gold from chemically reacting with the titanium and forming a compound, a sandwich layer of palladium was inserted to act as a diffusion barrier. Layers of titanium (500Å), palladium (1000Å), and gold (30,000Å) are blanket-evaporated on the delineated oxide pattern side. The substrate temperature during deposition of the titaninum palladium is 150°C and is lowered to 50°C for the gold layer. Deposition rates on the order of 10-12 Å/sec were used to ensure that the outer surface would be uniform, flat, and free of spikes which would affect the level of the laser arrays during the bonding process. The vacuum is broken, the wafers are inverted, and the process is repeated for the back side with the gold thickness reduced to 5000Å.

(*vii*) Using conventional photolithographic techniques and an "iron-oxide" mask, the 6 mil wide drive electrode patterns are aligned and delineated above the diffused junction windows. The alignment of the finger patterns with respect to the lens groove and the waveguides is extremely important for several reasons: Referring to Fig. 2, we see the end facet of the laser positioned in the z-direction with respect to the cylindrical lens positioned in the etched V-groove (x-direction). When the lasers are bonded to the silicon substrate, alignment is made by lining the end facets of the array to the edges of the drive electrodes. The viewing angle during positioning of the lasers is such that the highly reflecting gold surface aids in accurate placing of the array. Since coupling efficiency from the laser array to the application area depends on the laser's emission characteristics, the diameter of the lens, the core diameter of the lightguide, the indexes of refraction of the optical components, and the tolerances in component fabrication and packaging assembly, a minimum acceptable coupling efficiency of 50% was established for maximum radiance and minimum total power. This coupling efficiency (optical throughput) is measured at the outer surface of the lens. Variations in the y-direction shown in Fig. 4a and Table II indicate the sensitivity of optical throughput *vs.* vertical misalignment (Δy). Figure 4a indicates a misalignment of 5-6 μm for a 70 μm diam lens. Figure 4b indicates the second most critical alignment, the laser-to-lens spacing. The optimum position for the 70 μm diam lens is $Z_o = 12$ μm, but 50% throughput efficiency can be maintained for $Z < 37$ μm. This distance was achieved by compensating for isotropic undercutting during the 3 μm gold etch which was on the order

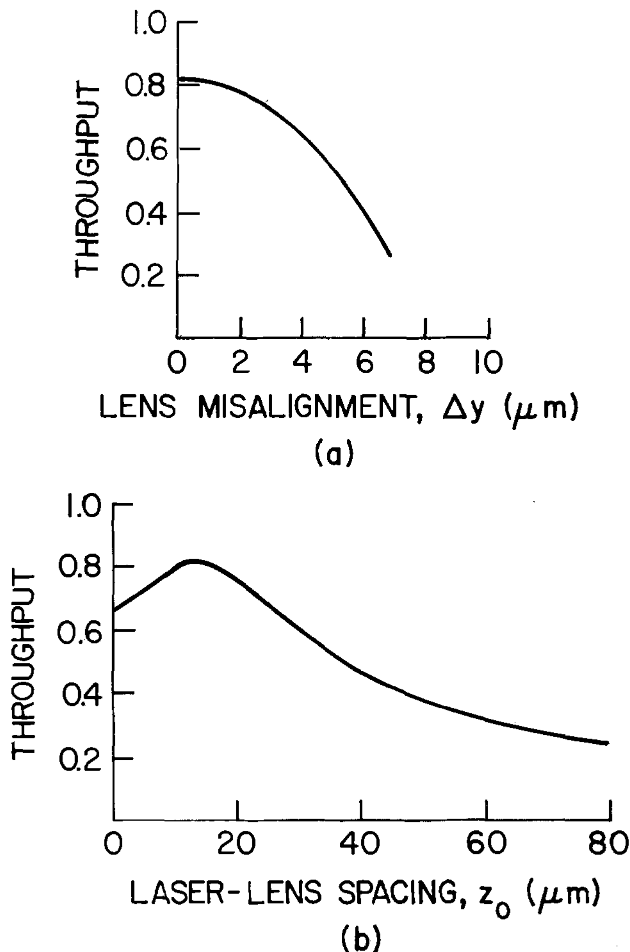

Fig. 4. (a) Variation in optical throughput as a 70 μm diam lens is shifted in the y direction with respect to lasers optic axis; (b) optical throughput as a function of the laser-to-lens distance.

of 12 μm. Positioning of the Fe_2O_3 mask with respect to the x direction, which was the most forgiving direction, was accomplished by optical alignment through a low power microscope and aligning the finger pattern with the etched SiO_2 window that forms the isolation junctions.

(*viii*) The gold and the palladium are chemically etched in an aqueous solution of KI + H_2O + I (1:1:1.5) at a temperature of 30°C. The titanium is then etched using a heated solution of H_2O + HF + H_2O_2 in a ratio of 50:1:1. Note that at this point the wafers are mounted so that the back side metallization is protected during the chemical etch back of the electrode pattern by mounting the wafers on glass disks with a low melting temperature wax. The photoresist stencil is then stripped from the wafers by flushing with acetone.

(*ix*) The 3000Å dry oxide grown during the N^+ diffusion is then removed from the lens and waveguide openings as well as the nonmetallized areas using buffered hydrofluoric acid. During this isotropic oxide etch back to expose the original silicon surface, overetching on the order of 5 min insures blanket removal of the dry oxide layer from tthe front side plus an additional 2000Å of the initial oxide layer.

Table II. Tolerance in the y direction (for 50% optical throughput) as the lens diameter changes

Lens diameter (μm)	Spot size (90% power) (μm)	y tolerance (50% thruput) (μm)
51	36	5
76	51	8
102	66	10
127	86	13

Source: λ = 0.85 μm, $w_{\perp}$ = 0.3 μm, $w_{\parallel}$ = 1.5 μm.

Recall that silicon, when exposed to the atmosphere, grows a native oxide layer on the order of 30-50Å. The initial layer of titanium, when deposited, has the ability to penetrate thin silicon dioxide layers, forming a strong surface bond. This shallow interface acted as a mask to the anisotropic etching (as explained below) and was the primary reason for growing the 0.3 μm of oxide in a dry oxidation furnace. Prior to preferential etching, the wafers are subjected to a detailed sequence of steps which have given consistently satisfactory results.

(*x*) The wafers are cleaned in solutions of trichlorethylene, acetone, and ethyl alcohol, ultrasonically, followed by a 30 min "ashing." The wafers are then placed vertically in a quartz boat, dipped in buffered HF for 10 sec, dipped into running DI water, and loaded directly into the anisotropic etching bath containing ethylene diamine, pyrocatechol, and water boiling at a constant temperature of 118°C. The etch rate for this solution is dependent upon crystallographic orientation, with the {111} faces being etched the slowest. Typical etch rate ratios of 50:30:3 μm/hr for the {100}:{110}:{111}, respectively, have been reproduced (9). Orientation dependent etching (ODE) rates of 400:1 for the {110}:{111} faces in {110} surface orientation wafers have been observed (10). Etch rates on the order of 50 μm/hr were consistently achieved. The silicon etching bath is shown in Fig. 5. Nitrogen gas was constantly bubbled through the etching solution to prevent oxidation, and a reflux apparatus was used to prevent evaporation of the chemical components. In addition, the solution is constantly stirred. The output of the system is vented through a fume hood.

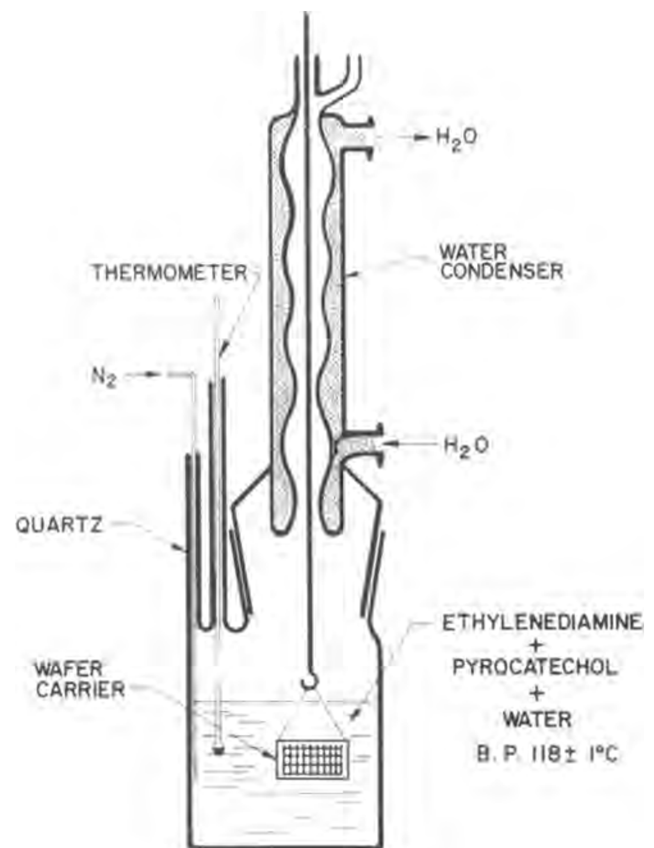

Fig. 5. Schematic of anisotropic etching bath apparatus (courtesy of E. Bassous).

(xi) Upon completion of the etching, the quartz boat is removed and rinsed in running DI water for 30 sec, then dipped in buffered HF for 10 sec, returned to running DI water, removed and blown dry in oil-free nitrogen. During the preferential etching no degradation of the metallized contact electrodes takes place. During the lens and waveguide etching in the silicon wafers, personalized chips of 250 mils square are outlined with intersecting 3 mil V-grooves. Upon completion of the etching, these intersecting V-grooves assist in cleaving of the wafer into chips. The width of the groove for the optical components is predetermined from the desired location of the optic axis with respect to the silicon surface, as shown in Fig. 6. If the center of the optical component of diameter "D" is to be a distance above the silicon surface, Eq. [1] determines the correct groove width

$$W = D \sec\theta - 2H \tan\theta \qquad [1]$$

where: H = the height of the active region of the laser source above the silicon dioxide surface, and includes all metals, as shown in Fig. 12; and $\theta = 35.3°$ for {100} surface orientation wafers.

Nominal values of H were 7 μm, which included approximately 3 μm of substrate metallurgy (titanium, palladium, and gold), 1.5-2 μm of indium bond material, and 2 μm from the p-side of the laser to the active region.

To provide mechanical support from the smooth-walled groove to the optical component, the groove depth must be greater than [$D/2H$]. Formation of the groove walls by the crystallographic {111} planes are extremely straight and smooth as shown by the SEM photo in Fig. 7. Because the etch process is self-terminating when the V-groove is formed, it is possible to fabricate lens and waveguide grooves of different depths on the same wafer. Figure 8 shows how this feature is utilized in order to align a 50 μm diam lens

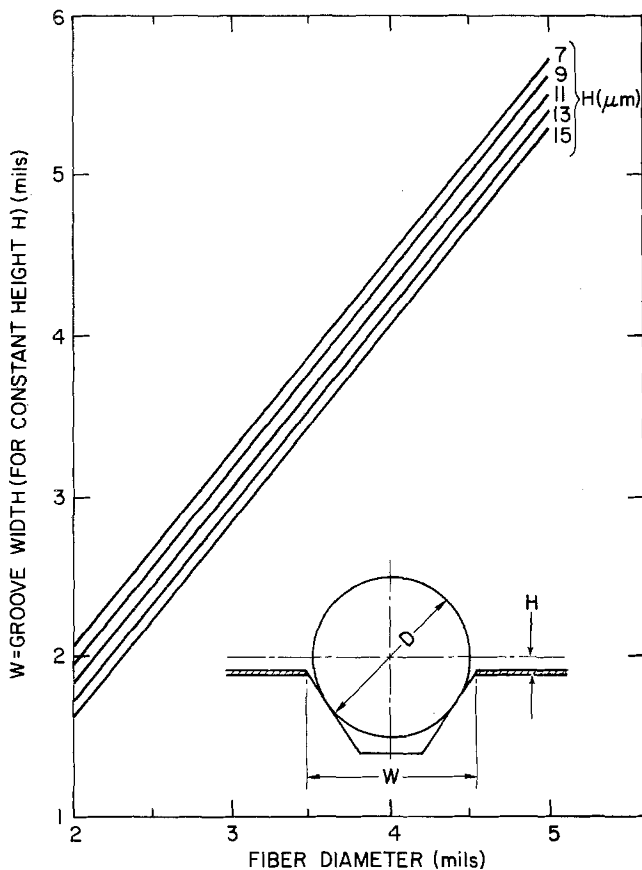

Fig. 6. Width of grooves vs. diam of fibers as a function of the height above the silicon dioxide surface.

with a 132 μm OD lightguide. Lens and waveguide fiber mounting grooves for various combinations of fibers has been accomplished, *i.e.*, 125 μm guide, 75 and 50 μm lens.

Processing Problems

Fabrication of the silicon optical bench was not without processing difficulties. Two major problem areas surfaced as the tolerances in the vertical direction became more demanding (see Table II).

The first problem developed with respect to Eq. [1]. Control over the width of the open window in the silicon is dependent on the photographic emulsion pattern width. If the emulsion mask width is generated, in our case, by a programed light table (PLT), the step and repeat process (in steps of ½ mil) can occasionally cause jogs in the pattern. These jogs or ripples in the oxide mask cause the pattern to open up to the widest dimension during anisotropic etching. An additional variation is caused by blooming of the pattern in transfer mask making as well as lateral undercutting during the silicon etching, especially in regions where perpendicular grooves intersect (Fig. 9). This undercutting is due to the exposure of the non {111} surfaces at the corners. The crystallographic planes exposed by the undercut are the {112} planes. For a groove 130 μm wide, the undercut extends about 100 μm along the groove wall so that fiber-grooved wall contact is not possible in this region. However, the fibers used are sufficiently stiff so that alignment or rigidity of the bench is not affected, since the placement of the lens fiber in the nonintersection region provides kinematic support. In the regions of nonintersecting lens and guide grooves, widths of $W = A + \delta$, (where A is the aperture command, *e.g.*, 125 μm) and δ allows for etching in the slow <111> planes and small imperfections in the silicon dioxide window. For etching depths on the order of 60-70 μm, δ had nominal values of 5-8 μm.

The second problem occurred during etching of the silicon wafer and was initially a two-part problem. Commercially available silicon wafers of standard quality for field effect transistor (FET) device fabrication which are 3.17 cm in diameter, 200 μm thick, and polished on one side exhibit a thickness variation of ± 25 μm. This would cause the grooved channel to vary along the length of the fiber some 2-3 μm. This problem was overcome by requiring both front and back wafers to be polished and plane parallel. In addition, stringent specifications were necessary to control the surface orientation to within a degree or less, *i.e.*, {100} surface $\pm < 1°$. Wafers sliced from crystals with surface orientations greater than 1° caused nonpreferential etching, and were easily observed on the {112} planes as shown in Fig. 10. The second part of the etching problem was residual crystallites. The chemical mechanism of silicon etching proposed by Finne and Klein (11) involves the oxidation of the silicon by

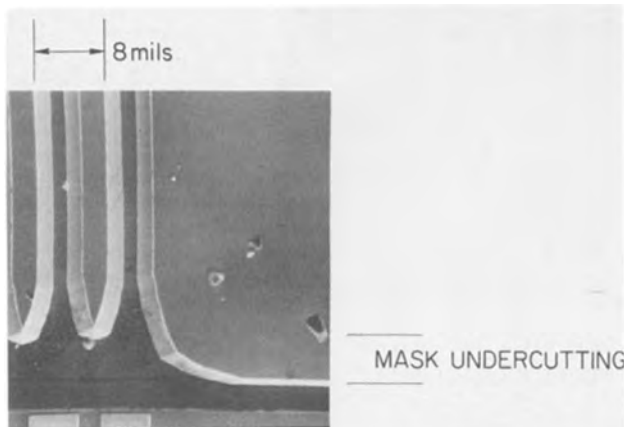

Fig. 9. Undercutting where the lens and waveguide grooves intersect.

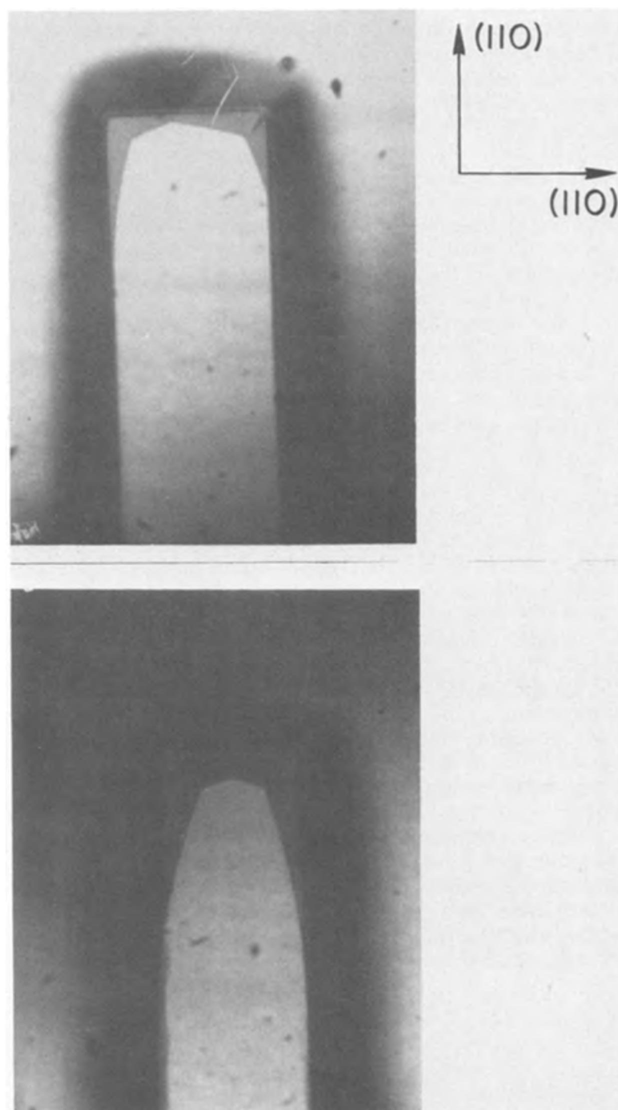

Fig. 10. (a) Misorientation of the {100} surface exposing etched asymmetric <112> planes; (b) symmetrical {112} planes on orientated {100} surface.

OH^- ions from the water present in the solution to produce hydrous silica Si $(OH)^=$ and hydrogen gas. An organo-silicon complex is then formed with the pyrocatechol C_7H_6 $(OH)_2$ which dissolves in the ethylene diamine $NH_2(CH_2)NH_2$. After extended etching periods, this solution tended to etch nonuniformly and, despite precautions to eliminate surface contaminations by ultrasonic cleaning, plasma etching, and maintaining clean room conditions, this nonuniform etching took place, causing the formation of crystallite residues on the etched {111} walls (see Fig. 11) and on the {100} surfaces. These slow etching multifaceted crystallites, which have been observed using hydrazine-water solutions (12), have been called pyrimidal hillocks. Obviously, retention of these defects along the walls would cause the fibers to be displaced in the vertical direction. A modified composition of the solution used in Ref. (11) was experimentally chosen to solve this problem and was achieved by increasing the concentration of the solvent and complexing agent in the etching solution (13).

At this point the individual 6 mm square substrate is ready for bonding of the lasers to the silicon. Figure 12 shows a cross section of the array (x-y plane) to be bonded with the indium interface between the lasers and the substrate electrodes. The bonding medium between the back side substrate metals and the copper heat sink is not shown. Detailed experimental

results addressing the bonding of lasers, optical performance, and thermal characteristics of the source package and potential applications will be presented elsewhere (14-19).

Summary

We have demonstrated that fabrication of a miniature optical bench utilizing single {100} crystal silicon is a viable process for optimizing coupling efficiency of a high radiance and highly divergent optical source through a cylindrical lens and fiber waveguide. Optical throughput efficiencies on the order of 70% were achieved (17), demonstrating that this is a feasible technique which provides a low cost, rigid, mechanical support. Precise placement of a lens with respect to the optical source in both the horizontal and vertical directions is achieved by control over anisotropic etching. Individual drive electrodes on the silicon allow the lasers to be addressed. Electrical isolation between lasers is maintained by diffusing an n^+ p junction in the silicon, so when the junction laser is forward biased, the silicon junctions are reversed bias. Thermal conduction from the lasers through the metallization and silicon substrate is provided to the heat sink, and better thermal expansion matching between silicon and gallium arsenide is achieved.

Acknowledgments

I would like to thank E. G. Lean for his support and persistence throughout this work. Comments and fruitful discussions with L. D. Comerford, J. D. Crow, and R. A. Laff were instrumental in achieving the optimum sequences in the fabrication steps. I am also grateful to J. S. Harper for the optical data, J. C. Dohm for processing of the photolithographic emulsion masks, S. Ruffini for the metallization films, B. Canavello for the SEM photographs, and the Silicon Processing line for the diffusion depositions.

Lateral Polysilicon p-n Diodes

M. Dutoit and F. Sollberger

Centre Electronique Horloger S.A., CH-2000 Neuchatel, Switzerland

ABSTRACT

The properties of lateral polysilicon p-n diodes as a function of doping level and temperature are discussed. Traps at grain boundaries greatly enhance charge-carrier recombination or generation and, consequently, diode current. In heavily doped diodes, an excess reverse current not accounted for by classical theories is observed. Thermal emission of charge carriers from traps followed by avalanche multiplication are proposed to explain this behavior. A current-controlled negative resistance at higher reverse bias is believed to be due to impact ionization of traps.

Integrated circuits often require high value resistors or leaky diodes. These elements can easily be implemented with lateral polysilicon diodes (1, 2). Among their advantages (3) are small size, no mandatory connection to either supply terminal, and small parasitic capacitances. In Si-gate CMOS technology they generally arise naturally without any additional process steps at the transition between the gates of p- and n-channel MOS transistors. Several years of production experience have shown that these diodes can be fabricated quite reproducibly.

p-n diodes in thin films of polycrystalline silicon were first studied by Manoliu and Kamins (4). In fine-grained films, as used in microelectronics technology, grain boundaries are expected to play a major role in determining diode properties. Compared to p-n junctions in single-crystal Si, polysilicon diodes carry much higher current densities (4-6). This increase cannot be accounted for solely on the basis of enhanced generation or recombination due to crystalline imperfections. Especially at reverse bias, heavily doped diodes carry a large excess current. At high reverse bias, a current-controlled negative resistance, not normally found in p-n junctions, is observed.

We measured the *I-V*, *I-T*, and *C-V* characteristics of p-n diodes and the influence of various process parameters. An attempt is made to explain these properties with a model derived from the work of Kamins (7) and Seto (8). They assume that the crystallites are depleted of charge carriers by traps located at their boundaries. At low doping levels, grains are completely depleted and free carrier density is very small. As the doping level increases, one reaches a critical concentration, N_t, where all traps are filled. Around N_t, free carrier density rises rapidly to approximately the same values as in single crystals. The potential barrier set up by charged traps limits mobility which is minimum near N_t. It is assumed that charge carriers cross this barrier by thermionic emission (8). An extension of this model to a p-n junction can explain some of the observed features of polysilicon diodes.

Device Processing

Standard CMOS processing (9) was simulated by growing undoped, 0.5 μm thick layers of polysilicon on thermal SiO_2 by pyrolysis of silane (0.2% SiH_4 in H_2; total gas flow, 30 l/min) at 700°C. The deposition rate was 0.05 μm/min. Average grain size, L, was about 50 nm as evaluated from TEM pictures. Next, the geometry of the devices was defined. B- and P-doped oxides deposited at 420°C were used as diffusion sources. Drive-in was carried out in N_2 at 1100°C for 45 min. Etching of contact windows, *e*-gun Al metallization, and annealing in forming gas (20% H_2 + 80% N_2) at 430°C for 1 hr completed the structure (Fig. 1a). In this case, nominal polysilicon resistivities were 100 $\Omega/\square$. The *I-V* characteristics of 10 μm wide diodes fabricated with this process are shown in Fig. 2a and 2b (uppermost curves). Diodes in polysilicon films grown by low pressure CVD had the same characteristics as those obtained with our standard process.

The influence of several polysilicon deposition variables was examined. The main effect of a change in carrier gas (N_2, Ar, or He in place of H_2) while maintaining the deposition rate, R_d constant by adjusting the flow of SiH_4 was to lower the final resistivities $\rho_s(n^+)$ and $\rho_s(p^+)$ by 10-30%. Diode reverse current, I_R increased by up to one order of magnitude. The reduction in ρ_s explains most of the change in I_R, as will be seen later. All further results concern H_2 polysilicon. In this case, ρ_s increases as R_d drops below 30 nm/min. I_R decreases with increasing R_d at a fixed deposition temperature, T_d, between 600° and 900°C. I_R varies approximately as $1/R_d$ at $T_d \leq 700°C$. The rate of change of I_R at higher T_d is lower. An increase in T_d at constant R_d decreases ρ_s and increases I_R. At this point, it is difficult to pinpoint any critical parameters, since they are generally closely interrelated. Grain size and doping level further depend on

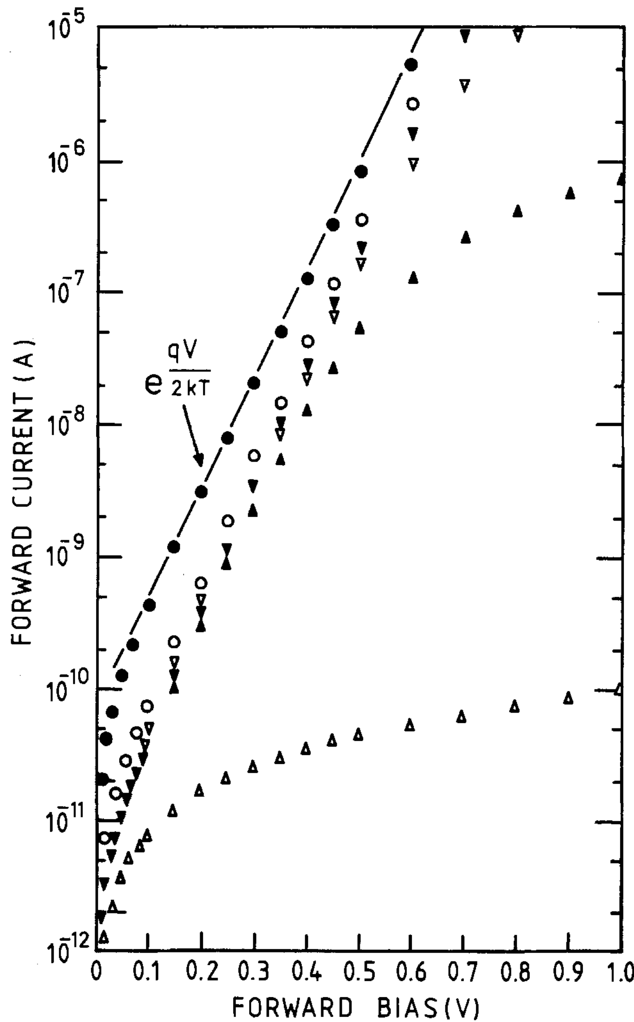

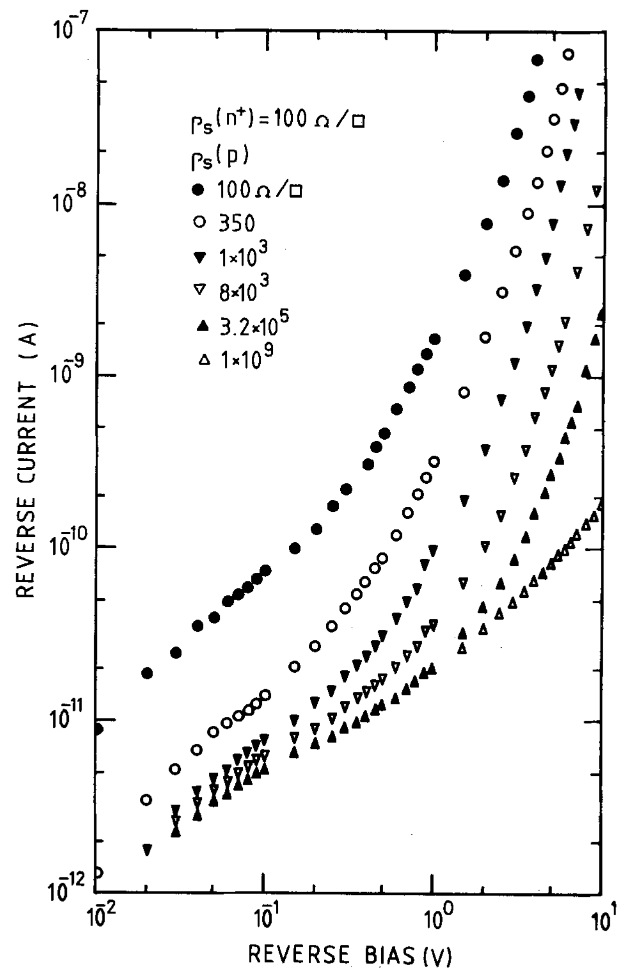

Fig. 2. (a) Forward; and (b) reverse characteristics of 10 μm wide n+p diodes

post-deposition heat-treatments. The effect of final polysilicon resistivity was studied in more detail since this parameter has a marked influence on diode properties and is easily controlled. For this purpose the structures shown in Fig. 1b were fabricated by implanting B (70 keV) or P (150 keV) into as-grown films. If doping is uniform (8), the impurity concentration N is the ratio of the implanted dose to the film thickness. This step was followed by an anneal in N_2 at 1100°C for 45 min. The 14 μm long weakly doped region was protected with a deposited SiO_2 layer. The rest of the process was unchanged. For comparison, some polysilicon films were doped during growth or with a doped oxide. No significant differences were observed (Fig. 3). The electrical properties of implanted films are accurately predicted by the model of Kamins and Seto (8). p- and n-type films have very similar properties. The parameters obtained for p-type films from fitting experimental variations of resistivity, mobility, and carrier density with doping level and temperature are trap density, $Q_t = 2 \times 10^{12}$ cm^{-2} and trap level $E_i - E_t = 0.25$ eV. These values are very close to those given in Ref. (8). The average volume density of traps is $N_t = Q_t/L = 4 \times 10^{17}$ cm^{-3}. Below 200°K, a break in the resistivity *vs.* temperature curve suggests the presence of another, shallower level in accordance with published results (10). This level has not yet been studied in detail. At low temperatures, tunneling of charge carriers through the potential barrier at grain boundaries, instead of thermionic emission, may play a role.

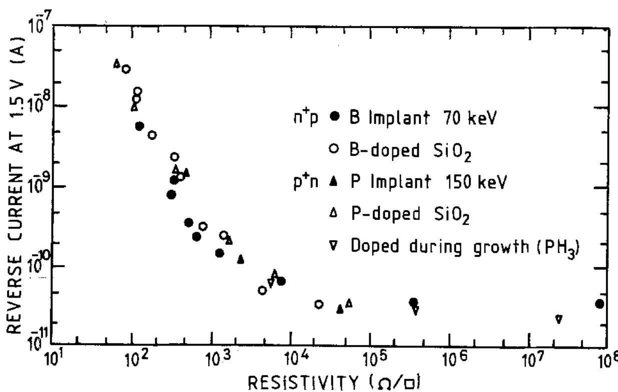

Fig. 3. Reverse current at 1.5V of 10 μm wide n+p and p+n diodes vs. resistivity of the weakly doped side.

Diode Properties

Figure 2 shows the I-V characteristics of 10 μm wide n^+p diodes with varying p-type resistivity, ρ_s. The uppermost curves represent standard n^+p^+ diodes as they are produced in CMOS technology (Fig. 1a). The other results were obtained on the devices shown in Fig. 1b.

Forward current is dominated by strong recombination, as can be inferred from its voltage dependence above 0.1V (4)

$$I_F = A \frac{qn_iW}{2\tau_o} \exp \frac{qV_F}{2kT} \quad [1]$$

where A is the junction area, q the electron charge, n_i the intrinsic carrier concentration, V_F the applied voltage, and kT the average thermal energy. The width of the space-charge region, W, is determined from

measurements of junction capacitance. The minority carrier lifetime, τ_o, determined from these results increases from 2×10^{-12} to 5×10^{-11} sec as ρ_s increases from 10^2 to 10^4 $\Omega/\square$. The generation current at 1.5V reverse bias calculated from the forward characteristics is between 10 and 100 pA. This is indeed the level measured in weakly doped diodes ($\rho_s > 10^4$ $\Omega/\square$). For lower ρ_s, I_R increases approximately as $1/\rho_s^2$ at room temperature (Fig. 3). This excess current is somewhat process dependent but insensitive to the method used to dope the p or n regions. The properties of n^+p and p^+n diodes are very similar. The reverse characteristics of heavily doped diodes depart significantly from the classical behavior of p-n junctions. I_R first increases linearly with applied bias up to a few tenths of a volt. As one approaches breakdown, the slope of the *I-V* curve gradually steepens. The breakdown voltage at 10 μA increases approximately as $\rho_s^{0.17}$ from 6V at 10^2 $\Omega/\square$ to 100V at 10^9 $\Omega/\square$. It has a positive temperature coefficient. Visible light is emitted from the junction area as reverse current approaches 1 mA. Between 2 and 5 mA, independently of ρ_s, a region of current-controlled negative resistance begins (Fig. 4). In some diodes, oscillations are observed. Diodes having been driven into this region show an irreversible increase in reverse current at low bias. A similar effect which appears at forward bias is always destructive. This behavior is similar to published results on p-i-n diodes (11, 12). Reverse current density is quite sensitive to the thickness, *t*, of the polysilicon film. It decreases by more than an order of magnitude between 0.2 and 1.2 μm, even though the average film resistivity $\rho = \rho_s t$ stays nearly constant.

The temperature dependence of the current of these diodes shows at least two thermally activated processes (Fig. 5). For standard n^+p^+ diodes the apparent activation energies near 0V are 0.2 and 0.4 eV. At sufficiently high forward bias, these two activation energies tend to decrease like $E_o - qV_F/2$, where $E_o = 0.55$ eV above 50°C and $E_o = 0.5$ eV below 50°C, independently of ρ_s (Fig. 6). This dependence is consistent with the conclusion that recombinations dominate in this range. Since in this case, $E_o = Eg/2 - |E_i - E_t|$, where Eg is the energy gap and E_i is the intrinsic Fermi level, the two levels involved are approximately 0.05 and 0.10 eV below or above E_i. The deviation from a straight line near 0V, as well as the decrease of these activation energies at reverse bias, shows that additional processes become important.

As ρ_s increases, the activation energies near 0V vary like $-\log N$ to reach limiting values near N_t that are very close to E_o (Fig. 7). Below N_t they stay

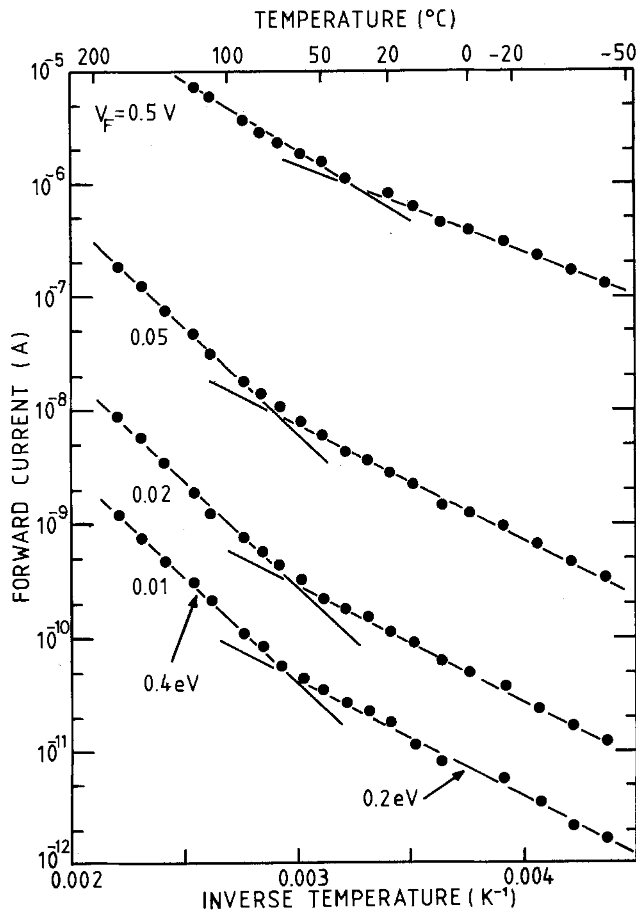

Fig. 5. Forward current of a 10 μm wide n^+p^+ diode (ρ_s = 100 $\Omega/\square$) vs. inverse temperature.

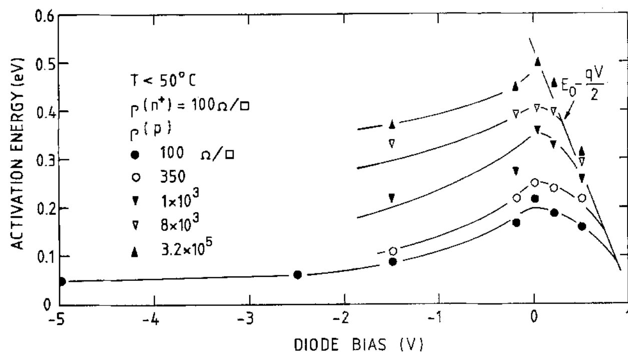

Fig. 6. Activation energy of diode current below 50°C vs. applied bias. Similar results are obtained above 50°C.

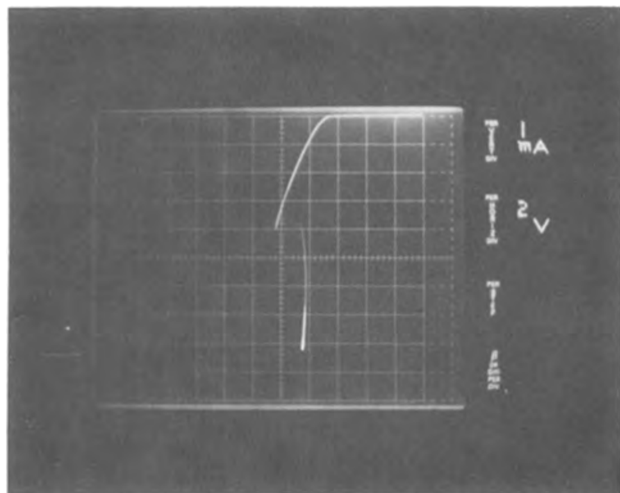

Fig. 4. Negative resistance in the reverse characteristics of a 10 μm wide n^+p^+ diode (ρ_s = 100 $\Omega/\square$).

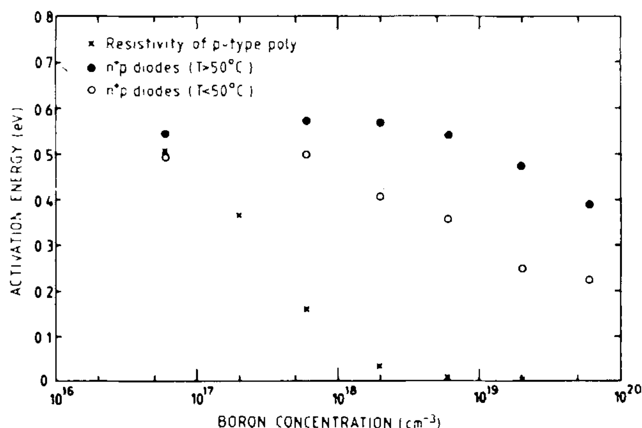

Fig. 7. Activation energies of diode current near 0V and of resistivity vs. doping concentration.

nearly constant. This confirms our earlier contention that charge-carrier generation dominates reverse current at high ρ_s. For comparison, we show the activation energy of resistivity near room temperature which falls to zero above N_t, in agreement with the model of Kamins and Seto (8).

Summarizing these measurements, an approximate expression for I_R, valid for $N > N_t$ and $T < 50°C$, can be written

$$I_R \approx \sigma_o w_d V_R \exp \frac{qV_R}{mkT} \exp \frac{-E_o + E_1 \ln \frac{N}{N_t}}{kT} \quad [2]$$

where σ_o, m, E_o, and E_1 are constants and w_d is the width of the diode. A fit to our experimental data yields $\sigma_o = 4 \times 10^{-4}\ \Omega^{-1}\ \text{cm}^{-1}$, $m = 50$, $E_o = 0.4$ eV, and $E_1 = 0.05$ eV. The value of E_o that gives the best fit is slightly different from the actual activation energy at $N = N_t$ because the voltage dependence of activation energy is not quite linear (Fig. 6). σ_o probably increases with N_t since otherwise I_R would decrease with increasing N_t, which is unlikely. As noted before, I_R does not vary linearly with polysilicon thickness.

Junction capacitance varies as $V_R^{-1/3}$ for these diodes (Fig. 8). This indicates a linearly graded doping profile, in agreement with the large lateral diffusion in polysilicon (about 5 μm in our case). The effective doping gradient determined from the slope of the curves varies from 2.6×10^{23} to 4.1×10^{22} cm^{-4} as ρ_s increases from 10^2 to 4×10^3 $\Omega/\square$. The width of the space charge region at 0V increases from 25 to 100 nm over the same range. The apparent built-in voltage is 0.1V for n^+p^+ diodes and increases with ρ_s, in contradiction with classical theories. For n^+p^+ diodes, a built-in voltage near 1V would be expected. Junction capacitance decreases slightly between 5 and 500 kHz.

Discussion

The properties of polysilicon diodes cannot be explained by simple analogy with classical p-n junctions. The enhanced rate of recombination or generation due to crystalline imperfections is not sufficient to account for all the observed features. In heavily doped diodes, reverse current is considerably higher than expected. Its voltage dependence is unusual. The width of the space-charge region and the built-in voltage are smaller than normal. Both increase at low doping.

Following Kamins and Seto, we assume that grain boundaries contribute a large density of deep levels in the bandgap. Three such levels are identified here ($|E_i - E_t| = 0.05$, 0.10, and 0.25 eV). The nearly identical properties of p- and n-type films show that holes or electrons can be trapped at grain boundaries. In a p-n junction, holes are predominantly trapped on the p side and electrons on the n side. These produce charged layers within the space charge region which screen the electric field of the junction and reduce its built-in voltage. Reverse conduction arises from thermally activated processes. We propose that thermal emission of carriers from these traps into the valence and conduction bands inside the grains is the limiting mechanism. The decrease in activation energy at low temperatures implies that multiple levels are involved. Tunneling through the barrier at grain boundaries must play a role. Avalanche multiplication probably accounts for the rapid increase in reverse current. A similar model was used to explain the characteristics of GaN MIS diodes (13). The predicted voltage and temperature dependence of current are in agreement with Eq. [2]. The negative resistance observed at high reverse bias in polysilicon diodes could be due to impact ionization of traps at grain boundaries (12), which is consistent with our model. Even though impact ionization requires a lower field than avalanche multiplication, it can start at a higher applied bias because of screening.

As the doping level decreases, fewer traps are populated and, at the same time, the field inside the junction decreases. Therefore diode current decreases until these traps merely play the role of additional recombination/generation centers. The displacement of the Fermi level with doping may explain the reduction in activation energy at high concentration.

Some experimental features are not explained by this model. In particular, the strong variation of reverse current with polysilicon thickness is still puzzling. This may indicate that surface effects need to be taken into account. Measurements on gated diodes should give more information on this point. Alternately, the variation of grain size with thickness may be important.

Electron Reemission Mossbauer Study of Tinplate

G. P. Huffman and G. R. Dunmyre

U. S. Steel Corporation, Research Laboratory, Monroeville, Pennsylvania 15146

ABSTRACT

Electron reemission Mossbauer (ERM) studies using the Sn^{119} Mossbauer isotope have been made on a series of tinplate samples with tin coatings ranging from 0.1 to 1.0 lb/bb (2.24 to 22.4 g/m²). With a recently developed theory of ERM spectroscopy, the ERM spectra could be analyzed to determine the thickness of the oxide (SnO_2), metallic Sn, and alloy ($FeSn_2$) layers on the tinplate samples. The resulting thicknesses were found to be in good agreement with the nominal coating weights and, for several samples, with the metal and alloy thicknesses determined by standard stripping techniques. The ERM method is shown to be very sensitive to thin tin oxide layers ranging from a few monolayers to several hundred angstroms thick.

In recent years, there has been much interest in the application of electron reemission Mossbauer (ERM) spectroscopy to the study of thin surface layers (1-8). In this technique, Mossbauer spectra are obtained by detecting the relatively low energy (typically ~1 to 20 keV) internal conversion and Auger electrons which are reemitted on deexcitation of Mossbauer nuclei following resonant absorption of recoilless Mossbauer gamma rays. Because these low energy electrons have relatively small escape distances (typically ~100-10,000Å), the bulk of the signal detected in an ERM experiment arises from the surface layers of the sample.

In a recent publication by one of the authors (7), reasonably simple analytic expressions were derived relating the ERM spectra obtained from multilayer surface films to the thicknesses of the various layers. This theory permits, for the first time, quantitative interpretation of ERM spectra; it has been initially tested and found to give reasonably accurate results in an ERM study of the oxidation of metallic Fe in oxygen at temperatures up to 500°C (8).

Although most previous ERM studies have utilized the Fe^{57} nucleus, the Sn^{119} nucleus also has excellent Mossbauer properties and is well suited to the ERM technique. The properties of Sn^{119} of most interest with regard to ERM spectroscopy have been summarized in a recent paper by Yagnik, Masak, and Collins (3). The internal conversion and Auger electrons emitted on deexcitation of the Sn^{119} nuclei have energies of 20 and 3 keV, respectively. Following resonant Mossbauer absorption of the recoilless 23.8-keV gamma rays emitted by Sn^{119m} nuclei in a suitable radioactive source, 84% of the absorbing Sn^{119} nuclei in the sample deexcite themselves by reemission of internal conversion electrons, and 89% of these internal conversion electrons are followed by Auger electrons. Therefore, for every one hundred 23.8 keV gamma rays absorbed in the sample, eighty-four 20 keV internal conversion and seventy-five 3 keV Auger electrons are reemitted. Those electrons that escape from the sample can be detected and used to obtain an ERM spectrum.

As is discussed in more detail later, the energies of these electrons are such that the bulk of the Sn^{119} ERM signal arises from approximately the top 10,000Å of the sample. This is precisely the range of most interest for tinplate with coatings of up to approximately 1 lb/bb[1] (0.1 lb/bb is equivalent to 1538Å of metallic Sn), and in the current report we summarize the results obtained by ERM studies of a fairly wide variety of tinplate samples.

Experimental Procedure

With the exception of the detection system, illustrated in Fig. 1, all aspects of the current Mossbauer experiments are the same as in conventional transmission Mossbauer spectroscopy and have been described in more detail elsewhere (9). A collimated and filtered beam of 23.8 keV gamma rays emitted by a suitable radioactive source (approximately 15 milli-Curies of Sn^{119m} in a $BaSnO_3$ matrix) is incident on the sample being investigated, which covers the rear window of a flow proportional counter; the 1 mil Pd filter serves to reduce the intensity of Sn x-rays with energies (25.0 and 25.3 keV) close to that of the Sn^{119} Mossbauer gamma rays.

When the Doppler shifted[2] energy of the incident gamma rays coincides with one of the energy separations between the various energy levels of the Sn^{119} nuclei in the absorber, resonant absorption occurs, with the absorbing nuclei being kicked into excited states. These excited Sn^{119} nuclei are deexcited 84% of the time by the internal conversion process. As noted earlier, for every one hundred 23.8 keV gamma rays resonantly absorbed, eighty-four 20 keV internal conversion and seventy-five 3 keV Auger electrons are reemitted from the absorber (3). Approximately half of these electrons are emitted in the backward direction (within the solid angle of the proportional counter window in Fig. 1); the 96% He-4% CH_4 flow gas is highly efficient for electron detection but very inefficient for detection of gamma rays and x-rays.

All tinplate samples studied in this investigation were commercial tinplate supplied by R. T. Davis and P. R. Carter of this laboratory. The tin coatings ranged from 0.1 to 1.0 lb/bb (2.4 to 22.4 g/m²). For several of the samples, independent measurements of the metallic tin and alloy layer thicknesses were made with standard stripping techniques (11).

Experimental Results

The ERM spectra of unmelted[3] tinplate samples are very similar to that of metallic tin, as illustrated in Fig. 2 which shows the spectra obtained from a metallic tin foil (top) and an unmelted 0.5 lb/bb (11.2 g/m²) tinplate sample (bottom). The labeled arrows identify the peaks arising from metallic tin (Sn) and stannic oxide (SnO_2). As discussed in a later section, the oxide layers on these samples are very thin (41Å for the metallic tin foil and 10Å for the unmelted tinplate sample). Similar oxide layers were present on all tinplate samples investigated.

After melting (reflow[4]), the tinplate samples exhibit an additional set of ERM peaks due to the alloy layer ($FeSn_2$). $FeSn_2$ is antiferromagnetic at room tempera-

Key words: surface layers, thickness determinations, SnO_2, $FeSn_2$, internal conversion.

[1] lb/bb = pounds per base box; 1 lb/bb = 22.4 g/m²

[2] The incident gamma-ray energy is Doppler modulated by vibrating the source in a controlled fashion over a small range of velocities. See Ref. (10) for a more detailed discussion.

[3] After plating, but prior to reflow, the electrodeposited tin coating is gray and nonreflective at this point.

[4] Reflow occurs for these commercially prepared tinplate samples by means of electrical resistance heating to temperatures of approximately 290-310°C, after which the strip is cooled by passage through a water bath. The resultant surface is highly reflective.

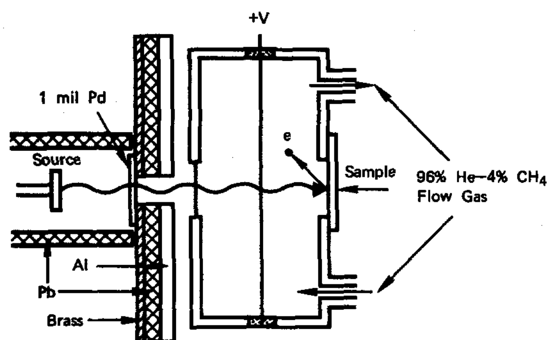

Fig. 1. Schematic diagram of the electron detection system. The dimensions of the proportional counter are approximately 10 × 4 × 4 cm.

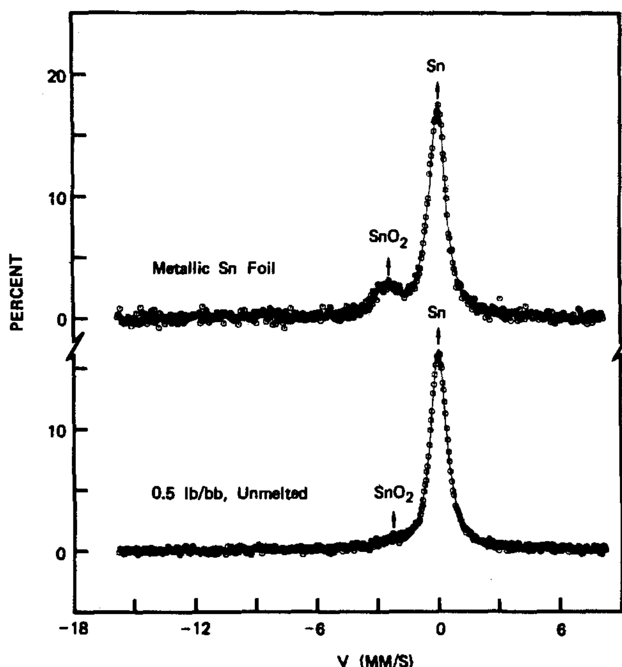

Fig. 2. ERM spectra of a metallic Sn foil (top) and an unmelted 0.5 lb/bb tinplate sample (bottom).

ture and gives the six-peak Mossbauer pattern characteristic of magnetically ordered samples (10). Because the magnetic hyperfine field is rather small, the six peaks overlap each other considerably, as shown in the top spectrum of Fig. 3, where the spectral components arising from SnO_2, metallic Sn, and $FeSn_2$, are separately indicated. The best values of the magnetic hyperfine field, isomer shift, and quadrupole splitting for $FeSn_2$ obtained from the results found for the 12 tinplate samples studied are $H = 24.5 \pm 0.5$ kiloG, $\delta = -0.07 \pm 0.02$ mm/sec,[5] and $\epsilon \approx 0.01 \pm 0.02$ mm/sec; these values are in reasonable agreement with those obtained for bulk $FeSn_2$ (12, 13). However, the average value of the stannic oxide isomer shift for the tinplate samples was found to be -2.27 ± 0.03 mm/sec, which is somewhat more positive than the value of -2.50 mm/sec observed for SnO_2 (9). This difference in isomer shift is probably due to the incorporation of Cr into the SnO_2; the chromium originates from a chromate electrochemical treatment used industrially to retard the oxidation of the tinplate during ambient temperature storage conditions. There was no evidence of any other oxide phases, such as SnO or mixed Fe-Sn oxides. It is unlikely that such oxides could have gone undetected if they had contributed more than about 10% of the total Mossbauer signal; however, the current data cannot be regarded as conclusive with respect to the possible existence of small amounts of such phases.

ERM spectra for several tinplate samples with tin coatings ranging from 0.1 to 0.7 lb/bb (2.24 to 15.7 g/m^2) are shown in Fig. 3 and 4. As expected, the intensities of the alloy peaks decrease relative to the intensity of the metallic Sn peak with increasing tin coating weight. The experimental quantities of most interest for present considerations are the percentages of the total ERM spectrum area contributed by the oxide, metallic Sn, and alloy layers. The values of these percentages for the samples studied in this investigation are given in Table I.

Thickness Determinations

As noted earlier, a recently developed theory of ERM spectroscopy (7) permits a quantitative interpretation of ERM data. In particular, the thicknesses of thin surface layers can be determined from the percentage of the total ERM spectrum area contributed by the various layers present. The spectral area contributed by the Nth layer is

[5] All velocities and isomer shifts are measured with respect to the position of the metallic Sn peak at room temperature (β-Sn).

* Measured by standard stripping techniques; all other values in column 2 are nominal coating weights.

$$A_N = \sum_{j=1}^{M_N} A_{N,j} \quad [1]$$

$$= C \exp(-B_{N-1}) \sum_{j=1}^{M_N} \langle F_{N,j} \rangle \{\exp(-D_{N-1}) H(\beta_{N,j}, Y_{N,j}) + 0.89 \exp(-G_{N-1}) H(\eta_{N,j}, Y_{N,j})\} \quad [2]$$

where the Nth layer contributes M_N peaks to the ERM spectrum ($M_N = 2$[6] for SnO_2, 1 for metallic Sn, and 6 for $FeSn_2$), and $A_{N,j}$ is the area under the jth peak from layer N. Here, C is a constant (7) and the exponential functions specify the attenuation of the incident gamma rays and outgoing electrons by atomic absorption processes in layers above the Nth layer, specifically

$$B_{N-1} = \sum_{K=1}^{N-1} \mu_K Z_K \quad [3]$$

$$D_{N-1} = \sum_{K=1}^{N-1} \rho_K Z_K \quad [4]$$

and

$$G_{N-1} = \sum_{K=1}^{N-1} \gamma_K Z_K \quad [5]$$

where μ_K, ρ_K, and γ_K are the attenuation coefficients per unit length in layer K for 23.8 keV gamma rays, 20 keV electrons, and 3 keV electrons, respectively, and Z_K is the thickness of layer K. $\langle F_{N,j} \rangle$ is a more complicated exponential function which gives the attenuation of the incident gamma rays by Mossbauer absorption.

The function H specifies the maximum area contributed by the jth peak of layer N; it has the form

$$H(\beta, Y) = H_o(\beta, Y) - S(\beta, Y) \quad [6]$$

$$H_o(\beta, Y) = (1 - e^{-\beta Y})/\sqrt{\beta^2 - 1} \quad [7]$$

where S is a rapidly converging series and is $<< H_o$ [see Appendix of Ref. (7)]. The parameters $\beta_{N,j}$, $\eta_{N,j}$, and $Y_{N,j}$ to be used in Eq. [7] and [2] are given by

$$\beta_{N,j} = \frac{2(\mu_N + \rho_N)}{q_{N,j} t_o^{(N)}} + 1 \quad [8]$$

$$\eta_{N,j} = \frac{2(\mu_N + \gamma_N)}{q_{N,j} t_o^{(N)}} + 1 \quad [9]$$

and

$$Y_{N,j} = q_{N,j} t_o^{(N)} Z_N / 2 \quad [10]$$

where Z_N is the thickness of layer N, $t_o^{(N)}$ is the effective Mossbauer absorption thickness per unit length in layer N, and $q_{N,j}$ is the probability of the Mossbauer transition giving rise to the jth peak contributed by the Nth layer. The values of the various parameters used in this work are given in Tables II and III.

[6] The quadrupole splitting for SnO_2 is small (0.63 mm/sec) and the two peaks contributed by that phase appear as a single broadened peak in Fig. 2-4.

The gamma-ray attenuation coefficients (μ_N) in Table II were determined from the equations and experimental data given by Heinrich (14) and the electron attenuation coefficients (ρ_N and γ_N) from the empirical expression derived by Cosslet and Thomas (15)

$$\rho_N = \frac{1.4 \times 10^2 \times d_N}{(E)^{3/2}} (A)^{-1} \quad [11]$$

where d_N is the density of phase N and E is the electron energy in eV. $t_o^{(N)}$ is given by

$$t_o^{(N)} = f^{(N)} N_{Sn}^{(N)} a_{119} \sigma_o \quad [12]$$

where $f^{(N)}$ and $N_{Sn}^{(N)}$ are the recoilless fraction and density of Sn atoms in the Nth layer, a_{119} is the isotopic abundance of Sn^{119} (0.086) for natural tin samples, and σ_o is the maximum cross section for resonant absorption. Since the recoilless fraction of $FeSn_2$ had not previously been measured, it was necessary to estimate t_o for this phase by adjusting it to give reasonable values for the $FeSn_2$ thicknesses determined from the measured ERM area percentages for two samples with alloy layer thicknesses that had been separately determined (11) (samples 89 and E of Table I). Additionally, it should be noted that the bulk value of the recoilless fraction for SnO_2 was used. Since the recoilless fraction for the very thin SnO_2 surface layers observed is not necessarily equal to this bulk value, it is possible that some error might arise from this approximation.

It should be emphasized that the validity of using the empirical expression of Eq. [11] to derive the electron attenuation coefficients required for ERM analysis has not been adequately tested. In particular, since it was derived from electron attenuation data for pure metal films (15), its applicability to oxide phases (SnO_2) and intermetallic compounds ($FeSn_2$) is rather questionable. Nevertheless, the oxide, metal, and alloy layer thicknesses determined in this study appear to be quite reasonable for all samples investigated.

With regard to Table III, the probability values for $FeSn_2$ were determined from the relative peak intensities obtained by least squares analysis of the three ERM spectra exhibiting the largest $FeSn_2$ percentages. While the error in these probability values could be as high as 20%, this causes only a small error ($\lesssim 1\%$) in the ERM spectrum areas and percentages, as discussed elsewhere (8).

Table II. Parameter values required for ERM analysis of tinplate

Layer No. (N)	μ_N (Å⁻¹)	ρ_N (Å⁻¹)	γ_N (Å⁻¹)	$t_o^{(N)}$ (Å⁻¹)
1 (SnO_2)	0.785×10^{-6}	3.440×10^{-4}	5.921×10^{-3}	1.425×10^{-5}
2 (Metallic Sn)	1.035×10^{-6}	3.608×10^{-4}	6.211×100^{-3}	2.108×10^{-6}
3 ($FeSn_2$)	0.776×10^{-6}	2.633×10^{-4}	4.533×10^{-3}	3.001×10^{-6}

Table III. Transition probabilities ($q_{N,j}$) used in peak area equations

Phase	Type of spectrum contribution	Transition probabilities
Sn	Single peak	$q_{1,1} = 1.0$
SnO_2	Quadrupole doublet	$q_{2,1} = q_{2,2} = 0.5$
$FeSn_2$*	Six-peak magnetic	$q_{3,1} = q_{3,6} = 0.24$, $q_{3,2} = q_{3,5} = 0.18$, $q_{3,3} = q_{3,4} = 0.09$

* The transition probabilities for $FeSn_2$ are average values determined from the relative areas of the six $FeSn_2$ peaks for the 0.1 and 0.25 lb/bb tinplate samples.

* The percentage errors in the ERM determined thicknesses are approximately 10% for the Sn and $FeSn_2$ layers and 20% for the SnO_2 layer.
** Measured by standard electrostripping technique; all other values in column 2 are nominal coating densities.

The ERM spectrum area percentages are given by

$$P_N = \frac{100 A_N}{\sum_K A_K} = \frac{100 \sum_{j=1}^{M_N} A_{N,j}}{\sum_K \sum_{l=1}^{M_K} A_{K,l}} \qquad [13]$$

where the sum over K extends over the three layers present, SnO_2, metallic Sn, and $FeSn_2$. The area percentages are determined experimentally (Table I), and substitution of Eq. [2] into Eq. [13] then gives three equations that can be solved for the three layer thicknesses, Z_{SnO_2}, Z_{Sn}, and Z_{FeSn_2}.[7] The solution of these three nonlinear equations is accomplished by using a computer program (ZNLAY), described in Ref. (8). The results are shown in Table IV. Column 2 gives either the nominal tin coating density or the value determined by electrostripping techniques (11), and columns 3 through 5 give the ERM-determined thicknesses of the oxide, metallic Sn, and alloy layers in angstroms. These thicknesses may be converted to more familiar units (lb/bb) by using the readily obtained relations

$$W_{SnO_2} = 0.489 \times 10^{-4} Z_{SnO_2} \qquad [14]$$

$$W_{Sn} = 0.650 \times 10^{-4} Z_{Sn} \qquad [15]$$

$$W_{FeSn_2} = 0.384 \times 10^{-4} Z_{FeSn_2} \qquad [16]$$

Equations [14], [15], and [16] give the coating densities in lb/bb of Sn contained in the oxide, metallic Sn, and alloy layers, respectively, with the thicknesses in angstroms. These values and the resulting total tin coating densities are shown in columns 6 through 9. As discussed above, there are a number of possible inaccuracies in some of the parameters used in this analysis of the ERM data; nevertheless, the ERM determined thicknesses and coating densities are seen to be in reasonable agreement with the values in column 2.

Discussion

Since the current report is primarily a survey study, it is useful at this point to discuss some possible future applications of ERM spectroscopy in the area of tinplate research.

Thickness determinations.—Most of the ERM spectra obtained in this study required 10-20 hr of accumulation time to attain reasonable counting statistics. This is clearly a much longer time than required by standard methods of metallic Sn and alloy thickness determination. However, the ERM technique does have the advantage of being nondestructive and might serve as a useful check in any cases where standard methods give results that are questionable for some reason. Additionally, it is worth noting that the current data were obtained using a relatively weak Sn^{119m} source and a constant acceleration Mossbauer spectrometer which scans all velocities simultaneously. By increasing the source strength by a factor of 4 or 5 and using a constant-velocity spectrometer to allow data accumulation only at the velocities where the metallic Sn and alloy layers given their maximum reemission percentages ($v_{Sn} \simeq 0$ mm/sec, $v_{FeSn_2} \simeq 1.5$ mm/sec; see Fig. 3 and 4), the time for ERM thickness determinations could be cut to perhaps 15-30 min.

Oxidation and corrosion studies.—One of the more interesting aspects of the current work is the high sensitivity of ERM spectroscopy to very thin surface layers of tin oxide. For example, the spectrum area percentages measured for the SnO_2 layers on the metallic Sn and unmelted tinplate samples shown in Fig. 2 indicate SnO_2 thicknesses of only 41 and 10Å, respectively, for these two samples. This high sensitivity arises because the recoilless fraction of SnO_2 is 9 times greater than that of metallic Sn (16) ($f_{SnO_2} = 0.45$, $f_{Sn} = 0.05$, at room temperature).

To further illustrate this point, we have used Eq. [13] and [2] to calculate the expected ERM spectrum area percentages for thin layers of SnO_2 over an "infinite"[8] metallic-Sn substrate. The results are tabulated in Table V and displayed graphically in Fig. 5, where the percentage of the ERM spectrum area contributed by SnO_2 (P_{SnO_2}) is plotted against the thickness of the SnO_2 layer (Z_{SnO_2}). It is seen that an SnO_2 layer only 270Å thick will contribute fully 50% of the

[7] The advantage of working with the percentages of the total spectrum area contributed by each phase rather than with the areas themselves is that the constant C in Eq. [2] is thereby eliminated; as discussed in Ref. (7), C involves a background component (arising principally from nonresonant photoelectrons) which is difficult to estimate.

[8] Because of the relatively small penetration range of the 20 keV conversion electrons, any layer thicker than about 20,000Å is effectively infinite to this measuring technique.

Table V. Calculated ERM spectrum area percentages contributed by SnO_2 (P_{SnO_2}) and Sn(P_{Sn}) for SnO_2 layers on a metallic Sn substrate

Z_{SnO_2} (A)	P_{SnO_2} (%)	P_{Sn} (%)

spectrum area, and that oxide layers only a few monolayers thick (~5-20Å) can be detected and studied by this method. As noted earlier, the precision with which the recoilless fraction of very thin layers of SnO_2 matches that of bulk SnO_2 is not known. This could alter our estimates slightly but is not expected to cause any large variation from the behavior shown in Fig. 5. ERM spectroscopy should, therefore, be an excellent technique for oxidation and corrosion studies of metallic Sn.

Summary and Conclusions

ERM spectroscopy has been shown to be a useful new method of studying the thin stannic oxide, metallic Sn, and alloy ($FeSn_2$) layers on tinplate. With a recently developed theory of ERM spectroscopy (7), the ERM data can be analyzed to determine the thicknesses of these three layers. Although such thickness determinations are currently relatively time consuming compared to more standard methods it seems possible that experimental improvements outlined herein might significantly reduce the time required for ERM analysis of tinplate.

Probably the most interesting aspect of the current work is the observed high sensitivity of ERM spectroscopy to very thin tin oxide layers. Oxide layers ranging from a few monolayers to several hundred angstroms thick are readily observed and we know of no other technique for oxidation and corrosion studies involving Sn which combines this high sensitivity to very thin layers with the capability of conclusively identifying the tin oxide compounds which are present.

Threshold Voltage Degradation of MNOS FET Devices

P. K. Chaudhari[*,1]

IBM Systems Product Division, Essex Junction, Vermont 05452

ABSTRACT

A film of Si_3N_4 deposited on thermally grown SiO_2 was studied to determine the effect that charge accumulation at the deposited film SiO_2 interface has on threshold voltage stability. V_T shifts under bias and temperature result from this charge accumulation at the nitride-oxide interface. In addition to this charge buildup-related shift, the second mechanism causing the enhanced shift in V_T is found to occur on long-time, bias-temperature stress. This second mechanism is proportional to the square root of biasing time and is exponentially dependent on temperature. The activation energy is found to be 0.36 ± 0.04 eV. Positive ionic drift is suggested as the mechanism causing this enhanced ΔV_T.

Metal-insulator-semiconductor (MIS) structures consisting of a film deposited on thermally grown SiO_2 have the inherent property of accumulating charge at the deposited film-SiO_2 interface. This charge buildup, which occurs due to different rates of current transport in the two dielectrics (1), presents a serious long-term reliability problem because of its effect on threshold voltage stability of devices. MIS structures consisting of a film of Si_3N_4 deposited on thermally grown SiO_2 were studied to determine the effect of charge accumulation on threshold voltage stability. Voltage shifts were studied as functions of bias, temperature, and stress duration. In this paper, we first describe the fabrication of MNOS FET devices and provide details of measurements. Threshold voltage degradation is next analyzed in terms of the charge accumulation at the insulator-insulator interface as a function of time. A model for threshold voltage degradation enhancement consistent with observed data is presented followed by some conclusions.

Experiment

Experimental MNOS FET devices were fabricated using p-type 1-2 Ω-cm silicon wafers. First, source and drain regions were formed using an arsenosilicate glass source as a dopant (2). After cleaning, the gate oxide was grown. Immediately following thermal oxidation, silicon nitride was deposited on the SiO_2 by decomposition of silane in ammonia.

Aluminum was the gate metal. After aluminum evaporation, the devices were treated with a forming gas anneal at 723°K for 2-5 min. Conventional photolithography was used throughout the fabrication. The high frequency (1 MHz) MNOS C-B technique was used to measure the maximum capacitance, C_{max}, with a control wafer. The equivalent gate dielectric thickness, t_{neq}, was determined from

$$t_{neq} = t_n + t_{ox}\epsilon_n/\epsilon_{ox} = \epsilon_n\epsilon_0 A_c/C_{max} \qquad [1]$$

where t_{ox} is the oxide thickness, t_n is the nitride thickness, ϵ_{ox} and ϵ_n are the dielectric constants of the oxide and nitride, respectively, and A_c is the capacitor area. Mobile ion contamination, checked with a control wafer by the high temperature quasistatic technique (3), was found to be consistently less than 5×10^{10} cm^{-2}.

The aging experiments were performed in the following manner. The gate bias was applied with respect to the commonly interconnected substrate, source, and drain. After a given period at the elevated temperature, the devices were cooled to room temperature with the bias applied. Measurements were made of drain junction leakage, gate-to-substrate leakage, and drain current at a drain voltage of +10V. The MNOS FET device threshold voltage was calculated by a least squares fit to the linear portion of the curve of the square root of the drain current as a function of gate voltage. A data listing was developed showing drain junction leakage current, gate leakage current, and threshold voltage shift, ΔV_{th}, from the initial value on each device throughout each experiment. After each test period, the median ΔV_{th} was calculated. The parameter that exhibited a consistent long-term drift problem was the threshold voltage.

The results presented in the next section deal with the time dependence of the median of the threshold voltage shift.

Results and Discussion

Figures 1 and 2 show the time, temperature, and voltage dependence of ΔV_T for metal-nitride-oxide-silicon devices plotted on a semilog scale. Each data point represents a median value obtained from a sample of 20-30 devices. The deviations from the median are shown as error bars in this and subsequent figures. In general, a maximum of 15-20% spread was observed in all these measured values. The enhanced shift above about 400 hr (Fig. 1) is discussed later.

Such a logarithmic behavior has also been observed by Rossel, Martinot, and Serhal (4) for MOSFET's. The V_T stability data of Fig. 1 and 2 cannot be explained by mobile ion motion or by slow surface-states

trapping. The mobile ion density is less than 5×10^{10} cm^{-2}. This density can produce a maximum ΔV_T of ~75 mV for the devices with $t_{neq} = 1000$Å gate dielectric. V_T shifts have been observed which are much larger than 75 mV. Slow surface-state trapping produces a positive V_T shift under positive stress and a negative V_T shift for negative stress. However, experimental data is of the opposite polarity, *i.e.*, $\Delta V_T < 0$ for positive stress. Therefore slow-state trapping cannot produce the observed V_T shifts. Charge buildup at the Si_3N_4-SiO_2 interface occurs as a result of different rates of current transported in the two dielectrics (1). This accumulation of the charge density Q_I at the insulator-insulator interface shifts the threshold voltage V_T when the device is biased because $J_n \neq J_{ox}$. This dual dielectric model predicts that a positive stress produces a negative ΔV_T and vice versa. This observation is found in our samples. For our samples, $J_n << J_{ox}$. Hence a large amount of charge accumulation will accumulate at the oxide-nitride interface, and ΔV_T will not show a saturation as is seen in Fig. 1 and 2. Therefore qualitative agreement between the experimental data and the model gives good evidence that the dual dielectric instability is the cause of the V_T shifts in MNOS FET devices. A detailed knowledge of the oxide and nitride conductivity *vs.* field relation, the various barrier heights, and the trap distributions throughout the nitride-oxide insulator is necessary to predict the time, temperature, and voltage dependence of the V_T shifts. For practical purposes, the results of this investigation can be combined into a single phenomenological expression

$$\Delta V_T = K \ln t/t_o \quad [2]$$

where K is a function of temperature and voltage and is expressed as (see Fig. 3 and 4)

$$K = K_o \exp\left[-\frac{\phi}{kT} + \beta E_n^{1/2}\right] \quad [3]$$

with $\phi = 0.65 \pm 0.05$ eV and K_o includes various incident constants.

Threshold Voltage Shift Enhancement

It is seen in Fig. 1 that beyond about 400 hr the shift in the threshold voltage increases faster than that observed below 400 hr. The results suggest that another mechanism seems to be operative in addition to the above-mentioned interfacial trapping mechanism. To establish the contribution of this second mechanism to the total threshold voltage shift ΔV_T, we will further assume that these two mechanisms are independent of each other. Under these two assumptions, the second mechanism can be identified as described below. The initial shift (below 400 hr) is extrapolated beyond 400 hr as shown dotted in Fig. 1. The difference between the extrapolated line and the observed data ΔV_i, also shown in Fig. 1, is then the contribution due to the second mechanism which causes the enhanced threshold voltage shift. Consistent with the experimental data analysis discussed below, we can now characterize the second mechanism and establish its physical model. Data of Fig. 5 indicate that with the positive bias and temperature (B-T) stress, the enhancement in V_{th} shift is negative.

Surface-state trapping produces a positive threshold voltage shift under positive stress and a negative V_{th} shift for negative stress. However, the experimental data is of the opposite polarity, *i.e.*, $\Delta V_{th} > 0$ for negative stress and vice versa, and therefore surface-state trapping cannot produce the observed V_{th} shifts. Secondly, from Fig. 5, important features of this degradation to be noted are that (*i*) the onset of ΔV_i occurs after some stress time; (*ii*) the onset is very sensitive to the temperature of stress; while (*iii*) it is almost independent of the stress voltage. Figure 6 shows the time dependence of ΔV_i with temperature as a parameter. It is clear that ΔV_i follows a $t^{0.5}$ behavior quite

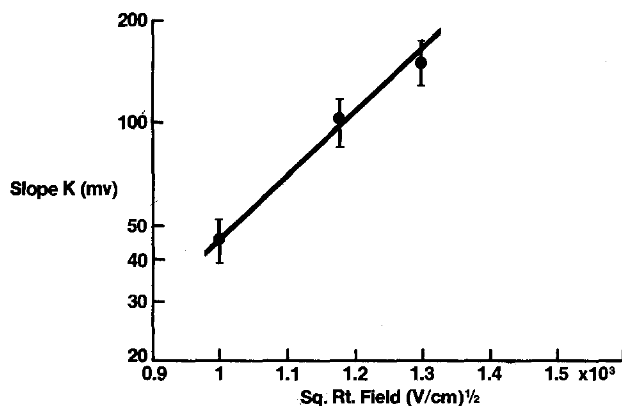

Fig. 3. Slope K derived from ΔV_{th} *vs.* ln t graph as a function of field at 438°K.

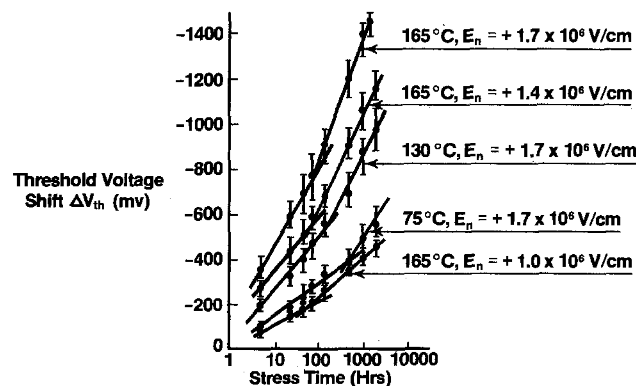

Fig. 5. Total threshold voltage shift as functions of time, bias, and temperature.

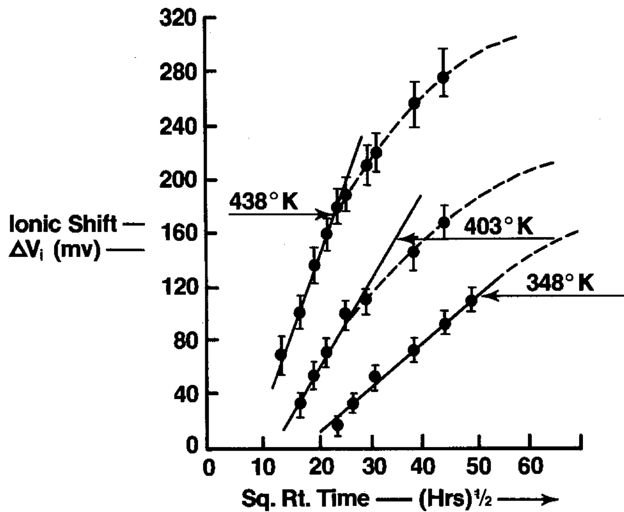

Fig. 6. Ionic component ΔV_i as a function of the square root of time.

well with the tendency to saturate. Note further that the saturation value is different for different temperatures. A plot of the slope $\Delta V_i \times t^{-0.5}$ obtained from Fig. 6 as a function of the reciprocal temperature is shown in Fig. 7, with an activation energy of 0.18 $\pm$ 0.02 eV. Therefore, the time and temperature dependence of the second mechanism can be represented by the empirical relation

$$\Delta V_i \sim t^{0.5} \exp(-H/kT), \text{ with } H = 0.18 \pm 0.02 \text{ eV} \quad [4]$$

Snow *et al.* (5) reported a ΔV_{FB} *vs.* $t^{0.5}$ dependence, and it was later verified by Singh *et al.* (6), of Na^+ transport through thermally grown SiO_2 films, deliberately contaminated in aqueous NaCl solutions. Eldridge and Kerr (7) have also reported such a time-dependent instability in sodium-contaminated PSG-SiO_2 films. This time dependence can be attributed also to the temperature- and field-induced emission of ions from trapping centers located near the metal-nitride interface. As shown by Hofstein (8), who computed the effect of small Gaussian distributed spreads in the activation energy for ion emission from such traps in MOS structures, the quantity of the drifted ions is closely proportional to $t^{0.5}$. The results thus conform to an enhanced V_T shift model based on the emission of positive ions from Si_3N_4 layer into the SiO_2 film. In addition, when all the device leads were shorted at stress temperature, subsequent measurement of the V_T shift indicated that after about 6 hr the threshold voltage shift followed the dotted line (see Fig. 1) which is the differential conductivity dominant mechanism. This observation verifies the fact that positive ions responsible for the ΔV_i are driven away from the SiO_2-Si interface (5).

The transport process is a thermally activated process with an activation energy $H = 0.18 \pm 0.02$ eV (see Fig. 7). If the transport of ions from the Si_3N_4-SiO_2 interface is assumed to be the diffusion dominant mechanism, the activation energy of the diffusion coefficient D can be determined as follows.

From simple diffusion kinetics, the diffusion coefficient is given by

$$D = t_n^2/t \quad [5]$$

Combining Eq. [3] and [4], we get

$$D \sim t_n^2 \exp(-2H/kT) \quad [6]$$

Therefore, from Fig. 7 and Eq. [6], the diffusion coefficient activation energy is determined to be 0.36 $\pm$ 0.04 eV. This value is about the same as that reported for hydrogen ions (protons) in SiO_2 (9, 10). The activation energy for Na^+ in SiO_2 is about 1.0 eV (5, 7). Secondly, the mobile ion contamination in the devices studied here was consistently less than 5×10^{10} cm^{-2}, which would cause ΔV_i max to be about 50 mV, which is not consistent with the data (see Fig. 1). Furthermore, if the ionic source is finite, then, for a fixed bias, the saturation value for different temperatures should be the same (5). But the value ΔV_i sat. is, as seen in Fig. 6, found to be different for different temperatures, indicating that the source of ions is not due to extraneous contamination, but is an inherent property of Si_3N_4 films. The supporting evidence for this conclusion is cited below. Si_3N_4 deposition with the components NH_3, H_2 used here, invariably results in Si-H, N-H traps (11, 12) as well as free hydrogen (12, 13). These traps are most likely to be concentrated at the two interfaces, Si_3N_4-SiO_2 and metal-Si_3N_4. Under B-T stress, these traps could release protons or H_2^+, thereby causing the observed enhancement in the threshold voltage shift. However, the role played by Na cannot be ruled out as well. Figure 8 shows schematically the proposed model for this ionic shift which conforms to the above discussion.

Conclusions

A study was made of the threshold voltage shifts in double layer insulator MNOS FET devices after bias-temperature treatment. The threshold voltage shifts encountered under positive bias can be explained by the existing dual dielectric instability model effect. The enhanced threshold voltage shifts observed can be explained only if, in addition to the dual dielectric instability model, a positive ion motion through the insulator is assumed. The positively charged ions initially located close to the metal-nitride interface are transported to the Si_3N_4-SiO_2 interface and are subsequently swept to the SiO_2-Si interface with an activation energy determined to be 0.36 $\pm$ 0.04 eV. In agreement with the experimental results, the source of these ions is proposed mainly to be hydrogen, the presence of which is inherent due to the Si_3N_4 process.

Although the large threshold voltage shifts described here are not necessarily typical of MNOS structures,

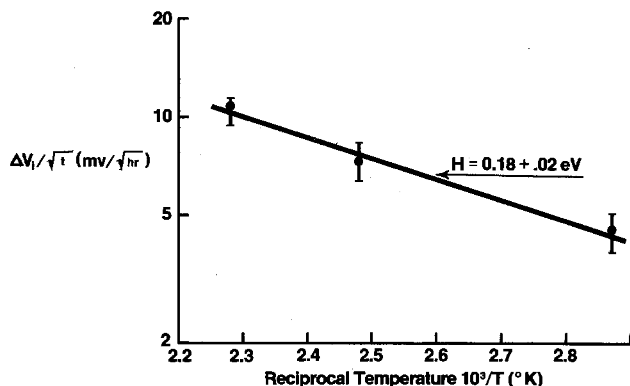

Fig. 7. $\Delta V_i \times t^{-0.5}$ as a function of reciprocal temperature

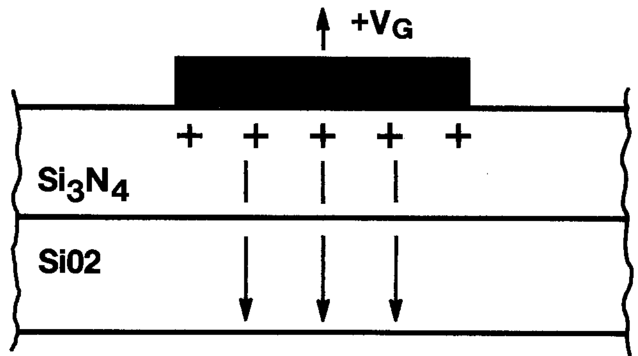

Fig. 8. Schematic representation of the enhanced threshold voltage shift model.

the data represents the kind of instability that can occur. Analysis of this data has led to the characterization of the responsible mechanisms presented here, and thereby provided a model from which insights can be obtained regarding appropriate process changes for enhancement of device reliability.

Acknowledgments

The author is grateful to Bernard Laflam for making many measurements. He also thanks Arup Bhattacharyya, Wendell Noble, and Robert Dockerty for many helpful discussions. Special thanks go to Joseph Franz and Nick Patrin for critically reviewing the manuscript.

Manuscript submitted Sept. 22, 1977; revised manuscript received May 11, 1978. This was presented in part as Paper 43 presented at the San Francisco, California, Meeting of the Society, May 12-17, 1974, and as Paper 123 presented at the Dallas, Texas, Meeting of the Society, Oct. 5-9, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by IBM Corporation.

Semiconducting Oxide Oxygen Electrodes

A. C. C. Tseung*

Department of Chemistry, The City University, London ECIV 4PB, United Kingdom

ABSTRACT

Traditional oxygen electrocatalysts do not dissociatively chemisorb oxygen, resulting in electrochemical irreversibility. The joint pseudo-splitting/peroxide mechanism suggests that the main requirement is for the oxygen molecule to be chemisorbed side on: O–O. This condition will be satisfied by paramagnetic oxides, such as high surface area lithiated nickel oxide and $La_{0.5}Sr_{0.5}CoO_3$ perovskite oxide. Such electrodes exhibit steady and reproducible open-circuit potentials which are very near the theoretical values and the variation with oxygen partial pressure follows the Nernst equation for a four-electron process. The current density at constant polarization is directly proportional to the square root of oxygen partial pressure. Homomolecular oxygen studies confirmed that oxygen is dissociatively chemisorbed on such oxides and there is a good correlation between the activation energies for the isotopic exchange and electrochemical reduction of oxygen, suggesting a similar mechanism is involved in each case.

The cathodic reduction of oxygen in alkaline solution

$$O_2 + 2H_2O + 4e \rightarrow 4\,OH^- \quad [1]$$

presents one of the challenging problems in electrochemistry. The standard reduction potential is

$$E^\circ = -0.401V \text{ vs. NHE} \quad [2]$$

resulting in a theoretical H_2/O_2 full cell potential of 1.229V at 25°C. This potential has seldom been achieved in practice and most oxygen electrocatalysts exhibit open-circuit potentials between 0.1 and 0.2V below the reversible value. Rotating ring disk measurements (1) have shown that the oxygen reduction does not go through a direct four-electron process but normally takes place via a HO_2^- intermediate

$$H_2O + O_2 + 2e \rightarrow OH^- + HO_2^- \quad [3]$$

This results in a drastic reduction of the open-circuit potential and over-all efficiency. On most catalysts other than carbon, HO_2^- can be further reduced either electrochemically by

$$HO_2^- + H_2O + 2e \rightarrow 3\,OH^- \quad [4]$$

or by direct chemical decomposition of HO_2^-

$$2HO_2^- \rightarrow O_2 + 2\,OH^- \quad [5]$$

Thus three possible routes are available for improving the kinetics of the oxygen reduction process:

(*i*) To speed up the rate of electrochemical reduction of HO_2^-. This is not likely to be fruitful since $HO_2^- \rightarrow 3\,OH^-$ is known to be highly irreversible.

(*ii*) To speed up the rate of chemical decomposition of HO_2^-. This approach has been tackled empirically by many industrial establishments, *e.g.*, the use of spinel oxides and Ag supported on carbon, with some degree of success. Theoretical and experimental studies on the system cobalt iron oxide/graphite by Goldstein and Tseung (2) showed that in order to achieve reversible oxygen electrode potentials, the $[HO_2^-]$ would have to be reduced to 6×10^{-18}M; this would require the peroxide decomposition catalyst to have a rate con-

* Electrochemical Society Active Member.

Key words: oxygen reduction, semiconducting oxides, paramagnetic behavior.

stant of 4×10^6 sec^{-1} g^{-1}. However, the most active cobalt-iron oxide tested, $Co_{2.4}Fe_{0.5}O_4$, the rate constant for peroxide decomposition is only 0.243 sec^{-1} g^{-1}. Pt-black and Ag-black catalysts are only marginally better. Consequently, several orders of magnitude increase in catalyst activity is required to achieve open-circuit potential close to the reversible oxygen potential.

(*iii*) To induce the oxygen reduction process to go directly, by passing the HO_2^- intermediate. Isotopic studies by Davies, Clark, Yeager, and Hovorka (3) showed conclusively that the O = O bond of the oxygen molecule remains unbroken on conversion to peroxide. Thus, the key to the solution of the oxygen electrode problem may lie in the electrocatalyst's ability to dissociatively chemisorb oxygen. If this condition is fulfilled, no HO_2^- intermediate can be formed and the oxygen reduction will go directly to hydroxyl ion via a four-electron process. This approach should be far more rewarding than the first two routes.

The Joint Pseudosplitting-Peroxide Mechanism

The direct splitting of the O = O bond requires 117°K cal/mole. Evans (4) proposed that O_2 molecules are adsorbed "side-on"; O–O, without dissociation, on surfaces covered by adsorbed anions, such as OH^-. The O_2 molecules enter into hydrogen-bonding with OH^- ions and this bonding spreads across the OH^- layer. At certain specific sites, *e.g.*, "kink" sites, there will be discontinuities in the OH^- "carpet" so that for steric reasons, the OH^- ions will be more likely to enter into hydrogen bonding with nearby H_2O molecules of the electrolyte. At this point the O = O bond is effectively broken (pseudo-split). One consequence of such proton-switching is that the activation energy for bond rupture is lowered considerably. Proton-switching is a process which occurs easily, *e.g.*, in the rapid neutralization of acid with alkali or of the great mobility in solution of such species as OH^- or H_3O^+. The four stages of pseudo-splitting are shown in Fig. 1. Goldstein and Tseung (5) proposed that since the reduction of oxygen on most electrocatalysts goes via the peroxide intermediate, it is necessary to consider the case when the oxygen molecule is chemisorbed "end on": O || O. In such cases, the pseudo-splitting process will lead to the formation of HO_2^- as well as OH^- (Fig. 2). It is therefore suggested that a necessary condition for dissociative chemisorption of oxygen is for the oxygen molecule to be adsorbed "side-on" on the electrocatalyst surface.

The Importance of Semiconducting Oxides

Apart from the exceptional cases of selected precious metals at high overpotentials, the oxygen reduction on nonnoble metal alloys or compounds takes place on oxide-covered surfaces. Since it is difficult to control or study the properties of oxide films, it is more convenient and practical to study oxygen reduction on specially prepared oxides. The conductivity of most transition metal oxides can be significantly improved by doping with suitable oxides whose cation is of lower valency than the cation in the host oxide (6). If doped oxide powders are used as Teflon-bonded electrodes supported on metal screens, then the likely ohmic drop due to the use of semiconducting oxide is given by (7)

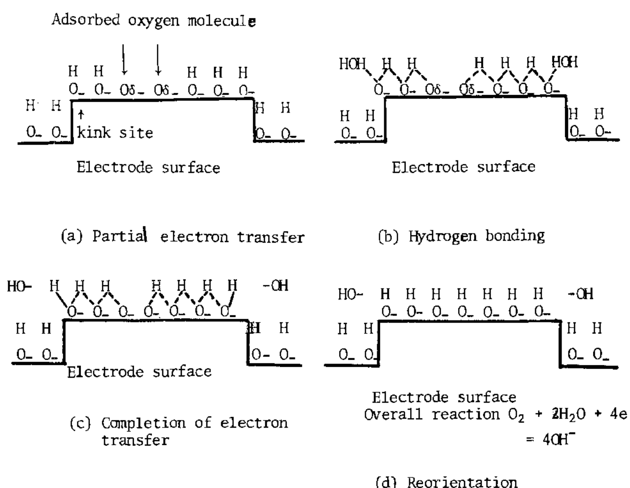

Fig. 1. Stages in pseudo-splitting

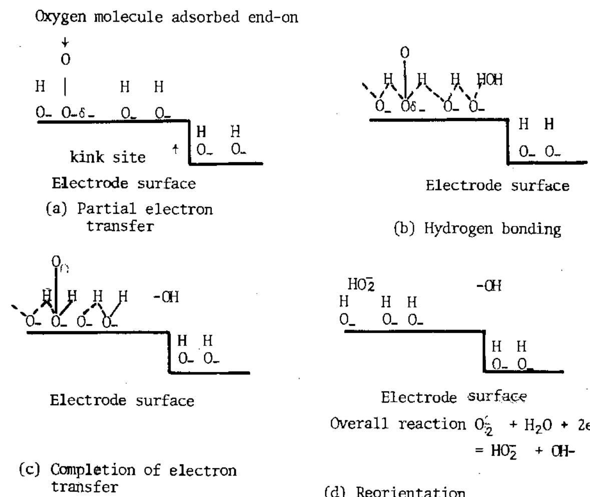

Fig. 2. Stages in the peroxide mechanism

$$IR = \rho \frac{iL^2}{16t}$$

Where I is the total current, amp; R is the total resistance of the electrode, Ω; i, current density, A/cm²; L, length of each side of the square hole in the metal mesh, cm; ρ, resistivity of the catalyst/Teflon layer, Ω cm; t, thickness of catalyst/Teflon layer, cm. Taking the typical case of Teflon-bonded porous electrode supported on 100 mesh metal screen, L is 0.04 cm and t is 0.025 cm. Hence if the catalyst/Teflon layer has a resistivity of 100 Ω cm and operating at 0.5 A/cm², the IR loss will be about 0.2V, which is just acceptable. In actual practice, taking into account the increased resistivity due to the presence of Teflon particles and contact resistance between the catalyst powder, the maximum allowable bulk resistivity of semiconducting oxide used for such applications is limited to 10-15 Ω cm.

Relationship Between the Mode of Oxygen Chemisorption and Magnetic Properties of Semiconducting Oxides

The oxygen molecule is paramagnetic. It has two unpaired electrons with parallel spins in antibonding π orbitals. Therefore, electrons transferred at, or subsequent to, bond-rupture, from the catalyst to the adsorbed oxygen species, must similarly be of parallel spin. This immediately suggests the use of paramagnetic or ferromagnetic oxides. On the other hand, antiferromagnetic compounds, in which cations are arranged with unpaired spins aligned on alternate (111) planes, will not be able to satisfy the above requirement. Lithiated nickel oxide has been studied in far greater detail than any other oxide since it is one of the first doped semiconducting oxides discovered by Verwey *et al.* (6).

Nickel oxide in its normal macroscopic state is antiferromagnetic. It becomes paramagnetic at the Neel point, T_N at 523°K (8). The magnetic transition is associated with a crystallographic transition from rhombohedral to cubic structure (9). Parravano and Boudart (10) found several physical anomalies near the Neel point of NiO. Its significance to catalytic activity was

briefly mentioned by other workers (11-13). Both Keier (14) and Charman, Dell, and Teele (15) noticed that a definite change of mechanism of O_2 chemisorption took place near 250°C. Winter (16), however, was the first to suggest that the change in the mechanism of O_2 chemisorption was attributable to the magnetic transition. He assumed that the chemisorption took place predominantly at exposed edges of magnetic domains. Below T_N, magnetostriction prevents the formation of two Ni^{+++} as adjacent nearest neighbors so that adsorption occurs as O_2^-. Above T_N, the restriction is removed and O_2 can be adsorbed as 2 O^-. Therefore, it would be interesting to observe changes in the electrochemical behavior on passing through the Neel point and, if the changes are favorable, to find methods of reducing the Neel point, or prepare other compounds with lower T_N, which will hopefully exhibit reversibility to O_2 reduction at lower temperatures.

Electrochemical Reduction of Oxygen on Lithiated Nickel Oxide Electrodes

Tseung, Hobbs, and Tantram (17) studied the electrochemical reduction of oxygen on lithiated nickel oxide at 150° and 220°C and found that there was a six-fold improvement in performance at 220°C. The open-circuit potential changed from 1.10 to 1.16V, very close to the theoretical open-circuit potential (75% KOH, 220°C, $E° = 1.17V$). Doping with lithium (18) is known to lower T_N by about 20°C. (Neel point of NiO single crystal is ~250°C). It is, therefore, suggested that oxygen is being dissociatively chemisorbed above the Neel point, thus by-passing the formation of peroxide intermediate, leading to reversible behavior and improved performance.

Richardson and Milligan (19) found a remarkable variation of magnetic susceptibility with specific surface area. As the mean particle size diameter decreased to below 200Å, the magnetic susceptibility curve developed a large peak, the position of which on the temperature axis was so dependent on the particle size diameter that for some powders, values of T_N below room temperature were observed. Cohen *et al.* (20) as well as Kawada and Kawai (21) confirmed the above results and showed that NiO powders with a mean particle size diameter of 130Å exhibited paramagnetism at room temperature. Bevan and Tseung (22) investigated the properties of high surface area lithiated NiO (180 M^2/g) prepared by the Technier method (23) and found that electrodes prepared from such powders exhibited reversible behavior at 150°C instead of 220°C found earlier for low surface area lihiated NiO samples (1-2 M^2/g). The steady-state polarization curves in 75 weight percent KOH are fundamentally different from those obtained previously for any oxygen reduction catalyst: the curve is linear over the whole potential range (Fig. 3). At a given polarization, the current density varies directly with $\sqrt{p_{O_2}}$. The variation of OCV with oxygen partial pressure is also interesting. The slopes in each case are almost exactly equal to $RT/4F \times 1/2.303$ per pressure decade, which suggests very strongly a four-electron over-all reaction. In addition, after cathodic polarization, the electrode potential returned to its original value in less than a minute. A plot of current density *vs.* $1/T$ gave a perfect straight line plot between 140°-250°C indicating that there is no change in mechanism (Fig. 4). The electrode exhibits irreversibility at temperatures below 140°C, even though the Neel point of the sample should be at room temperature (mean particle diameter 49.9Å). Though the mean particle diameter is small, electron microscopic examination confirmed the presence of particles whose diameter is greater than the critical particle diameter suggested by Richardson and Milligan (50 M^2/g, ~ 180Å particle). These large crystallites would be expected to show the normal antiferromagnetic behavior of massive nickel oxide, *i.e.*, Neel point 220°-250°C. These particles will not be able to dissociatively chemisorb oxygen below their Neel point and hence the reduction of oxygen on such particles will involve the production of HO_2^-, giving rise to a mixed potential and irreversible behavior, especially when the temperature is significantly lowered.

Sr-Doped $LaCoO_3$ Perovskite Oxides

The work on lithiated NiO has shown that it is necessary to use semiconducting oxides which are paramagnetic at room temperature, regardless of particle size. The Neel temperatures of the oxides of first row transition metals with rock-salt structure increase in the order Mn, Fe, Co, NiO. Unfortunately, all the oxides other than NiO are not sufficiently corrosion resistant in hot, concentrated KOH to merit consideration. Therefore, attention was concentrated on the perovskite oxides, such as Sr-doped $LaCoO_3$, which has a Neel point at 90°K (24). The Sr doping of $LaCoO_3$ increases the specific conductivity by increasing the number of Co^{3+}/Co^{4+} couples. In addition, the number of trivalent cobalt ions in the high spin state is increased (four unpaired spins per ion). Tseung and Bevan (25) prepared a series of $Sr_xLa_{1-x}CoO_3$ samples by freeze-drying (38 M^2/g). These oxides are corrosion resistant even at 220°C, 75% KOH and the resistivity of the powder is 0.1-1 Ω cm.

Of all the electrodes tested, only $La_{0.5}SrO_{0.5}CoO_3$ that had been leached at 220°C, 75% KOH overnight to remove unreacted free oxides, had open-circuit potential (OCV) approaching the theoretical value. Table I shows the observed value as a function of P_{O_2} at 25°C,

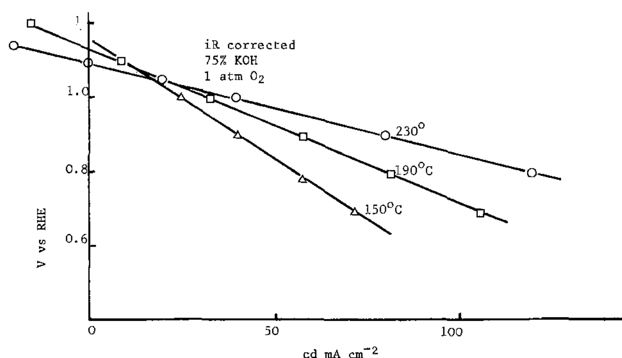

Fig. 3. V-i curves for lithiated NiO (180 M^2/g)

45% KOH electrolyte. This shows that the electrode obeys the Nernst equation for a four-electron process and that there is an excellent agreement with calculated values.

Figure 5 shows the current-potential curve of various leached Sr-doped $LaCoO_3$ electrodes as well as a Pt Teflon-bonded electrode at 25°C. It is worth noting that the Sr-doped $LaCoO_3$ electrodes, apart from showing the theoretical OCV, do not change the slope of the current-potential curve on changing from the cathodic to anodic mode or vice versa, again confirming that they are truly reversible. On the other hand, $LaCoO_3$- and Pt-black are not reversible. By plotting the current density at 900 mV *vs.* DHE as a function of temperature, a linear relationship is obtained (Fig. 6). The performance of $La_{0.5}Sr_{0.5}CoO_3$ surpasses that of Pt-black at 170°C.

At first, it was thought that the performance was controlled by the number of "active sites" at the surface which could associate with the absorbed oxygen molecules. At higher temperatures, the lattice expands and the interaction between cations in the bulk and between the bulk and surface cation is reduced. Thus the magnetic susceptibility decreases and the number of active sites is increased. However, recent "oxygen stripping" measurements by Yeung and Tseung (26) showed that the oxygen coverage is independent of temperature and the oxygen coverage is low, about 2-3% of the perovskite oxide surface. A comparison of the steady-state performance and potentiostatic pulse performance of $Nd_{0.5}Sr_{0.5}CoO_3$ and $La_{0.5}Sr_{0.5}CoO_3$ electrodes revealed significant differences in performance,

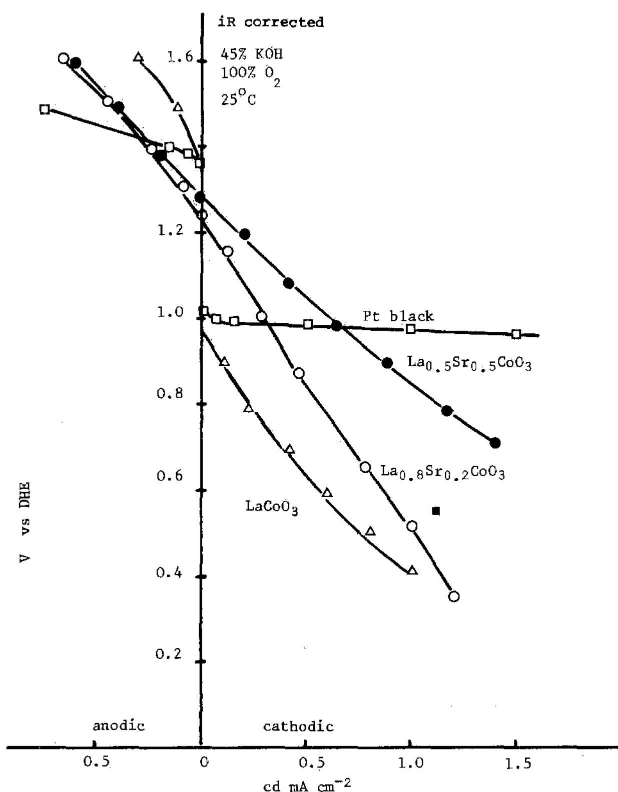

Fig. 5. *V-i* curves for Pt-black and $Sr_xLa_{1-x}CoO_3$ electrodes

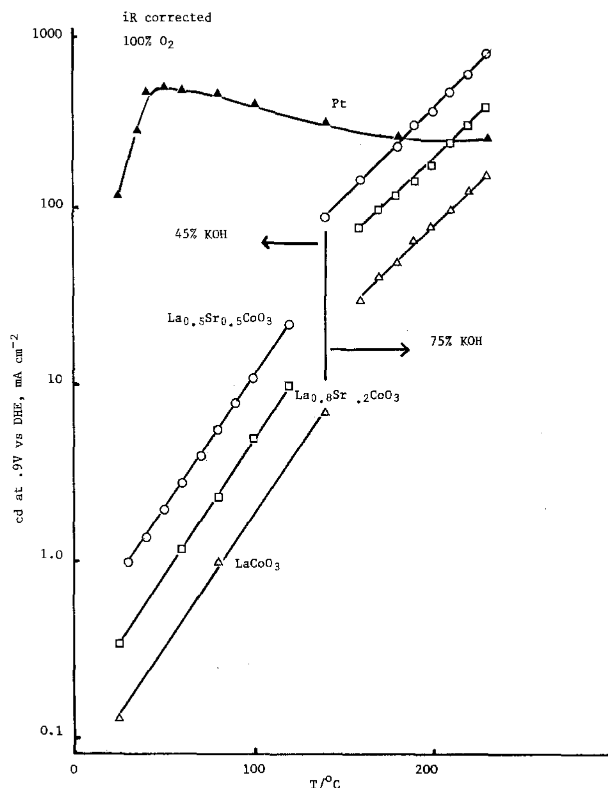

Fig. 6. *CD vs.* temperature

not accountable by mass transfer effects within the Teflon-bonded porous electrodes. The recent results suggest that the rate of oxygen chemisorption might be the controlling factor and further mechanistic investigations in this direction should be very fruitful.

Direct Evidence of Dissociative Oxygen Chemisorption

Up to now, all the electrochemical studies showed that there is a good correlation between the mode of oxygen chemisorption and the magnetic properties of lithiated nickel oxide and $La_{0.5}Sr_{0.5}CoO_3$. Hibbert and Tseung (27), by studying the rate of homomolecular exchange between $^{16}O_2$ and $^{18}O_2$, proved conclusively that oxygen can be dissociatively chemisorbed above the Neel point of lithiated nickel oxide and $La_{0.5}Sr_{0.5}CoO_3$. In addition there is close correlation between the activation energy for the dissociative oxygen chemisorption and electrochemical oxygen reduction, suggesting a similar mechanism is involved in each case.

Suggestions for Future Work

All the evidence obtained during the last ten years points to the importance of magnetic behavior of semiconducting oxides in determining the mode of oxygen chemisorption and, hence, more effort should be devoted to other paramagnetic oxides which satisfy other essential requirements such as specific conductivity and corrosion resistance. Furthermore, there is an urgent need to involve solid-state chemists and physicists to study the nature of the active sites in the paramagnetic oxides and the fundamental factors governing the rate of dissociative oxygen chemisorption (28).

Quenched-In Bulk Defects and Interface States in MOS Structures Measured by Transient Capacitance Spectroscopy

K. L. Wang*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The induced defects and interface states in MOS structures as a result of high temperature oxidation are investigated using a transient capacitance technique. Samples after dry oxidation at 1000 C were slowly cooled down to 700°C before pulling out. The densities of traps and interface states were shown to be two to five times lower for the slowly cooled samples than that for the fast cooled ones. The major bulk traps are at $E_c - 0.26$ and $E_c - 0.49$ eV, while the major interface state distribution resides at $E_c - 0.6$ eV. The carrier generation both in the bulk and at the interface is shown to be reduced on slow cooling. The results suggest that the interface states and the bulk traps are the consequence of quenched-in impurities.

The origins of defect states and interface states after a high temperature annealing is a subject of current interests and controversies (1-5). Their effects on the device degradation have been demonstrated. The oxidation-induced stacking faults in some cases have been demonstrated to be responsible for the minority carried generations (dark current in MOS capacitors and charge coupled devices, CCD, and other MOS related devices), while others are not (6, 7). The residual interface states on hydrogen annealing can result in surface generation and recombination. The origins of these interface states are considered as a result of the dangling bonds still present after the hydrogen bond coordination at the interface (8, 9). Others attributed to the effects of oxygen-induced phenomena (10, 11).

The purpose of this paper is to demonstrate that the induced-defect and interface-state densities can be further reduced by slow cooling. The "quenched-in" defects and interface states were measured using a highly sensitive transient capacitance technique (12-14). The effects of these states on carrier generations and gate-controlled diode reverse current characteristics are reported. It is concluded that the residual bulk traps and the interface-state densities may be the consequence of quench-in impurities and stress-induced phenomena and may be reduced through proper fabrication procedures.

Experiments

Sample preparations.—Test P-channel FET's were fabricated using a standard Al-gate process (on N-type substrate, $N_D = 1.5 \times 10^{15}$ cm^{-3}). The material used is commercial 4 Ω-cm crystals. The gate oxidation was carried out at 1000°C in dry oxygen followed by He annealing for 1 hr. After the He annealing, type A samples were cooled rapidly by pulling the samples out within a few seconds. Type B samples were cooled very slowly by shutting the furnace down until the sample temperature reached 700°C; the sample was then pulled out of the furnace. The cooling rate is about 0.5°C/min.

Transient capacitance spectroscopy.—The transient capacitance spectra were obtained as described elsewhere (12-14). For the fast cooled samples, the spectra of electron and hole emissions under different pulsing conditions were obtained. From the electron trap spectra when pulsing the gate bias from -6 to $+2$V,

the bulk trap emission and the interface-state emission (a continuous distribution) were calculated. The population of the interface states depends on the gate bias applied. All the interface states throughout the bandgap are populated when biased at +2V and entirely depopulated while at −6V. Thus, when pulsing from −6 to 2V, not only the emission for the interface states above the midgap, but also the emission from some of those states below the midgap can be detected; one obtains the distribution of densities of states (with some of bulk trap interference) from E_C to E_C −0.65 eV showing in the upper curve of Fig. 1. The details as of how to obtain the energy scale can be referred to elsewhere (2, 14). The bulk trap interference can be subtracted when their densities are measured. For convenient comparison purposes, the contributions of the bulk traps are left unsubtracted. The maximum peak signal of the surface-state densities occurs at E_c −0.6 eV. In the interface-state measurements, the bulk trap signal can be minimized by using a small gate bias (2). The doping density ($N_D = 1.5 \times 10^{15}$ cm^{-3}) and the depletion depth under various bias conditions used for calculating the densities of the states can be obtained from the depletion *C-V* curve. Similarly, in the hole trap measurements, one obtains the densities of states from the valence band up to the midgap. In the hole trap measurements, however, the signal mostly comes from the emission of the interface states. Thus, the bulk hole trap interference is small. The lower curve in Fig. 1 shows the interface-state density of slowly cooled samples for later comparison purpose.

When pulsing the gate from −6 to −4V, the interface states throughout the bandgap are depleted all the time. As a result, only the bulk trap emission is detected. Under this condition two distinct peaks, E_1 at E_c −0.26 and E_2 at E_c −0.49 eV, are obtained and illustrated in the upper curve of Fig. 2. Their corresponding capture cross sections are 9×10^{-17} and 3×10^{-16} cm^2, respectively. The energy was determined under the bias condition to avoid the interference from the interface-state signal. In the hole trap measurement, since the space charge depth in inversion cannot be altered by selecting the bias condition, the bulk traps cannot be unambiguously measured. Thus, only the electron bulk traps are illustrated in Fig. 2.

For the slowly cooled samples (type B), the densities of interface and bulk states are calculated similarly, as illustrated in the lower curves of Fig. 1 and 2, respectively. A reduction of the densities of states for the slowly cooled samples are clearly shown in the figures.

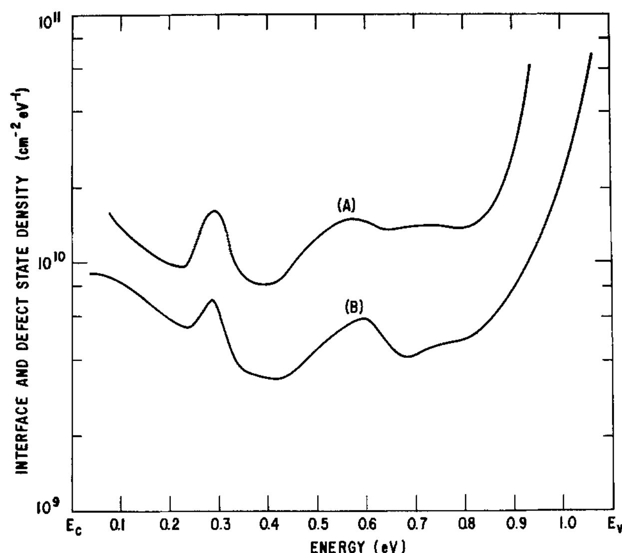

Fig. 1. The upper curve shows the interface state and the bulk trap density in the region from 1.3 μm to the surface for fast cooled samples. The lower curve shows the same density of state distribution for slowly cooled samples.

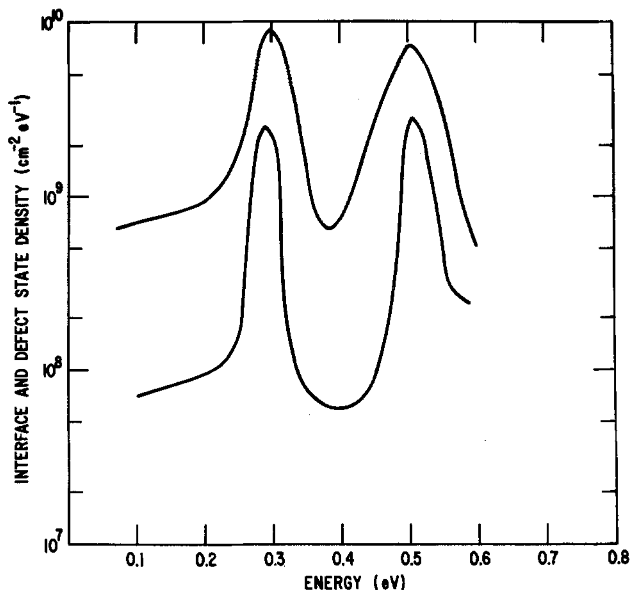

Fig. 2. The upper and lower curves illustrate the bulk traps in the region from 1.3 to 0.5 μm for fast cooled and slowly cooled samples, respectively.

For samples slowly cooled to 700°C when subjecting to a second 1000°C treatment, lower interface-state and bulk trap densities were observed as compared to those for the fast cooled ones. This suggests that the bulk trap and interface states observed bear no relations to the oxidation process per se. It should be noted that the oxygen content in the region of interest (*i.e.*, the space charge depth of 4 μm) is about 2×10^{17} cm^{-3} after the oxidation. This oxygen content depends on the oxidation temperature only, regardless of whether Czochralski material or float zone material is used (15).

Surface generation and bulk carrier lifetime.—To study the interface-state effects to the carrier generation under the gate, the gate-control diode measurements (16) were carried out in the same structures as those used in measuring the transient capacitances. The difference of the surface generation currents for the cases when the surface is depleted and when inverted is obtained as a function of temperatures. The A-type samples (fast cooled) have a higher over-all surface recombination velocity than the slowly cooled samples (B type). The Arrhenius plots of the surface current density for both sample A and B are illustrated in Fig. 3 showing almost identical activation energy, 0.68 and 0.67 eV, respectively. The surface generation current in terms of the surface recombination velocity S_o is

$$J_s \cong S_o(N_v N_c)^{1/2} \exp - (E_g/2 + \Delta E)kT \quad [1]$$

where N_c and N_v represent the densities of states of the conduction and valence bands, respectively. Usually the interface states near the midgap predominate for the surface generation for a uniform distribution (17). The ΔE is a slight deviation to indicate the small increase of activation energy to effectively take the nonuniform interface-state distribution into account. The activation energy appears to suggest that there are high densities of states at below the midgap. It should be stated that the activation energy obtained does not represent the dominant interface-state peak since the generation current is an integral of weighted average. The average is weighted more heavily near the midgap with the exponentials of energy levels in the Hall-Shockley-Read kinetics.

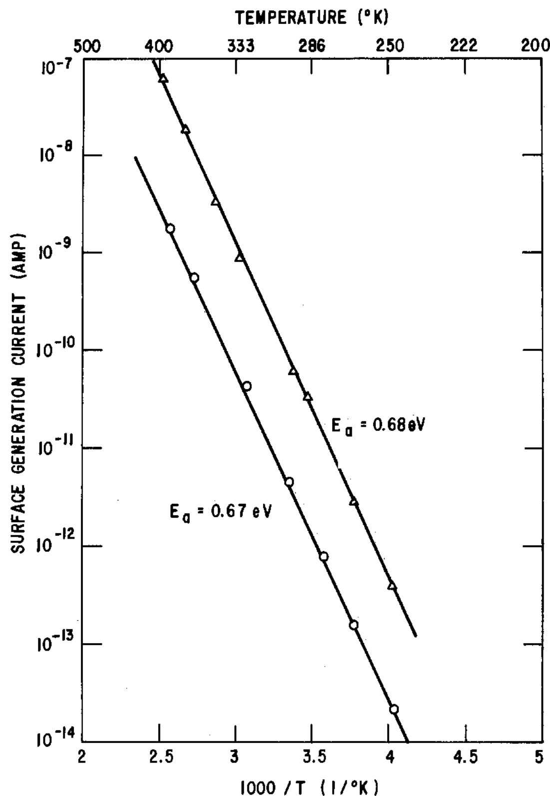

Fig. 3. Surface generation current vs. 1/T. The slowly cooled samples give an activation energy of 0.67 eV, while the fast cooled ones yield 0.68 eV.

The bulk trap effects can be best demonstrated in C-t studies or the Zerbst study (the MOS capacitance vs. the relaxation time from deep depletion to inversion) (18-20). The carrier lifetime was obtained from the slope of $d/dt\ (C_o/C^2)$ vs. (C_F/C^{-1}), where C_o is the oxide capacitance and C_F is the final inversion capacitance. As illustrated in Fig. 4 the carrier lifetime of the slowly cooled samples is longer than that of the fast cooled ones. The surface recombination velocity data in depletion are 0.9-0.2 cm/sec and 0.05-0.02 cm/sec, respectively, for fast and slowly cooled samples. These data are widely scattered in a large range. From the gate-controlled diode experiments, the depletion surface recombination velocity can also be obtained and they are 0.25 and 0.01 cm/sec for the respective samples. The surface recombination velocity near inversion obtained from the intercepts of the Zerbst plots are 6×10^{-3} and 5×10^{-4} cm/sec for fast and slowly cooled samples, respectively. They represent edge surface recombination effects. Because of the small surface recombination velocity for these samples, the surface generation in the depletion region near the circumferential edge of MOS capacitors does not have a significant effect on the values of obtained bulk carrier lifetime (20). In order to determine as to which defect levels control the carrier lifetime, the Zerbst plots and carrier lifetimes were obtained at different temperatures. The Arrhenius plots of the carrier lifetime, illustrated in Fig. 5, show that a different energy level controls the carrier lifetime in different temperature ranges: for relatively low temperatures the activation energy being $E_c - 0.51$ V and for high temperatures the activation energy being $E_c - 0.26$ eV. These activation energies agree with those of the electron emission levels at $E_c - 0.49$ and -0.29 eV as determined from the previously described transient capacitance measurements. The minority carrier lifetime for a two-level system can be expressed as

$$\frac{1}{\tau} = \frac{1}{\tau_1} + \frac{1}{\tau_2}$$

or

$$\frac{1}{\tau} = \sigma_1 N_{t1} \langle v \rangle \exp - (E_1 - E_i)/kT + \sigma_2 N_{t2} \langle v \rangle \exp - (E_2 - E_i)/kT \quad [2]$$

where σ_1 and σ_2 are the capture cross sections for the two levels at $E_c - E_1$ and $E_c - E_2$, respectively; N_{t1} and N_{t2} are the corresponding concentration of defects.

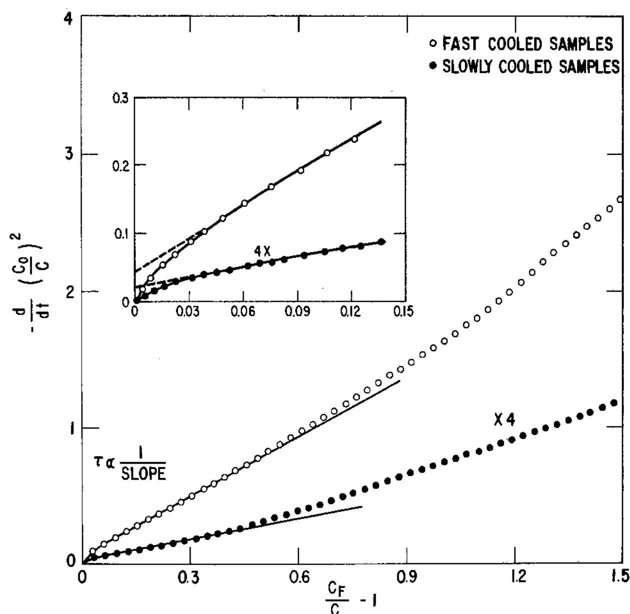

Fig. 4. The Zerbst plots obtained from capacitance vs. time taken from deep depletion to inversion of MOS capacitors. The minority carrier lifetimes for the fast cooled samples (A) and the slowly cooled samples (B) are 44 and 360 μsec, respectively. The inset shows the magnified view of the intercepts which correspond to the surface recombination velocity.

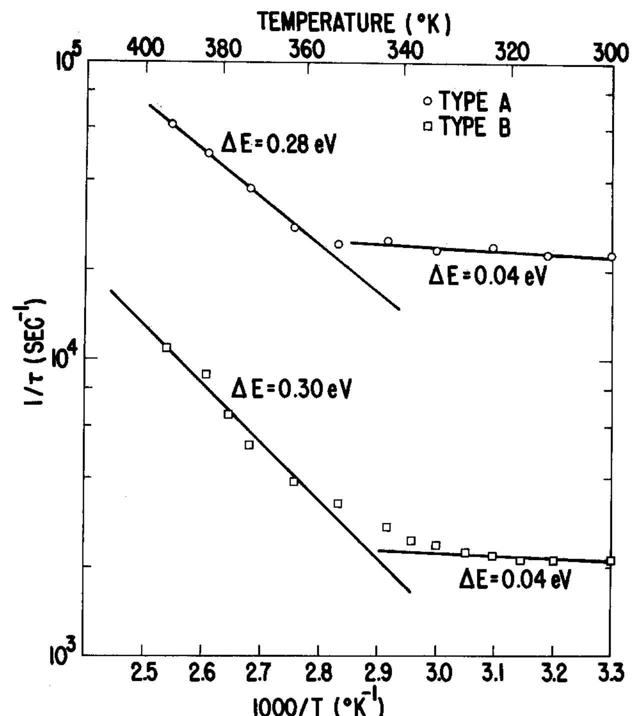

Fig. 5. Reciprocal of minority carrier lifetime vs. 1000/T. The activation energies at low and high temperatures are $E_t - E_i = 0.04$ eV, and $E_t - E_i = 0.29$ eV, respectively, for both kinds of samples. The corresponding energies as measured from the conduction band are $E_c - E_t = 0.51$ and 0.26 eV, respectively.

It is obvious from Eq. [2] that the level near the midgap controls the carrier generation at lower temperatures.

Discussion

The higher bulk trap concentration for the fast cooled samples suggests that these traps are the results of dissolved impurities in the interstitial sites when quenched, *i.e.*, some of them do not have time to precipitate. For example, a recent study for P-type samples by Lee *et al.* (1) shows that upon quenching from high temperatures they observed interstitial Fe° at E_v +0.40 eV in their EPR study. A similar quench study shows defect centers at E_v +0.45 eV and E_v +0.48 eV (5). Collins and Carlson (21) have observed E_c −0.55 eV in Fe-doped material, which is close to the present measured level at E_c −0.49 eV. The present study, however, does not reveal E_v +0.40 eV in the bulk. Furthermore, the defect concentrations measured in the present study are much lower than those of others. This may be in part owing to the result of an anneal carried out at 400°C in H_2 in the present investigation (used for practical MOS device fabrications to reduce interface-state densities). Owing to the lack of comprehensive deep level data, the precise configuration of these defects cannot be identified. It is likely that these presently observed levels are not simple Fe° interstitials but rather are complexes of impurity interstitials.

Similarly the larger interface-state densities for the fast cooled samples imply that the process-induced interface states reported here and by others likely resulted from dissolved impurities. Upon quenching, the dissolved impurities are frozen-in as active centers. Stacking faults may develop as impurities precipitate. The stress induced upon quench can enhance the precipitation of the impurities. The viscosity measurement in oxidized silicon by EerNisse (4) supports that such stress and the consequent strains near the interface are present. Another type of stress in the case of fast cooling has been demonstrated to reveal slips and dislocations and wafer warpage (22). In addition, active stacking faults have been shown to be electrically active responsible for short carrier lifetime using electron beam-induced current mode. The reduction of stacking fault length via HCl gettering during the oxidation process has been demonstrated and the improvement of carrier lifetime has also been reported (23, 24).[1] By slow cooling the strain is likely reduced and, in addition, the dissolved impurities can migrate to other regions to form precipitates.

Thus, the samples after the hydrogen anneal may intrinsically have lower interface-state densities than the values reported to date. In other words, the hydrogen bond coordination may be more effective than what we observed.

The presence of the strains owing to the viscous flow in the $Si\text{-}SiO_2$ structures suggests that all the processing should be carried out below 965°C (4). Moreover, the solid solubility would limit the dissolved impurity level as the processing temperatures are reduced. However such a processing is often too time consuming to be practical. Thus it is suggested to fabricate devices at convenient temperatures and then slowly cool samples down to 700°C, particular for the last high temperature process. By this procedure, the dissolved impurities can precipitate and form inactive complexes. Therefore the bulk traps and interface states can be reduced. The formation of such precipitation depends on the diffusivity of impurities and the strain formation time which, in turn, depends on the cooling rate. For fast diffusers, the cooling rate of the strain formation for $Si\text{-}SiO_2$ structure after the oxidation is a determining factor and estimated to be $1 \sim 2$°C/sec at 965°C (4, 25).

[1] Our recent experiment shows that the activation enthalpy of carrier lifetime improvement, 2.1 eV, suggests that the gettering of Fe may be responsible for it.

Conclusion

In conclusion, the present study has two implications. (*i*) Through a slow cooling from high temperature (1000°C), low bulk trap and interface-states densities can be obtained; and thus the minority carrier generations in MOS structures can be reduced. (*ii*) In addition to the improvement with hydrogen annealing, the interface-state densities can be still further reduced through proper procedures such as slow cooling. This suggests that the reported residual interface-state densities, to date, upon hydrogen anneal may be in part due to the impurities precipitated at near the interface and the hydrogen anneal could be still more effective. The interface-state densities may be further reduced if material impurity and processing induced contaminants are reduced.

Gallium Arsenide Films on Tungsten/Graphite Substrates

Shirley S. Chu,* T. L. Chu,* H. T. Yang, and K. H. Hong

Southern Methodist University, Dallas, Texas 75275

ABSTRACT

Gallium arsenide films have been deposited on tungsten/graphite substrates by the reaction of gallium, hydrogen chloride, and arsine in a hydrogen flow system. The effects of substrate temperature and reactant composition on the deposition rate and structural and electrical properties of gallium arsenide films have been investigated, Preliminary work on thin film gallium arsenide solar cells has also been carried out.

The current interest in the terrestrial utilization of solar energy by photovoltaic converters has stimulated considerable research and development efforts in low cost photovoltaic materials and devices. At present, single crystalline silicon solar cells are the best known photovoltaic converters; however, solar cells from some compound semiconductors have distinct advantages. For example, gallium arsenide solar cells have a higher theoretical conversion efficiency than silicon solar cells and can also operate at higher temperatures (1). In addition, gallium arsenide has high optical absorption coefficients near the bandedge, and solar radiation with energy in excess of the energy gap is essentially all absorbed within a few micrometers of the surface. The conversion efficiency of single crystalline gallium arsenide solar cells has been improved substantially during the past few years: the recently reported AM1 efficiencies are about 22% for cells with a gallium aluminum arsenide window and 15% for MIS-type cells (2, 3). Although the cost of single crystalline gallium arsenide is excessive, the use of a thin gallium arsenide film on a suitable substrate could provide a reasonable conversion efficiency and reduce substantially the cost per unit of power.

In the thin film approach, the selection of the substrate is an important consideration. The substrate must be compatible with gallium arsenide in chemical, electrical, and mechanical properties. Graphite is chemically inert toward gallium arsenide under the usual deposition conditions, and several types of graphite have a thermal expansion coefficient similar to that of gallium arsenide. However, the gallium arsenide/graphite interface has been found to exhibit a high electrical resistance, and a tungsten interlayer may be used to reduce the interface resistance to a tolerable level. In this work, gallium arsenide films have been deposited on tungsten/graphite substrates by the reaction of gallium, hydrogen chloride, and arsine in a gas flow system. The microstructure, crystallographic, and electrical properties of gallium arsenide films deposited over a wide range of conditions have been studied, and preliminary work on MIS type solar cells has been carried out. The experimental procedures and results are discussed in this paper.

Deposition of Gallium Arsenide Films

The chemical vapor deposition technique has been used extensively for the homoepitaxial growth of gallium arsenide in various device applications, and the thickness of and dopant concentration in gallium arsenide films can be accurately controlled. A number of chemical reactions have been used for the deposition of gallium arsenide films, including HCl-Ga-As (4), $AsCl_3$-H_2-Ga (5), HCl-Ga-AsH_3 (6), $GaCl_3$-H_2-As (7), and $(CH_3)_3$ Ga-AsH_3 (8). The reaction between gallium, hydrogen chloride, and arsine was selected in this work for convenience. In this process, gallium is maintained in a high temperature zone and the substrate is placed in a lower temperature zone of the deposition system. The chemical reactions are (*i*) the formation of gallium monochloride from gallium and hydrogen chloride in the high temperature zone; and (*ii*) the formation of gallium arsenide from gallium monochloride and arsine on the substrate surface in the lower temperature zone.

The apparatus used for the deposition of gallium arsenide films is shown schematically in Fig. 1. It consists of two parts: a gas flow control system and a fused silica reaction tube. Hydrogen purified by diffusion through a palladium-silver alloy was used as a diluent for the reactant mixture and as a carrier for zinc, the p-type dopant. The flow of various gases such as hydrogen, hydrogen chloride, and the hydrogen-hydrogen sulfide mixture (the n-type dopant) was directed by appropriate valves and measured by flowmeters. The reaction tube was of 55 mm ID and was held in a four-zone resistance-heated furnace with each zone separately heated and controlled; this arrangement allows sufficient flexibility in obtaining the desired temperature profile in the gallium and the substrate zones. A gallium container and the substrate were placed in the appropriate temperature zones of the reaction tube prior to the deposition process.

To evaluate the capability of the gallium arsenide deposition system, single crystalline gallium arsenide slices with main faces of a {100} orientation were first used as substrates for the deposition process. The substrates were etched with a 3:1:1 H_2SO_4:H_2O_2:H_2O solution at about 80°C for 2 min to remove the mechanical damage on the surface and were further etched *in situ* with a hydrogen-hydrogen chloride mixture prior to the deposition process. The temperatures of gallium and the substrate were 880°-890°C and 720°-750°C, respectively. Using hydrogen, hydrogen chloride, and arsine at flow rates of 1-2 l/min, 5-15 ml/min, and 15-45 ml/min, respectively, gallium arsenide films were deposited at rates of 0.5-1 μm/min. They were found to be single crystalline and epitaxial with respect to the substrates by metallographic examinations. The gallium arsenide films deposited without intentional doping were n-type, and those deposited on p-type substrates were used for the measurement of Hall mobility and resistivity at room temperature by

Key words: chemical vapor deposition, gallium arsenide, graphite, solar cells.

the van der Pauw method. Four contacts were made by alloying indium dots to the periphery of the specimen surface at 500°C in a hydrogen atmosphere or by using a gallium-indium alloy annealed at 400°C. The resistivity of typical epitaxial film is 9 Ω-cm at room temperature, and its Hall mobility is 6470 cm^2/V-sec. Neglecting the difference between the Hall mobility and drift mobility, the net carrier concentration is then approximately 1.1×10^{14}. These properties of epitaxial gallium arsenide films are very similar to those reported in the literature, indicating that the gallium arsenide deposition system is satisfactory.

The tungsten/graphite substrates used for the deposition of gallium arsenide films were prepared by depositing a tungsten film of about 5 μm thickness on grade DFP-2 or TAR-2 graphite supplied by Poco Graphite Incorporated. The linear thermal expansion coefficient of these two types of graphite, about 7.5×10^{-6}°C^{-1}, is similar to that of gallium arsenide, 6.8×10^{-6}°C^{-1}. The deposition of tungsten was carried out by the thermal reduction of tungsten hexafluoride with hydrogen using a conventional horizontal reactor. Graphite slices of 3.5 × 3.5 cm area were supported on a graphite susceptor in a fused silica tube of 55 mm ID, and the graphite susceptor was heated externally by an rf generator. Prior to the deposition process, graphite was first heated in hydrogen at 1100°-1200°C to remove the surface contaminations. The deposition rate of tungsten is determined by the substrate temperature and the composition and flow rate of the reactant mixture. Using hydrogen containing 1.5×10^{-2}% tungsten hexafluoride at a flow rate of 20 l/min, the deposition rate of tungsten at 500°C is approximately 1 μm/min. The deposited tungsten films are polycrystalline with an average crystallite size of 1-2 μm and exhibit a strong {100} preferred orientation.

The important process parameters in the deposition of gallium arsenide films are the temperatures of the gallium source and the substrate, and the composition and flow rate of the reactant mixture. A series of experiments were carried out to study the effects of these parameters on the structural and electrical properties of gallium arsenide films on tungsten/graphite substrates. In these experiments, the temperature of gallium, the flow rate of hydrogen, and the flow rate of hydrogen chloride were fixed at 880°-890°C, 1 l/min and 45 ml/min, respectively, and the substrate temperature and the AsH_3/HCl molar ratio were varied in the ranges of 725°-825°C and 0.5-2, respectively.

The thickness of deposited gallium arsenide films was determined by direct measurement on vertical cross-sectioned surfaces in order to determine the average deposition rate. The effect of the reactant composition on the deposition rate of gallium arsenide was pronounced only at the lowest temperature used, 725°C. At 725°C, the average deposition rate was found to increase with increasing AsH_3/HCl molar ratio; it increased from 1.2 to 1.5 μm/min as the AsH_3/HCl molar ratio was increased from 0.5 to 2. At 750°C and above, the average deposition rate is essentially independent of the AsH_3/HCl molar ratio in the range of 0.5-2. These results indicate that the deposition process is surface reaction-controlled at 725°C, and that the reaction rate is not rate limiting at 750°C and higher. At a given reactant composition, the average deposition rate of gallium arsenide peaks at about 750°C, 1.5 μm/min, and decreases with increasing temperature, about 1.2 μm/min at 800°C, for example. The lower deposition rate of gallium arsenide at higher temperatures is related to the thermochemistry of the reaction and is well established (9).

Structural Properties of Gallium Arsenide Films

Gallium arsenide films deposited on tungsten/graphite substrates are all polycrystalline, and the as-deposited surfaces were examined with optical and scanning electron microscopes to determine their microstructure. At substrate temperatures of 725° and 750°C, the average crystallite size in gallium arsenide films increases with increasing arsine concentration in the reactant mixture. For example, the average crystallite size in films deposited at 725°C increased from about 5 to more than 10 μm as the AsH_3/HCl molar ratio was increased from 0.5 to 2. Figures 2A and 2B show the surface of gallium arsenide films deposited on tungsten/graphite substrates at 725°C using AsH_3/HCl molar ratios of 0.5 and 2, respectively, where the effect of AsH_3/HCl molar ratio is apparent. At higher substrate temperatures the AsH_3/HCl molar ratio has no appreciable effects on the crystallite size. At a given AsH_3/HCl molar ratio, the substrate temperature has a pronounced effect on the crystallite size in gallium arsenide films. At a low AsH_3/HCl molar ratio, 0.5-1, the average crystallite size increases with increasing substrate temperature, reaching a maximum at 750°-775°C, and decreases at higher temperatures. Figures 3A and 3B show the surface of gallium arsenide films deposited on tungsten/graphite substrates using a molar ratio of 0.5 at 775° and 825°C, respectively. A comparison of Fig. 2A, 3A, and 3B shows clearly the effect of substrate temperature on crystallite size in

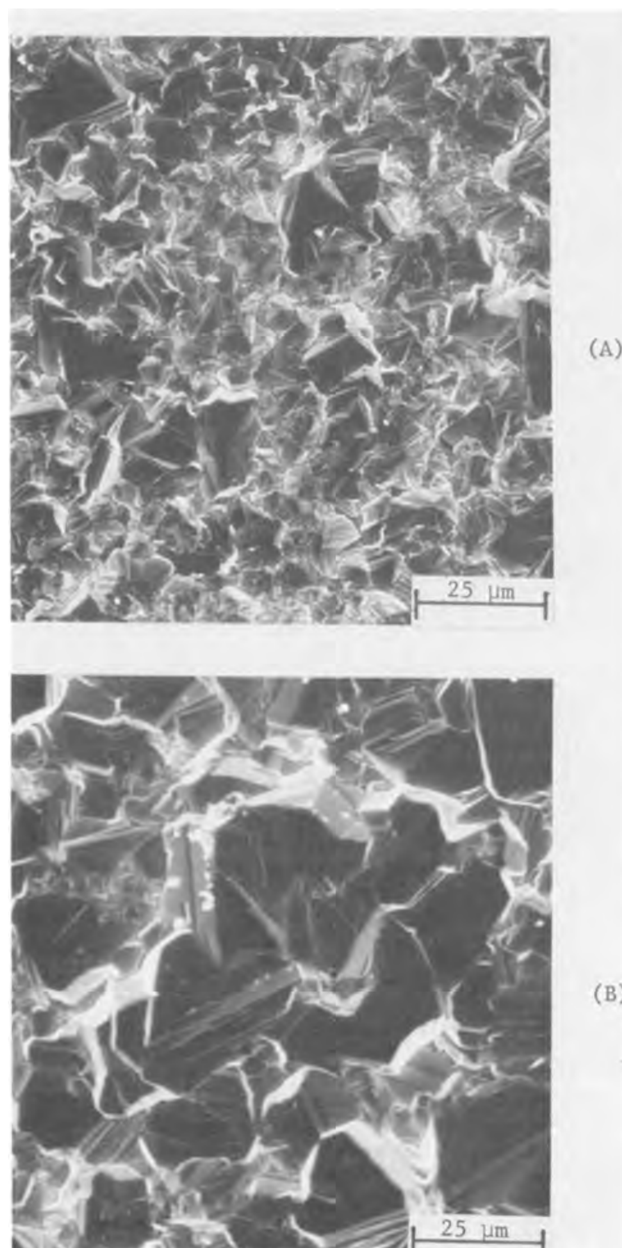

Fig. 2. Scanning electron micrographs of gallium arsenide films deposited on tungsten/graphite substrates at 725°C using AsH_3/HCl molar ratios of (A) 0.5; and (B) 2.

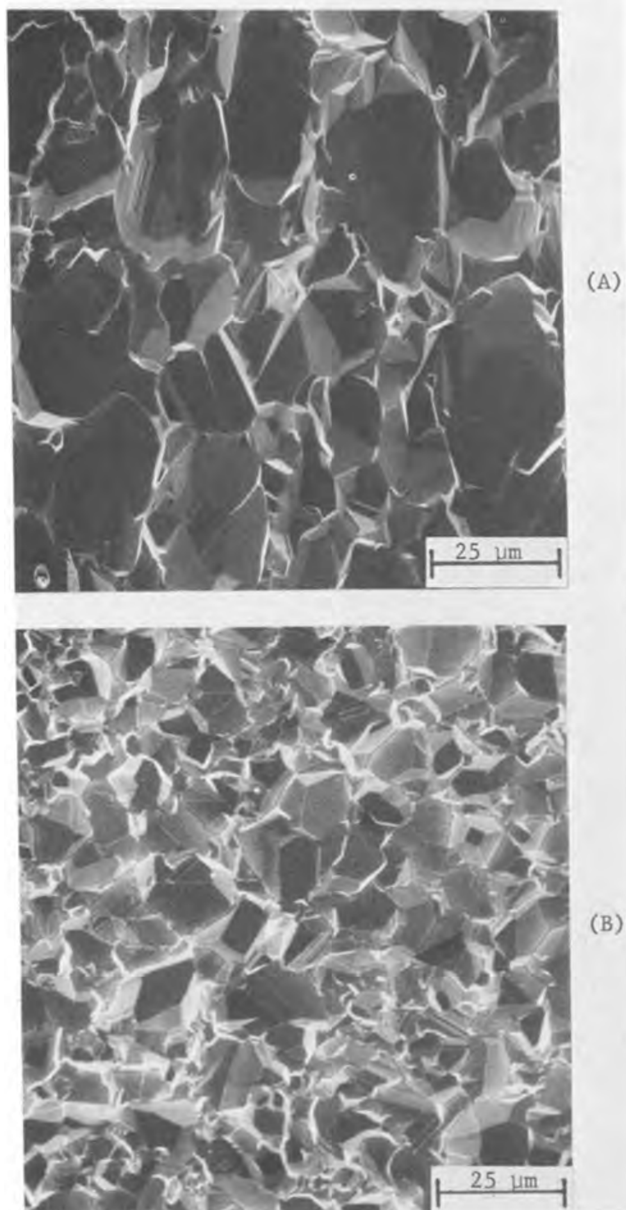

Fig. 3. Scanning electron micrographs of gallium arsenide films deposited on tungsten/graphite substrate using an AsH_3/HCl molar ratio of 0.5 (A) at 775°C; and (B)825°C.

gallium arsenide films deposited at low AsH_3/HCl molar ratios. At high AsH_3/HCl molar ratios, 2, for example, the average crystallite size is essentially independent of temperature in the range 725°775°C and decreases at higher temperatures. The crystallites in all films are of random shape and exhibit no well-developed faces.

The crystallographic properties of gallium arsenide films deposited on tungsten/graphite substrates were examined by the x-ray diffraction technique using a General Electric Model XRD-6 diffractometer with CuKα radiation. Polycrystalline gallium arsenide powder of random orientations is known to show three strong diffraction peaks associated with {111}, {220}, and {311} reflections with 2θ values of 27.3°, 45.3°, and 53.8° and relative intensities of 100, 35, and 35 (9). The diffraction spectra of the gallium arsenide films were obtained by scanning 2θ in the range of 20°-60°. When the gallium arsenide film was deposited at 725°C, the relative intensities of {111}, {220}, and {311} were found to depend strongly on the AsH_3/HCl molar ratio in the reactant mixture. Figures 4A and 4B show the diffraction spectra of gallium arsenide films deposited by using AsH_3/HCl molar ratios of 0.5 and 2, respectively. While the film deposited with a low AsH_3/HCl molar ratio shows a strong {110} preferred orientation, that deposited at a high AsH_3/HCl molar ratio shows a {111} preferred orientation. At higher substrate temperatures, no significant preferred orientations were observed, and the deposited films are essentially polycrystalline. Figure 4C shows the diffraction spectrum of a gallium arsenide film deposited at 775°C. The lack of preferred orientations in gallium arsenide films deposited at high temperatures is presumably due to local chemical transport associated with the chemical reversibility of the deposition reaction.

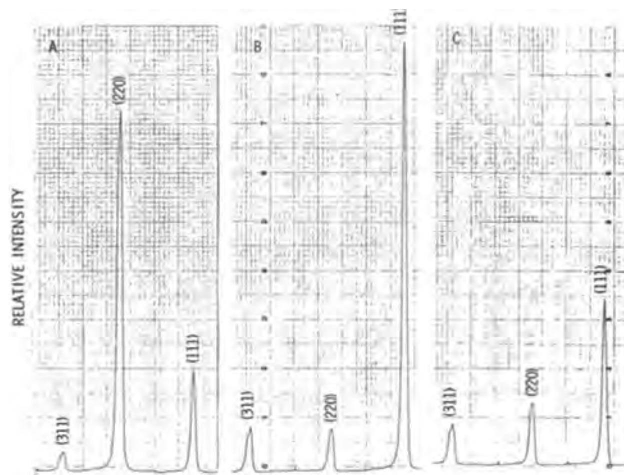

Fig. 4. X-ray diffraction spectra of gallium arsenide films deposited on tungsten/graphite substrates (A) at 725°C and an AsH_3/HCl molar ratio of 0.5; (B) at 725°C and an AsH_3/HCl molar ratio of 2; and (C) at 775°C and an AsH_3/HCl molar ratio of 2.

Carrier Concentration in Gallium Arsenide Films

Gallium arsenide films deposited on tungsten/graphite substrates without intentional doping are all n-type. The carrier concentrations in these films were determined at room temperature by the differential capacitance method. An array of sixteen silver dots of about 0.5 mm diam, 6-7 mm apart were evaporated onto each gallium arsenide film through a metal mask. The capacitance of these Schottky barriers was measured as a function of the reverse bias, and the dopant concentration in the gallium arsenide film under each Schottky barrier was calculated from the specific differential capacitance. The average dopant concentration and its standard deviation in each gallium arsenide film was then deduced from the dopant concentrations calculated from the sixteen Schottky barriers. The results are shown in Table I (no meaningful data were obtained for gallium arsenide films deposited on tungsten/graphite at 725°C because of the nonohmic interface). The carrier concentration in each gallium arsenide film is generally uniform within 50%. At a substrate temperature of 750°C, the carrier concentration is essentially independent of the reactant composition. At higher temperatures, however, the carrier concentration increases with decreasing AsH_3/HCl molar ratio.

While the carrier concentration in undoped homoepitaxial gallium arsenide films is approximately 10^{14} cm^{-3}, the carrier concentration in gallium arsenide films on tungsten/graphite substrates is two to three

Table I. Carrier concentration in gallium arsenide films ($\times 10^{-16}$)

AsH_3/HCl Temp., °C	0.5	1.0	1.5	2.0
750	7.8 ± 2	13 ± 6.5	11 ± 1.4	9 ± 0.9
775	7.5 ± 2	5.3 ± 1.8	3.8 ± 0.7	2.3 ± 0.2
800	30 ± 14	12 ± 1.7	8 ± 1.4	7.2 ± 1.6

orders of magnitude higher. This high carrier concentration could be due to the incorporation of tungsten or impurities in tungsten into gallium arsenide films, and gallium arsenide films deposited on substrates with tungsten coating on both sides have higher carrier concentrations.

Minority Carrier Diffusion Length

The minority carrier diffusion length in gallium arsenide films deposited on tungsten/graphite substrates was measured by a photoresponse technique (10). The apparatus consists of a source of monochromatic light, a light detector with known spectral response, and a lock-in amplifier for measuring the photoresponse. A Schottky barrier solar cell was made on the gallium arsenide film under test by evaporating a silver or gold film of 60-70Å thickness and a metal grid contact. The spectral response of the cell was measured at 7000 and 7500Å. The ratio of the measured responses is related to the minority carrier diffusion length in the gallium arsenide film. By comparing this ratio with the ratios calculated as a function of diffusion length for materials of the same dopant concentration, the diffusion length in the gallium arsenide film can be deduced. Most of the gallium arsenide films were found to have a diffusion length of 0.2-0.4 μm.

Solar Cell Characteristics

Preliminary work has been carried out to prepare Schottky barrier solar cells from gallium arsenide films deposited on tungsten/graphite substrates. They were n-type with a net carrier concentration of about 10^{17} cm^{-3}. A gold film of 60-70Å thickness was evaporated onto the surface of the gallium arsenide film under a pressure of less than 10^{-6} Torr. The silver grid contact was also formed by evaporation through a mask. Because of the large surface area of gallium arsenide films, a thin oxide interlayer is probably present.

The current-voltage characteristics of several solar cells were measured at room temperature under illumination with ELH quartz-halogen lamps calibrated with a standard silicon cell at AM1 conditions. Conversion efficiencies of up to 3% have been obtained. An example is shown in Fig. 5, where the characteristics of a solar cell of about 8 cm^2 area are reproduced. The open-circuit voltage, short-circuit current density, and fill factor are 456 mV, 10.4 mA/cm^2, and 59%, respectively, corresponding to an AM1 efficiency of about 2.8%. This efficiency can be increased substantially by the optimization of the gallium arsenide film and the solar cell configuration and the application of antireflecting coatings.

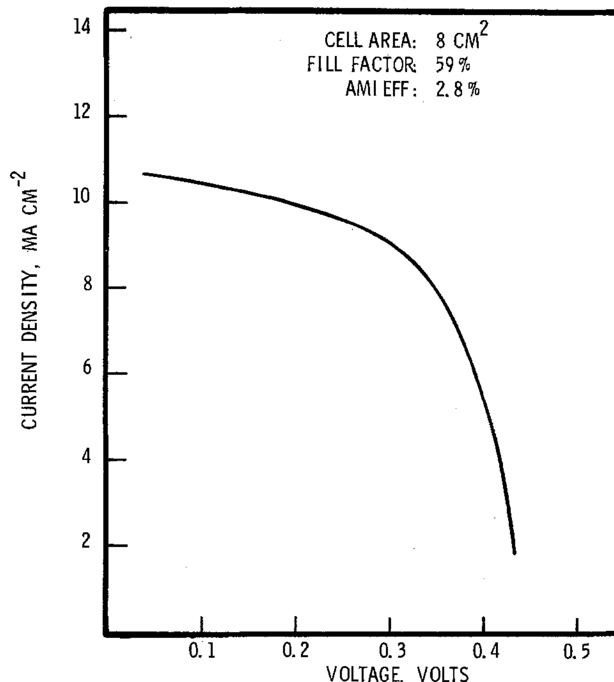

Fig. 5. Current-voltage characteristics of a thin film gallium arsenide Schottky barrier solar cell under illumination with ELH quartz-halogen lamps equivalent to AM1 conditions.

Summary and Conclusions

Tungsten-coated graphite is a suitable substrate for the deposition of gallium arsenide films by the reaction of gallium, hydrogen chloride, and arsine. The structural properties of and the carrier concentration in the gallium arsenide films are affected by the substrate temperature and reactant composition. Films deposited at 775°C using a high AsH_3/HCl molar ratio have relatively large crystallites (about 15 μm), however, the crystallites are random shaped and exhibit no strong preferred orientation. Gallium arsenide films on tungsten/graphite substrates appear to be promising for the fabrication of solar cells; the fabrication technique is simple and involves no wet chemical processing.

Spreading Resistance Measurements on Gallium Arsenide

G. Queirolo

SGS/ATES Componenti Elettronici S.p.A., Castelletto di Settimo Milanese, Milano, Italy

ABSTRACT

Spreading resistance measurements were performed on p- and n-type gallium arsenide slices and Zn-diffused GaAs. In a very short time the method gives information on starting material resistivity and resistivity inhomogeneities and makes it possible to obtain carrier concentration profiles of diffused layers which are in a fairly good agreement with the ones obtained with incremental sheet resistivity and Hall measurements. Concentrations in excess of $\sim 5 \times 10^{17}$ (n-type) and $\sim 1 \times 10^{17}$ (p-type) can be routinely measured.

Spreading resistance measurement is a well-known and accepted method for the evaluation of diffused or epitaxial silicon layers (1); it is, in fact, currently used in production plants to measure the resistivity and the thickness of multiple epitaxial silicon layers, and as unique feedback for the control of dopant flows in epitaxial reactors.

Very few results are so far reported on spreading resistance measurements on gallium arsenide (2). Due to the high contact resistance, the carrier concentration of GaAs slices and/or dopant profiles in diffused layers are evaluated with the van der Pauw method (3) which requires the fabrication of 4Ω contact at the edge of the sample and a very time-consuming measurement schedule. Successful spreading resistance evaluation of GaAs was recently reported by the author (4); the method is now routinely used in SGS/ATES as a process monitor in the production of diffused LED.

Experimental Techniques and Results

Sample preparation and SR measurements.—The spreading resistance (SR) was measured on a commercial two-point probe system (Automatic Spreading Resistance Probe ASR-100B) with 5 mV supply between the two preconditioned tungsten-osmium probes with 40g load.

Careful sample preparation is necessary to obtain reproducible quantitative SR values on gallium arsenide: Our results show that the sample surface must be as uniformly damaged as possible, and the thin oxide film which grows on GaAs at room temperature must be removed.

Several different grain-size aluminum oxide powders and the polishing and angle lapping processes were studied. Finally, two sizes of Al_2O_3 were selected, *viz.* 0.3 μm and 5.0 μm. The abrasive was diluted with DI water at a concentration of ~200 g/liter and the sample, mounted on a bevel mount of the ASR-100B, was lapped with a 12 in. Lapmaster machine equipped with a glass plate and a slurry recirculating system. Enough lapping compound was used to avoid direct contact with the glass plate which would result in scratches or other disuniformity in surface finish.

The reproducibility of the SR values was studied in detail for the two abrasives: five p-type GaAs samples, Zn doped with a concentration ranging from 1×10^{17} to 4×10^{19} cm^{-3} were measured after several lapping steps, with or without removing the thin layer of oxide. Some typical results for p-type GaAs, $N_A = 3.5 \times 10^{18}$ cm^{-3} are reported in Fig. 1a and 1b: the R_S values increase after aging in air at room temperature and decrease at or below the original value after a 2 ft ÷ 4 min etch in HCl:H_2O 1:1 solution or a 5 min etch in straight (40%) HF. The oxide thickness was measured by means of Auger electron spectrometry, and was found to be greater for aged than for etched samples (about 50 and 15Å, respectively).

This result explains why the scattering of the experimental points is much greater for aged than for etched samples, as reported in Fig. 2a and 2b. From the same figure it is also evident that the uniformity of the R_S measurements on a given sample is much better for samples lapped with 0.3 μm abrasive. The R_S mean value is nevertheless more reproducible for coarser abrasive, as indicated from bars in the calibration curves of Fig. 3 and 4, possibly due to the failure to obtain a reproducible mechanical damage for the

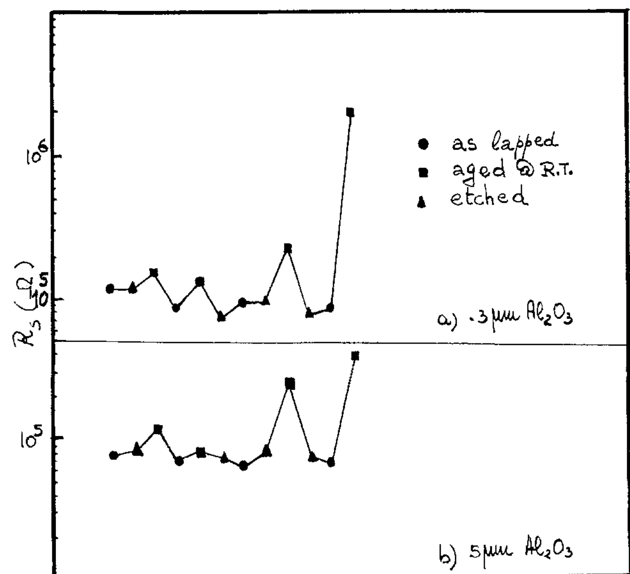

Fig. 1. Spreading resistance value for p-type GaAs, $N_A = 3.5 \times 10^{18}$ cm^{-3}, after various treatments.

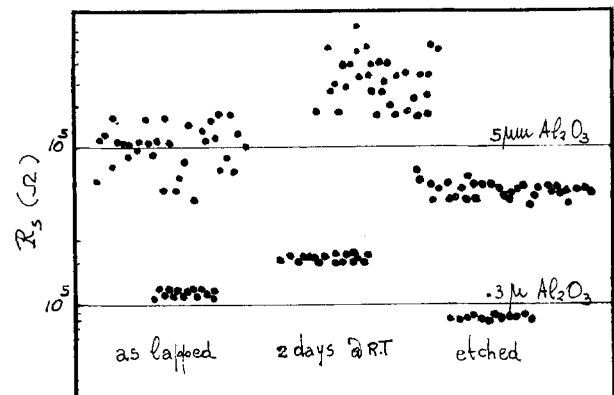

Fig. 2. Scattering of R_S values for a lapped, aged, and etched (5 min HCl:H_2O 1:1) sample ($N_A = 3.5 \times 10^{18}$ cm^{-3}).

Key words: spreading resistance, gallium arsenide, diffusion profiles, dopant concentration uniformity, contact resistance.

finer abrasive unless particular care is taken (*e.g.*, absence of scratches, scratches not detectable by visual observation, but only in SEM in cathodoluminescence mode) (5).

The metal-semiconductor contact.—A GaAs sample (n-type, Si doped at 2.9×10^{18} atoms/cm^3, horizontally Bridgman grown) was soldered to a bevel mount with a GaIn alloy and angle lapped. The value of the resistance offered by a single probe was measured as a function of the applied voltage between +50 and −50 mV, and a linear relationship was found. The $R_{s\pm}$ values obtained with the standard ±5 mV bias are the same for the two probes, and exactly half of the values of R_s are measured between the two probes.

The value of R_s is given by (6)

$$R_s = k(\rho/2a) + 2R_c \quad \text{(2 probes configuration)} \qquad [1]$$

where ρ is the sample resistivity, a is the contact radius, k is a constant not very different from unity which is a function of the nature of the sample, and R_c is the "true" contact resistance.

The first term of Eq. [1] is expected to be approximatively the same for two semiconductors of the same resistivity, apart from small variations on the constant k and the contact radius a. Nevertheless, our results show that for the same ρ and sample preparation process, the R_s value is from 3 to 6 orders of magnitude greater for GaAs than for silicon, depending on the conductivity type and the actual value of resistivity. Moreover, for silicon the contact resistance R_c is very low, and we can write

$$R_s(\text{Si}) \simeq k(\rho/2a); \quad R_c(\text{Si}) << k(\rho/2a)$$

On the contrary, for gallium arsenide

$$R_s(\text{GaAs}) >> R_s(\text{Si}) \simeq k(\rho/2a)$$

and

$$R_s(\text{GaAs}) \simeq 2R_c(\text{GaAs}) \qquad [2]$$

Hence the measure of the spreading resistance R_s on GaAs is actually a measure of the contact resistance, which is, in turn, a function of the carrier concentration (7). Separation of contact resistance from the spreading resistance was attempted using the a-c method of Wagner and Besocke (8), but no result was obtained, possibly due to the very small contact capacitance. The mechanical damage and the high pressure on the contact (9) lower the RC to a measurable value, but any damage inhomogeneities will be reflected in R_s measurements, which will be more reproducible on samples lapped with 5 μm abrasive due to more reproducible mechanical damage. Moreover, we can expect a dramatic increase of R_s value if the native oxide is not removed before the measurement.

On the basis of this result, routine work is done with the coarser abrasive, while the finer abrasive is used only when a good spatial resolution is required as in profiling thin diffused layers.

To convert R_s data to carrier concentration data, calibration curves were generated by measuring both p- and n-type GaAs slices of known resistivity with the two surface finishes studied in this work. Results are shown in Fig. 3 (p-type, 0.3 μm abrasive), Fig. 4 (p-type, 5 μm abrasive), and Fig. 5 (n-type, 0.3 μm and 5 μm abrasive, curves a and b, respectively). Note that the finer abrasive gives lower R_s values than the coarser one on n-type samples, whereas the reverse is true on p-type samples. It is difficult to explain this result due to the state-of-the-art of spreading resistance measurements, especially on GaAs, but it may be that the acceptor or donor center, the dislocation that is known to be in silicon, can be taken into account. These curves make it possible to extract quantitative information from the spreading resistance measurements, as reported in the application section below.

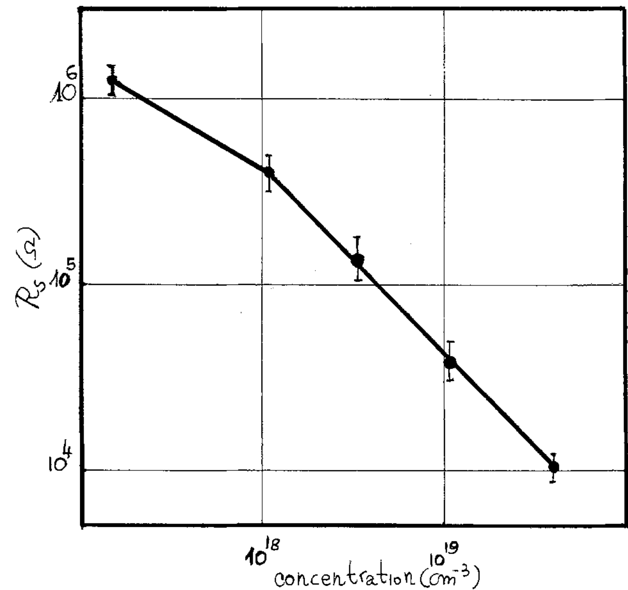

Fig. 3. Calibration curve (R_s vs N_A) for p-type GaAs lapped with 0.3 μm Al_2O_3.

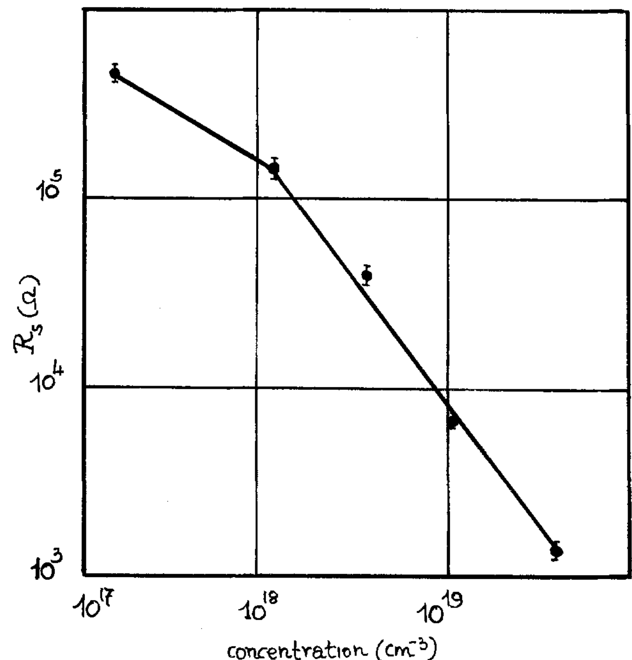

Fig. 4. Calibration curve (R_s v N_A) for p-type GaAs, lapped with 5 μm Al_2O_3.

Applications

Starting material uniformity.—The resistivity uniformity of a few GaAs slices was tested by scanning the probes across the surface. Two kinds of disuniformity were found which are described in Fig. 6.

(*i*) In some slices, a step variation on R_s values was found (Fig. 6a). This was also detected measuring the plasma resonance frequency in far IR reflectance experiments, but, of course, with much less spatial resolution.

(*ii*) Starting from the upper edge of the slice, which is also the free surface of the growing crystal, we often found an increase of a factor of ~2 in the R_s value (Fig. 6b), possibly due to some As evaporation. In this case the edge-correction factor cannot explain the result, due to the very high spatial resolution of the method (see also the following section) and the width of the transition region (~5 mm).

Concentration profiles.—For low contact resistance the spreading resistance value R_s is given by Eq. [1]

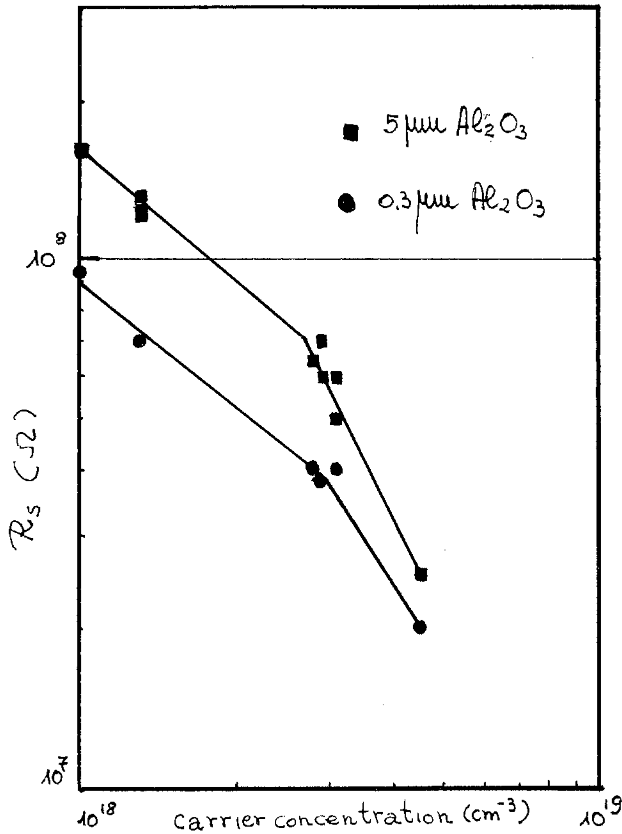

Fig. 5. Calibration curve (R_s vs N_D) for n-type GaAs

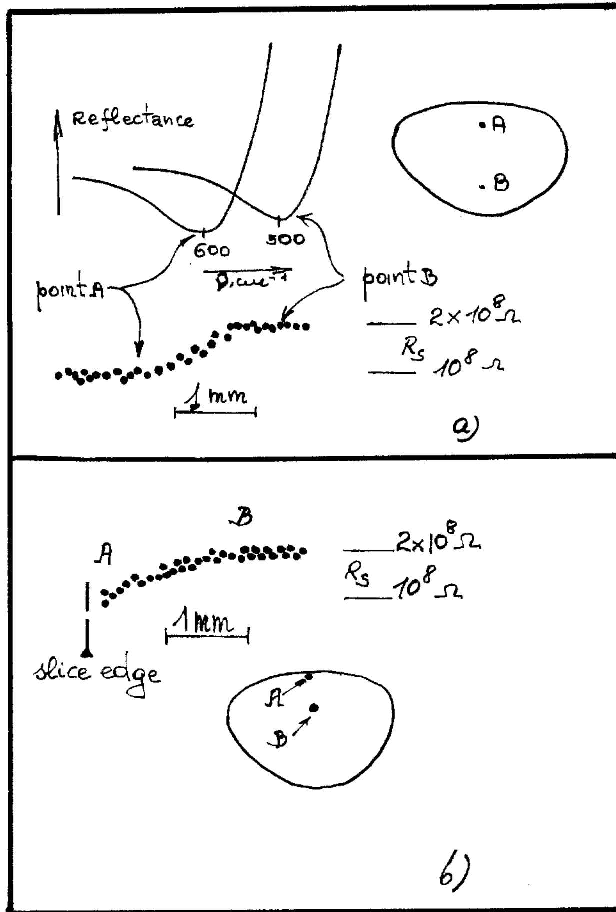

Fig. 6. Doping inhomogeneities on an n-type GaAs slice ($N_D \simeq 1.5 \times 10^{18}$).

only in the semi-infinite approximation, *i.e.*, when the sample thickness is much greater than the contact radius (6). It is necessary to apply some correction to the raw R_s data if a conducting or insulating boundary is present at a distance of less than 10 μm; in particular an R_s profile in a silicon-diffused or epitaxial layer will be distorted near the junction.

This effect should not be observed in gallium arsenide if the theory of the probe-semiconductor contact given here is correct. This was tested by evaluating a $p^+ - \nu$ double layer grown by LPE on an n-type GaAs substrate. The resulting profile shown in Fig. 7, is very flat on the doped epitaxial layer, and the transition to the high resistivity layer is very abrupt.

Figure 8 reports the R_s profile on a multiple layer epitaxial structure on which the bars indicate the position of the interfaces as determined after the bevel staining. Also in this case the R_s value is noticeably constant on a given epi layer with an abrupt transition between two layers.

This is a very interesting result because it allows us to deduce concentration profiles directly from spreading resistance data and calibration curves. A few examples of R_s and concentration profiles determined from R_s data and calibration curves in Zn-diffused GaAs are shown in Fig. 9 ($ZnAs_2$ source) and Fig. 10 (ZnGaAs source).

In Fig. 11 a profile obtained from R_s data is compared with the concentration profile obtained from the values of ρ_s (x) measured with the van der Pauw

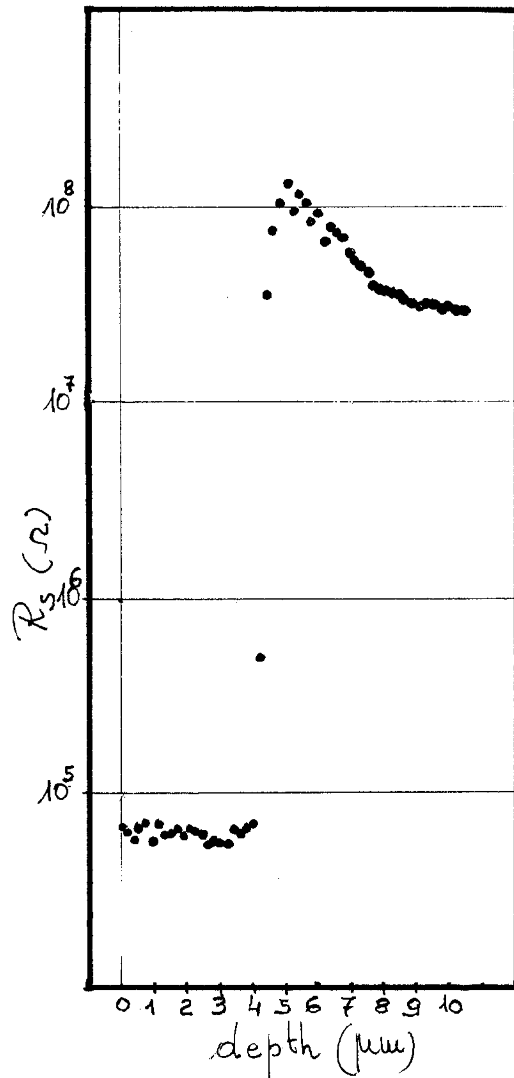

Fig. 7. R_s profile through a double epitaxial layer, grown by LPE. Note the very abrupt transition between the p-type and the undoped layer. Lapped with 0.3 μm Al_2O_3.

method. The two curves were normalized to the same junction depth. The error bars are the same as the

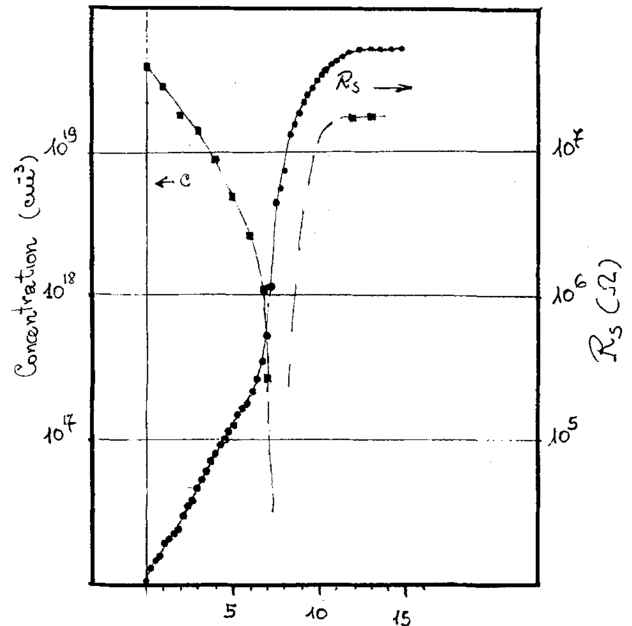

Fig. 10. R_s and concentration profiles for a Zn-diffused GaAs slice (1 hr in a 850°C closed tube, GaAsZn source). Lapped with 0.3 μm Al_2O_3.

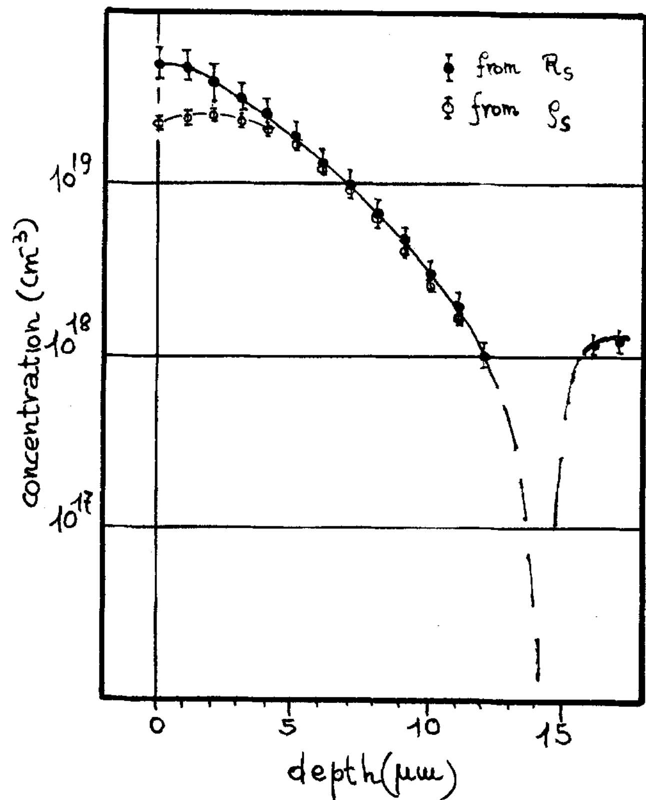

Fig. 11. Concentration profile of a Zn-diffused GaAs slice, as obtained from spreading resistance data (0.3 μm Al_2O_3, full circles) and from incremental sheet resistance measurements (open circles).

calibration curve of Fig. 3 for the R_s-derived profile and were estimated from experimental accuracies for ρ_s-derived profiles. At the moment it is not clear why the first points in the latter profile are lower.

The agreement between the two profiles is quite good and it makes it possible to establish a correlation with the diodes' performances. Other work on this subject is in progress and will be reported in a future article.

Conclusions

We have shown that spreading resistance measurements can be successfully performed not only in sili-

con, but also in gallium arsenide. Information on substrate resistivity, inhomogeneities in substrate resistivity, junction depth and concentration profiles in diffused layers, and thickness and resistivity of epitaxial layers can be obtained in a very short time.

The probe material used (tungsten-osmium alloy) was the one adopted for measurement on silicon, and probably it is not the best one for R_s measurements on GaAs. It is possible, therefore, that further improvement will be obtained with a more suitable probe material and/or pressure on the probes and other surface preparation.

Note Added in Proof

In a recent paper (10) R. C. Goodfellow *et al.* report their results on SR measurements on GaAs, using a tungsten carbide probe drawn along a bevelled sample. They too believe that the contact resistance is responsible for the measured R_s, the value of which is of the same order of magnitude found in an experiment.

Propane Gas Detector Using SnO_2 Doped with Nb, V, Ti, or Mo

Masayoshi Nitta, Shinji Kanefusa, and Miyoshi Haradome

The Physical Science Laboratories, Nihon University at Narashino, 7-24-1 Narashinodai, Funabashi 274 Japan

ABSTRACT

The propane gas concentration *vs.* its detection voltage characteristics have been investigated on SnO_2 doped with several transition metals. Doping with Nb, V, Ti, or Mo gives rise to a quite different behavior from the so-called Freundlich curve; that is, an inflection anomaly on the curve of the characteristics is found. The inflection point shifts toward lower gas concentration with increasing applied voltage. A remarkable jump of detection voltage observed for Nb-doped samples is also described.

A number of metal oxides have long been exploited extensively in connection with their applications to various gas-detection devices (1-3).

Recently, many attempts have been made to detect various kinds of gas involved in air by using sintered or powdered metal-oxide semiconductors (4). Among them, propane is one of the most important gases to be detected in order to prevent gas accidents. Detectors using stannic oxides have been developed for this purpose (5). Commercially available SnO_2 detectors, however, have a problem of unreliable detection. This results from the change in the detection voltage *vs.* gas concentration characteristics, depending on the humidity and ambient temperature. The detection voltage as a function of gas concentration, which is expressed by the Freundlich equation (6), tends to saturate over the range from 0.2 to 0.5% of the gas concentration. This is exactly the range of propane concentration of 0.2-0.4% to be detected for the practical use.[1] The instability of the characteristics in this region is reflected sensitively on the reliability of the detectors.

This paper describes the results of our study in an attempt to obtain an unsaturated portion on the voltage-concentration curve, especially at the gas concentration of 0.2-0.5%.

It has been found that the gas detectors of SnO_2 doped with the transition metals of Nb, V, Ti, or Mo show a different behavior from the Freundlich relation, and hence more reliable detection of leakage propane gas is expected.

Key words: sensor, semiconductor, surface, gas detection.

[1] The concentrations between 0.2-0.4% correspond to standard levels decided by the Society of Safety of High Pressure Gas Engineering: 1/10-1/5 of the lower explosion limit of propane gas.

Experimental

Stannic oxides mixed with 1 weight percent (w/o) of $PdCl_2$ and $Mg(NO_3)_2$, respectively, were used as host materials. The powders, to which Nb (max 20 w/o) were added, were presintered in air for 1-24 hr at 600°-800°C. These powders were dispersed uniformly in alcohol, painted between the electrodes on the 96% alumina substrate, and then sintered at 800°C for 1 hr. The same preparation procedure was used for V, Ti, or Mo-doped samples. The electrode was a thick film conductor (Pt-Au) which was previously prefired on the substrate at the distance of 0.5 mm. Commercial propane was used as a detective gas. As shown in Fig. 1, propane gas was introduced into a chamber at a constant flow rate through a controller. The gas concentration in the chamber was kept constant during the measurement using a stirring fan. The sample was heated by a heater of a thick film resistor at 280°C. Temperature and humidity in the chamber were kept at 25°C and 50-60% RH, respectively. A pick-up resistor (R_p) was connected in series to the sample. The value of R_p was adjusted so as to give one tenth of the resistivity of the sample before exposing to gas.

Results and Discussion

Figure 2 shows the change in resistivity as a function of propane concentration measured at 30V ap-

plied to the sample with various contents of Nb at 280°C. Electrical resistance of these samples decreases with increasing gas concentration. The relations for the sample with Nb of more than 20 w/o and less than 7 w/o are straight lines satisfying the Freundlich equation. For the samples with 9-17 w/o Nb, however, inflection point appears on these lines. A remarkable fact for the sample doped with 9 w/o Nb is that an abrupt change in electrical resistance occurs in addition to the inflection mentioned above. A detection voltage characteristic of this sample is shown in Fig. 3. The voltage increases abruptly from 13 to 25V at about 0.6% gas concentration as shown in the figure. Figure 4 shows the voltage as a function of the gas concentration at different applied voltages for the sample with 15 w/o Nb. The inflection is found to shift toward lower gas concentration with increasing applied voltage, and finally disappears above 40V. Thus, the occurrence of the inflection on the property depends on the Nb concentration and applied voltage. This is summarized in Table I. For the sample doped with 5 w/o Nb, the inflection anomaly is observable below 20V. For the higher concentration of Nb the

Table I. The conditions of applied voltages and Nb concentrations for the inflection anomaly to be observed. Symbols O and X indicate "yes" or "no" for the presence of the anomaly, respectively.

Nb concentration (w/o)	Applied voltage (V)						
	5	10	20	30	40	50	60
5	O	O	X	X	X	X	X
7	O	O	X	X	X	X	X
10	O	O	O	X	X	X	X
13	O	O	O	X	X	X	X
14	X	O	O	X	X	X	X
15	X	O	O	O	X	X	X
17	X	X	X	O	O	O	X
20	X	X	X	X	X	X	X

higher applied voltage is necessary to observe this anomaly. In the region marked by X in Table I, the voltage characteristics are almost of the Freundlich type. For the sample doped with 5-13 w/o Nb, however, the step phenomena as shown in Fig. 3 are observed at higher applied voltage.

For the sample doped with V, Ti, or Mo, similar inflection properties were also observed. For the sample doped with vanadium, the condition to create this phenomenon is critical. That is, it is observed only at the applied voltage between 20-30V and only for the sample doped with 15 w/o, while it is not for the sample doped with titanium or molybdenum. Figure 5 shows the gas concentration of the inflection point as a function of applied voltage. This point shifts to lower gas concentration with increasing applied voltage and also with the concentration of dopants. The shaded parts in the figure show the disappearance of the inflection phenomenon.

In Fig. 6 are shown the V-I characteristics of the Nb-doped sample (15 w/o) at the sample temperature of 280°C for different gas concentrations. Applied voltage below 20V does not have much effect on the self-heating of the sample. Therefore, the inflection phenomena observed at 10V of applied voltage in Fig. 4 are not due to the self-heating of the sample. Figure 7 shows the experimental results of the sample doped with 15 w/o Nb when the applied voltage is 20V. The variation of electrical resistance is plotted by heating the sample from 100° to 320°C at a constant heating rate of 0.14°C/sec. For the sample which showed anomaly of gas detection property, the resistance spectrum in this temperature range consists of two major minima, indicating that the lower temperature minimum is notable to the anomaly. This minimum strongly depends on the environmental gas concentration and applied voltage. From the above-mentioned facts, one can assume that the tail of the lower temperature minimum will affect the gas detection characteristics at certain gas concentration when the sample temperature is kept at the shaded region in Fig. 7. The remarkable step phenomenon found for the Nb-doped sample was not observed for the sample doped with V, Ti, or Mo within the present experimental conditions.

Let us discuss how the propane detectors of the anomalous properties can improve the reliability of the detection. Figure 8(A) shows the typical property of a Freundlich-type detector (properties of the host material) and Fig. 8(B) shows the same of the present detector which is of nonFreundlich type, in which is involved 5 w/o Ti. The detective accuracy is compared on the basis of the ±10% fluctuations of the voltage as indicated by dotted lines in Fig. 8 which would correspond to merciless circumstances like wide-range fluctuation of the ambient temperature and humidity. As an example, the accuracy is examined on the gas detector which gives an alarm when the gas concentration reaches 0.25%. As shown in Fig. 8, the errors of gas concentration at a setting voltage (V_o) for the detector of Freundlich type and nonFreundlich type are about ±0.1 and ±0.03%, respectively. Thus, one can see that our new propane gas detector is much superior to the widely used ones.

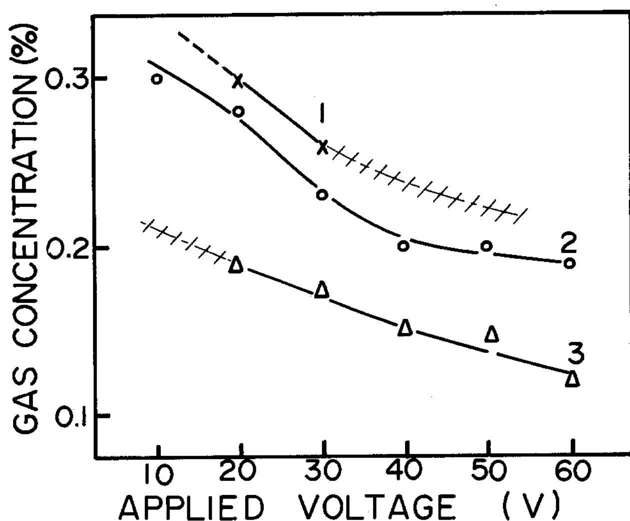

Fig. 5. The relations between the applied voltage and the gas concentrations which give the inflection at different doping levels of Mo; 1, 1 w/o; 2, 5 w/o; and 3, 10 w/o.

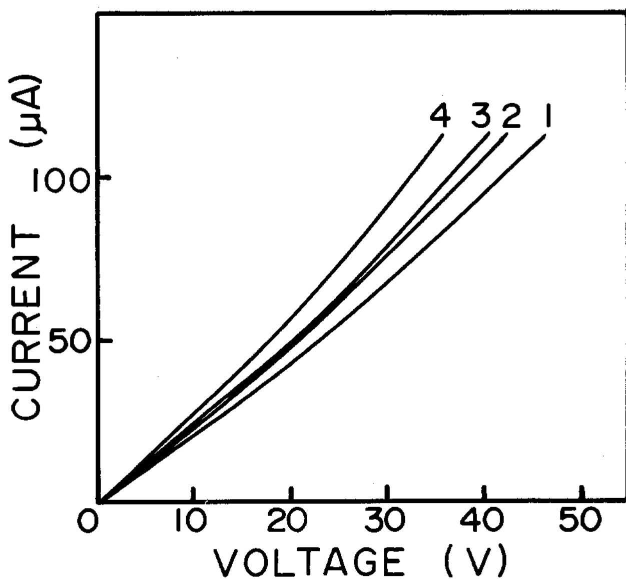

Fig. 6. V-I characteristics for the sample doped with 15 w/o Nb for different gas concentrations: 1, 0%; 2, 0.1%; 3, 0.4%; and 4, 0.6%.

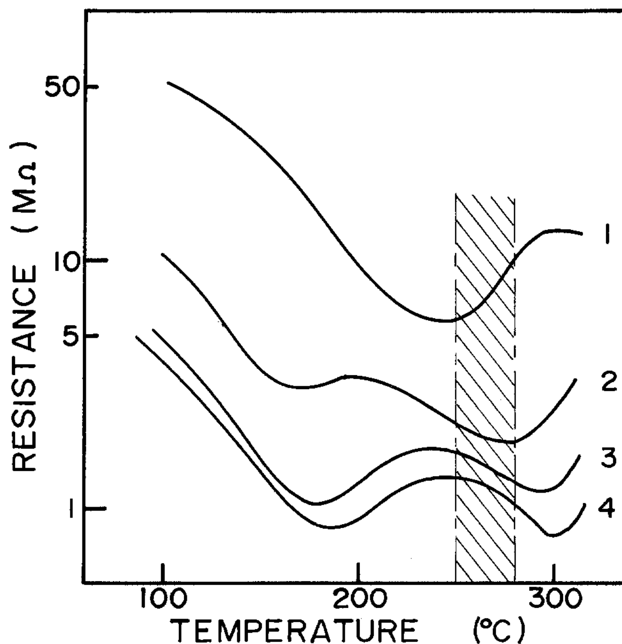

Fig. 7. Temperature dependence of the resistance for the sample doped with 15 w/o Nb for different gas concentrations: 1, 0%; 2, 0.24%; 3, 0.49%; and 4, 0.81%. The shaded regions correspond to adequate temperatures to observe the inflection phenomena in gas-detection properties.

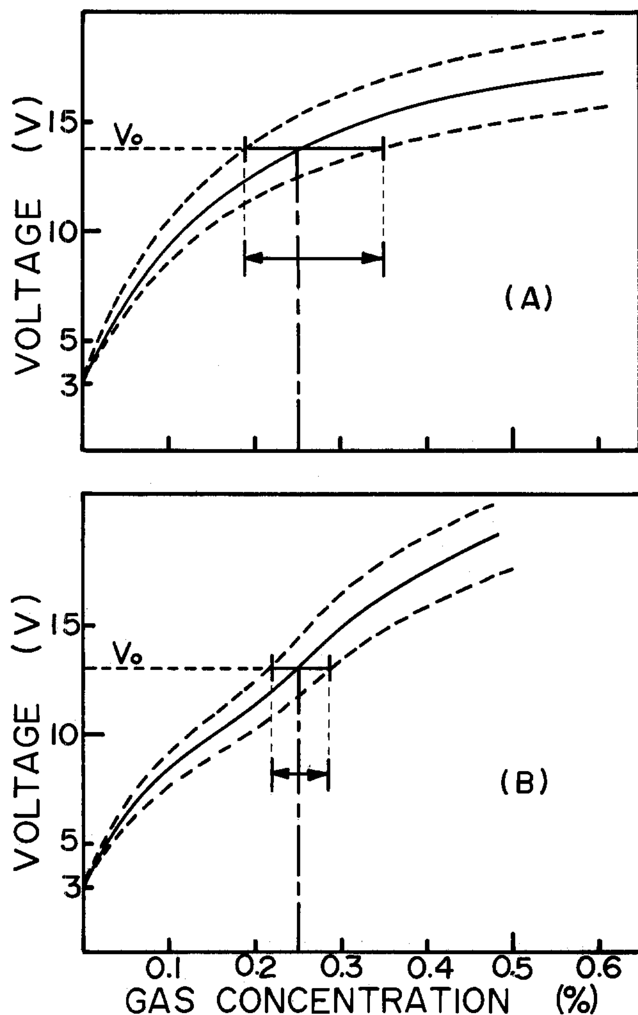

Fig. 8. The comparison of detective accuracy. (A) shows the results of a usual gas detector and (B) shows the one of our detectors. V_O indicates the point to give an alarm for the leakage of propane gas.

Conclusions

The resistance as a function of propane gas concentration for the sample of SnO_2 doped with Nb is quite different from the so-called Freundlich curve; that is, an inflection on the curve of resistance change is found in the gas concentrations of 0.3-0.5%. The similar phenomena are also observed for the samples doped with V, Ti, or Mo. The gas concentration of this inflection point depends on the applied voltage and the concentration of dopants.

From the results of the temperature dependence of resistance, it has been found that the minimum located in the lower temperature region is closely related to the observed inflection anomaly.

It has been expected that more reliable propane-gas detectors can be developed by utilizing this inflection property.

Defect Formation during High Pressure, Low Temperature Steam Oxidation of Silicon

L. E. Katz*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A series of experiments have been carried out to characterize the perfection of silicon wafers oxidized in an accelerated manner at 700°C and 20 atm steam. All experiments were performed using 3 in. diam wafers. High pressure steam oxidations of (100) and (111) oriented silicon, both n and p type, resulted in suppression of oxidation-induced stacking faults for all thicknesses studied (up to 5 μm oxide). Some wafers were subjected to normal 1 atm steam oxidations to produce stacking faults and subsequently steam oxidized at high pressure to study the behavior of these preexisting stacking faults. Results showed some shrinkage, but less than might be expected based solely on the consumption of silicon. Capacitance transient measurements have been made on the high pressure steam-oxidized samples and compared to wafers treated at higher temperatures at 1 atm. The defect-state concentration after high pressure steam oxidation was found to be nearly identical to the preoxidation condition.

Thermal oxidation of silicon typically produces stacking faults lying on (111) planes. These faults are extrinsic in nature and are bounded by Frank partial dislocations (1). The presence of such faults in a p-n junction can result in degraded electrical performance (2, 3). More recently, it has been observed that the formation of the stacking faults can be suppressed during oxidation. The important parameters are temperature and time of oxidation, ambient, and HCl concentration (4-8). Other important parameters are orientation and conductivity type (9, 10). It has also been observed that oxidation-induced stacking faults from previous processing can be dissolved, provided the processing conditions fall into the "retrogrowth" region (4).

While the above-mentioned parameters can be properly chosen to prevent stacking fault formation, the device processing requirements may conflict witn those conditions. Specifically, the temperature must be very high or very low (4-8) to avoid the defect formation. While addition of HCl to dry oxidations can shift the defect curves to somewhat lower temperatures, the avoidance of oxidation-induced stacking faults may be possible only in the initial oxidation where temperature is unimportant.

Since the length of the oxidation-induced stacking fault is greater at higher temperatures than at lower temperatures for the same oxide thickness, oxidizing the silicon at low temperatures in an accelerated manner should reduce the size or completely suppress such defects. Tsubouchi *et al.* (11) have recently reported a reduction in oxidation-induced stacking fault formation in the temperature range 950°-1100°C by using steam oxidation at 6.3 atm.

It is the purpose of this work to examine defect formation during high pressure steam (20 atm) and low temperature (700°C) oxidation of silicon.

Experimental

A steam oxidation apparatus capable of oxidizing 3 in. diam silicon wafers at 20 atm and 700°C has been built. The system is a flow-through type and will be described in a separate publication (12).

* Electrochemical Society Active Member.
Key words: defects, high pressure steam oxidation, silicon, stacking faults.

Silicon crystals of (100) and (111) orientations and n and p type were grown by the Czochralski technique. Wafers from these crystals were oxidized for various times at 700°C and 20 atm. Wafer doping levels were generally below $10^{16}/cm^3$. Oxide thickness ranged up to 5.5 μm. Generally wafers were stripped of oxide and Secco etched (13) followed by interference contrast microscopy examination.

Two groups of samples were studied. The first group consisted of virgin substrates which were examined for defect formation following the high pressure oxidation. The second group consisted of (100) n-type wafers which had received an 1100°C 1 atm steam oxidation to grow stacking faults approximately 34 μm in length. These wafers were then oxidized in the high pressure system and examined for size change of the stacking faults.

On some samples the oxide was stripped, and a Schottky barrier structure was fabricated for electrical evaluation of the underlying silicon. Ti and Au-Pd alloy metallizations were used for p and n materials, respectively. Capacitance transient (14) and SEM charge collection (15) measurements were performed on the resulting structure. The sample temperature did not rise above 60°C during fabrication of the test structure.

The detection limit for stacking faults is ~1 μm using the above techniques.

Results

Substrates of (100) and (111) n- and p-type silicon were oxidized at 700°C and 20 atm steam for various times to grow oxides which were in the 0.5-5.5 μm range. Wafers were Secco etched following removal of the oxide and compared to a control group of Secco etched wafers which had not be subjected to the oxidation. In all cases, using interference contrast microscopy, there was no difference in etching behavior between the oxidized wafers and the nonoxidized wafers. Both groups showed a level of hillock and saucer pit defects in $\sim 10^3/cm^2$ range. The important observation was that oxidation-induced stacking faults were not observed.

To study size change of stacking faults, lightly doped (100) n-type wafers were oxidized at 1100°C at 1 atm in steam to intentionally grow oxidation-induced stacking faults.

It has previously been established (16) that most of the surface-nucleated, oxidation-induced stacking faults will be in the same size range, whereas a size distribution will exist for the bulk faults. We observed similar results. The average oxidation-induced stacking fault size was approximately 34 μm for our 1100°C oxidation. An additional distribution of stacking faults (representing ~5% of the stacking faults) was observed which averaged 2-3 times the 34 μm length.

These wafers, with existing oxidation-induced stacking faults were steam oxidized at 700°C and 20 atm to form 1.6 and 4.2 μm thick oxides. Etching results showed little change in size of the stacking faults for the 1.6 μm oxide samples and some small shrinkage (as much as 20%) for the thicker oxide samples.

An additional group of wafers was oxidized at 1 atm and 1100°C to grow stacking faults which averaged 5 μm in length. This would project a stacking fault depth of approximately 1-1½ μm. The wafers were then steam oxidized in our high pressure system at the same temperature and pressure as previous samples. Oxide thickness for these wafers was ~5.5 μm. Such an oxidation should be sufficient to consume the already existing stacking faults if they do not grow during the high pressure oxidation. Results showed the original 5 μm stacking faults to shrink to 2.5 μm faults following the high pressure steam oxidation. A repeat experiment gave identical results.

Figure 1 depicts defect state spectra observed in the bulk silicon following three different oxidation treatments. The physical process under observation is electron emission from defect states as the Schottky barrier junction bias is repetitively pulsed from −10V to zero bias. The resulting train of junction capacitance transients is monitored through a lock-in amplifier which is tuned to a given emission time constant (12 msec). As the sample temperature is scanned, a peak is observed in the spectrum when the emission behavior of a particular defect passes through the fixed time constant window.

Both the wet and dry oxidation treatments at 1 atm introduce deep states in the 10^{11}-10^{12} cm^{-3} concentration range. The energy positions and capture cross sections given in Table I, indicate these defect states

are effective generation-recombination centers. The origin of these states is as yet unidentified. Variations in relative concentrations have been observed from run to run and furnace to furnace, independent of sample origin, which suggests that stray contamination is being detected. Float zone and Czochralski samples gave similar results. The defects are not purely interface related because they exhibit a uniform concentration beyond 5 μm in depth.

The high pressure steam oxidation introduces no new states; only a pair of shallow states in the 10^{11} cm^{-3} concentration range are present. This pair of states, E (0.08 eV) and E (0.09 eV), and concentration range is typical of as-received silicon which has undergone a ~700°C heat-treatment to remove oxygen-related donor states. These states are probably derived from oxygen associates. No states representative of contamination effects have been observed. This result follows from the low diffusivities and solubilities at 700°C.

Figure 2 shows typical SEM charge collection micrographs (EBIC) taken on the same Schottky diode structures. White features indicate reduced charge collection and, hence, defects which act as recombination centers. Both wet and dry oxidations are similar showing both stacking faults and dislocations characteristic of the thermal cycling. Complimentary etching studies reveal that both bulk and surface faults are present. Only a very few dislocation-related features are evident in the high pressure steam oxidized material.

This result is consistent with prior observations of bulk, heat-treated, Czochralski silicon (17). Below 700°C no defects are observed in SEM-CCM. Above 1000°C bulk stacking faults are seen.

Discussion

Virgin substrates.—Results presented above show that oxidation-induced stacking faults were not observed in silicon wafers steam oxidized at 700°C and 20 atm for 0.5-5.0 μm thick oxides. Murarka (18) has described the length of oxidation-induced stacking faults in (100) silicon as

$$L = K' p_{O_2}{}^m t^n \exp(-Q/kT) \quad [1]$$

where K' is a constant, p_{O_2} is the partial pressure of oxygen in the oxidizing ambient, m and n are number exponents, t is the oxidation time, Q is the activation energy, and T is the temperature of oxidation.

For the case of steam oxidation it is necessary to replace p_{O_2} term with a term representing the partial pressure of the oxidizing species. This term will be proportional to the steam pressure. To determine the accuracy of Eq. [1] for 1 atm steam oxidation we have calculated stacking fault lengths using the data of Hashimoto *et al.* (19) at 1000°C for (100) silicon. Good

Fig. 2. Charge collection micrograph of oxidized silicon. Bounding partials of stacking faults visible in (a) and (b). (a) 4 hr, wet, 1050°C, <100>: $L \simeq 17$ µm. (b) 48 min, dry, 1100°C, <100>: $L \simeq 5$ µm. (c) 5 hr, wet, 700°C, 20 atm, <100>: typical of clustered oxygen defects.

agreement is obtained; *i.e.*, ~7 µm calculated *vs.* ~6 µm experimental for a 5 hr oxidation.

The value of K' as a function of temperature has been determined by Murarka (20). Extrapolating Murarka's (18) K' data to 700°C and choosing values of $n \sim 0.75$, $m \sim 0.20$, and a Q value which was experimentally determined (18) as 2.3 eV independent of temperature in the 1050°-1150°C range, it is possible to estimate the length of oxidation-induced stacking faults which might be expected at 700°C assuming the extrapolated values are valid for high pressure steam. The pressure dependence of Q is negligibly small. Based on Eq. [1] as modified for steam, we arrive at a value of 0.07 µm for a 30 hr oxidation corresponding to ~4 µm oxide for (100) silicon. Similarly a value of L equal to 0.01 µm is calculated for an oxidation of 3 hr corresponding to a ~0.70 µm oxide for (100) silicon.

Experimentally n increases with decreasing temperature whereas, theoretically, it is independent of temperature (18). Choice of a value of 1 for n would increase the above calculated values by a factor of ~20. On the other hand, choice of the theoretical value (18) for Q of ~2.7 would decrease the L values by two orders of magnitude. Using reasonable estimates for n, Q, K', and the above-mentioned model, the size of any oxidation-induced stacking faults which could form for our oxidation conditions approaches zero. The experimental techniques used in this study would not detect stacking faults smaller than 1 µm.

Use of the above model for the data of Tsubouchi *et al.* (11, 21) at 1000°C and 6.3 atm shows that the calculated values for the stacking fault length compare favorably with those observed experimentally. For example, we calculate for their 3 µm oxide on (100) silicon a stacking fault length ~9 µm whereas their data show a value ~7 µm.

Substrates with preexisting stacking faults.—It has been shown that the length to depth ratio of oxidation-induced stacking faults is related to the oxidation conditions (22). Typically observed length to depth values for a 1 µm oxide at 1100°C are in the range of 3-4. During thermal oxidation of silicon, stacking faults (at a temperature in the growth region) are growing both in length and depth.

It has been observed here that preexisting stacking faults ~34 µm long showed shrinkage up to ~20% when oxidized in the high pressure system. Our measured length to depth ratio prior to high pressure oxidation was 3.1 indicating a stacking fault depth of 11 µm. The group of wafers oxidized at 1100°C to grow stacking faults ~5 µm long should, therefore, show a stacking fault depth ~1.6 µm. These wafers, when subjected to a 5.5 µm oxide growth at 20 atm steam and 700°C showed stacking fault lengths ~2.5 µm even though the consumption of silicon was greater than the original stacking fault penetration. It is probable that the preexisting stacking faults are growing to some extent during high pressure steam oxidation but at a rate slower than they are being consumed. The net result is that the stacking fault size decreases during high pressure low temperature steam oxidation.

Hu (4) observed the retrogrowth of existing stacking faults at high temperatures. Murarka (20) has pointed out that retrogrowth is observed to occur at that temperature at which the self-diffusion coefficient of silicon becomes equal to the parabolic rate constant (B). The experimentally determined B values at 700°C and 20 atm steam for our system are 2.89 μm^2/hr for (111) silicon and 1.90 μm^2/hr for (100) silicon. These values are significantly higher than observed for 1 atm oxidations at 700°C (23).

Since, even for 5 µm thick oxide growth we are not able to achieve complete retrogrowth of small stacking faults, the retrogrowth temperature must be >700°C for our oxidation conditions. To calculate the retrogrowth temperature for 700°C and 20 atm, we determine the temperature at which the self-diffusion coefficient of silicon becomes equal to the parabolic rate constant quoted above. Based on this model and self-diffusion coefficient data of Peart (24), the retrogrowth temperature calculates to be ~1400°C. Use of the self-diffusion data of Mayer *et al.* (25) results in a calculated retrogrowth temperature greater than the melting point of silicon. This, of course, implies that under our high pressure low temperature operating

conditions the preexisting stacking faults will not shrink.

The observations that stacking fault formation is suppressed in virgin silicon and that preexisting stacking faults shrink somewhat suggests that under accelerated oxidation the consumption of silicon becomes important. Preexisting stacking faults grow, but at a rate slower than they are consumed.

The unique time-temperature relation (Eq. [1]) for stacking fault length indicates a growth mechanism which is reaction limited at the fault. One can, thus, determine oxidation conditions under which fault growth is balanced by silicon consumption for a defect-free oxidation step. At low temperatures, fault formation may be nucleation limited.

General.—The high pressure steam oxidation treatment retains more silicon crystal perfection than any other oxidation treatment tested. In fact, the material maintains its preoxidation character with respect to point defect states as well as line or planar defects. These results most certainly are due to the low temperature of the process. Oxygen clusters when supersaturated, but, in support of empirical models, nucleation and growth of stacking faults, do not occur. One must be aware, of course, that subsequent processing above 1000°C may nucleate stacking faults at these cluster sites.

In this respect, low oxygen float zone silicon presents distinct advantages. The oxygen content would represent only the 700°C equilibrium value. Subsequent treatment at higher temperatures would produce no bulk precipitation. In Czochralski silicon, the 700°C oxidation step presents the same perturbation to crystal perfection as the standard boule soaking step.

Conclusions

Steam oxidation of silicon at 700°C and 20 atm results in suppression of oxidation-induced stacking faults for oxides of all thickness (up to 5 μm) examined. This applies to (100), (111), n-type and p-type lightly doped wafers.

Preexisting stacking faults tend to grow during the high pressure steam oxidation treatment, however, their net length is reduced by the consumption of silicon.

Based on defect-state concentration measurements, the 700°C, 20 atm oxidation treatment maintains excellent silicon crystal perfection.

ABSTRACT

The chemical diffusivity of copper in chalcocite has been determined electrochemically as a function of the copper activity at 400°C, using the cell

$$Cu|CuBr|Cu_{2-\delta}S|Pt$$

A potentiostatic technique involving a CuBr solid electrolyte has been used. The diffusivity changes from a value of 7.3×10^{-3} cm²/sec when the copper activity is 0.78 to a value of 4.2×10^{-3} cm²/sec when the copper activity is 0.23. The copper to sulfur ratio in cuprous sulfide has been determined as a function of the copper activity using a coulometric titration technique. The results of the measurements are consistent with a model involving neutral copper vacancies, V_{Cu}, as the predominant defect carrier in cuprous sulfide. Using this model, a value of 1.9992 has been calculated for the Cu/S ratio in cuprous sulfide having unit activity of copper at 400°C.

Cuprous sulfide (chalcocite) is a nonstoichiometric compound which is metal deficient. The nonstoichiometry is accommodated by the creation of copper vacancies in the lattice. The crystal structure at 400°C is hexagonal (1, 2). According to x-ray investigations, at 400°C, at least half of the copper ions are randomly distributed among a large number of nearly equivalent lattice sites (3). This is in conformity with the high value of the self-diffusion coefficient of copper ions (9×10^{-6} cm²/sec at 420°C) and ionic conductivity ($0.2\ \Omega^{-1} \cdot \text{cm}^{-1}$ at 400°C) (4, 5). The disorder in the sulfur sublattice seems to be negligible in view of the large size of the sulfur ions and their extremely low diffusivity (6).

A potentiostatic electrochemical technique was used to determine the chemical diffusivity of copper in cuprous sulfide. The cell may be represented as

$$\underset{x=0}{Cu|CuBr|}Cu_{2-\delta}\underset{x=l}{S|}Pt \quad [A]$$

Cuprous bromide is essentially an ionic conductor between 350° and 450°C when subjected to an applied voltage of less than 300 mV (7). A fixed activity and, therefore, a fixed concentration of copper in cuprous sulfide can be established at the copper bromide/copper sulfide interface by applying a preselected voltage across cell [A] with the sulfide at positive polarity. The applied voltage is given by the expression (8, 9)

$$E_{appl} = \frac{-RT}{\mathbf{F}} \ln a_{Cu} + I\Omega \quad [1]$$

where R is the gas constant, T is the absolute temperature, $\mathbf{F}$ is the Faraday constant, a_{Cu} is the activity of Cu, I is the current in the external circuit of cell [A], and Ω is the electrolyte resistance. Equation [1] assumes that polarization effects at the electrode/electrolyte interface are negligible. According to Eq. [1], the applied voltage will fix a constant copper activity (and therefore copper concentration) in cuprous sulfide at the electrode/electrolyte interface provided the second term in Eq. [1] is small when compared to the first term. When the current, I, has dropped to zero, a uniform copper concentration is attained throughout the cuprous sulfide electrode. If the applied voltage is now quickly changed to a higher value, a new lower copper concentration will be established at the electrode/electrolyte interface of cell [A]. Copper then diffuses out of copper sulfide until the new lower copper concentration is attained throughout the copper sulfide specimen. Fick's second law for this diffusion problem may be written as

$$\frac{\partial C_{Cu}}{\partial t} = \tilde{D}_{Cu} \frac{\partial^2 C_{Cu}}{\partial x^2} \quad [2]$$

In Eq. [2], C is the concentration of copper in cuprous sulfide in moles cm^{-3}, t is the time in seconds, $\tilde{D}_{Cu}$ is the chemical diffusion coefficient of copper in cuprous sulfide, and x is the coordinate of diffusion. For the initial and boundary conditions

$$C_{Cu} = C_{Cu}', \quad 0 \leq x \leq l, \quad t = 0$$

$$C_{Cu} = C_{Cu}'', \quad x = 0, \quad t > 0$$

$$\left(\frac{\partial C_{Cu}}{\partial x} \right)_{x=l} = 0$$

the solution to Eq. [2] is (10)

$$\frac{C_{Cu}' - C_{Cu}}{C_{Cu}' - C_{Cu}''} = 1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)} \exp\left(-\frac{(2n+1)^2\pi^2\tilde{D}_{Cu}t}{4l^2}\right) \cdot \sin\frac{(2n+1)\pi x}{2l} \quad [3]$$

The magnitude of current I is related to the concentration gradient at $x = 0$ through

$$|I| = A\mathbf{F}\tilde{D}_{Cu} \left| \frac{\partial C_{Cu}}{\partial x} \right|_{x=0} \quad [4]$$

where A is the cross sectional area of the copper sulfide electrode. When the diffusion times are sufficiently long, the first term in the summation in Eq. [3] is a

* Electrochemical Society Active Member.

Key words: chemical diffusivity, nonstoichiometry, cuprous sulfide, potentiostatic technique, coulometric titration.

good approximation to the total sum. Thus, at long time

$$\left(\frac{\partial C_{Cu}}{\partial x}\right)_{x=0} = \frac{2(C_{Cu}' - C_{Cu}'')}{l} \exp - \frac{\pi^2 \tilde{D}_{Cu} t}{4l^2} \quad [5]$$

On combining Eq. [4] and [5]

$$I = 2A\tilde{D}\mathbf{F}\left(\frac{C_{Cu}' - C_{Cu}''}{l}\right) \exp - \frac{\pi^2 \tilde{D}_{Cu} t}{4l^2} \quad [6]$$

It must be emphasized that the value of the Faraday constant in Eq. [6] has units of coulombs/gram equiv. whereas in Eq. [1], it has units of cals/volt.

A coulometric titration procedure has been used to determine the activity of copper in cuprous sulfide as a function of the Cu/S ratio. When cell [A] is shorted, the cuprous sulfide sample attains the composition corresponding to equilibrium with copper. A well-defined amount of copper may now be removed from the sample by passing a current, I, through the cell for time, t. The decrease, δ', in the Cu/S ratio in cuprous sulfide with respect to the sample having unit activity of Cu is given by

$$\delta' = \frac{It}{n_s \mathbf{F}} \quad [7]$$

In Eq. [7], n_s is the number of gram atoms of sulfur in the cuprous sulfide specimen. **F** has units of coulombs/gram equiv. After passing current, I, for time, t, the cell circuit is opened and the open-circuit voltage, E, of the cell is measured until it attains a steady value. The open-circuit voltage is related to the activity of copper in cuprous sulfide through

$$E = \frac{-RT}{\mathbf{F}} \ln a_{Cu} \quad [8]$$

The experiment is repeated by passing current, I, for different time intervals and in each case measuring the final steady open-circuit cell emf.

Experimental Procedure

Chalcocite powder of 99.999% purity (obtained from Poly Research Corporation, New York), cuprous bromide of 99.95% purity, and copper powder of 99.95% purity were used in the experiments. The experimental setup used is shown in Fig. 1. It consisted of a Kanthal-wound horizontal furnace which had a constant temperature zone of about 3 in. The cell could be placed in an alumina cell holder and kept in the constant temperature zone of the furnace. The furnace temperature could be controlled at 400° ±1°C by means of a Leeds and Northrup Electromax temperature controller. Purified argon gas was used to provide the inert atmosphere; the argon was purified by first passing through anhydrous calcium chloride and then through activated copper (BASF) kept at 180° ± 10°C. A regulated power supply was used to apply selected voltages. Applied or open-circuit voltages could be measured by means of a high impedance (≈$10^{10}\Omega$) electronic voltmeter.

In cell [A], the electrode and the electrolyte materials were in the form of cylindical pellets. Copper powder was pressed into pellets of 1 cm diam and nearly 0.5 cm thickness in a die at 10-12 tsi. Cuprous bromide pellets were also prepared in a similar way, with thicknesses in the range, 0.1 to 0.3 cm. Cuprous sulfide pellets with thicknesses in the range, 0.8-2 cm and diameters of 0.5 or 1 cm were pressed at a slightly higher pressure (15 tsi). The pressed pellets had densities of 97 + % of the theoretical value.

The cell was assembed in an alumina cell holder (Fig. 1) and inserted into the furnace. Electrical contact with the electrodes was made using platinum disks. The electrodes and electrolyte could be kept in intimate contact by means of an alumina push-rod which could be tightened by means of a brass screw (Fig. 1). The system was evacuated to a pressure of 10 mTorr and refilled with purified argon successively five times. Finally, a low flow rate of a few bubbles of argon per minute was maintained. The cell was now brought to a temperature of 400°C and maintained at this value by means of the Electromax temperature controller.

A low voltage in the range, 10-30 mV, was now applied across the cell using the regulated power supply with the sulfide electrode at positive polarity. When the current in the external circuit (recorded using a Sargent recorder) had dropped to zero, the circuit was opened and the open-circuit cell voltage was measured. The open-circuit cell voltage would now be equal to the initial applied voltage. A higher voltage (higher by 20 or 30 mV) was applied across cell [A] and simultaneously the current in the circuit was recorded as a function of time. The current-time plot was analyzed to determine the chemical diffusivity of copper. A further voltage step was now given and a new current-time plot was recorded. The highest voltage applied was 130 mV. At the higher voltages, the current dropped to a finite final steady value (of a few microamperes). This could be partly due to some vaporization of sulfur from cuprous sulfide and partly due to the introduction of a small amount of positive hole conduction in the CuBr electrolyte. When this occurred, the final constant current was subtracted from the total current and the resulting current-time plot was analyzed to obtain the diffusivity. The circuit used in the experiment is given in Fig. 2.

Cell [A] was also used to determine the Cu/S ratio in cuprous sulfide as a function of the copper activity. The cell was assembled with a thin cuprous sulfide sample. A uniform initial copper activity was established in the cuprous sulfide sample by imposing a voltage of 10 mV across cell [A] with the sulfide at positive polarity. The applied voltage was now cut off and a constant current of 2 mA was passed through the cell (so as to remove copper from cuprous sulfide) for a few minutes by means of a 15V d-c source connected in series with a variable resistance. The current could be accurately determined by measuring the voltage drop across a 100Ω precision resistor included in the cell circuit (Fig. 3). The cell current was now dis-

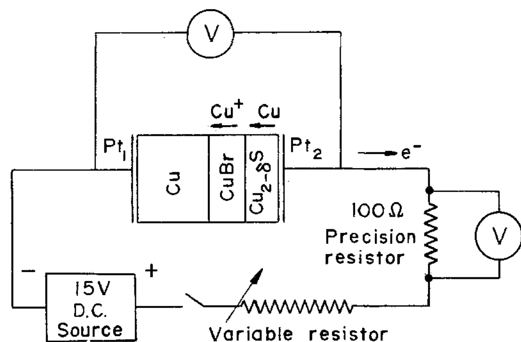

Fig. 3. Circuit used for the coulometric titration experiments

continued by opening the circuit and the final steady open-circuit cell voltage was measured. The current was imposed again and the experiment repeated. In this way, the change in the Cu/S ratio in cuprous sulfide as a function of the open-circuit cell voltage could be measured up to 200 mV.

Results and Discussion

The results reported are those obtained from five cells. Nine different cells were run, but data from four of these are considered inaccurate. Two of these cells got shorted because the CuBr pellet used was too thin. In the other two, the copper sulfide pellet was deformed because of the mechanical pressure exerted on the cell. Two typical current time plots for two sets of applied voltages (E_1 and E_2) are shown in Fig. 4. Figure 5 shows the corresponding log I *vs.* t plots. From the slopes of the straight lines in Fig. 5, the chemical diffusivity of copper can be calculated.

The chemical diffusivity values obtained from the measurements were found to depend on the ratio of the cuprous sulfide thickness to copper bromide thickness as shown in Fig. 6. The data points on Fig. 6 correspond to applied voltages of 10 and 30 mV. For each cell, at least five current-time plots were taken for each set of applied voltages. Thus each point shown on Fig. 6 is the average value obtained from five or more

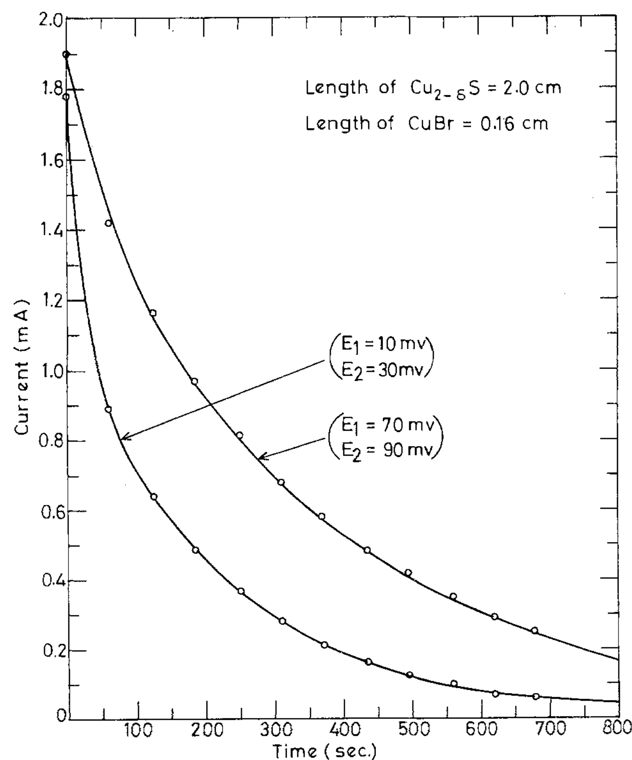

Fig. 4. Cell current *vs.* time in the potentiostatic single cell technique.

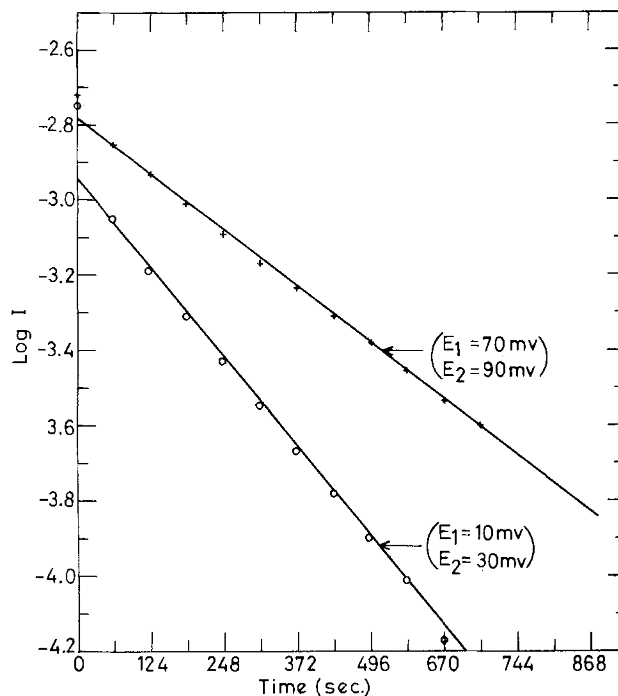

Fig. 5. Log I vs. time in the potentiostatic single cell technique

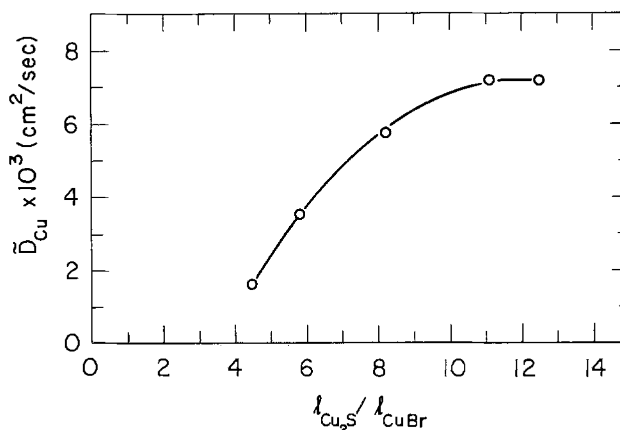

Fig. 6. Effect of the ratio of cuprous sulfide thickness to cuprous bromide thickness on the measured chemical diffusion coefficient.

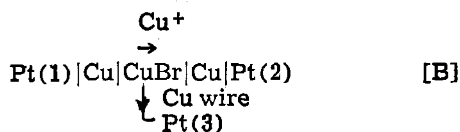
current-time plots. The average uncertainty of each point is between 10 and 15%. Two of the cells, with l_{Cu_2S}/l_{CuBr} ratios of 11 and 12.5, gave identical diffusivity results. At lower ratios, the diffusivity values were lower. An electrode/electrolyte ratio of 15 was used in one cell, but this cell got shorted before too many measurements could be made. The CuBr electrolyte used in this cell had a thickness of only 0.12 cm. However, measurements at higher applied voltages were obtained with this cell before it got shorted. The diffusivity value for applied voltages of 70 and 90 mV compares well with the value obtained from the two cells which had l_{Cu_2S}/l_{CuBr} ratios of 11 and 12.5.

At l_{Cu_2S}/l_{CuBr} ratios less than 11, the diffusivity values were lower. Lower ratios correspond to larger electrolyte thicknesses and smaller electrode thicknesses. The boundary conditions used for the diffusion problem are strictly valid only if the $I\Omega$ term in Eq. [1] is zero. This ideal situation cannot be realized since there is current flow during the diffusion process. However, it is practically feasible to make the $I\Omega$ term much smaller than the first term in Eq. [1]. The identical diffusivity results obtained at electrode/electrolyte ratios of 11, 12.5, and 15 indicate that at these ratios the $I\Omega$ drop is not significant. When larger electrolyte thicknesses are used, the $I\Omega$ drop is higher.

In a typical diffusion run, the $I\Omega$ drop is largest in the first minute or two. For smaller cuprous sulfide samples, the total diffusion time is smaller (as there is less copper to be removed) and correspondingly the contribution from the $I\Omega$ drop is more significant. However, when thicker cuprous sulfide samples are used, the total diffusion time is increased and the influence of the $I\Omega$ drop on the longtime solution of the diffusion equation (Eq. [6]) is considerably reduced.

Any overvoltage built up at the Cu/CuBr interface could influence the diffusivity results especially if it is time dependent. Strictly, an overvoltage term must also be included on the right hand side of Eq. [1]. To study the overvoltages which develop at the Cu/CuBr interface, the following symmetrical cell was used



[B]

The cell was assembled and heated to a temperature of 400°C in a purified argon atmosphere. The cuprous bromide pellet which was used had a thickness of 0.5 cm. Initially, the open-circuit voltages between Pt(1) and Pt(3) and between Pt(2) and Pt(3) were measured. A very small (between 1 and 2 mV) open-circuit voltage was observed, presumably due to a small temperature gradient across the cell. A d-c polarization current in the range, 1-6 mA, was passed between Pt(1) and Pt(2) so as to transport Cu from left to right in cell [B]. The cathodic voltage between Pt(2) and Pt(3) and the anodic voltage between Pt(1) and Pt(3) were recorded as a function of time. The results are shown in Fig. 7 and 8, respectively. The cathodic voltage reaches a steady-state value in about 30 sec for all the currents used. Furthermore, the cathodic voltage is mostly the $I\Omega$ drop, the polarization being negligible. The anodic voltage reaches a steady-state value in about a minute for polarization currents ranging from 1 to 4 mA. At larger currents, the anodic voltage continues to increase with time. The magnitude of the steady-state anodic voltage shows that it

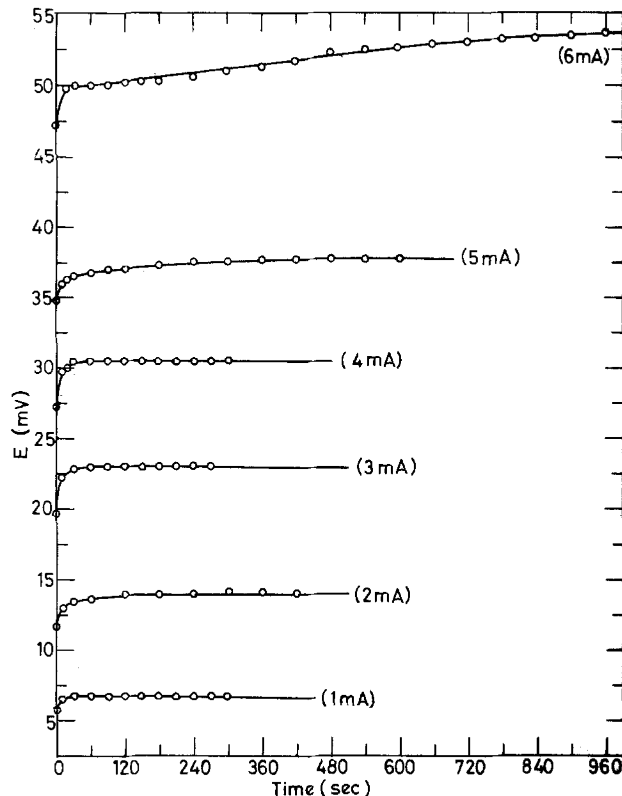


Fig. 8. Anodic voltage as a function of time in the polarization experiments with cell [B].

contains a steady-state overvoltage term in addition to the $I\Omega$ drop. This could be due to void formation at the anode when copper atoms are removed (11). All diffusivity values reported here were obtained using Cu as the cathode. The cathodic voltages in the diffusion experiments should be lower than those shown in Fig. 7 since the thickness of the CuBr electrolyte used in the polarization experiments was large (0.5 cm).

The chemical diffusivity values are plotted as a function of copper activity in Fig. 9. The diffusivity values plotted are the average of the results from the cells with l_{Cu_2S}/l_{CuBr} ratios of 11 and 12.5. The chemical diffusivity is found to increase with increase in the activity of copper.

Equation [6] indicates that the intercept at $t = 0$ of the straight line in the log I *vs.* t plots can also be used to calculate the diffusivity. The values so calculated agreed with the diffusivity values obtained from the slopes within a factor of 1.5. In calculating diffusivity values from the intercept, one needs the value

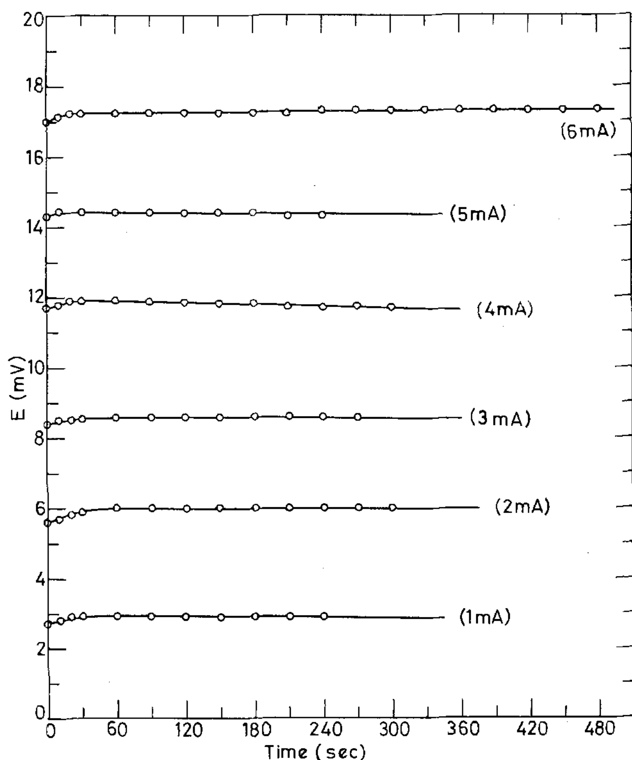

Fig. 7. Cathodic voltage as a function of time in the polarization experiments with cell [B].

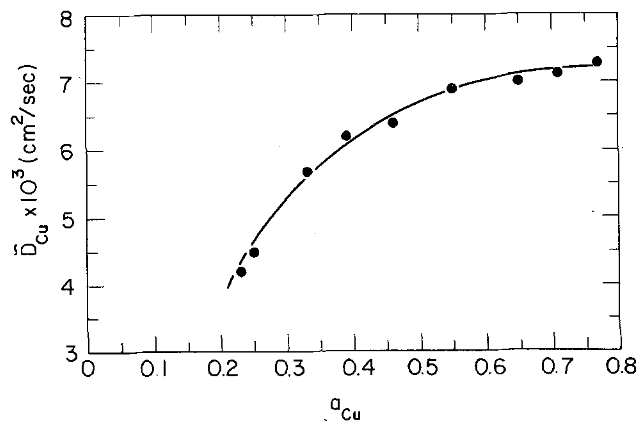

Fig. 9. Chemical diffusion coefficient as a function of copper activity.

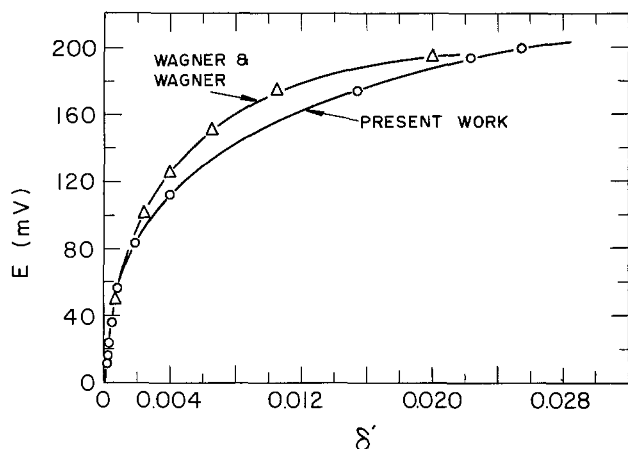

Fig. 10. The open-circuit voltage of cell [A] as a function of the deviation from stoichiometry, δ', in cuprous sulfide.

of ($C_{Cu}' - C_{Cu}''$). Reference to Fig. 10 indicates that it is difficult to pick an accurate value for this concentration difference for typical applied voltages (say 10 and 30 mV) used in the diffusion experiments. For this reason, the diffusivity values obtained from the slopes are considered more accurate and are recommended.

The results of the coulometric titration experiments are plotted in Fig. 10. Figure 10 also shows the values obtained by Wagner and Wagner (7). The agreement between the two measurements is satisfactory. In Fig. 10, δ' is the deviation in the Cu/S ratio in cuprous sulfide from the value corresponding to unit activity of copper.

The results of the coulometric titration experiments can be combined with the measured chemical diffusivity values of copper to obtain values of the self-diffusivity of copper. The chemical and self-diffusivities are related by

$$\tilde{D}_{Cu} = D_{Cu}\left(\frac{d\ln a_{Cu}}{d\ln C_{Cu}}\right) \quad [9]$$

In Eq. [9], $d\ln a_{Cu}/d\ln C_{Cu}$ is the thermodynamic factor for copper in cuprous sulfide. The thermodynamic factor can be calculated from the coulometric titration results as follows. In cuprous sulfide coexisting with metallic copper, the ratio of copper concentration to sulfur concentration is given by

$$\frac{C_{Cu}^{o}}{C_s} = 2 - \delta^* \quad [10]$$

where δ* is the copper deficit in cuprous sulfide having unit activity of copper. The concentration terms in Eq. [10] have units of moles per cubic centimeter. When the copper activity in cuprous sulfide is decreased, the copper deficit increases and one has

$$\frac{C_{Cu}}{C_s} = 2 - \delta^* - \delta' \quad [11]$$

where C_{Cu} is the copper concentration corresponding to δ'. Hence

$$\ln C_{Cu} = \ln C_s + \ln(2 - \delta^* - \delta') \quad [12]$$

$$d\ln C_{Cu} = \frac{-d\delta'}{(2 - \delta^* - \delta')} \quad [13]$$

since C_s and δ* are constants. From Eq. [8]

$$dE = \frac{-RT}{\mathbf{F}}\,d\ln a_{Cu} \quad [14]$$

Combining Eq. [13] and [14]

$$\frac{d\ln a_{Cu}}{d\ln C_{Cu}} = \frac{(2 - \delta^* - \delta')\mathbf{F}}{RT}\left(\frac{dE}{d\delta'}\right) \quad [15]$$

Combining Eq. [9] and [15]

$$\tilde{D}_{Cu} = D_{Cu}\frac{(2 - \delta^* - \delta')}{RT}\left(\frac{dE}{d\delta'}\right) \quad [16]$$

Thus using $dE/d\delta'$ values from Fig. 10, the self-diffusivity, D_{Cu}, can be calculated. Values of chemical diffusivity, self-diffusivity, and thermodynamic factor at various copper activities are presented in Table I.

Cuprous sulfide is an intrinsic semiconductor. When copper is removed from cuprous sulfide, copper vacancies are introduced into the lattice. The equilibration of a cuprous sulfide sample with an outer phase of fixed copper activity may be represented by the equilibrium

$$Cu_{Cu} = V_{Cu} + Cu \quad [17]$$

Cu_{Cu} represents a copper atom in its normal site in cuprous sulfide and V_{Cu} represents a neutral copper vacancy. The equilibrium constant for reaction [17] can be written as

$$K_{17} = [V_{Cu}]a_{Cu} \quad [18]$$

In Eq. [18], $[V_{Cu}]$ represents the concentration of copper vacancies in cuprous sulfide and a_{Cu} represents the copper activity. If the vacancy concentration in Eq. [18] is expressed as the ratio (number of copper vacancies)/(number of sulfur atoms), then

$$\delta = [V_{Cu}] \quad [19]$$

where δ is the exact copper deficit in cuprous sulfide. On combining Eq. [18] and [19]

$$\delta = K_{17} \cdot a_{Cu}^{-1} \quad [20]$$

Let δ* represent the copper deficit in cuprous sulfide when it is in equilibrium with copper. Then

$$\delta^* = K_{17} \quad [21]$$

Furthermore

$$\delta = \delta^* + \delta' \quad [22]$$

Combining Eq. [20] to [22]

$$\delta' = \delta^*[a_{Cu}^{-1} - 1] \quad [23]$$

Thus, if the removal of copper from cuprous sulfide generates neutral copper vacancies, then a plot of δ' *vs.* ($a_{Cu}^{-1} - 1$) should be a straight line passing through the origin. Furthermore, the slope should be equal to δ*. A plot of δ' *vs.* ($a_{Cu}^{-1} - 1$) is shown in Fig. 11. Our data as well as the data of Wagner and Wagner (7) are shown. The results of Wagner and Wagner would give a value of δ* = 1.9994 (from Fig. 11) whereas our data leads to a value of δ* = 1.9992.

Wagner and Wagner (7) have calculated a value for δ* in a different way using the following assumptions:

(*i*) The predominant defects in cuprous sulfide are excess electrons, electron holes, and singly ionized copper vacancies so that

$$p = n + [V_{Cu}'] \quad [24]$$

In Eq. [24] p is the concentration of holes, n is the concentration of excess electrons and $[V_{Cu}']$ is the con-

Table I. Chemical diffusivity, self-diffusivity, and thermodynamic factor at various copper activities

centration of singly ionized copper vacancies. Since $\delta = [V_{Cu}']$

$$\delta = p - n \qquad [25]$$

(*ii*) The chemical potential of copper ions, μ_{Cu^+}, is independent of the Cu/S ratio.

Their analysis leads to a value of $\delta^* = 1.9996$. The agreement between the values of δ^* obtained using two different defect models is surprisingly good. Recently, some authors have pointed out that neutral copper vacancies are the predominant defect in cuprous oxide (12, 13). According to Rau (14), in the high temperature cubic modification of cuprous sulfide ($Cu_{7-x}S_4$), neutral copper vacancy, V_{Cu}, predominates over a wide range of sulfur pressures. Thus cuprous sulfide (chalcocite) at 400°C, could have predominantly neutral copper vacancies, with some singly charged vacancies, V_{Cu}', to provide excess p-type conduction.

Self-Diffusion and Na-K Exchange in β- and β''-Na-Gallate Fast Ion Conductors

L. M. Foster,* D. R. Campbell,* and G. V. Chandrashekhar

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The self-diffusion coefficients for Na^+ migration in the two-dimensional, ionically conducting sodium gallates were determined as 2.0×10^{-5} and 7.6×10^{-5} cm²/sec for the β (hexagonal) and β'' (rhombohedral) phases, respectively, at 350°C. Part of the sodium of these compounds is immobile. It is proposed that this portion substitutes for Ga^{+++} in the spinel block and compensates the charge of additional sodium in the conduction plane. The correlation factor suggests a noncolinear interstitialcy diffusion model for migration of the mobile Na^+ in the β phase. The correlation factor for the β'' phase is unusually large and not explained by any present model. Activity coefficients for the Na- and K-gallates were determined in solid solutions. Na^+ and K^+ show essentially ideal behavior in the β'' structure and very nonideal behavior suggestive of ordering, in the β structure, in agreement with findings for β-Al_2O_3.

Gallium analogs of the fast ion conductors β- and β''-alumina exist and are themselves fast ion conductors (1). They exhibit many of the properties of their aluminum counterparts and, because of the relative ease of preparation, they provide an attractive new medium in which the phenomenon of exceedingly high alkali ion diffusivity can be studied. In particular, direct comparison between the β and β'' forms can be made in gallate system because pure (viz., unstabilized) monocrystals of each can be prepared (2),

Key words: defects, crystallography, equilibrium, stoichiometry.

whereas in the aluminate system, the β'' form must be stabilized with magnesia or lithia (3).

β-alumina has the stoichiometric formula $Na_2O \cdot 11Al_2O_3$ (4, 5), which provides for one sodium ion per conducting plane in the unit cell. The conducting plane in the β form (space group $P6_3/mmc$) is a mirror plane, and the sodium atom has a trigonal-prismatic coordination with a triangle of three oxygen atoms of an adjacent c plane centered immediately above it, and another immediately below. A view of the β structure normal to the sodium plane is shown in Fig. 1, top. The Na is shown in the favored Beevers-Ross position (5). If occupied, the higher-energy, anti-Beevers-Ross site would have one oxygen immediately above the Na and another immediately below, in a more or less linear O-Na-O configuration.

The β'' form results from a three-fold screw rotation about the c axis (space group R3m) which removes the mirror plane and provides two possible identical sites for the sodium in tetrahedral coordination (Fig. 1, bottom).

β-Al_2O_3 contains more sodium than the stoichiometric formula provides (typically $Na_2O \cdot 9Al_2O_3$) whereas the β'' form contains still more, but presumably less than the formula $Na_2O \cdot 5.5Al_2O_3$ provides, where the two equivalent Na sites are fully occupied. A "typical" analysis of pure β''-Al_2O_3 is difficult to ascertain because unstabilized (*viz.*, no Li_2O or MgO) compositions appear to be mixures of β'' and β, and stabilized compositions have the additional complication of the presence of the second cation. Roth (6) and Roth *et al.* (3) showed by x-ray and neutron diffraction that the excess Na in β-Al_2O_3 was compensated by additional oxygen in the conduction plane (mid-oxygen positions, Fig. 1), each bonded to two aluminum ions, one immediately above and one immediately below, that had moved from their octahedral (A-1) sites into interstitial sites, leaving their octahedral sites vacant. One such oxygen would compensate the charge on two excess sodium ions. The formula $Na_2O \cdot 9Al_2O_3$ would require one new interstitial oxygen and two excess sodium ions per 9-10 unit cells.

The formula $Na_2O \cdot 5.5Al_2O_3$ for β'' also requires that the charge on the second sodium going into the conduction plane be compensated by ½ oxygen. If, on the other hand, the extra sodium were compensated by an aluminum vacancy, the formula $Na_2O \cdot 5.33Al_2O_3$ would result. This is equivalent to the ternary oxide $Na_2OMgO \cdot 5Al_2O_3$ that Bettman and Peters proposed as the prototype of the β'' form (7), except that in the latter case, two-thirds of the charge of an aluminum vacancy in the spinel block is compensated by a magnesium and the remaining third by the extra sodium in the conduction plane. Roth *et. al.* (3) found by neutron diffraction that in MgO-stabilized β''-Al_2O_3 about 38% of the aluminum in the tetrahedral (A-2) sites that are near the center of the spinel block are replaced by magnesium and the remainder of the charge is compensated by extra sodium. The increase in conductivity of the β'' over the β phase presumably reflects both this higher sodium content and the lower interstitial oxygen content of the former.

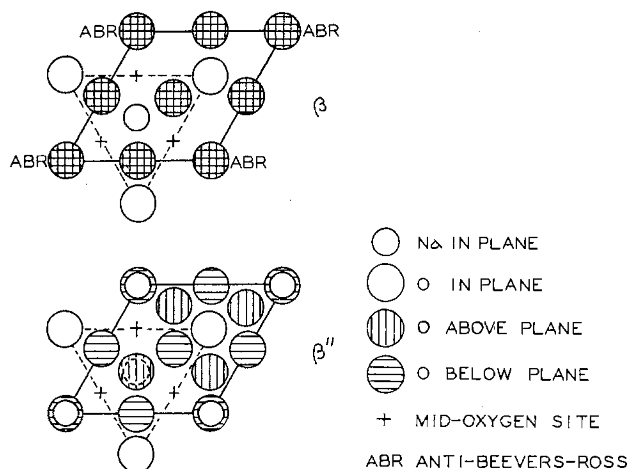

Fig. 1. Conduction plane of β- and β''-Al_2O_3

Foster and Scardefield (2) reported the growth of monocrystals of the gallium analog of β''-Al_2O_3, with the composition $Na_2O \cdot 5.7Ga_2O_3$. The β analog can now also be prepared. The ionic conductivity of these materials is considerably higher than that of their aluminum counterparts (1). Whereas at first glance this seemed to reflect the generally higher sodium content of the gallium materials, there was the complication that, in the β'' form especially, the sodium content was so high that most of the Na sites should have been full, and the disorder, which is thought to be the principal prerequisite for fast ion conductivity, should have been low. Moreover, since there was no Mg present in the β''-gallate, charge compensation for the excess sodium presumably would have had to be by additional interstitial oxygens in bridging positions where it would be expected to interfere with Na^+ migration.

Yao and Kummer (8) carried out self-diffusion and alkali ion exchange experiments in β-Al_2O_3 and obtained the diffusion coefficients and information about mixed alkali ion occupancy of the labile sites. In this paper we report similar studies with β- and β''-Na-gallate carried out in an effort to improve our understanding of the conduction process in this class of materials. We have also obtained new information about site occupancy and the alkali ion distribution.

Experimental

Self-diffusion in β- and β''-Na-gallate.—Sodium self-diffusion was followed by observing the exchange of radioactive sodium between a monocrystal of the gallate, which had been synthesized with a Na-22 tracer (2.6 yr half-life), and a melt of ordinary $NaNO_3$, at 350°C. Na-22 was obtained from the New England Nuclear Corporation as anhydrous carbonate with carrier added to a specific activity of approximately 100 μC/g.

Monocrystals of the β and β'' phases were grown in separate experiments by Na_2O vaporization from Na_2O-Ga_2O_3 melts. This procedure has been described elsewhere (2). Rectangular plates, 7-10 mm on a side and 2-3 mm thick, were employed. The ion migration was parallel to the large faces. A sufficient quantity of $NaNO_3$ was employed to contain roughly 250 times as much sodium as the crystal. Thus, once a steady state was achieved between the crystal and the melt, the equilibrium Na-22 content of the crystal would be reduced to roughly 0.4% of the original, if all of the sodium participated in the exchange. The melt was was vigorously stirred with a platinum stirrer for several minutes from the moment the crystal was dropped in, and intermittently thereafter. Approximately 0.25g samples of the melt were removed with preheated platinum scoops at timed intervals and their radioactivity compared to that of a standard.

Any radioactivity remaining in a crystal after the exchange was measured and compared to the activity before the exchange by counting with the identical geometry. The precision of this determination was limited only by counting statistics; however, it was only a relative measurement. The true composition was more difficult to ascertain. The possible variation in absolute sodium content of the two gallates as a function of growth temperature and charge composition was not known in detail and is presently under study. In general, the analytical problem with these materials is particularly severe because of the low sodium content. For example, a ±5% precision that would be considered acceptable for most analytical techniques

would give a possible range for a nominal $Na_2O \cdot 6Ga_2O_3$ composition of $Na_2O \cdot 5.70Ga_2O_3$ to $Na_2O \cdot 6.34Ga_2O_3$, which embraces a large part of the entire β''-β range. Even with the radiochemical technique, it still must be assumed that a portion of the boule that is analyzed is representative of the entire boule. From various analytical data and recent knowledge of the Na_2O-Ga_2O_3 phase diagram we assign compositions of $Na_2O \cdot 5.6 \pm 0.1Ga_2O_3$ and $Na_2O \cdot 6.8 \pm 0.1Ga_2O_3$ to the β'' and β crystals that were employed in the exchange experiments.

Na-K exchange in β- and β''-Na-gallate.—The rate of exchange of K for Na, and the equilibrium distribution of Na and K between the solids and $NaNO_3$-KNO_3 melts, were determined at 350°C.

The exchange of K for Na in the β and β'' crystals was carried out in the same manner as described above for Na-22-Na-23 exchange, but with molten KNO_3 as the liquid medium. The transfer of Na-22 to the molten salt was determined by radioactive counting, as before, and the assumption was made that the sodium was replaced one for one by K. This experiment gave information on the time that would be required to achieve equilibration of the composition of the solid crystals when in contact with melts of various $NaNO_3/KNO_3$ ratios. The results showed that a few hours would be adequate, but as a matter of convenience, the crystals were left in the melts overnight ($\simeq$16 hr).

The composition of the equilibrated crystals was determined by electron microprobe analysis with an accuracy of approximately ±5%.

Results

Self-diffusion of Na.—Figure 2 shows the extraction rate of tagged sodium from β''- and β-Na-gallate monocrystals. It is seen that after approximately 2.5 hr for β'' and 7 hr for β, the Na-22-Na-23 exchange had achieved equilibrium, even though substantial amounts of Na-22 remained in the crystals. Since this had the very important implication that part of the sodium was in immobile sites, it was essential to establish that the effect was real. Spurious observations could result from several sources. If the Na-22 stock contained a radioactive contaminant, such as Ca-45 or Sr-89, for example, which would selectively go into sites in the spinel block during synthesis of the compounds, it would not be distinguished from sodium when counting the gross activity of the crystals. This possibility was excluded by identifying the residual activity as entirely Na-22 by gamma-ray spectroscopy.

Accidental occlusion during growth of the crystal of some of the molten Na_2O-Ga_2O_3 charge would be another possible source of error, since this sodium would not be in labile sites and would not be exchangeable with the sodium of the $NaNO_3$. There would be the same end result if, in spite of visual evidence to the contrary, the samples were not monocrystals but contained some internal volume that was misoriented in such a way that the diffusion planes were blocked by c faces of the surrounding crystal. Figure 3 is an autoradiograph of the β'' crystal after the exchange. The residual activity is seen to be uniform throughout and cannot be due to a small internal volume of occluded or misoriented material. An autoradiograph of the β crystal showed a similar uniform distribution of the residual sodium.

The self-diffusion coefficients were determined in the following manner. The accumulation of Na-22 tracer in the molten salt bath is exactly equal to the loss of tracer by out-diffusion from the crystal. Following Yao and Kummer (8), the specimen can be treated as an infinitely long rectangular bar, since diffusion is confined to c planes and no concentration gradient develops along the c direction.

The loss of concentration of tracer from the sample after time t, $C(t)$, is given by

$$C(t) = C_o \frac{64}{\pi^4} \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \frac{1 - \exp\left\{-\left(\frac{\pi^2 Dt}{4}\right)\left(\frac{(2n+1)^2}{\omega^2} + \frac{(2m+1)^2}{l^2}\right)\right\}}{(2m+1)^2(2n+1)^2} \quad [1]$$

where C_o is the initial concentration, D is the diffusion constant, and ω and l are the width and length of the rectangular specimen.

The form of Eq. [1] (sums of many exponentials) is too complex to allow the determination of D by a direct method, such as least squares fit to the experimental data, and a trial and error method is employed. The procedure is to find an approximate value of D from a set of normalized curves of $C(t)/C_o$ *vs.* normalized time, Dt/ω^2. Several such curves are reproduced in Fig. 4 to provide a useful reference for others. They are labeled for different shape factors, *i.e.*, l/ω ratios. A single measurement of $C(t)/C_o$, preferably in the range of 0.4-0.6, for a sample characterized by a particular length/width ratio defines the ordinate for a point on the appropriate curve, then the diffusivity is obtained from the abscissa.

Departure from a perfect rectangular shape is taken into account by representing the sample as a stack of several smaller rectangular plates. Since diffusion occurs only out of the end faces, the contribution of each platelet to the over-all out-diffusion of tracer can be treated independent of the others.

The final curve of $C(t)/C_o$ *vs.* $\sqrt{t}$ is determined by summing the individual contributions of each platelet, weighted according to its volume fraction. The samples

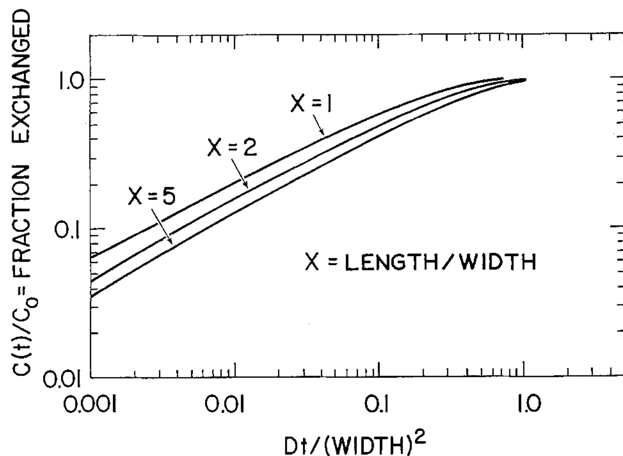

Fig. 4. Parameters for calculating D_t from out-diffusion data

were quite good and the total out-diffusion could be approximated by summing that from only two or three separate small platelets to account for deviations from perfectly rectangular shapes. The maximum error in D arising from shape irregularities is estimated as $\pm 1\%$.

To refine the calculation, several D values neighboring on the approximate one are selected and these, together with the detailed sample dimensions, are incorporated into a computer program which generates a curve of $C(t)/C_o$ *vs* $\sqrt{t}$ for each trial D. Successive refinements are made to yield a final diffusion coefficient that gives agreement between the calculated curve and experimental points to $\pm 5\%$.

Figure 5 gives the out-diffusion data for the β and β'' gallates, normalized to unity fraction exchange at long times by dividing by 0.895 for β and by 0.854 for β'' to allow for the fraction of sodium that was immobile. The solid lines are the best fits calculated by the procedure given above with the diffusion coefficients shown.

Na-K exchange in β and β'' gallate.—Figure 7 shows the equilibrium composition of β'' solid that was reached by interdiffusion of Na^+ and K^+ between monocrystals and molten $NaNO_3$-KNO_3 mixtures at 350°C. It is seen that even in the crystal that was in contact with pure KNO_3, only 85.4% of the sodium was exchanged, in agreement with the earlier Na-22-Na-23 self-diffusion result. The dashed line of Fig. 6 is the data curve, normalized to 100% replacement of the labile Na with K from a pure KNO_3 melt. Figure 7 gives similar information for β crystals.

The convex shape of the curves of Fig. 6 and 7 results from the distribution coefficient between the solid and liquid being greater for K than for Na, in-

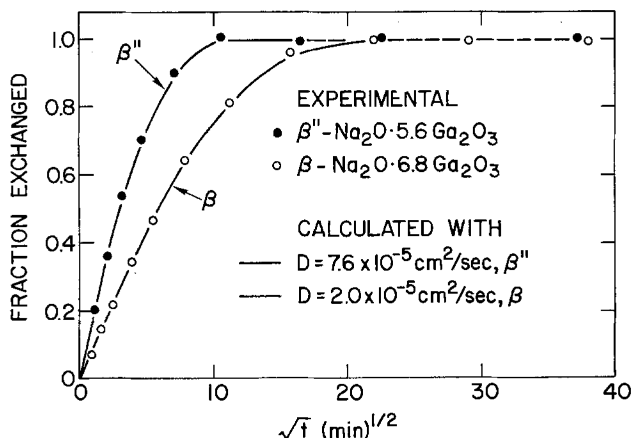

Fig. 5. Self-diffusion in β''- and β-Na-gallate monocrystals at 350°C.

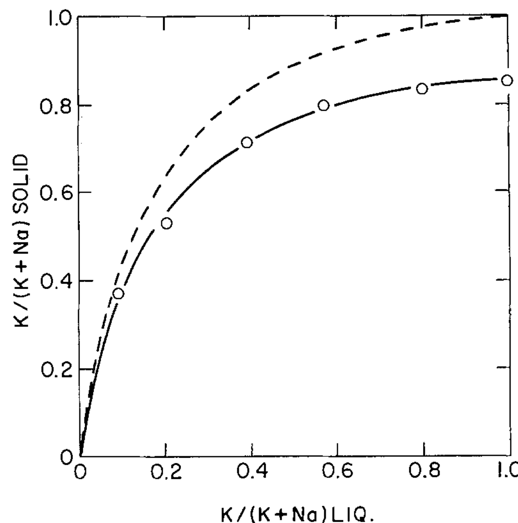

Fig. 6. Distribution of Na^+ and K^+ between B″-gallate and $NaNO_3$-KNO_3 melts at 350°C. ——— Data curve. - - - - - Normalized to K/(K+Na)solid = 1 at K/(K+Na)liq. = 1.

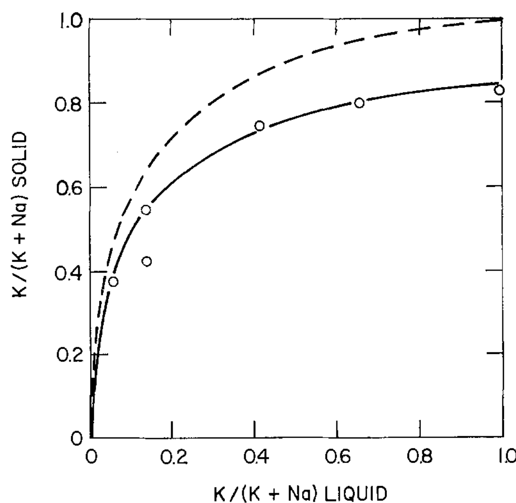

Fig. 7. Distribution of Na^+ and K^+ between β-gallate and $NaNO_3$-KNO_3 melts at 350°C. ——— Data curve. - - - - - Normalized to K/(K+Na)solid = 1 at K/(K+Na)liq. = 1.

dicating tighter binding of K in the lattice. The relative binding energies were calculated by the method of Ekedahl *et al.* (9) as employed by Yao and Kummer (8). The equilibrium is given by

$$Na(s) + K(l) = K(s) + Na(l) \qquad [2]$$

where (s) represents the Na or K gallate crystal, and (l) represents the Na or K nitrate melt.

The equilibrium constant for [2] is

$$K_{350°C} = \{[a_{K(s)}][a_{Na(l)}]\}/\{[a_{Na(s)}][a_{K(l)}]\}$$

$$= \frac{[x_{K(s)}][\gamma_{K(s)}][x_{Na(l)}][\gamma_{(Na(l)}]}{[x_{Na(s)}][\gamma_{(Na(s)}][x_{K(l)}][\gamma_{K(l)}]} \qquad [3]$$

where x_K and x_{Na} are mole fractions, and the γ's are activity coefficients.

The activity coefficients for $NaNO_3$ and KNO_3 in their mixed melts are available in the literature, so all the terms in [3] are known except the activity coefficients for the Na and K solid gallates in solid solution. The equilibrium constant then becomes

$$K_{350°C} = Z[\gamma_{K(s)}/\gamma_{Na(s)}] \qquad [4]$$

where

$$Z = \{[x_{K(s)}][x_{Na(l)}][\gamma_{Na(l)}]\}/\{[x_{Na(s)}][x_{K(l)}][\gamma_{K(l)}]\} \qquad [5]$$

From the Gibbs-Duhem relation and $dx_{K(s)} = -dx_{Na(s)}$ one obtains

$$x_{K(s)} d \ln \gamma_{K(s)} = -x_{Na(s)} d \ln \gamma_{Na(s)} \quad [6]$$

Differentiating [4] and combining with [6] gives

$$d \ln \gamma_{K(s)} = -x_{Na(s)} d \ln Z$$

$$d \ln \gamma_{Na(s)} = x_{K(s)} d \ln Z \quad [7]$$

Graphical integration of the plots of $x_{K(s)}$ and $x_{Na(s)}$ ($= 1 - x_{K(s)}$) *vs.* ln Z gives ln $\gamma_{K(s)}$ and ln $\gamma_{Na(s)}$, where the two pure alkali gallates are reference states. Table I gives the equilibria data and calculations for the β and β″ phases. The activity coefficients for $NaNO_3$ and KNO_3 in their melts are those used by Yao and Kummer (8) so that a direct comparison with their results will be possible. The consistency within the series of calculated values for the equilibrium constant is a measure of the consistency of the data. The average $K_{350°C}$ is used for calculation of the free energy change.

The standard free energy change for reaction [2] at 350°C, obtained from $\Delta G° = -RT \ln K_{350°C}$ is -2.59 kcal/mole for β″, and -3.58 kcal/mole for β. From the difference of 6.9 kcal/mole between the free energy of formation of $NaNO_3$ and KNO_3 that was employed by Yao and Kummer (8), we obtain ΔG° (K-gallate) $-$ΔG° (Na-gallate) of -9.5 kcal/mole for the β″ phase and -10.5 kcal/mole for the β.

Figure 8 shows the activity coefficients for the sodium and potassium gallates determined in the present work and the coefficients for Na- and K-β-Al_2O_3 reported by Yao and Kummer (8). No results for β″-Al_2O_3 are available because of the absence of pure crystals.

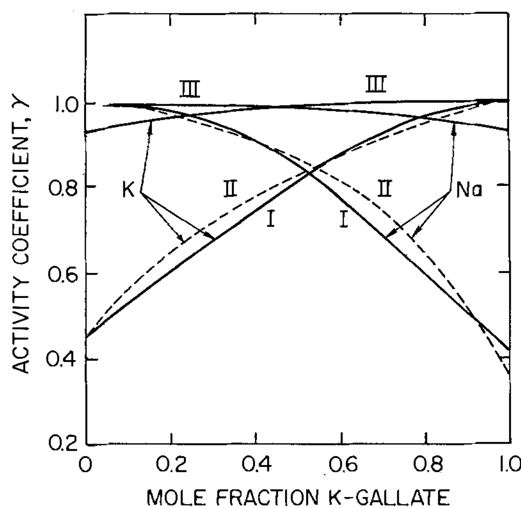

Fig. 8. Activity coefficients for Na^+ and K^+ in (Na,K)-β-gallate (I); (Na,K)-β-Al_2O_3 (II); and (Na,K)-β″-gallate (III) at 350°C.

Discussion

The self-diffusion of sodium in the sodium gallates is extremely rapid. To obtain the ionic transport from the mobility, the number of charge carriers must be known. Heretofore, it was generally assumed that all of the alkali in the class of materials typified by β-Al_2O_3 is mobile. One exception was the early work of Whittingham and Huggins (10) where it was assumed that in the β-Al_2O_3 structure only the alkali in excess of that required to completely occupy the Beevers-Ross sites should be considered "mobile" and contribute to conduction. This amounted to about 15% of the total in their case. The inference was that stoichiometric $Na_2O \cdot 11Al_2O_3$ might be a very poor (*i.e.,* normal) ionic conductor. This cannot be disproved because of the absence of a compound with the stoichiometric composition. However, it is now a commonly held view that the binding energy of sodium in the Beevers-Ross and anti-Beevers-Ross sites is not sufficiently different for a Na^+ ion to be considered immobilized in one site, particularly at elevated temperatures.

The finding that part of the sodium in the Na-gallates is immobile was new and unexpected. Whether the immobile fraction found here (14.6% for β″ and 10.5% for β) is fixed or, as is more likely, is a function of the over-all composition and the growth conditions is not yet known and is under investigation.

It is interesting to speculate on where the nonmobile sodium might be in the structures. In particular, the effect of substituting Na^+ for Ga^{+++} in the tetrahedral (A-2) sites of the spinel block will be considered. Na^+ would thus take the role of Mg^{++} in β″-Al_2O_3 (3). If in β″ and β crystals of composition $Na_2O \cdot 5.6Ga_2O_3$ and $Na_2O \cdot 6.8Ga_2O_3$, respectively, we assume that each immobile Na^+ ion substitutes for Ga^{+++}, and thereby provides charge compensation for two additional sodium ions in the conduction plane, we calculate the atom distribution given in Table II. The fraction of (A-2) gallium that is substituted for by sodium is 0.14 and 0.083 for β″ and β, respectively, compared to 0.38 of the (A-2) aluminum substituted for by magnesium in β″-Al_2O_3 (3).

It is seen that, according to this model, essentially all of the charge compensation required for the incorporation of mobile sodium beyond the $Na_2O \cdot 11Ga_2O_3$ composition is provided by sodium in the spinel block. (The very small number of additional bridging oxygens, 0.037 atoms per plane for β″ and 0.045 for β, is within the analytical error and can be disregarded.) The prototype compound for the sodium gallate then becomes $2Na_2O \cdot 5Ga_2O_3$, which would be equivalent to the $Na_2OMgO \cdot 5Al_2O_3$ suggested by Bettman and Peters as the prototype for β″-Al_2O_3 (7). $2Na_2O \cdot 5Ga_2O_3$ does not actually exist in the Na_2O-Ga_2O_3 system, which has only $Na_2OGa_2O_3$, $3Na_2O \cdot 5Ga_2O_3$, and $Na_2O \cdot 3Ga_2O_3$ as stable stoichiometric compounds.

The very high sodium contents (up to $Na_2O \cdot 5.25 Ga_2O_3$) that have been observed for β″-Na-gallate are now understandable in view of the partition of sodium between the conduction plane and spinel block.

In all studies in recent years on β-Al_2O_3 it has been assumed that all of the sodium is in the conduction plane and mobile. This had been indicated by the alkali ion exchange experiments of Yao and Kummer (8). We exchanged all of the mobile sodium of a

Table II. Atom distribution in β″- and β-Na-gallate

β-Al_2O_3 monocrystal with potassium from a KNO_3 melt at 350°C and found that no residual sodium could be detected in the crystal by an electron microprobe analysis. Although only a Czochralski-grown crystal obtained from Union Carbide was studied, and the situation might be different for crystals grown by other methods, the implication is that partition of sodium between mobile and nonmobile sites occurs only in the gallates. This possibly reflects the greater size disparity between Na and Al than between Na and Ga.

Correlation factors.—Having obtained the tracer diffusion constants for β''- and β-Na-gallate, we can determine the correlation factor, $f = D_t/D_\sigma$, from the ionic conductivity, which was reported earlier (1). Table III gives the pertinent information. The number of charge carriers, n, is taken as the sodium content of the crystals, corrected, in the case of the gallates, for the nonmobile sodium. The sodium concentration for β-Al_2O_3 was based on a $Na_2O \cdot 9Al_2O_3$ composition determined by us for the Union Carbide monocrystal. The conductivity of β-Al_2O_3 was also our value (1), which agrees well with that of Fielder *et al.* (11). The tracer diffusion constant for β-Al_2O_3 was taken from Yao and Kummer (8) on material of a different origin. The correlation factor of 0.64 for β-Al_2O_3 was calculated from the data shown. The value of 0.60 was calculated by Whittingham and Huggins from the conductivity of material similar to that employed by Yao and Kummer, but assuming that the charge carrier concentration was only the 15% sodium in excess of that required to fill the Beevers-Ross sites, as described previously. The range for f of 0.60-0.64 thus reflects the uncertainty in the data for β-Al_2O_3 and the different ways of treating it.

One calculation of the correlation factor for a two-dimensional-hexagonal lattice gives $f = 0.56$ (12). This is close to our value of 0.58 for the β-gallate and reasonably close to the lower end of the range for β-Al_2O_3. However, that calculation assumes a vacancy mechanism for diffusion. Inherent in the calculation is the assumption that the vacancies are identical and are few in number (0.001-0.01%, as typical for metals at elevated temperatures, for example), so a forward jump of an atom into a vacant site is likely to be followed by a reverse jump into the site from which it came; hence, the jump is highly correlated. This situation does not obtain in the β structure where the Beevers-Ross and anti-Beevers-Ross sites have different energies, and the vacancy concentration is large. (In the β-gallate example calculated in Table II, the vacancy concentration is 28.7%, where the Beevers-Ross and anti-Beevers-Ross sites are considered together.) Whittingham and Huggins (10) recognized this difficulty and proposed a noncolinear interstitialcy mechanism for diffusion in β-Al_2O_3, with the Beevers-Ross site as the normal site and the anti-Beevers-Ross site as the interstitial site. The complete jump path is through an angle of 120°. They calculated a correlation factor of 0.60 for the β structure, which agrees well with the 0.58 to 0.64 range observed experimentally for the β-gallate and aluminate.

The correlation factor of 0.82 for the β''-gallate is too large to be explained by any obvious diffusion mechanism. The Na^+ sites are identical and each complete jump is along a straight line. The simple vacancy mechanism might be more reasonable in this case, and an increase in the correlation factor beyond 0.56 might be attributable to the large concentration of vacancies, which in the extreme would lead to uncorrelated interstitial-like jumps with $f = 1$. Whether the observed correlation factor of 0.82 for the β'' phase could be accounted for by the vacancy content ($\simeq$18% from Table II) cannot be determined because of the lack of an accepted diffusion model. Sato and Kikuchi (13) presented a theoretical model for correlation effects in both β and β'' structures based on a "path probability" concept. Their model predicts that an ideal random walk process would give a linear dependence of f on the degree of cation site filling, terminating at $f = 0.5$ with complete site filling [or, with a more rigorous calculation, at $f = 0.33$, according to Ref. (13)] and extrapolation to $f = 1$ at zero filling. Attractive cation-cation interactions (leading to clustering) would lead to large values of f, especially at moderate to high site filling, and repulsive cation-cation interactions (leading to ordering) would lead to smaller values. The deviation from random walk behavior would be greater the lower the temperature where the interaction energies would be substantial compared to kT.

According to the model of Sato and Kikuchi, our value for f of 0.82 for the β''-gallate with approximately 82% site filling could only result from strong attractive Na^+-Na^+ interactions at low temperatures. This is contrary to their presumption that mobile cations should tend to order rather than cluster in superionic conductor lattices and, in fact, they predict that in the β'' structure f should be about 1/3. Their conclusions are more or less supported by Murch and Thorn (14) who also assume repulsive cation-cation interactions, with the principal difference being that Saito and Kikuchi assume that f_c, the charge correlation factor, is unity in the β'' structure, whereas Murch and Thorn give it nonunity values as a result of ordering, in spite of *a priori* site equivalency in the structure. Our correlation factor, f, is the Haven ratio, $H_R = f_t/f_c$, in the nomenclature of Saito and Kikuchi and Murch and Thorn.

No other diffusion measurements have been reported for β''-gallate. Correlation factors for sintered, polycrystalline, MgO and Li_2O stabilized β''-Al_2O_3 that were reported by Miles *et al.* (15) are vastly different from ours for β''-gallate monocrystals. Tentatively, we must ascribe this discrepancy either to the MgO-Li_2O stabilization of the β''-Al_2O_3 or, as they themselves suggest, to the polycrystallinity of their samples.

The great disparity between our observed correlation factor for the β''-gallate and the predictions of the various theoretical models leads us to examine our experimental procedure for possible error. The high correlation factor could result from a D_t that is too large, or a D_σ that is too small. Too large a D_t can be encountered with a material if there are unsuspected grain boundaries which, in the general case, provide highly disordered paths for rapid diffusion. A large apparent D_t could also result if the specimen has microcracks into which the "reservoir" liquid can creep and effectively shorten the path length. In β''-Na-gallate, however, diffusion through the bulk is actually easier than through crystal defects and boundaries. Moreover, it has been our experience that any microcracks in this material are invariably in the easy cleaving c planes parallel to the diffusion path. Reservoir liquid that penetrates such cracks would have no access to the conduction planes. Thus, it is difficult to visualize any circumstance that would result in a tracer diffusion constant for β''-gallate that is much too large.

It is easier to visualize ways in which the measured D_σ could be too small. The principal experimental problem in measuring the conductivity of a two-dimensional conductor is to insure that the edges of all

Table III. Transport results for gallates and β-Al_2O_3 at 350°C

	β-Gallate	β''-Gallate	β-Al_2O_3

$\sigma(\Omega\text{-cm})^{-1}$	0.481	1.316	0.197
$D_\sigma(cm^2/sec)$	3.46×10^{-5}	9.26×10^{-5}	1.65×10^{-5}
$D_t(cm^2/sec)$	2.0×10^{-5}	7.6×10^{-5}	1.07×10^{-5}
$f = D_t/D_\sigma$	0.58	0.82	0.64 (0.60)*

* The figure in parenthesis is from Ref. (10).

the c planes are contacted, because the spreading resistance between a contacted plane and an adjacent noncontacted plane is essentially infinite. There is no way to know that contacting is complete in each instance, but a considerable number of β''-gallate crystals have now been measured, and reproducibility has been excellent. Moreover, it would be difficult to explain conductivity of this material 2 to 2.5 times higher than observed, as would be necessary to give a correlation factor that conforms to the diffusion models that were cited above.

Crystal defects such as faults or small misalignments might seriously affect charge transport in a two-dimensional conductor. However, they should affect the tracer diffusion to the same degree and have minimal effect on the correlation factor.

A more serious matter is whether the number of charge carriers, n, for electrical transport should be equated to the mobile sodium concentration when calculating D_σ from the Nernst-Einstein relation, as done in Table III, for we do not have independent information about the carrier mobility. Perhaps the most significant observation that can be made about the correlation factors at this time is that when the data for the β'' and β phases are treated in the same manner, the large difference in D_t/D_σ exists.

Na-K exchange equilibria.—The principal information obtained from the Na-K exchange equilibria is the activity coefficients of the Na- and K-gallates when present together as a mixed crystal. Although the pure compounds were taken as the standard states, the activity coefficients will reflect the interaction between the Na^+ and K^+ ions if their environment does not change when the pure compounds mix. From our understanding of these materials, that appears to be a reasonable assumption.

When two compounds mix ideally, the free energy minimization results entirely from the entropy gain in achieving a random distribution. Activity coefficients greater than unity (positive excess free energy) are usually associated with repulsive interactions between unlike species which, in the extreme, lead to phase separation. Coefficients less than unity (negative excess free energy) are usually associated with attractive interactions between unlike species which, in the extreme, lead to ordering. There can be many complicating effects, for example, association to give unlike pairs which then repulse similar unlike pairs, which can confuse the picture, but the simplest interpretation of the activity coefficients in Fig. 8 is that Na^+ and K^+ ions in β''-gallate are essentially indifferent to each other, whereas in β-gallate there is a substantial attractive interaction, which should lead to ordering. The fact that the coefficients for β-gallate agree so well with those for β-Al_2O_3 determined by Yao and Kummer (8) suggests that the principal difference is between the β and β'' structures rather than between the gallates and aluminates of the same structure. Random distribution of Na^+ and K^+ over the identical sites in the β'' lattice, and preferential occupancy of the larger Beevers-Ross sites by K^+ and the smaller anti-Beevers-Ross sites, or perhaps the mid-oxygen positions, by Na^+, in the β structure would be consistent with the trends in the activity coefficients.

Summary

1. The self-diffusion coefficients for Na^+ in β''- and β-Na-gallate are 7.6×10^{-5} and 2.0×10^{-5} cm²/sec, respectively, at 350°C.

2. Approximately 10-15% of the sodium in these compounds is nonmobile and is presumably in the spinel block. It is proposed that a Na^+ ion substitutes for a Ga^{+++} ion in the block and provides charge compensation for two additional Na^+ ions in the conduction plane.

3. The correlation factor, $f = D_t/D_\sigma$, is 0.58 for the β phase in good agreement with that determined for β-Al_2O_3, where a noncolinear interstitialcy diffusion mechanism had been proposed. A much larger value of $f = 0.82$ was found for the β'' phase, which cannot be accounted for by any proposed diffusion model.

4. Na^+ and K^+ mix nearly ideally in the β''-gallate structure, whereas in the β structure, strong interactions suggestive of ordering are encountered.

The Use of 1.1.1.-Trichloroethane as an Optimized Additive to Improve the Silicon Thermal Oxidation Technology

Edmond J. Janssens,[1] and Gilbert J. Declerck*

Elektronica, Systemen, Automatisatie en Technologie, Departement Elektrotechniek, Katholieke Universiteit Leuven, B-3030 Heverlee, Belgium

ABSTRACT

Based on the pyrolysis of trichloroethene (C_2HCl_3), also referred to as TCE, and the thermodynamic analysis of its reaction products a substitute for TCE is found. It is characterized by better physical and chemical properties and behaves as an additive during silicon oxidation identical to HCl. This chlorinated hydrocarbon, 1.1.1.-trichloroethane (referred to as C33) is used for fabrication of MOS capacitors on n-type silicon to study the properties of oxides grown with this additive. Special attention is paid to the properties influencing the performance of charge coupled devices. Storage times of 500 sec, oxide defect density of 10/cm^2, and surface-state densities lower than 5×10^9/cm^2 eV are achieved. The cleaning effect on the furnace tube yields a mobile ion density lower than 2×10^9/cm^2. The fixed oxide charge on (100) material is 5×10^{10} cm^{-2}. Fabrication of CCD's with this technology proves its suitability in silicon device processing.

The superior behavior of SiO_2 grown in the presence of HCl has been described in detail (1-4). The lack of safety and special installation requirements involved with the use of HCl forced people to look for safer chlorine sources such as trichloroethene (TCE) (5) and carbon-tetrachloride (CCl_4) (8). TCE has already been proven to improve the oxide quality (4, 6-8). In the past a clear distinction between HCl oxides and Cl_2 oxides has been found (1, 8, 12, 13) and is discussed below. Moreover during recent work some similarity between Cl_2 and TCE oxides is observed:

1. From Fig. 1 one can see the same behavior in oxidation rate enhancement as a function of the additive concentration (expressed in molar ratio of additive to oxygen) for both Cl_2 and TCE as compared to the much lower increase for HCl. This difference is not fully explained by taking into account the total amount of chlorine atoms in the oxidizing ambient.
2. For oxides grown at 1000°C Osburn (4) observed a minimum oxide defect density for Cl_2 oxides at 0.5% Cl_2 and for TCE oxides at 1%. The minimum defect density for HCl oxides is much lower and occurs at 3% HCl.
3. The corrosion limit is between 2 and 3% for Cl_2 (1, 8) and 2% for TCE, while much higher concentrations of HCl, 10-20% are needed (1, 9) to introduce corrosion, dependent on substrate orientation, oxidation temperature, and time.
4. The same negative bias instability has been observed for Cl_2 and TCE oxides (10, 11).

By means of a theoretical study based on the thermodynamic equilibrium data we show in the next section the close relationship between Cl_2 and TCE oxides. Furthermore as a result of this chemical analysis, C33 (1.1.1.-trichloroethane) is proposed as a better substitute for HCl. The electrical properties of oxides grown with this additive are discussed in detail in the final section of this paper.

Chemical Analysis

In order to study the differences between HCl and TCE it was necessary to find out what reaction products are formed by heating mixtures of O_2 and HCl or TCE. Kaesche-Krischer (14) reported the combustibility of TCE in atmospheres containing at least 40% oxygen. From the low gas velocity in the furnace (about 1 cm/sec for a 1.5 liters/min flow in a 4 in. tube), compared to the burning velocity (10 cm/sec), and from the comparison of furnace temperatures (900°-1200°C) and the flame temperature (1100°C), one can conclude that there is total combustion. Because of the long transit time of the gas in the hot zone of the furnace (1 min) the combustion products will react until thermodynamic equilibrium is

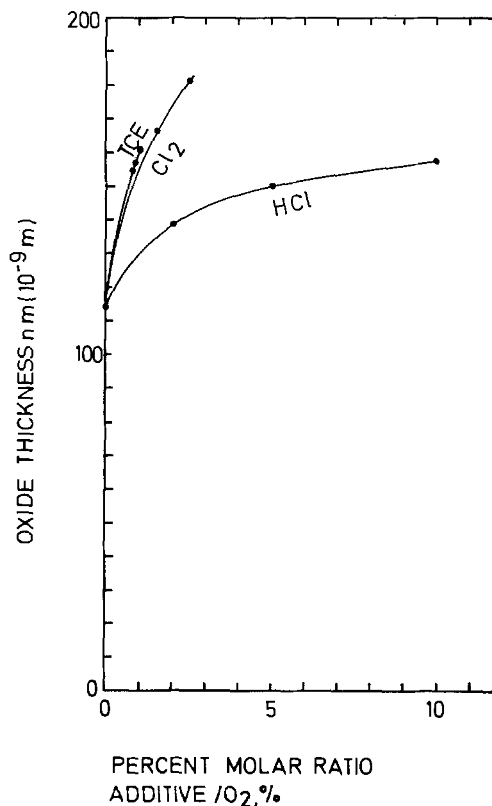

Fig. 1. The increase in oxidation rate, here shown as oxide thickness enhancement, as a function of halogen additive concentrations. The oxides are grown at 1150°C for 34 min on n-type (100) material. The HCl and Cl_2 data are from Kriegler (1).

reached. Kaesche-Krischer proposes following over-all reaction occurring in lean mixtures

$$4C_2HCl_3 + 9\,O_2 = 2H_2O + 6Cl_2 + 8CO_2 \quad [1]$$

Between the combustion products the following reaction can occur

$$2H_2O + 2Cl_2 = 4HCl + O_2 \quad [2]$$

This should also be the equilibrium reaction occurring when HCl/O_2 mixtures are allowed to react, *e.g.*, in a heated furnace (20). A computer performed thermodynamic analysis based on free energy data (15, 16) yields the partial pressures and concentrations of the gaseous reaction products as a function of temperature and additive concentrations. These results are represented in Fig. 2a for TCE, Fig. 2b for HCl, Fig. 2c for $C_2H_3Cl_3$ (C33), and Fig. 2d for CH_2Cl_2 (dichloromethane also referred to as C22). Because the concentrations of the reaction products are directly proportional to the additive concentration only the ratio of the former to the latter is used. This is valid as long as very lean mixtures are used, additive/O_2 ratios smaller than 10%, a condition which is always satisfied in this study.

At temperatures above 600°C the free energy of formation of HCl is lower than of H_2O. In a chlorine- and oxygen-containing atmosphere at normal oxidation temperatures the hydrogen reacts to form HCl rather than H_2O. The combustion of TCE yields three chlorine atoms for every hydrogen atom and thus almost all of the hydrogen is consumed to give HCl while only trace amounts of water are formed. The excess chlorine atoms form Cl_2, as shown in Fig. 2a. The atmosphere when using TCE consists mainly of almost equal amounts of Cl_2 and HCl. This explains

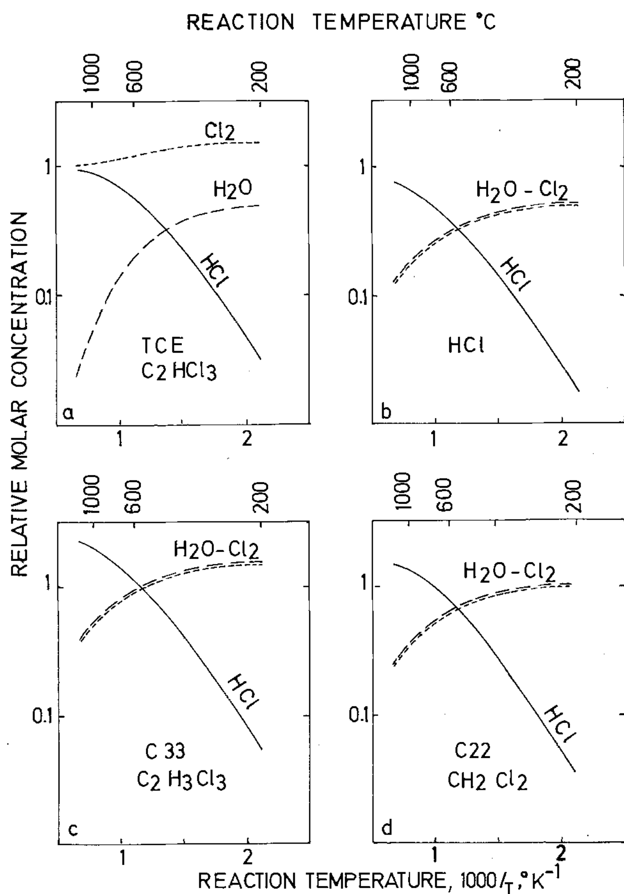

Fig. 2. The concentrations of the reaction products HCl, H_2O, and Cl_2, relative to the additive concentration are given as a function of the reaction temperature: a, the pyrolysis of TCE(C_2HCl_3): b, the pyrolysis of HCl; c, the pyrolysis of C33 ($C_2H_3Cl_3$); d, the pyrolysis of C22 (CH_2Cl_2).

the "chlorine-like" behavior of TCE. For HCl, however, an equal number of chlorine and hydrogen atoms is available, resulting at high temperature in a main quantity of HCl and a minor part of H_2O and Cl_2. In order to obtain an atmosphere in the furnace similar to HCl it is thus necessary to use an additive with an equal number of chlorine and hydrogen atoms. These additives such as $C_2H_3Cl_3$ (C33) and CH_2Cl_2 (C22) yield atmospheres as shown in Fig. 2c and 2d, respectively. They have exactly the same relative concentrations of reaction products as HCl. C33 yields three times higher and C22 yields two times higher concentrations than HCl. This unique dependence of the atmosphere on the H/Cl ratio is in agreement with the analysis of the Si-H-Cl system (17).

Our analysis is based on the assumption of thermodynamic equilibrium which is validated due to the high temperatures and the long transit time of the products through the hot zone of the furnace. The close agreement between the oxidation rate enhancement of HCl and C33 as is shown later on, confirms this.

Other reaction products with oxygen, such as HClO. ClO, and HO, are not included in the analysis because at high temperatures their free energy is too high to result in concentrations greater than 10^{-4} (18), so that they do not interfere in the comparison of the additives. Moreover different additives giving similar atmospheres will also yield the same byproducts. The carbon atoms of the additives do not intervene as long as lean mixtures are used to allow the formation of CO_2 (carbon dioxide). Although CO_2 is thermodynamically less stable than SiO_2 it is not expected to compete with oxygen in the oxidation reaction (19) also because of its lower diffusivity in SiO_2 due to its large molecular dimension. The formation of a Si-C (silicon-carbide) bond is also not likely because it is unstable in the presence of O_2 at high temperatures and will react to form SiO_2 and CO_2 (16). The carbon monoxide formed in mixtures which are too rich leads to the formation of the highly toxic phosgene ($COCl_2$) when it reaches the cold end of the furnace tube. This is a limiting factor in the safe use of every chlorinated hydrocarbon.

The choice of C33 as the optimum additive.—The conclusion from previous analysis is that the additive must have a molecular composition with the same number of chlorine and hydrogen atoms. Among the compounds satisfying this condition C33 is selected as the one with the most suitable physical and physiological properties: (*i*) boiling point of 75°C (21), it has also the suitable vapor pressure to be dissolved in a carrier gas at room temperature; (*ii*) noncorrosive; (*iii*) chemically stable; (*iv*) noninflammable in air; and (*v*) high purity semiconductor grade commercially available at low costs. In addition, C33 has improved physiological properties over TCE. The toxicity expressed by means of the TLV (threshold limit value) for C33 is 350 ppm and for TCE 100 ppm (23). It has to be distinguished from its isomer 1.1.2-trichloroethane which is highly toxic (TLV = 10 ppm). TCE is also known to cause liver and kidney injury and heart attack by repeated exposure even under the TLV value (22). TCE also suffers from instability under the influence of light by splitting off HCl.

Experimental Procedure

The experimental setup to grow C33 oxides consists of a standard resistance heated quartz tube equipped with a main N_2 and O_2 flow and with a bypass carrier gas (N_2 or O_2) which is led through a bubbler filled with C33 or TCE. The bubbler consists of two gas wash flasks put in series and held at room temperature. Weighing experiments were performed to prove that the carrier gas was saturated, within the accuracy of the measurement, for all flows used in the experiment. The amount of additive introduced

into the furnace was determined by controlling the vapor pressure of the liquid, depending on the temperature, and the gas flow through the bubbler. An extra valve is also needed between the bubbler and the furnace tube inlet to prevent C33 vapor from entering the furnace when there is no oxygen present.

The properties of the oxides are measured on MOS capacitors fabricated as follows: n-type Si-wafers, (100) oriented, 10-20 Ω-cm, were given a standard rinse (24) before oxidation at one of the following temperatures; 1000°, 1100°, 1150°, or 1200°C for different times with different concentrations of C33 or TCE. This oxidation is followed by an anneal *in situ* in N_2. Before E-beam metallization with aluminum the back side oxide is stripped in buffered HF. The MOS capacitor metal electrodes are 0.5 × 0.5 mm squares defined by photolithography. The back side metallization is followed by a low temperature anneal of 30 min at 450°C in forming gas. Other properties are tested on N-channel surface CCD's fabricated with the 3 level polysilicon gate technology (25).

Results and Discussion

Influence of C33 and TCE on the properties of the silicon dioxide film.—The increase in oxidation rate. —The use of chlorine-containing ambients enhances the oxidation. The thickness, determined ellipsometrically, of oxides grown under the same conditions (1150°C, 34 min, (100), n-type Si) but with different concentrations of additives is shown in Fig. 3. In the abscissa the equivalent HCl concentration (C33 concentration × 3) is used as a means of comparison between C33 oxides and HCl oxides.

The increase of oxidation rate is identical for C33 and HCl which confirms the assumption of total combustion made in the previous section. When using TCE the oxidation rate, as shown in Fig. 1, is much closer to that observed with Cl_2 gas. This increase in oxidation rate, cannot be explained by the influence of water vapor formed during the combustion of HCl since it occurs also in Cl_2 atmospheres according to Kriegler (1). Two other mechanisms account for the

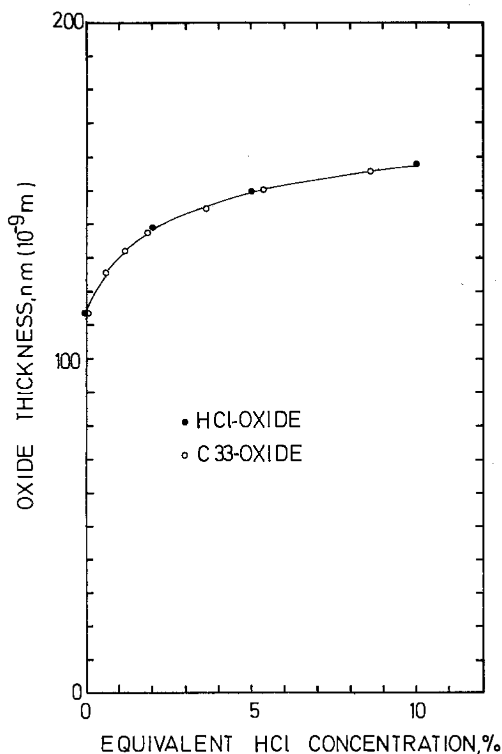

Fig. 3. The increase in oxide thickness by the use of HCl and C33 is given as a function of effective HCl concentration (C33 times 3), oxides grown at 1150°C, 34 min on n-type (100) material. The HCl oxides are from Kriegler (1).

enhanced oxidation (9, 20): (*i*) the higher diffusivity of O_2 in the presence of Cl_2 or HCl, or (*ii*) the increased reaction velocity. Chlorine acts as a catalyst on the oxidation reaction. The first step in the reaction should be the chlorination of silicon. This is a much faster reaction than the oxidation, the reaction velocity being related to the etch rate of silicon. This is about 1.5 μm/min in 0.5% HCl/H_2 at 1200°C for (111) surfaces and 3.4 μm/min for (100) surfaces (26). The oxidation reaction velocity is only 5.5 10^{-2} μm/min in 5% O_2/N_2 mixtures at 1200°C for (111) planes (27) and is slightly dependent on surface orientation. The second reaction step is the conversion into SiO_2 because of the higher thermodynamic stability of the latter. This two step reaction may proceed faster than a single step reaction. A too high chlorine concentration causes degeneration of the oxidation because the oxidation step is no longer competitive and etching of the silicon occurs.

Oxide defect density and dielectric breakdown.—The oxide defect density is one of the limiting factors in the fabrication of devices requiring large active areas. The addition of halogen during oxidation has been found to reduce this defect density (4). The improvement by the use of C33 and TCE is shown in Fig. 4. The distribution of the first self-healing breakdown and final breakdown electric fields are shown for a dry thermal oxide (referred to as DTO), a 1% C33 oxide and a 1% TCE oxide, all grown at 1000°C for 2 hr. These distributions are measured by an automated system based on a circuit similar to the one described by Osburn *et al.* (28). The thickness of the metal layer was only 30 nm to allow the self-healing breakdown to be distinguished from the final breakdown. The ramp rate was 1 MV/cm·sec.

It is observed that the maximum breakdown field as related to the intrinsic or electronic breakdown of the silicon dioxide (29) is not influenced by "chlorine" addition. More important however is the reduction of the defect density as shown in Fig. 5 where the densities averaged for several wafers are displayed. These densities are calculated according to Osburn and Ormond (30) using capacitors of three different areas, respectively, 0.072, 0.2, and 0.8 mm^2. These figures result from 1200 measurements performed over four different runs. The defect density decreases from about 150 cm^{-2} for the DTO oxide to 9 and 15 cm^{-2} for the 1% C33 and 1% TCE oxide, respectively. Occasionally C33 oxides are grown that show no defects. The increase at higher TCE concentrations, due to the higher corrosivity (4), limits the use of this additive.

Two kinds of effects are believed to explain the reduction of defects. First charged impurities, especially sodium and also interface states or oxide charges, enhance the applied field or reduce the barrier height (30). These defects are eliminated by HCl oxidation and are discussed in the following sections. A second origin of reduced dielectric breakdown is physical defects either on the silicon substrate or in the oxide film. Etching of the silicon prior to oxidation by means of HCl only reduces the defect density when subsequent oxidation is performed in a very clean ambient (29), although a strong relation is found between substrate and oxide defects (31). One of the reasons is the effect of sodium which not only acts as a charged contaminant but also as a silicon dioxide network modifier causing crystalline particulates to occur. These can be places of reduced strength and can also lead to a path of enhanced diffusion for the aluminum causing shorts during low temperature anneal (29). The formation of interface imperfections as described by Johannesson (33) during oxidation, which consists in Si-inclusions into the oxide, can also reduce the dielectric strength. This can be reduced by adding chlorine during oxidation. Physical defects resulting from the absorption at the Si-surface of airborne particulates during wafer storage or

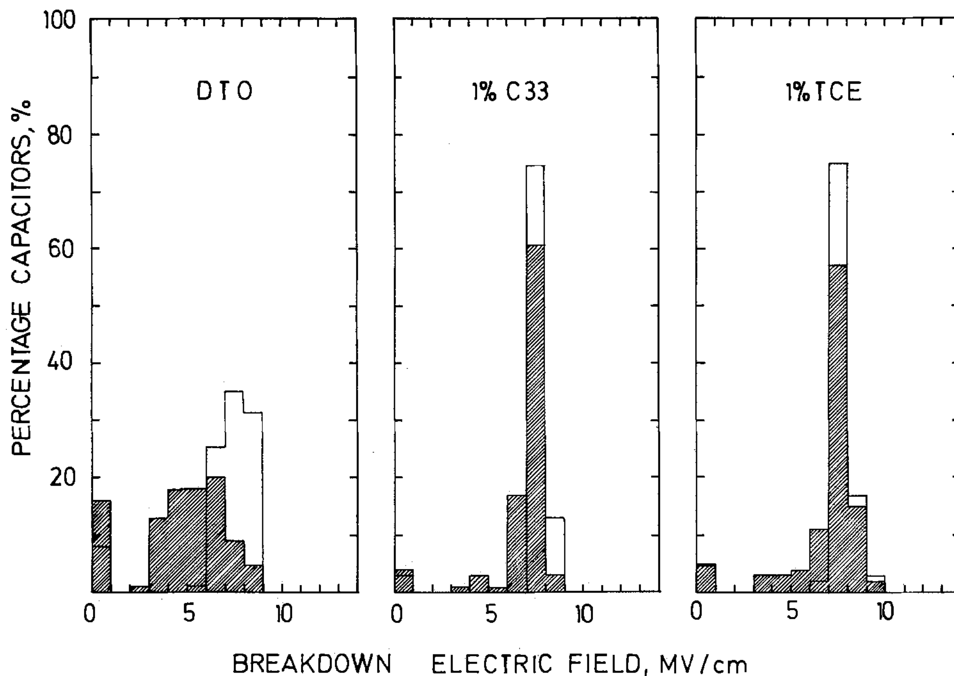

Fig. 4. The distribution of the first self-healing (shaded area) and final breakdown electric field for a dry thermal oxide (DTO), a 1% C33, and a 1% TCE oxide, all grown at 1000°C for 2 hr. The capacitor area is 0.8 mm^2. The defect density is, respectively, 120/cm^2, 9/cm^2, and 15/cm^2 due to the higher occurrence of low field breakdown observed for the DTO and the TCE oxide.

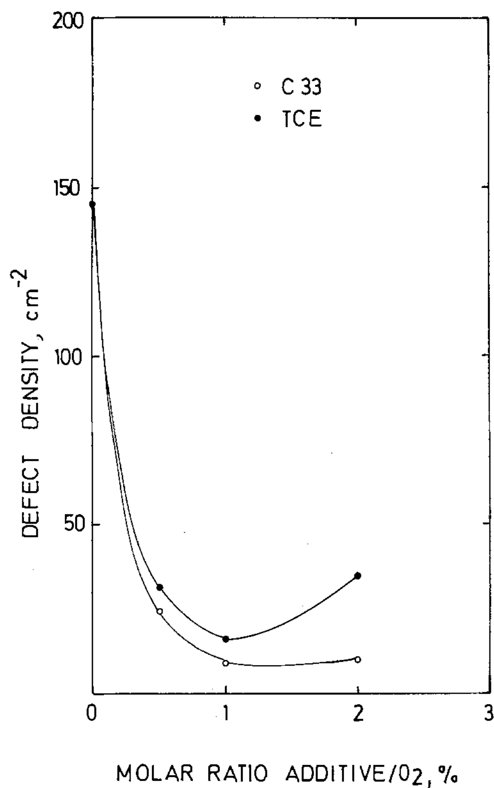

Fig. 5. The decrease of defect density as a function of additive concentration. The oxidations are the same as for Fig. 4.

drying in filtered nitrogen and residue of the cleaning solutions are found to be responsible for defects (32). Oxidation with HCl as well as H_2 high temperature treatment seems to be very effective for the desorption of these contaminants (32).

The mobile oxide charge.—This charge, mainly caused by sodium ions (34), is destructive for the reliability of MOS devices. Thus several methods have been investigated to immobilize them. Better, however, is to avoid the introduction of sodium into the oxide. Besides the metallization, the oxidation furnace has the highest contamination probability (35). C33 and TCE are effective in reducing the mobile charge during oxidation and also during previous cleaning of the furnace tubes prior to oxidation.

These experiments are performed on quartz tubes that are previously cleaned by etching them in diluted HF followed by a rinse in high purity water. Before growing the first oxide, without previous C33 or TCE cleaning, the furnace tube is flushed with N_2 for at least 3 hr. The experiments are done at 1100°C for TCE and 1200°C for C33. The wafers are oxidized in dry O_2 to yield about 90 nm thick oxide followed by a N_2 anneal *in situ*. Immediately after oxidation the oxide is covered with a silicon nitride layer to prevent any contamination from entering the oxide after oxidation. The furnace tube cleaning cycle is performed at oxidation temperatures with 0.75% TCE or 1.25% C33. After each cleaning cycle and before another oxidation, the furnace is exposed for 30 min to dry O_2 in order to avoid the effect of lingering traces of chlorine on the oxide growth. The mobile ion density is determined by applying a TVS (triangular voltage sweep) (36) at 200°C and by integrating the extra displacement current caused by the mobile ions. Independent experiments show that the oxide-nitride double layer causes no instabilities under these conditions. From Fig. 6 it is seen that

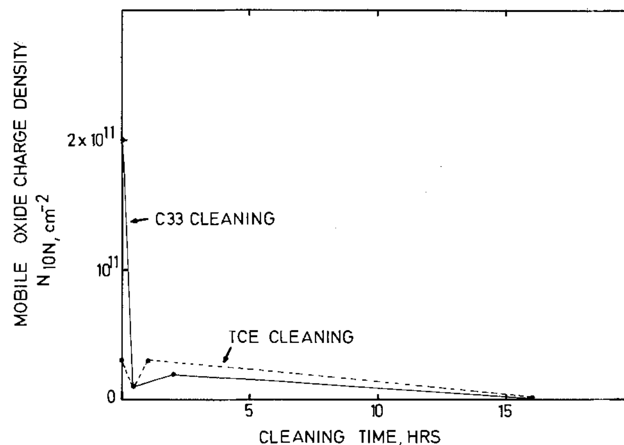

Fig. 6. The mobile ion density obtained from TVS measurements at 200°C, 200 mV/sec sweep, as a function of cleaning time with 0.75% TCE/O_2 mixture at 1100°C, or a 1.25% C33 mixture at 1200°C. The oxides are grown for 30 min at 1100°C and 14 min at 1200°C, respectively, always after a previous O_2 flow for ½ hr.

both TCE and C33 are effective in cleaning the furnace tube. The mobile ion density rapidly falls in 30 min to a low 10^{10}/cm^2 level. The increase immediately after HCl is allowed to flush the tube (37) is in agreement with Krieglers' result (12) and is explained by the higher sodium content in the atmosphere. An overnight rinse (960 min) reduces the density to the limit of detection ($2 \cdot 10^9$ ions/cm^2).

The neutralization of the mobile charge.—Oxidation in a chlorine-containing ambient leads to a neutralization capability of the oxide against mobile ions (38). From the shift in flatband voltage before and after a positive BT stress performed at 200°C with an electric field of 1 MV/cm for 20 min, the amount of unneutralized charge is calculated. The neutralization efficiency of an oxide is expressed as the ratio of the neutralized charge to the total mobile charge, the latter measured in DTO samples. This figure of merit is used to compare the TCE and C33 in Fig. 7.

The neutralization is attributed to the chlorine incorporated in the oxide and is independent of the contamination level, although the number of the neutralized ions are only a small fraction of the number of chlorine atoms in the oxide (39). Both additives show a threshold-like behavior in the dependence on additive concentration; a threshold in oxidation time is also expected as observed with HCl (12). The same threshold-like behavior is found in the chlorine content of an oxide, resulting in a close relation between the chlorine content and the neutralization efficiency (40).

The wafers are intentionally contaminated by evaporation of aluminum from a resistance-heated tungsten wire. This results in a rather good uniformity of the contamination level on samples metallized in the same run, however, large differences from run to run can occur.

The mechanism of neutralization is not well understood. It is proposed by Kriegler (41) that the mobile ions become trapped when they reach the vicinity of the chlorine, incorporated in a Si-O-Cl bond where chlorine is substitutional for oxygen. This trapping is also observed during TVS measurements (42). Results of these measurements performed at 200°C on a DTO and on a C33 oxide are represented in Fig. 8. In the DTO sample deformation of the displacement current peak occurs due to the trapping of the mobile ions at the metal-SiO_2 interface when they are swept from the metal to the silicon (39). The C33 sample, however, shows also heavy trapping when the sodium ions are at the silicon interface where the chlorine atoms are incorporated (43, 10). The sodium is not immobilized but neutralized when it reaches the interface as the flatband voltage shift is much lower for the C33

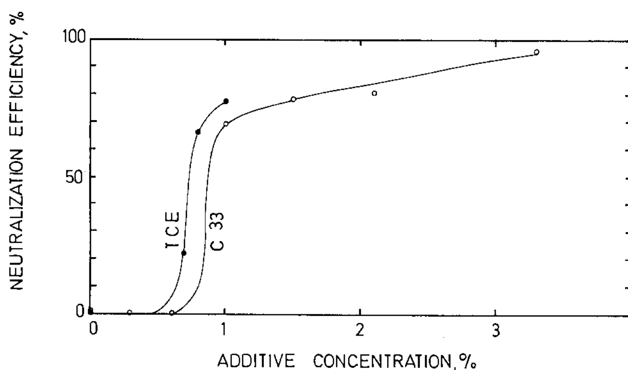

Fig. 7. The neutralization efficiency calculated from flatband shift after BT stress compared to the flatband shift with 0% additive as a function of additive concentration. The oxides are grown at 1150°C for 32 and 36 min for TCE and C33, respectively. The TCE oxide contamination level is 2×10^{12} and for the C33 oxides 4.5×10^{11} ion/cm^2.

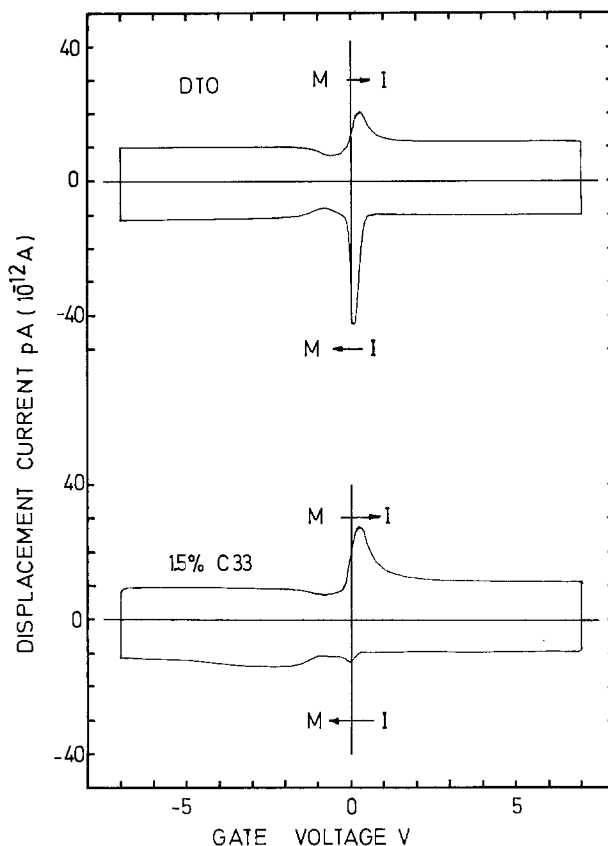

Fig. 8. TVS measurement at 200°C, 200 mV/sec sweep. Performed on a DTO (upper) and on a 1.5% C33 oxide (lower) grown at 1150°C for 36 min, showing 76% neutralization efficiency. The contamination level is 4.5×10^{11} ion/cm^2.

oxide than the DTO while integration of the displacement current yields the same total charge.

The influence of C33 and TCE on the silicon dioxide-silicon interface.—The fixed oxide charge (N_{ox}).—Samples grown in TCE/O_2 and C33/O_2 mixtures show a reduction in the fixed oxide charge (Fig. 9). This, however, is only found when the oxide charge is higher than the minimum value that can be reached by proper annealing (34). The samples referred to in Fig. 6 as C and E, grown with different TCE and C33 concentrations, respectively, have fixed oxide charge levels of about $5 \cdot 10^{10}$ charges/cm^2 as normally obtained for (100) interfacial planes by suitable processing (44). This is not influenced by the addition of chlorine species. The B and D series have a higher oxide charge decreasing with increasing chlorine concentration. From the sample A series, measured as oxidized without high temperature N_2 anneal, it is clear that the mechanism responsible for the decrease in oxide charge occurs during oxidation. A zero oxide charge as reported by Kriegler (1) has never been observed.

The origin of the fixed oxide charge is thought to be due to the oxygen deficiency and the excess ionized silicon resulting in a missing Si-O-Si bridge in the transition region near the interface (33, 34, 45).

The influence of sodium (46) is excluded because the wafers are oxidized in a sodium-free atmosphere. Moreover the samples show very low mobile ion densities even metallized. It is believed that the excess unbonded silicon ions are chlorinated because of the high reactivity of the chlorine and silicon. The analysis of the oxidation rate also supports this assumption. Consequently the oxide charge is reduced.

The interface-state density (N_{ss}).—Quasi static C-V measurements are performed on TCE and C33 oxides to obtain the interface-state density (47, 48). The samples were obtained at low temperature anneal for

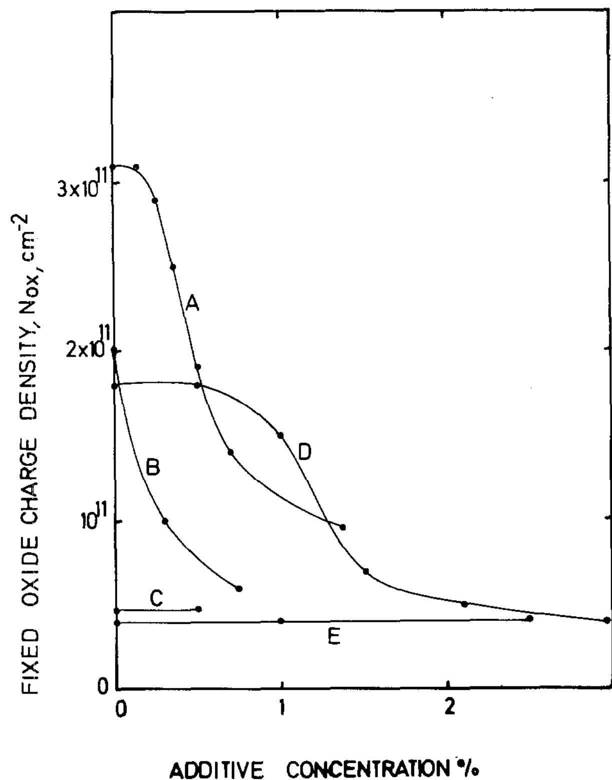

Fig. 9. The reduction in fixed oxide charge density (N_{ox}) with increasing chlorine addition. A, (TCE) 1200°C, 14 min oxidation, no anneal; B, (TCE) 1200°C, 14 min oxidation, 30 min 450°C wet N_2 anneal; C, (TCE) 1150°C, 32 min oxidation, 20 min N_2 *in situ*, 450°C, 30 min wet N_2 anneal; D, C33, 1150°C, 36 min oxidation, 5 min N_2 *in situ*, 450°C, 30 min wet N_2 anneal; E, same as D but 20 min N_2 *in situ* anneal. Sample A was measured by means of an Hg probe; B, C, D, and E after metallization.

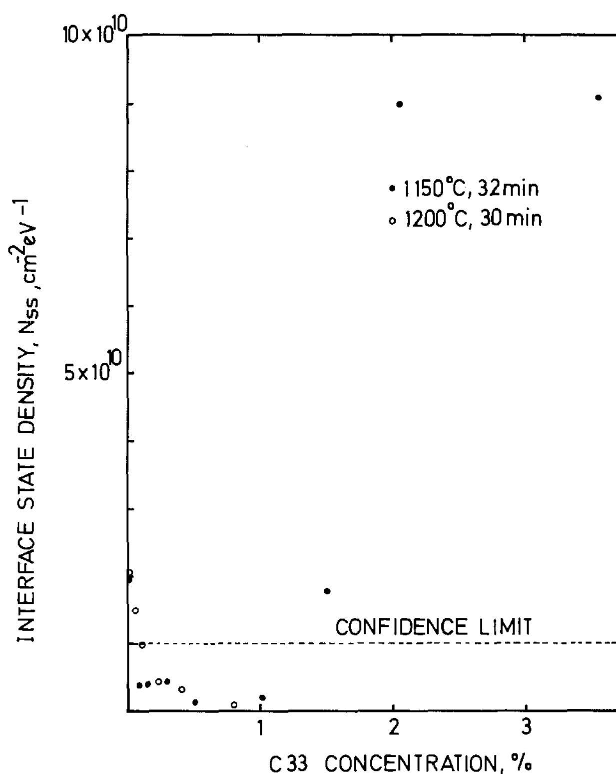

Fig. 10. The interface state density (N_{ss}) vs. C33 concentration for 1150°C, 32 min and for 1200°C, 30 min samples.

30 min in wet N_2 at 450°C after aluminum metallization. This is known as a very effective means of reducing the interface states (49). The interface-state density of oxides grown at C33 concentrations lower than 1% is beneath the limit of accuracy of the method ($10^{10}/cm^2$ eV) as shown in Fig. 10. From transfer loss experiments of charge coupled devices fabricated with the same C33 oxides as gate dielectric layer it has been found that N_{ss} is in the low $10^9/cm^2$ eV range (50). At higher C33 concentrations N_{ss} increases as has also been observed for TCE oxides (6).

According to Goetzberger the source of interface states is threefold (51), namely, chemical impurities at the interface (52), charges in the oxide, and structural imperfections such as dangling bonds. From previous sections it follows that C33 or TCE is effective in providing a clean atmosphere during oxidation minimizing the possible contamination by impurities or electrically charged ions. Also the fixed oxide charge is optimized. It is generally accepted that interface states can be annihilated by reducing ionized silicon centers at the interface during a low temperature anneal by the formation of Si-H bonds (46, 34, 53). This hydrogen can be present in the annealing atmosphere or is formed during anneal by the reaction of water vapor with the aluminum metal layer (49). The hydrogen can also be incorporated in the structure due to the previous processing step such as HCl (54), C33, or TCE oxidation. Hydrogen results from the water present in the atmosphere or from the reaction of silicon with HCl. A similar effect has been observed in oxides covered with a nitride layer formed by the reaction of SiH_4 and NH_3 (55). The higher interface-state density at higher concentrations is explained by the higher density of imperfections at the interface due to the corrosion of the silicon. The increase in imperfections is also observed during oxide defect density measurements in chlorine oxides (4).

Influence of C33 and TCE on the dark current generation.—The advantage of "chlorine" oxidation applied to CCD processing is the reduction of background dark current and dark current spikes. The dark current generation can be fully described by studying the relaxation times of MOS capacitors pulsed in deep depletion (Fig. 11a). In order to separate bulk minority carrier generation lifetime and surface generation velocity the Zerbst analysis (56) is performed on these pulsed *C-t* plots (Fig. 11b).

Care should be taken to account for the effect of surface generation at the periphery of the capacitor when making these *C-t* plots especially when very high bulk lifetimes occur, since this could lead to erroneous interpretation of the Zerbst plots (57, 58). Typical bulk generation lifetimes obtained from both Zerbst analysis and dark current CCD experiments (59) are between 0.5 and 3 msec. The surface generation velocity of an inverted surface is as low as 0.07 cm/sec raising to 1 cm/sec for the depleted surface. An optimum C33 or TCE concentration cannot be found. However a strong decrease in relaxation time is always observed at higher concentrations (1% for TCE, 2% for C33).

The thermal bulk generation is generally attributed to impurities of heavy metals (gold, copper, iron) having energy levels near the middle of the bandgap. The reduction of bulk generation is ascribed to two possible mechanisms: first the formation of volatile metal-chlorides (2, 8); second, the reduction of lattice defects, such as stacking faults, where impurities preferentially reside. A strong relation is found between stacking faults or dislocations and CCD video defects (60, 61). On the other hand, no large effect has been observed of a high temperature treatment in a mixture of HCl, H_2, and SiH_4 on the metallic content of a Si-wafer (32). Recently relaxation time experiments performed on MOS capacitors grown with HCl (62) show a strong relation between the relaxation time and crystal defects being not only large defects as stacking faults but also small etch pits whose nature is not fully understood but may be related to oxygen clusters (67). Several investigations are now undertaken that prove that the suppression of stacking faults is the predominant mechanism responsible for the lifetime

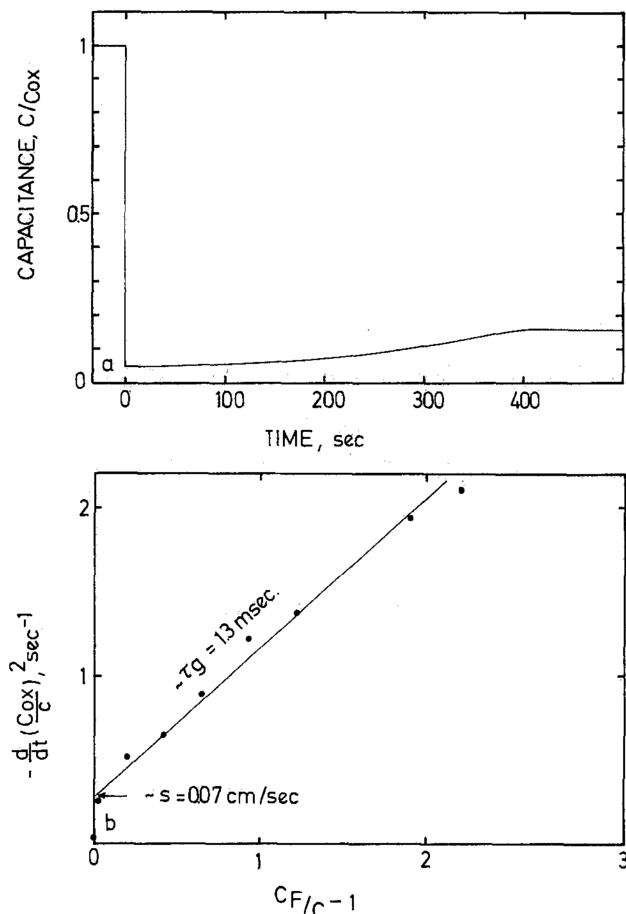

Fig. 11. a. C,t plot. b. Zerbst plot. Sample; 1150°C, 1% C33, 30 min oxidation, doping level $N_D = 1,6 \times 10^{14}/cm^3$. The Zerbst analysis yields $\tau_g = 1.3$ msec, $s = 0.07$ cm/sec, $s_o = 0.34$ cm/sec.

improvement (63). It has been proved already that HCl (64) and TCE (65) and recently also C33 (66) is effective in reducing the stacking faults. The decrease of relaxation time at higher concentrations is due to the corrosion of silicon by the chlorine resulting in a highly defective interface.

Conclusion

C33 (1.1.1.-trichloroethane) has been proved to be very effective in replacing HCl, giving oxides with identical properties. Moreover it is far less dangerous than HCl and it has also improved physical and physiological properties over TCE. The higher chlorine content of the latter tends to corrode the silicon surface during oxidation and limits the improvement on properties sensitive to interface imperfections, namely, the electric breakdown defect density, the fast interface states, and the storage times. The phenomena of neutralization of the mobile charge occur at concentrations where the structure-sensitive properties worsen, therefore, we do not recommend the use of this technology for making self-stabilizing oxides. Oxides with very low mobile ion content are achieved by the cleaning effect of C33 on the furnace tube.

The behavior of these oxides is explained by means of a very simple model. The high reaction velocity of HCl and Cl_2 with silicon compared to the oxidation reaction velocity makes silicon-chlorine bonds likely and accounts for the influence on oxidation rate, fixed oxide charge, and the neutralization capability, although the latter is not fully understood. This removal of excess silicon atoms at the interface causes lower defect density, longer relaxation times, and lower interface state densities, this also because of the hydrogen released from the reaction. The removal of contaminants especially sodium from the furnace tubes also accounts for the improved properties.

The impact of C33 oxidation on device properties as defect density, minority carrier generation lifetime, and surface-state density together with its improved physical and physiological properties makes it suitable in silicon device processing.

Acknowledgments

The authors wish to thank the staff of the ESAT laboratory for helpful discussions and technical assistance and K. Van Damme for performing the breakdown experiments. Part of this work was supported by BARCO-COBAR electronic N.V. through IWONL-Contract 2538. G. Declerck is indebted to the NFWO and E. Janssens to the IWONL for their fellowships.

Some Aspects of Oxide Isolation Technology

P. C. Parekh

Honeywell-SSEC, Plymouth, Minnesota 55441

ABSTRACT

Generation of defects and stain profiles have been investigated in the vicinity of the oxide isolation region for the <100> oriented wafers. The variables used were SiO_2 and Si_3N_4 thicknesses at the surface and isolation oxidation temperature. It was observed that the enhancement or retardation in the epitaxial dopant diffusivity in the vicinity of the isolation region was related to the presence or the absence of defects on the <111> plane, respectively.

The impact of oxide isolation technology in the manufacture of high speed high density circuits has been significant. Earlier this type of isolation (1) was applied to bipolar memories. However, presently it is being used in all types of integrated circuits. With increasing interest in this technology, an increasing number of publications on various aspects have been released (1-8). For example recent work by Cosand and Prussin (4) have shown that defects are generated in the vicinity of the oxide isolation region if the processing conditions are not optimized. Work of Sakai *et al.* (2) and Bassous *et al.* (3) attempts to reduce "birds beak" which is a nondesirable feature of oxide isolation. Chang and Chang (6) have characterized oxide isolated structures using device parameter as the vehicle.

Three basic problems that may be experienced with oxide isolated structures are: (*i*) nonplanarity in and around the vicinity of the structure which may cause poor step coverage of metallization, (*ii*) excessive leakage and low breakdown between two regions separated by an oxide isolated region, (*iii*) leakage on devices situated in the vicinity of the oxide isolated region. Nonplanarity at the periphery of the oxide isolation opening has been discussed by Sakai *et al.* (2) and Bassous *et al.* (3). In the present work this aspect of oxide isolation technology is not discussed further.

Key words: oxidation, defects, dielectric isolation.

The work of Cosand and Prussin (4) have shown that the generation of defects was a function of processing conditions. Their work used processing conditions in a fairly narrow range. The object of the present work is to investigate stain profile and generation of defects in the vicinity of the isolation region. From these data processing conditions can be optimized to reduce isolation and active device leakage currents. The range of processing conditions comprised of varying isolation oxidation temperatures from 950° to 1150°C, Si_3N_4 thickness varying from 500 to 2500Å SiO_2 (thermally grown under Si_3N_4) thicknesses varying from 0 to 2000Å.

The tools used for the above investigations were: (*i*) Bevel and stain technique to observe stain profile at the periphery of the isolation region, and (*ii*) the wafers were (100) orientated and were cleaved along <110> directions. The cleaved portions were Sirtl

etched to delineate etch pits formed due to dislocations along the (111) plane. The pits were observed using SEM.

Experimental

The starting material was p-type wafers of (100) orientation and resistivity 8.0-13.0 Ω-cm. The wafers were cleaned and split into two halves such that n-type epitaxial layers of resistivity 0.35 Ω-cm and thicknesses 2.0 and 3.0μ were deposited. Prior to this step some wafers were processed with buried layer deposition and diffusion. However, no differences in the final results were obtained between the wafers with and without buried layer process. After the epitaxial depositions, the wafers were cleaned and thermally oxidized at 950°C with varying SiO_2 thicknesses ranging from 0 to 2000Å. The wafers were then processed through Si_3N_4 deposition performed at 800°C. The thicknesses of Si_3N_4 ranged from 500 to 2500Å. For masking purposes, 1000Å of SiO_2 was deposited at 450 C on all the wafers. An oxide isolation mask was defined and the sandwich structure of SiO_2-Si_3N_4-SiO_2 was etched. Finally, silicon in the mask opening was etched to a depth of 2.25μ using a mixure of potassium hydroxide and isopropyl alcohol as shown in Fig. 1. Here the cross sections represent two devices with epiatxial thicknesses of 2.0 and 3.0 μm. The oxidation in the isolation region was performed at temperatures of 1150°, 1050°, and 950°C. The final oxide thickness in the isolation region (henceforth called groove) in all the cases was 2.2 μm.

Subsequent to the oxidation of the grooves, the wafers were beveled and stained to observe the n-type epitaxial stain profile in the vicinity of the groove region. The method of beveling was performed using the Philtec machine. This enabled large areas of wafers to be subjected to examination. Next the wafers were cleaved along the <110> direction. The cleaved regions were Sirtl etched and subjected to SEM analysis to reveal the presence of defects in the vicinity of the groove due to the oxidation process.

Results

Table I shows a summary of the experiments performed to observe different types of stain profiles and defects generated in the viciniy of the grooves. These are, for example, shown in Fig. 2 and 3, respectively. In the former case, the dark area represents the p-type substrate while the light area represents the phosphorus-doped epitaxial region. Here the boundary between the surface and the beveled region is clearly visible. The stain profiles for the oxidation temperatures used showed the following:

1. For the oxidation temperatures of 1150° and 1050°C, there was an increase in the epitaxial thickness away from the groove region due to the diffusion of phosphorus into the substrate. For the oxidation temperature of 950°C, no significant increase in the epitaxial thickness was observed.

2. There was an enhancement in the diffusivity of the n-type epitaxial dopant under the groove region with respect to that away from the groove region for all the oxidation temperatures used. Henceforth in the article the term "enhancement" assumes that it is referenced with respect to the epitaxial thickness away from the groove region.

Table I. Types of stain profiles

Batch No.	Epi thickness (μm)	Groove oxidation temperature (°C)	Dielectric thickness		Stain profile	Defects Generated?
			SiO_2 (Å)	Si_3N_4 (Å)		
1	3.0	1150	0-2000	2500	Fig. 2	Yes
2	3 0	1150	0-2000	500	Fig. 4	No
3	2.0	1150	2000	2500	Fig. 6	Yes
4	2.0	1150	0-2000	500	Fig. 6*	No
5	2.0	1150	0	2500	Fig. 6*	Yes
6	3.0	950	0-2000	500-2500	Fig. 7	Yes
7	2.0	950	0	500-2500	Fig. 8	Yes
8	2.0	950	2000	2500	Fig. 9	Yes
9	2.0	950	2000	500	Fig. 10	Yes

* Modified stain profile.

Figure 3 shows a SEM view of the cross section of an isolation groove. As mentioned above, the wafers were cleaved along the <110> direction and Sirtl etched. The etch pits and their positioning suggests that the defects are formed on the sloping <111> plane. Henceforth in the article the meaning of the term "the generation of defects in the vicinity of the groove region" assumes that the wafers were cleaved

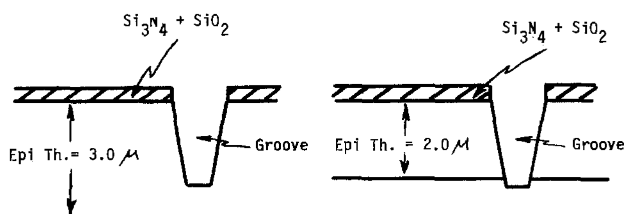

Fig. 1. Cross sections after silicon groove etching. In (a, left) epitaxial thickness > depth of groove. In (b, right) epitaxial thickness < depth of groove.

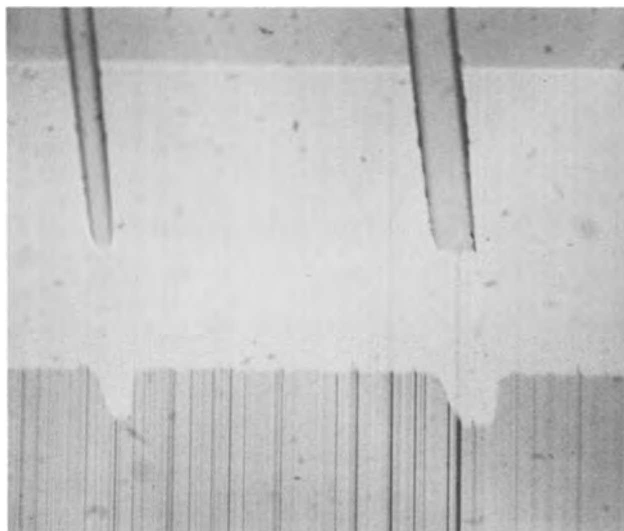

Fig. 2. Bevel and stain profiles for wafers in batch 1. SiO_2 thicknesses = 0-2000Å. Si_3N_4 thickness = 2500Å. Oxidation temperature = 1150°C. ×162.

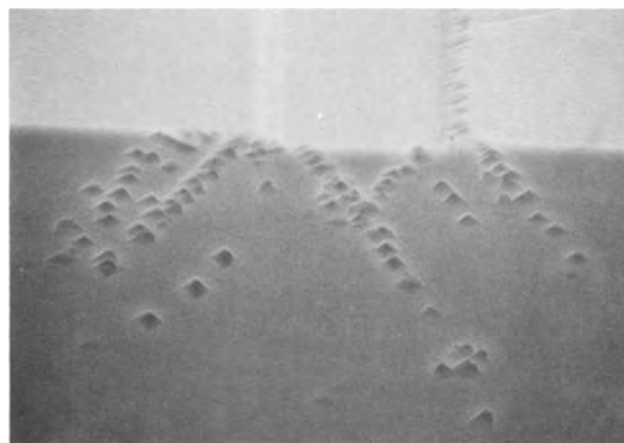

Fig. 3. SEM view of the cross section of samples in batch 1 cleaved in the <110> direction and Sirtl etched. Defects are observed on the (111) plane. ×700.

along the <110> direction and Sirtl etched. Subsequently, the cross section of the etched regions were subjected to SEM analysis and any defects present were found to lie on the (111) plane.

Groove oxidation temperature of 1150°C.—The following results were obtained and are shown in Table I:

Epitaxial thickness = 3.0 μm.—Here the interface of the epitaxial-substrate region was below the lower tip of the groove prior to the groove oxidation as shown in Fig. 1a. After the oxidation the increase in the epitaxial thickness away from the groove region was approximately 1.5 μm. Figure 2 shows typical stain profile in the vicinity of the groove for Si_3N_4 thickness of 2500Å and oxide thickness ranging from 0-2000Å. Here a significant enhancement in the diffusion coefficient of the n-type epitaxial dopant under the groove region is observed. In addition, defects were observed in the vicinity of the groove region as shown in Fig. 3. Figure 4 shows bevel and stain profile of the samples in batch 2 with Si_3N_4 and SiO_2 thicknesses of 500Å and 0-2000Å, respectively. It can be seen that there is a retardation in the diffusion coefficient of the n-type epitaxial dopant under the groove relative to that away from the groove region. Figure 5 shows that no defects were generated in the vicinity of the groove for these samples.

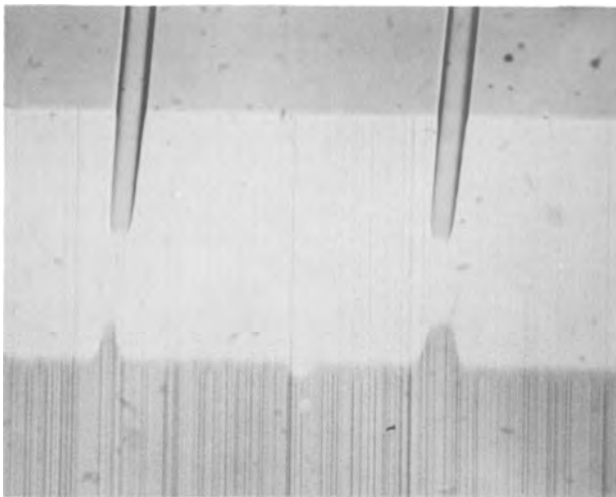

Fig. 4. Bevel and stain profile for wafers in batch 2. SiO_2 thicknesses = 0-2000Å. Si_3N_4 thickness = 500Å. Oxidation temperature = 1150°C. ×162.

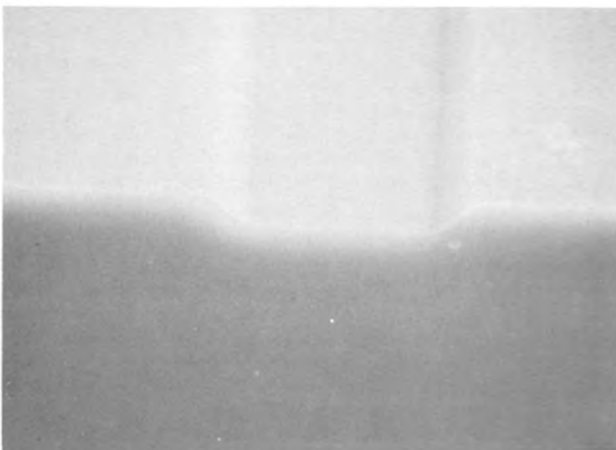

Fig. 5. SEM view of the cross section of samples in batch 2 cleaved in the <110> direction and Sirtl etched. No defects are observed on the (111) plane. ×900.

Epitaxial thickness = 2.0 μm.—Figure 1b shows that prior to the oxidation of the groove, its depth is slightly greater than the thickness of the epitaxial region. However, after the oxidation, the thickness of the epitaxial layer away from the groove region is greater than the depth of the groove. This is illustrated in Fig. 6 for wafers in batch 3 for Si_3N_4 and SiO_2 thicknesses of 2500 and 2000Å, respectively. Note that here the isolation between the two n-type regions is maintained by the continuity of the p-type region between the bottom of the groove and the substrate. During the initial phase of the oxidation of the grooves, some boron from the substrates is incorporated into the oxide. In the subsequent oxidation process, the oxide may act as a source of boron and consequently a continuity of the p-type region between the bottom of the groove and the substrate is maintained. Note that at the periphery of the groove an enhancement in the diffusion coefficient of the n-type dopant is observed. This is accompanied by the presence of defects similar to that shown in Fig. 3. For the samples in batch 4 where Si_3N_4 thickness was reduced to 500Å and SiO_2 thicknesses were allowed to range from 0-2000Å, stain profile as shown in Fig. 6 was observed but with the absence of the enhanced diffusion of the n-type dopant at the periphery of the groove. In addition no defects were observed in the vicinity of the groove region. The stain profile for the wafers in batch 5 with 2500Å Si_3N_4 and no SiO_2 under the Si_3N_4 was similar to that shown in Fig. 6 but with less enhancement at the periphery of the groove region. In addition, defects similar to that shown in Fig. 3 were observed although the density of defects was lower than shown in the figure.

Groove oxidation temperature of 950°C.—The following results were obtained and are shown in Table I:

Epitaxial thickness = 3.0 μm.—Here after the oxidation of the groove, the epitaxial thickness away from the groove region remained same as prior to the oxidation. For any combination of SiO_2 thicknesses ranging from 0-2000Å and Si_3N_4 thicknesses ranging from 500 to 2500Å, stain profile of the type shown in Fig. 7 was observed. This was also accompanied by the presence of defects in the vicinity of the groove regions.

Epitaxial thickness = 2.0 μm.—Figures 8-10 show stain profiles for samples with SiO_2 and Si_3N_4 thicknesses shown in Table I. It can be seen that on increasing the SiO_2 and Si_3N_4 thicknesses, a potential loss of isolation results between the two n-type epitaxial islands. In all the cases defects were observed in the vicinity of the groove regions.

Discussion

The results obtained in this work show that the enhancement or retardation of the epitaxial dopant under the groove region is a strong function of Si_3N_4/SiO_2 thicknesses. It is also interesting to observe that in the majority of the cases the enhancement was accompanied by the defects generated in the vicinity of the groove. However, in the absence of enhancement or only when retardation was present, no defects were generated.

For the oxidation temperature of 1150°C, the enhancement or retardation was a strong function of Si_3N_4 thickness and relatively insensitive to the SiO_2 thickness under the Si_3N_4. This is shown in Table I for wafers in batches 1 and 2. In the former case, irrespective of any SiO_2 thickness and Si_3N_4 thickness of 2500Å, enhancement of the n-type epitaxial dopant under the groove is observed as shown in Fig. 2. Figure 3 shows defects generated in the vicinity of the groove along the (111) plane. The generation of defects is a result of excessive stress experienced during the oxidation of the grooves. This stress is due to the thick Si_3N_4 film tending to resist the volume expansion of SiO_2 at the periphery of the groove. The enhanced diffusion observed under the groove may be a result of greater than equilibrium concentration of vacancies formed due to the generation of the defects.

The retardation of the n-type epitaxial dopant observed under the groove at the oxidation temperature of 1150°C for wafers in batch 2 is shown in Fig. 4. It must be clarified that the term retardation here implies that the n-type epitaxial dopant away from the groove diffused further into the substrate than the dopant under the groove during oxidation. Figure 5 shows the absence of defects in the vicinity of the groove for samples which experienced retardation. This can be understood by observing that the thickness of the Si_3N_4 film is only 500Å. Thus, during the oxidation of the groove, the tendency for the stress to occur at the periphery of the groove will be minimized significantly. The absence of defects, however, does not explain the decrease in the diffusivity (or retardation) of the n-type dopant under the groove. The only explanation the author can suggest is that during the oxidation, the growing oxide in the groove results in the deficiency in vacancies at the Si-SiO_2 interface. Thus vacancies from the surrounding regions such as the epitaxial-substrate interface may diffuse toward the Si-SiO_2 interface. This will result in a decrease in the diffusivity of the epitaxial dopant underneath the groove.

From Fig. 2 and 4 it can be seen that isolation between epitaxial regions on either side of the groove is

not accomplished. The primary reasons are two fold. First the depth of the groove prior to its oxidation was too shallow compared to the 3.0 μm epitaxial thickness. Second, the diffusion of the epitaxial region into the substrate is significant at 1150°C. The former objection was overcome by using vertical geometry such as shown in Fig. 1b. Here, prior to the oxidation, the depth of the groove was slightly larger than the epitaxial thickness. After the oxidation of the groove, isolation was maintained for wafers in batches 3, 4, and 5 as shown in Table I. For wafers in batch 3 with Si_3N_4 and SiO_2 thicknesses of 2500 and 2000Å, respectively, bevel and stain profiles as shown in Fig. 6 were observed. Note that here a continuity of the p-type region between the bottom of the groove and the p-type substrate is attained. In addition, it can be seen that enhancement in the diffusivity of the n-type epitaxial dopant is observed at the periphery of the groove. This was accompanied by the presence of defects in the vicinity of the groove region similar to that shown in Fig. 3. The continuity of the p-type region may be explained by the affinity of boron for SiO_2. During the initial oxidation of the groove, a significant amount of boron is incorporated into the oxide in the groove. The oxide can now act as a source of boron during the remaining phase of the oxidation. Consequently, a continuity in the p-type region is maintained between the bottom of the groove and the substrate.

Wafers in batch 4 with Si_3N_4 thickness of 500Å and SiO_2 thicknesses ranging from 0-2000Å exhibited stain profile as shown in Fig. 6 with the exception that the enhancement at the periphery of the groove was absent. In addition, no defects were generated in the vicinity of the groove region. This result is similar to that in batch 2 and was expected.

For wafers in batch 5 with no SiO_2 under 2500Å thick Si_3N_4, the enhancement at the periphery of the groove was smaller than that shown in Fig. 6. This is expected since Si_3N_4 in direct contact with silicon will reduce the volume expansion of SiO_2 at the periphery of the groove. This in turn reduces the formation of defects.

From above it can be seen that the enhancement in the diffusivity and the generation of defects was a strong function of Si_3N_4 thickness. At the lowest oxidation temperature used in the present work (950°C), enhancement was observed for all combinations of Si_3N_4/SiO_2 thicknesses. In addition, defects were observed in all cases. Cosand and Prussin (4) observed that reducing the oxidation temperature results in an increase in the viscosity of SiO_2 resulting in a large stress generated. Their work used groove oxidation temperature of 900° and 1020°C. The latter oxidation temperature generated no defects while at 900°C defects were observed.

The results for the groove oxidation temperature of 950°C are shown in Table I for wafers in batches 6 to 9. The bevel and stain profiles of these wafers showed that there was no increase in the epitaxial thickness away from the groove region after the oxidation. For wafers in batch 6 with any Si_3N_4 and SiO_2 thicknesses used, the bevel and stain profiles were similar to that shown in Fig. 7. Here a significant amount of enhancement in the diffusivity of the n-type dopant under the groove region is observed. Prior to the oxidation, the epitaxial thickness was larger than the depth of the groove. After the oxidation, the depth of the groove was larger than the epitaxial thickness since the latter did not increase during the low temperature oxidation. In spite of this, the loss in isolation that resulted is due to the enhancement in the diffusivity of the n-type dopant under the groove. The chances of maintaining isolation between the two n-type regions was greater for wafers in batches 7, 8 and 9 with epitaxial thickness of 2.0 μm. Here prior to the oxidation, the bottom tip of the groove was below the epitaxial-substrate interface. The bevel and stain profiles after the oxidation for batches 7, 8, and 9 are shown in Fig. 8, 9, and 10, respectively. Here it can be seen that a potential loss in isolation exists for wafers in batch 8 with Si_3N_4 and SiO_2 thicknesses of 2500 and 2000Å, respectively. For the same oxide thickness but using only 500Å Si_3N_4, the isolation was maintained although some enhancement at the periphery of the groove region was observed as shown in Fig. 10. For wafers in batch 7 with no SiO_2 and Si_3N_4 thicknesses ranging from 500 to 2500Å, the enhancement in the diffusivity of the n-type epitaxial dopant was minimal as shown in Fig. 8. In addition, some defects were observed in the vicinity of the groove although the density of the defects was significantly lower than those observed for wafers in batches 8 and 9. These results are somewhat similar to that observed for wafers in batch 5 which used oxidation temperature of 1150°C. It must be emphasized here that Si_3N_4 in direct contact with silicon did not always produce less enhancement than with the presence of SiO_2. Thus for batch 1 no differences were observed for oxide thickness under Si_3N_4 ranging from 0 to 2000Å. The disadvantage of using Si_3N_4 in direct contact with silicon has been well documented (7). Thus for device fabrication, a thin layer of SiO_2 between substrate and Si_3N_4 is required.

Conclusion

From the present study, the following optimum process may be recommended for oxide isolation.

1. In order to reduce defects in the vicinity of the groove region thin layers of Si_3N_4 and SiO_2 should be used.
2. The generation of defects is minimized as the groove oxidation temperature increases. However, the disadvantages in using hgh oxidation temperature is the out-diffusion of the buried layer into the epitaxial region. This can be partially offset by using a slower diffusant such as antimony instead of arsenic as the dopant for the buried layer. In addition where no buried layer is used, it is recommended that arsenic should replace phosphorus as the epitaxial dopant. The use of the former will reduce the increase in over-all epitaxial thickness after the oxidation of the groove.

Silicon Oxidation Studies: Some Aspects of the Initial Oxidation Regime

E. A. Irene

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

This study is concerned with the initial regime (*i.e.* up to 200Å SiO_2 thickness) of the thermal oxidation of single crystal Si. The kinetic data (SiO_2 film thickness *vs.* time of oxidation) has been generated at 780°, 893°, and 980°C in dry O_2 and H_2O-N_2 ambients and measured using an automated ellipsometer which follows the oxidation *in situ*. The data for the dry O_2 oxidation is considerably more linear than for the data produced from H_2O containing ambients which exhibit parabolic behavior. This may be attributed to a greater protectiveness for oxides grown in H_2O. Dielectric breakdown measurements show that there are fewer defects in the H_2O grown thin SiO_2 films. Transmission electron microscopy observations show that the films contain inhomogeneities which are smaller than 50Å. Therefore, the conclusion is that the pore structure is different in dry and wet grown SiO_2 films and that this microstructure is responsible for both the oxidation data and dielectric breakdown differences.

The thermal oxidation of single crystal silicon at high temperatures (800°-1000°C) in pure dry O_2, has been found to be represented adequately by a linear-parabolic film growth model (1), with an accuracy better than 10%, if the data fitted only includes film thicknesses greater than a minimum value (d_o) of several hundred angstroms (2). However, for oxidation in H_2O containing ambients (3, 4), the minimum thickness value of d_o, to be included for a good fit to the linear-parabolic model, decreases with increasing H_2O content of the oxidizing ambient. An examination of the regime of thicknesses less than d_o, shows that this thin SiO_2 region is characterized by a faster rate of oxidation than is anticipated from the rate constants for the linear-parabolic regime (1-5). One report (5) describes this region by another linear-parabolic equation with different rate constants while other authors (6, 7) assume it is the linear part of the linear-parabolic rate law. The former analysis (5) does not consider the possible curve fitting error associated with assuming a linear-parabolic initial regime and the latter authors have insufficient data to analyze for the determination of a best fit. The present study is concerned with an examination of the initial regime of oxidation (SiO_2 film thicknesses $\leqq d_o$) to determine why the initial regime for dry O_2 oxidation displays a more rapid oxidation mechanism while for H_2O oxidation $d_o \approx$ O, and the oxidation data follow the linear parabolic model throughout.

Results of the present study, indicated a decided difference between the linearity of the data for dry O_2 oxidation and oxidation in H_2O containing ambients for SiO_2 films up to 200Å thickness. The dry O_2 data are more linear. The linear-parabolic model (1) can be summarized by the integrated rate equation

$$t - t_o = \frac{1}{k_{LIN}}(d - d_o) + \frac{1}{k_{PAR}}(d^2 - d_o^2)$$

where t and d are the time of oxidation and SiO_2 film thickness, respectively, t_o and d_o represent the upper bound of the initial oxidation regime which does not conform to linear-parabolic kinetics, and k_{LIN} and k_{PAR} are the linear and parabolic rate constants, respectively. In this model, linear kinetics are the result of a surface controlled reaction while parabolic kinetics demonstrate that the oxidation is diffusion controlled. Therefore, this experimental finding suggested that wet grown SiO_2 films are more protective. Dielectric breakdown histograms support the contention that 150Å wet grown SiO_2 films have less defects than films grown in dry O_2. These results can be explained if micropores existed in the SiO_2 films. For the purpose of observing micropores in the films, transmission electron microscopy (TEM) studies were performed.

Experimental Procedures

Substrate preparation and oxidation.—The oxidation experiments were performed using an automated ellipsometer capable of measuring the SiO_2 film thickness *in situ* during oxidation. The instrument used for this study has been described in detail elsewhere (8). Basically, the ellipsometer uses a laser light source, polarizer, compensator, and a rotating analyzer-encoder. The light intensity measurement after the analyzer is automated. The ellipsometry measurements are made with the sample contained in a fused silica rf-heated reaction tube. Therefore, it is possible to collect and analyze ellipsometric data as the SiO_2 film grows without interrupting the oxidation run. The optical constants characteristic of the Si surface as a function of temperature were previously measured (8).

All substrates were <100> oriented chem-mechanically polished silicon wafers measuring 3.2 cm in diameter and 0.025 cm in thickness. All the wafers were p-type with a nominal resistivity of 2 Ω-cm. It was reported previously (3) that the resistivity type or value in the range 0.5-10 Ω-cm had no influence on the oxidation process. The wafers were cleaned as reported elsewhere (3) and an initial oxide thickness of 3-6Å SiO_2 was measured at room temperature (2).

The gases used in this study included Ar, N_2, and O_2. Both N_2 and O_2 were supplied from boil-off of liquid sources. As previously reported (2, 3) the O_2 contained trace amounts of methane (17 ppm) which at the oxidation temperature used combusts to form H_2O. This trace H_2O substantially increases the rate of oxidation (3, 4). For dry oxidations, the methane was removed by preheating the oxygen to about 1000°C, in order to combust the methane to H_2O and CO_2, and then cold trapping at −80°C to reduce the H_2O concentration to less than 1 ppm H_2O in the O_2. In order to add H_2O to N_2, the N_2 is flowed through a thoroughly cleaned fused silica vessel which contains deionized H_2O. By controlling the H_2O temperature with a variable temperature refrigeration unit, the concentration of H_2O can be adjusted to any desired level from less than 1 ppm upward. The Ar was purchased in pressurized cylinders and was the high-

est purity commercially available. The moisture content was less than 0.5 ppm as measured at the furnace exit during the actual annealing experiments to be described.

In order to check on the charge levels in the SiO_2 films grown, capacitance-voltage (C-V) measurements were made on some oxides. Evaporated aluminum counterelectrodes were used as electrical contacts. The C-V measurements (1 MHz) revealed an average fixed positive charge level of less than 5×10^{10} charges/cm^2. Bias-temperature stressing (10^6 V/cm at 200°C for 15 min and subsequent cooling under bias) revealed an average mobile positive charge level of 7×10^{10} charges/cm^2. These values are characteristic of MOS quality oxides.

Dielectric breakdown measurements.—Dielectric breakdown measurements were made using a special triggering circuit configuration previously described by Osburn and Ormond (9). Essentially a linear voltage ramp is applied to the MOS sample. The voltage ramp was obtained by charging a fixed capacitor using a constant current generator; the ramp rate was then controlled by adjusting the output current from the generator. Triggering is obtained by a circuit which senses a voltage across a resistor in series with the MOS device. The series resistor must be kept at a reasonably low value (10-1000Ω) to prevent a large error in the reading of the final breakdown voltage. The electrodes used were rf evaporated Al dots of 0.127 cm diam yielding a dot area of 1.27×10^{-2} cm^2 on the SiO_2 film side and Ga-In paste on the Si side. The Al thickness was approximately 5000Å and this thickness plus the use of a small sense resistor in the circuit configuration (9) insured that the measured breakdown voltage was the final destructive breakdown. The ramp rate was the same for all measurements and about 0.5 MV/cm-sec.

The breakdown measurements were done with the Al biased negatively, *i.e.*, with the 2 Ω-cm p-type Si in accumulation. At high fields electrons are injected from the Al into the SiO_2. If electrons were trapped near the Al-SiO_2 interface, the trapped charge would alter the field across the MOS device and possibly lead to erroneous conclusions concerning histograms of the number of breakdown events *vs.* applied field. For the purpose of determining if there is sufficient trapping near the Al-SiO_2 (injecting) interface to cause the observed effects a recently described (10) technique is employed which utilizes the Fowler-Nordheim (FN) current regime. This FN technique consists of a measurement of current while applying a voltage ramp to a MOS device. The FN current regime is identified by the linearity of the plot of log I *vs.* E. The fields at which the FN conduction mechanism dominates is usually greater than 6 MV/cm for SiO_2. If trapping occurs, the FN curve is shifted to higher fields due to the trapped negative charge. Trapped charge causes field reduction, F, at the cathode according to the equation (10)

$$F = \frac{qN_t}{\epsilon_{ox}} \frac{\overline{X}}{D_{ox}}$$

where q is the electronic charge, N_t is the total trap concentration, and ϵ_{ox} is the dielectric constant for SiO_2, $\overline{X}$ is the distance of centroid of the charge from the anode, and D_{ox} is the oxide thickness. This equation shows that the effect of the charge on the field at the cathode increases as the distance to the cathode decreases. Experimentally the current through the MOS device is measured using a logarithmic picoammeter while the field is increased by means of a linear ramp. The FN regime is scanned in field from about 6-10 MV/cm and then held at 10 MV/cm for a few seconds to insure large current flow through the device; then the field is removed and the experiment repeated. If trapping occurs the FN characteristic curve is shifted to higher fields. Results of this experiment are shown below.

Capacitance-voltage measurements (1MHz) at room and LN_2 temperatures were made to determine whether charges were trapped, and/or surface states (11, 12) created, near the Si-SiO_2 interface due to the large currents which exist prior to dielectric breakdown.

Transmission electron microscopy (TEM).—Specimens of 150Å SiO_2 films were prepared by chemically etching away the Si from the Si-SiO_2 composites. The details of this procedure have been previously described (13). The TEM specimen preparation was done in four different ways, in order to eliminate possible artifacts due to a particular etchant and to decorate features of interest. Type I samples were prepared by simply etching away Si with a mixture of HF and HNO_3. This etchant also attacks SiO_2 and the successful preparation of good TEM samples with this etchant is somewhat fortuitous. When the Si-SiO_2 interface is approached, the etchant mixture is changed to a solution more dilute in HF, in order to reduce the speed of attack on the SiO_2 film. Type II samples were prepared similarly to type I except that when about 80% of the Si was removed with a HF-HNO_3 etchant, the etchant was changed to a mixture of pyrocatechol-ethylenediamine-H_2O (14). This mixture attacks Si very vigorously (20 μm/hr at 100°C) but SiO_2 very slowly (200 Å/hr). Type III films were prepared exactly as type II and when the etching was finished the samples were annealed in dry N_2 at 1000°C for 2 hr. This treatment was used to simulate an observed degradation in dielectric reliability which is reported later. Type IV samples were prepared as type II samples but before etching they were either coated with 100Å of Au by evaporation or dipped in a solution of NaCl and annealed. The Au samples were annealed for ½ hr at 800°C and the NaCl contaminated samples were heated for 1 hr at 500°C. In some cases the Au coated samples were not annealed and in other cases the Au was removed after annealing with aqua regia. It was hoped that the Au would decorate preferred diffusion paths and the NaCl would decorate weak areas by reaction.

Experimental Results

Film growth kinetics.—Figure 1 shows the experimental data for the oxidation of <100> Si in dry O_2 and H_2O-N_2 ambients for SiO_2 film thicknesses of 20-150Å. Visually these data appear to be linear. Table I shows the results of fitting the data to the linear equation

$$t = k_1 d + k_2$$

by the method of least squares (15) where t is the oxidation time and d is the SiO_2 thickness. The dry O_2 data are relatively more linear than the H_2O-N_2 data. Indeed it is known that for a 2000 ppm H_2O in N_2 ambient $d_o \approx 0$, hence the data fits the linear-parabolic equation for all values of SiO_2 film thickness (4) while for dry O_2 a best fit is not obtained when film thick-

Table I. Results of fitting the data from Fig. 1 to the linear equation, $t = k_1 d + k_2$ where t is the time (min) and d the SiO_2 film thickness (Å). D represents dry O_2 oxidation ambient and W represents 2000 ppm H_2O in N_2

Temperature (°C)	Ambient	Std dev of fit	$1/k_1$ (Å/min)	k* (Å/min)

The rate constants in columns 4 and 5 are known with less than 10% total error.

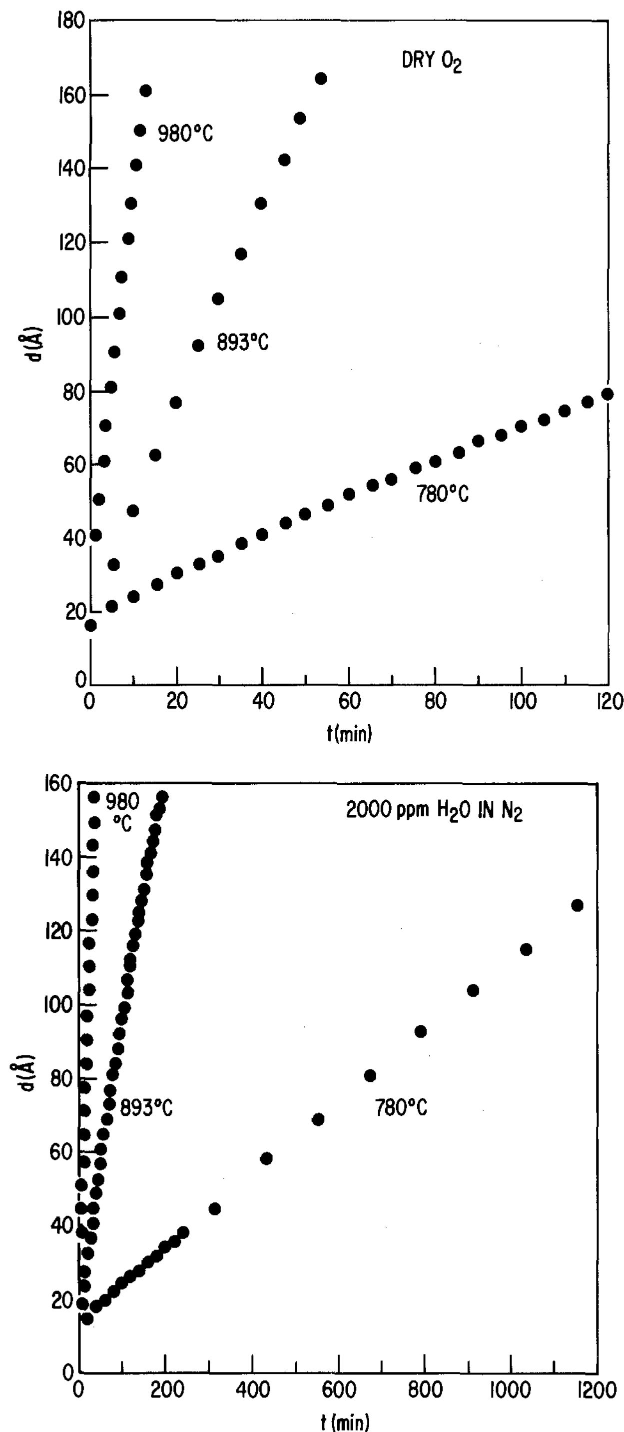

Fig. 1. SiO_2 film thickness, *d*, *vs.* time of oxidation, *t*, at 780°, 893°, and 980°C in (a, upper) dry O_2, (b, lower) 2000 ppm H_2O in N_2 as obtained from the automatic ellipsometer.

nesses less than ~200Å are included in the analysis. In keeping with the linear-parabolic model (1), the linear rate is associated with a surface controlled reaction. This plus the fact that the initial linear regime for dry O_2 displays a greater oxidation rate than the linear-parabolic mode, suggests that the SiO_2 films produced by ultra dry O_2 oxidation are less protective than films grown in an H_2O containing ambient. Enhanced protectivity for the H_2O grown 150Å films may be manifested in terms of reduced film defects. The results of dielectric breakdown measurements to be described can be interpreted in terms of film defects and will shed some light on this question of protectivity.

The difference in linearity of the oxidation data for wet and dry grown films is largest at the lower oxidation temperatures; and at the lower temperatures there is closer agreement between the slope of the straight line fitted to the data and the linear rate constant as obtained from the linear-parabolic model applied to film thicknesses up to 2000Å (2). For dry O_2 grown oxides this is understood by considering that the initial regime for dry O_2 films is not linear-parabolic and therefore agreement between k_{LIN} and k_l is not to be expected except where d_o is close to zero at the lower temperatures. For the H_2O grown films the parabolic rate constant is important even for these thin films and therefore agreement between k_{LIN} and k_l will depend on the importance of k_{PAR}.

Dielectric breakdown and trapping measurements.—The shape of the histogram of the number of dielectric breakdown events *vs.* the field at which breakdown occurs yields information relative to the defects in the SiO_2 films (9, 16). Figure 2 shows a comparison of the

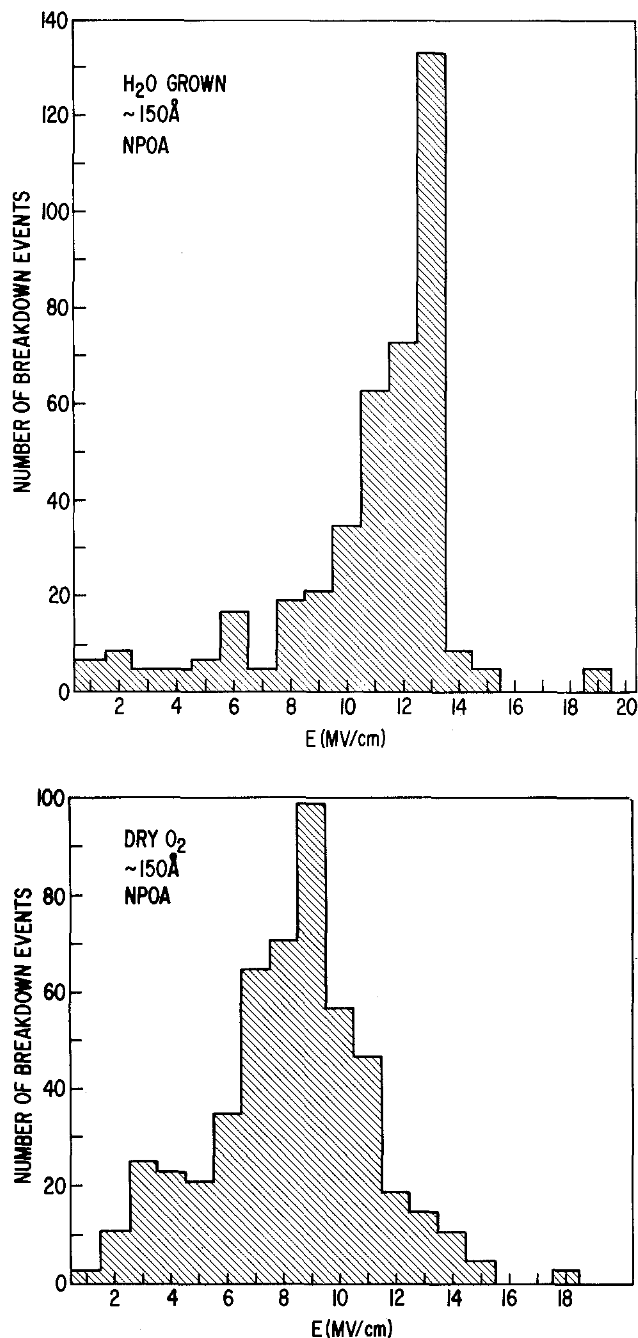

Fig. 2. A comparison of (a, upper) H_2O-N_2 and (b, lower) dry O_2 grown 150Å SiO_2 films according to the histogram of the number of destructive dielectric breakdown events *vs.* the applied electric field, *E*. Field values are calculated from the applied voltage and the ellipsometric SiO_2 thickness. NPOA means that no post oxidation annealing was performed.

histograms for 150Å SiO_2 films grown in H_2O-N_2 (Fig. 2a) and dry O_2 (Fig. 2b). It is readily seen that the maximum breakdown field for both wet and dry SiO_2 are nearly equivalent at a value of 14 MV/cm yet the shapes of the distributions are decidedly different. Theoretically, the histogram for a defect free SiO_2 film would be a delta function at the maximum breakdown field. Thickness fluctuations as well as random measuring equipment imperfections would broaden the delta function slightly, but SiO_2 film defects would cause a larger tail toward the lower fields. This type of tailing is observed in the histograms for both wet and dry grown SiO_2. However, the broadening is more severe for the dry oxides where the peak in the distribution is shifted about 2-3 MV/cm further toward low fields than for wet grown oxides and results in a distribution with a nearly Gaussian shape. The wet grown SiO_2 films have 80% of the breakdowns at fields $\geq$10 MV/cm while only 30% for dry grown films. Therefore, in view of these dielectric breakdown results the previous assertion based on the film growth kinetics that wet grown oxides are more protective seems justified.

Previously, it was reported that the effect of H_2O on the SiO_2 film oxidation kinetics is reversible (4), *i.e.*, the oxidation kinetics of an oxide growing in an H_2O containing ambient reverts to dry oxidation kinetics soon after the wet ambient is switched to a dry ambient. It is worthwhile to investigate whether the enhanced dielectric reliability of the wet grown thin SiO_2 films is coupled with the rather labile-OH in which case the enhanced dielectric integrity is easily lost or whether the enhanced reliability is due to a more stable form of OH in the SiO_2 network. Figure 3a shows that the histogram for a wet grown oxide reverts to that for a dry grown oxide after ½ hr 1000°C anneal in dry N_2. However, Fig. 3b, c, and d show that compared with the control (Fig. 3b) annealing at 1000°C in dry Ar for up to 18 hr caused only a small amount of degradation. In fact, the small amount of degradation could simply be due to sample to sample variations. In any case, the degradation in dry N_2 is unambiguously larger. Therefore, since the films were stable to the 1000°C Ar anneal, the enhanced reliability of wet grown thin oxides appears to be related to a stable form of OH in the SiO_2. The

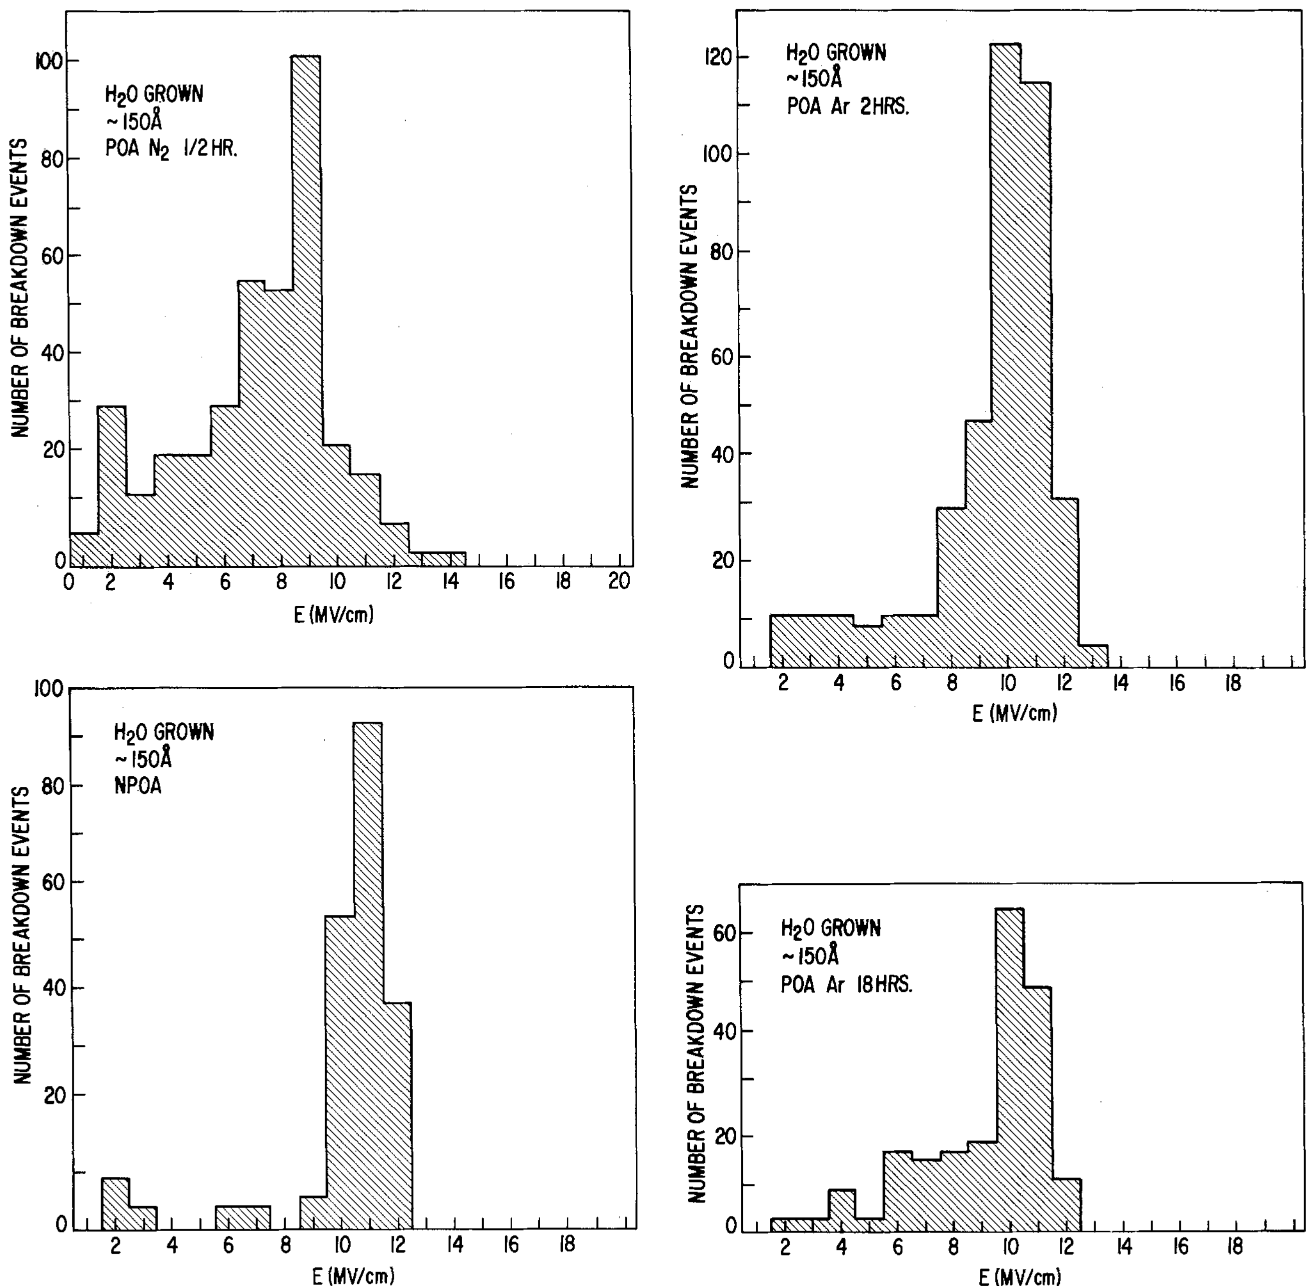

Fig. 3. A comparison of annealing H_2O-N_2 grown SiO_2 films at 1000°C in (a, upper left) N_2 for ½ hr, (b, bottom left) no anneal, (c, upper right) argon for 2 hr, (d, lower right) argon for 18 hr.

fact that there exists several forms of OH having different lability in fused silica has been reported (17). Also the reactivity of N_2 in the SiO_2-Si system in a nonoxidizing atmosphere has been reported (18) as well as the detrimental effect that the reaction of N_2 has on the dielectric reliability (19, 20). Thus, the degradation of the H_2O grown thin films is accelerated by N_2 reaction and not by the out-diffusion of labile OH.

Electron trapping and surface states.—Representative results for the electron trapping measurements by the previously described Fowler-Nordheim (FN) technique are shown in Fig. 4. The samples were ramped up to 10.5 MV/C and held there for 10 sec (i). Then the curve was retraced (re). The initial and retraced curves for a wet grown oxide (W104) differ at most by 0.5 MV/cm shift in the breakdown histogram peaks. Samples W104 and D113 displayed more than the average amount of trapping for wet and dry samples examined in this study; the average shift in the FN characteristic curve was found to be 0.2-0.3 MV/cm for both wet and dry samples with wet grown films usually exhibiting more trapping. It was sometimes difficult to find dots on dry grown SiO_2 samples which could withstand the high field for this experiment. Other than this problem however, the trapping behavior near the cathode was observed to be similar for wet and dry films and in no case was the trapping sufficient to cause the degree of electric field change necessary to explain the histograms of Fig. 2.

Capacitance-voltage (C-V) measurements at room temperature and liquid nitrogen temperature have shown that about $7.5 \times 10''$ positive charges per square centimeter are created at or near the Si-SiO_2 interface and about the same number of surface states are created by virtue of the above described FN currents. These results were the same for both dry and wet grown oxides and are in qualitative agreement with previous studies [see, for example, Ref. (21) through (24)].

Transmission electron microscopy (TEM).—Figure 5 shows representative results from type I and II samples. The results from type I, II, dry and wet samples were substantially the same. It is seen from Fig. 5 that the mode for the dissolution of the films is via attack by the etchant at selected small areas on the film surface. The differences seen between Fig. 5a and b are probably due to the time of exposure of the film to etchant. The time duration in which the sample was exposed to etchant would determine the size relationship between the final size of the hole and the original defect. This time was not controlled in this study. The nature of the defect, *i.e.*, whether a void, micropore, impurity cluster, crystallite, etc. depends on the relative reactivity of the etchant to these types of possible defects. It is clear that a void or micropore could yield the final observation, but other defects cannot be ruled out. The maximum size of the inhomogeneity must be as small or smaller than the hole found after etching. Holes which measured less than 100Å were observed, and therefore, considering the speed of the etchants, the inhomogeneities could be 50Å or less in diameter. No differences were seen upon annealing type I and II samples. Therefore, no figure for type III samples is shown.

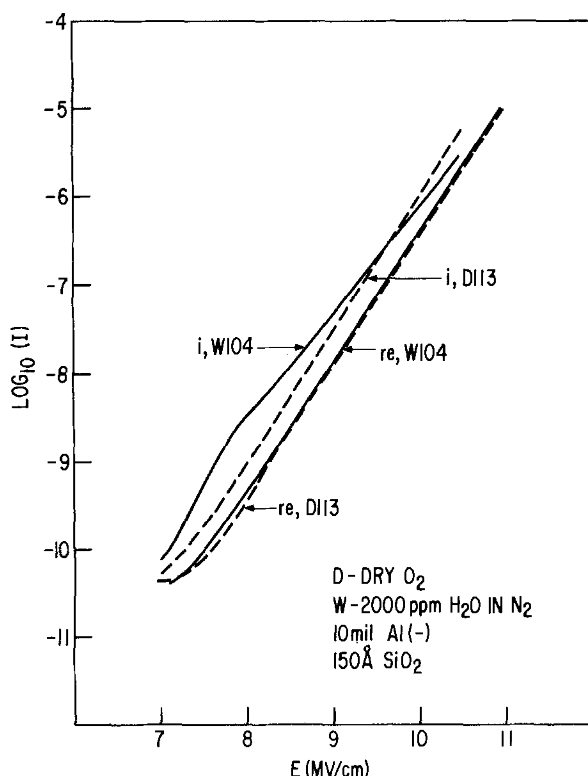

Fig. 4. A comparison of the Fowler-Nordheim conduction behavior between dry (D113) and H_2O grown (W104) SiO_2 films.

By way of explaining these results, gas permeation studies (25) have led to the assertion that pores in SiO_2 of less than 50Å diameter would explain the measured permeabilities for different gases. Another model was proposed (26) in which a nonrandom distribution of bond angles in the SiO_2 network may result in chain-like defects where $d\pi$-$p\pi$ orbital overlap between Si and O is greater than in surrounding regions. Such higher electron density regions may be more violently attacked by etchant. This latter model (26) predicts higher electrical conductivities for films which have this chain structure. However, the conduction measurements made in the present study do not show any systematic differences between wet and dry prepared 150Å SiO_2 films. Also, it is difficult to reconcile the oxidation kinetics results based on more dense localized regions.

Representative results from type IV samples are shown in Fig. 6. Figure 6a shows that less than monolayer of Au forms rod-shaped structures. A closer examination reveals that contained within the rod-like structures are smaller darker regions. Presumably these are the nuclei for the growth of the Au islands. The areal density of these nuclei ($\sim 10^{15}$ cm^{-2}) is much larger than the electrically active defect density ($<10^3$) as obtained by dielectric breakdown measurements. Figure 6b shows the results from Au decoration. Au was evaporated onto a 150Å SiO_2 film on Si. The Si was removed from a portion of the sample and then the Au was driven into the film at 800°C for ½ hr. The Au was then removed using aqua regia. The darker transparent region of Fig. 6b was caused by a piece of the film folding back to the silicon edge and then breaking off. Therefore, there is 300Å SiO_2 in the darker region. All the Au has not been removed and is seen as the nontransparent dots and islands formed by coalescence and growth. The regions where the Au has been removed appear as tunnels. However, it is known that Au reacts with SiO_2 (27) and the shape of the tunnel-like structures is similar to the shape of the Au islands. Therefore, it is believed that the tunnel-like structures are due to reaction of Au with SiO_2. Furthermore, if the Au is removed after a 300°C anneal or no anneal at all, the tunnel structures are less visible.

Figure 6c shows the result of decoration with NaCl. The NaCl nuclei appear to be located preferentially on the perimeter of holes which were produced by the etchant. Also, around the NaCl nuclei and clusters is another dark band. This is probably a region in which reaction has taken place between Na and SiO_2. The holes may have been preceded by areas which were the reaction product of NaCl and SiO_2 and this may be more vigorously attacked by the etchant. Sodium

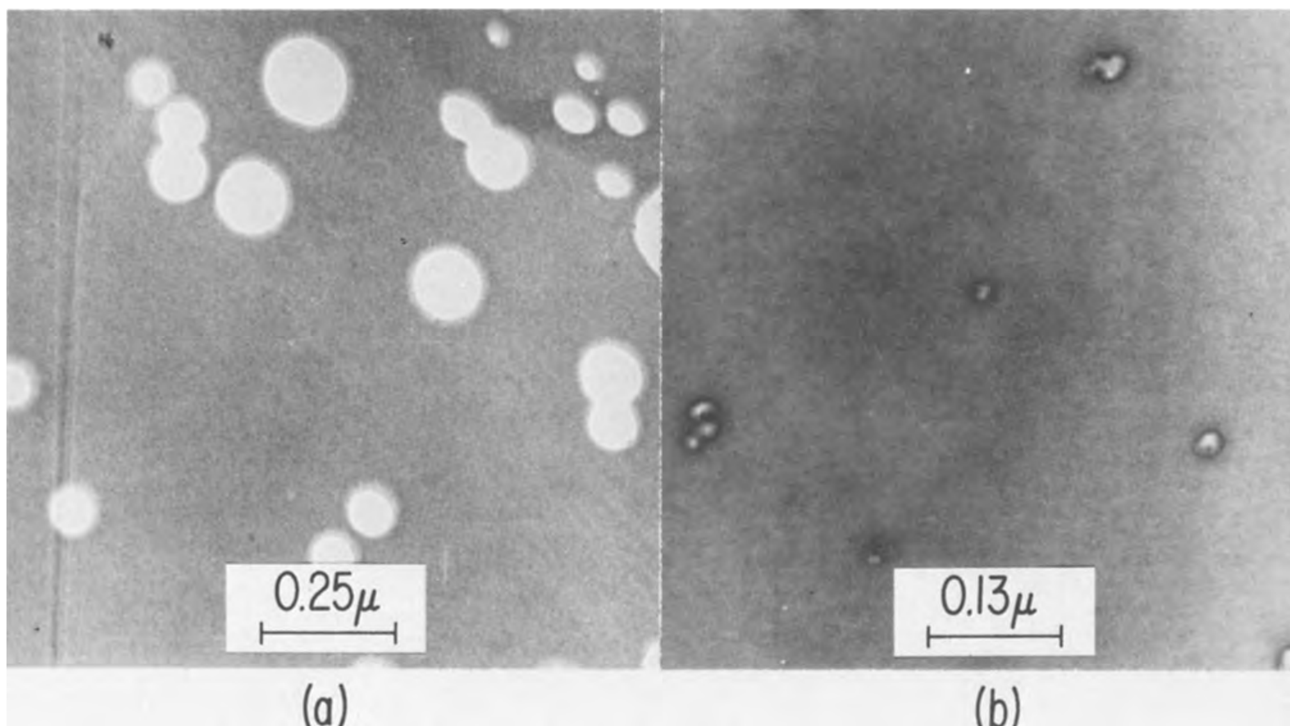

Fig. 5. Typical TEM results from 150Å SiO_2 films of type I (HF-HNO_3 etched), type II (organic etch), or type III (same as type I plus 1000°C N_2 anneal) showing holes etched through the films. Micrograph (a) shows a more advanced stage of etching than (b).

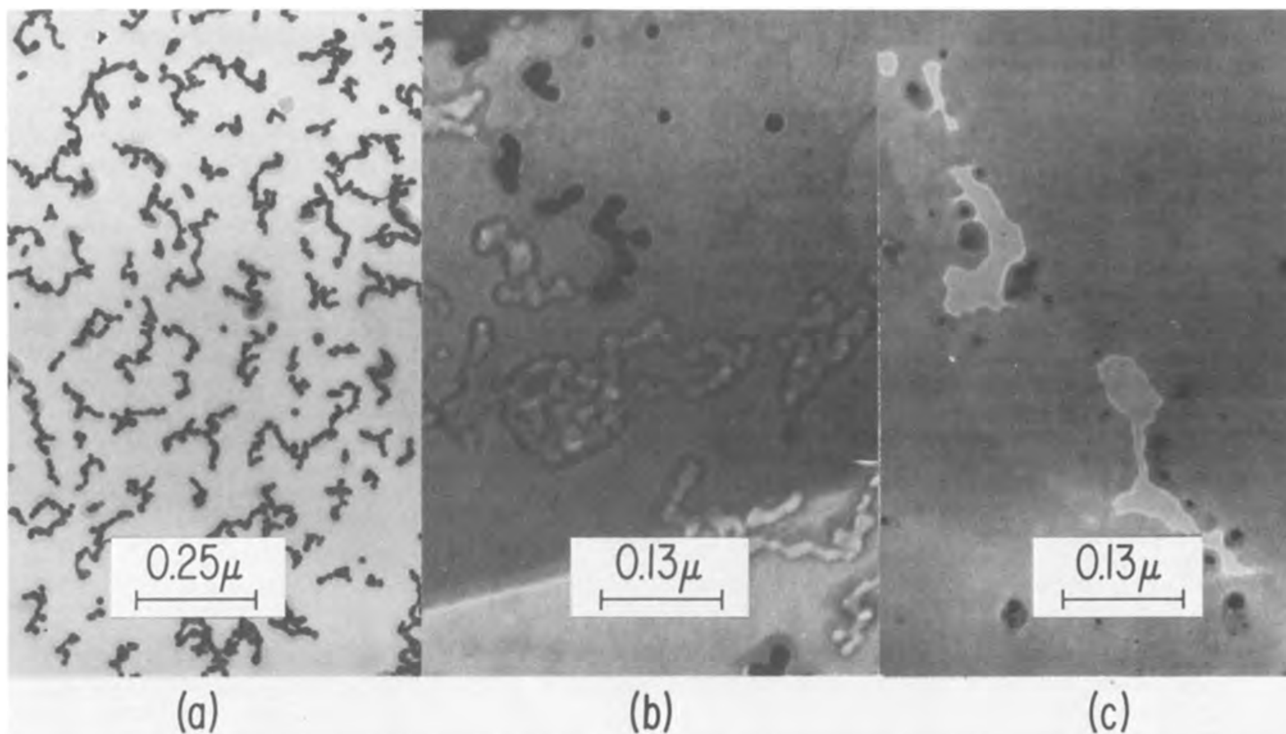

Fig. 6. Typical TEM results from Au (type IV) and NaCl (type V) decoration studies. Micrograph (a) shows Au islands as deposited on SiO_2; (b) shows the effect of annealing and then removing some of the Au; (c) shows the holes left after NaCl decoration and etching. NaCl islands are also seen as the dark spots.

silicates are usually soluble in H_2O. The shapes of the holes are irregular as compared with the circular holes which occurred without attempts at decoration.

There are several things learned from the TEM experiments. The type I and II samples strongly suggest that the films have inhomogeneities. The size of the inhomogeneities is certainly less than 100Å and probably less than 20Å which makes the resolution of the defects within the present study doubtful. The number of these inhomogeneities, assuming that they are related to the etched holes in a one to one ratio, is of the order of 10^{15} cm^{-2} which is more than 10^{12} times too large compared with the number of defects obtained from dielectric breakdown statistics. This probably means that although the type of inhomogeneity observed is part of the SiO_2 thin film structure, only a small fraction is sufficiently electrically active to cause dielectric failure. The shape of defects was not ob-

tained by decoration experiments because ambiguities arise from the reaction of the decorant with SiO_2. However, the number of nuclei of Au and NaCl is roughly the same as the number of holes observed from etching. This may mean that the decorants did indeed decorate the defects but also simultaneously obscured their shapes by reaction.

Summary and Discussion

The kinetic oxidation data suggest that the wet grown thin (~150Å) oxides are more protective than ultra dry O_2 grown films. The evidence for this is the greater linearity of the thickness-time data for the dry grown oxides as compared with wet grown films. The linearity suggests a surface reaction controlled mechanism for oxidation rather than diffusive transport of oxidant. In effect, for the case of ultra dry O_2 oxidation, the growing oxide film does not provide an effective barrier to the diffusion of oxidant. A comparison of the dielectric breakdown histograms for the wet and dry ~150Å SiO_2 films strongly supports the contention that the wet grown oxides are more protective. Annealing the wet grown oxides in dry Ar at 1000°C for long times does not cause degradation. Therefore, the enhanced dielectric reliability of the H_2O-grown films is due to a rather stable OH species. The TEM experiments offer significant evidence that SiO_2 films are not homogeneous and the size of the inhomogeneities is probably less than 50Å.

The experimental observations made in this study are consistent with the existence of micropores in the SiO_2 films, even though such small pores were not directly observed. Firstly, the presence of pores in solids is expected (28). The size and type of pore structure that a material displays is dependent on the material. Secondly, the pores would provide a "short circuit" path to the Si-SiO_2 interface for oxidant species which do not attack SiO_2 (such as O_2 related oxidant). Rapid lateral diffusion of these oxidant species would yield linear oxidation kinetics which is typical of surface controlled reactions. In addition, such pores could cause premature dielectric failure. For H_2O grown films the reactive OH attacks SiO_2 forming SiOH species. The micropores could then become partially clogged with OH groups thereby yielding parabolic oxidation kinetics and improved dielectric integrity. Thirdly, micropores are known to bind vapors tenaciously (28) in the interior of the pores thus explaining the irreversibility of the dielectric improvement even to 1000°C inert gas anneals. Further experiments would be necessary to prove the micropore model. Indirect measurements such as adsorption isotherm studies are usually performed to detect the existence and nature of pores (28, 29), particularly micropores. Only a few studies have reported the direct observation of pores smaller than ~100Å and no studies have been found in the literature by this author which show the direct (TEM, SEM), etc.) observation of micropores.

Water Droplet Formation during the Life Testing of IC's in a Humid Ambient

H. Koelmans and H. J. Kretschman
Philips Research Laboratories, Eindhoven, The Netherlands

After temperature-humidity-bias (THB) life tests at 85°C and 85% relative humidity we sometimes found strong local corrosion at the tracks and/or bondpads of IC's, with indications that water droplets had been present at some time during the test. The relative humidity in the test chamber, however, was well enough under control to exclude accidental condensation of water. This failure occurred much earlier (typically within a few hundred hours) than would have been warranted by the corrosive attack as a result of electrolysis in the film of a few monolayers of water that is formed when a hydrophilic surface of, for instance, SiO_2, is exposed to a humid ambient (1). The occurrence of this type of early corrosion appeared to be strongly enhanced in the presence of a source from which ionic impurities could leach out.

These observations led to the assumption that, in the presence of ionic impurities, electrolytic transport in the thin film of adsorbed water may lead to the accumulation of electrolyte at the current-carrying electrodes to a concentration high enough to cause condensation of water droplet. The presence of Na^+ and PO_4^{3-} ions, for instance, would then lead to accumulation of NaOH at the cathode and H_3PO_4 at the anode. Water droplets formed at closely spaced tracks of opposite polarity could then bridge these tracks and induce a current spike, causing local destruction of the tracks.

In order to check this assumption we built miniature moisture chambers in which test samples could be observed under a microscope while continuously monitoring the electrolytic leakage current. The predicted chain of events, *i.e.*, droplets formation-bridging-current spiking and strong local corrosion, was indeed observed. An example is shown in Fig. 1. The sample shown is the Al metallization pattern of a PCCD on top of a silicon chip which had first been provided with 2 μm of thermal oxide and a phosphorsilicate glass film. The SEM photograph of Fig. 2 is another example of current-induced condensation. It shows droplets (or rather what remains of droplets under the vacuum conditions of the SEM) on the bonding wires of a corrosion test sample mounted on a TO_5 header, after a THB test at 85°C, 85% RH in a standard humidity chamber. The droplets appeared only on negative bonding wires and contained NaOH to such a high concentration that they did not even dry out after the sample had been withdrawn from the humidity chamber. The origin of this condensation phenomenon could be traced back in a miniature moisture chamber of the type mentioned. Some time after the application of bias, water appeared on the glass of the header (Fig. 3) and subsequently droplets climbing up cathodic bonding wires were observed. Eventually these (alkaline) droplets reached the chip and caused heavy corrosion at the Au/Al bond (Fig. 4). Examination of the glass showed that its surface had roughened during the test. Apparently the current-induced condensation in this sample is connected with a slow leaching of Na^+ ions from the glass of the header. When the headers are carefully cleaned in boiling fuming nitric acid, and then made hydrophobic wih silanes, forced condensation of water on the glass can be avoided. The mechanism responsible for the transport of electrolyte along the bonding wire remains unclear—the effect has some

resemblance to the rise of liquids around electrodes known as the Sumoto effect (2).

Chips with the interdigital electrode pattern shown in Fig. 1 were also encapsulated in plastic and subsequently put on THB test while again monitoring the leakage current. These test samples (used without glass-over) were very suitable for this purpose because w/d, the total gap length over the gap width, was very large ($\sim$ 5000). A typical result is given in Fig. 5, for a sample on thermal SiO_2, with standard encapsulation in an epoxy DIL package.

The evolution of leakage current as a function of time can be divided into three periods. The first period is characterized by an increase in leakage current to a steady-state level (period 2). This behavior reflects the gradual penetration of moisture into the DIL package. The latter was confirmed in separate experiments on moisture absorption; the times needed for moisture saturation were found to be approximately equal to the times required for saturation of the leakage current. During the third period, violent increases in current occur. The time at which these current peaks appear and their height depend on the experimental conditions. When the steady-state current is high as a result of, for instance, a strong bias and/or the use of an impure plastic, current peaking tended to be earlier and

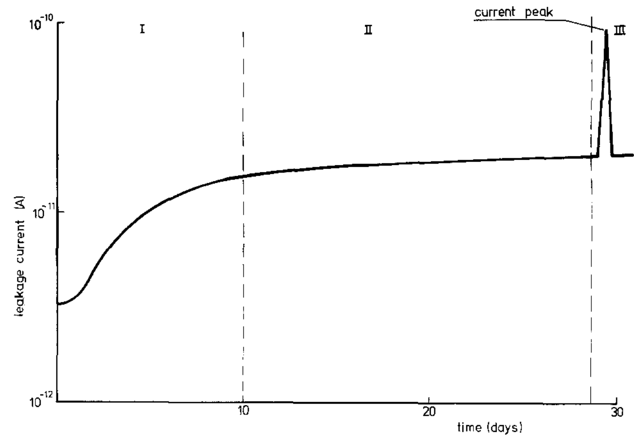

Fig. 5. The electrolytic leakage current of a test sample in epoxy as a function of time. The sample is a finely interdigitated Al electrode pattern deposited on 2 μm of thermal SiO_2. Bias 5V; temperature 85°C; relative humidity 85%. The current peaks have been simplified; their actual shape is much more complicated. The graph shows the maximum current observed and the time of duration (width at base) of the increase in current.

more violent. Under unfavorable conditions the current at maximum peak value could be 10^4 times higher than the steady-state level (period 2). Inspection of the samples after removal of the plastic in fuming HNO_3 revealed strong local corrosion when current peaks had occurred during the test. On the other hand, samples opened during period 2 hardly showed any (visible) corrosion. The behavior of the encapsulated samples with respect to current peaks coupled with strong local corrosion is very similar to that observed on bare samples. This suggests that in samples packaged in plastic too, current peaks and the accompanying local destruction of metal tracks are due to the phenomenon of forced condensation of moisture observed on bare samples. In the case of samples in plastic this could lead to the formation of voids filled with electrolyte at the interface between the plastic and the chip. In this respect it is interesting to note that void formation connected with strong local corrosion is a well-known phenomenon observed on painted steel in contact with saline water. Here the corrosion proceeds without an external bias, but still the process is electrochemical in nature, with parts of the metal surface acting as cathode and other parts acting as anode. It is also interesting to note that, similar to what we observed on IC's, the electrolyte in "cathodic" voids on steel was found to be alkaline (3).

Anodic Electrodeposition of Gold from Liquid Ammonia Solutions

Towfik H. Teherani,* William J. Peer, J. J. Lagowski, and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

The electroplating of metal and alloys, which is of importance in numerous applications, has always been accomplished by cathodic deposition (1-3). For example the industrially important process of gold electroplating is usually carried out by reduction of the gold(I) species from slightly acidic cyanide media. We report here the first example of anodic electrodeposition of gold by oxidation of auride ion (Au^-) in a liquid ammonia solution.

Recent results have demonstrated the formation of Au^- by reaction of gold metal with coulometrically generated solvated electrons (e_s^-) in liquid NH_3 containing 0.1 M KI at -40°C (4) or by reaction of Au with Cs metal in liquid NH_3 (5). The experimental procedures and apparatus for liquid NH_3 studies have been reported previously (6,7). A typical experiment involved the introduction of Au metal in liquid NH_3 containing excess e_s^- in a large coulometric cell. When the solution was kept at -40°C and stirred, the Au dissolved with the formation of Au^-. Alternately, the Au^- could be produced by starting with a solution of AuI in liquid NH_3. A typical cyclic voltammogram of such a solution at a Pt-electrode is shown in Fig. 1. Controlled potential electrolysis at -0.5 V resulted in the deposition of Au on the Pt working electrode. When the electrode potential was moved to the generation of e_s^- (-2.5 V), the freshly deposited gold was cathodically stripped. The cyclic voltammogram of the resulting solution after excess e_s^- was removed coulometrically, indicated the presence of an anodic wave at -2.15_0V corresponding to the oxidation of Au^- to Au^0. The electrolytic oxidation in the solution (at -2.0 V) resulted in deposition of Au on the Pt anode surface. The gold plate produced in this way was bright and could be polished to a high luster. Examination of the surface by ESCA spectroscopy showed strong bands at binding energies of 82, 85, 332, 350, and 545 eV, characteristic of metallic gold.

While it is difficult to project from these preliminary experiments whether this method of electrodeposition will be of practical use, this procedure does avoid the use of cyanide. Moreover, the oxidation of Au^- occurs with 100% current efficiency without the coevolution of hydrogen which occurs during the cathodic deposition in aqueous media. Finally liquid ammonia provides the unique opportunity to examine the course and nature of deposition of a metal both cathodically and anodically in the same medium.

The Corrosion of Carbon Black in Phosphoric Acid

Gary A. Gruver*

United Technologies Corporation, Power Systems Division, South Windsor, Connecticut 06074

Carbon as a material is thermodynamically unstable at phosphoric acid fuel cell cathode operating conditions. However, the kinetics of carbon corrosion are sufficiently slow so that carbon can realistically be considered for various materials applications at fuel cell operating conditions. One common use for carbon blacks in fuel cells is as a support for the (usually) noble metal catalyst required for oxygen reduction at the cathode and hydrogen oxidation at the anode. The electrochemical corrosion of various carbon blacks has been studied by several workers (1-4). Kinoshita and Bett (2) studied the corrosion of a high surface area carbon black in 96% H_3PO_4 at 135°C at several potentials and determined that two processes occurred: the formation of surface oxides and evolution of CO_2. They found that over several thousand minutes the rate of carbon corrosion decreased and that CO_2 evolution eventually became the major reaction. They speculated that while the mechanism for these processes was complex, corrosion might be controlled by mass transport of reactive species through the bulk carbon particle structure, with oxidation occurring at disorganized amorphous carbon sites inside the particle, much in the same way that Heckman and Harling (5) have observed for the gas phase oxidation of carbon blacks.

Experiments done in this laboratory indicate that the corrosion of carbon blacks in a phosphoric acid fuel cell environment does proceed in the same manner as noted by Heckman et al. for the gas phase oxidation of carbon blacks. Subscale fuel cell tests using Teflon-bonded electrodes have been performed at conditions expected to accelerate the corrosion of carbon blacks. The catalyst used in these tests was highly dispersed platinum supported on Vulcan XC-72 (Cabot Corp.). Figure 1 is a transmission electron micrograph showing the appearance of the carbon black in the catalyst before testing. Figure 2 is a transmission electron micrograph representative of the cathode catalyst after operating for 1000 hours at 191°C. The cathode was operated at an iR-free potential of 835 mV (vs a hydrogen electrode in the same electrolyte) on oxygen prehumidified with water to maintain a constant average H_3PO_4 concentration of approximately 95%. The carbon particles shown in Figure 2 do not exhibit the same uniform density throughout that appears in the untested samples in Figure 1. Detailed examination of these and other micrographs taken at higher magnifications reveals that the outer more crystalline "shell" of the carbon particles remains intact while the central portion (which is more disordered, having only short range crystallinity) has been oxidized away. These findings are in complete agreement with Heckman's observations and his "concentric crystallite model" for carbon blacks (5), and qualitatively could explain the apparently film diffusion-controlled corrosion processes noted by Kinoshita (2). Porosity in the turbostratic outer layers of the carbon particles allows access of reactive species (presumed to be H_2O) to the easily oxidizable inner portion of the particle.

As expected, no carbon corrosion was noted in the catalyst on the fuel cell anode used in this test.

Low Melting-Point Compositions in Alkali Metal Metaphosphate/Fluoride Systems Applications

D. Elwell*

Center for Materials Research, Stanford University, Stanford, California 94305

Molten salt compositions of low melting point are often of interest for applications in electrochemistry or as solvents for metal oxides. This investigation was performed in order to find a phosphate-based solvent for the electrodeposition of indium phosphide at temperatures at or below 600°C.

The system Na, K/PO_3, F was investigated by Bukhalova and Mardirošova (1) and the lowest melting-point for any composition in that system was found to be 424°C. Solvents containing Li^+ are expected to have a lower viscosity because of the relatively small mass of these ions, and are therefore preferable for electrocrystallization experiments provided that the liquidus temperatures are similar to or below those of the Na, K system.

In order to accelerate the task of finding compositions of lowest melting point in the Li, Na/PO_3F and Li, K/PO_3, F systems, melts containing equal molar concentrations of the four constituents in each case were unidirectionally solidified by slow horizontal traverse of a 15 cm long crucible through a furnace. The fraction which solidified last was analyzed and a melt of the composition so determined was subjected to a further unidirectional solidification to test the accuracy of the first analysis. Atomic absorption spectrographic analysis for the alkali melts was found to be reliable to within 1% but electron microprobe analysis for F, P and O did not give reliable data, although intensities were compared with standard materials.

The Li:K ratio in the lowest-melting sample in that system was found to be 1·16(5):1 and the Li:Na ratio for the corresponding composition was 0·98(4):1. A section through the quaternary phase diagram was therefore taken with these metal ratios held constant but with the F:PO_3 ratio varied. The results are shown in Fig. 1, together with liquidus data for the corresponding section in the Na, K/PO_3, F system for comparison.

*Electrochemical Society Active Member.

Liquidus temperatures were determined by a visual polythermal method, with the samples contained in vitreous carbon crucibles in argon at atmospheric pressure. The chemicals were of reagent grade and were subjected to a preliminary dehydration at 300°C in vacuo for several hours.

Since the lower melting point materials formed glasses on solidification, it was difficult to obtain precise measurements and the ultimate test of the state of the material was the observed response of the surface to a force applied via a graphite rod of spectrographic purity. Cycling the sample through the melting temperature was used in attempts to obtain an accurate determination.

Even with this precaution, the data are reliable only to ±10°C. Supercooling was not large compared with this estimated error except in the case of the fluoride-free composition in the Na, K/PO_3, F system, for which a supercooling of 140°C was observed. A separate calibration experiment was performed and temperatures quoted are taken from the mean of two chromel/alumel thermocouples with junctions located in the region previously occupied by the crucibles containing the samples.

The Li, Na/PO_3, F system is seen to give the lowest melting temperatures, the minimum occurring at about 300°C for a composition with 20 m/o fluoride. Both the Li, Na and Li, K systems do not indicate a sharply-defined minimum but the Na,K system (1) appears to exhibit eutectic-like behavior, although the data plotted in Fig. 1 is based on intersections with rather widely-spaced isotherms.

The value of 300°C for the lowest-melting composition compares very favorably with alternative systems. The lowest melting point occurs at 580°C in the system Li, Na/P_2O_7, F (2) and at 612°C in the system Na,K/P_2O_7, F(2). However, if greater complexity can be tolerated, it should be noted that the system Li, K/PO_3, PO_4 has a minimum melting point at

340°C (3) and fluoride addition may result in compositions which melt below 300°C.

Oxygen Determination in SIPOS Using a Differential Thickness Measurement

A. E. Widmer and M. L. Hitchman
Laboratories RCA Limited, Zurich, Switzerland

INTRODUCTION

Semi-insulating polysilicon (SIPOS) is a thermally deposited Si film containing oxygen (SiO_x) which is used as a passivation layer for silicon devices. In order to be able to assess the electrical quality of such films it is important to be able to have a means of characterization. This can be done directly by making resistivity measurements, but it would seem desirable to have a complementary method. One possibility would be to measure the oxygen content since the electrical properties depend on this parameter (1). Normally determination of oxygen in SIPOS is done with sophisticated techniques such as electron microprobe analysis or atomic absorption. We have developed a simple, indirect method for determining the oxygen content which only requires a thermal oxidation furnace and a surface profile monitor. This method is similar to that first described by Pliskin et al. (2).

EXPERIMENTAL

Two inch diameter ($1\bar{1}02$) Czochralski-sapphire substrates polished on one side were used as test wafers. They were placed at specific positions within a stack of silicon wafers in a low pressure CVD reactor. SIPOS was deposited from a N_2O-SiH_4 mixture with the ratio of the gas flow rates (γ) being varied from 0 to 0.8. The deposition conditions were: 650°C, 100-150 mTorr, and SiH_4 flow rates between 25 and 50 $cm^3 min^{-1}$. Layers with thicknesses in the range of 0.3 to 1.8 μm were grown with most of the measurements being made on layers 0.5 μm thick.

Key words: SIPOS, oxygen determination.

After deposition a small window of about 4x4 mm was defined on each wafer with Apiezon wax. A step was etched with 1 HF : 20 HNO_3 (by volume). The layers on the rear side of the wafers were etched off completely to allow better visual control during the subsequent processing steps. The etch rate for SIPOS prepared with γ = 0.2 is about 3 μm/min. Sapphire is not attacked by the etchant. Thickness measurements were made with a surface profile monitor (Sloan, Dektak). Then the SIPOS layers were converted to SiO_2 in wet oxygen at 1100° to 1200°C. A conservative estimate of the time required for complete conversion was obtained from the time needed to oxidize a layer of silicon of the same thickness as the SIPOS layer (3). For example, for a layer 0.5 μm thick we oxidized for 150 minutes at 1200°C. The thickness of the fully oxidized SIPOS layers was measured on the previously etched steps from which the fractional increase in thickness was calculated.

RESULTS AND DISCUSSION

Fig. 1 shows a plot of fractional increase in thickness on full oxidation as a function of γ. Except at $\gamma \leq 0.05$ the reproducibility is good. The reason for the scatter at low γ is not known, although it may be associated with the transition from polycrystalline silicon at γ = 0 to amorphous material at higher values of γ. For our reactor the shape of the curve is not dependent on the SiH_4 flow input for flow rates in the range 25-50 $cm^3 min^{-1}$. Fig. 1 thus provides a simple means for process control. For example, we have had points lying below the curve corresponding to a higher γ than that expected for the gas inputs used (e.g. point X in Fig. 1). On checking the calibration of the SiH_4 mass flow controller we found it to be inaccurate due to a partial blocking as a result of

decomposition of SiH_4 to SiO_2 particles by trace amounts of oxygen. This blocking reduced the SiH_4 flow rate with the result that γ was higher than that set on the controls. The measurement of the fractional thickness increase has faithfully reflected this change in γ.

The density, ρ_x, of a SiO_x film can be written as

$$\rho_x = \frac{N(A_S + x A_O)}{F d_x} \quad [1]$$

where N is the number of SiO_x "molecules" in a layer of thickness d_x and area F and A_S and A_O are the atomic weights of Si and O respectively. The density, ρ_2, of a SiO_2 layer formed by total oxidation of SiO_x can be written similarly:

$$\rho_2 = \frac{N(A_S + 2 A_O)}{F d_2} \quad [2]$$

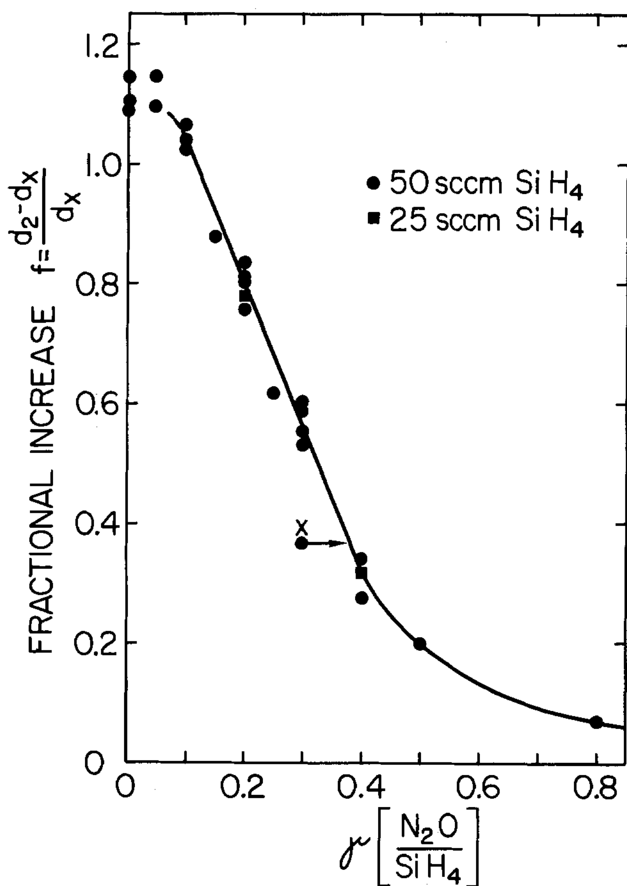

Fig. 1. Fractional thickness increase as a function of γ.

where d_2 is the oxidized layer thickness. A priori one cannot say how the density of SiO_x will vary as x changes from 0 to 2, but a linear relationship of the form

$$\rho_x = \rho_0 - \frac{x}{2}(\rho_0 - \rho_2) \quad [3]$$

where ρ_0 is the density of Si, would not seem unreasonable. However, if one takes typical values for the densities of Si and SiO_2 - approximately 2.33 and 2.2 (3), respectively - then the term $x/2\ (\rho_0 - \rho_2)$ is small compared with ρ_0 for all x in the range 0 - 2 and this suggests that one could approximate $\rho_x = \rho_2$. Making this assumption and solving eqn. [1] and [2] for the atomic fraction of oxygen gives

$$\frac{x}{1 + x} = \frac{8 - 7f}{12 - 3f} \quad [4]$$

where $f = (d_2 - d_x)/d_x$ and is the fractional thickness increase on oxidation. Fig. 2 is a plot of oxygen atomic percent, determined from the points on Fig. 1 and eqn. [4], against γ. Also plotted are values of atomic percent determined by electron microprobe analysis on some of the samples prepared in our reactor (designated reactor 1), and on samples prepared by LPCVD in a commercial reactor (designated reactor 2) at an RCA production facility. The good agreement between the determination of oxygen by the differential thickness measurement and electron probe microanalysis suggests that the assumption of $\rho_x = \rho_2$ is a reasonable one. The shape of the curves in Fig. 1 and 2 can be explained using a simple model for the growth kinetics of SIPOS (4).

CONCLUSIONS

The measurement of the thickness increase on oxidation of SIPOS to SiO_2 has been shown to be a simple method for oxygen determination and hence characterization of SIPOS. The technique requires only apparatus that is normally found in a semiconductor factory - a thermal oxidation furnace and a surface profile monitor. If the measurements are made on SIPOS grown on sapphire the oxidation needs no special control since it is self-limiting; also sharp steps can be readily etched and the sapphire test wafers can be reused. In general the results show good reproducibility and are not affected by variations in film thickness and

therefore nonuniformities. In the particular range of interest of $0.1 \leqslant \gamma \leqslant 0.4$ the variation of the fractional thickness increase with γ is linear and shows the maximum sensitivity.

Recovery of Shallow Junction GaAs Solar Cells Damaged by Electron Irradiation

Gilbert H. Walker* **and Edmund J. Conway**

National Aeronautics and Space Administration, Langley Research Center, Hampton, Virginia 23665

Solar cells operated in space are subject to degradation from the electron and proton radiation damage; however, it has been shown previously that for deep junction (4 μm p-GaAs layer) p-GaAlAs/p-GaAs/n-GaAs solar cells some of the electron radiation damage is removed by annealing the cells at 200°C (1). It is the purpose of this communication to show that shallow junction (0.8 μm p-GaAs layer) p-GaAlAs/p-GaAs/n-GaAs heteroface solar cells irradiated with 1 MeV electrons show a more complete recovery of short-circuit current than do the deep junction cells.

Heteroface pGaAlAs/pGaAs/n-GaAs solar cells were fabricated using the etch-back epitaxy process (2). The n-type substrates were Si doped with a carrier concentration of 1 to 2 x 10^{17} carriers/cm^3. The p-GaAlAs and the p-GaAs were Zn doped to a carrier concentration of 8 x 10^{18} carriers/cm^3. Large area back electrical contacts were Sn-Ag while the front finger contacts were Pd-Ag. The cells had no antireflection coatings nor cover glasses. The current-voltage characteristics of the illuminated cells were measured using an air mass zero solar simulator which was calibrated with a Si cell that had been standardized on a balloon flight. The spectral response of the cells was measured using an intensity calibrated spectrophotometer. Cells were irradiated in vacuum with 1-MeV electrons at fluences of 1 to 3 x 10^{14} electrons/cm^2, 1 x 10^{15} electrons/cm^2, and 1 x 10^{16} electrons/cm^2. The flux during irradiation was chosen so that the cells remained at ambient temperature. A fluence of 10^{16} 1 MeV electron/cm^2 is equivalent to the electron exposure which a solar cell with a 50 μm cover glass would encounter during 30 years in geosynchronous orbit. The current-voltage characteristics and the spectral response were again measured. The cells were annealed at 200°C in vacuum of 10^{-5} torr for 10-hour periods and their characteristics again measured after each period of annealing.

Key Words: Solar Cells, Radiation Damage, Annealing, Gallium Arsenide

Figure 1 shows the relative short-circuit current as a function of 1 MeV electron fluence for various annealing times. After 1 x 10^{16} electrons/cm^2 the ratio of the final short-circuit current to the initial short-circuit current (I_{SC}/I_{SC_0}) is reduced to 0.33. Annealing at 200°C for 10 hours restored the short-circuit current ratio to 0.77; after 20 hours of annealing the ratio rose to 0.82, and after 30 hours the ratio had stabilized at 0.83. Thirty-hour 200°C annealing of the cells irradiated at 10^{14} and 10^{15} 1 MeV electrons/cm^2 restored the short-circuit current to slightly greater than its original value. This increase in short-circuit current to greater than its original value after annealing (which has been seen before (1)) could be explained in terms of contact annealing or improvement in the minority carrier diffusion length.

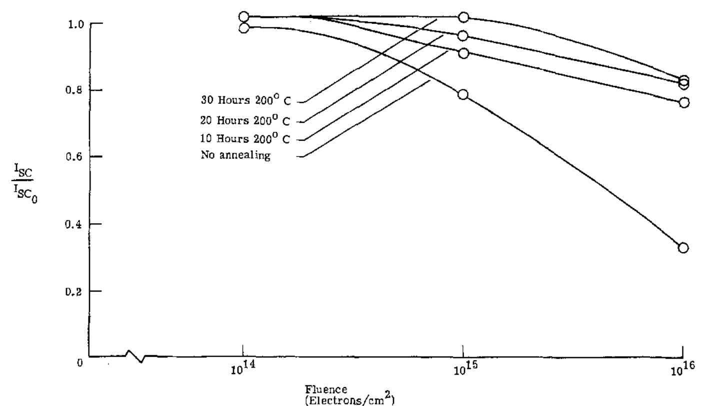

Figure 1.- Ratio of final short-circuit current to initial short-circuit current as a function of 1 MeV electron fluence for various annealing times at 200°C.

Figure 2 shows the current-voltage characteristics of a cell before irradiation and after irradiation with 1 x 10^{16} 1 MeV electrons/cm^2 at three annealing stages. The unirradiated cell, without AR coating, had a maximum power density of 15.1 mW/cm^2. Irradiation reduced the maximum power density to 29 percent of its original value; however, annealing for 10 hours at 200°C restored the maximum power density to 74 percent and after 30 hours the maximum power density stabilized at 81 percent of the original. The open circuit voltage increased from 0.82 volts before annealing to 0.875 volts after 30 hours at 200°C. The fill factor of the irradiated cell changed little with annealing.

1 MeV electron irradiation of deep junction (4 μm) GaAℓAs/GaAs solar cells produced severe degradation of the spectral response especially in the blue region of the spectrum. For the 0.8 μm cells, the spectral response after irradiation changed uniformly over the entire spectral region. Annealing for 30 hours at 200°C produced uniform recovery of the spectral response.

The improvement of the solar cell output with annealing can be correlated with an improvement of the minority carrier diffusion length over the damaged values. We believe the explanation for the improved annealing of these 0.8 μm cells as compared to the 4 μm cells (1) is due to junction location. For small junction depths, the junction effectively competes with surface and bulk recombination for minority carriers.

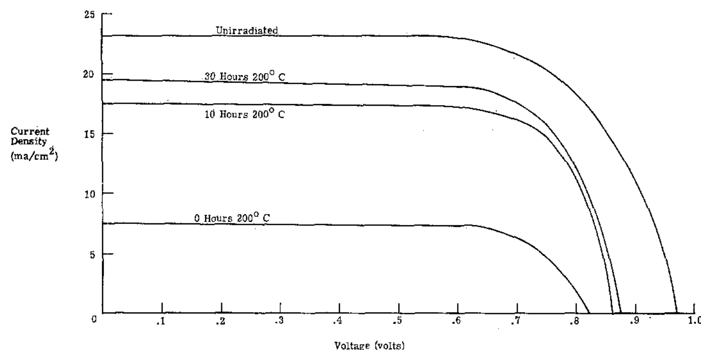

Figure 2.- Current density-voltage curves of a cell unirradiated and irradiated at 10^{16} electrons/cm^2 for various annealing times.

The recovery due to annealing of the 1 MeV electron-damaged 0.8 μm GaAℓAs/GaAs solar cells is large. Annealing can extend the useful life (defined here as more than 75 percent of maximum power) to fluences greater than 10^{16} electrons/cm^2 at 1 MeV or 30 years equivalent in geosynchronous orbit. Short periods of annealing can limit the degradation after 3 years equivalent in orbit to much smaller values. Assuming that the same type of annealing recovery occurs for cells irradiated with electrons of different energies and for cells irradiated with protons, it may be possible to periodically anneal GaAℓAs/GaAs solar cells while in space, thus significantly prolonging the life of the cells. Also, GaAℓAs/GaAs solar cells operated at high temperatures (200°C) may continually anneal radiation damage and never be degraded to any great extent.

Breakdown of the Passive State and Repassivation of Stainless Steels

I. L. Rosenfeld, I. S. Danilov, and R. N. Oranskaya

The Institute of Physical Chemistry, The USSR Academy of Sciences, Moscow, USSR

ABSTRACT

The mechanism of anodic dissolution and self-dissolution of stainless steels during local corrosion processes is discussed. The dissolution mechanism can be established only by determining actual velocities of metal dissolution at point anodes and their dependence on potential. In stably operating pits the actual rate of metal dissolution is potential independent. A similar relationship was found under uniform dissolution of steel in concentrated chloride solutions of low pH for the ability of steel to transform from the active to the passive state. Such an electrode dissolves at a rate similar to dissolution rates observed in the pits (50-60 mA/cm^2), and the rate is governed by diffusion kinetics. On the strength of the results, it is assumed that dissolution of steel in pits takes place by the mechanism of "salt passivity," the rate of which is controlled by the diffusion of anode reaction products through the salt film. The repassivation mechanism of steels in pits is also considered. Pits functioning in the kinetic regime repassivate easily, whereas for those operating in the diffusion regime an external effect on the system is necessary. Contrary to the point of view of some researchers an opinion is expressed that the repassivation potential does not correspond to the metal potential at the pit bottom. The repassivation potential is a variable value and, therefore, it cannot serve as a parameter characterizing the ability of steel to undergo pitting corrosion. Certain regularities of stainless steel dissolution and the causes for breakdown of the passive state are considered. Even small shifts in potential in the positive direction from the stationary one (ϕ_{cor}) can bring about activation in crevices and gaps. The corrosion resistance of stainless steels in crevices is determined essentially by their ability to resist activation in acidic chloride solutions.

The local breakdown of the passive state of stainless steels has attracted the attention of numerous researchers (1-21). Nonetheless the mechanism of the process is still obscure. In our opinion, there are questions, *e.g.*, the nature of the anodic process in point anodes, the repassivation mechanism and the nature of the repassivation potential, the mechanism of stable operation of a two-electrode system (pit-passive surface) unstable from the electrochemical point of view, the existence of the crevice corrosion potential (like that of pitting formation), etc., which are yet to be studied.

However, prior to examining these questions, we would like to draw attention to the reliability of the experimental results obtained from electrochemical kinetic studies of local corrosion processes, as well as to the conclusions drawn from them. We feel that the results of polarization measurements frequently published in the literature do not convey quantitative information on the electrochemical kinetics, because they do not reflect the true anodic dissolution rates of metal in point anodes. Moreover, false conclusions may be drawn, if the local dissolution mechanism is not taken into account. Let us illustrate this by an example. Figure 1 shows four anodic polarization curves plotted by the galvanostatic and the potentiostatic methods for Cr18Ni10Ti[1] stainless steel subjected to pitting corrosion. Curves 1 and 3 have been plotted with respect to the geometrical surface area of an electrode (just such curves are mainly published); while curves 2 and 4 have been plotted with respect to the true area[2] on which an anodic reaction occurred. It is seen that the two sets of curves have nothing in common: The true dissolution rate is potential independent, while the curves plotted without taking into account the true area of the anode indicate the presence of a quite different potential dependence of the anodic current.

From this, various conclusions may be drawn about the mechanism of the process; curves 1 and 3 suggest that the point anodes (pits) operate in the kinetic regime and the metal in them dissolves in the active part of the polarization curve, and curves 2 and 4 indicate that dissolution takes place in the passive state regime which differs from the general regime. The only difference is that the dissolution rates far exceed those noticed during normal passivation by an oxide film.

Key words: corrosion, diffusion, electron transfer kinetics, salt films.

[1] According to the USSR Standard the number after the letter indicates the average percentage of the alloying element. Thus, this steel contains 18% Cr, 10% Ni. Its total composition (weight percent) is: C $\leq$ 0.12; Si $\leq$ 0.8; Mn $\leq$ 2.0; Cr = 17-19.0; Ni = 9.0-11.0; Ti = 0.6-0.7; S $\leq$ 0.020; P $\leq$ 0.035; Fe = balance.

[2] The pits have a hemispheric shape with $\phi/h \simeq 2$ and, therefore, after determining their number and the diameter of each pit using a microscope, their surface can be calculated with sufficient accuracy. For details see Ref. (4).

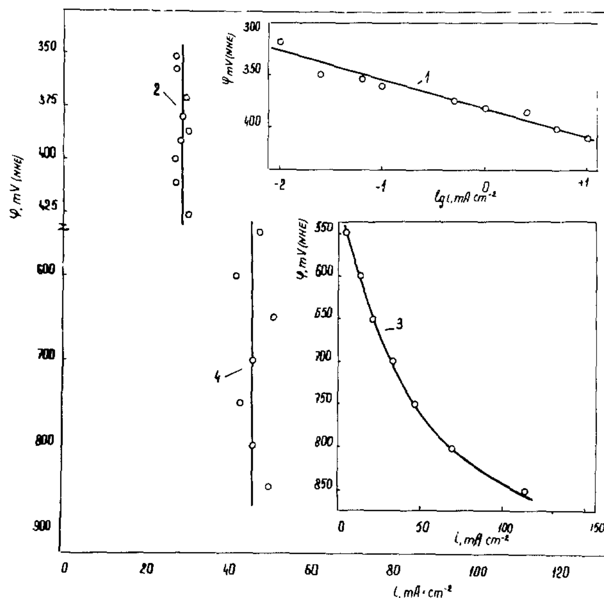

Fig. 1. Anodic polarization curves obtained for Cr18Ni10Ti stainless steel which underwent pitting corrosion in 0.1*N* NaCl. Curves 1 and 2 were obtained by the galvanostatic method; curves 3 and 4 by the potentiostatic method. Curves 2 and 4 are true polarization curves; curves 1 and 3 are imaginary plots. Polarization time was 60 min.

Dissolution rates, similar to the ones observed in pits (40-50 mA/cm^2) and the ability of steel to transform simultaneously into the passive state, are observed in concentrated acid chloride solutions with the anodic dissolution being uniform (Fig. 2a).

To understand the mechanism of steel dissolution in the passive region of potentials, we studied the anodic dissolution on the rotating disk electrode. We found that the current density in this portion of the polarization curve increases strongly as the electrolyte is agitated and that it varies according to the diffusion kinetics laws (Fig. 2b).

Taking into consideration that the studied electrolytes are similar in composition to those accumulated inside the pits and that in the considered cases one and the same relationship is observed, we can confirm that the dissolution of metal in the stably operating real pits proceeds in the diffusion regime (the same conclusion has also been drawn by authors of Ref. (7) in their studies of artificial pit model), and the steady-state (passivation) currents are determined by the properties of the electrolyte in the neighborhood of electrode surface and not by the properties of the metal surface, as suggested in Ref. (22).

Evidently, if the dissolution rate were to be determined by the properties of passivating oxide film on the electrode surface, then it could hardly be expected that the current will vary during agitation, which may increase the dissolution of the film, according to the diffusion kinetics laws.

We assume that the metal dissolution rate in a pit is controlled by the properties of the viscous salt film at the pit bottom, and, therefore, the nondependence of the dissolution current on potential can be regarded as specific "salt passsivity" when the passivating layer is in the liquid rather than in the solid phase.

In view of these facts, it is clear why pits can be easily repassivated with an insignificant potential shift in the negative direction. The true polarization curve for stainless steel, whose surface exhibits a steadily operating pit, is described by the curve ABCD (Fig. 3, plot 1). The potential across the pit bottom is close to point C; therefore, even a small potential shift in the negative direction (to C′) is sufficient to convert the steel into passive state.

These results may also explain the relationship between the repassivation potential and the time during which the pit is active and on the steel composition. The mechanism of the steady operation of the pit-passive surface system can also be explained.

As we have shown earlier (23-26), the overwhelming number of pits repassivate spontaneously fairly quickly, so that the principle "all or nothing," formulated by Frank (27, 28), is satisfied. As shown by the experimental data, the originally formed pits function in the kinetic regime (see Fig. 3, plot 2): Therefore, they are capable of spontaneous repassivation. Only those pits, which begin to operate in the diffusion regime, are able to function steadily, and some external action is needed to repassivate them.

However, as should be expected, repassivating such pits requires shifting the potential in the negative direction by an amount depending on their functioning time and, hence, on acidification of the medium and the accumulation of chloride ions inside the pits. This is obvious from the anodic potentiostatic curve which shows the anodic current *vs.* the electrode potential shift in the negative direction (Fig. 4). When the potential of an open surface is maintained at +0.55V, the corrosion current in a pit varies with time according to curve OABC. When the electrode potential is shifted

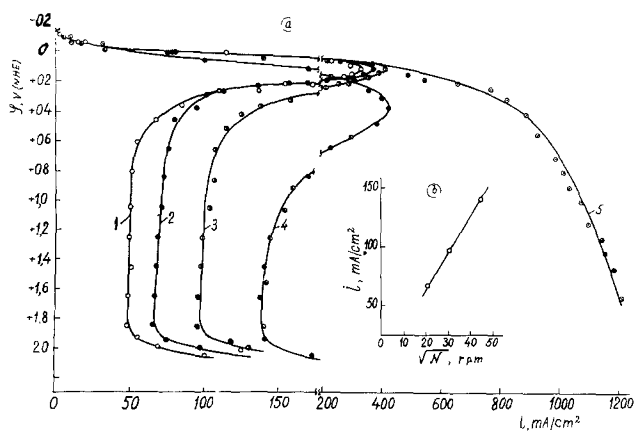

Fig. 2. Anodic polarization curves obtained with a rotating electrode of Cr18Ni10Ti stainless steel in 5*N* HCl. Curve 1 obtained without rotation; curve 2, with the electrode rotating at 421 rpm; curve 3, at 960 rpm; curve 4, at 1950 rpm; and curve 5, at 3825 rpm.

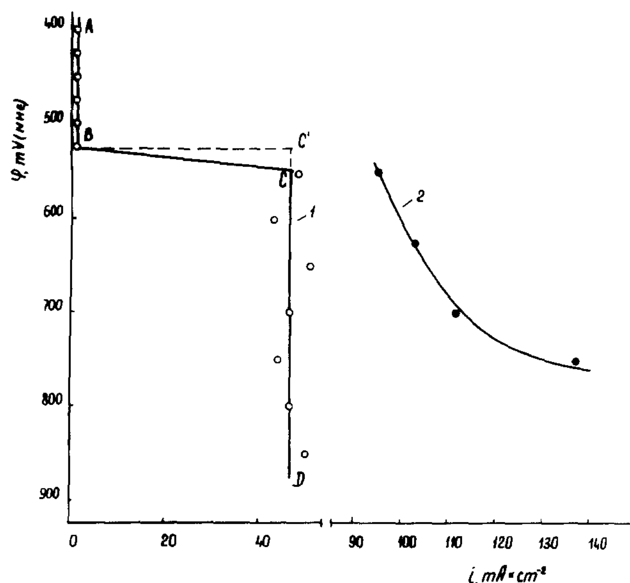

Fig. 3. True anodic polarization curves for pits operating in diffusion (curve 1) and kinetic regime (curve 2): 1, pits function steadily; 2, pits are capable of repassivating spontaneously.

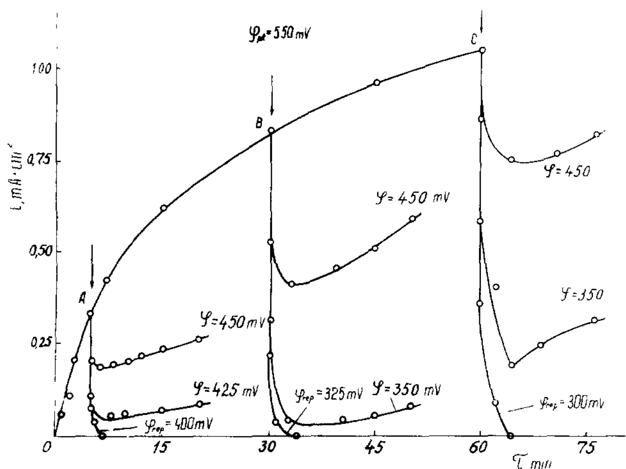

Fig. 4. Repassivation of Cr18Ni10Ti stainless steel that was pitted potentiostatically in 0.1*N* NaCl. The arrow indicates the moment of a gradual potential shift in the negative direction from the pitting-formation potential ($\phi_{pit} = +550$ mV). OABC illustrates time variation of the corrosion current; A, ϕ_{rep}; B, ϕ_{rep}; C, ϕ_{rep} indicate changes in the corrosion current with time when the potential is shifted in the negative direction.

in the negative direction (indicated by an arrow), the current first drops and thereafter begins to increase again. However, only on reaching a certain potential, which depends on the functioning time of point anodes (of pits), the system is passivated completely, and no electric current is generated by the system. It is this potential which is usually called the repassivation potential. As it appears, the longer the pit functioning time, the more negative the potential will have to be for the pit to cease functioning.

The pits also repassivate easily when they are formed under self-dissolution conditions, such as when the pitting potential is obtained by the oxidizing component of the solution. In the case of corrosion of Cr18Ni10Ti grade stainless steel in $FeNH_4(SO_4)_2 \cdot 12 H_2O + NH_4Cl$ solution, pits are formed at the steel surface fairly quickly ($\phi = +0.55$V). The potential of the steel decreases with time until it reaches a steady-state level of +0.3V; the total current of the pit-passive surface system increases to 0.36 mA/cm^2. Yet it was sufficient to shift the potential of the steel by only 25 mV in the negative direction (Fig. 5) to repassivate the surface of the pits. This may occur only in the case in which the potential of the pit-passive surface system is close to the potential at the pit bottom and when the pit operates under diffusion conditions.

We obtained direct indications that the dissolution rate of metal in a pit is determined by the composition of the electrolyte in the pit, not by the composition in the bulk of the solution. These indications were obtained in a study on the dependence of the pitting-formation potential and of the repassivation potential on the pH and the concentration of sodium chloride (Fig. 6). As is evident, the pitting-formation potential depends strongly on these factors, but the repassivation potential depends only slightly on the pH of the electrolyte and on the concentration of sodium chloride.

The pits repassivated easily also under galvanostatic polarization, which may be judged from the charging curves (Fig. 7). The pits operated steadily for 1 hr, a time period quite sufficient for the electrolyte to become highly concentrated in chloride and hydrogen ions. None-the-less, it was sufficient to reduce the anodic current density enough for the pits to repassivate. It can be seen from Fig. 7 (point E) that the repassivation time depends on the initial current density: the higher the current density, the longer the repassivation process (*i.e.*, the medium in the pit has changed to a larger extent).

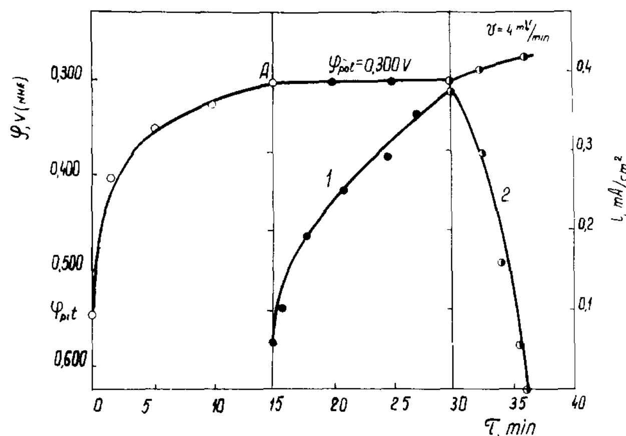

Fig. 5. Repassivation of Cr18Ni10Ti stainless steel that was pitted under self-dissolution [20 g/l $FeNH_4(SO_4)_2 \cdot 12 H_2O$ + 30 g/l NH_4Cl]: ϕ_{pit} A, indicates a change in the electrode potential with time, 1, change in the corrosion current with time at a constant potential (+0.3V); 2, a change in the corrosion current with time, as the potential is shifted in the negative direction (4 mV/min).

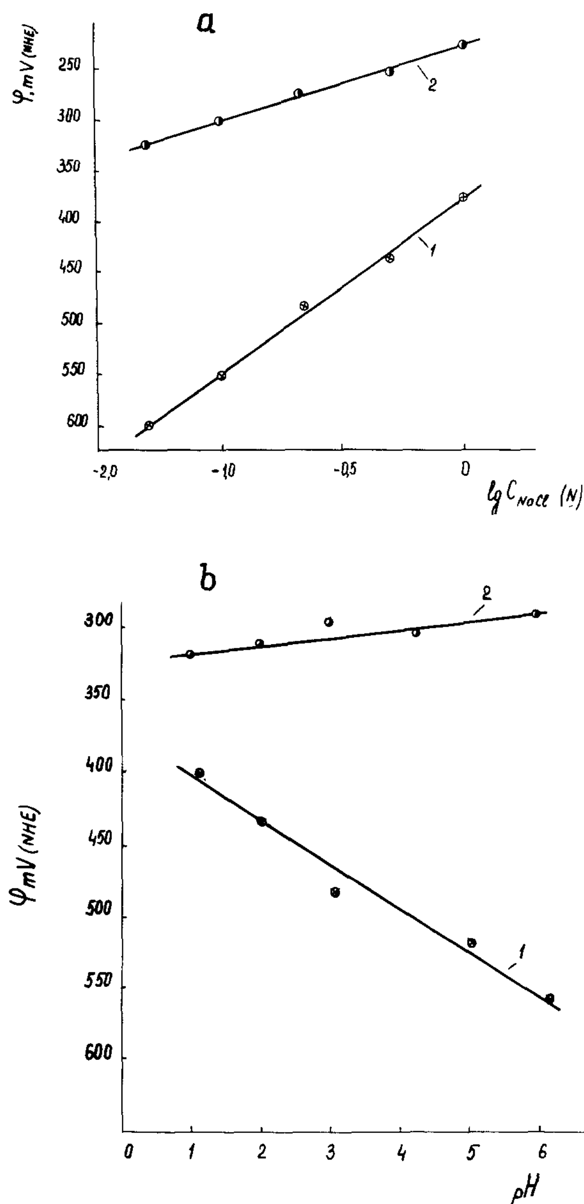

Fig. 6. Pitting-formation potential (curve 1) and repassivation potential (curve 2) vs. concentration of chloride ions (a) and pH value of electrolyte (b) for Cr18Ni10Ti stainless steel.

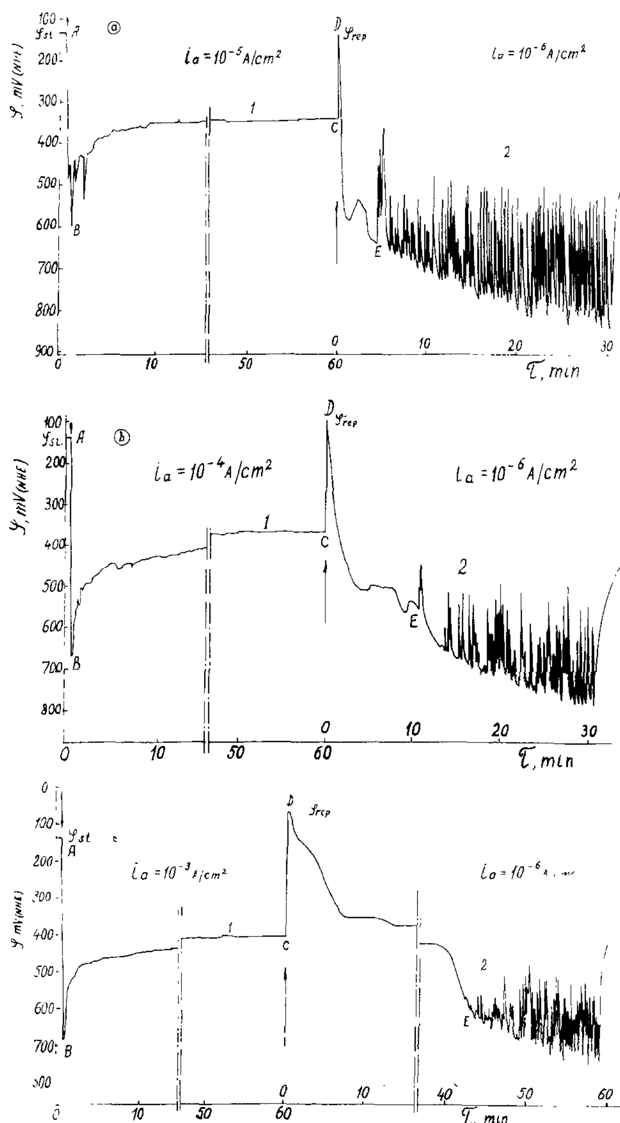

Fig. 7. Repassivation of stainless steel Cr18Ni10Ti subjected to pitting corrosion in 0.1*N* NaCl during galvanostatic polarization: point A, introduction of polarization current due to corrosion potential in the absence of pits; B, pitting-formation potential; BC, potential variation of the pit-passive surface system under conditions of stably operating pits; CD, potential shift when the polarization current is changed from its initial value up to 10^{-6} A/cm^2 (indicated by arrow CD); DE, time needed to repassivate pits; EF, potential fluctuations due to the appearance and repassivation of small, nongrowing pits.

High ability of metal in the pit to passivate is obviously a general property of the surface, independent of the polarization type. It is possible that the easy repassivation of the metal in the pits is also due to a disturbance of the equilibrium in the electrolyte when the external conditions vary.

Thus, direct proof has been obtained indicating that the steadily functioning real pit operates in the diffusion regime; hence, using the formal concepts of electrochemical kinetics as the basis, it is possible to understand why the pits repassivate so easily, when the potential is shifted in the negative direction. However, the same results suggest that the surface of the metal inside the pit possesses a surprising universal ability to passivate easily, which occurs as soon as the potential has shifted toward the values at which the stainless steel undergoing corrosion is found in the passive state. It is obvious that such an active surface is able to form passivating layers fairly easily as soon as the external effect has changed. It would be apt here to recall a phenomenon detected earlier (26), namely, that under galvanostatic polarization or self-dissolution of stainless steels, it is sufficient to switch off polarization or to extract the steel from the electrolyte, to passivate the metal in the pit.

When such an electrode was subjected to repeated polarization, the metal in earlier produced pits remained in the passive state and did not dissolve, but new pits appeared on the surface.

What is the nature of the repassivation potential and does it characterize the susceptibility of stainless steels to localized corrosion, as some authors suggest (29)? As shown above, the repassivation potential strongly depends on the pit operation time; hence, it cannot be used as the criterion of the susceptibility of stainless steels to localized corrosion processes. The pitting-formation potential is a more precise quantity, as seen in Table I. Cr18Ni10Ti stainless steel strongly differs from Cr18Ni12Mo2Ti steel in the susceptibility to pitting corrosion, the latter containing molybdenum; and this is reflected in the pitting-formation potential (+0.55V as compared with +0.825V). However, with regard to the repassivation potentials, these steels differ but slightly (in 60 min the difference amounts to only 0.050V). This is quite clear: Inasmuch as in pits a specific *p*H value is established, as well as their own concentration of chloride ions, the repassivation potential must depend but slightly on the composition of the surrounding medium, in respect to which the susceptibility of steels to localized corrosion is determined.

With regard to the repassivation potential, consider a two-electrode system with the pits as the anode and the passive surface as the cathode. Consider pitting corrosion under self-dissolution. Then from the theory of electrochemical protection, it is known that the system ceases to generate a current as its potential is shifted in the negative direction, when the potential of the system has reached the potential of the anode in the open state, *i.e.*, when there is no corrosion current through the system. From this point of view, the repassivation potential should not be identified with the potential applied to the bottom of an operating pit. Moreover, the following will have to be taken into account: When measuring the repassivation potential, the mixed potential of a complex electrode is measured, rather than the potential of the metal in a pit. Further, the question about the presence or the absence of noticeable ohmic potential drops in the system has not yet been definitely solved; hence, the nature of the repassivation potential remains obscure. The repassivation potential may coincide with that applied to the bottom of an operating pit only in the case for

which the pit-passive surface system is polarized to the full extent (there is no ohmic drop) and when the anodic process itself occurs in the pit without any noticeable polarization. Such are the main laws governing the breakdown of the passive state and the repassivation of stainless steels when pits are formed.

The mechanism of crevice corrosion has been discussed in full detail by us (30-32) and by others (33-39). In the present paper we wish to deal only with one question; namely, whether there is a certain potential at which crevice corrosion begins to take place. Figure 8 shows how the potential of Cr13 grade stainless steel changes with time in a crevice (0.1 mm wide) in 0.1*N* sodium chloride solution, when it is in contact with Cr18Ni10Ti grade steel (the ratio of surfaces is 1:1.5) that has been immersed in the electrolyte. Already in 1.5 hr the potential of the Cr13 grade steel in the crevice reaches a value of approximately −0.3V. The potential of Cr18Ni10Ti steel also grows more negative, but the potential difference between these two steels remains the same (about 0.14V). It should be noted that the potential of the steel in the crevice first grew more positive owing to anodic polarization, whereas the potential of the steel to which the electrolyte had a free access grew more negative owing to cathodic polarization. Similar results were obtained, too, when two electrodes of the same steel (grade Cr13) contacted one another.

It is quite natural to suppose that such a strong activation of steel in the crevice should be attributed to a change in the composition of the electrolyte in the crevice. Therefore, we studied the dependence of the potential of the same steel on the *p*H at various NaCl concentrations (Fig. 9). The results obtained show that the potentials close to those in the crevice (from −0.30 to −0.32V) are observed in solutions having a *p*H value in the range from 2 to 3. At such *p*H values, NaCl concentration plays a minor role and does not exert strong influence on the potential, as is the case with neutral and weakly acid solutions. These potential values allow the approximate composition of the electrolyte, which may be stored up in the crevice, to be evaluated.

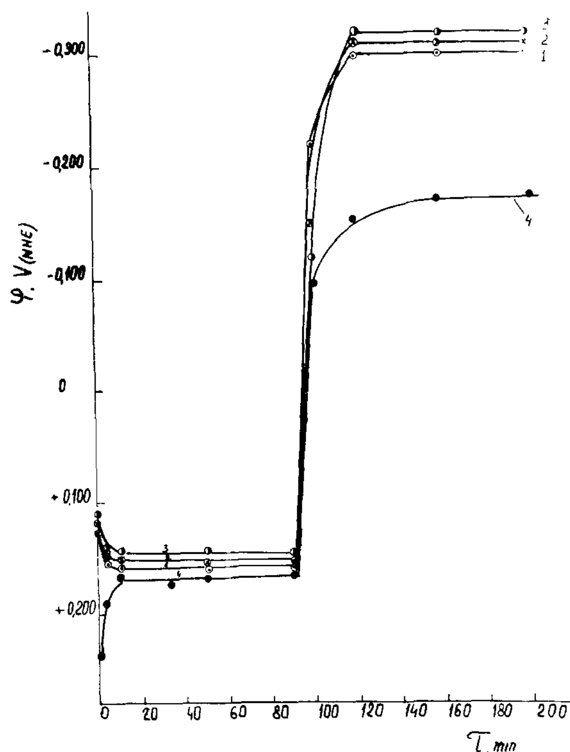

Fig. 8. Time variation of the potential of Cr13 stainless steel in a crevice (at the following depths: 1, 22 mm; 2, 44 mm; 3, 66 mm) in contact with Cr18Ni10Ti steel (open surface). The reference numeral 4 indicates the potential of Cr18Ni10Ti steels. Electrolyte: 0.1*N* NaCl.

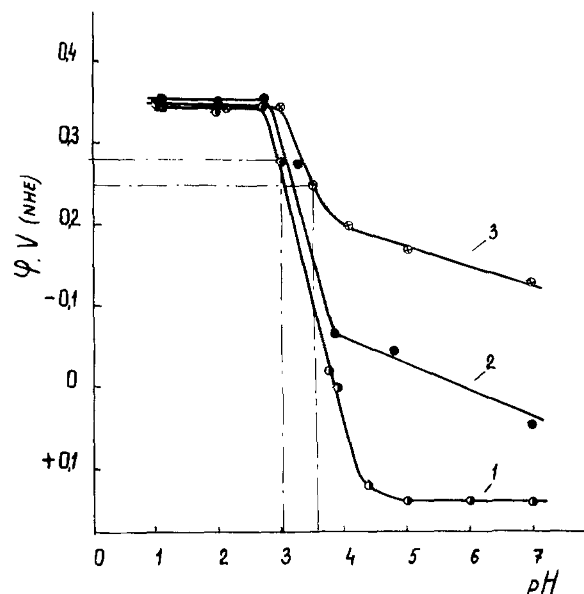

Fig. 9. Steady-state potential of chromium stainless steel (grade Cr13) vs. *p*H value of electrolyte at various concentrations of chloride ions. The reference numerals indicate: 1, 0.1*N* NaCl; 2, 1*N* NaCl; 3, 5*N* NaCl.

It is of interest to determine the extent of anodic polarization necessary for crevice corrosion to begin, that is, for the steel to be activated in the crevice over the entire surface. For this purpose, a series of anodic potentials were applied potentiostatically to the open surface of a complex electrode, and the potentials of steel within a crevice were recorded, as well as their variation with time. For Cr13 steel, even at insignificant initial potential shifts in the anodic direction within the crevice, which did not reach the pitting-formation potential (about +0.275V) for the steel, the steel in the crevice was activated with time, and its potential reached about −0.3V, that is the same value that Cr13 steel acquired when in contact with Cr18Ni10Ti steel. A difference existed only in the following: As the positive potential applied to the external electrode and, hence, to the crevice was increased, the time required for activation of the electrode in the crevice decreased (Fig. 10), whereas the current strongly increased. Hence, it may be concluded that there is no crevice corrosion potential, at least for the Cr13 steel. It is sufficient to subject such a steel in the crevice to a slight anodic polarization, and it will eventually be activated owing to variation in the electrolyte composition. The question about the susceptibility of steels to the crevice corrosion is obviously solved in respect to their sensitivity to a change in composition and character of the corrosion medium (40) (*e.g.*, the *p*H value, the concentration of sodium chloride, and temperature).

Finally, a further question remains to be discussed: Namely, how is it possible that the metal can be found in the active state within the pit or crevice and simultaneously in the passive state on the surrounding surface? As stated above, such a system is unstable from the electrochemical point of view; for in the absence of a noticeable potential difference, it should eventually be converted into either the active or the passive state.

As noted previously by us (23-26), studies of the intensity of an electric field over pits and the currents flowing from them have shown the following: As expected from the theory, the overwhelming number of pits forming on the surface repassivate spontaneously, and only a few of them (about 3-5%) function steadily; this, as shown above, is attributed to the fact

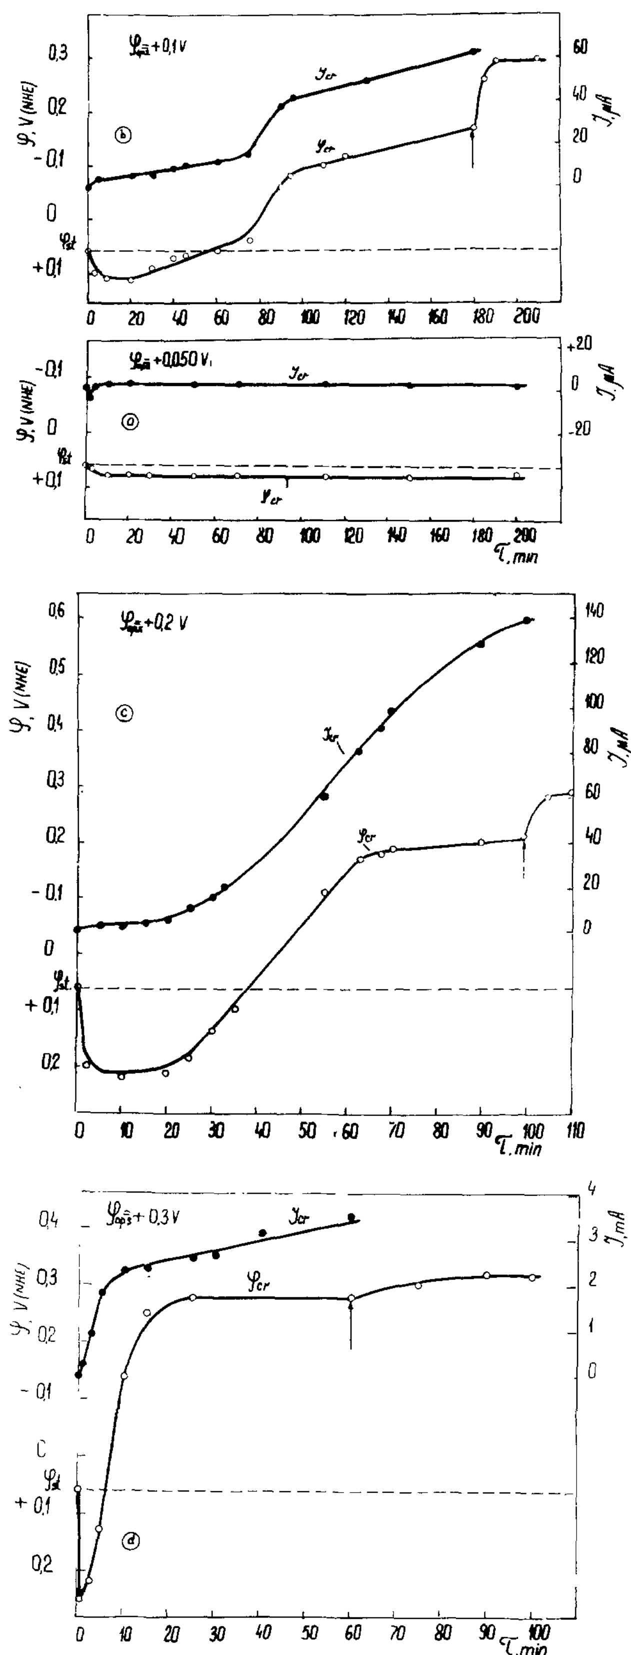

Fig. 10. Influence anodic polarization on the time variation of the potential of Cr13 chromium stainless steel in a crevice (ϕ_{cr}) and of the current (I_{cr}) at different potentials of the open surface ($\phi_{op.\ sur.}$). Electrolyte: 0.1*N* NaCl. Broken line indicates the steady-state potential before anodic polarization sets in. The arrow indicates the moment at which anodic polarization is stopped.

that they begin to operate in the diffusion regime. This is possible because localized corrosion occurs in a relatively closed volume, in which the anodic dissolution products are retained and acidify the solution by hydrolysis. Differentiation of electrochemical reactions over the surface also contribute to the concentration of activating agents in point anodes and to that of passivating agents on an open surface. Because the corrosion medium in point anodes and over the remaining portion of the electrode surface has a variable composition, even at the same potential, a part of the electrode may be in the active state, while the other part is in the passive state. That this mechanism is true is substantiated by the immediate repassivation of the system that takes place as soon as the point anodes are opened so that access of the electrolyte from the bulk has been established (25).

It is not ruled out that in the salt film at the bottom of the pit there is an ohmic potential drop that keeps the pitting-passive surface system in the stable state.

Anodic Oxidation of Cobalt in Neutral and Basic Solution

Norio Sato* and Toshiaki Ohtsuka

Electrochemistry Laboratory, Corrosion Research Group, Faculty of Engineering, Hokkaido University, Sapporo 060, Japan

ABSTRACT

The anodic oxidation and anodic oxide films of cobalt have been studied in borate buffer solutions in the pH range from 7 to 11. The anodic polarization curve shows the active dissolution, primary passivity, secondary passivity, tertiary passivity, and transpassivation. It is also shown that the anodic oxide film is hydrated oxide of CoO in the primary passive region, bilayered oxide CoO/Co_3O_4 in the secondary passive region, and bilayered oxide of CoO/Co_2O_3 in the tertiary passive and transpassive regions. The dissolution current of the anodic oxide film in the secondary and tertiary passive regions is much smaller than that in the primary passive region. By cathodic reduction the outer Co_2O_3 layer is first converted to Co_3O_4 and then reduced further to hydrated Co^{2+} ions before the inner CoO layer is reduced to metallic cobalt.

Early this century, it was reported that cobalt was passivated chemically in concentrated nitric acid and electrochemically in alkaline solutions (1). Later, Grube (2) found three potential arrests in galvanostatic transients of anodic oxidation of cobalt in alkaline solutions and attributed them to the formation of Co_3O_4, Co_2O_3, and CoO_2. El-Wakkad and Hickling (3) also found the three potential arrests but described them as corresponding to CoO, Co_2O_3, and CoO_2. Recently, by use of potential sweeps, Tikkanen *et al.* (4) observed three current peaks in the anodic polarization curves of cobalt in alkaline solutions and assumed the formation of CoO, Co_3O_4, and $Co(OH)_3$. Other potentiostatic studies (5-7) carried out afterward have also suggested the successive formation of cobalt oxides of different oxidation states in agreement with the thermodynamic predictions (8-9). No direct evidence, however, has been provided for the composition of anodic oxide films on cobalt, except that Leidheiser *et al.* (10-11) detected by Mössbauer spectroscopy cobalt(II) and cobalt(III) ions in the anodic oxide films.

In our previous paper (12) the thickness of anodic oxide films on cobalt has been measured by *in situ* ellipsometry in neutral borate solution. This paper deals with the anodic polarization curve and the composition of anodic oxide films on cobalt in neutral and alkaline solutions.

Experimental

The specimen was prepared from cobalt rods of 99.99% purity (Johnson-Matthey Company, Limited) into polycrystalline sheets, 0.8 mm thick and 5 or 10 cm^2 surface area. It was mechanically polished, annealed for 100 hr at 390°C in vacuum, and electropolished at 0.45 A/cm^2 in a mixture of 60% perchloric acid and pure acetic acid (5:1) at 3° ~ 5°C. The electrolytic cell was a two-compartment four-electrode cell of 50 cm^3 capacity connected with four separate solution reservoirs. It had a Luggin capillary to a saturated calomel reference electrode and two platinum counterelectrodes, one in the specimen compartment and the other in the countercompartment. The solutions, prepared from doubly distilled water and analytical grade reagents, were mixtures of 0.30 $mole/dm^3$ boric acid and 0.075 $mole/dm^3$ sodium borate solutions, and their pH was adjusted by changing the mixing ratio and, if necessary, by adding a small amount of sodium hydroxide. Before transfer into the cell, the solutions were deoxygenated practically completely by injecting purified nitrogen gas for more than 24 hr.

The specimen in the cell was first cathodically reduced at a constant current of 10 $\mu A/cm^2$ for 20 min in a borate solution of pH 8.42 to obtain the oxide-free surface, and after careful exchange of solution under nitrogen atmosphere it was anodically oxidized potentiostatically for 1 hr at a given potential in a given solution. The solution was then drawn out for chemical analysis to determine the amount of cobalt dissolution by a colorimetric nitro-R salt method sensitive to 5 $\mu g/dm^3$. The oxidation was repeated for various potentials and pH solutions starting every time from the cathodically reduced surface at pH 8.42. In some experiments the time of anodic oxidation was extended up to 24 hr and the solution was chemically analyzed for cobalt for one hour to determine the time change of cobalt dissolution at constant potential.

Cathodic reduction experiments were carried out in which the oxidized specimen, immediately after oxidation, was reduced by a constant cathodic current of 5 or 10 $\mu A/cm^2$ for different periods of time and the solution, immediately after the current was off, was taken out for chemical analysis to determine the amount of cobalt dissolved as a function of cathodic charge passed.

All measurements were performed at 20° ± 0.5°C. All electrode potentials were measured in reference to a saturated calomel electrode and converted to

the standard hydrogen electrode potential scale E_{SHE} or the hydrogen electrode scale in the same solution $E_{HESS} = E_{NHE} + 0.058$ pH.

Results

Oxide-free reference surface.—The oxide-free surface, with which coulometric measurements were carried out, was obtained by cathodic reduction of the specimen at a constant current 10 $\mu A/cm^2$ for 20 min in a borate solution at pH 8.42. The absence of oxide films on the cathodically reduced surface appears evident from measurements of galvanostatic reduction-oxidation cycles, in which the first oxidation curve for a surface prepared by cathodic reduction of the electropolished surface was consistent with the second oxidation curve obtained after cathodic reduction of the anodically oxidized surface. This reproducible surface is suggested to be free from oxides. It has also been shown by ellipsometry that the anodic oxide films on cobalt were completely removed by cathodic reduction (12) at pH 8.42.

Anodic oxidation.—The anodic polarization curves of cobalt in borate solutions at pH 7 ~ 11 are shown in Fig. 1, where the anodic currents represent the nearly stationary values observed 1 hr after the start of potentiostatic oxidation each with the oxide-free surface. Figure 2 shows the amount of cobalt dissolved during 1 hr oxidation as a function of potential. In these two figures, the three different degrees of passivity can be distinguished; the primary passive region I extending from +0.4 to +0.8V, the secondary passive region II from +0.9 to +1.25V, and the tertiary passive region III from +1.25V to about +1.6V in the HESS potential scale referred to the hydrogen electrode in the same solution. Transpassivation appears to occur at more anodic potential. The critical potential for anodic oxygen evolution is about +1.45V (HESS), which exceeds its equilibrium potential by about 0.37V. The Tafel line for the oxygen electrode reaction in Fig. 1 gives kinetic parameters; $(\partial E/\partial \log i)_{pH} = 75$ mV and $(\partial \log i/\partial \text{pH})_E \doteqdot 1$.

The transpassive dissolution at more anodic potentials is shown in Fig. 3, where the SHE potential scale is used. It is noticed that the critical potential for transpassivation is almost independent of pH, being about +1.1V (SHE) in the pH range from 7 to 11.

To compare the anodic current with the dissolution rate of cobalt in the same scale, the anodic current after 1 hr and the dissolution current averaged for 1 hr following the initial 1 hr oxidation at constant potential are plotted as a function of potential in Fig. 4. In the passive region I, the anodic current reached the steady value within 1 hr and is equal to the dissolution current of cobalt as cobalt(II) ion. In the passive regions II and III, however, the anodic current does not reach the steady state in 1 hr. Furthermore, the anodic current in region III is larger than the dissolution current as (III) ions, indicating

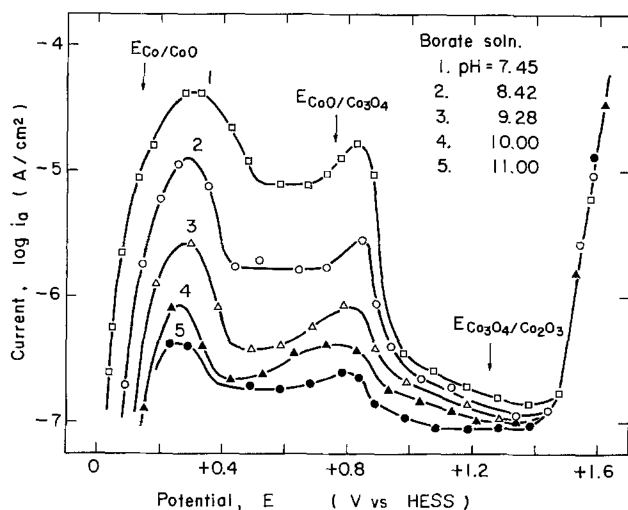

Fig. 1. Anodic current/potential curves of cobalt in borate solutions. The current is measured 1 hr after the start of potentiostatic oxidation of the oxide-free surface.

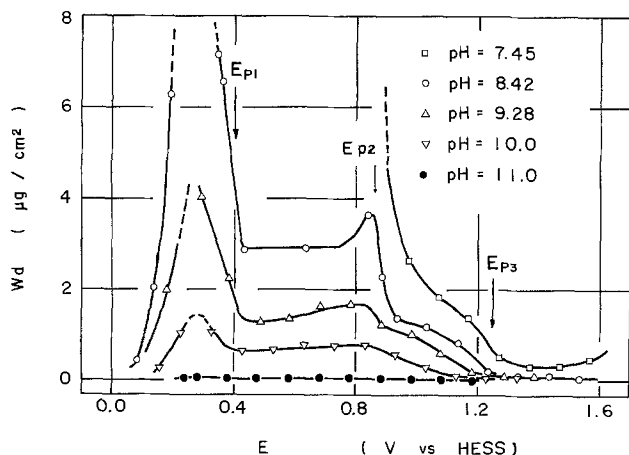

Fig. 2. Anodic 1 hr dissolution/potential curves of cobalt in borate solutions. The amount of dissolution W_d is measured for 1 hr of potentiostatic oxidation of the oxide-free surface.

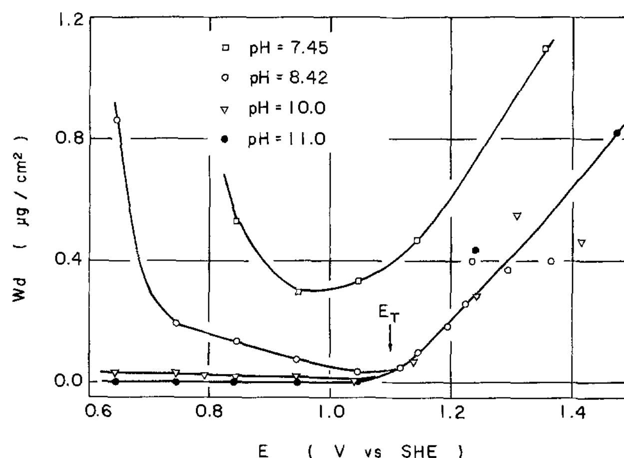

Fig. 3. Anodic 1 hr dissolution/potential curve of cobalt in passive and transpassive potential regions in borate solutions.

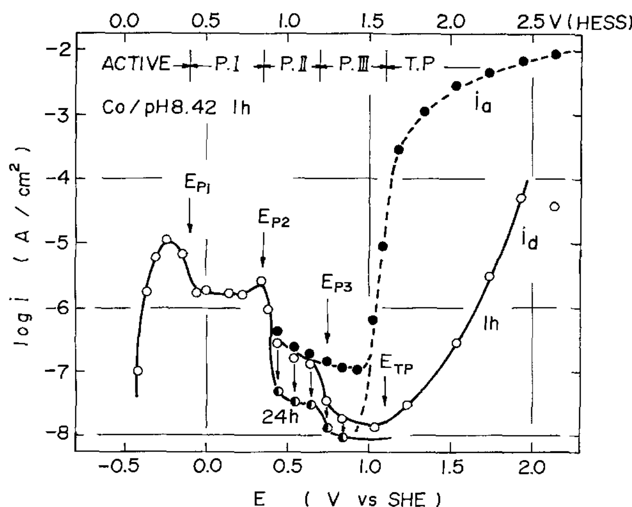

Fig. 4. Anodic current/potential and dissolution-current/potential curves of cobalt in borate solution at pH 8.42. The anodic current (●) is measured 1 hr after the start of oxidation, and the dissolution current is the average for 1 hr following first 1 hr (○) and 24 hr (◐).

that the thickening of the anodic oxide is in progress even after 1 hr. In the transpassive region, the anodic current mostly carries oxygen at more anodic potentials, and the transpassive dissolution current, though increasing with potential, takes only a diminutive part of the total anodic current. The anodic oxygen evolution current first increases with potential following a Tafel relation and then approaches a limiting current which increases with pH.

To examine how much time to take before the steady state is reached in passive regions II and III, 24 hr oxidation was carried out at constant potential. Figure 5 shows the anodic current and the cobalt dissolution current both decreasing with time of oxidation toward the steady values in 24 hr. It is evident that at the steady state the anodic current is equivalent to the cobalt dissolution rate as cobalt(II) ion in region II and as cobalt(III) ion in region III.

It has been shown in Fig. 1 and 2 that the pH dependence of cobalt dissolution is much larger in active and passive I regions than in passive regions II and III. Figure 6 shows the pH dependence of the active peak current i_{am} and of the potential-independent dissolution current i_{p1} in passive region I, leading for a pH range 7.4 ~ 9.4 to the following relations; $\log i_{am} = 0.34\text{-}0.63$ pH (A/cm²) and $\log i_{p1} = -0.44\text{-}0.63$ pH (A/cm²). In passive regions II and III, it was difficult to determine the pH dependence of the steady-state dissolution current because of the extremely small dissolution rate in this pH range.

To estimate the amount of anodic oxide formed in 1 hr, measurements were carried out of the anodic charge, Q_f, accumulated in the anodic oxide film, which could be obtained by subtracting the charge equivalent to the amount of dissolution as cobalt(II) or (III) ion from the total anodic charge passed. Figure 7 shows the anodic film charge Q_f as a function of potential. Evidently, the anodic film starts to form in the potential region of active dissolution. The amount of the anodic film charge is nearly potential independent in passive region I, but it increases with potential in passive regions II and III.

Cathodic reduction of anodic oxide films.—Figure 8 shows the galvanostatic-cathodic reduction of the anodic oxide films, where the potential decay and the amount of cobalt(II) ion dissolved from the films are plotted as a function of cathodic charge passed. In this figure, the film is formed for 1 hr at a given potential in the solution of pH 10.0 and reduced by a cathodic current of 10 μA/cm² in the solution of pH 8.42. Obviously, the anodic film formed in passive

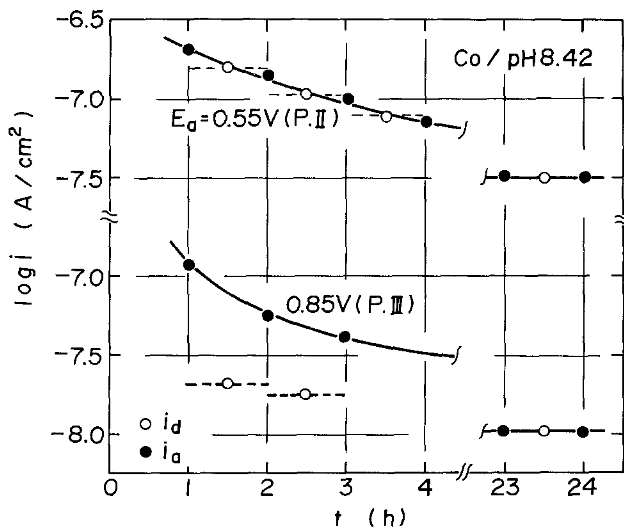

Fig. 5. Variation of anodic current i_a and dissolution current i_d with time for cobalt at constant potential in passive regions II and III in borate solution pH 8.42. The dissolution current is the average for 1 hr.

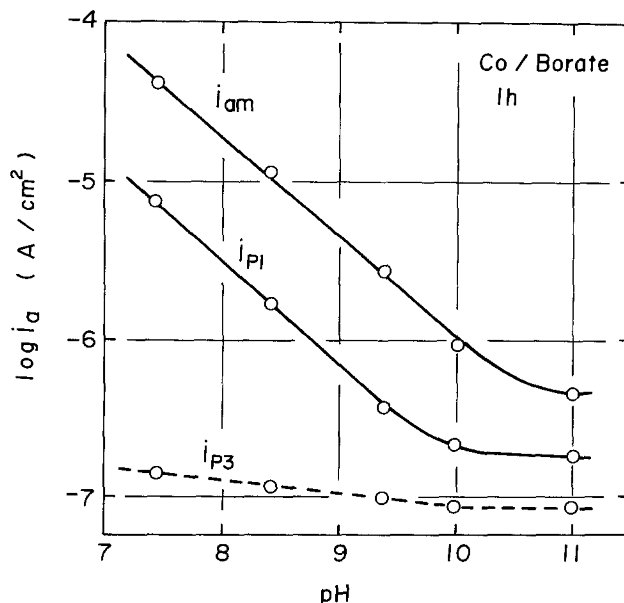

Fig. 6. Variation of active peak current i_{am}, primary passivity current i_{p1}, and tertiary passivity current i_{p3} with pH for anodic oxidation of cobalt in borate solutions. The current is measured 1 hr after the start of oxidation.

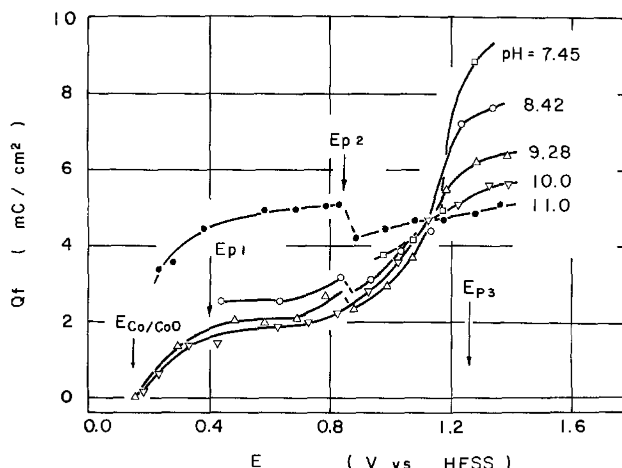

Fig. 7. Anodic film-charge/potential curves of cobalt in borate solutions. The film charge $Q_f = Q_a - Q_d$, where Q_a is the anodic charge passed for 1 hr and Q_d the charge equivalent to cobalt dissolution ($Q_d = W_d/2F$).

region I shows a rapid cathodic potential decay to an oxide reduction potential −0.55V (SHE) slightly more noble than the final potential and no cobalt(II) ion is produced in the solution during the cathodic reduction, indicating that the primary passive film of cobalt(II) oxide or hydroxide is reduced to metallic cobalt. The film formed in passive region III, however, shows a definite arrest in the potential decay and produces cobalt(II) aquo-ions in the solution during its cathodic reduction, indicating that a higher valent cobalt oxide is reduced to soluble cobalt(II) ions.

The cathodic dissolution of the film as cobalt(II) ions, which occurs only with the film formed in passive regions II and III, differs with different solution pH in which cathodic reduction is carried out. Figure 9 shows the cathodic dissolution curves in different pH solutions for the anodic oxide film formed at a constant potential in passive region III in the solution of pH 10.0. After an induction period of about 0.1 mC/cm², the amount of cobalt(II) ion dissolution increases nearly linearly with the cathodic charge passed and then gradually approaches a maximum value W_d^{max}. The broken line in Fig. 9 refers to the theoretical

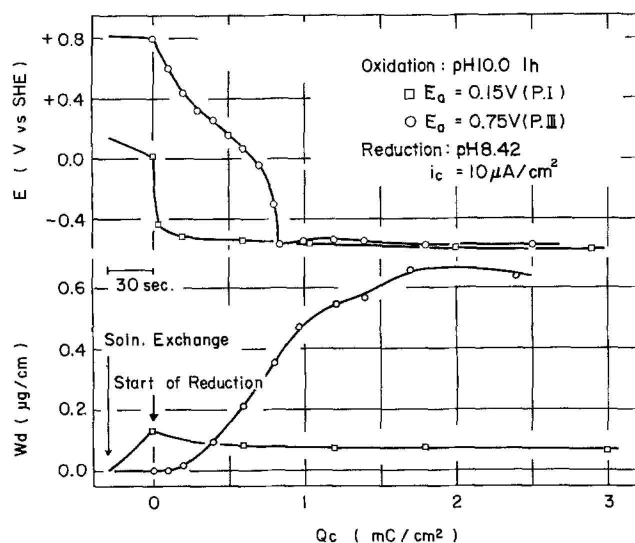

Fig. 8. Variation of potential and amount of cobalt(II) dissolution with cathodic charge passed during galvanostatic reduction of anodic oxide films formed in passive regions I and III. The film, formed potentiostatically for 1 hr in borate solution pH 10.0, is reduced by cathodic current 10 μA/cm^2 in borate solution pH 8.42.

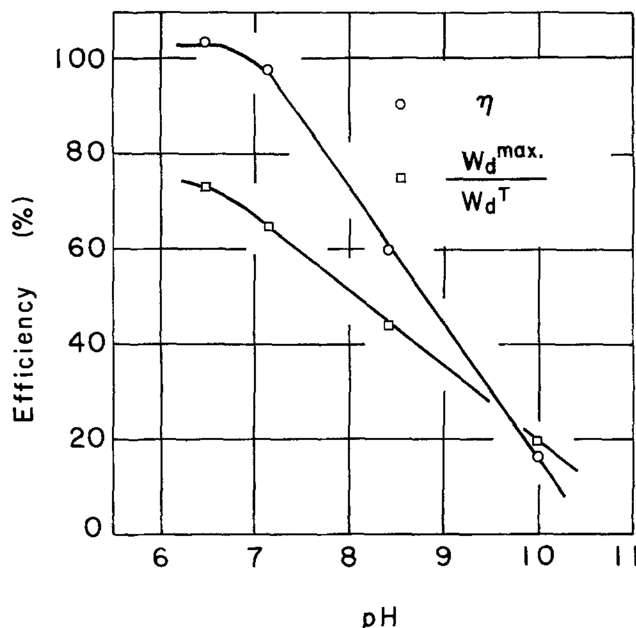

Fig. 10. Differential current efficiency η and integral efficiency W_d^{max}/W_d^T of reductive dissolution of an anodic oxide film on cobalt as a function of solution pH used for cathodic reduction.

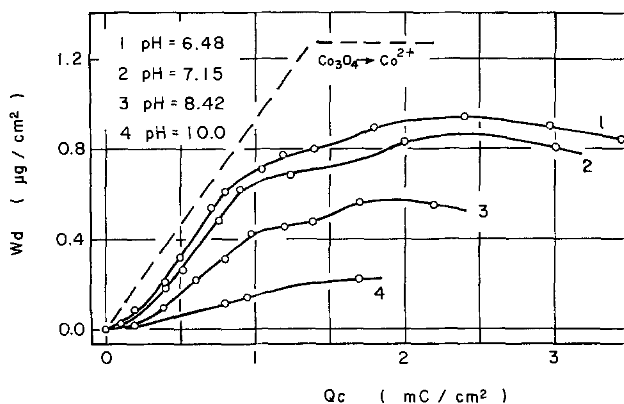

Fig. 9. Cathodic reduction curves of an anodic oxide film on cobalt in borate solutions pH 6 ~ 10. The film, formed for 1 hr at +0.75V (SHE) at pH 10, is reduced by cathodic current 10 μA/cm^2 to measure the amount of dissolution W_d as a function of cathodic charge Q_c in various solutions.

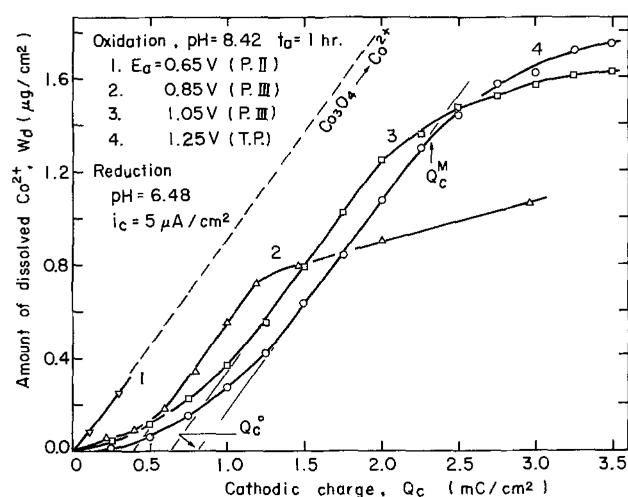

Fig. 11. Cathodic reduction curves of anodic oxide films on cobalt in passive regions II (+0.65V_{SHE}), III (+0.85V and +1.05V_{SHE}) and in transpassive region (+1.25V_{SHE}). The film, formed for 1 hr at pH 8.42, is reduced by cathodic current 5 μA/cm^2 in borate solution pH 6.48.

cathodic dissolution of stoichiometric Co_3O_4, $Co_3O_4 + 8H^+ + 2e \rightarrow 3Co^{2+} + 4H_2O$, and hence its slope can be used as a reference of differential current efficiency η for cathodic dissolution of the film. A limiting value in the broken line represents the total amount of cobalt W_d^T in the film assuming a single layer of Co_3O_4. As shown in Fig. 10, both differential current efficiency η and maximum amount of dissolved cobalt(II) ion W_d^{max} increase with decreasing pH. Notice that η reaches 100% at pH 6.48, though W_d^{max} is smaller than W_d^T even at this pH. The cathodic current density in a range 2 ~ 50 μA/cm^2 has a slight influence on W_d^{max} but produced no effect on η.

Because of the differential current efficiency η = 100%, the solution of pH 6.48 and the current density of 5 μA/cm^2 were employed as a standard cathodic reduction method to measure the composition of the anodic oxide films formed at different potentials in the solution at pH 8.42. Results are shown in Fig. 11, where the broken line again refers to the cathodic dissolution of Co_3O_4. Noticeably, the film formed at +0.65V (SHE) in passive region II dissolves along the theoretical Co_3O_4 dissolution curve without any induction charge for cathodic dissolution, indicating that at least the outer part of the film is Co_3O_4 or $Co_3O_4 \cdot nH_2O$. The film formed at +0.85, 1.05, and 1.25V (SHE) in passive region III, however, requires an induction charge Q_c^o before the cathodic dissolution occurs at the same rate as Co_3O_4, indicating that the outer part of the film is in the oxidation state higher than Co_3O_4 or contains a significant amount of cobalt ion vacancy, $Co_{3-\Delta}O_4$. Furthermore, it is found that the induction charge Q_c^o and the charge Q_c^M, beyond which the slope of the cathodic dissolution curve deviates from that of the theoretical Co_3O_4 dissolution curve, both increase with the potential of film formation. As shown below, these two charges Q_c^o and Q_c^M may be used to estimate the nonstoichiometric composition of the anodic oxide films.

Discussion

The anodic oxide film in passive region I.—As shown in Fig. 7, an anodic, prepassive oxide film begins to form at a critical potential of about +0.15-0.059 pH (V_{SHE}), where cobalt is in the active state (Fig. 1 and 2). This critical potential is close to the equilibrium potentials (13-15) for the anodic formation of CoO, α-Co(OH)$_2$, and β-Co(OH): E_{eq}(Co/CoO) =

$+0.135-0.059$ pH (V_{SHE}), $E_{eq}(Co/\alpha\text{-}Co(OH)_2) = +0.15-0.059$ pH (V_{SHE}), and $E_{eq}(Co/\beta\text{-}Co(OH)_2) = +0.08-0.059$ pH (V_{SHE}). This prepassive oxide film, which is assumed to be CoO or $Co(OH)_2$, grows to be the primary oxide film in passive region I. The fact that the galvanostatic cathodic reduction of the film formed in passive region I does not produce any detectable amount of cobalt(II) ions in the solution (Fig. 8) provides indirect evidence for a cobalt(II) oxide or hydroxide film, which is reduced to metallic cobalt at cathodic potentials.

It is also shown in Fig. 7 that the amount of anodic charge for the primary oxide film in passive region I is almost constant at $2 \sim 2.5$ mC/cm^2 in the pH range from 7 to 10, which corresponds to the thickness of $12 \sim 15$Å for a film of CoO (density $5.7 \sim 6.7$ g/cm^3) and $27 \sim 33$Å for a film of $Co(OH)_2$ (density 3.6 g/cm^3) with the roughness factor of the surface $\gamma = 1$. In the previous paper (12) the film thickness in region I has been estimated by ellipsometry to be about 25Å, which is close to the thickness calculated above for $Co(OH)_2$ rather than CoO. It thus appears that the anodic oxide film in passive region I is hydrated.

There is a slight increase in both dissolution current i_a (Fig. 1 and 2) and film charge Q_f at potentials close to the secondary passivation potential E_{p2}. This is due to the formation of a higher valence oxide, probably giving rise to the partial breakdown of the hydrated CoO film.

The anodic oxide film in passive regions II and III.—The anodic oxide films in passive regions II and III are characterized by the cathodic potential decay with two potential arrests and by their cathodic dissolution as cobalt(II) ion in the first potential arrest, which suggests a two-layered film consisting of an outer layer of higher valence oxide and an inner layer of lower oxide, probably CoO. The cathodic charge required for the first potential arrest corresponds to the reduction of a higher valence oxide layer and hence may be used as a measure of its thickness.

Figure 12 shows the cathodic charge for the first potential arrest as a function of the potential at which the anodic oxide film has been formed for 1 hr at various pH solutions. Evidently, the higher valence oxide begins to form at about +0.75V (HESS), which is consistent with the ellipsometric measurements (12). Since the higher valence oxide in passive region II has been identified as Co_3O_4 (Fig. 11), this critical potential is represented by $E_{CoO/Co_3O_4} = +0.75V-0.059$ pH (V_{SHE}), which is compared with the equilibrium potential (13), $E_{eq}(CoO/Co_3O_4) = +0.65-0.059$ pH (V_{SHE}). The secondary passivation potential, $E_{p2} = +0.85-0.059$ pH (V_{SHE}), is 0.1V more anodic than E_{CoO/Co_3O_4}, indicating that a certain thickness or coverage of the higher valence oxide layer is required for the secondary passivation to occur.

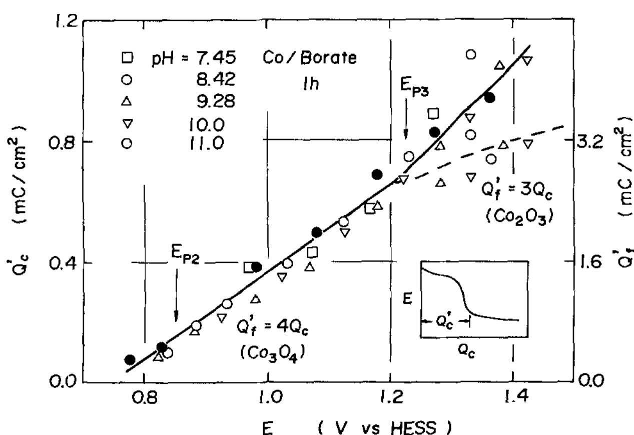

Fig. 12. Cathodic charge Q_c' for first potential arrest in cathodic reduction curves and anodic charge Q_f' for the outer layer (Co_3O_4 or Co_2O_3) as a function of potential of film formation. The film, formed for 1 hr at different pH, is reduced by cathodic current 5 μA/cm^2 in borate solution pH 6.48.

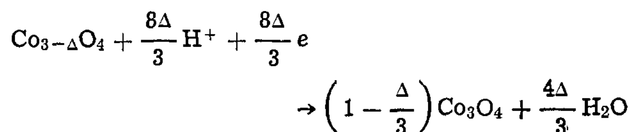
The anodic oxide film formed in passive region III exhibits an induction period in its cathodic dissolution as cobalt(II) ions (Fig. 11). This is attributed to the reduction of excess oxygen in the film



$$Co_{3-\Delta}O_4 + \frac{8\Delta}{3}H^+ + \frac{8\Delta}{3}e \rightarrow \left(1 - \frac{\Delta}{3}\right)Co_3O_4 + \frac{4\Delta}{3}H_2O$$

where Δ denotes the nonstoichiometry of Co_3O_4. It is thus assumed that the cathodic charge Q_c^o required for the induction period corresponds to the amount of nonstoichiometry Δ and that the cathodic charge Q_c^M (Fig. 11) is equivalent to the coulomb required for the dissolution of $Co_{3-\Delta}O_4$ to cobalt(II) ions. Then, the nonstoichiometry Δ may be estimated from Q_c^o and Q_c^M by use of the relation $Q_c^o/Q_c^M = 4\Delta/(3 + 3\Delta)$. Figure 13 shows Q_c^o/Q_c^M and Δ as a function of potential for the film formed at pH 8.42. The nonstoichiometry Δ is seen to change from $\Delta = 0$ to $\Delta = 0.33$ and hence the oxidation state of the film from Co_3O_4 to Co_2O_3 at about +1.2V (HESS). This potential agrees with the critical potential that separates passive region II from passive region III in the anodic dissolution curve (Fig. 2); $E_{p3} = +1.25-0.059$ pH (V_{SHE}). The corresponding equilibrium potential (13) is $E_{eq}(Co_3O_4/CoOOH) = +1.15-0.059$ pH (V_{SHE}). It has been shown in the previous paper (12) that the optical constant of the outer layer of the film also changes at this critical potential E_{p3}.

The anodic charge Q_f' for the higher valence oxide layer is estimated from the cathodic charge Q_c' required to reduce it to cobalt(II) aquo-ions, as shown in Fig. 12. The layer thickness is calculated from Q_f' by using the thickness/coulomb ratio 5.11 Å/mC for Co_3O_4 (density 6.1 g/cm^3) and 5.53 Å/mC for Co_2O_3 (density 5.2 g/cm^3). Furthermore, substraction of Q_f' from the total film charge Q_f (Fig. 7) gives the anodic charge for the inner CoO layer, which then allows the inner layer thickness to be computed. The thickness of both layers thus estimated for the anodic oxide

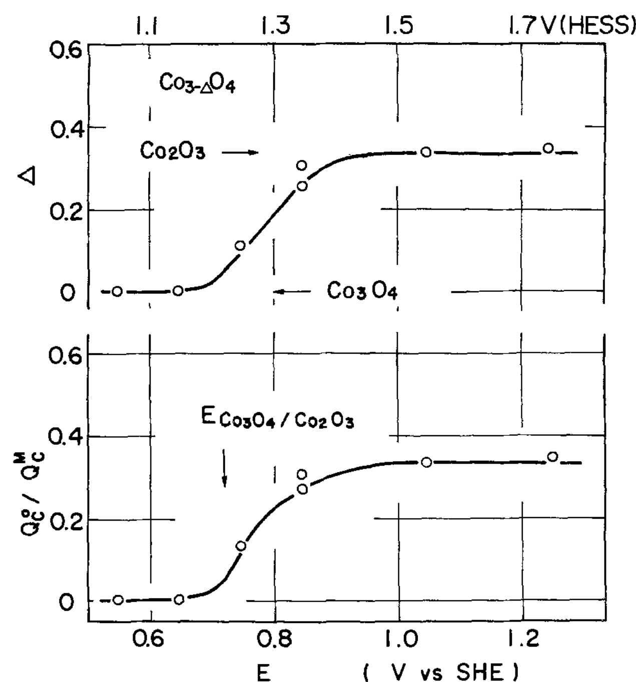


Fig. 13. Ratio Q_c^o/Q_c^M in cathodic reduction curves and nonstoichiometry Δ of the outer $Co_{3-\Delta}O_4$ layer of anodic oxide films as a function of potential of film formation.

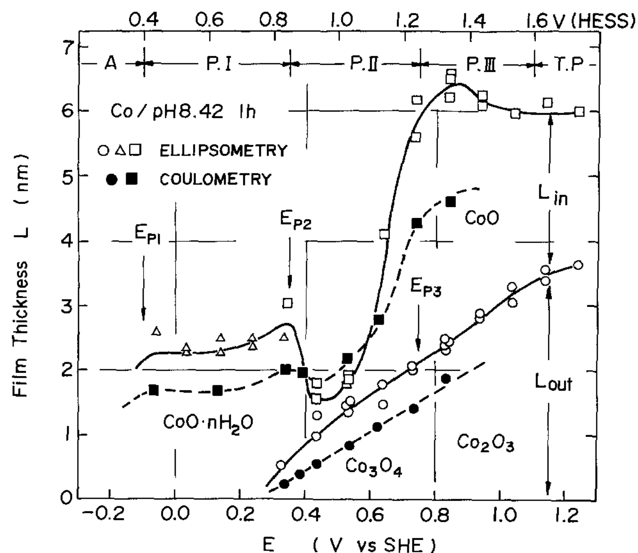

Fig. 14. Thickness/potential curves for anodic oxide films formed on cobalt for 1 hr in borate solution pH 8.42; L_{in} represents the inner CoO layer and L_{out} the outer layer.

film formed at pH 8.42 is shown in Fig. 14, where the ellipsometrically estimated thickness is also shown for comparison. Notice that the coulometric thickness estimation assumes anhydrated oxide films and hence would give a smaller thickness than expected for hydrated oxide films. The main reason for the discrepancy between the coulometric and ellipsometric thicknesses is probably the hydrated nature of the anodic oxide films.

Conclusion

1. The anodic oxidation of cobalt in borate solutions of pH 7 ~ 11 gives rise to the active dissolution, the passivation, and the transpassivation, depending on the potential.

2. The passive potential range can be divided into the three regions; the primary passivity (region I), the secondary passivity (region II), and the tertiary passivity (region III).

3. In region I, which extends from +0.4-0.059 pH (V_{SHE}) to +0.8-0.059 pH (V_{SHE}), a hydrated cobalt(II) oxide about 25Å thick is formed at pH 7 ~ 10, and the dissolution current i_{p1} nearly independent of potential decreases with increasing pH; log i_{p1}/A cm^{-2} = −0.44-0.63 pH in 1 hr oxidation.

4. In region II from +0.9-0.059 pH (V_{SHE}) to +1.3-0.059 pH (V_{SHE}), an oxide or hydrated oxide film of Co_3O_4, whose thickness increases with potential up to 15Å, is formed on the CoO film, and the dissolution current i_{p2} is much smaller than i_{p1}; log i_{p2}/A cm^{-2} = −7.5 at pH 8.42 in 24 hr oxidation. The total film thickness is estimated to increase from 15 to 50Å with potential.

5. In region III more anodic than +1.3-0.059 pH (V_{SHE}), an oxide or hydrated oxide film of Co_2O_3, whose thickness increases with potential from 15 to 35Å, is formed on the CoO film, and the dissolution current i_{p3} is smaller than i_{p2}; log i_{p3}/A cm^{-2} = −8.0 at pH 8.42 in 24 hr oxidation.

6. The transpassive dissolution begins to occur at about +1.1 (V_{SHE}) nearly independent of pH, and the anodic oxide film in the transpassive region is the same in composition as that in passive region III.

7. The anodic oxygen evolution begins to occur at +1.4-0.059 pH (V_{SHE}), irrespective of the passive and transpassive dissolution of cobalt.

8. The passive oxide films can be cathodically reduced to obtain an oxide-free cobalt surface. In borate solution at pH 6.48, the cathodic current of 5 μA/cm² reduces the outer Co_2O_3 layer to a Co_3O_4 layer, which is then reduced to Co^{2+} ions at the differential current efficiency η = 100% before the onset of the reduction of the inner CoO layer to metallic cobalt.

Characteristics of Immersion-Plated Gold Deposits on Aluminum

D. J. Levy* and D. H. Ma

Lockheed Palo Alto Research Laboratory, Palo, Alto, California 94304

ABSTRACT

An alkaline $KAu(CN)_2$ bath was developed for immersion (replacement) plating of adherent gold deposits on aluminum. The deposits grow in two stages: (*i*) initial attack of the aluminum oxide film at new sites and the formation of tiny gold nodules; followed by (*ii*) growth on the nodular deposits by the addition of long, crystalline needles of gold. Deposit weight increases with the log of time, log of gold concentration, and with bath pH. Deposition rates at ambient temperature of 0.3 μm/min or more are possible. The coatings, potentially useful as electrical contacts in a moisture-free environment, were evaluated for adhesion and contact resistance.

The natural oxide film on aluminum interferes with electrical contact to the basis metal. Gold contacts plated on the aluminum will obviate this problem. While the gold-aluminum galvanic couple could lead to serious corrosion problems in the ambient terrestrial environment, the potential corrosion problems are absent in space and in controlled environments. For example, aluminum wires have been bonded to gold conductor traces in semiconductor products for many years.

The technology for plating immersion (replacement) gold deposits on chromium, copper, lead, nickel, silicon, stainless steel, and tungsten has been summarized by Parker (1), but no literature references to immersion gold deposits on aluminum were found by the present authors. Gold is commonly electroplated on aluminum, but this is accomplished by a multilayer coating system after removing the oxide film and substituting a replacement coating of zinc or tin.

This paper describes a bath for the immersion plating of gold on aluminum. The deposit morphology and the effect of bath composition on deposition at ambient temperature are discussed. Gold deposits were evaluated for adhesion and electrical contact resistance and were compared with alternate materials.

Materials and Apparatus

Test specimens.—Types 1145 and 1235 aluminum foil (10-20 μm) were used as the substrate material. Composition is shown below.

	1145	1235
Al, min. w/o	99.45	99.35
Fe + Si, max %	0.55	0.65
Cu, max %	0.05	0.06
Mn, max %	0.05	0.00

A plating fixture was used that enabled plating of a 26 mm diam spot of gold on one side of a 36 mm diam aluminum disk.

Thickness.—Thickness of the gold deposit was measured by the beta-backscatter method with a Model 28 Micro-Derm using a carbon-14 source.

Contact-resistance.—Contact resistance was measured by a Wheatstone Bridge using a Leeds & Northrup Model 5205 resistance box. A cylindrical probe 10 mm diam, weighing 4g, and plated with high purity gold was used.

Adhesion.—The 180° peel tests were made with a polyimide tape coated with a pressure-sensitive acrylic adhesive. Adhesion to steel was rated at 30 oz/in. (33 g/mm) using ASTM D 1000.

pH.—An Orion Research Model 601 Digital Ionalyzer was used with glass and Ag-AgCl electrodes.

Oxide Stripping

Activation normally consists of removing the oxide film from a metal surface prior to plating. However, aluminum is very active electrochemically and the oxide film is rapidly reformed unless the active surface is immediately protected by a replacement film (*i.e.*, zinc, tin). Surface oxides will vary in thickness and character even on the same aluminum alloy depending on the prior history of the surface. It was desirable to start with a reproducible surface condition to evaluate immersion gold plating. Therefore the existing surface oxide was stripped from test specimens prior to plating so that the surface would have a reproducible, fresh, thin, hydrous oxide film.

Both alkaline and acidic solutions were evaluated for stripping the oxide. It was found that sodium hydroxide solutions effectively strip the oxide but they also attack the aluminum metal as evidenced by excessive etching and hydrogen evolution. In comparison, nitric acid merely dissolves the oxide film and does not appreciably attack the metal. The acidic solution is also free rinsing.

The gold plate thickness (Table I) is somewhat greater after stripping with nitric acid rather than sodium hydroxide, indicating that the fresh oxide film is thinner. Adhesion is also more reliable. Electrical contact resistance was not significantly different for any of the specimens tested.

The time necessary to strip an oxide film varies with the aluminum alloy and the condition of the oxide. As a general rule, 2-5 min in 250-400 g/l [25-40 v/o (volume percent), sp gr 1.42] nitric acid at ambient (15°-25°C) temperature is sufficient (2). The effectiveness of the acid to strip oxide films is diminished as

Table I. Effect of oxide stripping before immersion gold plating (5 g/l Au)

concentration is increased up to 500 g/l. Use of the oxide stripper is optional and depends upon the surface condition of the aluminum being processed.

Immersion Plating

After experimenting with several gold salts and observing no substantial differences, the common gold salt potassium gold cyanide, $KAu(CN)_2$, was selected for use in the alkaline plating solution. The increase in deposit thickness with time is shown in Fig. 1. The deposit is porous and not self-limiting in thickness. Therefore rather thick deposits can be produced although the deposition rate does diminish with time. Figure 1 shows that the equivalent thickness increases with the log of time. Equivalent thickness is that of a dense, continuous gold film of the same mass per unit area.

Figure 2 shows the effect of gold concentration in the plating solution on deposit thickness after plating 2 min. The deposition rate increases directly with the log of the gold concentration. Gold content of the bath should be at least 3 g/l Au in order to achieve good adhesion of the deposit at reasonable deposition rates. Higher concentrations are entirely satisfactory but are limited as a practical matter to minimize dragout losses. An upper limit of 5 or 6 g/l gold gives a suitable broad range for process control.

The principal parameter affecting deposition rate is pH. Figure 3 shows that the deposit thickness increases exponentially with pH. The hydroxyl ion functions by dissolving the hydrous aluminum oxide film and permitting the replacement reaction to proceed. A pH of at least 11.2 enables a satisfactory deposition rate. At a pH greater than 11.8, the substrate metal is attacked excessively and the resultant hydrogen evolution disrupts adhesion of the gold deposit.

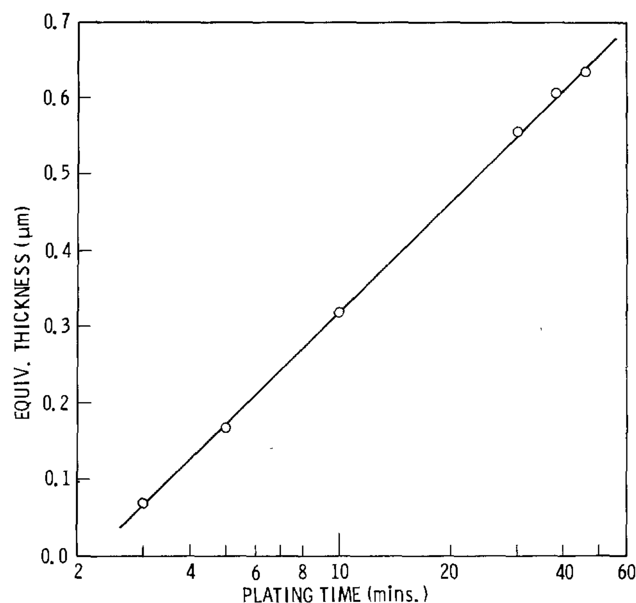

Fig. 1. Increase in gold thickness with plating time. 5 g/l gold at pH 11.8.

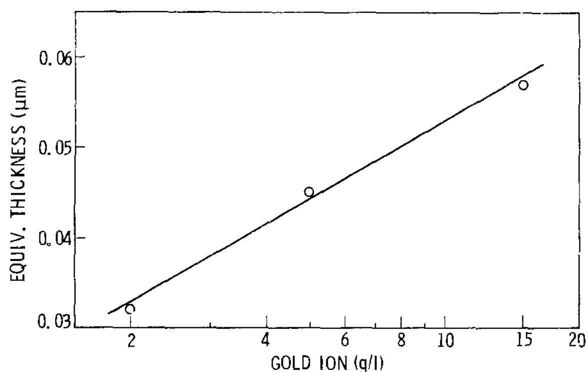

Fig. 2. Increase in deposit thickness with gold concentration. 2 min at pH 11.5.

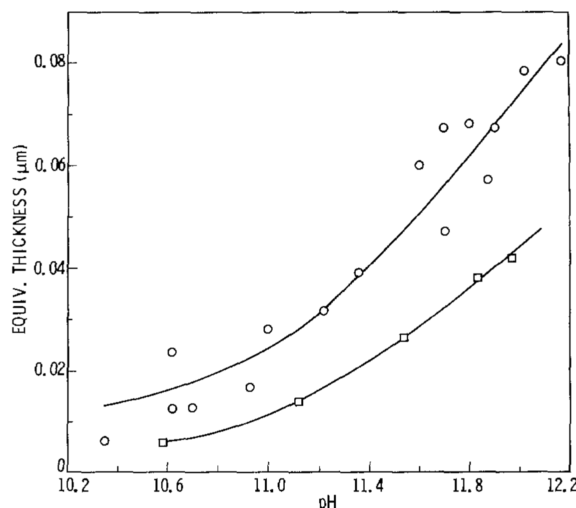

Fig. 3. Effect of pH on gold deposit thickness. 2 min plating time. 2 g/l Au, □; 5-7 g/l Au, ○.

The effect of both gold concentration and pH on average gold deposition rate can be seen in Table II. At 2 g/l Au, it was found that the gold deposits were no longer adherent when the deposition rate reached 0.10 μm/min. However, increasing the gold content to 7.0 g/l enables a deposition rate of at least 0.29 μm/min with good deposit adherence. The significant effect of pH to increase the deposition rate is also evident in the data. Average deposition rate during the plating period is listed in Table II; instantaneous rates are indicated in Fig. 1.

As the bath is used, the aluminum ion concentration will increase and eventually aluminum hydroxide will be precipitated. It is, of course, undesirable to have suspended solids present in a plating bath. A simple calculation shows that the solubility of aluminum hydroxide is only 0.06 and 0.25M at pH 11.2 and 11.8, respectively, based on the equilibrium dissociation reaction

$$Al(OH)_3 = H^+ + H_2AlO_3^- \qquad K = 4 \times 10^{-13}$$

In order to increase the bath life, a complexing agent was added. Sodium citrate was chosen because of its high solubility. A concentration of 60 g/l is very satisfactory. Addition of the citrate also increases the rate

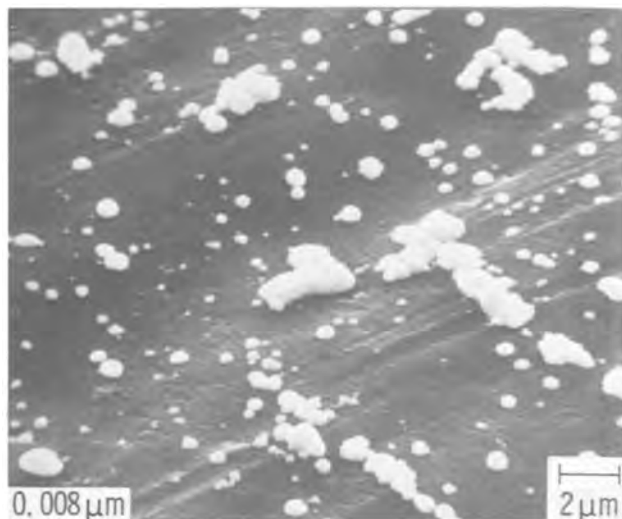
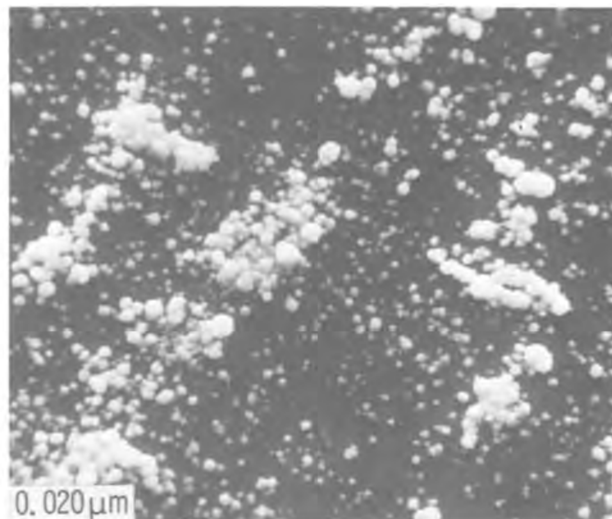
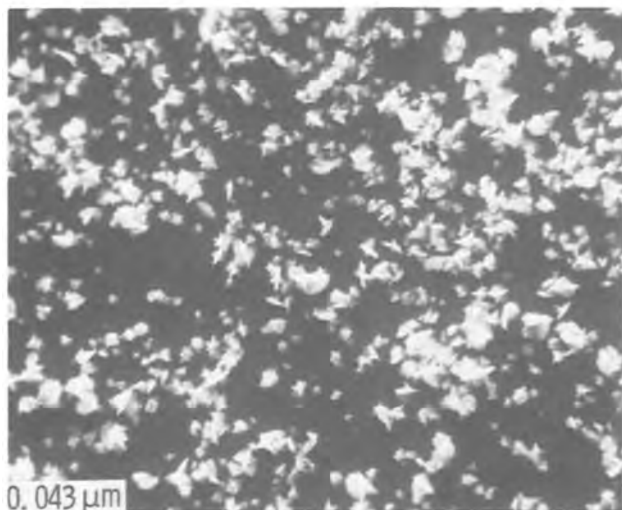
of gold replacement on the aluminum surface without any loss of adhesion. Furthermore, it creates a *p*H buffer system which slows the decrease in *p*H with solution use.

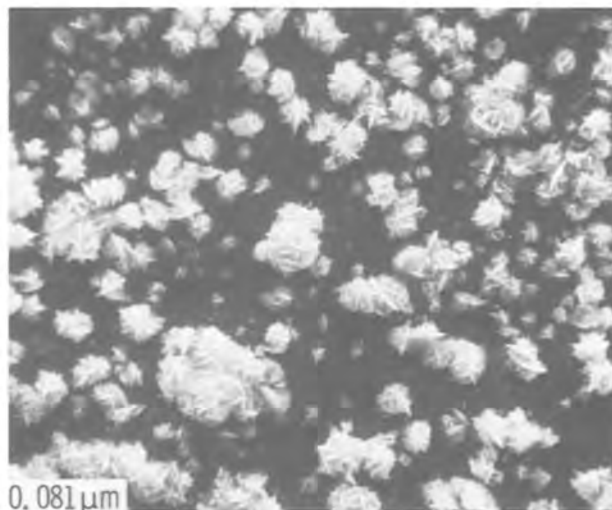
As the plating solution is used, free cyanide ions are released which compete with the citrate to form aluminum complexes. It was found by addition of sodium cyanide that the maximum concentration of free cyanide before the gold deposit becomes nonadherent is 6.8 g/l CN^-. In the absence of citrate, the tolerance for free cyanide is only 2.6 g/l. The plating bath was designed for convenience to be used at ambient temperature (15°-25°C) and the reaction was not studied at higher temperatures.

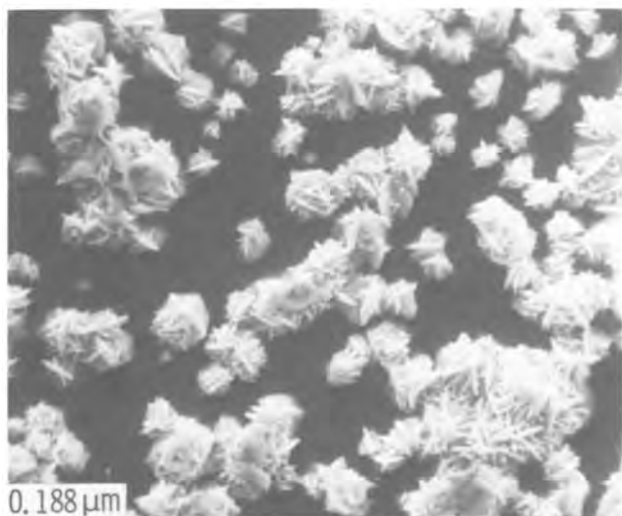
The principal half-reactions for the immersion plating are aluminum dissolution











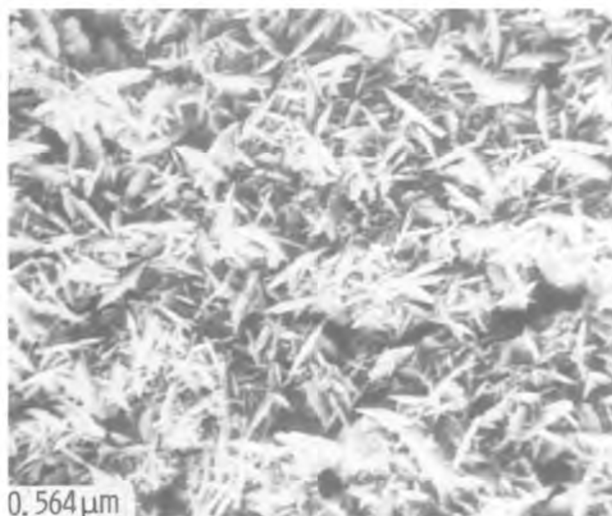


Fig. 4. Morphology of gold deposits. Original magnification 5000 times

$$Al + 4OH^- \rightarrow AlO_2^- + 2H_2O + 3e^-$$

and gold deposition

$$3Au(CN)_2^- + 3e^- \rightarrow 3Au + 6CN^-$$

Semibright to bright gold deposits are plated on 1235 Al in 1 min while a matte gold deposit forms on 1245 Al at a slower rate. However appearance differences had no effect on the measured electrical resistivity.

The suggested composition of the plating bath for immersion gold deposits on relatively pure aluminum is: potassium cyanoaurate (I), 3-5 g/l gold; sodium citrate, 30-60 g/l; pH (sodium hydroxide), 11.2-11.8; temperature, ambient (15-25°C).

Morphology

The gold deposits were examined by scanning electron microscopy. Figure 4 shows the appearance of deposits with an average thickness from 0.008 μm (0.3 μ-in.) to 0.56 μm (22 μ-in.) at 5000 times magnification. These photomicrographs reveal that a gold film of uniform thickness is not formed. Instead the alkaline plating solution attacks the oxide film on the aluminum surface only at specific sites where a tiny nodule of gold initiates. Growth takes place primarily by the formation of nodules at new sites until the amount of gold is equivalent to a film of about 0.02 μm (1 μ-in.) thickness. Further growth then takes place by the formation of long needles of crystalline gold with an aspect ratio of about 10. As the deposit grows, complete surface coverage is achieved at an equivalent thickness of 0.4 μm (15 μ-in.). At that point, some gold needles are as long as 2.5 μm.

Contact Resistance

Electrical contact resistance varies inversely with contact area and applied pressure in the region of relatively high resistance. When two test specimens are joined together in gold-gold contact by adhesive bonding around the perimeter of the gold deposit, contact pressure is essentially zero and contact resistance is found to decrease as the amount of immersion gold deposit is increased. Figure 5 shows that contact resistance is minimized at an equivalent thickness of about 0.04 μm (1.5 μ-in.). This is only 10% of the equivalent thickness required for complete coverage of gold over the aluminum surface.

Other techniques were used for creating an electrical contact on the cleaned aluminum surface, and the d-c resistance of these materials in face-to-face contact was monitored over a period of about six months in air. Comparative data is listed in Table III. The immersion gold deposit has an equivalent thickness of 0.1 μm. The brush-plated gold (electroclean, Cu strike, Ni strike, Au plate) rated high but evidently had some added electrical resistance due to the Ni strike. Most of the

other materials tested were electrically conductive coatings based on resins that are highly loaded with silver particles.

Summary

1. Immersion (replacement) gold coatings were deposited on relatively pure (99%) aluminum from an alkaline, cyanide gold plating bath at ambient temperature. Sodium citrate is added to prevent precipitation of aluminum hydroxide and thereby extend the bath life. Tolerance of the bath for accumulated free cyanide was also determined.
2. Metal deposition rate increases with gold content and pH of the plating bath. The maximum deposition rate before the coatings become nonadherent is proportional to the gold content. Coating thickness up to 2.5 μm and average deposition rates up to 0.3 μm/min were studied.
3. Nitric acid (250-400 g/l) at ambient temperature is effective in stripping the natural oxide on aluminum and substituting a fresh, thin, hydrous oxide film prior to plating. The use of this pretreatment is optional and dependent upon the condition of the oxide film on the aluminum surface.
4. The gold deposits are discontinuous and not limited in thickness. The alkaline plating bath penetrates the oxide film at specific sites and causes the nucleation of tiny gold nodules. Growth takes place primarily by the formation of nodules at new sites until the equivalent film thickness is about 200Å. Thereafter, the nodules grow by the formation of needle-like crystals, with an aspect ratio of about 10, until surface coverage is complete (equivalent thickness of 0.4 μm).
5. Immersion gold deposits on aluminum afford a potential means of making electrical contacts for use in environments where moisture is not present. Tests of the electrical contacts show that they exhibit a lower electrical resistance than that of a brush-plated gold or silver-filled resins.

Manuscript submitted March 20, 1978; revised manuscript received May 16, 1978. This was Paper 171 presented at the Pittsburgh, Pennsylvania, Meeting of the Society, Oct. 15-20, 1978.

"Polymer" Inclusions in Cobalt-Hardened Electroplated Gold

Y. Okinaka,* F. B. Koch, C. Wolowodiuk, and D. R. Blessington[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

When cobalt-hardened electroplated gold is dissolved in either aqua regia or mercury, carbon-containing inclusions are extracted. The chemical identity of the extracts is established here by a variety of chemical and physical analyses. The indiscriminate use of the word "polymer" to refer to both the original inclusions and the extracts is inaccurate. The "polymer" separated upon dissolution of the gold in aqua regia is not an organic material but a known cobalt cyanide compound with the formula $Co_3^{II}[Co^{III}(CN)_6]_2 \cdot xH_2O$. On the other hand, the extract obtained after dissolution in mercury was shown to contain $K_3Co^{III}(CN)_6$. Based on the observation of the two different extracts and the chemistry of the plating solution, the form of the original inclusions is proposed to be either a Co(II)- or Co(III)-cyanide complex. Additional analyses on the bulk gold and on the aqua regia filtrate led to the following conclusions: (*i*) There is an additional source in the gold deposit for both cobalt and carbon apart from the cobalt cyanide complex. (*ii*) For cobalt, this additional source is the substitutional metallic form. (*iii*) For carbon, the additional source is an as yet unidentified compound probably derived from cyanide ions but containing a C:N ratio greater than one. This compound may be the source of the carbon found in the aqua regia filtrate, and it may account for the extraordinary amounts of hydrogen found in hard gold deposits. (*iv*) Some cautions are necessary in the aqua regia analyses for Co and C because of the limited solubility of "polymer."

It is well documented that hard gold deposits formed in acid cyanide baths with a cobalt salt contain significant quantities of carbon, nitrogen, hydrogen, oxygen, and potassium in addition to cobalt (1-12). Since Munier's original work (1) in which a transparent film was isolated upon dissolution of the gold in aqua regia, it has been widely believed that some "organic polymer" is codeposited in the hard gold. However, the composition of this "polymer" has never been established, nor has the chemical reaction responsible for its formation been identified. A number of speculations have been advanced in the recent literature concerning the nature of incorporated materials. For example, Raub, Knödler, and Lendvay (7) list the following species as possible inclusions: cobalt cyanides, $K_6Co_2(CN)_{10}$, salts of $Co(CN)_5H^{-3}$ and $Co(CN)_5(OH)^{-3}$, H_2O, H_2 gas, AuCN, and K-Au-CN compounds. In their Mössbauer study, Cohen, West, and Antler (13) found no significant amounts of AuCN, $KAu(CN)_2$, or $KAu(CN)_4$ in hard gold. They then suggested that the CN in hard gold is either combined with cobalt or occluded in the plate without forming well-defined gold compounds. Reid (8) speculated that the following substances may be present: $Co(CN)_2$ (or its polymer), $Co(HCN)_4$, $(CN)(NH_2)C:C(NH_2)(CN)$, or the cobalt-coordinated polymer of this substance. More recently, Eisenmann (14) proposed the hypothesis that coordination compounds of cobalt with dicyanoaurate, such as $KCo[Au(CN)_2]_3$ and $Co[Au(CN)_2]_2$, are incorporated in the deposit, and that these compounds are responsible for various properties of the hard gold. The existence of such a variety of speculations without any support of hard analytical data clearly indicates a need for a more definitive work on the subject.

A recent investigation involving two of the present authors (10) has shown that cobalt-hardened gold deposits formed in citrate-based baths contain 5-9 atom percent (a/o) hydrogen. The nuclear analysis technique used would not distinguish between elemental hydrogen (either the dissolved form or gaseous bubbles in the gold) and a chemically combined form.

A Mössbauer study recently performed by Cohen *et al.* (15) has indicated that cobalt is incorporated in two different forms: metallic (*i.e.*, substitutional) and nonmetallic, and that the nonmetallic form is not $Co(CN)_2 \cdot 2.5H_2O$, which precipitates when equivalent amounts of Co^{+2} and CN^- ions are mixed together (16).

In the present investigation, a large amount of gold was plated under controlled conditions to extract the "polymer" in a quantity sufficient to carry out repetitive quantitative chemical analyses as well as x-ray diffraction and infrared spectroscopy examinations. Since it was thought probable that aqua regia may alter the composition of the inclusions because of its strong acidity and oxidizing power, the gold was also dissolved in mercury, and the residue analyzed by both chemical and physical methods. Based on the results of these experiments, an attempt was made to deduce chemical identities of the species in the as-incorporated form and chemical reactions which occur during the dissolution processes.

Experimental

Sample preparation.—Cobalt-hardened gold deposits were plated from a bath containing a potassium citrate buffer of pH 4.0, a cobalt(II) salt, and potassium cyanoaurate(I). The concentration ranges were essentially the same as those used in previous studies (9) (8.2 g/liter of Au as $KAu(CN)_2$, 110 g/liter citric acid, 50 g/liter KOH, and 0.1 g/liter Co as $CoSO_4$). Here, however, the gold concentration was increased approximately by a factor of two in order to allow the formation of bright, hard deposits at an increased current density. The bath was operated at 65°C and at a cathode current density of 50 mA/cm². A copper sheet cathode (1.5 × 1.5 × 0.002 in. or approximately 3.8 × 3.8 × 0.005 cm) was plated in a cell which was equipped with platinum sheet anodes and a magnetic stirrer and contained 3 liters of the plating solution. The concentrations of various bath constituents were maintained within about ±5% during plating using an automatic analyzer and controller designed

and constructed recently in this laboratory (17). A number of copper cathodes were plated successively with about 5g of gold on each. These plated cathodes were cut into small pieces and treated in aliquots of boiling 1:1 HNO_3 in order to dissolve away the copper completely. The complete removal of copper was confirmed by atomic absorption spectrometry.[2] The pieces of gold deposits thus obtained were thoroughly rinsed in boiling deionized water, dried at 110°C, and used in the experiments described in the subsequent sections.

Analysis techniques.—Chemical analyses were performed on the gold deposit itself as well as on residues and filtrates obtained in the aqua regia and mercury dissolution experiments described below. Potassium and cobalt in solutions were determined by atomic absorption spectrometry. In the aqua regia insoluble "polymer" residue, Co was determined by a gravimetric method involving ignition to Co_3O_4 or by the atomic absorption method after dissolution in a solution containing NaOH and NaCN. Carbon was determined either by the combustion technique[3] or by the wet persulfate method.[4] Hydrogen and nitrogen determinations were made using the standard microelemental analysis techniques.[3]

The extracts obtained after gold dissolution were also characterized by a number of physical analyses. These included (*i*) x-ray diffraction (by the Debye-Scherrer technique on extract powder contained in glass capillaries), (*ii*) infrared absorption (using a mull of the extract powders in mineral oil), and (*iii*) thermogravimetric analysis (to investigate both the reversible loss of water of hydration and the irreversible decomposition of the extract powders). The x-ray diffraction analyses were done with either Co or Cr radiation to avoid exciting cobalt fluorescent radiation from the sample. In order to check for the presence of trapped plating solution in the plated gold, the deposited foils (stripped from the copper substrate by 1:1 nitric acid) were subjected to differential scanning calorimetry.[5] By this method, the latent heat of fusion of any possible trapped solution would be detected as the temperature of the sample was cycled through the freezing point. A 10 mg sample of mercury on the reference pan provided a calibration of the observed signal in terms of millicalories from the heat of fusion.

Aqua regia extraction method.—About 20g of the gold deposit was carefully weighed and placed in a beaker containing 250 ml of 1:1 aqua regia. The contents were allowed to stand at room temperature overnight to achieve complete dissolution of the gold. After this treatment, the presence of an insoluble residue was evident on the bottom of the beaker. It was observed that a large portion of this residue retained the shape that the gold sample had before dissolution. After filtration through a preweighed, 0.2 μm, Millipore filter and thorough rinsing with water, the "polymer" had a distinct pink color. It was air-dried overnight at room temperature; at this point the weight was 40 mg. The "polymer" was then analyzed quantitatively for Co, C, H, N, Au, K, and water content. The entire plating-extraction process and analyses were repeated several times. An x-ray diffraction analysis and infrared spectroscopy were also carried out. The filtrate was diluted to 1 liter and analyzed for Co, C, and K.

Mercury extraction method.—The dissolution in mercury of the gold electrodeposits was carried out in an inert atmosphere to prevent oxidation by air of the mercury or any extracted compounds. To accomplish this, a closed, round bottomed, 50 ml flask with three ports was used. One port admitted flowing nitrogen gas, the second vented the nitrogen through a reflux tube, and the third held a thermometer. The exiting nitrogen was bubbled through water to prevent back diffusion of air. The flask, containing 5g of the gold and about 450g of mercury, was heated to 150°C in the flowing nitrogen atmosphere and held for 1 hr to insure complete dissolution. The flask was then cooled and a floating, gray powder extract was recovered from the surface of the mercury. A portion of this powder was removed with a stainless steel spatula and ground in a mortar and pestle to separate out most of the liquid mercury which was mixed in with the extract. During grinding, droplets of the liquid metal were formed and easily removed.

When the x-ray diffraction and *IR* identification of this extract indicated a water-soluble cyanide compound was present, the method of removing the extract from the surface of the mercury was modified. In this alternate extraction technique, 10 ml of water was introduced into the flask after the amalgam had cooled to room temperature. The sample was vigorously shaken to dissolve the extract and the resulting solution decanted off. This water addition procedure was repeated several more times to insure complete removal of the water-soluble component. The resulting solution was then diluted to a total volume of 100 ml and then chemically analyzed using procedures similar to those described above for the aqua regia extract.

Results and Discussion

Analysis of aqua regia extract.—Chemical analyses.—The results of quantitative analyses of the aqua regia "polymer" are listed in Table I along with calculated values for the composition of two likely compounds. An atomic absorption analysis of the "polymer" dissolved in an alkaline NaCN solution did not show the presence of K or Au. Compound (A) is $Co^{II}(CN)_2 \cdot 2H_2O$,[6] a simple pink cobalt(II) cyanide which was prepared and analyzed by Poskozim (16), while compound (B) is $Co_3^{II}[Co^{III}(CN)_6]_2 \cdot xH_2O$,[6] which was prepared and characterized by several investigators (18-20). Values ranging from 12 to 19 have been assigned to x, but a value of 16 was chosen here in agreement with Shriver and Brown (18, 19). There are three reasons why compound (B) is the more likely identification. First, the over-all composition of the "polymer" fits (B) considerably better than (A), especially for the cobalt content. Second, the reversible loss of water of hydration does not agree with that found by previous investigators (16) for (A). Finally, compound (B), hydrated cobalt(II) hexacyanocobaltate(III) is known to form upon mixing equivalent amounts of aqueous solutions of $CoSO_4$ or $CoCl_2$ and $K_3Co(CN)_6$ (18, 19) and also as an intermediate when aquo Co^{+2} ions are simply allowed to react with CN^- ions under certain conditions (20).

[6] A cobalt cyanide with the formula $Co(CN)_2 \cdot 2.5H_2O$ is also known (16). It is a gray compound, and its calculated composition does not agree with the observed values. Also, the Mössbauer spectrum of this compound did not agree with that of the "polymer" (15).

Table I. Elemental analysis of "polymer" extracted by aqua regia treatment

	% Found*	% Calculated	
		Compound (A) $Co(CN)_2 \cdot 2H_2O$	Compound (B) with $x = 16$ $Co_3[Co(CN)_6]_2 \cdot xH_2O$

[5] Du Pont Differential Thermal Analyzer, Model 900.

Moreover, compound (A) is apparently unstable and easily undergoes a partial oxidation to compound (B) (20, 21). For these reasons, it is concluded that the "polymer" is a well-defined cobalt compound (B) rather than (A) or an organic compound. It should be noted, however, that an unequivocal assignment of a number to x is not possible based on the elemental analysis alone because an equally good agreement between observed and calculated values is found with $X = 13\text{-}18$. Additional evidence supporting compound (B) for the "polymer" is described in subsequent sections.

X-ray diffraction and IR analyses of "polymer".—The result of an x-ray diffraction analysis is tabulated in Table II. The excellent agreement with the ASTM values listed for $Co_3[Co(CN)_6]_2 \cdot xH_2O$ and the values obtained with this compound prepared by mixing solutions of $K_3Co(CN)_6$ and $Co(NO_3)_2$, (called "synthetic polymer" in Table II) along with the chemical analysis results described above, can be considered as a conclusive proof for the proposed structure of the "polymer." The *IR* spectra of this compound showed a sharp absorption peak at 2180 cm^{-1} and a shoulder at 2130 cm^{-1} attributable to cyanide stretching and vibrations (20).

Thermal stability and loss of water of hydration of "polymer".—In repeated drying cycles, the pink polymer was heated to 110°C in an air oven and then allowed to cool and reabsorb moisture from the atmosphere. In each cycle the color changed to a bright blue in the dried form and then back to pink again as water was reabsorbed. The change of weight in drying determined by repeated weighings was a well-defined value of 19.8 ±0.5% of the original polymer weight. This value is in good agreement with the value of 20.1% calculated if compound (B) with $x = 16$ lost ten of its water of hydration molecules.

A more complete picture of the thermal stability was obtained by the thermogravimetric analysis shown in Fig. 1. This figure shows the loss in weight of the "polymer" in two stages of dehydration: the reversible loss discussed in the previous paragraph and a second stage of dehydration which occurs in the range 150°-450°C. The diffraction patterns obtained after both stages of dehydration showed very little difference from the original pattern reported in Table II; the same cubic pattern is obtained with only an increase of the lattice constant of less than 0.1%. After dehydration at 400°C, the "polymer" was black and remained black even after reabsorbing some moisture when exposed to ambient air at room temperature. The large loss in weight seen in the temperature range 450°-525°C corresponds to decomposition. The observed weight losses seen in Fig. 1 fit the values calculated from the formula weight of the compound $Co_3^{II}[Co^{III}(CN)_6]_2 \cdot xH_2O$ very well as indicated on the figure. The weight of the residue left at 525°C (after decomposition) is somewhat greater than the weight of the cobalt present; probably this residue is a combination of cobalt and cobalt oxide formed by exposure to the air.

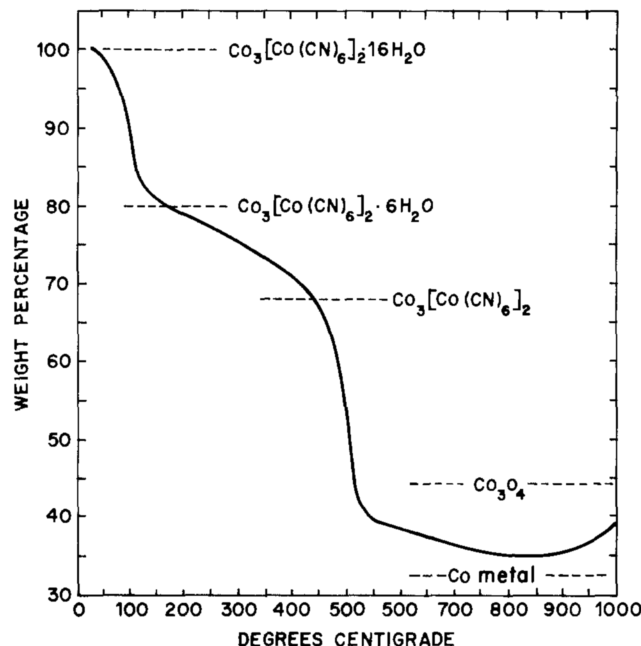

Fig. 1. Thermogravimetric analysis of "polymer"

Chemical analyses of aqua regia filtrate.—The aqua regia filtrate was analyzed for Co and C. The results are listed in Table III (first column) in weight percent (w/o) of deposit, in which the amounts of these elements found in the "polymer" are also tabulated. The sums of the amounts found in the "polymer" and in the filtrate are compared with the results of conventional deposit analyses, in which a small amount of gold deposit (<5 mg) was dissolved in 10 ml of 1:1 aqua regia and analyzed for Co by the atomic absorption method and for C by the persulfate method. Excellent agreement was obtained for both elements between the calculated sum and the total analysis result. It should be noted that this agreement can be expected only under the conditions where the "polymer" completely dissolves in aqua regia, because Co or C present in solid particles are not measured in the analytical techniques used. The solubility of the "polymer" in 1:1 aqua regia determined by the atomic absorption method was equal to 0.38 ppm as Co at room temperature. Thus, a simple calculation shows that for a deposit containing about 0.1 w/o of Co, the sample weight should not exceed about 4 mg per 10 ml of 1:1 aqua regia.

The comparison of analytical results for carbon in Table III is of great interest. The "polymer" contains only about 20% of the total carbon, the remainder being dissolved in the aqua regia. The question arises then as to the identity of the compound containing

Table III. Analysis of aqua regia filtrate, "polymer", and gold deposit for Co and C (results are expressed in weight percent of deposit)

	Filtrate	"Polymer"	Filtrate + "polymer"	Deposit
Co(%)	0.037	0.065	0.102	0.11 ± 0.02

C(%)	0.034	0.13	0.16
N(%)	0.036	0.049*	0.085
C:N	1:0.91	1:0.32	1:0.46

* Calculated as difference since N is masked by NO_3^- in aqua regia.

the filtrate carbon. In this respect, it is of interest to compare the molar ratios of carbon to nitrogen in the "polymer," filtrate, and deposit (Table IV). The C to N ratio in cobalt-hardened gold deposits has been extensively investigated by Raub, Knödler, and Lendvay (7), who found that it ranges from 1:0.47 to 0.62. The ratio that we found, 1:0.46, is thus similar to these previously reported values. In the "polymer," the ratio found was 1:0.91 (±0.07), the deviation from 1:1 being considered as an experimental error. These values yield a C/N ratio of 1:0.32 (≃3:1) for the substance dissolved in the filtrate.[7] Thus, it appears that the filtrate soluble compound is not a simple polymer of HCN, such as $(HCN)_4$, which has been said to form at the anode in the plating bath and codeposit with gold (22). Free cyanide ions will not survive in aqua regia and gold cyanide species do not seem to exist. Further work is needed to identify this C-containing compound.

The filtrate was also analyzed for K. All K was in the filtrate, and the K content of this particular gold deposit was found to be 0.08 w/o.

Analysis of mercury extract.—The identification of the "polymer" from the aqua regia extract leaves the question as to whether the "polymer" itself is the compound incorporated in the deposit, or whether it is a product formed from other materials as a result of a reaction in aqua regia. A Mössbauer spectroscopic study carried out by Cohen *et al.* (15), showed that the spectrum of the aqua regia extracted "polymer" does not agree with that of the cobalt-containing species recorded with the gold deposit itself. Clearly, the "polymer" is a product of some chemical reaction(s) occurring during the dissolution in aqua regia. The mercury dissolution experiment was performed in the hope that the included materials might be extractable without being altered chemically.

The mercury-insoluble material which floated on the surface was analyzed chemically after extraction in water and by x-ray diffraction before the extraction. Duplicate dissolution/extraction experiments gave the following results (weight percent of the deposit): K, 0.081 ± 0.002; Co, 0.047 ± 0.001; C, 0.063 ± 0.002; and Au, 0.013 ± 0.001. These values yield the molar ratio K:Co:C:Au = 2.6:1:6.6:0.08, which is indicative of the formula $K_3Co(CN)_6$. Evidently, gold is not a major component of the water-soluble material.

[7] The contribution of the solubility of the "polymer" (0.38 ppm Co or 0.19 ppm C) is negligible as compared to 26 ppm C found in the filtrate.

* ASTM 15-586.

The x-ray diffraction lines observed are summarized in Table V. The lines could be indexed only as originating from potassium hexacyanocobaltate(III), $K_3Co(CN)_6$. Based on this result together with the chemical analysis results, it is concluded that the water-soluble cobalt compound remaining after the mercury dissolution is $K_3Co(CN)_6$.

An attempt was made to analyze the water-insoluble residue and the gold amalgam for cobalt and carbon, but difficulties were encountered in quantitatively separating the residue from mercury and in determining a small amount of cobalt in the large amount of mercury. Qualitatively, however, the results showed that the water-insoluble residue contained carbon and a trace of cobalt, while a much greater amount of cobalt was present in the mercury. It appears that the unidentified C-containing compound is largely insoluble in water, and that the mercury contains metallic cobalt in the form of a two phase mixture or an amalgam.

Relationship between aqua regia and mercury extracts.—The amount of aqua regia or mercury extracts observed is too great to result from simple physical entrapment of plating solution;[8] it must therefore result from some more active chemical process of inclusion. On the basis of the results presented in the preceding sections and the additional considerations of the chemistry of the cobalt-cyanide system described below, an attempt is made here to formulate a reaction scheme for the incorporation and extraction processes. The gold deposition reaction generates cyanide ions at the cathode surface

$$Au(CN)_2^- + e \rightarrow Au + 2CN^- \quad [1]$$

At the low pH(≃4) of the plating solution, the CN^- ions readily combine with H^+ to form HCN ($H^+ + CN^- \rightleftharpoons HCN$; $K = 2.5 \times 10^9$ (23)). Simple calculations show that the total cyanide ($CN^- + HCN$) concentration at the cathode surface is in great excess over the concentration of cobalt under the ordinary plating conditions. For example, taking a limiting reduction current of about 4 mA/cm^2 for 0.0045M $KAu(CN)_2$ under moderate agitation conditions (24), and for a typical bath containing 8.2g of Au/liter (≡0.042M) and a plating current of 10 mA/cm^2 with about 40% current efficiency, the surface concentration of cyanide ($CN^- + HCN$) is estimated to be 0.023M. On the other hand, the cobalt concentration at the surface must be less than the bulk concentration (100 ppm or 0.0017M). Under the conditions of high speed plating, the difference between cyanide and cobalt concentrations becomes even greater because of the higher plating current. In view of the presence of such a large excess of cyanide and the high stability of Co(II)-cyanide complexes (25), it is reasonable to assume that the aquo Co^{+2} ions originally present in the bath form anionic cyanide complexes at the cathode surface. It is also apparent from the results of a Mössbauer study (15) and the aqua regia dissolution experiment that part of the cobalt is reduced to the metallic state to form an alloy with gold, while the remainder is incorporated in the deposit in some form of cyanide compound.

Two known Co(II)-cyanide ions are $Co^{II}(CN)_4^{-2}$ and $Co^{II}(CN)_5^{-3}$ (or their hydrated forms) (26-28). Both of these ions have been shown to adsorb strongly on mercury (28). In the presence of excess cyanide $Co^{II}(CN)_5^{-3}$ is likely to be predominant. The

[8] Differential scanning calorimetry was unable to detect any latent heat of freezing from trapped plating solution in the gold deposit. Calibration with a 10 mg droplet of mercury established that a peak of 10^{-3} cal in the 100 mg sample would have been observed corresponding to an upper limit of 10^{-2} w/o trapped plating solution. The contribution of plating salts from such a small volume of solution (10^{-3}-10^{-4} w/o) is negligible compared to the amounts of extract actually observed (Tables III and IV).

$Co^{II}(CN)_6^{-4}$ ion, which appears in the older literature, apparently does not exist in aqueous solutions (21). The $Co^{II}(CN)_5^{-3}$ ion is known to undergo oxidation to $Co^{III}(CN)_6^{-3}$ when excess cyanide is present either due to dissolved oxygen or by the reaction (21)

$$2Co^{II}(CN)_5^{-3} + 2CN^- + 2H_2O \rightarrow 2Co^{III}(CN)_6^{-3} + 2\,OH^- + H_2 \quad [2]$$

One may inquire when the transition from Co^{II} in the plating solution to Co^{III} in the extracts occurs. Under these circumstances, two possibilities are conceivable: (*i*) cobalt is incorporated as $Co^{II}(CN)_5^{-3}$ along with CN^- and H_2O, and it is oxidized to $Co^{III}(CN)_6^{-3}$ during the aqua regia or mercury extraction process, or (*ii*) the oxidized ion, $Co^{III}(CN)_6^{-3}$, is the incorporated species. In either case, the anions must attract cations as counterions to maintain electroneutrality, and therefore K^+ ions can be incorporated with the anions. Cohen *et al.* (15) made an attempt to identify $K_3Co^{III}(CN)_6$ in the gold deposit by Mössbauer spectroscopy, but no straightforward conclusion could be drawn because of the complex nature of the spectrum of this compound. Additional work would be necessary to distinguish the two possibilities mentioned above, but for practical purposes it is perhaps immaterial whether the cobalt is present in the divalent or trivalent form. From all of the considerations discussed above, the reactions at the gold surface and subsequent incorporation of cobalt species can be summarized as shown in the first two columns of Fig. 2. For the sake of simplicity, we shall assume in subsequent discussions that $Co^{III}(CN)_6^{-3}$ is present in the deposit.

When the deposit containing $Co^{III}(CN)_6^{-3}$ and metallic cobalt alloyed with gold is dissolved in mercury, a salt of this ion is isolated. The alloyed cobalt is probably present as a finely divided suspension in the mercury rather than a true amalgam as discussed by Hansen (29). These reactions are shown in the third column of Fig. 2.

When the deposit is dissolved in aqua regia, the metallic cobalt forms the divalent aquo cobalt ion, which combines with $Co^{III}(CN)_6^{-3}$ to produce a precipitate of $Co_3^{II}[Co^{III}(CN)_6]_2 \cdot xH_2O$, now identified as the "polymer." These reactions are depicted in the last column of Fig. 2. It should be noted that only two out of the five cobalt atoms in this compound result from the cobalt-cyanide species in the deposit, the remainder originating from the alloyed cobalt. In Table III, it was shown that the total cobalt content of the "polymer" corresponded to 0.065% of the deposit sample. Out of this, only 0.026% originated from the cyanide complex. The amount of cobalt which was present as the gold alloy is then the sum of the difference between these two values and the cobalt content found from the filtrate (0.037%, Table III). Thus, the cobalt from the alloy corresponds to

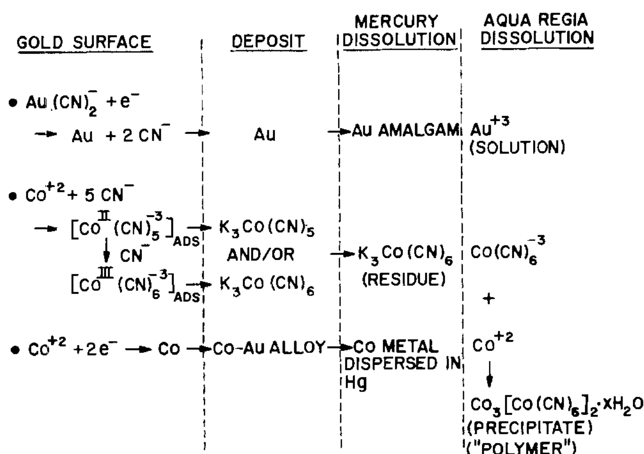

Fig. 2. Reaction paths of gold, cobalt, and cyanide

(0.065-0.026) + 0.037 = 0.076% of the deposit, and the ratio of the two types of cobalt (cyanide complex/alloy) becomes approximately equal to 1:3 in agreement with Mössbauer studies by Cohen *et al.* (15). Reid (8) reported that only about one-sixth of total cobalt is associated with this "polymer." This difference may well be due to the greatly different plating conditions used. Effects of plating conditions and bath age on the content of the two kinds of cobalt (and carbon) are currently being investigated in order to obtain understanding of the effect of the incorporated species on the properties of the deposit.

Relationship between inclusions, structure, and physical properties.—Okinaka and Nakahara (9) previously made a transmission electron microscopic (TEM) study of hard gold deposits, in which such deposits were shown to contain a large number of nonmetallic inclusions measuring about 25-70Å. In the absence of the knowledge concerning the composition of these inclusions, it was assumed that these objects represented molecules and agglomerates of the "polymer." The present study shows that the aqua regia "polymer" is a cobalt compound formed in the process of dissolving the deposit and that it does not exist in the as-plated deposit. We believe that the nonmetallic objects observed in the TEM study are perhaps molecules or agglomerates of the as-yet unidentified C-containing species, which accounts for part of the total carbon content as described in the preceding section. At present, however, the alternative that these objects are pockets of hydrogen gas has not been eliminated. More work needs to be done to identify this substance.

It is generally recognized that all hard gold deposits consist of very fine grains (100-500Å). Such fine grains result from the fact that nucleation is favored over crystal growth during the deposition process. It may be speculated that the adsorption of Co-cyanide complex on the gold surface inhibits the grain growth, bringing about the hardness of the deposit. This view is consistent with the work done by Lo and Pinnel (30) which shows that the hardening by alloying with cobalt is not sufficient to account for the observed hardness of hard gold deposits, and that the grain refining is the major factor contributing to the hardness.

Summary and Conclusions

1. Results of this investigation conclusively show that two kinds of cobalt and two kinds of carbon exist in the cobalt-hardened gold deposit. Cobalt is present partly in the form of an anionic Co(II) or Co(III)-cyanide complex in an adsorbed state and partly in the form of a gold alloy. Carbon is present partly in the above complexes and partly as an unidentified compound.

2. The so-called "polymer" isolated upon dissolution of the deposit in aqua regia has been found to be a cobalt compound with the formula $Co_3[Co(CN)_6]_2 \cdot xH_2O$, which apparently forms upon combination of the Co^{+2} ions from the alloyed cobalt and the $Co(CN)_6^{-3}$ ions. The latter may be originally in the deposit or may form from $Co^{II}(CN)_5^{-3}$ and CN^- during the dissolution process.

3. The residue obtained on dissolution of the deposit in mercury contains $K_3Co(CN)_6$.

4. In carrying out the conventional analysis of the deposit for total cobalt after dissolution in aqua regia, it is important to use a minimal amount of the gold (~4 mg in 10 ml of 1:1 aqua regia) to insure complete dissolution of cobalt because of the limited solubility of the cobalt compound.

5. Customarily, only total Co and C are analyzed with relatively small amounts of samples. Without the knowledge of the role of the two different types of each element, attempts to correlate results of the total analyses with deposit properties may be futile. More work is required to differentiate the functions of the two types of cobalt and carbon.

Acknowledgments

We are grateful to L. N. Schoenberg, R. L. Cohen, and R. Sard for discussion of the results of this study and to P. K. Gallagher for his assistance with the thermogravimetry and differential thermal analysis.

Manuscript received May 8, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1979 JOURNAL. All discussions for the June 1979 Discussion Section should be submitted by Feb. 1, 1979.

Publication costs of this article were assisted by Bell Laboratories.

Fluorenone Derivatives as Electron Transport Materials

The Relationship of Electron Affinity and Electrochemistry with Photoelectric Behavior

James E. Kuder, John M. Pochan, S. Richard Turner, and DarLyn F. Hinman

Xerox Corporation, Joseph C. Wilson Center, Webster, New York 14580

ABSTRACT

Electrochemical and charge transfer studies were used to determine the electron affinities (EA) of fifteen electron acceptor compounds. The behavior of these materials as electron transport species was evaluated by the photoinduced discharge curve (PIDC) method. The relation between the PIDC results and such electrochemical information as reversibility of the charge transfer step and polarization effects is discussed and it is shown that irreversible electrochemistry correlates with deep trapping phenomena. In addition, the results are discussed in terms of a simple model which relates electron affinity to charge carrier mobility.

Electrical conduction in organic solids is a widespread phenomenon whose implications extend from biological processes to such technological applications as electrophotography. The latter, in particular, has stimulated considerable research activity, including the study of disordered amorphous systems which consist of solid solutions of hole or electron transporting materials in various binders (1-5). A key question in any of these studies is to what degree the properties of the isolated molecules are reflected in the observed electrical transport behavior of the composite solids.

Unfortunately, the answer is not straightforward, in part because of the limited degree of variation in molecular properties reported in any given study. In one such study, an apparent correlation was observed between xerographic discharge rate and the reduction potential of the guest compound in a poly(vinylcarbazole) matrix (6). Another literature example cites a qualitative trend between the electron affinity of the acceptor compound and dark decay in complexes of dibenzothiophene and various fluorenone derivatives (7). At higher electron affinities the dark decay masked any contribution of the acceptor compound to the photocurrent.

In molecularly doped systems charge transport is thought to be due primarily to hopping of holes or electrons between active sites. On a molecular basis this may be regarded as the acquiring of charge by a neutral species in the charge injecting step

$$M + e^- \rightarrow M^-$$

and the exchange of charge between identical species

Key words polymers, photoconductivity, polarography, semiconductor, voltammetry, mobility.

in the transport step

$$M^- + M \rightarrow M + M^-$$

It might also be expected that with certain molecules the process described above might lead to an unstable chemical species which affects the ultimate electrical properties of the system, *i.e.*

$$M^- \rightarrow P$$

where P may be a charge trapping species.

Since the steps described above are similar to those that take place in an electrochemical experiment, a correlation between the electrochemical behavior of the dopant and its observed transporting properties might be expected.

In the following, we describe the results of such a study where the electrochemical properties of a series of substituted fluorenones and other materials thought to be active electron transporting materials are compared with their transport properties in a polymeric matrix. Additionally, the electron affinities (EA) determined via electrochemistry and charge transfer spectra are correlated with a proposed theory of transport as well as the observed transport properties of the materials dispersed in a polymeric matrix.

Experimental

Synthesis.—Synthesis of new acceptor compounds are described below. Others were either commercially available or were prepared by published techniques. Melting points are uncorrected.

4,5,7-Trinitrofluorenone-2-carboxylic acid chloride.—A 200 ml round-bottomed flask was charged with 10.0g (0.028 mole) of 4,5,7-trinitrofluorenone-2-carboxylic acid prepared by the method of Sulzberg and Cotter (8). To this 150 ml of thionyl chloride were added and the stirred mixture brought to a gentle reflux for approximately 8 hr. After a couple of hours the slurry dispersed to a clear brown-yellow solution. After cooling, the thionyl chloride was removed on a rotary evaporator and the yellowish solid that resulted was recrystallized from toluene to bright yellow crystals. Washing and stirring with hot hexane changed the color to a pale yellow, presumably by destroying the toluene-TNF complex. The yield of this solid was 7.3g (69.5%) after drying at room temperature under vacuum (mp 197°-199°C). Anal. Calcd. for $C_{14}H_4N_3O_8Cl$: C, 44.50; H, 1.00; N, 11.10; Cl, 9.20. Found: C, 44.52; H, 1.23; N, 10.92; Cl, 8.90.

n-Butyl-4,5,7-trinitro-9-fluorenone-2-carboxylate.—Into a 250 ml Erlenmeyer flask were placed 10.03g (0.026 mole) of 4,5,7-trinitro-9-fluorenone-2-carboxylic acid chloride and 100 ml of tetrahydrofuran. This was stirred via a magnetic stir bar until solution was effected. Triethylamine 0.28g (0.026 mole) dissolved in 20 ml of THF was added slowly to the reddish brown solution. Some cloudiness was noted. To this solution n-butanol 2.12g (0.029 mole, 10% excess) dissolved in 20 ml of THF was added dropwise. Precipitation was noted to occur during the course of the 1.5 hr reaction time. The insoluble triethylamine hydrochloride was removed by filtration (theoretical amount 3.6g, obtained 3.3g) and the THF solution carefully evaporated, using 35°C or less temperature, on the rotary evaporator. The yellow oil formed was dissolved in 75 ml of benzene and chromatographed on a silica gel column. The first fraction, 10 ml of yellow material, was discarded. The center fraction was taken, concentrated to about 50 ml and precipitated into stirring hexane. A very light yellow powder was obtained (6.0g, 54.5% yield) (mp range 115°-130°C). NMR ($CDCl_3$) δ 0.8-2.0 (m,7H,-CH_2-CH_2-CH_3), δ 4.5(t,2H,-O-CH_2-), δ 8.8 (m,4H, aromatic). Anal. Calcd. for $C_{18}H_{13}N_3O_9$: C, 52.10; H, 3.13; N, 10.15. Found: C, 51.88; H, 2.99; N, 10.28.

n-Dodecyl-4,5,7-trinitro-9-fluorenone-2-carboxylate and ethyl-4,5,7-trinitro-9-fluorenone-2-carboxylate.—These preparations were identical to the n-butyl TNF, except dodecyl or ethyl alcohol were used. Anal. (Dodecyl): Calcd. for $C_{26}H_{29}N_3O_9$: C, 59.20; H, 5.50; N, 7.96. Found: C, 59.77; H, 5.34; N, 8.27. Anal. (Ethyl): Calcd. for $C_{16}H_9N_3O_9$: C, 49.60; H, 2.32; N, 10.85. Found: C, 49.49; H, 2.39; N, 10.79.

2,4,7-Trinitro-9-fluorenylacetate and 2,4,7-trinitro-9-fluorenyl butyrate.—The esters were prepared according to the method of Colter and Wang (9) by esterification with 9-diazo-2,4,7-trinitrofluorene. Acetic acid, 80 ml, and 9-diazo TNF 3.3g (0.01 mole) were refluxed for 2 hr. After cooling, a yellow solid was removed by filtration, rinsed with ethanol, and then recrystallized from acetone. The yield was 2.3g (69%) with a melting point of 237°-240°C.

The butyrate was prepared in a similar fashion. The crude product was recrystallized twice from carbon tetrachloride to yield a solid of mp 145°-146°C. Anal. Calcd. for $C_{17}H_{13}N_3O_8$: C, 52.71; H, 3.36; N, 10.85. Found: C, 52.95; H, 3.51; N, 10.52.

Measurements.—All electrochemical measurements were made using the PAR 170 Electrochemistry System in the three-electrode mode. Sample concentrations were $5 \times 10^{-4}M$ with $0.1M$ tetraethylammonium perchlorate (TEAP, Southwestern Analytical Chemicals) as supporting electrolyte in acetonitrile (AN, Burdick and Jackson, dried over 4A molecular sieves, then percolated through a column of Grade I neutral alumina). For d-c and a-c polarography a dropping mercury electrode (DME) was used with the following capillary characteristics: $m = 1.50$ mg/sec, $t = 4.2$ sec when measured with an open circuit at $h = 80$ cm. For cyclic voltammetry (CV) a Beckman platinum disk or hanging mercury drop served as the working electrode. Potentials are referred to the saturated calomel electrode (SCE).

Ultraviolet visible spectra for use in electron affinity correlations were recorded on mixtures of 0.1 molar N-ethylcarbazole with 0.001 molar acceptor. In cases where the acceptor compound absorbed in the visible region of the spectrum, the 0.001 molar solution was run as a reference in order that only visible charge transfer could be measured.

The electron acceptor compounds were evaluated by the photo-induced discharge curve (PIDC), see following, mode of testing (10) in a variety of matrices: LEXAN® (bisphenol A polycarbonate), polysulfone, and poly(N-vinylcarbazole) (PVK). Some of the materials could not be tested because of poor solubility characteristics. Most of the PIDC studies were conducted on solution cast films (10-15 μm thick) of the test materials on 0.5 μm amorphous Se films. In cases where strong charge transfer complexes were formed (with mixtures of acceptor in PVK) and the samples were highly colored, the materials were cast onto aluminum sheets and coated with 0.5 μm amorphous Se films. When tested in PVK, acceptor concentrations were kept constant so that effective intermolecular distances for transport were constant (2, 4).

Results and Discussion

Voltammetry.—The compounds studied are shown in Fig. 1. Their voltammetric behavior is discussed below. The compounds are divided into four groups according to structure.

The fluorenones, I-VI.—The voltammetric curves for TNF (III) shown in Fig. 2 illustrate the electrochemical response typical of these compounds. The d-c polarograms of the fluorenones show two reduction waves whose average separation is 0.30V. Both waves correspond to reversible one-electron transfer processes as evidenced by the following criteria: (*i*) The diffusion current constants I_d obtained from the d-c polarograms are in reasonable agreement with the value of 2.6 ex-

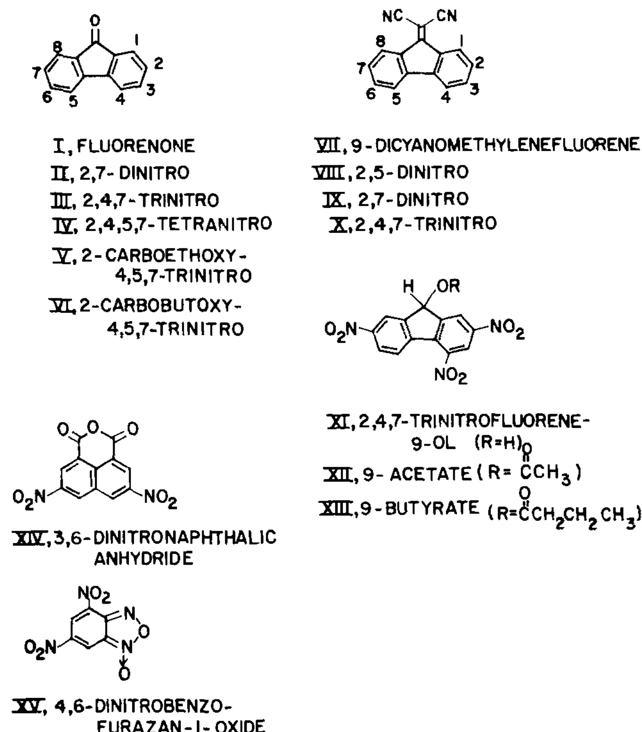

Fig. 1. Chemical structure of electron transport materials studied

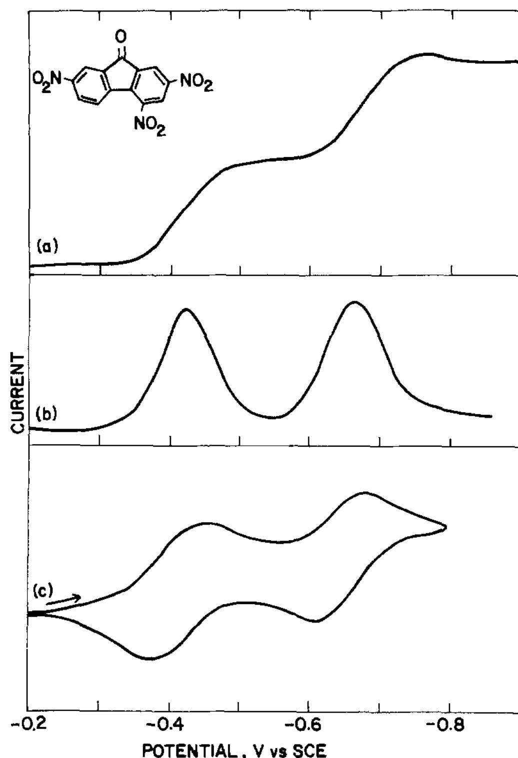

Fig. 2. Current-potential curves for 2,4,7-trinitrofluorenone: (a) d-c polargram, (b) a-c polarogram, (c) cyclic voltammogram.

pected for a one-electron process in acetonitrile (11). (*ii*) The quantity $|E_{3/4} - E_{1/4}|$ describing the slopes of the d-c wave are within 5 mV of the value 56 mV required by theory (12) for a reversible one-electron transfer. (*iii*) The peak potentials in the a-c polarograms are in good agreement with the d-c half-wave potentials and the peak half-widths are within 10 mV of the value 90 mV required by theory (13). (*iv*) The cyclic voltammograms show a reversible response, with separation of 78 mV between cathodic and anodic peak potentials, independent of scan rate (14). The reduction product formed at the working electrode has an intense color which ranges from red for fluorenone (I) to purple for compounds V and VI.

The 9-dicyanomethylenefluorenones (DCMF), VII-X.—The polarograms of these compounds also show two waves which correspond to reversible one-electron transfers as demonstrated by the criteria indicated above. For the DCMF compounds, however, the separation between the two waves averages 0.58V, *i.e.*, somewhat greater than that observed for compounds I-VI. Again, the reduction products are intensely colored, although the yellow color of the neutral species makes it difficult to describe the colors from visual observation.

The 2,4,7-trinitrofluoren-9-ols, XI-XIII.—These compounds are derived from 2,4,7-trinitrofluorenone (III) via chemical reduction of the carbonyl group. The first reduction waves of these compounds in the d-c polarograms are rather drawn out and the peaks in the a-c polarograms are broader and have lower peak currents than expected for reversible processes. The CV traces on these compounds indicate that the initial electron transfer is irreversible, although at more negative potentials (−1.14 and −1.35V) reversible reduction steps (possibly associated with the nitro groups) are seen. The cause of irreversibility is not known, but may be associated with bond cleavage at the 9-position as has been reported for other 9-substituted fluorenones (15).

3,6-Dinitronaphthalic anhydride and 4,6-dinitrobenzofurazan-1-oxide.—The d-c polarogram of the napthalic anhydride (XIV) shows two well-defined reduction waves, whose diffusion current constants indicate that each involves one electron. In the a-c polarogram the peak corresponding to the first d-c wave is preceded by a smaller peak suggestive of a nonfaradaic adsorption process.

As shown in Fig. 3, reversibility of the first reduction step depends on the nature of the working electrode. At a hanging mercury drop electrode a reversible charge transfer response is observed by CV, and the ratio of the anodic to cathodic peaks (1:17) suggests adsorption of the neutral species (16). At a platinum electrode, however, the CV response of XIV is clearly irreversible and the cathodic peak potential appears at −0.52V, some 0.2V more negative than the potential associated with reduction at a mercury electrode. Thus, there is some specific interaction of XIV with the mercury electrode, whose effect is not only to facilitate reduction relative to that observed at a platinum electrode but also to render the charge transfer process reversible.

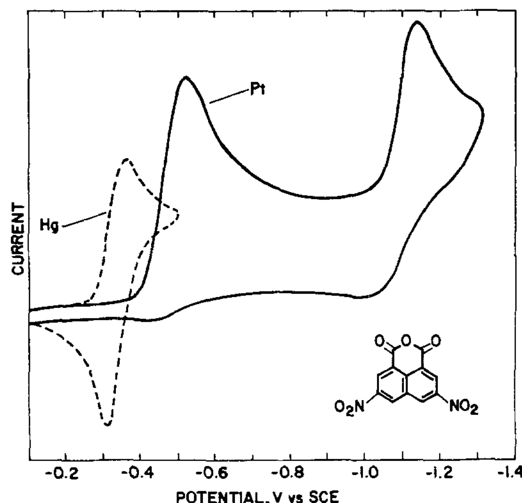

Fig. 3. Cyclic voltammograms of XIV at planar platinum electrode (solid line) and hanging mercury drop electrode (dashed line).

Compound XV, the last of the series, is the most easily reduced. Based on the diffusion current constant, the reduction involves one electron. All criteria show this to be an irreversible process. For both XIV and XV irreversibility is probably associated with cleavage of heteroatom bonds following the initial electron transfer.

Effect of structure on ease of reduction.—The half-wave potentials of compounds I-XV are shown in Table I, and for the present purpose attention is drawn to the reduction potential of the first wave. In the fluorenone series (I-IV) the ease of reduction is increased by an average of 0.28V per nitro group (as shown in Fig. 4). The attachment of a carboalkoxy group (compounds V and VI relative to III) results in a positive shift of 0.14V. The replacement of the carbonyl oxygen atom by the more electronegative dicyanomethylene group (I *vs.* VII, etc.) increases ease of reduction by 0.64V. In the DCMF series (VII-X) the ease of reduction is increased by 0.22V per nitro group on the average (Fig. 4). That the effect of nitrosubstitution is greater in the fluorenone series than in the DCMF series is in agreement with the observation of Zuman (17) that substituent effects are greater as the reduction potential of the parent compound is more negative; in other words, substituent effects are greatest in systems that are most difficult to reduce.

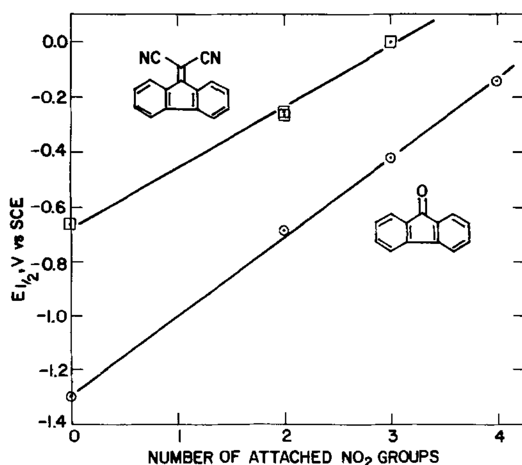

Fig. 4. Half-wave potential as a function of attached nitro groups for 9-fluorenone and 9-dicyanomethylenefluorenone.

In the fluorenol series (XI-XIII) the reduction potential is essentially unaffected by the group attached to the oxygen atom at the 9-position. Compounds XIV and XV are, of course, structurally unrelated to any others in the series, and ease of reduction could not have been predicted short of actually doing the voltammetric experiment.

Effect of solvent on half-wave potential.—In addition to the studies using AN as solvent, reduction potentials of 2,4,7-trinitrofluorenone (III) were obtained in the following solvents: propylene carbonate (PC), dimethylformamide (DMF), and dimethylsulfoxide (DMSO). In all cases two reversible one-electron reduction waves were seen. However, as shown in Table II, the measured half-wave potentials vary greatly from one solvent to another. Such solvent-induced shifts in $E_{1/2}$ have been discussed by a number of workers (18) and may include contributions from differences in liquid junction potential, ion pairing effects, and interactions of the solvent with the species undergoing the redox reaction, *i.e.*, changes in polarization.

These difficulties can be avoided in principle by referring all measurements to the reversible half-wave potential of a redox couple which does not interact with solvent and is, therefore, unaffected by a change in solvent. One such reference couple is bisbiphenylchromium (I) (BBCr), recently proposed by Duschek and Gutmann (19). The half-wave potentials of BBCr in the solvents used to study compound III are also given in Table II; relatively small shifts with solvent are seen for BBCr relative to III. The relatively large shifts in $E_{1/2}$ for III may then be assumed to be due to specific interactions of the radical anion or dianion of III with solvent or due to ion pair formation with the cation of the supporting electrolyte (20, 21). As shown in Fig. 5, changes in $E_{1/2}$ with solvent are correlated not with solvent dielectric constant (as might be expected by application of the Born equation) (22), but rather by Gutmann's donor number (23), which measures the ability of a solvent to donate electrons.

Electron affinities from half-wave potentials.—In the absence of entropy effects the free energy change for the reaction

$$M + e^- \rightleftharpoons M^-$$

is given by (24, 25)

$$\Delta G = EA + \Delta\Delta G_{sol} + C$$

where $\Delta\Delta G_{sol}$ is the difference in free energies of solvation between the neutral and charged species and C is a constant dependent on the reference electrode. If the diffusion coefficients of the neutral and charged species do not differ greatly, then the half-wave potential is given by

Table II. Reduction potentials of 2,4,7-trinitrofluorenone (III) in various solvents*

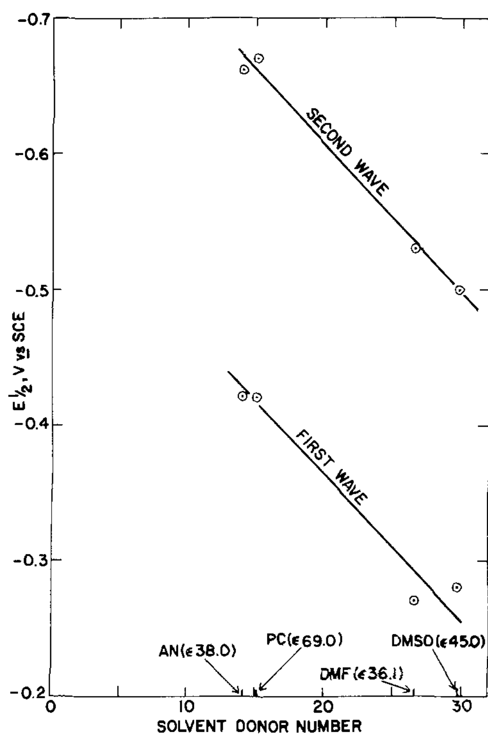

Fig. 5. Half-wave potential of 2,4,7-trinitrofluorenone as a function of solvent donor number.

$$E_{1/2} = \frac{\Delta G}{\mathbf{F}}$$

where **F** is the Faraday constant. It follows that if $\Delta\Delta G_{sol}$ is constant or varies linearly with EA then a linear relationship exists between $E_{1/2}$ and EA, which is given by (25b) and (25c) as

$$EA = E_{1/2} + 2.49 \quad [1]$$

where the value of $E_{1/2}$ is with respect to SCE and on which scale chloranil has the value $EA = 2.45$ eV. By use of the one-electron reduction potentials in Table I, the electron affinities of the compounds studied here may thus be obtained and are given in Table III. It should be pointed out that even if the assumption of constant solvation (polarization) energy is not strictly valid for the calculation of gas phase electron affinities. differences in $\Delta\Delta G_{sol}$ between compounds will, as shown above, be reflected in the half-wave potentials obtained from the solution redox measurement. Thus, while for convenience gas phase EA's are used, it is understood that such numbers are obtained from condensed phase measurements and as such are closely related to the molecule-matrix situation.

Mukherjee (26) has similarly studied compounds II-IV and VII-X and reported electron affinities which are 0.01 to 0.13 eV less than those obtained in the present study. This discrepancy may be due to his use of $LiClO_4$ as supporting electrolyte, since it is known (21) that ion pairing can cause shifts of up to 0.2V in polarographic half-wave potentials if the cation of the supporting electrolyte has a large charge to radius ratio. We also disagree with Mukherjee's claim that the second reduction wave of the DCMF compounds corresponds to the uptake of 3-4 electrons since, as was shown, for both these and the fluorenones all criteria indicate that the reduction pathway consists of two reversible one-electron steps.

Electron affinities via charge transfer spectra.—This method is essentially that of Briegleb (25) as modified by Mukherjee (27). It essentially involves measurement of the lowest energy charge transfer band of an acceptor with a donor, and referencing this transition energy to that of a known acceptor with the same donor. A specific equation is

$$h\nu_{ct}^{o} - h\nu_{ct} = EA - EA^{o} \quad [2]$$

where $h\nu_{ct}^{o}$ = energy of λ_{max}^{ct} with a standard acceptor, $h\nu_{ct}$ = energy of λ_{max}^{ct} of unknown acceptor, EA = unknown electron affinity, and EA^{o} = electron affinity of standard acceptor. Equation [2] can be changed to

$$EA - h\nu_{ct}^{o} = EA^{o} - h\nu_{ct} = K - \frac{hc}{\lambda} \quad [3]$$

This equation shows that there should be a linear relationship between EA and the wavelength of the lowest energy charge transfer band, provided that the donor material is held constant. For our correlation three known materials (III, IV, and X) have been used to generate correlation curves (EA *vs.* $1/\lambda$) with N-ethylcarbazole and the unknown materials' charge transfer λ used with these curves to obtain their EA (see Fig. 6). Interestingly, two charge transfer bands have been observed in most of the systems measured and these have been shown (28) to correspond to CT bands from the 1_{LB} and 1_{LA} energy levels of N-ethylcarbazole. Both levels have been used in our correlations and have provided similar results (Table III).

In evaluating electrical properties, it was found that many of the materials in Table III were not soluble to a sufficient level to be tested as electron transport materials. In these cases, CT spectra were not obtained.

With the exception of compound XIV, the EA obtained from CT spectra agree quite well with those from polarographic measurements. As was shown, compound XIV apparently undergoes a specific interaction with mercury, and the CV peak potential obtained at a platinum electrode probably better reflects the EA of the isolated (uncomplexed) molecule.

Table III. Electron affinities and PIDC results

Compound	Electron affinity, eV Polarography	Electron affinity, eV CT spectrum**	PDIC‡
I	1.19		ML
II	1.81		ML
III	2.07	2.03†	RM
IV	2.35	2.26†	TL-MDDTL
V	2.20	2.19	TL-RM
VI	2.22		TL-RM
VII	1.83		ML
VIII	2.23	2.26	TL
IX	2.24	2.27	TL
X	2.49	2.39†	HDDTL
XI	1.87		LDDNT
XII	1.93		LDDNT
XIII	1.93	1.86	LDDNT
XIV	2.14(1.97)*	1.96	LDDNT
XV	2.55		LDDNT

* The value in parenthesis is estimated from the CV peak potential at a platinum electrode.
** Average of both CT bands when obtained.
† Used for correlation purposes, see section on Electron affinities via charge transfer spectra.
‡ Key: ML = mobility limited, RB = reasonable mobility, TL = trap limited, HDDTL = high dark decay trap limited, and LDDNT = low dark decay no transport.

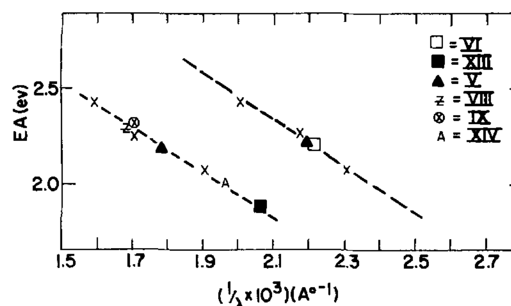

Fig. 6. Electron affinity vs. lowest energy charge transfer bands in N-ethylcarbazole/acceptor complexes. X = Standards for correlation curve.

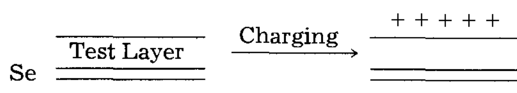
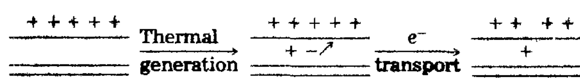
Electrical evaluation.—Explanation of PIDC method. —The PIDC test is conducted as follows. Materials to be tested as transporting media are solvent cast onto a 0.5 μm film of amorphous selenium. These composites are then thoroughly dried in vacuo at 312°K. The films are then placed in a device which will corona charge them (either positive or negative), measure the surface voltage as a function of time, and permit illumination of the sample some time after charging. Once the sample has been charged, care must be taken to exclude any form of radiation from the sample in order that the dark decay rate (the rate at which surface voltage decays without radiation) can be measured. In the above configuration, if the material to be measured is electron transporting, the sample is corona charged positively while, if it is hole transporting, the sample is charged negatively.

The sample is capacitively charged by the corona to a charge level $q = CV$ where q is the total charge on the system, C is the capacitance of the sample, and V, the voltage generated across the sample. This is schematically shown below.

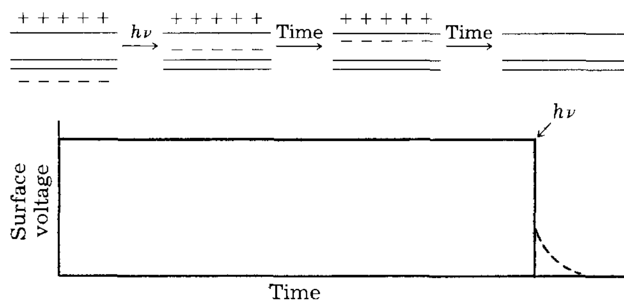


Once charged, if the sample is not conductive, it can be discharged in two ways: (*i*) photoinduction of hole/electron pairs either in the Se layer or the test layer, and (*ii*) thermal generation of hole/electron pairs in the Se layer or the test layer. The latter effect will lead to dark decay, as the thermally generated charge can lead to a reduction of the surface potential.



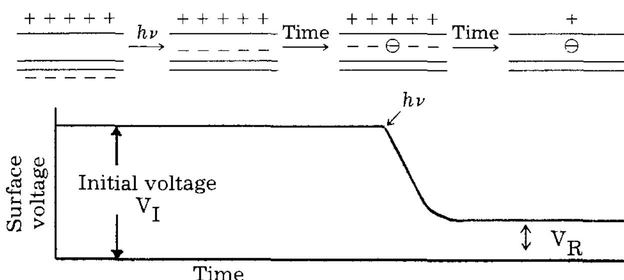
In the example shown, the coated material is an electron transport material. The surface voltage measured in the example would be 80% of the initial value. The rate of this dark decay can then be measured from the voltage/time plots. Normally, amorphous Se does not thermally generate a significant number of hole/electron pairs at room temperature (29) so that a decrease in surface voltage is due to the "dark decay" of our coated layers.

Since the photogeneration can take place in either of the layers, care must be taken to use radiative wavelength where the selenium layer is photosensitive and the organic layer is not. This requires knowing the electronic absorption spectra of the organic species and the photoresponse spectra of the amorphous Se. If these two overlap, the experimental configuration is changed so that the amorphous Se layer is on top and is made thick enough so as to allow no incident radiation to penetrate to the organic layer. If hole/electron pairs are generated in the organic layer (bulk generation), no information concerning charge trapping during transport can be obtained. If the above criteria concerning radiative absorption are met, only two other criteria need be considered; the amount of photogenerated charge and an injection barrier between the generator and transporting species. Although injection barriers have not been measured in the present systems, Mort and Emerald (30) have done so for amorphous selenium injection into PVK/TNF charge transfer complexes and found negligible injection barriers. Based on their work and the range of electron affinities being studied, negligible injection barriers are expected in the present results. In order to glean information on the transport of the charge through the sample, only enough charge need be generated in the selenium photogenerator layer to completely remove all surface charge. This would be equivalent to the capacitance charge on the sample (a so-called CV's work of charge). This charge is generated using a filtered strobe flash. If a CV's charge is generated and moves through the sample unimpeded, the sample will discharge as shown below and the surface voltage-time behavior will be described by the curve shown below.

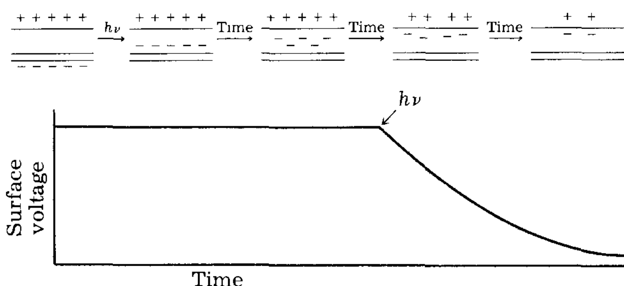


The horizontal time scale of such a measurement will depend on the transit time (the mobility of the charges moving through the sample). The voltage/time curve shown is totally idealized and will show a tailing phenomena (shown with dashes) because of space charge effects and the experimental inability to generate all charges simultaneously.

If the transporting charges encounter any molecular or morphological potential barriers, as they are traversing the sample, they can be stopped (deep traps) or slowed (shallow traps). These trapping effects cause changes in the shape of the voltage-time curves. If the transporting charges are deep trapped, a residual surface voltage V_R will remain in the time domain of the experiment.



If shallow trapping occurs, the residence time of the charge in the neighborhood of the trap is short compared to the time scale of the experiment, but the "sheet" of charges generated and injected from the photogeneration layer spreads out and the voltage/time curve is not as sharp.



It can be seen that by analyzing the PIDC curves on the same time scale that relative mobilities, trap levels, and dark discharge rates can be obtained. In the case of the experiments below, the discharges labeled reasonable mobility were those in which the surface voltage decreased to 50% of their original value in 0.1-0.2 sec.

It should be noted in this discussion that there is no way to distinguish between shallow trapping and low mobility materials and that, in fact, the two terms may be synonymous. Within the framework of these experiments and with the trends established, we have chosen low mobility to mean low dark decay and ap-

parent trap-limited mobility. Trap-limited discharge means high dark decay and apparent trap-limited mobility. This nomenclature fits the trends established.

Discussion of PIDC results.—It is our desire to discuss, in qualitative terms, the relationship of *EA* in fluorenone derivatives to observed transport (and in some cases generation properties). Two major difficulties have been encountered in measuring the electron transport properties of these materials: (*i*) instability of the molecule/matrix systems and (*ii*) limited solubility of the molecules in the matrix polymers. An example of the former effect is shown in Fig. 7 where it is seen that aging effects of TNF in binder polymers are deleterious causing increased residuals. This was a general phenomenon. It could only be overcome by testing the molecules of interest in a PVK matrix. In PVK the PIDC's did not appear time dependent.

Limited solubility materials such as VIII and IX could not be tested as transport materials because amorphous films of high loading could not be prepared. One idea to overcome this limitation was to ball mill these insoluble materials in a solution of PVK until a uniform distribution of small particles was obtained. It was felt that this distribution with its surface charge transfer complexes of PVK/acceptor might provide adequate electron transport matrices. The concept was tested with compounds III and VIII. In both cases ballmilling 40% of III and VIII to PVK causes charge transfer complexes to be formed (solutions become highly colored). However, as seen in Fig. 8, neither materials exhibited electron transport when a CV's worth of charge was injected from overcoated amorphous Se, but both behave as bulk generating photoreceptors when used with white light. Thus, although some of the electron transport candidates might be predicted to have good transport properties (see below) their solubility limits them to bulk generation type photoreceptors.

Figure 9 is a schematic representation of various PIDC curves observed for 40% acceptor loadings of fluorene derivatives in PVK. Although there must be gradual changes between the regions defined, four different modes of transport are apparent: (*i*) mobility limited, (*ii*) "reasonable" mobility characteristics, (*iii*) trap limited, and (*iv*) high dark decay.

These definitions of mobility are qualitative in nature and depend on the time scale of measurement. For these results (see Fig. 9) reasonable mobility is defined as light-induced discharge to 50% V_o in $\sim$0.1 sec. Mobility limited is defined as low dark decay-low light-induced discharge rate (Fig. 9A); trap limited is defined as increasing dark decay (Fig. 9C) low light-induced discharge; and high dark decay trap-limited

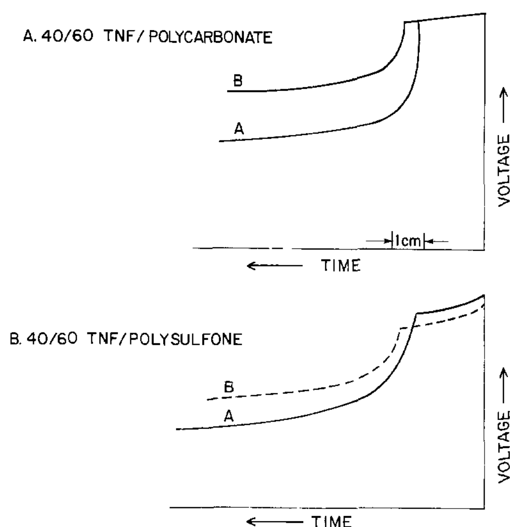


Fig. 7. PIDC of 40/60 (w/o) TNF in Lexan® and polysulfone. Horizontal scale = 10 mm/sec, vertical scale = 100 V/cm. A, Sample pumped 4½ days, 10^{-3} mm Hg, RT prior to test; B, 4 additional days stored in dark at ambient.

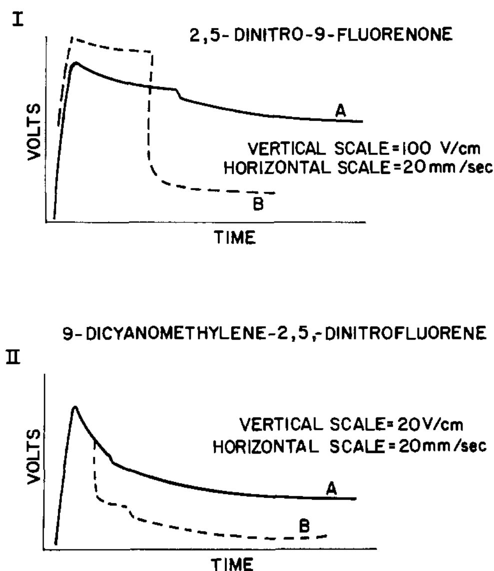

Fig. 8. PIDC of 40/60 (w/o) 2,5-dinitrofluorenone and 9-dicyanomethylene-2,5-dinitrofluorenone in PVK. Samples ball milled 24 hr in CH_2Cl_2 prior to preparation. A, Se overcoated; B, no overcoating, white strobe pulse, electron transport.

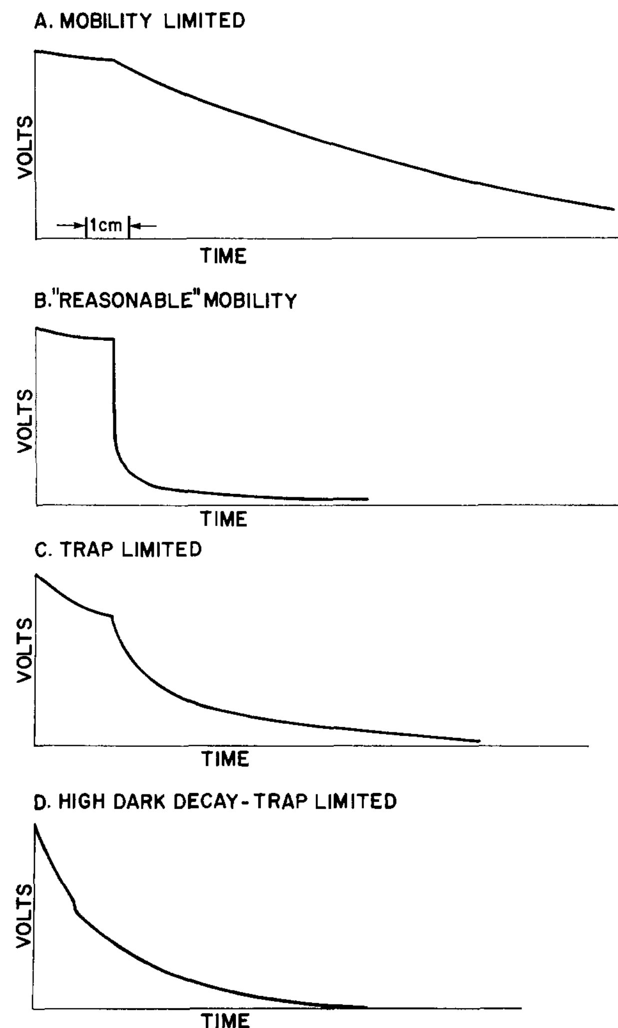

Fig. 9. Qualitative PIDC curves for PVK/acceptor mixtures. Horizontal axis = 20 mm/sec. 1 cm marker shown in A. Vertical scale dependent on dark decay. A and B, 100 V/cm, C, 50 V/cm; and D, 20 V/cm.

is defined as low charge acceptance due to dark decay and no obvious light-induced transport except the collapse of the field across amorphous Se (Fig. 9D). That trap limitations occur is seen in Fig. 8 where it is demonstrated that bulk generation (essentially trap depopulation) can discharge a sample to a much greater degree than injection from amorphous selenium.

The four regions of Fig. 9 correlate qualitatively with various ranges of *EA* values for fluorenone derivatives: the first (A) with *EA* less than ~2.0, the second (B) with $2.0 < EA < 2.2$, the third (C) with $2.2 < EA \leqq 2.4$, and the fourth (D) with $EA > 2.4$. As mentioned previously, if all *EA*'s within these regions could be tested, a gradual change in PIDC would be expected. A general increase in dark decay is also noted with increasing *EA*. These results are qualitatively described in Table III.

How are these general trends rationalized? Seki (31) has proposed a model of fluctuating hopping sites which provides a mathematical description of transport similar to that of Bagley (32) whose model is based on hopping between localized states over potential barriers. Seki (31) also included a probability factor due to tunneling or overlap of individual molecular wave functions, which has the form E^{-R/R_0}. The entire equation proposed by Seki is

$$\mu F = (\lambda_0/\tau_0)\exp(-R/R_0)\exp(-U_0/kT)\sinh(e\lambda_0F/2kT) \quad [4]$$

where μ is the mobility; F, the electric field; R, the intermolecular distance between exchange sites; τ_0, λ_0, and R_0 are constants of a specific system with units of time and characteristic distances, respectively; e is electronic charge, U_0 is the thermal barrier to transport, and kT is the thermal energy of the system. R_0 can be related to *EA* or the ionization potential (*IP*) by[1]

$$\frac{1}{R_0} = (2/\hbar)\sqrt{2mE_i} \quad [5]$$

where m is the mass of an electron and $E_i = EA$ or IP depending on whether there is hole or electron transport. An equation similar to Eq. [4] (without the R/R_0 term) can also be derived from rate theory where it is assumed that application of an electric field to a sample changes the potential well distribution (33, 34). Of importance in the above is the effect the changing *EA* or *IP* has on R_0 and its physical significance. In systems studied thus far, R_0 is of the order of an angstrom or less and thus all possible values of R are greater than R_0. On the basis of Eq. [4] and [5], it would be expected that decreasing *EA* and holding all other variables (concentration, field, etc.) constant would produce increasing electron mobility. Oppositely, increasing *EA* should result in decreasing mobility. Our results follow this in the range of $E \geqq 2.1$. It should be pointed out that the Seki equation has not been validated for a large number of materials and that experimental variables such as sample preparation, morphology, chemical structure, and inert matrix may also affect the observed transport behavior.

Materials of $EA \geqq 2.1$ eV that were tested provide discharge curves of types (B) through (D) indicating that as *EA* is increased trap-limited mobilities are observed. Trap-limited discharges were observed in compounds V and VI with extreme trapping limitations in IV, X, XIV, and XV. It is thus concluded that in the region $EA \gtrsim 2.1$ eV electron transport results for fluorenone derivatives in PVK can qualitatively be described in terms of Eq. [4] and [5]. At lower *EA* anomolies occur. On the basis of Eq. [5], the lower *EA* materials would be expected to be better electron transport materials than their high *EA* counterparts. This is not observed and the results are not unique, as Faucz (35) observed holes as the majority carrier in pure crystalline films of 9-fluorenone, a material with $EA = 1.2$ eV. There are a variety of possible reasons why the decreased electron mobility in fluorenone derivatives is seen below $EA \cong 2.1$. Impurities such as O_2 ($EA = 0.44$) (36) could interfere with transport. Injection into the low affinity materials could override other effects (Faucz observed this in 9-fluorenone, whereas mononitrofluorenone injected and transported electrons) (35). Fluorenone dispersions could be affected by the ability of the material to form charge transfer complexes with PVK, and thus, the lower *EA* materials may be dispersed differently from their high *EA* counterparts. Whatever the reason, the 9-fluorenone derivatives appear to be limited to an electron affinity region ~2.05 to 2.15 for reasonable PIDC results.

Another phenomenon noted in these studies is the increase in dark decay with increasing *EA*. Similar effects have been noted in other electron-donating systems complexed with fluorenone derivatives (37). In fact, with materials such as IV and X, dark decay was observed with no apparent electron mobility. This high dark decay occurred whether these materials were charged positively or negatively. Again, there is a variety of reasons why this increased dark decay may occur. With increased *EA* of the acceptor it may be easy for an electron to be thermally promoted from the highest occupied molecular orbital of PVK to the lowest unoccupied of the acceptor, thus creating a hole-electron pair in the media. Dark decay in this case may occur through thermally generated carrier movement. In light of our observations of trap-limited electron transport, but high dark decay, this explanation seems reasonable.

It is, of course, implicit in the preceding discussion, that if the relation between *EA* and electron mobility is valid, then it equally ought to apply to *IP* and hole mobility. Support for this approach is to be found in the work of Pfister *et al.* (4) involving xerographic discharge measurements on Lexan® doped with variously substituted derivatives of carbazole. Gibson (38) subsequently showed that the observed changes in xerographic discharge rates could be correlated with the ability of the substituents to release electrons (given by Hammett or Taft substituent constant) to the carbazole ring and thus lower the ionization potential. It should be pointed out in passing that the use of Hammett substituent constants to correlate molecular energy levels (and thus mobilities) is limited to perturbations on a given molecular framework, whereas use of redox data, such as in the present work, permits such correlations regardless of the molecular framework.

An additional consideration is the effect of the medium on the energy levels of the isolated molecule. In the condensed phase these energy levels will differ from those of the molecule in the gas phase by an amount termed the solvation (or polarization) energy. From simple theory this quantity is given by the Born equation (22)

$$\Delta G = -\frac{(ze)^2}{2r}\left(1 - \frac{1}{\epsilon}\right) \quad [6]$$

where ze is the charge acquired by the molecule, r its radius, and ϵ the dielectric constant of the surrounding medium. While this equation may be suitable for spherical ions in a continuous medium, it is not at all certain that it is applicable to planar molecules, particularly those in which heteroatoms and substituents induce a nonuniform charge distribution. Furthermore, specific solvation effects such as ion-dipole interaction, hydrogen bonding, and π bonding can effect the solvation energy to an extent beyond that esti-

[1] This equation is exact for square well potentials or the WKB approximation.

mated by considering the environment as a continuous dielectric medium.

These considerations are amply illustrated by the shifts in reduction potential of TNF (III, see Table II) which reflect the difference in solvation energies between the neutral molecule and anion formed on reduction in different solvents. As was shown, it is not dielectric constant (a macroscopic quantity) but donor number (a microscopic measure of solvating ability) which correlates the observed trend in reduction potential and thus *EA* in the condensed phase. If such effects are also operative in polymeric matrices, then the observed differences in carrier mobility when a given active transport molecule is dispersed in different binder resins could easily be explained via the donor number concept.

A final consideration involves the molecular nature of the charge transport process itself. This can be regarded as the reaction of a radical ion with a neutral molecule to give a neutral molecule and a radical ion

$$M^{\overline{\cdot}} + M \rightarrow M + M^{\overline{\cdot}}$$

The possibility also exists for the radical ion to undergo an irreversible chemical reaction

$$M^{\overline{\cdot}} \rightarrow P$$

The product of such a reaction could depend on or directly involve the surrounding medium and could easily be a compound that would act as a trap for the transport species. Thus, if the *EA* of chemical reaction product P is greater than that of molecule M, then according to the reasoning we have advanced, P will act as a trapping site. Analogous arguments, of course, hold for hole transport. When this possibility exists, the residence time of the electron at a given molecular site must be shorter than the time required for chemical reaction in order for such trap limitations not to exist.

Support of this approach is seen in the results of measurements on compounds XI-XIV. PIDC measurements on these compounds showed that although *EA* are reasonable for electron transport, none is observed. From a consideration of energy levels alone this would not have been expected since the experimental values of *EA* do not differ greatly from that of TNF. The compounds do differ from TNF, however, in that, as shown by cyclic voltammetry, each undergoes an irreversible chemical reaction coupled to the electron exchange step. It thus appears that there is a direct correlation of electrochemical stability and trap or mobility limitations in electron transport systems.

Thus, it seems that carrier mobilities and/or trap limitations can be correlated with the energy levels of the molecular species involved, but, in addition, the chemical or electrochemical reactivity of the molecules responsible for charge transport must be considered as well as their specific interactions with the host matrix.

ABSTRACT

The electrode reactions of Eu(III)/Eu(II), Cr(III)/Cr(II), Cu(II)/Cu(I), Fe(III)/Fe(II), and Pt(IV)/Pt(II) redox couples have been studied using cyclic voltammetry at n-type semiconducting SnO_2 electrodes in molten LiCl-KCl eutectic at 450°C. The highly doped oxide electrode is a stable indicator electrode usable at anodic potentials up to chlorine evolution. The redox couples examined are reversible at the tin oxide electrode, indicating no effect of electron depletion on the electron transfer kinetics. Electron tunneling through the space charge barrier takes place more easily in the high temperature melt system. For the oxidation of Cu(I) and Pt(II), which do not show diffusion controlled current peaks, an adsorption effect due to anionic bridge formation on the oxide covered with adsorbed chloride has been suggested.

A number of electrochemical reactions in molten salt systems have been studied on metal and carbon electrodes (1). Metal electrodes, even the platinum metals, are subject to anodic dissolution in LiCl-KCl eutectic, imposing an anodic limit when they are used as indicator electrodes. Carbon is one of the inert materials usable at anodic potentials up to chlorine evolution in the melt. Previous studies on redox systems that have a more positive redox potential than that of platinum dissolution have been mostly carried out on carbon electrodes (2-4). In view of electrochemical instability of metal electrodes at anodic potentials, semiconductive oxide electrodes are of special interest.

Delarue described a group of insoluble oxides including tin oxide in molten LiCl-KCl eutectic (5). Some of them are oxide semiconductors with large bandgaps, retaining semiconductive properties at high temperatures. A single crystal of TiO_2 was used as an oxygen electrode in the melt containing O^{2-} ions, but the experiments were unsuccessful because of the soluble nature of the oxide (6). On the other hand, Sb-doped polycrystalline SnO_2 was found to be stable in the melt at 450°C, and showed a small background current until chlorine evolution took place (7).

It has been pointed out in the previous work (7) that we can use highly doped SnO_2 as a stable indicator electrode in a polarizable region which is in the electron depletion situation characterized by the Mott-Schottky equation, postulating an electron tunneling mechanism through the space charge layer. The present work was undertaken to examine the occurrence and the reversibility of redox processes at the melt-oxide interface. We selected reversible redox couples with one-electron transfer processes such as Eu(III)/Eu(II), Cr(III)/Cr(II), Cu(II)/Cu(I), and Fe(III)/Fe(II), which had been studied previously on carbon (2, 3, 8) or Pt indicator electrodes (9), but not yet on SnO_2. Some technical details for the use of SnO_2 electrodes in molten salt experiments are presented.

Experimental

Electrodes.—Construction details of a tin oxide electrode are illustrated in Fig. 1. It was constructed from a Pyrex ground joint; the inner part was a tapered ground glass rod whose cross section (8 mm in diam) was given a mirror-like finish with fine alumina powder and coated with Sb-doped SnO_2 as described previously (7). To ensure a definite working area of the electrode, the inner part was matched precisely to the taper of the outer part. The gap between the two was filled with fine boron nitride powder; the powder suspended in isopropyl alcohol was brushed onto the oxide-coated taper of the inner part, which was twisted several times inside the outer part to spread out the boron nitride sealant. This procedure was necessary to prevent the melt from creeping into the gap. In order to make electrical contact between a lead wire and the SnO_2 film, a thin gold film was coated on a part of the oxide film with gold paste C-5040 supplied from Sumitomo Metal Mining Company. Several turns of platinum wire were wound on the gold coating.

We have tried a couple of different combinations of substrates and insulators to make melt-stable SnO_2 electrodes. A commercially available SnO_2 film, Nesa glass, was not suitable for molten salt experiments because the substrate was soda-lime glass, which was seriously attacked in the melt. Low temperature glass frits, so called solder glass, were used as an insulator, Sumitomo pastes I-9505 for Nesa Glass, and I-9004 for alumina substrate. Those compounds contained lead oxide which dissolved into the melt, and Pb(II) ions affected cyclic voltammograms when they were used in the melt. So far the combination of Pyrex substrate and boron nitride sealing was the best. However, a minor problem was encountered with this type of electrode. Creepage of the melt into the boron nitride seal could not be avoided when the electrode was left in the melt for a long time. In order to avoid this problem, experiments were finished within 2 hr, at most. A period of 1 hr was long enough to take a series of cyclic voltammograms.

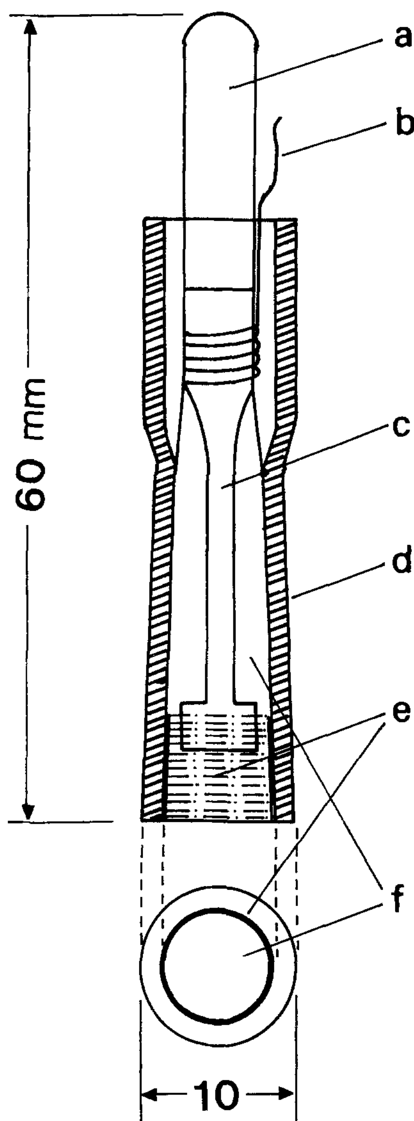

Fig. 1. Construction of a tin oxide electrode. (a) Pyrex rod; (b) platinum wire; (c) gold coating; (d) tapered ground joint; (e) boron nitride sealing; (f) tin oxide film.

The constructed electrode is demountable; the electrode is easily separated from the glass sheath after use in the melt. This is advantageous to facilitate surface conditioning of the electrode. The electrodes which had been used in the melt were sealed again with new boron nitride sealer before further experiments.

Sb-doped SnO_2 was coated onto a hot Pyrex substrate (500°C) by spraying the solution of 2.5M HCl containing 1.78M $SnCl_4$ and 0.0161M $SbCl_3$. The coating thickness was estimated as about 0.5 μm from the change in interference color, and the carrier concentration was 4.4×10^{20} cm^{-3} at room temperature, estimated from Mott-Schottky plots derived from capacitance measurements in 1*N* H_2SO_4 with an a-c bridge at frequencies from 0.7 to 4 KHz.

Glassy carbon electrodes (Beckwith Carbon Corporation) were used as working electrodes for comparison with SnO_2 electrodes. A rod of 3 mm diam was sealed into Pyrex by a technique described before (10).

Platinum reference electrodes and spectroscopic grade graphite counterelectrodes were used as in previous studies (11).

Reagents.—The LiCl-KCl eutectic was supplied from Anderson Physics Laboratories Incorporated, Urbana, Illinois.

Eu(III) and Cr(III) were added to the melt as chlorides, europium chloride (Alfa Ventron, anhydrous 99.5% pure), and chromium chloride (Alfa Ventron, sublimed, anhydrous 99% pure). Special care was needed to prevent their exposure to moisture because of their hygroscopic nature. For this purpose we designed a "powder buret" consisting of a separable type Teflon stopcock and a small glass ampul containing the chlorides. The chlorides were transferred into small ampuls (7 mm in OD and 10 cm in length) in a dry bag, and then they were sealed under an Ar atmosphere after vacuum drying. Before making an addition, one end of the ampul was cut and inserted into the opening of the stopcock. Another opening of the stopcock was connected to a long glass tube which reached the melt surface. The glass-to-Teflon fitting was so tight that the chemicals inside were not exposed to moisture. The amounts added were obtained by weighing the stopcock with the ampul before and after the addition. It was not difficult to add even 1 mg solid to the melt with fine manipulation of the stopcock.

Cu(I), Fe(II), and Pt(II) were generated by anodization of the metal wires with current densities of about 5 mA/cm^2. Currents were supplied by a Sargent coulometric current source, and the concentrations were calculated by assuming 100% current efficiency. Copper (0.64 mm in diam, m5N) and iron (0.25 mm in diam, m4N) were obtained from Alfa Ventron, Danvers, Massachusetts.

Apparatus.—Cyclic voltammograms were obtained with a Polarographic Analyzer Model-174A coupled to a Universal Programmer Model-175A (Princeton Applied Research Corporation), and the curves were recorded on a Moseley Model 7000 AM X-Y Recorder (Hewlett-Packard).

Cell impedance measurements were made with a Wayne Kerr Universal Bridge B221 equipped with a conventional polarization circuit. A 241-A Oscillator (Hewlett-Packard) as an a-c sine wave source and a Type 1232-A Tuned Amplifier and Null Detector (General Radio Company) as a zero detector were used.

Procedure.—A Pyrex container of 76 mm diam was set in a Hevi-Duty MK 3012-S Vertical Split Tube Furnace (Hevi-Duty Electric Company) regulated with a Wheelco Panel-Mount Capacitrol Temperature Controller (Wheelco Instrument Company). A Pyrex crucible and four sealing tubes with fine fritted disks were placed in the container, and about 60 ml of the melt sealed in an ampul was transferred into the cell. Two compartments of the four were small (14 mm in diam), and were occupied by the Pt(II)/Pt reference electrode and a graphite rode used as the counterelectrode. The melt solutions of the depolarizers were prepared in the large compartments of 25 mm diam. The volume of melt was calculated from the amount of chloride ion determined by argentometry and the density. Other details of experimental procedure have been given previously (2, 3). All potentials shown in this work were given with respect to the 1M Pt(II)/Pt electrode, and all experiments were carried out at 450°C under a purified argon atmosphere.

The tin oxide electrodes were subject to the following surface conditioning before experiments: the oxide surface was lightly polished with AB Alpha (0.3 μm) and AB Gamma (0.05 μm) Polishing Aluminas (Buehler Limited) on a flat disk covered with polishing cloth, and soaked in an acid mixture of H_2SO_4 and HNO_3 for 2 hr. After rinsing with distilled water and boiling in distilled water for 30 min, the electrode was assembled as shown in Fig. 1 and dried in an oven at 110°C. Finally the electrode attached to a holder was put into the cell container, where it was held for 30 min at 450°C before it came into contact with the melt.

Results and Discussion

Background current.—Current voltage traces in Fig. 2 show the background characteristics of SnO_2 with

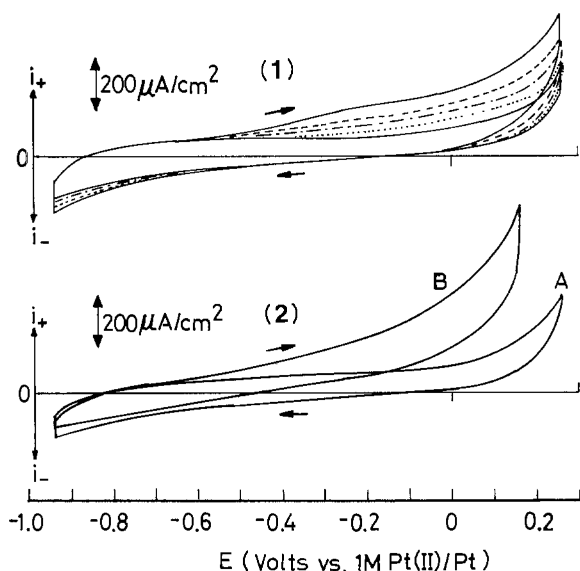

Fig. 2. Background characteristics for SnO_2 and glassy carbon electrodes with repeated potential scans (v = 100 mV/sec) in the eutectic at 450°C. (1) On SnO_2; 1st scan (——); 2nd scan (——); 3rd scan (–·–·–); 4th scan (.....); 5th scan (——). (2) Comparison of the SnO_2 with a glassy carbon electrode; (A) on SnO_2 after the 5th scan; (B) on GCE.

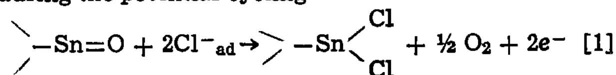
repeated potential scans (V = 100 mV/sec) in the melt. In the first scan, a relatively large background current was usually observed at anodic potentials, but it gradually decreased with the repetition of potential cycling (a-c treatment). After several a-c treatments the traces converged to a definitive and reproducible trace, indicating that the oxide-melt interface reached a steady state. This a-c treatment was necessary for the stabilization of electrodes.

The current increase observed at potentials more positive than −0.6V during the first few scans indicates that an irreversible oxidation process with a saturation effect takes place at the oxide-melt interface, where the specific adsorption of Cl^- ions is predominant as described elsewhere (7). The specific adsorption of Cl^- proceeds through the replacement of surface oxide groups by Cl^- ions, and then the released O^{2-} ions present at the interface can be anodically oxidized during the potential cycling



$$>\!Sn{=}O + 2Cl^-_{ad} \rightarrow\ >\!Sn\!<^{Cl}_{Cl} + \tfrac{1}{2}\,O_2 + 2e^- \quad [1]$$

According to this concept, the oxide surface subjected to a-c treatment is covered with adsorbed Cl^- ions which are strongly coupled with the surface. This is the actual condition of the electrode surface in the melt when we use it as an indicator electrode.

Figure 2 also shows that the usable anodic potential limit of the tin oxide electrode was slightly greater than that attained at a glassy carbon electrode (GCE). In comparison of SnO_2 with GCE, it was found that GCE showed a relatively large residual current at anodic potentials before chlorine evolution. This remarkable difference is due to the steep increase of the pseudocapacity at the carbon-melt interface with increasing anodic potentials because of the increased participation of adsorbed Cl^-. In contrast, the measurable capacity at the n-type oxide-melt interface is not that of the melt side, but the electrode side space charge which is smaller than that obtained at GCE and uniformly decreases with increasing anodic potentials as reported elsewhere (7).

In contrast with the amended anodic limit of SnO_2, the cathodic limit is better at GCE than at SnO_2, which undergoes cathodic decomposition at potentials beyond −1V. The available potential span of SnO_2 is about 1V.

Reduction of Eu(III) to Eu(II).—Well-defined voltammetric waves were obtained on SnO_2 at six potential scan rates ranging from 0.500 to 0.01 V/sec. Typical voltammograms are shown in Fig. 3.

The diagnostic criteria of Nicholson and Shain (12) were applied to determine the mechanism of the Eu(III)/Eu(II) reaction on SnO_2. The ratio of anodic to cathodic peak currents was measured for each scan, using the empirical expression developed by Nicholson (13)

$$i_{pa}/i_{pc} = (i_{pa})o/(i_{pc})o + 0.485\,(i_{sp})o/(i_{pc})o + 0.086 \quad [2]$$

where $(i_{pa})o$ and $(i_{pc})o$ are the measured anodic and cathodic peak currents and $(i_{sp})o$ is the cathodic current at the switching potential. The value of i_{pa}/i_{pc} plotted *vs.* scan rate are shown in Fig. 4, where the ratio is near unity over the entire scan range (0.01-0.5 V/sec). In agreement with the potentiometric study of Eu(III)/Eu(II) couple on Pt electrodes (9), the reaction on SnO_2 is a reversible diffusion-controlled process without kinetic complications.

Plots of the cathodic peak current *vs.* square root of the scan rate were linear through zero as shown in Fig. 5. The diffusion coefficient of Eu(III) in the melt at 450°C was calculated from the slope of Fig. 5; the *D*

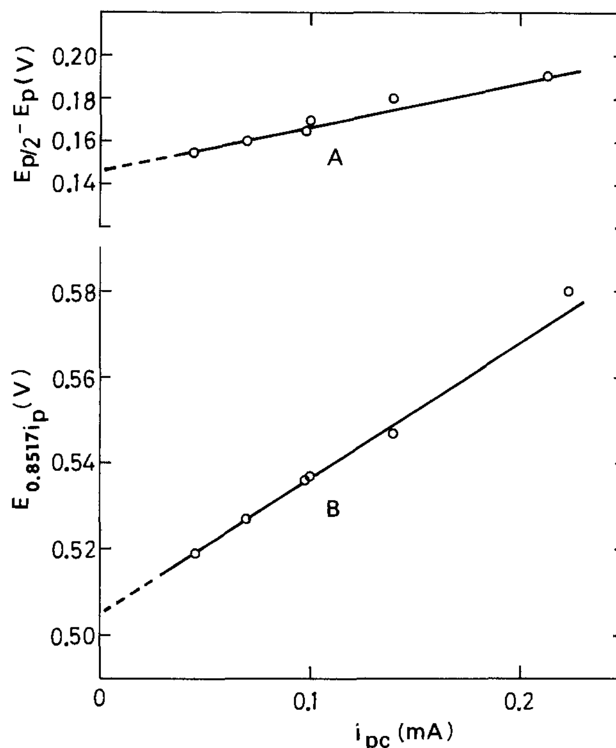

Fig. 6. Correction of *IR* effect due to electrode resistance in determination of ($E_{p/2} - E_p$) and $E_{1/2}$ for reduction of Eu(III) to Eu(II).

value was 0.61×10^{-5} cm²/sec by using the expression derived for the reversible case with $n = 1$ (12). Somewhat larger D values were obtained after various periods of standing the electrode in the melt. 2 hr after the experiments quoted in Fig. 5, an apparent 6% increase of the D value was observed. This difference is attributed to a change in the effective working area caused by penetration of the melt into the boron nitride sealer.

The most important problem in this work is the elimination of the IR drop caused by the electrode film resistance. Of the variety of methods available for correcting the resistance, a simple and reliable procedure to obtain IR-free $E_{1/2}$ and peak separation is to plot them as a function of the peak current as suggested by Kuwana *et al.* (14). Plots of observed ($E_{p/2} - E_p$) and the potentials corresponding to $0.8517 i_p$ ($E_{0.8517 i_p}$) against i_{pc} were linear, as shown in Fig. 6. The following expressions may be written for the reversible case including the IR effect

$$E_{p/2} - E_p = 2.199\, RT/n\mathbf{F} + 0.5 i_p R \quad [3]$$

$$E_{0.8517 i_p} = E_{1/2} + 0.8517 i_p R \quad [4]$$

where $2.199\, RT/n\mathbf{F}$ is $0.137/n$V at 450°C. Electrode resistance, R, is given by the slope of the line, and the IR-free $E_{1/2}$ and ($E_{p/2} - E_p$) are equal to the intercepts at $i_{pc} = 0$. The electrode resistances obtained from the slopes of (A) and (B) in Fig. 6 were 39 and 38Ω, respectively, in agreement with the values measured with an a-c bridge. The intercept of the plot (A) was 0.145V, being very close to the theoretical value with $n = 1$. The half-wave potential of the Eu(III)/Eu(II) couple was determined as $E_{1/2} = -0.504$V *vs.* 1M Pt(II)/Pt. This value is more positive by 34 mV than the standard electromotive force reported in the literature (9).

Reduction of Cr(III).—Cyclic voltammetric measurements followed by similar procedures for data analyses were carried out for the reduction of Cr(III) to Cr(II). The IR-free ($E_{p/2} - E_p$) was 0.155V, and $E_{1/2}$ was -0.529V *vs.* 1M Pt(II)/Pt, in agreement with the standard electromotive force [$E° = -0.535$V (2)]. These results indicate that the redox couple of Cr(III)/Cr(II) at SnO_2 is reversible. However, i_{pa}/i_{pc} was not unity over the whole range of scan rates ($0.01 < v < 1.00$ V/sec), and decreased with decreasing scan rate at lower scan rates between 0.1 and 0.01 V/sec, as revealed by Levy and Reinhardt (8) and the authors at GCE (10). According to the usual criteria (12), the variation of i_{pa}/i_{pc} indicates a slow chemical step following charge transfer and the reaction mechanism has been discussed in detail (8, 10).

The calculated D value of Cr(III) was 0.79×10^{-5} cm²/sec, agreeing with the D value determined at GCE (10). Strictly speaking, however, this D value was a little smaller than that obtained in a melt solution of Cr(III) saturated with dry HCl (10). As pointed out in the previous paper (10), $CrCl_6^{-3}$ in the melt easily undergoes a hydrolysis reaction with a trace of moisture, producing a less reversible species such as $CrCl_5(OH)^{-3}$ and an electro-inactive polymerized form. A greater participation of these complexes results in a smaller D value and a greater separation between $E_{p/2}$ and E_p. Unfortunately, measurements in the melt saturated with HCl were impossible because the tin oxide film chemically dissolved into the melt in the presence of HCl (15).

Oxidation of Cu(I) and Fe(II).—The standard electromotive force of the Cu(II)/Cu(I) couple is 0.061V *vs.* 1M Pt(II)/Pt, which is very close to that of the Fe(III)/Fe(II) couple, $E° = 0.086$V (2, 3). It was found that both redox couples are reversible on SnO_2, but the former oxidation process is different from the latter.

Typical cyclic voltammograms with different scan rates for the oxidation of Cu(I) are shown in Fig. 7 together with the background scan. There was no anodic peak, and only cathodic peaks were observable. Since the background current was still small at the anodic potentials, the uniform increase of anodic current could not be attributed to participation of chlorine evolution, while the location of the IR-free cathodic peak potential was -0.012V. Using the theoretical relationship between E_{pc} and $E_{1/2}$ (12), $E_{1/2} - E_{pc} = 1.109\, RT/n\mathbf{F}$, $E_{1/2}$ was estimated as $+0.057$V *vs.* 1M

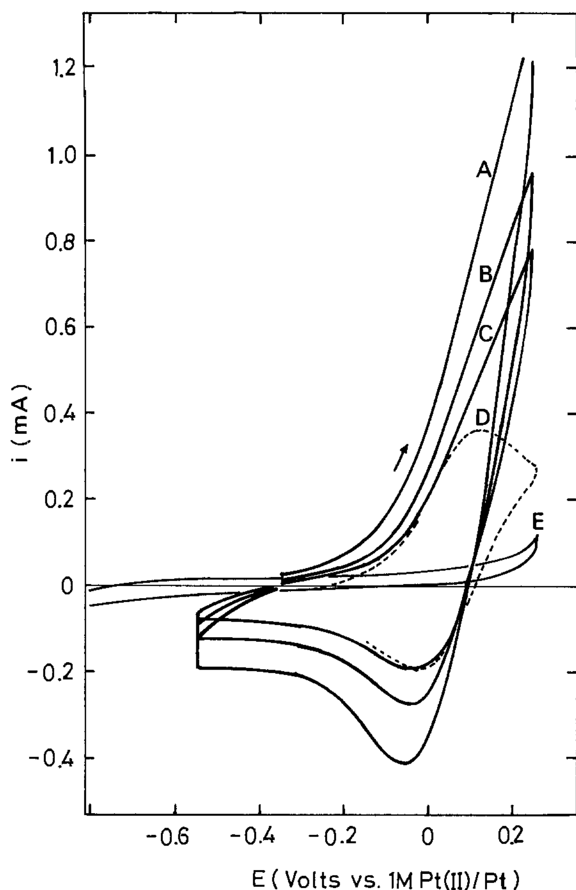

Fig. 7. Cyclic voltammograms for oxidation of Cu(I) to Cu(II) in a melt solution of 2.98 mM Cu(I) on SnO_2 (0.50 cm^2) at 450°C. (A) 0.500 V/sec; (B) 0.200 V/sec; (C) 0.100 V/sec; (D) theoretical curve for reversible one-electron transfer with $v = 0.1$ V/sec and $D - 2 \times 10^{-5}$ cm^2/sec; (E) background i-E.

Pt(II)/Pt. being very close to $E°$ of Cu(II)/Cu(I). It is obvious that the cathodic peak corresponds to rereduction of Cu(II) produced by the anodic scan.

A dotted curve in Fig. 7 is a theoretical voltammogram for a reversible one-electron transfer process with $v = 0.1$V; sec, where the D value was selected as 2×10^{-5} cm^2/sec to yield the same cathodic peak height as the observed one. The selected D value was reasonable in comparison with published data (16). The great discrepancy in the current behavior for the oxidation of Cu(I) suggests that the oxidation process is accompanied by catalytic or adsorption processes.

Similar behavior, showing no oxidation peak but a reduction peak, was observed for the oxidation of Pt(II) to Pt(IV). However, on glassy carbon electrodes De Lepinay *et al.* obtained the oxidation peak of Pt(II) in the melt at 450°C (4). Although we did not obtain the oxidation peak on SnO_2, the anodic oxidation of Pt(II) to Pt(IV) was quite evident.

In contrast with the behavior of Cu(I) and Pt(II), the oxidation peak of Fe(II) was obtained, as shown in Fig. 8, where the peaks were somewhat distorted by background currents. It was found that the anodic shoulders correspond to the diffusion-controlled current peaks with $n = 1$, if we correct for the background current.

The kinetic difference between the oxidations of Cu(I) and Fe(II) may be attributed to the different coordination structures of the ions in the melt. According to spectrophotometric studies in the melt, Cu(II) is reported to be a tetragonally distorted tetrahedral $CuCl_4^{2-}$ (17), which means a somewhat flattened structure, and Pt(II) is believed to have the D_{4h} symmetry, indicating some axial interaction between the square planar $PtCl_4^{2-}$ ion and solvent anions (18). On the other hand, Fe(II) is described as a purely tetrahedral $FeCl_4^{2-}$ in the melt at 400°C (17, 18). Unfortunately, the coordination of Cu(I) in the melt is still unknown. However, in concentrated aqueous HCl solutions (~12M) the Raman spectrum of Cu(I) suggests that the predominant species is a trigonal $CuCl_3^{2-}$ (19). From chronopotentiometric measurements of diffusion coefficients of univalent ions [Cu(I), Ag(I) and Au(I)] with different ionic radii (16), it was noted that the univalent cations are probably uncomplexed in the melt because the D values decrease as the ionic radii increase, while bivalent ions [Fe(II) and Ni(II)] are complexed because of lack of the correlation between the D values and the ionic radii. It is more likely that Cu(I) in the melt is $CuCl_3^{2-}$ or a less coordinated chloro-complex rather than tetrahedral $CuCl_4^-$. Generally speaking, a chloro-complex with a more flattened structure is accessible to the electrode surface, as suggested for the adsorption of square-planar $PtCl_4^{2-}$ in the melt (20).

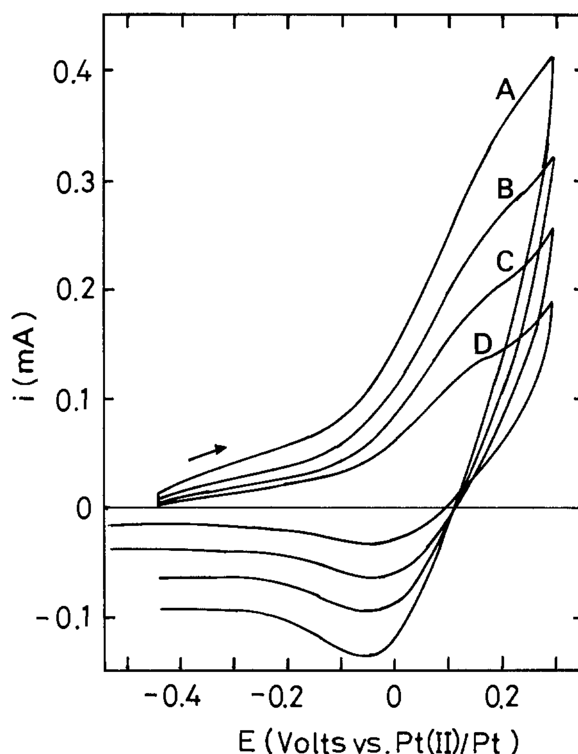

Fig. 8. Cyclic voltammograms for oxidation of Fe(II) to Fe(II) in a melt solution of 1.57 mM Fe(II) on SnO_2 (0.622 cm^2) at 450°C. (A) 0.200 V/sec; (B) 0.100 V/sec; (C) 0.050 V/sec; (D) 0.020 V/sec.

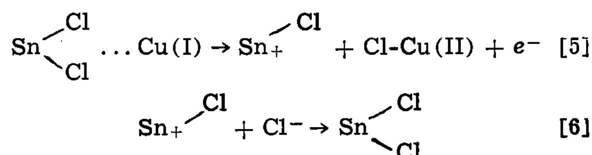
The oxide surface in the melt was drastically modified through the replacement of surface oxide groups by specifically adsorbed Cl^- ions, as shown in Eq. [1]. As for the effect of adsorption, the formation of an anionic bridge between adsorbed anions and electroactive species is a well-known phenomenon in aqueous systems in explanation of a rate-enhancing effect by specifically adsorbed anions (21). In studies on metal deposition in molten nitrate melts with halide ions, Inman *et al.* suggested anion bridging to facilitate the discharge of metal ions (22). We therefore believe that Cu(I) with the structures considered above interact with the surface chloride groups, which act as electron bridges to facilitate the oxidation. Assuming the trigonal structure, a folowing scheme may be written to produce $CuCl_4^{2-}$



$$Sn\genfrac{}{}{0pt}{}{Cl}{Cl} \ldots Cu(I) \rightarrow Sn_{+}^{\ Cl} + Cl\text{-}Cu(II) + e^- \quad [5]$$

$$Sn_{+}^{\ Cl} + Cl^- \rightarrow Sn\genfrac{}{}{0pt}{}{Cl}{Cl} \quad [6]$$

For the case of $FeCl_4^{2-}$ with pure tetrahedral coordination, the adsorption effect does not seem to be predominant because of its steric hindrance, in contrast with the square-planar complex $PtCl_4^{2-}$, which may be suited to the formation of anionic bridges. In addition, no adsorption effects of octahedral $EuCl_6^{3-}$ and $CrCl_6^{3-}$ (17) were observed on SnO_2, because plots $i_{pc}/v^{1/2}$ *vs.* v were constant up to the scan rate of 1 V/sec. No adsorption of the latter ions on GCE was observed (8).

We therefore conclude that all the systems examined in this work undergo reversible electron-transfer processes. However, the oxidations of Cu(I) and Pt(II) involve adsorption processes via anionic bridges.

Electron transfer at the oxide-melt interface.—The Sb-doped SnO_2 is an n-type semiconductor with a large bandgap (3.8 eV) which retains semiconductive properties up to higher temperatures (> 1300°C) (23). The oxide electrodes used for the voltammetric studies were highly doped specimens with a doping level of 4.4×10^{20} cm^{-3}, which was determined by capacity measurements in 1N H_2SO_4 at room temperature. According to the previous study (7), the interfacial capacities measured in the melt at an SnO_2 electrode with the same order of doping level obeyed the Mott-Schottky relationship as well as in aqueous solutions, and the flatband potential (E_{fb}) of the oxide at 450°C was estimated as -1.29V *vs.* 1M Pt(II)/Pt. The carrier concentration at 450°C was larger than that observed at room temperature.

The potential range in this study is more positive than E_{fb}, the redox couples being located at lower energy levels far removed from the edge of the conduction band. According to the semiconductor-liquid junction theory (24), the electron concentration near the electrode surface is depleted at the potentials where the space charge barrier is present at the surface. Since an electron transfer usually occurs via the conduction or the valence band, it has to be taken into account how much the energy states in the semiconductor overlap with the energy levels of the redox couples in the melt. The overlapping is determined by the position of the redox potential relative to the E_{fb}. For the couples under study, the overlapping of the corresponding energy levels seems to be quite small and consequently the exchange current is expected to be low on the tin oxide electrode.

In spite of this prediction, however, the redox couples examined at the tin oxide electrode are reversible, indicating that the electron transfer occurs by tunneling through the space charge barrier of this highly doped oxide electrode. The electron tunneling process at SnO_2 electrodes in aqueous systems has been presented by Elliott *et al.* (25) and reexamined by Möllers and Memming (26). According to the former study, the tunneling current prevails when the carrier concentration is larger than 3×10^{19} cm^{-3}, and at 5.9×10^{20} cm^{-3} the space charge barrier is completely transparent to electrons due to tunneling. In the high temperature melt system the observed carrier concentration becomes larger than that at room temperature, and the electrode surface does not have an oriented solvation layer as in aqueous systems. This situation must be more favorable to the tunneling process. It may be emphasized that the highly doped SnO_2 electrode in the melt is a metal-like electrode in view of the highly transparent nature to electrons, while it still has a characteristic interface of the semiconductor-liquid junction, *e.g.*, lower background currents due to the smaller space charge capacities in comparison with metal-melt interfaces.

Laplace Plane Analysis of Skin Impedance: A Preliminary Investigation

Maria Reichmanis, Andrew A. Marino, and Robert O. Becker

Veterans Administration Hospital, Syracuse, New York 13210
and Department of Orthopedic Surgery, SUNY Upstate Medical Center, Syracuse, New York 13210

ABSTRACT

The impedance and phase angle of skin as functions of frequency were determined by Laplace plane analysis of the time domain current resulting from an external voltage perturbation. Bode plots of these functions established a passive equivalent circuit model for skin impedance which is valid over a wide range of frequencies. Typical values for the model circuit elements are given for ten human subjects.

The electrical properties of any biological tissue depend on its intrinsic structure and, for *in vivo* studies, on the functional state of the organism. For the case of human skin, the impedance can vary with the thickness and moisture content of the stratum corneum, the concentration and activity of sweat glands, localized injury, the age of the subject, and environmental factors such as temperature and humidity. Seasonal and diurnal variations have been measured: For example, the d-c resistance of skin tends to increase during sleep. Short-term fluctuations are the basis for various monitoring techniques, including the electrocardiogram, electroencephalogram, and impedance plethysmography. Changes in impedance are also associated with the psychological state of the subject (1).

Studies of the a-c impedance of biological systems, including human skin, have generally involved direct measurement of the impedance and phase angle as functions of the frequency of the applied voltage or current (2-5). Any such measurement over a wide range of frequencies tends to be cumbersome and time-consuming. Measurements with an impedance bridge have the additional disadvantage that some *a priori* assumptions must be made regarding an equivalent circuit for the skin impedance. Other reports have presented approximation methods for deriving the equivalent circuit components from the current response to a square voltage pulse input (6, 7). Burton (8) applied Bode analysis to measurements of the skin impedance and phase angle. By means of this method a passive equivalent circuit can be synthesized for any electrical "black box" from plots of its impedance and phase angle *vs.* frequency. The only assumption required is that the system consists solely of passive linear lumped circuit elements (8, 9). Even though the resulting model is not necessarily unique (8), it must represent the system accurately in the frequency range studied.

By extending this technique one step further, the entire frequency spectrum of any system can be computed by applying a Laplace transformation to the current response to an arbitrary voltage perturbation, thus eliminating the tedious process of point-by-point measurement of the impedance and phase angle.

Method

In order to obtain the impedance of a system as a function of frequency, the input voltage perturbation $V(t)$ and the resulting current $I(t)$ must be converted from the time domain (t) to the complex frequency domain (s). This may be accomplished by means of a Laplace transformation. The transform $\mathbf{F}(s)$ of a time domain function $f(t)$ is defined as

Key words: transient analysis, skin equivalent circuit, galvanic skin response, Laplace plane analysis.

$$\mathbf{F}(s) = \int_0^\infty f(t) \exp(-st)\,dt \qquad [1]$$

where $s = \sigma + j\omega$ denotes the complex frequency plane with real axis σ and imaginary axis $j\omega$ (9-11). The integration (1) can be carried out along either the real or imaginary axis of the complex frequency plane. Considering the real axis $(s = \sigma)$

$$\mathbf{F}(\sigma) = \int_0^\infty f(t) \exp(-\sigma t)\,dt, \quad \sigma > 0 \qquad [2]$$

This integral exists for any converging function $f(t)$ $\exp(-\sigma t)$. Performing real axis transformations on both $V(t)$ and $I(t)$, we can define the real axis impedance of the system as

$$Z(\sigma) = V(\sigma)/I(\sigma) \qquad [3]$$

The analogous imaginary axis Laplace transformation $(s = j\omega)$ is given by

$$\mathbf{F}(j\omega) = \int_0^\infty f(t) \exp(-j\omega t)\,dt \qquad [4]$$

equivalent to a one-sided Fourier transform. The corresponding imaginary axis impedance function is

$$Z(j\omega) = V(j\omega)/I(j\omega) \qquad [5]$$

$Z(j\omega)$ is a complex function with a real component $\mathrm{Re}Z(\omega)$ and an imaginary component $\mathrm{Im}Z(\omega)$ which define the phase angle

$$\phi(\omega) = \tan^{-1}[\mathrm{Im}Z(\omega)/\mathrm{Re}Z(\omega)] \qquad [6]$$

A FORTRAN program for both real and imaginary axis Laplace transformations has been developed by Pilla (10, 11). The input data are points defining $V(t)$, an arbitrary voltage perturbation, and $I(t)$, the current response of the system under observation from time $t = 0$ to the time at which $I(t)$ reaches its d-c limit. The program is written for a $V(t)$ which increases from zero to some final constant value and an $I(t)$ rising from zero to a single maximum before decreasing to its d-c limit. We found that the subject current matched these constraints. The output data include $Z(\sigma)$, $\mathrm{Re}Z(\omega)$, $\mathrm{Im}Z(\omega)$, and $\phi(\omega)$ as functions of frequency over any desired range. The highest attainable frequency range is proportional to the reciprocal of the smallest time after $t = 0$ at which both $V(t)$ and $I(t)$ are measurable. The Laplace

transform method of obtaining these functions is particularly advantageous in that $Z(\sigma)$ and $Z(j\omega)$ are theoretically independent of the properties of the measuring electrodes, provided that these are as nearly identical as possible (11).

Experimental Procedure

The voltage $V(t)$, a pulse with a rise time of 10 μsec, a duration of 100 μsec, and a maximum amplitude of 1V, was displayed on one channel of a Tektronix 564 dual-trace oscilloscope; the subject current $I(t)$ was displayed on the second channel (see Fig. 1). Preliminary studies indicated that a pulse duration of 100 μsec was sufficiently long to establish the d-c current limit for all subjects. The interval was set at 1000 μsec (10 times the pulse duration) throughout the study. The resulting display was adequate for photography at sweep rates slower than 0.2 μsec/cm. After the skin has been cleaned with 90% ethanol and hydrated with distilled water, two 1 cm diam carbon-impregnated conducting-rubber electrodes (modified L1DC electrodes, Ritter Company) were applied to the dorsal surfaces of the hand and upper forearm, both in areas devoid of cuts, abrasions, or pigmented moles. We found that the results obtained with these electrodes were comparable to those with metal electrodes, with the advantages of greater flexibility and ease of application. In order to study the skin in as physiological a state as possible, no electrode paste was used. The ensuing oscilloscope display of $V(t)$ and $I(t)$ was photographed for later analysis; typical curves are shown in Fig. 2. Several exposures at sweep speeds ranging from 0.5 to 10 μsec/cm were needed to obtain sufficient data for subsequent mathematical analysis. This procedure was repeated on a total of 10 volunteer subjects.

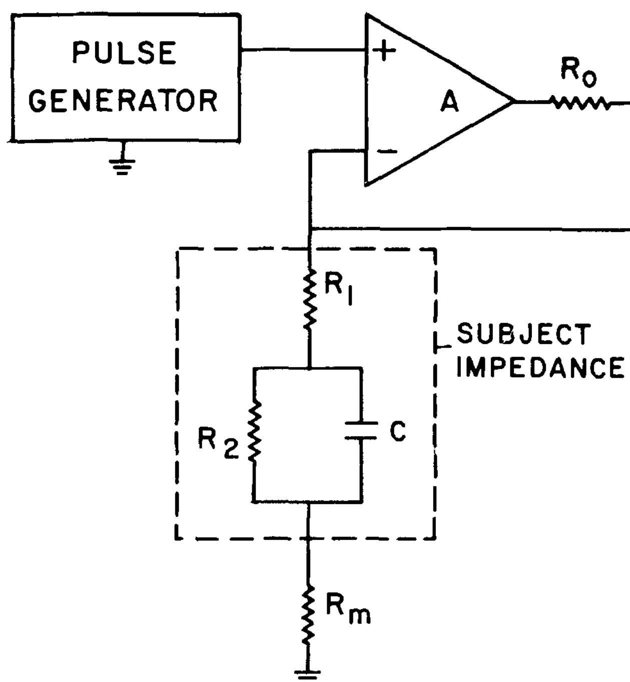

Fig. 1. Potentiostatic circuit for the study of skin impedance. The power supply consisted of a Tacussel model PRT-20-010-MOD potentiostat (A) with output impedance R_0, controlled by a model GSTP-10 pulse generator, applied to the subject. The voltage $V(t)$, a pulse with a rise time of 10 μsec and a duration of 100 μsec, was displayed on one channel of a Tektronix 564 storage oscilloscope with a 3A6 dual-trace input and 3B4 time base. The subject current response $I(t)$, proportional to the voltage across a small series resistor R_m, was displayed on the second channel. The model shown for the subject is a standard equivalent circuit for the a-c impedance of human skin (1,3,6,8).

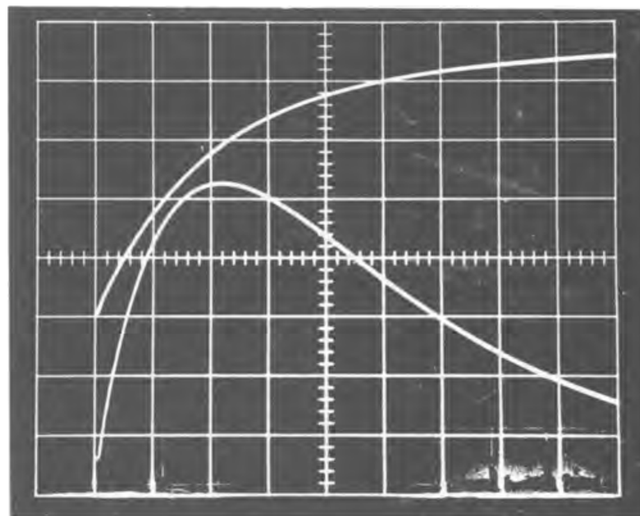

Fig. 2. Typical response curves at 2 μsec/cm. The upper trace is $V(t)$ at 0.2 V/cm; the lower trace is $I(t)$ at 5 μA/cm.

Points defining $V(t)$ and $I(t)$, taken from the photographs, were used as the input time domain data for real and imaginary axis Laplace transformations performed for each individual test by means of a FORTRAN program for numerical integration (10, 11). To attain an upper frequency limit of 1 MHz, it was necessary to record $V(t)$ and $I(t)$ from $t = 0.1$ μsec, with no more than a 10% variation in either parameter between successive data points. These conditions required 50-70 such data points per test. The output of the program included the phase angle and real and imaginary components of the impedance as functions of frequency (d-c to 1 MHz).

Results

Analysis of the frequency domain data for human skin resulting from the real and imaginary axis Laplace transformations established that all of the impedance *vs.* frequency curves were of the same form, and could be described by the real impedance function

$$Z(\sigma) = R_1 + 1/(\sigma C + 1/R_2) \quad [7]$$

This corresponds to a simple R-C circuit (see Fig. 1) found by Burton (8) to be an adequate representation of the skin impedance. Similarly, the data from the imaginary axis transformation yielded the complex impedance

$$Z(j\omega) = R_1 + 1/(1/R_2 + j\omega C) \quad [8]$$

$Z(j\omega)$ could be separated into its real and imaginary components

$$\mathrm{Re}Z(\omega) = R_1 + 1/(\omega^2 C^2 + 1/R_2^2) \quad [9]$$

and

$$\mathrm{Im}Z(\omega) = -\omega C/(\omega^2 C^2 + 1/R_2^2) \quad [10]$$

with a phase angle

$$\phi(\omega) = \tan^{-1}(\omega C/[1 + R_1(\omega^2 C^2 + 1/R_2^2)] \quad [11]$$

Once the form of the equivalent circuit was established, it was not necessary to repeat the entire analytical procedure for each individual test. When analyzing large volumes of data, the model circuit components (R_1, R_2, and C) could be derived from the appropriate low and high frequency limits of these functions (10, 11). These are listed in Table I.

Table I. Low ($R_2\omega C << 1$) and high ($R_2\omega C >> 1$) frequency limits of $Z(\sigma)$, $ReZ(\omega)$, $ImZ(\omega)$, and $\tan \phi (\omega)$

	$R_2\omega C << 1$	$R_2\omega C >> 1$
$Z(\sigma)$	$R_1 + R_2$	$R_1 + 1/\sigma C$
$ReZ(\omega)$	$R_1 + R_2$	$R_1 + 1/R_2\omega^2C^2$
$ImZ(\omega)$	$-\omega C R_2^2$	$-1/\omega C$
$\tan \phi(\omega)$	$-\omega C R_2^2/(R_1 + R_2)$	$-1/\omega C R_1$

In this case, the low frequency limit of both $Z(\sigma)$ ($\sigma CR_2 << 1$) and $ReZ(\omega)$ ($\omega CR_2 << 1$) is $R_1 + R_2$. $|ImZ(\omega)|$ *vs.* ω is a straight line through the origin with slope CR_2^2. At high frequencies ($\sigma CR_2 >> 1$; $\omega CR_2 >> 1$) $|ImZ(\omega)|$ *vs.* $1/\omega$ becomes a straight line with slope $1/C$; $Z(\sigma)$ and $ReZ(\omega)$ are lines with intercepts R_1 and slopes $1/C$. Sample curves are given in Fig. 3. All the equivalent circuit elements can be determined from the results of either transform: it is not necessary to the analysis to perform both real and imaginary axis transforms.

Values of R_1, R_2, C, and the minimum angle ϕ_{min} for all 10 subjects are listed in Table II. These results are compatible with those of earlier studies. As noted by Plutchik (4), the phase angle apparently varied much less between subjects than did the other parameters (see Table II). The equivalent circuit is valid for all anatomical locations. The actual values of the circuit elements would, however, vary with location for each individual. For example, the d-c resistance ($R_1 + R_2$) of the dorsum of the hand tends to be higher than that of the palm (1). R_2 represents the d-c resistance of the stratum corneum, probably separated by a discrete basal cell membrane from the inner tissue resistance R_1. An injury, such as a pinprick, results in a significant drop in the measured

d-c resistance in that area, followed by a return to the normal level during healing. It is at present unclear whether C is a structural or merely a polarization capacitance. If the former, it could be determined by the dielectric properties of skin in conjunction with the detailed structure of the epidermis (1).

Conclusion

Data on the time domain current response of human skin to an external voltage perturbation have been subjected to a Laplace transformation, yielding the impedance and phase angle in the frequency domain. Subsequent Bode analysis of this data provided a simple equivalent circuit for skin impedance, identical to a standard model for the steady-state impedance.

This technique could be useful for the study of the frequency response of any biological system which can be described by an equivalent circuit composed of passive, linear, and lumped circuit elements. Pilla (10) has noted the desirability of automating the data-recording process for this technique. If indeed this should prove feasible, the technique of frequency domain analysis would greatly extend the study of transient responses, at present limited to monitoring of resistance or potential levels.

On the Normal Oxygen Potential at a Platinum-Oxygen Alloy Diaphragm Electrode

James P. Hoare*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

Platinum foil electrodes were clamped between the compartments of a dual Teflon cell. The rest potential on the front side of the Pt diaphragm in contact with O_2-saturated 2*N* H_2SO_4 solution was observed while the back side was in contact with aerated, concentrated HNO_3. A value of 1.227V was observed on a Pt foil 0.00127 cm thick after 54 hr in contact with HNO_3 and 1.221V on a foil 0.00762 cm thick after 358 hr. This is the first time that the reversible potential has been reported on a prereduced Pt surface. The thickness effect is in agreement with the proposed model.

It has been shown (1) that the rest potential on a Pt/O_2 electrode is a mixed potential and the local cell is composed of the cathodic reduction of O_2

$$O_2 + 4H^+ + 4e \rightleftarrows 2H_2O \quad [1]$$

and the anodic oxidation of Pt

$$Pt + H_2O \rightleftarrows Pt\text{-}O + 2H^+ + 2e \quad [2]$$

Since Pt is not inert to oxygen, the establishment of the local cell prevents the potential from rising to the reversible value of 1.229V. A steady state is reached when the rate of formation of the adsorbed oxygen layer, Pt-O, by local cell action equals the rate of dissolution of oxygen in the Pt metal most likely by a place-change mechanism (2, 3)

$$Pt\text{-}Pt\text{-}O \rightleftarrows Pt\text{-}O\text{-}Pt \quad [3]$$

At this point, the coverage, θ, of the surface with adsorbed oxygen is about 0.3 and the rest potential has a value of 1.05 ± 0.01V (1). There is abundant literature (4-9) indicating that oxygen can dissolve in Pt metal.

To observe the normal oxygen potential (1.229V), it is necessary to suppress the local cell action. One way to do this is to generate a complete, conducting

* Electrochemical Society Active Member.

Key words: oxygen electrode, normal oxygen potential, platinum-oxygen alloy, rest potential, platinum diaphragm.

layer of adsorbed oxygen by oxidizing the Pt surface either thermally (10-14) or chemically (15-17). In such cases the reversible oxygen potential has been observed. However, it has not been observed on a prereduced Pt surface.

In another method, the reversible potential on a prereduced Pt electrode should be observed if the Pt metal were saturated with dissolved oxygen so that the Pt-O layer could no longer dissolve in the metal. Under these circumstances, the Pt-O layer would grow to a complete conducting layer and the rest potential would be determined by Eq. [1] alone.

It has been found (1, 4, 18-20) that significant amounts of oxygen may be dissolved in Pt which has been strongly anodized. A Pt diaphragm prereduced in H_2 was placed in contact with 1M H_2SO_4 solution on both sides in a dual Teflon cell (18). While the back side of the Pt foil was anodized, the rest potential in O_2-saturated acid solution was monitored on the front side. After an induction period, the rest potential reached a value of 1.180V, the highest potential (to my knowledge) reported in the literature on a prereduced Pt/O_2 electrode at rest.

Not only does the passivation of Pt in concentrated HNO_3 produce a complete layer of adsorbed oxygen on the Pt surface, but also it causes large amounts of oxygen to be dissolved in the bulk metal (15, 17, 20). Prompted by the reports of the behavior of hydrogen adsorption on and dissolution in Pt samples with stepped surfaces carried out by Lang, Joyner, and Somerjai (21), we proposed (20) that the HNO_3 etched the Pt surface in such a way that crystal faces favorable for the dissolution of oxygen were exposed.

In the dual Teflon cell (18), if the back side of a Pt diaphragm is exposed to air-saturated, concentrated HNO_3 while the rest potential on the front side is observed in O_2-saturated H_2SO_4 solution, it is expected, then, that rest potentials approaching the normal oxygen potential (1.229V) would be observed. This report describes the results of such an investigation.

Experimental

Four thicknesses (0.00127, 0.00254, 0.00508, and 0.00762 cm) of Pt foil (99.99% pure and about 3 cm^2 in area) were prepared and clamped between the compartments of a dual Teflon cell as described previously (18). Testing for leaks around and through the Pt diaphragm sealed with polyethylene washers, filling the cells with $2N$ H_2SO_4 solution, and purification of the system were carried out according to procedures presented in detail elsewhere (18).

After the system was preelectrolyzed for at least 48 hr, prepurified H_2 was bubbled through both compartments of the dual cell until all Pt electrodes registered 0V between one another. Then, a saturated calomel reference electrode (SCE) was inserted in the left compartment and the potential differences between the SCE and the Pt/H_2 electrodes were recorded.

The acid solution was removed from the right side with a syringe and replaced with air-saturated, concentrated HNO_3 exposed to the atmosphere. The H_2 stirring of the left side was then replaced with prepurified O_2 stirring and the rest potential of the front side of the Pt foil was followed with respect to the SCE. All potential values are recorded in this report with respect to the normal hydrogen electrode (NHE). The potential of the Pt gauze auxiliary electrode was also followed in the left-hand compartment in O_2-stirred $2N$ H_2SO_4 solution.

The partial pressure of oxygen, P_{O_2}, determinations and the potential measurement techniques have been described in detail in an earlier report (1). All measurements were obtained at ambient temperature, 24° ± 1°C. Most experiments were made on the thinnest and thickest Pt samples with shorter runs taken on the two samples of intermediate thickness to complete the thickness effect data.

Results

A plot of the rest potential on the front side of a Pt diaphragm in O_2-saturated $2N$ H_2SO_4 solution as a function of the time for which the back side was in contact with air-saturated, concentrated HNO_3 is presented in Fig. 1 for short and in Fig. 2 for extended periods of time. Also shown in Fig. 2 is a plot of the rest potential of the Pt gauze auxiliary electrodes in the left-hand compartment as a function of time, showing that these electrodes behaved in the usual way characteristically determined by the local cell (Eq. [1] and [2]).

To check on the nature of the potential-determining reaction, the rest potential is plotted in Fig. 3 as a function of P_{O_2}. A line with a slope of 0.015V is drawn on the plot to show that the data are consistent with a four-electron electrode process involving oxygen. After the rest potential had reached the reversible oxygen potential, 1.227V on the 0.00127 cm thick foil after 54 hr and 1.221V on the 0.00762 cm thick foil after 358 hr the O_2 stirring was replaced with H_2 stirring. Within 700 sec, the potential of the front side of the Pt foil and of the two Pt gauze auxiliary electrodes had reached the same potential *vs.* SCE as were observed at the beginning of the run. The three Pt potentials agreed within a millivolt. When H_2 was

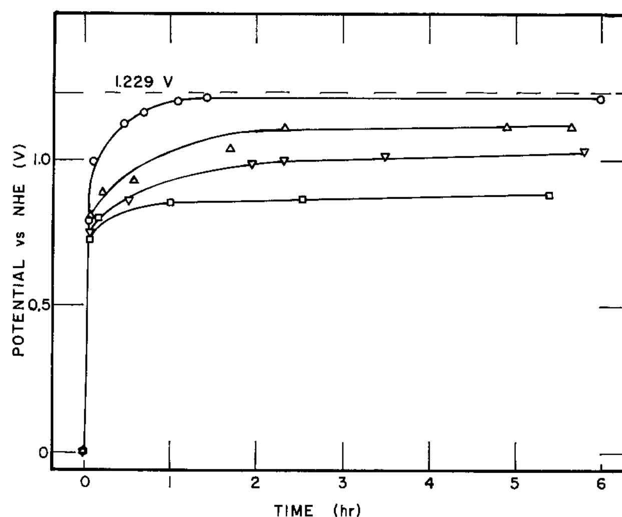

Fig. 1. Rest potential on front of Pt diaphragm in O_2-saturated $2N$ H_2SO_4 solution as a function of the time the back side of the diaphragm was in contact with air-saturated, concentrated HNO_3 for 0.00127 (circles); 0.00254 (triangles); 0.00508 (inverted triangles); and 0.00762 cm (squares) thick foil.

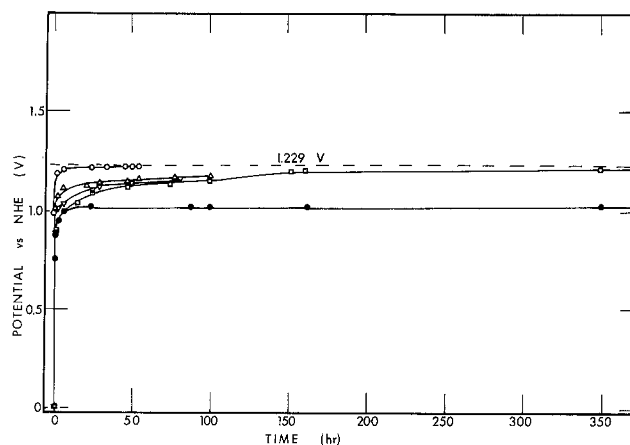

Fig. 2. Same as Fig. 1 for extended periods of time. Also shown is potential of auxiliary Pt gauze electrode (filled circles).

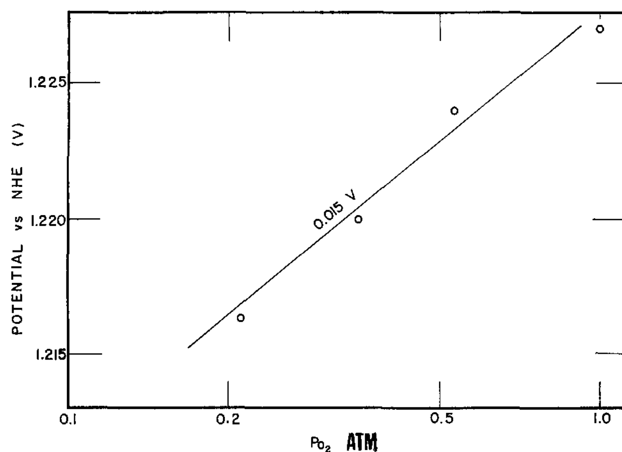

Fig. 3. A plot of the rest potential as a function of log of P_{O_2} on the front side of the Pt diaphragm electrode. A line with a slope of 0.015V is drawn on the plot to show that the data is consistent with a four-electron oxygen reaction.

replaced with O_2 stirring once more, the potential approached the reversible value at a rate similar to that shown in Fig. 2. Apparently, the H_2-saturated acid solution not only removed the adsorbed oxygen layer but also some of the dermasorbed or dissolved oxygen as well.

After the cell was dismantled, it was observed that the Pt foil in the region enclosed by the polyethylene washers was bulged toward the compartment containing the HNO_3. A similar observation was recorded in Fig. 2 of Ref. (19), where the back side of the Pt diaphragm had been strongly anodized. The Pt sample was then analyzed with x-ray photoelectron spectroscopy (XPS). From a depth profile obtained by ion-sputtering away layers of metal, dissolved oxygen was detected in the bulk metal. In passing, it was noted that nitrogen or nitrates were not detected on the surface or in the bulk metal.

Discussion

By etching the back side of the Pt diaphragm with HNO_3, it is possible to charge the Pt with dissolved oxygen to such an extent that a Pt-O alloy is formed (17, 22). Expansion of the lattice by the dissolved oxygen caused the Pt foil to buckle. Since the Pt layers next to the HNO_3 would be charged first, the lattice in these layers would expand first, causing the foil to bow toward the HNO_3 compartment of the cell in agreement with the experimental observations.

On the front side of the Pt diaphragm, the local cell (Eq. [1] and [2]) produces a partial layer of adsorbed oxygen (Pt-O). As the Pt foil becomes saturated with dissolved oxygen caused by contact with the aerated HNO_3 on the back side, the adsorbed oxygen on the front side can no longer dissolve in the Pt metal and the Pt-O layer grows. It is well known (4, 17, 23-29) that the rest potential of a Pt/O_2 electrode increases linearly with increasing coverage of the surface with dissolved oxygen. When θ approaches a monolayer, the potential approaches the reversible potential (17), 1.227V on the 0.00127 cm thick foil after 54 hr and 1.221V on the 0.00762 cm thick foil after 358 hr. To my knowledge, this is the first time that the normal oxygen potential has been observed on a prereduced Pt electrode in O_2-saturated acid solution.

From the data in Fig. 1 and 2, there is observed an effect of diaphragm thickness on the time required to approach the normal oxygen potential. The following model assists in understanding this behavior.

If S is the total number of O-penetration sites on the Pt surface on the back side of the foil, $\sigma = S/A$ where σ is the surface density of active sites and A is the surface area. Let dp/dt be the rate of penetration of O atoms per second at an active site. Then, the rate, R, at which O atoms enter the bulk metal ($cm^{-2}\ sec^{-1}$) is $R = \sigma dp/dt$. If Z is the total number of residence sites for dissolved O atoms in the bulk metal, the density of sites, ζ, is $\zeta = Z/V$ where V is the volume of the Pt foil. Assuming that the surface penetration step (Eq. [3]) is the slow step in the process, the time, t_s, required to saturate a unit of thickness of the bulk metal with dissolved oxygen atoms is

$$t_s = \frac{\zeta}{R} = \frac{\zeta}{\sigma}\frac{dt}{dp} \qquad [4]$$

To saturate the total sample requires $t_s d$ sec where d is the thickness of the diaphragm

$$t_t = t_s d = (\zeta/\sigma)(dt/dp)(d) \qquad [5]$$

Equation 4 shows that the time to saturate the Pt sample with dissolved oxygen is inversely proportional to the rate at which O atoms penetrate the metal surface, and to the ratio of the density of surface active sites to the density of bulk residence sites.

Since all of the foils were made from Pt prepared and treated in the same way, the rate of penetration of O atoms through the Pt surface should be constant from sample to sample to a first approximation. If it is assumed that a surface penetration site is a bulk residence site at the surface and that the distribution of bulk sites is uniform throughout the metal samples, then ζ and σ are also constant from sample to sample. Under these conditions, $t_t \sim d$.

According to the model presented before (18), θ approaches unity and the rest potential approaches 1.229V as the Pt sample approaches saturation with

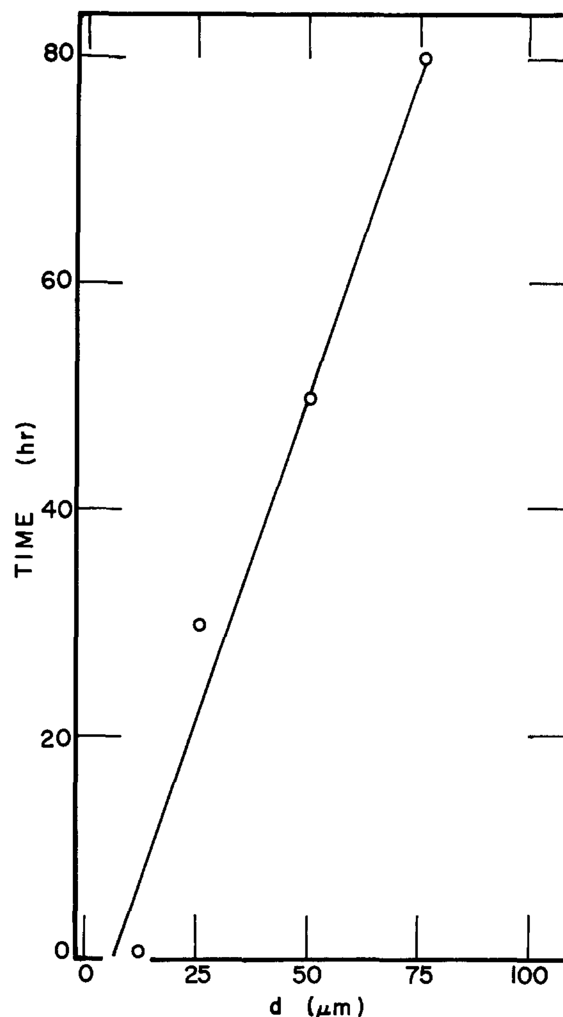

Fig. 4. Time required to reach a potential of 1.15V on the front side of the Pt diaphragm as a function of diaphragm thickness.

dissolved oxygen. Consequently, it is expected that the time required to reach a given potential increases directly with increasing foil thickness. In Fig. 4, the time required to reach 1.150V is plotted as a function of the thickness of the Pt diaphragm. These data exhibit the expected linear relationship between time and thickness. Also, after a given period of time has elapsed, the rest potential reached is inversely proportional to the diaphragm thickness as demonstrated by the linear plot of the rest potential value observed after 1 hr as a function of the reciprocal of the Pt foil thickness in Fig. 5.

What the nature of the bulk residence sites is is not clear at this time. Earlier work (20) indicates that dissolved oxygen may reside in the grain boundaries as well as in the platinum lattice. Possibly the sites in the lattice are associated with the octahedral holes in the face-centered cubic lattice. Etching the Pt surface with HNO_3 apparently exposes high index crystal faces which facilitate the passage of oxygen to the bulk residence sites after the place-change step (Eq. [3]) has taken place.

Since oxygen was found in the interior of the Pt samples from XPS depth-profile analyses, since P_{O_2} measurements of the rest potential indicate that a four-electron oxygen reaction is potential determining, and since this high rest potential can be converted to the H_2 potential by treatment with H_2-saturated acid solution and subsequently recovered by treatment with O_2-saturated acid solution again, strong support for the proposed (1, 18, 20) model of the Pt/O_2 electrode at rest is provided by these data presented in this report.

Acknowledgments

The author wishes to express his sincere gratitude to Mr. T. P. Schreiber and Dr. S. Gaarenstroom of the Analytical Chemistry Department of GM Research Laboratories for carrying out the XPS analyses on the Pt samples and to Mr. J. D. Thomas and Mr. D. W. Hardesty of the Electrochemistry Department of GM Research Laboratories for helpful discussions.

The Application of Pulsed Current Electrolysis to a Rotating-Disk Electrode System

I. Mass Transfer

K. Viswanathan,* M. A. Farrell Epstein, and H. Y. Cheh**

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

ABSTRACT

A numerical solution was obtained for mass transfer to a rotating-disk electrode under pulsed current conditions. Good agreement was reached on the calculation of rate of mass transfer between the numerical solution and the solution by Cheh from a simplified diffusion model. The concept of a pulsating diffusion layer was introduced and it was shown that the thickness of the pulsating diffusion layer was a function of the pulsed current characteristics as well as the Reynolds and Schmidt numbers of the system. Experimental verification of the theoretical results was obtained by using a model ferri-ferrocyanide electrolysis.

The application of pulsed-current electrolysis to practical systems has generated a considerable amount of interest during the past several years. For instance, pulsed electrodeposition of copper, silver, and gold was reported by Cheh and co-workers (1-3). Sullivan (4) and Chen and Sautter (5) deposited cobalt under pulsed current conditions. More recently, Ibl *et al.* (6) studied the effect of pulsed electrolysis on the physical properties of electrodeposits. Pulsed electrolysis was also used in battery charging by Wagner and Williams (7) and by Bedrossian and Cheh (8).

Theoretical considerations of pulsed electrolysis were also reported in the recent literature. Cheh (9, 10) developed a simple diffusion model to calculate the rate of electrodeposition by a pulsed current and by a periodic reversal of the current. Popov *et al.* (11) studied mass transfer under pulsed potential conditions in both stirred and unstirred solutions. Wan *et al.* (12) analyzed the application of pulsed techniques to sequential electron transfer reactions.

One of the most important advantages of pulsed electrolysis is the enhancement of mass transfer during the on period of the pulse cycle. Therefore, under suitable conditions, high instantaneous current density can be obtained without the initiation of a second and perhaps undesirable reaction. Also, since mass transfer limitations can very effectively be reduced, pulsed current electrolysis can in principle be developed into a new tool to study fast electrode reactions. In order to obtain quantitative kinetic information on fast electrode reactions, it is essential that mass transfer rates be calculated exactly. An exact solution to both mass transfer and electrochemical kinetics in a stirred system under pulsed conditions is very difficult to obtain. On the other hand, the problem could be simplified considerably if the diffusion model developed by Cheh (9) can be used with confidence to account for mass transfer effects. In this paper, a rigorous theoretical calculation as well as an experimental investigation on the mass transfer rates to a rotating-disk electrode system is presented. A kinetic study of fast electrode reactions by pulsed current electrolysis is presented in a subsequent paper (see Editor's Note, p. 1775).

Theoretical

Assume that a rotating-disk electrode (RDE) is situated in an electrolyte of large extent and the electrode is rotating at a constant velocity. Both the radius of the RDE and the distance between the RDE and the counterelectrode are large as compared to the thickness of the Nernst diffusion layer. The number of coulombs passed during an experiment is assumed to be so small that the depletion of the reacting species in the solution can be neglected. An excess of supporting electrolyte is present so that electrical migration and nonfaradaic effects are negligible. Finally, the Schmidt number of the solution is orders of magnitude larger than unity so that the diffusion layer is thin as compared to the momentum boundary layer. Under these conditions, the concentration of the reacting species is governed by the following convective diffusion equation

$$\frac{\partial c}{\partial t} + v_z \frac{\partial c}{\partial z} = D \frac{\partial^2 c}{\partial z^2} \qquad [1]$$

with the following boundary conditions

$$c = c_\infty \qquad \text{at } t = 0 \text{ and all } z \qquad [2]$$

$$c = c_\infty \qquad \text{at } t > 0 \text{ and } z \to \infty \qquad [3]$$

$$-D \frac{\partial c}{\partial z} = \frac{i}{n\mathbf{F}} \qquad \text{at } t > 0 \text{ and } z = 0 \qquad [4]$$

where c is the concentration of the reacting ion, c_∞ is its concentration in the bulk of the solution, D is the diffusion coefficient of the reacting ion, $\mathbf{F}$ is Faraday's constant, i is the applied current density, n is the number of electrons transferred during reaction, t is time, v_z is the axial component of the velocity, and z is the axial coordinate extending from the electrode surface.

The form of the pulsed current is shown schematically in Fig. 1. Consequently, the pulsed current density in Eq. [4] can be expressed as

$$i = i_p \qquad \text{at } 0 < t \leq t_1, t_2 < t \leq t_3, \text{etc.} \qquad [5]$$

$$i = 0 \qquad \text{at } t_1 < t \leq t_2, t_3 < t \leq t_4, \text{etc.} \qquad [6]$$

where i_p is the pulsed current density and t_n is defined in Fig. 1. Note that one may also consider that the current is on when $t_{m-1} < t \leq t_m$ and the current is off when $t_m < t \leq t_{m+1}$ where m is an odd number.

Before one proceeds to solve Eq. [1] subject to boundary conditions, Eq. [2]-[6], it is useful to put these equations into dimensionless form. Let

$$C = \frac{c}{c_\infty}, \quad G = -\frac{i_p \delta}{n\mathbf{F}Dc_\infty}, \quad K = -\frac{v_z \delta^3}{z^2 D} \qquad [7]$$

and

$$\tau = \frac{Dt}{\delta^2}, \quad \text{and} \quad \zeta = \frac{z}{\delta} \qquad [8]$$

Key words: pulsed electrolysis, rotating-disk electrode, mass transfer.

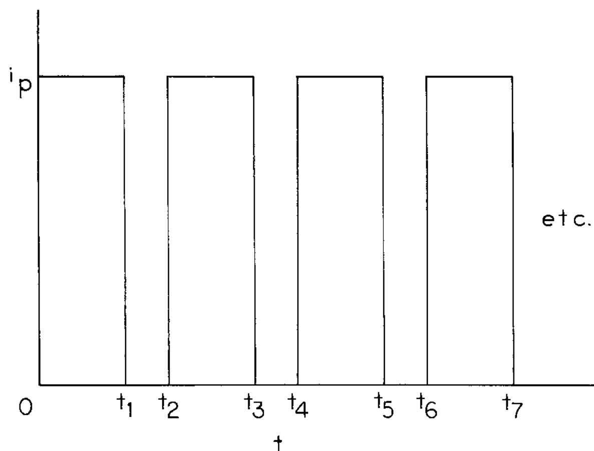

Fig. 1. Schematic diagram of a pulsed current

where δ is the Nernst diffusion layer thickness. The dimensionless equation and the boundary conditions are

$$\frac{\partial C}{\partial \tau} - K\zeta^2 \frac{\partial C}{\partial \zeta} = \frac{\partial^2 C}{\partial \zeta^2} \quad [9]$$

and

$$C = 1 \qquad \text{at } \tau = 0 \text{ and all } \zeta \quad [10]$$

$$C = 1 \qquad \text{at } \tau > 0 \text{ and } \zeta \rightarrow \infty \quad [11]$$

$$\frac{\partial C}{\partial \zeta} = G \quad \text{at } \zeta = 0 \text{ and } 0 < \tau \leq \tau_1, \tau_2 < \tau \leq \tau_3, \text{etc.} \quad [12]$$

$$\frac{\partial C}{\partial \zeta} = 0 \quad \text{at } \zeta = 0 \text{ and } \tau_1 < \tau \leq \tau_2, \tau_3 < \tau \leq \tau_4, \text{etc.} \quad [13]$$

where

$$\tau_n = \frac{Dt_n}{\delta^2} \quad [14]$$

By substituting into the definition of K the approximate velocity at small values of ζ (13)

$$v_z = -0.5102(\omega^3/\nu)^{1/2}z^2 \quad [15]$$

and the thickness of the Nernst diffusion layer at large Schmidt number (13)

$$\delta = 1.612\left(\frac{D}{\nu}\right)^{1/3}\left(\frac{\nu}{\omega}\right)^{1/2} = 1.612R\text{Sc}^{-1/3}\text{Re}^{-1/2} \quad [16]$$

where ω is the rotation speed of the electrode, ν is the kinematic viscosity of the electrolyte, R is the radius of the electrode, Sc is the Schmidt number, and Re is the Reynolds number, K is found to be a constant, 2.136, independent of the physical properties of the electrolyte as well as the rotation speed of the electrode.

An exact solution in closed form of Eq. [9] with boundary conditions, Eq. [10]-[13] is extremely difficult if not impossible. For numerical solution in terms of a series, the boundary condition Eq. [11], may be modified as follows

$$C = 1 \qquad \text{at } \tau > 0 \text{ and } \zeta = 2 \quad [17]$$

The justification of this modification was suggested by Riddiford (14). It appears that a change of the upper limit of integration from infinity to a finite value of 2 has litle effect in changing the numerical results of the solution. For instance, even at the extreme condition of performing a d-c electrolysis at limiting current density, the dimensionless concentration reaches a value exceeding 0.9995 at $\zeta = 2$.

A series solution of Eq. [9] is proposed as follows

$$C(\tau,\zeta) = \sum_{n=0}^{\infty} C_n R_n(\zeta) \exp(-\lambda_n^2 \tau) \quad [18]$$

where λ_n is the eigenvalue and C_n is the coefficient of the infinite series. The solution corresponding to $\lambda_n = 0$ satisfies the inhomogeneous part of the boundary conditions, Eq. [12] and [17]. It can be derived easily as

$$R_0 = 1 - G + G\int_0^{\zeta} \exp\left(-\frac{K\alpha^3}{3}\right) d\alpha \quad [19]$$

Note that R_0 represents physically the steady-state d-c solution.

The solution corresponding to $\lambda_n \neq 0$ is considerably more difficult to obtain. A combination of an asymptotic method and a trial-and-error method using a fourth-order Runge-Kutta technique was used to obtain the first forty series coefficients and eigenvalues. Details of the calculations are presented in the appendix and the results are shown in Table I.

From a knowledge of these coefficients and eigenvalues, the concentration of the reacting species at the electrode surface, c_i, can be calculated by

$$\frac{c_i}{c_\infty} = 1 - G + \sum_{n=1}^{\infty} C_n \exp(-\lambda_n^2 \tau) \quad [20]$$

Following the same approach by Cheh (9), the value of c_i at its periodic state and the ratio of the limiting current density under pulsed and d-c conditions can be calculated from the following equations.

During periods when the current is on, $\tau_{m-1} < \tau \leq \tau_m$

$$\frac{(c_i - c_\infty)nFD}{i_p\delta} = 1 - \sum_{n=1}^{\infty} \frac{C_n}{G} \exp[-\lambda_n^2(\tau - \tau_{m-1})] \frac{(1 - \exp[-\lambda_n^2(\tau_2 - \tau_1)])}{[1 - \exp(-\lambda_n^2 \tau_c)]} \quad [21]$$

During periods when the current is off, $\tau_m < \tau \leq \tau_{m+1}$

$$\frac{(c_l - c_\infty)nFD}{i_p\delta} = \sum_{n=1}^{\infty} \frac{C_n}{G} \exp(-\lambda_n^2(\tau - \tau_m)) \frac{[1 - \exp(-\lambda_n^2\tau_1)]}{[1 - \exp(-\lambda_n^2\tau_c)]} \quad [22]$$

and

$$\frac{(i_p)_l}{(i_{dc})_l} = \frac{1}{1 - \sum_{n=1}^{\infty} \frac{C_n}{G} \frac{[\exp(-\lambda_n^2\tau_1) - \exp(-\lambda_n^2\tau_c)]}{[1 - \exp(-\lambda_n^2\tau_c)]}} \quad [23]$$

where $(i_p)_l$ and $(i_{dc})_l$ are the limiting current densities under pulsed and d-c conditions and τ_c is the dimensionless cycle time. The ratio of the two limiting current densities as derived by Cheh (9) from a diffusion model is expressed as

$$\frac{(i_p)_l}{(i_{dc})_l} = \frac{1}{1 - 2\sum_{n=1}^{\infty} \frac{1}{\mu_n^2} \frac{[\exp(-\mu_n^2\tau_1) - \exp(-\mu_n^2\tau_c)]}{[1 - \exp(-\mu_n^2\tau_c)]}} \quad [24]$$

where

$$\mu_n = (2n - 1)\frac{\pi}{2} \quad [25]$$

A numerical comparison of the limiting-current ratios predicted by Eq. [23] and [24] is shown in Table II. The agreement between the two equations is excellent. It can therefore be concluded that the diffusion model provides an accurate calculation of the mass transfer rates. A major advantage of the simple model is that it enables one to extend the analysis to systems with kinetic hindrance, which is the subject of our subsequent paper.

Recently Ibl *et al.* (6) introduced the concept of a pulsating diffusion layer. This layer refers to a region extending from the electrode surface in which the time-dependent concentration variation is important. In accordance with the Nernst diffusion layer concept, the thickness of the pulsating diffusion layer, δ_p, can be defined by

$$i_p \equiv \frac{nFD}{\delta_p}(c_l - c_\infty) \quad [26]$$

By applying this definition to the diffusion model under a periodic state condition (9), δ_p can be calculated from

$$\frac{\delta_p}{\delta} = 1 - 2\sum_{n=1}^{\infty} \frac{1}{\mu_n^2} \exp(-\mu_n^2(\tau - \tau_{m-1})) \frac{(1 - \exp[-\mu_n^2(\tau_2 - \tau_1)])}{[1 - \exp(-\mu_n^2\tau_c)]} \quad [27]$$

Since δ is a function of the Schmidt and Reynolds numbers of the system, δ_p depends on these parameters as well as on the pulsed-current characteristics. A numerical example for the pulsating diffusion layer at $\tau_c = 0.01$ is shown in Fig. 2. The value of 0.01 for τ_c corresponds to a realistic experimental condition of the RDE system. Results clearly indicate that the thickness of the pulsating layer is a function of time during a pulse. It increases as the pulse progresses and reaches a maximum value at the end of the pulse. It also depends on the ratio of τ_1/τ_c, frequently referred to in the literature as the duty cycle (15); the shorter the duty cycle, the thinner is the pulsating diffusion layer. The maximum value of δ_p which occurs at the end of each pulse can be calculated by

$$\frac{(\delta_p)_{max}}{\delta} = 1 - 2\sum_{n=1}^{\infty} \frac{1}{\mu_n^2} \frac{[\exp(-\mu_n^2\tau_1) - \exp(-\mu_n^2\tau_c)]}{[1 - \exp(-\mu_n^2\tau_c)]} \quad [28]$$

This equation is of course the reciprocal of Eq. [24]. Numerical results of Eq. [28] are presented in Fig. 3 which clearly shows that the pulsating diffusion layer is always thinner than the corresponding d-c diffusion layer.

Experimental

The limiting current density for the reduction of a 0.01M ferricyanide in a solution also containing 0.01M ferrocyanide and 1M KCl was chosen for this study. Due to the fast kinetics of the ferri-ferrocyanide re-

action, the same system was also used for our subsequent kinetic study under pulsed conditions.

A Pine Instrument high speed rotator with a Pt electrode of 0.461 cm^2 area was used as the RDE. A coil of Pt was used as the counterelectrode and a Fisher Scientific saturated calomel electrode was used as the reference electrode. All experiments were carried out at room temperature which was 22° ± 1°C. The kinematic viscosity of the electrolyte was measured by using an Ostwald viscometer and the value was found to be 0.00914 cm^2/sec. The diffusion coefficient of the ferricyanide ion was measured from a d-c limiting current density *vs.* square root of rotation speed plot by using Eq. [16]. The value was found to be 7.2×10^{-6} cm^2/sec.

For pulsed current electrolysis, the current was supplied by feeding the square wave output of a Tacussel GSTP2 function generator to a Kepco PC2 power supply. The amplitude and frequency of the current pulse was determined by measuring the voltage drop across a 1000Ω standard resistor connected in series to the cell. The results were recorded on a Tektronix 5103N dual trace oscilloscope. The potential difference between the RDE and the reference electrode was recorded simultaneously on the same oscilloscope.

Experiments were carried out at rotation speeds of 400, 900, and 1600 rpm and at duty cycles and pulse periods ranging from 0.1 to 0.667 and from 0.001 to 0.006 sec, respectively. The value of τ_c varied from 0.0015 to 0.0180. Pulsed limiting current density was measured by observing the sudden jump of potential of the RDE during a gradual increase of the pulsed current density. Experimental as well as theoretical results calculated by using Eq. [23] are presented in Table III. A graphical comparison is also shown in Fig. 4. The good agreement obtained between experimental and theoretical results is evident in both displays.

Conclusions

A numerical calculation on the mass transfer rate in pulsed current electrolysis was carried out. The results were in excellent agreement with those predicted by using a simplified diffusion model developed by Cheh. It is therefore the conclusion of the work that the diffusion model can be used to account for mass transfer effects in systems with kinetic limitations.

A quantitative analysis on the pulsating diffusion layer was made. The diminishing diffusion layer under pulsed conditions is responsible for the ability of carrying out pulsed electrolysis at high instantaneous current densities under suitable conditions.

Experimental measurements on the pulsed limiting current densities were made by using a ferri-ferrocyanide system. Good agreement was obtained between the experimental measurements and theoretical predictions.

Editor's Note

By mischance, this is Part I of a two-part series, and is being printed after Part II, which appeared in the October 1978 issue of the JOURNAL, Vol. 125, No. 10, pp. 1616-1618. The JOURNAL regrets very much this inadvertent transposition.

APPENDIX

Numerical Solution of Eq. [9] for $\lambda_n \neq 0$

Substituting Eq. [18] into Eq. [9] and the homogeneous part of Eq. [12] and [17], one obtains

$$\frac{d^2R_n}{d\zeta^2} + K\zeta^2\frac{dR_n}{d\zeta} + \lambda_n{}^2R_n = 0 \quad \text{[A-1]}$$

with the boundary conditions

$$\frac{dR_n}{d\zeta} = 0 \quad \text{at} \quad \zeta = 0 \quad \text{[A-2]}$$

$$R_n = 0 \quad \text{at} \quad \zeta = 2 \quad \text{[A-3]}$$

For large values of λ_n ($n > 5$), the solution can be achieved by using an asymptotic expansion method. It is, however, convenient to first introduce the following transformation (16)

$$R_n = \psi_n(\zeta)\exp\left(-\frac{K\zeta^3}{6}\right) \quad [A\text{-}4]$$

By substituting Eq. [A-4] into Eq. [A-1]-[A-3], one obtains

$$\frac{d^2\psi_n}{d\zeta^2} + \left(\lambda_n^2 - K\zeta - \frac{K^2\zeta^4}{4}\right)\psi_n = 0 \quad [A\text{-}5]$$

with

$$\frac{d\psi_n}{d\zeta} = 0 \quad \text{at} \quad \zeta = 0 \quad [A\text{-}6]$$

$$\psi_n = 0 \quad \text{at} \quad \zeta = 2 \quad [A\text{-}7]$$

Now, one seeks an asymptotic solution of Eq. [A-5] in the following form

$$\psi_n = \psi_{n0} + \epsilon\psi_{n1} + \epsilon^2\psi_{n2} + \ldots \quad [A\text{-}8]$$

$$\lambda_n = \lambda_{n0} + \epsilon\lambda_{n1} + \epsilon^2\lambda_{n2} + \ldots \quad [A\text{-}9]$$

where

$$\epsilon = K/\lambda_{n0}^2 \quad [A\text{-}10]$$

By introducing the first three terms of Eq. [A-8] and [A-9] into Eq. [A-5], it can be shown that the following equations must be satisfied

$$\frac{d^2\psi_{n0}}{d\zeta^2} + \lambda_{n0}^2\psi_{n0} = 0 \quad [A\text{-}11]$$

$$\frac{d^2\psi_{n1}}{d\zeta^2} + \lambda_{n0}^2\psi_{n1} = \lambda_{n0}^2\psi_{n0}\zeta + \frac{K}{4}\lambda_{n0}^2\psi_{n0}\zeta^4 - 2\lambda_{n0}\lambda_{n1}\psi_{n0} \quad [A\text{-}12]$$

$$\frac{d^2\psi_{n2}}{d\zeta^2} + \lambda_{n0}^2\psi_{n2} = \lambda_{n0}^2\psi_{n1}\zeta + \frac{K}{4}\lambda_{n0}^2\psi_{n1}\zeta^4 - 2\lambda_{n0}\lambda_{n2}\psi_{n0} - 2\lambda_{n0}\lambda_{n1}\psi_{n1} - \lambda_{n1}^2\psi_{n0} \quad [A\text{-}13]$$

The boundary conditions of these equations are

$$\psi_{n0} = 1, \quad \psi_{n1} = \psi_{n2} = 0 \quad \text{at} \quad \zeta = 0 \quad [A\text{-}14]$$

$$\frac{d\psi_{n0}}{d\zeta} = \frac{d\psi_{n1}}{d\zeta} = \frac{d\psi_{n2}}{d\zeta} = 0 \quad \text{at} \quad \zeta = 0 \quad [A\text{-}15]$$

$$\psi_{n0} = \psi_{n1} = \psi_{n2} = 0 \quad \text{at} \quad \zeta = 2 \quad [A\text{-}16]$$

The solution of the above equations can be obtained easily by following standard procedures as described by Wylie (17).

The first five eigenvalues can be calculated by a trial-and-error method using a fourth-order Runge-Kutta technique (18). The coefficients in Eq. [18] can then be calculated by

$$\frac{C_n}{G} = \frac{\int_0^2 \left(1 - \int_0^\zeta \exp\left(-\frac{K\alpha^3}{3}\right)d\alpha\right)\exp\left(\frac{K\zeta^3}{6}\right)\psi_n(\zeta)d\zeta}{\int_0^2 \psi_n^2(\zeta)d\zeta} \quad [A\text{-}17]$$

LIST OF SYMBOLS

- c concentration of reacting ion
- c_i, c_∞ concentration of reacting ion at the electrode surface, and in the bulk solution, respectively
- C dimensionless concentration defined in Eq. [7]

Studies of the Nickel Electrode in a Rotating Multipolar Wiper-Blade Cell

M. Farooque[1] and T. Z. Fahidy*

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1

ABSTRACT

The usefulness of nickel as the working electrode in a rotating multipolar wiper-blade cell is demonstrated by experiments related to oxygen reduction and evolution, alcohol oxidation, and anodic dissolution of nickel.

In previous publications [e.g., (1-5)] the use of a recently developed rotating multipolar wiper-blade cell to study electrochemical reactions occurring on platinum has been described. It has been shown that such a device is well suited for continuous reactivation of electrode surfaces and for maintaining relatively high mass transport rates at a properly chosen electrode rotation rate. The use of platinum, however, is a serious impediment from the viewpoint of industrial potential, which requires cheaper electrode materials.

The present study was undertaken to investigate the usefulness of nickel as an economically more attractive rotating electrode in the wiper-blade cell and this communication reports pertinent experimental results in four major areas: (*i*) oxygen reduction, (*ii*) the oxidation of ethanol, (*iii*) oxygen evolution, and (*iv*) the anodic dissolution of nickel. The experimental conditions, especially electrode pretreatment, choice of electrolyte species and concentrations, working potential and temperature (range) correspond closely to previously reported research in these areas, in order to minimize the importance of effects spurious to rotating multipolar wiper-blade cell operation. On account of their specific aspects related to these areas, experimental details are described in their respective sections rather than in a separate part of the paper, the common characteristics of the cell having already been presented in earlier communications (1, 5, 6). Although certain questions involving reaction paths and mechanisms have inevitably been faced in this work, the emphasis here is on the performance of the rotating wiper-blade electrode relative to conventional electrodes, rather than on further insights into alternative mechanistic reaction schemes. It is hoped that the results of this effort will facilitate the development of an industrial device based on the rotating wiper-blade electrode principle.

The Reduction of Oxygen on Nickel

In preliminary experiments performed in a parallel-plate cell (5), inhibition of the reduction process was found to be in agreement with previous literature where passivation was ascribed to the oxide species: Adsorbed oxygen on the electrode surface may exist at −0.15V (RHE) (7) and its strength of bonding increases with time. At potentials higher than 0.1V oxygen adsorption is possibly combined with the formation of the poorly conducting phase oxide $Ni(OH)_2$ (7, 8). The layer of oxygen adsorbed on Ni does not appreciably inhibit oxygen ionization (7), but at potentials more positive than 0.1V the rate of ionization drops sharply. In order to counteract passivation, chemical and electrochemical means of removing adsorbed oxygen and/or oxide layers have been shown successful (7, 9-11) in reestablishing high initial oxygen reduction rates.

Key words: anodization, anodic dissolution, anodic oxidation, oxygen, ethanol.

Experiments in the rotating cell were carried out using a 0.1 mole/dm^3 KOH solution, usual in similar studies (9, 10), and specially constructed (Pt) Hg, HgO/KOH (aq) reference electrodes for determining solution potentials. Using an appropriately prepared H_2 electrode (12), the reference cell potential was found to be 0.96265V at 293°K, with a temperature coefficient of −287.8 μV/°K, in good agreement with the previous literature. Particular care was taken to minimize the misalignment of the Luggin capillaries in the working cell and the potentiostat was controlled via an average solution potential using a 3 resistor T network which also allowed biasing toward any of the compartment potentials. This arrangement also allowed comparisons of a reaction rate existing in one particular compartment under tripolar conditions with the rate in the same compartment when all compartments were operating under identical conditions. Temperature was controlled at 23°C throughout. The details of the cell construction and principles of operation have previously been described (1-6); the essentially novel feature is the rotating cylindrical nickel electrode fabricated from a Nickel 200 rod (C, 0.04; Mn, 0.25; Fe, 0.05; S, 0.005; Si, 0.06; Cu, 0.03; Ni, 99.50% composition; courtesy of INCO, Canada).

Figure 1 shows the variation of the rate of oxygen reduction with potential in the electrolyte made up of BDH quality KOH and doubly ionized water. Prior to each measurement the electrode surface was held at −0.2V for 60 sec to minimize the amount of adsorbed oxygen on its surface. The sequence of potentials was selected randomly in order to eliminate possible effects of electrode "history," hence to ensure good reproducibility. Curve 2 corresponds to decay at 120 sec after the start of the reaction, on a pretreated surface, while curve 1 shows the reduction current density observed on an oxidized surface, obtained by oxidizing nickel at 1.2V (RHE) for 2 min. In contrast, curve 3 represents reduction taking place on the continuously reactivated anode surface at a rotation rate of 0.162 rad/sec, when the cell was operated in a tripolar fashion. In so doing, the cathode potential was kept at −0.2V (with respect to the solution in the first compartment) to ensure that the oxide formed during the passage of the electrode through compartments 2 and 3 be completely reduced. The potential drop across these two compartments was maintained independently at the same desired reduction value, since (*i*) relatively large currents passed through the cell compartments due to oxide film formation and reduction, and (*ii*) the double layer charging current, especially at lower current flows, is also significant. Since the initial quick formation of oxide and double layer charging take place in the second compartment, the current flow in the third compartment is due almost exclusively to surface reactivation, except for a small contribution (about 1.3 μA/cm^2) from leakage current flow between the first and third compartments.

The beneficial effect of the electrode rotation rate on the current flow is observed best under mass trans-

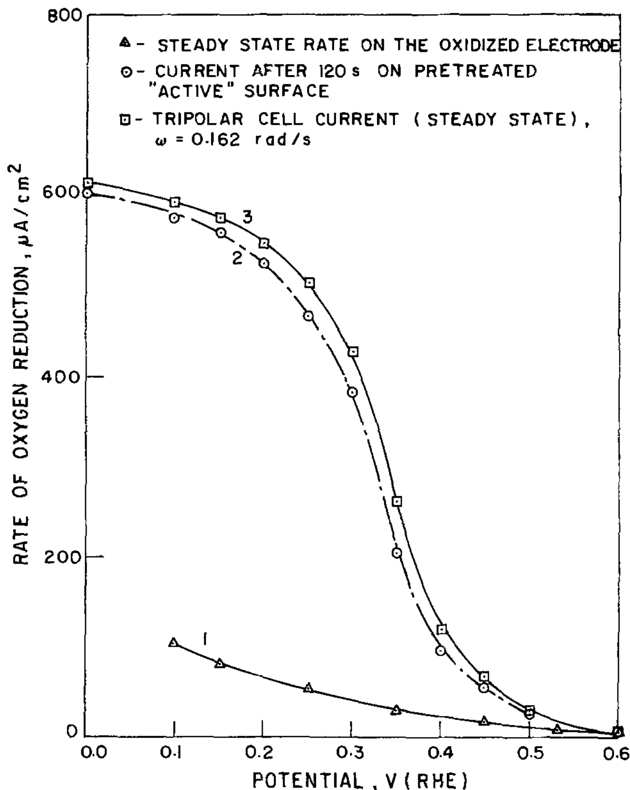

Fig. 1. The variation of oxygen-reduction current density with potential and pretreatment (electrolyte, 0.1 mole/dm^3 KOH; T = 23°C).

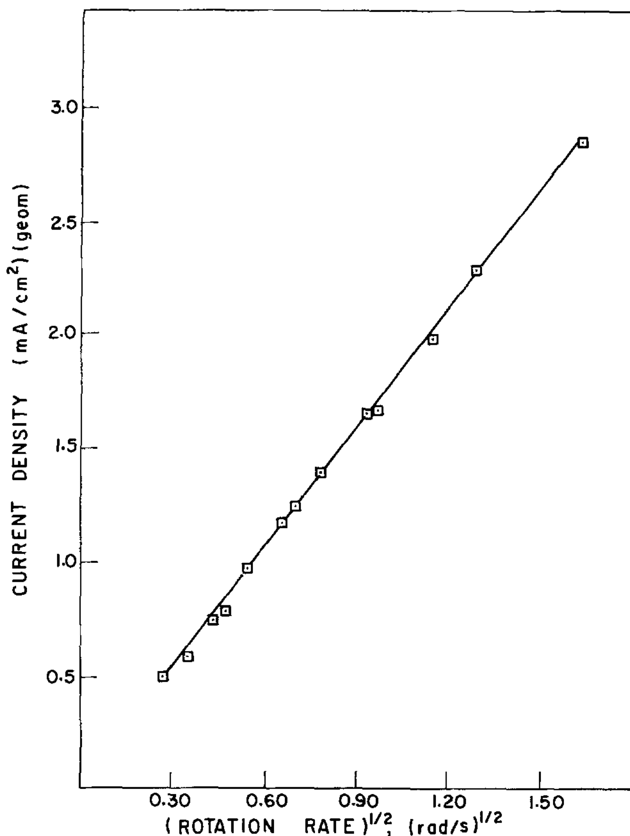

Fig. 2. The variation of oxygen-reduction current density with rotation rate in monopolar operation [electrolyte, 0.1 mole/dm^3 KOH; T = 23°C; potential = 0.1V (RHE)]. The solid line corresponds to Eq. [1].

port control. Figure 2 shows the typical linear dependence between current flow and the square root of the rotation rate, demonstrated previously (1, 6) for various reaction systems and observed here in monopolar operation, at 0.1V where O_2 reduction is mass-transport limited [pretreatment as in (7)]; the solid line represents the theoretical model (5, 13)

$$\bar{i}_L = \frac{zFDc_b}{\sqrt{t_s}}\left[\frac{1}{\sqrt{\pi D}} + \frac{1}{\psi(\sqrt{\pi\nu})}\right] \qquad [1]$$

where

$$\psi(\sqrt{\pi\nu}) \equiv \int_0^{\sqrt{\pi\nu}} \epsilon^{(y^3/6D\sqrt{\pi\nu} - y^2/4D)}dy$$

For the electrolyte used, $\nu = 8.5825 \times 10^{-3}$ cm^2/sec at 298°K and the bulk concentration of oxygen is computed as (14) $C_b = 1.175 \times 10^{-3}$ mole/dm^3 at the experimental atmospheric pressure of 98.43 kPa. The diffusion coefficient of oxygen being estimated (14) as $D = 1.815 \times 10^{-5}$ cm^2/sec, $\psi\sqrt{\pi\nu} \cong 7.71 \times 10^{-3}$ cm/sec$^{1/2}$. The magnitude of the relative error between predicted and experimental mass transport rates is less than 10%. In tripolar operation, the slope of the experimental regression line (2.4) is appreciably larger than the model-predicted slope of 1.76 in Fig. 2: It appears that the electrode rotation rate has an additional effect on surface activation and has the same role as the rate of pulsing in voltage-pulsing activation. This particular aspect of the cell is not well understood and a comprehensive analysis of the relationships involved cannot yet be given.

The Oxidation of Ethanol on Nickel

The electrooxidation of organic compounds (such as alcohols) has been the subject of numerous studies in the past and findings indicate that passivation may be ascribed to various Ni oxides whose formation depends strongly on the electrode pretreatment and oxidation potential. The positively charged Ni electrode is covered mainly by β-NiOOH in moderately alkaline solutions (15) and its discharging to $Ni(OH)_2$, studied extensively by Vertes *et al.* (15-17), is a rather complex function of time, anode potential, and electrolyte composition. Kinetic studies of the electrooxidation of alcohols (17, 18) yield rate constants two orders of magnitude apart and there is also considerable disagreement on the feasibility of reaching steady state in ethanol oxidation (18, 19). Differing oxidation mechanisms, proposed by Vertes *et al.* (15-17, 19-21), and Fleischmann *et al.* (18, 22), further indicate the incompleteness of present understanding in this area, where there is still much to learn.

The current study of ethanol oxidation on nickel may be summarized as follows. Figure 3 shows an essentially identical effect of a specific anodization procedure and tripolar operation of the rotating nickel anode, in the region of low oxidation rates. Both produce significantly higher reaction rates than conventional operation (curve 1). In a series of tests performed under various experimental conditions, the oxidation rate of ethanol was found to depend on the amount of oxide on the surface as expected from the literature: The coverage of the electrode by NiOOH increases with an increase in the potential, but at higher potentials the rate of this increase becomes smaller. Thus, the initial rate of electrooxidation of ethanol depends strongly on the anodization potential and anodization time which directly controls the amount of dischargeable oxide on the surface. Figure 4 shows the typical electrode behavior. Since oxidation starts at 1.392V, the NiOOH present on the surface is higher than the equilibrium amount corresponding to the oxidation potential; the resulting high oxidation rate gradually decreases toward a steady-state value. The decay may be characterized by the regression curve

$$i = i_2 + kQ_oe^{-kt} \qquad [2]$$

where i_2 is the steady-state component and Q_o is the initial oxide coverage of the surface, in excess

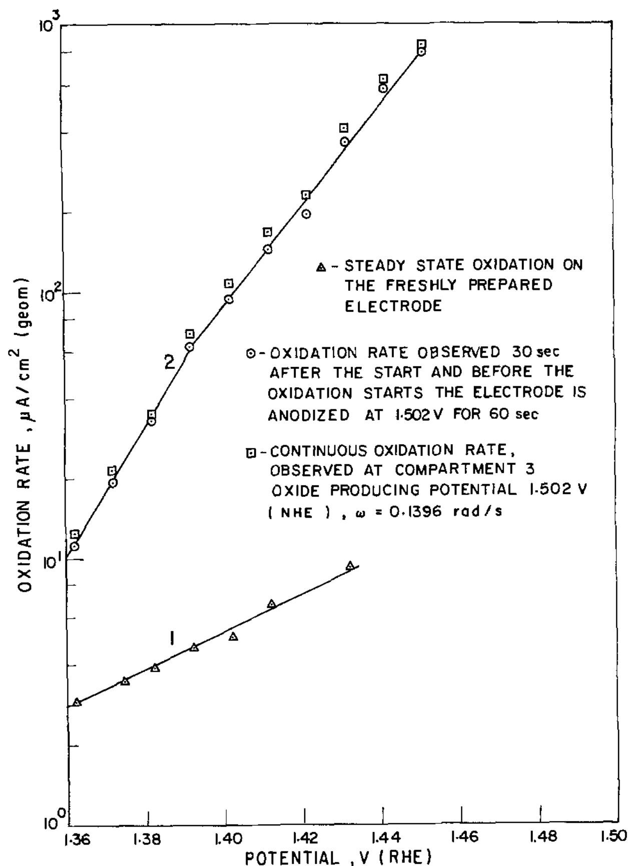

Fig. 3. The effect of electrode pretreatment on the oxidation rate of ethanol (electrolyte, 0.1 mole/dm^3 ethanol in 0.1 mole/dm^3 KOH; $T = 23°C$).

of the equilibrium value. The solid line in Fig. 4b corresponds to the experimental regression parameters of $i_2 = 48.93$ $\mu A/cm^2$, $k = 0.013614$ sec^{-1}, and $Q_o = 4.586$ mC/cm^2. It appears from Fig. 4 that the tripolar operation (where the potential of the rotating anode is kept at 1.502V in compartment 1, and in the range of 1.36-1.452V in compartments 2 and 3) maintains a continuously high oxide coverage of the surface and serves, as usual, as a continuous surface "reactivator." The experimentally observed oxidation rate, averaged over $(\tau_2 - \tau_1)$, where τ_1 is the time spent by the electrode surface in compartment 1 (before entering compartment 2) and τ_2 is the effective time during which the electrode process passes through compartments 1 and 2, varies approximately with the 0.07th power of the electrode rotation rate in the 0.08-1.1 rad/sec range, beyond which the effect of the rotation rate is essentially negligible. A similar averaging of Eq. [2] yields a 0.06th power relationship in the same range of rotation rate and the computed average current density values differ not more than -10% from the experimentally measured values.

In the region of high oxidation rates (initial current densities in the 1.0-2.0 mA/cm^2 range) decay behavior under potentiostatic conditions was found to agree with the results of Vertes *et al.* (19). While the true causes of passivation are not yet understood, two possibilities may be envisaged: (*i*) the formation of nickel-oxide-hydroxide, beyond some critical value, might inhibit the oxidation process by blocking the ethanol adsorption sites or by decreasing the surface concentration of one of the reactants, and (*ii*) with aging, the structure of the oxide may change, and the newly formed compound may have a passivating influence on the reaction rate. It may also be envisaged that the oxide gradually penetrates into the electrode surface and forms inclusions responsible for partial inactivity. At any rate, a detailed study (5) of each removal path (*i.e.*, discharge in an electrolyte; galvanostatic discharge; potentiostatic discharge; discharge by resistance loading) indicates that when the inhibiting oxide is removed from the electrode surface, the initial electrooxidation rate on the surface may be almost completely reestablished and this recovery is at relative maximum under galvanostatic reduction conditions. In this respect, the rotating tripolar wiper-blade cell offers an additional, and continuous, method for the reactivation of the rotating electrode surface when coupled with resistance shorting: This mode of operation was studied by keeping the potential of the anode surface in compartments 1 and 2 at the desired oxidation potential and shorting the portion of the anode surface in the third compartment to the outer electrode of the same compartment through a properly chosen load. Ethanol was thus oxidized in compartments 1 and 2 and the passivating

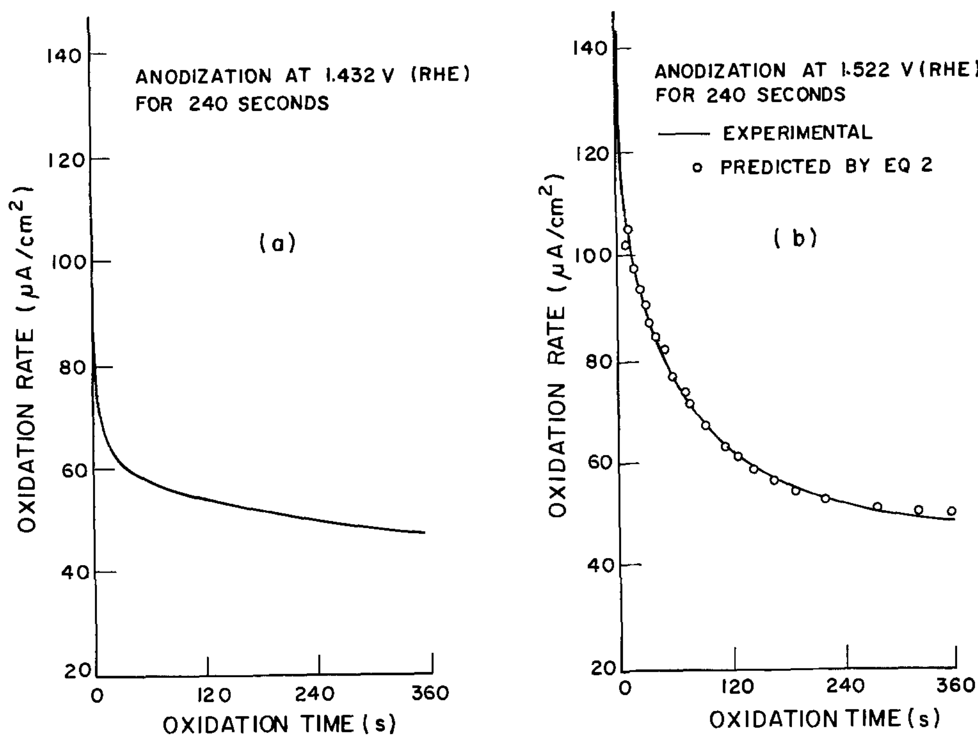

Fig. 4. The effect of anodization (anode coverage by oxide) on the oxidation rate of ethanol [electrolyte, 0.1 mole/dm^3 ethanol in 0.1 mole/dm^3 KOH; $T = 23°C$; potential $= 1.392V$ (RHE)].

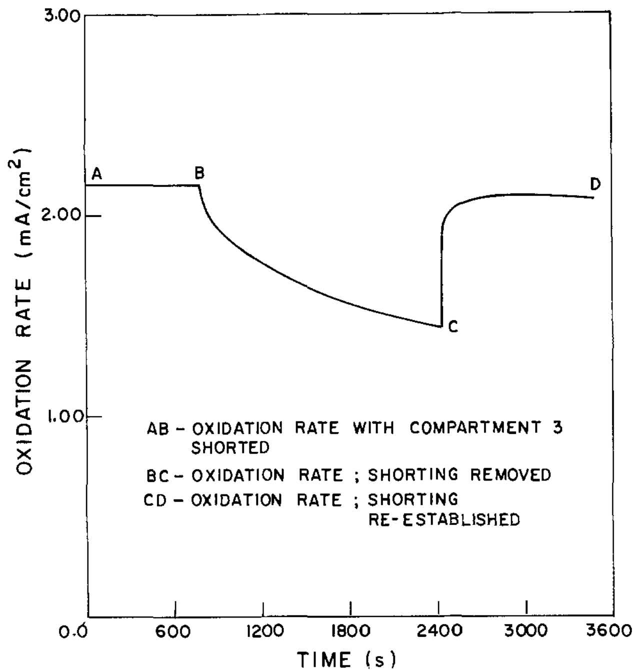

Fig. 5. The effect of shorting on the oxidation rate of ethanol [electrolyte; 0.1 mole/dm^3 ethanol in 0.1 mole/dm^3 KOH; T = 23°C; electrode rotation rate, 0.131 rad/sec; potential, 1.502V (RHE); shorting resistance, 0.976Ω].

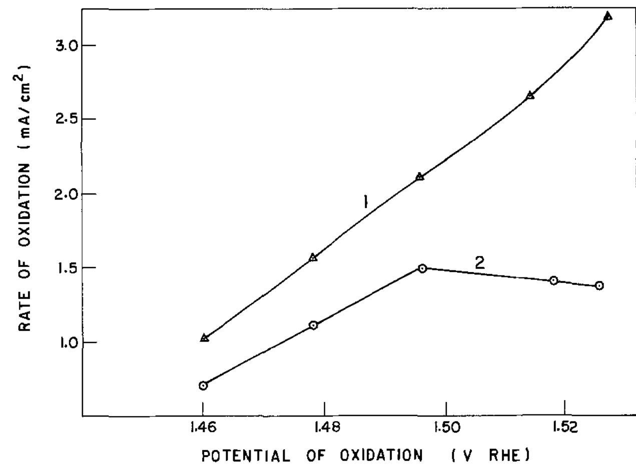

Fig. 6. The effect of oxidation potential on the rate of oxidation of ethanol in tripolar operation (curve 1) in comparison to monopolar operation (curve 2, observed at 9000 sec after start). (Electrolyte, 0.1 mole/dm^3 ethanol in 0.1 mole/dm^3 KOH; T = 23°C; electrode rotation rate, 0.131 rad/sec).

substance formed in these compartments on the anode surface was removed in the third compartment in the presence of electrode discharges. Typical results are shown in Fig. 5: In the zone designated as AB passivation is virtually absent as ethanol is continuously oxidized at a high rate, during short circuiting. At point B shorting was removed and the usual decay phenomenon is now observed until shorting was reestablished at point C, whereupon the oxidation rate, characteristic of the AB zone, is nearly fully recovered. Note also that a careful cell design may take advantage of the electrical energy produced in resistance shorting.

The oxidation rate under shorting conditions increases with the potential of oxidation at a fixed anode rotation rate (see Fig. 6); the effect of the anode rotation rate on the individual compartment reaction rates is illustrated in Fig. 7. It is seen that the related change in oxidation time on any portion of the anode surface in the first and second compartments has little effect on the rather slow decay rate (Fig. 7a); the rate of oxide reduction in the third compartment is strongly dependent on the electrode rotation rate (Fig. 7b), indicating that the latter has a positive effect on the rate of surface "rejuvenation." Note, however, that these new experimental results do not offer straightforward evidence for any of the hitherto proposed mechanisms of the oxidation reaction (such an investigation would be beyond the scope of this work) and they refer to surface-averaged phenomena; microscopic surface behavior, *i.e.*, local charge distributions, local oxide species, etc., will have to be studied in the future for a much better comprehension of what exactly happens on the electrode surface during activation and reactivation.

The Evolution of Oxygen on Nickel

The evolution of oxygen on nickel takes place on surface oxides which may exist in various oxidation states depending on the anode potential and the corresponding current density for oxygen evolution. While many studies have been reported on anodic oxygen on nickel in alkaline solutions, there is only

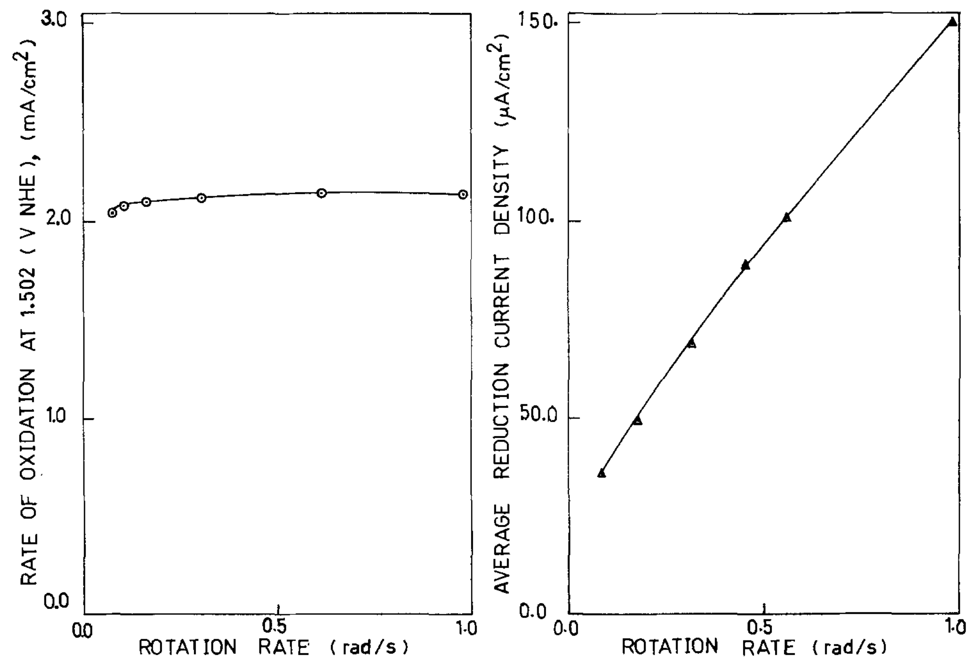

Fig. 7. The effect of electrode rotation speed on ethanol oxidation in bipolar operation: (a) activated surface, (b) compartment 3. (Electrolyte, 0.1 mole/dm^3 ethanol in 0.1 mole/dm^3 KOH; T = 23°C; shorting resistance, 0.976 Ω).

limited agreement amongst the kinetic results of various workers, as shown in Table I. The scatter of numerical values of the Tafel slope is most likely due to the different states of the electrode surface employed or to differences in surface pretreatment, or to different thicknesses of the oxide layer. The reaction is inhibited (29) on oxidized nickel surfaces, the passivation being inversely related to temperature. A number of kinetic mechanisms have been proposed (*e.g.*, 25, 29-31) apart from the general scheme for any metal by Bockris (32). An earlier mechanism proposed by Krasil'shchinkov (33) relates distinct Tafel slope values to various rate-determining steps involving, among other species, the Ni_2O_3, Ni_2O_2, and Ni_2O_4 oxides. It appears from the literature that this oxidation process is rather complex.

Of particular importance for the current apparatus are previous observations on the existence of hysteresis between ascending and descending polarization curves (29), and on the self-passivation of oxygen evolution (29, 34); these phenomena and previous findings (5) suggest that the rotating, wiped multipolar electrode may be successfully used to increase the reaction rate at a particular potential (or in a particular potential range) via continuous surface rejuvenation.

First, polarization phenomena were studied in further detail, using the cell in a conventional monopolar manner, with the outer electrodes connected together. Since pertinent literature on oxide formation phenomena, obtained via potentiodynamic triangular sweep techniques (7, 34), indicates that adsorption of oxygen on Ni begins at about -0.15V (RHE) the rotating electrode was kept at -0.15V for 2 min, before raising its potential to the working range of 1.322-2.222V. There is some evidence that the $Ni(OH)_2$ formed in anodic polarization cannot fully be reduced by subsequent cathodic reduction even over a prolonged time period (7) and, in consequence, it is likely that the above pretreatment did not yield a fully oxide-free surface. On the other hand, it is seen from the Pourbaix diagram for Ni (35) that in a 0.1 mole/dm^3 KOH electrolyte and at -0.15V, $Ni(OH)_2$ is the only thermodynamically permissible oxide species. Thus, it is expected that although a certain portion of the hereby pretreated electrode surface has $Ni(OH)_2$ (but no other oxide species) on it, the surface is sufficiently activated to observe the pursued phenomena.

Figure 8 shows the characteristic hysteresis effect observed in anodic polarization elsewhere (29). The value of the Tafel slope was next estimated by carrying out potentiostatic oxygen evolution in the 1.432-1.507V potential range, with three replica runs in order to obtain an unbiased estimate of the experimental error variance. The electrode pretreatment was identical to that of the polarization study. The probability distribution of the Tafel slope was estimated by the conventional linear model

$$V_i = a + b \ln i_i + \epsilon_i \quad i = 1, \ldots, n \qquad [3]$$

and the statistically unbiased nonlinear model

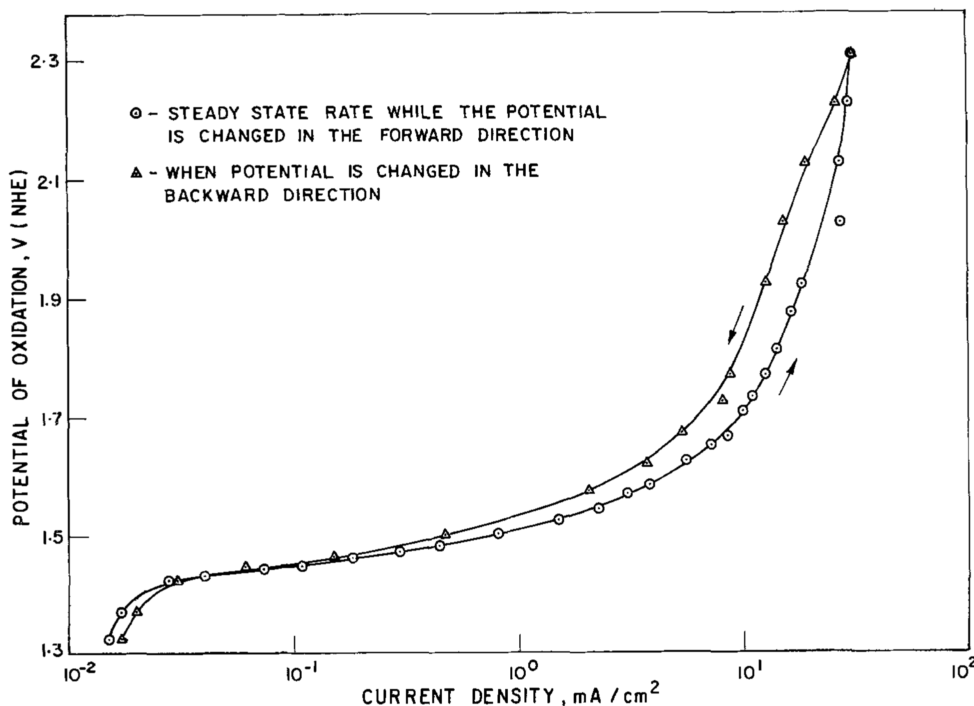

Fig. 8. Typical steady-state potentiostatic polarization curves for oxygen evolution (electrolyte, 1.0 mole/dm^3 KOH; T = 23°C).

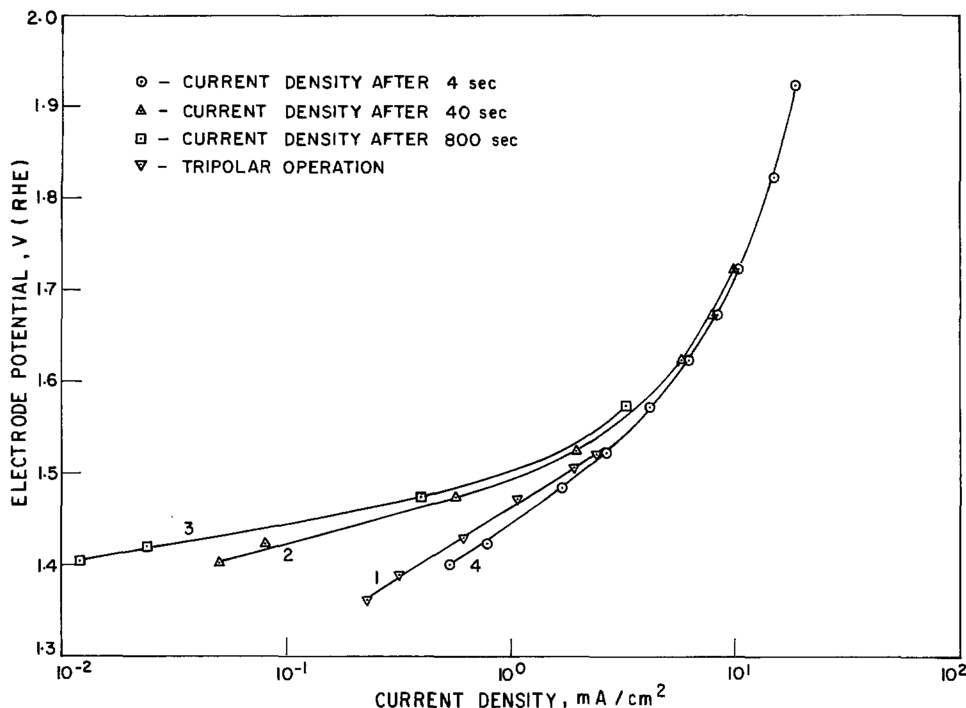

Fig. 9. Comparison of polarization curves for oxygen evolution in monopolar (curves 2, 3, 4) and tripolar (curve 1) operation.

$$i_i = a \exp(V_i/b) + \epsilon_i \quad i = 1, \ldots, n \qquad [4]$$

the experimental error variance, σ_e^2, being computed at 34 degrees of freedom. The statistically most probable value of the Tafel slope, $b = 0.0275$, obtained via Eq. [4], is somewhat different from the biased value of $b = 0.0261$ based on Eq. [3].

The usefulness of the rotating wiped electrode cell in tripolar operation is well demonstrated in Fig. 9; tripolar operation is equivalent to a continuous reduction of the oxide layer film thickness on the electrode. Curve 1 represents current flow in the third compartment, oxygen film formation being confined essentially to compartment 2; the electrode potential in compartment 1 was held at -0.15V. The contribution of oxide film growth to the current flow in the third compartment is at most 10%, this magnitude being inversely proportional to the time length of activation.

As in the case of ethanol oxidation an explanation of the experimental results in terms of mechanistic models is not yet possible. Neither the mechanism proposed by Sato (25) involving adsorbed O and OH species, nor the Krasil'shchinkov mechanism (26) involving surface reactions between various nickel oxides and atomic oxygen, nor the generalized Bockris mechanism (32) can be employed for a quantitative comparison of predicted and observed phenomena. Much more work remains to be done in this area before electrode behavior becomes fully understood.

The Anodic Dissolution of Nickel

The anodic activation phenomenon (*i.e.*, the existence of a more negative initial potential than the equilibrium value, on approaching from the oxidized state toward the free corrosion potential) for Ni has been described by several researchers (36-38) but the correct activation mechanism is not known. Gerischer (39) describes activation to (nonequilibrium) intermediate oxygen compounds formed at anodic potentials, while Oshe and Lovachev (36) to excess surface oxygen; Losev and Kabanov to oxygen penetration into the metal crystal lattice (37); Trusov *et al.* (38) to the creation of excess dissolution centers. In any event, the fact that the initial rate of nickel dissolution is much higher than the steady-state dissolution rate corresponding to the potential applied, indicates that at a given average anodic overvoltage, larger dissolution rates may be achieved by voltage pulsing techniques, such as in multipolar operation.
